Poly(3-octylthiophene)
Field-effect transistor

ABSTRACT

Persistent post-photocurrents (PPC) have been studied in organic field-effect transistors (FET) made of thin films of regioregular poly(3-octylthiophene). The phenomenon occurs after illumination of FET with UV light. The drain-source current persisting after switching off the illumination is ca. three orders of magnitude higher than that in a virgin sample, and lasts for a long time. It may be erased by applying a negative potential to the gate electrode or by reversing the drain-source voltage. The magnitude and kinetic behaviour of the current depend on ambient atmosphere, particularly on the presence of O_2 molecules. The effect has been explained by formation of mobile O_2^- anions during irradiation. These slowly recombining anions are responsible for the occurrence of PPC. The effect may be used in opto-electronic switches.

1. Introduction

Rapidly growing interest in organic electronic devices has been due to current and emerging applications of organic materials as elements of organic light emitting diodes, organic field-effect transistors, etc. In particular, low-cost and easy high-volume production of thin film transistors (TFT) is possible using e.g. ink-jet printing technique [1,2]. Polymeric field-effect transistors (FET) have been developed using, in most cases, two types of semiconducting polymers – polyfluorenes and poly(3-alkylthiophene)s (PAT) [3]. In the case of substituted polythiophenes, the FET performance critically depends on the regioregularity of the polymer and its ordering at the polymer–insulator interface. High charge carrier mobilities, up to 0.1 $cm^2/(V\,s)$ were found only for poly(3-hexylthiophene) FET with the chains ordered edge-on to the surface [3]. This value is comparable with the mobility in amorphous silicon generally used in up-to-date TFT electronics. Nowadays, however, the major problem preventing a wider application of organic TFTs is not attaining higher mobilities but making these devices more stable and enduring [2,4].

One of the effects affecting operation of field-effect transistors is a persistent current following illumination of a FET structure. The post-illumination drain-source current does not return to its initial value but, instead, to a value some orders of magnitude higher. The decay, without an external stimulus, may take days. The phenomenon, referred to as persistent photoconductivity, or photo-induced memory effect has been observed in transistors made of both, inorganic and organic materials, and extensively studied as it may be interesting for development of photosensing transistors with ability of writing and erasing information. In this paper, we shall employ the name of persistent post-photocurrent (PPC).

Several explanations of the phenomenon have been offered, involving both, physical and chemical processes. For example, in silicon and GaAs [5,6], the effect of photo-in-

duced persistence of current after illumination has been explained by a spatial separation of photogenerated charge carriers occurring at local potential barriers of point trapping centres and/or p–n junctions.

Appearance of PPC was also reported for poly(phenylene vinylene) [7,8] and interpreted invoking self-trapping of charge carriers and formation of polarons and bipolarons in the polymer. It was postulated that photocurrent in the polymer is predominantly carried by mobile polarons near the surface, while photogenerated charges are stored in long-lived bipolarons with low mobility within the bulk. The decay of PPC is limited by diffusion of bipolarons towards the surface of the film and dissociation into polarons.

The persistent current was also observed in poly(3-hexylthiophene) [9–12]. In Ref. [10], PPC was explained by electron trapping at Al donor sites because such an effect was detected only in samples with thin layer of Al deposited on top and/or bottom of the polymer. Dutta and Narayan [11] showed, however, that PPC exists in polythiophene without Al electrodes, being practically independent of intensity and duration of illumination. The persistent current has not been observed in FETs with the negatively biased gate while at zero or a positive gate voltage PCC lasted for hours [10–13]. The persistent current could be erased by applying a short pulse of negative voltage to the gate electrode [11–13]. The effect was attributed to negatively charged traps that effectively screened the gate voltage [11,12]. The same effect was observed in FETs made of low-molecular-weight tetrathiafulvalene derivatives [13] and interpreted as due to enhanced recombination of trapped electrons upon applying a negative gate voltage.

It has been well established that in vast majority of organic semiconductors charge transport is realized by holes. In these materials, molecular oxygen and oxidation products form traps for electrons [14]. Consequently, in p-type devices (such as all the devices mentioned above), electrons are efficiently localized on such species, inevitably present in the active materials. The situation is more complex in n-type devices. Here, a possibility of formation of electron traps by oxygen depends on position of the electron affinity of the impurity molecules relative to that of the host ones. n-Channel transistors may be much more robust to oxidation (or photooxidation) and as such be much more stable in air [15] giving the possibility of manufacturing photoresponsive FETs free of PPC. Such devices may act as very fast and reversible opto-electronic switches [16].

Although several papers have been devoted to study of PPC, the matter of this phenomenon remains unclear. The origin of slow current decay after switching off illumination and its recovery to the initial (pre-illumination) level after applying a gate voltage have not been explained. This work is a contribution to study of the kinetics of photocurrent and persistent post-photocurrent in an organic FET, aiming at explaining the origin of persistent current. We measured the kinetics of photocurrent and persistent current in the FETs made of regioregular poly(3-octylthiophene-2,5-diyl) (p3OT) (Fig. 1a), in various atmospheres and at several temperatures. The material was chosen as it shows promising FET characteristics and sensitivity to light with a high ratio of photocurrent to dark current (up to 10^4 [17,18] or even exceeding this value).

2. Experimental

Steady-state current–voltage characteristics, and the temporal behaviour of photocurrent and of persistent current, have been measured in FET made of p3OT. Thin films of molecular weight optimised ($M_n \sim 25{,}000$) [19,20] regioregular p3OT (Aldrich) were fabricated by spin coating (in ambient air, at 800 rpm) from chloroform solutions (concentration amounting to 2 mg/ml). The thicknesses of the films ranged between 20 and 50 nm, as measured with an atomic force microscope (AFM, NanoScope V, Veeco). Absorption spectra of the films on quartz substrates were measured using a Perkin–Elmer Lambda 20 UV–vis spectrophotometer.

Silicon/SiO_2 wafers (from CEMAT Silicon, Poland) with 200 nm thick thermal oxide were used as substrates for FET. The oxide was thinned by chemical etching in the areas where the source and drain multifinger electrodes were to be later deposited (Fig. 1b). The contact metalization was e-beam evaporated and defined by lift-off lithography. In this way, the surface of the substrate was planarized providing proper conditions for polymer deposition. The length and width of the FET channel were equal to 20 μm and 11.6 mm, respectively, and the surface capacitance was equal to 20 nF/cm^2.

The drain-source current was measured with a Keithley 6517A electrometer, the voltage source of the electrometer

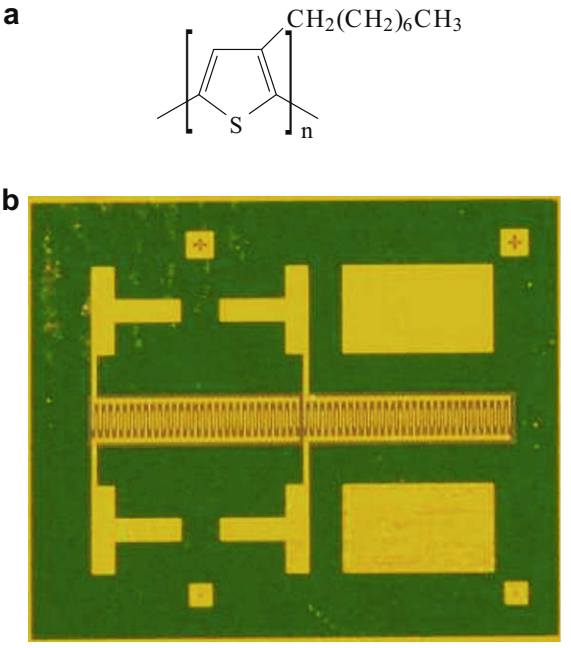

Fig. 1. (a) Molecular structure of poly(3-octylthiophene-2,5-diyl) (p3OT). (b) Top view of an Si/SiO_2/Au substrate used for fabrication of FETs. Dimensions of the substrate amount to 6×5 mm^2, $L = 20$ μm, $W = 11.6$ mm.

being used for supplying the drain-source voltage, U_{DS}. The gate-source voltage, U_{GS}, was supplied from a High Voltage Power Supply (Stanford Research Systems) equipped with a decade resistive voltage divider. The measurements of current–voltage and kinetic characteristics were performed in vacuum ($p < 0.02$ mbar). Additionally, some kinetic curves were measured in dry nitrogen atmosphere or in ambient air. The measurements were automatically controlled with LabView software. A ZXE-150 xenon lamp (Optel, Poland) equipped with an UV UG11 optical filter (with transmission band maximum at 335 nm) and quartz optical fibre were used for illumination of the samples.

The mobility of charge carriers, μ, threshold voltage, U_T, and on–off ratio have been calculated from the current–voltage characteristics. According to the conventional FET theory, μ can be calculated from the current–voltage dependencies

$$I_{DS} = \mu \frac{WC}{L}\left(U_{GS} - U_T - \frac{U_{DS}}{2}\right)U_{DS} \quad (1)$$

$$I_{DS} = \mu \frac{WC}{2L}(U_{GS} - U_T)^2 \quad (2)$$

where I_{DS} and U_{DS} stand for drain-source current and voltage, U_{GS} is gate-source voltage, L and W are length of channel (i.e. the distance between source and drain electrodes) and width of channel, respectively, and C stands for surface capacitance. Eqs. (1) and (2) apply to the linear section and to the saturation regime of the current–voltage characteristics, respectively.

3. Results

Current–voltage characteristics of TFT made of p3OT were measured for gate-source voltages ranging from −50 to 0 V (Fig. 2). A hysteresis of drain-source current vs. U_{GS} was observed, similar to that reported earlier [21]. The time necessary for the stabilisation of drain-source currents was found longer if subsequent curves were taken with increasing gate fields (i.e. taken with U_{GS} changed from 0 to −50 V), and the dependence of the saturation current on U_{GS} did not follow the quadratic dependence expected from Eq. (2). For decreasing gate fields (U_{GS} ranging from −50 to 0 V) the current in studied FETs stabilised sufficiently fast, and the saturation current quadratically depended on the gate voltage (Fig. 3). The faster the stabilisation, the better was the fit of measured characteristics with Eq. (2). Consequently, the characteristics were measured with the gate voltage changing from −50 to 0 V (Fig. 2).

The mobility of charge carriers determined from current–voltage characteristics measured on as-deposited samples in both, linear and saturation regime was about 10^{-4} cm^2/(V s), i.e., was one order lower than that reported previously [17,18]. The on–off ratio in saturation regime was in the range of $(0.5–1.0) \times 10^5$, threshold voltage was about −20 V (Fig. 3). The electrical parameters of as-deposited structures could be improved by a treatment of the samples with chloroform vapours [22]. Under illumination, the drain-source current in the off state substantially increased whereas the on current remained essentially unchanged. Consequently, the on–off ratio (in the saturation regime) decreased to about 10^2.

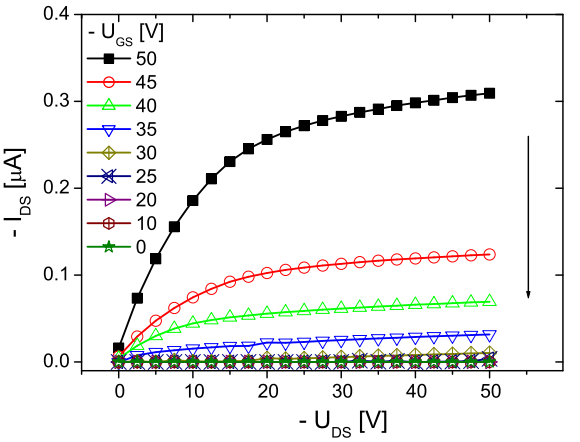

Fig. 2. Output dark current–voltage characteristics for p3OT FET, measured in vacuum. The arrow indicates the sequence of measurements of the characteristics.

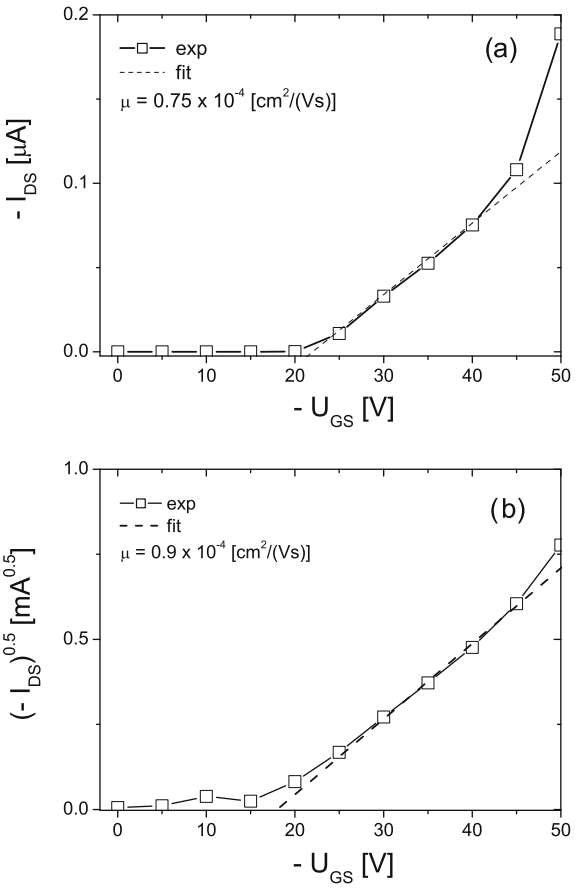

Fig. 3. Transfer current–voltage characteristics for p3OT FET, measured in the linear regime ($U_{DS} = -5$ V) (a) and in the saturation regime ($U_{DS} = -45$ V) (b), in vacuum. The broken lines show fits to the experimental curves using Eq. (1) in (a) and Eq. (2) in (b).

The temporal behaviour of the drain-source current following the illumination of the structure was examined in more detail. Upon illumination, the drain-source current rises within tens of seconds to reach a plateau. The magnitude of the effect depends primarily on the gate voltage and, to some extent, on ambient atmosphere: for example, if the measurements are carried out in air, at $U_{GS} = 0$ V and $U_{DS} = -40$ V the current increases by ca. six orders of magnitude (from pA up to μA level; Fig. 4), whereas at gate voltages lower than −10 V the increase does not exceed the factor of 4. In vacuum, during a prolongued illumination (15–30 min), the drain-source current increases to a maximum and then decreases very slowly (Fig. 5). At higher temperatures, the maximum appears at shorter times, and the decay is steeper. Such a maximum has not been found in samples measured in ambient atmosphere in spite of a prolongued illumination (Fig. 4). Measurements taken after the measuring chamber was flushed with nitrogen (i.e. after the concentration of oxygen was lowered to a fraction of mol. %) yield results qualitatively similar to those taken in ambient atmosphere, the magnitude of both photocurrent and the persistent current being, however, much lower.

After switching off the illumination, the current slowly decreases to the nA level (Figs. 4 and 5). The current does not return to the previous pA level, measured before the illumination, and lasts for more than 72 h (Fig. 4). The photocurrents and PPC measured in air are higher and the decays of PPC are slower than those measured in vacuum or in N_2 atmosphere as can be clearly seen from the data in Table 1. The dependencies of photocurrent and PPC on drain-source voltage (measured at 600 s after switching off the illumination) are linear for U_{DS} ranging between 0 and −75 V. The current is also temperature dependent: small changes of the magnitude of PPC are observed on increasing the temperature (Fig. 5). The measured decays are not monoexponential, and may be fitted with two exponentials for measurements taking up to ca. 3 h. Three exponents or stretched-exponential dependence [9] are required to fit the kinetics at longer times.

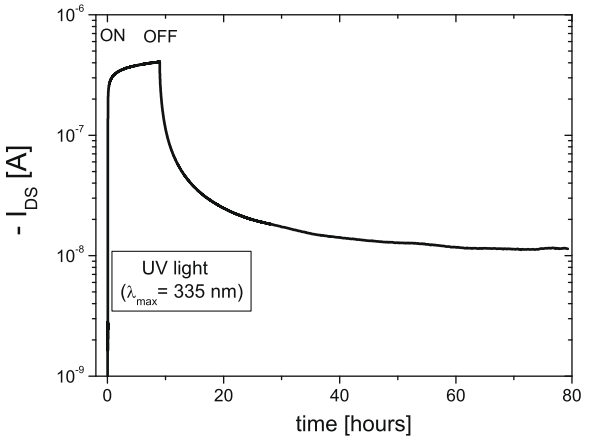

Fig. 4. Kinetics of photocurrent increase and of PPC decay, measured in ambient air. $U_{DS} = -40$ V, $U_{GS} = 0$ V.

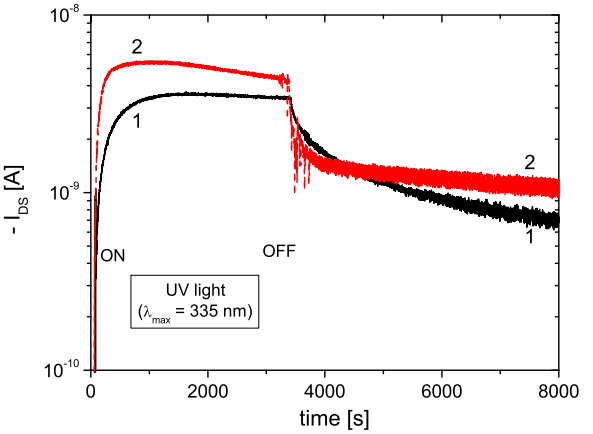

Fig. 5. Kinetics of photocurrent increase and PPC decay, measured in vacuum at 300 K (1) and 370 K (2). $U_{DS} = -30$ V, $U_{GS} = 0$ V.

The effect of the gate voltage on the behaviour of PPC was examined: the gate voltage was either set at 0 V or at a negative value and kept constant during the entire experiment, or pulses of voltage were applied to the gate at various times after switching off illumination. In the former case, we observed quantitative, but not dramatic, changes in the kinetics (compared to that measured at zero gate-source voltage), the latter procedure resulted in an irreversible decrease of the drain-source current to the pA level.

Contrary to the results presented in Refs. [11,12], we did observe PPC at $U_{GS} \leqslant 0$ V, i.e., in our samples the memory effect did not require keeping positive voltage on gate. The persistent current at $U_{GS} < 0$ V decays faster than that at $U_{GS} = 0$ V, merging into the dark current after a relatively short time.

The persistent current was quickly erased by applying a negative electrical potential to the gate electrode: in the experiment described below, U_{GS} was equal to 0 during illumination and a certain period after the illumination (cf. Fig. 6). After switching off the illumination, we observed a typical slow decay of PPC (Fig. 6, $300 < t < 500$ s). A positive voltage applied to the gate electrode did not erase PPC; just opposite, the persistent current slightly increased after setting $U_{GS} = 0$ again (Fig. 6, compare the magnitudes of current at 500 s and at 550 s). Application of $U_{GS} < 0$ resulted in an increase of the absolute value of the drain-source current but after setting $U_{GS} = 0$ again, the current returned to the low level of ca. 10^{-12} A (Fig. 6, $t > 1500$ s). The rate of erasing was found voltage-dependent: the higher negative voltage applied, the faster was the erase of PPC to the level from before illumination. For example, at $U_{GS} = -10$ V a few minutes and at $U_{GS} = -50$ V only few seconds are needed to completely reset the current. After erasing the persistent current with $U_{GS} < 0$ V, a subsequent biasing of the gate electrode with a positive potential does not affect the current, like before exposing the sample to illumination (Fig. 6, $25 \text{ s} < t < 75$ s).

The magnitude and temporal behaviour of PPC was found dependent on the way the experiment was carried out. After switching off the drain-source voltage for a short

Table 1
Dependencies of photocurrents and PPC on ambient atmospheres. All measurements were taken at $U_{DS} = -40$ V, $U_{GS} = 0$ V.

(μA)	Vacuum ($p < 0.02$ mbar)	Nitrogen	Air
Photocurrent (10 min after switching on the illumination)	0.10	0.10	0.40
Persistent post-photocurrent (10 min after switching off the illumination)	0.01	0.01	0.20

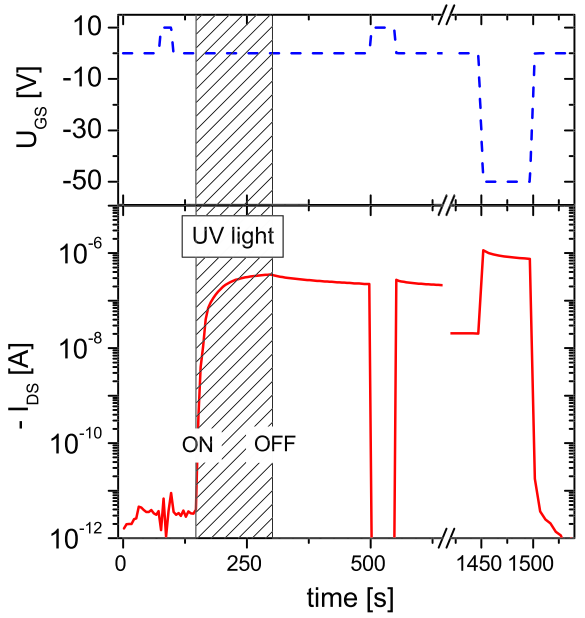

Fig. 6. Kinetics of photocurrent increase and PPC decay at various U_{GS}, measured in ambient air. $U_{GS} = 10$ V was applied in the time spans 25–75 s and 500–550 s; the illumination of sample was turned ON at 150 s and turned OFF at 300 s (striped area); $U_{GS} = -50$ V was applied between 1450–1500 s. $U_{DS} = -40$ V.

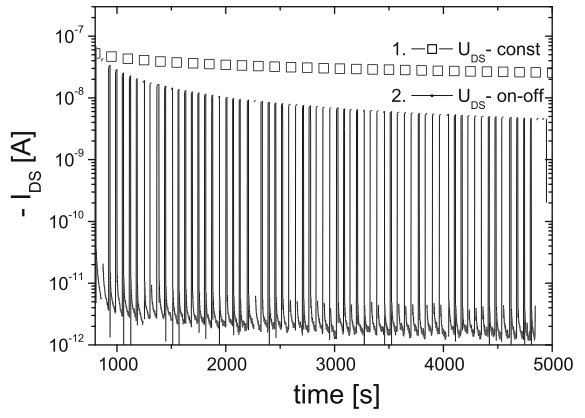

Fig. 7. Kinetics of PPC decay, measured in vacuum at constant $U_{DS} = -10$ V (1) and under periodically switched U_{DS} (2). The cycle in (2) consisted of 10 s at $U_{DS} = -10$ V, followed by 50 s at $U_{DS} = 0$ V.

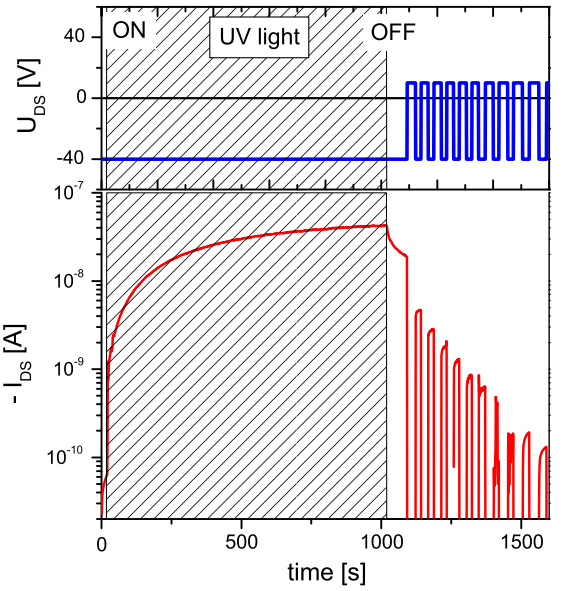

Fig. 8. Rapid erase of PPC induced by subsequent changes of U_{DS} polarity. $U_{GS} = 0$ V, $U_{DS} = -40$ V (during illumination) and -40 V or $+10$ V (after illumination). The period of illumination with UV light is marked with a striped pattern.

period of time (of the order of tens of seconds) and subsequent switching it on again, the persistent current was restored at a lower level. Periodic changes of U_{DS} resulted in a faster decay of PPC (Fig. 7). Reversing the sign of U_{DS} and switching it back also decreases the persistent current, the rate of decrease being faster for higher U_{DS} and for longer time of application of the reversed voltage. The persistent current could be completely erased after a few such cycles (Fig. 8).

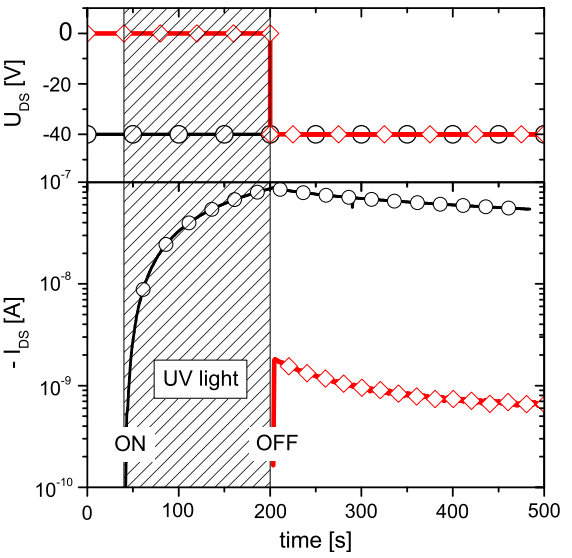

Fig. 9. Comparison of magnitude of PPC measured after biased (circles) and unbiased illumination (diamonds). $U_{GS} = 0$ V, during illumination $U_{DS} = -40$ V (biased) or 0 V (unbiased) and -40 V after illumination (in both cases). The period of illumination with UV light is marked with a striped pattern.

Illumination of an unbiased TFT prior to applying the drain-source voltage also resulted in the appearance of the persistent current, its value, however, was about two orders of magnitude lower than that observed after illumination of a biased sample (Fig. 9).

4. Discussion

The results shown in the preceding section demonstrate that both, the photocurrent and persistent post-photocurrent weakly depend on temperature (Fig. 5). Thus the thermal activation of trapped carriers is unlikely to be the main source of persistent current. On the other hand, the magnitude and the temporal behaviour of the photocurrent depend on the ambient atmosphere. A long illumination in ambient air or under reduced amount of oxygen resulted in a continuous increase of the current (possibly attaining a saturation beyond the time scale of our experiments), while in vacuum a maximum followed by a slow decrease was observed (Figs. 4 and 5). Photocurrents and persistent currents measured in vacuum or under a reduced concentration of oxygen, lower than those measured in air, evidence the doping of the polymer with molecules present in air, most probably with molecular oxygen. O_2 is omnipresent in organic materials even under ultrahigh vacuum, and, according to the literature, it is one of the most efficient dopants for p-type organic semiconductors, including polythiophenes [23–25]. A special feature of polythiophenes is a reversible enhancement of conductivity caused by illumination of samples in presence of O_2 [24–27], explained by formation of long-lived charge transfer complexes of oxygen with thiophene rings. The complexes of oxygen with polythiophene have an ionic character [23]. An evident influence of O_2 on persistent current was also observed in transient measurements for oxotitanium phthalocyanine [24], in which the post-photocurrent was found to persist after exposure of sample to O_2 atmosphere, while the current dropped to zero in vacuum.

Appearance of PPC in polythiophene has been explained [11,12] by the presence of electrons trapped on the polymer/insulator interface. The layer of immobile negatively charged species adds its own electric field to that originating from the gate potential. This model explains the similarity of the drain-source post-photocurrent at $U_{GS} = 0$ V and the current at $U_{GS} < 0$ V in the unilluminated sample. It fails, however to explain some phenomena observed in our experiments, for example vanishing of the PPC after a few subsequent changes of the sign of U_{DS} or appearance of a small PPC if the sample is illuminated under $U_{DS} = 0$ V. These phenomena can be simply explained assuming the presence of long-lived mobile ions created during illumination of the samples.

Our experiments indicate that the primary event, responsible for the behaviour of the samples under study (and, in particular, for the appearance of the persistent current) is the light-induced charge transfer, resulting in creation of holes on the polymer chains and of long-lived negatively charged small dopant molecules (most probably, O_2^-). The efficiency of creation of such pairs depends on the voltage, hence at $U_{DS} = 0$ V the concentration of charges should be low as is indeed the case in our experiments. Due to their small size, the negatively charged species are likely to be mobile in the polymer matrix, one could therefore expect their accumulation near the positive electrode until a steady-state has been reached. Note that this implies the build-up of a gradient of negatively charged molecular species. The dynamic equilibrium results from a competition of two driving forces: the electric field due to applied voltages (U_{DS} and U_{GS}) and the concentration gradient, the supply of ionic species being due to the illumination. Switching off the illumination (with the drain-source voltage still on) results in a decrease of the current: there is no supply of negative ions. The accumulated negative ions can discharge at the positive electrode being one of sources of the persistent current.

The persistent current can be erased by setting $U_{DS} = 0$ V (Fig. 7), by reversing the sign of U_{DS} (Fig. 8), or, finally, by applying a negative potential to the gate electrode (Fig. 6). In all cases, the effects can be rationalised taking into account a combination of drift and diffusion of mobile negative species and their following recombination with positive charges in the polymer or with the positive electrode.

The decay of PPC under $U_{DS} = 0$ V can be rationalised taking into account the diffusion of the negative species from the positive electrode area towards the bulk, followed by recombination. When the drain-source voltage is switched off, the persistent current vanishes. This feature confirms that there are no parasitic capacitor-discharge currents in studied FETs. In the absence of the external biasing field, the rate of recombination of the light-induced species is enhanced, they are, however, relatively long-lived and may exist without biasing voltage for a time extending up to a few hours. Re-application of U_{DS} effectively stops (or at least slows down) the diffusion of light-induced long-lived species, their concentration (and hence the persistent current), however, being lowered by the fast recombination during the period of $U_{DS} = 0$.

The reasoning presented above is supported by results of additional experiments: (i) illumination of TFT prior to applying U_{DS} and (ii) several inversions of the polarity of U_{DS} after illumination. As shown in Fig. 9, very low magnitude of persistent current in (i) points to the importance of the field-enhanced charge separation during illumination. The rapid decay of PPC in (ii) (Fig. 8) is a result of change in the direction of drift. Negative ions concentrated near the positive electrode after switching the polarity of U_{DS} move towards the bulk (both drift and diffusion currents) where they can recombine.

The most interesting phenomenon is a fast erasing of persistent current after applying a short pulse of negative potential to the gate electrode (Figs. 6 and 10), observed also by other authors in their studies of polythiophene FET [11,12]. The effect has been explained there by accumulation of polarons existing in the bulk of the poly(3-hexylthiophene) near the polymer–insulator interface, where the layer of negatively charged species was earlier formed. That caused rapid recombination and erasing of negatively charged layer screening the gate voltage. In our model, in which a gradient of concentration of mobile anions between drain and source is responsible for the appearance of PPC, the erasing effect may be explained in

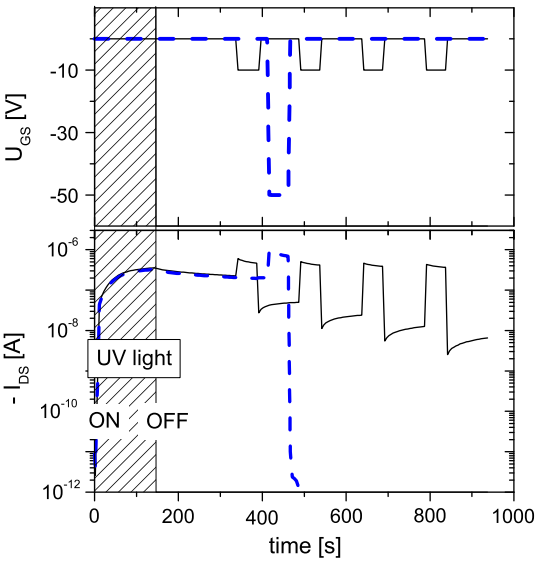

Fig. 10. Influence of U_{GS} on the kinetics of PPC erasing. $U_{DS} = -40$ V, $U_{GS} = 0$ V during illumination and was periodically switched to -10 V (solid line) or -50 V (dashed line) after illumination. The period of illumination with UV light is marked with a striped pattern.

the following way: When a negative gate voltage is applied, the transistor works in a usual way, i.e., a channel for positive carriers is formed between source and drain electrodes at the polymer–insulator interface in TFT. As a result, the current rises (cf. Fig. 6, 1450 s < t < 1500 s). Simultaneously, due to electric field originating from negative potential on gate electrode, the electric field gradient in the vicinity of source and drain electrodes drastically changes. This, together with diffusion, allows the negative ions to move into the bulk and recombine with positively charged polymer chains. The higher negative voltage is applied, the faster recombination occurs, resulting in erasing the persistent current (Fig. 10). Application of a positive gate potential decreases the measured I_{DS} current due to emptying of the channel. A temporary increase of PPC after switching off the gate voltage is the effect of discharging the gate – source and drain capacitance. The permanent post-photocurrent returns to its previous level after a few minutes.

It must be stressed, however, that the mechanism put forward in this paper, albeit explaining several features observed in our experiments, does not explain the magnitude of the persistent current: to maintain the measured currents for 3 days, ca. 10^{16} ions (i.e. ca. 10^{-8} moles of ions) should discharge – a number that by ca. one order of magnitude exceeds reasonable estimates. This means that the proposed mechanism of PPC, in our opinion, is not the only one operative in the poly(3-octylthiophene). Possibly, other mechanisms, postulated by other authors may contribute to a degree depending on the material, sample morphology, and experimental conditions.

5. Final remarks

A reversible opto-electronic switching with on–off ratio of about 10^6 has been observed in thin film field-effect transistor made of regioregular poly(3-octylthiophene). The turning on is realised by UV illumination, after which a long-lived persistent post-photocurrent occurs, and the switching off may be achieved upon applying a negative electrical potential to the gate electrode. The effect may be used in an opto-electronic memory device, where information is written optically and erased electrically in a reversible manner.

The origin of persistent post-photocurrent has been explained by formation of long-lived charge transfer polythiophene–oxygen complexes with their subsequent dissociation to negatively charged oxygen ions and holes on polythiophene chains. The gradient of negative ions formed at the positive electrode prevents fast decay of the current. Recombination of ions, that is erasing of persistent current, can be realised by changing the gradients of electric field near the source and drain electrodes either by applying negative voltage to the gate or by reversing drain-source voltage.

According to our model, the permanent post-photocurrent may occur in samples consisting of materials fulfilling two basic conditions: (i) the illumination results in the charge transfer and creation of well separated ionic pairs; (ii) the pairs are long-lived, one of the ionic species being mobile. In the case of poly(3-octylthiophene), the positive component of the pair are holes on the thiophene chains, the negative (mobile) one – single charged molecular oxygen. A similar scheme should also be operative for other poly(alkylthiophene)s as their energy levels do not differ much from those of poly(3-octylthiophene). One can presume that persistent post-photocurrent can be observed also in other classes of materials provided they fulfil the conditions mentioned above.

ABSTRACT

A wide band-gap polymer derived from 3,6-carbazole and tetraphenylsilane has been employed as a host for ternary phosphorescent iridium complexes in a white polymer light-emitting device (PLED). By studying both electroluminescence and photoluminescence of the doped polymeric light-emitting layer, it was found that both energy transfer and direct trapping attribute to the emission. Balanced white light with an external quantum efficiency of 4.26%, corresponding to a luminous efficiency of 8.55 cd/A and a power efficiency of 4.55 lm/W, as well as a color rendering index of 82 were achieved at 100 cd/m^2.

1. Introduction

White polymer light-emitting devices (PLEDs) have attracted increasing attention due to their advantage of allowing inexpensive solution processing technologies, such as spin-coating and ink-jet printing, which are more suitable for the preparation of large area displays and lighting sources [1]. To achieve high efficiency, host–guest systems are widely used in the emitting layer (EML) of PLEDs, due to the possibility of combining the advantages of high charge mobility of host polymers and high emission efficiency of guest dyes. Among various dyes employed, heavy metal complexes have shown theoretical 100% efficiency due to their efficient intersystem crossing from singlet to triplet excited states followed by relaxing through phosphorescence [2]. Therefore, the usage of this kind of phosphorescent dyes as emitters in white organic light-emitting devices based on both small molecular and polymeric hosts are intensively investigated. Compared to those based on small molecular hosts [3–6], white phosphorescent PLEDs are less efficient due to the deficiency of suitable polymeric hosts, which should have higher triplet energy than those of guest dyes, especially blue ones, to prevent backward energy transfer [7]. Although non-conjugated polymer poly(vinyl-carbazole) (PVK) has been used as a host in white PLEDs [8,9], it suffers from problems with charge injection and transport because of its non-conjugated nature. Therefore, the development of highly conductive conjugated polymers with high triplet energy is strongly desired. For this purpose, δ-Si structure has been introduced into conjugated polymers to interrupt the extended π-conjugation and achieve high values of triplet energy [10–14]. Complete energy transfers from the polymers to green phosphorescent dyes have been realized [10,11]. However, the triplet energy of this kind of polymers seems not high enough as hosts for blue phosphorescent dyes [12,14]. Recently, it was found that carbazole-based polymers with an interconnection of carbazole units in 3,6 positions have higher triplet energy than their 2,7-counterparts and are suitable hosts for green iridium complexes [15,16]. Based on these achievements, to realize a more suitable polymeric host for blue phosphorescent dyes, we have introduced δ-Si structure into a 3,6-carbazole based polymer and synthesized a wide band-gap poly-

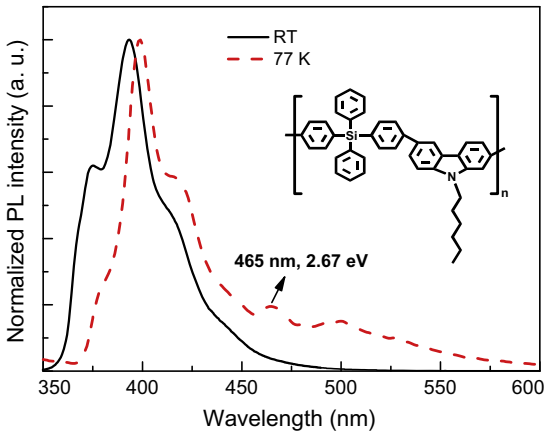

Fig. 1. Normalized PL spectra of P36HCTPSi in THF solution at RT and 77 K. Inset: chemical structure of P36HCTPSi.

mer, namely P36HCTPSi, as shown in the inset of Fig. 1. The synthesis and characterizations of this polymer have been reported elsewhere in detail [17]. From the onset of its absorption, a band gap of 3.26 eV has been estimated and a highest occupied molecular orbital (HOMO) level of 5.53 eV was calculated via cyclic voltammetry. Consequently, the lowest unoccupied molecular orbital (LUMO) energy level of 2.27 eV can be deduced. This wide band gap makes P36HCTPSi a possible candidate for a suitable host in white PLEDs.

In this paper, we demonstrate a white phosphorescent PLED based on P36HCTPSi, in which blue, green, and red phosphorescent dyes, bis[(4,6-difluorophenyl)pyridinato-N,C^2]-(picolinato)iridium (III) (FIrpic), *fac*-tris[2-(2-pyridyl-kN)-5-methylphenyl]iridium(III) [Ir(mppy)$_3$], and tris(1-phenylisoquinoline) iridium (III) [Ir(piq)$_3$] were respectively dispersed as an EML. In addition, monochromatic blue, green, and red PLEDs using single iridium complex doped P36HCTPSi as EMLs, were fabricated and characterized as well.

2. Experimental details

Devices consisting of ITO/PEDOT:PSS/EML/TPBI/LiF/Al were fabricated as follows; PEDOT:PSS was spin-coated onto cleaned ITO-coated glass substrate from its aqueous solution and then heated at 120 °C for 20 min to remove the residual water solvent at atmosphere. Doped P36HCTPSi was spin-coated from chlorobenze solution atop the PEDOT:PSS layer as an EML in a nitrogen-filled glove box. In the white device, the concentrations of P36HCTPSi, FIrpic, Ir(mppy)$_3$, and Ir(piq)$_3$ were respectively 5, 0.4, 0.04, 0.02 mg/ml, while in the monochromatic devices, the concentrations of host and guest were fixed at 5 and 0.4 mg/ml, respectively. After the spin-coating, all devices were transferred into a vacuum chamber immediately without exposure to the atmosphere. Inside the chamber, 40 nm-thick 2,2′,2″-(1,3,5-phenylene)tris(1-phenyl-1H-benzimidazole) (TPBI), 0.5 nm-thick LiF, and 200 nm-thick Al were in sequence deposited by thermal evaporation at a pressure of 4.0×10^{-4} Pa.

UV–visible absorption spectra were recorded on a UV-3100 spectrophotometer. Photoluminescent (PL) spectra were carried out with a RF-5301PC fluorometer. Atom force microscope (AFM) measurements in air were performed using a Solver scanning probe microscope (NT-MDT) in tapping mode. Electroluminescent (EL) spectra and Commission Internationale De ÍEclairage (CIE) coordination of these devices were measured by a PR650 spectrometer. The luminance–current density–voltage characteristics were recorded simultaneously with the measurement of the EL spectra by combining the spectrometer with a Keithley model 2400 programmable voltage–current source. All measurements were carried out at room temperature under ambient conditions.

3. Results and discussion

As has been reported in our previous paper [17], P36HCTPSi has a high thermal decomposition of 451 °C and a high glass transition of about 217 °C, indicating its good thermal stability. To estimate its triplet energy, PL spectra of P36HCTPSi in THF solution (10^{-5} M) at room temperature (RT) and 77 K were measured and compared in Fig. 1. The measurement was carried out with a RF-5301PC fluorometer with excitation at 330 nm. Compared with the spectrum at RT, where only fluorescent emission can be detected, a new emission band with a maximum peak at 465 nm appears, indicating that the triplet energy of the polymer might be around 2.67 eV [16,18]. This value is higher than that of FIrpic (2.62 eV) [19], the widely used blue phosphorescent emitter. Therefore, P36HCTPSi is expected to be a suitable host material for a full phosphorescent white PLED.

In order to testify this possibility, a white PLED respectively dispersing FIrpic (8 wt%), Ir(mppy)$_3$ (0.8 wt%), and Ir(piq)$_3$ (0.4 wt%) into P36HCTPSi host as red, green, and blue phosphorescent emitters was fabricated and characterized. Normalized EL spectra of this white device at differ-

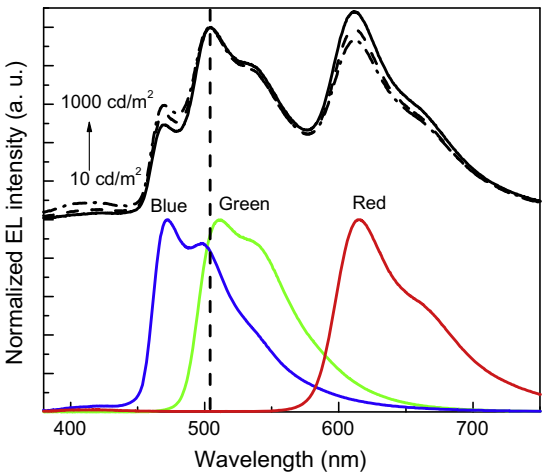

Fig. 2. Normalized EL spectra of the white PLED at 10, 100, and 1000 cd/m^2, as well as those of blue, green, and red devices at 100 cd/m^2. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

ent luminance and those of the monochromatic devices at 100 cd/m^2 are compared in Fig. 2. Balanced emission is observed in the white device with three emission peaks at 469, 504, and 612 nm. According to the EL spectra of the monochromatic devices, the peaks at 469 and 612 nm are from the radioactive decay of FIrpic and Ir(piq)$_3$, respectively, while the one at 504 is an overlapped emission of FIrpic and Ir(mppy)$_3$ as indicated by the dashed line. It is worthy to note that a weak emission at around 415 nm becomes obvious at higher luminance, which can also be observed in the blue device, but not in green and red devices. To investigate the origin of this emission, PL spectrum of P36HCTPSi in film state and absorption spectra of FIrpic, Ir(mppy)$_3$, and Ir(piq)$_3$ in toluene were measured and shown in Fig. 3a. PL of P36HCTPSi with an main peak at 399 nm and a shoulder at round 415 nm shows better overlaps with the absorptions of Ir(mppy)$_3$ and Ir(piq)$_3$ than FIrpic, indicating more efficient Förster energy transfer from P36HCTPSi to Ir(mppy)$_3$ and Ir(piq)$_3$. Therefore, the incomplete energy transfer might be the main reason for the weak emission at 415 nm in the blue device. Since the concentration of FIrpic (8 wt%) is much higher than that of Ir(mppy)$_3$ (0.8 wt%) and
Ir(piq)$_3$ (0.4 wt%) in the white device, it is not surprised that this device shows a similar weak emission from the host like the blue one.

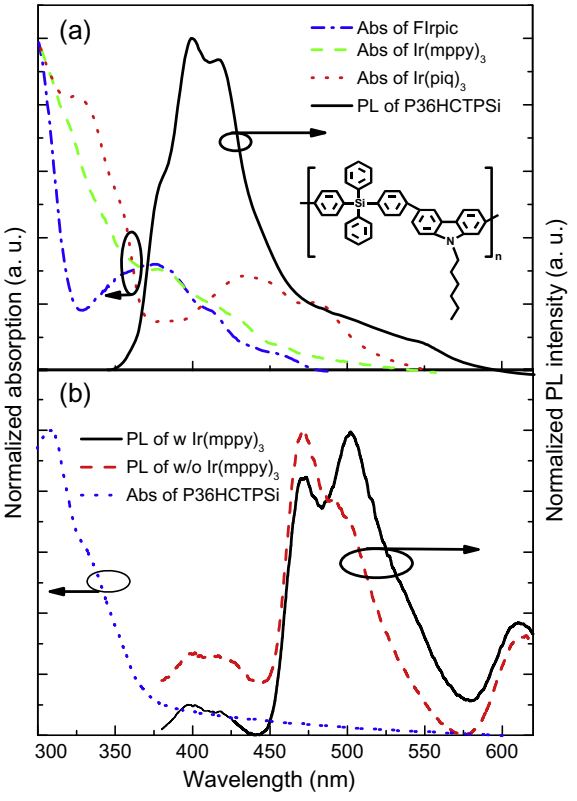

Fig. 3. (a) Normalized absorption spectra of FIrpic, Ir(mppy)$_3$, and Ir(piq)$_3$ in toluene and PL spectrum of P36HCTPSi in thin film; (b) Normalized absorption spectrum of P36HCTPSi in thin film and normalized PL spectra of blended films of P36HCTPSi (5 mg/ml):FIrpic (0.4 mg/ml):Ir(mppy)$_3$ (0.04 mg/ml):Ir(piq)$_3$ (0.02 mg/ml) and P36HCTPSi (5 mg/ml):FIrpic (0.4 mg/ml):Ir(piq)$_3$ (0.02 mg/ml).

To further investigate the mechanism behind the EL of the white device, blended films of P36HCTPSi (5 mg/ml):FIrpic (0.4 mg/ml):Ir(mppy)$_3$ (0.04 mg/ml):Ir(piq)$_3$ (0.02 mg/ml) and P36HCTPSi (5 mg/ml):FIrpic (0.4 mg/ml): Ir(piq)$_3$ (0.02 mg/ml) were spin-coated on glass substrates. The former has the same component as the EML of the white device, while Ir(mppy)$_3$ is absent in the latter. Normalized PL spectra of the blended films with and without Ir(mppy)$_3$ are shown in Fig. 3b, excited by radiation at a wavelength of λ = 330 nm, where P36HCTPSi has strong absorption (see Fig. 3b). Compared to the one without Ir(mppy)$_3$, PL of the film with Ir(mppy)$_3$ shows a increased intensity of Ir(piq)$_3$ and decreased intensities of P36HCTPSi and FIrpic, indicating energy transfers take place from both P36HCTPSi and FIrpic to Ir(mppy)$_3$, and successively to Ir(piq)$_3$. In addition, compared to EL of the white device shown in Fig. 1, PL of the film with Ir(mppy)$_3$ shows a stronger emission of P36HCTPSi and higher emission ratios of FIrpic/Ir(mppy)$_3$ and FIrpic/Ir(piq)$_3$, suggesting that direct charge trapping is involved in the EL process. According to the energy level diagram shown in Fig. 4, Ir(mppy)$_3$

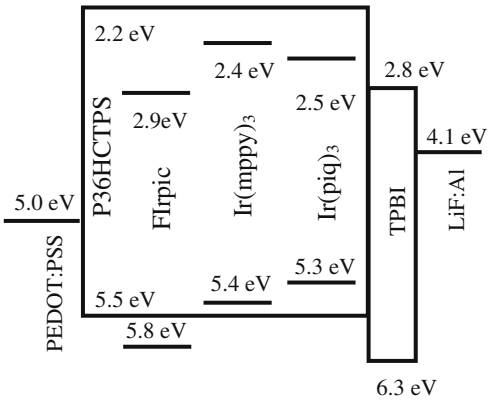

Fig. 4. Proposed energy diagram of the materials used in our devices.

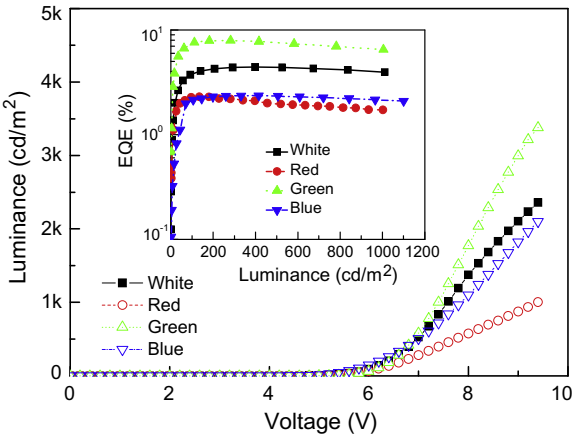

Fig. 5. Luminance–voltage characteristics of white, blue, green, and red devices; Inset: EQE-luminance curves of these devices. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

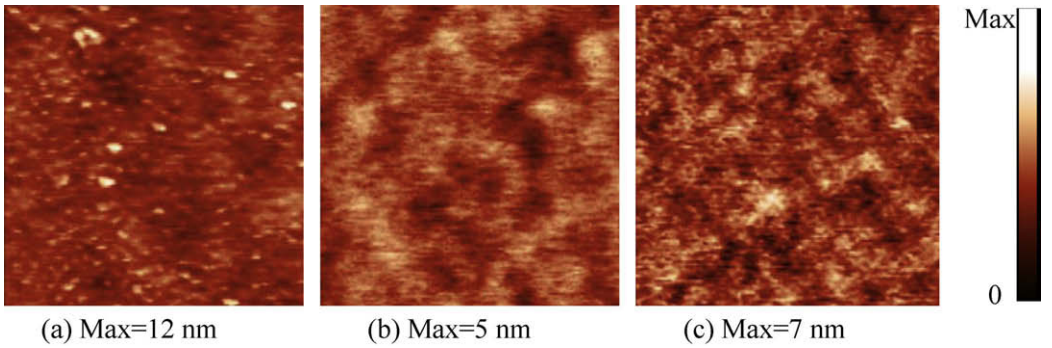

Fig. 6. AFM height imagines of P36HCTPSi films doped with (a) FIrpic, (b) Ir(mppy)$_3$, and (c) Ir(piq)$_3$, with concentration of 8 wt%. The size for all images is 2.5 × 2.5 μm.

and Ir(piq)$_3$ molecules in the polymer are traps for both holes and electrons, which facilitates the direct injection of both charges. For FIrpic molecules, on the other hand, only electrons can be trapped in. This might be another reason for the relatively stronger host emission in the blue device. As discussed previously in Fig. 3b, energy transfers occur in the white device from higher energy iridium complexes to lower energy ones, it is understandable that the concentration of FIrpic (8 wt%) is higher than a Ir(piq)$_3$ (0.4 wt%) by 20 times. The concentration of Ir(mppy)$_3$ (0.8 wt%), on the other hand, is only two times higher than Ir(piq)$_3$. To understand the relatively similar concentration of Ir(mppy)$_3$ and Ir(piq)$_3$, external quantum efficiency (EQE)-luminance curves of blue, green, and red devices are plotted in the inset of Fig. 5. The maximum EQE (7.9%) of Ir(mppy)$_3$ is much higher than those of FIrpic (2.4%) and Ir(piq)$_3$ (2.3%). This high EQE demands a lower concentration of Ir(mppy)$_3$ to achieve the balanced white emission. AFM measurements were applied on P36HCTPSi films doped with FIrpic, Ir(mppy)$_3$, and Ir(piq)$_3$ to investigate the relatively low efficiencies of blue and red devices. Herein, the doping concentration is 8 wt% in all films. As shown in Fig. 6, the morphology of Ir(mppy)$_3$ and Ir(piq)$_3$ doped films are quite homogeneous while slight phase-separation is observed in the FIrpic doped film, which might lower the efficiency of the blue device. For the red device, the low efficiency may be attributed to the poor match between the energy levels of P36HCTPSi and Ir(piq)$_3$ [20].

Luminance–voltage characteristics of these devices are shown in Fig. 5. Luminances of blue, green, red, and white devices at 9.4 V are 1000, 3300, 2100, and 2300 cd/m^2, respectively. Main performances at different luminance of the white device are listed in Table 1; EQE, luminous efficiency, power efficiency, and CRI at 100 cd/m^2 are 4.26%, 8.55 cd/A, 4.55 lm/W, and 82, respectively. CIE coordinates slightly vary from (0.40, 0.46) to (0.38, 0.45) with the increasing luminance from 10 to 1000 cd/m^2 because of the change of EL spectrum as shown in Fig. 1.

Table 1
Performances of the white device at difference luminance.

L[a] (cd/A)	EQE (%)	LE[b] (cd/A)	PE[c] (lm/W)	CIE coordinates (*x*, *y*)	CRI
10	1.37	2.79	1.75	0.40, 0.46	81
100	4.26	8.70	4.55	0.39, 0.45	82

[a] Luminance.
[b] Luminous efficiency.
[c] Power efficiency.

4. Conclusion

We demonstrated a white phosphorescent PLED by employing a wide band-gap polymer P36HCTPSi as a host material for blue, green, and red emission phosphorescent iridium complexes. Energy transfers from the host to guests and from higher energy iridium complexes to lower energy ones are observed. Direct trapping is found playing an important role in EL as well. In our white PLED, EQE, luminous efficiency, power efficiency, and CRI at 100 cd/m^2 are 4.26%, 8.55 cd/A, 4.55 lm/W, and 82, respectively.

ABSTRACT

Blue organic light emitting devices (OLEDs) with high efficiency were reported by the designing of double emission layers (DELs) and changing doping concentration of fluorescent material in DELs. The carrier injection in each emission layer was greatly improved with the aid of different doping concentration, which resulted in carriers' recombination with a well balance. The maximum current efficiency and power efficiency of the OLEDs were 18.99 cd/A and 11.63 lm/W at 2.0 mA/cm^2, respectively, and the maximum brightness of the optimum device was 40,040 cd/m^2 at 14 V. Consequently, besides a better color and efficiency stabilization, these devices with the DELs presented a higher current efficiency and brightness than the conventional devices with single emission layer (SEL) by more than 70%.

1. Introduction

White organic light emitting devices (WOLEDs) have been developed intensively in the past 20 years due to its great potential applications in large flat panel display and solid-state lighting [1–4]. There are two main methods to realize white light emitting including the mixture of red, green and blue three prime colors or blue and orange-yellow complementary colors. Apparently, blue light emitting plays a key role for the white light devices, which is still confronted with some problems such as low efficiency and short lifetime compared with other colors-emitting [5]. In order to improve the EL performance and optimize the structure of blue OLEDs, researchers have paid great attentions for this recently i.e., Divayana et al. reported a blue OLED with exciton-confining structure [6]. Jonghee Lee et al. demonstrated an adjustment of interlayer between transporting and emitting layer [7]. Bacsa et al. reported a multi-layer configuration for blue OLEDs [8]. In addition, double emitting layers structure was employed into blue OLEDs by utilizing phosphorescent materials doped in hosts, as a result, broadening carrier recombination zone in the EMLs and reducing carrier accumulation in the interface were achieved [9,10]. i.e. Meng-Ting Lee et al. described the blue OLEDs with double emission layers (DELs) through using same phosphorescent material doped in two different hosts, which achieved the current efficiency of 29.5 cd/A, and the power efficiency of 21 lm/W at 4.4 V [9]. However, the phosphorescent materials have some common drawbacks such as quenching phenomena of triplet–triplet excited states, and relatively short lifetime. Fluorescent materials can avoid these drawbacks efficiently, but its efficiency is lower compared with phosphorescent materials. Previously, our research group reported a single emitting layer (SEL) blue OLED doping with fluorescent material, which showed the current efficiency of 11.8 cd/A and brightness of 25,690 cd/m^2, respectively, [11]. Therefore, it is expected that the EL performances of blue

doi:10.1016/j.orgel.2009.11.032

OLEDs doping with fluorescent materials would be enhanced efficaciously through employing DELs structure. By now, there is no any report that utilized the fluorescence DELs by using same host and same dopant with different doping concentration for the blue OLED.

In this paper, we demonstrated a high efficiency blue OLED with DELs, which was realized through modulating the doping concentration of the fluorescent material N-(4-((E)-2-(6-((E)-4-(diphenylamino)styryl)naphthalen-2-yl)vinyl)phenyl)-N-phenylbenzenamine(N-BDAVBi) in the host 4,4′-N,N′-dicarbazole-biphenyl(CBP) with wide band gap. Doping concentration is 2%, 5% and 8% in each emission layer. This novel structure of DELs could expand light-emitting region and improve carrier combination rate efficiently. Moreover, the EL performances of this device is better than those of SEL OLEDs doped with fluorescent materials, which has the satisfactory current efficiency of a high value closed to that of the OLEDs doped with phosphorescent materials.

2. Experimental

The device's structure and energy level diagram of DELs are shown in Fig. 1, N,N′-bis(naphthalen-1-yl)-N,N′-bis(phenyl)-benzidine(NPB) and 4,7-diphnenyl-1,10-phenanthroline(BPhen) were used as hole transport and electron transport materials, respectively. 4,4′-N,N′-dicarbazole-biphenyl(CBP) acted as the bipolar host material, and N-(4-((E)-2-(6-((E)-4-(diphenylamino)styryl)naphthalen-2-yl)vinyl)phenyl)-N-phenylbenzenamine(N-BDAVBi) acted as blue fluorescent material, respectively. And different doping concentration of N-BDAVBi with 8%, 5%, 2% doped in each emitting layer was shown in Fig. 1. All the organic layers were deposited onto a pre-cleaned ITO glass substrate with a sheet resistance of 20 Ω/sq, by thermal evaporation coating system at a pressure of about 2×10^{-4} Pa. Two light-emitting layers were deposited unsuccessively in twice during the process of thermal evaporation, which results in the EML I, EML II and their interface. From Devices A–F, the double EMLs were constructed by CBP:N-BDAVBi/CBP:N-BDAVBi, in which the doping concentration of EML I/EML II were 8%/8%, 5%/5%, 2%/2%, 8%/2%, 8%/5% and 5%/2%, respectively. The followed by a deposited LiF, which as a buffer layer, and an Al as cathode, all of the above step without breaking the vacuum. The deposition rates and thickness of the various layers were monitored using a quartz crystal oscillator. The evaporation rates were 0.1–0.3 nm/s for the each organic layer, and 1 nm/s for the LiF layer and Al cathode. The electroluminescent (EL) spectra and the brightness of the devices were measured with the PR650 spectra scan spectrometer. The current and current density versus voltage characteristics were measured simultaneously with the EL spectra by using the Keithley model 2400 programmable voltage–current source. And all of the records were carried out at room temperature.

3. Results and discussion

It was universally acknowledged that the mobility of holes transport materials is far greater than that of electron transport materials for general organic materials [12]. This unbalancedness will reduce the combination rate of electrons and holes in the light-emitting layers and lead to performance degradation for devices. In this report, we used NPB and BPhen as the hole and the election transport materials, respectively, for the balance of carrier injection in view of their similar mobility of each. As shown in Fig. 1, the highest occupied molecular orbital (HOMO) level is 5.4 eV, 5.9 eV and 5.3 eV for NPB, CBP and N-BDAVBi, respectively. An injection barrier about 0.5 eV appears at the NPB/CBP interface, which is unfavorable for holes injection into host material (CBP). Alternatively, an injection barrier about 0.1 eV at the NPB/N-BDAVBi interface promotes holes transport directly and may be trapped at the doping site. On the other hand, the lowest unoccupied

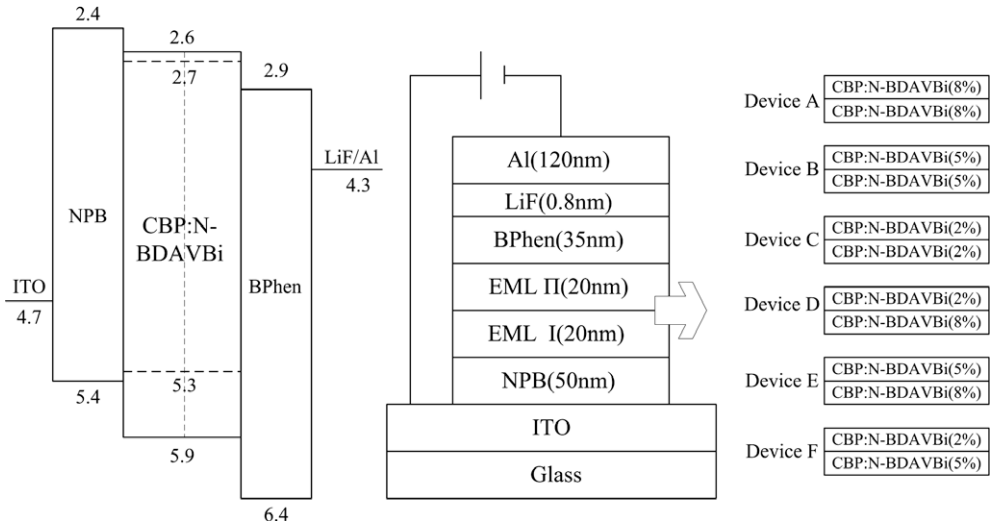

Fig. 1. Configurations of Devices A–F with DELs and the Energy level diagram of device (unit: eV).

molecular orbital (LUMO) level is 2.9 eV, 2.6 eV and 2.7 eV for BPhen, CBP and N-BDAVBi, respectively, and the energy barrier is about 0.3 eV (at the interface of BPhen/CBP) and 0.2 eV (at the interface of BPhen/N-BDAVBi). Therefore, electrons can be injected into host and dopant easily with a higher mobility [13]. In order to improve the carrier balance and the combination rate in the exciton region, we constructed DELs (Devices A–F). Firstly, we focused our work on the DELs with the same doping concentration in each light-emitting layer for each device, corresponding to the light-emitting layer's structure of the three devices presented below.

Device A: CBP: N-BDAVBi (20 nm, 8%)/CBP: N-BDAVBi (20 nm, 8%)
Device B: CBP: N-BDAVBi (20 nm, 5%)/CBP: N-BDAVBi (20 nm, 5%)
Device C: CBP: N-BDAVBi (20 nm, 2%)/CBP: N-BDAVBi (20 nm, 2%)

The dependence of current efficiency on current density, current density and brightness on voltage of devices were presented in Fig. 2a and b, respectively. It is derived that the current efficiency decreases with the increasing of current density, and the current density and brightness increases with the increasing of voltage for a certain doping concentration. The maximum current efficiency and brightness were about 10.1 cd/A and 26,750 cd/m^2 at 2.0 mA/cm^2, respectively, when the doping concentration is optimized to 8% (for both of EML I and EML II). There is a slight enhancement in brightness for the double emitting layer devices with the same doping concentration compared with the SEL devices reported by our group [11]. For Devices A–C, holes could easily across from EML I to EML II, and electrons could easily across from EML II to EML I for the double light-emitting layers with the high doping concentration in each emission layer, which would result in efficient combination for the holes and electrons in the light-emitting region. But holes could not easily inject into emitting layer due to the high barrier (NPB/CBP), especially for the case of the lower doping concentration. Therefore, high doping concentration was needed to reduce the barrier for the injection of holes in emission layer [12].

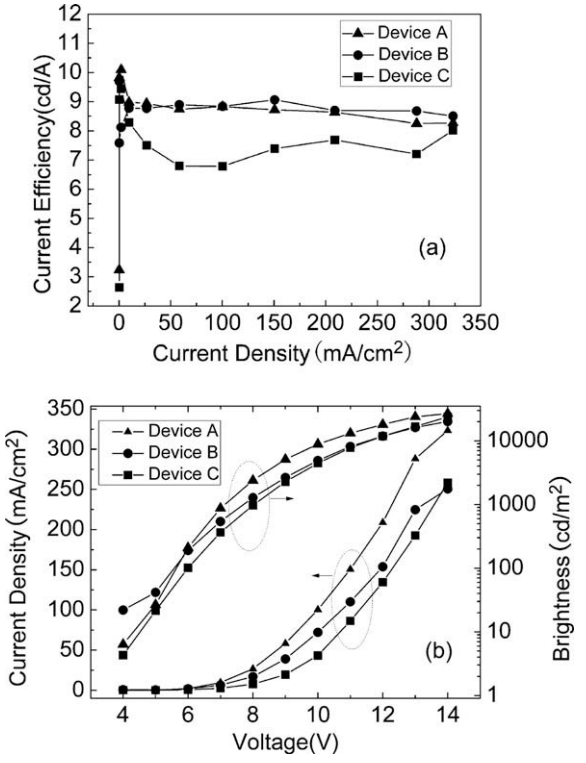

Fig. 2. Result for DELs Devices A–C, in each layer with the same doping concentration. (a) Dependence of current efficiency on current density. (b) Dependences of current density and brightness on voltage.

For the further consideration, the emitting layer with low doping concentration was considered as the assistant emitting region relative to the dominating emitting region which doped with a higher concentration. At the low driving voltage, the carriers could be easily injected into the assistant emitting region, which due to the superior mobility of hole than that of the electron in N-BDAVBi. For this reason, the carrier balance could be fulfilled and excitons combination rate could be enhanced in EML II. With the increase of the voltage, more electrons could be injected into the dominating emitting region to combine the holes to form the excitons in the EML I, which resulted in a better balance of the carriers in both EML I and EML II with high and low doping concentration, respectively, at a large range of driving voltage. This clue provides an optimal route that with high doping concentration (in EML I) and low doping concentration (in EML II) simultaneously to achieve excellent EL performance of these devices.

Nextly, we investigated the DELs doping with different concentration in each emission layer. EML configurations of the devices were demonstrated by followings.

Device D: CBP: N-BDAVBi (20 nm, 8%)/CBP: N-BDAVBi (20 nm, 2%)
Device E: CBP: N-BDAVBi (20 nm, 8%)/CBP: N-BDAVBi (20 nm, 5%)
Device F: CBP: N-BDAVBi (20 nm, 5%)/CBP: N-BDAVBi (20 nm, 2%)

Apparently, the introduction of the DELs using different doping concentration in each emission layer improves the device's EL performances significantly, which showed in Fig. 3a and b. It was worth to note that the EL performances of Devices D–F have been enhanced efficiently compared with those of Devices A–C, shown in Table 1, which presented the EL performances of all devices. The maximum current efficiency and brightness of Devices D–F were about 18.99 cd/A, 17.15 cd/A, 17.24 cd/A and 33,050 cd/m^2, 31,010 cd/m^2, 40,040 cd/m^2, respectively. Apparently, the efficiency was nearly 1.7 times higher than that of the SEL device. Additionally, In DELs devices, the current efficiency and brightness both were increased greatly with the increase of voltage (from 4.5 V to14 V), which is more quickly than the increasing trend in SEL device. With a higher current efficiency for Devices D–F, the recombina-

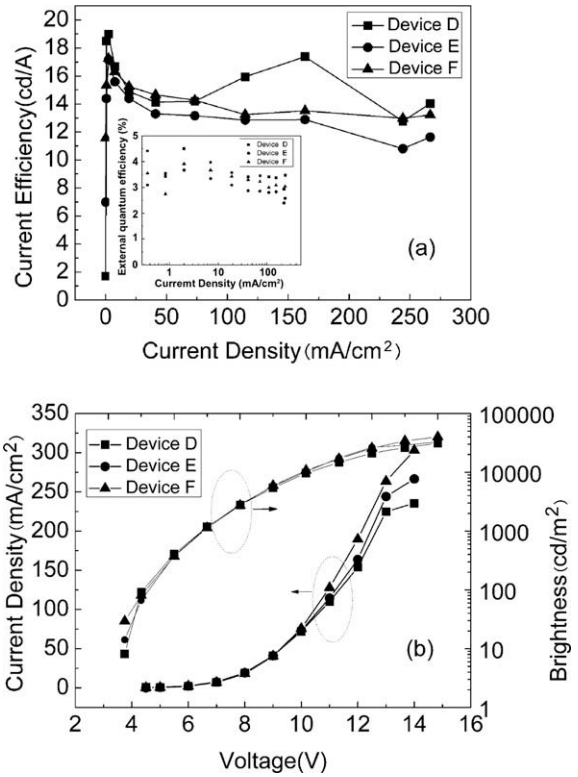

Fig. 3. EL performance for DELs Device D–F, in each layer with the different doping concentration. (a) Dependence of current efficiency on current density. (b) Dependences of current density and brightness on voltage. The insert of (a) exhibits external quantum efficiency on current density.

tion rate of two types of carriers was greatly improved, which could be mainly ascribed to the enhancement of carriers balance in the dominating and assistant regions at different driving voltage. With the increase of the driving voltage, the carriers' combination regions would be broadened and emitting light regions would be away from the cathode gradually [14], which could prevent accumulation of the excessive excitons around the cathode.

The enhancement of performances could be explained with the double emitting regions model. When the operating voltage was lower, the recombination between holes and electrons was only appeared in the interface of EML II/ETL as assistant emitting region due to their different mobility. But, when the operating voltage was increased, the electrons injected from cathode were further transferred to interface of EML I/EML II and the dominating emitting region with a larger width occurred with that the assistant emitting region moves to it gradually. As a result, the recombination rate of electrons and holes was further improved by comparing with the SEL devices which only have a narrower emitting region.

At a certain current density, it was obvious that current efficiency and brightness of the devices doped with varied concentration in EML I and EML II were higher than that of the device with same doping concentration in them. It was well known that more electrons and holes were recombined in else at a higher doping concentration, and the device performances could be enhanced to a certain extent. For the EML I and EML II with same doping concentration (about 8%) in which holes and electrons were accumulated in the assistant emitting region, on the contrary, only a little of holes and electrons were appeared in the dominating emitting region, so it is more difficult to achieve the effect of broading emitting region by doping with high concentration. Otherwise, although the device of DELs could obtain wider emitting region for the low doping concentration, but recombination rate of the holes and electrons was lower in the emitting region. So the EL performance of devices could not be obviously enhanced. In this work the different doping concentration adjusted in EMLs (Device F) were employed to avoid the accumulation of excitons farthest in the assistant emitting region and improve the recombination rate of excitons in the dominating emitting region. Fig. 3 showed that the optimization balance of excitons was realized through the lower doping concentration in the assistant emitting region (2%) and the higher doping concentration in dominating emitting region (8%), respectively. Therefore, the performances of devices were enhanced through optimizing doping concentration in the each EML. Furthermore, the stable current efficiency in the Devices D–F was achieved, which exhibited a high value at the high brightness in Fig. 3. Meanwhile, the insert of the Fig. 3a shows the external quantum efficiency (EQE%) of the Devices D–F with a stable efficiency characteristic at the driving voltage of 4.5–14 V. The photoelectric performances of all devices were shown in Table 1. Therefore, the current efficiency of Device D was

higher than that of others. This result may be owed to the superiority of DELs.

Fig. 4 showed the normalized EL spectra of the Devices D–F with different doping concentration of N-BDAVBi at 10 V, in which the dominant peaks locate at 472, 470 and 468 nm, respectively. Accordingly, the blue shift occurs in the dominant peaks from Device D to F. This could be explained that the recombination region would transferred from the EML II/ETL to the EML I/EML II, gradually, and the excitons could reduce the excessive accumulation around the EML II/ETL. Meanwhile, the EL intensity increase corresponding to the Devices D–F. The insert of Fig. 4 showed the CIE chromaticity of Devices D–F at which the operating voltage varies from 4.5 V to 14 V gradually, which presented the good color stability at different driving voltage.

4. Conclusions

In summary, a strategy to optimize and enhance the performance of blue OLED with the designing of double emission layers (DELs) and changing doping concentration of fluorescent material in DELs. Devices with the DELs structure can expand the light-emitting region efficiently compared with the single emitting layer devices. In addition, an optimal route of dominating emitting region with high doping concentration and assistant emitting region with low doping concentration was employed to balance the injection ration of holes and electrons at the interface of emission layers. A result shows that the EL performance of the DELs devices can be enhanced efficiently and color and efficiency stability could also be improved greatly. The maximum current efficiency and power efficiency of device were 18.99 cd/A and 11.63 lm/W at 2.0 mA/cm^2, respectively. Moreover, the maximum brightness of 40,040 cd/m^2 at 14 V was also achieved in the optimized device.

ABSTRACT

The characteristics of solution processed top-gate-type organic field-effect transistors (OFETs) with indium–tin oxide (ITO) drain/source electrodes using polyfluorene derivatives were investigated. An OFET with poly(9,9-dioctylfluorene) (F8) as an active layer, which contains only a fluorene backbone, exhibited ambipolar characteristics with hole and electron field-effect mobilities of approximately 10^{-3} cm^2 V^{-1} s^{-1}. All OFETs with fluorene derivatives exhibited ambipolar characteristics because the value of the work function of the ITO electrode is approximately in the middle between the highest occupied molecular orbital and lowest unoccupied molecular orbital levels of fluorene derivatives. Fluorene derivatives can conduct both holes and electrons. Ambipolar OFETs with F8 and a fluorene derivative doped in F8 can be applied to various color tunable light-emitting devices.

1. Introduction

Organic semiconductors have attracted considerable attention due to their simple and low-cost processing, and potential electronic and optoelectronic applications. In particular, they have demonstrated the possibility of electronic and optoelectronic devices fabricated by solution processing for large-area and flexible devices. Recently, organic field-effect transistors (OFETs) have been extensively studied in view of their applications to low-cost, large-area, flexible electronics [1–9]. High performance of organic field-effect transistors (OFETs) fabricated using highly crystalline organic materials have been realized; however, solution processing has still attention in simple fabrication process for large area devices. The characteristics of polymer devices fabricated by solution processing are strongly dependent on the self-organized structure. OFETs with various device structures have been reported to show ambipolar characteristics and light emission [8–18]. In particular, ambipolar materials are useful for fabricating OFETs, because they can be used either as a p-channel or a n-channel by changing the polarity of the gate voltage.

Poly(9,9-dioctylfluorene) (F8), which contains only a fluorene backbone, exhibits blue emission and various morphological behaviors [19–22]. Fluorene-type polymers have emerged as an important class of conducting polymers due to their efficient emission, high stabilities and relatively high mobility. Fluorene-type polymers also have the potential for full color emission via energy transfer to longer wavelength emitters in blends with other emissive materials.

For n-channel OFETs, the injected carrier is the electron, and therefore it is preferable for the source electrode work-function value to be lower. However, most metals with a low work-function (i.e. Ca, Li, Cs, etc.) are very sensitive to oxygen and moisture in the air, and thus it is difficult to fabricate and handle devices using these metals. Indium–tin oxide (ITO) is suitable for the electrode of organic devices such as organic light-emitting diodes and organic photovoltaics due to its optical transparency. The work function of ITO is relatively low.

In this study, we investigated the characteristics of top-gate type OFETs with ITO drain/source electrodes using polyfluorene derivatives. We also discuss ambipolar characteristics of OFETs and the application of light-emitting field-effect transistors by varying the gate voltage.

2. Experimental procedure

A top-gate structure, whose device has a gate electrode on the gate insulating layer, was employed for the OFETs based on polyfluorene derivatives. Poly(9,9-dioctylfluorene) (F8, Mw = 82k, ADS129BE) and poly[(9,9-dihexyl-2,7-(2-cyanodivinylene)-fluorenylenyl-2,7-diyl)] (CN-PDHFV, Mw = 20k, ADS127GE) purchased from American Dye Source Inc. were used as the organic layer without further purification. Fluorene copolymers of poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-bithiophene] (F8T2, Mw = 52k) and poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(1,4-benzo-{2,1′,3}-thiadiazole)] (F8BT, Mw = 363k) were supplied by Sumitomo Chemical Co., Ltd. Fig. 1 shows the device structure and schematic energy level diagrams of F8, F8T2 and F8BT films. The energy levels of the highest occupied molecular orbitals (HOMOs) of polyfluorene derivatives were taken from previously published work [15,23,24]. The bandgap energy was simply estimated from the edge of the absorption spectrum. Polished ITO precoated on a glass substrate, obtained commercially, was used for the source and drain electrodes. Surface morphologies were observed by atomic force microscopy (AFM; JEOL, JSPM-5200). The average surface roughness of the ITO was estimated to be about 0.5 nm from the AFM image. The channel length and width were 0.1 and 2 mm, respectively. The substrate was degreased with solvents and cleaned in a UV ozone chamber. A semiconducting layer was formed by spin coating from a xylene solution onto patterned ITO electrodes, which served as source and drain electrodes, in air. The typical thickness of the semiconducting layer was approximately 50–70 nm. Organic layers were baked at 290 °C in a dry nitrogen glove box, and Poly(methyl methacrylate) (PMMA) was then used as a gate insulator on the active layer without intermixing. Using anhydrous *n*-butyl acetate as a solvent, a PMMA solution was spun onto an active layer and baked above 150 °C. The typical thickness of the gate insulator was approximately 600 nm. An Au gate electrode with a 30-nm thickness was vacuum evaporated at a background pressure of about 10^{-4} Pa onto the polymer gate insulating layer formed on the polyfluorene semiconducting layer. The deposition rate and thickness of the deposited electrode were monitored using a quartz crystal oscillator.

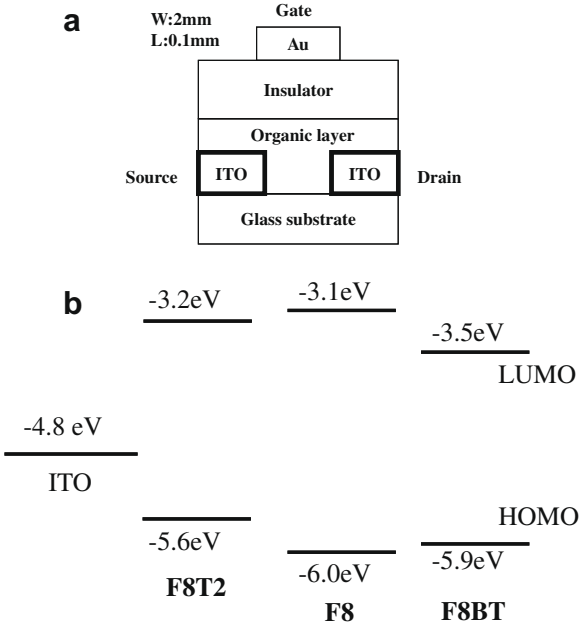

Fig. 1. (a) Device structure and (b) energy diagram of the materials used in this study.

After the deposition of the Au gate electrode, devices were exposed to air. Then, measurements of electrical characteristics of the OFETs were carried out at room temperature in a vacuum chamber with a background pressure of about 10^{-4} Pa after evacuation for more than 6 h. The current–voltage characteristics were obtained using 2400 and 6517 A source meters (Keithley). The electroluminescence (EL) output was measured using a photodiode (Hamamatsu Photonics). The EL spectra were measured using a photonic multichannel spectral analyzer (Hamamatsu Photonics PMA-11). For the measurement of EL spectra, the devices were covered with a glass plate and encapsulated by epoxy resin in an argon gas atmosphere to prevent oxidation of the electrode and the organic layer.

3. Results and discussion

Poly(9,9-dioctylfluorene) (F8), which contains only a fluorene backbone, exhibits blue emission and various morphological behaviors. Polyfluorene-based block copolymers of F8T2 with thiophene group as a hole transporter and F8BT with an electron-withdrawing group were used as hole- and electron-transport materials, respectively. The value of the work function of the ITO electrode is located approximately in the middle between the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of fluorene derivatives, as shown in Fig 1b. Therefore, for top-gate type OFETs with fluorene derivatives as active layers, both holes and electrons can be expected to be injected from the ITO drain/source electrodes into the HOMO and LUMO levels of fluorene derivatives by applying a voltage.

It is well known in OFETs that charge carriers run a few nanometers around the insulator/semiconductor interface[25,26]. The OH groups at the interface between the polymer gate insulator and the organic active layer interfere with n-type carrier transport[8,9,15,18,27]. PMMA, which does not contain electron-trapping groups, such as OH, was used as a gate insulator.

Fig. 2a and b show the output characteristics of top-gate type OFETs with F8. For both the hole and electron enhancement modes, the drain–source current increased superlinearly at lower drain–source voltages. The injection barriers of both holes and electrons from ITO drain/source

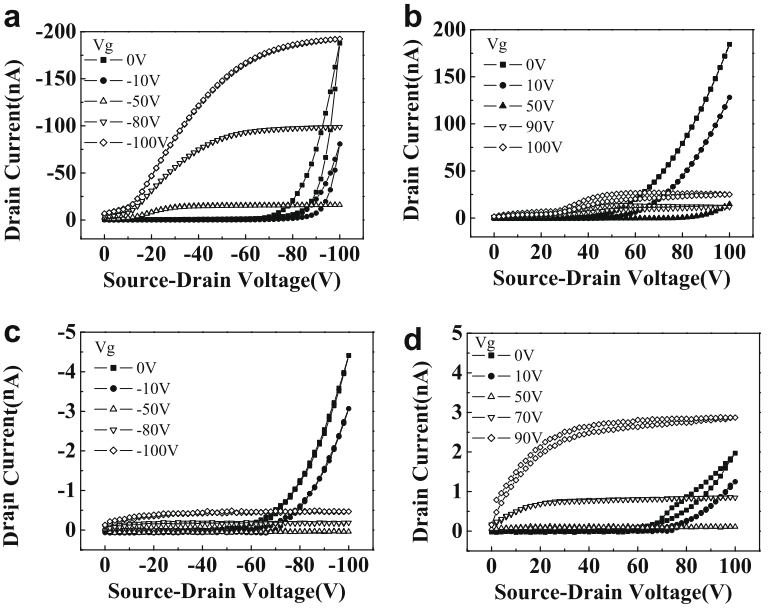

Fig. 2. Output characteristics of top-gate-type OFETs with (a and b) F8 and (c and d) CN-PDHFV, for different gate voltages in the hole and electron enhancement modes, respectively.

electrodes into the HOMO and LUMO levels are relatively high, more than 1 eV. These superlinear currents result from the relatively large contact resistance for both hole- and electron-injection. From measurements of drain–source current characteristics, shown in Fig. 2a, the saturation characteristics were typical for a p-channel OFET working in the accumulation mode. Output characteristics of the F8 device operated in the electron enhancement mode are shown in Fig. 2b. The leakage drain–source current increased superlinearly with drain–source voltage at lower gate voltages. Application of positive gate voltage suppressed this component, and typical saturation characteristics of an n-channel OFET were observed at high gate voltages. That is, ambipolar characteristics were obtained from the top-gate-type F8 device with ITO drain/source electrodes. Hysteresis was observed due to the charge trapping in the electron enhancement mode.

Fig. 3 shows transfer characteristics of top-gate-type OFETs based on F8. The hole mobility and threshold voltage of the top-gate type F8 device were estimated to be $\mu = 7.2 \times 10^{-4}\,cm^2\,V^{-1}\,s^{-1}$ and $V_{th} = -24$ V, respectively, at the drain-source voltage V_{DS} of −100 V. For n-channel OFET operation, the effective electron mobility and threshold voltage were estimated to be $\mu = 1.2 \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$ and $V_{th} = 61$ V, respectively, at a drain-source voltage V_{DS} of 100 V. For the F8 device, the threshold voltage in the hole enhancement mode is lower than that in the electron enhancement mode because the hole injection barrier is lower than the electron injection barrier, as shown in Fig. 1b.

The LUMO level of CN-PDHFV with the electron-withdrawing cyano group to the vinylene bonds is lower than that of F8. For bottom-gate-type CN-PDHFV OFET with Ca drain/source electrodes, only n-channel characteristics have been reported [28]. By using the top-gate type OFET

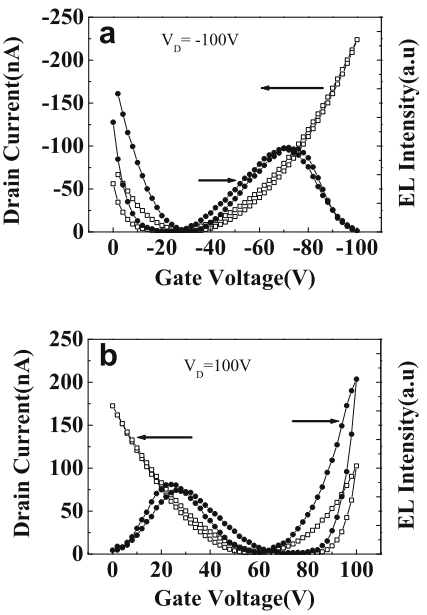

Fig. 3. Transfer characteristics and corresponding light output of the F8 device for different drain voltages of (a) −100 V and (b) 100 V.

structure with ITO electrodes, ambipolar characteristics were observed, as shown in Fig. 2c and d. It is to be noted that fluorene derivatives can conduct both holes and electrons. That is, fluorene polymers as transport materials for holes and electrons are thus essential in functionalizing electronic devices.

Transfer characteristics of top-gate-type OFETs based on F8T2 and F8BT are shown in Fig. 4a and b. For top-gate-type OFETs with F8T2 and F8BT as active layers,

ambipolar characteristics were also observed. As shown in Table 1, F8, F8T2 and F8BT devices exhibited ambipolar characteristics with both hole and electron field-effect mobilities of approximately 10^{-3} cm^2 V^{-1} s^{-1}. For devices with bottom-contact/top-gate geometry, charge injection can be expected to occur a large area away from the edge of electrodes and be aided due to the influence of the applied gate filed because the drain/source electrodes and the gate electrode were overlapped[15]. Although these devices with ITO source/drain electrodes have relatively large contact resistance, these carrier mobilities are in relative agreement with those of bottom-gate-type OFETs with Au and Ca drain/source electrodes for p- and n-channel OFETs measurements, respectively [8].

For the p-channel OFET characteristics, the threshold voltage of the F8T2 device was lower than that of the F8 device. This is because the injection barrier of holes from ITO drain/source electrodes into the HOMO level of F8T2 is relatively lower than that of F8. On the other hand, for n-channel OFET characteristics, the threshold voltage of OFET based on F8BT with an electron-withdrawing group was lower than that of the F8 device, because the injection barrier of electrons from ITO into the LUMO level of F8BT is relatively lower than that of F8. These results suggest that by OFET measurements using top-gate-type OFETs with ITO drain/source electrodes, the carrier transport characteristics in various polyfluorene derivatives can be characterized.

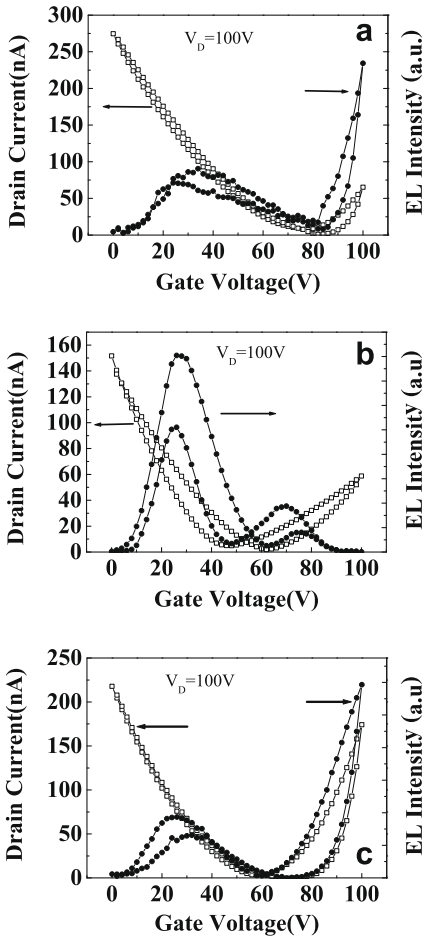

Fig. 4. Transfer characteristics and corresponding light output of (a) F8T2, (b) F8BT and (c) F8:F8BT devices for a positive drain voltage of 100 V.

For this ambipolar OFET with F8, blue light emission was observed by varying the gate voltage as shown in Figs. 3 and 5. A peak of EL intensity was observed when hole current dominated at gate voltages between 0 (−30) and 60 (−100) V. The EL intensity was at a minimum when the drain current reached a minimum. On the other hand, EL intensity increased with gate voltage when electron current dominated above approximately 60 (−20) V. The typical output power of devices was on the order of 10^{-1} nW. For ambipolar OFETs with F8BT and F8T2, yellow–green and yellow light emissions, respectively, from F8BT and F8T2 were also observed. It is to be noted that top-gate-type fluorene OFETs with ITO drain/source electrodes can be applied to light-emitting transistors.

For both the F8 and F8T2 devices, a peak of EL intensity was observed when hole current dominated as shown in Figs. 3 and 4a. The behavior of the gate voltage dependence of the EL intensity in the F8T2 device is the same as that in the F8 device. On the other hand, for an F8BT device, two EL intensity peaks were observed when either hole or electron currents dominated. In ambipolar OFETs, simultaneous electron and hole injection can be achieved by applying the gate voltages. For both F8 and F8T2 devices, the electrons cannot be injected easily in organic layer at lower gate voltages due to high injection barrier of electrons although the electron mobility is the same as the hole mobility as shown in Table 1. Therefore, EL intensity continued to increase at high gate voltages when the injected electrons increased with gate voltages. These results suggest that carrier transport of holes is predominant in our F8 and F8T2 devices.

The dye doping method is of practical importance because it allows for easy improvement in performance, such as color tunability. OFETs with 5 wt.% F8BT doped in F8 as an active layer also showed ambipolar characteristics as indicated in Fig. 4c. For an F8:F8BT device, white emission with a CIE coordinate of (0.34, 0.40) was obtained due to blue and yellow–green emission from F8 and F8BT. This emission mechanism from the F8:F8BT device can be interpreted in terms of the following two mechanisms. In the first mechanism, electrons and holes are injected from the source and drain electrodes, respectively, to the F8. As a result, excitons are formed on the F8 and excitonic energy is then effectively transferred to the F8BT by the Förster energy transfer process. In the second mechanism, injected holes and electrons are directly trapped on F8BT molecules; excitons are then formed after carrier recombination. As a result, the emission from F8BT molecules is obtained. The transfer characteristics of the F8:F8BT device are the same as those of the F8 device as shown in Fig. 4c. That is, for the F8:F8BT device, carrier transfer is still dominant in the F8 film. This result suggested that excitons are formed on the F8, and the excitonic energy transfers to the F8BT by the Förster energy transfer process, because the band gap of F8BT is lower than that of F8.

Table 1
HOMO and LUMO levels of fluorene derivatives, and field-effect mobility and threshold voltage obtained from polyfluorene OFET measurements.

Polymer	HOMO	LUMO	Field-effect mobility ($cm^2V^{-1}s^{-1}$)		Threshold voltage (V)	
	(eV)	(eV)	Hole	Electron	Hole	Electron
F8	6.0	3.1	0.7×10^{-3}	1.2×10^{-3}	−24	61
F8T2	5.6	3.2	1.0×10^{-3}	1.3×10^{-3}	−7	71
F8BT	5.9	3.5	0.8×10^{-3}	0.4×10^{-3}	−18	40
CN-PDHFV	6.0[28]	3.6[28]	0.7×10^{-5}	4×10^{-5}	−20	30

4. Conclusions

We demonstrated the characteristics of solution processed top-gate type ambipolar polyfluorene OFETs with ITO drain/source electrodes. An OFET with F8 as an active layer, which contains only a fluorene backbone, exhibited ambipolar characteristics with hole and electron field-effect mobilities of approximately $10^{-3}\,cm^2\,V^{-1}\,s^{-1}$. All OFETs with fluorene derivatives exhibited ambipolar characteristics because the value of the work function of the ITO electrode is located approximately in the middle between HOMO and LUMO levels of fluorene derivatives. It is to be noted that fluorene derivatives can conduct both holes and electrons. By OFET measurements using top-gate type OFETs with ITO drain/source electrodes, carrier transport characteristics in various polyfluorene derivatives can be characterized. Ambipolar OFETs with F8, F8BT and F8T2 exhibited blue, yellow–green and yellow EL emissions, respectively, with varying gate voltage. For F8 and F8T2 devices, a peak of the EL intensity was observed when hole current dominated. On the other hand, for an F8BT device, two peaks of the EL intensity were observed when either hole or electron currents dominated. These results suggested that carrier transport of holes is predominant in the F8 and F8T2 films. White emission was also observed from an ambipolar OFET with 5 wt.% F8BT doped in F8 as an active layer. We thus demonstrated that top gate-type fluorene OFETs with ITO drain/source electrodes can be applied to light-emitting transistors.

ABSTRACT

We present a model for organic bistable devices (OBDs) embedded with metallic nanoparticles. The model takes into account charge transport through the organic material, field-dependent charge carrier mobility, and injection from the electrodes. The charge trapped by the nanoparticles induces space charge effects that reduce the electric field at the electrode and inhibit charge injection leading to the low conductivity state of the OBD. Between the two situations where the nanoparticles are neutral and charged with 15 units of charge, the ON-to-OFF ratio is more than two orders of magnitude. We also discuss the relevance of our model to various OBD devices in the literature.

1. Introduction

Non-volatile organic thin film memory devices are being explored as a replacement to flash memory or as an alternative to some devices in specific niches of applications. The latter include applications requiring some characteristics which are specific to organic semiconductor based devices, such as flexibility, low cost and large area [1,2]. Organic memory devices with different organic materials and device architectures were explored in the literature. Two types of devices were mainly studied;: single layer and three layer devices. Among single layer devices there are devices where the organic is a small molecule material or a polymer sandwitched between two metal electrodes [3,4], and devices with dispersed metal (usually gold) nanoparticles in the organic [2,5]. Then there are the devices where the nanoparticles are embedded between two layers of the organic material [6]. We refer to this device here as the three layer device. All these devices show bistability and switch reliably at a threshold voltage V_{th} between an OFF- and ON-states which correspond to the low and high impedance states. The memory state is retained for hours to days even when the bias voltage is suppressed.

The three layer device with the embedded metallic layer (Al cathode/AIDCN or Alq3/Al metal layer/AIDCN or Alq3/Al anode) has received considerable interest [5,6]. Although the experimental results seem to be reproducible, the parameters that control the device characteristics (e.g. the threshold voltage, the ON/OFF ratio, and erase voltage) remain still hard to determine accurately. In fact, those parameters depend most probably on the detailed structure of the intermediate metal layer and on the presence of impurities in the organic material. The middle metal layer must have a nominal thickness of 5–10 nm for the device to switch [5]. In fact, the metal layer must be granular (i.e. disconnected nanoparticles) in order to obtain bistability [2,5]. Recently, Wang et al. [7] reported a new method to achieve a good control of the nanostructured metal middle layer using self-assembled gold nanoparticles (NPs). The resulting OBDs show strong and highly reproducible electrical bistability. In fact, in this case, unlike in the case of the three layer devices where the nanostructured middle layer is produced by thermal evaporation, we have accurate data and control on the structure of the middle layer, such as the size of the nanoparticles and their density distribution.

In addition to the recent results on organic semiconductor devices, electric bistability was already observed in inorganic device as early as 1960s [8,9]. The devices consisted of a thin oxide layer sandwiched between metal electrodes (e.g. cathode(Al)/insulator(SiO)/anode(Au)). However, in such case, the switching was observed only after applying a high voltage; the so called "forming process". Simmons and Verderber proposed a model (henceforth referred to as SV model) that accounted for all the experimental observations. In the SV model, the charge transport is due to tunneling between localized states in the SiO matrix. The space charge effects of the filled localized states (or traps), reduces the electric field at the electrode, which inhibits tunneling and results in an OFF-state. Based on the similarity of the observed characteristics between this device and the organic three layers device, Bozano et al. [10] suggested that the SV model could be applied to their organic devices. However, one can easily figure out that the direct application of the SV model to organic devices is confronted with many difficulties. For instance, transport takes place via tunneling from the electrodes to the localized states in the SV device. In the organic device no such tunneling between the electrodes and the middle metal layer is possible, as the organic layer thickness is more than 30 nm. Furthermore, the mobility of charge carriers in the organic layer should also be considered; unlike in the case of the insulating matrix in the SV device.

Wu et al. [11] attributed the mechanism of bistability in the three layer devices to the separation and storage of charge at the middle metal nanocluster layer, which subsequently induces charges through the organic layer. This process is similar to the field effect process in the channel of an organic transistor. However, it is unlikely that such a mechanism is able to increase the conductivity of the whole organic layer, which is some 30 nm thick. For instance, in organic field effect transistors, the channel where charge induction is effective is 1nm thick in spite of the very high gate polarization field. Moreover, simple electrostatic considerations lead to the conclusion that at maximum charge separation (permitted by the bias voltage) in the nanocluster, the induced charge region in the organic material is confined to the molecules in contact with the nanoparticles. Thus, most of the organic layer is not concerned by the induced charge enhanced conductivity. Additionally, according to that model, an insulating oxide layer around the nanocluster islands (or particles) is necessary in order to achieve charge separation, which is at the origin of the charge storage. Surprisingly, in a previous work, the same authors reported bistability and switching characteristics in a gold middle layer device [12]. In this case, it seems hard to accept the fact that the gold nanoclustered particles are surrounded by an oxide layer.

We should also emphasize here that, unlike the inorganic devices described above, the three layer device and the Wang et al. device, i.e. devices with metal nanoparticle inclusion, do not need forming before switching. We propose here a model that explains the bistability of the organic devices based on metal nanoparticle inclusion. Our model is based on the space charge effects of the charged nonoparticles, and takes into account the transport of carriers inside the organic layer and the injection from the electrodes. All the parameters used in the model correspond to the Wang device as described in Refs. [7,13].

2. Experimental device characteristics

To build our model we give here a summary of the device structure and the experimental results. More details can be found in the original publications [7,13]. The device is represented in Fig. 1, showing also the parylene nanopillars supporting the gold nanoparticles. There are two stable states in the *IV*-characteristics for which the corresponding value of current differs by three orders of magnitude (Fig. 2). The high current state is the ON-state and the low current state is the OFF-state. After fabrication, the devices is in the OFF-state. By increasing the applied voltage from zero, the device switches to the ON-state at a threshold voltage V_{th}. The current continues to increase until a voltage V_{max}, then follows a region of negative differential resistance (NDR) and finally the current increases again after a voltage V_{min}. If the voltage sweep scan do not pass V_{min} then the device will remain in ON-state and will keep this state after removing the applied voltage. The retention time is observed to be about several months. At an applied voltage of $V_{Off} > V_{min}$ the device switches back to the OFF-state.

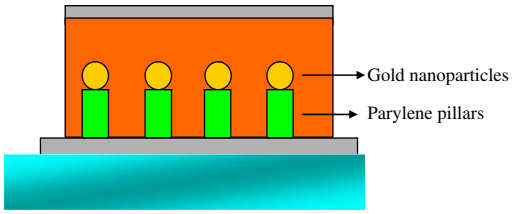

Fig. 1. Device structure: Al/Alq3:Au NPs/Al [7].

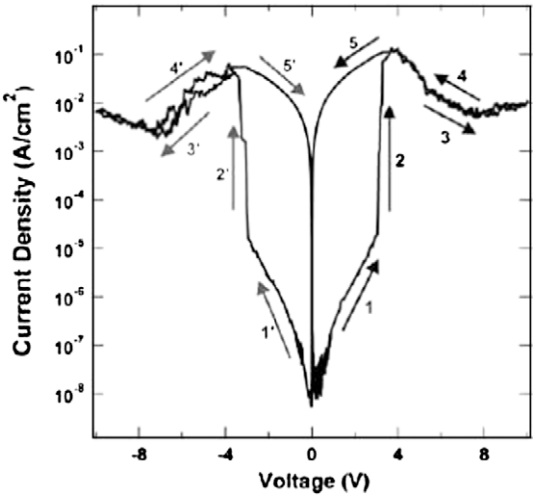

Fig. 2. *IV*-characteristics for the device shown in Fig. 1 [13].

3. One-dimensional device simulation

It has been reported previously in the literature that trapping of charges by impurities or trap levels can induce hysteresis and bistability. An example is the SV model mentioned above. Also in OLEDs [14], Brütting et al. concluded that trapped charges at the organic/organic interfaces of the multilayer diode were at the origin of the hysteresis observed in *IV* curves. We propose to study, as a first step, the trapping of charges in the metal nanocluster using a simulation model originally developed for multilayer organic light-emitting diodes [15]. Taking into account of the symmetrical structure in multilayer diodes, the model is one-dimensional and includes all the physical processes privailing in these devices like charge transport through the organic layer and between different layers, electron–hole recombination, and charge injection from the metal electrodes. Also included in the code is the electric field-dependence of the mobility of electrons and holes, which is an important feature of charge transport in organic semiconductors. There is no way, however, to introduce a middle metal layer because the simulation code considers charge transport only through hopping between molecular energy levels. Fortunatly, Bozano et al. [5] reported that replacing the metal middle layer with a CuPc layer preserves the bistability and the memory characteristics. Thus, we assume, instead of the middle metal layer, a uniform CuPc middle layer. Because the model is one-dimensional all the layers are uniform. Following reference [5], the device structure is thus: Al/Alq3(40 nm)/CuPc(5 nm)/Alq3(40 nm)/Al. Fig. 3 shows the resulting charge distribution (electrons and holes) at a bias voltage of 10 V. At low voltage (not shown), the injection of electrons is blocked due to the energy barrier at the cathode. At high voltage, bipolar injection occurs and the space charge effects of the trapped carriers in the CuPc layer (due to energy level offset) are important. The space charge effects of these trapped charges induces an additional electric field that influences both charge injection at the electrodes and charge transport due to mobility variations.

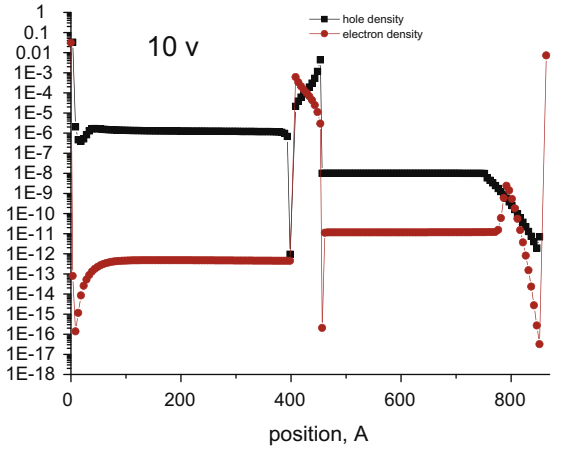

Fig. 3. Results of the 1D simulation giving the electron and hole density distributions in the device: ITO/Alq3/CuPc/Alq3/Al-LiF

The electric current calculated for two different initial states: without and with trapped charges in the CuPc layer, gave the same value. The only difference is the time required to reach equilibrium. Thus there is no bistable state. We checked, also, that even for the case of trapped charges the time to reach equilibrium is large but not enough to suggest a quasi-equilibrium state that might be compared to quasi-stable state. We conclude that trapping effects in 1D, i.e. same path for all carriers, cannot be at the origin of bistability. These findings support the experimental fact that devices with thick middle metal layers do not switch [5]. In fact, as mentionned in the introduction, the middle layer must be thin enough to form disconnected clusters or nanoparticles.

4. Drift-diffusion model

From the previous section it is now clear that to account for the disconnected nature of the middle metal layer we must consider a 2D model that includes two carrier paths: one through the middle layer i.e. the nanoparticles and the other in between the nanoparticles. The carriers following the first path change the charge of the metal nanoparticles, which will modify the distribution of the electric field through the device and affect the movement of the charge carriers that follow the second path.

We assume metallic NPs with a radius $R = 6$ nm as in Wang's devices. The amount of charge that can be captured or stored by the nanoparticle is limited by its capacitance. In fact, the charging energy for one electron on the nanoparticle with radius R is given by $E_c = e^2/2C$, where the capacitance is $C = 4\pi\epsilon_0\epsilon_r R$. $epsilon_r$ is the relative dielectric constant of the organic material. In our case, for a radius of 6nm we have $E_c = 0.034$ eV, a value which is comparable to the thermal energy at ambient temperature; $kT = 0.025$ eV. Thus at thermal equilibrium the mean charge on the nanoparticle is one electron (or hole). The electric field around the nanoparticle will change this limit as the potential drop on a distance comparable to the nanoparticle extension is already much bigger than the charging energy. In the literature, metallic nanoparticles with 12 nm diameter were reported to have a charge of 15 units [16], whereas 5 nm diameter nanoparticles were reported to have a charge of 4 units [17].

We consider monopolar (electron-only or hole-only) devices. We will justify our choice in the discussion below. The electron concentration in the device, ρ_n, is given by the continuity equation:

$$\frac{\partial}{\partial t}\rho_n - \nabla \cdot \mathbf{J} = 0, \tag{1}$$

with the electron current $\mathbf{J}$, given as the sum of the drift and diffusion currents:

$$\mathbf{J} = e\rho_n\mu_n\mathbf{F} + eD_n\nabla\rho_n. \tag{2}$$

The electric field, $\mathbf{F}$, is determined by the Poisson equation:

$$\nabla \cdot \mathbf{F} = -\frac{e}{\epsilon_0\epsilon_r}\rho_n, \mathbf{F} = -\nabla V, \tag{3}$$

where V is the electric potential and ϵ_r the relative dielectric constant of the organic material. The diffusion coefficient of electrons, D_n, and their mobility, μ_n, verify the Einstein relation:

$$D_n = \frac{\mu_n kT}{e}, \tag{4}$$

with k the Boltzmann constant and T the temperature. We assume the well established Poole–Frenkel law for the mobility of charge carriers in organic semiconductors: [18]

$$\mu_n(F) = \mu_0 \exp\left(\sqrt{\frac{F}{F_0}}\right). \tag{5}$$

We used finite elements method in order to solve these equations in 2D for the appropriate boundary conditions at the electrodes and the NP surface. The device thickness is 75 nm along the x-axis, which is the direction of the electric field. The perpendicular (lateral) dimension of the device (y-axis) has a length of 42 nm with only one nanoparticle. Periodic boundary conditions are then imposed on the y-direction to take into account the large extension of the device in that direction with respect to its thickness. Thus the surface density of the nanoparticles is 5.66×10^{10} cm^{-2}. The electrostatic potential on the electrodes is fixed by the applied bias whereas the electron concentration is determined through the carrier injection. We used Scott and Malliaras injection formula [19] which considers most of the effects inherent to metal/organic interfaces. The injection current is given by

$$J_{\text{inj}} = \frac{16\pi\epsilon_0\epsilon_r N_0 k^2 T^2}{e^2}\mu_n \exp\left(-\frac{\Delta}{kT}\right)\psi^2 f \exp\left(f^{1/2}\right), \tag{6}$$

where

$$\psi = f^{-1} + f^{-1/2} - f^{-1}\left(1 + 2f^{1/2}\right), \qquad f = \frac{e^3 F}{4\pi\epsilon_0\epsilon_r k^2 T^2}. \tag{7}$$

The density of sites (molecules) of the organic material at the interface with the metal is given by $N_0 = 0.46\times 10^{22}$ cm^{-3}, and the energy barrier at the cathode $\Delta = 0.5$ eV [15].

The equations of the model are solved for a fixed charge on the NPs. The model does not allow dynamic variation of the nanoparticle charge. In order to apply appropriate boundary conditions on the nanoparticle surface we consider the NP as a thin dielectric shell. The mobility of electrons inside the shell is taken sufficiently high in order to be consistent with the metallic conductivity of gold, whereas the dielectric constant is infinite as it should be for a metal. The boundary of the geometry is thus the inner boundary of the shell where the electron perpendicular current is set to zero. The electric potential on the inner boundary, V_{NP}, is derived from the nanoparticle charge, Q_{NP}, through the relation: $V_{\text{NP}} = Q_{\text{NP}}/C_{\text{NP}}$.

5. Results and discussion

Fig. 4, shows the resulting electron density distribution at an applied voltage of 2 V and zero charge on the NPs i.e. $Q_{\text{NP}} = 0$. We can see an almost uniform electron density and electric field. The observed current density is 0.6 A/cm^2. Consider now Fig. 5 which gives the electron density and the potential distribution for the same parameters as the previous figure except for the nanoparticle charge which is now $Q = 15$ units. We observe that the carrier density is greatly reduced between the NPs and the anode. The current density is 0.0018 A/cm^2. Therefore, from these results, we can attribute the OFF state of the device to charged nanoparticles, and ON-state to uncharged nanoparticles. The ON-to-OFF ratio is 300 which is comparable to Fig. 2. Higher ratio for higher NPs charge are obtained.

From the electric field distribution in the charged case (OFF-state) given in Fig. 6, the electric field magnitude in

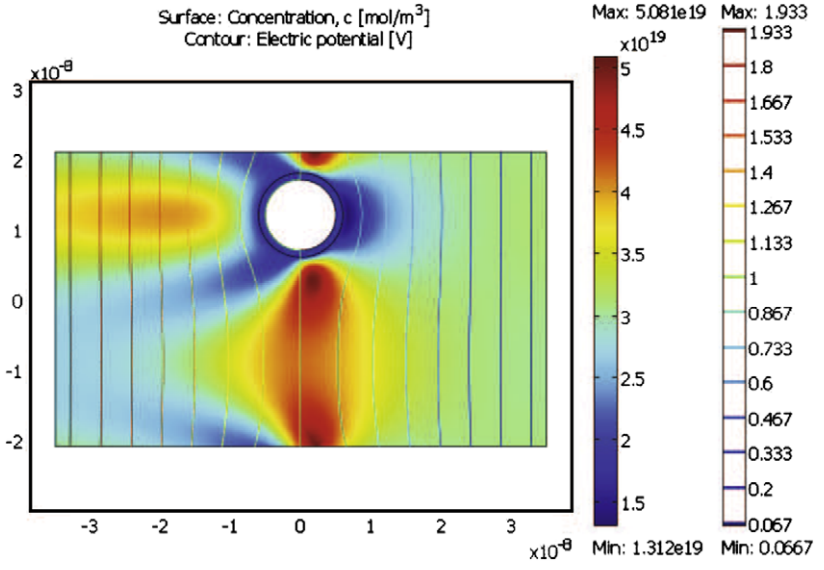

Fig. 4. Electric field distribution and electron concentration for a bias of 2 V and $Q_{NP} = 0$.

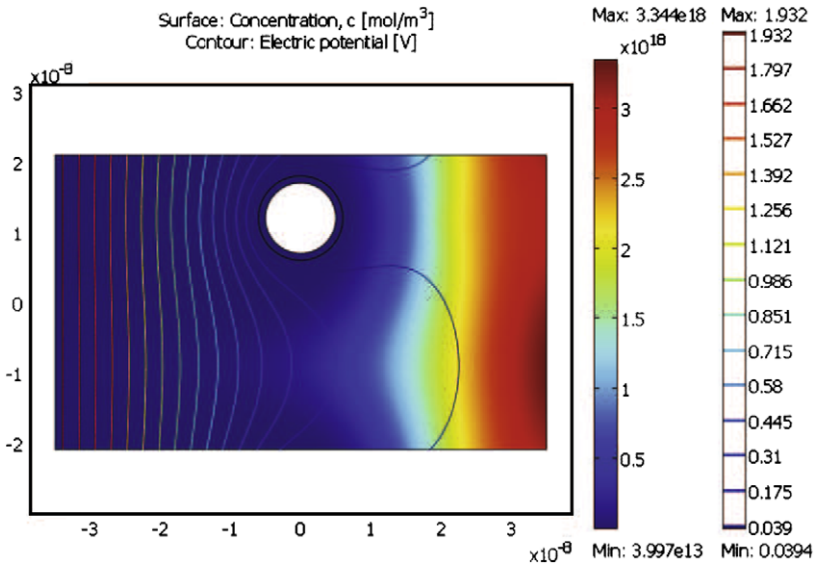

Fig. 5. Electric field distribution and electron concentration for a bias of 2 V and $Q_{NP} = 15$ units.

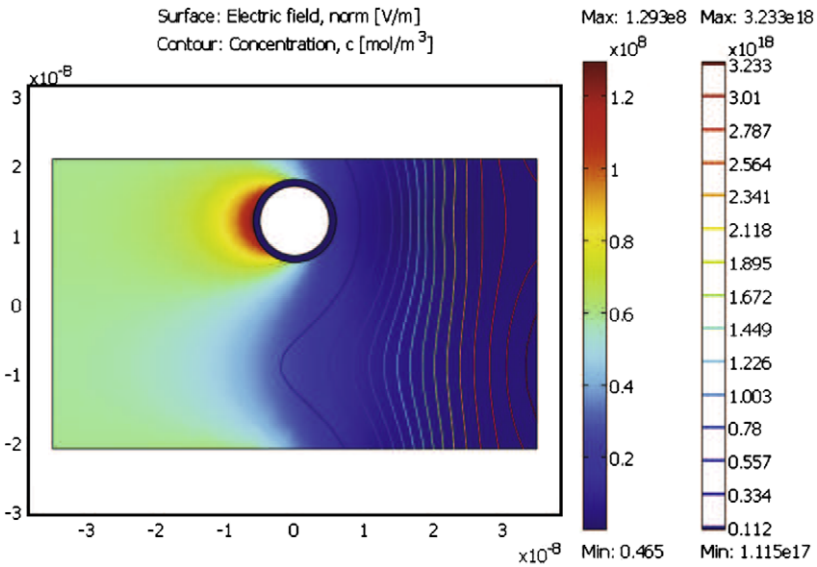

Fig. 6. Electric field distribution and electron concentration for a bias of 2 V and $Q_{NP} = 15$ units.

the part of the device between the cathode and the NPs, is several orders of magnitude lower than in the other part of the device between the NPs and the anode. Thus, due to the space charge effect of the nanoparticles (corresponding to OFF-state), the small electric field at the cathode reduces greatly the injection of electrons. This reduction of the injection is at the origin of the low current caracterizing the OFF-state. By measuring the electric potential at the middle metallic layer, the UCLA group [20] found that the potential drops essentially through one half of the device in the OFF-state. The corresponding electric field is thus very small, a fact which in agreement with the results of our model. A main feature of our model is that the OFF-state corresponds to charged nanoparticles. In this respect our model differs from some proposed models based on the assumption that the ON-state corresponds to charged nanoparticles [21,22]. In fact, these models treat the nanoparticles as traps in the organic material. When empty these traps reduce the transport as a consequence of trapping and de-trapping of charge carriers, whereas when they are filled the transport increases. What is surprising in those models is the fact that they neglect space charge effect of the traps/nanoparticles. With the exception of the SV model [9] in the case of inorganic devices, our model is the first to account correctly for this effect in the case of organic/nanoparticle devices. In fact, our calculation

above showed that at a reasonable charge state of the NPs the electric field is low enough to inhibit the charge injection from the electrodes. At the same time, the electric field is increased in the part of the device between the NPs and the anode. As the device is electron-only, this increase of field may only increase the mobility of electrons due to the field-dependence in the Poole–Frenkel law. However, from our results, no noticible increase in current is observed as the primary effect is the reduction of the number of electrons injected from the cathode.

A strong support to our model can be found in Fig. 3 of Ref. [22] concerning ITO/Alq_3/Al devices with MoO_3 nanoparticles. In fact, it was shown there that the magnitude of the current for the device without nanoparticles is comparable to the ON-current for the device with nanoparticles. This observation confirms that the ON-state corresponds to uncharged nanoparticles, whereas OFF-state corresponds to charged nanoparticles.

We now address our assumption of monopolar devices (electron-only or hole-only). Actually, devices with a single layer of an organic material present always an asymmetry with respect to electron injection from the cathode and hole injection from the anode. In our case, the barrier for electron injection is 1.3 eV whereas the barrier for hole injection is 1.5 eV, which makes the device essentially electron-only. With an ITO anode as in Ref. [22], the barrier for hole injection is 0.7 eV and the device is hole-only. The presence of both electrons and holes in the OBD device will not suppress entirely the switching but can reduce the ON-to-OFF ratio by orders of magnitude. This effect was reported in a nice experiment in Ref. [23] where the switching was observed for ITO/Alq_3/Al metal layer/Alq_3/Al device with an ON-to-OFF ratio of 10^4. With an additional PEDOT:PSS layer bewteen ITO and Alq3, which facilitates hole injection, the switching was still there but with an ON-to-OFF ratio of 10^2.

It is worth to note that the capacitance of the nanoparticles used so far is only valid for an isolated nanopraticle. The presence of the other nanoparticles and also the electrodes modify the value of the capacitance. Increasing the nanoparticle density to 2.83×10^{10} cm^{-2}, we obtained the same current and ON-to-OFF ratio as in Fig. 5 when the nanoparticle charge is $Q = 7$. This decrease of the nanoparticles charge means that the capacitance of the nanoparticles decreases due to the electrostatic influence between nanoparticles. Decreasing the nanoparticle radius will also decrease the capacitance and leads to the same effect. In contrast, the electrostatic influence of the electrodes increases the capacitance although the effect is much less pronounced. In fact for a thickness of 35 nm (the bias is set to 1V in order to have the same electric field) and nanoparticle density of 2.83×10^{10} cm^{-2} we obtained $Q = 7.5$.

In our OBD devices [7,13], after the fabrication process, the NPs are highly charged (Q_{OFF}) so that initially the device is in the OFF-state. When the applied voltage increases beyond the threshold voltage V_{th}, the electric field is high enough on the NP side facing the anode (see Fig. 6) to enable the escape of electrons from the NPs leading to ON-state with a low or zero charge. Then, the current increases with voltage until V_{max}. After the negative differential resistance (NDR) region, as the voltage increases beyond V_{min} the NPs are again charged so that OFF-state will be recovered. Depending on the voltage attained, the newly acquired charge of the NPs will determine the levels of the current in the OFF-state. Multi-OFF states are also observed in experiments [13]. The fact that once in the ON-state and when the voltage does not exceed V_{min}, the NPs do not get charged again when the potential drops below the threshold voltage is worth explaining. Clearly, this issue is related to the retention time. We suggest that this is related to the interface dipole between the metal and the organic material. In fact metal surfaces with plasma treatment present in general high electric dipoles at the interface with the organic [24]. When the NPs are highly charged (OFF-state), the dipole effect is negligible. When the NPs have a small charge then the effect of the dipole is to repel electrons (the negative part of dipole is in the organic material). Thus, in the ON-state, the NPs cannot be charged by electrons below the threshold voltage because of this repulsion. Thus, retention can be explained by this interface dipole. A quantitative approach to the latter point as well as the *IV*-characteristics cannot be obtained by the present model because the charge of the nanoparticles is fixed. We expect to account for these processes more quantitatively when we introduce the variation of the charge of the NPs. We are currently investigating a charging equation for the NPs which will account for the discharging effect of the electric field on one side of the nanoparticle and the charging due to current flow on the other side.

The device current–voltage characteristics as a function of temperature can give insights into the conduction mechanism. We emphasize however that this temperature dependence has essentially three contributions: (i) the temperature dependence on the injection current given, in our model, through Eq. (6), (ii) the temperature dependence of the carrier mobility through the parameters F_0 and μ_0 in Eq. (5) and (iii) the escape of electrons trapped in the nanoparticles. In its present state, our model, does not include the last two contribution. Although the mobility temperature dependence can be readily introduced, the temperature dependence of electron escape from the metal nanopraticles is related to the charging equation mentioned above. We believe that the last contribution is the most important origin of the current temperature dependence in OBDs. The experiment reported in Fig. 7 of Ref. [23] show that when increasing the temperature from 303 K to 333 K, the OFF-current increases by four orders of magnitude and joins the ON-current at a temperature of 373 K. Such an increase in OFF-current cannot be attributed to the Poole–Frenkel mobility nor to the temperature dependence of the injection current. In fact, using the 1D code described in Section 3, we calculated the current–voltage characteristics of the device without nanoparticles and found that even at 400 K the current increases by less than one order of magnitude. Thus the OFF-current increase in the experiment is essentially due to the fact that the nanoparticles have a small charge due to high escape rate of electrons at high temperature. Further evidence for this interpretation is the decrease of the threshold voltage when temperature increases (reported in the same experiment). In fact, at higher temperature the electric field for electron escape from the nanoparticle trap is lower.

The physical process described by our model applies also to the organic vertical transistor described in Ref. [25]. An electrode with a nano-aperture placed between source and drain electrodes serves as a gate. When biased positively it closes the transistor channel preventing the holes, which are injected from the source, from reaching the drain electrode. Compared with the OBD devices, the nanoparticles act like a floating gate.

As for the bistability of organic devices without nanoparticles or middle metal layer, we suggest there are other processes involved like filaments formation [26]. During the forming process, conductive filaments form through the organic layer giving the ON-state. At higher voltage, the filaments break due to Joule heating and OFF-state is recovered. We do not discard also the possibility that the space charge process described by our model and the filaments formation process coexist in organic OBDs with nanoparticles depending on the fabrication and operation methods. For instance, in the device of Ref. [22] it is almost certain that switching is due only to the space charge effect of the MoO_3 nanoparticles because the current of the device without nanoparticles is comparable to the ON-current. In contrast, the device of Ref. [23] with Aluminum middle layer involves probably the two switching mechanisms because the device without middle layer switches and its current is comparable to OFF-current as can be seen in Fig. 5 of the same reference.

6. Conclusion

We presented a model for the organic memory devices embedded with metallic nanoparticles. The high (ON) and low (OFF) current states of the device are accounted for through the charge states of the nanoparticles. As a consequence of this charge, the electric field at the injecting electrode is reduced leading to OFF-current. The ON-to-OFF ratio obtained is more than three orders of magnitude for an average of only 15 electrons on each nanoparticle for the OFF-state and zero charge for the ON-state. The devices described by our model do not need forming before switching and would give a current comparable to ON-current when the nanoparticles are not included. Even though for some OBD devices reported in the literature, there could be a different switching mechanism, our model demonstrates the importance of the space charge effects of the nanoparticles and the possibility to fabricate OBD devices that switch only through this mechanism.

ABSTRACT

A solution processed polymer tandem cell has been fabricated by utilizing organic layer coated TiO_2 nanoparticle (OL-TiO_2) as an interlayer. The crystalline phase of the OL-TiO_2 was anatase. The dispersed solution of the OL-TiO_2 showed high optical transparency and excellent film forming property. The top and bottom cell were clearly separated by the OL-TiO_2 interlayer without interlayer mixing, which was not observed for the tandem cell utilizing commercially available TiO_2 nanoparticle (N-TiO_2) as an interlayer. The conversion efficiency of a polymer tandem cell was enhanced from 1.43% to 3.44% by replacing the interlayer from N-TiO_2 to OL-TiO_2. The tandem cell performance was further enhanced by adjusting the thicknesses of the active layers in the subcells and adjusting the conductivity of the PEDOT:PSS layer in the bottom cell. The highest conversion efficiency of 3.66% was obtained from the tandem cell having the structure of ITO/Baytron P VP AI 4083/P3HT:PCBM (100 nm)/OL-TiO_2/Baytron PH 500/P3HT:PCBM (100 nm)/Al. In addition that, it was found that the OL-TiO_2 interlayer enhanced the stability of the tandem cell comparing to that of the single junction cell by the reduction of the oxygen diffusion to the bottom layer by the interlayer. It is expected that the performance of the tandem cell can be further enhanced by adopting efficient low band gap materials.

1. Introduction

The single junction solar cell has limitations to overcome Shockley–Queisser limitation because excess energy of the photons, absorbed with energies greater than the semiconductor band gap, are lost as heat and photons with energies less than the semiconductor band gap are not absorbed [1]. The tandem solar cell technology could be one way to overcome the limits of the single junction solar cell. However, it is difficult to fabricate polymer tandem solar cells because the previously deposited layer could be destroyed by the following solution process. Therefore, it is important to use a proper separation layer (or interlayer), which isolates two subcells. The interlayer protects the bottom cell as well as recombining the charge carriers from the subcells. There are several reports on the formation of the interlayer and middle electrode by the vacuum deposition method [2–7]. However, it is desirable to fabricate polymer tandem cells with all solution processes in terms of large area fabrication, the production cost and the high throughput. It is essential to develop solution processed interlayer materials to fabricate the polymer solar cell with solution process. Semiconducting metal oxides are thought to be promising candidates for the interlayer due to their optical transparency, electron mobility and chemical stability. Gilot et al., used ZnO nanoparticles/PEDOT interlayer for the

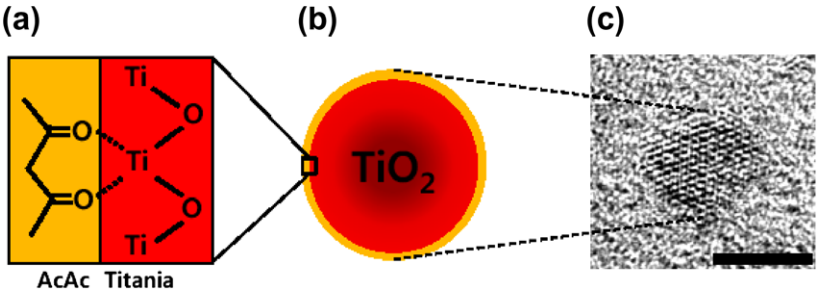

Fig. 1. Organic layer coated TiO_2 nanoparticle used in this study. (a,b) Schematic illustration of the nanoparticle surface where acetylacetone (AcAc) is bound to Ti exposed on the surface (c) HR-TEM image of an individual TiO_2 nanoparticle crystalline lattice. Scale bar represents 5 nm.

polymer tandem cell [8]. However, the neutral pH PEDOT was used for the interlayer instead of commercially available acidic PEDOT:PSS solution due to the chemical instability of the ZnO against the weak acid solution. Recently, Kim et al., successively fabricated solution processed polymer solar cells by utilizing the TiO_x/PEDOT:PSS interlayer, and the power conversion efficiency reached more than 6% under the 1 sun illumination condition [9]. Thought the TiO_x is promising interlayer material for the polymer tandem cell, the TiO_x layer formation needs a hydrolysis process, which might affect the throughput of the polymer tandem cell production and storage stability of the TiO_x solution is thought to be concerned. The nano-crystalline TiO_2 nanoparticle (NC-TiO_2) is possible candidate material for the interlayer due to their chemical stability, crystallinity and optical transparency. In this study, we fabricated polymer tandem solar cell by using NC-TiO_2 interlayer. Two types of NC-TiO_2 (TiO_2 nanoparticle with or without organic layer on the surface) were utilized as interlayer for the tandem cell. The effects of NC-TiO_2 interlayers on the performance of polymer tandem solar cell will be discussed.

2. Experimental

2.1. Materials and solutions

The P3HT and PCBM blended solution was used to form bulk-heterojunction active layers for the polymer tandem solar cell. The regioregular poly(3-hexylthiophene) (P3HT, Aldrich) and the fullerene derivative [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM, American Dye Source, Inc.) were dissolved in chlorobenzene with the weight ratio of 1:0.8, and used for active layer of subcells. Three kinds of PEDOT:PSS solutions (Baytron P VP AI 4083, Baytron P, and Baytron PH 500) were purchased from Baytron, H.C. Starck and diluted with methanol by 1:1 vol%. Two types of titanium oxide solution were prepared for the transparent interlayer in the polymer tandem cell. One is the solution that organic layer coated TiO_2 nanoparticles (OL-TiO_2) are dispersed in ethanol. The OL-TiO_2 were synthesized through the hydrolysis of titanium butoxide at 60 °C in the presence of acetylacetone as an organic modifier and p-toluene sulfonic acid as an acid catalyst [10,11]. The mean size and the crystallinity of particles were adjusted by tuning the ratio of reactants. As synthesized nanoparticles were precipitated in toluene, and redispersed in ethanol by 5 wt% which exhibited a transparent yellow color. The schematic diagram of OL-TiO_2 nanoparticle showing acetylacetone coordinated to TiO_2 at the nanoparticle surface and high resolution transmission electron microscope (HR-TEM) image of an individual nanoparticle are shown in Fig. 1. From the selected area electron diffraction (SAED) on TiO_2 nanoparticles and XRD data, it was confirmed that their crystalline structure of OL-TiO_2 was anatase. The other solution (N-TiO_2) was obtained from the dispersing the TiO_2 nanoparticles (F-6, Showa Denko, Japan) in ethanol by bead-mill. The particle size of the N-TiO_2 was about 15 nm.

2.2. Device fabrication and measurements

The polymer tandem solar cell structure used in this study is shown in the Fig. 2. The tin doped indium oxide (ITO) was used as bottom electrode (BE in Fig. 2) for the tandem cell. The patterned ITO/glass substrates were cleaned in an ultrasonic bath of isopropanol and acetone repeatedly, followed by a UV treatment for 20 min. For the hole injection layer of the bottom cell (HIL in Fig. 2), the PEDOT:PSS aqueous solution (Baytron P VP AI 4083, Baytron P, or Baytron PH 500) was spin-coated onto ITO substrates and dried in the vacuum oven at 120 °C for 10 min. The thickness of the HIL was approximately 40 nm. P3HT:PCBM solution was spun onto the HIL and dried in air at room temperature for 10 min to form a bottom active layer (BL in Fig. 2). Three different thicknesses (70, 100 and 200 nm) of the BL were prepared and the

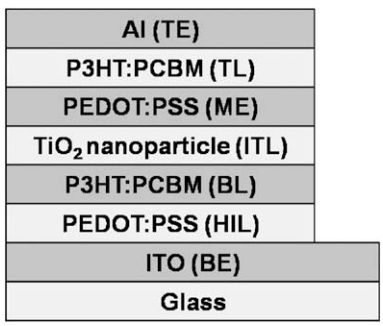

Fig. 2. The polymer tandem cell structure used in this study.

thickness of the layer was controlled by R.P.M of the spin coater. Subsequently, the interlayer (ITL in Fig. 2) for the tandem cell was formed by spinning the TiO_2 nanoparticle solution and drying at 60 °C for 10 min in the vacuum oven. The obtained thickness of the ITL was about 40 nm. Highly conductive PEDOT:PSS (Baytron PH 500, H.C. Starck) was used for the middle electrode (ME in Fig. 2). Since the surface of the ITL is hydrophilic, the aqueous PEDOT:PSS solution can be deposited on it. The same P3HT:PCBM solution was used for the formation of top active layer (TL in Fig. 2). Also, the thickness of the TL was varied from 70 to 200 nm. Finally, Al top electrode (TE in Fig. 2) was vacuum deposited in the base pressure of 2×10^{-6} torr. The thickness of the TE was about 80 nm. The deposited Al electrode area defines an active area of the device as 0.09 cm^2. The prepared tandem cells were directly annealed at 150 °C by a radiation heater for 10 min in the same thermal vacuum evaporator. The base pressure of the evaporator was maintained in the range of 2×10^{-6} to 7×10^{-6} torr.

Photocurrent–voltage measurements were performed on the tandem cells by using a Keithley model 2400 source measuring unit. A class-A solar simulator with a 150 W Xenon lamp (Newport) served as a light source, where its light intensity was adjusted by a NREL-calibrated mono Si solar cell, with a KG-2 filter, for approximately AM 1.5 G 1 sun light intensity. External quantum efficiency was measured as a function of wavelength from 300 to 800 nm using incident photo-to-current conversion system (IPCE) (PV measurements, Inc.). Calibration was performed using a silicon photodiode G425, which was NIST-calibrated as a standard. The atomic force microscopy (AFM) was used to investigate the surface morphology formed by TiO_2 nanoparticle solutions. The AFM measurements were carried out on an Asylum Research MFP-3D-SA AFM mounted on AC160-TS cantilever in noncontact mode. The cross-sectional image of the polymer tandem solar cell was taken with the Dual Beam FIB/SEM system (Nova 200, FEI Company), which allows sectional analysis for the cross-section of delaminated region.

3. Results and discussion

The device structure of the polymer tandem cell used in this experiment is glass/ITO (bottom electrode; BE)/PEDOT:PSS (hole injection layer; HIL)/P3HT:PCBM (bottom active layer; BL)/TiO_2 nanoparticle layer(interlayer; ITL)/PEDOT:PSS (PH 500) (middle electrode; ME)/P3HT:PCBM (top active layer; TL)/Al (top electrode; TE) (Fig. 2). Since this study focuses on the development of the TiO_2 nanoparticle interlayer, the same active layer (P3HT:PCBM) is used for the bottom and top cells.

Two different types of TiO_2 solutions have been examined for the formation of ITL of the polymer tandem cells. The commercially available TiO_2 nanoparticle (F-6, Showa Denko, Japan) was dispersed in ethanol solution (N-TiO_2 solution), and used for the ITL of a polymer tandem cell (TC-N). For the other solution, organic layer (acetylacetone, (AcAc)) coated TiO_2 nanoparticles (OL-TiO_2 solution) were used to form the ITL for another tandem cell (TC-OL). The

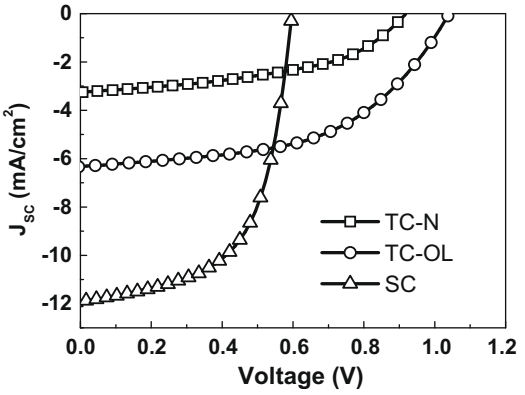

Fig. 3. Current density–voltage characteristics of single junction cell (SC) and tandem cells (TC-N and TC-OL) under the AM 1.5G 1 sun illumination.

N-TiO_2 solution had turbid milky color and precipitated after several days. Whereas, the OL-TiO_2 solution was highly dispersive, transparent and stable over six months without any precipitation.

Fig. 3 shows the current density–voltage characteristics of TC-N and -OL under the AM 1.5 1 sun illumination. The V_{OC} of TC-N (0.92 V) is higher than that of single junction cell (0.6 V). However, there is significant decrease in the J_{SC} and FF of TC-N compared to those of SC. The performance of the tandem cell was enhanced by replacing the interlayer from N-TiO_2 to OL-TiO_2. The V_{OC}, J_{SC} and FF of the tandem cell was increased from 0.92 V, 3.24 mA/cm^2 and 0.48 to 1.04 V, 6.33 mA/cm^2 and 0.52 by changing the interlayer, respectively. As a result, the power conversion efficiency of TC-OL was 3.44% which is 141% higher than that of TC-N (1.43%).

The surface of the interlayer was investigated using atomic force microscopy (AFM). AFM images were obtained after spinning the corresponding TiO_2 nanoparticle solutions on the P3HT:PCBM film. As shown in Fig. 4, large aggregations (ca. 150–300 nm) are observed from the film prepared from the N-TiO_2 solution. The inset of Fig. 4(a) reveals that large aggregations are composed of small nanoparticles (~20 nm). However, no notable aggregation was observed from the surface of the film prepared by the OL-TiO_2 solution (Fig. 4(b)). The RMS roughness of the OL-TiO_2 film was 4.5 nm, which is significantly lower than that of the N-TiO_2 film (87.4 nm). The height profiles of the corresponding film (Fig. 4(c) and (d)) clearly show the difference in the roughness between films. The height of the OL-TiO_2 film is around 10 nm and that of the N-TiO_2 film is in the range of 100–150 nm. However, small voids with size around 30 nm were observed from the OL-TiO_2 film. Those voids are thought to be formed during the solvent evaporation.

The focused ion beam (FIB) image of the TC-OL (Fig. 5(b)) shows the bottom and top cell are clearly separated by the OL-TiO_2/PEDOT:PSS interlayer. In contrast, the TC-N does not show a clear separation of subcells, and large voids (bright region) are observed where the N-TiO_2/PEDOT:PSS ITL is located (Fig. 5(a)). Based on the AFM and FIB experiments, it is believed that the dense

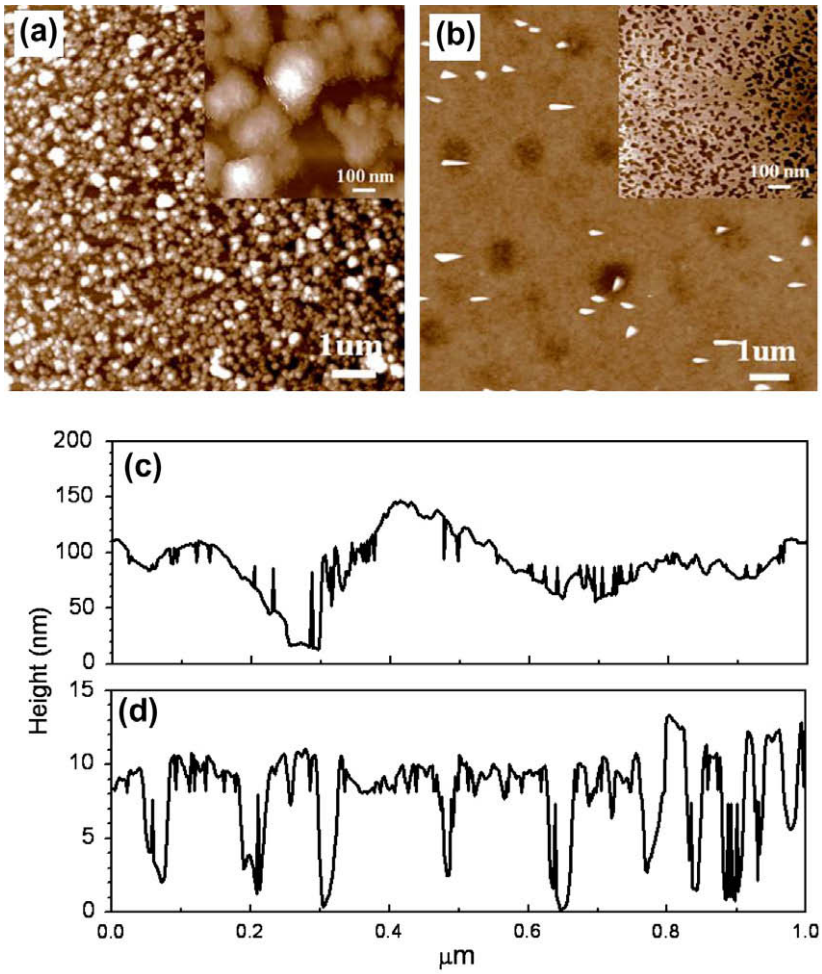

Fig. 4. (a) AFM image and (c) height profile of the film from N-TiO_2 solution, and (b) AFM image and (d) height profile of the film from OL-TiO_2 solution.

OL-TiO_2 interlayer helps the separation of subcell and forms better interfacial contact between the OL-TiO_2 and PEDOT:PSS layer. This implies that the recombination efficiency at the N-TiO_2/PEDOT:PSS interlayer will be significantly lower than that at the OL-TiO_2/PEDOT:PSS interlayer, which leads to voltage drop across the interface, and results in a lower V_{OC} of the TC-N [7].

These properties, however, were obtained after several repeated measurements under the 1 sun illumination. Fig. 6 shows the change in the photovoltaic properties of

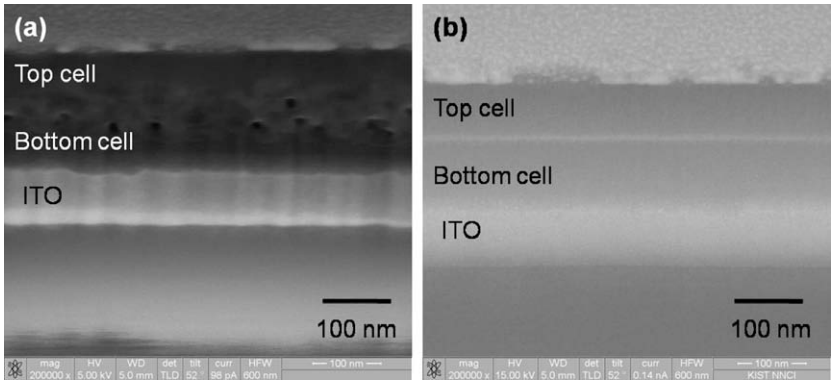

Fig. 5. The Focused Ion Beam (FIB) cross-sectional image of the polymer tandem cells (a) TC-N and (b) TC-OL.

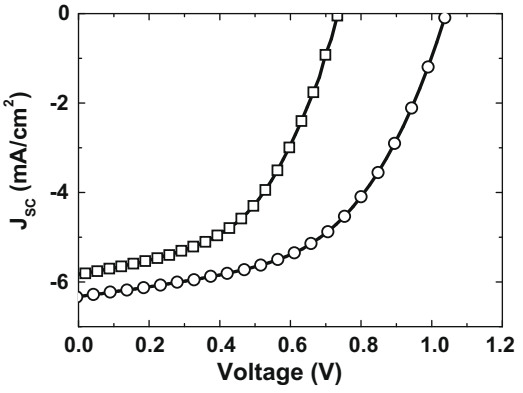

Fig. 6. Current density–voltage characteristics of a tandem cell utilizing OL-TiO_2 as interlayer before (square) and after (circle) AM 1.5G irradiation for 3 min.

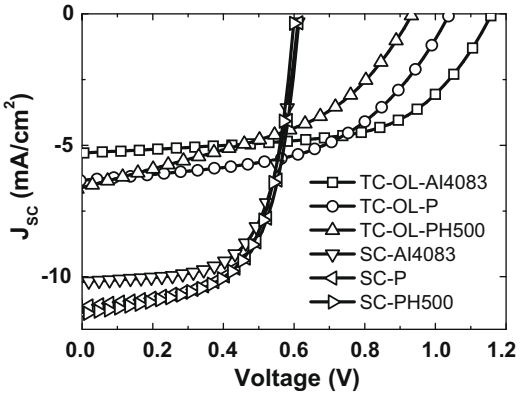

Fig. 7. Influence of hole injection layer conductivity on the current density–voltage characteristics of single cells and tandem cells.

the TC-OL after 3 min of 1 sun illumination. As shown in Fig. 5, the J_{SC} and V_{OC} were increased from 5.83 mA/cm^2 to 6.33 mA/cm^2 and from 0.73 V to 1.04 V after the illumination, respectively. It is reported that the non-ohmic contact between metal oxide and the PEDOT layer could reduce the V_{OC} of the tandem cell [8]. The ohmic contact between the interface can be achieved by increasing the conductivity of the metal oxide and it can be improved by exposing the UV light on the metal oxide [12]. Since there is UV portion in the AM 1.5 light, it is possible that conductivity of the TiO_2 film can be increased by the AM 1.5 illumination.

Although the V_{OC} of the tandem cell was significantly increased by using OL-TiO_2, the V_{OC} is still lower than the sum of the V_{OC} of the bottom and top cells. In the polymer tandem solar cell having the TiO_2/PEDOT:PSS interlayer, electrons from the bottom cell recombine with the hole from the top cell, at the TiO_2/PEDOT:PSS interface. If the bottom cell generates more photo-current than the top cell, the excess electrons cannot recombine with the hole from the top cell, and will be accumulated at the interface between the bottom cell and the interlayer. The electron accumulation will partially compensate the built-in voltage across the bottom cell until the photo-current from the bottom cell matches with that of the top cell [7]. Moreover, excess electrons could act as a resister inside the bottom cell and reduce the fill factor of the cell. This results in a reduced performance of the tandem cell.

It was reported that photo-generated holes can be collected from the area where ITO electrode is not deposited due to the conductivity of the PEDOT:PSS [13]. Based on the report, it is highly possible that the mismatch of J_{SC} value between the bottom and top cells depends on the conductivity of PEDOT:PSS, which is used in the bottom cell, and this becomes significant as the conductivity of the PEDOT:PSS layer is increased. The photovoltaic properties of the single and tandem cells were examined by changing the conductivity of the PEDOT:PSS layer. The three different conductivities of the PEDOT:PSS solution, Baytron P VP AI 4083 (σ = 0.0002–0.002 S/cm), Baytron P (max σ = 0.1–1 S/cm), and Baytron PH 500 (σ = 10–50 S/cm), were used for the hole transporting layer (HTL) of the bottom cell [14]. Hereafter, the tandem cell using Baytron P VP AI 4083, Baytron P and Baytron PH 500 as HTL for the bottom cell will be denoted as TC-OL-AI4083, TC-OL-P, and TC-OL-PH 500, respectively. As shown in Fig. 7 and Table 1, the J_{SC} of the single junction cell increased by increasing the conductivity of the PEDOT:PSS. This implies that the J_{SC} mismatch between the bottom and top cell of the tandem cell will be increased as the conductivity of PEDOT:PSS increases. The J_{SC} mismatch between subcells accommodates the charging of ITL and increase the internal resistance of the tandem cell, which resulted in the reduction of the V_{OC} and FF of the tandem cell. The J_{SC} of the tandem cell was decreased from 6.7 mA/cm^2 to 5.3 mA/cm^2 as the HTL of the bottom cell was changed from the highly conductive Baytron PH 500 (TC-OL-PH 500) to the less conductive Baytron P VP AI 4083 (TC-OL-AI4083). However the V_{OC} and FF of the TC-OL-AI4083 were significantly enhanced, in particular, the V_{OC} of the cell was almost doubled compared to that of the single junction cell. As a result, the power conversion efficiency of the TC-OL-AI4083 (3.66%) was 6%, and 37% higher than that of TC-OL-P and TC-OL-PH 500, respectively. Based on the experimental results, the conductivity of the PEDOT:PSS is considered to be closely related to J_{SC}, V_{OC} and FF in the tandem cells.

However, the J_{SC} value of the tandem cell was significantly lower than that of the single cell. In order to optimize the photo-current of the tandem cell, we varied the thickness of the active layers of the top and the bottom cell. First, the thickness of active layer of the top cell (TL) was varied while maintaining the thickness of active layer of the bottom cell (BL) at 100 nm. Table 2 summarizes the photovoltaic performance of the tandem cell and Fig. 8(a) shows their *I–V* curves. The J_{SC} of the tandem cell was increased from 4.88 to 5.91 mA/cm^2 as the thickness of the TL increased from 70 to 200 nm. The highest photo-current of 5.91 mA/cm^2 was obtained from the T3 and the value is 21% higher than that from the T1. The external quantum efficiency (EQE) for these tandem cells (Fig. 9(a)) are consistent with the J_{SC} result of the tandem cells. The EQE of the tandem cell was increased at around 400 and 600 nm as the thickness of the top cell increased. Whereas, no

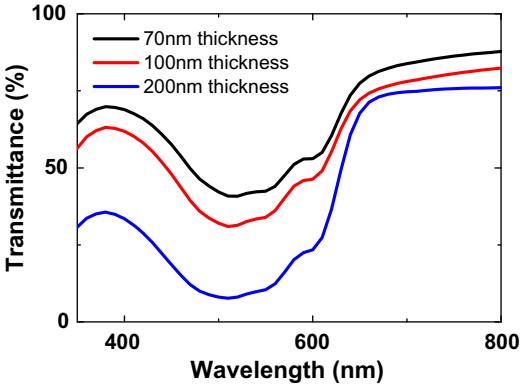

Fig. 10. Transmittance of P3HT:PCBM film with various thickness.

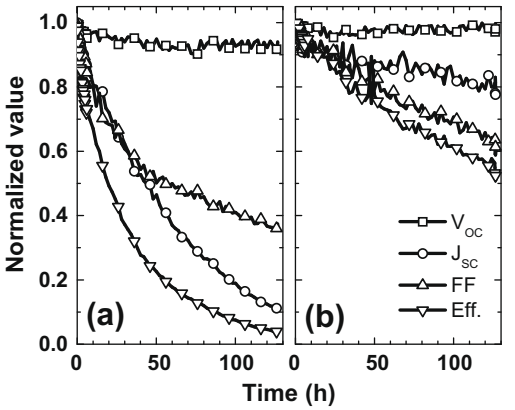

Fig. 11. Comparison of the cell stability under the 1 sun illumination for (a) a single cell (b) a tandem cell TC-OL. The stability test of the single and tandem cell were conducted without any passivation or glass encapsulation.

change in the EQE at 500 nm was observed by varying the thickness of the TL. This is related to the transmittance of the P3HT in the BL. The transmittance of 100-nm thick film of P3HT was about 30% at 500 nm (Fig. 10). This implies only 30% of incoming light of 500 nm wavelength can reach to the TL. Because P3HT has the largest molar extinction coefficient at the wavelength, thin layer of the TL (70 nm) is enough to absorb all the 500 nm light arriving on it. As a result, the EQE of the tandem cell at 500 nm is independent with the thickness of TL. On the other hand, the transmittance of the P3HT at around 400 and 600 nm is relatively higher than that at 500 nm due to the lower molar extinction coefficient. Because larger amount of 400 and 600 nm wavelength light reaches to the TL and P3HT in the TL has lower molar extinction coefficient at the wavelength, the EQE values of the tandem cell at the wavelengths are proportional to thickness of the TL.

For the next experiment, the thickness of the BL was varied while maintaining the thickness of active layer of the TL at 100 nm. The result of their photovoltaic performance and *I–V* curves are shown in Table 2 and Fig. 8(b). The J_{SC} of the tandem cell was increased from 3.16 to 5.95 mA/cm^2 as the thickness of BL decreased from 200 to 70 nm. The highest photo-current of 5.95 mA/cm^2 was obtained from the T4 and the value is 88% higher than that from the T5. The EQE of the tandem cell was inversely correlated with the thickness of BL without concerning the wavelength. Because the light arriving on the TL will be increased as decrease the thickness of BL. As a result of varying the thickness of active layer, the thinner BL (T4) or the thicker TL (T3) generated more photo-current than other tandem cells. Based on the experiments, it seems that the photo-current of our tandem cells are mainly determined by the photo-current generation from the top cell. However, the highest conversion efficiency was obtained from the tandem cell of T2 which has intermediate thickness (100 nm for the top and bottom cell). It is ascribed to the enhanced V_{OC} and FF of the T2 compare to the other tandem cells.

Interestingly, the tandem cell showed enhanced stability compared to the single cell (Fig. 11). The active layers of the cells were covered with commercial epoxy resin (Clear Epoxy, Dong Sung Uni. Tech. Co., Korea) in air before the light soaking test. The stability of the cells was monitored by continuous irradiation under a sulfur plasma lamp. The light intensity of the lamp was adjusted using a NREL-calibrated mono Si solar cell with a KG-2 filter, for approximately AM 1.5G 1 sun light intensity. The temperature of the testing chamber was approximately 35 °C. Fig. 10 compares the stability of the TC-4083 and the single junction cell, and it was found that there was 94% degradation after 125 h irradiation for the single junction cell, whereas the TC-OL-4083 maintained 56% of its initial efficiency. The degradation is mainly ascribed to the decreased J_{SC} and FF for both the single and tandem cells. The decline of the J_{SC} and FF of the single cell was much faster than that of the tandem cell. It is thought that the better stability of the tandem cell is ascribed to the dense TiO_2 nanoparticles interlayer, which can protect the active layer in the bottom cell from the oxygen. Similar results have been reported, where the stability of a cell was enhanced by utilizing the TiO_x as an electron transporting layer [15].

4. Conclusions

In conclusion, solution processed polymer tandem cells have been fabricated by utilizing the highly dispersive organic layer coated crystalline TiO_2 nanoparticles (OL-TiO_2)/PEDOT:PSS interlayer. The top and bottom cell were clearly separated by the interlayer without interlayer mixing, which was not observed for the tandem cell utilizing commercially available TiO_2 nanoparticle (N-TiO_2) for the interlayer. The conversion efficiency of the polymer tandem cell was enhanced from 1.43% to 3.44% by replacing the interlayer from N-TiO_2 to OL-TiO_2. The J_{SC} of the tandem cell was increased by decreasing the bottom layer thickness or increasing the top layer thickness. This implies that the photo-current of our tandem cells are mainly determined by the photo-current generation from the top cell. However, the highest conversion efficiency was obtained from the tandem cell having intermediate thickness (100 nm for the top and bottom cell) due to the enhanced V_{OC} and FF by minimizing the charging of the excess charge

carriers at the interlayer. Based on the V_{OC}, J_{SC} and FF of the tandem cell, it is thought that the OL-TiO_2 layer performs the role of interlayer in the tandem cell with little loss of J_{SC} and V_{OC}. In addition that, it was found that the OL-TiO_2 interlayer enhanced the stability of the tandem cell comparing to that of the single junction cell. It could be ascribed to the reduction of the oxygen diffusion to the bottom layer by the interlayer. We believe the highly dispersive OL-TiO_2 has several advantages for the solution processed polymer solar cell in terms of excellent film forming property, crystallinity, transparency, stability and processability. It is expected that the performance of the tandem cell can be further enhanced by adopting efficient low band gap materials to the bottom cell.

ABSTRACT

We report highly efficient white polymer light-emitting devices (WPLEDs) using a newly synthesized, deep-blue emitting fluorene-co-dibenzothiophene-S,S-dioxide copolymer as host, doped with two narrow-bandgap iridium complexes. Despite the low-lying triplet energy levels of the host, phosphorescent quenching by the polyfluorene copolymer host was significantly suppressed with poly(*N*-vinylcarbazole) (PVK) as hole-injecting, anode buffer layer. The energy transfer process had been studied via transient photoluminescence spectra and confirmed that PVK layer is responsible for the efficient electrophosphorescence in the devices. As a result of balanced red–green–blue (RGB) emission from the host and the triplet emitters, white emission with Commission Internationale de L'Eclairage (CIE) coordinates of (0.278, 0.312) was achieved, with a peak luminous efficiency of 15.1 cd A^{-1} and a color rendering index (CRI) of 79–86.

1. Introduction

White polymer light-emitting devices (WPLEDs) [1,2] have attracted intense attention due to their potential applications as backlight for liquid crystal displays as well as lighting sources. Despite the relatively lower efficiency when compared to its vapor deposition counterparts [3–6], WPLEDs based on solution processing technology have particular advantages, such as low-cost manufacturing and easy-processibility over large-area size by roll-to-roll printing technology. Several approaches towards WPLEDs have been reported, including multi-layer structure capable of red–green–blue (RGB) emission [7,8], polymer blends containing RGB emitting species with appropriate ratio [9], doping polymer host with RGB phosphorescent or fluorescent dopants [10–12], or white emitting single polymer [13–15]. Of these approaches, WPLEDs based on non-conjugated polymer host, i.e. poly(*N*-vinylcarbazole) (PVK) and phosphorescent dopants give the highest efficiency since these devices may convert 100% injected electrons into photons as they can utilize singlet as well as triplet excitons via Dexter energy transfer owing to strong spin–orbit coupling induced by the heavy atom effect [11,12,16,17].

In contrast, electrophosphorescent WPLEDs based on conjugated polymer host, such as polyfluorenes [18], usually suffer from inefficient energy transfer since the host may act as quenching sites for the triplet excited states due to their relatively low triplet energy level [19]. As a result, the application of blue and green emitting triplet emitters (with energy level higher than 2.3 eV) in such systems is limited. An alternative approach to address this problem is to use polyfluorenes/PVK mixed hosts [18], which had been shown to have good chemical compatibility and raised triplet energy level for the host polymer

doi:10.1016/j.orgel.2009.12.008

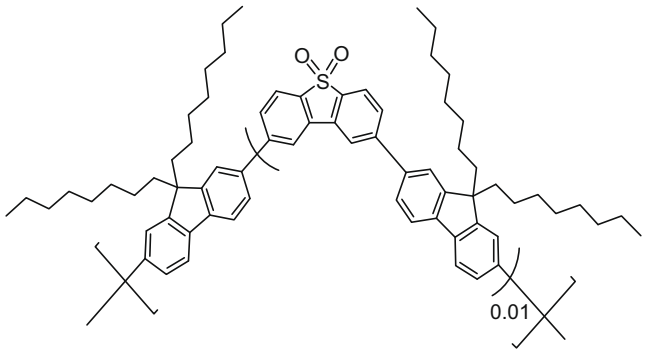
blend, thus leading to efficient energy transfer from polyfluorenes to the iridium dyes. We report here a new approach to realize highly efficient WPLEDs using polyfluorenes as host, doped with green and red emitting iridium complexes, from a multilayer device structure in which PVK was used as the anode buffer layer. Recently, our group reported an enhanced green electrophosphorescent emission using polyfluorene as host via interfacial energy transfer from PVK [19]. Steady and transient PL spectra revealed that PVK buffer layer plays an important role in energy transfer process, and can thus minimize phosphorescent quenching by the polyfluorene copolymer host with superior device performance.

In this contribution, we demonstrate that this device structure can be utilized to fabricate highly efficient WPLEDs based on polyfluorenes host. Optimized device shows a peak luminous efficiency (LE) of 15.1 cd A^{-1} and a peak power efficiency (PE) of 8.4 lm W^{-1}, with Commission Internationale de L'Eclairage (CIE) coordinates of (0.278, 0.312) at 10 mA cm^{-2}. To our knowledge, the obtained efficiencies are one of the highest reported value for WPLEDs based on fluorescent polymer host materials.

2. Experimental

2.1. Materials

The molecular structures of the RGB emitters are shown in Scheme 1. A newly synthesized conjugated polymer PF-2,8FSO1 was selected as the host material and deep-blue



PF-2,8FSO1

emitters for the WPLEDs due to its high efficiency (with an external quantum efficiency (EQE) of 3.6% and a LE of 3.7 cd A^{-1}), deep-blue emitting properties and excellent spectral stability [20,9]. The two highly efficient electrophosphorescent narrow-bandgap iridium(III) complexes used for this study are $Ir(mppy)_3$ [2,21] for green emission and Ir-G2 [22] for red emission, respectively.

2.2. Device fabrication

The fabrication of the devices followed a well-established procedure [11]. Patterned indium tin oxide (ITO) coated glass with a sheet resistance of 15–20 ohm/square were cleaned by a surfactant scrub, then underwent a wet-cleaning process inside an ultrasonic bath, beginning with deionized water, followed by acetone and isopropanol. After oxygen plasma cleaning for 4 min, a 40-nm thick poly(3,4-ethylenedioxythiopene):poly(styrenesulfonate) (PEDOT:PSS) (Bayer Baytron 4083) anode buffer layer was spin-cast on the ITO substrate and then dried by baking in a vacuum oven at 80 °C overnight. A hole transporting layer of poly(*N*-vinylcarbazole) (PVK) with a thickness of 40 nm was deposited from chlorobenzene solution, then annealed at 100 °C on a hotplate for 10 min. The fluorescent host and phosphorescent guests were dissolved in *p*-xylene and chlorobenzene, respectively, then blended together to form targeted solution for the devices. The active layer, with thickness in the 40–50 nm range was spin-

All of the EL spectra were obtained at a current density of 10 mA cm^{-2}.

Table 1
Summary of device performance of the WPLEDs.

Device structure	Maximum LE (cd A^{-1})	Maximum EQE (%)	Maximum PE (lm W^{-1})	CIE coordinates	CRI
PEDOT/EML/Ba/Al	0.5	0.38	0.26	(0.170, 0.109)	–
PEDOT/PVK/EML/Ba/Al	10.6	6.3	4.9	(0.302, 0.367)	86
PEDOT/PVK/EML/PFN/Ba/Al	15.1	9.4	8.4	(0.278, 0.312)	79

coated atop of the PVK layer, and kept at the temperature of 100 °C for 30 min to remove the solvent residue. After that, a home-made water/alcohol soluble conjugated polymer, poly[(9,9-bis(3′-(*N*,*N*-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)] (PFN) [23–25], was used as an electron injection layer (with a thickness of 20 nm) was spin-coated on the top of the resulting emissive layer. Finally, 4 nm barium and 100 nm aluminum layer were evaporated with a shadow mask at a base pressure of 3×10^{-4} Pa. The thickness of the evaporated cathode was monitored by a quartz crystal thickness/ratio monitor (Model: STM-100/MF, Sycon). The overlapping area between the cathode and anode defined a pixel size of 19 mm^2. Except for the deposition of the PEDOT layers, all the fabrication processes were carried out inside a controlled atmosphere of nitrogen dry-box (Vacuum Atmosphere Co.) containing less than 10 ppm oxygen and moisture. The current density–luminance–voltage (*J*–*L*–*V*) characteristic was measured using a Keithley 236 source-measurement unit and a calibrated silicon photodiode. The forward-viewing luminance was calibrated by a spectrophotometer (SpectraScan PR-705, Photo Research) and the forward-viewing LE was calculated accordingly. Throughout the whole manuscript, reported value of luminance and LE are for forward-viewing direction only. The external quantum efficiency (EQE) of electroluminescence (EL) was collected by measuring the total light output in all directions in an integrating sphere (IS-080, Labsphere). The photoluminescence (PL) spectra were recorded by a single-grating monochromator (Instaspec IV, Oriel Co.) equipped with a CCD detector, and EL spectra were collected by a PR-705 photometer. Time-resolved spectra were measured by fluorescence lifetime spectrometer (FLS-920, Edinburgh Instrument Ltd.).

3. Results and discussions

The 1931 CIE coordinates of the individual RGB devices in a single active layer configuration of ITO/PEDOT:PSS (40 nm)/RGB emissive layer/Ba(4 nm)/Al (100 nm) are (0.65, 0.30), (0.27, 0.63), and (0.16, 0.07), respectively. While the CIE coordinates of the primary RGB color system adopted by National Television System Committee (NTSC) for color TV are (0.67, 0.33) (R), (0.21, 0.71) (G) and (0.14, 0.08) (B), it can be clearly seen that the red and blue emitters match the NTSC standard very well (see Fig. 1a). Therefore, when WPLEDs based on these RGB emitters are used for flat panel displays, a wide color gamut (79%) is expected (Fig. 1a), close to that of other displays, such as liquid crystal displays (72%) and plasma displays (100%). From Fig. 1b, the EL spectra of the RGB devices cover the entire visible light spectrum from 400 to 700 nm. As a result, it is expected that white emission with very high color quality can be realized if emission of each color is carefully balanced.

To obtain white emission with high efficiencies, a series of devices with various doping concentrations were fabricated and evaluated [9,19], and the device performance of the obtained WPLEDs is summarized in Table 1 for comparison. Depending on the doping concentration of the red and green iridium complexes, the emission color of the WPLEDs can be tuned in a wide range (Fig. 1c). With a device configuration of ITO/PEDOT:PSS (40 nm)/PVK (40 nm)/PF-2,8FSO1 (100 wt%):Ir(mppy)$_3$ (*x* wt%):Ir-G2 (*y* wt%)

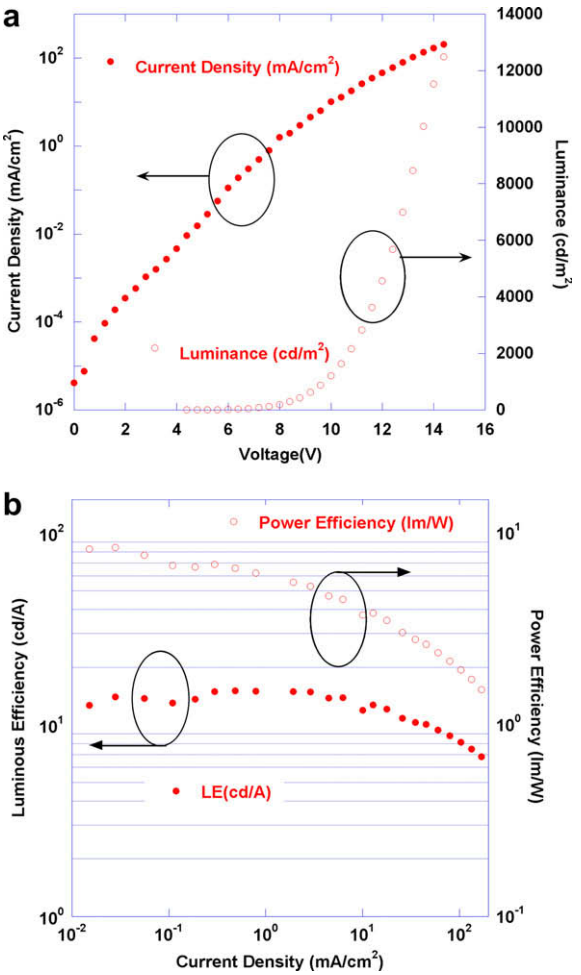

Fig. 2. (a) *J*–*L*–*V* and (b) LE–PE–*J* characteristics of a device with configuration of ITO/PEDOT:PSS (40 nm)/PVK (40 nm)/PF-2,8FSO1 (100 wt%):Ir(mppy)$_3$ (0.4 wt%):Ir-G2 (0.6 wt%) (40 nm)/PFN (20 nm)/Ba (4 nm)/Al (100 nm).

(40 nm)/cathode, it was found that when the blend ratio between PF-2,8FSO1:Ir(mppy)$_3$:Ir-G2 is fixed at 100:0.4:0.6, a white emission with a LE of 10.6 cd A^{-1} and CIE coordinates of (0.302, 0.367) was obtained at a current density of 10 mA cm^{-2}. Remarkably, the white emission has a high color rendering index (CRI) of 86. The device performance of WPLEDs can be further enhanced when a thin layer of alcohol/water-soluble polymer PFN [23–25] was incorporated as the electron injection layer at the cathode side. As a result of efficient electron injection and more balanced carrier transport, a nearly pure white emission was realized, with a peak LE of 15.1 cd A^{-1}, CIE coordinates of (0.278, 0.312) and a CRI of 79.

Fig. 2 shows typical *J*–*L*–*V* and LE–PE–*J* characteristics of an optimized WPLEDs. The turn-on voltage (defined as the voltage at a luminance of 1 cd m^{-2}) of the device is as low as 4.4 V, which can help to reduce power consumption and obtain high PE. As a result, a forward-viewing PE of 8.4 lm W^{-1} was reached at 5.2 V (i.e. at 0.03 mA cm^{-2}). It was found that high LE (over 10 cd A^{-1}) was retained over a wide range of *J* values, for example, from 0.01 to 60 mA cm^{-1}, corresponding to *L* between 1 and 6000 cd m^{-2}.

We note that for the control devices in which PVK interlayer is absent, only a degraded device performance was obtained, with a peak LE of 0.5 cd A^{-1} and a peak EQE of 0.38%. Furthermore, the green emission from Ir(mppy)$_3$ is hardly detected in this device (Fig. 1c), but an intense green emission can be observed in the devices with PVK interlayer. As reported by Wang et al., the triplet energy of the charge transport layer can have significant impact on the energy transfer quenching from the excited state of the Ir complexes and the subsequent device performance [26]. Since the triplet energy of Ir(mppy)$_3$ is 2.38 eV [27], and the triplet energy of the conjugated polymer is typically below 2.3 eV [28], so the inefficient Ir(mppy)$_3$ emission in the control device can be attributed to the energy back transfer from the triplet excitons on the Ir(mppy)$_3$ molecules to the low-lying triplet states of the polymer [19]. On the other side, with the presence of PVK interlayer, which have a triplet exciton with energy of 3.0 eV [29], exothermal energy transfer quenching from the excited state of the emitters can be avoided [26]. Furthermore, since the electrical excitation of the EL process in the devices is dominated by charge trapping mechanism (which can be inferred from the energy level of the device, characterized by deep hole traps with depths of 0.6 eV and densities of 10^{18} cm^{-3}) [2], we speculate that the recombination zone was located at the interface between the PVK layer and the emitting layer. Therefore, triplet exciton with energy of 3.0 eV was formed on PVK at the interface and can be readily transferred to the iridium dyes within a few nanometers via Förster or Dexter energy transfer, leading to efficient green and red electrophosphorescence, thus avoid the quenching from the excited state of the emitters to the triplet state of PF-2,8FSO1. In addition, due to different solubility of PVK in chlorobenzene and *p*-xylene, we can eliminate the possibility of intermixing at the interface which has also been addressed by the analysis on the cross section of the profile of the bilayer in our previous publication [19,30].

The role of the PVK layer can be further clarified by transient PL spectra. Fig. 3 shows the transient PL spectra of the films of PVK:Ir(mppy)$_3$ (2 wt%) (40 nm), PVK (40 nm)/PF-2,8FSO1:Ir(mppy)$_3$ (2 wt%) (40 nm) and PF-2,8FSO1:Ir(mppy)$_3$ (2 wt%) (40 nm), which are denoted as A, B, and C, respectively. When sample A was excited at 300 nm which is around the absorption peak of PVK, and the probe was fixed at the emission peak of Ir(mppy)$_3$ (~510 nm), a single exponential decay with a lifetime of 703 ns was recorded, which is consistent with our previous measurement [19]. In contrast, for sample C, in which the PVK layer is absent, when excited at the absorption peak of PF-2,8FSO1 at 375 nm, the phosphorescence decay is significantly faster (with τ_1 = 9.8 ns, valued 68% and τ_2 = 69 ns, valued 32%). This difference in the density of excited states can be attributed to the quenching by PF-2,8FSO1 due to the low-lying triplet energy level. More-

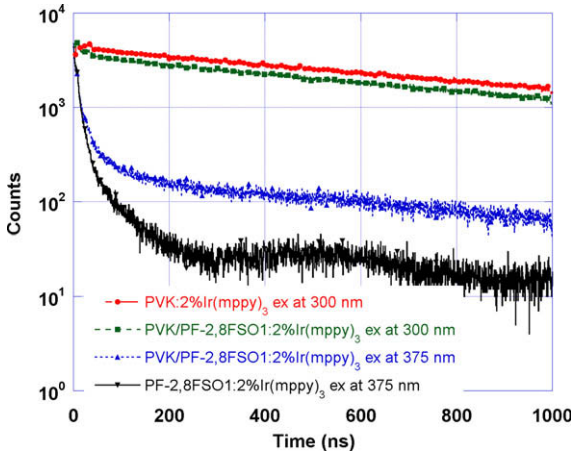

Fig. 3. Transient PL spectra of samples with configurations of PVK:Ir(mppy)$_3$ (2 wt%) (40 nm) (sample A), PVK (40 nm)/PF-2,8FSO1:Ir(mppy)$_3$ (2 wt%) (40 nm) (sample B), and PF-2,8FSO1:Ir(mppy)$_3$ (2 wt%) (40 nm) (sample C), excited at 300 nm and 375 nm, respectively.

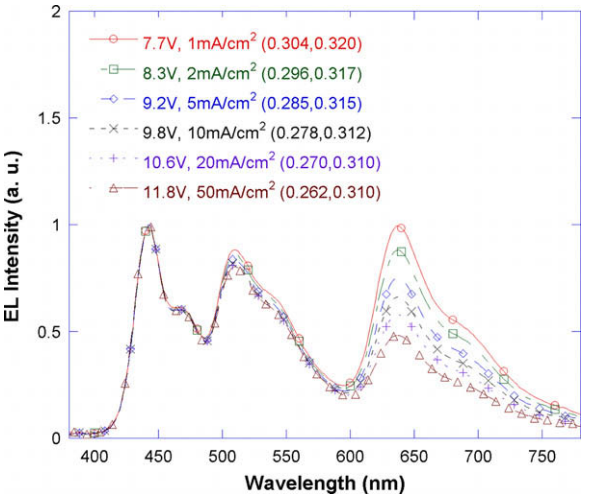

Fig. 4. The EL spectra of a typical WPLEDs upon variations of applied current density from 1 mA cm^{-2} to 50 mA cm^{-2}.

over, for sample B, when excited at 300 nm, a nearly single exponential decay with a lifetime of 795 ns (with a value of 99%) was observed, suggesting that the decay of the phosphorescence is not affected by PF-2,8FSO1. In contrast, when the same sample was excited at 375 nm, a much faster decay (with τ_1 = 12.9 ns, valued 43% and τ_2 = 285 ns, valued 57%) was found, representing a significant quenching of the phosphorescence.

In fact, our devices showed a voltage/current density-dependent emission color. Taking a device with PFN interlayer as an example, as shown in Fig. 4, as the applied current density increase from 1 mA cm^{-2} (corresponding to a luminance of 150 cd m^{-2}) to 50 mA cm^{-2} (corresponding to a luminance of 5000 cd m^{-2}), the CIE coordinates shift from (0.304, 0.320) to (0.262, 0.310). Color shift upon increasing current density is common in dopants based WOLED/WPLEDs, which was usually attributed to the facts that the doping concentration of narrow energy gap dopants are usually very low (not higher than 1 wt%), thus the possibility of charge trapping on such dopants or energy transfer from wide energy gap dopant will decrease as the low energy excited sites are saturated [18]. However, according to our estimate, in order to excite the all of the narrow gap iridium complex Ir-G2 in our devices, an injected current density of 10,000 mA cm^{-2} should be applied. In other words, the blue shift of color in our devices with increasing current density may not simply attribute to saturation of low energy excited sites. In fact, the color shift in our devices upon the change of applied current density (voltage) can be attributed to the competition between hole trapping on narrow gap iridium complex Ir-G2 sites and undisturbed hole transport across the emissive layer [31,32]. Endeavor for improvement of the EL spectral stability is on going in our group by adopting the concept of management of charges and excitons in the single active layer [33].

4. Conclusions

In summary, we have reported a white polymer light-emitting devices based on a newly synthesized conjugated polymer which dually functions as the host and the blue emitter, which can be blended with two phosphorescent materials $Ir(mppy)_3$ and Ir-G2 as the green and red emitters. By spin coating the emissive blend atop the PVK hole transporting layer, we obtained white emission with a luminous efficiency of 15.1 cd A^{-1}, and a good color quality (i.e. a CRI of 86). Our results demonstrate that with the presence of high-triplet-lying PVK, phosphorescent quenching by the polyfluorene copolymer host can be significantly avoided, thus highly efficient white emitting polymer light-emitting devices with very good color quality can be fabricated from a fluorescent host.

ABSTRACT

Semi-transparent polymer solar cells from a blend of poly-(3-hexylthiophene-2,5-diyl) and [6,6]-phenyl C_{61} butyric acid methyl ester (P3HT:PCBM) comprising a poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) cathode and a vacuum deposited n-doped organic buffer layer have been realized. Among the investigated organic material systems for n-doping, the use of lithium doped bathophenanthroline (BPhen:Li) allowed for proper energy level alignment and subsequently for an open-circuit voltage $V_{oc} \approx 600$ mV. Upon deposition the PEDOT:PSS adheres selectively on the BPhen:Li buffer layer in order to form the laterally defined transparent cathode.

1. Introduction

Due to the recent progress in power conversion efficiencies to more than 5%, polymer solar cells have increasingly attracted attention [1–5]. Taking the absorption bands of organic materials into account, polymer solar cells open pathways to semi-transparent devices that can be used e.g. for façade-integrated photovoltaics. As a matter of principle such semi-transparent devices need two transparent but conducting contacts where indium tin oxide (ITO, workfunction $\Phi_a \approx 4.8$ eV) or highly conductive poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, workfunction $\Phi_a \approx 5.2$ eV) [6–9] can be used to form the anode. However, the realization of a transparent and conducting cathode with a low work function is challenging. So far transparent cathodes have been realized by ultrathin metal layers [10], sputtered ITO [11] or by a combination of a lithiumfluoride (LiF) or lithium cobalt oxide ($LiCoO_2$) interlayers with an ultrathin aluminium cathode and a sputtered aluminium doped zinc oxide layer [12,13]. Utilizing a lamination process, semi-transparent organic photovoltaic devices comprising cathodes based on vapor phase polymerized PEDOT can be fabricated [14]. Another approach features the incorporation of zinc oxide nanoparticles below a PEDOT:PSS cathode [15]. In general, transparent cathodes can be fabricated from high work function materials in conjunction with n-doped buffer layers or an ultrathin low work function metal layer.

N-doped organic layers can be considered as standard buffer layers for vacuum deposited organic photovoltaic devices [16]. In particular alkali metal doping of electron transport materials is a well investigated material combination for organic optoelectronic devices [17,18], but also cationic dye doping (e.g. rhodamine B, RhB) of fullerenes or 1,4,5,8-naphthalenetetracarboxylic dianhydride (NTCDA) is a common approach [19,20].

In this work we demonstrate a semi-transparent polymer solar cell incorporating vacuum deposited lithium doped bathophenanthroline (BPhen:Li) buffer layers below a cathode from PEDOT:PSS.

2. Experimental

In order to fabricate semi-transparent polymer solar cells following the architecture depicted in Fig. 1a ITO coated glass samples (Merck, $R_{\square} = 13\ \Omega/\square$) were structured in hydrochloric acid and solvent cleaned following established standard procedures. A 20 nm film of PEDOT:PSS (Clevios VP AI 4083) was spincast on the ITO anode followed by a 200 nm thick film from a blend of poly-(3-hexylthiophene-2,5-diyl) and [6,6]-phenyl C_{61} butyric acid methyl ester (P3HT:PCBM, 1:0.9 by weight, 40 mg/ml in *o*-dichlorobenzene). Then the samples were transferred to a vacuum chamber (10^{-7} mbar) where a 20 nm BPhen:Li layer with a molar ratio of 1:1 was co-deposited from effusion cells through a shadow mask followed by a thin layer of gold with a nominal thickness of 3 nm. At such small nominal thicknesses gold is known not to form a closed thin layer but clusters [21]. Finally, we spincast a 120 nm layer of highly conductive PEDOT:PSS (Clevios PH 750 with 5% dimethylsulfoxide) on top of the layer stack in order to form the transparent and conductive cathode. We determined the conductivity $\sigma \approx 570$ S/cm of the PEDOT:PSS formulation on a glass substrate previously [9]. Subsequently, the active area of the solar cell was determined by the cross section of the 12 mm wide ITO anode and the 2 mm wide PEDOT:PSS contact.

We found that PEDOT:PSS performs self patterning in a way that it only wets the BPhen:Li pads but not the P3HT:PCBM surface. This finding was substantiated by contact angle measurements between the respective PEDOT:PSS formulation and the surfaces under investigation. While the contact angle of the PEDOT:PSS formulation on P3HT:PCBM was determined to 99° ± 2° indicating very bad adhesion, it measured only 69° ± 6° on BPhen surfaces. This contact angle was further reduced by doping BPhen with lithium to 55° ± 3°. Gold clusters on top of both BPhen and BPhen:Li changed the contact angle to 70° ± 3° that is still well below the contact angle of PEDOT:PSS on P3HT:PCBM. The difference in contact angles can be attributed to different surface energies of P3HT:PCBM and the BPhen:Li/Au pads and explains the exclusive wetting of PEDOT:PSS on P3HT:PCBM.

For comparison, solar cells with vacuum deposited buffer layers based on BPhen:Li and the matrix-dopant systems C_{60}:RhB and NTCDA:RhB on top of the P3HT:PCBM bulk heterojunction followed by a 250 nm thick aluminium electrode were fabricated.

The current voltage characteristics of the solar cells were recorded with a source measure unit (Keithley 238). A spectrally monitored Oriel 300 W solar simulator was used to simulate the sunlight according to the ASTM-G173-03e1, AM 1.5 standard with an irradiation of 100 mW/cm^2 [22].

3. Results and discussion

On their way to the contact, electrons that were generated in the active layer, have to pass two interfaces that can potentially account for losses.

In order to minimize the losses at the first interface between the organic layer stack and the buffer layer we investigated different n-doped transport layers. From the range of material combinations for n-doping we chose the matrix-dopant systems C_{60}:RhB (molar 15:1), NTCDA:RhB (42:1) and BPhen:Li (1:1). From the *JV* curves of polymer solar cells comprising either of these n-doped layers and an aluminium cathode as depicted in Fig. 2 we conclude, that doped C_{60} and NTCDA do not form suitable buffer layers. The deep lying LUMOs of C_{60} ($E_{LUMO} = -4.3$ eV) and NTCDA ($E_{LUMO} = -4.5$ eV) and subsequently their even lower Fermi levels lead to reduced open-circuit voltages (V_{oc}) and hence to moderate power conversion efficiencies. In contrast, incorporating BPhen:Li ($E_{LUMO} \approx -3.0$ eV) as a buffer layer results in a $V_{oc} \approx 600$ mV being comparable to P3HT:PCBM solar cells with established standard architectures. Consequently, we further investigated BPhen:Li buffer layers for their use in semi-transparent organic solar cells.

In the next step we studied the electrical properties of the BPhen:Li/PEDOT:PSS interface in order to improve the conversion between the electron current in the BPhen:Li layer to a hole current in the PEDOT:PSS cathode. Therefore we investigated the *JV* curve of a bilayer pn-heterojunction (ITO/PEDOT:PSS/BPhen:Li/Al) with and without gold clusters between the organic layers. As depicted in Fig. 3 the vacuum deposited gold clusters improve the current through the pn-junction by about one to two orders of magnitude. This concept is similar to the concept of recombination zones that have been reported for organic tandem solar cells so far where noble metal clusters establish efficient recombination of charge carriers between two stacked and monolithically linked solar cells [23,24].

Taking both results into account, we built semi-transparent solar cells with a cathode from PEDOT:PSS and a BPhen:Li buffer layer. A typical *JV* curve of these devices is shown in Fig. 4 (solid line) together with the corresponding transmission spectrum (inset). We found a good device transmission $T = 50\%$ in the 650–700 nm regime, where

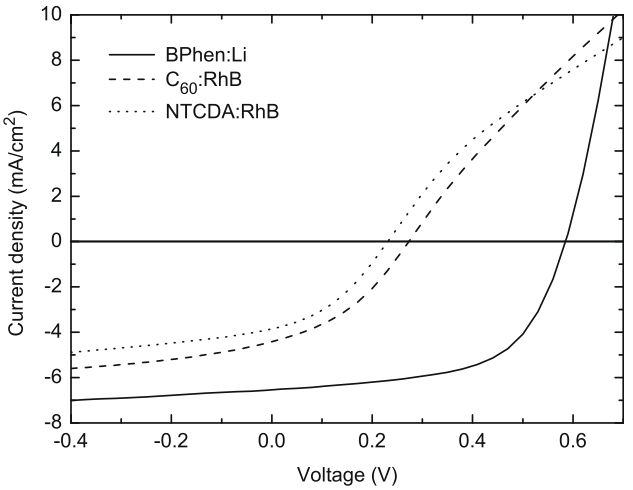

Fig. 2. *JV* curves of P3HT:PCBM solar cells incorporating n-doped buffer layers from C_{60}:RhB, NTCDA:RhB and BPhen:Li, respectively, as well as an aluminium cathode. Due to the energetically higher transport energy level of BPhen:Li compared to C_{60}:RhB and NTCDA:RhB, a higher $V_{oc} \approx 600$ mV can be achieved.

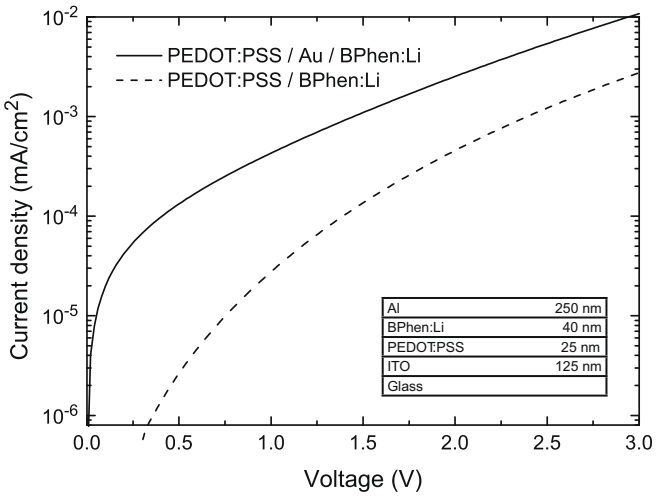

Fig. 3. *JV* curves of an ITO/PEDOT:PSS/BPhen:Li/Al bilayer device (dashed line). The current density through this pn-junction increases by about one to two orders of magnitude when gold clusters are introduced between the PEDOT:PSS and the BPhen:Li layer (solid line). Thus the resistance of this pn-junction decreases significantly. Inset: layer stack.

both the active layer and the electrodes exhibit only moderate absorption. Due to efficient photon harvesting of P3HT around 500 nm and of the fullerenes for wavelengths below 400 nm, the solar cell transmits only a small fraction of the sunlight in the lower wavelength part of the solar spectrum. The device $V_{oc} = 513$ mV is close to the maximum V_{oc} of about 600 mV that can usually be achieved with the absorber blend P3HT:PCBM when utilizing e.g. a calcium cathode. This indicates an ohmic contact between BPhen:Li and PEDOT:PSS due to proper energetic alignment of the respective transport levels. N-doping with lithium shifts the Fermi energy in BPhen towards the LUMO preventing electrons from dissipative energy losses upon recombination with holes in the PEDOT:PSS layer (work function $\Phi_a = 5.2$ eV).

The *JV* curve is affected by a high serial device resistance of 105 Ω cm^2 that can be derived from the reciprocal slope of the *JV* curve at higher voltages. We attribute this high serial device resistance to the moderate conductivity of the PEDOT:PSS cathode as compared to standard metal electrodes.

In order to examine the influence of the PEDOT:PSS lateral conductivity on the solar cell performance, we built devices with an additional thin gold layer on top of the PEDOT:PSS cathode. As derived from the *JV* curve of these devices in Fig. 4 (dashed line), the serial device resistance was reduced to 25 Ω cm^2, due to the gold layer supporting lateral conductivity. Consequently, the fill factor increased from 30% to 40%. At the same time, the V_{oc} of the device increased to 570 mV. This can be attributed to a smaller

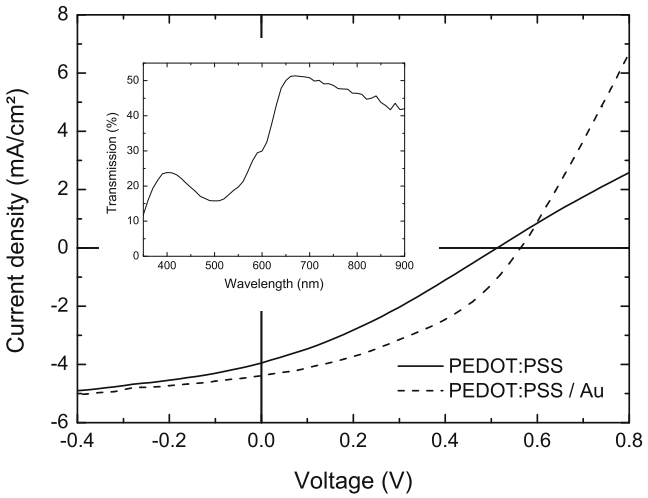

Fig. 4. *JV* curve of a semi-transparent organic solar cell comprising a PEDOT:PSS cathode and a BPhen:Li buffer layer (solid line). The device performance is strongly limited by the serial resistance of the PEDOT:PSS cathode. An additional gold layer on top of the PEDOT:PSS cathode reduces the device serial resistance by a factor 4 (dashed line). Inset: transmission spectrum of the semi-transparent device.

voltage drop along the PEDOT:PSS cathode. Although the device with the additional gold layer on top of the PEDOT:PSS was almost non-transparent, it can be concluded, that the limited lateral conductivity of PEDOT:PSS in this device architecture accounts partly for the moderate power conversion efficiency of 0.6% of the device.

4. Conclusion

In conclusion we have demonstrated semi-transparent organic solar cells comprising n-doped buffer layers and PEDOT:PSS cathodes. The material system BPhen:Li proved itself superior over cationic dye doped material systems in order to achieve open-circuit voltages as high as in conventional devices. Efficient current conversion between the electron current in the buffer layer and the hole current in the cathode was achieved by the incorporation of gold clusters between both layers.

ABSTRACT

This work addresses the long-term aging of organic solar cells based on a flat zinc phthalocyanine (ZnPc)/C_{60} heterojunction. We investigate both the typical degradation behavior of the short circuit current and of the saturated photocurrent, defined as $I(-1V)$. The latter remains constant after a relatively small initial decay, which is directly related to a substantial reduction of the contribution of excitons generated in C_{60} to the external quantum efficiency. Mass spectroscopy analysis of the organic material after aging revealed oxidized C_{60} and sub-products thereof. The reduction of $I(-1V)$ is thus attributed to the reaction of C_{60} molecules with oxygen impurities. The results strongly suggest that ZnPc/C_{60} photovoltaic cells are intrinsically very stable on a time scale of thousand of hours if such reactions are prevented.

1. Introduction

Efficient photovoltaic conversion in a heterojunction organic solar cell was first demonstrated by Tang [1] and have recently been more intensively investigated due to their potential as flexible, light-weight, and low-cost devices [2,3,5]. The main challenges in organic solar cell research are currently to improve the device efficiency and lifetime [6,7].

There are a number of reports which show that organic solar cells can be relatively stable. For instance, some dye sensitized solar cells exhibited no visible degradation operating at 75 °C over 7000 h [8], or only small changes even after 13,000 h under 400 Wm^{-2} [9]. A polymer solar cell using proprietary materials showed only a minor drop in short circuit current (I_{SC}) after 2000 h [10]. Several recent publications investigated the lifetime of polythiophene/PCBM bulk heterojunction cells [11–14,16]. For instance, all of them show that these polymer devices have an initial increase in efficiency that is related to a temperature effect [17] and morphological rearrangement of the bulk layer [14]. The degradation that follows the initial increase in efficiency is due to photo-oxidation of the polymer chain, reducing the absorption and the mobility [13]. The degradation is further related to the material of the top electrode [16]. It was also suggested, but not proven, that an increased roughness of the polymer surface takes place [14,15].

Small molecule based solar cells offer greater flexibility in the device stack over polymer and dye sensitized solar cells due to the easier deposition of multiple layers. However, lifetime data for complete encapsulated devices are still rare. In 1987, Manabe et al. produced a rather stable solar cell [18], that even had an improvement on I_{SC} over more than 600 h. Wang et al. compared different C_{60}/CuPc solar cells and showed that the devices live longer if C_{60} was moved far away from the Al electrode, leading to a shelf lifetime to half of its initial efficiency of 950 h [19].

High efficiency tandem solar cells were shown to be very stable with less than 3% of decrease in power conversion efficiency over 1000 h at 50 °C [20]. An extensive review of lifetime of organic solar cells is given in [21].

Non-encapsulated CuPc/C_{60} devices live only for a few minutes in air, in contrast to vacuum, where they are stable for at least several hours [22]. This is attributed to a strong degradation effect from oxygen with light assisted diffusion of oxygen. One of the main degradation processes for non-encapsulated devices is the quenching of excitons caused by anionic oxygen associated with C_{60} [23]. Molecular oxygen can diffuse through the whole device, in which the Al and Ag electrodes are only weak barriers [24–26]. Furthermore, oxygen causes a strong reduction in the electron mobility in C_{60} [27]. Modified electrodes and also a shift of the position of C_{60} layer further away from the Al electrode can improve device stability [11,19].

Yet, oxygen contamination acts an electron acceptor, causing p-doping of ZnPc, which improves the conductivity and lowers the barrier for hole injection/extraction to a diode anode such as Au or ITO [28,29]. Sobbi et al. extensively studied the stability of ZnPc in solution and film, concluding that ZnPc is very stable in the solid state [29].

Given the high known stability of ZnPc, this work focuses on the intrinsic stability of the C_{60} layers of the organic solar cell. In this paper, accurate measurements of solar cell electrical parameters are presented: I_{SC}, saturated photocurrent ($I(-1V)$), and fill factor (FF) of samples with a general device structure of glass/UV treated ITO (90 nm)/buffer layer/ZnPc (18 nm)/C_{60} (52 nm)/buffer layer/Al (100 nm). Table 1 summarizes all different device structures which are analyzed. Four modifications of anode and cathode are compared: structure A is the general structure using 4 nm ZnPc as cathode buffer layer. Structure B uses 4 nm ZnPc as cathode buffer layer and ITO modified with 1 nm Au followed by 1 nm of the proprietary organic dopant NDP2, which is comparable to the commonly used F_4-TCNQ [30]. Structure C is the general structure using 5 nm C_{60} doped with acridine orange base (AOB) as cathode buffer layer. Finally, structure D has a C_{60} layer doped with AOB and again the ITO is modified with 1 nm Au/1 nm NDP2. These systems were chosen due to their well known standard materials which allow for efficiencies up to 3.6% [31]. ZnPc is preferred over BCP or BPhen as buffer layer, due to its intrinsic higher thermal stability. It was previously shown that the BCP buffer can be replaced with CuPc or other materials [4], without compromising the device's performance, in house experiments have shown that ZnPc works as well. These layer sequences are building blocks for p–i–n solar cells, where the thin ZnPc and C_{60} layers are placed into the maximum of the optical field. The position of the absorption layers can be tuned by using transparent transport layers to achieve higher conversion efficiencies [5].

Table 1
List of the four different device structures, the value in brackets is the thickness in nm. The molar concentration of AOB in the AOB:C_{60} layer is 2%.

	Anode	Buffer	Donor	Acceptor	Buffer	Cathode
A	ITO(90)		ZnPc(18)	C_{60}(52)	ZnPc(4)	Al(100)
B	ITO(90)	Au(1)/ NDP2(1)	ZnPc(18)	C_{60}(52)	ZnPc(4)	Al(100)
C	ITO(90)		ZnPc(18)	C_{60}(52)	AOB:C_{60}(5)	Al(100)
D	ITO(90)	Au(1)/ NDP2(1)	ZnPc(18)	C_{60}(52)	AOB:C_{60}(5)	Al(100)

2. Experimental setup and methods

In total, 40 devices on 10 substrates (10 with each structure type) were prepared by vacuum deposition in a custom-made setup (Kurt J. Lesker Ltd.), of which four devices were left out due to short circuits or contact problems. Eight devices were stored in dark. The encapsulation is done on the wafer with a glass cover using the light curing sealant XNR5516 (Nagase GmbH). The samples are illuminated with blue light of 475 nm at 30 ± 7 mW/cm^2 using focused high power LEDs (LXHL-PB01, Philips GmbH). Blue LEDs were chosen as a compromise between light intensity and photon energy.

The LEDs are actively air cooled and their operation current is adjusted such that no significant (less than 4%) deviation of light intensity occurs during the experiment. Each LED is independently monitored using silicon photodiodes and the values of I_{SC} are corrected for the very small variation of illumination. The drawback of using LEDs is that the spectrum is very narrow and not related to the solar AM 1.5; nevertheless, the spectrum is very well defined and very stable over a very long time. The stability of this setup cannot be easily provided by conventional solar simulators.

The samples are aged under different temperatures, at 35 °C, 40 °C, 50 °C, 60 °C (also 63 °C for structure C and D). The temperatures are controlled by individual electronic controllers, using resistive heaters and digital thermometers with platinum film resistors (PT1000). The temperatures of all samples are calibrated with the same thermocouple reference with an experimental error smaller than ±0.5 °C.

The equation used to fit the transient measurements is a stretched exponential of type $A = A_0\exp[-(t/\tau)^{\beta}]$ [32], where A is the measured quantity, A_0 is the initial value at time $t_0 = 0$, t is the time (abscissa), τ is the decay constant, and β is the stretching factor [32]. The most straightforward value fitting procedure is the fitting of $I(-1V)$ and I_{SC} because of their direct relation to the generated charge. Using the stretched exponential $I_{SC}(t) = I_{SC}(t_0)\exp(-(t/\tau)^{\beta})$, the time for the I_{SC} decay to 50% of its initial value is $t_H = \tau(-\ln(0.5))^{1/\beta}$.

3. Experimental results

3.1. Electrical analysis

Device C is used to show the typical behavior of the ZnPc/C_{60} flat heterojunction device over time. The sample is aged with a substrate temperature of 50 ± 0.5 °C. The overall behavior of the main extracted parameters can be seen in the normalized transients in Fig. 1. At the end of the measurements, after 1200 h, the FF is around 0.25 and the I_{SC} is below 70% of its initial value. After the fast

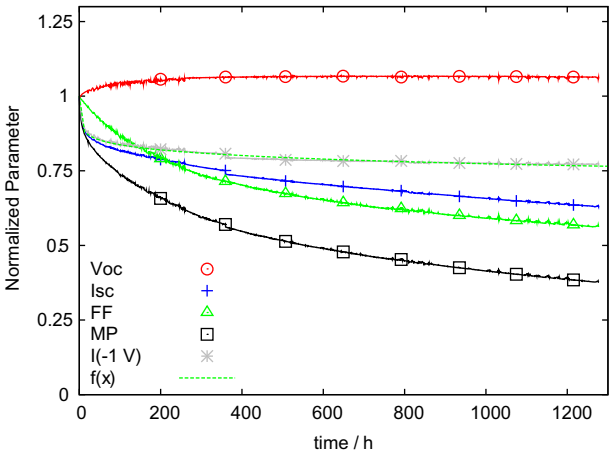

Fig. 1. Normalized values of characteristic parameters of a device with structure (C) aged at illumination of 475 nm and temperature of 50 °C. The initial values are: open circuit voltage (V_{OC}) = 0.41 V, short circuit current (I_{SC}) = -1.52×10^{-4} A (area = 6.2 mm^2), fill factor (FF) = 0.45, maximum power (MP) = -2.78×10^{-5} W, $I(-1V) = -1.13 \times 10^{-4}$ A. $f(x)$ is a stretched exponential shown fitted over $I(-1V)$. The fit parameters are $\tau = 4.8 \times 10^6$ h, $\beta = 0.16$ resulting in t_H = 485,736 h.

initial decay, the $I(-1V)$ remains remarkably constant. The observed time behavior of the normalized parameters is typical for all device structures, even for the device aged at 35 °C. Fig. 2 is an overview of the time to half of the initial value (t_H) of I_{SC}. The values obtained by fitting the $I(-1V)$ curves are scattered with no clear correlation to the experiment temperature. A reference device stored at room temperature in dark shows only minor changes in the I–V curve before and after the experiment, indicating that the observed degradation of the illuminated devices is photo- and thermically activated.

Fig. 3 shows the complete dynamics of the light I–V curve under aging conditions (T = 50 °C). The high current region (bright region, upper left corner) almost disappears after the first 200 h indicating a drastic increase in the series resistance. The broadening of the region with low current values (green and blue) shows how the I–V curve gets flatter and consequently the FF gets lower. The region of negative voltage remains almost unaffected. The inset shows the J–V curves of the first and the last measurement.

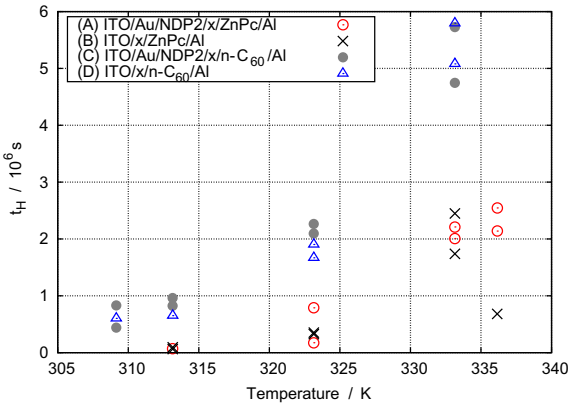

Fig. 2. Time to half (t_H) of initial short circuit current for the four different device structures. × Stands for the ZnPc (18 nm)/C_{60} (52 nm) bilayer.

The FF seems to be affected not only by the increase in series resistance, but also by the appearance of an 'S'-shape. This S-shape is related to an internal energy barrier for hole or electron transport [33]. During the accelerated aging experiment, the dark I–V curves (not shown) have a strongly reduced forward current compared to the first I–V curve. After 100 h, the exponent (n) from the current dependence on the applied voltage $I \propto V^n$ tends to 2 for the forward current. The voltage range of the I–V curve with this constant exponent ($n \sim 2$) increases over time. This is an indication of a space charge build up [34], probably due to low mobility in one or both main materials (ZnPc and C_{60}).

The characteristic values under AM1.5G of the reference device were V_{OC} = 0.49 V, J_{SC} = −6.5 mA, FF = 0.37, $I(-1V)/I_{SC}$ = 1.31 at the beginning of the experiment. At the end of the experiment, the values under AM1.5G were V_{OC} = 0.39 V, J_{SC} = −5.0 mA, FF = 0.29, $I(-1V)/I_{SC}$ = 1.42.

3.2. Chemical analysis

To address the material stability, additional 3 samples with structure A are analyzed with laser desorption/ionization time of flight mass spectrometry (LDI-TOF-MS, short LDI, as described elsewhere [35]). One sample is kept in the dark (1), this sample did not show any significant alteration of its I–V curve after 1200 h. Two samples are aged for 1000 h at 80 °C (2 and 3), one of these is further heated at T = 115 °C for 200 h (3), leading to a darkening of the sealant and subsequently to a complete loss of all photovoltaic characteristics. ZnPc and ZnPc + O are observed in the mass spectrum for positive charge. C_{60}, C_{60} + O, and C_{58} are observed in the negative spectrum. C_{56} and C_{54} signals are observed only for higher laser intensities. The ratio of intensities from ZnPc + O/ZnPc for the 3 characterized samples is: (1) > (2) ≃ (3). The ratio of ZnPc + O in the device leads to the conclusion that there are oxygen impurities in the fresh sample and, upon heating, ZnPc + O is

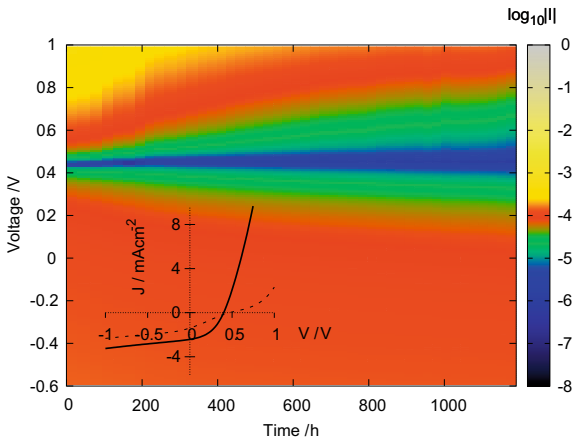

Fig. 3. Color map of $\log_{10}|I(V)|$ as function of time for a device with structure C illuminated at 475 nm and held at 50 °C. The inset shows the *J–V* curves at the beginning of the measurements initial (solid line) and after 1200 h (dashed line).

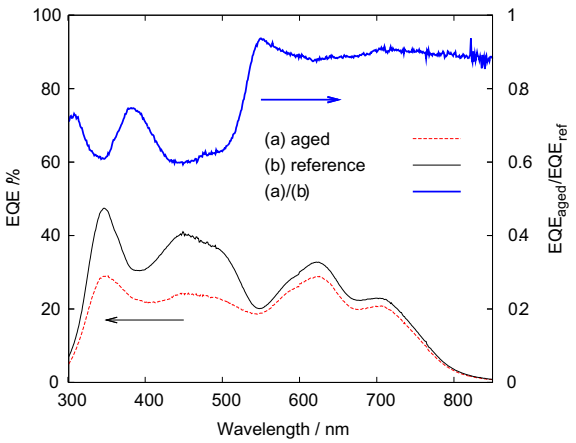

Fig. 4. EQE of device with structure (C), after aging (a) and reference (b). The ratio (a)/(b) is shown to emphasize the changes in the aged sample.

destroyed, either by losing the oxygen or by the fragmentation of the ZnPc part.

Stronger C_{60} + O and C_{58} signals are observed in the sample (2), indicating that the oxygen impurities are not reacted with C_{60} in the fresh sample. In sample (3) the oxidized C_{60} is probably reacted further to compounds with very low mass (such as CO_2).

The two obvious sources of oxygen contamination are the ITO and the organic materials. The ITO, used as anode, was treated with UV, then baked under vacuum at 100 °C for 1 h, and subsequently moved into nitrogen atmosphere, before loading the substrate into the deposition chamber. The organic materials were briefly exposed to air after the purification by sublimation, and afterwards always contained in nitrogen atmosphere. Most probably a joint contribution of oxygen from ITO and from ZnPc is responsible for the contamination. ZnPc and ZnPc + O cannot be separated by sublimation.

The thermal activation energies for the dark reaction described by Wohlers et al. [36] can be easily overcome by photoexcitation of C_{60} [37], creating two single or one double bonds in the form C_{60} > O (two different C atoms bound to one O atom) and C_{60}=O; and subsequently breaking the C_{60} cage into smaller molecules, which are stable only with an even number of C atoms [38]. It is likely that in the fresh sample, molecular oxygen is already available in the bulk and is partially reacted (1). Over time, atomic oxygen is created and reacts forming C_{60} + O which later dissociates in C_{58} (2). After further heating (3) the partially oxidized C_{60} or C_{58} further decomposes (CO_2), or polymerizes.

3.3. External quantum efficiency spectrum

Despite the changes in the ZnPc layer, the main loss in the I_{SC} is due to a reduction of the C_{60} contribution, most probably due to the illumination centered at 475 nm. Dividing the wavelength dependent external quantum efficiency (EQE) of the aged cell by the EQE of the reference cell (Fig. 4), it is seen that the main drop of I_{SC} comes from C_{60}. The normalized signal has a similar pattern to the EQE itself and the C_{60} contribution can be seen inverted, indicating that there is a much stronger degradation of C_{60} than of ZnPc. The major loss is the due to C_{60} layer, which is probably related to quenching or trapping effects of O_2 on excitons in C_{60}. The traps created upon aging have a negative effect on the charge carrier mobility. Nevertheless, there is also a loss in the ZnPc contribution, with a relatively weak signal change at around 600 nm to 700 nm. It is possible that the loss of the ZnPc part is due to decreasing of electron mobility in C_{60}, not necessary related to degradation in ZnPc film. This is consistent with the *I–V* after degradation. The degradation in ZnPc can thus be neglected in these devices.

3.4. Remarks

No clear correlation has been found between the changes in $I(-1V)$ and the aging temperature. If chemical reactions are related to $I(-1V)$, it can be concluded that main chemical reactions occur in the first 400 h of the experiment, after that time $I(-1V)$ remains practically constant showing that the materials are intrinsically very stable. The fact that I_{SC} and $I(-1V)$ have a fast initial drop can be explained by a photo-assisted process, in agreement with the literature [22]. Another interesting observation is that, besides the low active area, no sudden death (complete failure) occurred during the aging experiments, in any of the 36 devices.

4. Conclusions

In summary, we present detailed measurements of the aging of encapsulated organic solar cells under controlled temperature and illumination with blue LEDs for 1200 h. Transients show a fast initial degradation of I_{SC}, FF and $I(-1V)$. The decay of I_{SC} of the illuminated samples is temperature dependent. After the initial decay, $I(-1V)$ remains almost constant. The measurements indicate

materials degradation: Partially oxidized C_{60} and oxidized ZnPc degrade during the experiment as proven by LDI measurements. I_{SC} is strongly affected by loss of the current contribution from C_{60}, more than from ZnPc, as shown by EQE measurements. A common decrease of the EQE signal throughout the visible range can be ascribed to the effect of traps on charge transport, which is consistent with the decreased current under forward bias. On the other hand, the significant loss in blue range due to C_{60} can be explained by quenching of excitons in the C_{60} films. Therefore, degradation in ZnPc layer should be very limited or negligible. Our results shows that C_{60} and ZnPc are intrinsically very stable. ZnPc/C_{60} solar cells have the potential to be very stable on a time scale of many years, if reactions with oxygen are prevented.

ABSTRACT

Dibenzo[b,d]thiophene (**DBT**) based oligomers with carbon–carbon double and triple bonds were synthesized. Their thermal stability and energy levels were studied by thermal analyses, UV–vis absorption spectra and electrochemistry. Single crystals of 3,7-bis(phenylethynyl)dibenzo[b,d]thiophene (**BEDBT**) revealed the introduction of unsaturated bonds eliminated the steric repulsion between adjacent aromatic rings and **BEDBT** displayed planar structure in crystals. Thin film transistors of these compounds displayed typical *p*-type behaviour. The best performance was obtained from 3,7-distyryldibenzo[b,d]thiophene (**DSDBT**) on OTS modified substrates with mobility as high as 0.15 cm^2/Vs and on/off current ratio up to 10^8, one of the highest performance for **DBT** based oligomers.

1. Introduction

Organic field-effect transistors (OFETs) have attracted great interest because of their merits (low cost, could be fabricated on large scale and on flexible substrates) and potential applications in flexible electronic devices (roll-up displays, smart card, RFID and so on) [1–4]. The typical structure of OFETs includes source, drain and gate electrodes, an organic semiconductor layer, and a dielectrical layer. Among them, organic semiconductor layer is the key point to determine the performance of OFETs. Till now, much progress has been made to the design and synthesis of novel organic semiconductors for OFETs. Some organic semiconductors such as pentacene and heteroacenes with mobility larger than 0.5 cm^2/Vs have been reported [5–11]. The reason for the high performance of these fused ring organic semiconductors could be attributed to their large planar conjugated structures which would lead to large charge transfer integral and low reorganization energy. However, these fused ring compounds usually suffered tedious synthesis steps, complex purifications, low stabilities and solubilities. Studies have showed that oligomers would have good solubility and are easy to be modified to fit different applications, but oligomers usually exhibit low device performance because of their nonplanar structures caused by the steric repulsion between adjacent aromatic rings [12–17]. We and some researchers have reported, by introduction of carbon–carbon double [18–24] and triple bonds [25–32], planar conjugated oligomers which combined the merits of fused ring compounds and single bonds linked oligomers can be obtained. For instance, phenylvinylene oligomer [19] and its alkyl functionalized derivates [20] showed a maximum mobility of 1.3 cm^2/Vs; similar thiophenylvinylene oligomers [21] exhibited mobility up to 0.4 cm^2/Vs, seven times of its single bonds linked components [13,14]. Similar results have also been observed from the organic semiconductors with carbon–carbon triple bonds. For example, single crystals of 9,10-bisphenylethynyleneanthracene showed mobility as high as 0.73 cm^2/Vs [26]; the performances of transistors

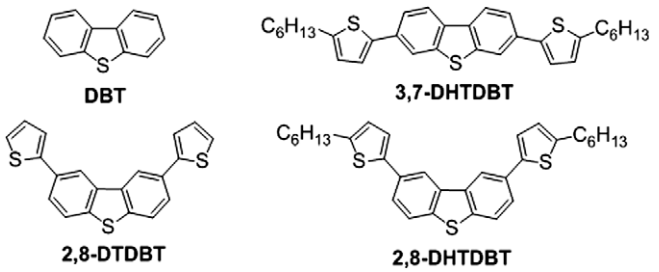

Scheme 1. The chemical structures of **DBT** and some of its single bonds linked oligomers.

of thiophene-phenyl cooligomers with carbon–carbon triple bonds was much better than those of their single bond components [25].

Dibenzo[b,d]thiophene (**DBT**, chemical structure see Scheme 1) is a commercial available chalcogenophene coumpound [33,34]. It has high ionization potential compared with anthracene, fluorene and carbazole which has conjugated planar structure and is commonly used as blocking unit in semiconductors. Additionally, the S atoms in **DBT** could introduce S···S and S···π intermolecular interactions which might facilitate charge transport. All of these merits suggested that **DBT** should be an ideal conjugated unit for organic semiconductors. In our previous work [34], we have observed single bonds linked **DBT** oligomer 3,7-bis(5′-hexylthiophene-2′-yl)dibenzothiophene (**3,7-DHTDBT**) displayed good transistor performance. In order to further investigate the application of **DBT** in organic semiconductors and the effect of carbon–carbon double and triple bonds to the performance of materials, herein two new 3,7-disubstituted **DBT** derivates, 3,7-bis(phenylethynyl)dibenzo[b,d]thiophene (**BEDBT**) and 3,7-distyryldibenzo[b,d]thiophene (**DSDBT**) were synthesized. Their physicochemical properties and charge transport characteristics were studied.

2. Results and discussion

The synthesis routes of **BEDBT** and **DSDBT** were outlined in Scheme 2. **BEDBT** were synthesized through modified Pd catalyzed Sonogashira coupling reaction [35]. **DSDBT** were synthesized through Heck reaction using $Pd(OAc)_2$ as catalyst [36]. **BEDBT** was easy to form crystals and was purified through recrystallization from toluene. **DSDBT** was obtained through column chromatography and further purified by vacuum sublimation. Both compounds were soluble in normal organic solvents such as CH_2Cl_2, THF, toluene and chlorobenzene, and totally characterized by ^1H NMR, MS and elementary analysis.

Single crystals of **BEDBT** suitable for X-ray diffraction (XRD) measurements were grown from toluene solution. As we expected, the single crystals of **BEDBT** revealed that it had nearly planar structure and belonged to a crystal system of monoclinic space group $P2_1$ with unit-cell parameters of $a = 11.666(2)$, $b = 7.6007(15)$, $c = 22.162(4)$ Å and $\beta = 94.89(3)°$. As showed in Fig. 1A, **BEDBT** adopted herringbone geometry in the crystals, and the herringbone angle was about 51.7°. Interestingly, adjacent **BEDBT** molecules along *a* axis formed Head-to-Head and Tail-to-Tail pairs (relative to S atoms). Fig. 1B showed the intermolecular interactions among neighbor molecules along *a* axis. S···H, S···π and C–H···π intermolecular interactions were found in Head-to-Head pairs, and only C–H···π intermolecular interactions existed in Tail-to-Tail pairs.

The thermal stabilities of **BEDBT** and **DSDBT** were characterized by thermogravimetric analysis (TGA). From their TGA curves (see Supplementary data), we could see **BEDBT** and **DSDBT** decomposed onset of 300 °C and 350 °C respectively, suggesting their good thermal stabilities. Fig. 2A showed the UV–vis absorption spectra of **BEDBT** and **DSDBT** in CH_2Cl_2 solution at the concentration of 10^{-5} M. The two compounds showed similar absorption peaks, but the maximum absorption of **DSDBT** was about 30 nm red shift than that of **BEDBT**, indicating a larger π-conjugation length of **DSDBT**. This phenomenon has also been observed by others [25,37]. The optical energy gaps estimated from UV–vis spectra were 3.35 and 3.1 eV for **BEDBT** and **DSDBT** respectively. The UV–vis absorption of vacuum deposited thin films of **BEDBT** and **DSDBT** were also tested to show the molecular arrangement in solids. They all showed very broad absorptions and the initial absorptions were red shifted compared with those of the solutions, indicating the ordered arrangements in solid states. The cyclic voltammetry of **BEDBT** and **DSDBT** in CH_2Cl_2 solutions at the concentration of 10^{-3} M were illustrated in Fig. 2B and C (using ferrocene (Cp_2Fe) as internal standard substance). The HOMO energy levels calculated from electrochemistry were −5.87 eV for **BEDBT** and −5.57 eV for **DSDBT** (the HOMO energy level of ferrocene was about −4.8 eV). The HOMO energy level of **BEDBT** was even lower than 2,8-disubstituted **DBT** derivatives 2,8-di(5'-hexyl-thiophen-2'-yl)-dibenzothiophene (**2,8-DHTDBT**, chemical structure see Scheme 1) reported in our previous work [33]. The lower HOMO energy level of **BEDBT** should be attributed to its short conjugated length (which was determined by UV–vis spectrum), the high ionic potential of **DBT** and the stronger electron-withdrawing effect of ethynylene group than that of the vinyl group. And this low HOMO energy level would cause carriers accumulation difficulty and charge injection barrier, which usually leads to low transistor performance. The energy gaps and HOMO/LUMO energy levels of **BEDBT** and **DSDBT** were summarized in Fig. 2D. The low HOMO energy levels suggested the good environmental stability of **BEDBT** and **DSDBT**.

The charge transport properties of **BEDBT** and **DSDBT** were examined to study their applications in OFETs. The

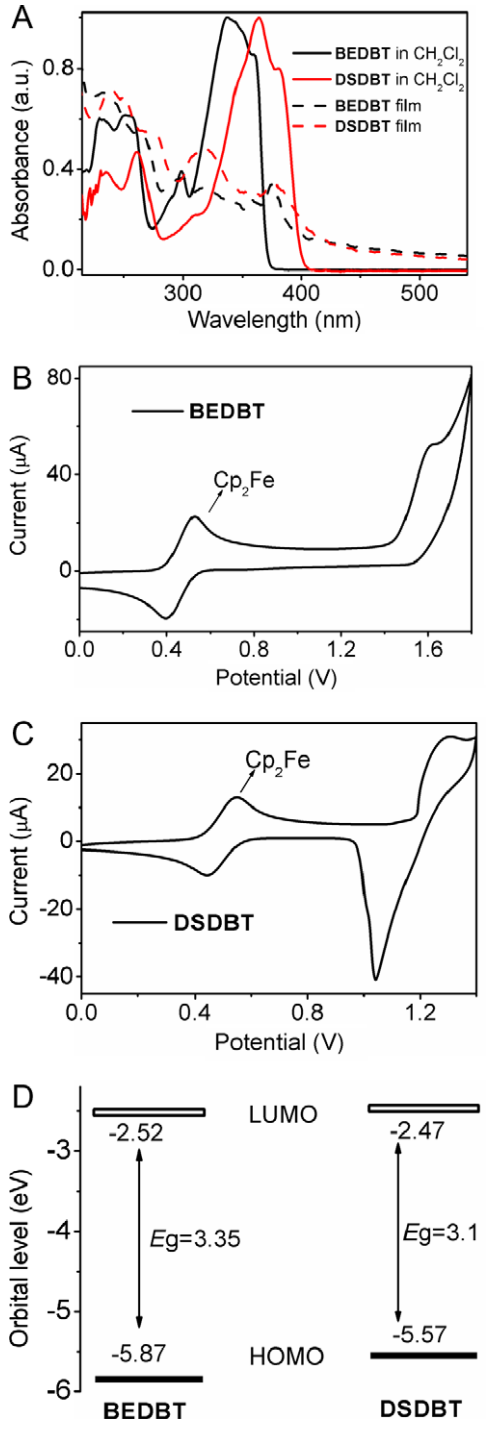

Fig. 2. (A) UV–vis absorption spectra, (B and C) cyclic voltammograms and (D) orbital levels of **BEDBT** and **DSDBT**.

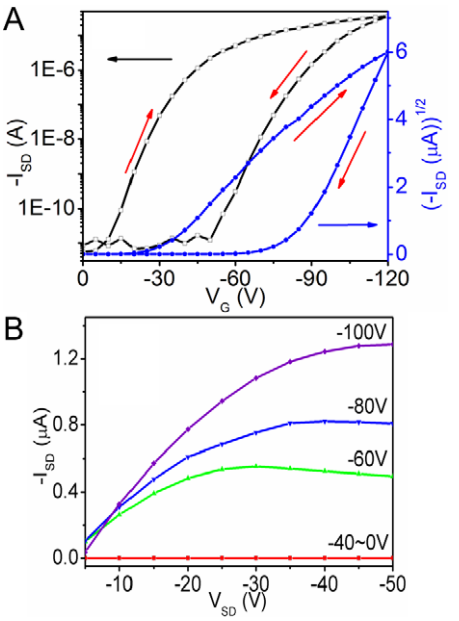

Fig. 3. (A) An example transfer with hysteresis loop (V_{DS} = −100 V) and (B) output curves of devices based on **DSDBT** films deposited on OTS modified SiO_2/Si substrates at 50 °C.

transistors were fabricated in top-contact mode using gold as the source and drain electrodes. The field-effect mobilities (μ) were calculated in the saturation regime according to the following equation: $I_D = \mu Ci(W/2L)(V_G - V_T)^2$, where I_D is the drain current, Ci is the capacitance per unit area of the gate dielectric, W and L are the channel width and length, respectively, V_G and V_T are the gate and threshold voltage, respectively. All the devices showed typical *p*-type channel FET performance under ambient conditions. Fig. 3 showed typical transfer and output curves of an example device obtained at 50 °C on octadecyltrichlorosilane (OTS) modified SiO_2/Si substrates using **DSDBT** as a semiconductor layer. The FET performance of **DSDBT** and **BEDBT** on different deposition temperature were summarized in Table 1. From Table 1, we could see the devices of **DSDBT** displayed mobility larger than 0.03 cm^2/Vs. And when the temperature of substrate increased (from 25 °C to 50 °C), the mobility of devices increased; further increasing the substrate temperature, the performance of devices decreased. The highest mobility of **DSDBT** could reach up to 0.15 cm^2/Vs, one of the highest mobility reported for **DBT** based oligomers. While scanning V_G from 0 to −120 V and then retraced scanning from −120 to 0 V at V_{DS} = −100 V, hysteresis behaviour was observed (Fig. 3A). This might be attributed to the instability of the oxidized species which was proved by the irreversible oxidations from the electrochemistry results. The performance of **BEDBT** devices was much lower compared with **DSDBT**, which was probably due to its lower HOMO energy level. The highest performance of **BEDBT** devices was obtained at T_{sub} = 25 °C.

In order to investigate the mobility-substrate temperature dependence, the morphologies and the structures of **DSDBT** and **BEDBT** films deposited at different substrate temperature were investigated by atomic force microscopy (Fig. 4 for **DSDBT** and Fig. 5 for **BEDBT**) and X-ray diffraction (Fig. 6) respectively. From the AFM images, we could see with the increase of substrate temperature, the grain size of **DSDBT** film increased. The step height of crystalline terrace layers at T_{sub} = 50 °C was about 2.2 nm (Fig. 4E, left)

Table 1
FET characteristics of **DSDBT** and **BEDBT** prepared by vacuum deposition on OTS modified SiO_2/Si substrates at different temperatures.

Entry	T_{sub} (°C)	μ_{max} (cm^2/Vs)	On/off ratio
DSDBT	25	0.039	4×10^6
	50	0.15	2×10^8
	100	0.06	3×10^7
BEDBT	25	1.3×10^{-4}	7×10^5
	50	8.0×10^{-5}	9×10^4

which was nearly equal to the simulated molecular length (about 2.24 nm) by minimized energy optimization (Fig. 4E, right), indicating that the **DSDBT** molecules grown layer-by-layer and took nearly perpendicular orientation on the substrate in the films. Further increasing the substrate temperature to 100 °C, larger grain was obtained. However, the continuity of the films became worse (see Supplementary data), and this should take the responsibility for the lower device performance at T_{sub} = 100 °C. From

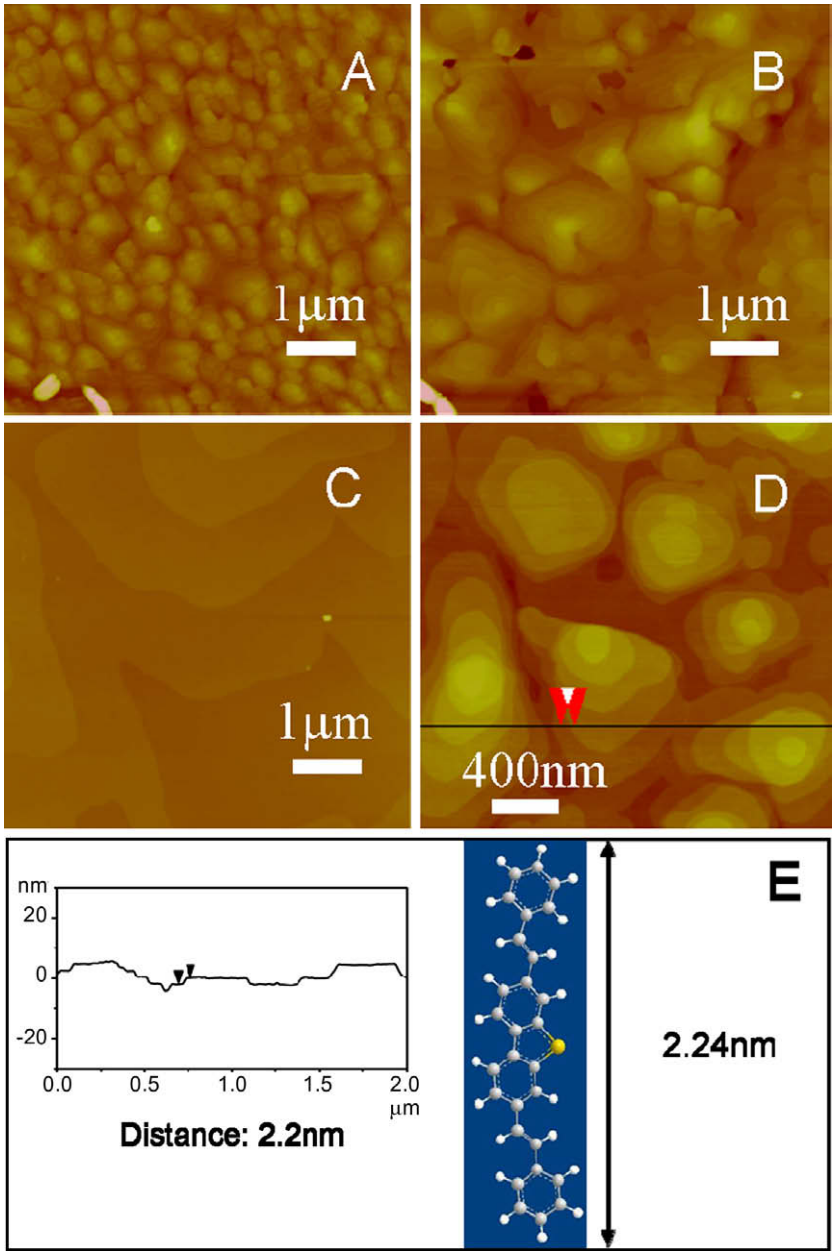

Fig. 4. (A–C) AFM images (5 × 5 μm) of thin films of **DSDBT** on OTS modified SiO_2/Si substrates at the substrate temperature of (A) 25 °C, (B) 50 °C, (C) 100 °C. (D) AFM images (2 × 2 μm) of **DSDBT** thin films on OTS modified SiO_2/Si substrate at the substrate temperature of 50 °C and (E) the step heights of crystalline terrace layers as measured by a section analysis along the line marked in (D) (left) and optimized model molecular structure (right).

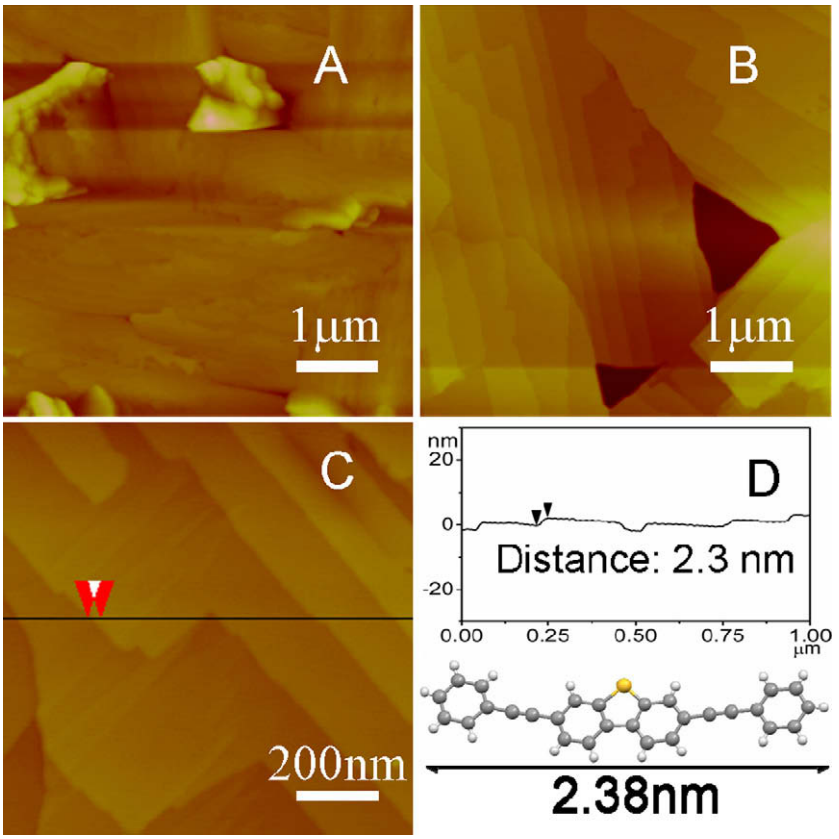

Fig. 5. (A and B) AFM images (5 × 5 μm) of **BEDBT** thin films on OTS modified SiO_2/Si substrates at the substrate temperature of (A) 25 °C, (B) 50 °C. (C) AFM images (1 × 1 μm) of **BEDBT** thin films on OTS modified SiO_2/Si substrates at the substrate temperature of 25 °C and (D) the step heights of crystalline terrace layers as measured by a section analysis along the line marked in (C) (top) and molecular structure in crystal (bottom).

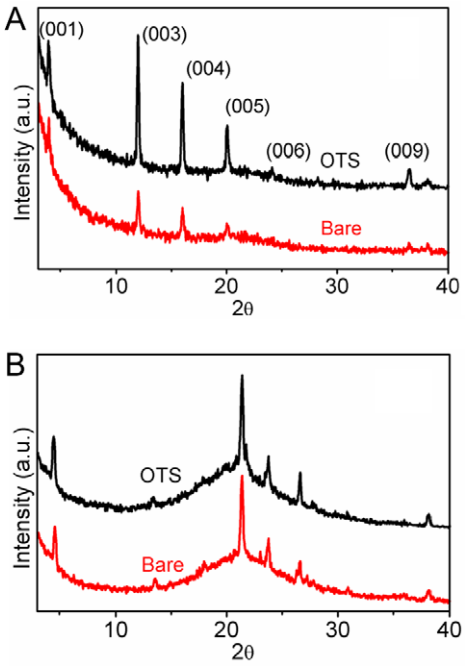

Fig. 6. XRD patterns of thin films of (A) **DSDBT** and (B) **BEDBT** on bare and OTS modified SiO_2/Si substrate at 25 °C.

the XRD patterns of **DSDBT** films (Fig. 6B), the *d*-spacing determined from their dominant peaks were 1.97 nm, closed to the simulated molecular length (2.24 nm), which also proved that the molecules were grown almost vertically to the substrates when deposited. **BEDBT** films exhibited similar results as **DSDBT**. When the substrate temperature increased to 50 °C, larger grains were obtained, but larger grain boundaries were also formed at the same time. The step height of layers of thin films determined from AFM results was about 2.3 nm (very close to the molecular length, Fig. 5D), suggesting **BEDBT** was grown layer-by-layer and nearly vertically on the substrate.

3. Conclusions

In summary, dibenzothiophene oligomers with carbon–carbon double and triple bonds were synthesized. TGA, UV–vis spectra and electrochemistry results indicated that both compounds had high stability and high oxidation resistance. Single crystal structure of **BEDBT** revealed that the introduction of carbon–carbon unsaturated bonds eliminated the steric repulsions between adjacent aromatic rings. Thin film transistors of these compounds exhibited typical *p*-channel performance. **DSDBT** displayed high FET performance with mobility up to 0.15 cm^2/Vs, and

on/off ratio as high as 10^8. The performance of **BEDBT** was much lower compared with **DSDBT**, which could be attributed to its smaller π-conjugated system and lower HOMO energy level. Further optimization of the devices, field-effect transistors based on solution-processed films and single crystals of these materials are underway.

4. Experimental

4.1. General

All reactants and solvents were purchased from commercial suppliers and used as received unless ultra noted. The reactant 3,7-dibromodibenzo[b,d]thiophene was synthesized using *N*-bromosuccinimide (NBS) as bromination reagent according to literature [34,38–39]. MS (EI) was recorded on a Shimadzu GCMS-QP2010 Plus mass spectrometer. ^{1}H NMR spectra were obtained on a Varian 400 MHz spectrometer in $CDCl_3$ with tetramethylsilane as an internal reference. Elemental analyses were performed on a Carlo Erba model 1160 elemental analyzer. UV–vis spectra were recorded on a Hitachi U-3010 spectrometer. Cyclic voltammograms were obtained on a CHI660C analyzer in a conventional three-electrode cell using a glassy carbon working electrode, a platinum wire counter electrode, an Ag/AgCl reference electrode and Bu_4NPF_6 as supporting electrolyte. X-ray diffraction (XRD) measurements for films were carried out on a *D*/max2500 instrument (Cu Kα radiation, $\lambda = 1.54056$ Å). XRD measurements for single crystals were carried out in the reflection mode using a Rigaku Saturn CCD area detector system (Mo Kα radiation, $\lambda = 0.71073$ Å). AFM images were obtained in air using a Digital Instruments Nanoscope III in tapping mode.

4.2. Materials synthesis

4.2.1. Synthesis of 3,7-distyryldibenzo[b,d]thiophene (*DSDBT*)

A 100 mL flask was charged with 3,7-dibromodibenzo-[b,d]thiophene (1.71 g, 5 mmol), PPh_3 (0.13 g, 0.5 mmol), $Pd(OAc)_2$ (0.112 g, 0.5 mmol) and dry Et_3N (20 mL). After the mixture was degassed three times and backfilled with N_2, styrene (5.2 g, 50 mmol) was added. The reaction solution was stirred at 100 °C for 3 days. The mixture was evaporated under reduced pressure. The residual solid was purified by chromatography on silica gel (petroleum ether:dichloromethane = 1:1) to provide **DSDBT** as light yellow powder (yield: 1.2 g, 62%). mp: >300 °C. MS (EI) *m*/*z*: 388 [M^+]. ^{1}H NMR (400 MHz, $CDCl_3$): 8.01 (d, 2H), 7.97 (s, 2H), 7.64 (d, 2H), 7.56 (d, 4H), 7.39 (t, 4H), 7.29 (t, 2H), 7.24 (d, 4H). Anal. calcd for $C_{28}H_{20}S$: C, 86.56; H, 5.19; found: C, 86.31; H, 5.28.

4.2.2. Synthesis of 3,7-bis(phenylethynyl)dibenzo[b,d]-thiophene (*BEDBT*)

A 100 mL flask was charged with 3,7-dibromodibenzo[b,d]thiophene (1.71 g, 5 mmol), $Pd(PPh_3)_2Cl_2$ (0.21 g, 0.3 mmol), CuI (0.115 g, 0.6 mmol), THF (30 mL) and aqueous 2-aminoethanol (2 M, 20 mL). After the mixture was degassed three times and backfilled with N_2, phenylacetylene (1.86 g, 18 mmol) was added. The reaction solution was stirred at 80 °C overnight. THF was removed, and the aqueous layer was extracted by CH_2Cl_2. The combined organic layer was evaporated under reduced pressure. The residual solid was purified by recrystallization from toluene to give **BEDBT** as white crystals (yield: 1.15 g, 60%). mp: 234 °C. MS (EI) *m*/*z*: 384 [M^+]. ^{1}H NMR (400 MHz, $CDCl_3$): 8.10 (d, 2H), 8.03 (s, 2H), 7.63 (d, 2H), 7.57 (m, 4H), 7.37 (m, 6H). Anal. calcd for $C_{28}H_{16}S$: C, 87.47; H, 4.19; found: C, 87.25; H, 4.29.

4.3. Device fabrication and electrical characterization

The SiO_2/Si substrates used were heavily doped *n*-type Si wafer with 500 nm-thick SiO_2 layer and capacitance of 7.5 nF/cm^2. After rinsed with conc. H_2SO_4/H_2O_2, water, and iso-propanol, they were surface modified with OTS. Before sublimation, the OTS modified substrates were rinsed with hexane, chloroform and iso-propanol successively. The organic semiconductors were deposited at a rate increasing gradually under a pressure of about 10^{-4} Pa to a final thickness of 50 nm determined by a quartz crystal monitor. The source and drain electrodes were deposited with gold by using shadow masks with W/L of ca. 48.2. Device characteristics were obtained with a Keithley 4200 SCS and Micromanipulator 6150 probe station in a clean and shielded box at room temperature in air.

Submicron channel length

ABSTRACT

In this study, we report on an innovative residue-free nanoimprint lithography process for the patterning of submicron-spaced contacts, used as source and drain electrodes in downscaled organic thin-film transistors. The method is based on thermally initiated radical polymerization of a novel imprint resist whose outstanding chemical and physical properties are responsible for the excellent results in processability and structure transfer. In combination with a pretreated stamp the thermally curable resist enables residue-free imprinting, thus making etching obsolete. In addition, this process implies only moderate temperature budgets and it is eco-friendly due to a water-based lift-off. To validate the process, source and drain patterned submicron organic thin-film transistors with pentacene as the semiconductor were fabricated, which show excellent transistor behavior parameterized by a low switch-on voltage of $V_{so} = -3$ V, an on–off ratio of more than 10^5 and a charge carrier mobility of $\mu = 0.25$ cm^2/V s.

1. Introduction

Organic electronics has currently reached a stage of development in material properties, device understanding and reproducibility that allows aiming for more challenging applications than those realized today. Examples are flexible radio-frequency transponders, large-area read-out circuits for complex sensor networks, flexible high-density memories and large backplanes for high-resolution active-matrix displays [1]. In any of these products, organic thin-film transistors (OTFTs) and corresponding circuits are essential elements. Needless to say, more advanced applications make higher demands on the transistor circuit's performance. Required are higher cut-off frequencies, increased current levels, higher integration densities and decreased operation voltages. Like in "silicon world" adequate downscaling of the critical transistor dimensions, which are channel length, dielectric layer thickness and electrode overlap, is believed to improve all the above-mentioned performance parameters. In this regard, one of the main arguments for organic electronics comes into play that is the fabrication of circuits on flexible substrates over large areas with high throughput techniques. Without any doubt, advanced and flexible organic electronics generate a need for a high-resolution structuring technique that can easily be integrated in an in-line manufacturing environment. Once a nanoscale patterning technique shall be compatible with roll-to-roll (r2r) or sheet-to-sheet (s2s) fabrication, nanoimprint lithography (NIL) is an interesting alternative to the well-established but low-resolution standard printing techniques. Reasons for that are the

doi:10.1016/j.orgel.2009.12.012

unrivalled high resolution (10 nm) typical for all imprinting techniques, the short process times due to a parallel pattern transfer enabling high-throughput, the straightforward implementation into a roller-based manufacturing facility and its universal applicability (for all types of structures, materials, devices and length scales) thus facilitating integration of components from different device classes (optical, electrical, photonic, sensory). The compatibility of nanoimprinting with r2r manufacturing was recently shown by Ahn et al. [2,3] on the basis of a metal wire-grid polarizer with 200 nm periodicity and by Jackson [4] by means of amorphous silicon-based backplanes for active-matrix displays using a roll-to-roll self-aligned imprint lithography technique.

There are some examples found in literature dealing with the fabrication of nanoscale OTFTs based on serial writing techniques such as e-beam lithography [5–9] but only few examples of submicron transistors fabricated on the basis of nanoimprint lithography [10–15]. Apart from one group that describes the fabrication of submicron-spaced electrodes via a combination of lamination and nanotransfer printing [15], most studies apply Hot Embossing (HE) [10–14]. In Hot Embossing the resist is heated above the glass transition temperature and cooled down again during the imprinting step. Although possessing a few disadvantages, Hot Embossing is the longest well-established technique and has already proven to be applicable in defining sub-micrometer channel lengths of OTFTs in a common gate configuration on rigid silicon substrates [10–13], as well as of fully patterned OTFTs on polyester film substrates and thin organic gate dielectrics [14]. One drawback of HE is the temperature budget of about 125 °C, which is unfavorable for low-cost flexible film substrates and can generate dimensional instabilities. Moreover, with HE a residual layer of the thermoplastic resist remains after the imprinting step and has to be removed by anisotropic etching. The reactive ion etch process is very undesirable because it is costly, hard-to-control, complicated to integrate in an in-line production and might be harmful for an organic layer underneath.

In this paper we describe the fabrication of submicron organic thin-film transistors in a bottom-gate configuration by a novel thermally initiated radical polymerization based nanoimprint lithography process (TIP-NIL). The TIP-NIL method relies on a novel imprint resist that provides residue-free nanoimprinting at moderate temperatures (90 °C) and can be lifted-off with water. Residue-free and lift-off capable TIP-NIL has a lot of advantages. On the one hand production costs are decreased due to the expendability of the etching step and the possibility to use standard Hot Embossing tools. On the other hand the usage of water for the lift-off increases environmental sustainability and process safety. Furthermore, an improvement of the functionality of imprinted bottom-gate OTFTs can be expected, since the reactive ion etching implies a high probability for damaging the underlying gate dielectric. Oxygen plasma etching of organic dielectrics is known to increase the gate leakage and the number of OH-groups acting as traps at the interface. All that qualifies TIP-NIL as a very powerful high-resolution patterning process for large-area fabrication of flexible organic electronics.

2. Fabrication

To demonstrate the huge potential of TIP-NIL, we have fabricated short-channel OTFTs with pentacene as the active semiconducting layer. For this purpose doped silicon wafers were used as the substrates thus forming the bottom-gate electrode covered by 100 nm thermal SiO_2 as the gate dielectric. The TIP-NIL step was used for the definition of the source and drain electrodes with a separation L in the range 0.9 μm < L < 2.4 μm. We used a home-made silicon stamp patterned by electron beam lithography. The e-beam resist pattern was permanently transferred into the silicon stamp by reactive ion etching (SF6-Ar) resulting in a final stamp depth of about 1 μm. After stripping the resist, an anti-sticking layer (perfluorchloroctyl–tricholorosilane) was applied onto the stamp.

The principle of the TIP-NIL process is illustrated in Fig. 1a. After application of the imprint resist on the substrate by drop coating the first step (A) is to align the silicon stamp roughly with respect to the substrate by means of an EVG 520 mask aligner. The aligned stamp is pressed into the low-viscous resist at low pressure, displacing the resist underneath the source–drain patterns completely (B). Curing is performed by a thermally initiated radical polymerization for up to 10 min at 90 °C. This results in a permanent transfer of the source–drain pattern into the resist. The curing time can be controlled by the initiator concentration. After removing the stamp (C), the source–drain material (30 nm gold) is applied onto the device either by e-beam or by thermal evaporation (D). The subsequent lift-off is performed by dissolving the resist with deionized water. This removes the gold layer on top of the resist while preserving it at the imprinted areas (E). An optical microscopy image of the device after the lift-off is shown in Fig. 1b illustrating the appearance of the source–drain electrodes. Finally, the active material (50 nm pentacene) is thermally evaporated to complete the transistor structure (F). In Fig. 1c an AFM phase image is displayed revealing a pentacene grain size of about 1.5 μm in the channel.

The key component of our TIP-NIL process for the patterning of submicron-spaced source and drain electrodes is a novel imprint resist that is curable by thermally initiated radical polymerization, is water soluble, low-viscous and is further referred to as TIP-NIL-ACMO. It is a blend of an acrylic resist and a thermal initiator. The actually applied special formulation is composed of acryloyl morpholine monomers (ACMO) mixed with 1.5 wt.% of the thermal initiator AIBN, yielding a low-viscous material. This low-viscose resist formulation exhibits outstanding properties during temperature-assisted imprinting. The residue-free imprint is additionally facilitated by an adjustment of the stamp's surface energy to maximize the contact angle, i.e. a high difference in polarity of resist and stamp. This was achieved by coating the silicon stamp with perfluorchloroctyl–tricholorosilane thus minimizing its polarity. Both properties, the low viscosity and the big difference in polarity, are required to achieve a residue-free imprint. In

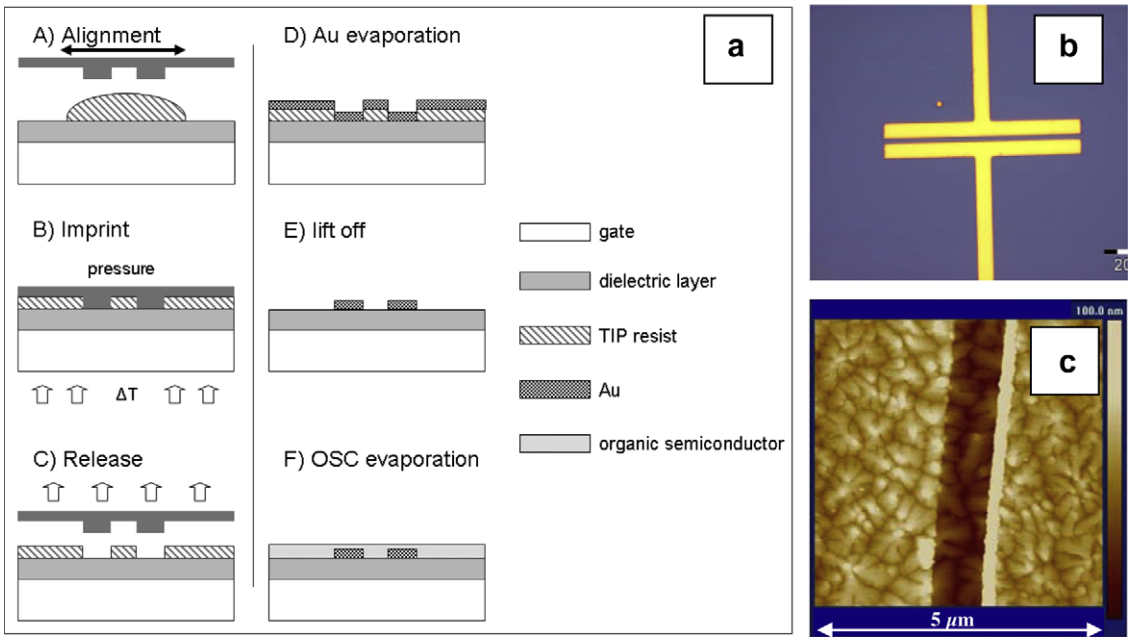

Fig. 1. (a) Scheme of the TIP-NIL process: A silicon stamp containing the source–drain structures is aligned roughly onto the substrate (A). The stamp is pressed into the resist thus completely displacing the resist under the source–drain structures (B). Subsequently, the resist is cured by thermal initiated polymerization. After the stamp removal (C) the source–drain material is evaporated onto the substrate (D). The imprint resist is dissolved with water, which leaves the metal source–drain electrodes well preserved (E). Finally, the sample is covered by the organic active layer, pentacene (F). (b) Image of the source and drain structures after the lift-off. (c) AFM topographic image (5×5 μm) of the pentacene layer formed on top of the contacts and in the channel (L = 900 nm).

addition, the treatment of the stamp facilitates its separation from the patterned imprint resist.

Of particular importance is the residue-free displacement of the TIP-NIL-ACMO enabling an etch-free process of manufacture. Furthermore, in comparison to HE, a lower temperature budget is needed to achieve a permanent pattern transfer since the thermal initiation of the polymerization starts at about 90 °C. This facilitates the usage of thermally sensitive flexible substrates and decreases processing times. Additionally, the cured resist is not heated over its glass transition temperature, therefore the cooling step before stamp removal becomes redundant and the production time is further shortened.

3. Microscopic characterization

To characterize the imprint result, the specimens were investigated by transmission electron microscopy. Post column energy filters were used for zero-loss imaging and elemental mapping. The cross section lamellae of the samples were prepared using a focused ion beam instrument (FIB) [16]. Fig. 2a shows a SEM image of a sample after the imprint step where a lamella has already been cut out. A TEM bright field image of the lamella is displayed in Fig. 2b, showing the troughs for the electrodes on the sides and the appearance of the resist (bright trapezoid) in the middle acting as place-holder for the channel. The organic layer of the resist can clearly be distinguished from the Si/SiO_2 substrate. In order to investigate whether the imprint is residue-free or not, a close-up of the region near the resist edge was analyzed by energy filtered TEM, which enables the distinction of materials according to their elemental composition. Fig. 2c represents an elemental map of the nitrogen distribution. Here, regions of materials containing nitrogen, such as TIP-NIL-ACMO, appear bright. It clearly reveals the limited spatial distribution of the imprinted TIP-NIL-ACMO layer in the channel region and its absence in the electrode areas. This is explicit evidence that the resist is displaced completely during the TIP-NIL process; no residue of the resist is observed in the imprinted areas. Thus, the specimen can directly be covered with gold without prior etching.

After lifting-off the gold layer on top of the TIP-NIL-ACMO resist by using deionized water, pentacene is thermally evaporated to finalize the transistor structure as shown in Fig. 3. Here, a cross section TEM image (Fig. 3a) and a corresponding scheme of the transistor (Fig. 3b) are presented. Additionally, one tear-off edge of an electrode is shown in Fig. 3c. As expected, the gold electrode is perfectly preserved in the imprinted region (right part of Fig. 3c), whereas it is gone in the channel where the TIP-NIL-ACMO was dissolved (left part of Fig. 3c). Thereby, it is proven that the introduced TIP-NIL route gives excellent downscaled transistor structures with respect to their appearance and therefore appropriate device characteristics are expected.

4. Electrical characterization

The electrical characterization of TIP-NIL fabricated OTFTs indeed reveals very good performance of devices

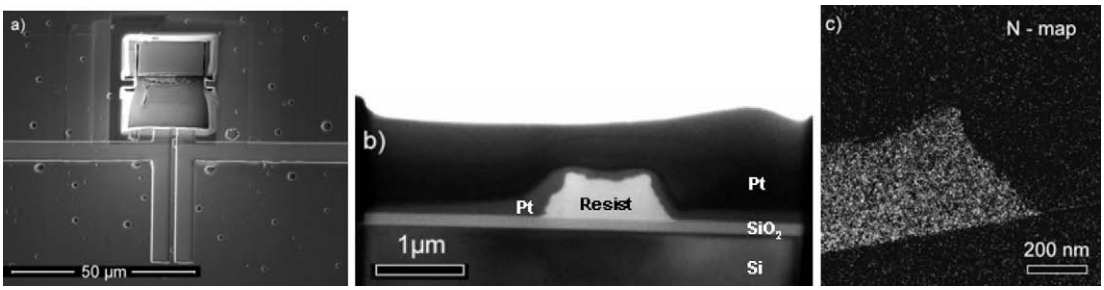

Fig. 2. A sample after the imprinting step: (a) SEM image of the cross section of a lifted-out FIB lamella. (b) A TEM zero-loss filtered bright field image of the cross section lamella, where the imprinted organic layer appears bright in-between the Si/SiO_2 and protective Pt layers. (c) An energy filtered TEM elemental map of nitrogen representing TIP-NIL-ACMO showing the edge of the channel. The resist can clearly be distinguished from all other involved materials.

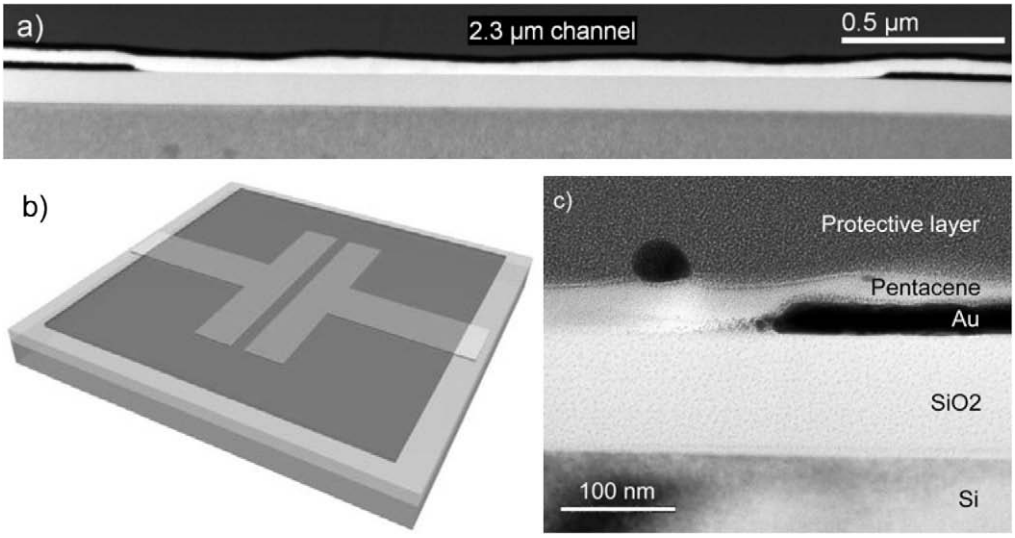

Fig. 3. A TEM zero-loss filtered bright field image of a cross section lamella of a completed transistor structure (a) and an according scheme (b). The gold electrode is well preserved at the imprinted areas and lifted-off elsewhere. A tear-off edge of an electrode is shown in (c).

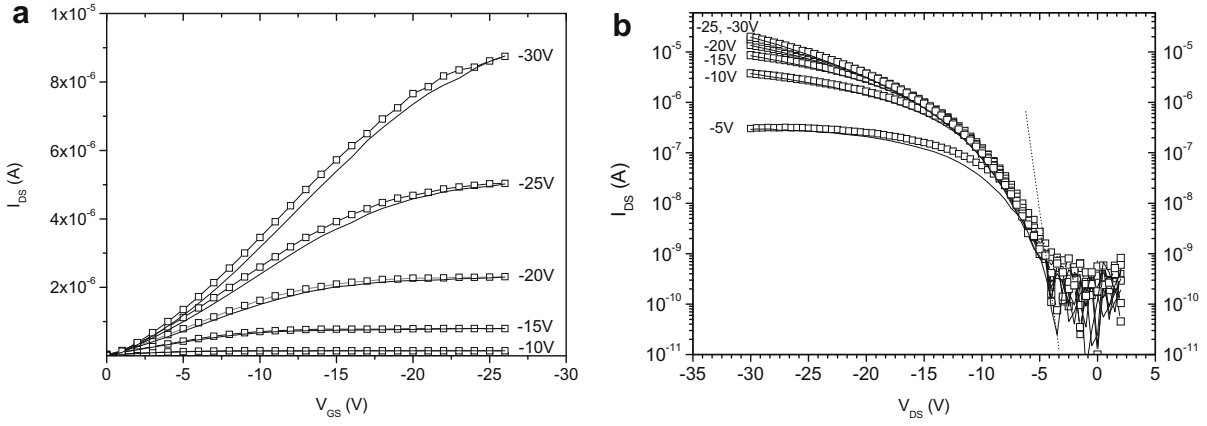

Fig. 4. $I(V)$-curves of a TIP-NIL fabricated OTFT with a channel length of 950 nm. (a) In the output characteristics the gate voltage is varied in steps of 5 V between $-5\ V \leqslant V_{GS} \leqslant -40\ V$ whereas (b) in the transfer characteristics the drain voltage is varied in steps of 5 V between $-5\ V \leqslant V_{DS} \leqslant -40\ V$. Lines with square symbols correspond to forward drain voltage sweep and solid lines to reverse drain voltage sweep.

with submicron channel lengths. In Fig. 4, the output and transfer characteristics of a device with a channel length $L = 950$ nm is displayed. In the $I_{DS}(V_{DS})$-curve clear saturation of the drain current is observed together with a small hysteresis between forward and reverse sweep which is typical for SiO_2 gate dielectrics [17] and is related to the existence of shallow interface traps. Accordingly, in the linear part of the $I_{DS}(V_{DS})$-curve at very small drain voltages a small curvature appears that probably stems from interface traps [18]. An influence of a contact resistance barrier is unlikely, since the morphology of the semiconductor on top of the gold contacts is similarly coarse as it is in the channel region. This indicates that carriers travelling to the accumulation layer only feel a small access resistance [12]. From the semi-logarithmic plot of the transfer curve $I_{DS}(V_{GS})$, a small onset voltage of $V_{so} = -3$ V, a subthreshold swing of $S = 1$ V/dec (corresponding to an interface trap density of about 5×10^{12} cm^{-2} eV^{-1}) [19], an on–off ratio of more than 10^5 and a charge carrier mobility $\mu = 0.25$ cm^2/V s is deduced. The high mobility is mainly a result of the coarse pentacene morphology in the channel being around the threshold for intragrain-dominated transport (grain size $\sim$1.5 μm) found earlier in long-channel SiO_2-based OTFTs [20].

The performance of TIP-NIL fabricated submicron OTFTs based on pentacene as the semiconductor and SiO_2 as the gate dielectric, is comparable to that one of the best devices fabricated earlier with Hot Embossing [12]. However, the latter always implies a hard-to-control reactive ion etch step. Moreover, in order to minimize contact resistance effects, a UV-ozone treatment of the hot embossed gold contacts was introduced for inducing a better growth of pentacene on top of the gold contacts and thus minimizing the access resistance [12]. With the TIP-NIL process all that appears to be obsolete.

5. Conclusion

In summary, we have fabricated well performing OTFTs with submicron channel lengths using an improved thermally initiated nanoimprinting process (TIP-NIL). The nanoimprinted OTFTs are comprised of pentacene as active semiconductor and SiO_2 as dielectric layer. With the novel TIP-NIL process, high performing devices with channel lengths down to 800 nm were fabricated showing complete drain current saturation, low switch-on voltages ($V_{so} = -3$ V) and a high charge carrier mobility ($\mu = 0.25$ cm^2/V s). The process is based on a specially formulated resist (TIP-NIL-ACMO) optimally adapted to fast and precise nanoimprinting of organic electronic components. TIP-NIL-ACMO allows a very fast thermal curing, which reduces the fabrication time decisively, thus enabling a high throughput. Exceptional is the absence of any residual layer of TIP-NIL-ACMO after the imprint step, making the etching step obsolete, which is a huge advantage for the whole process. Finally, TIP-NIL-ACMO allows a lift-off with deionized water, which is a big advantage with respect to ubiquitous availability, the potential for immediate recycling and environmental sustainability, resulting in a decrease of production costs and an increase of process safety. Overall, TIP-NIL has a huge potential as a high-resolution patterning process for large-area fabrication of flexible organic electronics in a roll-to-roll manufacturing environment.

Clearly, there are several further steps that have to be taken before residue-free TIP-NIL can be transferred to roll-to-roll fabrication of OTFTs, which are the usage of soft gate dielectrics and the problem of alignment of the nanoimprint stamp. Very recently we could show that UV-based nanoimprinting is successfully applicable in an etch-free process on fully patterned OTFTs with organic based gate dielectrics [21]. Similar results are also expected for the TIP-NIL process. Concerning the proper alignment of the nanoimprint tool to the sample one has to combine the imprint step with a technique for self-alignment of gate to source–drain level. Such developments are ongoing.

6. Methods

OTFTs: The OTFTs are based on SiO_2 as the gate dielectric and have coplanar bottom-gate device architecture with a W/L ratio of about 50. For substrates highly-doped silicon wafer with 100 nm thermally grown silicon dioxide are used.

Fabrication of contacts by nanoimprinting: The TIP-NIL patterning of the gold source–drain electrodes is done in an EVG 520 nano imprinting equipment. The imprint stamp is made of silicon patterned by electron beam lithography. The resist structures are permanently transferred into the silicon stamp by reactive ion etching (SF_6-Ar) resulting in a final depth of about 1 μm. After stripping, an anti-sticking layer (perfluorchloroctyl–tricholorosilane) is applied onto the stamp. The ACMO based TIP-NIL-resist is fabricated by a mixture of ACMO (acryloyl morpholine) by Rahn AG and 1.5 wt.% AIBN (by Aldrich) yielding a low-viscous material. The resist is applied on the substrate by drop coating. The curing is done at 90 °C for 10 min. A 30 nm thick gold layer is deposited by either e-beam or thermal evaporation. The lift-off is performed by dissolving the resist with deionized water. The 40 nm thick pentacene layer is thermally evaporated onto the sample in high-vacuum conditions at a rate of 0.2 nm/min for the first 5 nm and 0.8 nm/min for the remaining 35 nm.

FIB/SEM: Prior to the FIB/SEM investigations the specimens are covered with a 20 nm carbon layer to minimize charging of the sample. In the focused ion beam instrument Pt layers are grown by electron beam induced deposition (EBID) followed by ion beam assisted deposition (IBAD). These Pt layers protect the surface against incoming Ga ions during cutting out and milling the lamellas. The lamellas are transferred to a TEM grid and thinned down to several tens of nm.

TEM: The TEM investigations are performed using a Philips CM20 (S) TEM (twin lens) with a thermionic LaB_6 cathode operated at 200 kV equipped with a Gatan Imaging Filter (GIF 200). For energy dispersive X-ray spectroscopy an HPGe detector (Noran/Thermo Fisher Scientific) running under Noran System Six software is used. EELS and energy filtered TEM (EFTEM) are performed using a Gatan Imaging Filter (GIF) with a 1024 × 1024 CCD (YAG scintillator) at-

tached to the microscope. Elemental maps were calculated using three-window-technique.

ABSTRACT

Most conjugated polymer field-effect transistors rely on charge accumulation between an organic semiconductor and a gate dielectric. Much less use has been made of devices based on heterojunctions between two semiconducting polymers. Here we have realized ambipolar polymer field-effect transistors based on bilayers of two polyfluorene-based semiconducting polymers, poly(9,9-dioctylfluorene-*alt*-*N*-(4-butylphenyl)diphenylamine) and poly(9,9-dioctylfluorene-*alt*-benzothiadiazole). We show that the energy offset between the lowest unoccupied molecular orbitals of the two polymers of 1–1.5 eV is sufficient to confine electrons at the bi-layer interface for n-type operation. However, the transfer current–voltage characteristics exhibit an unusual plateau. This is shown to be due to hole charge trapping in donor-like states in the TFB layer during p-type operation.

1. Introduction

In organic field-effect transistors (OFETs) the choice of gate dielectric determines the charge transport properties in the thin accumulation layer formed at the interface between the organic semiconductor and the dielectric. Key factors for selecting an optimum gate dielectric are the dielectric breakdown strength, leakage current density and dielectric constant [1]. In particular, any charge transfer from the organic semiconductor into the dielectric will affect device performance and induce, for example, threshold/turn-on voltage shifts during operation [2]. It is important to understand under which conditions electrons in the lowest unoccupied molecular orbital (LUMO) states (or holes in the highest occupied molecular orbital (HOMO) states) of the organic semiconductor can transfer across the interface into trap states or, less likely, into the conduction/valence bands of the dielectric. This transfer can be induced by the gate field or illumination [2]. However, in most systems charge transfer across the interface cannot be studied systematically because it relies on the often poorly characterized trap state distribution of the polymer dielectric. In comparison, the density of states of many polymer semiconductors is known better. We can choose a series of semiconducting polymers with a well controlled energy offset between the HOMO or LUMO states of the two polymers, respectively, to study the interfacial charge transfer between two semiconducting polymers in bi-layer polymer transistor structures in which one of the polymers acts as the semiconductor and the other one as the gate dielectric. The energy offset can be tuned to a sufficiently small value such that interfacial charge transfer is expected to be more significant than in the case of the conventional semiconductor/dielectric structures. A potential application of such semiconducting polymer heterojunctions could be in electrically programmable and erasable memory devices. However, in this work we focus on a basic electrical characterization of such structures. Our main aim is to understand how charge transfer across the interface manifests itself in the electrical characteristics. A particularly interesting question is what energy offset is needed to essentially block charge transfer across the interface.

2. Experimental section

2.1. Materials

Bi-layer heterojunction OFETs with vacuum sublimed small molecule organic semiconductors have been widely researched for ambipolar transistors and light emitting transistors [3–6]. Solution-processed polymer multilayers are much harder to fabricate due to problems with finding sufficiently orthogonal organic solvents. They have been successfully realized by various methods, primarily to enhance luminescence efficiency of organic light-emitting-diodes (OLEDs) [7,8]. In contrast, to the best of our knowledge bi-layer polymer OFETs have not been reported yet. Here, we have investigated bilayers based on combining two semiconducting polyfluorene copolymers. Poly(9,9-dioctylfluorene-*alt*-benzothiadiazole) (F8BT) [9] was used as a first semiconducting polymer layer in contact with the source–drain electrodes. F8BT exhibits stable ambipolar transistor characteristics with electron and hole mobilities of 10^{-4}–10^{-3} $cm^2\,V^{-1}\,s^{-1}$ in top-gate architectures with polymethylmethacrylate (PMMA) top-gate dielectric [10,11]. However, rather than depositing a PMMA dielectric directly on top of the F8BT layer we inserted a layer of poly(9,9-dioctylfluorene-*alt*-*N*-(4-butylphenyl)diphenylamine) (TFB) as an interfacial layer on top of the F8BT. Single-layer TFB transistors with PMMA dielectric do not exhibit electron transport owing to the low electron affinity of TFB, but exhibit stable p-type operation with hole mobilities of 10^{-4}–10^{-3} $cm^2\,V^{-1}\,s^{-1}$ and good stability in air [12]. The electron affinity of TFB is by more than 1 eV lower than that of F8BT and it should therefore be possible to induce an electron accumulation layer under positive gate bias at the internal bi-layer interface between F8BT and TFB.

2.2. Device fabrication

Both F8BT and TFB were obtained from Cambridge Display Technology (CDT) (F8BT, molecular weight M_n: 97 kg/mol; TFB, M_n: 55 kg/mol). The F8BT solutions were prepared with a concentration of 8 mg/ml in xylene and heated at 80 °C for 30 min before being filtered through a 0.45 μm pore size PTFE membrane syringe filter. The transistors for this study were fabricated in the top-gate/bottom-contact configuration, as illustrated in Fig. 1. 15–20 nm thick source/drain electrodes of thermally evaporated gold were patterned by photolithography on Corning glass substrates using an adhesion layer of vapour deposited 3-mercaptopropyltrimethoxysilane ($HS(CH_2)_3$-$Si(OCH_3)_3$). F8BT solutions were spin-cast at 2000 rpm in a nitrogen glove-box. The thickness of F8BT and TFB films was around 30 nm. TFB films spun from 10 mg/ml solution in xylene were fabricated on top of the F8BT layer by one of the two following methods: (1) TFB was spin coated on a Mica wafer and then floated off into de-ionised water. The glass substrate with the F8BT layer was then pushed onto the layer of TFB and removed such that the TFB layer attaches to the F8BT. (2) We also employed a "transfer-printing procedure" using elastomeric poly(dimethylsiloxane) (PDMS) stamps to transfer the TFB film onto the F8BT layer [8]. After the lamination of the TFB, the substrates were subsequently heated above 130 °C for 10 h in a nitrogen or vacuum atmosphere to remove any residual water. Then a layer of PMMA was spin coated on top from an 80 mg/ml solution in n-butyl acetate to form a 650 nm thick layer. A 25–30 nm Au top-gate electrode was finally evaporated through a shadow mask in a vacuum of 3×10^{-6} mbar. Transistor characteristics were measured in pulsed mode, i.e., only a short (∼ms) voltage pulse was applied to the gate electrode to diminish the effect of bias stress [13,14], using an Agilent 4145B Semiconductor Parameter Analyser (SPA) in inert N_2 atmosphere.

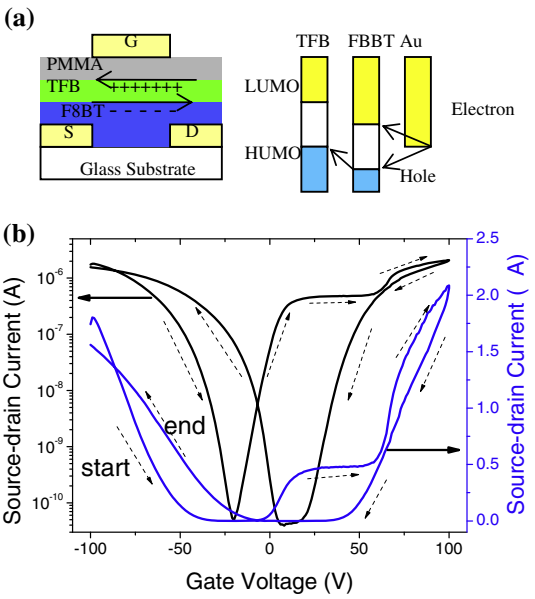

Fig. 1. (a): Cross-section of "F8BT/TFB/PMMA" FET together with a schematic energy diagram. The arrows indicate the expected charge transfer of electrons and holes under positive and negative gate voltages, respectively; (b): Transfer characteristics of a "F8BT/TFB/PMMA" transistor operated at $V_d = -100$ V with a channel length $L = 10$ μm and channel width $W = 1$ cm plotted on a logarithmic (black) and a linear current scale (blue). The dashed arrows show the direction of the voltage sweep. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3. Results and discussions

3.1. Transfer characteristics

The structure of the "F8BT/TFB/PMMA" transistors and the associated schematic energy diagram is shown in Fig. 1. Under negative gate voltage V_g holes can be injected from the gold electrodes into the F8BT layer and from there into the TFB layer. The accumulation layer for negative V_g is expected to be formed at the interface between the TFB and the PMMA. Because the ionisation potential of TFB ($I_p \approx 5.3$ eV) is lower than that of F8BT ($I_p \approx 5.8$ eV), there is no energy barrier for holes at the F8BT/TFB interface [9,12]. On the other hand, for positive V_g electrons are injected from the gold source/drain electrodes into the

F8BT. Because the electron affinity of TFB ($\chi \approx 2.3$ eV) is 1.2 eV higher than that of F8BT ($\chi \approx 3.5$ eV), there is a significant barrier for electron transfer across the interface. If this barrier is high enough to block electrons, the electron accumulation layer should be at the F8BT/TFB interface. In fact, it is straightforward to verify this from the electrical characteristics, since any electron current observed under positive gate voltage must arise from electron accumulation in F8BT, since TFB is not capable of transporting electrons. Therefore, we expect such bi-layer transistors to exhibit ambipolar behavior with electron mobilities similar to that of F8BT-only devices for positive gate bias and hole mobilities similar to that of TFB-only devices for negative gate bias.

The transfer characteristics of a transistor fabricated by the float-off technique are shown in Fig. 2. They confirm our expectation that the device is able to operate in ambipolar mode as the current rises for both negative and positive gate voltages. However, there are clear deviations from idealized ambipolar behavior. Most notably, the forward scan of V_g (from negative to positive voltages) exhibits a first threshold around $V_g = -20$ V at which the electron current starts to rise, but then a current plateau is reached between $0 < V_g < 50$ V. The electron current continues to rise only above a second threshold voltage above 50 V. On the backward scan (from positive to negative voltages) we observe a normal monotonous decrease of the electron current. Devices made by the two lamination techniques exhibited very similar characteristics and in the following we will focus on samples prepared by the float-off technique.

3.2. Dependence on starting point of gate voltage

To understand the origin of the unusual current plateau we investigated how the shape of the characteristics depends on the gate voltage range. When the maximum positive V_g of the scan was less than the second turn-on voltage around $V_g = 50$–60 V, the current on the backward scan decreased immediately, i.e., it did not retrace along the current plateau exhibiting a large hysteresis. The hole mobility extracted from the negative gate voltage region was 1.8×10^{-4} cm^2 V^{-1} s^{-1}, which is close to that of a single-layer TFB/PMMA device. The electron mobility extracted from the current rise above the second threshold using the equation for the saturated FET mobility was about 2×10^{-4} cm^2 V^{-1} s^{-1}, close to that extracted from a single layer "as spun" F8BT/PMMA device (the small reduction of capacitance induced by the TFB layer was taken into account). This indicates that the electron accumulation layer was indeed well confined at the interface between F8BT and TFB, and that an energy offset on the order of 1.2 eV between the LUMO of the two semiconducting polymers is sufficient to block electron transfer across the interface up to high gate voltages of 100 V. We have observed previously in p-type bi-layer polymer FETs with lower energy barrier at the heterointerface that gate voltage induced charge transfer across the interface manifests itself in a characteristic current saturation behavior of the transistor transfer curves at high gate voltages [15]. The behavior observed here is different. We will discuss the origin of the current plateau at intermediate gate voltages below, but at high gate voltage we observe clean electron accumulation at the F8BT/TFB interface with evidence for gate-induced charge transfer.

We observed similar current plateaus also in devices in which TFB was replaced with poly(9,9′-dioctylfluorene)-co-*bis*-N,N′-(4-butylphenyl)-bis-N,N′-phenyl-1,4-phenylenediamine (PFB) and poly(triarylamine) (PTAA), all of which have similar electronic structure and LUMO levels compared to TFB. Current plateaus were, however, not found for ambipolar devices in which TFB was replaced with a second laminated F8BT layer or a poly(9,9-dioctylfluorene-*alt*-bithiophene) (F8T2) film. Therefore, we can exclude that the effect might be due to residual moisture, impurities or other artefacts introduced by the lamination process [16,17]. We observed some variation in the shape of the current plateau from device to device. In most devices the current in this region was either saturated or increased very gently. In some devices the current was found

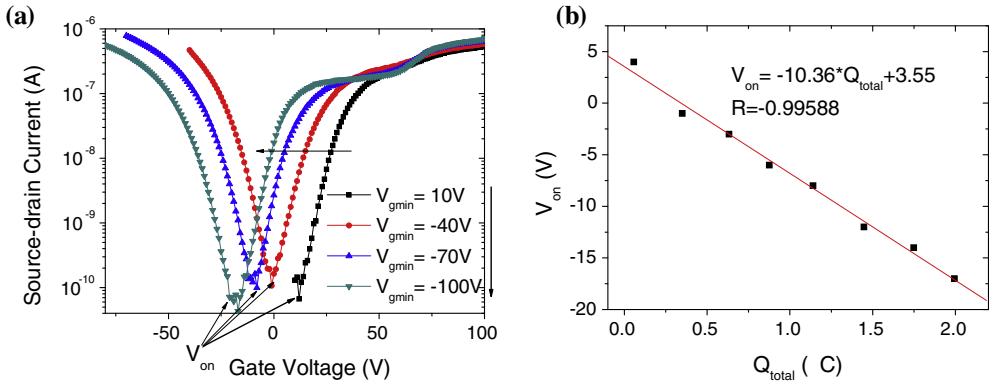

Fig. 2. (a) Transfer characteristics of an "F8BT/TFB/PMMA" device with channel length of 2 μm and channel width of 1 cm on a logarithmic current scale ($V_d = -60$ V). (b) Linear fit of V_{on} versus the total hole charges passed through the channel, estimated by integrating the current passed through the device during the p-type portion of the transfer scan. Black squares are values extracted from the integration of the transfer characteristics and the red line is a linear fit. The fitting parameters for slope, intercept and correlation coefficient (R) are listed. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

to decrease slightly producing a "bump" shape. We note that the observed current plateau is distinct from the case of single-layer transistors with interface or bulk trap states, which have been reported to exhibit a shoulder in the sub-threshold region, but not current saturation observable on a linear current scale as seen here [17,18].

When the starting point of the forward gate voltage sweep V_{gmin} was moved to more negative gate voltage we observed pronounced changes in the transfer characteristics (Fig. 2a). When the V_g scan started at V_{gmin} = +10 V, i.e., the device was never operated in hole accumulation, the plateau in the electron regime was not present and the electron current increased monotonously above a turn-on voltage of 10–15 V. As V_{gmin} was set to more negative values, the current plateau became increasingly pronounced, and the plateau region extended from V_g = 20–60 V when the scan started from $V_g = -100$ V. The onset voltage V_{on} at which the first electron current rise was observed, i.e., the voltage at which the minimum in the transfer characteristics occurs (see Fig. 2), shifted from V_{on} = 12 V for scans starting at V_{gmin} = +10 V to $V_{on} = -15$ V for scans starting at $V_{gmin} = -100$ V. In contrast, the turn-on voltage for the second turn-on of the electron current remained almost unaffected.This result clearly suggests that the appearance of the plateau is caused by operating the device in hole accumulation prior to inducing the electron accumulation layer. We have found that V_{on} is in fact proportional to the total positive charge injected into the channel during the hole-accumulation portion of the transfer characteristics. This can be estimated by integrating the measured drain current I_d from $V_g = V_{gmin}$ to $V_g = V_{on}$. In the pulsed measurement mode used here, $Q_{htotal} = \sum_{V_g=V_{min}}^{V_g=V_{on}} Q(V_g) = Nt_{pulse}\sum_{V_g=V_{min}}^{V_g=V_{on}} I_d(V_g)$, where the constant N is number of applied pulses per gate voltage step and t_{pulse} is the time during which each gate voltage pulse is applied ($Nt_{pulse} \sim 0.04$ s). V_{on} is found to shift to more negative voltages linearly with the total hole charge passed through the channel: $\Delta V_{on} \propto Q_{htotal}$ (Fig. 2b). This suggests that the origin of the current plateau is the presence of deeply trapped charges that remain in the TFB layer after the hole operation. The number of trapped charges can be expected to be a fraction of the total hole charge passed through the device and the probability β that a particular charge injected into the device ends up being a trapped charge, was estimated to be $\beta = 2 \times 10^{-5}$ from the data in Fig. 2b using $\Delta V_{on} = -\beta Q_{total}/(C_i WL)$, where C_i is the capacitance of the PMMA gate dielectric per square centimeter, W is the channel width and L is the channel length. This relationship is similar to the photo-induced charge transfer across the interface between semiconducting rubrene and dielectric parylene, for which a linear relationship was also found between injected charges and integrated incident light intensity [2].

3.3. Proposed model

We would now like to provide a qualitative explanation for the observed current plateau in the device characteristics. Since V_{on} shifts to negative values with prolonged hole accumulation at the beginning of the transfer scan we assume that donor-like traps are responsible for the current plateau. A donor-like trap state, i.e., a donor level located near the HOMO level, is positively charged when not occupied by an electron and neutral when filled with an electron. Previous device simulation studies have shown that interface or bulk donor-like traps with energies below the mobile states result in shoulder-like features in the sub-threshold region of single-layer OFETs [17,18], but not in a pronounced current plateau on a linear current scale.Based on this assumption the dynamic process of the formation of the current plateau can be explained in terms of the energy diagram in Fig. 3. For simplicity, only a single level trap is considered here but the following discussion is also applicable to a distribution of traps, which is more likely in a polymer semiconductor. When holes are accumulated in the TFB in the p-type region of the I_d–V_g curve, some of them become trapped in positively charged donor-like trap states in the TFB bulk. The positive space charge of these trapped holes then aids the injection of electrons and formation of an electron accumulation layer when applying a positive gate bias. This explains the shift of V_{on} to more and more negative voltages with increasing Q_{htotal}. Once an electron accumulation layer is formed at the F8BT/TFB interface the quasi-Fermi level of electrons moves close to the LUMO of F8BT. Aided by the Coulombic attraction between the electrons and the trapped holes electrons begin to transfer from F8BT into TFB and recombine with the trapped holes in TFB. As a result the donor-like states are occupied and become neutral. This process keeps the mobile electron concentration at the F8BT/TFB interface from increasing until most trapped holes have recombined, and this results in the current saturation in the I_d–V_g curve. When most trapped holes have recombined raising the gate voltage above the second turn-on voltage then leads to a further increase of the electron concentration at the F8BT/TFB interface and the electron current rises again. Under conditions where no positive space charge in the TFB layer aids the charge transfer across the interface, the electron accumulation layer can be maintained at the F8BT/TFB interface up to the highest gate voltages applied, i.e., the electron current continues to rise up to gate voltages of +100 V. In the absence of the positive fixed charge of the trapped holes, the backward scan of the transfer characteristics is also normal as it is in

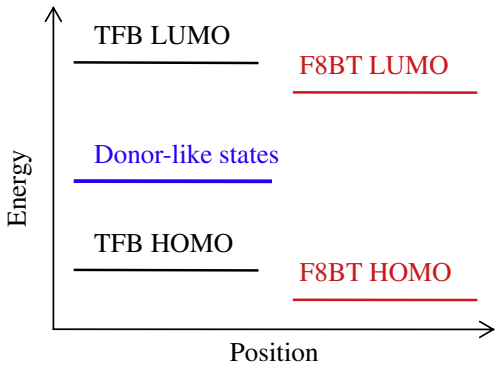

Fig. 3. Schematic energy diagram at the heterojunction with LUMO level and trap states in the bi-layer structure.

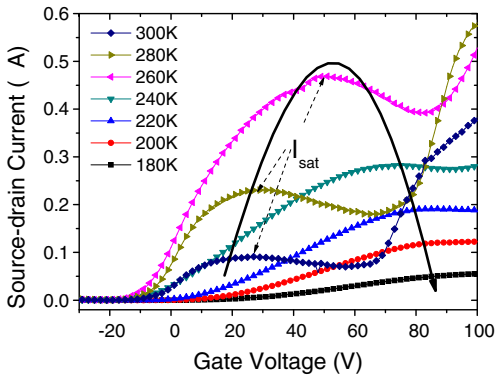

Fig. 4. Transfer characteristics of an "F8BT/TFB/PMMA" transistor measured at different temperatures (during cool down), with a channel length of 10 μm and channel width of 1 cm ($V_d = -100$ V), on a linear scale. The black arrow indicates how the height and position of the current plateau evolves with temperature.

single-layer devices, i.e., does not retrace the current plateau. The nature of the hole trap state in TFB and its energy in the bandgap of TFB is not known, and Fig. 3 is merely a schematic diagram. It is possible that some of the holes injected into the TFB film during hole accumulation might simply be hindered from transferring sufficiently fast back to the source–drain electrodes due to the energy barrier of around 0.5 eV between the HOMO levels of TFB and F8BT.

3.4. Temperature dependence

The dependence of the transfer curves on temperature is shown in Fig. 4. A value of −100 V was used for V_{gmin}. As the temperature (T) is reduced from 280 to 180 K, the current of the bi-layer transistors at high V_g (90–100 V) decreases monotonously in a similar way as that of single-layer F8BT transistors. However, the current observed in the plateau region exhibits clearly a non-monotonous temperature dependence. At 300 K the plateau current is about a factor of 4–5 lower than at 260 K. In the temperature region between 300 and 260 K the maximum current I_{sat} at which the source–drain current in the plateau region saturates or peaks increases with decreasing temperature. Below 260 K the plateau current then decreases with decreasing temperature and the plateau is in fact gradually lost. V_{on} remains relatively temperature independent between 300 and 240 K. The same non-monotonous temperature dependence was also observed when the device was heated up again. Five individual samples were measured and exhibited similar temperature dependence.

This temperature dependence could be explained in the following way. The initial rise of the plateau current with decreasing temperature indicates that the recombination of electrons in the F8BT with the trapped holes in the TFB is a thermally activated process. We have estimated an approximate activation energy on the order of 280 meV by fitting this narrow temperature regime to $I_{sat} \propto \exp(E_a/kT)$. This could be due to an energy barrier for electron injection into empty electronic states in the TFB, which electrons need to be injected into before they can reach/recombine with the holes trapped in the TFB. Such an energy barrier would reduce the rate of recombination during the transfer scan at lower temperatures and as a result lead to an increased plateau current. This behavior would be expected to be superimposed on the thermally activated temperature dependence of the field-effect mobility of F8BT. It appears that below 260 K the latter dominates.

4. Conclusions

We have investigated the current–voltage characteristics of ambipolar polymer FETs in which the active layer is a bilayer of two semiconducting polymers. We found that an energy offset on the order of 1.2 eV between the LUMO levels of the two polymers is sufficient to block electron transfer between the two polymers up to high gate voltages, such that an electron accumulation layer can be induced at the internal interface between the two polymers. The formation of such an electron accumulation layer is facilitated by the presence of positive holes trapped in donor-like states in the layer with the lower ionisation potential resulting in a negative shift of the turn-on voltage for electron accumulation. However, the presence of these positive holes also enables electrons to transfer across the interface and recombine with these holes, resulting in a plateau followed by another turn on region in the I_d–V_g curve in the electron accumulation regime.

The device investigated here could in principle be used as a memory device [19,20], and resembles somewhat in its operation a floating-gate memory transistor [21,22]. The procedure of injecting positive charges across the interface during the p-type operation of the device is equivalent to the "write" process in these memory devices, during which charges are stored in the floating-gate. The "read" process might correspond to recording the current at $V_g = 0$ V. By controlling the total number of holes flowing through the device during the write-process one could vary the information stored in the device. However, to use such devices for memory applications we need to understand better the nature of the hole trap states in the polymer and how the recombination process of electrons could be controlled to achieve suitably long retention times.

Iridium complex
Deep-blue emitter
External quantum efficiency
Picolinic acid N-oxide ancillary ligand

ABSTRACT

A new series of highly efficient deep-blue phosphorescent Ir(III) complexes, $(F_2CH_3ppy)_2$-Ir(pic-N-oxide) **6** and $(F_2CF_3CH_3ppy)_2$Ir(pic-N-oxide) **7**, based on phenylpyridine (ppy) as the main ligand and picolinic acid N-oxide (pic-N-oxide) as the ancillary ligand, were synthesized for applications in phosphorescent organic light-emitting diodes (PhOLEDs). The photophysical, electrochemical, and electroluminescent (EL) properties of these substances were investigated. The energy levels of these substances were adjusted by the introduction of electron-donating and electron-withdrawing substituents on the ppy ligand. The Ir(III) complexes have high phosphorescent quantum yields as well as high thermal stability. High performance PhOLEDs fabricated using the Ir(III) complexes showed bright deep-blue emissions with the Commission Internationale de L'Eclairage (CIE) coordinates of (0.147, 0.210) at the current density of 0.1 mA/cm^2, and high external quantum (23.3%) and current (36.1 cd/A) efficiencies.

1. Introduction

Organic light-emitting diodes (OLEDs) are currently attracting great attention owing to their potential applications in full-color flat panel displays that serve as an efficient and low cost alternative to the widely used liquid crystal displays. An intense effort has been devoted to developing emitting materials and device structures for OLEDs in order to obtain higher efficiencies that are required for commercialization [1–4]. For commercial full-color OLEDs, materials that emit in the three basic color regions of blue, green, and red are required. Blue emitting materials are not only one of the major constituents in red-green-blue full-color displays, they also serve as the key emitting element for generating white light in combination with a complementary yellow color. As a result, explorations for new blue emitting materials that have higher performances remains one of the major challenges in this field.

Heavy-metal complexes, particularly those containing Ir(III), have been employed successfully in the construction of high efficiency phosphorescent organic light-emitting diodes (PhOLEDs) in displays and solid-state lighting [5–16]. In these systems, both triplet and singlet excitons are harvested as light by doping the phosphorescent emitters into charge-transporting hosts. Close to 100% internal quantum efficiencies have been reported for Ir(III) complexes in PhOLEDs [17–20]. Deep-blue Ir(III) complexes are needed in order to effectively reduce power consumption and increase the color gamut of full-color OLEDs. Importantly, the emission wavelengths of these complexes

doi:10.1016/j.orgel.2009.12.014

can be readily tuned from red/green to sky blue by modification of the metal ligands. For example, emission from Ir(III) complexes can cover the whole visible region by simply modifying the 2-arylpyridine main ligand and the ancillary ligand [21]. However, in contrast to green and red phosphorescent complexes, the design and synthesis of deep-blue emitting Ir(III) complexes is a more challenging task [22–29].

Two strategies exist for creating phosphorescent Ir(III) complexes whose deep-blue emission is governed by the energy difference between the hightest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO). The first involves low-lying the energy of the HOMO of the Ir(III) complexes [30–36]. 2-(2,4-Difluorophenyl)pyridine based Ir(III) complexes are good examples of the implimentation of this strategy. In these types of Ir(III) complexes, electron-withdrawing fluorines are introduced on the phenyl ring to cause an high HOMO energy. The second method relies on an high-lying the energy of the LUMO. This strategy has been used in the design of *fac*-Ir(F_2MeOppy)$_3$ [F_2MeOppy: 2-(2′,4′-difluorophenyl)-4-methoxypyridinato] and (F_2MeOppy)$_2$Ir(ptz) [ptz: 5-(2-pyridyl)tetrazolate], which emit at 464 nm [31] and 452 nm [37], respectively. The blue shift seen in these substances is ascribed to the effect of the strong electron-donating substituents at the 4-position of the pyridyl moiety low LUMO energy level. Several groups have demonstrated that phosphorescent wavelengths can be tuned in the blue to red region by functionalization of the main ligands of Ir-complexes with electron-withdrawing and electron-donating substituents [38–41].

Another important requirement for PhOLED applications is that the Ir(III) complexes have high phosphorescent quantum efficiencies. The physical properties, such as charge transfer character and solubility, of the Ir(III) complexes in heteroleptic Ir(III) complexes can be regulated through a proper choice of the ancillary ligand. Also, the nature of the ancillary ligand can profoundly effect the properties of lowest energy emitting excited state of the complex [42,43]. The electron density at the metal center can be controlled by the electron-donating or electron-withdrawing character of the ancillary ligand. The ground state electron density at the metal center governs the amount of metal to ligand charge transfer (MLCT) character that is mixed into the lowest energy electronic transition and, consequently, it governs both the emission wavelength and excited state radiative lifetime.

Despite the fact that significant work has been carried out in this area, efficient and stable deep-blue Ir(III) complexes are still rare. As a result, the design and synthesis of high performance, deep-blue Ir(III) complexes is a subject of great continuing [44,45]. Below, we describe the synthesis and properties of novel deep-blue emitting Ir(III) complexes **6** and **7** that have been designed by using the two strategies discussed above. Importantly, picolinic acid N-oxide (pic-N-oxide) is used for the first time in these complexes as the ancillary ligand. In addition, the complexes contain a methyl group at the 4-position of the pyridyl ring of the 2-(2,4-difluorophenyl)pyridine ligand **1** and the 2-(2′,4′-difluoro-3′-trifluoromethylphenyl)-4-methylpyridine ligand **3**. The combination of these substituents promotes an increase in the HOMO–LUMO energy gap, resulting in a hypsochromic shift compared to emission from the parent Ir(III) complex. PhOLEDs fabricated using these deep-blue Ir(III) complexes exhibit a maximum external quantum efficiency of 23.3% and deep-blue emission with the Commission Internationale de l'Eclairage (CIE) coordinates of (0.147, 0.210). To our best knowledge, the quantum efficiency is the highest among PhOLEDs emitting deep-blue color with the y value close to 0.2 in the CIE coordinate.

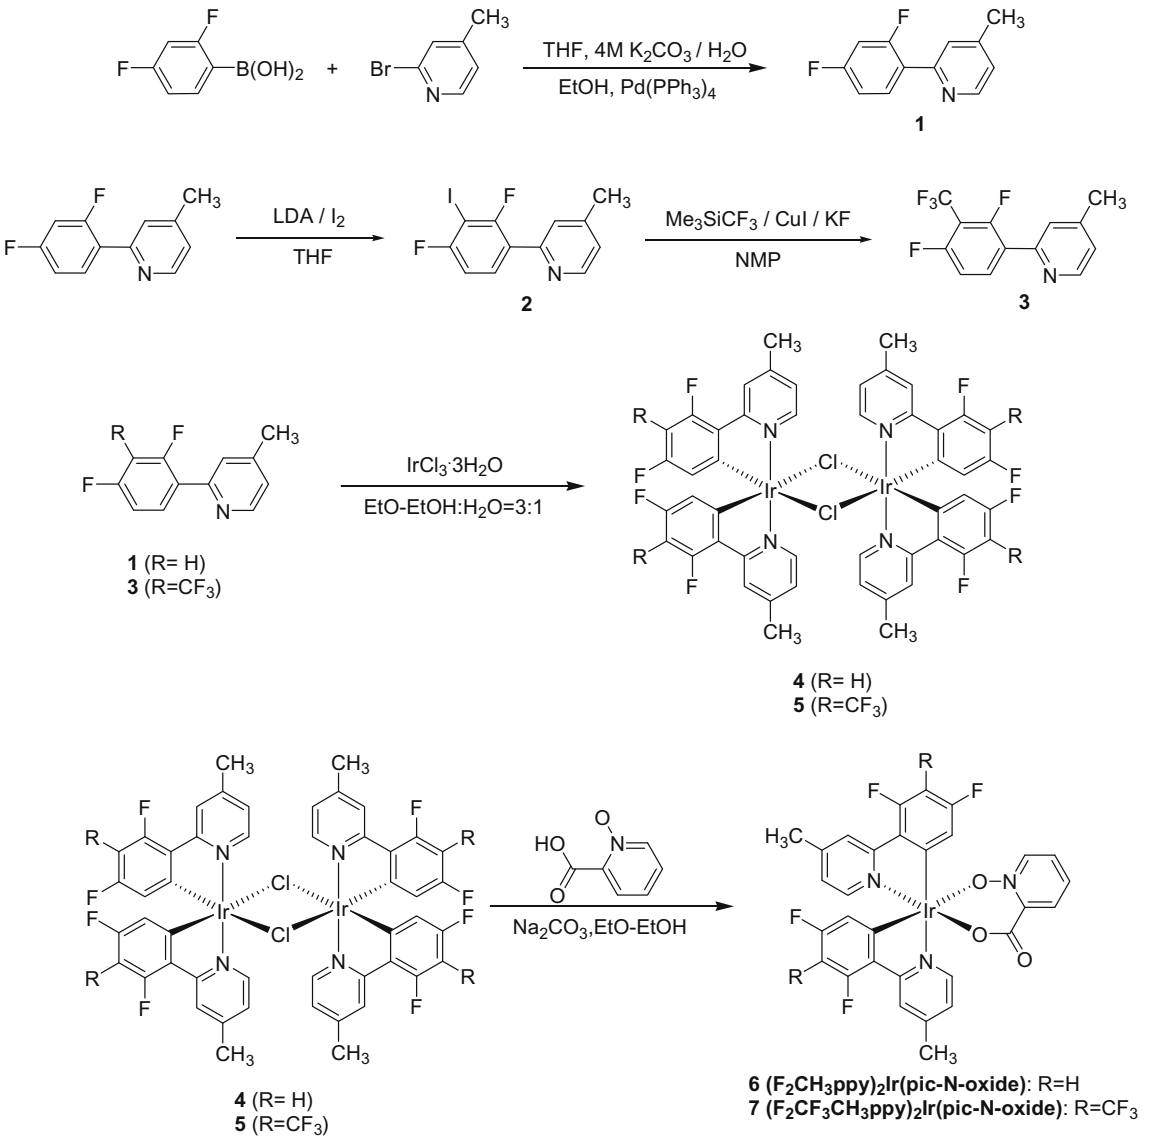
2. Results and discussion

The deep-blue emitting Ir(III) complexes ($F_2CH_3ppy)_2$-Ir(pic-N-oxide) **6** and ($F_2CF_3CH_3ppy)_2$Ir(pic-N-oxide) **7** (Scheme 1) were designed on the basis of considerations that include the ability to tune (1) HOMO–LUMO energy gaps by introduction of electron-donating and electron-withdrawing substituents into the phenylpyridine main ligand, and (2) electro-optical properties for enhanced PhOLED performance by modify the ancillary ligand. As a result, the target Ir(III) complexes **6** and **7** contain difluoro or difluoro and a trifluoromethyl group substituents on the phenyl group of the 2-phenyl-4-methylpyridine main ligand and pic-N-oxide as the ancillary ligand.

The procedure used to prepare the target Ir(III) complexes **6** and **7** involves coupling of $IrCl_3{\cdot}3H_2O$ with the main ppy ligand followed by introduction of the ancillary pic-N-oxide ligand (Scheme 1) [46]. In order to prepare the main ligand **3**, 2-(2′,4′-difluorophenyl)-4-methylpyridine (**1**, Fig. S1), prepared in 83% yield by employing a Suzuki coupling reaction between 2,4-difluorophenylboronic acid and 2-bromo-4-methylpyridine, was transformed to the iodo derivative **2** (Fig. S2) in 76% yield by sequential treatment with LDA and iodine. Reaction of **2** with (trifluoromethyl)trimethylsilane in the presence of CuI and KF gave 2-(2′,4′-difluoro-3′-trifluoromethylphenyl)-4-methylpyridine (**3**, Fig. S3) in 39% yield.

The cyclometalated Ir(III) μ-chloride bridged dimeric ($[(C\hat{}N)_2Ir(\mu\text{-}Cl)]_2$ complexes **4** and **5** were independently synthesized by reacting $IrCl_3{\cdot}3H_2O$ with an excess of the respective main ligands 2-(2′,4′-difluorophenyl)-4-methylphenylpyridine (**1**) and 2-(2′,4′-difluoro-3′-trifluoromethylphenyl)-4-methylpyridine (**3**) in 79–86% yields. Finally, replacment of the two bridging chlorides in **4** and **5** with pic-N-oxide produces the desired complexes ($F_2CH_3ppy)_2$-Ir(pic-N-oxide) **6** and ($F_2CF_3CH_3ppy)_2$Ir(pic-N-oxide) **7** in yields of *ca.* 50%. Ir(III) complexes **6** and **7** were purified by using silica gel column chromatography followed by multiple sublimation with a high vacuum, gradient temperatute train sublimation procedure. The structures, purities, and properties of the Ir(III) complexes **6** and **7** were determined by using ^{1}H NMR spectroscopy (Figs. S4 and S5), elemental analysis, differential scanning calorimetry (DSC), thermal gravimetric analysis (TGA), CV, UV–visible, and PL spectroscopy.

The thermal stabilities of the Ir(III) complexes **6** and **7** were evaluated using TGA and DSC under a nitrogen atmosphere. The 5% weight loss temperatures ($\Delta T_{5\%}$), recorded in Table 1, indicate that ($F_2CH_3ppy)_2$Ir(pic-N-oxide) **6** and



Scheme 1. Synthesis of Ir(III) complexes **6** and **7**.

Table 1
Thermal and photophysical property of Ir(III) complexes.

Complex	T_g [°C][a]	T_d [°C][b]	λ_{max} [nm][c]	HOMO [eV][d]	LUMO [eV][e]	τ[μs][f]	η_{PL} [%][g]
$(F_2CH_3ppy)_2Ir$(pic-N-oxide)	165	346	463, 491	−5.9	−3.0	1.46	67 ± 5
$(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide)	216	377	454, 482	−6.2	−3.2	1.48	80 ± 5

[a] T_g: glass transition temperature.
[b] T_d: decomposition temperature.
[c] λ_{max}: wavelengths of photoluminescence peaks.
[d] HOMO: highest occupied molecular orbital energy levels referenced to vacuum level.
[e] LUMO: lowest unoccupied molecular orbital energy levels referenced to vacuum level.
[f] τ: exciton lifetime when doped with 6 wt% in mCP film.
[g] η_{PL}: PL efficiency when doped with 6 wt% in mCP film.

$(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** have excellent thermal stabilities of 346 °C and 377 °C, since picolinic acid N-oxide ligand formed thermodynamically stable six membered ring with Ir(III) metal ion. The observations indicate that the Ir(III) complexes **6** and **7** have enhanced the rigidities that should prevent degradation of emitting layers of

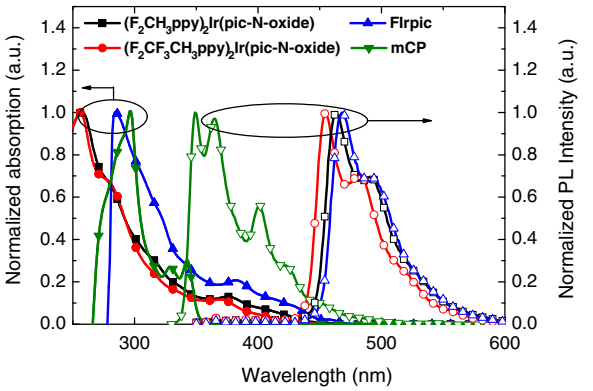


Fig. 1. Normalized absorption spectra (closed symbols) and PL spectra (open symbols) of $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** (square), $(F_2CF_3CH_3ppy)_2$-Ir(pic-N-oxide) **7** (circle), FIrpic (up triangle), and mCP (down triangle).

PhOLEDs caused by the current-induced heat. The glass transition temperatures of Ir(III) complexes **6** and **7** are 165 and 216 °C, respectively. Importantly, the blue Ir(III) complex **7** that contains the trifluoromethyl substituent exhibits a higher thermal stability than the Ir(III) complex **6** which lacks this substituent.

The absorption spectra of the Ir(III) complexes $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** and $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** as well as FIrpic in dilute solutions (*ca.* 10^{-5} M in dichloromethane) and the absorption spectrum of mCP in film states are shown in Fig. 1 along with the PL spectra of the Ir(III) complexes and mCP. As is commonly seen with most Ir(III) complexes, the absorption spectra of these Ir(-III) complexes **6** and **7** can be divided into two regions [47,48]. The intense peaks in the short wavelength regions below 400 nm are assigned to spin-allowed $^1\pi$–π^* transitions that closely resemble those present in spectra of ppy main ligands (λ_{max}: 273 nm). The weaker absorption shoulders that appear above 400 nm are associated with charge transfer transitions [49]. The data suggest that substantial mixing takes place between ligand-based $^3\pi$–π^* states, spin forbidden metal to ligand charge transfer (^{3}MLCT) states, and higher-lying ^{1}MLCT transition states induced by the spin–orbit coupling effect [50,51]. The spin–orbit coupling is enhanced by the presence of closely-spaced π–π^* and MLCT states and the heavy-atom effect of Ir(III) center [52,53].

PL spectra were obtained on doped films of the Ir(III) complexes **6** and **7** in mCP with the concentrations of 8 wt.%. Optical band gaps of Ir(III) complexes **6** and **7**, deduced from the absorption edge of the absorption spectra, are 2.92 eV and 3.00 eV, respectively, both of which are larger than that of FIrpic (2.90 eV). The Ir(III) complexes **6** and **7** were found to emit intense deep-blue light, as shown in Fig. 1. The $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** and $(F_2CF_3$-$CH_3ppy)_2Ir$(pic-N-oxide) **7** complexes exhibit maximum PL peaks at 463 nm and 454 nm, deriving predominantly from ligand-centered $^3\pi$–π^* excited states, that are blue shifted from the maximum peak of 468 nm arising from FIrpic. Triplet energy levels (T_1) are 2.65 eV for FIrpic, 2.68 eV for $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6**, and 2.73 eV for $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7**, respectively.

The PL efficiencies of mCP films doped with the Ir(III) complexes were determined using an integrating sphere with a He:Cd laser (λ: 325 nm and continuous wave) as the excitation light source. $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** exhibits a very large PL quantum efficiency of 80 ± 5%, which is almost the same as FIrpic (87 ± 3%). In contrast, $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** has a slightly lower PL efficiency of 67 ± 5%.

The transient PLs of the Ir(III) complexes, doped in mCP at a concentration of 6 wt.%, display single exponential decays, indicating that the bi-molecular interactions are negligible at this concentration (Fig. S6). Exciton lifetimes of the Ir(III) complexes were determined to be 1.46 μs and 1.48 μs for $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** and $(F_2CF_3$-$CH_3ppy)_2Ir$(pic-N-oxide) **7**, respectively, values that are comparable to that of FIrpic (1.43 μs). The HOMO energy levels of the Ir(III) complexes, obtained by using CV measurements, are −5.9 eV for $(F_2ppy)_2Ir$(pic-N-oxide) **6** and −6.2 eV for $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7**. Both CVs are reversible and stable over repeated scans, implying that the Ir(III) complexes are stable under the oxidation conditions. By combining HOMO energy and optical band gap measurements, LUMO energy levels of −3.0 eV and −3.2 eV were determined for $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** and $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7**, respectively. The higher electron density on the oxygen atom of N-oxide in pyridyl ring is expected to increase the energy level of LUMO and cosequently results in a blue-shifted emmision. Although the higher energy level of LUMO from the $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** was observed, compared to that of FIrpic, the electron-withdrawing CF_3-group in $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** makes both energy levels of HOMO and LUMO lower. This is primarily responsible for the blue-shift of an emission peak. The energy levels and the photophysical data for $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** and $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** are summarized in Table 1.

PhOLEDs were fabricated using the Ir(III) complexes **6** and **7** as dopants in mCP, selected as the host material because of its large spectral overlap with Ir(III) complexes **6** and **7** (Fig. 1) and higher triplet energy level than the Ir(III) complexes **6** and **7**. PhOLED with FIrpic as a dopant were also fabricated for comparison purposes. The PhOLEDs performance of these Ir(III) complexes **6**, **7**, and FIrpic are summarized in Table 2.

In Fig. 2 is shown the structures of the PhOLEDs and the energy levels of the compounds used in this study. The Type I PhOLEDs, fabricated on a clean glass substrate precoated with indium tin oxide (ITO), have the following components: ITO/4,4′,4″-tris(N-(2-naphthyl)-N-phenyl-amino)triphenylamine (2-TNATA) as a hole transporting layer (30 nm)/1,1-bis[(di-4-tolylamino)phenyl]cyclohexane (TAPC) (30 nm) as an electron blocking layer/mCP:8 wt.% dopant (20 nm)/*p*-bis(triphenylsilyl)benzene (UGH2):15 wt.% dopant (10 nm)/aluminium(III) bis(2-methyl-8-quinolinate)-4-phenylphenolate (BAlq) (40 nm) as the electron transporting layer/LiF (1 nm)/Al (100 nm). The PhOLEDs have dual emission layers in order to bring about a better balance between the electron and hole. mCP and UGH2 were selected as the *p*-host and the *n*-host, respectively. mCP has a large spectral overlap with Ir(III)

Table 2
EL performance of Ir(III) complexes.

Type	EML	EQE [%][a]	CE [cd/A][a]	PE [lm/W][a]	CIE [x, y][b]	EQE [%][c]	LE [cd/A][c]	PE [lm/W][c]	CIE [x, y][c]
I	FIrpic	22.6	42.8	27.5	0.151, 0.307	7.1	14.1	2.7	0.158, 0.322
I	$(F_2CH_3ppy)_2Ir$(pic-N-oxide)	19.6	34.5	22.6	0.161, 0.278	5.7	10.8	2.1	0.168, 0.291
I	$(F_2\ CF_3CH_3ppy)_2Ir$(pic-N-oxide)	21.4	31.6	14.3	0.149, 0.193	5.3	8.0	1.5	0.153, 0.200
II	$(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide)	23.3	36.1	17.3	0.147, 0.210	4.2	6.7	1.1	0.152, 0.221

[a] Maximum efficiency.
[b] Values collected at a current density of 0.1 mA/cm^2.
[c] Values collected at a current density of 20 mA/cm^2.

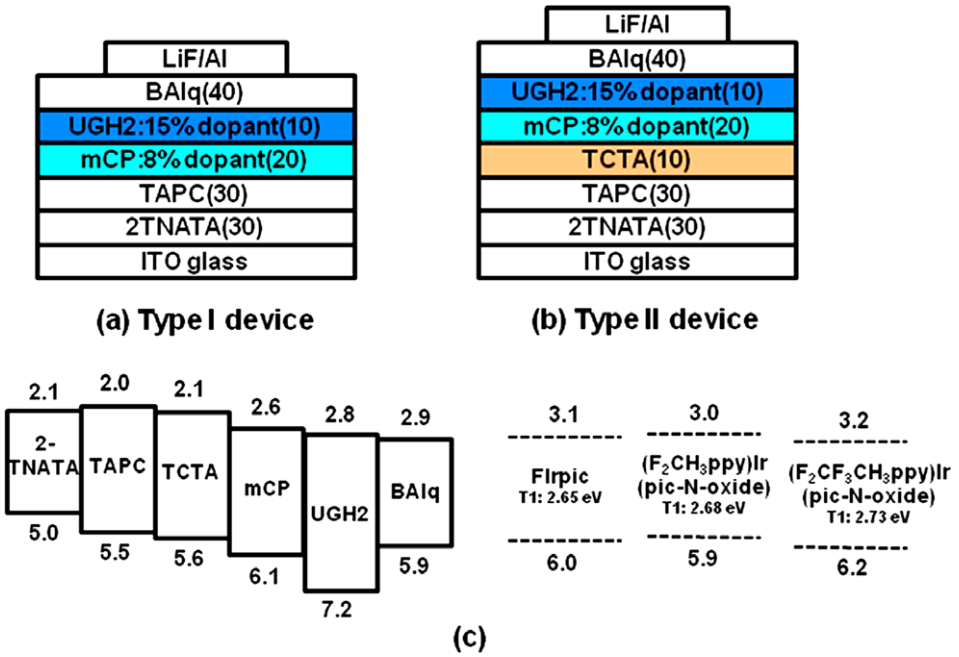

Fig. 2. Structures of the devices for (a) Type I and (b) Type II, and (c) energy levels of materials used in the study.

complexes **6** and **7** (Fig. 1) and as a result, it should promote efficient energy transfer. Both of the hosts have higher triplet energy levels than the Ir(III) complexes **6** and **7** in order to block triplet energy transfer from the Ir(III) complexes **6** and **7** to the hosts. UGH2 also works as an electron transport and exciton blocking layer. Concentrations of the Ir(III) complexes **6** and **7** were selected to be 8 wt.% in mCP and 15 wt.% in UGH2, respectively, which give optimal performances of the PhOLEDs.

Another type of $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** derived PhOLED (Type II) was fabricated by adding a TCTA layer in an attempt to reduce accumulation of holes at HTL/EML interface. This PhOLED that has the following components: ITO/2-TNATA (30 nm)/TAPC (30 nm)/TCTA (10 nm)/mCP:8 wt.% **7** (20 nm)/UGH2:15 wt.% $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) (10 nm)/BAlq (40 nm)/LiF (1 nm)/Al (100 nm).

As shown in Fig. 3, current density–voltage–luminance curves (*J–V–L*) of the PhOLEDs prepared from FIrpic and $(F_2CH_3ppy)_2Ir$(pic-N-oxide) **6** are almost the same, indicating that the small energy differences in the HOMO and LUMO energy levels of the Ir(III) complexes **6** and **7** have little effect on charge transport. The turn-on voltage is slightly high (4.5 V) owing to the high injection barrier of holes from TAPC and low electron mobility in UGH2. The PhOLED doped with $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** require a slightly higher driving voltage than those studied

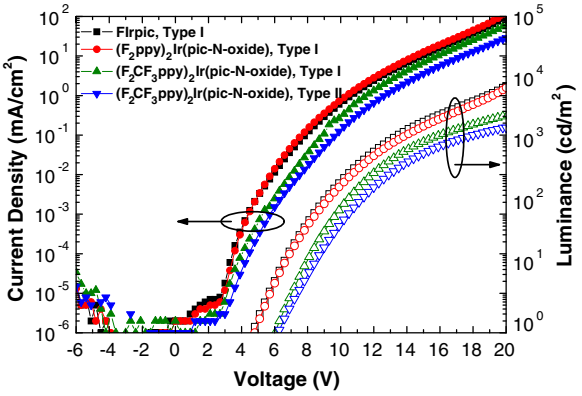

Fig. 3. Current density–voltage–luminance characteristics of the devices.

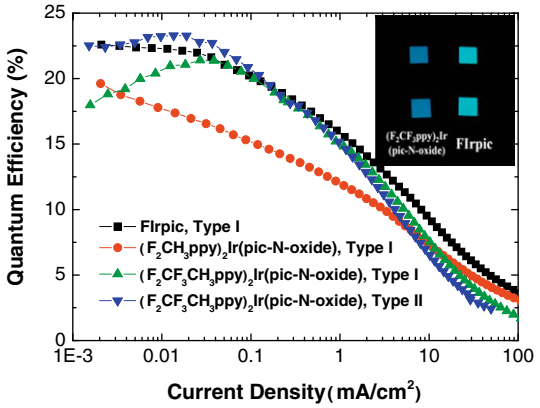

Fig. 4. External quantum efficiency of the devices. Inset: images of $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** devices and FIrpic devices.

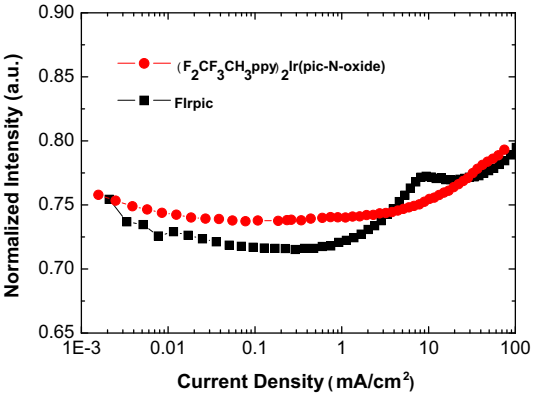

Fig. 5. Variation of relative peak intensity of longer wavelength vibronic peak to that of shortwavelength vibronic peak in EL spectra with increasing current.

previously most likely caused by the low HOMO and LUMO energy levels of the Ir(III) complexes **6** and **7**.

External quantum efficiencies of the PhOLEDs are displayed in Fig. 4. The Type I PhOLED doped with $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** as the emitter has the very large maximum external quantum efficiency of 21.4%, which is very close to the reference FIrpic. Insertion of a 10 nm thick TCTA layer between the TAPC and mCP/$(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) layers in the Type II device results in the even larger maximum external quantum efficiency of 23.3%.

The EL spectra of the PhOLEDs, especially at the low current density of 0.1 mA/cm^2, are the same as the solution PL spectra of the Ir(III) complexes **6** and **7**, displaying deep-blue emissions with Commission Internationale de l'Eclairage (CIE) coordinates of (0.149, 0.193) for the Type I and (0.147, 0.210) for the Type II devices, compared to a Type I device with FIrpic (0.151, 0.307) (Fig. S7). The emission color of the $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** based PhOLED is compared with the FIrpic based PhOLED in the inset in Fig. 4, clearly displaying deep-blue color. The observed efficiencies and deep-blue emission demonstrate that these PhOLEDs have the best performance of any blue PhOLEDs studied to date with the *y* value close to 0.2 in the CIE coordinate. The PhOLEDs doped with $(F_2CH_3ppy)_2$-Ir(pic-N-oxide) **6** have a slightly lower maximum external quantum efficiency (19.6%) as a consequence of the lower PL quantum efficiency. The CIE coordinate of the $(F_2CH_3ppy)_2Ir$(pic-N-oxide) based PhOLED is (0.161, 0.278) at the current density of 0.1 mA/cm^2. All the PhOLEDs made using $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** showed better performance for the Devices II structure than the Devices I, as listed in Table 2.

All the PhOLEDs prepared in this investigation show a large roll-off efficiencies with increasing current, which likely originates from a shift of the recombination zone as well as triplet–triplet and triplet-polaron annihilation at high current density [54]. The hypothesized existence of a recombination zone shift is supported by the observed variation of the emission spectra of the PhOLEDs with current density. The intensity ratios of the two vibronic peaks in the EL spectra of the dopants of $(F_2CF_3CH_3ppy)_2Ir$(pic-N-oxide) **7** ($I_{482\ nm}/I_{454\ nm}$) and FIrpic ($I_{491\ nm}/I_{463\ nm}$) are displayed in Fig. 5. The ratios increase with increasing current density above 1 mA/cm^2 for both PhOLEDs. The increasing ratio, associated with an intensified emission of the long wavelength vibronic peak with increasing current, suggests that the recombination zone shifts away from the Al electrode with increasing current. This roll-off can be minimized by a proper choice of electron and hole transporting, and host materials, as demonstrated for the FIrpic doped PhOLEDs.

3. Conclusions

Deep-blue emitting Ir(III) complexes containing electron density modulated phenylpyridine main ligands and a pic-N-oxide ancillary ligand have been synthesized. The new Ir(III) complexes are thermally and electrochemically stable and they have high photoluminescence efficiencies of over 80%. PhOLEDs fabricated using these Ir(III) complexes showed high external quantum (23.3%), current efficiencies (36.1 cd/A) and deep-blue emission with a CIE coordinate of (0.147, 0.210). Owing to these important characteristics, PhOLEDs prepared from these deep-blue Ir(III) complexes hold high potential for applications in display and solid-state lighting technologies.

4. Experimental

4.1. General information

All reagents and solvents were purchased from Adrich Chemical Co., Fluka and Alfa Aesar, and used without further purification. Anhydrous tetrahydrofuran (THF) was distilled over sodium and benzophenone under a nitrogen atmosphere. Silica column chromatography was performed using silica gel 60 G (particle size 5–40 μm, Merck Co.).

4.2. Synthesis of 2-(2′,4′-difluorophenyl)-4-methylpyridine (1)

2-(2′,4′-Difluorophenyl)-4-methylpyridine (1) was prepared by using a Suzuki coupling reaction between 2,4-difluorophenylboronic acid and 2-bromo-4-methylpyridine

[55]. 2-Bromo-4-methylpyridine (2.54 g, 20 mmol) and 2,4-difluorophenylboronic acid (3.47 g, 22 mmol) were dissolved in freshly distilled THF (100 mL) under nitrogen atmosphere. Potassium carbonate in water (10 mL, 2 M) and ethanol (2 mL) were added and the resulting mixture was cooled in a liquid nitrogen bath and thoroughly degassed. Tetrakis(triphenylphosphine)palladium(0) (1.2 g, 1 mmol) was added and the resulting mixture stirred at 70 °C for 24 h, cooled to room temperature, poured into water (100 mL), and extracted with diethyl ether (50 mL × 3 times). The combined organic layers were washed with water (50 mL) and brine (50 mL), dried over anhydrous magnesium sulfate, and concentrated *in vacuo* giving a residue, which was subjected to flash chromatography on silica gel using *n*-hexane/ethyl acetate as the eluent to yield **1** (3.41 g, 83%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 8.55 (d, 1H, J = 4.8 Hz), 7.94 (td, 1H, J = 6.6, 10.5 Hz), 7.55 (s, 1H), 7.08 (d, 1H, J = 4.5 Hz), 6.89–7.01 (m, 2H), 2.41 (s, 3H).

4.3. Synthesis of 2-(2′,4′-difluoro-3′-iodophenyl)-4-methylpyridine (2)

2-(2′,4′-Difluoro-3′-iodophenyl)-4-methylpyridine (2) was prepared by using the published procedure [56]. 2-(2′,4′-Difluorophenyl)-4-methylpyridine (3.41 g, 16.6 mmol) was dissolved in freshly distilled THF (50 mL) under a nitrogen atmosphere. Lithium diisopropylamide (10 mL, 2 M) in *n*-hexane/THF was added dropwise to the solution at −78 °C and the mixture was stirred for 1 h. A solution of iodine (4.64 g, 18.3 mmol) in THF (20 mL) was added and the mixture was stirred for 3 h at −78 °C, warmed to room temperature, and poured into water (50 mL). The combined organic layers obtained by extraction with diethyl ether (50 mL × 3 times) was washed with saturated sodium thiosulfate (50 mL) and brine (50 mL), dried over anhydrous magnesium sulfate and concentrated *in vacuo* giving a residue which was subjected to flash chromatography on silica gel using *n*-hexane/ethyl acetate as the eluent to give **2** (4.18 g, 76%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 8.57 (d, 1H, J = 4.8 Hz), 7.95 (td, 1H, J = 6.3, 8.7 Hz), 7.57 (s, 1H), 7.13 (d, 1H, J = 4.8 Hz), 6.99–7.05 (m, 1H), 2.42 (s, 3H).

4.4. Synthesis of 2-(2′,4′-difluoro-3′-trifluoromethylphenyl)-4-methylpyridine (3)

2-(2′,4′-Difluoro-3′-trifluoromethylphenyl)-4-methylpyridine (3) was prepared by using the published procedure [56]. A mixture of copper(I) iodide (6.00 g, 31.5 mmol) and anhydrous potassium fluoride (1.10 g, 19.0 mmol) was heated under reduced pressure while being gently shaken until the color changed to yellow. 2-(2′,4′-Difluoro-3′-iodophenyl)-4-methylpyridine (4.18 g, 12.6 mmol), 1-methyl-2-pyrrolidone (30 mL), and (trifluoromethyl)trimethylsilane (4 mL) were added to the mixture which was then vigorously stirred for 24 h at room temperature. The mixture was poured into aqueous ammonia (14%, 100 mL) and extracted with dichloromethane (50 mL × 3 times) to give an organic phase that was washed with water (50 mL) and brine (50 mL), dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The residue was subjected to flash chromatography on silica gel using *n*-hexane/ethyl acetate as the eluent to give **3** (1.39 g, 39%). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 8.59 (d, 1H, J = 5.1 Hz), 7.98 (td, 1H, J = 6.3, 9 Hz), 7.60 (s, 1H), 7.17 (d, 1H, J = 4.8 Hz), 7.01–7.07 (m, 1H), 2.46 (s, 3H).

4.5. General procedure for the synthesis of (C^N)$_2$Ir(pic-N-oxide) complexes 6 and 7

The (C^N)$_2$Ir(pic-N-oxide) complexes were synthesized in two steps using standard method [5,57]. A solution of $IrCl_3{\cdot}3H_2O$ (0.70 g, 2 mmol) and 2.5 equivalents of the main ligand **1** or **3** in 2-ethoxyethanol/water (16 mL, 3:1 v/v) was stirred at 125 °C for 24 h, cooled to room temperature, and concentrated *in vacuo*. Washing the residue with ethanol gave rise to the dimeric iridium complexes $[(C^N)_2Ir(\mu\text{-}Cl)]_2$ **4** or **5**. After drying, the crude product was directly used for next step without further purification. A solution of either **4** or **5** (1 mmol), Na_2CO_3 (10 mmol) and 5 equivalents of pic-N-oxide in 2-ethoxyethanol (10 mL) was stirred at 130 °C under a nitrogen atmosphere for 20 h, cooled, and poured into water. Extraction with dichloromethane (30 mL × 3 times) gave an organic layer which was dried over anhydrous magnesium sulfate, and concentrated *in vacuo* giving a residue that was subjected to flash chromatography on silica gel using dichloromethane/methanol as the eluent to afford the desired Ir(III) complexes **6** and **7**, respectively.

4.5.1. Dimer iridium complex 4

Tetrakis[2-(2′,4′-difluorophenyl)-4-methylpyridine-C^2,N′]-bis(μ-chloro)diiridium(III) $[Ir(F_2CH_3ppy)_2Cl]_2$. Yellow solid. Yield: 86% (2.19 g). *Anal.* Calc. for $C_{48}H_{32}Cl_2F_8Ir_2N_4$: C, 45.32; H, 2.54; N, 4.40. Found: C, 46.12; H, 2.44; N, 4.46%.

4.5.2. Dimer iridium complex 5

Tetrakis[2-(2′,4′-difluorophenyl-3′-trifluoromethylphenyl)-4-methylpyridine-C^2,N′]-bis(μ-chloro)diiridium(III) $[Ir(F_2CF_3CH_3ppy)_2Cl]_2$. Yellow solid. Yield: 79% (2.41 g). *Anal.* Calc. for $C_{52}H_{28}Cl_2F_{20}Ir_2N_4$: C, 40.45; H, 1.83; N, 3.63. Found: C, 41.12; H, 1.72; N, 3.68%.

4.5.3. Iridium(III)bis[2-(2′,4′-difluorophenyl)-4-methylpyridinato-N,C$^{2'}$]picolinate N-oxide, (F_2CH_3ppy)$_2$Ir(pic-N-oxide) (6)

Yellow solid. Yield: 46%. (340 mg). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 8.55 (d, 1H, J = 5.7 Hz), 8.32 (d, 1H, J = 7.5 Hz), 8.10 (s, 1H), 8.04 (s, 1H), 7.93 (td, 1H, J = 1.5, 7.5 Hz), 7.77 (d, 1H, J = 5.4 Hz), 7.38–7.43 (m, 1H), 7.24 (d, 1H, J = 6.3 Hz), 7.00 (dd, 1H, J = 1.2, 5.7 Hz), 6.78 (dd, 1H, J = 1.2, 5.7 Hz), 6.34–6.50 (m, 2H), 5.85 (dd, 1H, J = 2.4, 8.7 Hz), 5.59 (dd, 1H, J = 2.4, 8.7 Hz), 2.55 (s, 6H). *Anal.* Calc. for $C_{30}H_{20}F_4IrN_3O_3$: C, 48.78; H, 2.72; N, 5.69. Found: C, 48.58; H, 2.91; N, 5.29%.

4.5.4. Iridium(III)bis[2-(2′,4′-difluoro-3′-trifluoromethylphenyl)-4-methylpyridinato-N,C$^{2'}$]picolinate N-oxide, ($F_2CF_3CH_3ppy$)$_2$Ir(pic-N-oxide) (7)

Yellow solid. Yield: 34% (297 mg). ^{1}H NMR (300 MHz, $CDCl_3$, ppm): 8.57 (d, 1H, J = 6.0 Hz), 8.35 (d, 1H, J = 7.2 Hz), 8.18 (s, 1H), 8.13 (s, 1H), 8.00 (td, 1H, J = 1.5,

7.8 Hz), 7.76 (d, 1H, J = 4.5 Hz), 7.49 (t, 1H, 5.7 Hz), 7.12 (d, 1H, J = 6.0 Hz), 6.90 (d, 1H, J = 6.3 Hz), 5.64 (d, 1H, J = 10.2 Hz), 5.69 (d, 1H, J = 10.8), 2.59 (s, 6H). *Anal.* Calc. for $C_{32}H_{18}F_{10}IrN_3O_3$: C, 43.94; H, 2.07; N, 4.80. Found: C, 44.18; H, 2.35; N, 4.57%.

4.6. Measurements of physical and electrochemical properties

UV–visible absorption spectra of **6** and **7** were recorded by using a Varian 5000 spectrophotometer. Photoluminescence (PL) spectra were measured with a He:Cd laser (λ: 325 nm, and continuous wave) as the excitation light source and a photomultiplier tube (PMT, Hamamatsu) with a monochromator (Acton Research Co., SpectraPro 2300i) as the detector. Cyclic voltammograms (CV) of the Ir(III) complexes were recorded by using a Princeton Applied Research (AMETEK VSP) potentiostat at room temperature on 0.1 M solutions of the Ir(III) complexes in acetonitrile or dichloromethane containing tetrabutylammonium perchlorate (Bu_4NClO_4) at a scan rate of 100 mV/s under nitrogen gas. Pt was used as the working and counter electrode and Ag/AgCl electrode as the reference electrode.

The PL efficiencies of doped films containing **6** and **7** were measured using the integrating sphere (Newport) with a He:Cd laser (λ: 325 nm, and continuous wave) as the excitation light source. The absolute PL efficiency measurement system was calibrated by using two standard lamps of LS-1-CAL calibrated light source and DH-2000 deuterium–tungsten halogen light source (Ocean Optics, Inc.). Transient photoluminescence of the phosphorescent dye doped films were measured using a Nd:YAG laser (λ: 355 nm, 10 Hz, and 9 ns pulse width) as the excitation light source and PMT (Hamamatsu) with a monochromator (Acton Research Co., SpectraPro 2300i) as the detector. The samples were kept in a vacuum chamber maintained at pressures under 10^{-3} Torr during the measurement.

4.7. Fabrication of the PhOLEDs using Ir(III) complexes 6 and 7

The PhOLEDs were fabricated by using thermal evaporation onto a cleaned glass substrate precoated with indium tin oxide (ITO) under a vacuum. Prior to organic layer deposition, the ITO substrates were exposed to UV-ozone flux for 10 min following degreasing in acetone and isopropyl alcohol. All of the organic layers were deposited by using thermal evaporation at a base pressure of $<5 \times 10^{-8}$ Torr. Current density–voltage–luminescence (J–V–L) characteristics of the PhOLEDs were measured simultaneously using a Keithley 2400 programmable source meter and SpectraScan PR650 (Photo Research). All the materials were purified using train sublimation before use.

Thiophene dendrimers
Bulk heterojunction solar cells
Charge mobility
Charge carrier lifetime

ABSTRACT

Charge mobilities of *all*-thiophene dendrimers were studied using the charge extraction by linearly increasing voltage technique (CELIV). Four dendrimers differing in size, shape and with and without trimethylsilyl (TMS) protecting groups have been compared yielding important structure–property correlations: The hole mobility of the dendrimers with 21 or 42 thiophene units was found to be very similar and around 10^{-5} cm^2 V^{-1} s^{-1}, indicating that shape and size of the studied dendrimers have little effect on their charge transport properties. Hole mobility is decreased by a factor of 3–10 by incorporation of TMS groups, which is attributed to the intrinsically slower electron transfer rates between the TMS-protected dendrimer molecules. Bulk heterojunction solar cells using 1:2 mixtures of the thiophene dendrimers and the electron acceptor [6,6]-phenyl-C_{61} butyric acid methyl ester ($PC_{61}BM$) were fabricated and their performances were analyzed. The decreased hole mobility in the blend, the unbalanced electron and hole mobility and a rather short charge carrier lifetime measured by charge extraction and transient absorption techniques are thought to be important factors that limit overall power conversion efficiency in theses devices. Improved free charge generation with increasing dendrimer size was observed, which was related to increased separation distance between electron and hole pairs.

1. Introduction

Conjugated polymer–fullerene bulk heterojunction (BHJ) solar cells represent one of the promising organic photovoltaic technologies due to their ease of solution-processing, low costs, and the potential of producing large-scale flexible devices [1]. The key component of a BHJ solar cell is the photoactive layer comprised of a conjugated polymer as electron donor and a soluble fullerene derivative as electron acceptor. In the blended film, nano-scale phase separation between donor and acceptor occurs providing sufficient donor–acceptor interface for charge separation [2,3]. Another particularly important issue in improving power conversion efficiencies of a BHJ solar cell is the efficiency of charge collection, which is governed by the product of mobility (μ) and free charge carrier lifetime (τ). Generally, high and balanced charge carrier mobilities and sufficiently long charge carrier lifetime are necessary to achieve efficient charge collection at the electrodes. Regioregular poly(3-hexylthiophene) (rr-P3HT) is considered as current benchmark for BHJ solar cells reaching external quantum efficiencies above 80% and a power conversion efficiencies up to 5.5% [4–8]. Copolymers in cooperation with electron accepting benzothiadiazole unit to form a

doi:10.1016/j.orgel.2009.12.016

push–pull structure were developed and showed excellent performance in BHJ solar cells application [9–13]. As an example, by using blends of a copolymer poly[N-9″-heptadecanyl-2,7-carbazole-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole) and $PC_{71}BM$ in cooperation with a TiOx buffer layer, power conversion efficiencies of more than 6% were achieved for solution processed BHJ solar cells [13].

In comparison to polymeric materials with linear conjugated chains, conjugated dendrimers represent a novel class of three dimensional macromolecules with shape-persistent and defined, monodisperse structures [14,15]. Due to their branched 3D structure, conjugated dendrimers usually have good solubility and film forming ability. More importantly, conjugated dendrimers are regarded as a class of organic materials with isotropic and homogenous properties, which could be beneficial for charge transport in solid films [15]. In this respect, several examples of semiconducting conjugated dendrimers were reported in literature, including: phenylenes, phenylene–ethenylenes and carbazole dendrimer or thiophene dendrimers [14,15].

Thiophene-based materials typically exhibit excellent charge transport properties. Therefore, 3D dendritic structures are of interest for applications in organic electronics. Since the development of the first *all*-thiophene dendrimers, which were reported by Advincula and coworkers [16,17] variation of oligothiophene-based dendrimers by changing core, branching units or position of oligothiophene blocks were developed by several research groups [18–23]. Aiming at increasing dimensionality and functionality of thiophene-based materials, our research group has recently developed a novel synthetic strategy in synthesizing large *all*-thiophene dendrimers [24]. Due to their defined chemical structures, these dendrimers serve as good model compounds for structure–property-performance relationship investigation. As an example, photovoltaic performance of BHJ solar cells using thiophene dendrimer as p-type semiconductor blended with n-type fullerene derivative [6,6]-phenyl-C_{61}-butyric acid methyl ester ($PC_{61}BM$) highly depended on the molecular structure [25]. All the reported thiophene dendrimer-based devices showed high open circuit voltages (V_{oc}) around 1.0 V, whereas the short circuit currents (J_{sc}) of these devices were limited by the light harvesting ability of the dendrimer films used and perhaps also by inefficient charge collection. The fill factor of all devices was found to be rather low (around 0.4) [25]. To clearly determine the origin of the limiting factors of performance of dendrimer-based BHJ solar cells, investigations on charge mobility and charge carrier lifetime is necessary. Despite the increasing number of reports on optoelectronic applications of conjugated dendrimers, there are only a few studies focused on detailed charge mobility and charge carrier lifetime measurements [23,26–29].

Herein we have investigated the charge transport properties of four different thiophene dendrimers varying in size, shape and protecting group in pristine films and also in their 1:2-blends with $PC_{61}BM$ using the photo-induced charge extraction by a linearly increasing voltage (photo-CELIV) technique. The lifetime of the reasonably mobile (free) charge carriers was determined in the dendrimer:$PC_{61}BM$ mixture using a delayed-field charge extraction technique and compared to transient absorption measurements, where the spectral decay of dendrimer cation radicals was optically monitored. The results are correlated with the molecular structure of the dendrimers, providing insights into designing the next generation of electro- and photoactive dendrimers with enhanced charge mobility.

2. Materials and methods

The dendrimers were synthesized according to previously published procedures [24,25].

The photovoltaic devices were prepared by spin-coating EL-grade PEDOT:PSS (Baytron P AI 4083) onto pre-cleaned, patterned indium tin oxide (ITO) substrates. The photoactive layer was deposited by spin-coating from a chlorobenzene solution with a total concentration of 25 mg/ml. Film thickness was determined by profilometry (Veeco Dektak 150+ Surface Profiler). The counter electrode of LiF (1 nm) and aluminum (100 nm) was deposited by vacuum evaporation at 5×10^{-6} mbar. The solar cells were illuminated at 100 mW cm^{-2} using 1 kW Oriel solar simulator with an AM 1.5G filter in air and *J–V* curves were measured using a Keithley 2400 source measurement unit. For accurate measurement, the light intensity was calibrated using a reference silicon solar cell (PV measurements Inc.) certified by the National Renewable Energy Laboratory. The devices with thick active layers (more than 200 nm) were fabricated in a similar device structure as mentioned above. To get a thick solid film, solution with concentration of 75 mg/ml was used.

Photo-CELIV measurements performed on sealed PV devices using the 2nd harmonics of a Q-switched Nd:YAG laser (10 Hz, INDI, Spectra-Physics) as the excitation source and voltage pulses applied using a function generator. The extraction currents were recorded using a 500 MHz Tektronix oscilloscope and a set of resistors. Delay time between the laser pulse and the voltage pulse was set using a digital delay generator. No effect of changing illumination side or sign of the applied voltage bias was observed for any of the samples indicating that the charge concentration prior to charge extraction was uniform throughout the thickness of the samples.

Transient absorption measurements were performed on the same PV devices characterized above using the 2nd harmonics of a Q-switched Nd:YAG laser (10 Hz, INDI, Spectra-Physics) as the pump and a pulsed Xe lamp, a band pass filter and a monochromator as the 890 nm probe. A 200 MHz Femto photoreceiver and 500 MHz oscilloscope was used to record the traces.

3. Results and discussion

3.1. Charge mobilities of all-thiophene dendrimers

The experimental arrangement of the photo-CELIV technique and the device architecture of a BHJ solar cell are schematically illustrated in Fig. 1. The photo-CELIV technique, in which charge carriers are photo-generated

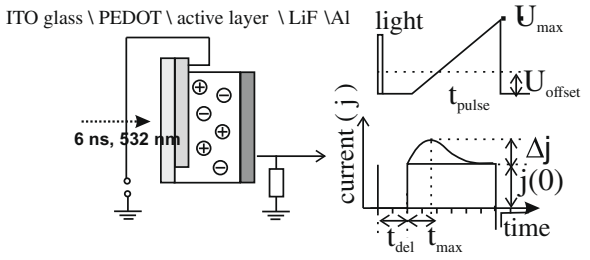

Fig. 1. Schematic representation of the experimental arrangement and pulse sequence of the photo-CELIV technique.

by a short laser pulse and then subsequently extracted by a linearly increasing voltage pulse, has been shown to be particularly useful for thin organic photodiodes and BHJ solar cells [30]. The main advantage is that this technique can be directly applied to thin organic diodes and operational solar cells without a need to change contacts, device geometry or the film thickness [31]. This is important because charge carrier drift mobilities in disordered organic materials may depend on a number of parameters, including electric field (E), temperature (T) [32] and charge carrier concentration (n) [33]. Various mobility techniques, therefore, tend to yield different mobility values that can be partially attributed to the different E and n regime they operate [34].

The chemical structures of the four thiophene dendrimers investigated here are displayed in Chart 1. The synthesis of these compounds and a detailed study on their BHJ solar cell device performance have been reported [24,25]. These four compounds have been selected to allow comparison of three of their main characteristics: (i) TMS-protected or non-protected structure (*42T-Si* vs. *42T*); (ii) dendrimer generation and size (*18T-Si* vs. *42T-Si*); (iii)

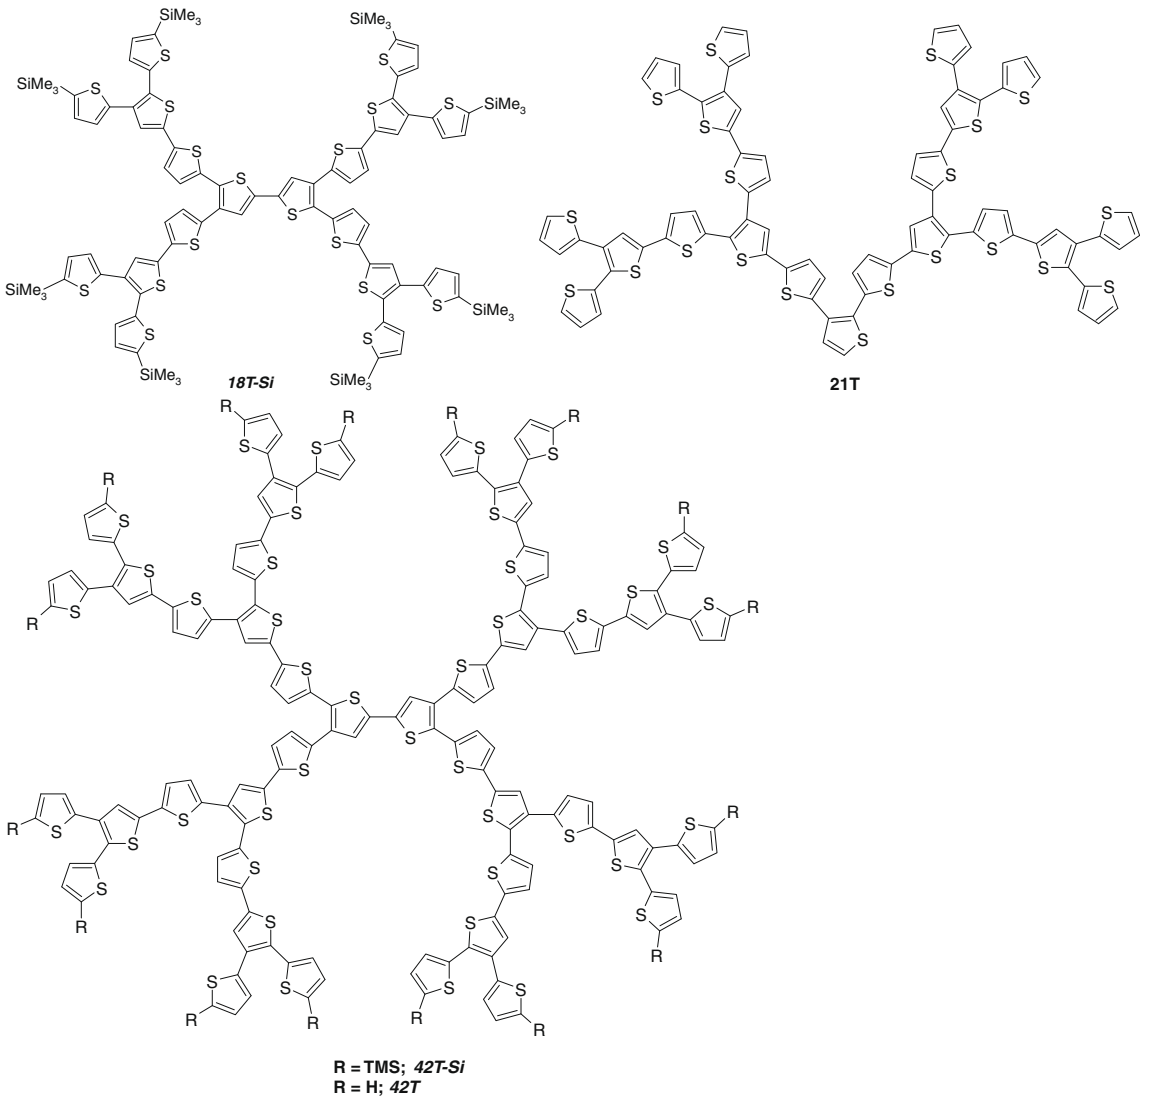

Chart 1. Chemical structure of *all*-thiophene dendrimers.

dendrimer shape (*21T* vs. *42T*). Thin films of the dendrimers were deposited onto PEDOT-covered ITO glass and sandwich-type diode structures were completed by evaporating thin LiF/Al electrodes (see Fig. 1). The devices were encapsulated with a glass slide bonded with UV-epoxy adhesive. The devices (active area 0.2 cm^2) were illuminated by 6 ns pulses at 532 nm of a Nd:YAG laser while they were held at open circuit by an externally applied offset bias. After a tunable delay time, a linearly increasing voltage pulse was applied and the current response was recorded using an oscilloscope and a set of resistors.

The recorded photo-CELIV current traces using 300 nm *21T* active layer are displayed in Fig. 2A and B. First, the delay time t_{del} between the light pulse and the voltage pulse was varied (Fig. 2A). The extraction maximum shifted to longer times with increasing delay time and the extraction current decreased. The former is indicative of a delay-time dependent mobility. A similar trend was observed previously for poly[2-methoxy-5-(3,7-dimethyloctyloxy)-1,4-phenylenevinylene] (MDMO-PPV) films and was attributed to dispersive (time dependent) relaxation of the charge carriers [35]. Charges could be extracted ~100 μs after charge generation indicative of their relatively long lifetime, which is comparable to other conjugated systems measured previously. Photo-CELIV traces recorded at fixed 12 μs delay time and at varying voltage rise speed $(A = U_{max}/t)$ are shown in Fig. 2B. The charge extraction peak is shifted to longer times due to the smaller applied voltages. Similar traces were recorded for all four dendrimers, and the mobility values calculated according to Eq. (1) are plotted in Fig. 3A and B

$$\mu = \frac{2d^2}{3At_{\max}^2\left[1 + 0.36\frac{\Delta j}{j(0)}\right]} \quad (1)$$

where d is the film thickness, t_{max} is the time at which the extraction current reaches its maximum value (Δj), and $j(0)$ is the capacitive current [36].

The extracted charge for all dendrimers were close to the capacitive charge CU ($(\Delta j \sim j(0))$ and was very similar for all samples.

No difference in the mobility or in its delay time dependence at shorter delay times was observed for the *21T* dendron and the *42T* dendrimer. The mobility values at very long delay times (>30 μs), where the extracted charge concentration is much lower due to recombination, were measured at increased charge carrier concentrations by increasing the laser intensity. This resulted in increased mobility reaching the values measured at shorter delay

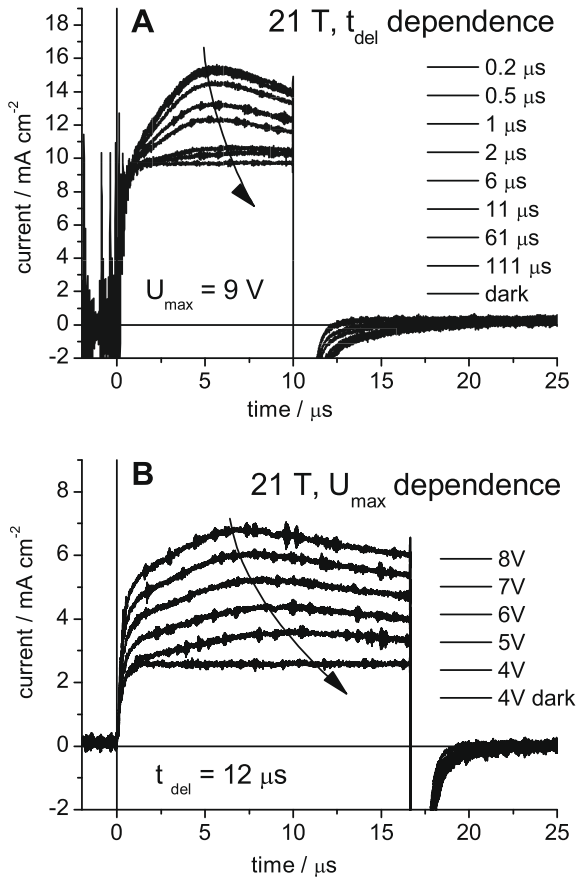

Fig. 2. Photo-CELIV current traces recorded at (A) various delay times and fixed voltage rise speed or (B) fixed delay time and various voltage rise speed.

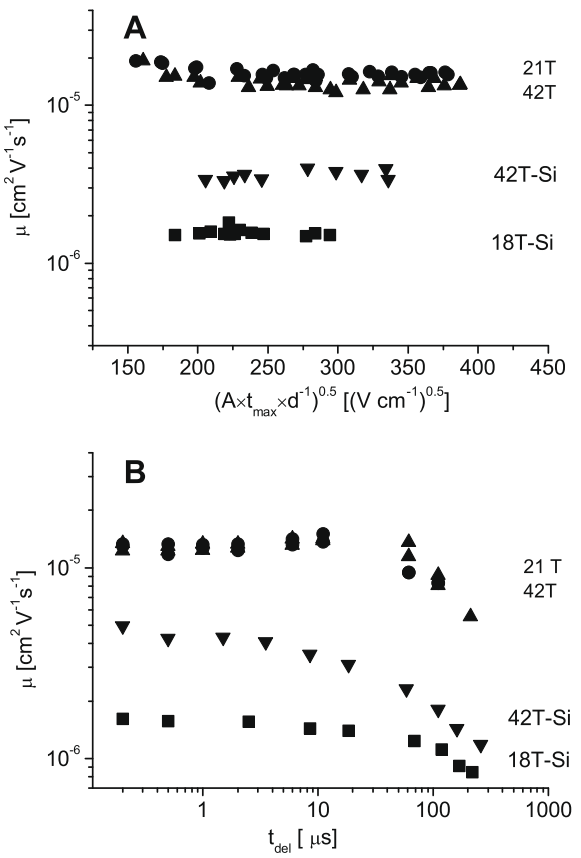

Fig. 3. Charge mobility of the (●) 21T, (▲) 42T, (▼) 42T-Si, (■) 18T-Si thiophene dendrimers (A) as a function of effective electric field at maximum extraction (B) vs. delay time.

times (<30 μs), suggesting that the drop of mobility at longer delay times in Fig. 3B is due to charge transport mediated by deep traps. The delay-time independent mobility at shorter delay times suggests that the shape and the size of the dendrimers without TMS protecting groups does not play a significant role. This is somewhat surprising, since *42T* has larger conjugated segments than *21T*, and correspondingly, the energy of the cation radicals depends on the size of the dendrimer. For example, the difference in the first oxidation potential of *42T* vs. *21T* is 0.22 eV [25]. Studies of excited state dynamics of a series of dendrimers with varying size showed a very rapid (200–300 fs) energy transfer of the photoexcitation to the longest conjugated segment [37]. Similarly, it is expected that at sufficiently long delay times (>200 ns, as measured using photo-CELIV), the charge cation radicals will be primarily localized on the longest conjugated segments. The very similar mobility (and its delay time dependence) of *21T* and *42T* is thought to be controlled by inter-dendrimer charge transfer rates between units located on the periphery rather than the conjugated core. We note that this result is in contrast to a previous mobility study, where a two order of magnitude increase in the field-effect mobility was observed in dendritic oligothiophenes having 25 and 65 thiophene units [23]. The following reasons may be responsible for this difference. Firstly, the charge carrier concentration is significantly higher in a field-effect configuration [33] and the direction of charge transport is alongside the substrate confined to the first couple of layers of the conjugated material near the gate dielectric surface [38,39]. Secondly, the peripheral groups in the oligothiophene dendrimers are linked through a benzene ring instead of the thiophene ring used in the *all*-thiophene dendrimers. The phenyl groups may promote better inter-dendrimer interaction as indeed reported in Ref. [23], therefore increasing the electronic coupling.

It is apparent that the TMS protecting groups significantly impedes mobility (*42T-Si*, *18T-Si* vs. *42T* and *21T*, see Fig. 3). The hole mobility decreased by a factor of 3–10 by the incorporation of the TMS groups at the periphery. The delay time dependence shows that the mobility is rather constant for all dendrimers till around 10 μs and then drops significantly at longer times. The fact that the mobility of the TMS-protected dendrimers is lower even at the shortest t_{del} indicates that it is intrinsic to their molecular structure. It is not due to higher concentration of traps or increased disorder, which is expected to play a role at longer delay times. The electronic structure of the dendrimers is not influenced noticeably by the TMS groups. Their UV–vis absorption and photoluminescence spectrum as well as their HOMO/LUMO energy levels are virtually identical [25]. Since these dendrimers should have a spherical shape with little interaction between them, we assume that charge hopping will predominantly occur at their interface. The insulating TMS groups located at this crucial interface may reduce the inter-dendrimer electronic coupling and lower the charge transfer rates between the molecules. Interestingly, the larger *42T-Si* exhibits larger mobilities than the *18T-Si*. It is known from concentration dependent ^{1}H NMR measurements [40], that *42T-Si* has more intensive intermolecular interactions than *18T-Si*, which results in increased electronic coupling and therefore reducing the insulating effect of the TMS groups.

Clearly, further studies that include a wider range of dendritic thiophene materials will be necessary to fully uncover the effect of molecular size and shape on their charge transport properties. Based on the comparison presented here, we propose that increased interaction enabling a direct coupling of the longest conjugated segments should significantly enhance their mobility. Moreover, introducing a largely asymmetrical dendrimer shape allowing molecular packing in proximity to the dendrimer core should be beneficial. A dendrimer shell containing electronic units with extended wavefunctions promoting electronic coupling between neighboring units is another modification that may increase charge mobility.

3.2. Charge mobility in the thiophene dendrimer:$PC_{61}BM$ (1:2 w/w) bulk heterojunctions

Our previous solar cell results showed that for thiophene dendrimers:PCBM blends the best weight ratio is

Table 2
Photovoltaic properties of dendrimer:PCBM 1:2 based bulk heterojunction solar cells.

Dendrimer	Thickness (nm)	J_{sc} (mA cm^{-2})	V_{oc} (mV)	*FF*	η (%)
18T-Si	105	1.49	753	0.29	0.32
21T	70	2.76	970	0.27	0.72
42T	75	5.19	950	0.32	1.57
42T-Si	105	2.21	922	0.29	0.58

Table 1
Charge mobility in dendrimer and dendrimer: $PC_{61}BM$ (1:2 w/w) mixtures measured by the photo-CELIV technique.

Dendrimer	Thickness (nm)	μ_h[a] (cm^2 V^{-1} s^{-1})	μ_h^{blend}[a] (cm^2 V^{-1} s^{-1})	μ_h/μ_h^{blend}
18T-Si	720	1.5×10^{-6}	1.7×10^{-7}	8.8
21T	260	1.5×10^{-5}	8.3×10^{-6}	1.8
42T	224	1.2×10^{-5}	3.0×10^{-6}	4

[a] At ~90,000 V cm^{-1} effective extraction field at extraction maximum.

1:2 by weight. Accordingly, the four thiophene dendrimers were mixed with $PC_{61}BM$ in a 1:2 ratio, and the performance of the photovoltaic devices were tested. The photovoltaic parameters including V_{oc}, J_{sc}, *FF* and power conversion efficiency η for 1:2 mixtures of dendrimer:$PC_{61}BM$ at various active layer thickness are shown in Table 2. Generally, the PV performance of the 1:2 mixtures shows similar trend to the previously reported 1:4 mixtures [25]. The lower J_{sc} and slightly lower *FF* of the devices shown here indicate that the fabrication of these cells may not be fully optimized particularly in terms of film thickness. All devices show high V_{oc}, moderate *FF* and somewhat limited J_{sc}. The best η of 1.6% is achieved for *42T*:$PC_{61}BM$ BHJ solar cell using 75 nm active layer. In the following, charge mobility and recombination is studied in these dendrimer: $PC_{61}BM$ (1:2 w/w) heterojunction primarily to understand the factors limiting efficiency in these devices.

First, charge mobility is determined using the photo-CELIV technique. As an example, Fig. 4 shows photo-CELIV transients for a *42T*:$PC_{61}BM$ (1:2) blend as a function of time delay (Fig. 4A) and voltage rise speed *A* at a fixed 12 μs time delay (Fig. 4B). Unlike in the pristine films, two extraction peaks are observed depending on t_{del}. At shorter delay times ($t_{del} < 0.5$ μs) a small extraction peak appears at around $t_{max} = 1$ μs, corresponding to a charge carrier mobility of around 5×10^{-5} $cm^2\,V^{-1}\,s^{-1}$. A second extraction peak, which is observable to up to several tens of μs time delays and corresponding to a much lower mobility value, is also observed. Similarly to the pristine dendrimer photo-CELIV curves, the time to reach extraction maximum t_{max} shifts to longer times with decreasing voltage rise speed (Fig. 4B).

Mobility values were calculated both from the first and the second extraction peaks and shown vs. the square root of the effective extraction field at extraction maximum in Fig. 5. We note that the sign of the charge carriers cannot be directly determined from the photo-CELIV transients shown here. We attribute the first extraction peak to electron transport in the $PC_{61}BM$ phase, and the second peak is assigned to the hole mobility in the thiophene dendrimer phase based on the following argument. The first peak is absent in the pristine dendrimer and its value is on the same order of magnitude as the reported values of electron mobility of the $PC_{61}BM$ phase in various donor:$PC_{61}BM$ mixtures. For example, it is around 10^{-4} $cm^2\,V^{-1}\,s^{-1}$ in the as cast P3HT:$PC_{61}BM$ 1:1 blend [41], and around 3×10^{-4} $cm^2\,V^{-1}\,s^{-1}$ in the MDMO-PPV:$PC_{61}BM$ 1:2 mixture [42,43]. Inganäs and coworkers have reported two extraction peaks in a series of fluorene–thiophene copolymer:$PC_{61}BM$ (1:4) mixtures and assigned the first peak to electron extraction with mobility values reaching 10^{-3} $cm^2\,V^{-1}\,s^{-1}$ [44]. The shape of the second extraction curve and the calculated mobility values are similar to the pristine dendrimer mobility values, therefore it is assigned to the hole mobility in the dendrimer phase.

The mobility values determined at an electric field of $E = 90{,}000$ $V\,cm^{-1}$, which corresponds to a typical value of extraction field in a dendrimer-based BHJ solar cell at short circuit conditions, are summarized in Table 1. Generally, hole mobilities for all dendrimers are reduced in their

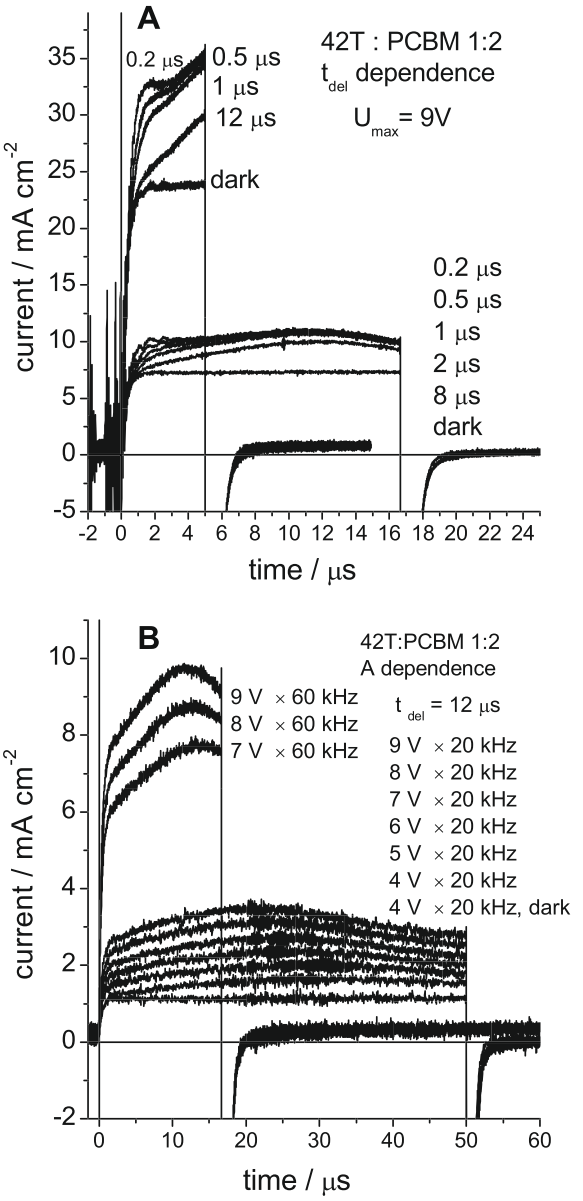

Fig. 4. Photo-CELIV current traces recorded at (A) various delay times and fixed voltage rise speed or (B) fixed delay time and various voltage rise speed (*A*) for *42T*:$PC_{61}BM$ (1:2) bulk heterojunction solar cells.

mixture with $PC_{61}BM$ (column μ_h/μ_h^{blend} in Table 1), but not to the same extent. The larger decrease of the hole mobility in the TMS-protected dendrimers is attributed to the smaller molecular molar ratio of the thiophene dendrimer to $PC_{61}BM$ due to their larger molecular weight. Increased interaction or the more extended π-conjugated system of the larger *42T-Si* (2.8×10^{-7} $cm^2\,V^{-1}\,s^{-1}$) may also contribute to its higher hole mobility in the blend in comparison to that of *18T-Si* (1.7×10^{-7} $cm^2\,V^{-1}\,s^{-1}$).

The hole mobilities in *21T*:$PC_{61}BM$ and *42T*:$PC_{61}BM$ mixtures did not drop so dramatically as compared to the TMS-protected dendrimer blends (1.8 and 4 times, respectively). Contrary to expectations, it is well known that the

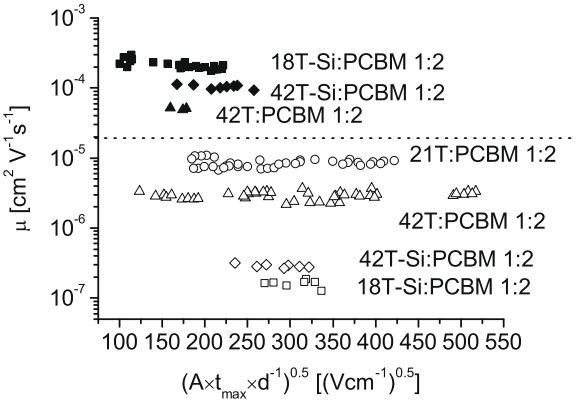

Fig. 5. Charge mobility in thiophene dendrimer/$PCB_{61}M$ 1:2 bulk heterojunctions calculated for the first (closed symbols) and second (open symbols) extraction peak using the photo-CELIV technique.

hole mobility in MDMO-PPV is *increased* quite significantly when mixed with $PC_{61}BM$ in a 1:4 ratio [42,43,45], which has recently been explained by the interpenetration of $PC_{61}BM$ molecules into the side-chain structure of MDMO-PPV [46]. It is evident that no such improvement is observed here. The less dramatic *decrease* in hole mobility of dendrimer *21T* may be related to its different size and shape. Although in pristine films no major difference was observed between *21T* and *42T* in the pristine films, mixing $PC_{61}BM$ (ratio 5–6 thiophene units to one $PC_{61}BM$ molecule) [25] may promote better alignment of the slightly asymmetric *21T* in the blend. We note that the AFM images of the films showed very smooth films with smooth surfaces confirming that an intimate mixture of the donor and acceptor is formed. No indication of large scale ordering or aggregation on the surface was observed. Also, the thiophene to $PC_{61}BM$ ratio is the same in *21T* and *42T* mixtures. Due to the inherently smaller cluster size (determined by the dendrimer size) of *21T*, a more uniform distribution of the thiophene units and $PC_{61}BM$ is possible, which may explain its slightly higher mobility in the blend.

The electron mobility in the dendrimer:$PC_{61}BM$ mixture (assigned to the first extraction peak in Fig 4A) decreases in the order of *18T-Si*, *42T-Si* and *42T*. We have observed a small extraction peak for *21T*:$PC_{61}BM$ at short delay times, but could not determine the mobility values because the first and second peaks overlapped. The reported electron mobility values in best performing conjugated donor:$PC_{61}BM$ heterojunctions are typically around 10^{-3} $cm^2\,V^{-1}\,s^{-1}$ in 1:4 donor:PCBM mixtures and slightly lower (around $3\times10^{-4}\,cm^2\,V^{-1}\,s^{-1}$) in 1:2 mixtures [41–44]. A morphology dependent electron mobility in annealed vs. as cast P3HT:PCBM 1:1 films has been also reported [41]. The observed very smooth surface morphology may suggest that the dendrimer and $PC_{61}BM$ could be well intermixed and no $PC_{61}BM$ crystallites are formed, which may be responsible for the somewhat lower electron mobility. As indicated in the Supplementary data Table 1, the TMS-protected dendrimers have higher molecular weight, which, at the same weight ratio of 1:2, results in almost twice as high $PC_{61}BM$ molar ratio in the blend. The higher molar ratio of $PC_{61}BM$ in the TMS-protected dendrimer films is proposed to be responsible for their higher electron mobility.

3.3. Charge carrier lifetime in thiophene dendrimer:$PC_{61}BM$ (1:2 w/w) mixtures

Free charge generation efficiency and charge carrier lifetime are crucial parameters influencing charge extraction. Free charge carrier lifetime in dendrimer:$PC_{61}BM$ mixtures were determined using (i) a delayed electric-field extraction technique [47]; or (ii) visible/NIR transient absorption spectroscopy. In the first case, similarly to the photo-CELIV technique, charges are photo-generated at open circuit conditions by 6 ns laser pulses and subsequently extracted by a square wave voltage pulse applied after a tunable delay time (see SI1). The concentration of the extracted charges is plotted vs. time delay and charge carrier lifetime is determined from the decay of the charge concentration. Using this charge extraction method, recombination of the reasonably mobile (free) charge carriers is monitored [48].

Charge extraction curves recorded at various delay times for *21T*:$PC_{61}BM$ and *42T*:$PC_{61}BM$ are shown in a logarithmic plot in Fig. 6A and B, respectively. The extraction current decreases gradually with increasing t_{del} due to recombination. The magnitude and shape of the extraction curve is quite different for these two dendrimer:$PC_{61}BM$ mixtures even at the shortest delay times. At longer delays, the extraction current decreases to the baseline indicating efficient charge extraction within the applied extraction pulse. The extraction currents were integrated and the extracted charge density normalized to the fraction of absorbed photons ($1–10^{-A}$, where A is the absorbance of the films at the 532 nm excitation wavelength) is plotted vs. delay time in Fig. 7A. The magnitude of the normalized extracted charge density is related to the yield of charge generation minus any fast component of the recombination kinetics, and possibly trapped charges that are not extracted within the applied extraction pulse. The decays in Fig. 7A, on the other hand, are related to the lifetime of the extracted charges. Clearly, all dendrimer:$PC_{61}BM$ films exhibit similar time-decays within the experimental certainty, therefore similar lifetimes. In our previous report, we found that J_{sc} of dendrimer:PCBM solar cells are linearly correlated to the light absorbing ability of the dendrimers [25]. In addition, herein we observed that extracted charge concentration normalized to the absorbed photon intensity for the *42T*:$PC_{61}BM$ and *42T-Si*:$PC_{61}BM$ mixtures was ~2× higher as compared to that of *18T-Si*:$PC_{61}BM$ and *21T-Si*:$PC_{61}BM$. The higher extracted charge concentration for the larger dendrimers is clearly not due to difference in charge mobility, since *42T* and *42T-Si* have quite different mobility yet same charge extraction yield. We propose that the increased extracted charge concentration is related to increased free charge generation yield, which depends on the dendrimer size. Photoluminescence quenching experiments, which are indicative of photoinduced electron transfer from the excited donor to the electron acceptor, show very similar and highly efficient quenching from all four excited dendrimer molecules to $PC_{61}BM$ (see SI 2). Initial charge separation may result in coulombically bound

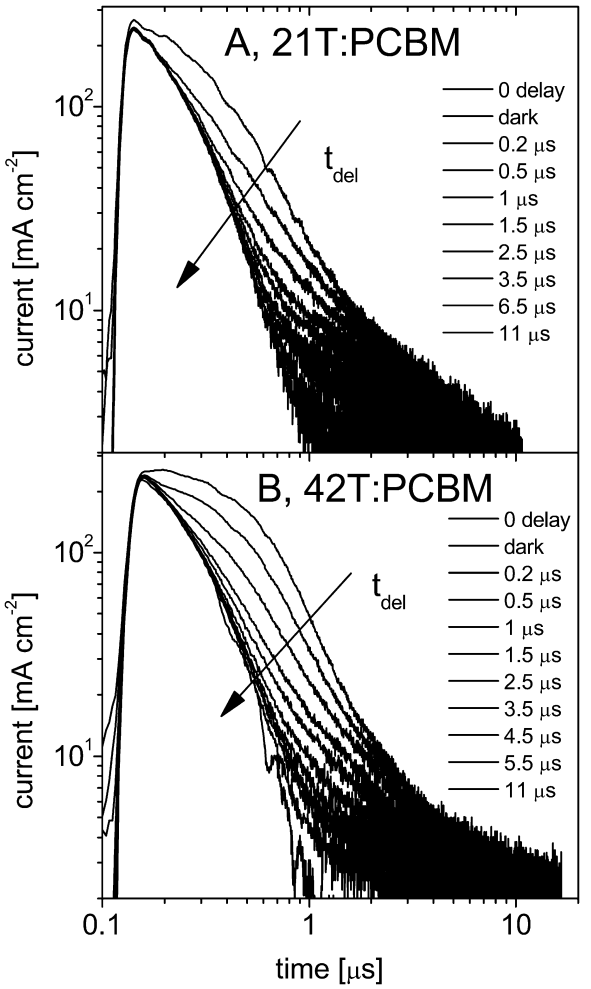

Fig. 6. Photocurrent transients recorded using a delayed-field charge extraction technique for (A) *42T*:$PC_{61}BM$ 1:2 and (B) *42T-Si*:$PC_{61}BM$ 1:2 mixtures. The arrow indicates increasing delay time between the light pulse and the square-shaped voltage pulse.

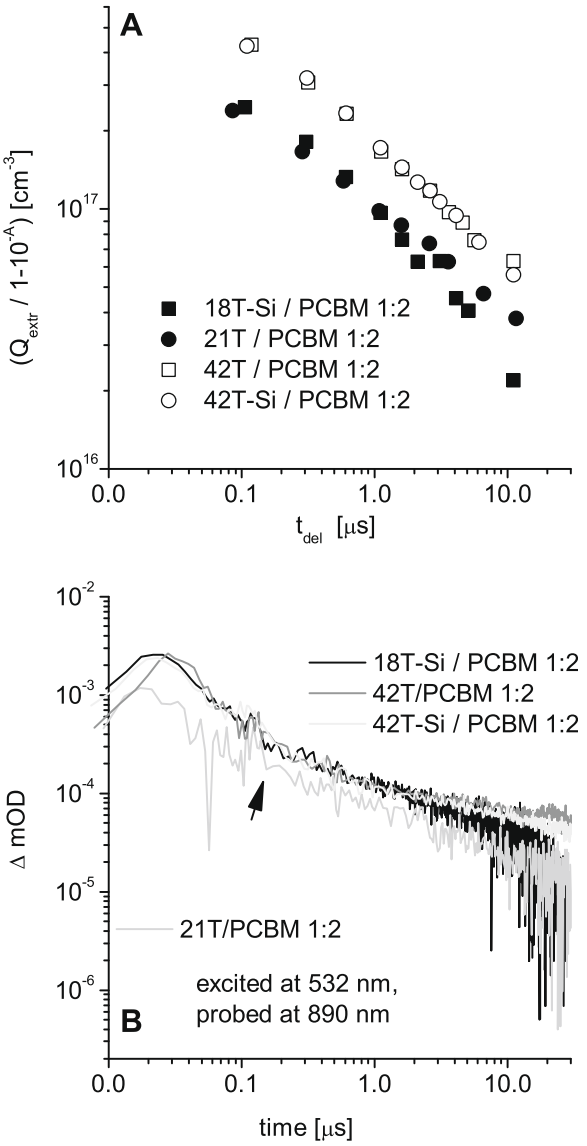

Fig. 7. Extracted charge normalized to the faction of absorbed excitation intensity $1–10^{-A}$ vs. delay time (A) and transient absorption traces recorded at 890 nm for various dendrimer:$PC_{61}BM$ blends (B).

electron and hole pairs. In such cases, the generation of free charge carriers (that are probed by charge extraction) is a secondary, thermally activated process. The generation of free charge carriers from the coulomb-coupled pairs depends on a number of parameters including temperature, initial charge separation distance between the electron and hole, mobility and the dielectric constant. All other parameters being very similar, we propose that the difference in charge separation distance, which itself related to the molecular size, controls the free charge generation efficiency in these dendrimer:$PC_{61}BM$ mixtures. Deibel et al. have performed a Monte-Carlo simulation of hopping transport of Coulomb-bound electron–hole pairs in an energetically disordered donor–acceptor blend system, which predicted an increased geminate electron–hole pair dissociation yield with increasing length of the conjugated segments [49].

Contrary to the charge extraction technique above, which measures the lifetime of the reasonably mobile (free) charge carriers, using transient absorption the time-decay of the charged radical ions was optically followed. We have performed visible pump/NIR probe transient absorption measurements on the dendrimer:$PC_{61}BM$ 1:2 films. The films were excited at 532 nm and the changes of the sample transmission were monitored at 890 nm with ~10 ns time resolution. According to previous photoinduced absorption studies [25], the signal at 890 nm in the dendrimer:$PC_{61}BM$ blends is due to absorption by dendrimer cation radicals. The recorded transient absorption signals are shown in Fig. 7B. The signal magnitude is related to the absorption coefficient of the cation radicals at 890 nm as well as their concentration, while the decays are related to their time dependent recombination. The curves all show biphasic decays: a fast component till ~100 ns and a second, power law decay extending to the recorded 30 μs time scale.

A comparison of Fig 7A and B provides an opportunity to compare charge recombination kinetics of mobile charge carriers and all of the optically monitored photo-generated holes within the same films. For e.g., in MDMO-PPV:PCBM blends [35] we have observed a bimolecular recombination law using charge extraction, while transient absorption measurements on the same system usually gave a power-law dependence [50,51]. This difference was explained by the fact that only reasonably mobile charges are extracted in the photo-CELIV, while all the charges including the deeply trapped ones are monitored optically. In the present manuscript, we have used a square-voltage-pulse delayed field extraction technique, which yields stronger extraction fields than used in CELIV. A similar power-law charge concentration decay was observed using this square-voltage-pulse technique in various other material combinations published to date, indicating its better suitability when the concentration decay in the presence of strong dispersion is studied [30,47].

The main difference is at the shorter <100 ns time delays, where the transient absorption shows an additional, fast component of the recombination. Such biphasic decay has been previously observed in a number of electron donor:acceptor systems [50,52] and has been attributed to the recombination of dissociated electron and holes in the presence of an exponential distribution of hole traps. The decays are characterized by signal decay half times $\tau_{1/2}$ in Fig. 7A and B. The $\tau_{1/2}$ values are similar between the charge extraction and the second component of the transient absorption decay and are around 0.7 μs, which is quite short as compared to other donor:acceptor systems. For example, measurements on MDMO-PPV:$PC_{61}BM$ 1:4 blends have yielded 3× longer effective lifetimes of around 2 μs [31]. The charge recombination appears to be faster in the blends as compared to the pristine dendrimers (see Fig. 3), which is thought to be related to the increased (electron) mobility enhancing recombination.

4. Conclusions

Charge mobilities of four *all*-thiophene dendrimers varying in size, shape and with or without TMS protecting groups have been studied using the photo-CELIV technique. No difference in charge mobility due to variation of size or shape of the dendrimer without TMS protecting groups has been observed between the dendrimer containing 21 or 42 thiophene units. It was also found that the incorporation of the TMS protecting groups significantly impedes mobility, which was attributed to the insulating effect of the peripheral TMS groups reducing charge transfer rates between neighboring dendrimer molecules. Charge carrier mobility is reduced when the dendrimers were mixed with the electron acceptor $PC_{61}BM$, but in varying extents depending on the molecular structure and the thiophene to $PC_{61}BM$ molar ratio. Very similar cation radical lifetimes (characterized by signal decay times $\tau_{1/2}$ of 0.7 μs) have been determined using a delay-field extraction technique and transient absorption spectroscopy, which together with the small hole mobility is expected to cause short hole drift lengths. Charge extraction measurements revealed significant molecular size dependence: 2× more charge could be extracted from the larger *42T* and *42T-Si* dendrimer:$PC_{61}BM$ mixture. This was attributed to higher free charge generation yield due to larger initial charge separation distance in the larger dendrimer molecules. Strategies to improve charge mobilities have been discussed, which includes the increase of molecular interaction between the neighboring dendrimers, introducing an asymmetric dendrimer shape and a stronger electronic coupling using modified dendrimer periphery.

ABSTRACT

The advent of organic solar cells promises access to inexpensive solar electricity. Major advances in this thin film technology bear on biphasic and bicontinuous mesoscopic structures composed of an electron donor and acceptor material. Here, we demonstrate a high efficiency organic solar cell with simple planar bilayer architecture based on a soluble cyanine dye as electron donor and fullerene C_{60} as electron acceptor. Upon doping the trimethine cyanine layer and optimizing the device cathode, the cell reaches a power conversion efficiency of 2.0% under simulated AM1.5 solar irradiation. The external quantum efficiency approaches 80% at maximum and is among the highest reported in organic photovoltaic devices. Soluble cyanines are compatible with low-cost coating processes, adding to the merits of this class of photographic dyes for organic solar cell applications.

1. Introduction

Organic photovoltaics can be dated back to 1960, when Meier and Haus conceived a double layer device consisting of an electron donor and acceptor material, respectively [1]. In 1986 power efficiencies close to 1% were demonstrated by Tang using the same concept [2]. It is now well understood that photovoltaic action in bilayer devices relies on light absorption and subsequent formation of electronically excited states (excitons) that diffuse to the donor–acceptor interface where they are separated into positive and negative charge carriers. Most bilayer heterojunction devices suffer from a limited photoactive zone at the organic heterointerface, due to the rather small exciton diffusion length of typically 5–20 nm [3]. For thicker films, an important part of the organic layer just acts as light absorbing filter. Bulk-heterojunctions consisting of bicontinuous donor–acceptor microstructures bypass this difficulty [4]. Solution processed bulk-heterojunction devices presently constitute the most efficient organic photovoltaic devices with power conversion efficiencies up to 6.6% for polymers [5] and 4.4% for small molecules [6]. However, it is generally challenging to produce optimized meso-structures; while large structures will not suffice to dissociate all photogenerated excitons, very small phase dimensions are likely to hinder the separation of geminate electron–hole pairs formed after exciton ionization [7]. Alternatively, crystalline and pure organic materials having very high exciton diffusion lengths combine efficient charge carrier generation and transport in a bilayer device architecture. Exciton diffusion lengths exceeding 40 nm have indeed been realized for small evaporable molecules such as pentacene [8] and exhibit power conversion efficiencies of 2.1% [9].

Organic dyes with extraordinary high extinction coefficients offer yet another possibility to go around the constraints of small exciton diffusion length and modest charge transport, since ultrathin films could be applied in a planar bilayer fashion. Photographic polymethine dyes such as cyanines, merocyanines or squaraines are among the strongest light absorbers and were first developed as sensitizers in the photographic process [10]. They have also been successfully used in data storage devices [11], as fluorescent labels [12] and more recently in dye sensitized solar cells [13–15], where power conversion efficiencies ranging from 4% to 7% were achieved. There are only few examples of high efficiency solid organic solar cells

employing polymethine dyes. Merocyanine single layer Schottky barrier solar cells approaching a power conversion efficiency of 1% have long hold the world record [16]. Recently, vapor deposited squaraine dyes reached an efficiency of 3.1% [17]. Solution deposited donor–acceptor blends of a merocyanine dye and a squaraine dye revealed power conversion efficiencies of 1.7% [18] and up to 1.8% [19,20], respectively. Cationic cyanine dyes have received even less attention in organic solar cell construction. In previous work, soluble cyanine dyes were shown to act as electron donors and electron acceptors in planar heterojunction devices, though with poor efficiency [21]. The power conversion efficiency benchmark of 1% was achieved in subsequent work evidencing the importance of ameliorating charge transport in cyanine films [22]. Very recently, cationic and anionic heptamethine dyes showed promising near infrared sensitivity [23].

Here, we report on bilayer devices consisting of a soluble trimethine cyanine dye and C_{60}. We optimize the cell performance by oxidative doping of the cyanine layer and by adding a cathode buffer layer leading to a power conversion efficiency of 2.0% under standard solar irradiation and an outstanding external quantum efficiency approaching 80% at maximum. Hence, this classical cyanine dye employed as organic semiconductor in a bilayer solar cell architecture outperforms other soluble small molecules that have mostly been applied in bulk-heterojunction cells [24].

2. Experimental

1,1′-Diethyl-3,3,3′,3′-tetramethylcarbocyanine perchlorate (CyC) was synthesized based on a published procedure [25]. For further purification the cyanine dye was twice recrystallized in ethanol. Buckminster fullerene C_{60} (SES Research), poly(styrene sulfonate) doped poly(3,4-ethylenedioxythiophene) (PEDOT:PSS, Sigma–Aldrich) and tris-(8-hydroxyquinoline) aluminium (Alq_3, Sigma–Aldrich) were used without further purification. Etched indium tin oxide glass substrates (ITO, from AFC) were first cleaned in ozone, followed by ultrasonic cleaning in acetone, ethanol, soap and Milli-Q water, before being dried in a nitrogen flow.

Organic multilayer solar cell devices with ITO/PEDOT:PSS/CyC/C_{60}/Al architecture were deposited layer by layer on the clean conducting glass substrates. First, a 40 nm thick film of the hole conducting PEDOT:PSS film was spin coated on the ITO substrate, then heated to 120 °C for 12 min in order to remove residual water. The coated substrates were then transported into a nitrogen glove box to avoid exposure to oxygen and moisture. CyC was then spin coated from 1 wt% chlorobenzene solutions doped with various concentrations of $NOBF_4$ within the $NOBF_4$/CyC range from zero to 0.08 mol/mol. The doping concentration was adjusted by adding different amounts of $NOBF_4$ from a 0.01 M stock solution in acetonitrile to the cyanine solution in chlorobenzene.

For the subsequent vapor deposition steps, substrates were conveyed to a high vacuum deposition chamber directly linked to the glove box. A 40 nm thick C_{60} layer followed by a 60 nm thick aluminium electrode were vapor deposited at a pressure of 10^{-6} – 2×10^{-6} mbar. A total of eight solar cells with surface areas of 3.1 mm^2 and 7.1 mm^2 were produced on each conducting glass substrate to allow for some averaging. To improve the contact at the aluminium/C_{60} interface, a 2 nm thick Alq_3 film was vapor deposited on the C_{60} layer prior to aluminium cathode deposition. It has to be noted that from the PEDOT:PSS deposition on, all further fabrication steps occurred in inert atmosphere to avoid uncontrolled effects of water and oxygen uptake. Average film thicknesses were determined by profilometry (Ambios XP1) and absorption was measured using a Varian Cary 50 UV–vis spectrophotometer.

For solar cell characterization, the substrates were sealed in a vacuum tight box with current feedthroughs and an optical window. Current–voltage characteristics of the solar cells were measured by a Keithley 2400 source/measure unit in the dark and under simulated AM1.5 solar irradiation using the spectrum of a 300 W Xe lamp together with an AM1.5G filter set. The white light intensity P_{in} was calibrated in order to correspond to standard solar irradiation at 100 mW/cm^2 for full sun and 33 mW/cm^2 for 1/3 sun irradiation (see Supplementary material). Using a diaphragm, the irradiation spot was adjusted to match the surface of the solar cells. Open-circuit voltage (V_{OC}) and short-circuit current–density (J_{SC}) were obtained directly from the current–voltage characteristics. Power conversion efficiencies (PCE) were calculated as $PCE = FF \times V_{OC} \times J_{SC} \times P_{in}^{-1}$, where $FF = (J \times V)_{max} \times V_{OC}^{-1} \times J_{SC}^{-1}$ and $(J \times V)_{max}$ relates to the current–density and voltage measured at the maximum power point. A Cornerstone 130 monochromator (Oriel) was used together with the Xe lamp to measure the incident photon-to-current conversion efficiencies (IPCE). They were calculated as $IPCE = hc/\lambda e \times J_{SC} \times P_{in}^{-1}$ where h is Planck's constant, e is the elementary charge and λ is the monochromatic irradiation wavelength. Reflection losses at the solar cell substrate were not considered in the calculation. To verify the calibration of our characterization equipment, selected solar cells were also measured at the Laboratory for Photonics and Interfaces at the Swiss Federal Institute of Technology Lausanne (EPFL). For this purpose, cells were transported in a vacuum tight measurement box. The characteristics of all solar cell devices studied in this work are summarized in Table 1.

Electrical conductivity of the doped CyC films was measured by a standard four-probe method using a Keithley

Table 1
Photovoltaic performance of ITO/PEDOT:PSS/CyC/C_{60}/Al devices using pristine and doped CyC films. For doped cells, the $NOBF_4$/CyC concentration is 0.02 mol/mol. The photovoltaic parameters are measured under standard AM1.5 simulated solar irradiation, unless indicated. Usage of a 2 nm thin Alq_3 cathode buffer layer is also indicated.

	J_{SC} (mA/cm^2)	V_{OC} (V)	FF	η_P (%)
Pristine	0.96	0.24	0.18	0.04

[a] Measured at 1/3 of the simulated standard AM 1.5 irradiation intensity.

2400 source/measure unit. The glass substrates comprised four finger-like gold electrodes separated by a channel distance of 10 μm. The height of the fingers was measured to be 186 nm while the length of the finger-like structure was 1.18 cm. A current of 500 nA was applied at the outer electrodes, while the voltage was measured at the inner electrodes.

3. Results and discussion

The chemical structure of the trimethine cyanine dye (CyC) together with the energy level diagram of the other organic materials and electrodes used in the device construction are shown in Fig. 1. The hole conducting poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) film (40 nm) and the CyC donor film (30 nm) were spin coated successively on top of a transparent indium tin oxide (ITO) substrate. Thereafter, the C_{60} acceptor film (40 nm) and the aluminium top electrode (60 nm) were deposited via thermal sublimation to form typical ITO/PEDOT:PSS/CyC/C_{60}/Al multilayer devices with an active area of 7.1 mm^2. To increase the conductivity of the donor layer, the cyanine was doped using nitrosonium tetrafluoroborate ($NOBF_4$). Oxidation of the cyanine dye is driven by the higher oxidation potential of NO^+, which in acetonitrile is 0.87 V vs. ferrocene/ferrocenium (Fc/Fc^+) as compared to 0.63 V vs. Fc/Fc^+ for the dye [26]. The merit of this doping agent is that the cyanine can be oxidized in solution in a controlled way. We first produced a concentrated $NOBF_4$ stock solution in acetonitrile where the NO^+ cation is stable for several hours. Small aliquots of the stock solution were then added to a 1 wt% cyanine solution in chlorobenzene, which turned out to be the best spin-coating solvent to form smooth doped films. To provide spectroscopic evidence of the doping process, CyC solutions were prepared with increasing doping concentrations up to a $NOBF_4$/CyC ratio of 2.2 mol/mol. While the monomer signature at 540 nm disappears with increasing $NOBF_4$ concentration, a clear cyanine dication peak at 483 nm emerges along with an isosbestic point at 500 nm (Fig. 2a). When thin films are produced from these solutions, the features are similar but no isosbestic point is observed due to the presence of dimers and aggregates in the solid (Fig. 2b). Full conversion of the cationic dye into its dication occurs at a $NOBF_4$/CyC molar ratio of 2 mol/mol. We believe the oxidation reaction to be quantitative and attribute the twofold excess needed for full conversion to the degradation of the $NOBF_4$ stock solution by water contamination.

Doping induces a steep rise of the short-circuit current J_{SC} going from 1 mA/cm^2 to 8 mA/cm^2 when the $NOBF_4$ concentration in the CyC solution is increased from zero to 0.02 mol/mol and unexpectedly decreases for higher doping concentrations (Fig. 3a). As we have verified by four-probe conductivity measurements, this behaviour is paralleled by the conductivity of the film reaching 2×10^{-6} S cm^{-1} at the optimum concentration of 0.02 mol/mol (Supplementary material, Fig. S2). We attribute this feature to film disruption upon aggregation of the charged cyanine dyes. At higher doping concentrations this behaviour is indeed observed by atomic force microscopy (Supplementary material, Fig. S4). The open-circuit voltage V_{OC} rises from 0.25 V to more than 0.6 V, similar to the current density, but stays rather constant for higher doping concentrations (Fig. 3b). Regarding the fairly low fill factor *FF* of about 0.2, it is independent of the doping concentration. At the optimum doping level of 0.02 mol/mol the power conversion efficiency (PCE) reaches 0.55% when measured at standard simulated AM1.5 solar irradiation which is an order of magnitude higher than 0.04% obtained for the undoped cyanine solar cell (Fig. 3c). The increase of photovoltaic performance upon oxidative doping corresponds to our previous findings using oxygen as doping agent [22]. In the latter work cyanine films were deposited from tetrafluoropropanol and solar cell efficiencies were typically around 0.1%. Photooxidative doping of the cyanine layer exposed at ambient atmosphere drastically increased the power conversion efficiency to 1.2% at 1/3 of the standard irradiation intensity. However, while the

photooxidative doping method partly destroys the CyC film and deteriorates the C_{60} layer, $NOBF_4$ doping provides a controlled and non-destructive way of adjusting conductivity in the cyanine film.

Despite the important rise in short-circuit current density, the power conversion efficiency of the device is limited by the marked "S-shape" in the current–voltage characteristics (Fig. 3c). This phenomenon has been reported for different organic solar cells and has been shown to originate from defects at the C_{60}/aluminium cathode interface [27]. Different methods have been proposed to achieve Ohmic contacts at the aluminium cathode implying annealing steps or various buffer layers. In $NOBF_4$ doped cyanine solar cells, annealing of the completed devices led to reduced device performance. Therefore we opted for the insertion of a 2 nm thin tris-(8-hydroxyquinoline) aluminium (Alq_3) buffer layer between C_{60} and aluminium [28]. As shown in Fig. 4a, the "S-shape" is largely reduced in the current–voltage characteristics of both the doped and undoped cell. We attribute the remaining small kink to the anode contact, since the aluminium cathode using the Alq_3 buffer layer is known to be Ohmic. In the same manner as for the devices lacking the Alq_3 buffer layer, doping induces an important shift of V_{OC} from 0.32 V to 0.72 V and gives rise to a dramatic short-circuit current increase from 2.4 mA/cm^2 to 8.3 mA/cm^2. Combining both a doped cyanine layer and a cathode buffer layer in the device construction results in fill factors of 0.43 and 0.34 at 1/3 sun and full sun irradiation, respectively. Consequently, we obtain high power conversion efficiencies of 2.6% (1/3 sun) and 2.0% (full sun).

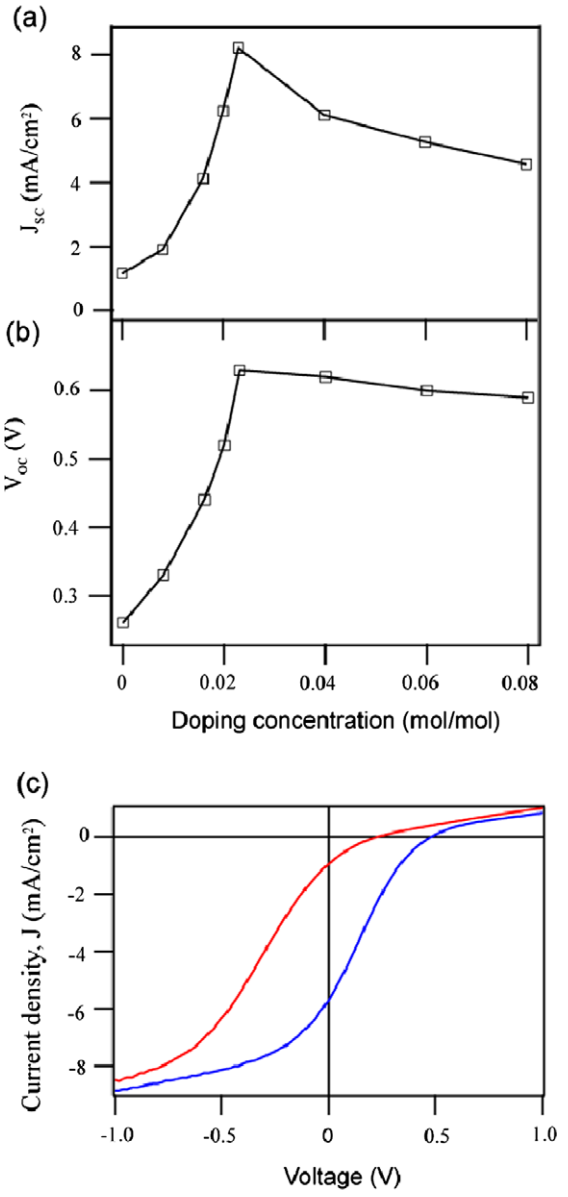

Fig. 3. Dependence of the photovoltaic parameters on the $NOBF_4$ doping concentration of the CyC film: (a) short-circuit current and (b) open-circuit voltage measured at 140 mW/cm^2, (c) current–voltage characteristics of devices using pristine CyC films (red) and doped CyC films with a $NOBF_4$/CyC molar ratio of 0.02 mol/mol (blue) and measured at 100 mW/cm^2 full sun irradiation. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

One of the major benefits of doping the cyanine layer is obviously related to the intriguing rise in open-circuit voltage. The origin of the open-circuit voltage in planar heterojunction solar cells is not fully understood yet but was shown to be related to a combination of various device parameters, the most important being the difference between the quasi Fermi levels of electrons in the acceptor and holes in the donor material. Doping certainly lowers the quasi Fermi level of the holes in the cyanine layer [29]. To estimate the importance of this lowering on the

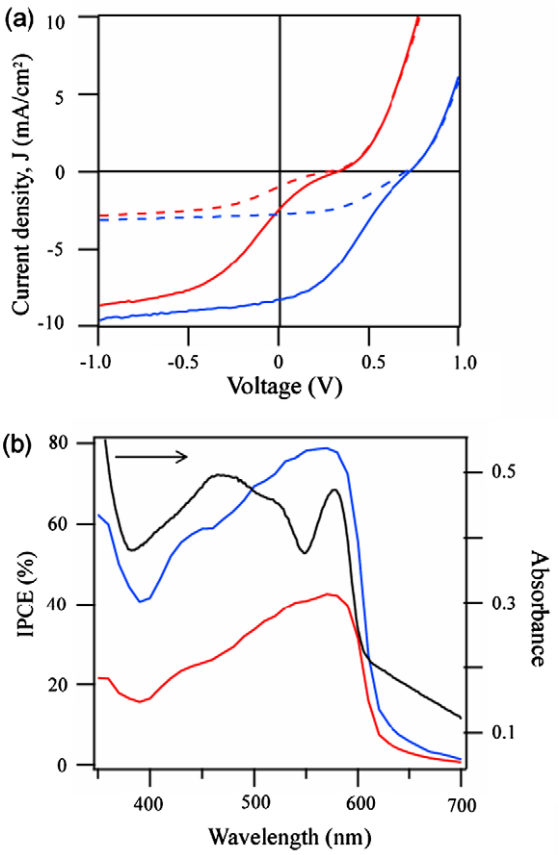

Fig. 4. Photovoltaic performance of solar cells having an Alq_3 cathode buffer layer. open-circuit voltage increase ΔV_{OC} the following expression can be easily derived (see Supplementary material):

$$\Delta V_{OC} = \frac{kT}{e} \ln\left(\frac{n_1 p_1}{n_0 p_0}\right) \quad (1)$$

Here p_0 and p_1 are the densities of photoinduced holes in the cyanine layer before and after doping, respectively, while n_0 and n_1 are the respective electron densities in the C_{60} layer, k is the Boltzmann constant, $T = 298$ K is the temperature and e is the elementary charge. Numerical evaluation of Eq. (1) then yields $\Delta V_{OC} = 0.10$ V (see Supplementary material), which is clearly inferior to the observed changes. Therefore, we have attributed the important change in open-circuit voltage to the creation of a Schottky junction at the PEDOT/CyC interface. As a consequence, the effective anode workfunction is lowered, thus the built-in field of the device is increased, which is corroborated by the change of 0.4 V in the onset voltage of the diode. Schottky barrier formation upon oxidative doping of the organic layer at the electrode interface has already been studied extensively [16,30,31]. More recently, p or n-doped transport layers deposited by controlled co-sublimation have been introduced in small molecule solar cells demonstrating the possibility of achieving photoactive pn- and pin-type heterojunctions [32,33].

Perhaps the most striking effect of doping the cyanine film is manifested in the photocurrent increase at short-circuit conditions. The incident photon-to-current conversion efficiency (IPCE) of doped and pristine CyC solar cells shows a maximum which corresponds to the cyanine absorption at 580 nm as well as a shoulder at 440 nm, which is attributed to the photoactivity of C_{60} (Fig. 4b). Doping improves the IPCE by a factor of two, reaching nearly 80% at maximum. This is astonishingly high given the modest solar cell absorbance of 0.47 at the maximum IPCE wavelength of 580 nm. In a simple model we can assume that incident light, being reflected by the aluminium cathode, penetrates twice through the photoactive layers thereby loosing 89% of its intensity. Accounting for additional reflection losses of 5–10% it follows that the monochromatic photon to electron conversion efficiency must be close to unity. This also means that the full cyanine layer has to be active in charge generation. As we have verified by varying the thickness of the CyC layer, a typical filter effect appears for thicker layers showing that doping is not leading to charge carrier generation in the bulk cyanine layer (Supplementary material, Fig. S3).

Unlike highly crystalline organic layers grown by physical vapor deposition, cyanine films are spin casted from solution and do not reveal large crystalline grains (Supplementary material, Fig. S4) provided with high exciton diffusion lengths. Possibly C_{60} diffuses into the cyanine layer leading to exciton dissociation and extraction of the electrons. Diffusion of C_{60} into conjugated polymer layers has already been observed [34]. On the other hand large cyanine aggregates may also be responsible for efficient exciton transport to the charge separating heterointerface. Indeed, we have recently found that CyC aggregates nucleate at the surface of a fullerene derivative, as it may at the C_{60} interface [35]. By all means, the very high monochromatic photon-to-current conversion efficiency indicates that electron–hole recombination processes are insignificant in our devices. As reported in previous work [36], cyanine counterions can diffuse across the donor–acceptor interface giving rise to surface dipoles. The latter could act as energy barrier for the recombination of photogenerated charges. Work is in progress to scrutinize this mechanism.

4. Conclusion

The present work demonstrates the full potential of soluble cyanine dyes used as solid organic semiconductors in solar cell devices. Solution doping of cyanines increases the conductivity of spin casted films and leads to efficient photovoltaic cells using simple bilayer heterostructure architecture. High power conversion efficiencies are achieved despite the rather narrow absorption spectrum of the cyanine dye. The results obtained lead the way to the application of related dyes harvesting solar light in other spectral

domains, particularly in the near-infrared domain. The fact that planar bilayer structures can be used obviates the need for tedious control of film morphology and therefore simplifies technological implementation. Importantly, this class of photographic dyes has been studied for more than a century. Large scale production of cyanine dyes is already occurring, which promises competitive materials prices for the emerging organic solar cell technology.

ABSTRACT

The novel *p*-dopant 2,3-di(*N*-phthalimido)-5,6-dicyano-1,4-benzoquinone (BAPD) was synthesized and compared to the state-of-the-art dopant F_4TCNQ. BAPD shows a higher evaporation temperature and thermal stability than F_4TCNQ, presumably due to its higher molecular weight and bulkiness. The efficiency of the host-to-dopant electron transfer as well as the diffusion characteristics of the *p*-dopants were investigated by ultraviolet photo emission spectroscopy (UPS) and X-ray photo emission spectroscopy (XPS). Although BAPD is a less strong *p*-dopant than F_4TCNQ, the lower diffusion tendency and higher thermal stability of this new class of dopants forms an attractive potential for the lifetime improvement of organic electronic devices.

1. Introduction

Organic light-emitting diodes (OLEDs) are expected to become the next-generation flat-panel displays and solid-state lighting devices because of their low power consumption, high brightness, high contrast and low costs [1–5]. For commercialization, OLEDs have to combine high power conversion efficiencies with long lifetimes. Therefore, highly efficient charge carrier injection and transport combined with a low driving voltage is required [6]. Hole-injection and transport can be enhanced by the introduction of an organic electron-accepting dopant [7–9] into an appropriate hole-transport layer (HTL). However, problematic issues still remain. Organic *p*-dopants such as F_4TCNQ have high vapor pressures due to their small molecular weight. Thus, these compounds tend to evaporate at very low temperatures complicating the control of the evaporation rate. Furthermore, it has been shown that small dopants tend to diffuse [10–12]. This diffusion precludes the fabrication of interface-only doped devices [10,12,13] because dopants tend to penetrate into other layers of the device and thereby change their composition and electrical properties. Hence, a change of the performance and lifetime of an OLED could be expected. In order to study the influence of the molecular weight and structure on the diffusion of the *p*-dopants in an OLED, a new *p*-dopant 2,3-di(*N*-phthalimido)-5,6-dicyano-1,4-benzoquinone (BAPD, Fig. 1a) was developed. The molecular weight of BAPD is higher than this of F_4TCNQ (M_{BAPD} = 448 g/mol, M_{F_4TCNQ} = 276 g/mol). Furthermore, the bulky structure of BAPD could lower the diffusion tendency. The calculated [14] electron affinity (EA) of BAPD is slightly lower (4.8 eV) than this of F_4TCNQ (5.0 eV).

2. Synthesis of BAPD

A mixture of 2,3-dichloro-5,6-dicyano-benzoquinone (33.4 g, 147.1 mmol) and potassium phthalimide (54.5 g, 294.2 mmol) in acetonitrile (500 ml) was stirred under

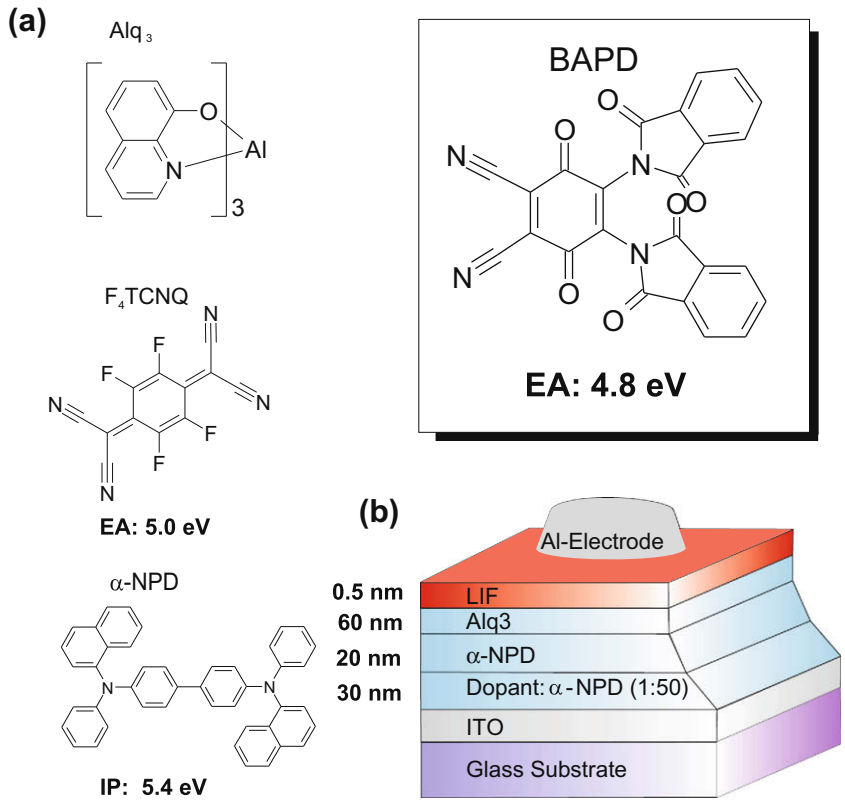

Fig. 1. (a) Chemical structure of the emitter Alq_3, *p*-dopants F_4TCNQ and BAPD with EA, HTL α-NPD with IP. (b) Schematic OLED device setup.

reflux for 12 h. The resulting deep brown suspension was filtrated. The solid was washed three times with warm water and one time with ethanol. After drying at 100 °C under vacuum, a yellow solid was obtained (9.3 g, 14%). ^{1}H NMR (D_2SO_4), δ = 7.6 ppm; Maldi-MS: m/z = 447.9. Before device fabrication, BAPD was purified by gradient zone sublimation.

3. Thermal stability and evaporation temperature

Due to the high molecular weight, BAPD evaporates at (150 ± 10) °C under a vacuum of 10^{-7} mbar. As a comparison, F_4TCNQ evaporates at (90 ± 10) °C at the same pressure. Since the thermal stability of the dopants is important for the processability, thermogravimetric analysis (TGAs) were made. Here, BAPD shows a higher thermal stability ((1 ± 0.4)% weight loss at 403 °C) than F_4TCNQ ((1 ± 0.4)% weight loss at 268 °C).

4. Doping and diffusion investigation by UPS and XPS

In order to understand the basic behavior of BAPD and F_4TCNQ in organic electronic devices, ultraviolet photo emission spectroscopy (UPS, He I, 21.22 eV) measurements were made. The doping strength of BAPD and F_4TCNQ was investigated on samples of type *A* (Figs. 2a and 2b): a 10 nm thick α-NPD layer, doped with 5 weight % of BAPD or F_4TCNQ, respectively. The HOMO level of a 30 nm undoped α-NPD layer acts as the reference (−1.52 eV below Fermi level ε_F). The stronger the dopant, the closer the HOMO level of sample type *A* will move to ε_F. The HOMOs of the BAPD- and F_4TCNQ-doped α-NPD layers are located at −0.89 and −0.57 eV with respect to ε_F. This means that BAPD acts as a *p*-dopant, but less strong than F_4TCNQ. This confirms the weaker electron-accepting properties of BAPD compared to F_4TCNQ, predicted by the lower calculated EA (*vide supra*).

Diffusion of dopants into the light-emitting layer of OLEDs could decrease their lifetime due to exciton quenching [15]. This quenching process is caused by the lower band gap of the radical anion of the dopant compared to the emitter. Therefore, the diffusivity of F_4TCNQ was investigated in comparison to BAPD with X-ray photo emission spectroscopy (XPS, Al Kα, 1486.6 eV) and UPS. In the XPS analysis, the F(1 s) core level intensities of a 10 nm thick pure F_4TCNQ layer, evaporated on a silicon wafer, were compared to samples in which this F_4TCNQ layer was covered by 30 nm of α-NPD. The measurements were carried out 24 h after the evaporation, in order to get a realistic picture of the diffusivity of the dopant. The amount of fluorine present on top of the 10 nm thick pure F_4TCNQ layer was measured to be (10.6 ± 0.3)%. When the F_4TCNQ layer was covered by 30 nm of α-NPD, only (0.2 ± 0.1)% of fluorine could be detected.

For BAPD, a comparable XPS investigation was difficult due to its elemental composition: In contrast to F_4TCNQ,

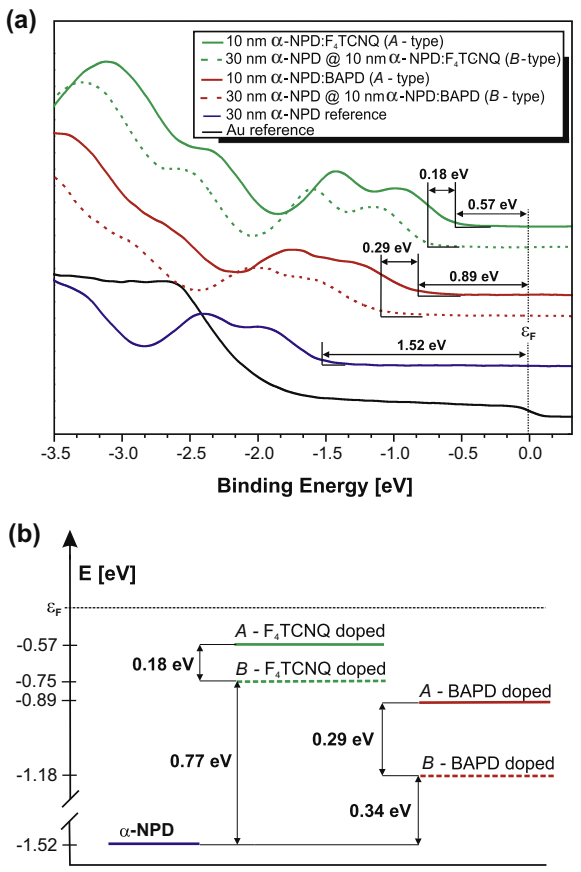

Fig. 2. UPS measurements of the HOMO level with respect to the Fermi level ε_F of (a) 5% homogeneously doped α-NPD layers (sample type *A*) in comparison to doped layers additionally covered by 30 nm of undoped α-NPD (sample type *B*). The respective cutoffs followed the HOMO shifts accordingly. The Fermi energy of the UPS measurement setup was calibrated with reference to gold. (b) Energy gap between ε_F and the HOMO of BAPD (F_4TCNQ)-doped *B*-type samples in relation to the doped *A*-type samples and the undoped α-NPD reference.

BAPD contains no atoms which make the molecule clearly distinguishable from the α-NPD surface.[1] To overcome this problem the diffusion of dopants was indirectly probed by UPS. This investigation was based on the fact, that UPS probes only the energetic conditions right at the surface [16].

Two types of samples were prepared: 10 nm thick 5% homogeneously doped α-NPD layers (sample type *A*, *vide supra*) and samples which doped layers were additionally covered by 30 nm of undoped α-NPD (sample type *B*, Fig. 2). As a reference an undoped 30 nm thick α-NPD layer was chosen. To relate the characteristic shifts (ε_F-HOMO) of the energy levels of sample type *A* and *B* (see Fig. 2) to the diffusivity of the respective dopants, one has to understand the relation of the Fermi energy ε_F to the doping density N_A within the samples:

[1] (4.6 ± 0.1)% of oxygen atoms were found by XPS on all samples, caused by the air exposure during the sample transfer into the measurement set up. Therefore, it was not possible to distinguish between oxygen included in the BAPD molecule and oxygen originated from the air exposure.

The electron density in the conduction band of an intrinsic semiconductor is given by

$$n(T) = 2\int_{E_{CB}}^{\infty} g_{\varepsilon}^{CB}(\varepsilon') f_{FD}(\varepsilon', \varepsilon_F, T)\, d\varepsilon', \tag{1}$$

where g_{ε}^{CB} is the normalized density of states in the conduction band and $f_{FD}(\varepsilon', \varepsilon_F, T)$ is the Fermi–Dirac distribution function. Congruently, the hole density created by thermal excitations are given by

$$p(T) = 2\int_{-\infty}^{E_{VB}} D_{\varepsilon}^{VB}(\varepsilon')[1 - f_{FD}(\varepsilon', \varepsilon_F, T)]\, d\varepsilon'. \tag{2}$$

At room temperature, the valence electrons of an *p*-doped semiconductor are rather excited into the acceptor states E_A of the *p*-dopant than into the conduction band of the semiconductor. Thus, the normalized density of states g_{ε}^{A} of the acceptor states E_A of the *p*-dopant determines the electron density and Eq. (1) changes to

$$n(T) = 2\int_{E_A}^{\infty} g_{\varepsilon}^{A}(\varepsilon') f_{FD}(\varepsilon', \varepsilon_F, T)\, d\varepsilon'. \tag{3}$$

It has been reported for F_4TCNQ-doped amorphous hole-transport layers, that small doping concentrations lead to deep acceptor states E_A [17]. Thus, the occupation probability of the respective states can be described in good approximation by Boltzmann statistics. Therefore, Eqs. (2) and (3) can be written as

$$n(T) = \underbrace{2\int_{E_A}^{\infty} g_{\varepsilon}^{A}(\varepsilon') \exp\left(-\frac{\varepsilon' - E_A}{k_B T}\right) d\varepsilon'}_{\equiv n_0(T)} \cdot \exp\left(-\frac{E_A - \varepsilon_F}{k_B T}\right), \tag{4}$$

$$p(T) = \underbrace{2\int_{-\infty}^{E_{VB}} g_{\varepsilon}^{VB}(\varepsilon') \exp\left(-\frac{E_{VB} - \varepsilon'}{k_B T}\right) d\varepsilon'}_{\equiv p_0(T)} \cdot \exp\left(-\frac{\varepsilon_F - E_{VB}}{k_B T}\right), \tag{5}$$

and are considered to be also qualitatively applicable to describe organics. Assuming a very narrow density of acceptor states g_{ε}^{A}, the integral in Eq. (4) is similar to the doping density N_A ($n_0(T) \approx N_A$). Since semiconductors are not charged, the relation $n(T) = p(T)$ is valid. Therefore, using Eqs. (4) and (5) the position of the Fermi level $\varepsilon_F(T)$ within the organic semiconductor can be derived to

$$\varepsilon_F(T) = \frac{E_A + E_{VB}}{2} + \frac{k_B T}{2} \ln \frac{p_0(T)}{N_A}. \tag{6}$$

If two samples (A and B) contains the same matrix molecule (in this case α-NPD) but different doping concentrations N_A^A and N_A^B of the same dopant, the energetic difference of their respective Fermi-levels $\varepsilon_F^A(T)$ and $\varepsilon_F^B(T)$ can be derived as

$$\varepsilon_F^A(T) - \varepsilon_F^B(T) = \frac{k_B T}{2} \ln\left(\frac{N_A}{N_B}\right). \tag{7}$$

Thus, the energetic difference of the Fermi-levels is only dependent on the respective doping densities.

If BAPD and F_4TCNQ would show the same diffusivity, the energy difference between the HOMO's of the respectively doped samples *A* and *B* should be identical according

to Eq. (7). BAPD sample *B* shows a difference of 0.29 eV compared to BAPD sample *A*, whereas F_4TCNQ sample *B* shows a difference of 0.18 eV compared to F_4TCNQ sample *A* (Fig. 2). This 0.11 eV larger shift for BAPD sample *B* indicates that the surface of the BAPD sample *B* is less *p*-doped than the respective F_4TCNQ sample *B*.

It has to be stated here, that in contrast to F_4TCNQ-doped samples, where we see a clear presence of fluorine in XPS, no diffusion of dopants for the BAPD case could also explain the discrepancy in Fermi level shift between F_4TCNQ and BAPD. In such cases, reported studies say, that the Fermi-levels of two organic layers are determined by dipole rather than band bending, i.e., flat bands [18,19]. The energy alignment mechanism on such interface is out of scope of our paper. However, in any case, our measurement verifies, that the dopant diffusivity of BAPD is smaller than that of F_4TCNQ.

5. Device fabrication and results

In order to investigate the potential of the new dopant, standard OLED devices [20] with a 2 weight % (wt%) *p*-doped α-NPD hole injection layer (HIL) and an Alq_3 emitter were prepared (Fig. 1b). The hole injection layer (HIL), consisting of F_4TCNQ or BADP doped into *N,N*-diphenyl-*N,N* '-bis(1-naphthyl)-1,1-biphenyl-4,4-diamine (α-NPD), was formed by vacuum co-evaporation on a precleaned indium tin oxide (ITO) substrate with a sheet resistance of 15 ohm/sq. On top of the HIL, organic layers were vacuum deposited at a base pressure of 1×10^{-7} mbar. α-NPD was deposited as the hole-transport layer (HTL), and aluminium tris(8-hydroxyquinoline) (Alq_3) was deposited as an electron-transporting emitting layer. Finally, LiF and aluminium were vacuum-deposited using a metal shadow mask to define an emitting area of 4.0 mm^2. After the cathode formation, the devices were encapsulated using UV-epoxy resin and a glass lid with desiccant under a dry nitrogen atmosphere (<1:0 ppm H_2O and O_2). Luminance and operational lifetime measurements were carried out at room temperature.

Here, the BAPD-doped device showed a slightly higher turn-on voltage (Fig. 3a), which is in agreement to the expected less efficient host-to-dopant electron transfer from α-NPD to BAPD compared to F_4TCNQ (*vide supra*). The current efficiency of the BAPD-doped device was slightly higher than the F_4TCNQ-doped device (3.6 and 2.6 cd/A at 500 cd/m^2, respectively), which could be due to a better charge-carrier balance in the diode. The diode lifetimes ($t_{1/2}$) were measured at a constant current density of 125 mA/cm^2. Under these conditions the BAPD device showed a lifetime of 140 h at an initial luminance of L_0 = 4800 cd/m^2 (see Fig. 3b). In contrast, the F_4TCNQ-doped device showed a shorter lifetime of 122 h at an initial luminance of L_0 = 3350 cd/m^2. Calculated with an extrapolation factor [21,22] n = 1.5, the lifetimes at an initial luminance of 500 cd/m^2 are estimated to be 4200 h for BAPD-doped devices and 2100 h for F_4TCNQ-doped devices, respectively. The improvement in device lifetime can be a result from the reduced diffusion of BAPD and/or from the better charge-carrier balance.

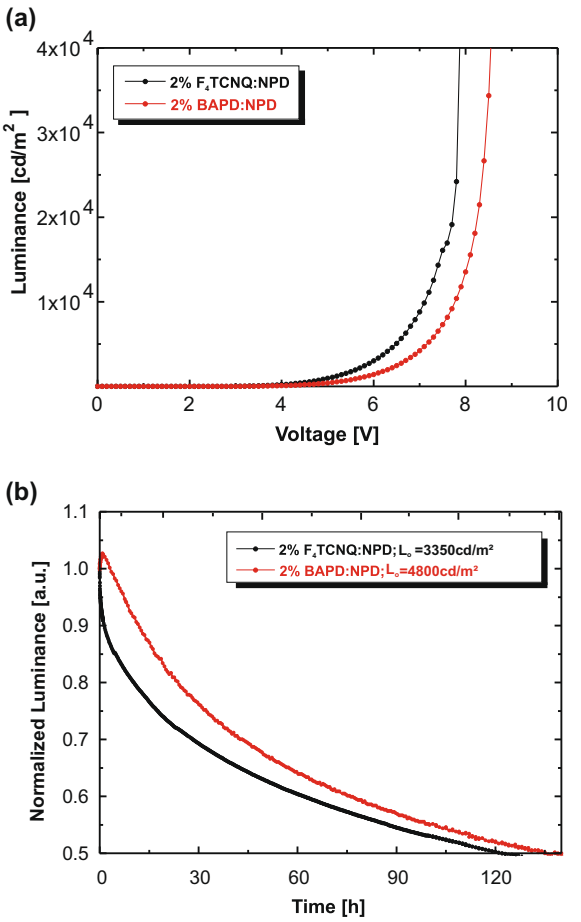

Fig. 3. (a) Luminance vs. bias voltage and (b) lifetimes of 5 wt% F_4TCNQ and BAPD doped α-NPD/Alq_3-based OLED devices. The lifetime measurement data was acquired based on a constant current density of 125 mA/cm^2 for both device types.

6. Conclusion

In summary, the novel *p*-dopant 2,3-di(*N*-phthalimido)-5,6-dicyano-1,4-benzoquinone (BAPD) was synthesized and compared to the state-of-the-art dopant F_4TCNQ. BAPD shows a significant higher evaporation temperature and thermal stability than F_4TCNQ. This can be an important advantage in handling and processing the material in mass-production. Furthermore, it was shown with precise UPS and XPS measurements, that the diffusion capability of BAPD was effectively lowered. Although BAPD is a less strong *p*-dopant than F_4TCNQ, the lower diffusion tendency and higher thermal stability of this new class of organic dopants forms an attractive potential for the lifetime improvement of organic electronic devices. Further improvements on the electron-accepting strength of this class of dopants are under way.

ABSTRACT

The interface trap level in top-contact pentacene thin-film transistors (TFTs) is obtained by displacement current measurement (DCM) during device operation at temperatures ranging from 260 to 340 K. The carrier injection voltage at the source electrode (V_{inj}) was measured from the displacement current and found to be independent of temperature, suggesting an Ohmic contact at the Au source electrode/pentacene interface. On the contrary, the threshold voltage (V_{th}) depended on the temperature. The interface trap level at the pentacene/gate dielectric interface was estimated as 36 meV from the temperature dependence of the interface trap density. By using the DCM method, it becomes possible to demonstrate the carrier injection and transport properties of top-contact pentacene TFTs.

1. Introduction

The device operation of organic thin-film transistors (OTFTs) is described by carrier injection at the source and the drain electrodes/organic thin-film interface and carrier transport in the channel at the organic thin-film/gate dielectric interface [1–4]. In top-contact OTFTs, carrier sheet formation at the organic thin-film/gate dielectric interface under the source and drain electrodes is related to both the carrier injection and the carrier transport properties, because the injected carriers accumulate as the carrier sheet and are then transported through the channel. Therefore, simultaneously measuring the carrier injection and carrier transport properties of OTFTs is important from the viewpoint of their practical use. Carrier injection properties have been investigated by Kelvin probe microscopy [5–7], four-terminal measurement [8,9], and displacement current measurement (DCM) [10–13]. DCM is a direct method that is used to probe the carrier motion, and therefore, it has been used to study the carrier injection properties in organic semiconductors having electrode/organic thin-film/dielectric/electrode sandwiched structures [12,13]. Recently, we developed a DCM method for top-contact OTFTs that expands the conventional DCM method to three-terminal devices under OTFT device operation [14,15].

In this study, we examine the interface trap level by the DCM method in top-contact pentacene TFTs during device operation. The carrier injection voltage at the source electrode (V_{inj}) and threshold voltage (V_{th}) are evaluated at temperatures ranging from 260 to 340 K. The interface trap level at the pentacene/gate dielectric interface is evaluated from the temperature dependence of the interface trap density.

2. Experimental

A schematic diagram of the DCM for top-contact OTFTs is shown in Fig. 1. Because we have already provided a detailed description of DCM for top-contact OTFTs in our previous paper [14,15], we only provide a brief outline here. The displacement current (I_{dis}) and channel current (I_{DS}) are evaluated from simultaneously measured source (I_S) and drain (I_D) currents under the application of a triangular-wave gate voltage (V_{GS}) and a constant drain voltage

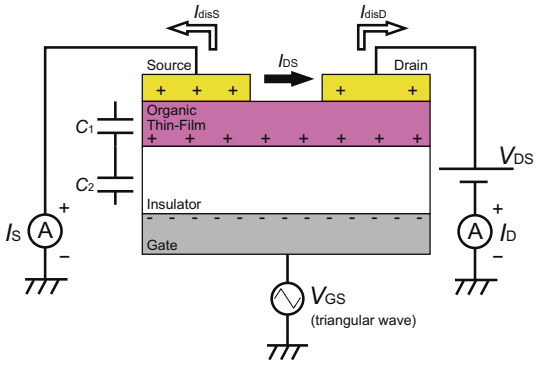

Fig. 1. Schematic diagram of displacement current measurements (DCMs) for top-contact organic thin-film transistors. Displacement current ($I_{dis} = I_{disS} + I_{disD}$) and channel currents ($I_{DS}$) are evaluated from simultaneously measured I_S and I_D under the application of a triangular-wave gate voltage (V_{GS}) and a constant drain voltage (V_{DS}). Capacitances C_1 and C_2 are the capacitance of the gate dielectric layer and the organic thin-film layer, respectively.

(V_{DS}). I_{dis} is obtained by differentiating the sum of the charges $Q_{S,D}$ that are stored on the source/drain electrodes $\sigma_{1S,1D}$ on the organic thin-film/gate dielectric interface $\sigma_{S,D}$ under the source/drain electrodes as

$$I_{dis} = -\frac{d(Q_S + Q_D)}{dt} = I_S + I_D, \tag{1}$$

where $Q_{S,D}$ are given by

$$\begin{aligned} Q_S &= (\sigma_{1S} + \sigma_S)S_S = \int_{t_S}^{t} (-I_S - I_{DS})dt, \\ Q_D &= (\sigma_{1D} + \sigma_D)S_D = \int_{t_D}^{t} (-I_D + I_{DS})dt. \end{aligned} \tag{2}$$

Here $S_{S,D}$ are the areas of the source/drain electrodes and $t_{S,D}$ is the time when $Q_{S,D}$ becomes zero. I_{dis} is re-expressed as

$$I_{dis} = -(C_S(t)S_S + C_D(t)S_D)\frac{dV_{GS}}{dt}, \tag{3}$$

where $C_{S,D}(t)$ is the effective capacitance between the gate electrode and the source/drain electrodes, respectively [15]. When the displacement current at the source electrode equals that at the drain electrode, I_{DS} is given by

$$I_{DS} = \frac{-I_S + I_D}{2}. \tag{4}$$

Pentacene OTFTs with an SiO_2/polyimide dual-gate dielectric structure were fabricated as follows [14–17]. An n^+-Si substrate was used as a gate electrode; SiO_2 (thickness: 90 nm, relative dielectric constant: $\varepsilon_r = 3.9$), was subsequently spin-coated on this substrate with a polyimide film (thickness: 40 nm, Nissan SUNEVER, Nissan Chemical Industries Ltd., Japan) [18,19]. Then, a pentacene thin-film (thickness: 30 nm, $\varepsilon_r = 3.2$, Sigma Aldrich, Japan) as an active electronic material was uniformly formed by physical vapor deposition through a shadow mask. Finally, source/drain gold electrodes were deposited by thermal evaporation through a shadow mask. The area of the pentacene thin-film was the same as the sum of the areas of the channel and source/drain electrodes, and the areas of the drain and source electrodes were both 8.9×10^{-3} cm^2. The channel length (L) was 11 μm, which was directly measured using an optical microscope, and the channel width (W) was 1.0 mm. The lengths (L_e) of the source and drain electrodes were both 0.89 mm, and the ratio of L/L_e was 1.2×10^{-2}. The displacement current is given by Eq. (1). The crystalline grain size of pentacene was measured to be 20–40 μm using a polarized optical microscope. Pentacene OTFTs were exposed to air after both the pentacene thin-film and gold source/drain electrodes were formed by evaporation. The pentacene OTFTs were annealed at 400 K for 9 h in nitrogen atmosphere before the measurements, and all measurements were conducted in nitrogen atmosphere. I_S and I_D were simultaneously measured using a digitizing storage oscilloscope (Hioki, 8855) under the application of a constant drain voltage (V_{DS}) and a triangular-wave gate voltage (V_{GS}) in the top-contact pentacene OTFTs. V_{GS} was applied as three cycles of triangular waves with an amplitude of 24 $V_{p\text{-}p}$ at 1 kHz. During all the measurements, V_{DS} was maintained at −12.9 V. Transfer curves were also measured using a conventional semiconductor parameter analyzer (Agilent 4156C). The measurements were performed at temperatures of 260, 280, 300, 320, and 340 K.

3. Results and discussion

Fig. 2 shows the experimental transfer curves (square-root of channel current ($\sqrt{I_{DS}}$) − V_{GS} and I_{dis} − V_{GS} characteristics) for temperatures ranging from 260 to 340 K. I_{DS} and I_{dis} were calculated from simultaneously measured I_S and I_D using Eqs. (1) and (4).

From the $\sqrt{I_{DS}} - V_{GS}$ characteristics in Fig. 2, the linear relationships between $\sqrt{I_{DS}}$ and V_{GS} were clearly observed, and the field-effect mobility μ and threshold voltage V_{th} were evaluated as 0.50, 0.60, 0.67, 0.78, and 0.97 cm^2/V s and −3.8, −3.4, −2.8, −2.3, and −0.69 V at temperatures of 260, 280, 300, 320, and 340 K, respectively. There existed peaks in the V_{GS} range between V_{th} and ~4 V at every temperature. This is because I_{disS} was not equal to I_{disD} in this V_{GS} range, as discussed in detail later.

Because carrier transport in the polycrystalline pentacene thin-film is thermally activated in the temperature range employed in this study, the field-effect mobility μ is given by $\mu = \mu_0 \exp(-\Delta/k_B T)$, where μ_0 is the prefactor field-effect mobility; Δ is the activation energy; and k_B is the Boltzmann constant [17]. Fig. 3 shows the Arrhenius plot of μ obtained from Fig. 2. The mobilities obtained by the two methods were identical at every temperature, and Δ was determined to be ~60 meV. This value is in good agreement with the reported value for the case of polycrystalline pentacene field-effect transistors [20].

From the $I_{dis} - V_{GS}$ characteristics in Fig. 2, I_{dis} had constant values of ±20 μA in the range of $-12 < V_{GS} < -7$ V and ±16 μA in the range of $5 < V_{GS} < 12$ V.

Because a pentacene thin-film acts as a p-type semiconductor, the carrier (hole) is fully injected from the interface of the pentacene/gold source and drain electrode at $V_{GS} = -12$ V, and the effective capacitance $C(t)$ in Eq. (3) consists of only the capacitance of the dual-gate dielectric

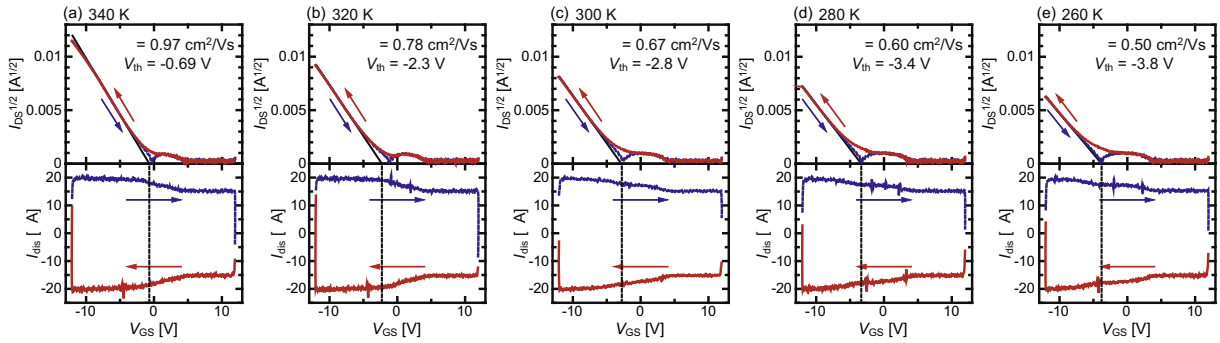

Fig. 2. Experimental $\sqrt{I_{DS}} - V_{GS}$ and $I_{dis} - V_{GS}$ characteristics at (a) 340, (b) 320, (c) 300, (d) 280, and (e) 260 K. Backward and forward gate voltage sweeps are plotted in red solid line and blue dashed line, respectively. Fig. 3. Temperature dependence of field effect mobility μ.

layer (C_2). The calculated value of capacitance from the displacement current of 20 μA at $V_{GS} = -12$ V is 24 nF/cm^2, which is in good agreement with the theoretical capacitance C_2 of 25 nF/cm^2. On the other hand, the injection of carriers is inhibited in the range of $V_{GS} > V_{inj}$. In this case, the effective capacitance $C(t)$ is the series capacitance of the pentacene thin-film layer C_1 and C_2. The capacitance evaluated from the displacement current of 16 μA is 18 nF/cm^2; this value, too, corresponds well with the theoretical capacitance of $(1/C_1 + 1/C_2)^{-1} = 20$ nF/cm^2.

On comparing the temperature dependence of the $I_{dis} - V_{GS}$ characteristics shown in Fig. 2, different slopes were observed where the displacement current increases in the range $-3 < V_{GS} < 5$ V on the backward bias sweep; the slope increased at lower temperatures, and in particular, a two-step increase in I_{dis} was observed at 280 and 260 K for $-8 < V_{GS} < -4$ V and $-2 < V_{GS} < 4$ V, respectively. This discrepancy can be explained as follows.

Fig. 4 shows the temperature dependence of the $(I_S - I_c)$, $(I_D - I_c)$, and $(I_S - I_D)$ relationships in the backward bias sweeps of V_{GS}, where I_c is the displacement current at the source or drain electrode due to the series capacitance of the pentacene thin-film and the dual-gate dielectric of $(1/C_1 + 1/C_2)^{-1}$. $(I_S - I_c)$ begins increasing at a certain voltage corresponding to the charge injection voltage at the source electrode, V_{inj}, as indicated in each figure. V_{inj} is larger than V_{th}; therefore, the increase in I_S is attributed to carrier injection at the source electrode [14,15]. V_{inj} was evaluated to be 4.1, 4.5, 4.5, 4.4, and 4.6 V at 260, 280, 300, 320, and 340 K, respectively. The positive values of V_{inj} suggest that the gate dielectric is negatively charged.

Note that both V_{inj} and the shapes of I_S for $V_{th} < V_{GS} < V_{inj}$ were independent of temperature. Therefore, the interface of the pentacene thin-film and the Au source electrode interface was believed to be an Ohmic contact. A carrier sheet was formed smoothly at the interface between the pentacene and the gate dielectric below the source electrode at every temperature for $V_{GS} < V_{inj}$. Therefore, the carrier is ready to transport at the channel for $V_{GS} < V_{inj}$.

On the other hand, carrier sheet formation below the drain electrode is delayed and it has a temperature dependence because the $(I_D - I_c)$ relationship exhibited a temperature dependence; in Fig. 4, peaks appeared at around V_{th} at temperatures of 340 and 320 K, but no peaks were observed at lower temperatures. Because the direction of the displacement current at the drain electrode is negative and the channel current is positive, the peak around V_{th} in the $(I_D - I_c)$ relationship is due to the displacement current at the drain electrode side. At higher temperatures (320 and 340 K), the carrier sheet below the drain electrode spread faster than that at temperatures lower than 300 K. In Fig. 2, a two-step increase in I_{dis} was clearly observed at low temperatures. These results correspond well with the slow spread of the carrier sheet under the drain electrode.

The interface trap level is evaluated as follows. The temperature dependence of V_{th} and V_{inj} are shown in Fig. 5a. When there exists an interface trap at the channel, the interface trap densities directly depend on the threshold voltage and carrier injection voltage [21,22]. As carriers accumulate at the source electrode edge at $V_{GS} = V_{inj}$, the effective interface trap density is given by

$$\Delta N = \frac{C_2}{q}(-V_{th} + V_{inj}), \tag{5}$$

where q is the unit charge. The temperature dependence of the effective interface trap density is given by

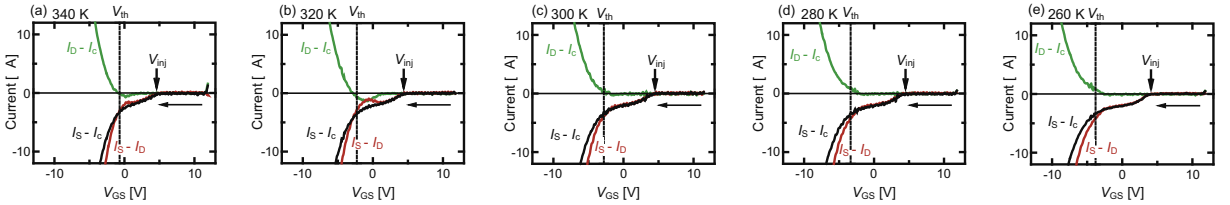

Fig. 4. Experimental $(I_S - I_c)$, $(I_D - I_c)$, and $(I_S - I_D)$ relationships in backward V_{GS} sweep, where I_c is the displacement current at the source or drain electrode due to the series capacitance of the pentacene thin-film and the dual-gate dielectric of $(1/C_1 + 1/C_2)^{-1}$ ($I_c = -7.6$ μA).

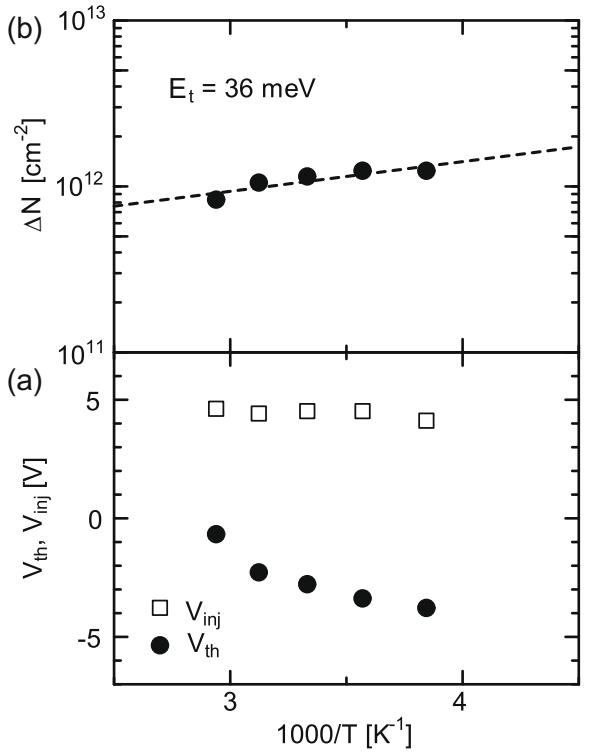

Fig. 5. (a) Temperature dependence of carrier injection voltage (V_{inj}) and threshold voltage (V_{th}). (b) Temperature dependence of effective interface trap density $\left(\Delta N = \frac{C_2}{q}(-V_{th} + V_{inj})\right)$.

$$\Delta N = N_t e^{\frac{E_t}{kT}}, \tag{6}$$

where N_t is the total concentration of the interface trap and E_t, the interface trap level [23]. Fig. 5b shows the temperature dependence of ΔN. From the slope of Fig. 5a, E_t is obtained as 36 meV, suggesting that a shallow interface trap exists at the interface between the pentacene and the gate dielectric. It should be noted that E_t is of the same order as the activation energy of the mobility (60 meV). The effect of the shallow interface trap appears only in the subthreshold region; however, it affects the closing of the channel and subthreshold swing. Consequently, the threshold voltage shift is due to the shallow interface trap, and a constant V_{inj} is due to Ohmic contact. These results provide us with information that can be used to understand the carrier injection and transport properties of top-contact pentacene TFTs.

4. Conclusions

The interface trap level in top-contact pentacene TFTs is demonstrated from the temperature dependence of the interface trap density as the difference between the threshold voltage and carrier injection voltage at the source electrode. The interface trap level has been evaluated as 36 meV, suggesting that the threshold voltage shift is due to a shallow interface trap. For the development of OTFTs, DCM for top-contact OTFTs is a simple and powerful technique to understand the carrier transport properties and carrier injection properties.

ABSTRACT

Several groups reported fabrication method of organic solar cells through a stamping technique by using PDMS mold. Although PDMS is a good stamp material, they have several problems in polymer transfer printing, especially when we use organic solvent (easily swollen). In this study, the polymer solar cells with an active layer of BHJ are successfully prepared via a simple imprinting transfer technique with help of UV-curable resin-coated polycarbonate (UV-PC) film. The transferred BHJ active layer from UV-PC film was perfectly retained at 220-nm thick on top of the PEDOT:PSS-coated ITO glass, and the device showed enhanced J_{sc} and device performance up to 3.19% after insertion of the TiO_x interlayer between the active layer and Al cathode. This unique imprinting transfer can be considered as an alternative approach to replace the spin-coating when the matters, pre-coated layers are affected by the solvent for next layer.

1. Introduction

Photovoltaic (PV) devices based on thin films from [6,6]-phenyl C61-butyric acid methyl ester (PCBM) and conjugate polymers of bulk-heterojunction (BHJ) have been extensively studied throughout the world due to their great potential applicability and the advantages of easy solution processability. They can be used as a flexible devices over large areas since solution-processable organic materials are adapted [1–6]. BHJ is considered more efficient than corresponding bilayer devices, since it would offer a high interfacial contact area between the donor and acceptor from the charge separation point of view. Thus BHJ make it possible to enhance charge carrier mobility, resulting in an increase of photocurrent density of polymer based PVs [7–10]. Recently, it is very common to use a single spin-coating process to prepare BHJ active layer. However, it is not proper to use the spin-coating process not only to fabricate photovoltaic modules with large areas but also to deposit the BHJ active layer to specific regions of the substrate [11,12].

Recently, Chu and Ho's group reported fabrication method for organic solar cells through a stamping technique [13]. Even though they used non-destructive solvent treatment method to spin-coat BHJ film on the top of PDMS surface this technique is still time-consuming process. In this study, it will be demonstrated that the active layer of BHJ polymer solar cells can be prepared via a simple transfer of active layer by stamping technique by using Norland Optical Adhesive 63 UV-curable resin based stamp without any surface pre-treatment. The BHJ film prepared from the imprinting transfer process has enough uniformity due to following fairly smooth silicon wafer substrate that it is comparable to with that from the spin-coating process.

2. Experimental details

BHJ polymer solar cells from an imprinting technique with a UV-curable resin-coated polycarbonate (UV-PC) film were prepared sequentially by making the UV-curable film and fabricating the device. Fig. 1 shows the schematic diagram of the proposed device structure via active layer transfer by stamping technique with UV-PC film. First, a cleaned silicon wafer was treated by Trichloro-(1H,1H,2H,2H-perfluorooctyl) silane (FOTS) to reduce the surface energy, and then the self assembled monolayers (SAMs) were created to perform the imprinting process [14]. Norland Optical Adhesive 63 UV-curable resin was dropped on the flexible PC film and flattened with a common roller. Then the PC film was cured by UV and the silicon wafer was detached. The UV-PC film with very uniform morphology was realized and the maximum size was only dependent on the area of used silicon wafer. Fig. 2(a) shows the photograph of the UV-PC film. The active layer of BHJ composed of P3HT and PCBM from the chlorobenzene was spin-coated 900 rpm for 5 s of 220 nm thickness on the UV-PC film. Since the total UV-PC film has a few millimeter thickness, the UV-PC film can act as a well supporting substrate during the spin-coating process. Note that even though the spin-coating method was used to cover the active BHJ film on the UV-PC film as a model case in this study, the BHJ film can be also formed by spread method or spray method, both of which are suitable for the roll-to-roll process. Secondly, ITO glass was washed by organic solvents chloroform, acetone, and isopropanol to remove residual impurities. It was then exposed to oxygen plasma treatment for 10 min to reform the ITO surface. A hole transporting materials that is widely known for conducting polymer, poly(3,4-ethylene dioxythiophene:poly(styrene sulfonate) (PEDOT:PSS, Baytron P), was spin-coated up to ~40-nm thickness on the ITO. The PEDOT:PSS-coated ITO was thermal treated using a digital controllable hotplate for 5 min at 200 °C to evaporate the water. Then BHJ was transferred from the PC film to the continuously heated PEDOT:PSS-coated ITO substrate on a hotplate at 90 °C (Fig. 1). The UV-PC film with the active layer was attached to the heated substrate as shown in Fig. 2(c) and rubbed with cotton swabs to induce uniform force until the coated active layer from the UV-PC film was adhered to the heated substrate. The coated active layer from the UV-PC film was transferred to the PEDOT:PSS-coated ITO easily and reproducibly, when the stamping process was conducted with simple physical force at suitable temperature. After detaching the UV-PC film, the entirely transferred active layer onto the PEDOT:PSS-coated ITO could be observed as shown in Fig. 2(d). Then, the spin-coated TiO_x interlayer with ~3-nm thick was added on the active layer to increase the device performance [15]. Polymer solar cells as a reference device were prepared by the following steps. A spin-coated BHJ device with a solution consisting of poly(3-hexylthiophene)/[6,6]-phenyl C61-butyric acidmethyl ester (P3HT/PCBM) at a ratio of 1:0.6, the same as the former imprinting transferred BHJ film, was spin-coated on the top of PEDOT:PSS-coated ITO substrate that was washed

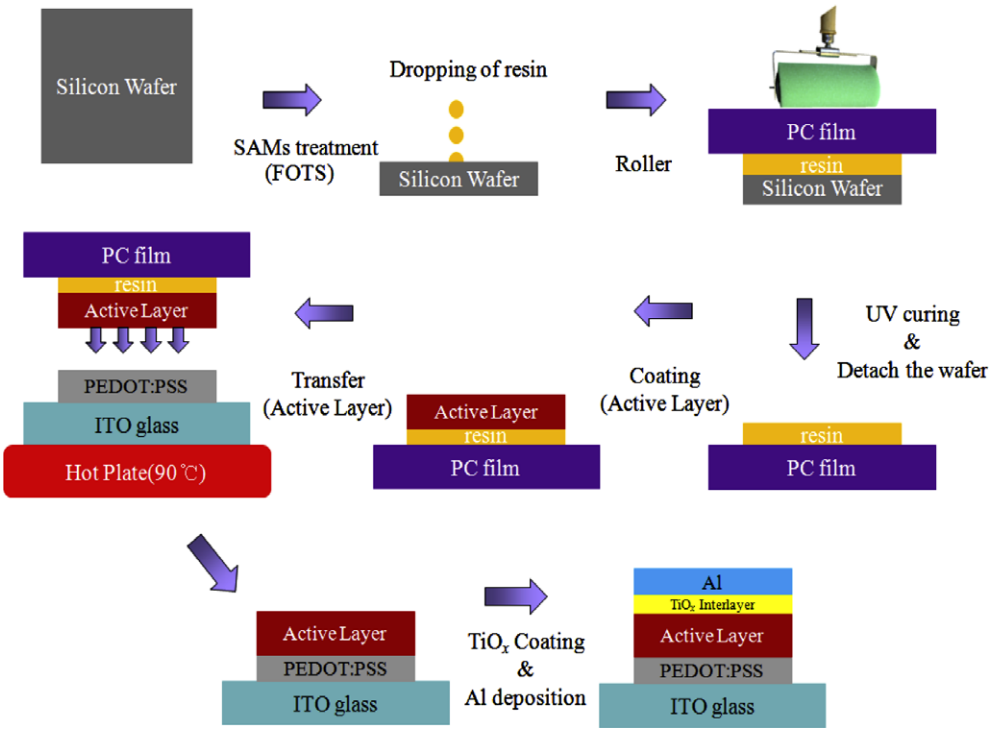

Fig. 1. Schematic diagram of the proposed device structure via an active layer transfer by stamping technique of the BHJ with a UV-curable resin-coated polycarbonate film.

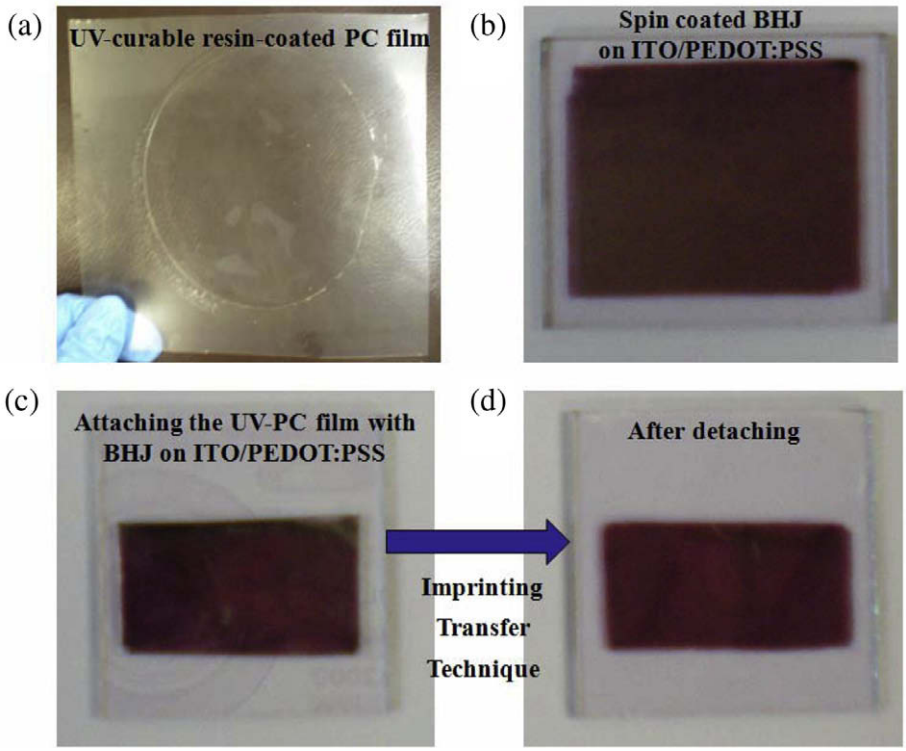

Fig. 2. (a) UV-curable resin-coated polycarbonate film, (b) spin-coated BHJ active layer on ITO/PEDOT:PSS substrate, (c) attaching the UV-PC film with BHJ active layer on ITO/PEDOT:PSS substrate, and (d) after detaching the UV-PC film with BHJ active layer on ITO/PEDOT:PSS substrate.

by the proper cleaning process. Next, TiO_x interlayer with ~3-nm thickness was added on the active layer with 2500 rpm for 30 s. Subsequently, an Al metal electrode with a 150 nm thickness was uniformly deposited under a pressure of 1.6×10^{-6} torr by thermal evaporator. Thermal annealing process was executed by directly placing the fabricated devices on a hotplate at 150 °C for 30 min. The active area device with the deposited Al electrode was confirmed in the range of 3–6 mm^2 by video microscope (SV-35). The photocurrent (J)–potential (V) curves were measured using a Oriel 91193, a 1000 W xenon lamp that served as the light source to the device. Its intensity was calibrated using a silicon reference cell (Fraunhofer ISE, Certificate No. C-ISE269) with an illumination rating of AM 1.5 by using a Keithley 2400 source measure unit.

3. Results and discussion

In order to confirm the morphologies of the device's BHJ, we investigated the AFM (Atomic Forced Microscope) images as shown in Fig. 3, which demonstrate the changing of surface morphology. Fig. 3(a) shows the spin-coated BHJ top-surface of 220-nm thick after the post annealing process. The RMS (root mean square surface roughness) value of the spin-coated BHJ surface is 17.1 nm. Fig. 3(c) shows the surface morphology of imprinting transferred BHJ film of 220-nm thick after the post annealing process. Interestingly, the RMS value of the imprinted BHJ is much lower as 2.2 nm. Fig. 4 shows the photocurrent (J)–potential (V) curves of devices with spin-coated BHJ film and imprinting transferred BHJ film. The spin-coated BHJ cell exhibits a conversion efficiency of 2.51%, whereas the imprinted BHJ cell exhibits 2.22%. In comparison to the spin-coated BHJ or imprinted BHJ, the short-circuit current (J_{sc}) decreased from 8.58 to 7.17 mA/cm^2, and the fill factor was not significantly changed, from 0.51 to 0.52. The decreased overall cell performance in the case of the imprinting method might be attributed to the lower surface roughness of the transferred active layer, which decreased the contact area between Al and the active layer. More roughened surface contacted with Al cathode can increase the cell performances [17]. On the other hand, the open circuit voltage (V_{oc}) of the imprinted BHJ cell increased from 0.57 to 0.60 since the smoother surface morphology leads to reduced series resistance at the BHJ/cathode interface and also better interfacial contact between ITO and BHJ from providing the regular force of the rubbing process [16]. Recently, our group showed that TiO_x interlayer inserted between the active layer and a metal cathode can enhance electron harvesting efficiency due to the more enhanced interfacial contact quality [16,18]. Fig. 4 also shows the J–V curves of devices prepared from two different methods with TiO_x interlayer. The spin-coated BHJ with TiO_x cell showed increased performance up to 2.98%. The critical factor of the increased efficiency was J_{sc}. The J_{sc} value of the spin-coated BHJ is 8.58 mA/cm^2 while the spin-coated BHJ with the TiO_x interlayer shows 9.14 mA/cm^2. The

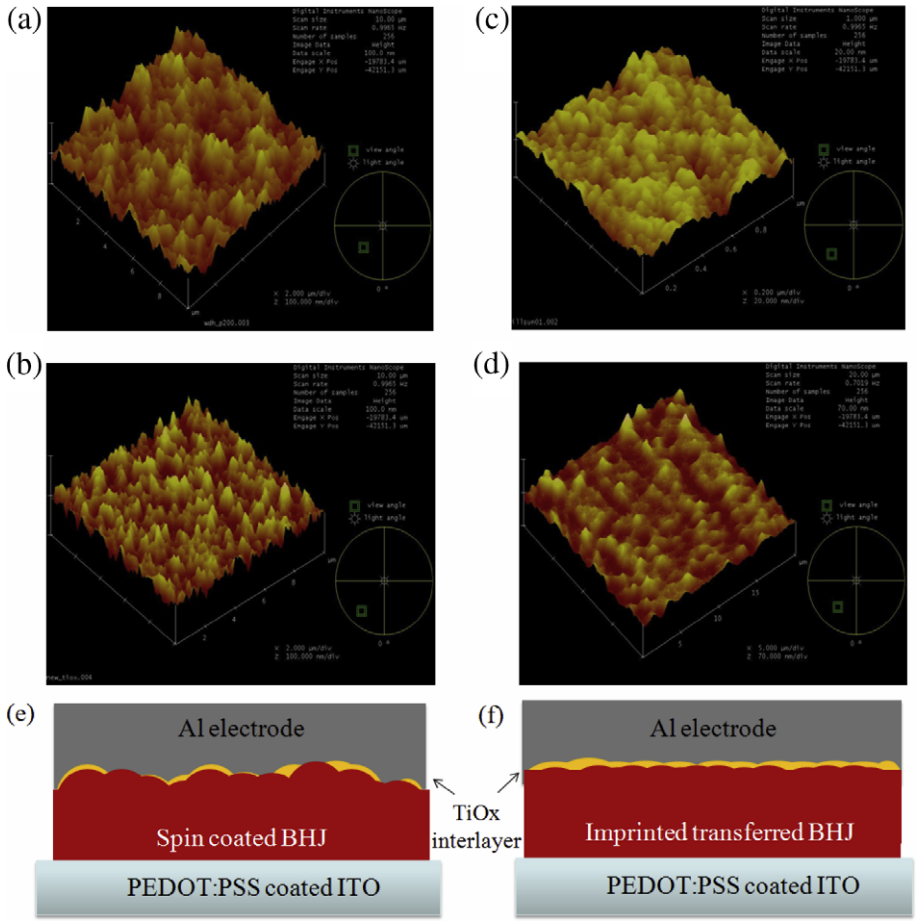

Fig. 3. (a) AFM 3D images of the spin-coated BHJ, (b) AFM 3D images of the spin-coated BHJ with TiO_x interlayer, (c) AFM 3D images of the imprinted transferred BHJ using UV-curable resin-coated polycarbonate film, (d) AFM 3D images of the imprinted transferred BHJ with TiO_x interlayer using UV-curable resin-coated polycarbonate film, (e) whole device sequential inner structure of spin-coated BHJ with TiO_x interlayer on the PEDOT:PSS-coated ITO, and (f) whole device sequential inner structure of imprinted transferred BHJ with TiO_x interlayer on the PEDOT:PSS-coated ITO.

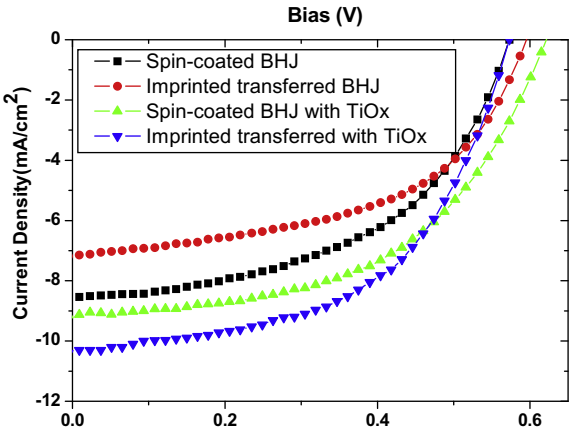

Fig. 4. *J–V* curves of devices with spin-coated BHJ or spin-coated BHJ with TiO_x and imprinted transferred BHJ or imprinted transferred BHJ with TiO_x interlayer. (-■- Spin-coated BHJ, -●- Imprinted transferred BHJ, -▲- Spin-coated BHJ with TiO_x interlayer, -▼- Imprinted transferred BHJ with TiO_x interlayer).

photocurrent value of the device with imprinting transferred BHJ is 7.17 mA/cm^2 while the imprinted transferred BHJ with the TiO_x interlayer shows 10.34 mA/cm^2 and 3.19%. Therefore, it suggests improved charge carrier harvesting since the TiO_x interlayer can serve a special role of hole blocking and as an electron transporting layer [15,18,19]. Interestingly, the effect of the TiO_x interlayer in the transferred system was much stronger than that of the spin-coated system. Generally, the effects of the TiO_x interlayer have been influenced by its thickness. Yoshikawa group reported that the conductivity of TiO_x is strongly influenced by its thickness [20]. Even though inserted TiO_x have shown various positive effects on cell performance and long-term stability the conductivity of 50-nm thick TiO_x film decreased to 1/5 value of 10-nm thick TiO_x film. Park's group and Yoshikawa group reposted the optimum thickness of TiO_x layer was between 3 and 5 nm [15,20]. As can be seen in Figs. 3(b) and S3, the RMS of the spin-coated BHJ surface with TiO_x interlayer is 13.4 nm, whereas, the imprinting transferred BHJ with TiO_x interlayer from Fig. 3(d) is 5.851 nm. When the surface roughness of the spin-coated systems with and without TiO_x

interlayer was compared, the surface roughness of the active film decreased after the insertion of the TiO_x interlayer. This means that the undulation surface might be covered by the TiO_x interlayer, and the thickness of the inserted TiO_x layer is not uniformed too, because the thin TiO_x layer is coated by following the pre-coated fluctuated active layer surface, as shown in Fig. 3(e). However, the morphology of imprinting transferred BHJ shows much lower RMS value, which means it had nearly flat surfaces due to the imprinting of the rubbing process. As shown in Fig. 3(f), this flat surface would help the formation of more uniform thickness of the TiO_x interlayer resulting in maximization of its positive functions. Therefore, we believe that this uniform surface morphology of the active layer prepared from the transfer by stamping technique can have more positive characteristics when the technique is combined with the TiO_x interlayer system.

4. Conclusions

It has been successfully demonstrated that the polymer solar cells with transferred BHJ film can be fabricated via a simple active layer transfer by stamping technique with help of a UV-curable resin-coated polycarbonate film. Due to the UV-curable resin that is not soluble in the organic solvent chlorobenzene, the BHJ film was coated on the flexible polymer substrate and then successfully transferred to the heated PEDOT:PSS-covered ITO glass substrate with smother surface. After inserting the TiO_x interlayer, the imprinting transferred BHJ device shows higher J_{sc} and better performance compared to the device with a spin-coated BHJ with TiO_x interlayer. This method will serve to the meaningful application of polymer solar cells fabricated by the imprinting process.

OLED

ABSTRACT

The photophysical properties of asymmetric indolylmaleimide derivatives (**4a–4f**) with a variety of aryl substituents at C(4) were analyzed. Their absorption spectra vary in the region of aryl substituents, whereas their emission spectra are nearly identical. The red emission is derived from a charge transfer transition along the indole-maleimide chromophore, which is not significantly disturbed by the introduction of a nearby aryl substituent at C(4). All compounds displayed intensive emissions both in solutions as well as in the form of solid films. Light emitting diodes (LED) were fabricated successfully by using the neat film of these materials as emitters. The performance of devices among the series varied slightly as a result of different film morphology. The best performance was found on the compound with a pyrene substituent, which exhibited optimal external quantum efficiency of 1.1%. This device could be turned on at 4 V and reached to optimal brightness of 9750 cd/m^2. The red color, according to the Commission Internationale de l'Eclairage (CIE) coordinates at (0.65, 0.34), was very close to pure red (0.67, 0.33).

1. Introduction

In the past decades active research investigations in bis-indolylmaleimides have revealed that these derivatives may exhibit multidisciplinary functionalities on diversified applications, such as biological activities for pharmaceutical applications [1] and luminescent properties for making organic light emitting diodes (OLEDs), etc. The structure of maleimides expresses a twofold symmetry when both substituents on the olefinic carbons are identical. Remarkable performances utilizing such type of symmetrical compounds as red color emitters in OLEDs have been done by Chow and Chen et al. [2,3]. It has been recognized, however, that maleimides containing a single substituent at C(3) may exhibit distinctively different physical properties from those of the symmetrical ones [4]. Through our works we have found that the characteristic red emission deriving from the asymmetrical derivatives is nearly as intensive as those of the symmetrical ones. The mono-substituted maleimide derivatives provide us an extra flexibility for modifying the structure of the second substituent at C(4), so that a tuning mechanism may be developed on this site. Either the chromaticity or intensity of the luminescence may become adjustable by the control of the second substituent. Report on unsymmetrical maleimides in this regard is not known to date, except a limited number of publications focusing on certain special pharmaceutical effects [5].

In this report a serial of asymmetric indolylmaleimide derivatives, in which an aromatic group is attached at C(4), are prepared. Their physical properties are discussed with a particular attention on their photo and electroluminescence (EL) characteristics. Maleimides are among the rare materials, which display intensive red emission even in the solid state, e.g., either in crystalline form or as neat film. Their high quantum efficiencies are attributed to their ready formation of an amorphous phase with a high glass-transition temperature. The asymmetric indolylmaleimides are expected to perform in a similar manner.

Successful fabrication of LEDs with these materials will light up a way toward future designs in luminescence sensors. A typical device made of asymmetric indolylmaleimide with a pyrene substituent, as shown in this report, can be turned on at 4.0 V with maximal intensity close to 10^4 cd/m^2.

2. Experimental section

2.1. General

Absorption spectra were taken on a Hewlett–Packard 8453 spectrophotometer and emission spectra on a Hitachi F-4500 fluorescence spectrophotometer. Infrared spectra were taken on a Perkin–Elmer L118-F000 FT-IR spectrometer. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AV400, AV500, and AMX400 superconducting FT spectrometers. The signal of tetramethylsilane at δ 0.00 was used as an internal standard for both. Microanalyses were completed on a Perkin–Elmer 2400 elemental analyzer. Mass spectra were taken on a Joel JMS 700 double-focusing spectrometer, facilitated with fast atom bombardment (FAB) for sample ionization. Melting points of the compounds were uncorrected. Differential scanning calorimetry was done on a Perkin–Elmer DCS-7 instrument. The fluorescence quantum yields were determined in CH_3CN solutions at 293 K against Nile red as a reference (Φ_p = 0.78) [6]. Cyclic voltammetry measurements were carried out on a BAS 100B electrochemical analyzer equipped with a conventional three-electrode system, i.e., glassy carbon, platinum wire, and $Ag/AgNO_3$ as the working, counter, and reference electrodes, respectively. Degassed acetonitrile solution with 0.1 M tetra-*n*-butylammonium hexafluorophosphate was used as the electrolyte. E_{ox} and E_{red} data were measured with reference to a ferrocene (F_c) internal standard that was calibrated to +350 mV against a $Ag/AgNO_3$ reference electrode [7]. Measurements were taken at a scan rate of 100 mV s^{-1}. The aromatic boronic acids for the preparation of **4a**–**4f** were prepared according to the known procedures [8].

2.2. Device fabrication

Indium-tin oxide (ITO)-coated glass with a sheet resistance of <50 Ω was used as the substrate. Pretreatment of ITO includes a routine chemical cleaning using detergent and alcohol in sequence, followed by oxygen plasma cleaning. Thermal evaporation of organic materials was carried out using ULVAC Cryogenics at a chamber pressure of 10^{-6} Torr. Two types of devices were configured with ITO/NPB/dye/BCP/AlQ_3/LiF/Al (device A) and ITO/NPB/dye/TPBI/LiF/Al (device B), in which NPB, BCP, AlQ_3, TPBI, and *m*-MTDATA are 4,4′-bis[*N*-(1-naphthyl)-*N*-phenylamino]biphenyl, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, tris(8-hydoxyquinolinato)aluminum, 2,2′,2″-(1,3,5-benzenetriyl)tris(1-phenyl-1H-benzimidazole), and 4,4′,4″-tris(phenyl-*m*-methylphenylamino)triphenylamine, respectively. Current–voltage and light–intensity measurements were done on a Keithley 2400 source meter and a Newport 1835C optical meter equipped with a Newport 818-ST silicon photodiode, respectively. All measurements were completed under ambient conditions.

2.3. Synthesis of 3-bromo-4-(2′-methyl-3′-indolyl)-N-benzylmaleimide (*2*)

To a toluene (130 mL) solution of 2-methylindole (3.35 g, 25.50 mmol) was added MeMgCl (25.51 mmol, 9.87 mL) at an ice temperature under a nitrogen atmosphere, and the solution was warmed up gradually and heated to 60 °C for 1 h. A solution of 2,3-dibromo-*N*-benzylmaleimde (**1**, 8.00 g, 23.2 mmol) in toluene (10 mL) was then added to the above solution, and it was heated to reflux for 3 h. The solution was cooled to room temperature and diluted with ethyl acetate (100 mL). The solution was washed successively with 1 N aqueous HCl (150 mL), water (150 mL) and brine (150 mL). The solution was then dehydrated over anhydrous $MgSO_4$ and evaporated *in vacuo* to form a yellow residue. The crude product was purified by silica gel column chromatography with ethyl acetate/hexane (1:4) as an eluant to afford compound **2** in 68% yield (6.22 g, 15.8 mmol). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.51 (s, 3H), 4.81 (s, 2H), 7.06–7.10 (m, 1H), 7.12–7.16 (m, 1H), 7.28–7.30 (m, 1H), 7.33–7.36 (m, 2H), 7.38–7.43 (m, 3H), 7.47–7.49 (m, 1H), 10.78 (s, 1H). ^{13}C NMR (CD_3COCD_3, 125 MHz): δ 13.34, 41.99, 101.52, 110.99, 119.94, 120.45, 121.67, 126.66, 127.50, 127.84, 128.54, 136.09, 136.87, 138.41, 139.63, 165.86, 168.53, 205.14, 205.40. IR (KBr, cm^{-1}): 3381, 3061, 3033, 2928, 2360, 2340, 1773, 1709, 1624, 1610, 1458, 1430, 1396, 1351, 739, 431.

2.4. General procedure for synthesis of *3a*–*3f*

To a THF (20 mL) solution of **2** (2.00 g, 5.1 mmol) under a nitrogen atmosphere was added $Pd(PPh_3)_4$ (0.29 g, 0.25 mmol), and the mixture was stirred for 15 min. To the mixture was then added arylboronic acid (5.6 mmol) and aqueous Na_2CO_3 (2 M, 20 mL). Then the mixture was heated to 110 °C for 24 h. After cooled to room temperature, the mixture was diluted with ethyl acetate (20 mL) and followed by washing with water (30 mL) and brine (30 mL). It was then dehydrated over anhydrous $MgSO_4$ and dried *in vacuo*, forming a red residue. The crude product was purified by silica gel column chromatography with ethyl acetate/hexane (1:3) as an eluant to afford compounds **3a**–**3f**.

3-(2′-Methyl-3′-indoyl)-4-phenyl-*N*-benzylmaleimide (**3a**). Physical data of **3a** (yield 70%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.25 (s, 3H), 4.83 (s, 2H), 6.82–6.86(m, 1H), 7.01–7.05 (m, 2H), 7.25–7.37 (m, 7H), 7.45–7.56 (m, 2H), 7.57–7.59 (m, 2H), 10.61 (s, 1H). ^{13}C NMR (CD_3COCD_3, 125 MHz): δ 13.37, 41.69, 102.63, 110.37, 120.07, 120.15, 121.84, 126.51, 127.55, 128.21, 128.54, 128.61, 129.05, 129.36, 130.28, 133.25, 134.04, 135.73, 136.94, 137.17, 170.63, 171.00. IR (KBr, cm^{-1}): 3396, 2362, 2342, 2091, 1771, 1760, 1748, 1734, 1697, 1650, 1637, 1492, 1474, 1458, 1431, 1399, 742, 694, 440. HRMS (*m*/*z*) calcd for $C_{26}H_{20}N_2O_2$: 392.1525 (M^+); found: 392.1526. LRMS (FAB, *m*/*z*): 392.1 (M^+, 100%), 307.2 (17), 154.1 (76), 136.2 (57), 107.2 (23).

3-(2′-Methyl-3′-indoyl)-4-(4″-biphenyl)-*N*-benzylmaleimide (**3b**). Physical data of **3b** (yield 47%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.29 (s, 3H), 4.84 (s, 2H), 6.82–6.86 (m, 1H), 7.01–7.07 (m, 2H), 7.26–7.30 (m, 1H), 7.34–7.38 (m, 4H), 7.41–7.47 (m, 4H), 7.58–7.60 (m, 2H), 7.62–7.65 (m, 2H), 7.68–7.70 (m, 2H), 10.75 (s, 1H). ^{13}C NMR (CD_3COCD_3, 125 MHz): δ 12.84, 41.32, 102.42, 110.73, 119.60, 120.03, 121.36, 126.34, 126.66, 127.33, 127.65, 127.83, 128.47, 128.83, 129.82, 129.96, 132.88, 133.42, 136.41, 137.43, 137.80, 139.89, 141.06, 170.35, 170.85. IR (KBr, cm^{-1}): 3383, 3059, 3031, 2922, 2361, 2340, 1793, 1761, 1734, 1698, 1651, 1622, 1606, 1457, 1429, 1399, 746, 697, 452. HRMS (*m*/*z*) calcd for $C_{32}H_{24}N_2O_2$: 469.1910 ([M+H]$^+$); found: 469.1910. LRMS (FAB, *m*/*z*): 469.1 ([M+H]$^+$, 100%), 307.2 (17), 154.1 (36).

3-(2′-Methyl-3′-indoyl)-4-(1-naphthyl)-*N*-benzylmaleimide (**3c**). Physical data of **3c** (yield 62%). ^{1}H NMR (acetone-d_6, 400 MHz): δ 2.02 (s, 3H), 4.90 (s, 2H), 6.73–6.77 (m, 1H), 6.92–6.96 (m, 1H), 7.13–7.22 (m, 3H), 7.30–7.32 (m, 1H), 7.36–7.40 (m, 3H), 7.48–7.51 (m, 3H), 7.57–7.59 (m, 1H), 7.76–7.78 (m, 1H), 7.84–7.92, (m, 2H), 10.43 (s, 1H). ^{13}C NMR (acetone-d_6, 125 MHz): δ 12.74, 41.57, 119.59, 119.73, 121.23, 125.21, 125.72, 125.76, 125.82, 127.18, 127.38, 127.89, 128.27, 128.54, 128.73, 128.96, 129.40, 130.66, 133.63, 134.12, 135.95, 136.99, 137.50, 138.08, 170.43, 170.87. IR (KBr, cm^{-1}): 3419, 2361, 2340, 2090, 1793, 1760, 1748, 1733, 1698, 1649, 1635, 1490, 1458, 1429, 1398, 740, 698, 489. HRMS (*m*/*z*) calcd for $C_{30}H_{22}N_2O_2$: 443.1760 ([M+H]$^+$); found: 443.1753. LRMS (FAB, *m*/*z*): 443.2 ([M+H]$^+$, 100%), 154.1 (14).

3-(2′-Methyl-3′-indoyl)-4-(9-anthryl)-*N*-benzylmaleimide (**3d**). Physical data of **3d** (yield 50%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.02 (s, 3H), 4.96 (s, 2H), 6.57–6.61 (m, 1H), 6.83–6.87 (m, 1H), 7.05–7.08 (m, 1H), 7.10–7.13 (m, 1H), 7.30–7.39 (m, 4H), 7.39–7.45 (m, 3H), 7.52–7.54 (m, 2H), 8.01–8.03 (m, 4H), 8.59 (s, 1H), 10.40 (s, 1H).^{13}C NMR (CD_3COCD_3, 125 MHz): δ 12.78, 41.76, 102.97, 110.46, 119.46, 121.11, 125.22, 126.01, 126.10, 127.22, 127.37, 127.76, 128.57, 128.68, 129.99, 131.39, 133.70, 135.75, 137.59, 138.17, 170.29, 170.85. IR (KBr, cm^{-1}): 3365, 3055, 2924, 2854, 2361, 2340, 1794, 1770, 1748, 1734, 1699, 1650, 1635, 1622, 1457, 1431, 1397, 734, 435. HRMS (*m*/*z*) calcd for $C_{34}H_{24}N_2O_2$: 493.1916 ([M+H]$^+$); found: 493.1908. LRMS (FAB, *m*/*z*): 493.1 ([M+H]$^+$, 72%), 154.1 (76).

3-(2′-Methyl-3′-indoyl)-4-(9-phenanthryl)-*N*-benzylmaleimide (**3e**). Physical data of **3e** (yield 62%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.92 (s, 3H), 4.92 (s, 2H), 6.71–6.74 (m, 1H), 6.90–6.91 (m, 1H), 7.15–7.18 (m, 1H), 7.25–7.27 (m, 1H), 7.30–7.32 (m, 2H), 7.38–7.40 (m, 2H), 7.51–7.58 (m, 4H), 7.59–7.67 (m, 1H), 7.86–7.90 (m, 2H), 7.94 (s, 1H), 8.76 (d, J = 8.4 Hz, 2H), 10.41 (s, 1H). ^{13}C NMR (CD_3COCD_3, 125 MHz): δ 12.95, 41.70, 103.16, 110.60, 119.67, 119.87, 121.31, 122.65, 122.91, 126.16, 126.71, 126.91, 127.45, 127.63, 127.99, 128.60, 129.04, 130.24, 130.37, 131.15, 134.08, 135.99, 137.28, 137.52, 138.26, 170.51, 170.94. IR (KBr, cm^{-1}): 3423, 2360, 2339, 1793, 1771, 1748, 1733, 1698, 1650, 1636, 1474, 1457, 1428, 1397, 740, 429. HRMS (*m*/*z*) calcd for $C_{34}H_{24}N_2O_2$: 493.1916 ([M+H]$^+$); found: 493.1908. LRMS (FAB, *m*/*z*): 493.1 ([M+H]$^+$, 100%), 391.2 (16), 107.2 (47).

3-(2′-Methyl-3′-indoyl)-4-(1-pyrenyl)-*N*-benzylmaleimide (**3f**). Physical data of **3f** (yield 61%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 2.08 (s, 3H), 4.95 (s, 2H), 6.64–6.68 (m, 1H), 6.85–6.89 (m, 1H), 7.12–7.16 (m, 2H), 7.30–7.34 (m, 1H), 7.38–7.42 (m, 2H), 7.53–7.55 (m, 2H), 7.89 (d, J = 9.3 Hz, 1H), 8.00–8.03 (m, 2H), 8.09–8.13 (m, 1H), 8.14–8.20 (m, 3H), 8.25–8.27 (m, 2H), 10.40 (s, 1H). ^{13}C NMR (CD_3COCD_3, 100 MHz): δ 13.27, 42.11, 103.49, 111.00, 120.16, 120.24, 121.74, 124.29, 124.70, 124.91, 125.33, 125.66, 125.77, 126.18, 126.28, 127.35, 127.41, 127.57, 127.78, 128.38, 128.71, 128.89, 129.06, 130.68, 131.12, 131.85, 134.52, 136.31, 137.31, 137.66, 138.69, 171.003, 171.56. IR (KBr, cm^{-1}): 3394, 3050, 2360, 2340, 1794, 761, 1749, 1734, 1699, 1650, 1636, 1623, 1457, 1428, 1397, 741, 455. HRMS (*m*/*z*) calcd for $C_{36}H_{24}N_2O_2$: 517.1916 ([M+H]$^+$); found: 517.1909. LRMS (FAB, *m*/*z*): 517.2 ([M+H]$^+$, 100%), 391.2 (5), 307.1 (6), 289.1 (5), 154.1 (33), 136.1 (21).

2.5. General procedure for the synthesis of ***4a–4f***

Compound **3** (1.40 g, 3.6 mmol) was mixed with NaOH (0.16 g, 4.0 mmol) in acetone (20 mL) under a nitrogen atmosphere, while the solution turned gradually from red to dark blue. To the mixture was added benzyl bromide (0.64 mL, 5.4 mmol), then the solution was stirred with a magnetic bar for 30 min, while the color tuned red. The mixture was stirred for another 1 h at room temperature. The reaction was quenched by the addition of water (500 mL), then was filtered. The filtrate was concentrated *in vacuo*, and the product was recrystallized from CH_2Cl_2 and hexane as red crystalline solids.

3-(2′-Methyl-*N*-benzyl-3′-indoyl)-4-(phenyl)-*N*-benzylmaleimide (**4a**). Physical data of **4a** (yield 78%). ^{1}H NMR (CD_2Cl_2, 400 MHz): δ 2.00 (s, 3H), 4.83 (s, 2H), 5.28 (s, 2H), 6.94–7.21 (m, 4H), 7.22–7.23 (m, 1H), 7.27–7.35 (m, 10H), 7.47–7.54 (m, 4H). ^{13}C NMR (CD_2Cl_2, 100 MHz): δ 12.17, 41.78, 46.75, 102.94, 109.57, 120.38, 120.45, 121.91, 125.95, 126.19, 127.50, 127.64, 128.30, 128.36, 128.63, 128.82, 129.13, 129.39, 130.47, 133.64, 134.26, 137.04, 137.07, 137.19, 138.32, 170.70, 170.99. IR (KBr, cm^{-1}): 3032, 2940, 2361, 1762, 1701, 1621, 1467, 1454, 1399, 1350, 739, 432. HRMS (*m*/*z*) calcd for $C_{33}H_{26}N_2O_2$: 482.1994 (M$^+$); found: 482.1986. LRMS (FAB, *m*/*z*): 482.2 (M$^+$, 100%), 307.1 (20), 136.1 (40). Anal. calcd for $C_{33}H_{26}N_2O_2$: C, 82.13; H, 5.43; N, 5.81, found: C, 82.01; H, 5.47; N, 5.93.

3-(2′-Methyl-*N*-benzyl-3′-indoyl)-4-(4″-biphenyl)-*N*-benzylmaleimide (**4b**). Physical data of **4b** (yield 75%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 2.12 (s, 3H), 4.84 (s, 2H), 5.31 (s, 2H), 6.97–7.04 (m, 3H), 7.10–7.13 (m, 1H), 7.20–7.21 (m, 1H), 7.26–7.30 (m, 1H), 7.33–7.35 (m, 4H), 7.37–7.41 (m, 3H), 7.43–7.46 (m, 2H), 7.50–7.52 (m, 6H), 7.62–7.64 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 12.57, 41.94, 46.84, 103.18, 109.46, 120.60, 120.74, 122.08, 125.97, 126.88, 126.94, 127.69, 128.78, 128.87, 129.76, 133.15, 133.42, 136.77, 137.29, 138.18, 140.15, 141.51, 170.73, 171.01. IR (KBr, cm^{-1}): 3032, 2938, 2362, 2342, 1762, 1700, 1618, 1456, 1418, 1398, 1350, 740, 425. HRMS (*m*/*z*) calcd for $C_{39}H_{30}N_2O_2$: 558.2307 (M$^+$); found: 558.2310. LRMS (FAB, *m*/*z*): 558.2 (M$^+$, 100%), 154.1 (25), 105.2 (10).

3-(2′-Methyl-*N*-benzyl-3′-indoyl)-4-(1″-naphthyl)-*N*-benzylmaleimide (**4c**). Physical data of **4c** (yield 76%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 1.63 (br, 3H), 4.93 (s, 2H), 5.08 (br, 2H), 6.54 (br, 2H), 7.04–7.15 (m, 7H), 7.30–7.40 (m, 4H), 7.46–7.60 (m, 6H), 7.53–7.81 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 11.99, 42.16, 46.44, 109.25, 120.16, 120.76, 121.97, 125.28, 125.48, 125.75, 125.91, 127.22, 127.74, 128.49, 128.68, 128.74, 128.88, 129.22, 129.82, 133.56, 136.39, 136.79, 136.91, 138.51, 170.71, 170.11. IR (KBr, cm^{-1}): 3060, 2361, 1762, 1701, 1650, 1619, 1455, 1420, 1397, 1351, 738, 697, 442. HRMS (*m*/*z*) calcd for $C_{37}H_{28}N_2O_2$: 533.2229 ([M+H]$^+$); found:533.2238. LRMS (FAB, *m*/*z*): 533.2 ([M+H]$^+$, 22%), 307.2 (45), 136.1 (56). Anal. calcd for $C_{37}H_{28}N_2O_2$: C, 83.43; H, 5.30; N, 5.26, found: C, 82.87; H, 5.39; N, 4.93.

3-(2′-Methyl-*N*-benzyl-3′-indoyl)-4-(9″-anthryl)-*N*-benzyl maleimide (**4d**). Physical data of **4d** (yield 76%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.60 (s, 3H), 4.98 (s, 2H), 5.01 (s, 2H), 6.34 (d, J = 8 Hz, 2H), 6.86–6.87 (m, 1H), 6.89–7.00 (m, 2H), 7.01–7.04 (m, 2H), 7.09–7.10 (m, 1H), 7.27–7.28 (m, 2H), 7.30–7.34 (m, 2H), 7.35–7.53 (m, 4H), 7.58 (d, J = 8 Hz, 2 H), 7.77 (d, J = 9 Hz, 2H), 7.94 (d, J = 9 Hz, 2H), 8.41 (s, 1H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 12.09, 42.30, 46.24, 109.17, 119.87, 120.73, 121.89, 124.23, 125.11, 125.19, 125.81, 128.74, 128.87, 129.29, 129.76, 131.31, 134.03, 136.36, 136.70, 136.87, 138.79, 139.60, 170.60, 170.97. IR (KBr, cm^{-1}): 3056, 2398, 2361, 2341, 1734, 1702, 1619, 1470, 1455, 1396, 1351, 732, 493. HRMS (*m*/*z*) calcd for $C_{41}H_{30}N_2O_2$: 582.2307 (M$^+$); found: 582.2300. LRMS (FAB, *m*/*z*): 583.1 ([M+H]$^+$, 100%), 391.3 (6), 289.1 (10), 136.2 (21). Anal. calcd for $C_{41}H_{30}N_2O_2$: C, 84.51; H, 5.19; N, 4.81, found: C, 84.07; H, 5.25; N, 4.93.

3-(2′-Methyl-3′-indoyl)-4-(9-phenanthryl)-*N*-benzylmaleimide (**4e**). Physical data of **4e** (yield 82%). ^{1}H NMR (CD_3COCD_3, 400 MHz): δ 1.63 (br, 3H), 4.95 (s, 2H), 5.04 (br, 2H), 6.48 (br, 2H), 7.03–7.19 (m, 7H), 7.30–7.34 (m, 1H), 7.37–7.40 (m, 2H), 7.50–7.66 (m, 7H), 7.85–7.91 (m, 2H), 8.59–8.63 (m, 2H). ^{13}C NMR (CD_3COCD_3, 125 MHz): δ 12.16, 42.24, 46.41, 109.34, 120.29, 120.88, 122.04, 122.54, 125.43, 126.55, 126.79, 127.67, 127.81, 128.68, 128.74, 128.94, 130.47, 130.62, 131.01, 133.91, 136.33, 136.59, 136.83, 136.93, 138.72, 170.77, 171.11. IR (KBr, cm^{-1}): 3061, 3032, 2939, 2361, 2341, 1761, 1702, 1619, 1469, 1453, 1397, 1350, 740, 432. HRMS (*m*/*z*) calcd for $C_{41}H_{30}N_2O_2$: 583.2386 ([M+H]$^+$); found:583.2386. LRMS (FAB, *m*/*z*): 583.2 ([M+H]$^+$, 100%), 391.3 (4), 289.2 (4), 154.1 (21), 107.2 (6). Anal. calcd for $C_{41}H_{30}N_2O_2$: C, 84.51; H, 5.19; N, 4.81, found: C, 84.15; H, 5.24; N, 4.75.

3-(2′-Methyl-*N*-benzyl-3′-indoyl)-4-(1-pyrenyl)-*N*-benzylmaleimide (**4f**). Physical data of **4f** (yield 84%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 1.30 (br, 3H), 4.97 (s, 2H), 5.02 (br, 2H), 6.29 (br, 2H), 7.02–7.03 (m, 4H), 7.30–7.34 (m, 1H), 7.37–7.40 (m, 2H), 7.58–7.60 (m, 3H), 7.74 (br, 3H), 7.96–8.01 (m, 3H), 8.05–8.07 (m, 3H), 8.14–8.20 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz): δ 12.01, 42.28, 46.39, 101.92, 103.88, 109.35, 119.61, 120.23, 120.89, 122.06, 124.42, 124.83, 124.98, 125.32, 125.60, 125.69, 126.08, 127.09, 127.29, 128.38, 138.78, 129.02, 130.09, 130.08, 130.59, 120.90, 131.11, 131.44, 131.86, 132.26, 134.23, 136.21, 136.56, 136.90, 137.03, 138.55, 170.87, 171.41. IR (KBr, cm^{-1}): 3034, 2936, 2362, 2339, 1761, 1700, 1618, 1470, 1455, 1396, 1350, 737, 431. HRMS (*m*/*z*) calcd for $C_{43}H_{30}N_2O_2$: 607.2386 ([M+H]$^+$); found: 607.2386. LRMS (FAB, *m*/*z*): 607.1 ([M+H]$^+$, 100%), 154.1 (20), 136.2 (14). Anal. calcd for $C_{43}H_{30}N_2O_2$: C, 85.12; H, 4.98; N, 4.62, found: C, 84.91; H, 5.31; N, 4.54.

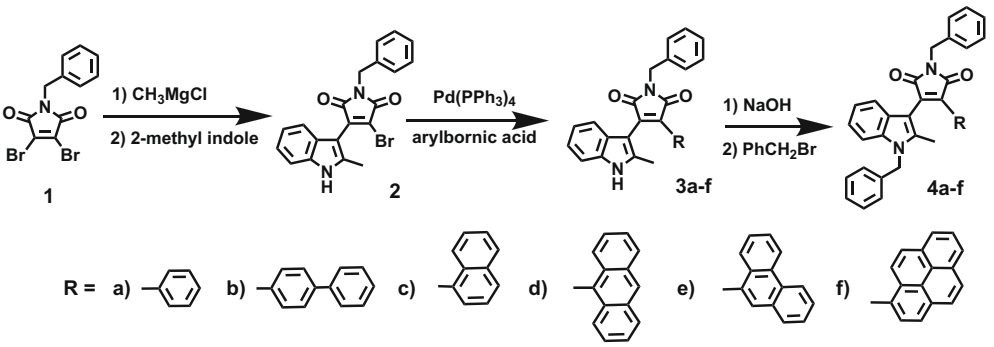
3. Results and discussion

3.1. Synthesis and characterization

The synthesis of the asymmetric indolylmaleimide derivatives **4a**–**4f** is illustrated in Scheme 1. 3-Bromo-4-(2′-methyl-3′-indolyl)-*N*-benzylmaleimide (**2**) was synthesized in a yield of 68% by a substitution reaction of 3,4-dibromo-*N*-benzylmaleimide (**1**) [1a] with one equivalent of 2-methylindole in the presence of CH_3MgCl, and it was utilized as the pivotal compound in the following coupling reactions. The addition of the second substituent at C(4) was performed by a Suzuki coupling reaction with aromatic boronic acids, i.e., phenylboronic acid, 4-biphenylboronic acid, naphthalene-1-boronic acid, anthracene-9-boronic acid, phenathrene-9-boronic acid, and pyrene-1-boronic acid, respectively, to yield **3a**–**3f** in 47–70% yield. In ^{1}H NMR the hydrogens at methylene moieties appeared as a singlet at $\delta \sim 5.0$ ppm, whereas in ^{13}C field the carbonyl groups appeared at $\delta \sim 170$ ppm. The indolyl hydrogens in **3a**–**3f** were masked by alkylation with benzyl bromide in the presence of base. Compounds **4a**–**4f** were obtained as red color solids in yields of 75–84%. The additional substituents at C(4) of **4a**–**4f** hindered the rotation between the maleimide ring and the two aromatic substituents, so that line broadening in ^{1}H NMR spectra was appeared at both the methyl and methylene positions of indole. This phenomenon is more pronounced in **4c**, **4e** and **4f**, whereas the line broadening was weaker in **4d** due to the symmetrical geometry of anthracene group.

3.2. Physical properties

Compounds **4a**–**4f** exhibit three major absorption regions in the range of 260–550 nm (Fig. 1). The absorptions shorter than 300 nm are derived mainly from the local transitions of both indole π–π^* (major) and maleimide n–π^* (minor). The region between 300 and 400 nm comes from the π–π^* transitions on the second aryl substituents, while their exact positions depend on the nature of the aryl group. The broad featureless band on the longest wavelength side above 400 nm belongs to a charge transfer transition along the dipole from indole toward maleimide, which has been well documented in the literatures [4,9]. The emission spectra of all compounds **4a**–**4f** overlap heavily with each other (Fig. 1), which are essentially the same as those of the symmetrical bis(indolyl)maleimide. The lowest energy radiative transition is derived from a charge-separated dipole directing from the indolyl nitrogen group toward the maleimide carbonyl. Such a charge transfer (CT) transition normally exhibits a distinctive solvatochromic effect (ESI, S1, S2 and S3). A typical example is shown in Fig. 2, where an apparent blue shift can be seen in the emission spectra of **4b** along with the increasing of



Scheme 1. The synthetic sequence of compounds **4a**–**4f**.

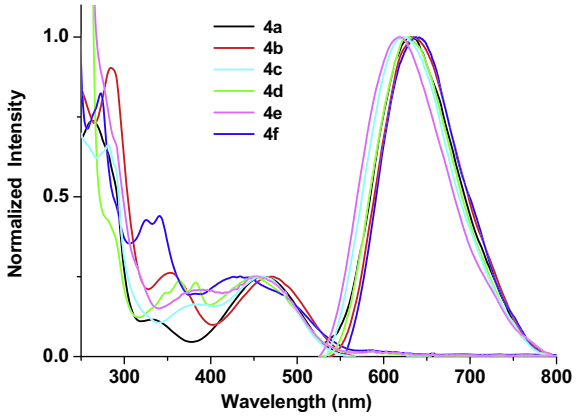


Fig. 1. Normalized absorption and emission spectra of compounds **4a**–**4f** in CH_2Cl_2. The emission spectra were obtained by irradiation at λ_{max} of the long wavelength absorption bands.

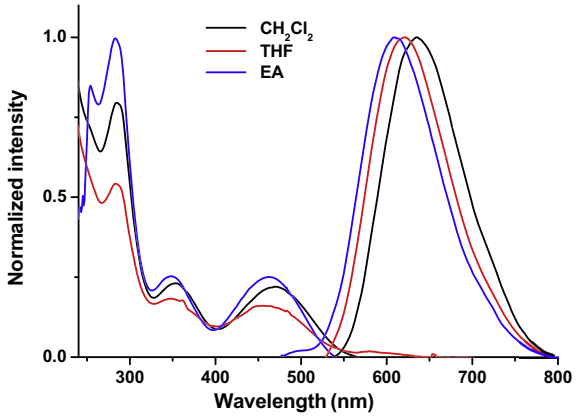

Fig. 2. Absorption and emission spectra of compound **4b** in different solvents.

solvent polarity. The red emissions with similar characteristics are found in all compounds **4a**–**4f**. A summary of their spectroscopic parameters is listed in Table 1.

The thermal stability of **4a**–**4f** was evaluated by differential scanning calorimetry (DSC). In a typical scan on a crystalline sample of compound **4d** (ESI S4), a sharp endothermic peak was detected at 251 °C, corresponding to the melting point (T_m) of the crystals. After cooling the same sample was heated again, yet a melting signal was not observed in the second scan. Nevertheless, a small endothermic hump at 98 °C was detected, which can be assigned to a glass-transition (T_g) temperature. The absence of T_m as well as the presence of T_g revealed the amorphous nature of solid films. All compounds **4a**–**4f** exhibited analogous glass-transition phenomena at considerable high temperatures, i.e., 63–109 °C (Table 1). The compact and round shape of these compounds is presumably responsible for the high T_g values. Red fluorescence was observable not only in solutions, but also in the solid state (ESI S5). This property provides an unusual advantage for the fabrication of LED devices in the form of neat films. In a common practice doping is usually necessary to avoid self-quenching in order to separate individual chromophores apart from each other.

Each compound showed two consecutive oxidative waves in dichloromethane by cyclic voltammetry (CV). The first wave at ca. 1.0 V corresponds to the oxidation of the indolyl group and second one at ca. 1.15 V is due to the aromatic substituent (Table 1). In the reductive sweep a single wave was observed at about −1.45 V by the reduction of maleimide moiety. The lowest unoccupied molecular orbital (LUMO) could be estimated by these redox potentials. The 0–0 transition energies were estimated at the interception of the absorption and emission spectra.

The physical nature of compound **4c** was further examined by semiempirical method AM1 implanted in Spartan software. In an optimized geometry the two aryl substituents at C(3, 4) are twisted from each other, while each maintains a dihedral angle of ca. 35° with respect to the central plane of maleimide. The irregular geometrical shape is favorable to the formation of amorphous solid during film preparation. Therefore high glass-transition temperatures (T_g) were detectable for all compounds (Table 1). As for their electronic configurations, the electron densities on the highest occupied molecular (HOMO) and the second highest occupied molecular orbital (SHOMO) are localized on the indolyl and naphthyl substituents, respectively (Fig. 3). The lowest energy transition from HOMO to LUMO (S_1 state) induces a charge separation between the indole and maleimide moieties. Charge recombination from S_1 to the ground state (S_0) results in an intensive red CT emission. It is interesting to find that the energy of this emission is only slightly perturbed by

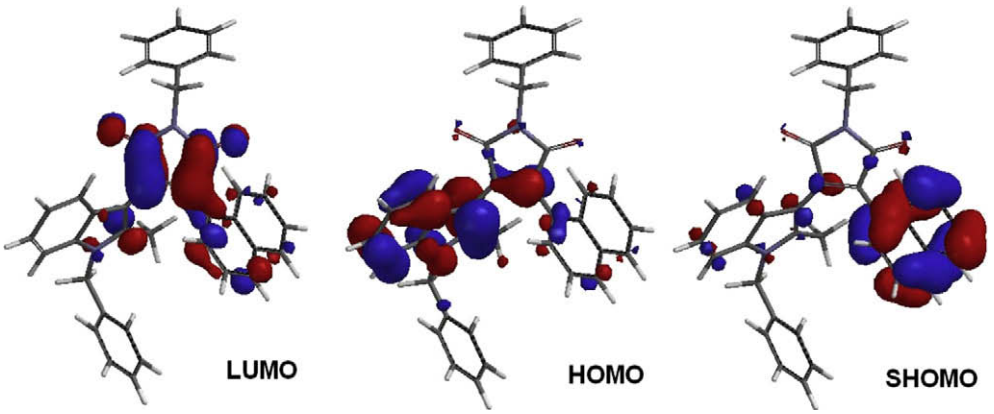

Fig. 3. Simulated frontier molecular orbitals of compound **4c**. From left to right are LUMO, HOMO, and SHOMO, respectively. The lowest energy transition from the first excited state, i.e., S_1 corresponding to HOMO → LUMO, is polarized from the indolyl substituent toward the central maleimide group. The transition involved the naphthyl moiety is at higher energy, and will transmit its energy rapidly through internal conversion to S_1. The simulation was performed by semiempirical method AM1 implanted in Spartan software.

adjacent aryl group, so that it explains the high similarity of PL spectra among all compounds **4a**–**4f**.

3.3. Device optimization

The electroluminescence of these materials was examined by the fabrication of LED devices. A typical lay-out of device configuration was ITO/HT/dye/ET/LiF/Al, whereas the hole transporter (HT) is either NPB or a combination of *m*-MTDATA/NPB, and the electron transporter (ET) is either TPBI or a pair of BCP/AlQ_3. A few selected combinations were compared in order to optimize the quantum yield as well as the purity of the red emission color. The parameters of devices made with compound **4a** in five trials I–V are given in Table 2. The ET material used in devices I and II was TPBI, while that in devices III–V was BCP/AlQ_3. The electroluminescence spectra of all devices are plotted in Fig. 4. A noteworthy feature in spectra I–IV is the presence of two emission bands, i.e., an extra peak appeared on the high energy side deriving from the emission of ET. Normally in the presence of TPBI the migration of holes can be blocked mostly at the film junction due to its exceptional low HOMO level (at −6.2 V). Therefore it functions both as an ET as well as a hole-blocker. However in the case of device I, a highly intensive band at 400 nm is observed, indicating holes have moved across the boundary into the bulk of TPBI. In certain occasions such dual emissions may be desired for the production of a white light [2,11]. However, in the present case we sought to reduce the hole leakage by inserting an additional layer of *m*-MTDATA between ITO and NPB to slow down the movement of holes. This new material is known to be capable of forming a highly uniform amorphous film, while its high HOMO level along with a moderate charge mobility can smooth the injection of holes [12]. With an additional layer of *m*-MTDATA, the quantum efficiency of device II was slightly improved. It was also clear that the intensity of 600 nm band was reduced to about half that of I (Fig. 4).

The HT material TPBI in devices III–V was replaced by a two-layer combination of BCP/AlQ_3. In this design AlQ_3 functioned as an electron injector and BCP a hole-blocker. The film thickness of **4a** in both III and IV was maintained 10 nm, while a layer of *m*-MTDATA was included in device IV. In the EL spectra of III and IV, a minor shoulder was found at peak maximum ca. 520 nm, which corresponded to the emission of AlQ_3. It was an evidence of a mild hole leakage from the emitting layer to the medium of ET. The improvement made by *m*-MTDATA in II and IV was some-

what limited. Although it is able to promote the light efficiency, however with an increased total thickness it also resulted to a higher turn-on voltage as well as a lower power efficiency comparing with those of I and II. A pure red emission was finally achieved by increasing the film thickness of **4a** from 10 nm to 30 nm. The EL spectrum of device IV, as shown in Fig. 4, exhibited a single emission band deriving from the maleimide.

Devices made with dye **4c** in different configurations were further examined with an optimized thickness of 30 nm. The ET materials in devices VI, VII, and VIII were composed of TPBI, BCP/AlQ_3, and BCP/TPBI, respectively. Their EL spectra are shown in Fig. 5, while each of them exhibits a single major emission nearly identical to each other. Hole leakage to ET is effectively blocked without noticeable side band. The light efficiency of these three devices was about 1%, with an optimal brightness in a range of 6000 cd/m^2 (Table 3). The CIE coordinate (Commission Internationale de l'Eclairage 1931) was located in the proximity of (0.6, 0.4), quite close to pure red color. The most unique feather in the fabrication of these devices was the use of neat films without doping. Devices made of neat films are relatively easier to fabricate and better in color stability especially under different operating conditions. For doped devices another factor need to be considered is the polarity of the host. For the charge transfer emission of **4a**–**4f**, the absorption maxima are quite sensitive to the influence of solvent. To illustrate the effect, a special device IX was made, in which dye **4c** was co-deposited in 5% weight ratio with CBP as a host material. This doped device performed with a remarkable light efficiency 4.5%, and an optimal brightness exceeding 1.2×10^4 cd/m^2. However, its emission maximum was blue shifted ca. 44 nm (from 615 to 571 nm) from those made of neat films as a result of the lower polarity of CBP. The CIE coordinate of device IX therefore was drifted to (0.47, 0.49), substantially away from pure red.

As concluded from above, a device of either type VI or type VII will be most suitable for producing a red emission, while the thickness of emitting films was kept in 30 nm. When the film is too thick, the turn-on voltage becomes higher and power efficiency reduced; yet when it is too thin, the color purity is lowered as a result of hole leakage. To comply with the above limitations, device type VII was selected for the fabrication using compounds **4b** and **4d**–**4f**. The EL spectra of these devices are shown in Fig. 6,

Table 3
Performance of electroluminescence devices made with **4c** as the emitting dye. The configuration of devices are listed in the following, with the thickness of films in nm embraced in the parentheses: VI: ITO/NPB (40)/**4c** (30)/TPBI (40)/LiF (1)/Al (150); VII: ITO/NPB (40)/**4c** (30)/BCP (10)/AlQ_3 (30)/LiF (1)/Al (150); VIII: ITONPB (40)/**4c** (30)/BCP (10)/TPBI (30)/LiF (1)/Al (150); IX: ITO/NPB (40)/**4c** (5%): CBP (40)/TPBI (40)/LiF (1)/Al (150).

Device type	Turn on (V)	L[a] (cd/m^2)	η_{ex}[b] (%)	η_l[c] (cd/A)	η_p[d] (lm/W)	CIE[e] (x, y)

and parameters of performance in Table 4. The emission spectra of **4a**–**4e** were found to be nearly identical, except **4f** which displayed a mild ~13 nm red shift with respect to others. Nevertheless this mild shift is consistent with its photoluminescence spectrum (Fig. 1).

The performance of devices of type VII fabricated for all the materials **4a**–**4f** can be depicted by both the L–V (Fig. 7) and η–J (Fig. 8) plots. Most devices displayed quantum efficiencies within the range of 0.4–0.6%, and maximal emission intensity 5500–6500 cd/m^2. The high similarity of these devices indicated that the variation of a C(4) substituent on maleimide does not influence their electrolumi-

nescence significantly. Among all devices the one made with **4f** performed the best, which exhibited an optimal 1.2% quantum efficiency (Fig. 8), along with a maximal brightness close to 10,000 cd/m^2 (Fig. 7).

4. Conclusions

In summary, asymmetric indolylmaleimide derivatives with different aryl substituents at C(3) and C(4) were synthesized and applied successfully to the fabrication of OLED devices. These devices were made with neat films of the dyes, and exhibited stable red emission with CIE coordinate very close to pure red. This work has demonstrated that the unsymmetrical maleimide derivatives possess nearly the same spectroscopic properties as the symmetrical ones. It gives us a higher flexibility for the future design of red maleimide dyes. Other potential applications requires more complicated structures, such as ion sensors and solar cell materials, may also become feasible for maleimide derivatives.

ABSTRACT

We demonstrated the first aggregation-induced enhanced emission (AIEE) materials for white organic light-emitting diodes (WOLEDs). AIEE properties of materials provide a possibility to turnaround the bad thermal effects to positive effects for device performance as WOLEDs working under the condition of the high brightness and high current density. The blue AIEE molecule **TDPVBi** shows high glass transition temperature (T_g) and special applicability for OLEDs, ca. enhanced smoothness as annealing its film. Constructing WOLED by combining both AIEE materials (**TDPVBi** and **CN-DPASDB**) results in devices with a maximum current efficiency of 7.9 cd A^{-1}, a maximum power efficiency of 6.2 lm W^{-1} and a maximum luminance of 25350 cd m^{-2}, respectively. The AIEE WOLED displays simplification in device fabrication and excellent color stability, which belongs to the best fluorescent WOLED reported.

1. Introduction

Recently white organic light-emitting diodes (WOLEDs) have attracted particular attention because they have the merits of low-cost fabrication process, high efficiency, ultra-thin thickness, light weight, planar light emitting and so on. They offer great potential applications in flat-panel displays, as well as next generation solid-state indoor light sources [1–8]. Generally, WOLEDs are required to have long-term stability as working at high brightness and high current density, thus device working at rigorous conditions becomes a crucial issue. For example the Joule heat may induce the change of chemical structure and morphology of active layer materials and makes the destroying of device. In this context, the materials with high glass transition temperature (T_g) and/or aggregation-induced enhanced emission (AIEE) properties are of special significance for WOLEDs, because they afford a possibility to turnaround the thermal effects ca. induced the aggregation to a positive effect for device performance. The AIEE materials combining with other approaches that are used to increase the device efficiency may be propitious to obtain long-term and color stable WOLEDs.

In the past few years, materials with AIEE properties have drawn more attention, because they possess our desired property that is enhanced emission from aggregate state. A few AIEE materials including silole derivatives [9,10], styrylbenzene derivatives [11,12], and others [13–15] have been developed by various research groups. Some of them have been used for EL device exhibiting excellent device performance [16]. Here we report two oligo(paraphenylene vinylene) derivatives exhibiting typical AIEE properties with very high emission efficiency in solid state as well as excellent thermal stability. AIEE compounds of 1,4-bis(α-cyano-4-diphenylaminostyryl)-2,5-diphenylbenzene (**CN-DPASDB**) and 2,5,2′,5′-tetrakis(2,2-diphenylvinyl)biphenyl (**TDPVBi**) (their structures shown in Fig. 1) emit orange and blue light, respectively. The white OLEDs are constructed by **CN-DPASDB** and **TDPVBi** light-emitting layers exhibiting a significant stability in color, as a result their Commission Internationale de l'Eclairage (CIE) coordinates have little shift with increasing the voltage after optimizing the structures. By our knowledge, this is the

first WOLEDs based on AIEE materials as the emitting layer. Herein we report the results.

2. Results and discussion

Fig. 2 shows the emission spectra of **CN-DPASDB** and **TDPVBi** in solution and solid state. **CN-DPASDB** in diluted THF solution emits orange light with peak wavelength of 583 nm and fluorescence efficiency of 9%. **TDPVBi** in diluted toluene solution emits blue light with peak wavelength of 464 nm and fluorescence efficiency of 11%, such fluorescence efficiencies of both compounds in solution are relatively lower compared with high fluorescent molecules ca. unsubstituted oligo(para-phenylene vinylene) distyrylbenzene (DSB) (fluorescence efficiency of 90% in solution). From the molecular configurations of **CN-DPASDB** and **TDPVBi** as shown in Fig. 1, the common characters of both molecules are non-planar and very twist molecular structure. The corresponding intramolecular motions ca. relative cis–trans isomerization of double bonds and free-rotation of end phenyl groups in solution may be the origin of weak fluorescence. In the solid state, the free-rotation occurring in both compounds in solution will be depressed due to intermolecular interaction, which is beneficial to enhanced fluorescent efficiency. The solid state fluorescence efficiency of **CN-DPASDB** and **TDPVBi** arrives at a very high value of 30%, and 80%, respectively, increasing up to 3–8 folds compared with their solutions.

Differential scanning calorimetry (DSC) analysis indicates that glass transition temperature (T_g) of **TDPVBi** is 110 °C, and no crystallization or phase transition occur upon heating beyond T_g. This suggests that the amorphous nature of the **TDPVBi** in condensed state, which may greatly benefit the formation of homogeneous and amorphous films through thermal evaporation. Atomic force microscopy (AFM) measurement indicates that the pristine vacuum deposition films of **TDPVBi** have a fairly smooth surface morphology with a root mean square (rms) roughness of 2.5 nm, and annealing for this film at 90 °C for 15 min makes surface more slippery with a rms roughness of 0.9 nm (detail shown in Fig. S1 in SEI). Such phenome-

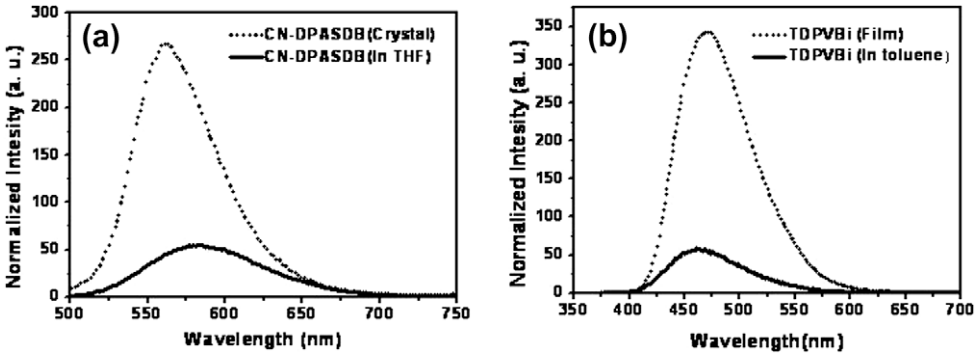

Fig. 2. (a) PL spectra of **CN-DPASDB** at room temperature in dilute THF solution (5×10^{-6} mol L^{-1}) and in crystal. (b) PL spectra of TDPVBi at room temperature in film on the quartz substrates and in dilute toluene solution (5×10^{-6} mol L^{-1}).

non should be related to enhance intermolecular interaction after annealing as the heating temperature is close to T_g, the molecules in film can adjust themselves to a suitable situation through free-rotation of end phenyl groups and the rotation of biphenyl core, which makes amorphous film of **TDPVBi** become more dense and rigid. **CN-DPASDB** is a crystalline material, but a film with smooth surface still can be obtained under a controlled vacuum deposition condition.

The devices performance based on **CN-DPASDB** and **TDPVBi** are characterized by utilizing a standard device with the structure of indium tin oxide (ITO)/N,N′-di-1-naphthyl-N,N′-diphenylbenzidine (NPB) (40 nm)/AIEE emitter layer (10–40 nm)/1,3,5-tri(phenyl-2-benzimidazolyl)-benzene (TPBi) (40–50 nm)/LiF (0.5 nm)/Al (100 nm). TPBi is chosen as the electron-transporting and hole-blocking layer because it has the much higher electron mobility than that of Alq_3 (the classic electron-transporting material) and relatively low highest occupied molecular orbital (HOMO) level [17]. The **CN-DPASDB** (10 nm) device shows the EL spectra with peak wavelength at 579 nm corresponding to the CIE coordinates of (0.50, 0.50), and EL spectra keeps unchanged when the driving voltage increases from 5 to 12 V. The turn-on voltage, maximum luminance and maximum luminescent efficiency are 5 V, 14667 cd m^{-2} and 4.0 cd A^{-1}, respectively (detail shown in Fig. 3). The performance of **CN-DPASDB** based device is better than that of the classic orange material ca. rubrene [18], while non-doped film fabrication of **CN-DPASDB** is relatively simple as compared with rubrene device in which rubrene must be doped into certain host materials due to their strong concentration quenching. So in the view of simplifying the fabrication process of OLED, **CN-DPASDB** is the suitable candidate to take the place of rubrene.

The OLED based on **TDPVBi** shows the blue emission (electroluminescent (EL) peak of 468 nm) with a CIE coordinates of (0.16, 0.21), maximum luminance exceeding 31170 cd m^{-2} and luminescent efficiency of 6.2 cd A^{-1} (detail shown in Fig. S3b in SEI). **TDPVBi** exhibits significantly improved film quality and thermal stability due to the cruciform structure compared with the classic blue-emitting material, 4,4′-bis(2,2-diphenylvinyl)-1,1′-biphenyl (**DPVBi**) and belongs to the best blue materials reported.

The non-doped WOLEDs with varied structure are fabricated (detail shown in Fig. S4a, S4d, S4g in SEI). These are the first demonstration of WOLEDs which are combined all by AIEE molecules with a high luminance and luminescent efficiency. A special design in WOLEDs is a very thin **CN-DPASDB** layer (0.1–0.5 nm) combining with a thick **TDPVBi** layer (20 nm), which is based on the consideration of the color match and the crystalline properties of **CN-DPASDB**. The very thin **CN-DPASDB** layer may decrease its crystalline effect. The device with the structure of ITO/NPB (50 nm)/**TDPVBi** (20 nm)/**CN-DPASDB** (0.5 nm)/TPBi (60 nm)/LiF (0.5 nm)/Al (100 nm) shows a high performance. Turn-on voltage, maximum luminance, maximum luminescent efficiency and maximum power efficiency are 3.5 V, 25350 cd m^{-2} (12.5 V), 7.9 cd A^{-1} (4.0 V), 6.2 lm W^{-1} (4.0 V), respectively. (detail shown in Fig. S4c(b) in SEI) Such device shows the CIE coordinate localized at white light zone at various voltages, the shift of CIE coordinate with driving voltages is significant, ca. CIE of (0.36, 0.38) at low voltage (4 V), and CIE of (0.24, 0.29) at high voltage (10 V) (detail shown in Fig. S4b(b) in SEI). Significant increase in blue spectra with increased voltage reflects a change of emitting region in device at high driving voltage. According to the theoretical analysis for multilayer OLED by Chen and Meng [19]. We can demonstrate that in this device the recombination is firstly concentrated on the orange **CN-DPASDB** layer at low voltages likely due to the relatively low electron mobility of **CN-DPASDB**, and then the recombination extends to the **TDPVBi** layer because the electric field strongly enhances the electron mobility as the voltage increases. An exchange of blue and orange emitting layer to construct a device with structure of ITO/NPB (50 nm)/**CN-DPASDB** (0.1 nm)/**TDPVBi** (20 nm)/TPBi (60 nm)/LiF (0.5 nm)/Al (100 nm), shows high device performance with a maximum luminance of 39790 cd m^{-2} (11.5 V) and maximum luminescent efficiency of 8.4 cd A^{-1} (6.0 V), (detail shown in Fig. S4f (b) in SEI) but blue spectra in such device are strongly suppressed, the CIE coordinates of the device is found to be located at the orange light zone (detail shown in Fig. S4e(b) in SEI). Such spectra behaviors are likely due to the energy transport between two emitting layer and/or shift of emission zone under device operation. Thus a thin layer of NPB (3 nm) is inserted between the **CN-DPASDB** and **TDPVBi** layers aiming at the balance of orange and blue emission. The optimized device structure of ITO/NPB (50 nm)/**CN-DPASDB** (0.1 nm)/NPB (3 nm)/**TDPVBi** (20 nm)/TPBi (60 nm)/LiF (0.5 nm)/Al (100 nm) shows the stable white emission and high device performance. From the energy level shown in Fig. 5, the lowest unoccupied molecular orbital (LUMO) level of NPB is −2.3 eV which is about 0.3 eV higher than that of **TDPVBi**, and exciton energy of NPB is 0.2 eV higher than that of **TDPVBi**, so the inserted NPB layer can play a role in partly block the electrons injection and energy transfer from blue **TDPVBi** layer to **CN-DPASDB** layer. From EL spectra of device shown in Fig. 4, the device shows excellent spectral stability, and CIE of (0.28, 0.35) at 4 V (2.9 cd m^{-2}) and (0.28, 0.34) at 11 V (17990 cd m^{-2}) localized at white light zone. Fig. 5 shows the luminance-voltage and luminescent efficiency–voltage characteristic of the device, respectively. The maximum luminance and the maximum luminescent efficiency of the device are 19450 cd m^{-2} (at 11.5 V) and 7.5 cd A^{-1} (at 6.5 V), respectively. As brightness of 1000 cd m^{-2}, the efficiency is 7.1 cd A^{-1}.

WOLEDs made of phosphorescent dyes have a high performance [20–23]. But phosphorescent dyes are not suitable for non-doped systems, which make the device process complex. Now reported best fluorescent WOLEDs showed the efficiency of 9.37 cd A^{-1}, 4.20 lm W^{-1} [24], and by utilizing a p-i-n structure efficiency arrive to 8.7 lm W^{-1} [25], but their color stability was not so good behaving a driving voltage depended spectra characteristics. There were up to nine organic layers in these WOLEDs which were too complex for practical application. The devices made by our AIEE materials are relatively simple in fabrication, which are combined by less than five organic layers. Currently, the blue materials are still the key com-

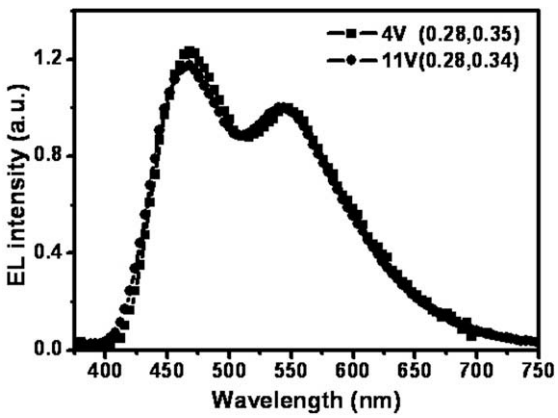

Fig. 4. The EL spectra and CIE coordinate of the WOLED at 4 V and 11 V.

ponent to determine the device performance in OLEDs, in this context, our AIEE blue material **TDPVBi**, which exhibit annealing induced more smooth surface morphology and enhanced PL intensity, provides the great potentials for the fabrication of stable device.

3. Experimental

3.1. Materials

The compounds, **CN-DPASDB** [26] and **TDPVBi** [27], were synthesized in our laboratory as previously reported. N,N′-di-1-naphthyl-N,N′-diphenylbenzidine (NPB), 1,3,5-tri(phenyl-2-benzimidazolyl)-benzene (TPBi) and lithium fluoride (LiF) were purchased commercially and used as the hole-transporting layer, electron-transporting layer, and electron-injection layer, respectively. They were used without purifying. The chemical structures of materials in this work are shown in Fig. 1.

3.2. Instruments

The indium tin oxide (ITO) coated glass substrates were cleaned in an ultrasonic bath with toluene, acetone, ethanol and deionized water, respectively, and then dried with nitrogen, finally irradiated in UV-ozone chamber. The organic materials were sequentially deposited onto the cleaned ITO coated glass substrate through thermal evaporation. The layer thickness of the deposited material was monitored in situ using an oscillating quartz thickness monitor. Finally a LiF buffer layer and Al cathode were deposited onto the organic films through a shadow mask. The background pressure of the chamber was under 10^{-6} Torr during the deposition process. The electroluminescent (EL) spectra and CIE coordinates of the devices were measured by using a PR 650 spectrometer. The luminance-voltage and current–voltage characteristics were measured simultaneously with a programmable Keithley 2400 voltage–current source. UV–vis absorption spectra were recorded on UV-3100 spectrophotometer. Fluorescence measurements were carried out with RF-5301PC instrument. The PL quantum efficiency of films were measured in an integrating sphere [28]. AFM images were recorded on a Seiko SPA 400 with an SPI 3800 probe station in tapping mode (dynamic force mode). All measurements were carried out at room temperature under ambient conditions.

4. Conclusion

In summary, the first AIEE materials based WOLEDs which showed simple device structure and high performance have been demonstrated by us. The blue AIEE molecule **TDPVBi** showed the special applicability for OLEDs, ca. enhanced smoothness as annealing its film. The blue and orange AIEE materials showed high EL performance, which are comparable with the classic blue material **DPVBi** and orange material rubrene. Combining both AIEE materials to construct WOLED exhibits a maximum current efficiency of 7.9 cd A^{-1}, a maximum power efficiency of 6.2 lm W^{-1} and a maximum luminance of 25350 cd m^{-2}, respectively. Important impress of the AIEE WOLED is its simplification in device fabrication and excellent color stability, which render such device the potential application as the solid-state indoor lighting sources.

Low voltage OTFT
Organic dielectric
Random copolymer

ABSTRACT

In this article, a low voltage organic thin-film transistor (OTFT) was accomplished by using a random copolymer, poly(styrene-co-methyl methacrylate) (PS-r-PMMA), as the gate dielectric. The thickness of PS-r-PMMA polymer can be controlled well by thermal process and shows an ultra-thin property after toluene rinse. The thickness of PS-r-PMMA can be controlled in the range of 2–14 nm. By the densely packed copolymer brush, a leakage current as low as 10^{-9} A/cm^2 was obtained. By utilizing this polymer as gate dielectric, pentacene based organic thin-film transistor could be operated at 5 V with 0.1 cm^2/V s mobility and 0.27 V/dec subthreshold swing. In addition to good OTFT properties, the coating, annealing and removing sequential process of PS-r-PMMA ensure that this technique is compatible with the large area printing methods such as ink-jet printing and doctor blade coating. The random copolymer dielectric is therefore suitable for OTFT in large area printed flexible electronic applications.

1. Introduction

Research efforts devoted to polymer based microelectronic and optoelectronic devices have grown significantly in recent years. The advantages are low processing temperature which is compatible with the plastic substrates, simple processing steps that is potentially low cost, low elastic modulus which is flexible and deposition by printing process that could be produced in large area. Consumer products such as flexible display, radio frequency identification tag (RFID), smart cards, polymer solar cell and polymer sensors are therefore demonstrated [1–5]. Among all products, the organic thin-film transistor (OTFT) is no doubt the most important device. They are used not only as the logic circuit in sensors, RFID and smart cards but also the addressing and current source components in flexible display [30].

Although many efforts have been done to improve the properties of OTFTs, there are still some issues to be explored [6–8]. Main challenge is controlling the properties of the organic dielectric [9,10] which is printed in large area for low voltage OTFTs. Low voltage is essential for OTFTs, since the above-mentioned applications are portable products that have very limited energy capacity. Low driving voltage could save the usage of electrical power. Another is printing in large area with controlled properties. Both logic circuit and the active addressing circuit need OTFT performance with high uniformity. Very less thickness or interface properties variation could make those circuits unstable or even fail. For these requirements, the dielectric layer of OTFT must be well controlled and should have high uniformity over a large area.

One of the key factors that determine the driving voltage of a thin-film transistor is the capacitance of the gate dielectric layer expressed by the following equation:

$$Q_{ch} = C_i \times V \tag{1}$$

where Q_{ch} is the carrier density for channel, C_i is the density of the gate capacitance and V is the driving voltage.

The density of capacitance can be further expressed as follows:

$$C_i = \frac{\varepsilon_o \varepsilon_r}{t} \quad (2)$$

where ε_o is permittivity of free space, ε_r is dielectric constant of the organic insulator and t is the thickness of the dielectric. Therefore, by Eq. (1), low driving voltage requires high gate capacitance. To achieve high capacitance for gate dielectric, by Eq. (2), there are two methods in general. One is adopting high dielectric constant material and the other is utilizing ultra-thin dielectric. High dielectric constant metal oxides such as HfO_2, Y_2O_3, Ta_2O_5, TiO_2 and Al_2O_3 [19–23] are not only popular for Si technology but also for the OTFTs. The metal oxides generally exhibit hydrophilic surface, higher roughness and fixed oxide charge in the dielectric layer. In addition, the metal oxides could not be deposited well by printing process in large area. However, the surface energy of gate dielectric greatly affects the morphology of organic semiconductor. Both small molecular and polymer organic semiconductor such as pentacene and polythiophene tend to form better film structures on the hydrophobic surface, leading to the higher mobility and better interface [11,12]. The roughness of the dielectric surface significantly influences the carrier transport mobility of OTFT [13,14], since the carriers scattering with the interface roughness will slow down the carrier transport velocity. These imply that the high dielectric constant metal oxides are not adequate materials for high quality and low voltage OTFTs in current situation even hybrid organic/inorganic material are used for higher mobility and better interfaces [24,25].

To obtain ultra-thin, robust and hydrophobic gate dielectric, techniques of self-assembled monolayer (SAM), are generally used [15–18]. The organic material for SAM, which is designed with several nanometers chain length, ensure that the OTFT could be operated in a voltage as low as ~1 V. The possibility of well packing of the SAM also keeps very low leakage current through the gate dielectric at high electrical field. Although SAM layer demonstrates the low voltage operational properties of OTFTs, it is hard to find demonstration of SAM in large area, which is the essential factor for low cost flexible electronics. This might be due to the inherent property of "monolayer". Any place between gate electrode and organic semiconductor without chemical bonding to the monolayer molecular will cause severe leakage current that might make the OTFT fail. Therefore, the basic requirements for gate dielectric are high capacitance, low current leakage, controlled thickness and fully printing compatibility.

In this work, an ultra-thin polymer dielectric layer with temperature-dependent thickness property for low voltage OTFTs was developed based on random copolymer. The random copolymer, poly(styrene-co-methyl methacrylate) (PS-r-PMMA), was studied well in the field of self-assembled nano-patterning [26–29]. In the nano-patterning, PS-r-PMMA was used as a surface modification layer for the following block copolymer layer. After thermal annealing, a very thin layer of PS-r-PMMA formed on the underlying surface, about several nanometers thick. The random polymer brushes ensured the coverage on the whole surface to restrict leakage current. Therefore, random copolymer such as PS-r-PMMA is suitable for the gate dielectric of low voltage OTFTs.

2. Experimental

2.1. Preparation of PS-r-PMMA dielectric

The PS-r-PMMA random copolymer (M_w = 100,000–150,000) solution was prepared by dissolving PS-r-PMMA in toluene in a concentration of 20 mg/ml. After stirring overnight, the PS-r-PMMA solution was either drop casted or spin coated on the Si substrate at 500 rpm for 60 s for material analysis. After coating, the PS-r-PMMA was thermally annealed at the temperatures varied from 130 to 190 °C for 12 h. By thermal annealing, the PS-r-PMMA polymers near the Si surface chemically bonded to the native oxide. After this bonding process, the sample was dipped in toluene, the residue PS-r-PMMA was dissolved and a sub-10 nm layer of PS-r-PMMA was formed.

For thin film characteristics, ellipsometer was used to measure the film thickness. For the accuracy of thickness measurement, the n and k parameters set in the ellipsometer were adjusted according a known thickness of rinsed PS-r-PMMA that was obtained from AFM image. Besides, scanning electron microscopy (SEM) and atomic force microscopy (AFM) were applied to observe the surface morphology.

2.2. OTFT fabrication

A bottom gate and top contact structure was applied to realize the PS-r-PMMA-based OTFT. A 100 nm thick aluminum was grown by thermal evaporation on the glass through a shadow mask as the gate electrode. Prior to the PS-r-PMMA coating, Al was illuminated by ultra-violet light (254 nm) for 30 min. In this step, a 7.5-nm-thick Al_2O_3 was grown on the Al surface. After coating, the PS-r-PMMA was thermally annealed at either 150 °C or 190 °C for 12 h and then removed the unattached chains by toluene. After ultra-thin PS-r-PMMA dielectric formation, the 40-nm-thick channel layer and 30-nm-thick source/drain electrodes were sequentially grown by thermal evaporation through associated shadow mask. Pentacene is used as the channel material and gold is used as the electrodes for source and drain. The electrical properties including leakage current of dielectric and current–voltage characteristics of OTFT were measured by a HP 4145A semiconductor analyzer. The capacitance measurements were carried out by 4284A impedance analyzer at 10 kHz. All electrical measurements were performed under dark and ambient environment.

3. Results and discussion

3.1. Physical properties of the PS-r-PMMA copolymer

Fig. 1a shows the schematic concept of the PS-r-PMMA thin film for large area application. While the PS-r-PMMA

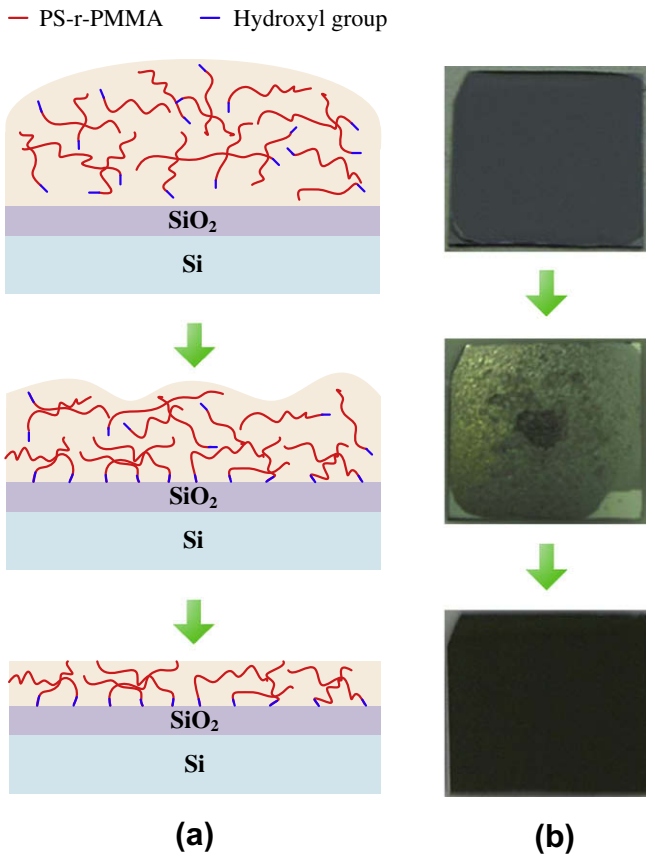

Fig. 1. The evolution of PS-r-PMMA dielectric material. (a) Schematic diagram of the formation mechanism from the solution to thin film. (b) Optical images for those process steps.

solution was casted on the native oxide layer, the copolymer chains stack with each other and distribute randomly in about 3 μm thick. After annealing the PS-r-PMMA (T_g = 101 °C) at the temperature above glass transition temperature (T_g) of both PS (T_g = 100 °C) and PMMA (T_g = 99 °C) in oxygen-free and humidity-free environment, the small amount of hydroxyl groups (OH^-) produced during the copolymer synthesis process will diffuse and react with the native oxide surface to from a chemical bond [26]. The un-bound PS-r-PMMA random copolymer chains are removable by toluene to form an ultra-thin and uniform dielectric film. Fig. 1b shows the evolution of PS-r-PMMA thin film observed by an optical microscope. The drop casted PS-r-PMMA solution was spread well over the entire Si substrate. After thermal annealing, the toluene evaporates and leaves a very rough PS-r-PMMA surface with irregular cavities that is a typical case in a large area printing process for dielectric films. After being rinsed by toluene, the irregular cavities and mounts were removed, obtaining a remarkable smooth surface of PS-r-PMMA film.

For further microscopic confirmation, Fig. 2a shows the SEM image of PS-r-PMMA film without toluene rinse in which many mounds and cavities were found. In contrast, after being rinsed by toluene for 30 s, large numbers of unattached PS-r-PMMA chains were taken away that mounds and cavities were removed as shown in Fig. 2b. The uniformity was significantly improved over the entire sample. After being rinsed in toluene, the thickness of the PS-r-PMMA film determined by the ellipsometer was reduced to nanometer regime. The scale bars in Fig. 2a and b are 100 μm and 100 nm, respectively. Fig. 2c and d shows the AFM topography image for the spin coated PS-r-PMMA film with and without rinse, respectively, in small scale. The pristine PS-r-PMMA layer showed a root mean square roughness (RMS) of 0.28 nm. After being rinsed in toluene, the smoother PS-r-PMMA surface with RMS roughness of 0.2 nm was found. Follow by optical microscopy, SEM image and AFM topography measurements, the toluene rinsed PS-r-PMMA film shows flat surface from macroscopic to microscopic. The results imply the possibility to grow better organic semiconductor on rinsed PS-r-PMMA. Fig. 2e and f shows the morphology of 40-nm-thick pentacene evaporated on the pristine and rinsed PS-r-PMMA and the pentacene grain sizes were 180 and 210 nm, respectively. Larger grains were found on flat PS-r-PMMA surface.

In addition to the smooth surface, the brush thickness of PS-r-PMMA can also be controlled. After complete film formation process, we divided each sample (2 cm × 2 cm) into nine regions (3 × 3 grid) and measured the thickness of these regions at once without considering swelling effect. Nine data from each condition were obtained for statistics analysis. Fig. 3a shows the relationship between the

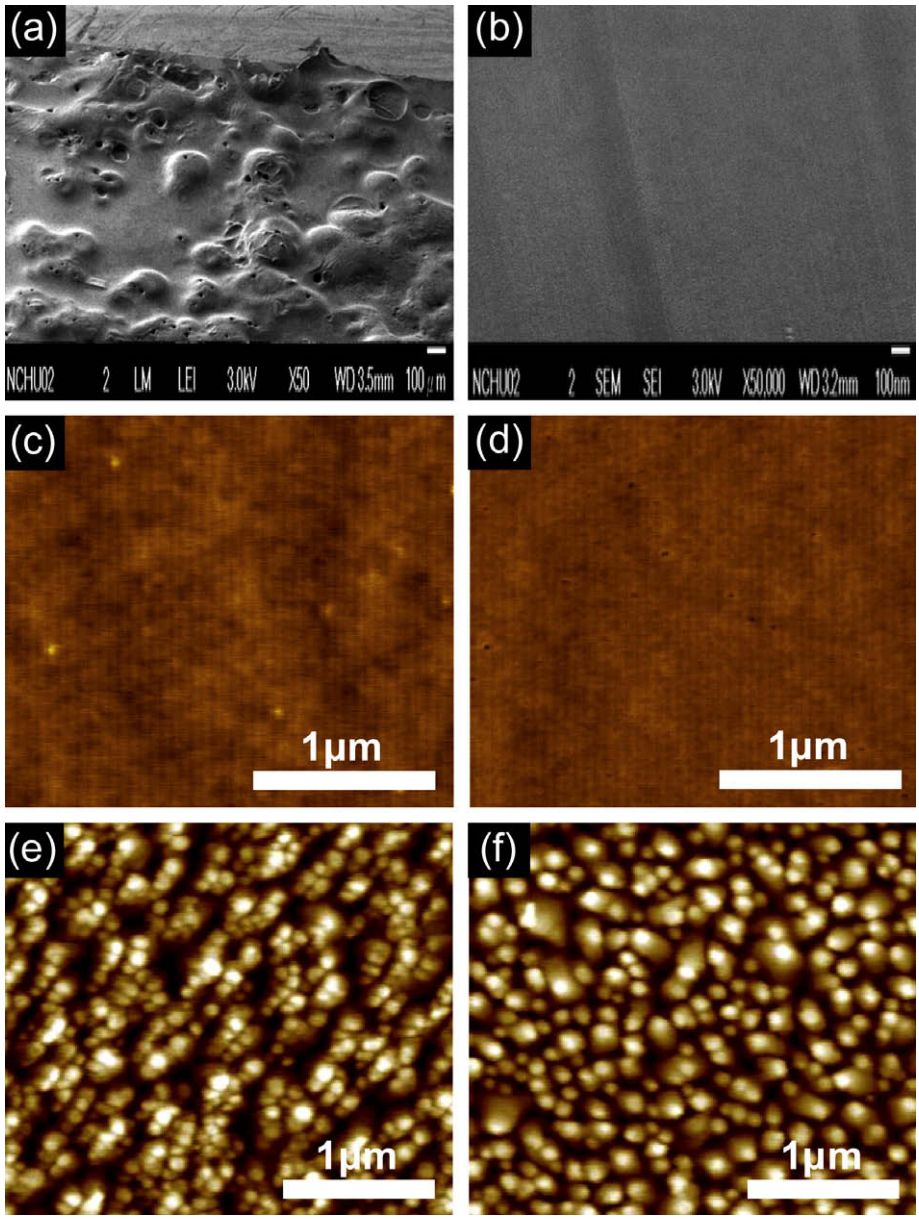

Fig. 2. The morphology of random copolymer dielectric material and organic semiconductor on it. (a) SEM image of PS-r-PMMA formed by drop casting. (b) PS-r-PMMA surface of drop casted PS-r-PMMA after toluene rinse. Tapping mode AFM images of spin coated PS-r-PMMA film (c) without toluene rinse and (d) with toluene rinse. thickness and annealing conditions. Below 150 °C, the PS–PMMA film thickness was kept around 2–3 nm. At higher temperature, the thickness increased rapidly in the first 10 h and then kept around. The thickness of 10–14 nm and 6–8 nm were obtained for 190 and 170 °C annealed sample, respectively. This saturation in thickness can be explained by the following mechanism. The attached polymer chains will stretch to provide a high entropic barrier restricting the further adhesion of supplementary chains upon thermal annealing [26]. As the temperature increases further, sufficient thermal energy probably enhances the diffusion ability that would overcome the entropic barrier to attach on the hydrophilic oxide surface. If PS-r-PMMA did not strongly bond to the native oxide, the copolymer would be almost removed by toluene. Based on experimental results, the PS-r-PMMA thickness is temperature-dependent even after toluene rinsing. Therefore, we quoted the statements from the literature [26] and regard PS-r-PMMA chemically bond to silicon oxide.

Fig. 3b and c shows the schematic diagram for the PS-r-PMMA chain attachment on the oxide surface at low and high temperature, respectively. At low temperature, the thermal energy is not high enough to exceed entropic barrier for the unattached PS-r-PMMA chains so that only few

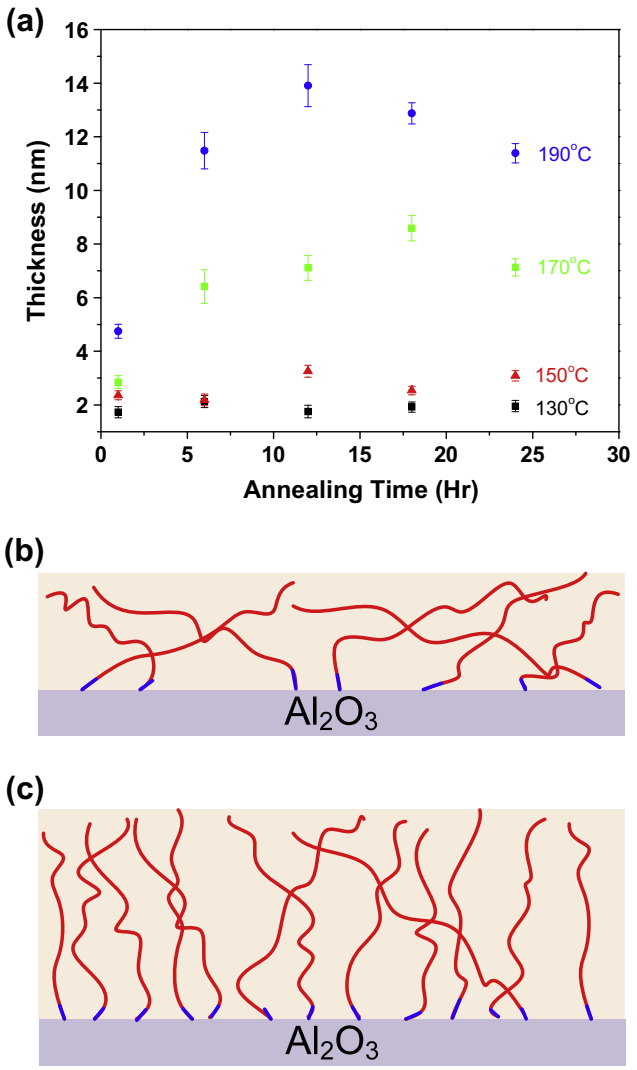

Fig. 3. Arrangement of PS-r-PMMA annealed at different temperatures. (a) Relationships between grafted layer thickness and annealing temperature. (b) The chains packed randomly at low temperature. (c) Contribution of line up effect strengthened the PS-r-PMMA chains and densely packed at high temperature.

polymer chains can reach and attach on the hydrophilic oxide surface. As a consequence, the long polymer chain laid along the oxide surface yields PS-r-PMMA film that is 2–3 nm thick. At high annealing temperature, 190 °C for instance, the grafting reaction occurs easily at surface due to enough thermal energy. The high-density PS-r-PMMA polymer chains attached on the oxide surface squeeze each other, causing the polymer chains to partly line up to form thicker film. The thickness of PS-r-PMMA therefore depends on chain stretching conditions and is controlled by thermal process.

3.2. Electrical properties of the PS-r-PMMA copolymer

The leakage current of PS-r-PMMA with metal–insulator–metal sandwich structure is presented in Fig. 4a. The leakage current was presented by current density and the contact area for the leakage current measurements was 0.04 cm^2. For pure polystyrene (PS), the current density raised up to 10^2 A/cm^2 at the electrical field of 1 MV/cm. Leakage current increases with raising the electric field and charge carriers easily transported through the pure polystyrene. For pure PMMA, the leakage current was in a range of 10^{-9}–10^{-7} A/cm^2 from 0.01 to 3 MV/cm. In contrast, the random copolymer PS-r-PMMA achieved an excellent leakage current density around 10^{-9} A/cm^2 and maintained at this order even in a strong electric field of 3 MV/cm. By comparing with pure PMMA and copolymer PS-r-PMMA, the remarkable leakage current reduction about two orders of magnitude was observed. This could be explained by the densely packed PS-r-PMMA film at high temperatures as depicted in Fig. 3c. During the annealing process, most of the PS-r-PMMA chains pack well that the defects existing in the organic insulator can be decreased and carriers hardly jump along the traps to form the leakage current.

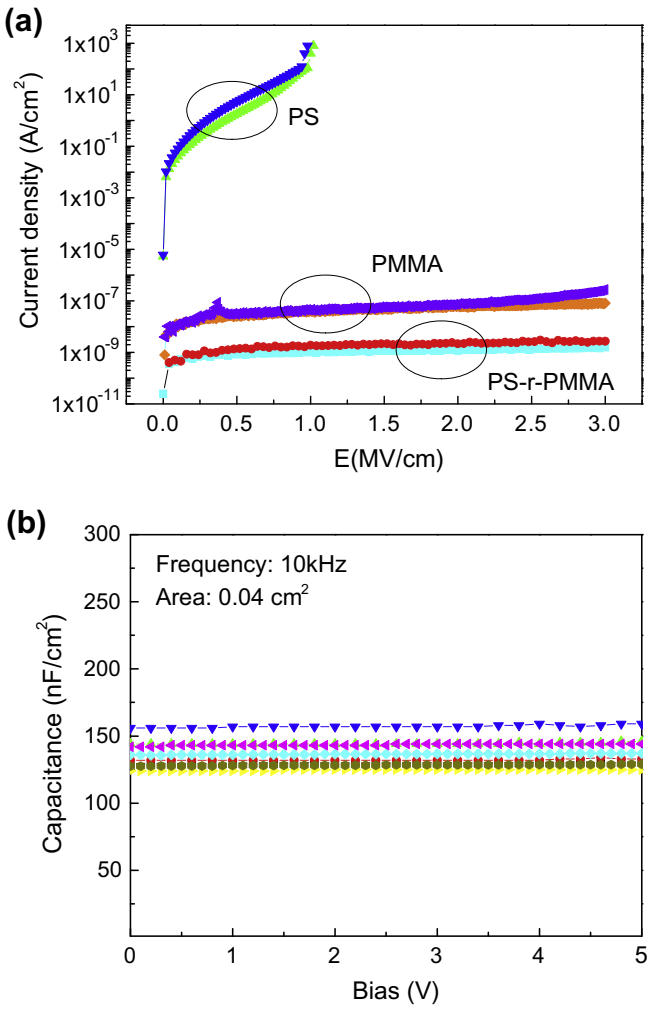

Fig. 4. Electrical properties of the PS-r-PMMA insulator. (a) Leakage current comparison between PS-r-PMMA, PS and PMMA. (b) Capacitance for 190 °C annealed PS-r-PMMA polymer film after toluene rinse.

The capacitance–voltage characteristics were measured for the PS-r-PMMA film with the metal–insulator–metal structure as shown in Fig. 4b. The capacitance density is in the range of 125–156 nF/cm^2. As a consequence of the high capacitance density and low leakage current density, the operation voltage was estimated around 5 V. In general, the channel carrier density of "on state" for TFT is about 10^{12}–10^{13} cm^{-2} that indicates charge density of 1.6×10^{-7}–1.6×10^{-6} C/cm^2. By applying this charge density and measured capacitance to Eq. (1), the operating voltage is estimated to be around 5 V, being compatible to silicon-based very large scale integration (VLSI) circuit technology at gate length of 1 μm [31].

3.3. Characteristics of OTFT with PS-r-PMMA dielectric

Fig. 5a shows the top contact structure of the PS-r-PMMA based OTFT by using pentacene as the channel material. Fig. 5b shows the chemical structure of PS-r-PMMA. To further investigate the surface energy of the PS-r-PMMA, the contact angle was shown in Fig. 5c. The water contact angle about 85° was obtained, thus indicating a hydrophobic surface after PS-r-PMMA coating. Fig. 6a and b illustrates the output and transfer characteristics of the OTFT with PS-r-PMMA annealed at 190 °C. The 5 V operation voltage was achieved. The mobility in which extracted from the saturation regime is ~0.1 cm^2/V s. The threshold voltage is −2.5 V and the subthreshold swing of 0.27 V/dec is obtained. The on/off current ratio is ~5000. In comparison, the transfer characteristics for OTFT with 150 °C annealing and original PS–PMMA film as dielectric layer are also depicted in Fig. 6c and d, respectively. By using 150 °C annealed PS-r-PMMA as the gate dielectric, even higher drain current at 5 V is obtained. The OTFT with PS-r-PMMA without rinse reasonably requires a voltage as high as 40 V to operate. For the environmental stability, PS-r-PMMA is not a hydroxyl-rich material, unstable effect of ambient oxygen and water on threshold voltage shift is not obvious. After polymer chains grafting on the native oxide, the intrinsic properties of PS

and PMMA do not affect the interface and bulk properties seriously in the ambient air and the hysteresis can be ignored.

The performance comparison with various annealed PS-r-PMMA are listed in Table 1. There is a noteworthy improvement in subthreshold swing by using ultra-thin

Table 1
Performance of pentacene based OTFT with various temperature annealed PS-r-PMMA dielectric layer.

Temperature (°C)	Rinse[a]	μ (cm^2/V s)	Vt (V)	On/off ratio	S.S ($V^{-1}dec^{-1}$)
190	Y	0.10	−2.5	10^3-10^4	0.27
150	Y	0.14	−1.9	10^4	0.29
190	N	0.07	−10	10^4	4.7

[a] After the dielectric layer annealed at appropriate temperature, the samples were rinsed with toluene for 30 s.

PS-r-PMMA as the OTFT gate dielectric. The surface is more regular for the ultra-thin PS-r-PMMA dielectric after toluene rinse than the original random coated PS-r-PMMA dielectric layer. Such a regular arrangement of chain performs a smooth surface for pentacene growth with less interface traps and high carrier mobility.

Moreover, relative small on/off current ratio of OTFT is observed. The phenomenon is attributed to the mobility of OTFT dominated by pentacene growth conditions. The purity of the pentacene and process temperature (substrate heating temperature) are regarded as the most important factors for a high quality channel layer. In this study, the 40-nm-thick pentacene channel layer was formed without substrate heating, leading to the mobility of ~0.1 cm^2/V s. Such a relatively low carrier mobility suppressed the channel current which associated with on/off current ratio. The other reason is regarded as the leakage current from the gate electrode. For the good PS-r-PMMA attachment and arrangement, the aluminum oxide played an important role. The AlO_x formed by UV treatment is not stable enough in the ambient air that oxygen molecules will release from the AlO_x surface. However, the lack of oxygen will lead to the PS-r-PMMA insufficient bonding or attachment during the annealing process. As the reason, we suggest other methods to form a robust and stable AlO_x such as oxygen plasma treatment to improve on/off ratio in the future [32].

4. Conclusions

In summary, we have demonstrated that the random copolymer such as PS-r-PMMA could have the potential in printable gate dielectric for low voltage OTFT. The print capability is evaluated by the casting, annealing and removing procedure which is compatible to ink-jet printing, slot-coating, screen printing, doctor blade and other printing methods. The developed dielectric also exhibits a temperature-dependent behavior in thickness which is controlled by thermal annealing. For the electrical properties, this random copolymer achieved well properties in low leakage current (~10^{-9} A/cm^2), smooth morphology and high capacitance density (~150 nF/cm^2). By applying this random copolymer to an OTFT as the gate dielectric, a small operation voltage as low as 5 V was obtained that is comparable to the real electronics in the VLSI technology of 1 μm technology node. In addition to 5 V operation, the PS-r-PMMA based OTFT exhibited subthreshold swing of 0.29 V/dec, threshold voltage of −1.9 V, I_{on}/I_{off} ratio of 10^4 and mobility of 0.14 cm^2/V s at process temperature of 150 °C.

Thin film transistors
Scaling behavior
Switching speed

ABSTRACT

The scaling behavior and the influence of the device geometry on the switching speed of organic thin film transistors were investigated. Thiophene transistors were characterized and the influence of contact effects and overlap capacitance was studied. Fundamental scaling limits of the switching frequencies were derived. The maximum transfer frequency is limited by the device design and the specific contact resistance between the drain/source electrode and the organic semiconductor. Finally, strategies will be presented how to realize organic transistors operating at frequencies of up to 100 MHz.

1. Introduction

Electronics based on organic materials has experienced unprecedented progress in recent years. The prospect of flexible, unbreakable, extremely low-weight electronics at relatively low cost has stimulated a lot of research and development on flexible display media [1], organic memories [2] and organic radio frequency identification (RFID) tags [3]. Progress in this field has been sustained by the synthesis of new materials [4], and the improvement of electronic devices [5–7]. In order to realize high performance organic integrated circuits the devices have to be electrically stable [1,3,8] and the switching frequency of the transistors should be as high as possible. High switching frequencies can only be achieved by using organic materials with high charge carrier mobilities and small or very small device dimensions [9,10]. When scaling down the transistor dimensions the channel length, the channel width and the thickness of the gate dielectric are reduced by a scaling factor $1/\kappa$ (see Fig. 1b). Scaling the device dimensions by $1/\kappa$ allows for lowering of the applied voltages by $1/\kappa$, while the electric field distribution within the device remains unchanged. As a result the overall current flow scales by $1/\kappa$, so that the power dissipation is reduced by $1/\kappa^2$. Therefore, the power dissipation per area of an integrated chip remains constant. The transfer frequency of the transistor scales by the scaling factor κ.

It has been demonstrated that the thickness of the gate dielectric of organic transistors can be reduced by using self-assembled monolayers (SAMs) as gate dielectric [11]. The channel length and channel width can be scaled down by using nano-patterning techniques like electron beam lithography, nanoimprint lithography or micro contact printing [12–14]. However, most of the realized short channel transistors exhibit a distinct drop of the device charge carrier mobility with decreasing channel length [14,15].

A basic introduction into the scaling behavior and the switching speed of field effect transistors is given in Section 2. The fabrication of the device structures will be given in Section 3. Afterwards the scaling behavior and the switching speed of organic thin film transistors will be described in Section 4. In particular the influence of contact effects on the scaling behavior and the overlap capacitance on the transfer frequency of organic transistor will be described. In Section 5 an upper limit of the transfer frequency will be derived for organic thin film transistors. Finally, a strategy will be presented how to overcome the existing scaling limits. The results will be summarized in Section 6.

2. Switching speed of field effect transistors

The transfer frequency defines the highest possible frequency at which the thin film transistor can be used as a current amplifier. The operating frequency of a field effect transistor is equal to the transfer frequency if the current gain is equal to unity, which means that the gate current of the transistor is equal to the transistor drain current [16,17]. The transfer frequency of an ideal field effect transistor is given by

$$f_T = \frac{1}{2\pi} \cdot \frac{g_m}{C_G W L}, \tag{1}$$

where g_m is the transconductance of the transistor [17]. C_G is the gate capacitance per unit area, W the channel width, and L the channel length. The product of the channel length and the channel width, WL, represents the channel area of the thin film transistor. The transconductance of the transistor is determined by $g_m = \partial I_{DS}/\partial V_{GS}$. The drain/source current of an organic transistor in the linear region of operation is given by

$$I_{DS} \approx C_G \cdot \frac{W}{L} \cdot \mu_{eff} \cdot V_{DS} \cdot (V_{GS} - V_T), \tag{2}$$

where μ_{eff} is the effective device mobility, V_{GS}, V_{DS}, and V_T are the gate/source voltage, the drain/source voltage, and the threshold voltage, respectively. After determining the transconductance, the transfer frequency in the linear region can be calculated by

$$f_T = \frac{1}{2\pi} \cdot \frac{\mu_{eff} V_{DS}}{L^2}. \tag{3}$$

The transfer frequency scales by $1/L^2$, so that a reduction of the channel length by one order of magnitude leads to an increase of the transfer frequency by two orders of magnitude.

3. Experimental

The measured transfer frequency was determined for organic thin film transistors. The cross section of an organic transistor structure is shown in Fig. 1b. The gold electrodes of the bottom gate coplanar transistor were realized by optical and electron beam lithography. The channel length of the transistors was varied from 50 nm to 50 μm. Optical and electron micrographs of the device are shown in Fig. 2.

In order to realize transistors with very short channel length down to 50 nm the devices were realized on a silicon substrate. The gate electrode of the transistors was not patterned resulting in relatively large overlap capacitance between the gate and the drain/source electrodes. An equivalent circuit of the transistor is shown in Fig. 1c.

The organic semiconductor used in this study was dihexyl-7-thiophene (DH7T), a soluble oligothiophene with seven thiophene units in the molecule (Fig. 1a). The semiconductor was evaporated at a substrate temperature of 190–195 °C in ultra-high vacuum at deposition rates of 0.2 nm/min. To improve the device performance, the silicon oxide dielectric was prior treated with a hexamethyldisilazane (HMDS) monolayer. All measurements were performed under ambient conditions after controlled cooling of the samples to room temperature. Further details on the device operation are given in Ref. [16]. Organic transistors based on DH7T exhibit high charge carrier mobilities exceeding 0.1 cm^2/Vs for long channel devices in air [18]. The measured transfer characteristic of the transistors with a short channel of 350 nm is shown in Fig. 3. The transistor exhibits a device charge carrier mobility of 0.02 cm^2/Vs.

4. Switching speed of organic thin film transistors

The measured transfer frequency as a function of the channel length is shown in Fig. 4. For simplicity only the channel length was scaled down in this experiment. For channel lengths from 5 to 50 μm the transfer frequency can be described by Eq. (3) and the transfer frequency scales by $1/L^2$. The transfer frequency maximum is reached for a channel length of approximately 1 μm. For transistors with a submicrometer channel length a drop of the transfer frequency is measured. The reduction is caused by the influence of parasitic resistors and parasitic capacitors on the device operation. Parasitic contact resistances at the drain and source electrodes of the transistor lead to a reduction of the effective charge carrier mobility and therefore to a drop of the transfer frequency. Furthermore,

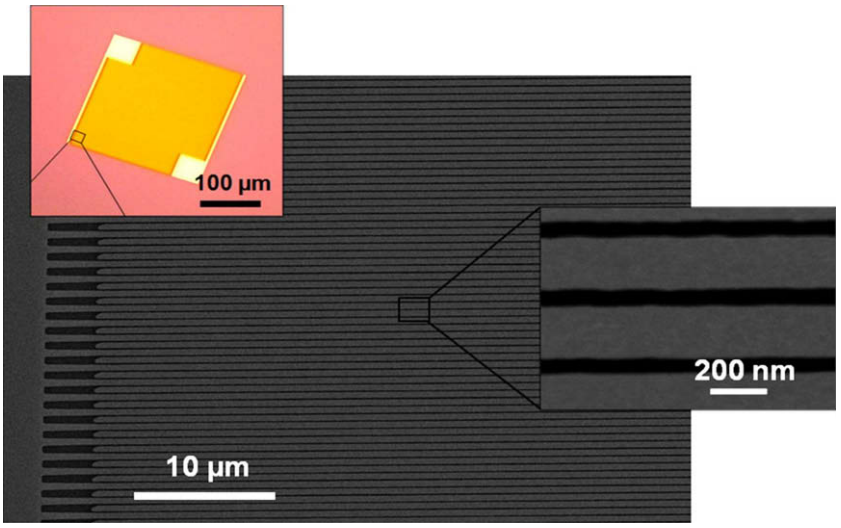

Fig. 2. Optical micrograph and SEM images of the drain and source electrodes of the bottom gate coplanar organic transistor.

the transfer frequency is reduced by the overlap capacitance between the drain/source electrodes and the gate electrode.

In the first step the influence of contact effects on the transfer frequency was investigated. In this case the expression for the transconductance in the linear regime has to be modified taking the influence of the contact effects on the drain current into account, which causes a voltage drop at the contacts resulting in a reduced effective drain/source voltage of the transistor. The drain/source current of an organic transistor is given by

$$I_{DS} \approx C_G \frac{W}{L} \cdot \mu_0 \frac{L}{L + W \cdot C_G \cdot R_C \cdot \mu_0 \cdot (V_{GS} - V_T)} \cdot V_{DS} \cdot (V_{GS} - V_T), \quad (4)$$

considering the influence of contact resistances [19]. The contact resistance R_C is equal to the sum of the drain and the source contact resistances. An equivalent circuit of the transistor including the contact resistances is shown in Fig. 1c. In order to compare the contact resistance of transistors with different device geometries the contact resistance is typically described by a normalized contact resistance, $r_C = R_C \cdot W$. After calculating the transconductance the transfer frequency can be determined by

$$f_T = \frac{1}{2\pi} \cdot \frac{\mu_0 \cdot V_{DS}}{[L + C_G \cdot r_C \cdot \mu_0 \cdot (V_{GS} - V_T)]^2}. \quad (5)$$

A similar expression can be derived for a transistor operating in the saturation region [16]. Based on the experimental data a normalized contact resistance of 3.5 kΩ cm was determined. The extracted value is consistent with contact resistances determined by fitting the channel dependent device charge carrier mobility of the DH7T organic transistors [18]. Lowering of the contact resistance leads to distinctly higher transfer frequencies of transistors with shorter channel lengths.

The contact resistance is affected by the contact geometry, the energy band alignment between the metal contact and the organic semiconductor. Furthermore, the structural order of the molecules in the vicinity of the drain and source contacts have a distinct influence on the band alignment and the contact resistance [19]. An expression for the contact resistance can be derived by considering the electric field distribution in the contact region. The current spreading under the contacts can be described by an ordinary 2nd order differential equation [20]. The equation provides a description of the charge spreading in a semiconductor film with lateral contacts. Solving the differential equation leads to an expression for the normalized contact resistance as a function of the transfer length, which is given by

$$r_C = \frac{\rho_C}{L_T} \cdot \coth\left(\frac{L_{DS}}{L_T}\right). \quad (6)$$

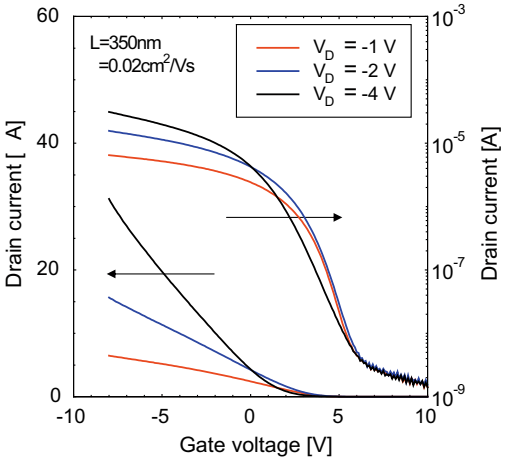

Fig. 3. Current voltage characteristic of a dihexyl-7-thiophene (DH7T) thin film transistor with a channel length of 350 nm.

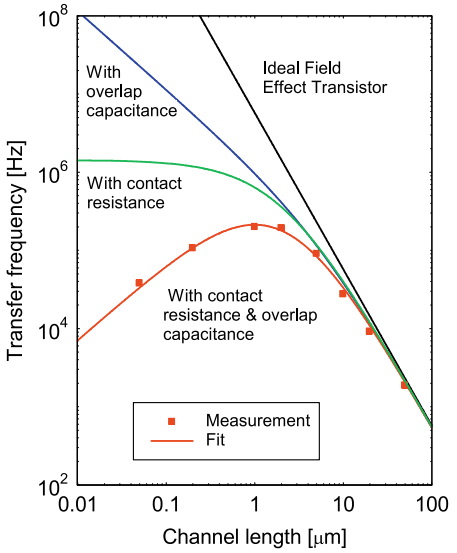

Fig. 4. Measured transfer frequency of a dihexyl-7-thiophene (DH7T) thin film transistor. The data was fitted by taking contact resistances and overlap capacitances between drain/source and gate electrode into account.

The transfer length, L_T, defines the critical distance over which most of the charge is transferred from the metal to the organic semiconductor. The transfer length is measured from the edge of the drain and the source electrodes (Fig. 1b). The transfer length is calculated by

$$L_T = \sqrt{\frac{\rho_C}{R_S}}. \tag{7}$$

The transfer length is determined by the specific contact resistance and the sheet resistance of the channel material. The parameter ρ_C describes the specific contact resistance between the drain/source electrode and the organic channel. The resistance R_S corresponds to the sheet resistance of the transistor channel. If the sheet resistance of the channel is high the transfer length will be small, so that most of the charges are injected close to the edge of the drain and source contacts. In this case the contact resistance is high. If the sheet resistance of the channel is small the transfer length will be large, so that the charges spread under the drain and source contacts. In this case the contact resistance is low. In the following calculation we assumed a uniform distribution of the charges in the channel, so that the sheet resistance is given by $1/R_S = L/W\,\partial I_{DS}/\partial V_{DS}$. This is a valid assumption since the thickness of the organic film is comparable to the thickness of the accumulation layer in the channel [34]. This leads to the following expression for the transfer length:

$$L_T = \sqrt{\rho C_G \mu_0 (V_G - V_T)}. \tag{8}$$

If the transistor operates in saturation a similar expression for the transfer length can be derived. If the length of the drain and source electrodes, L_{DS}, in Fig. 1b is significantly larger than the transfer length, L_T, the normalized contact resistance can be approximated by ρ_C/L_T resulting in the following expression for the normalized contact resistance

$$r_C \approx \frac{\rho_C}{L_T} = \sqrt{\frac{\rho_C}{C_G \mu_0 (V_G - V_T)}}. \tag{9}$$

As a consequence the contact resistance does not depend on the drain and source electrode length. However, the normalized contact resistance depends on the transfer length, which again depends on the charge carrier mobility and the applied voltages. Subsequently the contact resistance is gate voltage dependent, which is in very good agreement with experimental results of silicon and organic thin film transistors [21,22]. If the length of the electrodes is smaller than the transfer length the normalized contact resistance can be approximated by ρ_C/L_{DS}. Subsequently the normalized contact resistance depends on the contact geometry and a reduction of the drain and source electrode dimension leads to an increase of the normalized contact resistance. For the dihexyl-7-thiophene thin film transistors the transfer length was determined to be 1–5 μm, which means that most of the charges are injected in the organic semiconductor within a region of 1–5 μm from the edge of the drain and source contacts. The determined values for the transfer length are very similar to values obtained for other organic semiconductors like pentacene [23]. The sheet resistance of the transistor was determined to be 20–60 MΩ/□. The specific contact resistance is equal to 1–5 Ω cm^2. The determined values are comparable to the values determined for other organic thin film transistors with gold drain and source electrodes. Similar values of the transfer length can be expected for transistors with inkjet or microcontact printed drain and source electrodes [24,25].

In the following calculation it is assumed that the transfer length is smaller than the drain and source electrode length resulting in a normalized contact resistance that is independent on the geometry of the drain and source contacts. The transfer frequency can be expressed in terms of the transfer length by

$$f_T = \frac{1}{2\pi} \cdot \frac{\mu_0 V_{DS}}{(L + L_T)^2}. \tag{10}$$

In the next step the influence of the overlap capacitance on the transfer frequency is investigated. The equivalent circuit of the transistor including the overlap capacitance is shown in Fig. 1c. The overlap capacitance of conventional thin film transistors is determined by the registration of the drain/source and gate mask level. In the linear regime the gate/source and the gate/drain capacitances are equal to half of the channel capacitance plus half of the overlap capacitance, $C_{GS} = C_{ch}/2 + C_O/2$ and $C_{GD} = C_{ch}/2 + C_O/2$. The overlap capacitances between the drain and source contact, C_{DS}, can be neglected, since the capacitance is much smaller than the gate/source and gate/drain overlap capacitance.

The parameters C_{ch} and C_O are the channel and the overlap capacitances. The channel capacitance, C_{ch}, is given by $C_{ch} = C_G \cdot W \cdot L$, where C_G, is the gate capacitance per unit area and $W \cdot L$ the active channel area. The gate capacitance

per unit area is given by $C_G = \varepsilon_o \cdot \varepsilon_r/d$, where ε_0 is the dielectric permittivity of vacuum, and ε_r is the relative dielectric constants of the gate dielectric. The parameter d represents the thickness of the gate dielectric. The overlap capacitance is given by $C_O = 2C_G \cdot W \cdot L_O/2$, where $W \cdot L_O$ is the area in which the gate electrode is overlapped by the drain and the source electrode. The overlap capacitance is determined by the thickness of the gate dielectric and the technology used to pattern the electrodes of the transistor.

At unity current gain the gate current of a transistor corresponds to $2\pi\ f_T \cdot (C_{ch} + C_O)$ including the parasitic capacitances instead of just $2\pi\ f_T \cdot C_{ch}$. The expression taking the overlap capacitance into account $C_{ch}/(C_{ch}+C_o)$ can be substituted by $L/(L+L_o)$. Therefore, Eq. (10) has to be modified leading to the following expression for the transfer frequency:

$$f_T = \frac{1}{2\pi} \cdot \frac{\mu_0 V_{DS}}{L^2} \cdot \frac{L^2}{(L+L_T)^2} \cdot \frac{L}{L+L_O} \tag{11}$$

The equation can be divided in three terms, where the first term describes the ideal relationship between the transfer frequency and the channel length and the charge carrier mobility. The second terms can be considered to be a correction factor, which accounts for the influence of the contact effects on the transfer frequency. The influence of the contact effects on the transfer frequency is described by the transfer length. The third and last terms accounts for the influence of the overlap capacitance on the transfer frequency. The overlap effect is described by the overlap length between drain/source and gate electrodes. The influence of the contact resistance and the overlap capacitance on the transfer frequency is shown in Fig. 4. The DH7T transistor exhibits a maximum of the transfer frequency of 200 kHz. The experimental data can be described very well by the proposed equation taking the contact resistance and the overlap capacitance into account. A transfer length of 2–3 μm and an overlap length of 5 μm were determined by fitting the experimental data. If the overlap length would be reduced to zero the transistor would reach a transfer frequency of 2 MHz. The overlap length and the overlap capacitance are mainly determined by the alignment of the lithographic masks that define the drain/source and the gate electrodes. For transistors prepared by printing technologies the achievable transfer frequency might be significantly lower due to poor alignment of printed layers.

5. Scaling limits of organic thin film transistors

The influence of different charge carrier mobilities and specific contact resistances on the transfer frequency is shown in Fig. 5. It was assumed that the gate dielectric has a thickness of 50 nm, the drain source voltage is equal to −5 V and the overlap length was considered to be 2 μm. The transfer frequencies are plotted for charge carrier mobilities of 0.1 and 1 cm^2/Vs. The specific contact resistance was varied from 0.03 to 3 Ω cm^2. The measured experimental values of the specific contact resistances were equal to 0.2–0.8 Ω cm^2.

For long channels the transfer frequency is proportional to $1/L^2$ and determined by the first term of Eq. (11). In the

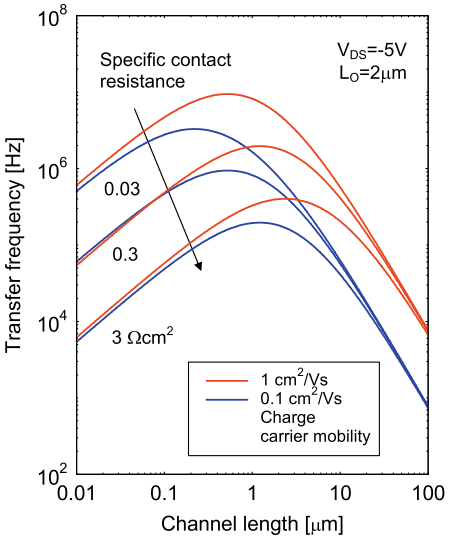

Fig. 5. Influence of the charge carrier mobility and the specific contact resistance on the transfer frequency of organic thin film transistors.

region of intermediate channel lengths the transfer frequency reaches its maxima. For shorter channels the transfer frequency drops due to the influence of the specific contact resistance. In the same region, the charge carrier mobility does not have an influence on the transfer frequency anymore. Based on Eq. (11) the channel length can be calculated at which the transfer frequency reaches its maxima. If the drain/source to gate overlap, L_O, is much larger than the transfer length, L_T, the optimal channel length would be equal to the transfer length, $L_{max} = L_T$. This is the case for most of the transistors fabricated on silicon oxide substrates or transistors prepared by inkjet printing, where the drain/source to gate overlap might be larger than the channel length. If the length of the drain/source to gate overlap is reduced to values comparable to the transfer length the maxima of the transfer frequency is reached for a channel length of

$$L_{max} \approx \frac{L_T}{2}. \tag{12}$$

This is the case for devices realized in this study. Based on Eq. (12) an optimal channel length of 1–5 μm can be calculated. If the overlap length can be reduced to values smaller than the transfer length, the channel length at which the transfer frequency reaches its maximum is given by

$$L_{max} \approx \sqrt{\frac{L_T L_O}{2}}. \tag{13}$$

In this case the highest transfer frequency is reached for channel lengths of 0.5–2 μm. Based on Eq. (12) an upper limit of the transfer frequency can be derived by

$$f_T^{max} \approx \frac{1}{2\pi} \cdot \frac{1}{\rho_C \cdot C_G} \cdot \frac{V_{DS}}{V_{GS} - V_T}. \tag{14}$$

The maximum of the transfer frequency does not depend on the charge carrier mobility and the channel length of the transistor. The transfer frequency is mainly deter-

mined by the specific contact resistance and the gate capacitance per unit area. Eq. (14) can be understood in the following way: During a switching cycle the gate capacitance has to be charged by the gate/source voltage. The charging process is ultimately limited by the contact resistance, which is described by the specific contact resistance. The experimental values of the specific contact resistance for the DH7T transistors were in the range of 0.2–0.8 $\Omega\,cm^2$. A reduction of the specific contact resistance by a factor 10–100 would lead to an increase of the transfer frequency by a factor of 10–100, so that transfer frequencies well above 50 MHz can be achieved [10]. The specific contact resistance can be minimized by selecting the best organic/metal material combination [18]. Furthermore, the interface property can be optimized and fine tuned by using self-assembled monolayers [19,26]. Alternatively the contact resistance can be minimized by doping of the contact region [27]. In order to minimize the overlap capacitance of thin film transistors self-alignment processes can be used [24,28]. Such processes are commonly used in the fabrication of amorphous or polycrystalline silicon thin film transistors realized on glass substrates [29,30]. In order to apply organic transistors in flexible displays or radio frequency identification tags addition requirements have to be fulfilled. The operating voltages of the transistors have to be low. To operate the organic transistor at low operating voltages the threshold voltage of the transistors has to be minimized. The threshold voltage is mainly determined by electronic defects in the organic film and the gate dielectric [31,32]. Organic transistors with low threshold voltages have been demonstrated allowing for the operation of organic transistors at only 2 V [33].

High transfer frequencies can only be achieved for transistors with high charge carrier mobility, low contact resistance, small overlap capacitance and short channel length. Very high transfer frequencies exceeding 50 MHz can only be realized for transistors with channel lengths of 500 nm or less. For such short channel lengths additional parasitic effects like short channel effects might have to be taken into account when describing the operation of the transistors. Further investigations are needed to study the operation of very short channel organic transistors.

6. Summary

The scaling behavior of organic thin film transistors was investigated. High transfer frequencies can be achieved by using short channel transistors with high charge carrier mobilities. However, the maximum of the transfer frequency is limited by contact effects and the overlap capacitance between drain/source and gate electrodes. The transfer frequency reaches a maximum if the channel length is comparable to half of the transfer length. An upper limit of the transfer frequency was derived which is determined by the specific contact resistance between the drain and source electrodes and the organic channel material. The charge carrier mobility does not affect the upper limit of the transfer frequency. Lowering of the contact resistances in combination with a self-aligned patterning process of the drain/source and gate electrodes will allow for the realization of integrated organic circuits operating at frequencies of up to 100 MHz.

Excimer emission

ABSTRACT

A red-emitting iridium complex $(DMBA)_2Ir(acac)$ (DMBA = 5,6-dihydro-9,10-methylenedioxy benzo[c]acridine, acac = acetylacetone) containing rigid cyclometalated ligand DMBA was synthesized and its photophysical, electrochemical and electroluminescent properties were characterized. Organic light emitting devices utilizing the complex as dopant emitter were fabricated. When double hole-transporting layers were adopted, the brightness and efficiencies of electroluminescent devices were improved greatly. Based on the excimer emission, a maximum brightness of 66,312 cd m^{-2} at 15 V, together with a maximum external quantum efficiency of 17.7% at 5.0 V was achieved at a doping concentration of 5%. The result suggests that the introduction of a methylenedioxy group into the N-heterocycle of the cyclometalated ligand leads to higher-energy MLCT transitions and a blue shift of the photoluminescence spectrum.

1. Introduction

Research on organic light-emitting diodes (OLEDs) has been actively pursued in last two decades because of their numerous applications in flat-panel displays and lighting sources [1–3]. Since Forrest and Thompson's group reported the first example of electrophosphorescence at room temperature [4], phosphorescent OLED materials and devices have been intensively studied because of high external quantum efficiencies (EQEs) in their electroluminescence (EL) devices [5,6]. It has been widely accepted that the strong spin–orbit coupling induced by a heavy-metal ion, such as Ir, Pt, and Os promotes an efficient intersystem crossing (ISC) between the singlet and the triplet excited state manifold. Therefore, both singlet and triplet excitons can be harnessed and the strong electroluminescence with an internal efficiency theoretically approaching to 100% can be achieved. Of these phosphorescent materials, iridium complexes have been regarded as the most appropriate emitters because of their relative short lifetime and high quantum efficiency. The emission wavelength of iridium complexes can usually be tuned finely by the introduction of substituent groups with different electronic effects or variations of the conjugation system on ligands. We have reported two red emitters based on rigid quinoxaline derivative–Ir complexes, $Ir(DBQ)_2(acac)$ and $Ir(MDQ)_2(acac)$, and the OLEDs with very high external quantum efficiency and brightness (reached to 12.4% and 73,870 cd m^{-2}) were achieved [7]. Recently, $Ir(MDQ)_2(acac)$ was used for the fabrication of white OLEDs and a striking power efficiency of 124 lm W^{-1} corresponding to an EQE value of 46% was achieved [8]. In our recent work, a maximum brightness of 79,640 cd m^{-2}, together with a maximum EQE of 12.1%, was obtained by adopting rigid benzoimidazole derivative–Ir complex $(biio)_2Ir(acac)$ with a cyan emission [9]. Very recently, 4-phenylbenzoquinoline (PBQ) was used as cyclometalated ligand of the

doi:10.1016/j.orgel.2010.01.003

complex $Ir(PBQ)_2(acac)$ and a high external quantum efficiency and brightness were achieved from the OLED based on this complex (14.6%, 61,693 cd m^{-2}) [10]. All of the above results provided evidences for our strategy that adopting rigid ligands of Ir complexes leads to high brightness and efficiencies of EL devices. As part of our ongoing efforts devoted to the development of phosphorescent emitters containing rigid ligands, we originally devised 5,6-dihydro-benzo[c]acridine (DBA) as cyclometalated ligand and pure red emission was achieved, but the maximum brightness and EQE of the EL device were 9540 cd m^{-2} and 4.66%, respectively, which were not so high as we expected [11]. In order to get better device performances, the optimization of the chemical structure and device structure was carried out in our lab.

In this work, we synthesized a novel Ir complex containing 5,6-dihydro-9,10-methylenedioxy benzo[c]acridine (DMBA) as cyclometalated ligand, and studied its photophysical and electrochemical properties. The EL devices utilizing this iridium(III) complex $(DMBA)_2Ir(acac)$ as a dopant emitter were then fabricated. After optimization of the device structure and doping concentration, high brightness and efficiencies were achieved, demonstrating our strategy that adopting Ir complexes containing 5,6-dihydrobenzo[c]acridine derivatives as rigid cyclometalated ligand leads to high performances of EL devices.

2. Experiments

Where necessary, reactions were carried out under nitrogen atmosphere. $TiCl_4$ was used after distillation. ^1H nuclear magnetic resonance (NMR) spectra were obtained on a Bruker AVANCE 400 spectrometer in $CDCl_3$ using tetramethylsilane (TMS) as an internal reference. Mass spectra (MS) were carried out on a VG-ZAB-HS instrument. Elemental analysis was performed on a Perkin–Elmer 240C elemental analyzer. UV–Vis absorption spectrum was recorded on a Varian Cary 50 UV–Vis spectrophotometer. Photoluminescence (PL) and electroluminescence (EL) spectra were measured on Hitachi F-4500 fluorescence spectrometer. Cyclic voltammetry (CV) measurements were carried out with a CHI660C electrochemical analyzer (CH instruments) at room temperature. Current, voltage, and light-intensity measurements were made simultaneously using a Keithley 2400 source meter and a Newport 1835-C optical meter equipped with a Newport 818-ST silicon photodiode.

2.1. Synthesis of the ligand DMBA

Concentrated sulfuric acid (1.5 mL) and 3,4-methylenedioxy-6-nitrobenzaldehyde (3.90 g, 20 mmol) were dissolved in acetic acid (40 mL). After cooled to 0 °C, 1-tetralone (2.92 g, 20 mmol) was then slowly added in it. The mixture was stirred at room temperature for 2 h. After setting aside for 48 h, the precipitate was filtered off and recrystallized from 95% ethanol to yield the pure product 2-(3,4-methylenedioxy-6-nitrobenzylidene)-1-tetralone.
$TiCl_4$ (2.2 mL, 20 mmol) was added dropwise using a syringe to a stirred suspension of zinc dust (2.6 g, 40 mmol) in anhydrous THF (30 mL) at room temperature under a dry nitrogen atmosphere. The mixture was refluxed for 2 h to form the low-valent titanium. Then the solution of 2-(3,4-methylenedioxy-6-nitrobenzylidene)-1-tetralone (1.6 g, 5 mmol) in THF (20 mL) was added slowly at room temperature. The mixture was stirred at room temperature over night under nitrogen atmosphere and then quenched with 10% HCl (50 mL) and the precipitate was collected and washed with sodium carbonate solution and water. The crude product was purified by recrystallization from ethanol followed by column chromatography on silica gel with dichloromethane and hexane (1:1, v/v) as eluent to furnish pure 5,6-dihydro-9,10-methylenedioxy benzo[c]acridine (DMBA) in 55% yield.

Yellow solid; m.p. 204–206 °C. ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.50 (*d*, *J* = 7.6 Hz, 1H), 7.79 (*s*, 1H), 7.49 (*s*, 1H), 7.42 (*t*, *J* = 7.2 Hz, 1H), 7.35 (*t*, *J* = 7.6 Hz, 1H), 7.28 (*d*, *J* = 7.2 Hz, 1H), 7.01 (*s*, 1H), 6.30 (*s*, 2H), 3.09 (*t*, *J* = 6.0 Hz, 2H), 3.00 (*t*, *J* = 6.0 Hz, 2H). 2.2. Synthesis of the complex $(DMBA)_2Ir(acac)$

DMBA (2.2 mmol) was dissolved in 2-ethoxyethanol (10 mL) in a 50 mL round bottomed flask, then the solution of iridium trichloride (1.0 mmol) in 3.0 mL water was added. The mixture was stirred under nitrogen at 120 °C for 24 h and then cooled to room temperature. The precipitate was collected and washed with ethanol, acetone, and then dried in vacuum to give a cyclometalated Ir-chloro-bridged dimmer. Without further purification, the dimmer complex was used for the synthesis of corresponding mononuclear Ir complex. The dimmer complex, acetylacetone (2.0 mmol), and Na_2CO_3 (5.0 mmol) were dissolved in 2-ethoxyethanol (10 mL) and the mixture was then refluxed under nitrogen atmosphere for 12 h. After cooling to room temperature, the precipitate was filtered off and washed with water, ethanol, and ether. The crude product was purified by column chromatography on silica gel using dichloromethane and hexane (2:1, v/v) as eluent, then sublimated at 300–320 °C and 4×10^{-3} Pa to give the pure desired iridium complex $(DMBA)_2Ir(acac)$ as orange powder in 65% yield. ^1H NMR ($CDCl_3$, 400 MHz) δ: 8.08 (*s*, 2H), 7.71 (*s*, 2H), 7.01 (*s*, 2H), 6.64 (*d*, *J* = 7.2 Hz, 2H), 6.56 (*t*, *J* = 7.2 Hz, 2H), 6.33 (*d*, *J* = 7.6 Hz, 2H), 6.04 (*s*, 2H), 6.00 (*s*, 2H), 4.90 (*s*, 1H), 3.26–3.30 (*m*, 2H), 3.04–3.15 (*m*, 6H), 1.60 (*s*, 6H). Anal. Calcd for $C_{41}H_{31}IrN_2O_6$: C, 58.63; H, 3.72; N, 3.34. Found: C, 58.48; H, 3.85; N, 3.48.

2.3. Fabrication of the EL devices

The EL devices were fabricated by vacuum deposition of the materials at 10^{-4} Pa onto a clean glass that was precoated with a layer of indium tin oxide with a sheet resistance of 25 Ω square^{-1}. The deposition rate for the organic compounds was 0.1–0.2 nm s^{-1}. The cathode of LiF/Al was deposited by first evaporating LiF (1 nm) at a deposition rate of 0.01 nm s^{-1} and then evaporating aluminum (100 nm) at a rate of 0.1–0.2 nm s^{-1}. The cathode was then

capped with silver metal (100 nm) by evaporating silver at a rate of 0.3 nm s^{-1}.

3. Results and discussion

The rigid ligand DMBA was synthesized according to the synthetic procedure of DBA as we reported previously with some modifications (Scheme 1) [11]. Low-valent titanium reagent induced intramolecular reductive coupling reaction of 2-(3,4-methylenedioxy-6-nitrobenzylidene)-1-tetralone, which was obtained by an aldol condensation of 3,4-methylenedioxy-6-nitrobenzaldehyde and 1-tetralone catalyzed by sulfuric acid, afforded the ligand DMBA with moderate yield. The iridium complex $(DMBA)_2Ir(acac)$ was synthesized by a conventional two-step reaction from $IrCl_3{\cdot}3H_2O$ via Ir(III)-μ-chloro-bridged dimer complex [12,13]. The complex was characterized by ^1H NMR and elemental analysis.

The UV–Vis absorption and photoluminescence (PL) spectra of $(DMBA)_2Ir(acac)$ were shown in Fig. 1, and the photophysical data are summarized in Table 1. There are four major absorptions at 275, 375, 454, and 500 nm in the UV–Vis spectrum. Similar results were observed for many other iridium complexes [13–15]. The former two intense bands can be assigned to the allowed π–π^* transition of the DMBA ligand, whereas the later two absorptions are assigned to ^{1}MLCT (metal to ligands charge transfer) and ^{3}MLCT transitions. The ^{1}MLCT and ^{3}MLCT are not clearly resolved where a broad band is observed between 420 and 530 nm. The formally spin forbidden ^{3}MLCT at about 500 nm gains intensity by mixing with the higher lying ^{1}MLCT transition through the strong spin–orbit coupling of iridium atom. This mixing is strong enough in this Ir complex that the formally spin forbidden ^{3}MLCT has an extinction coefficient that is more than half that of the spin-allowed ^{1}MLCT transition. Compared with $(DBA)_2Ir(acac)$, the MLCT transitions of $(DMBA)_2Ir(acac)$ are higher in energy indicating an increase in energy separation between the metal *d*- and π^*-orbitals of the ligand. This may be due to the fact that the π^*-orbitals of DMBA are higher in energy than that of DBA, which may resulted from the introduction of a methylenedioxy group with a strong electron donating effect on the N-heterocyclic moiety [16,17].

Irradiating of dichloromethane solution of $(DMBA)_2Ir(acac)$ with 356 nm light led to strong photoluminescence at 572 nm. The PL quantum yield (Φ) was measured to be 0.40 using $Ir(ppy)_2(acac)$ (Φ = 0.34) [13] as reference. Compared with $(DBA)_2Ir(acac)$, a blue shift of 18 nm was observed. It is widely accepted that the lowest unoccupied molecular orbital (LUMO) predominantly locates at the N-heterocyclic part of the cyclometalated ligand and intro-

duction of electron donating groups into the N-heterocycle (usually the pyridyl moiety) can raise the LUMO energy state of the corresponding Ir complex [16,17]. Hence, the energy gap will be enlarged and consequently lead to a PL hypsochromic shift. Compared with DBA, a methylenedioxy group with strong electron donating effect is introduced into the N-fused heterocycle, so a blue shift of 18 nm is rationalized, and this is consistent with the higher-energy MLCT transitions observed for $(DMBA)_2Ir(acac)$.

The emission spectrum of the complex in the solid state (powder sample) at room temperature is also presented in Fig. 1. Irradiation of $(DMBA)_2Ir(acac)$ with 480 nm light gave an orange-red emission with a peak wavelength of about 612 nm, namely a red shift of 40 nm relative to the solution spectrum. A non-obvious shoulder peak at about 572 nm was also observed. Face to face π–π interactions between aromatic molecules in the solid state often lead to a red-shifted luminescence and is typically ascribed to excimer formation. The square planar Pt complexes with excimer formation has been reported [18–22], while the influence of π stacking on the emission properties of octahedral Ir complex has also been depicted by Thompson [14] and Kang [23]. According to these previous reports, we presume that the red shift of the PL spectrum may be ascribed to excimer emission.

The emission lifetime of $(DMBA)_2Ir(acac)$ in CH_2Cl_2 solution at room temperature was measured to be 0.207 μs, which is shorter than 1.6 μs of $Ir(ppy)_2(acac)$ [14], but a little longer than 0.15 μs of *mer*-$Ir(ppy)_3$ [15]. The radiative (k_r) and non-radiative (k_{nr}) rate constant of $(DMBA)_2Ir(acac)$ were calculated to be 1.9×10^5 and 2.8×10^5, respectively, according to the equations $k_r = \Phi_{PL}/\tau$ and $\Phi_{PL} = k_r/(k_r + k_{nr})$ [15]. Previous report [18] showed that emission lifetimes are important evidences for excimer emission mechanism, so the solid state emission lifetimes at the wavelength of 572 and 612 nm were also measured in order to provide more evidences for the excimer emission mechanism. The measured life time of $\tau = 0.018$ μs of the emission at 572 nm, compared with 0.034 μs at 612 nm, is also consistent with excimer formation on $(DMBA)_2Ir(acac)$.

Cyclic voltammetry (CV) was employed to investigate the electrochemical behavior of $(DMBA)_2Ir(acac)$. The conventional three electrode configuration consists of a plati-

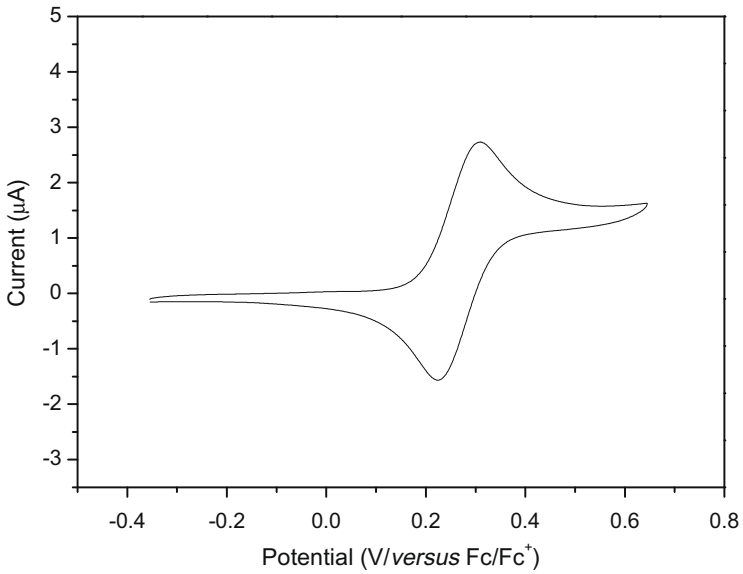

Fig. 2. Cyclic voltammogram of $(DMBA)_2Ir(acac)$.

num working electrode, a platinum wire auxiliary electrode, and a silver wire quasi-reference electrode. The ferrocene/ferrocenium couple was used as internal reference. The cyclic voltammogram was made in a one compartment glass cell in dichloromethane containing 10^{-3} M complex and 0.1 M tetra(*n*-butyl)ammonium hexafluorophosphate (*n*-Bu_4NPF_6) as a supporting electrolyte [24]. Fig. 2 depicts the cyclic voltammogram of the complex, where the potential is cycled at 50 mV s^{-1}.

The CV curve of this complex displayed a clean reversible one-electron oxidation wave at $E^{ox}_{1/2} = 0.27$ V versus Fc/Fc^+ couple reference indicating the good electrochemical stability of the complex. The oxidation process is usually considered as a metal-centered couple, i.e. Ir^{III}/Ir^{IV+} in the present complex, and the highest occupied molecular orbital (HOMO) energy level of the complex can be estimated according to the half-wave oxidation potential with regard to the energy level of the ferrocenium/ferrocene redox couple (being approximately 4.8 eV negative to the vacuum level [25]). The energy gap between HOMO and LUMO was obtained from the wavelength at the intersection of normalized absorption and emission spectrum. All the data are summarized in Table 2.

In order to study the electroluminescent properties of $(DMBA)_2Ir(acac)$, four devices (A–D) using this complex as dopant emitter were fabricated. These devices have the following structure: ITO/HTL/Ir:CBP/BCP/Alq. Either NPB (4,4′-bis[1-naphthylphenylamino]-biphenyl) or NPB together with TCTA (4,4′,4″-tris[*N*-carbazolyl]-triphenylamine) was used as the hole-transporting layer (HTL) and was first deposited on the indium tin oxide (ITO)-coated glass. CBP (4,4′-*N*,*N*′-dicarbozole biphenyl) as the host, and the complex $(DMBA)_2Ir(acac)$ as the dopant, were then deposited. A layer of BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) was used as the hole-blocker. Alq (tris(8-hydroxyquinolinato)aluminum) was used as electron transporting material, while LiF was used as electron-injection layer and Al was used as the cathode. The detailed structure of each device and key performance data are listed in Table 3; the molecular structures and energy level diagrams of the compounds used in the EL devices are presented in Fig. 3, and the data of energy levels of the related compounds are cited from literature [26,27]. The EL spectra and the brightness–voltage–current characteristics are shown in Figs. 4 and 5, respectively, while the external quantum efficiency–current density–current efficiency characteristics of the EL devices are presented in Fig. 6.

Device A was fabricated first, where NPB was used as the hole transporter and CBP doped with 7% $(DMBA)_2Ir(acac)$ as the emitting layer. This device emitted a red light with an emission maximum at 620 nm without any Alq contribution in the EL spectrum. An EQE of 7.6%, with a

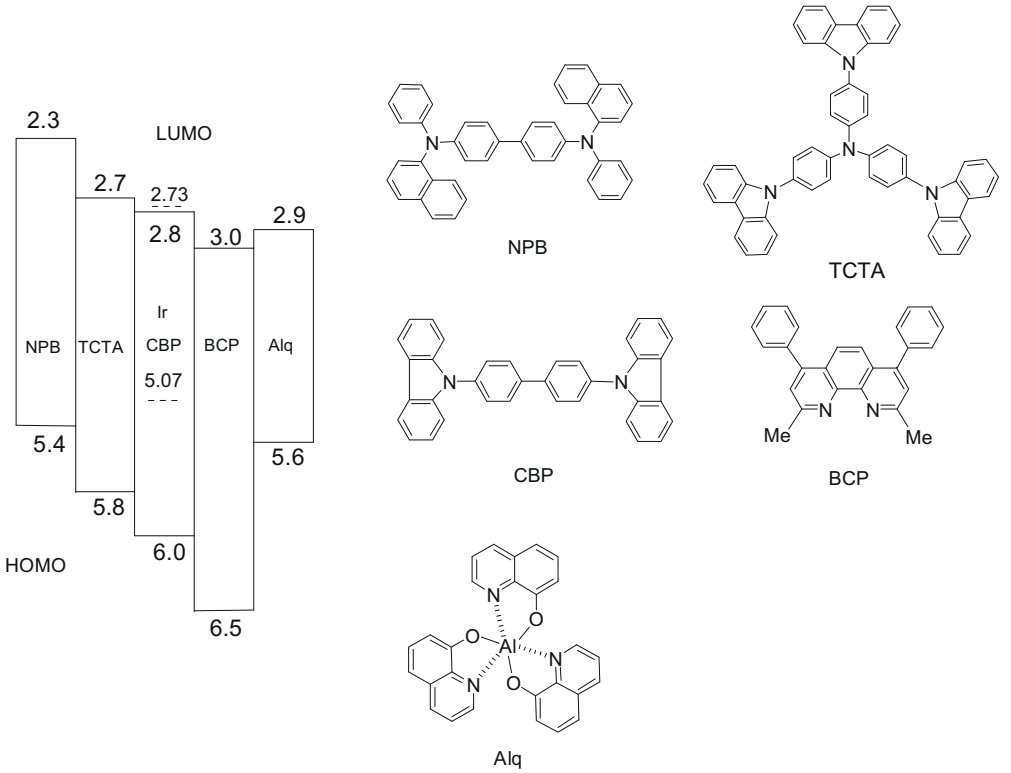

Fig. 3. Molecular structures and energy level diagrams of the compounds used in the devices.

current efficiency of 12.6 cd A^{-1}, power efficiency of 8.8 lm W^{-1} at 4.5 V, and a brightness of 15,100 cd m^{-2} at 15.5 V, were achieved. Compared with EL devices using $(DBA)_2Ir(acac)$ as dopant emitter with similar structure, device A showed a higher brightness and efficiency.

For further optimization of device structure, device B was fabricated, where NPB and TCTA were utilized together as the hole transporting materials. The thickness of BCP layer was reduced to be 10 nm, while the doping concentration was remained 7%. Considering the energy level, adding a layer of TCTA may help the transportation of holes from NPB to the emitting layer. As the results, an EQE of 10.9%, with a current efficiency of 17.7 cd A^{-1} at 5.5 V, a power efficiency of 13.4 lm W^{-1} at 4.0 V, and a brightness of 35,994 cd m^{-2} at 13.5 V, were achieved. The performance of device B was much better than that of device A, while the EL spectrum of device B remained almost the same, which thanks to the efficient holes and triplet excitons blocking effect of BCP. As a frequently used hole-blocker, BCP has a HOMO level of 6.5 eV deeper than that of the dopant complex (5.07 eV) and host material (6.0 eV), so the holes can be effectively blocked from the luminescent layer to Alq layer. An added benefit of the BCP layer is its higher triplet energy level of 2.5 eV [28] than the LUMO energy level of $(DMBA)_2Ir(acac)$, which efficiently blocks the diffusion of the dopant excitons. Based on the EL spectrum at an applied voltage of 6 V, Commission International de l'Eclairage (CIE) coordinates were calculated to be (0.62, 0.38), which were close to (0.59, 0.39) of device A.

The EL spectral shape of both devices A and B were similar to that of the powder sample and doped film emission spectra of $(DMBA)_2Ir(acac)$, where the emission peak at 620 nm may be the result of excimer emission, as we de-

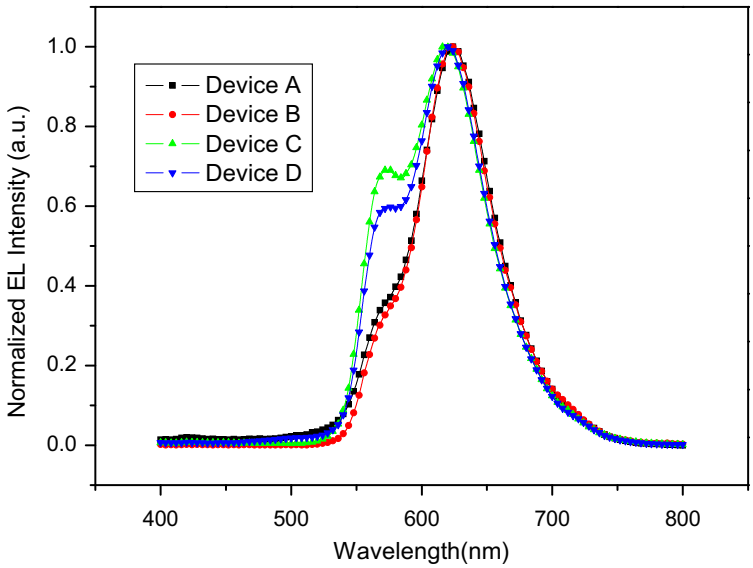

Fig. 4. EL spectra of devices A–D at a voltage of 6 V.

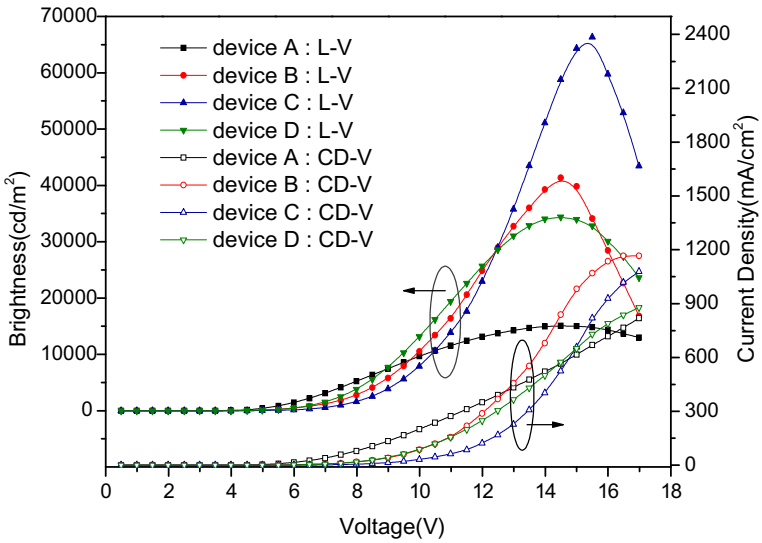

Fig. 5. The brightness–voltage–current characteristics of devices A–D.

scribed above, while the non-obvious shoulder peak at about 572 nm can be ascribed to monomer emission of $(DMBA)_2Ir(acac)$. To achieve efficient excimer emission from a doped layer, control of the dopant concentration is crucial, so devices C and D were fabricated with different doping concentration (5% and 3%, respectively). The structures of the devices C and D remained the same as device B.

The normalized EL spectra of devices B and C (inset) at various applied voltages are shown in Fig. 7. For device B, the shoulder peak at 572 nm becomes more obvious when the applied voltage increases. The relative intensity of the shoulder peak varies from 0.3 to 0.5, so the EL spectrum at 6 V is not a far cry from that of 12 V. For device C with a lower doping concentration of 5%, the shoulder peak becomes much more obvious where the relative intensity of the shoulder peak varies from 0.7 to 0.9. The emission spectrum depends on the applying voltage, but the CIE coordinates at different voltages do not change much since the main emission peak does not change. For device C, at the voltages of 6, 8, 10, and 12 V, the CIE coordinates were (0.57, 0.42), (0.56, 0.42), (0.56, 0.42), and (0.54, 0.43), respectively.

The lower doping concentration of device C improved the device performance, giving a maximum brightness of 66,312 cd m^{-2} at 15.5 V, an EQE of 17.7% at 5.0 V, a current efficiency of 35.7 cd A^{-1} and a power efficiency of 25.0 lm W^{-1}. This may be resulted from the effective prevention of triplet–triplet annihilation. It should be noted

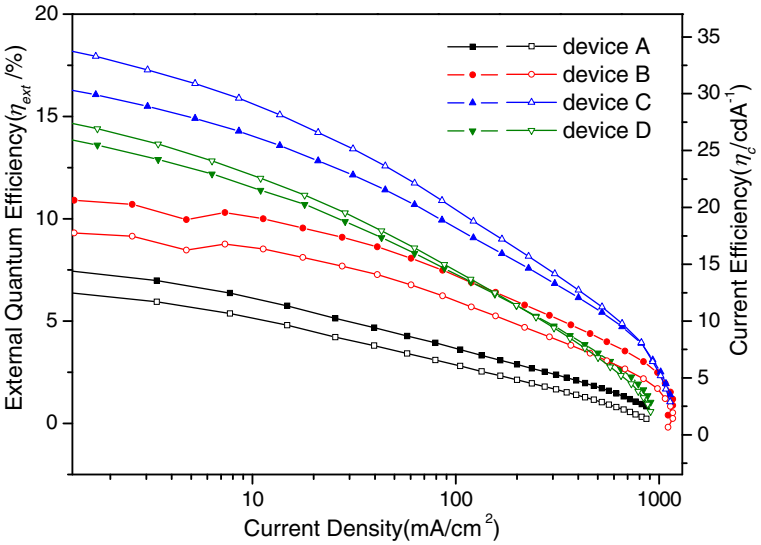

Fig. 6. External quantum efficiency–current density–current efficiency characteristics of the EL devices.

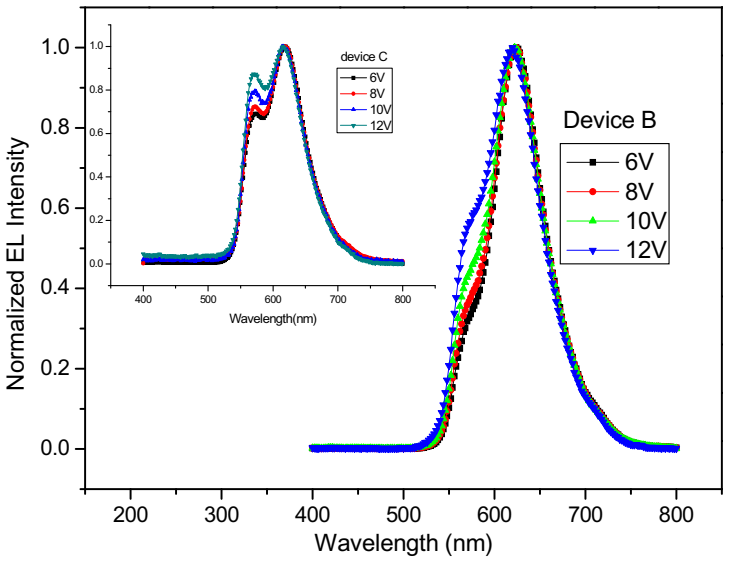

Fig. 7. EL spectra of devices B and C at various applied voltages (the inset shows the EL spectrum of device C).

that the LUMO energy level of $(DMBA)_2Ir(acac)$ is higher than the LUMO level of the CBP host (Fig. 3), which is similar to previous report [26]. The higher efficiency of device C may also be due to more balanced injection and transport of electrons and holes. Because the HOMO and LUMO levels of the dopant are higher than that of the host, the dopant complex will behave as hole traps and electron-scattering centers. As a result, a better recombination of electrons and holes in the emitting layer leads to a higher efficiency of the EL device. This result provides an example of highly efficient red-emitting OLEDs based on excimer emission of iridium(III) complex.

Device D was fabricated by using 3% $(DMBA)_2Ir(acac)$ as the dopant emitter. This device, respectively, achieved a maximum brightness of 34,411 cd m^{-2} at 14.5 V, EQE of 14.3%, current efficiency and power efficiency of 28.2 cd A^{-1} and 20.7 lm W^{-1}. The results are lower than that of device C but higher than that of devices A and B, so we can conclude that a doping concentration lower than 5% would be not profitable to the device performance.

4. Conclusions

The complex $(DMBA)_2Ir(acac)$ exhibits an orange emission in CH_2Cl_2 with a high quantum yield of 0.40 due to the adoption of rigid cyclometalated ligand, an orange-red emission in the solid state and doped thin film resulted

from the excimer formation. Good performances of the EL devices using the complex as dopant emitter can be achieved by optimization of the structure and doping concentration. When NPB and TCTA were used together as the hole transporting materials, the EL devices exhibit much higher brightness and efficiencies. Control of the doping concentration is crucial. A maximum brightness of 66,312 cd m^{-2} and a maximum EQE of 17.7% can be achieved at a doping concentration of 5%. This is a new successful example of our strategy for achieving highly efficient EL device by adopting rigid cyclometalated ligand for phosphorescent iridium complex as dopant emitter. Such a strategy shall provide useful guidelines for the future design and selection of highly phosphorescent materials for OLEDs. Further investigation on this series of complexes used for the fabrication of white OLEDs is currently in progress in our laboratory.

Mixed host

ABSTRACT

We investigated characteristics of solution-processed films of 4,4′-bis(2,2-diphenylvinyl)-1,1′-bibenyl (DPVBi), *N,N′*-bis(naphthalene-1-yl)-*N,N′*-bis(phenyl)-benzidine (NPB), and their blends, and it was found that the spin-coated films of NPB, and blends of NPB and DPVBi, though having lower densities, were more uniform than their vacuum-deposited counterparts. Using the spin-coated films of NPB:DPVBi as mixed host, doped with blue dye (4,4′-bis[2-(4-(*N,N*-diphenylamino)phenyl)vinyl]biphenyl) and yellow dye (5,6,11,12-tetraphenylnaphacene), new white organic light-emitting devices (WOLEDs) were demonstrated. The luminance (maximum luminance of 35822 cd/m^2), efficiency (5.3 lm/W (100 cd/m^2) and 8.3 cd/A (1000 cd/m^2)) and stability of these solution-processed devices are better than or equivalent to the vacuum-deposited one, which was expected as an alternative route to the fabrication of small-molecular WOLEDs, reducing the cost of devices and avoiding the complexities of the co-evaporation of multiple dopants and host materials in the vacuum deposition.

1. Introduction

White organic light-emitting devices (WOLEDs) have highly promising applications in areas such as full-color flat-panel displays, liquid–crystal-display backlighting and large area illumination. The white emission from WOLEDs are generally obtained by mixing complementary (e.g., blue and yellow or orange) or primary colors (red, green, and blue). Many approaches have been proposed to achieve white light emission, such as doping several dyes into one [1–4] or more emissive layers (EMLs) [5–7]. In WOLEDs with multiple EML structures, two or more EMLs are physically separated from each other. Thus the location of exciton recombination and the doping concentration [8] must be controlled carefully to obtain balanced white emission. This usually leads to a fabrication process of great complexity, poor reproducibility and high cost when the vacuum deposition technique is employed. Several methods and processes [9,10] have been reported to avoid the complexity of co-evaporation and/or reduce the manufacturing cost. Fusing organic solid solution is an effective method to avoid the complexity of co-evaporation process [9], where, the dopants are introduced prior to the device fabrication process through high-temperature and high-pressure fusion process. However, for this method to be possible, compatible material systems have to be found to match each other.

Solution processing of organic materials is another attractive technique for low-cost manufacturing device because it is easy to realize co-doping of several dopants and compatible with low-cost, large area manufacture technol-

ogy such as screen-printing, and inkjet printing [11]. In the past decades, organic materials in solution processing for fabricating devices are mainly polymers [12–15]. Alternatively, many solution-processible organic molecules were designed and synthesized to fabricate the light-emitting devices by spin-coating, such as dendritic molecules [16–18], oligomers [19], spiro-molecules [20,21], and binuclear metal chelates [22,23]. Recently, Lee et al. have also reported a spin-coated blue light-emitting devices based on 2-(t-butyl)-9,10-bis(2′-naphthyl) anthracene [24], which combines the simple materials of OLED and low-cost process of solution processing. Thus, it is desirable to develop solution-processed devices based on high-efficient molecular materials which films were usually made by vacuum-deposition.

In this paper, we investigated the characteristics of spin-coated films of DPVBi (4,4′-bis(2,2-diphenylvinyl)-1,1′-bibenyl), NPB (*N,N*′-bis(naphthalene-1-yl)-*N,N*′-bis(phenyl)-benzidine) and their blends, which were widely used in fabrication of OLEDs by vacuum-deposition. It was found that the spin-coated small-molecular films of NPB, and blends of NPB and DPVBi, though having lower densities, were more uniform than their vacuum-deposited counterparts. We demonstrate WOLEDs based on solution-processed films of the blends of NPB and DPVBi. In these WOLEDs, the white EML was formed by spin-coating a solution containing mixed hosts (MH) of NPB and DPVBi, blue dopant 4,4′-bis[2-(4-(*N,N*-diphenylamino)phenyl)-vinyl]biphenyl (DPAVBi) and yellow dye 5,6,11,12-tetraphenylnaphacene (rubrene). Besides avoiding complexity of co-evaporated process in vacuum deposition, these devices show high luminance and stable white-emitting under different driving voltages.

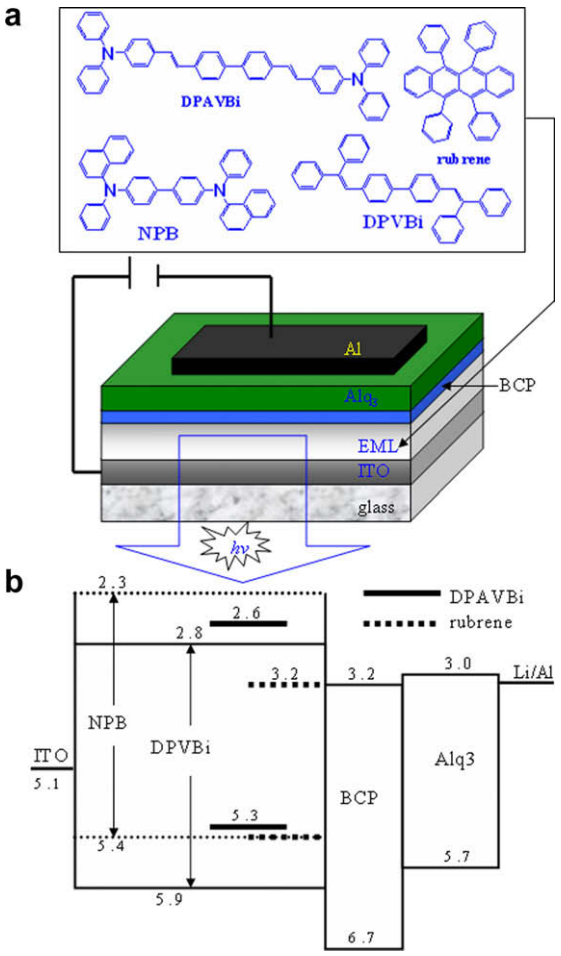

Fig. 1. (a) Chemical structures of the key materials used and structure of devices A–F, (b) schematic energy-level diagrams of devices A–F.

2. Spin-coated molecular films

The chemical structures of DPVBi, NPB, blue dye DPAVBi and yellow dye rubrene are shown in Fig. 1(a). The chlorobenzene was used as a solvent for dissolving these molecular materials. The solution-processed films of blends of NPB:DPVBi were fabricated as follows. The blends with NPB:DPVBi weight ratio of 0:10, 1:9, 1:4, 3:7, 2:3, 3:2, 4:1, 10:0 were first dissolved in chlorobenzene (~14 mg/ml), the solution was then spin-coated on indium tin oxide (ITO)-coated glass substrates to form a film with a thickness of 50 nm (1000 rpm). Finally, the spin-coated films were transformed to the oven for baking. Following previous reports [25], the spin-coated films are baked at 80 °C for 30 min in the oven to guarantee the removal of residual solvent of chlorobenzene in the spin-coated films. The surface morphology was investigated by AFM and 10× microscope objective with a numerical aperture of 0.3 (Nikon, Japan). The thickness and refractive indices of the films were measured by an ellipsometer.

Fig. 2 shows the microscope images of spin-coated films of NPB:DPVBi with different mixing ratios. Fig. 2(a)–(h) corresponds to NPB:DPVBi ratio of 0:10, 1:9, 1:4, 3:7, 2:3, 3:2, 4:1, and 10:0, respectively. Fig. 2(a) shows the spin-coated film of DPVBi, where significant crystallization and coagulation of DPVBi was observed. These effects are due to the low glass-transition temperature (T_g) of DPVBi (64 °C) during the annealing process [26]. If the NPB (10%) is blended with DPVBi (90%), however, crystallization of the spin-coating film of the blends was reduced as shown in Fig. 2(b). With the increasing NPB concentration in the blends, the crystallization of spin-coated film of the blends was further reduced as can be seen from Fig. 2(c) and (d). As the NPB concentration is increased to 40%, the crystallization and coagulation can no longer be observed (see Fig. 2(e)–(h)). The suppressing of the crystallization and coagulation of DPVBi can be attributed to two factors. One is that the NPB molecules in the blends function as defects and hence prevents the formation of an ordered crystal of DPVBi. This phenomenon is similar to a previous report [10], where the glass-transition temperature of NPD:rubrene was found to be higher than that of pure NPD(4,4′-bis[*N*-(1-naphthyl)-*N*-phenyl-amino]-biphenyl) because the doped rubrene serve as defects. The other is that a polymer with a high T_g was reported to effectively suppress the crystallization and coagulation of molecular material in molecularly doped polymers [27]. Since NPB has a T_g of about 95 °C, it is effective on preventing the crystallization and coagulation from happening in spin-

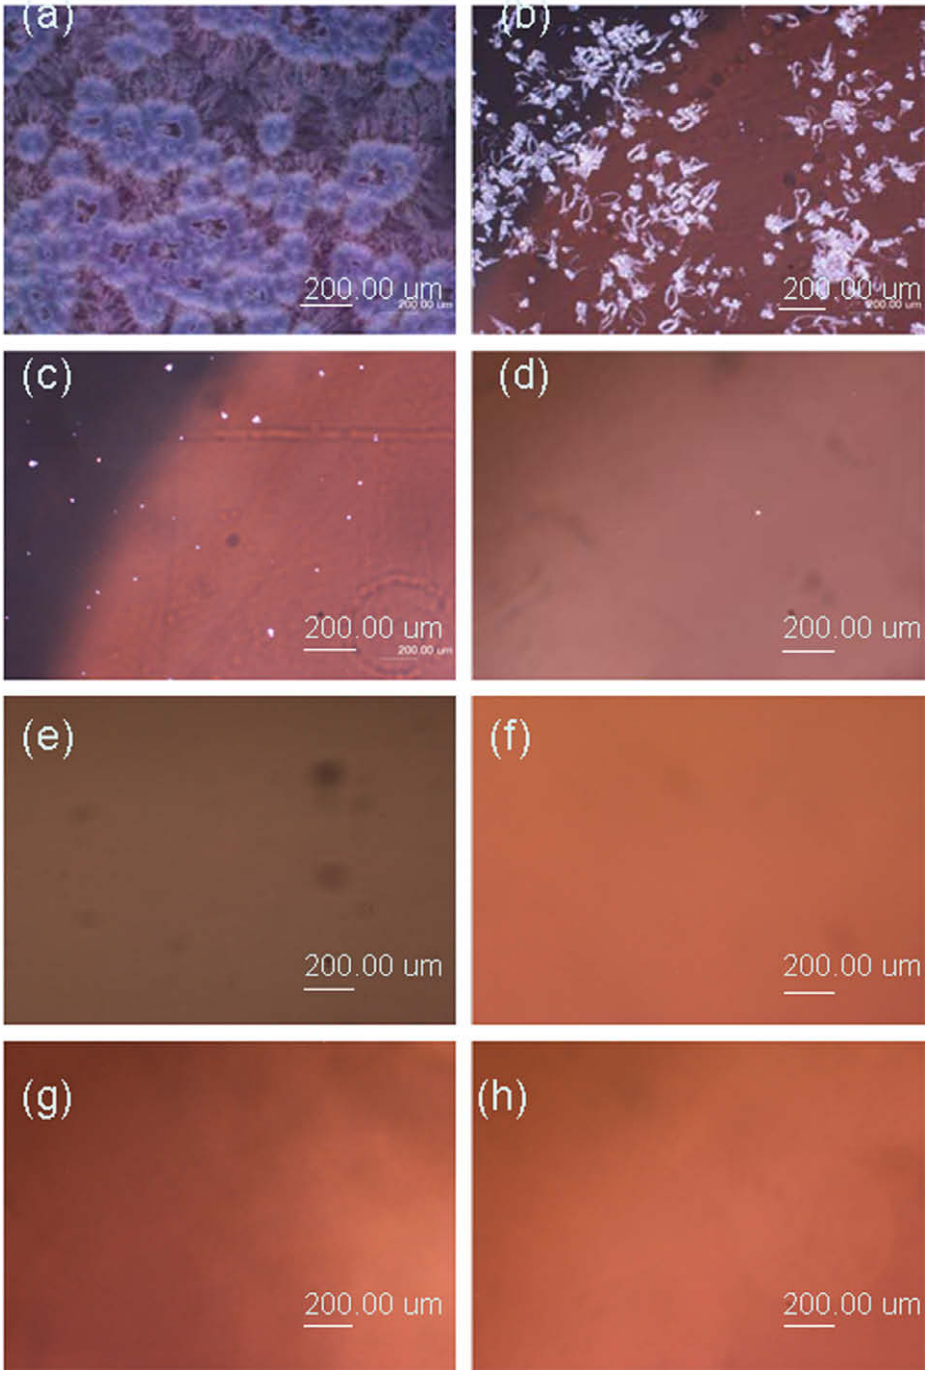

Fig. 2. The microscope images of organic films spin-coated on top of ITO. (a)–(h) Corresponding to NPB:DPVBi ratios of 0:10, 1:9, 1:4, 3:7, 2:3, 3:2, 4:1, and 10:0, respectively.

coated films and thus provides these films with better thermal stability.

Fig. 3 shows the surface morphology of spin-coated and vacuum-deposited films by atomic force microscopy (AFM). Fig. 3(a) is the surface of the ITO film, on which other organic materials were deposited or spin-coated. The root-mean-square of surface roughness (R_{RMS}) of ITO film is 1.51 nm. Fig. 3(b)–(f) is the surface morphology of spin-coated films of the blends with NPB:DPVBi ratios of 10:0, 3:7, 2:3, 3:2, and 4:1 (these films has no crystallization) on ITO film, which R_{RMS} of surface roughness is 0.319, 0.247, 0.254, 0.277, and 0.312 nm, and all the spin-coated films show a pin-free and smooth surface morphology. The surface morphology of vacuum-deposited films of NPB and NPB:DPVBi (3:2) were also shown in Fig. 3(g) and (h) with the R_{RMS} of 1.62 and 0.91 nm. The AFM investigations indicate that

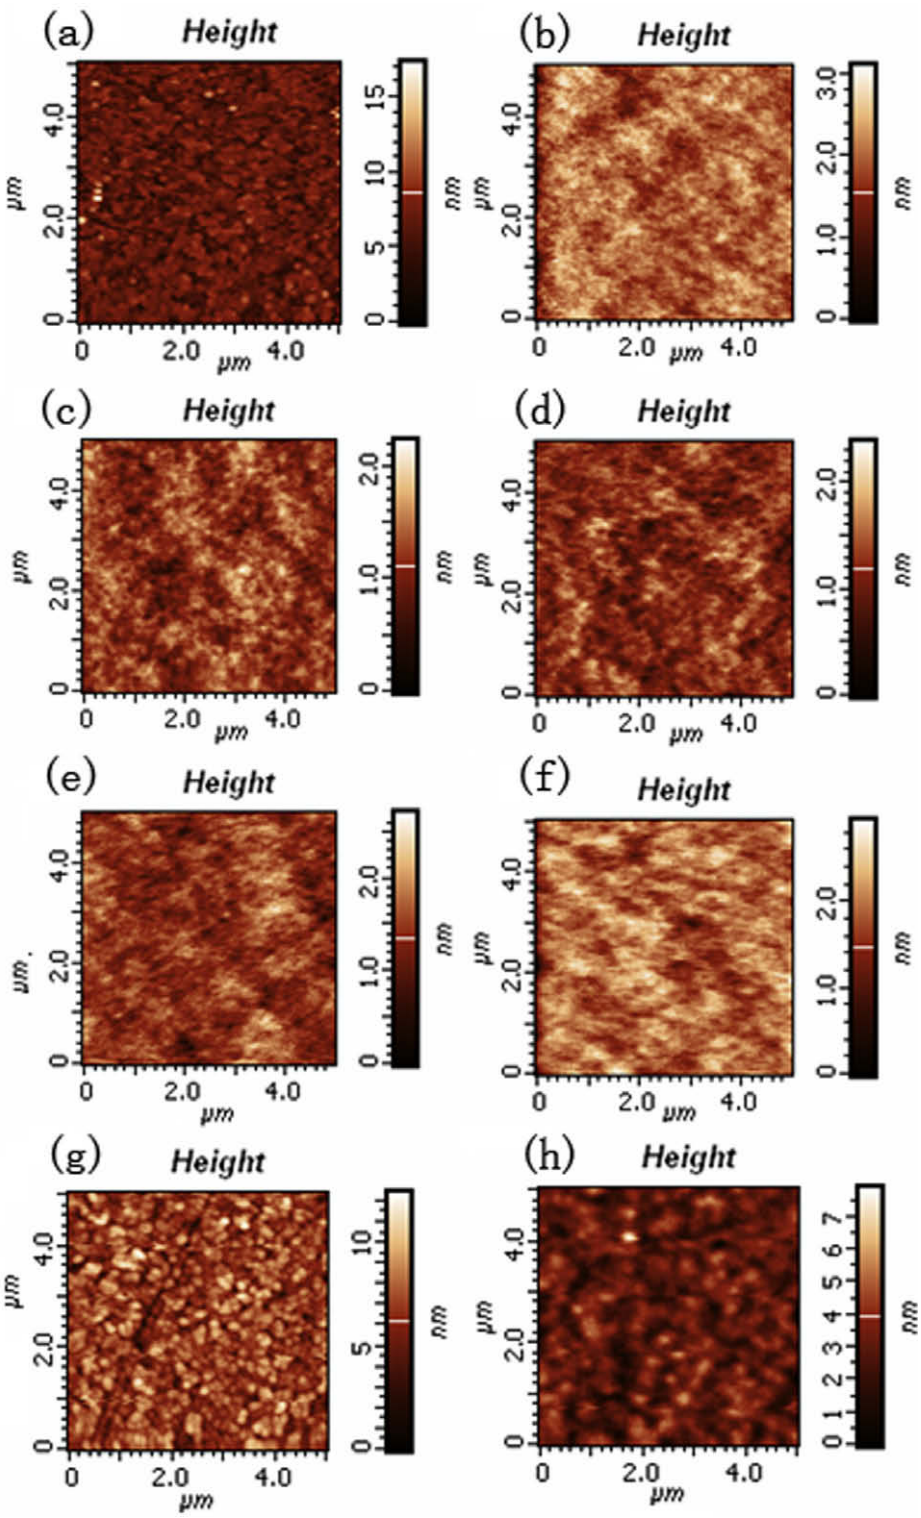

Fig. 3. The AFM images of ITO films (a) (R_{RMS} = 1.51 nm) and spin-coated films with NPB:DPVBi ratios of, (b) 10:0 (R_{RMS} = 0.319 nm), (c) 3:7 (R_{RMS} = 0.247 nm), (d) 2:3 (R_{RMS} = 0.254 nm), (e) 3:2 (R_{RMS} = 0.277 nm), (f) 4:1 (R_{RMS} = 0.312 nm), and the vacuum-deposited films with NPB:DPVBi ratios, (g) 10:0 (R_{RMS} = 1.62 nm) and (h) 3:2 (R_{RMS} = 0.91 nm) (scan size: 5 × 5 μm).

the spin-coated films of NPB, and NPB:DPVBi blends are more uniform than the vacuum-deposited ones.

The refractive indices of the spin-coated films can be obtained by spectroscopic ellipsometry, which can be used

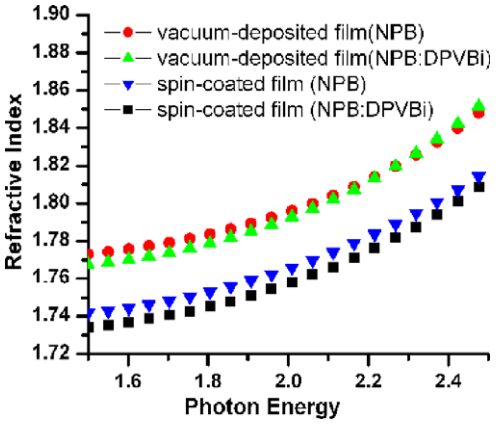

Fig. 4. The refractive indices of the spin-coated and vacuum-deposited films of NPB and the blends of NPB:DPVBi (3:2).

to evaluate the porosity of the films. The refractive index (n_f) of the film can expressed as $n_f = n_s(1-q) + n_p q$, where n_s and n_p are the mean indices of skeleton of the film and the pore space respectively, and q is the porosity, or the fractional volume of the pores in the film [28]. So the refractive index, n_f, is reversely in proportional to q, the porosity of films. Fig. 4 shows the refractive index of spin-coated films of NPB, the blends of NPB and DPVBi (3:2), and their vacuum-deposited counterparts. It was found that the refractive indices of spin-coated films of NPB and the blends of NPB and DPVBi (3:2) were smaller than those of vacuum-deposited counterparts. These showed that the spin-coated films were more porous and had lower density than the vacuum-deposited ones. How to deposit more dense molecular films by solution-processing will be a challenge in future research.

3. Fabrication and performances of WOLEDs

Based on spin-coated films of NPB:DPVBi, the device structure of WOLEDs in our experiments is ITO/EML (50 nm)/BCP (10 nm)/Alq_3 (30 nm)/LiF/Al. BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) is used as hole-blocking material and Alq_3 (tris(8-hydroxyquinoline)aluminum) as electron-transporting material. The spin-coated EML consist of MH doped with blue dye DPAVBi (4%) and yellow dye rubrene (0.27%) [29]. The composition of the EMLs used in six devices (labeled as A, B, C, D, E, and F) is summarized in Table 1. The six devices A, B, C, D, E, and F have different NPB:DPVBi weight ratios, which are 10:0, 4:1, 3:2, 2:3, 1:4, and 0:10, respectively. The details of device fabrication are as follows: (1) the chlorobenzene solution (~14 mg/ml) was spin-coated on clean patterned ITO-coated glass substrates to obtain a film of 50 nm thickness; (2) the spin-coated films of the devices A–D were annealed at 80 °C for 30 min and that of the devices E and F were annealed at 80 °C for 10 min to avoid the crystallization of spin-coated films; (3) the samples A–F were then loaded into a vacuum chamber to have the BCP hole-blocking layer (10 nm thickness), electron-transporting layer (30 nm thickness) and the cathode, LiF (0.6 nm)/Al (100 nm) deposited by thermal evaporation. The schematic energy-level diagram of the devices is shown in Fig. 1(b). The photoluminescence (PL) spectra of the films were measured with a fluorescence spectrophotometer (Fmax-4, JY Co.) and the absorption spectra were measured with UV3010 (Hitachi Co.). The electroluminescence (EL) spectra and CIE coordinates of the devices were measured by a spectrometer (PR650) and the current–voltage-luminescence characteristics were analyzed by Keithley 2602 source meter and Luminance meter.

The EL characteristics of devices A–F were summarized in Table 1. Fig. 5(a) and (b) shows their luminance–current density and current efficiency–luminance characteristics. Among all the devices, device C shows the best performances, it presents a power efficiency of 5.3 lm/W (100 cd/m^2) and current efficiency of 6.5 cd/A at a luminance of 1000 cd/m^2 and a maximum luminance of 35,822 cd/m^2 at 11.7 V. The luminance and current efficiency of the devices with MH (B–E) are higher than that with only NPB (device A) or DPVBi (device F). As we can see, device A shows a current efficiency of 3.83 cd/A (1000 cd/m^2) and a maximum luminance of 14,113 cd/m^2, while device F shows a current efficiency of 0.65 cd/A (1000 cd/m^2) and a luminance of 1476 cd/m^2.

The higher efficiency and luminance of devices B–E can be attributed to the blend of NPB and DPVBi used as MH, which effectively adjust the hole-injecting/transporting of devices by varying the ratio of the blend. DPVBi is a light-emitting material with intense fluorescence in the blue region [30], and NPB is widely used as a hole-transport material, whose hole mobility (10^{-4} cm^2 V^{-1} s^{-1}) is much higher than that of DPVBi and the hole-injecting bar-

Table 1
The composition of the EML and the EL characteristics of WOLEDs.

No.	Weight ratio				Performances		
	NPB	DPVBi	DPAVBi (*x*%)	Rubrene (*y*%)	Maximum luminance (cd/m^2)	Efficiency at 1000 cd/m^2	CIE (*x*,*y*)[a] 4 V/9 V

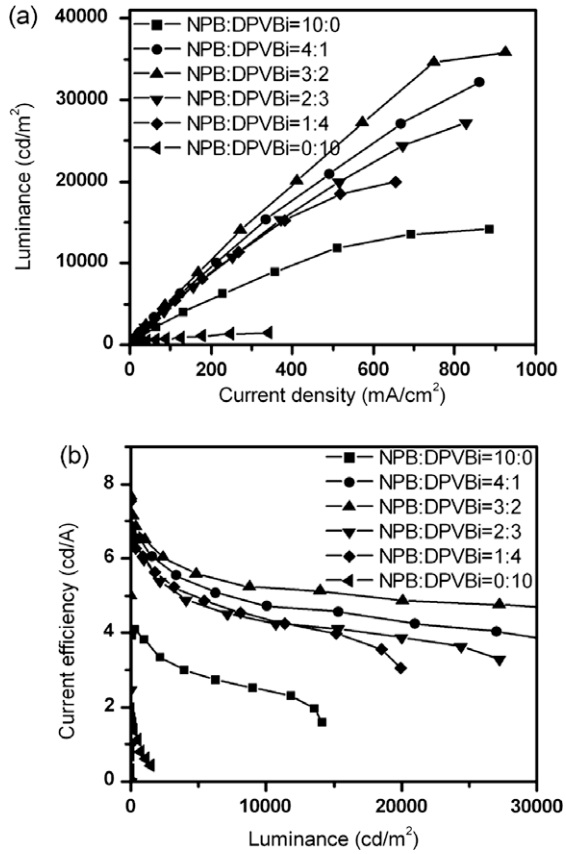

Fig. 5. (a) The luminance–current density and (b) current efficiency–luminance characteristics of the devices A–F.

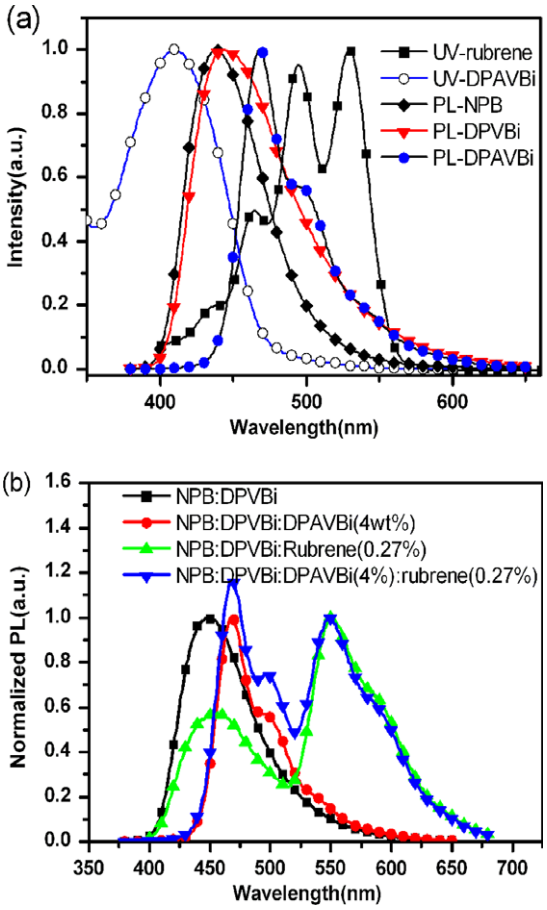

Fig. 6. (a) The UV absorption spectra of DPAVBi and rubrene in chlorobenzene solution and PL spectra of pure DPVBi, NPB, and 4% DPAVBi doped into PMMA film and (b) PL spectra of mixed film of NPB:DPVBi (3:2), DPAVBi (4%), rubrene (0.27%) and both DPAVBi (4%) and rubrene (0.27%) doped mixed film.

rier of NPB from ITO (0.3 eV) is lower comparing to DPVBi (0.8 eV) [30,31]. So the blend of NPB and DPVBi used as MH play the roles of both hole-transport layer (HTL) and EML in WOLEDs, and the hole injection and transport in WOLEDs can be adjusted by changing the ratio of NPB and DPVBi in EML, which could improve the balances of carriers (holes and electrons) in EML and achieve the high performance of devices.

In order to distinguish the energy-transfer processes in the EMLs of the WOLEDs, the absorption and PL spectra of the dyes, the MH and the dye-doped MH films are investigated. Fig. 6(a) shows the absorption spectra of DPAVBi and rubrene in chlorobenzene solution, and PL spectra of DPVBi, NPB and DPAVBi in films. In Fig. 6(a), there is a large spectral overlap between the fluorescent band of the MH (NPB:DPVBi) and the absorption bands of both DPAVBi and rubrene, which indicates that the lowest singlet-excited states in the MH can be energetically transferred to the dyes (DPAVBi or rubrene) via förster energy transfer. In addition, the spectra overlap between the fluorescent band of DPAVBi and the absorption band of rubrene suggests that the energy-transfer process between them can happen. Fig. 6(b) shows the PL spectra of the mixed NPB:DPVBi film (3:2), the DPAVBi (4%), rubrene (0.27%) and both DPAVBi (4%) and rubrene (0.27%) doped films. The excitation peak wavelength was at 350 nm for all the PL measurement. The DPAVBi and rubrene show a peak at 468 and 550 nm, respectively. In Fig. 6(b), no emission from the MH is observed in PL spectra of MH doped by DPAVBi, indicating that the energy in the excited MH molecule is completely transferred to DPAVBi with a doping concentration of 4%. On the other hand, a strong emission from MH is observed when the MH is doped with rubrene, suggesting the energy transfer from the MH to rubrene is incomplete with the doping concentration of 0.27%. When we doped both DPAVBi (4%) and rubrene (0.27%) in the MH, nearly comparable intensity of blue and yellow-emitting band are observed, which implies that the energy in the MH is shared by both dyes.

Fig. 7(a)–(d) shows the EL spectra of devices A–D under different applied voltages, where the EL intensity is normalized to the blue wavelength peak, and the CIE coordinates are shown in insets. As can be seen, the devices B–D with MH show quite stable CIE coordinates with various applied voltages. The CIE coordinates of device C change from (0.305, 0.390) at 4 V to (0.320, 0.392) at 9 V, in which the change of CIE coordinates is only (0.015, 0.002), while the CIE coordinates of device A with NPB as host shift from

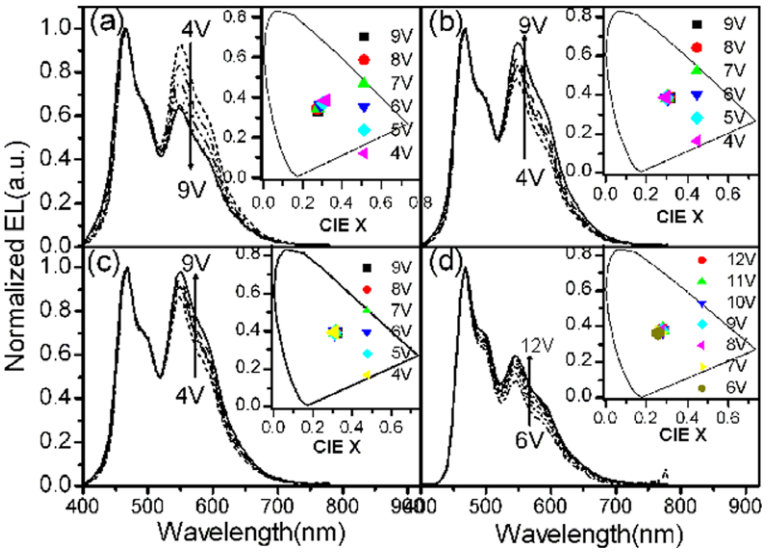

Fig. 7. The normalized EL spectra of the devices A–D and CIE coordinates in inset. (a)–(d) correspond to devices A–D, respectively.

(0.315, 0.386) to (0.275, 0.336), showing a change of (−0.040, +0.050). According to previous reports [32,33], the blueshift under increasing applied voltages in WOLEDs with lightly doped rubrene is attributed to the saturation effect of the rubrene molecules, which could account for the spectral variation of device A with NPB host doped with little amount of rubrene (only 0.27%). Therefore the stable color coordinates of devices B–D with MH are due to DPVBi in the blends that has an electron-transporting character [30,34], which transports electrons to the bulk of the EML effectively and consequently avoids the saturation effect of rubrene molecules. In addition, the role of BCP in WOLEDs is expected to prevent holes from entering electron-transporting layer and confine all the electron–hole pairs in the EML for efficient recombination, which also helps stabilize the color coordinates of WOLEDs.

The device performance of above device C still has room for improvement if we introduce a hole-injection layer such as poly(3,4-ethylenedioxythiophere):poly(styrene sulfonate) (PEDOT:PSS). Fig. 8(a) and (b) presented the comparison of efficiency and stability of solution-processed WOLEDs (device G) and the vacuum-deposited one (device H). The devices G and H have the same structure as ITO/PEDOT:PSS (50 nm)/EML (50 nm)/BCP (10 nm)/Alq_3 (30)/LiF (0.5)/Al(100 nm), in which the PEDOT:PSS was introduced as hole-injection layer, and EML consisted of the same ratio of NPB, DPVBi, DPAVBi, and rubrene as device C in Table 1. The water-dispersed PEDOT:PSS mixture was spin-coated on the top of ITO to form a film with a thickness of 50 nm. As for the solution-processed WOLEDs (device G), the fabrication of EML was the same as device C except the annealing condition is changed to be 130 °C for 15 min in the oven. As for the vacuum-deposited one (device H), the EML was formed by vacuum deposition of a solution-promixed deposition target with mixed hosts DPVBi and NPB doped with DPAVBi and rubrene [35]. In Fig. 8, device G shows a current efficiency of 8.3 cd/A at the luminance of 1000 cd/m^2 and an

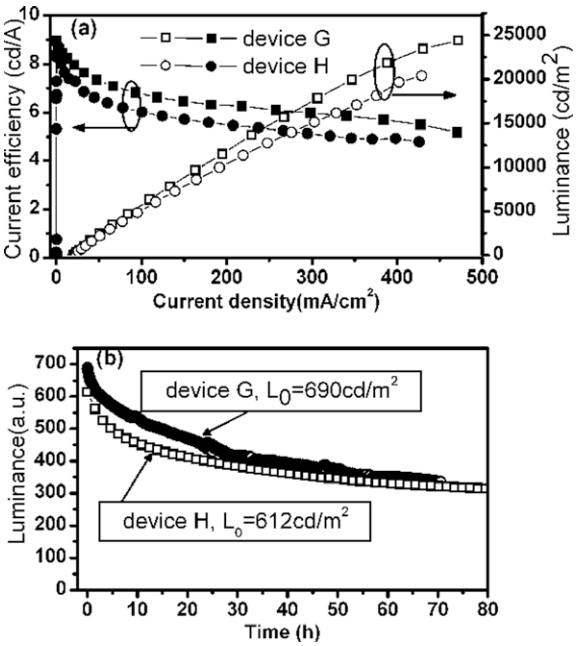

Fig. 8. (a) Current efficiency–luminance–current density characteristics of the devices G and H and (b) luminance decay versus time characteristic of devices G and H.

over 70 h lifetime with initial luminance of 690 cd/m^2, which were better than or equivalent to those of vacuum-deposited one, device H. In addition, the efficiency of device G was comparable to that of the vacuum-deposited multilayer WOLEDs based on the DPAVBi and rubrene as dopants in previous reports, in which the reported best efficiency is 7.7 cd/A (112 cd/m^2) [33] and 10.9 cd/A (10 mA/cm^2) [36]. So, solution-processed molecular films in our works provide a new route for the easy and simple

fabrication of WOLEDs without the sacrifice of device performance.

4. Conclusion

We have investigated solution-processed small-molecule films, such as DPVBi, NPB, and their blends. The more uniform films of NPB and the blends of DPVBi:NPB can be achieved by spin-coating, though having a lower density, in comparison with their vacuum-deposited counterparts. With the spin-coated films of DPVBi:NPB doped with DPAVBi and rubrene, which serves as the EML, a new WOLEDs were demonstrated. The solution-processed WOLEDs show the considerable efficiency and stability, which were prior or equivalent to the vacuum-deposited counterparts. Solution-processed small molecular films are expected to be a new route to fabricate their WOLEDs to reduce manufacture cost and avoid the complexity of the vacuum co-deposition process.

ABSTRACT

The modification of MEH-PPV/TiO_2 photovoltaic devices with the lithium salt, Li[CF_3SO_2]$_2$N, is shown to result in a 40% increase in both the short-circuit current and fill factor while not affecting the open-circuit voltage. The power conversion efficiency of the modified devices is 1.05% under 80 mW/cm^2 simulated solar illumination, which is twice that of the control device without the salt and the highest reported to date for a polymer/TiO_2 solar cell. The increased performance is attributed to a large improvement in the hole mobility of the MEH-PPV, as measured by space-charge-limited current measurements, in the presence of the lithium salt. Modification of the devices with $LiClO_4$ is not as effective at improving device performance. Secondary ion mass spectroscopy measurements reveal that the poorer performance is due to a lower degree of Li diffusion into the polymer layer for $LiClO_4$ than for Li[CF_3SO_2]$_2$N.

1. Introduction

Conjugated polymers are attractive for use in organic photovoltaic devices because they are flexible, can be deposited from solution, and avoid the containment problems associated with the liquid electrolytes used in high-efficiency dye-sensitized solar cells (DSSCs). Although dye-sensitized solar cells are the most efficient variety of organic solar cell at present, polymer/electron transport material (ETM) devices are particularly attractive due to their simplicity and potential for low-cost processing. While the absorption coefficients of conjugated polymers are reasonably high ($\sim 10^5$ cm^{-1}) [1] their usefulness in devices has typically been limited by their relatively high exciton binding energies, the short exciton diffusion lengths ($\sim$10 nm) [2] and low hole mobilities ($\sim 10^{-7}$–10^{-4} cm^2/Vs) [3] with the latter due to their amorphous nature. The first two limitations can be overcome by blending the polymer with an electron accepting and transporting material (e.g. C_{60} or TiO_2), such that the distance excitons must travel to reach an appropriate interface and dissociate is reduced to the order of the exciton diffusion length [4]. Once separated, the charges must still traverse the thickness of the device in order to be collected and put to use, so it is desirable to increase the charge mobility of the polymer in order to get charges out more quickly and reduce recombination.

The lithium salt lithium bis(trifluoromethylsulfonyl)-amide (Li[CF_3SO_2]$_2$N or LiTFSI) has recently been shown to improve the hole mobility of the molecular hole transport material 2,2′,7,7′-tetrakis(*N*,*N*-di-*p*-methoxyphenylamine)-9,9′-spirobifluorene (Spiro-MeOTAD) [5], as well as improving the photovoltaic performance of various dye-sensitized [6–11] and organic/organic bilayer [12] solar cells. We have studied the effects of LiTFSI on charge

transport in the polymer poly[2-(2-ethylhexyloxy)-5-methoxy-1,4-phenylenevinylene] (MEH-PPV), and on the performance of ITO/TiO_2/MEH-PPV/Au photovoltaic (PV) devices modified with LiTFSI using simple, solution-based procedures that are amenable to high-throughput fabrication techniques. By fitting the current–voltage data of ITO/MEH-PPV/Au hole-only diodes to a field-dependent space-charge-limited-current (SCLC) model, we find that the mobility of MEH-PPV can be increased by more than an order of magnitude by the addition of LiTFSI. We also find that the current and fill factor of PV devices can be increased by as much as 40% upon the addition of LiTFSI, resulting in a two-fold increase in device efficiency from 0.52% to 1.05% under 80 mW/cm^2 simulated solar illumination.

2. Results

2.1. Photovoltaic device performance – pre-treatment with LiTFSI

Three different device architectures were studied whereby the position of the lithium salt in the device was varied. In each case photovoltaic devices of the type ITO/TiO_2/MEH-PPV/Au were made, and their current–voltage (I–V) characteristics tested under 80 mW/cm^2 simulated solar illumination. The first device architecture involved treating the TiO_2 with the lithium salt before deposition of the polymer layer. Fig. 1 shows current–voltage curves for devices made with and without pre-soaking of the ITO/TiO_2 substrate in a 40 mg/ml LiTFSI/4-*t*-butylpyridine (tBP) solution (see Section 5 for details of fabrication and modification procedures). Lithium modification substantially improved the fill factor (FF) and short-circuit current (J_{sc}), with both increasing by 40%. The open-circuit voltage (V_{oc}) was not affected and remained at around 0.8 V. Devices with TiO_2 layers which had been soaked in neat tBP performed identically to the control devices, so the performance enhancement cannot be attributed to tBP. The highest power conversion efficiencies (η_{max}) obtained for individual control and lithium salt modified devices were 0.52% and 1.05%, respectively. For the lithium-modified device, this is the highest efficiency reported to date for a polymer/TiO_2 device. Fig. 2 shows the variation

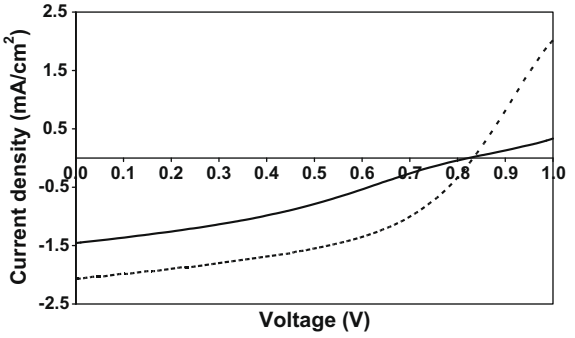

Fig. 1. Current–voltage curves of ITO/TiO_2/MEH-PPV/Au devices, under 0.8 sun simulated solar illumination, with (dashed line) and without (solid line) pre-treatment in a 40 mg/ml LiTFSI/tBP solution.

of the device performance parameters (J_{sc}, V_{oc}, FF, and η_{max}) with the concentration of LiTFSI in the soaking solution. The J_{sc} and FF increase with increasing salt concentration, before reaching a plateau at ~25 mg/ml. During this work we found that the maximum efficiency reached was strongly dependent on the batch of commercial Ti-Nanoxide used. For the device characteristics shown in Fig. 2 the cells were made from the same Ti-Nanoxide batch and the slightly lower efficiency may be due to it having a lower degree of crystallinity. Also, as device performance has been shown to be very sensitive to the thickness of the MEH-PPV layer for TiO_2/MEH-PPV bilayer devices [13], especially for an MEH-PPV layer thickness of roughly 40 nm, it is possible that small variations in the thickness of the MEH-PPV layer from one batch of devices to the next (even for devices cast at the same spin-speed from solutions of very similar concentration) might at least partially account for the difference in efficiency.

Kelly et al. showed that Li^+ adsorption onto TiO_2 can lower the energy of the conduction band and improve the injection yield from adsorbed dye molecules [14]. To determine whether this was the cause of the observed increase in current in our devices, we studied the photocurrent as a function of illumination wavelength. Fig. 3 shows the external quantum efficiency (EQE) of devices with and without pre-treatment with a 40 mg/ml LiTFSI/tBP solution. The maximum EQE value of 12% for the control device compares well with the value for similar devices reported in literature [1,15]. The maximum EQE of the lithium-modified device is a factor of 1.9 larger than that for the control device (Fig. 3a). If the increased current was the result of a downward shift in the TiO_2 conduction band allowing injection from vibrationally relaxed excited states in the polymer, then the increase in EQE should be greatest at long wavelengths, where absorbed photons would promote electrons to the lowest lying vibrational levels of the excited state. The spectra are qualitatively similar, as emphasized by the normalized EQE spectra, indicating that there is no shift in the onset of photocurrent generation (Fig. 3b). This suggests that any downward shift of the TiO_2 conduction band caused by Li^+ adsorption is not responsible for the observed increase in photocurrent, unlike the results of Kelly et al. This was not entirely unexpected, as there is already a substantial offset between the LUMO of MEH-PPV (3.0 eV) [13] and the conduction band level of TiO_2 (4.2 eV) [13], so a further increase in the offset caused by an interface dipole would not contribute significantly to exciton dissociation/charge injection.

2.2. Photovoltaic device performance – co-deposition of LiTFSI and MEH-PPV

The second device strategy utilized a blended film of the lithium salt and MEH-PPV. Fig. 4 shows the performance of ITO/TiO_2/MEH-PPV/Au devices made with an increasing amount of LiTFSI in the polymer spin-coating solution. A small amount of tBP was added as a co-solvent, as LiTFSI is not soluble in chlorobenzene. The addition of neat tBP to the polymer solution reduces the short-circuit current (J_{sc}) and open-circuit voltage (V_{oc}), possibly by creating a poorer solvent for the polymer and affecting the morphol-

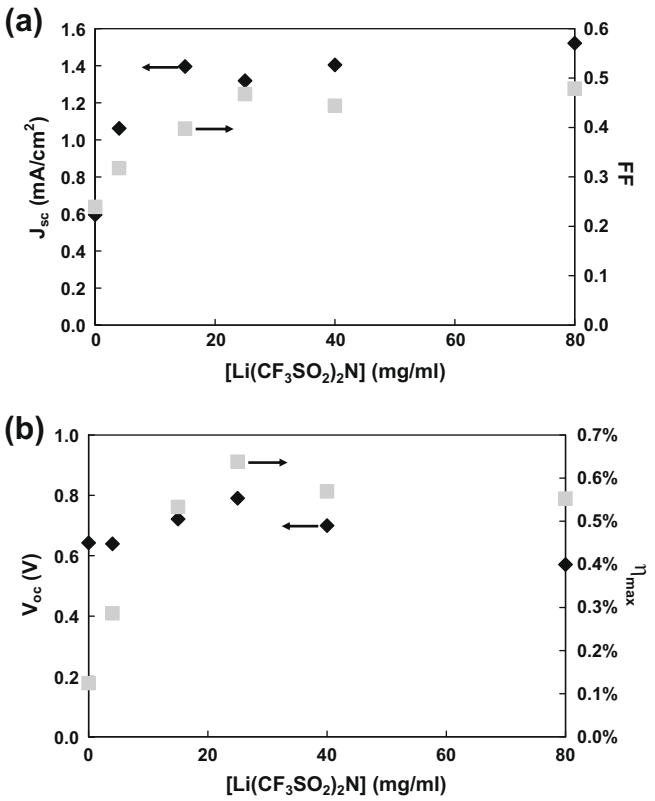

Fig. 2. Short-circuit current, fill factor (a), open-circuit voltage, and efficiency (b) of ITO/TiO_2/MEH-PPV/Au devices (under 0.8 sun simulated solar illumination) vs. concentration of LiTFSI in the pre-treatment solution.

ogy and transport properties of the polymer layer. Relative to devices with neat tBP added to the polymer solution, increasing the concentration of LiTFSI increases J_{sc} by 27% and FF by 49%, resulting in an 85% increase in η_{max} at the optimum concentration of 0.13 mg/ml LiTFSI in the spin-coating solution.

2.3. Photovoltaic device performance – post-treatment with LiTFSI

In the final device configuration the LiTFSI was deposited onto the MEH-PPV films before the completion of the cell with an Au contact. Fig. 5 shows the performance of these ITO/TiO_2/MEH-PPV/Au devices. As the concentration of LiTFSI in the spin-coating solution is increased, the J_{sc} and FF of the devices increase dramatically, and the V_{oc} is improved as well. It should be noted that these devices had an MEH-PPV layer thickness of 95 nm, more than double that for devices discussed above. This was necessary to avoid the introduction of partial shorts in the post-treated devices, but resulted in much lower efficiency in the control devices due to the increased series resistance of the thicker polymer layer. Fig. 6 shows the effect, on device performance, of varying the MEH-PPV layer thickness deposited prior to treatment with a LiTFSI/tBP spin-coating solution of fixed concentration of 40 mg/ml. It is clear that LiTFSI-modified devices with a thin MEH-PPV layer suffer from a low V_{oc} due to partial shorting, but the J_{sc} is independent of MEH-PPV thickness.

2.4. Photovoltaic device performance – pre- and post-treatment with $LiClO_4$

The next aspect of the study was to ascertain whether the counter anion played an important role in the improvement of cell performance. Devices were prepared with either a pre- or post-treatment with a $LiClO_4$/acetonitrile solution of different concentrations. It was found that when the TiO_2 was treated with the $LiClO_4$ solution the TiO_2 was slightly cloudy and when it was deposited onto the polymer it left a visible film on top of the MEH-PPV once the acetonitrile had evaporated, with the latter indicating re-crystallization of the salt and lack of incorporation into the polymer. Photovoltaic device results showed poor reproducibility for pre-treated devices, while the only effect following post-treatment with $LiClO_4$ was a decrease in FF with increasing $LiClO_4$ concentration. Washing the TiO_2 substrate with neat acetonitrile after soaking in the $LiClO_4$/acetonitrile solution (but before spin-coating the polymer) improved the device performance and reproducibility slightly, but the observed increase in photocurrent was much less than for LiTFSI treatment and it is not clear how much of the salt was washed away.

2.5. Hole mobility in MEH-PPV – effect of LiTFSI

To study the effect of LiTFSI on hole mobility in MEH-PPV, hole-only diodes of the type ITO/MEH-PPV/Au were fabricated, with a 40 mg/ml LiTFSI/tBP solution spun onto

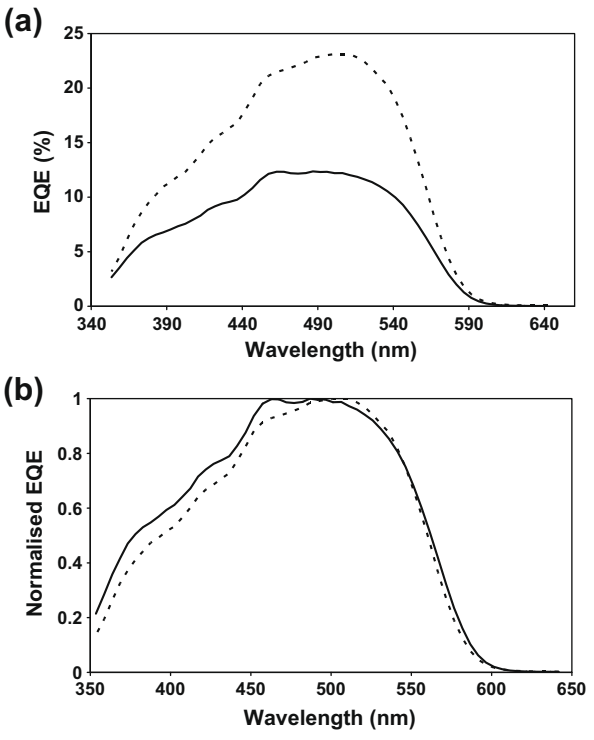

Fig. 3. External quantum efficiency vs. wavelength of ITO/TiO_2/MEH-PPV/Au devices pre-treated in 40 mg/ml LiTFSI/tBP solution, raw data (a) and normalized (b).

the ITO prior to MEH-PPV deposition. For space-charge-limited currents to be observed it was important to plasma treat the ITO electrode (prior to LiTFSI deposition) in order to create an ohmic contact with the polymer, as reported previously for poly(fluorene)-based polymers [16]. Fig. 7 shows the current–voltage characteristics of these devices after various pre-bias routines. The current in the devices was found to increase following a period of pre-bias at −5 V (a negative applied bias corresponds to driving Li^+ from the ITO contact into the polymer), and showed Poole–Frenkel (PF) type space-charge-limited current (SCLC) behavior. The hole mobility (μ_h) of the devices following pre-bias was therefore determined by fitting the *I–V* curves to a field-dependent SCLC model [17]:

$$J = \frac{9}{8}\varepsilon\varepsilon_0\mu_0 V^2 \exp\left(0.89\sqrt{\frac{E}{E_0}}\right)L^{-3}$$

Zero-bias capacitance measurements of the LiTFSI pre-treated devices studied here indicate that the dielectric constant increases from $\varepsilon_r = 3$ (before pre-bias) to as much as $\varepsilon_r = 20$ (after 2 min at −5 V). More extended pre-bias periods (greater than 2 min) did not increase the dielectric constant further. After 10 min at −5 V, the mobility of the pre-treated MEH-PPV reaches $\mu_h = 1.8 \times 10^{-6}$ cm^2/Vs, more than an order of magnitude higher than that of the control device. This increased mobility is consistent with previous reports in the literature, including a.c. impedance measurements showing increased conductivity in PPV which was 'doped' with $LiCF_3SO_3$ [18], and time-of-flight measurements on LiTFSI-modified Spiro-MeOTAD showing that LiTFSI does indeed improve hole mobility, rather than just increasing the carrier concentration in the hole transport material [5]. We note that if the current in our devices is in fact space-charge-limited, as suggested by the good fit to PF SCLC theory, then it is by definition independent of the equilibrium carrier density in the device, and is instead limited by the injected space charge.

Work on light-emitting electrochemical cells has shown that ion diffusion to the electrode interface can result in a large electric field at the interface [19]. In the cells of this study a larger electric field might aid exciton dissociation, providing an alternative explanation for our observed increase in current in LiTFSI-modified devices. However, it is unlikely that this is the case, as the MEH-PPV/TiO_2 interface has already been shown to be an efficient exciton dissociation site [13] due to the >1 eV difference between the MEH-PPV LUMO and the TiO_2 conduction band, which is at least double the exciton binding energy in MEH-PPV.

A related possibility for the improvement in determined hole mobility is that while there is a small barrier to charge extraction at the Au/MEH-PPV interface in control devices, doping of the polymer layer by the addition of LiTFSI serves to narrow this barrier, allowing improved hole extraction via tunneling. A similar effect has been observed for OLED structures containing ZnPc doped with F4-TCNQ [20]. However, due to the strong dependence of J_{sc} and FF on polymer layer thickness in our devices, as mentioned in Section 2.3, we believe that our devices are limited by bulk, rather than interfacial, series resistance prior to LiTFSI treatment.

2.6. Secondary ion mass spectroscopy (SIMS)

The distribution of lithium ions with depth within the devices was determined by SIMS depth profiling. Fig. 8 shows the distribution of positive ions throughout a control device (Fig. 8a) and a device which has been pre-treated with a 10 mg/ml solution of LiTFSI (Fig. 8b) as a function of sputtering time. The Ga signal is due to the sputtering of implanted primary ions. The polymer, TiO_2 and ITO layers are clearly delineated although the interfaces are broad because the outer polymer layer is not of a uniform thickness, as the spun polymer layer will tend to planarise the relatively rough TiO_2 surface. For the pre-treated device it is clear that lithium is present throughout the TiO_2 layer, and also appears to have migrated into the polymer. Indeed there is a substantial lithium signal from the surface of the polymer before there has been any significant erosion of the surface. The small lithium signal from the control is probably the result of some surface contamination. Fig. 9 shows the distribution of positive ions throughout a control device (Fig. 9a) and a device which has been post-treated with $LiClO_4$ (Fig. 9b). In this case the lithium signal of the post-treated device falls off well before the TiO_2 is reached, indicating that the lithium is confined to the near surface of the polymer. The residual tail in the lithium signal is probably an artifact resulting from a low intensity halo round the primary ion beam. Although the current in this halo is small it is strik-

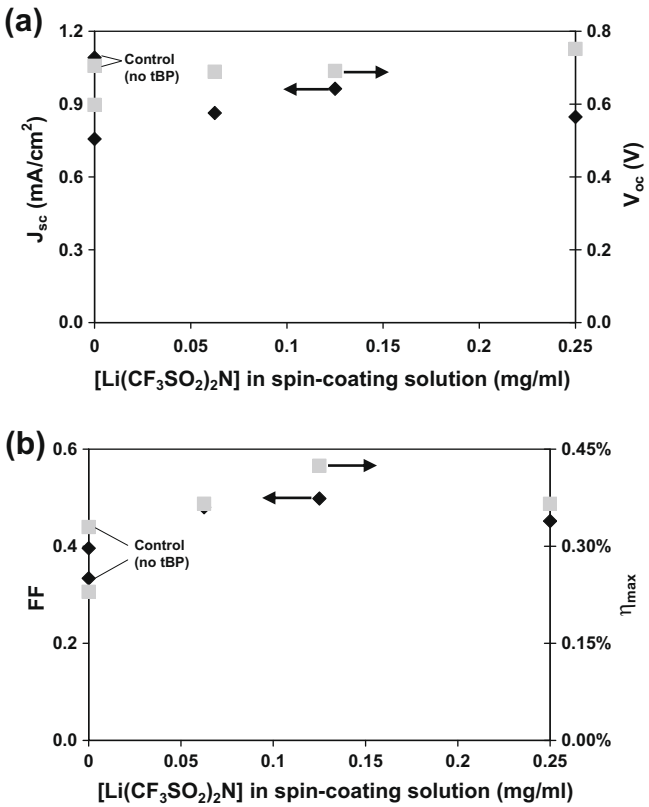

Fig. 4. Short-circuit current, open-circuit voltage (a), fill factor, and efficiency (b) of ITO/TiO_2/MEH-PPV/Au devices (under 0.8 sun simulated solar illumination) vs. concentration of LiTFSI in the MEH-PPV spin-coating solution (co-deposition).

ing the lithium rich surface outside the sputtered pit. There is also the possibility that a proportion of the mobile lithium atoms may migrate ahead of the sputtering front as a result of surface charging.

3. Discussion

The effect of LiTFSI on the performance of ITO/TiO_2/MEH-PPV/Au devices was found to depend on the concentration of LiTFSI as well as the procedure by which it is added to the device. When the ITO/TiO_2 substrate is pretreated with LiTFSI prior to MEH-PPV deposition, the J_{sc} and FF are improved and the V_{oc} is unaffected. According to recent models of device operation [21,22], this is consistent with an increase in hole mobility of the polymer. The increased hole mobility would result in a higher current due to reduced recombination, both under forward bias and zero applied bias, resulting in an increased short-circuit current, and also under small reverse bias, giving an improved fill factor. In the absence of additional contributions to the photocurrent following LiTFSI modification (e.g. from an increase in the exciton diffusion length), both Li-salt modified and control devices should have the same current under high forward bias due to field-assisted charge collection. Unfortunately this could not be verified experimentally as the injected current became much larger than the photocurrent at small forward biases, obscuring the region of the curve where the photocurrent of the modified and control devices should converge to a similar value.

When a small amount of LiTFSI/tBP was co-deposited with MEH-PPV, the tBP causes a decrease in J_{sc} and V_{oc}, which is compensated by the LiTFSI, resulting in a small improvement in device performance. The decrease in performance upon tBP addition could be due to the solution quality being degraded, resulting in a polymer morphology which is less favorable for hole and/or exciton transport, thereby reducing the J_{sc} by reducing the exciton diffusion length and/or increasing the series resistance of the MEH-PPV layer. A similar effect has been observed for MEH-PPV films cast from chlorobenzene (CB) vs. tetrahydrofuran, with the more open conformation of polymer chains in films cast from CB leading to higher mobilities [23]. Adding the LiTFSI counteracts the effect of the tBP by improving hole mobility in the polymer layer to overcome the detrimental effects of the tBP.

When the LiTFSI/tBP solution was spin-coated on top of the MEH-PPV layer, J_{sc} is found to be independent of the MEH-PPV thickness. This is also consistent with improved hole mobility, such that the series resistance of the polymer no longer limits the operation of the device. The FF is also improved, but thinner devices suffer from a low shunt resistance which reduces V_{oc}. The low shunt resistance could indicate over-doping of the polymer layer or

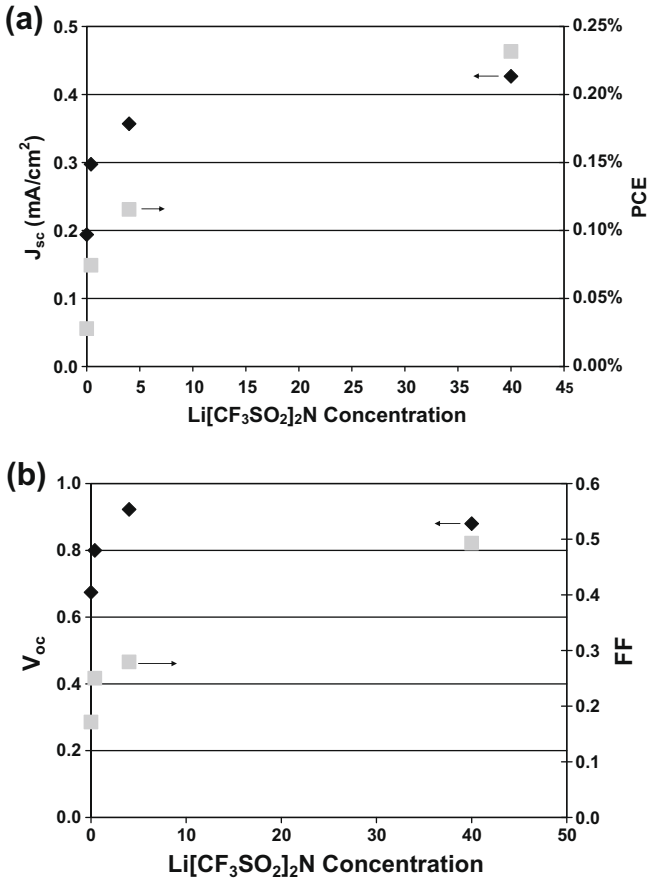

Fig. 5. Short-circuit current, efficiency (a), open-circuit voltage and fill factor (b) of ITO/TiO_2/MEH-PPV/Au devices (under 0.8 sun simulated solar illumination) vs. concentration of LiTFSI in the post-treatment spin-coating solution.

pinholes in the polymer layer leading to shorting through the device.

Thus, whether the LiTFSI is added to the TiO_2 layer, co-deposited with the MEH-PPV layer, or deposited on top of the MEH-PPV layer, the hole mobility of the polymer is improved. This is supported by measurements on SCLC hole-only diodes, which show that the conductivity of the polymer is greatly increased by spin-coating LiTFSI (from a tBP solution) at either the ITO or Au contact, and by SIMS experiments which indicate that lithium is present throughout the polymer layer in either case. $LiClO_4$ does not have the same effect on device performance, most likely because it recrystallizes rather than being absorbed into the polymer. This is supported by results of SIMS experiments which show that post-treatment with $LiClO_4$ does not result in the presence of lithium throughout the polymer layer. It should also be noted that any change to the conductivity of the TiO_2 cannot be responsible for the observed improvement in device performance. Doubling the thickness of the TiO_2 layer in control devices had no impact on device performance, indicating that the series resistance of the TiO_2 layer is small relative to that of the polymer layer. More importantly, SIMS measurements indicate that lithium is not present in the TiO_2 layer of post-treated devices, and therefore TiO_2 modification cannot account for their improved device performance.

While the mechanism underlying this improved hole mobility is unclear, a similar increase in hole mobility in TiO_2/dye/Spiro-MeOTAD devices has been reported [5], and was attributed to an effect equivalent to a broadening of the tail of the density of states. At high doping levels, Li^+ ions fill the deepest traps in the organic layer, while overlap between Coulomb wells of the accompanying anions reduces the barrier height for hole-hopping between these traps, increasing hole mobility. A similar effect may be responsible for the increased mobility reported here.

4. Conclusions

The performance of ITO/TiO_2/MEH-PPV/Au photovoltaic devices was improved by modification with LiTFSI. The best LiTFSI-modified devices exhibited a power conversion efficiency of 1.05% under 0.8 sun white light illumination, a world-leading efficiency for this type of device. Through a combination of hole-mobility measurements, SIMS experiments, and modeling results, the most likely mechanism behind the improved performance was found to be the increased hole mobility in the polymer leading to improved

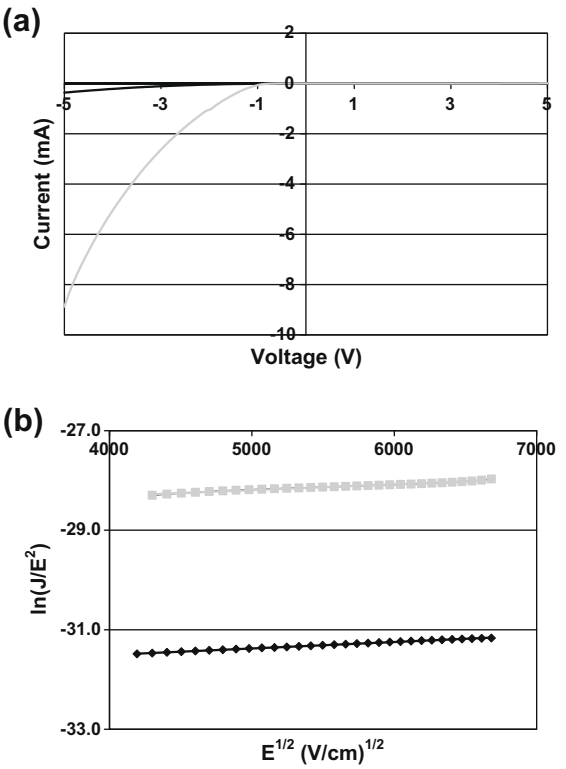

Fig. 7. (a) Current–voltage curves for ITO/MEH-PPV/Au hole-only diodes, which have been pre-treated with a 40 mg/ml LiTFSI/tBP solution, following various pre-bias routines. The curves are for 0 min (black dashed line), 5 min (solid black line), and 10 min (solid grey line) pre-bias at −5 V. The 0 min line coincides with the voltage axis in this figure. (b) Linear fit to field-dependent space-charge-limited current regime of current–voltage curves.

charge collection. $LiClO_4$ was not effective in increasing device performance, and this is believed to be due to a lower incorporation of lithium into the polymer due to re-crystallization of the salt following solution-based pre- or post-treatment. These results are exciting because the modification procedure(s) are simple, solution-based, and amenable to high-throughput processing. Also, the mechanism behind the improvement in device performance is not specific to this device architecture, opening up future avenues to explore for improving, e.g., bulk-heterojunction devices.

5. Experimental

5.1. Device fabrication

Photovoltaic devices with the structure ITO/TiO_2/MEH-PPV/Au were fabricated on patterned ITO glass. Porous TiO_2 layers were produced by the doctor blading technique. Solaronix Ti-nanoxide HT (Solaronix SA, Switzerland) was spread onto the patterned ITO substrate and sintered sequentially at 100 °C for 5 min, 300 °C for 10 min, and 500 °C for 45 min. The resulting film was 1.2 μm thick, with an average pore size of 9–10 nm as measured by gas sorption experiments [24]. MEH-PPV, which had an average $M_w = 5.4 \times 10^5$ and polydispersity of 20 or $M_w = 2.8 \times 10^5$ and polydispersity of 12, was deposited by spin-coating from a chlorobenzene solution. Unless otherwise specified, the spin-speed and solution concentration were chosen to give an MEH-PPV layer thickness of 35–40 nm. As no post-deposition sintering of the film was performed, polymer penetration into the TiO_2 pores was minimal, resulting in a bilayer rough-interface device architecture. Au contacts were evaporated under a vacuum of $\sim 10^{-6}$ mbar, to a thickness of 45 nm. ITO/MEH-PPV/Au hole-only diodes were fabricated as above, but without the TiO_2 deposition and sintering steps. In this case the ITO layer was also plasma-treated, in order to ensure ohmic contact with the MEH-PPV (HOMO = 4.9 eV [25]). The active area of each device was 6.25 mm^2.

5.2. Lithium modification

Three different lithium modification procedures were studied, which are termed pre-treatment, co-deposition, and post-treatment. Pre-treatment was done by soaking ITO/TiO_2 substrates in a solution of $Li[CF_3SO_2]_2N$ in 4-*t*-butylpyridine (tBP) prior to the deposition of the polymer layer. The substrates were immersed in the solution for

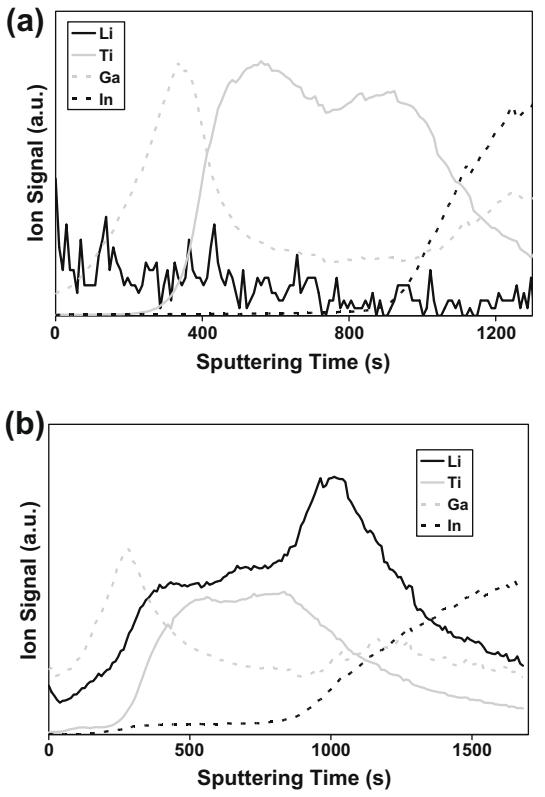

Fig. 8. Secondary ion mass spectroscopy data showing the distribution of lithium ions throughout an ITO/TiO_2/MEH-PPV device without (a) and with (b) pre-treatment in a 10 mg/ml solution of LiTFSI in tBP.

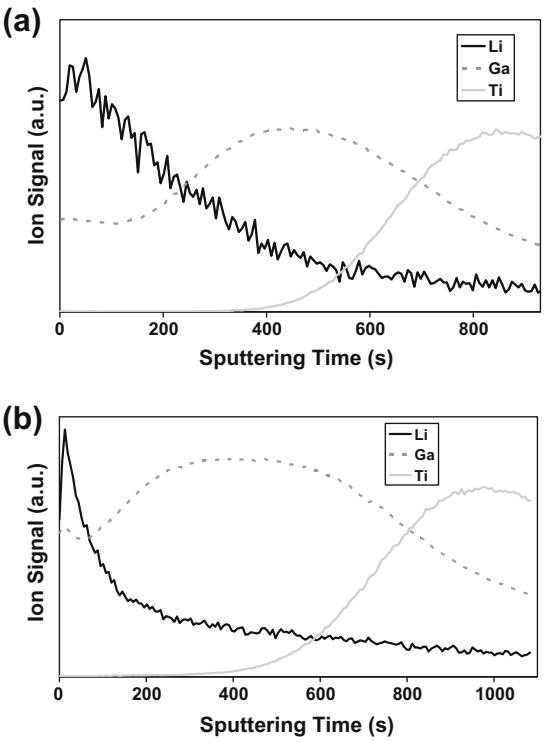

Fig. 9. Secondary ion mass spectroscopy data showing the distribution of lithium ions throughout an ITO/TiO_2/MEH-PPV device without (a) and with (b) post-treatment in a 2.5 mg/ml solution of $LiClO_4$ in acetonitrile.

20 min before being removed and the excess solvent blown off with a compressed air stream. The solution concentration was changed in order to vary the amount of $Li[CF_3SO_2]_2N$ adsorbed on the TiO_2 layer. Device fabrication then proceeded as described above. Pre-treatment of ITO/MEH-PPV/Au hole-only diodes was done by spin-coating a 40 mg/ml $Li[CF_3SO_2]_2N$/tBP solution onto ITO at 3000 rpm for 60 s. Co-deposition was done by adding a small amount of $Li[CF_3SO_2]_2N$/tBP solution to the MEH-PPV spin-coating solution. The concentration of the $Li[CF_3SO_2]_2N$ in the spin-coating solution was changed in order to vary amount of salt present in the resulting film. Post-treatment was performed by spin-coating a solution of $Li[CF_3SO_2]_2N$/tBP onto the polymer layer at 3000 rpm for 60 s prior to evaporation of the Au contacts.

5.3. Device testing

I–V measurements of devices were done using a Keithley 2400 digital multimeter controlled by in-house software created using LabVIEW. Devices were tested under 0.8 sun AM 1.5 illumination from a Xenon arc lamp solar simulator. A 420 nm cutoff long-pass UV filter was used, and devices were mounted in an Oxford Instruments cryostat and tested under a vacuum of 10 mTorr. Unless otherwise stated, results presented are average values from at least three devices.

5.4. EQE measurements

External quantum efficiency measurements were done using a CVI spectral products Xenon arc lamp, a CVI CM 110 monochromator and an Ocean Optics USB 2000 spectrometer with a cosine corrector. Devices were mounted in an Oxford instruments cryostat and tested under a vacuum of 10 mTorr.

5.5. SIMS measurements

SIMS profiles were recorded using a 20 keV gallium ion probe in conjunction with a quadrupole mass spectrometer, MM1212 (VG Scientific Ltd.) [26]. The ion beam was rastered over a 75 μm square with an electronic gate to eliminate wall effects.

ABSTRACT

We synthesized naphthyl end-capped divinylbenzenes, in which naphthyl replaces phenyl as the substituent at the terminal positions of the oligo-*p*-phenylenevinylenes, and investigated the performance of organic field-effect transistors (OFETs), air stability and molecular packing in poly- and single-crystalline films. The OFETs exhibited field-effect hole mobility up to 0.21 $cm^2 V^{-1} s^{-1}$ when the organic semiconductor was evaporated on substrate at 90 °C. Field-effect mobility in air at a controlled temperature of 30 °C and high humidity of 80% was almost constant for a period of up to 220 days, indicating that the material is a very stable organic semiconductor in air.

1. Introduction

Organic field-effect transistors (OFETs) are attracting considerable attention due to their potential applications in optoelectronics, such as displays and integrated circuits [1–3]. Organic semiconducting materials with high field-effect mobility and remarkable environmental stability are critical for the fabrication of OFETs. In this regard, we recently characterized OFETs based on oligo-*p*-phenylenevinylene derivatives (OPVs) in which three phenylene rings are linked together with rigid vinylene units. In our previous reports, OFETs based on OPVs stored in air for one year showed good ambient stability [4] with field-effect hole mobility ranging from 0.024 to 0.17 $cm^2 V^{-1} s^{-1}$ [5–7]. To obtain higher carrier mobility without decreasing the chemical stability, it is crucial that the organic molecules be arranged in a specific molecular configuration.

Extended acenes such as tetracene and pentacene enhance the intermolecular overlap of organic semiconductors in the solid state and lead to high field-effect mobility. However, in contrast to their promising charge carrier transporting properties, the molecules are very reactive and environmentally unstable in air [4,8]. As a method to improve the air stability of organic semiconductors without decreasing the mobility, recent studies have shown that introducing naphthalene or anthracene terminal units to the oligothiophene leads to OFETs with high field-effect mobility and improved device stability under ambient conditions [9–11]. In line with this investigation, we synthesized naphthyl end-capped divinylbenzenes in which naphthyl replaces phenyl as the substituent at the terminal positions of OPVs and investigated the performance of OFETs, air stability and molecular packing in poly- and single-crystalline films.

2. Experimental details

To examine the effects of extending π-conjugation, we prepared two organic semiconductors: Nap-PV and CH_3-

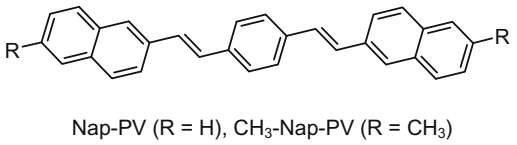

Fig. 1. Chemical structure of organic semiconductors used in this study.

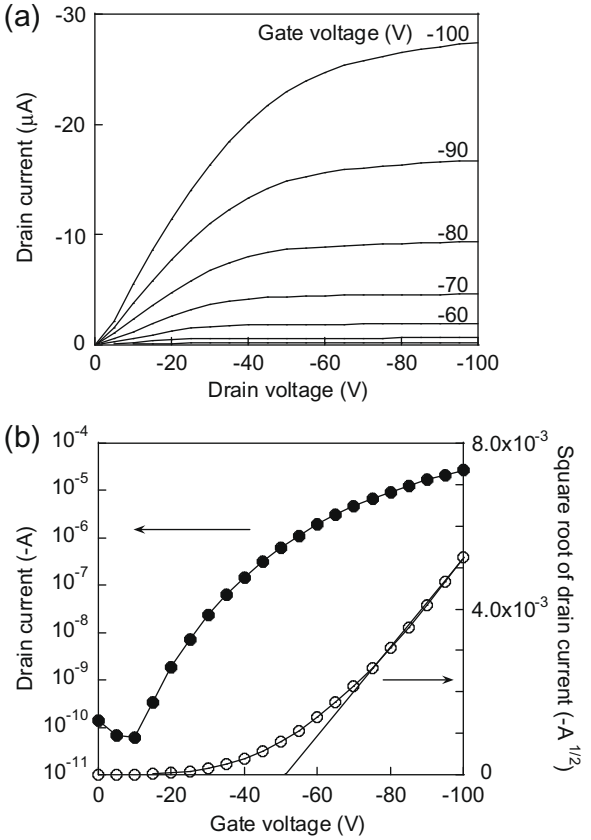

Fig. 2. (a) Plots of drain current versus drain voltage at various gate voltage values for OFETs using Nap-PV as organic semiconductor. (b) Plots of drain current (left) and square root of drain current (right) versus gate voltage at drain voltage of −100 V for the OFETs.

Nap-PV, which were end capped by naphthyl groups. The chemical structure of these compounds is shown in Fig. 1. The materials were synthesized by means of Horner–Wadsworth–Emmons reaction of corresponding aldehydes and tetraethyl *p*-xylylenediphosphonate [12]. These compounds were purified by train sublimation before use.

We fabricated OFETs having top-contact geometry [13]. An Au gate electrode was sputtered through a shadow mask onto a cleaned glass substrate to form 5-mm-wide, 30-nm-thick stripes. Poly(chloro-*p*-xylene) (Parylene-C) was subsequently deposited by thermal chemical vapor deposition at a thickness ranging from 800 to 1000 nm to serve as a gate insulator. The organic semiconductors were vacuum evaporated below 2×10^{-6} torr at a deposition rate of 0.05 nm/s and a thickness of 40–60 nm onto the substrate at room temperature (RT: around 23 °C) or higher (45–105 °C). A shadow mask with interdigitated configuration was attached to the film to form Au source–drain electrodes. The channel length L and width W were 75 μm and 5 mm, respectively. OFET measurement was conducted under vacuum conditions using an Agilent 4156C Precision Semiconductor Parameter Analyzer.

The highest occupied molecular orbital (HOMO) energy level of condensed matter was measured by photoelectron yield spectroscopy in air commercially available from Riken Keiki (AC-2) using vacuum-evaporated films on indium-tin-oxide electrodes.

Table 1
OFET characteristics (field-effect mobility, threshold voltage, and on/off current ratio) of organic semiconductors used in this study.

Compounds	Vacuum evaporated at RT			Vacuum evaporated at 90 °C		
	Field-effect mobility ($cm^2\ V^{-1}\ s^{-1}$)	Threshold voltage (V)	On/off ratio	Field-effect mobility ($cm^2\ V^{-1}\ s^{-1}$)	Threshold voltage (V)	On/off ratio
Nap-PV	0.11	−51	4.5×10^5	0.18	−51	6.7×10^5
CH_3-Nap-PV	0.11	−45	3.1×10^4	0.21	−39	1.0×10^6

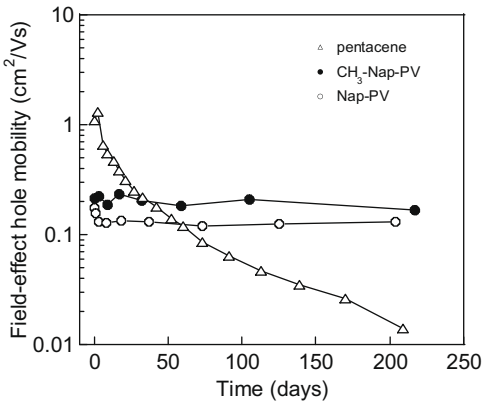

Fig. 4. Field-effect hole mobility plotted as a function of time of exposure to air at a controlled temperature of 30 °C and high humidity of 80%.

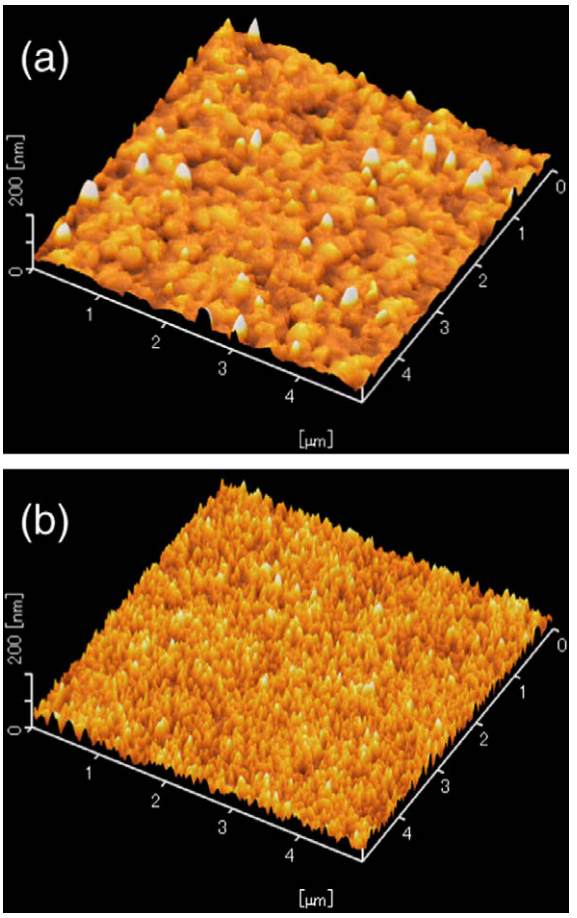

Fig. 5. AFM images of (a) Nap-PV and (b) CH_3-Nap-PV films vacuum-evaporated onto Parylene-C coated glass substrates held at room temperature.

Out-of-plane X-ray diffraction (XRD) measurement was carried out with a RINT2500 (Rigaku Corporation). Thin films of the material deposited onto Parylene-C coated Si wafers were analyzed by XRD using a standard θ–2θ scan with Cu-Kα radiation operated at 50 keV and 300 mA.

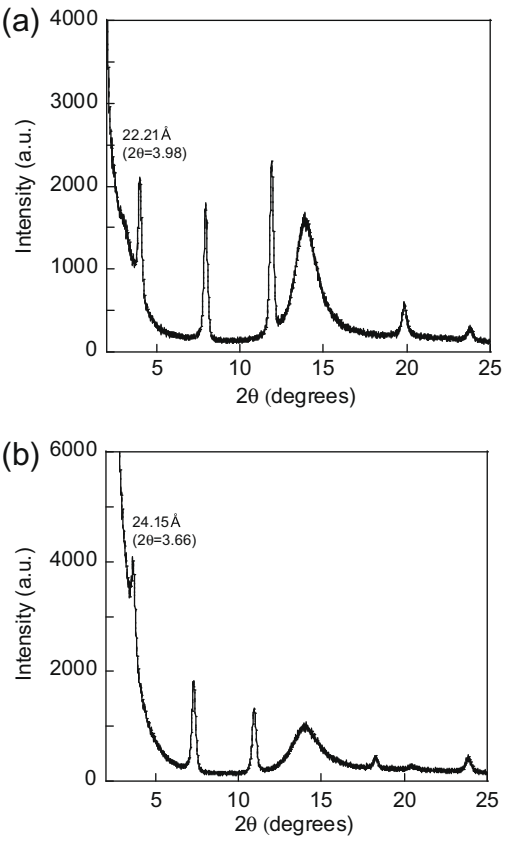

Fig. 6. X-ray diffraction pattern of θ–2θ scan of (a) Nap-PV and (b) CH_3-Nap-PV as a thin film vacuum-evaporated on Parylene-C coated Si wafers. The broad peak around $2\theta = 14°$ is attributed to the crystallinity of Parylene-C.

Single crystals of the organic semiconductors suitable for single-crystal X-ray analysis were obtained by the following procedure: the materials were placed inside the edge of glass tubes (630 mm in length and 28 mm in diameter). The tubes were evacuated and the air was replaced with nitrogen. The tubes were sealed under pressure of around 0.1 atm and then placed on an apparatus for train sublimation. The temperature was set to 240 °C near the source materials and 150 °C at the other edge. Single crystals typically appeared within 6 h.

XRD data on single crystals was collected by a Rigaku AFC10 diffractometer (Mo-Kα radiation, $\lambda = 0.71070$ Å, graphite monochromated). The structures were solved by direct methods [14]. Non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were inserted at calculated positions. All calculations were performed using the crystallographic software package Crystal Structure Version 2.00.

The bandwidths formed by HOMO were calculated using the semiempirical intermediate neglect of differential overlap (INDO) method employed in Gaussian 03 [15]. Molecular coordinates of one-dimensional clusters were directly extracted from the experimental geometries determined by single-crystal X-ray analysis. Within the framework of the tight-binding theory, the bandwidths

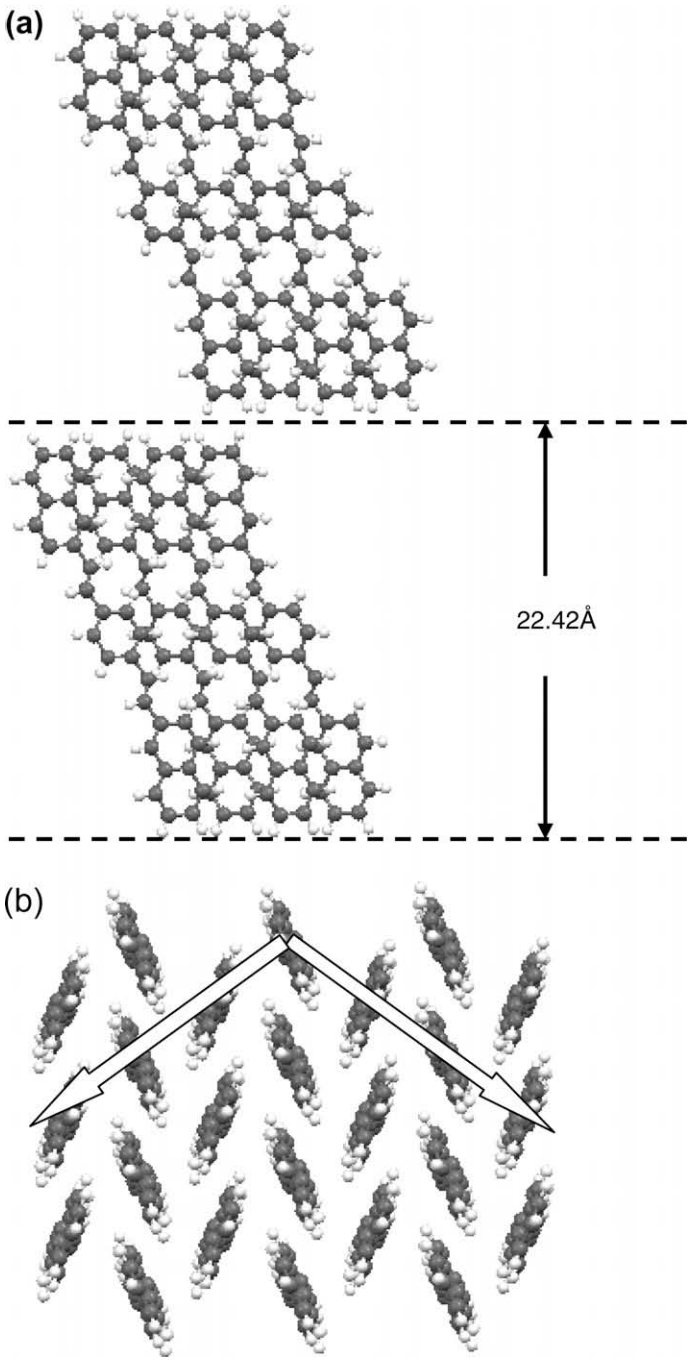

Fig. 7. (a) Single-crystal structure of Nap-PV and (b) illustration of herringbone packing structure as viewed down the long axis of a molecule. The arrows represent the T-shaped molecular arrangement.

were calculated as the extrapolation of the bandwidth versus $\cos(\pi/(N+1))$ plots to $\cos(\pi(N+1)) = 1$, where N is the number of molecules in the clusters [16].

3. Results and discussion

Fig. 2 shows the drain current–voltage relationships in the gate voltage range from 0 to −100 V for Nap-PV. The field-effect mobility is calculated using the standard analytic theory for metal–oxide–semiconductor field-effect transistors according to the following equation:

$$I_{D,sat} = \frac{WC_i}{2L}\mu(V_G - V_T)^2 \quad (1)$$

where $I_{D,sat}$ is the saturation drain current, C_i is the capacitance per unit area of the insulating layer, V_T is

the threshold voltage, V_G is the gate voltage, and μ is the field-effect mobility. The field-effect hole mobility and threshold voltage were calculated to be 0.11 $cm^2 V^{-1} s^{-1}$ and −51 V, respectively. The OFET characteristics (field-effect mobility, threshold voltage and on/off ratio) of Nap-PV and CH_3-Nap-PV evaporated on substrate at room temperature are summarized in Table 1. To further improve the performance of OFETs, organic semiconductors were vacuum evaporated on the Parylene-C coated substrate with an increase in substrate temperature [17–19]. Fig. 3 shows the dependence of field-effect mobility on the substrate temperature during the evaporation of organic semiconductors. The best performance was obtained when the temperature was set to 90 °C for both materials, and the field-effect mobility of CH_3-Nap-PV reached 0.21 $cm^2 V^{-1} s^{-1}$. The OFET characteristics of Nap-PV and CH_3-Nap-PV evaporated on the substrate at 90 °C are also summarized in Table 1. Compared with OPV field-effect mobility (0.024–0.17 $cm^2 V^{-1} s^{-1}$), that of CH_3-Nap-PV was slightly higher.

To study their stability, we stored OFETs with the organic semiconductors evaporated on substrate at 90 °C in air at a controlled temperature of 30 °C and high humidity of 80%. Field-effect mobility as a function of exposure time to air is shown in Fig. 4. The closed circles (CH_3-Nap-PV) and open circles (Nap-PV) were above 0.1 $cm^2 V^{-1} s^{-1}$ for a period of up to 220 days, indicating that both materials are a very stable organic semiconductor in air. On the other hand, the field-effect hole mobility of pentacene (open triangle) after 200 days is three orders of magnitude lower than the initial value.

The HOMO energy level of Nap-PV was found to be −5.50 eV. The introduction of two π-donating methyl groups to the skeleton raised the HOMO level of CH_3-Nap-PV to −5.38 eV. Our previous paper indicated that OFETs using organic semiconductors with a HOMO energy level below −5.20 eV show good ambient stability even after storage in air for one year [4].

The mobility of Nap-PV slightly decreased at the initial time in Fig. 4. Though the cause for the decrease is not clear, our observations of the degradation might be related to the adsorption of H_2O on the Nap-PV layer. The thin film morphology of Nap-PV (Fig. 5(a)) observed by atomic force microscope (AFM) was clearly different from that of CH_3-Nap-PV (Fig. 5(b)). So, when H_2O is adsorbed on the both films, increase in hole trap concentration or change of the morphology resulting in decrease of hole motilities [8] might occur more easily in the Nap-PV film compared to the CH_3-Nap-PV film.

Thin films of Nap-PV and CH_3-Nap-PV grown on Parylene-C coated Si substrates through thermal evaporation under vacuum showed only multiple (0 0 *l*) XRD patterns (Fig. 6). Sharply resolved diffraction peaks up to the fifth order indicate a highly ordered structure. The primary diffraction peaks appeared at 3.98° for Nap-PV and 3.66° for CH_3-Nap-PV, corresponding to *d*-spacing of 22.21 and 24.15 Å. These values correspond well to one-half the *c*-axis of 22.42 and 23.67 Å of Nap-PV and CH_3-Nap-PV, respectively, as determined by single-crystal X-ray analysis. These results suggest that the molecular assembly in the thin film is quite similar to that in bulk crystals: the molecules are oriented nearly orthogonally to the substrate as shown in Fig. 7(a), and the π-orbital direction in the film is parallel to the substrate, favorable for in-plane charge transport. Fig. 7(b) shows the crystal packing of Nap-PV projected along the long axis of a molecule. It is classified as a herringbone arrangement, similar to the crystal structure of pentacene and sexithiophene showing high field-effect mobility [3].

To clarify the origin of high field-effect hole mobility of Nap-PV and CH_3-Nap-PV, we performed semiempirical INDO calculations for the molecular geometries directly extracted from single-crystal analysis. HOMO bandwidths along the T-shaped molecular arrangement shown in Fig. 7(b) are calculated to be 211.3 and 244.7 meV for Nap-PV and CH_3-Nap-PV, respectively. This arrangement allows the formation of a two-dimensionally expanding electronic structure parallel to the *ab*-plane, which is responsible for the high field-effect hole mobility of Nap-PV and CH_3-Nap-PV even in the thin-film phase.

4. Conclusions

We have reported the performance of organic field-effect transistors (OFETs), air stability and molecular packing in poly- and single-crystalline films of naphthyl end-capped divinylbenzenes. High-performance OFETs were obtained when the organic semiconductor was evaporated on substrate at 90 °C. The field-effect hole mobility reached 0.21 $cm^2 V^{-1} s^{-1}$. Compared with that of OPVs (below 0.17 $cm^2 V^{-1} s^{-1}$), the field-effect mobility of CH_3-Nap-PV and Nap-PV is slightly higher. The field-effect mobility of the OFETs in air at a controlled temperature of 30 °C and high humidity of 80% was above 0.1 $cm^2 V^{-1} s^{-1}$ for a period of up to 220 days, indicating that the materials are a very stable organic semiconductor under air. XRD results suggest that the molecular assembly in the thin film is quite similar to that in bulk crystals: the molecules are oriented nearly orthogonally to the substrate and the π-orbital direction in the films is parallel to the substrate, favorable for in-plane charge transport.

Acknowledgment

We thank Mr. T. Ashimine of Kyushu University for the measurement of pentacene OFETs.

ABSTRACT

The insertion of thin MnO layer between organic photoactive layer and metal electrode significantly improved the power conversion efficiency (PCE) and the air stability of organic photovoltaic cell (OPV). PCE (2.91%) was obtained by inserting 3-nm-thick MnO, higher than 0.91% for the device without MnO, and 2.59% for the device with 0.5-nm-thick LiF. In addition, the PCE of MnO device retained 28.42% of initial value after 2 weeks while the device without MnO dropped down to only 6.03% just after 2 days, even better than that of LiF device which dropped down to 7.29% of initial value after 2 weeks without encapsulation. Insulator MnO is promising to improve the electron transport and operation stability in OPVs.

1. Introduction

Organic photovoltaic cell (OPV) has been considered as the next promising generation of solar energy conversion device due to its advantage in the fabrication of large-area, cost-effective, flexible, low-weight organic films with high absorption coefficient [1], and even high exciton separation efficiency (nearly 90%) [2]. However, the power conversion efficiency (PCE) is still the major course and needed to be improved further. Although many efforts have been made to improve PCE, including efforts from materials to structure of devices [3,4], low efficient charge transport and injection (collection) are still the bottle-neck of the improvement of PCE.

The modification at the interface between organic active layer and electrodes has been found to be effective for charge collection in OPV, many strategies have been developed on it. In the aspect of indium tin oxide (ITO) anode, plasma and UV-ozone treatment, buffer layer, e.g., poly(3,4-ethylene dioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS) [5], self-assembled mono-layers (SAMs) [6] or ultra-thin metal layer, e.g., Au, Pt [7] have been successfully used to modify the surface of it. Meanwhile, in the aspect of metal cathode especially aluminum (Al), ultrathin (less than 1.0 nm) LiF [8] is still the most effective buffer layer among the few options.

Besides the charge transport, the device operation stability is also crucial to the application of OPV. If the improvement of charge transport and operation stability can be carried out simultaneously, the fabrication will be simplified and cost-effective. Titanium oxide (TiO_x) could be used as hole blocking layer and optical spacer to improve PCE [9], and as shielding layer to prevent the intrusion of oxygen and humidity into the polymer layer [10], but the solution process may give change on the organic layer surface. Considering the results which were previously reported about the effect of MnO (manganese mono-oxide) in organic light-emitting device (OLED) [11], we introduced a thin layer (optimal thickness ~3.0 nm) insulator MnO between organic layer and metal cathode, and obtained higher PCE and longer operation lifetime in the air than the device without it, and even higher PCE and longer operation lifetime in the air than device with LiF as the n-type dopant.

2. Experimental

The OPV devices were fabricated with traditional sandwich structure as follows: ITO/PEDOT:PSS/poly(3-hexylthiophene) (P3HT): [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM)/Al (as the reference device), ITO/PEDOT:PSS/P3HT:PCBM/MnO/Al (hereafter referred to as MnO device), ITO/PEDOT:PSS/P3HT:PCBM/LiF/Al (hereafter referred to as LiF device). The pre-cleaned ITO/glass substrate (light-incident-side electrode) was spin coated with PEDOT:PSS aqueous solution at 3000 rpm, and dried at 200 °C for 5 min in air, and 15 min in vacuum subsequently. The P3HT:PCBM film was prepared from P3HT:PCBM orthodichlorobenzene solution (15 mg:12 mg/ml) at 600–800 rpm on top of the PEDOT:PSS layer, and then baked at 150 °C for 1 h in vacuum. The remaining parts of fabrication were just the same as OLED. Finally, MnO, LiF, Al were separately thermal deposited on top of the photoactive layer under a vacuum of 10^{-4} Pa. The thickness of organic layer, MnO, LiF and Al is around 90, x (x = 0, 1.5, 3.0, 6.0, and 10.0), 0.5 and 150 nm, respectively. The active area of the device in cathode area is 0.126 cm^2. The structure of device is shown in Fig. 1a. All the devices were fabricated under the same conditions without encapsulation, and there were no more annealing for the device after fabrication. The current density–voltage (I–V) characteristics were measured through Keithley 2611 source meter under dark and illumination with a solar simulator (Oriel 300 W) with AM 1.5G filter under a power of 100 mW/cm^2. The absorption was measured using a Lambda 950 UV/Vis spectrometer. All the measurements were performed at room temperature in ambient atmosphere.

3. Results and discussion

To explore the doping effect of MnO on the charge transporting of OPV, we investigated the device performance via inserting of thin MnO layer (0, 1.5, 3.0, 6.0, and 10.0 nm) between organic photoactive layer and metal electrode. As shown in the upper part of Fig. 2, the dark current of the device containing MnO was lower than that of the device without MnO (reference device), indicating that the insertion of MnO buffer layer can prevent the permeation defects from cathode metal evaporation, and then the leakage current was reduced. Therefore, exciton quenching was alleviated and the device performance was improved [12].

In addition, the MnO devices exhibited increase in short-circuit current (I_{sc}) and great enhancement in open-circuit voltage V_{oc} in the lower part of Fig. 2. The great enhancement in V_{oc} could be interpreted by the increase of shunt resistance (R_{sh}) resulted from the prevention of diffusion into organic layer from the cathode metal atoms with MnO buffer layer, which generally resulted in an enhancement on V_{oc} and fill factor (FF) [13]. The insertion of MnO to reduce *Schottky* barrier for charge transport and injection could also contribute to the enhancement of V_{oc}. The energy diagram of MnO device is shown in Fig. 1b. Within the MnO layer, a dipole layer might be formed at the interface to lead to energy level realignment as well as band bending to adjust electrical properties of device and optimize the electron collection process. Furthermore, the electron attenuation length of inorganic insulating interfacial layer is much longer than organic solid with Van der Waals interaction. From the view point of that, Wolf and Bassler [14] proposed that a thin inorganic insulator between organic semiconductor and metal electrode can enhance electron injection in OLED. Therefore, an enhancement of I_{sc} in OPV could also be deduced by inserting of MnO layer. The enhanced I_{sc} might also be due to the hole blocking of MnO resulting from its deep energy level (−6.5 eV) of the highest occupied molecular orbit (HOMO), as previously reported in OLED [11], to reduce the recombination of charge carriers.

The V_{oc} of MnO devices with different thickness was almost the same, while the I_{sc} was improved as the MnO

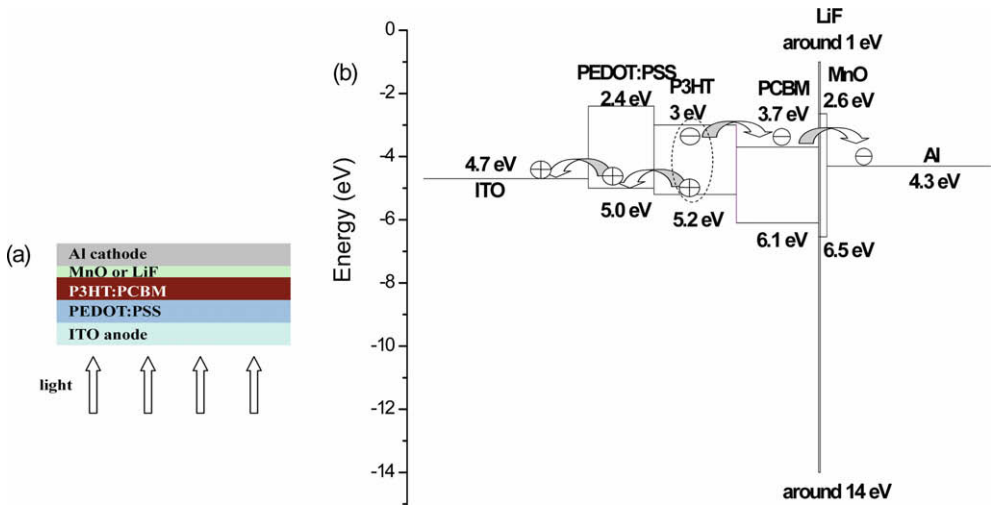

Fig. 1. (a) OPV structure; (b) energy level diagram of the OPV.

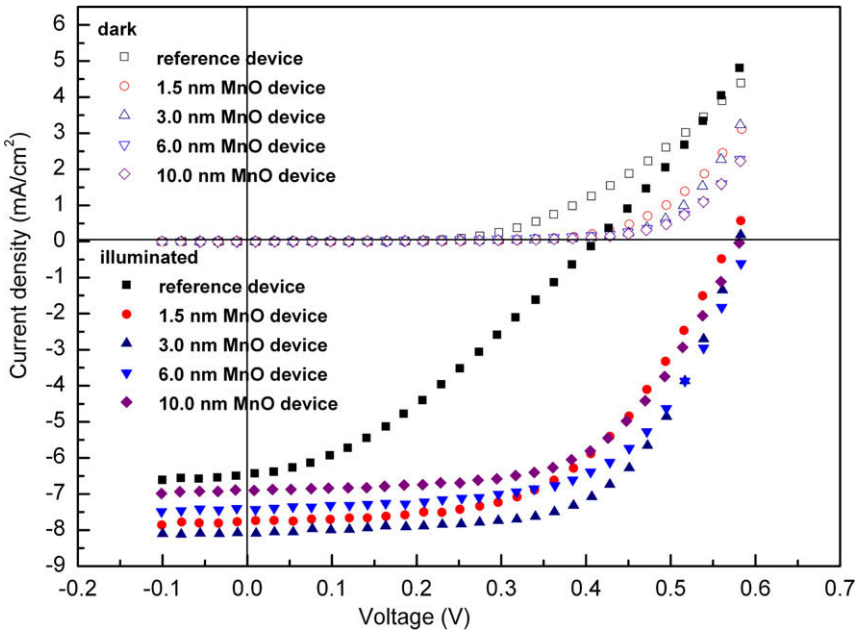

Fig. 2. *I–V* plot of devices with and without MnO in the dark and under illumination.

thickness initially increased from 1.5 to 3.0 nm, but it declined when the thickness increased further, which can be interpreted by a tunneling model as previously reported [11,15]. There exists an optimal thickness of an insulating buffer layer (3.0 nm in this study) which made the total barrier (both original energy barrier and the extra barrier introduced by insulating layer itself) lower to achieve more efficient electron transport and collection.

Owing to the enhancement of V_{oc} and I_{sc}, the PCE and FF of MnO device were higher than the reference one. Compared to the reference device, PCE of devices with 1.5, 3.0, 6.0, and 10.0 MnO increased up 62%, 82%, 76%, and 71%, respectively. There were 2.7-, 3.2-, 2.9-, and 2.6-folds enhancement for the FF of the devices with 1.5, 3.0, 6.0, and 10.0 MnO in comparison to the reference one as listed in Table 1. The higher FF of MnO devices was originated from the decrease of series resistance (R_s) denoted by the inverse slope of the *I–V* curves near V_{oc} and the increase of R_{sh} calculated from the inverse slope of the *I–V* curves at 0 V under illumination.

Moreover, MnO device (3.0 nm) showed even higher PCE than that of LiF device (the common efficient device) as shown in Fig. 3. The I_{sc} of LiF device was 7.46 mA/cm^2, while the I_{sc} of MnO device was increased to 8.05 mA/cm^2. The enhanced I_{sc} for MnO device might be due to the more efficient electron injecting of MnO than that of LiF as previously reported in OLED [11]. As shown in Table 1, the R_s of MnO device slightly decreased to 13 from 18 Ω cm^2 for LiF device, and the R_{sh} increased to 1931 Ω cm^2 from 1334 Ω cm^2 for LiF device. These indicate that less defects in MnO device is induced than in the LiF device. Although the R_s and R_{sh} could affect V_{oc} and FF, V_{oc} mainly depends on energy level arrangement of active materials and electrode work function as well as the interface properties. Comparing with LiF device, the organic active materials and the electrodes of MnO device were the same. Moreover, the mechanism of inserting MnO was similar with LiF to reduce *Schottky* barrier, which is almost the same in MnO and LiF devices, thus V_{oc} keeps the same value in both MnO and LiF devices. FF has the same situation, which also depends on the interface properties. Because FF strongly depends on recombination strength [16], in addition, the recombination situation was partly influenced by interface properties. Owing to the larger I_{sc}, the PCE of MnO device was increased to 2.91% from 2.59% for that of LiF device. These indicate that insulator MnO is more efficient n-type doping layer than LiF for OPVs.

Table 1
Performances of the resultant OPVs.

Device	Reference	LiF	1.5 nm MnO	3.0 nm MnO	6.0 nm MnO	10.0 nm MnO
V_{oc} (V)	0.41	0.58	0.57	0.58	0.60	0.59
I_{sc} (mA/cm^2)	6.43	7.46	7.74	8.05	7.41	6.91
FF	0.34	0.60	0.55	0.62	0.60	0.58
PCE (%)	0.91	2.59	2.43	2.91	2.64	2.35
R_s (Ω cm^2)	44	18	21	13	17	21
R_{sh} (Ω cm^2)	391	1334	1499	1931	2364	1827

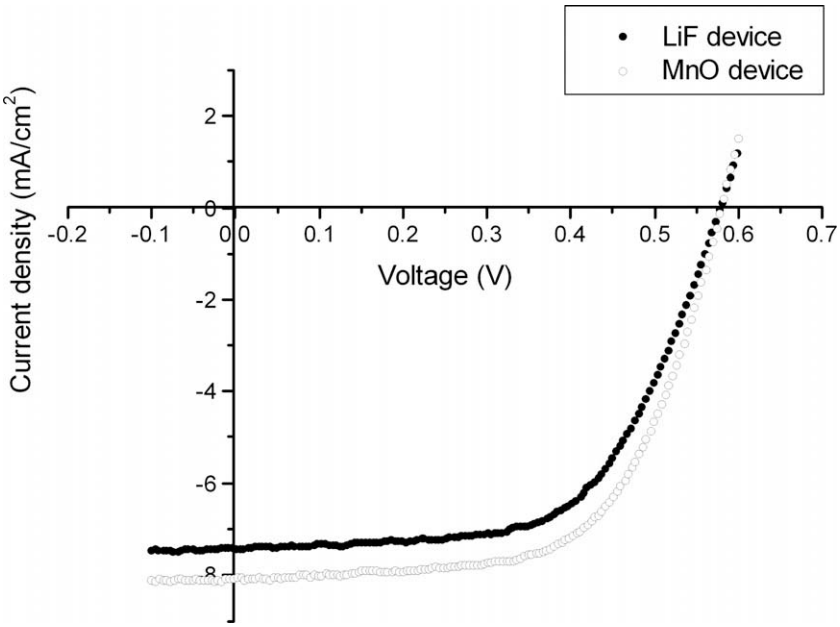

Fig. 3. *I–V* plot of LiF and MnO (3.0 nm) devices under illumination.

Table 2
Air stability of MnO (3.0 nm), LiF and reference devices.

PCE maintenance (%)	24 h	48 h	72 h	2 weeks
MnO (3.0 nm) device	81.58	72.63	66.84	28.42
LiF device	77.08	58.33	46.88	7.29
Reference device	51.72	6.03	2.91	0.02

Furthermore, the air stability of device can be improved by inserting a MnO layer. The air stability of device was investigated through the measuring of PCE maintenance of the MnO (3.0 nm) device, the LiF device and the reference device stored in ambient environment (80% RH) without encapsulation in the dark within 2 weeks. We observed the PCE of the MnO device still kept 28.42% of the initial

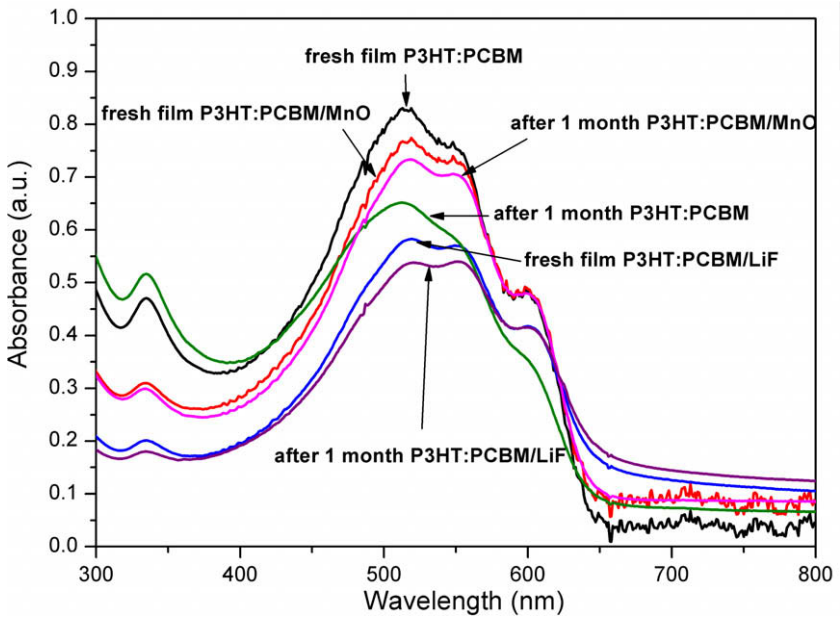

Fig. 5. The absorption spectra of P3HT:PCBM, P3HT:PCBM/MnO and P3HT:PCBM/LiF films (fresh and after 1 month).

value of fresh made device after 2 weeks, while the reference device dropped down to only 6.03% just after 2 days, and even the LiF device decreased to 7.29% of initial value after 2 weeks without encapsulation. The maintenance of PCE (ratio of after storage/fresh made device) is listed in Table 2, and the *I–V* curve before and after air stability study is shown in Fig. 4. These results indicate that the MnO device is the most air stable, even more stable than the LiF device.

To study the mechanism of MnO to prolong the lifetime of device, we investigated the air stability of absorption spectra of P3HT:PCBM film, P3HT:PCBM/MnO film (P3HT:PCBM covered with MnO) and P3HT:PCBM/LiF film (P3HT:PCBM covered with LiF) stored in ambient environment (80% RH) without encapsulation in the dark (Fig. 5). After 1 month, the intensity of the absorption band between 500 and 570 nm (the main absorption peak for the P3HT) of P3HT:PCBM film decreased the most (18.6–24.1%), while P3HT:PCBM/MnO film only decreased a little (0.8–5.5%). The decrease of absorption of P3HT:PCBM/LiF film (2.6–8.2%) is slightly more than that of P3HT:PCBM/MnO film, which is consistent with the air stability of device performance as stated above. The intensity decrease possibly related to the reduction of corresponding functional groups and the variation of inter-chain order degree of polymer which were resulted from photo- and thermo-oxidation [17,18]. The absorption of P3HT:PCBM/MnO film varied little after 1 month maybe due to the shielding effect of highly air-stable MnO. The MnO layer can protect organic layers from oxygen and humidity penetration which can decrease the conductivity of C_{60} film by several orders of magnitude [19]. We surmise that oxygen and humidity influence on the conductivity of PCBM (derivative of C_{60}) film should be in a comparable extent. There is also a probability that the trace water and organic solvent from spin-coating operation after annealing can be removed during MnO deposition [20]. These results implied that the operation stability of OPV can be improved by inserting of insulator MnO thin layer.

4. Conclusion

In summary, a facile way to fabricate air stable and highly efficient OPV with insulator MnO as n-type doping layer was devised. Not only the PCE, but also the air stability of OPV can be improved via inserting thin MnO layer between organic photoactive layer and metal electrode. The optimal thickness of MnO is 3.0 nm. A PCE of 2.91% was obtained by inserting 3-nm-thick MnO, which was even higher than the PCE of 2.59% for the device with 0.5-nm-thick LiF. Moreover, the PCE of MnO device maintained 28.42% of initial value after 2 weeks without encapsulation while the reference device without MnO dropped down to only 6.03% just after 2 days. The air stability of MnO device was even better than that of LiF device which dropped down to 7.29% of initial value after 2 weeks. Insulator MnO is promising to improve the electron transport and operation stability in OPVs.

ABSTRACT

The emerging demand for flexible display panels has created a demand for coating techniques capable of depositing high-quality transparent conductive coatings (TCOs) on polymeric materials. This study demonstrates indium tin oxide (ITO) films deposited on polyethylene terephthalate (PET) substrates using a thermionic emission (TE) enhanced DC magnetron sputtering system to improve electrical and optical properties under static and dynamic mechanical bending.

Experimental results show that the ITO-coated PET specimen prepared with TE and without TE presents an average transmittance in the visible region of the spectrum of 83% and 70%, and an electrical resistivity of 4.5×10^{-4} and $1.7 \times 10^{-3}\,\Omega\,cm$, respectively. By contrast, the static bending test revealed that the critical radius of curvature (R_c) is 13.9 and 17.0 mm for the ITO-coated PET with and without TE. The dynamic bending test showed that the ITO-coated PET with TE is durable for more than 1200 cycles, while the corresponding number for the ITO-coated PET without TE is smaller than 50 cycles for the ITO-coated PET without TE. These results evidence that the ITO film deposited using the TE approach exhibits a higher degree of crystallinity and film adhesion than that deposited without TE. TE improves optical and electrical properties of the ITO coatings and their longer durability under mechanical bending.

1. Introduction

Indium tin oxide (ITO) films have been extensively applied in flat panel displays [1,2] and photovoltaic devices [3,4] as transparent conductive oxide (TCO) electrodes because of their low electrical resistivity and high optical transmittance. The emerging demand for flexible display panels has created a demand for coating techniques capable of depositing high-quality TCOs on polymeric materials to particularly achieve light-weight, compactness, impact tolerance [5,6] and mechanical bending durability [7,8]. Among commonly used polymeric materials, PET (polyethylene terephthalate) and PC (polycarbonate) have been considered as substrate materials for flexible displays because of their satisfactory optical transmittance and low material cost compared to other materials [9].

Modified sputter deposition techniques have directly obtained promising results to deposit ITO films on flexible substrates at a low deposition temperature. Yang [10] found a resistivity of $6.3 \times 10^{-4}\,\Omega\,cm$ and an average optical transmittance of 80% by utilizing an RF magnetron sputtering system with supplemental substrate biasing to deposit ITO film on PPA (polypropylene adipate) substrates. Kim [11] added negative cesium ions into a glow discharge sputtering system to impart additional energy into the growing ITO film, to achieve an electrical resistivity of $6.2 \times 10^{-4}\,\Omega\,cm$ and an average optical transmit-

tance of 87%. Hoshi and Kiyomura [12] accomplished an electrical resistivity of $3.5 \times 10^{-4}\,\Omega\,cm$ and an average optical transmittance over 80% by using an RF applied grid in the DC sputtering system to increase ion density. Our previous study also demonstrated a thermionic electron emission (TE) approach as a supplement to the DC sputtering system to obtain an ITO film with an electrical resistivity of $4.5 \times 10^{-4}\,\Omega\,cm$ and an average optical transmittance of 80% [13]. The TE approach can be utilized to deposit high-quality ITO deposition at relatively low substrate temperature with low-cost equipment. The quality of the film thus formed, in terms of electrical resistivity and optical transmittance, is improved by the increased crystallinity of the film under intense ion bombardment. However, thermal expansion and elastic properties for both TCO films and polymer substrates are very different, resulting in large mechanical stresses. A TCO film on a PET polymer substrate subjected to such stress cracks and eventually fractures, markedly reduces its electrical conductivity. Cairns et al. [14] investigated the mechanical properties of ITO films on a PET substrate, focusing on the cracking mechanism and its relationship to electrical properties. In addition, Fortunato et al. [15] also observed that ZnO:Al cracking under increasing strain increases its resistance. This result is consistent with similar studies of silicon oxide deposited on the PET substrate [16].

Most studies on the above subject have been performed using thin films on polymer substrates and have demonstrated initial cracking and the mechanism failure of electrical conductivity of thin films. The current authors' earlier study sought to obtain high-quality ITO films deposited by TE, and motivates this study. The goal of this study is to improve electrical response the ITO-coated PET under static and dynamic mechanical bending to improved crystallinity and the film adhesion through the TE technique which contributes to resist damage under mechanical action. This paper investigates the effect of mechanical bending of an ITO film deposited by DC magnetron sputtering on a PET substrate with and without TE. A discussion follows about the change in electrical resistance of ITO-coated PET specimens under a single static bending event and their durability under dynamic repeated bending.

2. Materials and methods

The schematic of the DC magnetron sputter system incorporating thermionic emission apparatus is shown in Fig. 1(a) and the filament assembly is shown in Fig. 1(b). The current study used a 0.6 mm diameter tungsten filament for electron emission. The filament was negatively biased to a voltage of −30 V relative to the coating chamber by a DC current power supply and resistively heated to generate electron emission current at 3 A. The ITO target used for sputtering was In_2O_3:SnO_2 = 90:10 (wt.%). The distance between the substrate and the target was 6 cm. ITO films deposited on the PET substrates with a 10 mm × 45 mm strip and 135 μm thick were used for the mechanical bending test, while the other samples with dimensions of 20 mm × 20 mm were used for microstructure analysis, adhesion measurement, optical transmittance and electrical resistivity measurement. The deposition was carried out in argon plasma at a pressure of 0.15 Pa. Table 1 lists deposition conditions as well as the substrate temperature measured by a thermometer placed on the substrate. Although no external heating was employed during deposition, the substrate temperature as exposed to the plasma increased to 50 and 90 °C, respectively without and with TE. Thermal radiation from the thermionic filament when employing TE caused a higher substrate temperature.

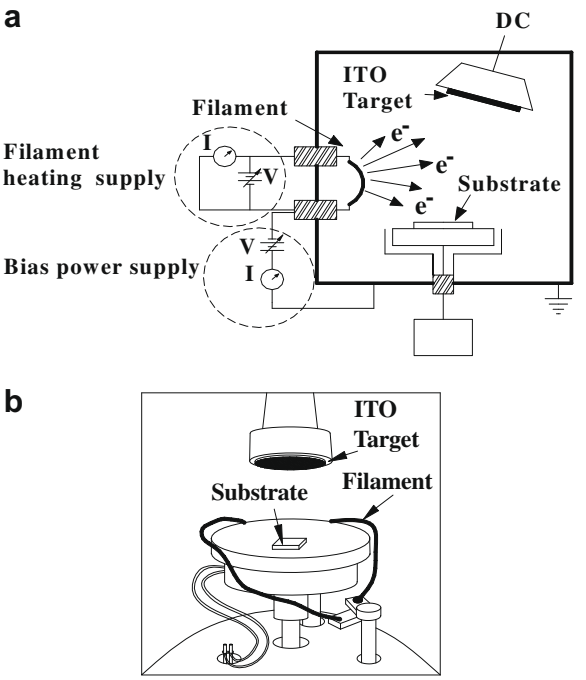

Fig. 1. Schematic diagram of: (a) the thermionic enhanced DC magnetron sputter system and (b) the filament assembly.

The crystal structure of deposited films was investigated by a grazing incident X-ray diffractometer (GIXD, Bruker D8 Discover, by CuK_α radiation) with a grazing incidence angle of 1°. Surface morphology of the deposited ITO films was observed using a field emission scanning electron microscope (FESEM, Hitachi S-4800). Optical transmittance of the ITO-coated PET specimen was measured using a UV–Visible spectrophotometer (Shimadzu UV-1601). Electrical resistivity of ITO-coated PET specimens was measured using a Four-Point Probe method (Quatek QT-50) and the carrier concentration and mobility were determined by an Ecopia Hall effect measurement system under a magnetic field of 0.55 T (Ecopia HMS-3000).

After deposition, film adhesion was measured using a crosscut tester, according to the ASTM D3359 standard [17]. The tester consisting of eleven blades within a pitch of 1 mm was used to scratch the coating vertically and horizontally for causing one hundred squares (crosshatching). A tape was attached onto the crosshatched surface then quickly ripped off from the specimen. The coating adhesion was rated by visually comparing the sample to a series of six levels depicted in the ASTM method. Subsequently,

the mechanical bending test, consistent with the ASTM D1593 standard [18], was conducted on the coated sample, as shown in Fig. 2. During the test, the single-stroke distance and cycle times were controlled and recorded. The radius of curvature associated with each bending was then calculated based on the recorded stroke distance. The ITO-coated strip was placed with the ITO side upwards, and subjected to tensile stress under each bending. Both ends of the strip were electrically connected to an LCR meter. Static and dynamic tests were performed separately. In the static bending test, the sample was bent by controlling the stroke distance to obtain a designated radius of curvature (R) while electrical resistance of the ITO-coated specimen was recorded using the LCR meter. Progressively reducing the R value caused a sudden increase in electrical resistance of the ITO-coated PET specimen when cracks formed in the ITO film. The corresponding R value was defined as R_c (critical radius of curvature), which is the minimum bending radius of curvature that the ITO film can tolerate.

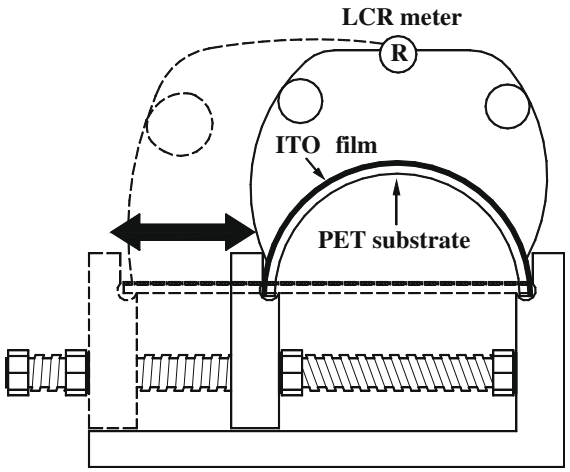

Fig. 2. A schema of the static and dynamic tester for the durability of the ITO-coated PET specimen.

The dynamic bending test was performed by repeatedly bending the sample at a constant R value of 18.6 mm. The electrical resistance and optical transmittance of the ITO-coated specimen were recorded after every 50 bending cycles. After performing the dynamic mechanical bending test, film morphology of the ITO-coated specimens was observed using the scanning electron microscope (SEM, Hitachi S-3000).

3. Results and discussion

3.1. Microstructure of the deposited ITO films

Fig. 3 shows the X-ray diffraction patterns and the corresponding cross sectional film morphologies of ITO-deposited specimens. The XRD pattern of ITO film deposited without TE shows an amorphous feature. In the case of the film deposited with TE, diffraction peaks of ITO (2 2 2), (4 0 0), (4 4 0) and (6 2 2) clearly demonstrate a crystalline structure in the deposited ITO film. The presence of the crystalline structure is likely due to the accompanying substrate temperature elevation and intensified plasma density when employing TE. Researches have previously reported that enhanced crystallinity of the ITO film deposited using TE mainly results from increased plasma density [13]. The ion flux toward the substrate promotes ion bombardment, enhancing surface migration of adatoms on the growing film. The literature has shown that increasing power density in an RF sputter system [19] and applying an RF biased grid [12] also enhances the crystallinity of deposited ITO films.

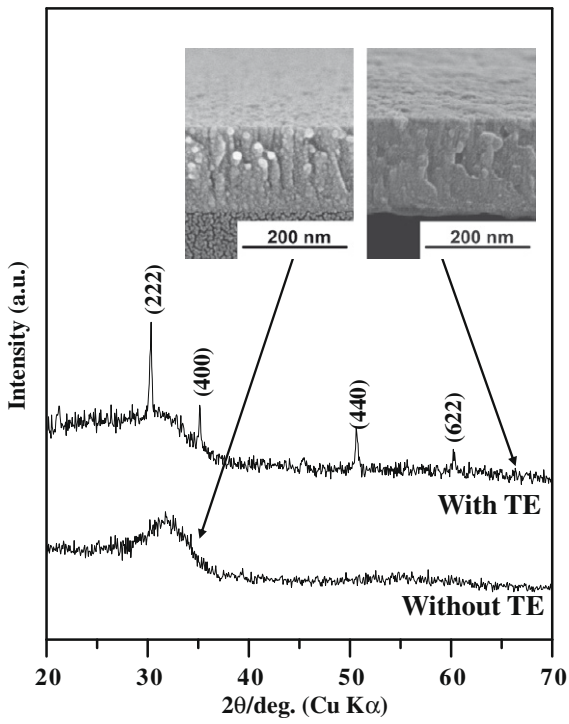

Fig. 3. X-ray diffraction patterns and cross sectional morphology (the inset) of ITO films deposited without and with TE.

Fig. 3 (inset) shows the corresponding SEM morphologies of the deposited ITO films without and with TE. The figure shows that the ITO film deposited without TE reveals a loosely packed feature while the ITO film deposited with TE exhibits a dense morphology. Intensified ion bombardment results in TE employment for a denser film. SEM observations agree with the result of XRD characterization.

3.2. Optical transmittance of the deposited ITO films

Table 2 presents the measured optical transmittance of ITO-coated specimens deposited without and with TE. The average optical transmittance in the 400–700 nm wavelength range is 70% and 83% respectively for the ITO films deposited without and with TE. Using TE obtains a significant transmittance increase of ITO film. For a thin film material, optical transmittance is governed by absorption, reflection and scattering, all of which depend on chemical composition, chemical bonding, crystal structure and discontinuities (impurities and defects). The ITO film, composed of indium, tin and oxygen atoms in a bixbyite structure [20], is a highly degenerated wide band gap semiconductor with band gap energy roughly between 3.5 and 4.3 eV. This results in high transmittance of ITO film in the visible region (1.7–3.1 eV). Unfortunately, defects including vacancies, line defects, grain boundaries, etc., exist in the deposited film. These discontinuities form scattering centers and are detrimental to film transparency. The higher transmittance observed for TE deposited film is attributed to fewer scattering effects and structural homogeneity resulting from a higher degree of crystallinity [21,22]. From the result of XRD characterization, improved optical transmittance for the film deposited with TE is attributed to an increased degree of film crystallinity.

3.3. Electrical resistivity of the deposited ITO films

Table 2 shows the electrical properties of ITO films deposited on PET substrates without and with TE. The ITO films deposited without and with TE have an electrical resistivity around 1.7×10^{-3} and $4.5 \times 10^{-4}\ \Omega$ cm, respectively. The ITO film deposited with TE also exhibits higher carrier concentration as well as a considerably higher carrier mobility. This demonstrates that TE employment favors the crystalline structure of the ITO film resulting in higher carrier concentration and mobility compared to the film deposited without TE. The higher carrier concentration is probably associated with a greater amount of Sn^{+4} activated as an effective donor in the crystalline structure; passive neutral Sn atoms are commonly found in amorphous ITO film [23]. With respect to the carrier mobility of the ITO film, previous reports [24,25] have discussed several electron scattering mechanisms that may influence the carrier mobility in the ITO thin film. These mechanisms include grain boundary scattering, ionized impurity scattering and neutral impurity scattering. The ITO film deposited with TE shares fewer extent of aforementioned carrier scattering events. However, it is believed that the enhanced carrier mobility of the ITO film deposited with TE predominantly governs the electrical resistivity of the deposited ITO film [26].

3.4. Adhesion of the deposited ITO films

Fig. 4 presents the SEM and optical microscopic (shown at the bottom-left corner) photographs of the ITO-coated PET specimens following the crosscut adhesion test. The darker regions in the SEM pictures are those of the delaminated ITO film whereas the lighter regions are those of the

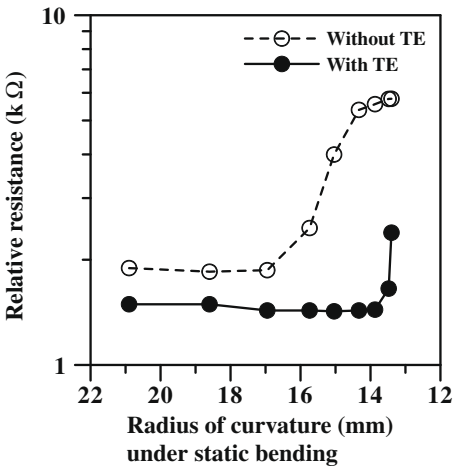

Fig. 5. Relative resistance as a function of bending radius of curvature for the ITO-coated PET specimens prepared without and with TE.

retained ITO film. Clearly, the ITO film deposited with TE, Fig. 4(b) was only damaged and delaminated in areas in which a shear force tore apart the ITO film and the PET substrate. In the remaining flat areas in Fig. 4(b), the ITO films remain on the PET surface but suffer from extensive parallel cracking. In contrast, either the flat regions or the shoulders of the scratch scars of ITO coatings on PET, presented in Fig. 4(a), were destroyed in the crosscut test. The adhesion classification of the ITO film deposited with TE and without TE is ASTM-4B and ASTM-0B, respectively, according to the ASTM standard [17]. The contribution to the increased film adhesion is debatable. The intensified ion bombardment, associated with TE supplement, apparently plays the role of removing surface contamination from the polymer substrate surface before the ITO coating is formed. Moreover, a substrate surface intensively bombarded with ions can be chemically activated and its surface wettability [27,28] physically increased, such that the initially grown film is strongly bonded to the substrate surface. However, thermal radiation generated by the TE filament may also increase the film adhesion by promoting the surface migration of adatoms. We therefore separately carried out an experiment by intentionally maintaining the substrate temperature at 90 °C (equivalent to the substrate temperature when TE is employed) when depositing ITO without using the TE technique. The result of the film adhesion test for the sample deposited without TE appears the same as those samples deposited at 50 °C without TE (no additional heating). This indicates that the additional thermal radiation effect of using TE to cause substrate temperature elevation to 90 °C did not show any observable influence on the film adhesion.

3.5. Mechanical bending durability of the deposited ITO films

Fig. 5 plots the result of static bending test on the ITO-coated PETs. The R_c values of ITO films deposited without and with TE are determined as 17.0 and 13.9 mm, respectively; above these values, the measured electrical resistance increases abruptly. This rapid increase in the electrical resistance of ITO film is caused by crack formation in the ITO films, which breaks the conduction path for the free carrier [29,30], shown in Fig. 6. The parallel cracks are formed in the ITO film deposited without TE, while the ITO film deposited with TE retains its integrity throughout the static bending test. Increased film adhesion by the TE supplement contributes to the increased bending resistance. Results of the static bending tests show that the TE supplement enables an ITO film that is deposited on the substrate to tolerate greater mechanical bending.

Fig. 7 plots the repeating dynamic bending test result of the ITO-coated PETs. The initial electrical resistance of an ITO film deposited without TE exceeds that of such a film deposited with TE. This result is consistent with the electrical resistivity measured using the Four-Point Probe, as presented in Table 2. A significant difference in electrical resistance between the ITO film deposited without and with TE is also found to be 10 kΩ. Electrical resistance value increases sharply from 3 to 10 kΩ in the case of the ITO deposited without TE, after the first 50 cycles. In contrast, the electrical resistance of ITO films deposited with TE does not observably change, even after over 1200 cycles. This finding indicates that the ITO film deposited with TE is more durable over mechanical bending cycles. The sharp increase in electrical resistance of the ITO film deposited without TE after the first 50 cycles is caused by rapid crack formation in the film, which releases bending stress. The roaming of free carriers in the ITO film drives the observed constant high electrical resistance. An ITO film that

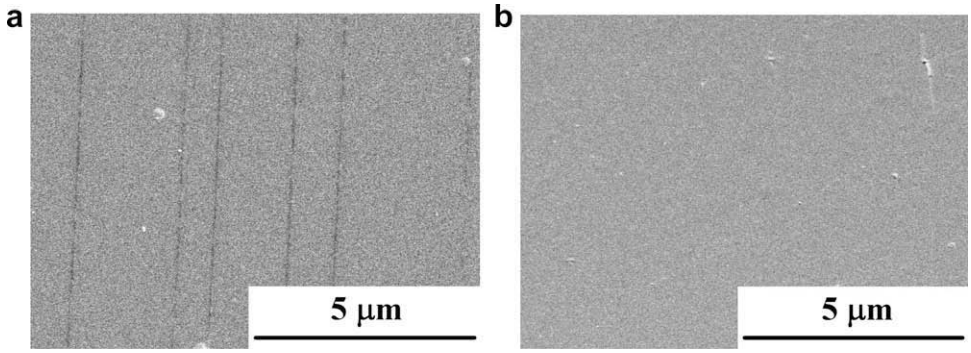

Fig. 6. SEM surface morphology of the ITO films deposited on PET substrates (a) without and (b) with TE after bending test.

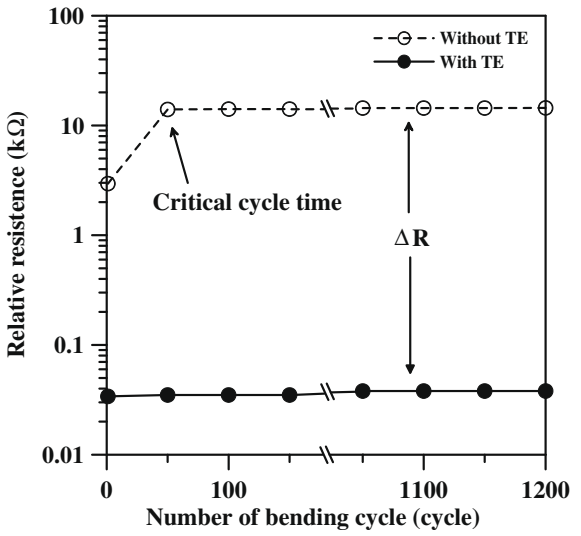

Fig. 7. Relative resistance as a function of bending cycle for the ITO-coated PET specimens deposited without and with TE.

strongly adheres to the PET substrate responds to repeated bending without cracking, retaining low electrical resistance through the test. Microscopically, the well-crystallized ITO film deposited with TE has a higher mechanical strength (than the amorphous ITO film deposited without TE), and thus better resists crack formation, and responds synergistically with the substrate because of strong film adhesion.

During dynamic bending, the electrical resistance and optical transmission of the deposited ITO film is also primarily concerned to resist. Fig. 8 shows the average transmittance of the ITO film deposited without and with TE through the dynamic bending test. The ITO-coated PET specimens prepared both without and with TE average transmittance value remain unchanged through the whole cyclic history, 70% and 83%, respectively. The only exception is that the transmittance of the ITO-coated PET specimens prepared without TE declines slightly after 800 cycles, perhaps because the substrate undergoes unrecoverable plastic deformation under the ITO coating after a certain number of cycles. The inset of the SEM image is Fig. 8 shows observations inside the crack of some fibers peeled off from the substrate matrix.

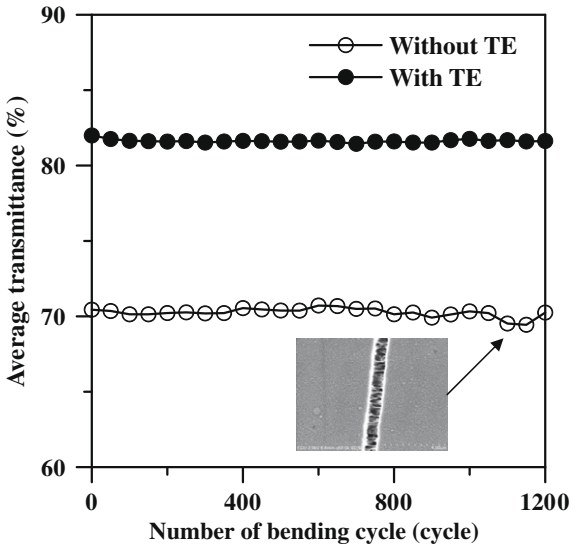

Fig. 8. Average optical transmittance of the ITO films deposited without and with TE as a function of bending cycle.

4. Conclusions

The current study involves the microstructure investigation of an ITO thin film, deposited on a flexible PET substrate by DC magnetron sputtering with thermionic emission enhancement. The microstructure explains enhanced durability of electrical and optical properties of the film under static and dynamic mechanical bending. The film deposited with TE has a higher average visible transmittance of 83%, compared to the ITO film deposited without the thermionic emission enhancement and a lower electrical resistivity of $4.5 \times 10^{-4}\,\Omega$ cm. A lower critical radius of curvature of 13.9 mm under static bending and a longer cycle time (over 1200 cycles) in the dynamic bending test are obtained in this study. In contrast, the ITO film deposited the without thermionic emission enhancement has an average optical transmittance of 70% and an electrical resistivity of $1.7 \times 10^{-3}\,\Omega$ cm. Its critical radius of curvature under static bending and the available cycle time in dynamic bending test are only 17.0 mm and fewer than 50 cycles, respectively. This work therefore concludes that thermionic emission enhancement not only enhances ITO film crystallinity for better optical transparency and electrical properties, but also significantly improves film adhesion on the PET substrate for stronger bending durability.

ABSTRACT

This article studies the magneto conductance (MC) responses of regioregular poly(3-hexylthiophene) (P3HT)-based polymer photovoltaic devices. The net MC results of devices are the sum of the positive and negative MC effects. The positive MC effect is due to the increased population of the singlet polaron-pair (PP) states (of the high dissociation rate to charge carriers) under the magnetic field. The negative MC effect results from the decline on the triplet exciton–charge reactions to charge carriers (the mobility and concentration of triplet excitons are decreased by the magnetic field). The MC responses of P3HT-based photovoltaic devices can be manipulated by the applied magnetic field, the electrical bias, the built-in potential, and the interfacial dipole layer. An inversion in the MC response is observed at the electrical bias near the open-circuit voltage. In addition, blending of an electron acceptor material, [6,6]-phenyl C61-butyric acid methyl ester, in P3HT active layer quenches the photo-excited states at the donor–acceptor interface and results in distinct MC responses of photovoltaic cells, which probably are related to the features indicating the formation of inter-molecular charge–transfer complexes at donor–acceptor junction.

1. Introduction

Organic conjugated molecules/polymers have very unique properties [1–3], they can be used as organic semiconductors in fabricating novel electronic devices [4–9]. In addition, the electronic devices incorporating organic conjugated molecules/polymers as the active layers, exhibit strong magneto responses [10,11]. The output performance, such as the electroluminescence [10,12–14], resistance or conductance [10–16], and photocurrent [11,17–20] in organic/polymer diodes and photovoltaic (PV) cells can be modulated by the applied magnetic field, although the basic device configurations are composed of intrinsically non-magnetic components. The magneto responses of organic semiconductors would have new applications in organic electronics and spintronic devices. [21–24].

A large magneto resistance (MR) or magneto conductance (MC) response in organic/polymer light-emitting diodes (O/PLEDs) has been reported by many researchers, which is intimately associated with the threshold of light emission and the ambipolar injection of charge carriers [10,25]. While the organic/polymer diodes are operated at PV regime with illumination, the magnitude of photocurrent is varied with the applied magnetic field [11,17–20]. These results suggest that the dissociations and charge-reaction processes of the photo-excited states to the generation of free charge carriers are susceptible to changes by the applied magnetic field. The excited states, induced either electrically (in O/PLEDs) or optically (in PV

doi:10.1016/j.orgel.2010.01.009

cells) in organic semiconductor layers, are essentially important to the MR or MC responses in organic/polymer diodes and PV cells [12,26–29].

The excited states (excitons) in the regioregular poly(3-hexylthiophene) (P3HT)-based polymer diodes are Coulombically bound electron–hole (e–h) pairs, commonly having a short range of the separation distance [27,30–33]. Those excitons may undergo a relaxation process to become the excited polaron-pairs (PP) states with a longer range of e–h separation distance than that of excitons. Fig. 1a illustrates the schemes for formation of intra- and inter-molecular excited PP states from excitons. Both the excitons and PP states are the excited states of conjugated organic molecules possessing singlet and triplet electronic configurations. The lifetime of the singlet and triplet PP states is shorter than that of the singlet and triplet exciton states [34,35]. The magnitude of exchange energy for the singlet/triplet excited states is exponentially decayed with respect to the e–h separation distance and is related to the energy difference between singlet and triplet states [30,31]. Accordingly, the status of the long-range (>1 nm) PP states having exchange energies of the order smaller than 10^{-3} meV is subjected to changes brought in by the applied magnetic field. Sakagughi et al. reported that the external magnetic field dependencies on the photodecomposition reaction in solution, which were attributed to the electronic Zeeman and hyperfine interactions in the intermediate radical pair [36]. The intersystem crossing process of singlet/triplet PP states as illustrated in Fig. 1b involves the spin orbital coupling (SOC) [37,38] and the hyperfine interaction (HFI) [19,27,39–41]. The population of singlet and triplet PP states can be modified by the external magnetic field, such as the changes of the splitting and difference of the energy states by Zeeman effect [19,27,28]. Since the photocurrent of P3HT-based diodes is the sum of "current flows" generated by the photo-excited states (excitons and PP states), any variations induced by an applied magnetic field on the distribution, dissociation, and charge-reaction processes of the singlet/triplet excited states (excitons and PP states) would certainly modulate the magnitude of photocurrent and MC response in PV devices [18,29]. In this manuscript, we studied how the change of the electrical bias and the device electrode influences the dissociation and charge-reaction processes of photo-excited states in P3HT-based polymer diodes. Increasing the applied magnetic field increases the distribution of singlet PP states and reduces the mobility of triplet excitons by Zeeman splitting [28,29]. The dissociation rate of the singlet PP states is higher due to the stronger ionic feature than that of triplet PP states, [19,42,43] which is accountable for an increase of free charge carriers and a positive MC effect. However, the decline of triplet exciton–charge reactions to charge carriers (reduce in mobility and concentration of triplet excitons), caused by the applied magnetic field [44–46], results in the decrease of free charge carriers and contributes to a negative MC effect. The net MC responses of the photovoltaic cells are the sum of positive and negative MC effects, in which the processes are schematically illustrated in Fig. 1c. Additionally, the MC responses are influenced by built-in electrical field of the diodes, which is tunable by varying the bias voltages

and the work function of electrodes. An inversion in MC response is observed at the electrical bias near the open-circuit voltage (V_{oc}). The magneto responses for inter-molecular charge–transfer complex states at the donor–acceptor interface are investigated by blending an electron acceptor material, [6,6]-phenyl C61-butyric acid methyl ester (PCBM), in P3HT as the active layer. The distinct MC features suggest the formation of inter-molecular charge–transfer complexes at donor–acceptor junction.

2. Experimental

The polymer diodes and photovoltaic devices are fabricated in a standard arrangement by sandwiching the active layer between a transparent electrode and a metal electrode. The transparent electrode is comprised of the cleaned indium–tin–oxide (ITO) covered glass substrate (RITEK Corp., 15 Ω/□) coated with poly (3,4-ethylenedioxythiophene) poly (styrenesulfonate) (PEDOT:PSS; Baytron P, Bayer AG, Germany) layer. Regioregular P3HT (98.5% electronic grade, Rieke Metals, Inc., USA) and PCBM (procured from Nano-C, USA) are dissolved in dichlorobenzene to yield the P3HT (20 mg/ml) and P3HT:PCBM (20:20 mg/ml) solutions. The active layers are obtained by spin-coating the solutions on the PEDOT:PSS/ITO/glass substrates at the drying process of the films in a slow-growth regime [47,48]. The thicknesses of P3HT and P3HT:PCBM films are approximately 160 ± 10 nm and 200 ± 10 nm, respectively [49]. Ca (40 nm) and Al (100 nm), as metal electrodes, are thermally deposited onto the surface of the active layer inside a vacuum chamber (4.0×10^{-6} h Pa).

A halogen lamp is used as the light source (80 mW/cm^2) to investigate the MC response of the photovoltaic cells in this study. The devices are encapsulated by the UV-curable epoxy with a cover glass and placed at the direction parallel

to the magnetic field. In order to eliminate the influence due to drifting with different bias voltages, the MC curves are averaged, based on the approach reported by Desai et al. [13]. The MC magnitude presented in this manuscript is defined as;

$$\mathrm{MC} = \frac{\Delta I(B)}{I(0)} = \frac{I(B) - I(0)}{I(0)} \quad (1)$$

Where $I(B)$ and $I(0)$ are the current intensity of the photovoltaic cells with and without the applied magnetic field, respectively. All the measurements are performed at room temperature. The magneto conductance of polymer diodes in our study is found to be independent of external magnetic field's direction [20]. The schematic drawings of the device configuration, the measurement of MC responses for polymer diodes under the applied magnetic field with illumination, and the chemical structures of P3HT and PCBM in this study are illustrated in Fig. 2a and b presents the emission spectrum of halogen lamp and the absorption spectra of P3HT and P3HT:PCBM films used in this studies. The spectrum overlap are high for the emission of the halogen lamp and absorbance of P3HT and P3HT:PCBM films.

3. Result and discussion

3.1. Effect of applied magnetic field and device electrodes on MC responses

Fig. 3 presents the measured MC of the short-circuit current (I_{sc}, photocurrent measured at 0 V bias voltage) for devices with the configurations of ITO/PEDOT:PSS/P3HT/Al (P3HT/Al-device) and ITO/PEDOT:PSS/P3HT/Ca/Al (P3HT/Ca-device) with illumination. MC response of the I_{sc} for P3HT/Al-device is positive and sharply increased from 0% to 0.8% in the low magnetic field (<30 mT) and then gradually decreased as the applied magnetic field is increased. The MC of P3HT/Al-device is reduced to zero and inversed from positive to negative at the applied magnetic field near $B \sim 150$ mT, and is of $\sim -1.4\%$ at $B = 900$ mT. The positive

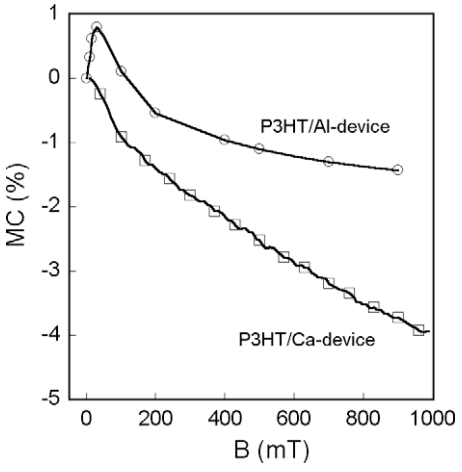

Fig. 3. MC curves of the I_{sc} (photocurrent measured at 0 V bias voltage) for P3HT/Al-device (○) and P3HT/Ca-device (□) with illumination by a halogen lamp (white light) at the intensity of 80 mW/cm^2.

and negative MC response of the I_{sc} for P3HT/Al-device is modulated by the applied magnetic field.

As illustrated in Fig. 1c, the singlet excitons (S) can dissociate into inter-molecular singlet PP states ($(PP)_1$) due to their lower binding energies towards the generation of photocurrent as compared to that of triplet excitons (T). The singlet PP states ($(PP)_1$) can partially convert into triplet PP states ($(PP)_3$) through the intersystem crossing process. Excitons and PP states in singlet and triplet configurations can be involved in the dissociation and charge-reaction processes to generate the photocurrent. In PP states, an external magnetic field can cause an external Zeeman splitting on triplet states and thus change the intersystem crossing if the external Zeeman splitting is greater than the internal Zeeman splitting. This suggests that an external magnetic field can increase the singlet/triplet population ratio in inter-molecular excited states (PP states) [50].

Kalinowski et al. reported the dissociation rates are different for singlet and triplet PP states ($k1 \gg k3$) due to the fact that singlet PP state has a stronger ionic character than triplets and therefore singlet PP states are stronger coupled with the ionic reaction products of separated holes and electrons [19]. Tandon et al. suggested both the original pair of polarons and the singlet exciton state are ionic in nature, whereas the triplet exciton is covalent [43,51]. Accordingly, the singlet PP states have higher dissociation rate than that of triplet PP states is reasonably assumed in our work.

Xu et al. also suggested that a low magnetic field (<30 mT) usually affects the formation rate of singlet/triplet PP states at the relaxation process of photo-excited excitons [18,29]. The increased distribution of singlet PP states by the applied magnetic field raises the I_{sc} (singlet PP states have a relatively higher dissociation rate for converting into free charge carriers than that of triplet PP states) [19,28], and contributes to a positive and sharply elevated MC response in the low magnetic field for P3HT/Al-device.

Although the initial excited states in P3HT by photo illumination are singlet based on the selection rule, the singlet excited states can be partially converted into triplet excited state through intersystem crossing caused by internal magnetic interaction from SOC and HFI. Both singlet and triplet excitons can exist in P3HT active layer under the illumination. The densities of triplet exciton of P3HT under illumination are about 77% as reported by Burrows et al. [52] for the study of $S1 \sim > T1$ intersystem crossing in pi-conjugated organic polymers. It is noticed that there is no heavy atoms in the system.

As the applied magnetic field is gradually increased, the decrease of triplet exciton–charge reactions causes a simultaneous reduction in the I_{sc} and accounts for a negative MC response. The exciton–charge reaction is essentially Coulombic interaction between an excited state and a trapped or free charge carrier [53,54]. The studies of phosphorescence and delayed fluorescence quenching effect indicate that the excitons can interact with trapped charge carriers to de-trap the charge carriers. [44,55,56] Alternatively, the triplet excitons can react with free charge carriers in organic materials to dissociate the

electron–hole pairs. [45,57] However, a magnetic field can decrease the reaction-rate constant by removing the triplet degeneracy and deducing the triplet mobility due to the external Zeeman splitting [26,28,39,55]. The triplet exciton–charge reactions can be decreased with magnetic field and yield a negative component in MC effect. Although the exciton–charge reactions of both singlet and triplet excitons can contribute the device current, the influence of the applied magnetic field on the exciton–charge reaction of the triplet excitons is more apparent, probably due to their longer diffusion length and sufficient contacts with charge carriers than those singlet excitons. It is assumed that the change on the exciton–charge reaction of the singlet excitons by the magnetic field is not comparable to that of the triplet excitons. The triplet exciton–charge reactions are decreased with magnetic field and yield a negative component in MC effect. The other possibility of the negative MC effect on I_{sc} is a reduction in the initial concentration of triplet excited states. An external magnetic field can increase singlet/triple population ratio in intermolecular excited states (PP states) by reducing the intersystem crossing within PP states [50], that would lead to a decrease in the population of triplet PP states and consequently in the concentration of triplet excitons. As a result, the current due to the exciton–charge reaction of triplet excitons should be decreased and contributed to the negative MC effect on I_{sc}. The magnetic field dependence of the I_{sc} for P3HT/Al-device can be attributed to the tradeoff between the distribution and dissociation of the singlet PP states (positive MC response) with the changes on the triplet exciton–charge reactions to charge carriers (negative MC response) under the influence of applied magnetic field.

While the Ca is used instead of Al as the metal electrode for P3HT-based polymer diode, the MC curve of P3HT/Ca-device is negatively increased with the applied magnetic field (unlike that of P3HT/Al-device), as show in Fig. 3. Since the interfacial barrier height at the polymer/metal junction is reduced by the low work function Ca electrode, P3HT/Ca-device has a better polymer/metal interface for the generation and collection of charge carriers than that of P3HT/Al-device, as applied for photovoltaic cells [58,59]. Alternatively, the high built-in potential of P3HT/Ca-device would accelerate the dissociation of the polaron-pair states in P3HT layer without the magnetic field that would improve the charge extraction. (The magnitudes of V_{oc} are ~0.25 and ~1.01 V for P3HT/Al-device and P3HT/Ca-device, respectively.) Noted that MC effect is defined by the current ratio with and without the magnetic field. The improvement of the charge extraction without the magnetic field did not contribute the MC response. Since most of the polaron-pair states probably are dissociated due to the higher built-in electrical field in P3HT/Ca-device, the exciton–charge reactions of triplet excitons would be the dominated mechanism. The charge reaction of triplet excitons are reduced as the applied magnetic field is increased, which decreases the overall photocurrent and hence results in net negative MC responses. The MC of P3HT/Ca-device is of ~−4.0% in an applied magnetic field of B = 1000 mT.

The devices with the configuration of ITO/PEDOT:PSS/P3HT/LiF/Ca/Al (P3HT/LiF/Ca-device) are also fabricated to investigate the influence of the additional dipole layer at P3HT/Ca interface on MC responses. Fig. 4 illustrates the MC curves of the I_{sc} for P3HT/LiF(X nm)/Ca-device with varied thicknesses of LiF layers. The measured MC responses of I_{sc} in an applied magnetic field of B = 1000 mT are of ~−4.0%, −2.9%, and −2.3% for P3HT/LiF(X nm)/Ca-device of X = 0, 1.5, and 5.0 nm, respectively. The magnitudes of MC responses decrease with increasing thickness of LiF layer. These results suggest that the additional dipole layer (LiF) functions as an electrical dipole field to accelerate the dissociation of the photo-excited states near (or diffused to) the polymer/metal junction, but lower the influence of the applied magnetic field on the triplet excitons. The inset of Fig. 4 presents the thickness of LiF layer versus MC response at B = 1000 mT and I_{sc} plots. The magnitudes of I_{sc} are increased with the thickness of interfacial dipole layer, which are of 0.007, 0.023, and 0.076 mA/cm^2 for P3HT/LiF(X nm)/Ca-device of X = 0, 1.5, and 5.0 nm, respectively, and are associated with the decreased magnitude of MC responses. The interaction of the photo-excited states with electrodes is important to determine the magnitude of I_{sc} and MC responses of P3HT-devices in our studies. Recent publications by Kalinowski et al. and Lei et al. had reported the photocurrent and device current are partially contributed by the exciton-induced injection of electrons [60,61]. MC responses of tri(8-hydroxyquinoline) aluminum (Alq3)-based diodes are possibly due to the magnetic field modulation of the stream of singlet excitons reaching the cathode as proposed by Kalinowski et al. [50].

3.2. The effect of electrical bias on MC responses

Fig. 5a presents the MC curves of P3HT/Ca-device with illumination at various bias voltages. The MC responses are of ~−4.0% for the P3HT/Ca-device biased at 0.00 and 0.50 V in an applied magnetic field of B = 1000 mT, and they significantly increase to ~−6.2% and ~−23.0% when

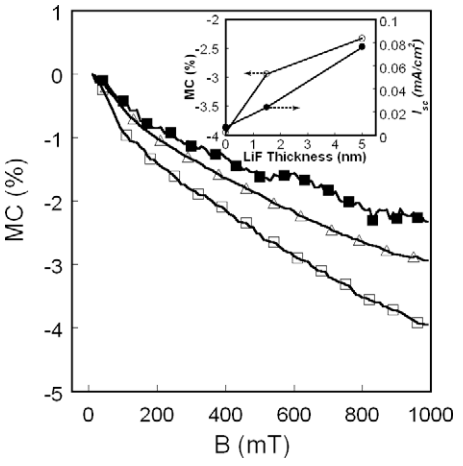

Fig. 4. MC curves of the I_{sc} (photocurrent measured at 0 V bias voltage) with illumination by a halogen lamp (white light) at the intensity of 80 mW/cm^2 for P3HT/LiF(X nm)/Ca-device at B = 1000 mT of X = (□) 0, (△) 1.5, and (■) 5.0. The inset presents the thickness of LiF layer versus (○) MC response at B = 1000 mT and (●) I_{sc} plots.

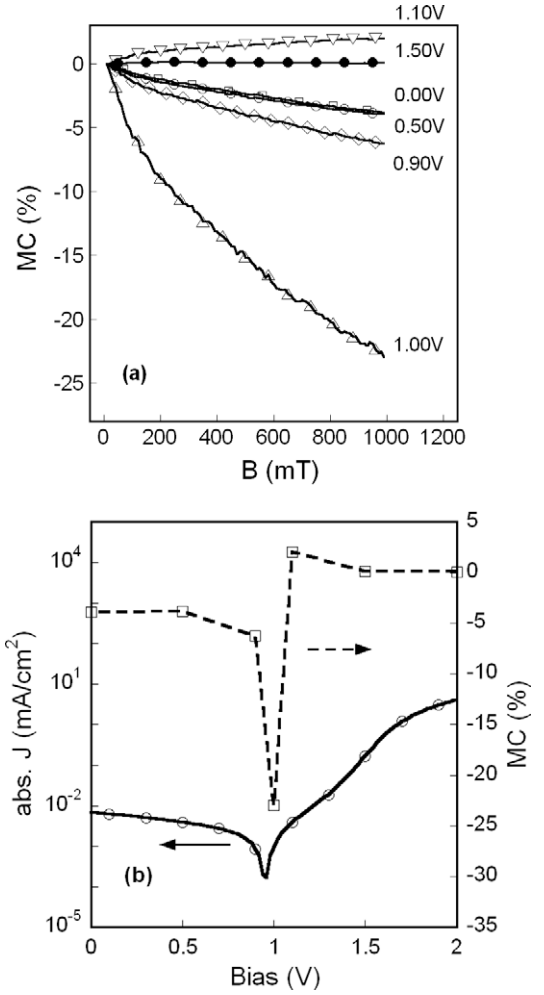

Fig. 5. (a) MC curves of P3HT/Ca-device with illumination by a halogen lamp (white light) at the intensity of 80 mW/cm^2 in the bias voltages of 0 V (○), 0.50 V (□), 0.90 V (◇), 1.00 V (△), 1.10 V (▽), and 1.50 V (●), (b). MC curve (□) of the P3HT/Ca-device with illumination versus bias voltage at B = 1000 mT and semi-logarithm current–voltage (J–V) plot (○).

the devices are biased at 0.90 and 1.00 V, respectively. However, the MC response is reversed from negative (∼−23.0% at 1.00 V) to positive (∼2.0% at 1.10 V) as the bias voltage was raised to 1.10 V and is almost vanished (<0.1%) at a bias voltage that exceeds 1.50 V. Fig. 5b plots the MC curve of the P3HT/Ca-device with illumination versus bias voltage and semi-logarithm current–voltage (J–V) plot at B = 1000 mT. The inversion of the MC curve is found at the bias voltage close to the V_{oc} in the semi-logarithm J–V plot.

The photo-excited states in P3HT active layer are the Coulombically bound e–h pairs. The Coulombic interaction of those excited e–h pairs is varied with the separation distance and is subjected to change with magnitude and direction of the internal (built-in electrical field: difference in the work function of two electrodes) and external (the applied bias) electrical fields. As the applied bias voltage of P3HT/Ca-device approaches V_{oc}, the influence of the built-in electrical field on the Coulombically bound e–h pairs is minimized, because the built-in electrical field is offset by the applied electrical bias (V–$V_{oc} \sim 0$). The internal and external electrical fields are of opposite directions at the bias regime in which the applied voltage is lower than the V_{oc}. As a result, the denominator $I(0)$ in Eq. (1) is nearly zero as the bias voltage approaches V_{oc}. Therefore, a drastic MC response (negative) as calculated by Eq. (1) at an applied bias voltage close to V_{oc} is observed as shown in Fig. 5a and b. However, the influence of the applied magnetic field on the I_{sc} at the electrical bias approaches V_{oc} should also be considered as a factor for the significant increase of MC responses. Noted that it requires the very delicate control to precisely measure the current (very small magnitude) at the effective electrical field of the device down to zero (V–$V_{oc} \sim 0$). The $I(0)$ and $I(B)$ for P3HT/Ca-device biased at the voltages, 0.90 and 1.00 V (very close, but not equal to V_{oc}), are of -8.51×10^{-4} and -7.98×10^{-4} mA/cm^2, 9.28×10^{-4} and 7.15×10^{-4} mA/cm^2, respectively. Although the device current at the bias voltage very close to the V_{oc} is small, the finite differences, $I(B) - I(0)$, of -0.53×10^{-4} and -2.13×10^{-4} mA/cm^2 correspond to the −6.2% and −23.0% of MC responses for the device biased at 0.90 and 1.00 V, respectively. These results probably suggest that the MC responses at the bias voltage close to V_{oc} (the effective voltage $V - V_{oc} \sim 0$) would be determined by the influence of the applied magnetic field on the photo-excited states, in which the mechanism for the decrease in exciton–charge reactions of the triplet excitons are eminent as mentioned in the previous paragraph and thus results in the maximum (negative) MC responses.

The injection of charge carriers occurs at the bias voltage larger than V_{oc}. Firstly, $I(0)$ is exponentially increased in this bias regime. Secondly, the excited states in P3HT active layer should include the electrical-induced excitons and PP states from the recombination of the injected and oppositely-charged carriers. Thirdly, the Coulombic interactions of those excited (photo- and electrical-induced) states may be reduced (or the average intercarrier distance of excited states is changed) by the external electrical field at the bias voltage larger than the V_{oc}, which affects strongly the energy gap between the singlet and triplet excited state and influences the mixing of the spin states. The increased distribution of singlet PP states under the influences of the magnetic field at the bias voltage larger than the V_{oc} probably contributes a positive MC response. The MC curve is positively increased and inversed from ∼−23.0% at 1.00 V to ∼2.0% at 1.10 V when B = 1000 mT. However, the MC response is almost suppressed as the current densities or bias voltages increase. This result can be interpreted by the current generated due to the formation and dissociation of excited states under the influence of external magnetic field only and accounts for a relatively small amount of the total current density. The denominator $I(0)$ is exponentially increased at the bias voltage larger than V_{oc}, which is responsible for a relatively small MC response based on the calculation in the Eq. (1). The above summaries fortify the assumption that the measured MC is basically associated with the interaction of excited states with the applied magnetic field and electrical bias.

3.3. Features of inter-molecular charge–transfer complexes on MC responses

Fig. 6 illustrates the MC curves of P3HT/Ca-device and P3HT:PCBM/Ca-device at the applied bias voltage, 2.00 and 0.70 V, respectively, larger than its V_{oc} without illumination. For the P3HT/Ca-device, a positively increased MC response is observed at the low magnetic field ($B < \sim 200$ mT), which is associated with the dissociation of electrical-excited PP states from the injected charge carriers (without illumination and the bias voltage large than V_{oc}) as facilitated by the applied electrical and magnetic field. However, the influence from the applied electrical and magnetic field on the total current density of P3HT/Ca-device reaches a saturated level at $B > \sim 400$ mT. Further increasing the applied magnetic field above ~400 mT did not enlarge the MC response and account for a flat MC curve as shown in Fig. 6.

Blending an electron acceptor, (PCBM), with P3HT as the active layer (a bulk-heterojunction conjugated system) effectively causes the charge separation of the excited states at the donor–acceptor (P3HT-PCBM) interface and therefore markedly changes the MC responses as illustrated in Fig. 6. The MC curve of P3HT:PCBM/Ca-device without illumination is almost inhibited (showing a flat line close to zero) at the low magnetic field from 0 to ~180 mT, but is positively increased with the applied magnetic field at $B > \sim 180$ mT. The observation of MC curves for the P3HT:PCBM/Ca-device in Fig. 6 confirms very well the characteristic features for the existence of the inter-molecular charge–transfer complexes at the donor–acceptor interface [29]. The dissociation of the inter-molecular charge–transfer complexes is interrupted by the strong Coulmbic interactions in donor–acceptor molecules at the low magnetic field. Therefore, the MC curve is almost zero and has a threshold of increase at $B \sim 180$ mT. The increased distribution of singlet inter-molecular charge–transfer complexes states due to the magnetic field dependent intersystem crossing by the applied magnetic field ($B > 180$ mT) raises the I_{sc} through the dissociation of singlet charge–transfer complex, which are responsible for the positively increased MC response of P3HT:PCBM/Ca-device.

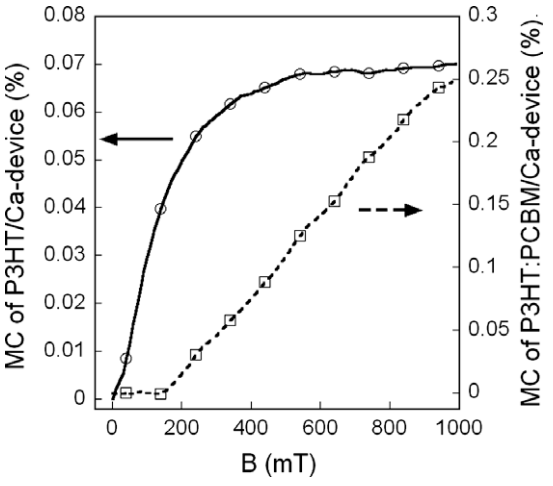

Fig. 6. MC curves of P3HT/Ca-device (○) and P3HT:PCBM/Ca-device (□) at the applied bias voltage, 2.00 and 0.70 V, respectively, larger than its V_{oc} without illumination.

Fig. 7a presents the MC curves of P3HT:PCBM/Ca-device with illumination at various bias conditions. Fig. 7b plots the MC curve of the P3HT:PCBM/Ca-device with illumination versus bias voltage and semi-logarithm J–V plot at $B = 1000$ mT. The MC curves presented in both the Figs. 7a and b have sharply increased (negatively) and inversed MC responses at the bias voltages near the V_{oc}. However, the magnitude of MC response for P3HT:PCBM/Ca-device is relatively low (<0.1%) as compared to that of P3HT/Ca-device (Fig. 5) at the applied bias lower than the V_{oc} (~0.59 V for P3HT:PCBM/Ca-device). This observation can be interpreted in terms of quenching most of the

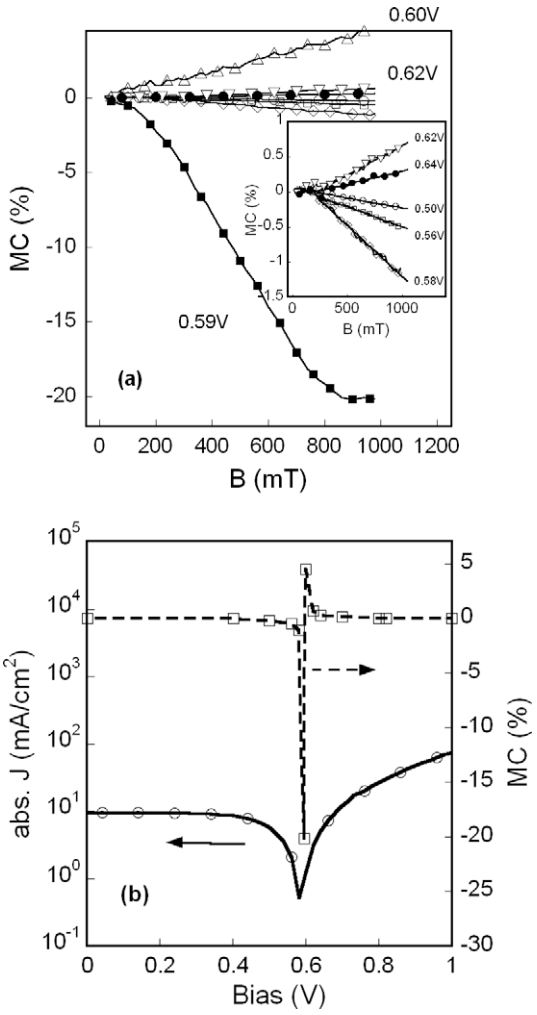

Fig. 7. (a) MC curves of P3HT:PCBM/Ca-device with the illumination by a halogen lamp (white light) at the intensity of 80 mW/cm^2 at bias voltages of 0.50 V (○), 0.56 V (□), 0.58 V (◇), 0.59 V (■), 0.60 V (△), 0.62 V (▽) and 0.64 V (●). The inset shows the MC curves at enlarged scale at the biased voltages of 0.50 V (○), 0.56 V (□), 0.58 V (◇), 0.62 V (▽) and 0.64 V (●). (b) MC curve (□) of the P3HT:PCBM/Ca-device with illumination versus bias voltage at $B = 1000$ mT and semi-logarithm current–voltage (J–V) plot (○).

photo-excited excitons and PP states (magnetic-sensitive) by the separation of oppositely-charged carriers at the P3HT-PCBM (donor–acceptor) interface. Consequently, the P3HT:PCBM/Ca-device has the low MC responses at the bias voltages lower than the V_{oc}. Nevertheless, the observed MC responses at $V < V_{oc}$ are negative and increased negatively with the applied magnetic field. We suggest that the negative MC responses are due to the reduced charge reactions of excitons in P3HT-PCBM/Ca-device by the applied magnetic field, in which the excitons probably are generated by the back transfer of the charge–transfer complex states at the high magnetic field. However, this assumption needs more investigations in detail. The sharply increased (negatively) MC response at bias voltage of 0.59 V in Figs. 7a and b is suggested to be due to the drastic reduction of the denominator $I(0)$ in Eq. (1), which is nearly zero at the bias voltage close to V_{oc}. The inset of Fig. 7a shows the MC curves at the enlarged scale as the biased voltages are nearby V_{oc}. Those curves have a threshold of MC response at the low magnetic field and are increased negatively or positively at the high magnetic field, which are associated with the presence of inter-molecular charge–transfer complexes in the donor–acceptor interface as discussed in the previous paragraph.

4. Conclusions

In conclusion, the mechanisms to interpret the MC responses for polymer photovoltaic devices made of P3HT and P3HT:PCBM as the active layers are presumably correlated with the influence of the applied magnetic filed and electrical bias on the photo- and electrical-excited states (excitons and PP states) and inter-molecular charge–transfer complexes of conjugated molecules. Our results have indicated that the MC responses can be modulated to yield positive, negative, and/or inverse effects by the photo illumination, the usage of different metal electrodes, interfacial dipole layer, the applied magnetic field and electrical bias, and the composition of polymer active layers. We regard the studies to change the excitation light intensity and wavelength would be essential to verify the origin of the device current (injected or photo-induced) in organic/polymer photovoltaic devices and further understand the mechanisms of MC responses [62]. This part of research is important and in progress at this time. As for P3HT:PCBM-based bulk-heterojunction photovoltaic cells, the charge–transfer complexes would be the critical excited states to influence the overall power conversion efficiency. The magnitude of photocurrent as well as the device performance can be further improved, if the dissociation of inter-molecular charge–transfer complexes is facilitated, probably by manipulating and optimizing the bulk-heterojunction and the polymer/electrode interfaces. The studies to understand the inter-molecular charge–transfer complex states in the active layer under the influence of applied magnetic field are currently underway.

Table 1
Molecular weight data for PTAA polymers.

PTAA	M_n ($gmol^{-1}$)	Mw ($gmol^{-1}$)	PDi	HOMO (eV)	LUMO (eV)
1	5400	11,070	2.05	5.07	2.18
2	10,000	19,100	1.91	5.12	2.23
3	15,700	38,800	2.47	5.12	2.23
4	18,200	40,300	2.21	5.11	2.22

2.2. Solution preparation

Of 1% w/w stock solutions of PTAA in toluene were prepared and filtered using a 0.45 μm PTFE filter. Solutions of both single component and simple blends were prepared 24 h prior to device fabrication to allow complete mixing.

2.3. Devices fabrication

Discrete bottom-gate, top-contact organic field effect transistor (OFET) devices were fabricated on OTS treated heavily *n*-doped silicon wafers comprising a 3000 Å thermally grown gate oxide layer. Substrates were cleaned by sonication in de-ionised water for 15 min, then acetone for 15 min and finally methanol for 15 min, prior to immersion in a solution of 10 mM OTS in toluene for 20 min maintained at 60 °C. Substrates were then dried on a hot plate for 2 h at 150 °C in ambient conditions. PTAA solutions were drop cast on the substrate, and dried at room temperature under vacuum (0.1 mBar/60 min) to remove any entrapped solvent. Film quality for all measured devices was good with no evidence of pin holes or de-wetting from the substrate. Samples were drop cast on bare silica without OTS treatment or OTS treated silica were also thermally annealed for 1 h at 100 °C under reduced pressure of 0.1 mBar as indicated. Gold source and drain channel electrodes with a 60 μm channel length and 2 mm channel width were thermally evaporated, at 10^{-6} mBar at a rate of 0.5 nm/s until a layer thickness of 50 nm was obtained, yielding nine transistors per substrate.

2.4. Characterisation

Scanning Force Microscopy (SFM) was performed using an AFM XE100 (PSIA Inc, Seoul, Korea) in true non contact mode at 0.3 Hz. We used a commercial silicon cantilever with a nominal spring constant of about 40 N/m, whose resonant frequency was 325 kHz, the back of the cantilever being coated with aluminum to increase signal feedback. Topography as well as phase contrast images were recorded.

UV–vis absorption spectra of various compounds were recorded on a Varian Eclipse between 200 and 800 nm. Toluene solution sample were placed in quartz cuvettes (1 cm path) and baseline correction was done by subtracting the signal for pure solvent.

Cyclic voltammograms were recorded using a BASI cell system. Of 0.1% w/w solutions of PTAA in toluene was drop casted on platinum foil and left to dry before measuring against ferrocene. The electrochemical cell consists of a three electrodes system: Platinum wire as counter electrode, platinum foil covered in polymer as working electrode and silver/silver nitrate reference electrode. Of 0.1 M TBAHFP in acetonitrile was used as supporting electrolyte. Electrolyte was purged under nitrogen for 5 min prior to introduction of the PTAA coated platinum foil. After introduction the nitrogen purge was left on for 2 min until the measurement started.

DC characteristics of the devices were obtained using an E5270B 8 Slot precision measurement frame from Agilent Technology coupled to a 3 Agilent E5287A atto level High Resolution Module. Contacts were made using Karl Süss PH100 manual microprobes. Output characteristics were obtained at a constant gate voltage $V_G = -80$ V and transfer characteristics at a constant drain voltage $V_{sd} = -80$ V. From the slope of the square root of the drain current characteristic, we were able to calculate the saturated hole mobility (μ_{FET}) and the threshold voltage, according to the following equation:

$$I_D = \frac{\mu_{FET} W C_i}{2L}(V_G - V_T)^2 \quad (1)$$

where W is the width of the channel (2 mm), L the length of the channel (60 μm), C_i is the equivalent capacitance of the dielectric intercepting the channel and V_T the threshold voltage. Measurements were performed in air, in the dark under normal atmospheric pressure. In all cases when a transistor effect was measurable film quality was pinhole free leading to more than 70% responsive devices with a variation over the substrate of less than 20%.

3. Results and discussion

3.1. Optical and electrochemical properties

UV–vis absorption spectra and cyclic voltammograms were recorded for all PTAA samples the results being summarized in Table 1. The optical absorption and fluorescence spectra of PTTA solutions at a concentration of 10^{-4} M in toluene confirm no Stokes Shift with the slight peak broadening and more intense absorption at lower wavelength linked to the flexibility of the backbone chain of this particular PTAA derivative as shown in Figs. 2a and b. The onset of the absorption peak at 415 nm was well defined for all polymers and was used to calculate the value of the optical

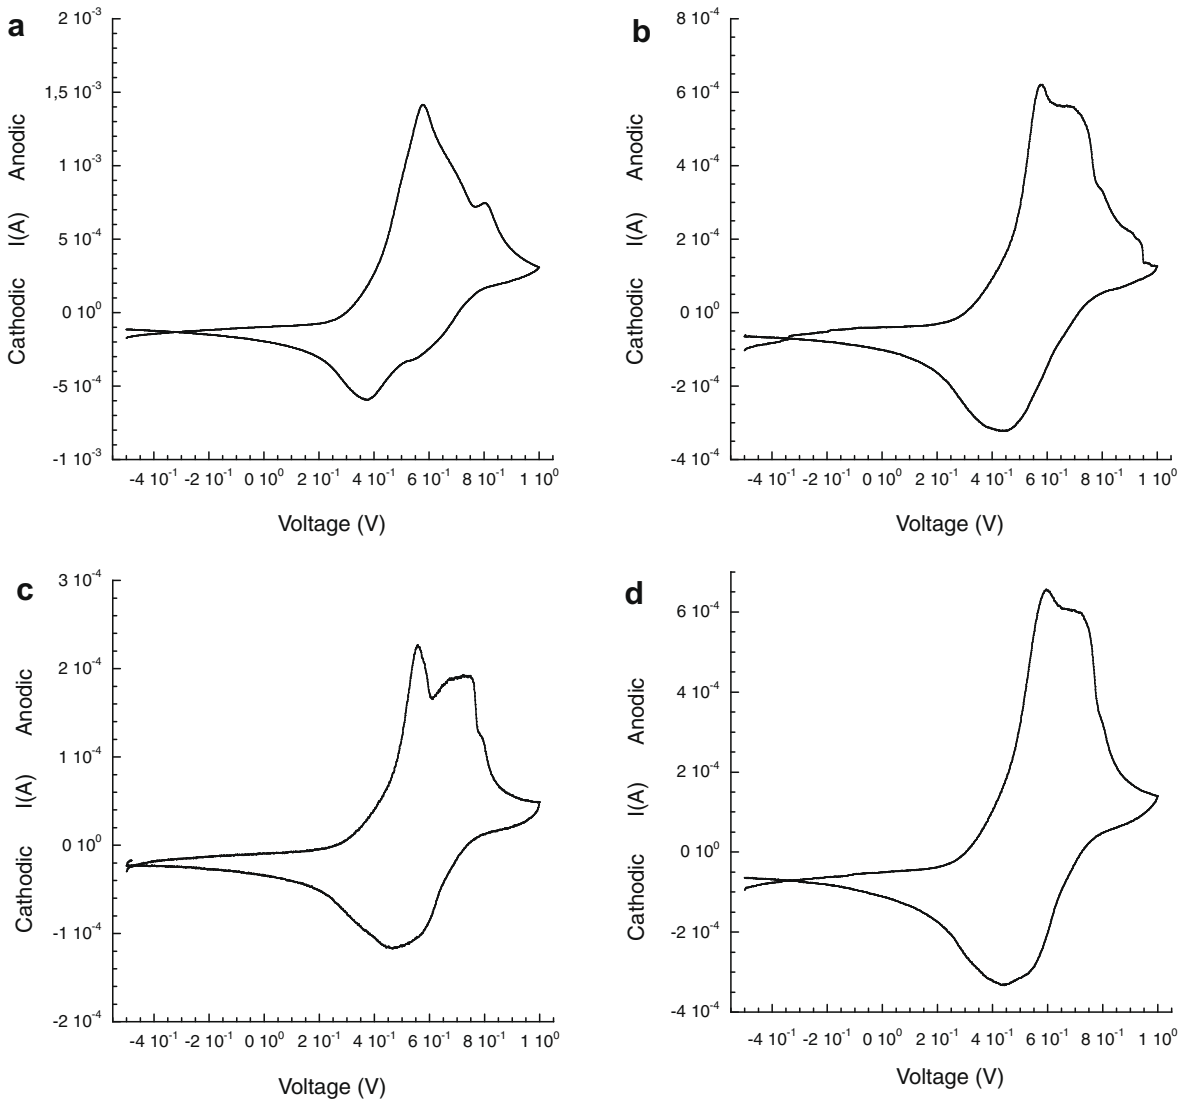

Fig. 2a. Cyclic voltamograms of (a) M_n = 5400, (b) M_n = 10,000, (c) M_n = 15,700 and (d) M_n = 18,200 as thin film deposited on platinum foil, in acetonitrile containing 0.1 M of tetrabutylammonium hexafluorophosphate.

band gap of the material, 2.89 eV. In our calculation we use the optical and electronic band gap to calculate the HOMO level of the material which shows only a weak molecular weight dependency at $M_n < 10{,}000$ gmol^{-1}. CV curves for PTAA 1–4 thin films, shown in Figs. 2a and b, are reproducible and stable upon cycling. Whilst samples in solution however do not exhibit a reversible characteristic [11] due to diffusion issues into the solid film [12], this does not restrict energy level determination since we use the formalism of Scharber et al. [13].

3.2. Electronic properties

The threshold voltage (0.4 ± 0.05 V), off current and on/off ratio were found to be independent of molecular weight with minimal current–voltage hysteresis as shown in Fig. 3 shows both the effect of PTAA molecular weight and surface treatment of mean saturated hole mobility. The insertion of an OTS SAM between the dielectric and the active semiconductor polymer increases the hole mobility by one order of magnitude independent of polymer molecular weight. Since the all polymer films by both optical and Atomic Force Microscopy were pinhole free and in the case of bare silica devices, wafers were cleaned and annealed prior to solution deposition and stored under dry vacuum to limit the adsorption of moisture and organic pollutants, the increase in mobility after insertion of the SAM layer is indicative of the rapid diffusion of oxygen and moisture through PTAA. Since both the threshold voltage and off current are independent of molecular weight this rules out any differences due to low molar mass ionic impurities [14]. Further indication of material purity across the range of polymers studied is shown in Fig. 3(a) and (b), where there is no difference in the minimal hysteresis. In all cases

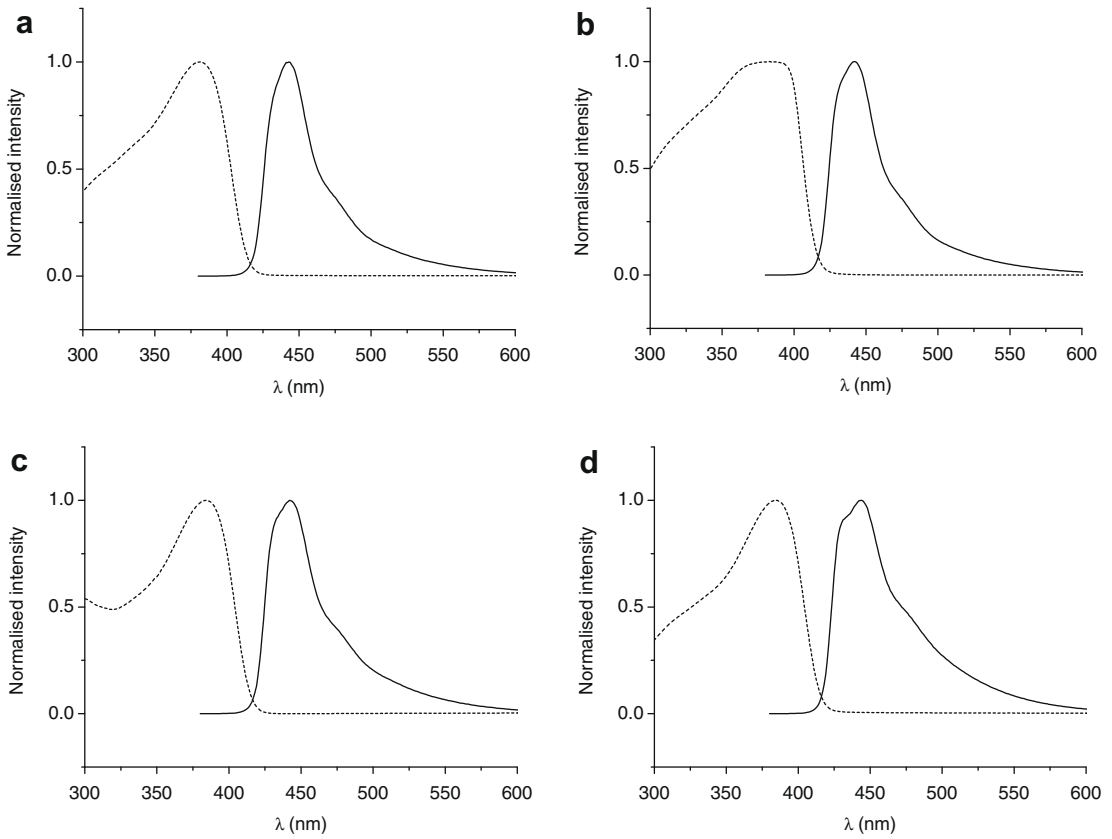

Fig. 2b. Absorption and fluorescence spectra of (a) M_n = 5400, (b) M_n = 10,000, (c) M_n = 15,700 and (d) M_n = 18,200 PTAA in solution of toluene. For more visibility, spectra have been normalized.

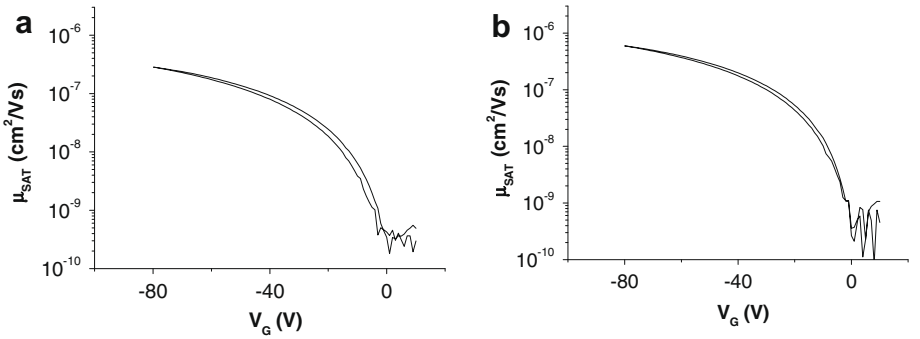

Fig. 3. Transfer characteristics in the saturated regime (V_{sd} = −80 V) for (a) PTAA 1 and (b) PTAA 4 on OTS treated silica.

on/off ratio was greater than 1000 and reproducible further confirming the absence of unwanted doping species. Annealing the dry polymer film has only a minor positive effect compared to film deposited on OTS at room temperature, lying within the 10% error margin and can be explained by the amorphous nature of the PTAA (see Fig. 4).

It is known that monomeric arylamine compounds can exhibit high mobility and that this value decreases sharply upon dimerisation and subsequent oligomerisation [15]. Here we report for the first time for low molar mass PTAA in the open literature [16] the increase in saturated hole mobility with increasing degree of polymerisation (DP) between 20 and 70 and the evidence of a plateau at around DP = 70, M_n = 20,000 gmol^{-1}. When a charge is generated on a polymer chain it is usually delocalized with the conjugation length being less than the degree of polymerisation, due to multiple defects present on a chain with the consequence that the charge is trapped in a 1D system if it cannot be delocalized further. Active transport in disordered

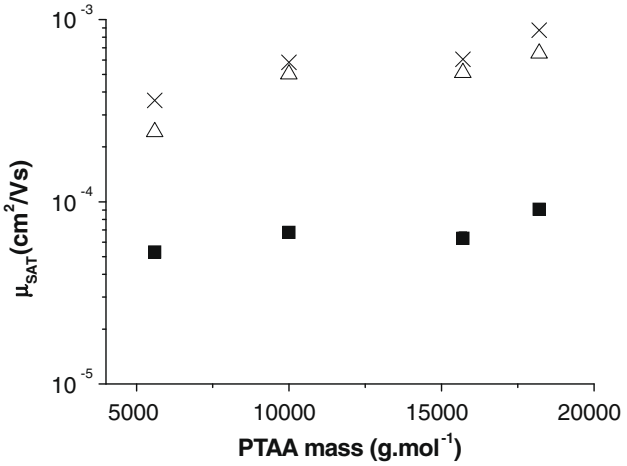

Fig. 4. Mean saturated hole mobility (μ_{FET}) of PTAA as a function of molecular weight for various deposition condition and post thermal annealing treatment (△, OTS treated silica; ■, bare silica; ×, OTS treated silica and post annealing.

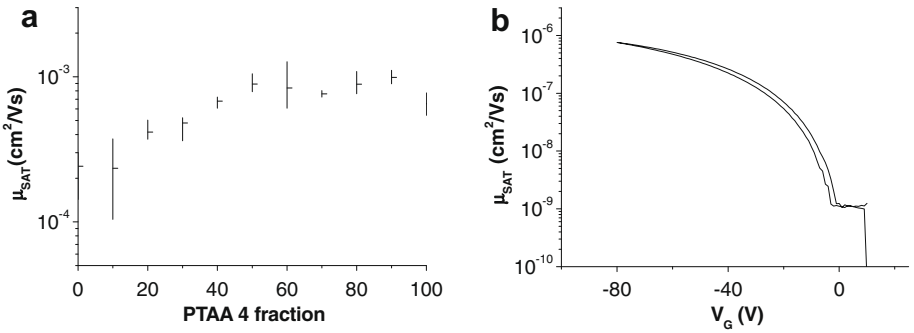

Fig. 5. (a) Mean saturated hole mobility (μ_{FET}) and (b) transfer characteristics in the saturated regime (V_{sd} = −80 V)on OTS treated silica of solution blends of PTAA 1 and PTAA 4.

systems is attributed mainly to charge hopping between polymer chains and in the case of high molecular weight polymers the conjugation length is statistically larger [9,17]. With decreasing polymer molecular weight the chain end density increases so lowering the saturated hole mobility. This is exacerbated in the case of poly(4,4-diphenyl-(4-methoxy-2-methyl-phenyl)amine) where the end caps give rise to *N*-triaryl sites with two *para*-methoxyphenyl substituted electron donating groups rather than the single *p*-methoxy-*o*-methylphenyl substitution that exists along the polymer chain.

Blends of PTAA 1 and PTAA 4 were drop cast onto OTS treated silica and the electronic properties determined, see Fig. 5. Dilution of high molecular weight PTAA 4 with low molecular weight PTAA did not result in the anticipated fall in saturated hole mobility, but in formulations having a PTAA 4 content >50 wt.%. Within the experimental error of the experiment there is evidence to suggest that indeed the performance of the blend is greater than that of either single component. Whilst the glass transition temperature of the PTAA polymers are extremely diffuse, making measurement impossible, we believe the improvement in electrical performance is due to improved polymer chain coalescence during the film formation process leading to a reduction in overall free volume within the film and so aiding charge hopping between the high molecular weight polymer chains [18].

4. Conclusions

The molecular weight of amorphous semiconductor PTAA polymer has an influence on the hole mobility on the saturated regime in bottom-gate top-contact thin film transistors. The best performances are found when the low and the high molecular weight PTAA are blended in equal ratio. Although the smallest molecular weight polymer exhibits a low mobility, it has a beneficial effect in terms of film coalescence and reduction in film free volume.

currents. Our vertical-type complementary organic inverter exhibited a transfer gain of up to −9 at a supply voltage (V_{DD}) of 4 V. To the best of our knowledge, this device is the first organic complementary inverter formed by integrating p- and n-channel OVTs.

2. Experimental

Fig. 1(a) and (b) display three-dimensional and circuit schematic representations, respectively, of the organic complementary inverter. Initially, a 30 nm-thick gold (Au) layer was deposited on a cleaned glass substrate to function as the collector electrode for the p- and n-channel OVTs. For the n-channel OVT, N,N′-dioctyl-3,4,9,10-perylenedicarboximide (PTCDI, ca. 98% purity, Sigma–Aldrich) was deposited on the Au layer to function as the collector layer. A 30 nm-thick aluminum (Al) strip was deposited on the collector layer to serve as the common-base electrode for the p- and n-channel OVTs. Next, a thin Al film (15 nm), to operate as the base electrode, was deposited on the strip. To decrease the OFF current, the sample was heated at 150 °C for 2 h [11]. A 100 nm-thick layer of C_{60} was thermally evaporated onto the thin Al layer to function as the emitter layer. A 30 nm-thick silver (Ag) layer was deposited onto the emitter layer of the n-channel OVT to behave as the emitter electrode. For the p-channel OVT, a 50 nm-thick layer of copper phthalocyanine (CuPc, Luminescence Technology) was thermally deposited onto the Au layer to smooth the surface morphology and then a 270 nm-thick layer of pentacene (ca. 98% purity, Luminescence Technology) was thermally evaporated to function as the collector layer. A thin Al film (10 nm) was then deposited and a lithium fluoride (LiF) layer (0.4 nm) was thermally evaporated to function as a hole injection enhancement layer. Next, a 20 nm-thick layer of N,N′-bis(naphthalen-1-yl)-N,N′-bisphenylbenzidine (NPB) was thermally evaporated to enhance the carrier energy. Pentacene was then thermally evaporated to form the 100 nm-thick emitter layer. Finally, a film of WO_3 (10 nm)/Al (30 nm) was deposited onto the emitter layer of the p-channel OVT to function as the emitter electrode. All the organic materials were used as received; they were thermally evaporated at a base pressure of 10^{-6} torr. The devices were patterned using a metal mask; the active area for both the p- and n-channel triodes was 0.04 cm^2. The current–voltage (I–V) characteristics of the devices were measured in the dark under a nitrogen (N_2) atmosphere using a Keithley 4200-SCS semiconductor parameter analyzer.

3. Results and discussion

In previous reports describing the performance of p- and n- channel OVTs [11,12], a p-channel OVT employing Au as the emitter electrode could be operated through voltage-driving under an apparent saturation region, although the ON current was much less than that of an n-channel OVT. This behavior was attributed to the longer mean free path of electrons in metal films than that of holes [13]; electrons have a lower probability of recombining at the metal base than do holes and, thus, a greater number of electrons could diffuse through the metal base layer into the collector layer. Therefore, to enhance the ON current of the p-channel OVT, we inserted a WO_3 layer

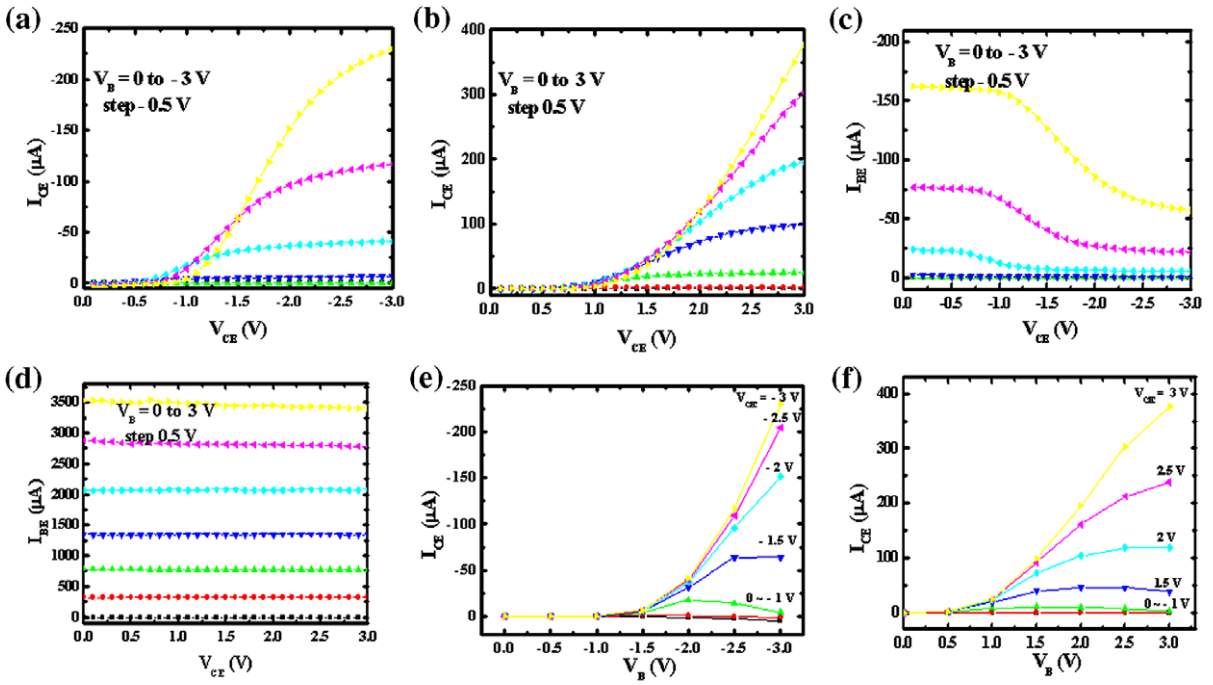

Fig. 2. (a) and (c) Collector-to-emitter current (I_{CE}) and the base current (I_{BE}) plotted with respect to the collector-to-emitter voltage (V_{CE}) for the p-channel organic triode at base voltages (V_B) ranging from 0 to −3 V at a step of −0.5 V. (b) and (d) I_{CE} and I_{BE} plotted with respect to V_{CE} for the n-channel organic triode at values of V_B ranging from 0 to 3 V at a step of 0.5 V. (e) and (f) the I_{CE} versus V_B characteristics of the p- and n-channel OVTs at V_{CE} ranging from 0 to −3 V at a step of −0.5 V and ranging from 0 to 3 V at a step of 0.5 V, respectively.

at the Al–pentacene junction to lower the barrier between the electrode and organic semiconductor and prevent the reaction and/or diffusion of the metal into the active layer [14,15]. Current matching between p- and n-channel OVTs is important for an effective complementary inverter. Fig. 2(a) and (c) display the collector-to-emitter current (I_{CE}) and base current (I_{BE}) with respect to the collector-to-emitter voltage (V_{CE}) of the p-channel OVTs and Fig. 2(b) and (d) display the I_{CE} and I_{BE} with respect to the V_{CE} of the n-channel OVTs. Fig. 2(e) and (f) display the I_{CE} versus the base voltage (V_B) characteristics of the p- and n-channel OVTs, respectively. Due to the carriers without large enough energy, most of carriers would become recombination current at the base electrode, as result of the lower current gain [14]. To enhance the current gain, there are two possible ways to decrease the carrier recombination at based electrode. One is that increasing the tunneling current by optimizing LiF thickness [16]. The other is that the enhancing the carrier energy by replacing NPB layer with the material with higher HOMO level. For the p-channel OVT, the ON current (V_B = −3 V), OFF current (V_B = 0 V), and turn-on voltage were −229 μA, −67.6 nA, and −0.8 V, respectively; for the n-channel OVT, these values were 377 μA (at V_B = 3 V), 86.9 nA (at V_B = 0 V), and 0.4 V, respectively. Owning to the OVTs composed of the EB and the CB diode, while the V_B was applied for zero, the most of the OFF current was caused by the leakage current of the CB diode. Therefore, the OFF current could be decreased by heating the device [11] or/and increasing the thickness of the CB diode. As the Fig. 1(e) and (f) shown, a leakage current exists at small V_{CE} bias. It was observed in organic and inorganic vertical-type triodes due to the asymmetry of the CB diode and the EB diode and unideal transport factor [12,17,18]. As the V_{CE} increasing, the I_{CE} would be appropriately small current or near zero and this V_{CE} was defined as the turn-on voltage. Although the ON current of the p-channel OVT could be increased by one order of magnitude, it remained somewhat less than that of the n-channel OVT. To further improve the performance of the p-channel OVT, we suspect that it would be necessary to insert a material possessing a higher energy level between the NPB layer and the thin Al layer to

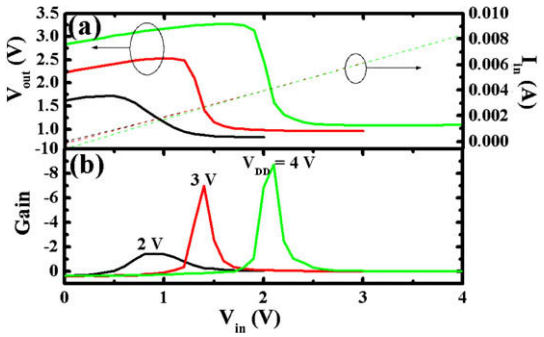

Fig. 3. (a) Measured transfer characteristics and input current (I_{in}) and (b) corresponding gain of an organic complementary inverter at supply voltages (V_{DD}) ranging from 2 to 4 V at a step of 1 V.

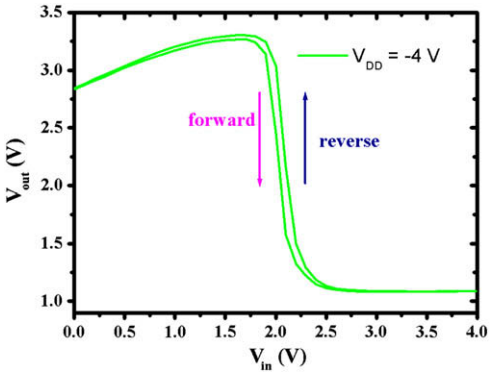

Fig. 4. Transfer characteristics in both forward and reverse directions for the complementary organic inverter at a value of V_{DD} of 4 V.

raise the carrier energy; such studies are currently under investigation.

Fig. 3 displays the transfer characteristics, the input current and corresponding gain of the complementary vertical-type organic triode in the supply voltage (V_{DD}) range from 2 to 4 V at a step of 1 V. The larger input current was caused by the base current of the OVT. Although the complementary inverter could be operated by the lower voltage, larger input current may consume more power. Besides, it was not beneficial to drive the next device in the integrated circuit application. Therefore, enhancing tunneling current or/and increasing carrier energy could decrease the input current and improve the power dissipation. In addition, the electrical characteristics of the complementary inverter, corresponding gain, was also worth discussing. The corresponding gain, defined as $-dV_{out}/dV_{in}$, increased gradually upon increasing the value of V_{DD}, reaching its highest value of −8.75 when V_{DD} was equal to 4 V. Relative to the corresponding resistance-load inverter [12], the complementary vertical-type organic triode exhibited an enhanced gain and a lower driving voltage. Fig. 4 displays the transfer characteristics for both the forward and reverse directions when V_{DD} was 4 V. In the ideal case, the OVTs would not employ the insulator and the complementary inverter would not exhibit the hysteresis phenomenon. Fig. 4 reveals only minor hysteresis, which presumably resulted from the presence of impurities in the organic materials, thereby trapping some carriers within the active layers. In addition to hysteresis phenomena, the noise margin is another important electronic characteristic. Fig. 4 reveals values for the noise margin low (N_{ML}) and noise margin high (N_{MH}) of 0.97 and 0.82 V, respectively [19]. These measured values are less than the theoretical values ($N_{MH} = N_{ML} = V_{DD}/2$), presumably because of (i) the current mismatch and larger OFF current in the p- and n-channel OVTs and (ii) the gradual shift in the turn-on voltage upon increasing the base voltage. The p-channel OVT operated under the linear region at the lower value of V_{in} of the inverter. A shift in the turn-on voltage would result in a change in the value of V_{out} upon increasing V_{in} and then a decrease in the values of N_{ML} and N_{MH}. We suspect that the electrical characteristics of the vertical-type complementary organic inverter would be improved further upon lowering the base currents, OFF currents and turn-on voltages of both OVTs.

4. Conclusions

In summary, we have fabricated the first organic complementary organic inverter incorporating p- and n-channel OVTs that could be operated at a low-voltage of 4 V to provide a corresponding gain of −9. Our results suggest that these OVTs have the same electronic applications as planar-type OTFTs – while displaying the advantageous properties of lower driving voltages and a faster operating frequencies.

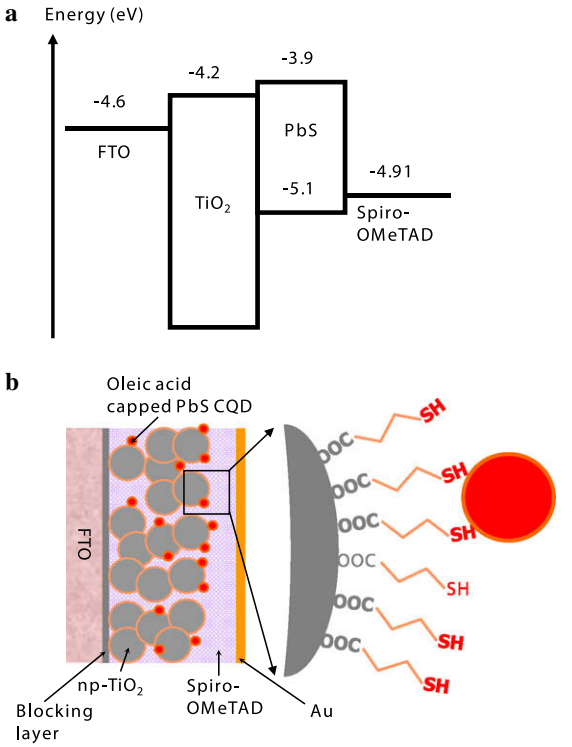

Scheme 1. Schematic of (a) band diagram and (b) device structure.

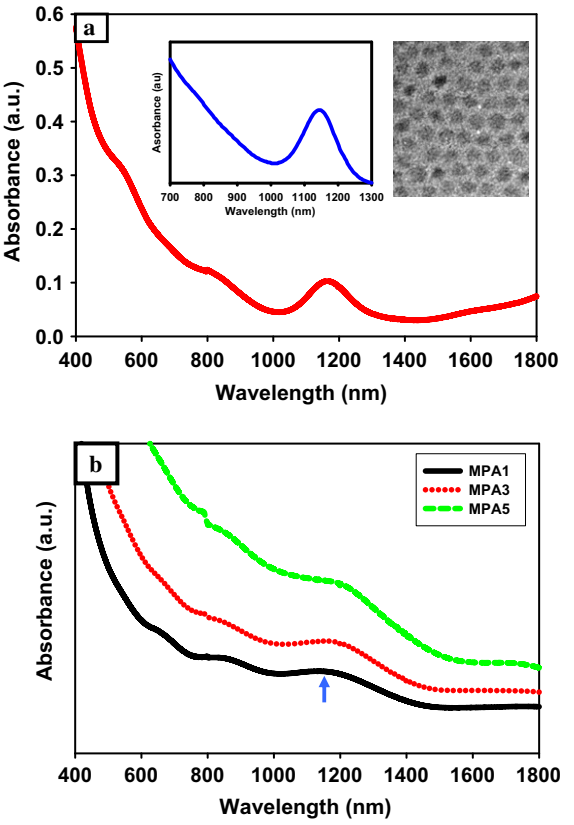

Fig. 1. Vis-NIR absorption spectra. (a) PbS CQD film deposited on a glass substrate; upper left inset: NIR absorption spectra of PbS CQDs in chloroform, upper right inset: TEM image, and (b) Vis-NIR absorption spectra of devices subjected to a different number of the dipping process.

In general, np-TiO_2 is used as a photoanode in dye-sensitized and hybrid solar cells because of its versatility, processability, high surface area, and easily controlled porosity. Further, it is very difficult to load a large amount of NIR PbS CQDs on a flat electrode material with low surface area. In addition, the single layer of CQDs on the electrode prevents rapid quenching of electron-hole recombination by a mutual interaction. To obtain a single layer of immobilized PbS CQDs on a np-TiO_2 surface, we treated the surface with a linker molecule, 3-mercaptopropionic acid (MPA). Scheme 1b shows a schematic diagram of the device structure used in this study. In a typical process, an approximately 50 nm-thick TiO_2 blocking layer is deposited on FTO (Fluorine doped Tin Oxide) glass (TEC15, USA) by the spray pyrolysis deposition (SPD) method using a 0.02 M solution of titanium diisopropoxide bis(acetylacetonate) so as to prevent direct contact between FTO and the hole-transport layer (HTL). Then, using a home-made TiO_2 (Degussa P25) paste, a 700 nm-thick np-TiO_2 layer is screen-printed on the blocking layer and sintered at 500 °C for 30 min. The surface of the np-TiO_2 layer is treated with MPA and the substrate is then dipped into a solution of PbS CQDs for 1 min, followed by washing in ethanol to remove the unattached PbS CQDs; this substrate is denoted "MPA1", where the number "1" shows that the substrate was dipped once for 1 min. Higher loadings are obtained by repeating the dipping process three and five times; the corresponding substrates are denoted "MPA3" and "MPA5", respectively. Next, following a recently published procedure [14], the PbS CQDs loaded np-TiO_2 layer is spin-coated with a 0.17 M solution of Spiro-OMeTAD dissolved in chlorobenzene containing ionic dopants lithium bis(trifluoromethylsulfonyl)imide salt (Li-TFSI) and tris(p-bromopheny)ammoniumyl hexachloroantimonate (N[p-C_6H_4Br)3$SbCl_6$). Finally, a 50 nm-thick gold electrode is deposited by thermal evaporation in a high vacuum. The device parameters such as current density are known to strongly depend on the sensitizer concentration. Hence, we ensure that more PbS CQD sensitizer is loaded onto the np-TiO_2 layer by increasing the number of repetitive dipping process. Further, oleic-acid-capped PbS CQDs were prepared by a hot colloidal synthetic method [15] and dispersed in hexane/*i*-propanol (1:0.8 v/v).

Fig. 1 shows the Vis-NIR absorption spectra of a pristine PbS CQDs film deposited on glass (Fig. 1a) and np-TiO_2 layers loaded with PbS CQDs by repeated dipping (Fig. 1b). The absorption peak of the pristine PbS CQD film appears distinctly at 1150 nm, as shown in Fig. 1a. The unchanged absorption peak position of the PbS CQDs loaded onto np-TiO_2 (Fig. 2b) indicates that these CQDs are physically spaced apart inside the matrix. The left inset in Fig. 1a also shows the characteristic absorption spectrum of PbS CQDs in chloroform. It is well known that the absorption peak position of PbS CQDs strongly depends on their size due to a strong quantum confinement effect [16]. The peak at 1180 nm corresponds to 4.5 nm-diameter PbS CQDs in

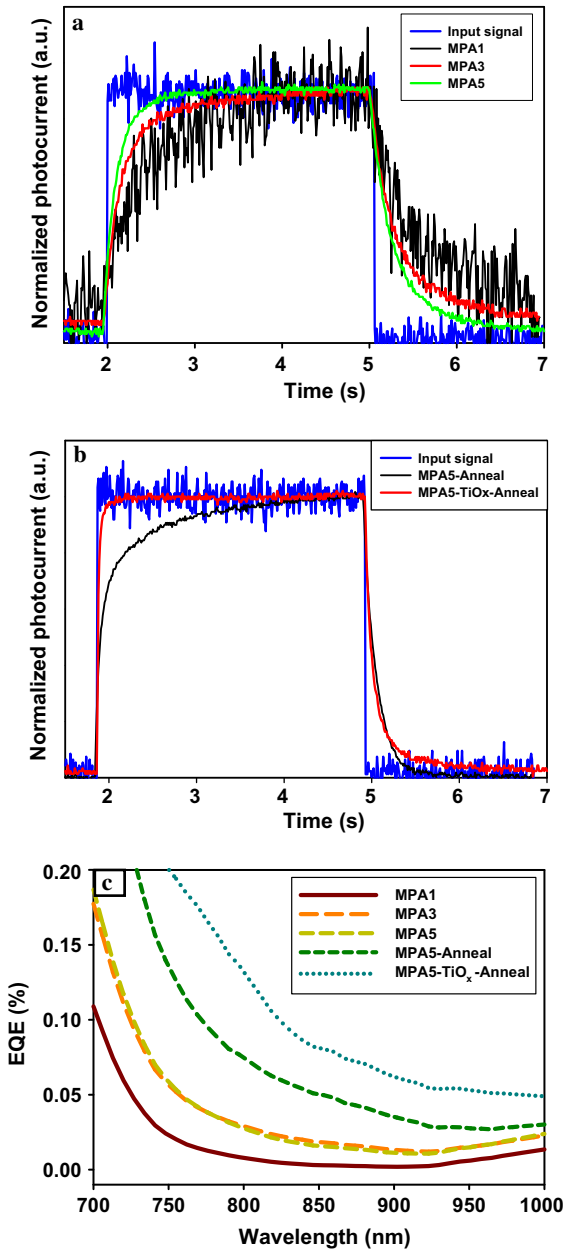

Fig. 2. Transient response time under illumination by 980 nm laser (power: 116 mW, modulation: 0.2 Hz). (a) Effect of the number of times the dipping process is repeated. (b) Effect of thermal annealing and TiO_x surface treatment/thermal annealing. (c) EQE in the NIR region.

the present case. The transmission electron micrograph (TEM) image (inset in Fig. 1a) also confirms the size, ~4.5 nm, and monodispersity of PbS CQDs. Under the consideration of the energy-level alignment between the LUMO (lowest unoccupied molecular orbital) of PbS CQDs synthesized by us and the conduction band of TiO_2 [16], we would expect efficient electron injection from the CQDs into the np-TiO_2 layer. Fig. 1b shows the Vis-NIR absorption spectra of MPA1, MPA3, and MPA5 np-TiO_2 substrates loaded with PbS CQDs. All absorption spectra were calibrated using an np-TiO_2 film without PbS CQDs so that PbS CQDs peaks could be obtained without any interference from the underlying np-TiO_2 layer. In this figure, the monotonic increase of the absorbance from MPA1 to MPA3 indicates an increase in the amount of PbS CQDs loaded into the pores of the np-TiO_2 layer. When the dipping process was repeated up to five times, the absorption steadily increased with the number of PbS CQDs adsorbed on the np-TiO_2 surface. However, further repetition of the dipping process could not result in any additional increase in the absorption peak; this indicates that no further increase was obtained in the amount of PbS CQDs adsorbed on the np-TiO_2 surface by repeating the dipping process for more than five times.

Fig. 2 shows the transient response time of the devices that were fabricated by repeating the dipping process for a different number of times; the transient response was obtained under illumination of 980 nm laser (power: 116 mW, modulation: 0.2 Hz). The transient response time was measured using a home-designed system consisting a 980 nm laser diode (Axcel AX-040: 116 mW), a modulator (Neos AOBD), a function generator (Tektronix CFG250), a photodiode (Newfocus), an oscilloscope (Yokogawa DL1702) and a multimeter (Keithley 2002). Both the rise and decay response times are very important because slow transient response time during either rise or decay determines the quality of a photodetector. In the present study, the rise-saturation time is shortened from ~2 s (for MPA1) to ~0.7 s (for MPA5) due to an increase in the number of generated charge carriers, as shown in Fig. 2a [17]. The long saturation time implies the existence of deep surface traps in np-TiO_2 and PbS CQD layers. Deep surface traps are filled preferentially by the generated charge carriers so that the rate of trap filling becomes faster as the number of charge carries increases [17]. From the external quantum efficiency (EQE) and photocurrent at 980 nm, it is confirmed that the number of charge carriers increased from device MPA1 to MPA5, as shown in Table 1. The EQE was also measured using a fully computerized home-designed system comprising a light source (300 W Xe lamp, Newport, 66902) with a monochromator (Newport cornerstone 260) and a multimeter (Keithley 2002). The slight difference in the EQE values for the photocurrent at 980 nm may be due to the different power levels of the EQE (0.1 mW) and the transient response equipment (116 mW) at 980 nm. We believe that the oleic-acid-capped PbS CQDs are almost insulating, and hence, the serial resistances of the devices pertaining to the loaded oleic-acid-capped PbS CQDs may increase with the number of times the dipping process is repeated [11,12]. Thus, the insulating layer of oleic-acid-capped PbS CQDs may hinder the transport of generated charge, increasing the decay time. The heat treatment of the MPA5 device at 110 °C for 1 min under ambient condition before spin-coating of spiro-OMeTAD increases the interfacial contact at the np-TiO_2/PbS CQDs layer; consequently, an increase in the EQE and the photocurrent of the device from 10 to 35 μA and 0.02% to 0.03% are observed as shown in Fig. 2c and Table 1, respectively. The slight decrease in the device resistance implies that the interfacial contact between np-TiO_2 and PbS CQDs is improved by annealing. Moreover, the transient decay time significantly shortened

Table 1
List of device characteristics.

Sample	MPA1	MPA3	MPA5	MPA5-anneal	MPA5–TiO_x-anneal
Cell resistance (MΩ)[a]	0.65	0.7	1	0.9	0.95
Photocurrent (μA)[b]	1	7.5	10	35	60

[b] Under illumination of 980 nm laser (116 mW/cm^2).

when the rise-saturation time is increased. The shortened decay time seems to occur by efficient extraction of charge carriers from PbS CQDs, and the increased photocurrent results from improved interfacial contact. However, the net response time of the device is diminished owing to the retardation of the rise-saturation time over 2 s. During the process of annealing, the retardation of rise-saturation time may be attributed to the formation of extra traps caused by oxidation of PbS CQDs [18]. The formation and filling of surface traps can produce the asymmetric rise and decay transient response [17]. Further annealing at 110 °C after spin-coating of spiro-OMeTAD results in low efficiency. Apart from this, the introduction of a TiO_x interlayer between np-TiO_2/PbS CQDs and spiro-OMeTAD prevents and/or reduces the unwanted oxidation of PbS CQDs and also promotes the transportation of charge carries. In order to introduce a TiO_x interlayer, a methanolic solution of partially hydrolyzed titanium(IV) tetra-isopropoxide (10 mM) (Aldrich) was spin-casted on the np-TiO_2/PbS CQD layer and annealed at 110 °C for 1 min. An increase in the EQE (from 0.03% to 0.05%) and the photocurrent (from 35 to 60 μA) was observed by the introduction of the TiO_x interlayer followed by heat treatment. The significant shorting of rise-saturation time (Fig. 2b) in this case may be due to the generation of more charge carriers and/or decrease in the number of surface traps in the device.

In summary, a photovoltaic effect from the cell structure of np-TiO_2/PbS CQDs/spiro-OMeTAD is investigated in the NIR region. Oleic-acid-capped PbS CQDs were incorporated into np-TiO_2 with the help of a linker molecule (MPA). The amounts of PbS CQDs loaded into np-TiO_2 layer not only increase of EQE but also reduce the response time at NIR region. Further, the thermal annealing improves the interfacial contact between the np-TiO_2 layer and PbS CQDs, and hence, an increase in EQE and a shortening of the transient decay time are observed in an annealed system. However, the net response time is deteriorated by prolonged rise-saturation time due to the oxidation of PbS CQDs. Further, the insertion of a TiO_x interlayer followed by thermal annealing led to a further increase in the efficiency and reduction in the response time of the device system as the interlayer provides a pathway for easy transport of electrons and simultaneously decreases the oxidation of PbS CQDs. Further research is going on to improve and optimize the performance of the structure so that it can be used as an NIR photodetector.

ABSTRACT

We incorporated an additional *p*-type organic semiconductor layer (APL) between the anode and the phthalocyanine layer, which is an indispensable *p*-type semiconductor layer (IPL) in forming a *p*/*n* junction with a fullerene C_{60} layer. We used two thiophene/phenylene co-oligomers as the APL. The incorporation increases the short-circuit current density (J_{SC}) and enhances incident photon–current conversion efficiency (IPCE) over the wavelength region where the APL shows strong absorption. Combined dependence of the APL/IPL implies that Förster resonance excitation transfer is the main factor in J_{SC} and IPCE enhancements. We demonstrate clearly that the 'positive' hole injection barrier at the interface between the APL and the IPL impacts the smooth transportation of holes to the indium-tin-oxide anode. However, the small positive hole barrier of 0.1 eV has no noticeable influence on the fill factor of the current density versus voltage characteristic under photoirradiation, or on those devices with 'negative' hole barriers.

Organic photovoltaic (PV) cells have received a lot of attention because of their potential use in applications, such as in flexible solar cells, and the low-cost production of those applications [1]. The power conversion efficiency (PCE) of organic PV cells has been increasing [2–9], but further enhancements are required before being utilized in practical applications. To enhance the PCE, researchers must first increase the intensity of light absorption as well as broaden the available spectrum. In this context, tandem-stacking organic PV cells [7,10,11] is one viable option, because we can basically use four different organic semiconductors (two *p*-type and two *n*-type) in a tandem device, and each material would cover its own specific absorption spectrum [7,11]. However, in the case of tandem devices, performance matching between each cell is very important. For example, in the case of series-connected tandem PV cells, while the open-circuit voltage (V_{OC}) is the summation of each individual V_{OC}, the short-circuit current (J_{SC}) should be limited to the lowest J_{SC} in each cell [7]. Although balancing each cell is the key, matching the performance of each cell in the best state will be difficult. Here, we will demonstrate another method by which we can use three or more organic semiconducting materials, and in which all the materials contribute to light absorption and to the generation of charge carriers.

We introduced an additional *p*-type organic semiconductor layer (APL) into organic PV cells that have a single *p*/*n* junction. In this sense, the devices are not tandem, as shown in Fig. 1(a). The APL was located between an electrode and an indispensable *p*-type layer (IPL), which was directly connected to an *n*-type layer (NL). By tuning the energy difference between the bandgap energies of both *p*-type materials, an APL bandgap larger than that of the IPL could be achieved, and the APL exciton produced by optical absorption could be transferred to the IPL, resulting in the creation of additional IPL excitons. Essentially, there is no distinguishable difference between the two types of

IPL excitons produced by direct optical excitation and transfer, and consequently, the IPL exciton created by exciton transfer should also separate into charge carriers at the *p*/*n* junction in the same way. In short, by achieving interlayer excitation energy transfer between the APL and the IPL, PV cells can be sensitized by utilizing the light absorbed by the APL.

In relation to this work, Hidel et al. have reported the sensitization of organic PV cells by incorporating an 'antenna' layer [12]. The antenna layer was positioned externally between the cathode and the anode, and was coupled with an organic PV component based on energy transfer via surface plasmon polaritons (SPPs) through a thin Ag cathode. While the 15–20-nm thick Ag cathode successfully increased the quantum efficiency of energy transfer from the antenna, such a thin metal electrode leads to undesirable higher series resistances. The device proposed in the present study used an APL placed internally between the anode and the cathode as an antenna; it therefore requires no thin electrode with high resistivity. In addition, the SPP-based antenna required high photoluminescence (PL) efficiency [12], whereas the APL does not require high light emissivity. This is essentially because excitation transfer from the APL to the IPL is based on a common form of non-radiative excitation energy transfer, such as Förster resonance excitation transfer (FRET) and Dexter electron exchange excitation transfer [13,14].

Fig. 1(b) shows the schematic device structure employed in the present study, and Fig. 1(c) shows the chemical structures of the materials used. We used BP3T or P6T as the APL materials, and metallophthalocyanines (MPc; *M* = Cu, Zn, and Sn) as the IPL materials. APL materials should possess good hole-transporting ability, and (thiophene/phenylene) co-oligomers such as BP3T and P6T have been reported as having this ability [15–18]. The chemicals BP3T and P6T (Institute Research and Innovation), ZnPc and SnPc (Aldrich) and BCP (TCI) were purified by temperature-gradient train sublimation with Ar gas flow before use. We used C_{60}, purchased from Frontier Carbon (nanom purple SUH grade) and CuPc (for the organic light-emitting device) donated by Nippon Steel Chemicals, without further purification. We prepared the devices by depositing several materials sequentially onto commercially available indium-tin-oxide (ITO) coated glass substrates, which had sheet resistance of 15 Ω/square. To begin with, the substrates were washed with detergent water, pure water, and 2-propanol under ultrasonification and treated with O_2 plasma at a power of 50 W for 5 min. We prepared a poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) layer on the substrates by spin-coating a commercially available formula (H.C. Starck, Clevios P Al 4083). We deposited several organic layers by thermal evaporation under vacuum (2.0×10^{-4} Pa) at a rate of 1 Å/s. Finally, the aluminium electrode was prepared on top of the organic layer stack by thermal evaporation in vacuum at a rate of 10 Å/s. Active areas of the cells were about 6 mm^2. We transferred the produced devices into a highly inert glove box (O_2 concentration 5 ppm; dew point < −50 °C) with no exposure to ambient conditions, and then mounted them in a small chamber, which had a quartz window, in the glove box. A source meter (Keithley 2410) measured their current density versus voltage (*J*–*V*) curves both with and without 100-mW/cm^2 artificial solar light irradiation of airmass 1.5 global (AM1.5G) from a Newport Oriel solar simulator (Model 91160) with an AM1.5G filter (Newport Oriel 81088) and a light-intensity stabilizer (Newport Oriel, Model 68945). The power density of irradiation was measured with a pyroelectric optical power meter (Ophir P3). We recorded the incident photon–current conversion efficiency (IPCE) spectra of the devices

with a digital multimeter (Advantest AD7461A) at zero bias, under monochromatic light irradiation from a light source (Bunko Keiki SM-25A); the intensity of the monochromatic light for each wavelength was measured with a calibrated silicon photodiode (Hamamatsu Photonics S1337-1010BQ). Surface morphologies of thin films were evaluated with a scanning probe microscope (Veeco, Dimension ICON) in tapping mode. Note that in this study we employed relatively thinner layers of MPc and C_{60} compared to other studies of organic PVs with MPc and/or C_{60}, because we aimed to determine exactly how the interlayer excitation energy transfer influences organic photovoltaic devices.

Fig. 2 shows the *J–V* curve of the BP3T/CuPc/C_{60} device that had a BP3T layer as the APL. The figure also shows the curve of another PV cell (CuPc/C_{60}) with no APL layer, as a reference. In the case of this control, we simply omitted the BP3T and the thicknesses of the other layers remained the same. As shown in the figure, placing the BP3T layer in front of the CuPc layer mainly enhanced J_{SC} but not V_{OC}. The PCE of the BP3T/CuPc/C_{60} device was 0.63%, much lower than that reported for CuPc/C_{60} planar junction-based PV cells [19], because we used thinner CuPc and C_{60} layers to evaluate the effectiveness of the APL. Fig. 3 shows the IPCE spectra of the two devices. The IPCE increases in the shorter wavelength region where BP3T has strong absorption, as shown in the inset of the figure. This result suggests that the BP3T exciton produced by optical absorption is transferred to the CuPc layer and that the CuPc exciton created by the transfer was converted to charge carriers at the interface of CuPc/C_{60}. It is possible that the sensitization resulted from a direct contact between BP3T and C_{60}, through defects in the CuPc layer because of the thinness of the layer; we will discuss this point later. Note that another increase occurs around 600 nm, which may not have been caused by the transfer. We are not sure why this other increase occurred, but we believe that the BP3T layer can prevent the CuPc exciton, produced by optical absorption, from quenching by the PEDOT:PSS layer.

Fig. 4 shows the IPCE spectrum of another cell using BP3T, in which we replaced CuPc with SnPc as the IPL (device structure abbreviated as BP3T/SnPc/C_{60}). We observed

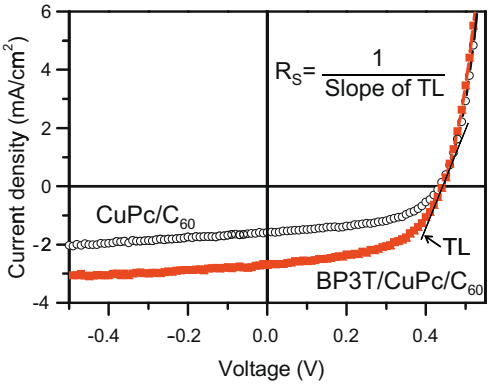

Fig. 2. *J–V* curves of PV cells with or without BP3T as the APL under 1 sun irradiation. TL: tangential line at V_{OC}.

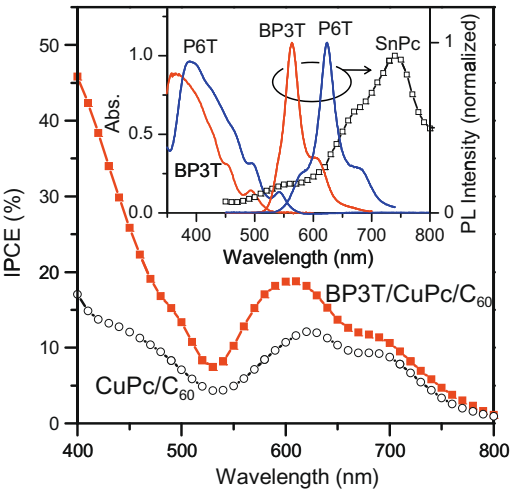

Fig. 3. IPCE spectra of PV cells with and without BP3T as the APL. Inset: absorption spectra of thin films of BP3T, P6T, and SnPc, and PL spectra of BP3T and P6T thin films. Thin films were deposited on quartz plates by thermal evaporation.

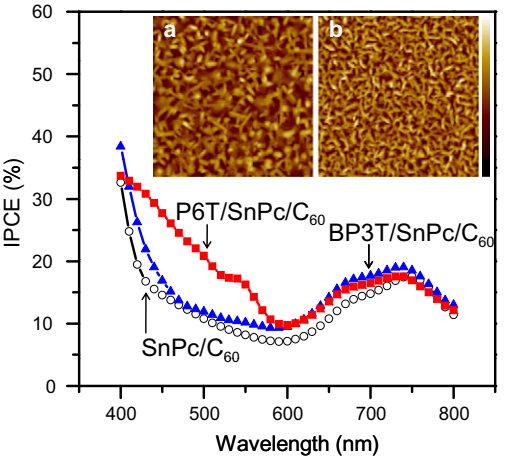

Fig. 4. IPCE spectra of SnPc-based PV cells incorporating BP3T (blue solid triangles), P6T (red solid squares) as the APLs, and a control cell (black open circles). The inset shows the surface morphologies of 40-nm thick BP3T (a) and P6T (b) layers deposited on a 40-nm thick PEDOT:PSS layer. The field size of both images are the same (1 μm × 1 μm) and the colour bar next to image (b) is the height scale: full scales of the bar for (a) and (b) are 58.5 nm and 48.7 nm, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

no noticeable enhancement of IPCE due to light absorption by BP3T as compared to its reference device that contained no BP3T layer (SnPc/C_{60}). These devices include two heterojunctions: one is IPL/C_{60} and the other is APL/IPL. It would be believed that charge separation occurred in the case of the APL excitons at the APL/IPL interfaces possibly because the lowest unoccupied molecular orbital (LUMO) levels of BP3T and P6T are higher than those of the phthalocyanine (Pc) derivatives used [20]. If the sensitization by the APL occurred because of charge separation at the APL/IPL interface, the negative LUMO level of SnPc more than

CuPc should lead to more efficient charge separation in the case of the Marcus normal region [21]. However, no noticeable enhancement of IPCE due to BP3T occurred for the BP3T/SnPc device, as shown in Fig. 4. Consequently, the sensitization mechanism by the APL differs from the double exciton dissociation at both sides of a Pc layer reported by Sista et al. [22] and Zhang et al. [23]. There could essentially be a difficulty with this double exciton-dissociation in that the layer, both sides of which would contribute to exciton dissociations, would need to have sufficient charge carrier mobilities for both electron and hole.

On the other hand, a remarkable enhancement appeared from 400 to 550 nm in the case of the device with the P6T/SnPc/C_{60} structure. As shown in the inset of Fig. 4, the surfaces of both the BP3T and P6T layers were slightly rough as a result of the high crystalline nature of these materials, and the root-mean-square roughness (RMS) of the layers, each 40-nm thick, was 8.1 nm for BP3T and 7.6 nm for P6T. It is possible that these rough surfaces induce a fairly direct contact between the APL and C_{60}, through defects in the 10-nm thick IPL. However, no IPCE enhancement in the BP3T/SnPc/C_{60} system and the remarkable IPCE improvements in both BP3T/CuPc/C_{60} and P6T/SnPc/C_{60} systems, greatly refute that the APL mainly touches the C_{60} layer directly and causes the sensitizations when introducing the APLs.

The sensitized spectral region of the P6T/SnPc/C_{60} device increased in wavelength as compared to the BP3T/CuPc/C_{60} device, as shown in Figs. 3 and 4. This change occurred because P6T shows absorption in a larger wavelength region than BP3T, as shown in the inset of Fig. 3. Furthermore, P6T displays photoluminescence (PL) in a longer wavelength region than BP3T, and SnPc preferentially absorbs longer wavelength light than CuPc. Consequently, the overlap integral becomes large in the case of combined P6T and SnPc, where the overlap integral indicates a spectral overlap between the photoluminescence of an excitation energy donor and the absorption of an excitation energy acceptor. In addition, we observed clear sensitization due to P6T as the APL in the case of the P6T/CuPc/C_{60} cells, where there was a sufficient spectral overlap between the PL of P6T and the optical absorption of CuPc. From these results, we believe that it was probably the following scheme that increased IPCE: the BP3T or P6T layer in front of the Pc derivative layer absorbed the corresponding light, resulting in the formation of its exciton; the exciton was transferred to the back Pc derivative layer; and finally, the Pc exciton separated both the charge carriers at the Pc–C_{60} interface. The abovementioned spectral overlap dependence suggests that the mechanism of excitation transfer from front layer to back layer may be FRET. We are planning further studies to shed light on the mechanism of excitation transfer occurring in the cells; its quantum efficiency, including the determination of Förster radii between those thiophene derivatives and the phthalocyanines; and the intrinsic exciton diffusion lengths of those thiophenes.

It is worth noting that, while finalizing the present manuscript, Hong et al. reported an organic PV device with a pentacene/ZnPc/C_{60} multi-heterojunction [24]. The concept described in that literature is very similar to that in the present study, and they utilized pentacene as a sensitizer for a ZnPc/C_{60} heterojunction. They concluded that endothermic triplet energy transfer occurred between pentacene and ZnPc. Although both singlet and triplet energy transfers have the potential to sensitize by means of excitation transfer, what multiplicity of exciton is more advantageous in this sensitization needs to be discussed in the next stages of research. This is because a compromise between exciton lifetime and the reachable range of excitation transfer for the two types of excitons – singlet and triplet should be considered. In any case, an increase in both J_{SC} and IPCE, and moreover, an unchanged V_{OC} have been clearly observed in the present study as a result of singlet-exciton transfer between APL and IPL as discussed above.

Finally, we discuss the case where the hole generated at the p/n (Pc/C_{60}) junction is required to pass over the additional IPL–APL interface. Depending on the combination of materials, there is a hole injection barrier at the interface, and then the barrier probably affects hole transportation from the p/n junction to the electrode. We estimated the series resistance of a device from the inverse of the slope of the tangential line (TL) of the J–V curve at V_{OC}, as shown in Fig. 2. Fig. 5 summarizes the resistances of six devices with an APL, where the injection barrier of holes (ΔE_H) is defined as the energy difference between the highest occupied molecular orbital (HOMO) levels of the APL and the IPL [20]. Negative ΔE_H means that the hole is injected endothermically from the IPL to the APL. The resistance decreases gradually with decreasing ΔE_H, but increases rapidly when ΔE_H is positive. However, the fill factors (FF) of all the cells prepared are about 0.5 whether with or without the APL. In short, normalized FF for each device with the APL is almost 1 as shown in Fig. 5, where the normalized FF is defined as the ratio of FFs between PV cells using a certain Pc with and without each APL. This means that neither the large exothermic hole injection at the P6T/SnPc interface nor the small 'positive' hole injection barrier of

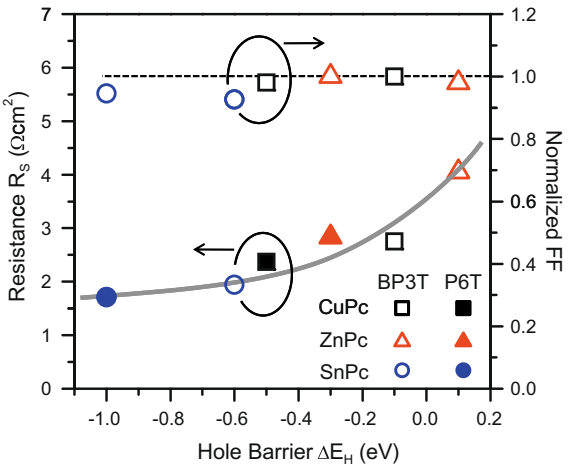

Fig. 5. Hole injection barrier ΔE_H dependence of R_S and normalized FF (see text) of all the devices with APLs obtained under photoirradiation. The thick grey line is a guide for the eye. ΔE_H was calculated from the difference in HOMO levels between the APL and the IPL for each cell.

0.1 eV at the BP3T/ZnPc interface influenced the charge collection through the APL/IPL interface. Furthermore, as one can see from the fairly good FFs of the cells, the entire devices show clear rectifying characteristics whether with or without APLs. Consequently, this concept would probably work well when we adjust the difference of the bandgaps of both the APL and the IPL and align their HOMO levels, appropriately.

In conclusion, we have demonstrated the sensitization of organic PV cells with a single *p*/*n* junction-based on interlayer excitation energy transfer. We incorporated an additional *p*-type semiconducting organic material layer (APL) between the PEDOT:PSS layer and a Pc layer, indispensable *p*-type semiconductor layer (IPL), to form a *p*/*n* junction with the C_{60} layer for generating charge carriers from excitons. Incorporating the APL led to sensitization of the IPCE, and the sensitized wavelength regions changed depending on the absorption spectra of the APL. The combination dependence of APL/IPL suggests that IPCE enhancements mainly result from Förster resonance excitation transfer (FRET). We demonstrated clearly that the 'positive' hole injection barrier at the APL–IPL interface has an impact on the smooth transportation of holes to the anode (indium-tin-oxide). The PV cells demonstrated here showed an insufficient PCE of below 1%, but we believe that this approach will lead to further improvements in the PCE of organic PV cells in the future. We are now working to incorporate more APLs for more efficient light collection with cascading excitation transfer toward the IPL.

ITO deposition, MoO_3 contributes to hole extraction and the suppression of electron leakage [9]. The effects of varying the MoO_3 layer thickness and cathode materials are also investigated.

To prepare both conventional and inverted devices shown schematically in Fig. 1, bare and ITO-coated glass substrates were cleaned by a standard solvent regimen followed by UV-ozone treatment [10]. Materials were deposited at a rate of 2 Å/s for metals, and 1 Å/s for purified organics and MoO_3 in a high-vacuum (base pressure < 4×10^{-7} Torr) thermal evaporation chamber. Prior to the deposition of the top contact, samples were transferred to a high purity N_2 ambient (<1 ppm H_2O and O_2) where a shadow mask defining arrays of 1-mm diameter circular openings was attached. The top ITO contact was sputter-deposited at a power of 40 W (0.2 Å/s) and a pressure of 2 mTorr using Ar plasma [11]. All deposition rates and thicknesses were measured by quartz crystal monitors and checked by variable-angle spectroscopic ellipsometry. Device performance was measured in air using a semiconductor parameter analyzer in the dark and under illumination from a 150 W Xe lamp with AM1.5G filters using standard procedures [12]. Lamp intensity was varied with neutral density filters and measured by an NREL-calibrated Si photodiode. A transfer-matrix formalism was used to simulate the optical field and absorption, and to predict the short-circuit current (J_{SC}) of the devices [1]. The absorption spectra of the materials were measured using a Lambda 1050 UV/Vis/NIR spectrophotometer.

Previously, conventional planar small-molecule OPVs lacking a BCP blocking layer have exhibited greatly reduced efficiency [13,14]; however, we find that SubPc/C_{60} devices with Al cathodes can achieve similar performance without BCP, yet is sensitive to the C_{60} layer thickness. The comparable performance is achieved when C_{60} is thick enough to prevent the excitons generated within a diffusion length of the donor–acceptor (DA) interface from migrating to the metal-C_{60} interface where they quench, yet is not too thick to negatively impact performance by increasing resistance or placing the peak optical absorption far from the DA interface. Under simulated, 1 sun AM1.5G illumination, the device with BCP (Device 1, Fig. 1) showed a responsivity ($R = J_{SC}/P_0$, where P_0 is the incident light intensity) of 0.048 ± 0.001 A/W, a fill factor FF = 0.63 ± 0.01, and V_{OC} = 1.10 ± 0.02 V, leading to a power conversion efficiency of η_P = 3.3 ± 0.1%, while the device without BCP (Device 2, Fig. 1) achieved η_P = 3.0 ± 0.2%, with R = 0.049 ± 0.001 A/W, FF = 0.61 ± 0.03 and V_{OC} = 1.01 ± 0.02 V.

To prevent damage to the donor during ITO deposition, a MoO_3 buffer layer was inserted into the following inverted structure: glass/Al 1000 Å/C_{60} 500 Å/SubPc 90 Å/MoO_3 100 Å/ITO 400 Å (Device 3 in Fig. 1). This device showed η_P = 0.86 ± 0.08%, with R = 0.032 ± 0.002 A/W, FF = 0.48 ± 0.01 and V_{OC} = 0.56 ± 0.02 V under 1 sun, AM1.5G illumination. For the inverted device, the ideality factor n = 2.0 ± 0.1, series resistance R_{SA} = 4.9 ± 0.1 Ω cm [2], and reverse saturation current density, $J_S = (2 \pm 1) \times 10^{-5}$ mA/cm^2, were obtained by fitting the dark current–voltage (J_D–V) characteristics with the modified Shockley equation [15].

The low V_{OC} of the inverted device is attributed to the lower work function of sputtered ITO (4.03 eV) as compared to commercially-deposited and UV-Ozone-treated ITO (4.7 eV) used in the conventional cell [11]. This decreases the built-in electric field (E_{bi}) from 1.2×10^7 V/m to 6.8×10^6 V/m for an ITO or sputtered ITO anode, respectively. Accumulated charge at the interface can result in an S-shaped J–V characteristic [16], which is not observed here. Therefore in calculating the electric field, we assume that all free carriers are depleted from the active region, and hence the field is uniform throughout the device. Without a sufficient E_{bi}, the charge separated pair that forms at the donor–acceptor interface on exciton dissociation is likely to recombine, leading to reduced J_{SC} and V_{OC}. This is also reflected by the increase in the ideality factor from 1.89 ± 0.06 for the conventional cell, to 2.0 ± 0.1 for the inverted cell, indicating a larger recombination current. The decreased fill factor is primarily due to the higher series resistance of the device, a result of the higher contact

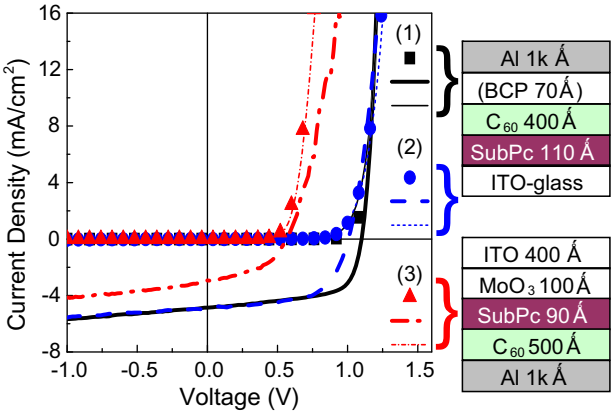

Fig. 1. Current density *vs*. voltage characteristics of conventional and inverted solar cells with the structure (1) indium tin oxide (ITO)-coated glass/SubPc 110 Å/C_{60} 400 Å/BCP 70 Å/Al 1000 Å in the dark (squares) and under 1 sun, AM1.5G simulated illumination (solid line); (2) ITO-coated glass/SubPc 110 Å/C_{60} 400 Å/Al 1000 Å in the dark (circles) and under 1 sun, AM1.5G simulated illumination (dashed line); and (3) glass/Al 1000 Å/C_{60} 500 Å/SubPc 90 Å/MoO_3 100 Å/ITO 400 Å in the dark (triangles) and under 1 sun, AM1.5G simulated illumination (dash-dotted line). resistance of the C_{60}/Al interface compared to that of an Al/C_{60} interface.

To increase V_{OC}, a series of inverted devices was fabricated with varied MoO_3 layer thicknesses (t) from 100 Å to 700 Å, while using a low work function, 5 vol% Mg:Ag cathode. It was found that V_{OC} increases from 0.78 ± 0.02 V to 1.02 ± 0.02 V when t changes from 100 Å to 300 Å, and saturates for thicker MoO_3 films, as shown in Fig. 2(a). Consistent with optical simulations, the responsivity peaks at t = 300 Å, yielding η_P = 2.4 ± 0.2%, as shown in Fig. 2(b).

The measured absorption of MoO_3 films on quartz substrates is shown in Fig. 3. The absorption edge corresponds to the MoO_3 band gap [17] (E_g). It is found to increase by 0.43 eV as t increases from 100 Å to 300 Å, and saturates thereafter. The absorption edge is also influenced by optical interference. After subtracting this effect, the increase in E_g is approximately 0.3 eV over this range of thicknesses. It has been found previously that the work function of MoO_3 (Φ_{MoO_3}) increases logarithmically with the layer thickness [18]. The energy shift improves device performance by: (1) creating a greater difference between the LUMO of MoO_3 and SubPc, thereby reducing the electron leakage current, and (2) promoting band bending in the highest occupied molecular orbitals (HOMO) of SubPc at the SubPc/MoO_3 interface.

The parallel resistance, R_P, and the photocurrent density, J_{ph}, are found at J = 0 using [19]:

$$V_{OC} = \frac{nkT}{q} \ln\left[\frac{J_{ph}(V_{OC})}{J_S} + 1 - \frac{V_{OC}}{R_P J_S}\right]$$

where q is the electron charge, k is the Boltzmann constant, and T is the absolute temperature. Typically [9] $J_{ph}/J_S >> 1$ and $V_{OC}/R_P << J_{ph}$ (V), and hence V_{OC} depends logarithmically on J_{ph}/J_S. By assuming a constant J_{ph} (V) = J_{SC}, the calculated V_{OC} matches the experimental data for conventional cells, but overestimates that of the inverted cells by 10% (see Table 1 and Fig. 2(a), dashed line). This is likely due to the reduction in J_{ph} with increasing voltage, deviating from the assumption of a constant J_{ph}.

As inferred from the energy level diagram of the MoO_3/SubPc interface in the inset of Fig. 3, the increase in Φ_{MoO_3} with thickness reduces the energy difference between the valence band maximum of MoO_3 and the HOMO of SubPc, consequently producing steeper band bending when these materials are brought into contact. This favors hole extraction from SubPc to the contact, reflected by the decrease in the ideality factor with MoO_3 thickness changing from 100 Å to 500 Å (see Table 1). When the MoO_3 thickness reaches 700 Å, however, the increase in device resistance becomes dominant and the ideality factor increases again. The combined effects of the reduced electron leakage and enhanced hole extraction due to the presence of MoO_3 results in a maximum V_{OC} = 1.02 ± 0.02 V, close to that of the conventional device.

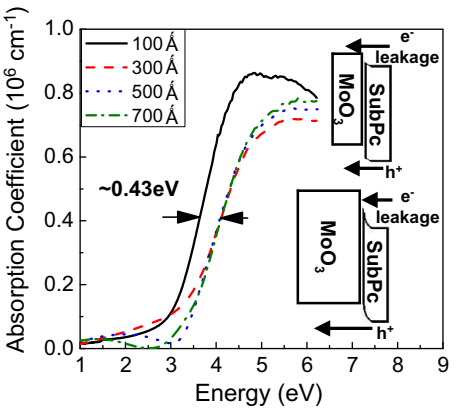

Fig. 3. Measured absorption spectra for 100 Å (solid lines), 300 Å (dashed lines), 500 Å (dash-dotted lines), 700 Å (short dashed lines) thick MoO_3 films on quartz substrates. *Inset*: Schematic band diagram of the MoO_3/SubPc interface for a MoO_3 thickness of t = 100 Å (upper) and 500 Å (lower).

Finally, the influence of the cathode work function (Φ_{Cat}) on performance was investigated, with results shown in Fig. 4. Values used for Φ_{Cat} are from Ref. [20]. Here, 1000 Å thick layers of Ag, Au, Al and Mg:Ag were used as cathodes, with MoO_3 t = 100 and 500 Å. For devices with t = 100 Å, V_{OC} increased significantly from 0.14 V to 0.91 V, while Φ_{Cat} decreased from 5.0 eV (Au) to 3.7 eV (Mg:Ag), as shown in Fig. 4(a). Different cathode optical

properties shift the optical field distribution, therefore changing the responsivity. The power conversion efficiency has a maximum at 2.23 ± 0.06% for Mg:Ag cathodes and t = 500 Å MoO_3 (see Fig. 4(b). The decrease in Φ_{Cat} results in an increased E_{bi} (from -1.9×10^7 V/m for Au to 1.2×10^7 V/m for Mg:Ag), leading to a higher V_{OC}. The built-in field for the Au-cathode devices is negative, giving rise to an increased electron leakage. Hence, the increase in t shows a much more dramatic impact on V_{OC} (from 0.91 V to 1.02 V for Mg:Ag and from 0.14 V to 0.7 V for Au). We conclude that to achieve a high-efficiency inverted cell, the electrodes must be chosen such that a sufficiently high E_{bi} is provided based on the energy levels of the photoactive layers and the contacts, and the electron leakage is effectively suppressed.

Note that there currently is disagreement as to the assignment of the energy levels of MoO_3. For example, there are reports that the conduction and valence band energies of MoO_3 are at E_C = 2.3 eV and E_V = 5.2–5.3 eV [21,22], while more recently, E_C = 6.7 eV and E_V = 9.7 eV [23] have been reported. Since photoelectron spectroscopy used to measure these energies is sensitive to factors such as surface conditions and the presence of inter-gap defect states, variations in source materials and sample preparation conditions may lead to this discrepancy. Previously [9], where the growth conditions were nearly identical as in this work, MoO_3 was used as an electron blocking layer in organic solar cells with transport properties similar to those from an organic (SubPc) blocking layer where its HOMO energy is 5.6 eV and its LUMO is at 3.6 eV. Therefore, we conclude that it is likely that the MoO_3 film reported here has E_C = 2.3 eV and E_V = 5.3 eV, consistent with earlier reports. This assignment is consistent with measurements made in our laboratory, and to be reported elsewhere.

In summary, 2.4 ± 0.2% power efficiency, inverted small molecule organic photovoltaic cells have been demonstrated. We have shown that an organic cathode buffer layer is not necessary in either conventional or inverted planar SubPc/C_{60} OPVs. The inverted device performance can be substantially improved by employing a compound MoO_3/ITO anode that suppresses electron leakage while maximizing the incident optical field intensity in the donor/acceptor interface region. The work function of layers adjacent to the donor or acceptor plays an important role in determining the V_{OC}.

periodic corrugation to the angular and spectral emissions [19]. These processes, however, require either very high pressure and temperature or vacuum process for the fabrication of the structure. It was also not very clear whether the enhancement is originated from the PC effect or from the reflection from the corrugated metallic mirror or from the combined effects.

In this study, we report on corrugated OLEDs fabricated on polymer based PCs to enhance the light extraction. The photonic crystals are fabricated using ultraviolet (UV)–NIL process at room-temperature and low-pressure, thereby it can be applied in large-area imprinting and in roll-to-roll fabrication process. Improvement of the efficiency in the corrugated OLEDs is achieved due to the coupling of the PC effect on the polymer, anode and organic layers and the Bragg-diffraction effect by the corrugated metallic mirror. The corrugated OLEDs with various PC heights are fabricated and evaluated. FDTD calculation is carried out to understand the contribution of the coupling to PC and the reflection from the corrugated metallic mirror to light extraction.

2. Experimental

Corrugated green emitting OLEDs were fabricated on PC substrates and compared with a reference planar OLED without a PC structure. The fabrication process is schematically represented in Fig. 1. PC patterns in silicon stamps were transferred to the polymer layer on glass substrates using UV–NIL. The silicon stamps were fabricated via DUV lithography and RIE. The lattice constant and diameter of the holes are 530 nm and 265 nm, respectively, and the depths of the holes are controlled by etching time to get 15 nm, 50 nm, 65 nm, 80 nm and 100 nm. The PC patterns in the stamps have hexagonal lattice structures as shown in Fig. 2(a). The holes produce polymer circular pillars on the glass substrates by UV–NIL. OLEDs were fabricated on the PC substrates by successively depositing a 300-nm-thick IZO layer by sputtering, 60-nm-thick 2TNATA (4,4′,4″-Tris(N-(2-naphthyl)-N-phenyl-amino)-triphenylamine) as a hole injection layer, 20-nm-thick NPB (N,N′-diphenyl-N,N′-bis(1,1′-biphenyl)-4,4′-diamine) as a hole transporting layer, 60-nm-thick Alq_3 (tris-(8-hydroxyquinoline)-aluminum) as an emitting and electron transporting layer and 100-nm-thick LiF/Al as a cathode by thermal evaporation under high vacuum ($\leqslant 10^{-7}$ torr), respectively. The current–voltage characteristics and the light-output power of the devices were measured using a Keithley 237 source measurement unit and a photodiode (Newport Model 818-UV) connected to an optical power meter (Newport Model 1835-C).

3. Results and discussion

Fig. 2 shows the cross-sectional images of the fabricated PC structure of a stamp (a) and corrugated OLEDs (b–f). The images were obtained using high-resolution (field emission) ion imaging with dual-beam focused-ion-beam (DB–FIB) microscope (NOVA200). The images show multi-layers consisting of the PC structures of the resin and the corrugated IZO, organic and aluminum layers. The OLEDs with pillar heights (corrugation depths) of 15 nm and 50 nm have perfectly conformal layers with the imprinted polymer pattern. On the other hand, the OLEDs fabricated on the PC substrates with the pillars higher than 65 nm (Fig. 2d–f) showed cracks in the IZO layer and voids at the interface between the IZO and the organic layers. Void formation leads to unstable current distribution, resulting in a considerable decrease in the light emitting efficiency. Deposition of organic layers on the cracked IZO layer leads to the formation of sharp edges in the crevices, leading to high leakage current as described later. Therefore these high PCs have larger electrical negative effect than optical advantage.

Fig. 3 displays the current–voltage (J–V) characteristics of the devices. The turn-on voltages of all the devices are

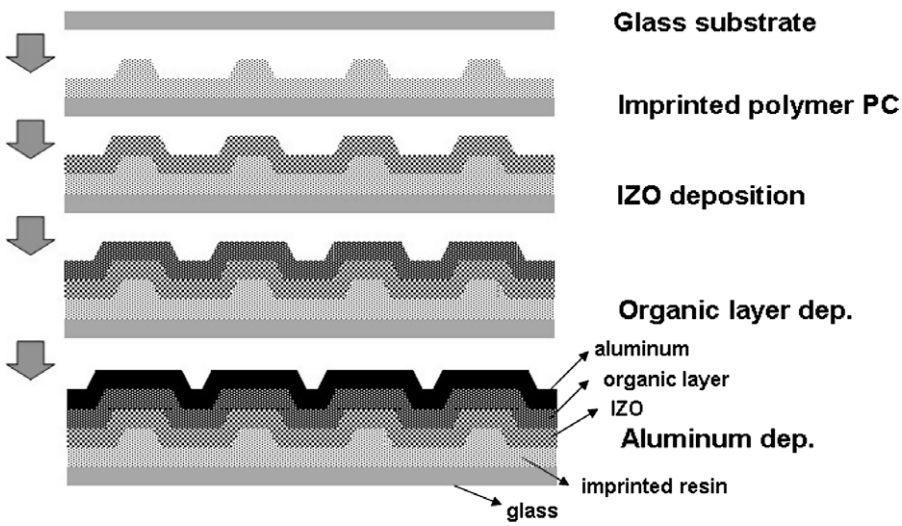

Fig. 1. Fabrication process of corrugated OLEDs.

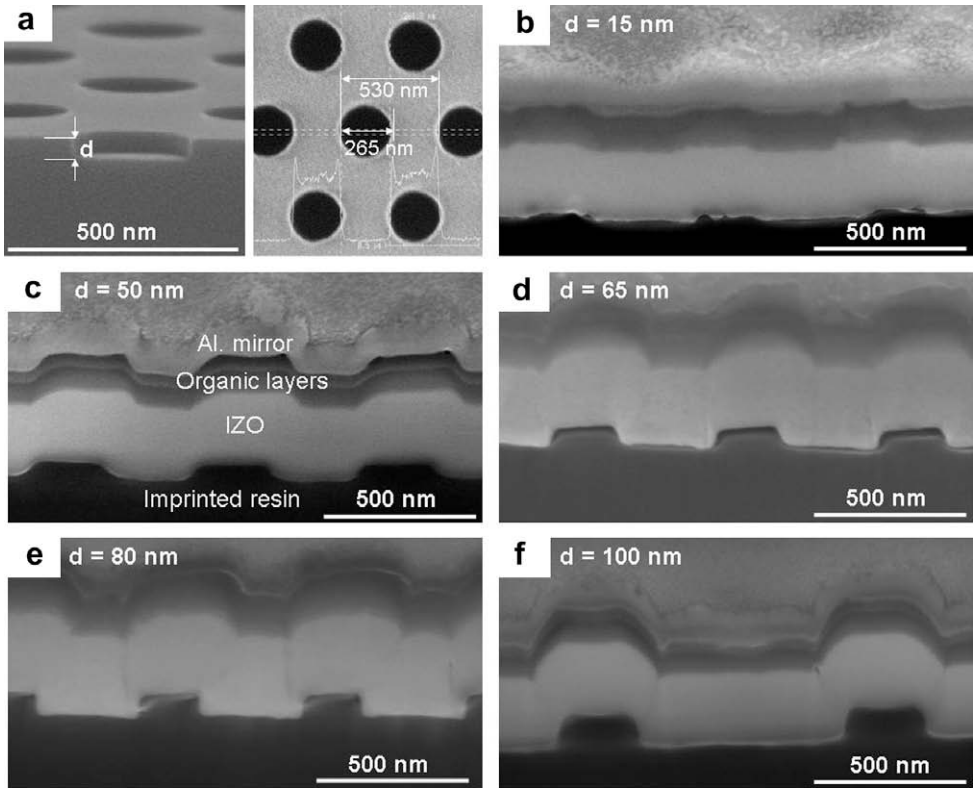

Fig. 2. SEM image of one of the stamps used in the UV–NIL process (a), and DB–FIB images of the cross-sections of fabricated corrugated OLED samples with (b) 15 nm corrugation depth, (c) 50 nm corrugation depth, (d) 65 nm corrugation depth, (e) 80 nm corrugation depth and (f) 100 nm corrugation depth.

approximately 3 V. It is interesting to note, however, that higher pillars in the PC substrate result in higher current densities at a same voltage, and it is consistent with previous reports [13]. This is another important advantage of corrugated OLEDs to reduce the operating voltage and to improve the power efficiency. This phenomenon can be explained by the increase of the interface area of the layers and by the enhancement of the electric-field intensity of the corrugated anode [14].

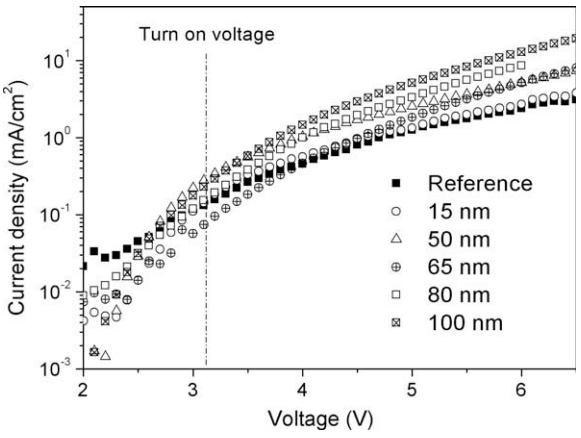

Fig. 3. Voltage–current characteristics of the corrugated OLEDs with different corrugation depths.

The electroluminescence (EL) intensities of the OLEDs were measured using an integrating sphere (Labsphere Co., 6″ in diameter). The devices were attached to a port on the integrating sphere where the glass side faced the inside of the integrating sphere. A 20 mm hole in diameter was used as the port to collect all the forward emitted light including the diffracted light, which is larger than the active area (3×3 mm^2) of the devices. All the devices including the reference OLED were characterized using the same system. Fig. 4 shows the efficiency enhancement with respect to the current density and the electrical input power density. Forty nine percentage enhancement of the light extraction with respect to the current density was obtained from the device having the corrugation depth of 50 nm. The improvement of the power efficiency is even higher. Remarkably high improvement of 93% was achieved with 50 nm pillars resulting from the decrease of the operating voltage as shown in Fig. 3. In our previous study, the improvement in the light extraction was 50% for SPC–OLED with a corrugation depth of 265 nm having identical lattice constant and diameter [15]. The improvement in the power efficiency was almost the same as the luminous (current) efficiency, as there was no reduction in the operating voltage because of the existence of a planarization layer below the ITO layer. The superior power efficiency and the simple fabrication method of the corrugated OLEDs demonstrate that they are practically more meaningful than the SPC–OLED. However, too high pillars resulted in uneven charge distribution and light emission

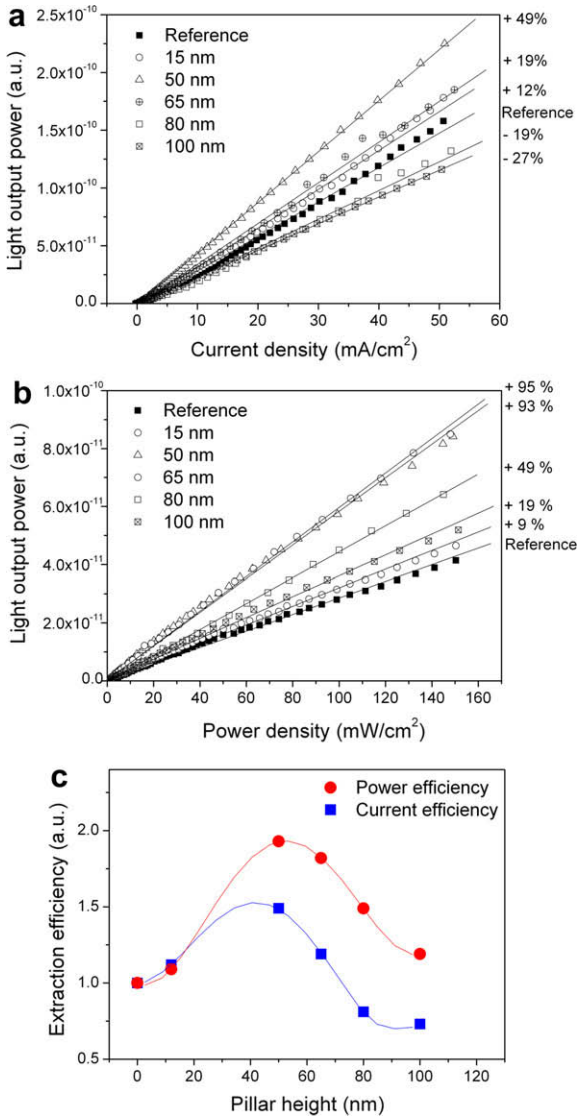

Fig. 4. (a) Light-output power versus current density, (b) light-output power versus electrical input power density and (c) the relative extraction efficiencies with respect to corrugation depth normalized to the OLEDs without pillars.

induced from the uneven electrode as shown in Fig. 5. The corrugated OLED fabricated on a 100 nm high PC structure is not able to emit light uniformly. This effect may also accelerate the degradation of the OLED.

The variation of emission spectrum and intensity with viewing angle were measured using a rotating stage and optical fiber at the current of 1 mA and are shown in Fig. 5(b–d).The reference OLED with planar substrate shows little change in the emission spectra and Lambertian pattern of emission intensity with viewing angle as expected. In contrast the OLED with the corrugation depth of 50 nm showed regularly fluctuated spectra and intensity with the angle [19]. Thereby the far-field radiation of the 50 nm corrugated OLED gets a profile similar to the shape of tulip as depicted in Fig. 5(d). The radiation profile of 10 nm-PC OLED is almost the same as the Lambertian emission, but the diffraction wings are getting more apparent as the pillar height increases. In this way, the intensity at the angle about 30° gets stronger and its shape becomes close to a butterfly wing which is consistent with our previous research [15].

Device lifetime can be a significant issue in corrugated OLEDs because of the possibility of non-uniform film thickness, electric field distribution and current. It is true for large corrugation depth of 100 nm as displayed in Fig. 5(a). Non-uniform distribution of emission intensities is apparent. In contrast, however, emission intensity of the OLED with the corrugation depth of 50 nm is uniform over the emission area. Moreover, the leakage current at low voltage is very low as displayed in Fig. 3. These facts imply that the film thickness and the current are rather uniform without significant concentrated electric field if the corrugation depth is less than certain value, which turns out to be 50 nm in this study. Further study on the effect of corrugation depth on the device stability is going on and will be reported later.

4. FDTD Analysis

In a corrugated OLED, as seen in Fig. 2, the corrugation depth of the PC layers and the metal grating can be considered as identical. However, as a future study, using certain planarization techniques, (such as sol–gel of high refractive index materials like TiO_2 or ZnO) according to the thickness of the coating layer and number of sol–gel steps a complete planarization can be attained as well as a partial planarization. In other words, PC layers of the anode and organic layers can be designed to have a different corrugation depth from that of to the metal grating. Therefore, it is important to have an insight on the relation of the corrugation depth with Bragg-diffraction and Bragg-reflection efficiencies, separately. Three sets of 3 dimensional (3D) FDTD simulations were performed using the structures shown in the inset of Fig. 6. The first structure has a flat anode surface on a planarized PC layer, i.e., single-layer PC structured OLED having the effect of only Bragg-diffraction. The second set of the simulations was performed for the corrugated OLED with no polymer PC structure to estimate the effect of the Bragg-reflection only. In this structure, the Bragg-diffraction effect on the anode and the organic layers must be negligible as the refractive index difference between the organic layers and the anode is very small. Finally, the simulations were performed for the multi-layer corrugated OLEDs. Corrugation depth was varied as a parameter in the simulations. Gaussian dipole sources were assumed to be located at the interface of NPB/Alq_3 with random distribution of dipole orientation. The number of dipoles was kept the same for all the structures in order to compare the extraction efficiencies from pure PC effect and Bragg-diffraction even though the surface area of the emission layer in corrugated OLEDs increases as the corrugation depth increased.

Fig. 6 shows the result of simulations in which the improvement in the light extraction is compared in terms of corrugation depths. In the single-layer PC structured OLEDs, the light extraction efficiency increases linearly as

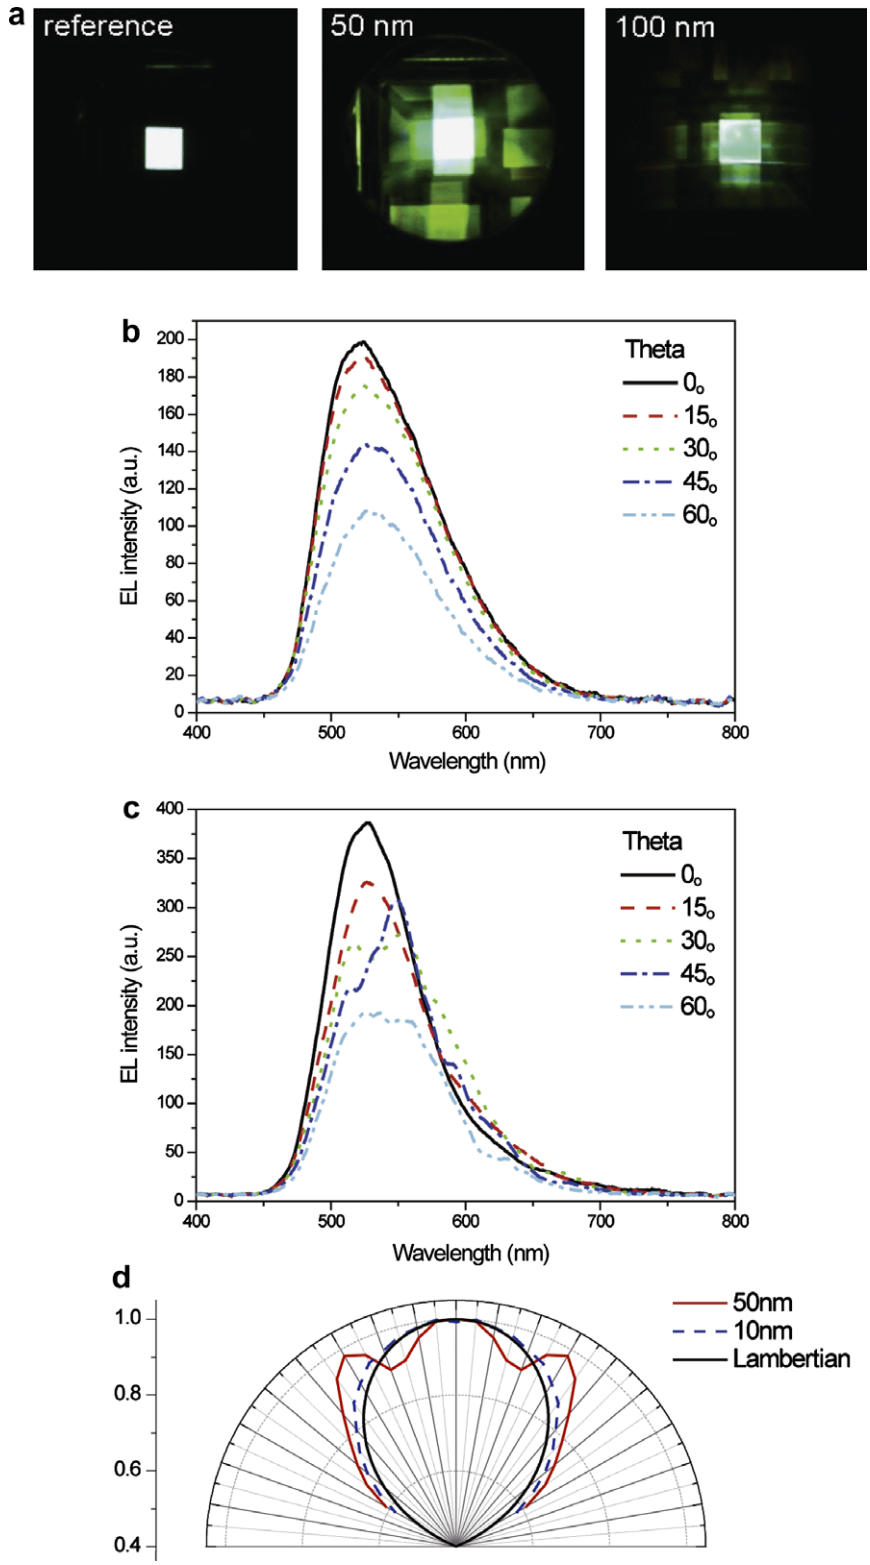

Fig. 5. (a) Photographs of the reference OLED and corrugated OLEDs with pillar heights of 50 nm and 100 nm, the angular emission characteristics of OLEDs with (b) planar and (c) 50 nm corrugated substrates and (d) the radiation profiles.

the corrugation depth increases. This result indicates that large portion of emitted light can be extracted using high pillars if there is a method to fill up a gap with a high refractive and transparent material avoiding any void or defect.

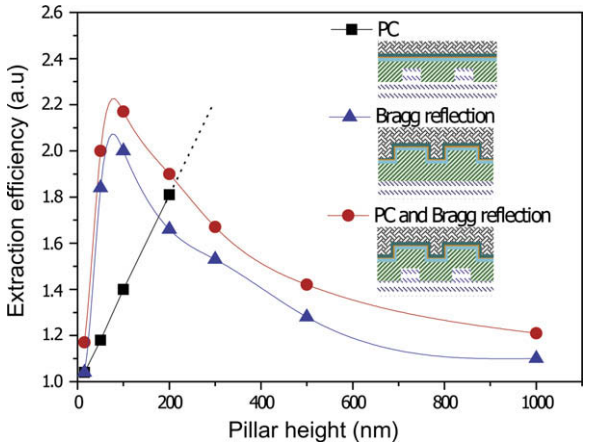

Fig. 6. Simulated relative light extraction efficiency versus the corrugation depth for three different structures shown in inset.

This is an expected result in accordance with previously reported findings [16]. The simulations were limited to corrugation depth below 300 nm in this device as the thickness of the anode was 300 nm. In the second case where the Bragg-reflection is the main factor in the improvement of the efficiency, the increase in the efficiency is substantial even at the corrugation depth of 50 nm and it reaches a peak value at the corrugation depth of 100 nm. Interestingly enough, however, the enhancement of the light extraction efficiency begins to decrease as the corrugation depth exceeds 100 nm. This simulation result can be explained as follows. When the corrugation depth exceeds a certain value, the deeper metal pit causes random phased electromagnetic waves due to multi-reflection and diffraction from the metal surface and side walls. Energy absorption by the surface plasmon from the metal surface leads to the reduction of the light extraction as well. These factors reduce the amount of Bragg-reflected light waves, resulting in less improvement of efficiency [21]. The light extraction in the third structure was further enhanced by the PC structure. The enhancement of extraction is dominated by the Bragg-reflection from the corrugated organic and metallic layers if the height of nanostructure is below 100 nm. Combined effect of light extraction becomes the maximum at the corrugation depth of 100 nm. This result suggests that further improvement of the light extraction than 49% achieved in this experiment is possible by using the corrugated OLEDs with the corrugation depth of 100 nm if we can prevent the formation of cracks and sharp edges in IZO layer, thereby to have good electrical contact.

5. Conclusions

High-efficiency corrugated OLEDs were fabricated on PC structured substrates using UV–NIL process at room-temperature and low-pressure. The Bragg-diffraction effect on the PCs of substrate, anode and organic layers and the Bragg-reflection from the corrugated metal mirror result in high light extraction efficiency even with a sub-100 nm corrugation depth. Furthermore the corrugated anode structure reduces the operating voltage. As a result, 93% enhancement of the power efficiency was obtained from an OLED even with a very shallow corrugation depth of 50 nm compared to the reference OLED with planar structure. The roles of corrugated metal mirror and PC layers on the efficiency enhancement were separately examined through FDTD analyses. The analyses showed that the increase in the efficiency reaches a peak value at a critical corrugation depth of 100 nm and the major enhancement comes from the Bragg-reflection by the corrugated metal mirror.

Acknowledgments

This research was supported by a grant (2009K000069) from Center for Nanoscale Mechatronics & Manufacturing, one of the 21st Century Frontier Research Programs, which are supported by Ministry of Education, Science and Technology, KOREA. In addition, the authors are grateful to Dr. Se-Heon Kim from the Department of Physics, KAIST for his constructive comments regarding the results of the FDTD simulations.

2. Experimental

2.1. Syntheses and characterization of compounds

Unless otherwise noted, all chemicals were obtained from commercial suppliers and used without further purification. ^{1}H NMR spectra were measured in deuterated solvents on a JEOL ECX 400 MHz spectrometer. Elemental analyses were carried out by the Elemental Analysis Service, Yamagata University, Japan. Thermal gravimetric analysis (TGA) was performed on Seiko SII EXSTAR 6000 and TGA/DTA 6200 analyzers. Differential Scanning Calorimetry (DSC) was performed on a Perkin–Elmer Diamond DSC calorimeter. Ionization potentials were measured with a photoelectron spectrometer surface analyzer (RIKEN KEIKI AC-3). UV–visible absorption spectra were recorded of solutions in chloroform or films on quartz with a Shimadzu UV-3150 spectrometer. PL spectra were recorded on a Jobin Yvon Fluoromax-2 fluorometer. PL quantum efficiencies were measured on a Hamamatsu C9920-01 integral sphere system under nitrogen.

Compound **2**: A mixture of 2,7-dibromo-9,9-diethylfluorene (**1**) (22.8 g, 60.0 mmol), carbazole (5.01 g, 30.0 mmol), copper (11.4 g, 180 mmol) and potassium carbonate (25.2 g, 180 mmol) in *o*-dichlorobenzene (200 ml) was stirred under reflux for 24 h under a nitrogen atmosphere. After cooling to room temperature, the mixture was poured into water and then extracted with toluene. The combined organic phases were washed with brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (chloroform/hexane = 1/3) affording **2** (8.61 g, 61.6%) as a white solid. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.44 (6H, t, J = 7.4 Hz), 2.02–2.07 (4H, m), 7.26–7.32 (2H, m), 7.39–7.45 (4H, m), 7.49–7.55 (4H, m), 7.64 (1H, d, J = 8.8 Hz), 7.89 (1H, d, J = 8.8 Hz), 8.16 (1H, d, J = 7.8 Hz).

BCzBF: A mixture of **2** (4.20 g, 9.00 mmol), bis(pinacolato)diboron (2.00 g, 15.0 mmol), $PdCl_2$(dppf) (0.183 g, 0.225 mmol), and potassium acetate (2.21 g, 22.5 mmol) in DMSO (350 ml) was stirred at 80 °C for 8 h under a nitrogen atmosphere. After cooling the solution to room temperature, **2** (3.80 g, 6.00 mmol), $PdCl_2$(dppf) (0.183 g, 0.225 mmol) and 2 M aqueous potassium carbonate (10 ml, 5.0 eq) were added and the mixture was stirred at 80 °C under nitrogen overnight. The mixture was cooled to room temperature and then the product was extracted with chloroform and washed with water, brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (chloroform/hexane = 1/2), giving BCzBF as a yellow solid. The product was further purified by train sublimation. Yield: 2.08 g, 35.4%. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.53 (12H, t, J = 7.4 Hz), 2.08–2.23 (8H, m), 7.30–7.34 (6H, m), 7.42–7.46 (6H, m), 7.53–7.59 (4H, m), 7.69 (2H, s), 7.75 (2H, d, J = 7.4 Hz), 7.75 (2H, d, J = 8.1 Hz), 7.96 (2H, d, J = 7.5 Hz), 8.18 (4H, d, J = 8.0 Hz). Elemental Anal. Calcd for $C_{58}H_{48}N_2$: C, 90.12; H, 6.26; N, 3.62. Found C, 89.93; H, 6.26; N, 3.56%.

Compound **3**: A mixture of **1** (5.89 g, 15.5 mmol), diphenylamine (1.31 g, 7.75 mmol), $Pd(OAc)_2$ (34.8 mg, 0.155 mmol), 1,1′-bis(diphenylphosphino)ferrocene (0.687 g, 1.24 mmol) and sodium *tert*-butoxide (1.49 g, 23.4 mmol) in toluene (60 ml) was stirred under reflux for 24 h under a nitrogen atmosphere. After cooling to room temperature, the mixture was poured into water and then extracted with toluene. The combined organic phases were washed with brine and dried over $MgSO_4$. The product was purified by column chromatography on silica gel (chloroform/hexane = 1/3), affording **3** (2.09 g, 57.6%) as a white solid. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.35 (6H, t, J = 6.5 Hz), 1.9 (4H, t, J = 7.8 Hz), 7.00 (3H, t, J = 7.3 Hz), 7.06 (1H, s), 7.10 (4H, d, J = 7.3 Hz), 7.21–7.27 (4H, m), 7.39–7.47 (3H, m), 7.52 (1H, d, J = 8.2 Hz).

BDABF: A mixture of **3** (1.20 g, 2.56 mmol), bis(pinacolato)diboron (0.541 g, 2.13 mmol), $PdCl_2$(dppf) (60.0 mg, 0.0768 mmol) and potassium acetate (0.627 g, 6.39 mmol) in DMSO (60 ml) was stirred at 80 °C for 5 h under a nitrogen atmosphere. After cooling the solution to room temperature, **3** (0.80 g, 1.70 mmol), $PdCl_2$(dppf) (0.04 g, 0.0510 mmol) and 2 M aqueous potassium carbonate (5.5 ml, 5.0 eq) were added and the mixture was stirred at 80 °C under nitrogen overnight. The mixture was cooled to room temperature and then the product was extracted with chloroform and washed with water, brine and dried over $MgSO_4$. The product was purified by column chromatography on silica gel (chloroform/hexane = 1/2), giving BDABF (0.880 g, 53.2%) as a yellow solid. The product was further purified by train sublimation. Yield: 0.801 g, 47.9%. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.42 (12H, t, J = 7.32 Hz), 1.9–2.1 (8H, m), 7.00–7.07 (6H, m), 7.13 (10H, d, J = 8.1 Hz), 7.23–7.28 (8H, m), 7.55–7.69 (8H, m). Elemental Anal. Calcd for $C_{58}H_{52}N_2$: C, 89.65; H, 6.75; N, 3.61. Found C, 89.65; H, 6.82; N, 3.48%.

Compound **4**: *n*-Butyl lithium (1.6 M, 49.3 ml, 78.9 mmol) was added to a stirred solution of **1** (30.0 g, 78.9 mmol) in dry THF (500 ml) under a nitrogen atmosphere at −78 °C. After stirring for 0.5 h, trimethylchlorosilane (11.1 ml, 94.7 mmol) was added. The mixture was warmed to room temperature, then the product was extracted with chloroform and washed with water, brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (hexane) to give **4** (27.6 g, 93.7%) as a colorless oil. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.28–0.35 (15H, m), 1.95–2.06 (4H, m), 7.41–7.46 (4H, m), 7.48 (1H, d, J = 7.5 Hz), 7.56 (1H, d, J = 8.7 Hz), 7.65 (1H, d, J = 7.3 Hz).

Compound **5**: *n*-Butyl lithium (1.6 M, 55.3 ml, 88.7 mmol) was added to a stirred solution of **1** (27.5 g, 73.8 mmol) in dry THF (500 ml) under a nitrogen atmosphere at −78 °C. After stirring for 0.5 h, trimethylchlorosilane (27.2 ml, 133 mmol) was added. The mixture was cooled to room temperature, then the product was extracted with chloroform and washed with water, brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (hexane) followed by recrystallization from toluene/ethanol = 1/4 to give **5** (21.9 g, 52.0 mmol) as a white solid. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.26–0.32 (15H, m), 1.4 (12H, s), 2.0–2.1 (4H, m), 7.45 (1H, s), 7.49 (1H, d, J = 7.3 Hz), 7.70 (2H, d, J = 7.3 Hz), 7.75 (4H, s), 7.8 (1H, d, J = 7.3 Hz).

Compound **6**: A mixture of **2** (5.68 g, 12.2 mmol), **5** (6.14 g, 14.6 mmol), $Pd(PPh_3)_4$ (0.28 g, 0.244 mmol) and 2 M aqueous potassium carbonate (5.00 g, 36.6 mmol) in toluene (60 ml) and ethanol (30 ml) was stirred under reflux for 24 h under nitrogen. After cooling to room temperature, the mixture was poured into water and then extracted with toluene. The combined organic phases were washed with brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (chloroform/hexane = 2/3), affording **6** (6.32 g, 76.1%) as a white solid. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.33 (9H, s), 0.42 (6H, t, J = 7.3 Hz), 0.51 (6H, t, J = 7.4 Hz), 2.0–2.2 (8H, m), 7.28–7.35 (2H, m), 7.44–7.56 (8H, m), 7.63–7.74 (5H, m), 7.80 (1H, d, J = 7.8 Hz), 7.86 (1H, d, J = 8.2 Hz), 7.95 (1H, d, J = 7.8 Hz), 8.19 (2H, d, J = 7.8 Hz).

Compound **7**: A mixture of **6** (6.50 g, 9.55 mmol) and iodine monochloride (1 M in CH_2Cl_2, 10.5 ml, 10.5 mmol) in CH_2Cl_2 (80 ml) was stirred at 0 °C for 1 h under nitrogen. After cooling to room temperature, the mixture was poured into water and then extracted with toluene. The combined organic phases were washed with brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (chloroform/hexane = 1/3), affording **7** (4.60 g, 65.6%) as a white solid. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.40 (6H, t, J = 7.8 Hz), 0.51 (6H, t, J = 7.8 Hz), 2.0–2.2 (8H, m), 7.28–7.35 (2H, m), 7.44 (4H, d, J = 4.2 Hz), 7.50 (1H, d, J = 3.2 Hz), 7.53–7.71 (8H, m), 7.76 (1H, d, J = 7.8 Hz), 7.77 (1H, d, J = 7.8 Hz), 7.85 (1H, d, J = 7.8 Hz), 7.95 (2H, d, J = 7.8 Hz).

CzDABF: A mixture of **7** (3.50 g, 4.77 mmol), diphenylamine (1.21 g, 7.16 mmol), $Pd_2(dba)_3$ (34.9 mg, 0.0382 mmol), tri(*tert*-butyl)phosphine (0.0114 ml, 0.0477 mmol) and sodium *tert*-butoxide (0.688 g, 7.16 mmol) in toluene (60 ml) was stirred under reflux for 24 h under nitrogen. After cooling to room temperature the mixture was poured into water and then extracted with toluene. The combined organic phases were washed with brine and dried over $MgSO_4$. The crude mixture was purified by column chromatography on silica gel (chloroform/hexane = 1/2), affording *CzDABF* (2.17 g, 58.7%) as a white solid. The product was further purified by train sublimation. Yield: 0.801 g, 51.7%. ^{1}H NMR (400 Mz, $CDCl_3$, ppm) δ 0.44 (6H, t, J = 7.0 Hz), 0.51 (6H, t, J = 6.8 Hz), 1.9–2.2 (8H, m), 7.00–7.07 (3H, m), 7.14 (5H, d, J = 7.2 Hz), 7.25–7.30 (6H, m), 7.44 (4H, d, J = 3.6 Hz), 7.53–7.72 (8H, m), 7.85 (1H, d, J = 8.2 Hz), 7.94 (1H, d, J = 7.8 Hz), 8.17 (2H, d, J = 7.8 Hz). Elemental Anal. Calcd for $C_{58}H_{50}N_2$: C, 89.88; H, 6.50; N, 3.61. Found C, 89.75; H, 6.51; N, 3.58%.

2.2. Device fabrication and characterization

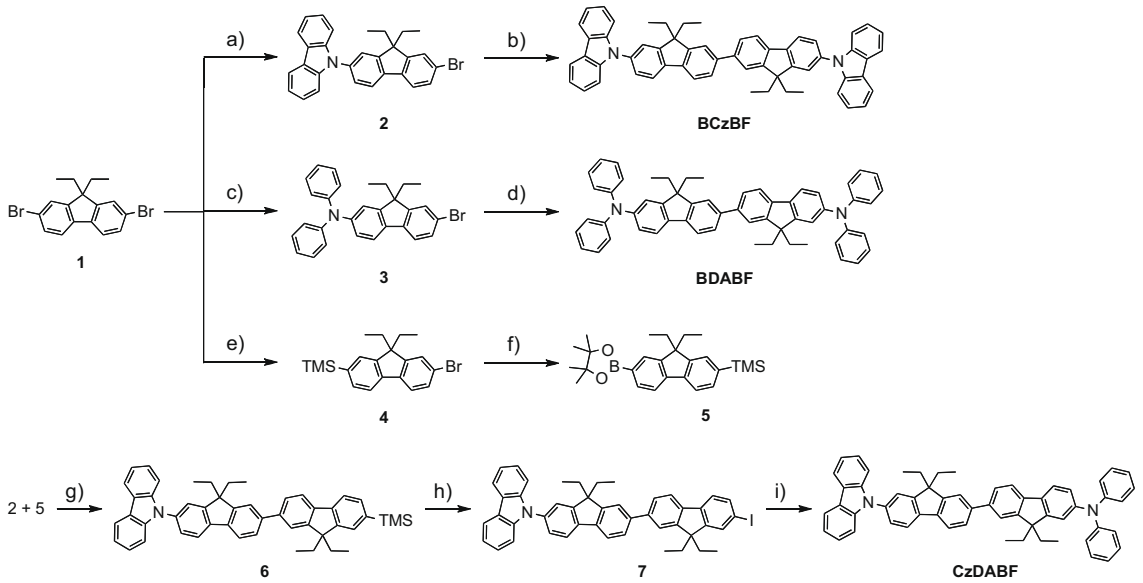
Light emitting devices were fabricated on indium tin oxide (ITO) coated glass substrates, which were prepared by ultrasonication sequentially in detergent, methanol, 2-propanol and acetone, then exposed to UV-ozone under ambient conditions for 15 min. MoO_3, Cs, rubrene and the bipolar materials were deposited by thermal evaporation at less than 1×10^{-4} Pa. Finally, the aluminum cathode was deposited through a shadow mask at less than 1×10^{-4} Pa. The active area of each device is 2 mm × 2 mm. Layer thickness calibration was performed using a Dektak 3 surface profilometer. The EL spectra were measured on a Hamamatsu PMA-11 photonic multichannel analyzer. The current–voltage (I–V) characteristics and luminance of the devices were measured using a Keithley 2400 Source Meter and Konica Minolta CS-200 chromameter, respectively. External quantum efficiencies were calculated assuming a Lambertian emission pattern and considering all spectral features in the visible region.

3. Results and discussion

Scheme 1 shows the synthetic routes to the carbazole and/or diphenylamine substituted-difluorene derivatives. Monocarbazolyl compound **2** was synthesized by an Ullmann coupling reaction between **1** and carbazole. After synthesis of the boronic ester derivative of **2** by the reaction of *bis*-(pinacolato)diboron and **1** with a palladium catalyst, dicarbazolyl compound BCzBF was synthesized successively in the same pot, *via* palladium-catalyzed Suzuki coupling of **2** with the boronic ester derivative of **2**. **3** was synthesized by palladium-catalyzed C–N coupling between **1** and diphenylamine. BDABF was synthesized in the same manner as BCzBF. In the synthesis of CzDABF, the coupling reaction between **2** and the boronic ester of **3** and the coupling reaction between **3** and boronic ester **2** gave a small amount of BCzBF or BDABF, respectively, as byproducts because of a homocoupling side reaction. These byproducts are difficult to remove from CzDABF because of their similar structure and polarity. Therefore, CzDABF was synthesized using a different route. **6** was obtained from a coupling reaction between **2** and **5**, then reacted with ICl to form **7**. Finally, a diphenylamine group was introduced to **7**, giving CzDABF.

TGA showed that the decomposition temperatures (T_d) with loss of 5 wt.% of the compounds were over 400 °C. The glass transition temperatures (T_g) of BDABF and CzDABF determined by DSC were higher than 100 °C. On the other hand, a T_g for BCzBF, which has a symmetrical structure and rigid carbazole substituents, was not observed in our experiment, probably because of its high crystallinity.

The UV absorption and PL spectra of the compounds were measured in the solution state and in the film state on a quartz substrate (Table 1). Absorption and PL maxima exhibited red shifts as the number of diphenylamine groups increased, suggesting that the electron donating diphenylamine group reduced the HOMO (highest occupied molecular orbital)–LUMO (lowest unoccupied molecular orbital) gap of the compounds. The ionization potentials (I_p) of the compounds were measured by ultraviolet photoelectron yield spectroscopy under atmospheric conditions. The I_p increased as the number of diphenylamine groups increased because diphenylamine moieties are better at donating electron density than carbazole moieties, which increases the HOMO energy level. Tentative electron affinity (E_a) values were estimated from the difference between I_p and the optical energy gap obtained from the edge of the UV absorption of the films. As the number of diphenylamine groups increased, the E_a of the compounds decreased and the I_p increased. DFT calculations



Scheme 1. Synthetic route to the bipolar compounds. (a) carbazole, Cu, K_2CO_3, dichlorobenzene, 180 °C, 20 h, (b) (i) Pd(dppf)Cl_2, KOAc, bis(pinacolato)diboron, DMF, 80 °C 3 h; (ii) **2**, Pd(dppf)Cl_2, K_2CO_3, 80 °C, 20 h, (c) diphenylamine, Pd(OAc)$_2$, 1,1′-bis(diphenylphosphino)ferrocene, NaO-*t*-Bu, toluene, reflux, 20 h, (d) (i) Pd(dppf)Cl_2, KOAc, bis(pinacolato)diboron, DMF, 80 °C 3 h; (ii) **3,** Pd(dppf)Cl_2, K_2CO_3, 80 °C 20 h, (e) (i) *n*-BuLi, −78 °C 1 h; (ii) $(CH_3)_3SiCl$, −78 °C to r.t., 20 h, (f) (i) *n*-BuLi, −78 °C 1 h; (ii) 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane, −78 °C to r.t., 9 h, (g) Pd$(PPh_3)_4$, K_2CO_3 *aq*., toluene, ethanol, reflux, 20 h, (h) ICl, dichloromethane, 0 °C, 1 h, (i) $Pd_2(dba)_3$, tri(*t*-butyl)phosphine, NaO-*t*-Bu, toluene, reflux, 24 h.

Table 1
Thermal and optoelectrochemical properties and charge mobilities of the bipolar compounds.

	T_g (°C)	$T_{d5\%}$ (°C)	UV[a] (nm)	PL[a] (nm)	I_p (eV)	E_a[b] (eV)	E_g^{OPT}[a] (eV)	HOMO[c] (eV)	LUMO[c] (eV)	μ_h ($cm^2V^{-1}s^{-1}$)	μ_e ($cm^2V^{-1}s^{-1}$)
BCzBF	N.D.	477	350, 297	425	5.98	2.89	3.09	5.51	1.85	2.3×10^{-3}	1.5×10^{-3}
BDABF	106	417	380, 310	452	5.57	2.69	2.88	5.16	1.72	1.0×10^{-3}	N.D.

[c] Obtained from DFT calculations using B3LYP 6311+G(d,p)//631G(d).

showed that the HOMO energy levels of BCzBF and BDABF are delocalized over the whole molecule, while the HOMO of CzDABF is localized on the diphenylamine and bifluorene units. On the other hand, the LUMOs of all three compounds are localized on the bifluorene unit (Fig. S1). HOMO and LUMO levels estimated from the calculations were consistent with the values obtained experimentally for I_p and E_a.

The charge transport properties of the compounds were investigated by the TOF transient photocurrent technique at room temperature (Fig. 1). The carrier transit times were determined from the folding point in the double-logarithmic plots of the data (insets in Fig. 1). The hole mobilities of all three compounds were high, comparable to the mobilities of common hole transporting materials [15]. BDABF did not exhibit a photocurrent during measurement of electron mobility. On the other hand, BCzBF and CzDABF showed sufficient electron photocurrent to determine their electron mobilities. The electron mobilities of these two compounds were as high as their hole mobilities, and much higher than the electron mobility of 10^{-6}–10^{-7} $cm^2V^{-1}s^{-1}$ of the well-known electron transporting material, *tris*-(8-hydroxyquinoline) aluminum (Alq_3). These results demonstrate that the diphenylamine group increased the hole transport ability of bifluorene, while the carbazole group gave the compound bipolar charge transport abilities. The bipolar charge transport properties of these carbazole compounds are consistent with previously reported bipolar compounds such as CBP [9].

Fig. 2 shows the current density–voltage (*J*–*V*) characteristics of the hole-only devices containing *p*-doped bipolar compounds (ITO/bifluorene:MoO_3 50 mol% (120 nm)/Au) and undoped bifluorene (ITO/bifluorene (120 nm)/Au). While the undoped hole-only devices exhibited low current densities, the current density of the *p*-doped hole-only devices increased considerably in an Ohmic manner. The conductivities of the *p*-doped devices at 4.0×10^5 Vcm^{-1} were 1.5×10^{-6} Scm^{-1}, 1.7×10^{-6} Scm^{-1} and 1.1×10^{-6} Scm^{-1} for BCzBF, BDABF and CzDABF, respectively. Similarly, electron-only devices containing

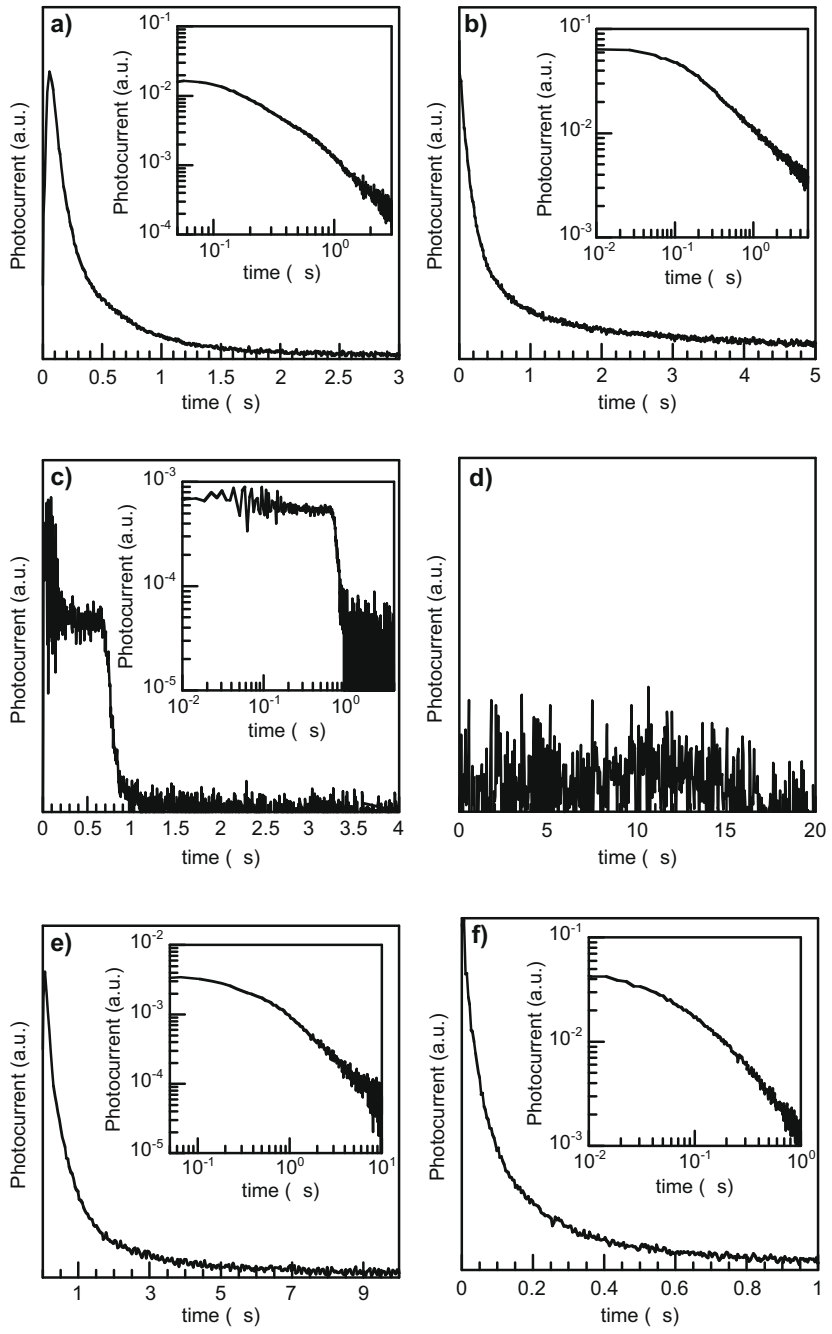

Fig. 1. Time-of-flight (TOF) transients of the bipolar compounds: (a) BCzBF, hole, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 3.0 μm. (b) BCzBF, electron, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 8.0 μm. (c) BDABF, hole, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 3.0 μm. (d) BDABF, electron, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 3.0 μm. (e) CzDABF, hole, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 3.0 μm. (f) CzDABF, electron, $E^{1/2}$ = 700 (V/cm)$^{1/2}$, d = 3.0 μm.

n-doped bipolar compounds (ITO/BCP (10 nm)/bifluorene:Cs 30 wt.% (120 nm)/Au) and undoped bipolar compounds (ITO/BCP (10 nm)/bifluorene (100 nm)/Au) were fabricated. The Cs-doped electron-only devices exhibited conductivities that were seven orders of magnitude higher than the undoped electron-only devices. At 4.0×10^5 Vcm^{-1}, the conductivities of the *n*-doped electron-only devices were 4.7×10^{-6} Scm^{-1}, 1.0×10^{-6} Scm^{-1} and 1.2×10^{-6} Scm^{-1} for BCzBF, BDABF and CzDABF, respectively. These results demonstrate that the bifluorene compounds have small enough I_p to be *p*-doped and E_a to be *n*-doped effectively, in addition to their bipolar charge transport ability in an undoped state.

OLEDs with a homo-junction structure were fabricated containing BCzBF and CzDABF with the device configurations: device I = ITO/bifluorene:MoO_3 (50 mol%, 20 nm)/

bifluorene (80 nm)/bifluorene:Cs (30 wt.%, 20 nm)/Al (80 nm) and device II = ITO/bifluorene:MoO_3 (50 mol%, 20 nm)/bifluorene (10 nm)/bifluorene: rubrene (20 wt.%, 60 nm)/bifluorene (10 nm)/bifluorene: Cs (30 wt.%, 20 nm)/Al (80 nm). Fig. 4a shows the PL spectra of the bipolar compounds and the EL spectra of the OLED. The EL spectra of device I did not correspond to the PL spectra of the bipolar compounds. This might be caused by absorption in the blue region by a radical species in the doped layers or exciplex emission in the interface between the doped and undoped layers. External quantum efficiencies (EQE) of device I were low at around 0.5% at 100 cd m^{-2} (Table 2). The low EQE of these devices were probably caused by the lack of an energy barrier between the layers making charge recombination poor and exciton quenching caused by the close proximity of doped layers to the emission zone. Device II was fabricated with rubrene doped into the emission layer to efficiently trap carriers and undoped bifluorene layers between the emission layer and the doped layers to prevent quenching. For device II, only yellow emission derived from

rubrene was observed (Fig. 4a). Although the driving voltages increased compared to those of device I because of carrier trapping by rubrene (Fig. 3a), device II exhibited higher EQEs than that of device I (Fig. 4b). The maximum EQE of 1.5% for device II containing CzDABF is consistent with the theoretical EQE of 1.35% estimated from the PL quantum yield of 27% of 20 wt.% rubrene in CzDABF. Doping concentrations of rubrene of less than 20 wt.% increase the PL quantum yield, but incomplete carrier trapping causes emission from the bifluorene host and results in lower overall EQE. The homo-junction structure of the OLEDs was expected to extend the lifetimes of the devices because of a lack of organic interfaces but the lifetime measurements did not show an improvement over typical device structures. Further detailed investigations are under way and will be presented in the future.

4. Conclusion

Bipolar fluorene compounds were synthesized by palladium-catalyzed C–C and C–N coupling reactions. The energy levels of these compounds were related to the number of carbazole and diphenylamine groups. TOF measurements demonstrated that these compounds have bipolar charge transport abilities. Hole mobilities were as high as that of NPD and electron mobilities were much higher than that of Alq_3. These bifluorene compounds have small enough I_p to be *p*-doped and E_a to be *n*-doped. Hole- and electron-only devices containing these compounds with *p*-type doping with MoO_3 and *n*-type with Cs showed Ohmic current density–voltage characteristics. OLEDs with a homo-junction structure containing these bipolar compounds as the emitting material exhibited poor efficiencies. Addition of rubrene as an emitting material into these devices improved the EQEs to 1.5–2.0%.

complex series (PtL^{26}Cl), where N^C^N represents a 1,3-di(2-pyridyl) benzene-based tridentate ligand, *L*. We focus on its generally non-monotonous drive current evolution which appears to vary with the Pt(II) complex concentration. Although such a non-monotonous evolution has already been observed in other systems (for an overview see Ref. [1]), the main interest had been in the ELQE roll-off reflecting various processes that quench the emissive states and/or their precursors at large current densities [10,11]. Recently, it was realized and illustrated experimentally on a few examples of molecular exciton EL [1,12] that the importance of another process had been overlooked in the past: the current (voltage)-enhanced recombination efficiency leading often to the substantial ELQE increase seen particularly well in the lower driving current densities regime. The purpose of this work is to establish unified approach to and universal description of the current dependence of the ELQE within the whole current densities range accessible for OLEDs including their emission simultaneously from both monomolecular and bi-molecular excited states, and to critically compare the results with experiment based on the high performance data obtained here for PtL^{26}Cl emitter LEDs treated as a distinctive example.

2. Experiment

The originally synthesized, highly phosphorescent platinum N^C^2^N-[1,3-di(4-methoxy-pyrid-2-yl)-4,6-difluorobenzene] chloride (PtL^{26}Cl)-doped (4,4′,4″-tris(*N*-carbazolyl-triphenylamine) (TCTA) blends have been used as either the low-concentration bluish-green (molecular exciton), high-concentration red (excimer) or concentration-optimized white (molecular exciton + excimer) emitters with the phosphorescence yield between 0.49 and 0.74 for low-concentration and neat film EMLs, respectively. Our LED structures ITO/TPD75 wt%:PC25 wt% (60 nm)/TCTA(10 nm)/TCTA($100-x$)wt%:PtL^{26}Cl*x*wt% (30 nm)/TAZ(30 nm)/LiF/Al, were fabricated by casting a sequence of thin layers on clean glass substrates pre-coated with a 150 nm-thick layer of indium tin oxide (ITO) with a sheet resistance of 20 Ω per square. A 60 nm-thick diamine derivative (TPD):polycarbonate (PC) blend hole-transporting layer (HTL) was deposited on top of the ITO glass by spin coating from a 10 mg/ml dichloromethane solution at room temperature. All remaining organic layers were deposited in succession by thermal-evaporation under vacuum of $\sim 10^{-6}$ hPa, followed by high vacuum ($\sim 10^{-6}$ hPa) thermal-evaporation of the cathode layer consisting of 0.5 nm-thick LiF and by a 100 nm-thick Al cap. The EML was evaporated by co-deposition of the phosphor and TCTA to form a 30 nm-thick blend film. Holes are injected from the ITO anode, and pass through (TPD:PC) and TCTA hole-transporting layers, and re-combine with electrons that were injected from a Al/LiF cathode and transported through the electron transporting layer (ETL) of a triazole derivative, TAZ. The 10 nm-thick TCTA layer has been used to block triplet exciton transfer from the Pt complexes to the non-radiative triplet of TPD. The 30 nm-thick layer of TAZ plays a similar role of inhibiting quenching of the Pt complex triplet excitons at the cathode while at the same time blocking holes, both properties that enable the recombination process to be confined to a 30 nm-thick EML [6]. Resulting LED architecture allowed us to maximize its performance parameters (for general mechanisms of organic LED function see e.g. Ref. [1]).

3. Results

The EL spectra of the LEDs based on different concentrations of PtL^{26}Cl blended with TCTA as EMLs, along with the phosphor concentration dependent relative contribution of the monomer and excimer emissions, are shown in Fig. 1. Like in other PtL^{x}Cl-based emitter LEDs [6] the EL spectra constitute of two, monomer blue and excimer reddish-yellow (amber), bands, the amber band component increasing with complex concentration up to reddish only emission from PtL^{x}Cl neat films. Fig. 2 shows the EL external quantum efficiency (QE) as a function of the driving current density (j) for a series of LEDs at varying concentration dopant emitters. The essential information in the figure is: (i) an increase of the QE with increasing current in the

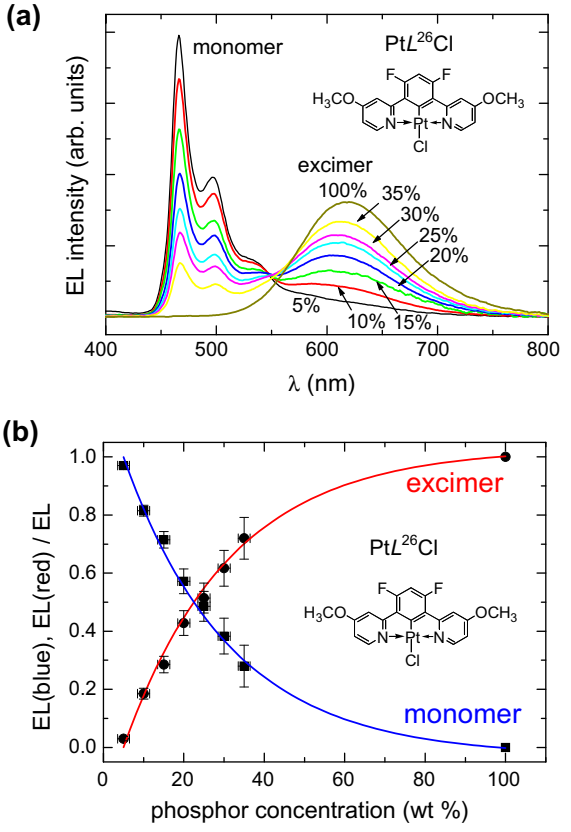

Fig. 1. (a) EL spectra of the device studied with different concentrations of the phosphor (PtL^{26}Cl) as indicated in the figure. (b) The relative contributions of the monomer blue and excimer red emission band components (EL_{blue}, EL_{red}) to the total EL emission (EL) as a function of the phosphor concentration in the EML (taken suitably as the blue part, red part and total spectrum under-curve area ratios). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

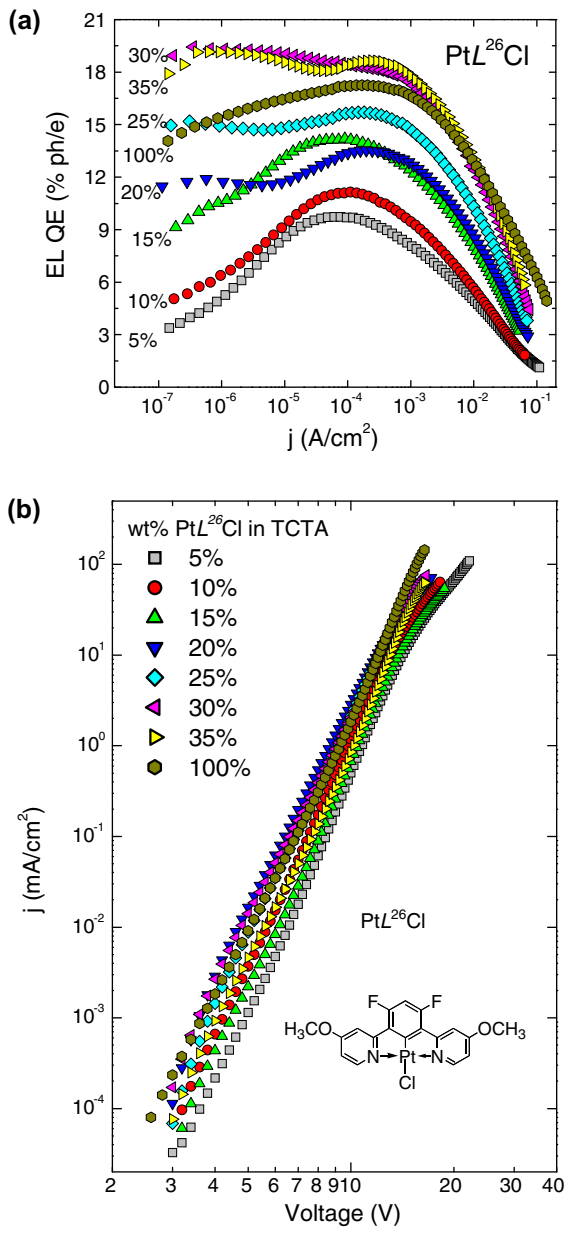

Fig. 2. (a) External EL quantum efficiency (EL QE) of PtL^{26}Cl emitter-based LEDs as a function of the driving current and parametric in the concentration (c in wt%) of PtL^{26}Cl in their emitting layers. Note a distinctive change in the curve shape, accompanying the phosphor content. (b) Current–voltage characteristics of the same LEDs.

low-current regime for the dopant concentration below 15 wt%, (ii) a maximum or a bump in the moderate-current regime whose position varies slightly with the PtL^{x}Cl content in the EML, (iii) a drop at large current densities, (iv) an enormous increase of the EL QE with phosphor concentration tending to saturation at 30–35 wt%, where it reaches 20% (photon/electron) corresponding to almost 100% of the internal QE – the upper limit of the LED performance, (v) an excess of the light output for neat PtL^{x}Cl over blend EMLs at the highest current densities accessible.

4. Modeling

We determine the external EL QE from the general expression representing all electronic processes involved in creation and fate of n different excited states, modified by the phosphor concentration, c:

$$\varphi_{EL}^{(ext)}(c) = P_R(c)P_d \sum_{i=1}^{n} \xi_i(c)\,\varphi_i^{PL}(c)P_{qi}(c)P_{si} \qquad (1)$$

Here, $\xi_i(c)$ (<1) is the light output coupling factor accounting for LED optical side modes escaping of usual front face detected EL light flux and dependent on the LED's material composition, their architecture as well as their operation conditions, φ_i^{PL} is the quantum efficiency of the radiative decay of excited state i created in the electron-hole recombination process, which is commonly identified with the photoluminescence (PL) quantum efficiency. The fundamental message of Eq. (1) is that the ELQE is a result of the superposition of four independent processes operating in the LED at the same time, and represented by the factors

$$P_R = (1+\tau_r/\tau_t)^{-1}, \quad P_d = (1+\tau_c/\tau_d)^{-1},$$
$$P_{qi} = (1+\tau_{0i}/\tau)^{-1}, \quad 0 \leqslant P_{si} \leqslant 1 \qquad (2)$$

which account for the probability of the formation of a charge pair (CP) state (P_R), its dissociation avoidance (P_d), and escape of a quenching process by the final emissive i state (P_{qi}), irrespective of the type of emissive material and LED architecture. The P_{si} stands for the probability of creation of a singlet or triplet ith emitting state. They are defined by spin multiplicity and a set of time constants characterizing the formation and decay of various electronic species as depicted in a scheme presented in Fig. 3. These are: the charge carriers encounter (recombination) time (τ_r), effective transit time of charges out of the recombination zone (τ_t) corresponding to the maximum of the monomolecular decay rate constant of electrons $(\tau_t^e)^{-1}$, and holes $(\tau_t^h)^{-1}$, $(\tau_t)^{-1} = (\tau_t^e)^{-1} + (\tau_t^h)^{-1}$, dissociation time of CP states (τ_d), formation time of an emissive state (T_1) ≡ charge pair internal capture time (τ_c), intrinsic lifetime of the emissive state (τ_0) and its lifetime (τ) triggered

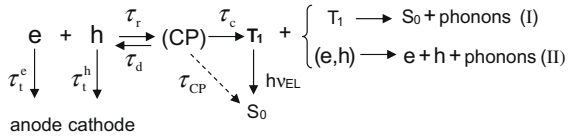

Fig. 3. The kinetic scheme illustrating formation of emissive states (T_1) in the recombination process of electrons and holes injected at the electrical contacts (e + h). Naturally, the emissive state is preceded by an intermediate state of a coulombically-correlated charge pair (CP). In general, CP can also directly decay to the ground molecular state (S_0) either in a radiative or radiationless transition with a time constant τ_{CP}. The radiative decay of T_1 produces the only optical emission called electroluminescence ($h\nu_{EL}$) if τ_{CP} is much longer than charge capture time (τ_c). For description of other time constants see text. The yield of the radiative decay can be reduced by (T_1 + T_1) (I) and (T_1 + e and/or h) (II) interactions. We note that here the emissive state (T_1) stands for either the first monomolecular triplet exciton or excimer triplet state, and factor P_{si} = 1 ($P_{s1} = P_{s2}$) since due to the heavy Pt atom a strong spin-orbit coupling transforms all singlet into triplet states.

off by the exciton–exciton ($T_1 + T_1$) and exciton-charge carrier interactions (T_1 + e and/or h).

The analytic treatment rests upon the assumption that all the above time constants can be related to physical observables of the current density, j, electric field strength, F, organic layers thickness, d, and independently determined parameters including carriers mobility (μ_e, μ_h), the (CP)-dissociation rate constant, η, dielectric permittivity, ε, and the intrinsic lifetime of the emissive species, τ_0:

$$\tau_r = (\gamma n)^{-1}, \quad \tau_t^{e,h} = d/\mu_{e,h}F, \quad \tau_c/\tau_d = \tau_c \nu_0 \eta(F), \quad \tau_0/\tau = \tau_0 j/\varepsilon_0 \varepsilon F \tag{3}$$

We consider the carrier motion to be dominated by the hole hopping for all emitters, $\tau_t \approx \tau_t^h$, except for neat films forming ambipolar conductive organic layers. Consequently, the τ_r-to-τ_t ratio for blend emitters can be approximated by $\tau_r/\tau_t = (8/9)(\mu_{e,h}/\mu_{eff}) j_{SCL}/j \approx (8/9) j_{SCL}/j$ obtained with $j_{SCL} = (9/8)\mu_{eff}\ \varepsilon_0\varepsilon F^2/d \approx (9/8)\mu_h \varepsilon_0 \varepsilon F^2/d$ and $\mu_{eff} \approx \mu_h$ standing for the effective charge carriers mobilities under double injection, and assuming the second order recombination rate constant, $\gamma = e(\mu_e + \mu_h)/\varepsilon_0\varepsilon$, to obey the Langevin recombination mechanism [1] between balanced concentration ($n = j/e(\mu_e + \mu_h)F$) of electrons and holes within the EML. The electron (hole) mobility is assumed to obey the ubiquitous dependence $\mu_{e,h}(F) = \mu_{e0,h0} \exp(\beta_{\mu_e,\mu_h} F^{1/2})$, where $\mu_{e0,h0}$ is the zero-field limit of the mobility and the scaling factor β_{μ_e,μ_h} is determined by the energetic and positional disorder of the material, the dielectric constant and the temperature [1,13]. To be correct one has to note that such defined β_{μ_e,μ_h} (as determined from charge carrier mobility experiments) differs from that included in the formula for j_{SCLC} by a factor 0.89 which is due to the approximations made in its derivation [14,15]. The magnitude of this factor which is close to unity does not alter the scaling coefficient to a significant degree and the final results fall in the experimental error and the accuracy of the fitting procedure. The τ_0/τ ratio follows from the general steady-state kinetic equation for the density of T_1 states, taking into account ($T_1 + T_1$) and [T_1 + (e,h)] exciton annihilation processes (see Fig. 3):

$$\frac{dT_1}{dt} \cong \frac{j}{ew} - \gamma_{TT} T_1^2 - \gamma_{Tq} n T_1 = 0 \tag{4}$$

where 'w' is the width of the recombination zone, and γ_{TT} and γ_{Tq} are the second order ($T_1 - T_1$) and ($T_1 - q$) annihilation rate constants, respectively. The effective lifetime imposed by these interactions is given by $\tau^{-1} = \gamma_{TT} T_1 + \gamma_{Tq} n$ and the analytic solution of Eq. (4) by

$$T_1 = -\frac{\gamma_{Tq}}{\gamma_{TT}} \frac{j}{e\mu F} + \frac{1}{2\gamma_{TT}} \sqrt{\left(\frac{\gamma_{Tq} j}{e\mu F}\right)^2 + \frac{4\gamma_{TT} j}{ew}} \tag{5}$$

If the ($T_1 - q$) interaction becomes the dominating quenching process, as observed recently for Ir(III)-tetrazolate phosphors [12], $\tau^{-1} \approx \gamma_{Tq} j/e\mu F$ or $\tau^{-1} \approx j/\varepsilon_0\varepsilon F$ for slow triplets quenched by mobile holes, allowing Langevin relation to be applied for $\gamma_{Tq} \approx e\mu_h/\varepsilon_0\varepsilon$. This is a rough approximate expression resulting from the general definition of $\gamma_{Tq} = 4\pi R_{eff}(D_T + D_h)$, where D_T and D_h are the diffusion coefficients of triplet and a hole, respectively, and R_{eff} is the exciton effective capture distance (see e.g. Ref. [16]). This definition bases on the premise that the triplet quenching reaction is controlled by the diffusion motion of mutually approaching triplet and hole like that in the case of the recombination of two oppositely charged carriers which is called Langevin recombination process. Since in our emissive layers the triplets are well localized on PtL^{26}Cl molecules a natural assumption is that $D_T \ll D_h$, reducing γ_{Tq} to $4\pi R_{eff} D_h$. The R_{eff} is not exactly known and can vary between one up to 10 intermolecular spacings (~2–20 nm) dependent on the charge separation (dipole moment) on the dopant molecule, thus the local dielectric constant. To simplify the calculations we assumed R_{eff} to be somewhere within the upper limit of this range that is approaching the Coulomb radius $R_C = e^2/4\pi\varepsilon_0\varepsilon kT$ like in the e–h recombination process. Consequently, it could be roughly approximated by $\gamma_{Tq} \approx e\mu_h/\varepsilon_0\varepsilon$ which means that the triplet-charge carrier interaction rate constant is comparable with that for the second order e–h recombination rate constant. Being aware of this simplifying approximation, we point out that an expected lower value of R_{eff} ($<R_C$) would not change the character of the function $\tau(j)$ and consequently EL QE (j). Possible differences in values of some other fitting parameters might be expected due to variation of R_{eff}. This will be considered as a refinement to be made in our works being underway. We note that PtL^{26}Cl triplet exciton transfer within their blends with TCTA is impeded due to the triplet energy mismatch for these blend components (2.65 eV vs. 2.85 eV, respectively). This is the case expressed by τ_0/τ in Eq. (3).

In order to examine the validity of Eq. (1), the mechanism of the field-assisted (CP)-dissociation process must be established in addition. In contrast to the dissociation of molecular excitons when the primary step formation of nearest-neighbor charge transfer state controls the field dependence of the dissociation rate, the dissociation quantum efficiency of CPs is governed by the separation ability of CP associated with field-dependent diffusion of a carrier in the Coulombic field of the countercharge, and can be expressed by [17],

$$\eta(F) = \frac{\sin h(e\delta F/kT)}{A + \sin h(e\delta F/kT)} \tag{6}$$

where δ is the hopping distance of the carrier and $A = (\tau_c^{-1} + \tau_{CP}^{-1})\tau_d(F = 0)$. This is the field-dependent CP dissociation efficiency to be inserted in (3) along with a standard frequency factor ν_0.

We use Eqs. (2) to calculate the ELQE (1) taking into account two emissive states ($T_1^{(n)}$, n = 1,2), monomer (n = 1) and excimer (n = 2), created with different proportions dependent on the dopant concentration. In general, more emissive states ($n > 2$) can contribute to the LED's emission (see e.g. Ref. [7]). For simplicity we assume $\xi_1 = \xi_2 = \xi = 0.3$ a typical value for OLEDs. We take the measured values of τ_{01} = 3.4 μs, τ_{02} = 1.3 ± 0.3 μs, and $\varphi_1^{PL}(5\ wt\%) = 0.53$, $\varphi_2^{PL}(100\ wt\%) = 0.74$ which vary with the dopant concentration as follows from the blue and red component contributions to the EL shown in Fig. 1b, $\varphi_1^{PL}(c) = \varphi_1^{PL}(5\ wt\%) \times$ [EL(blue)/EL] and $\varphi_2^{PL}(c) = \varphi_2^{PL}(100\ wt\%) \times$ [EL(red)/EL]. In Fig. 4 we display the j dependence of the three of the

probability factors defined by Eq. (2) taking into account Eqs. (3) and (6) for different phosphor concentrations in the LED EMLs. The displayed curves have been obtained by suitable parametrization procedures in order to fit the experimental data in Fig. 4a. We find that the j dependence of $P_R(j)$ can be approximately modeled by the current evolution of the ratio $(j_{SCL}/j)_m$ at different dopant concentrations c_m ($m = 1,2,3,4$), j_{SCL} being calculated employing a Poole–Frenkel type field-dependent mobility with a field independent prefactor varying with dopant concentration, $\mu_{eff0} = \mu_{h0}(c_1) = 6.5 \times 10^{-12}$, through $\mu_{h0}(c_2) = 1.4 \times 10^{-12}$, $\mu_{h0}(c_3) = 2 \times 10^{-14}$ to $\mu_{h0}(c_4) = 1.9 \times 10^{-13}$ cm^2/Vs and $\beta_{\mu h}$ from 7×10^{-3}, through 8.5×10^{-3}, 10^{-2} up to 1.35×10^{-2} (cm/V)$^{1/2}$ for respective c_m, and j taken from experiment (Fig. 2b). The low values of the zero-field mobilities may create an impression of very low mobility in emissive layers under working conditions of the LEDs studied. However, taking into account its Poole-Frenkel type field dependence with the fitted values of the scaling factors one comes to the mobility values comparable with those of other organic complex-doped blends. For example, our μ_h ($F = 8 \times 10^5$ V/cm) $= \mu_{h0} \exp(\beta_{\mu h} F^{1/2}) = 1.9 \times 10^{-13} \exp(1.35 \times 10^{-2} \times 9 \times 10^2) \approx 3.3 \times 10^{-7}$ cm^2/Vs, the value comparable with those measured for other blends (e.g. $\sim 10^{-8} - 10^{-7}$ cm^2/Vs for electrons and holes in Ir(ppy)$_3$ doped CBP films at electric fields above 10^5 V/cm [18]). Furthermore, we note that j at a given voltage differs at different c_m and for all dopant concentrations: though it shows a strong increase with applied voltage, it cannot be strictly described by a power dependence within the whole range of V, characteristic of the volume-controlled double injection currents in the presence of exponentially distributed in energy charge traps [1]. Thus, the capacitor charge related to the unit volume ($\varepsilon_0 \varepsilon F/d$) may be lower than the average concentration of the total charge in the sample ($j/\Theta\mu_{eff}F$; Θ-the free-to-trapped charge concentration ratio), indicating substantial j deviation towards injection-limited currents. It is clearly seen in the current evolution of the j_{SCL}-to-j ratio (Fig. 4c), which largely exceeds unity for the 5%-doped sample at the lowest current densities. To fit the $P_d(j)$ we used Eq. (6) with $\delta_1 = 1.02$, $\delta_2 = 1.06$, $\delta_3 = 1.22$ and $\delta_4 = 1.20$ nm, and $(\tau_c \nu_0)_m = 6.5$, 9, 10 and 8 for $m = 1,2,3,4$, respectively. One would expect δ to reflect the distance between molecules forming hopping sites for the carriers. For $m = 1,2$ these correspond exactly to the intermolecular distance between TCTA molecules, $\delta(\text{nm}) = 10^7 (M/c_m \rho N_A)^{1/3}$, where $M = 741$ g/mol is its molecular weight, $\rho \approx 1.2$ g/cm^3- typical density of organic films, and $N_A = 6 \times 10^{23}$/mol is the Avogadro's number. The fit numbers δ_m for $m = 3,4$ differ from the intermolecular distance between molecules of PtL^{26}Cl ($M = 558$ g/mol), 1.37 and 0.91 nm, respectively, that suggests progressive clustering of dopant molecules. An excess of the current in neat films of the phosphor relative to the blends is observed in the high voltage range applied. This suggests the effect of increased carrier (electrons and holes) transport parameters (μ_0 and β_μ), being partly a consequence of the decreased distance between carrier molecular hopping sites. Finally, the $P_{qn}(j)$ curve has been reconstructed based on the experimental dependence of j [$(V/d) = F$] (Fig. 2b) and independently determined τ_{01} and τ_{02} for

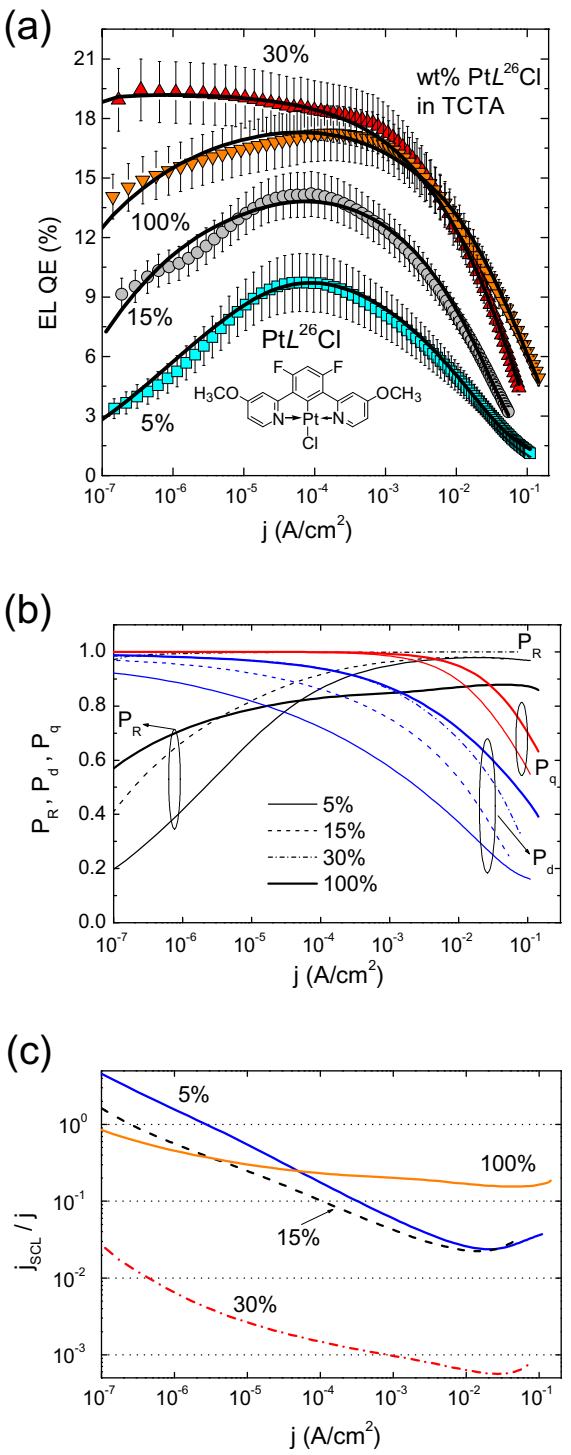

Fig. 4. (a) Selected experimental (figure points) and theoretical curves based on the current evolution of P_R, P_d and P_q from part (b) (solid lines) external ELQE vs. device current density for the devices with four different concentrations of PtL^{26}Cl as indicated in the figure (cf. Fig. 2). (b) The recombination (P_R), dissociation evasion (P_d), and quenching escape (P_q) probabilities defined by Eqs. (2) as a function of current density at different dopant concentrations, $c_1 = 5$ wt%, $c_2 = 15$ wt%, $c_3 = 30$ wt% and $c_4 = 100$%. The values of fitting parameters are given in the text. (c) The calculated space-charge-limited hole (hole + electron) current/measured current ratio (j_{SCL}/j) vs. j.

monomer and excimer microemitters as given above. A dielectric constant $\varepsilon = 3$, typical for organic solids, has been assumed and the carriers pathway identified with total device thickness $d = 130$ nm. Such a choice of d assumes the carrier mobility to be an average over all four layers of the device and makes the carrier transition time to approach its lower limit, but the alternation of d does not affect the functional shape of the $P_R(F)$ and QE(j) curves. An apparent difference in neat film emitters characteristics (Figs. 2 and 4) must be associated with the increased role of electrons. Their injection barrier from TAZ ETL of electronic affinity of ca. 2.8 eV into emitter is here reduced due to its greater electronic affinity (ca. 2.77 eV) as compared with that of ca. 2.3 eV for the emitter dominating material (TCTA) in blends. It is reasonable to assume their substantial role in electrical transport with $(\tau_t)^{-1} = (\tau_t^e)^{-1} + (\tau_t^h)^{-1} \neq (\tau_t^h)^{-1}$. The μ_{eff} becomes a combination of μ_e and μ_h, different for the SCL and plasma flow conditions [1,19], but still fitting to the Poole–Frenkel type field mobility dependence $\mu_{\text{eff}}(F)$ can be possible with μ_0 and β_μ corresponding to the combined electron and hole transport parameters. They apparently differ from their counterparts for TCTA and explain differences in optoelectrical characteristics of (PtL^{26}Cl doped TCTA) blend and neat film PtL^{26}Cl emitters-based LEDs. In addition, the increased molecular packing and negligible contribution of the monomer emission in the latter lead to higher values of P_d and P_q (Fig. 4b) resulting in the increased QE at the largest current densities as shown in Figs. 2a and 4a.

5. Discussion and conclusions

The good reproduction of the experimental data on the driving current evolution of the ELQE for PtL^{26}Cl-based LEDs strongly suggests that the underlying approach to the quantum efficiency of organic LEDs is within the experimental accuracy correctly described in this work, at least for practically accessible range of current densities. Our analysis indicates that increasing current leads not only to quenching of excited states imposed by growing exciton–exciton and exciton-charge carrier (P_q) interactions accompanied by their or their precursors field-assisted dissociation (η included in P_d) but at the same time may lead to increasing recombination probability (P_R) of injected carriers for low (<15 wt%) phosphor content. It has become clear that of these three factors only P_R can be an increasing function of the current (j) as long as its field (F) dependence is more steep than the space-charge-limited one carrier dominating current (j_{SCL}). Its constant value is expected if $j(F) \sim j_{\text{SCL}}(F)$, and goes to unity for $j_{\text{SCL}} \ll j$. We note that increasing P_R can be related to a decreasing current leakage invoked to explain the low-current regime QE(j) increase in earlier experiments on Ir complex-based OLEDs [20]. While both P_d and P_q by their definition decrease with the driving current (applied electric field), though almost invisible at low-current densities, a maximum of the ELQE is expected at a certain current ($j = j_{\max}$). It moves towards higher values at higher (>15 wt%) dopant contents, which reflects the increasing role of electrons in the current and sets the carrier flow at which the increasing recombination rate becomes suppressed by quenching processes. For the same reason no low-current increase of the ELQE is observed for high dopant content blend emitters. Electrons and holes are expected to have very different scaling factors ($\beta_{\mu e}$, $\beta_{\mu h}$) in their field-dependent mobilities – what is clearly confirmed from the fitting procedures for blend and neat film-based emitters. Instead of an increase a mild fall down to a dramatic roll-off of the ELQE (j) dependence at low values of the driving current in high dopant content blend emitters is observed. Some recent publications indicate the essential role of the recombination rate on the QE (j) dependence for color OLEDs based on single monomolecular exciton emission centers [12,21]. This work extends these previous analyses to multi-center emissive OLEDs and includes their premises by replacing a qualitative discussion of the (HTL/ETL)/EML energy barrier effects and carrier transport properties of each layer material [21] by a quantitative description that relates the recombination and transit times of the carriers to physical observables. We present a generalized formula for analyzing experimental data that accurately describes the current evolution of QE in OLEDs independent of their architecture. Our approach shows how the recombination probability can be expressed by the measured current and charge transport parameters. The latter, if not available from experiment, can be determined in a way that an optimal overall fit QE(j) is obtained.

P3HT:PCBM solar cell are still being reported. However, the relatively large band gap of P3HT, limits the fraction of solar spectrum that can be harvested, and the relatively small energy difference between the LUMO of PCBM and HOMO of P3HT, results in a lower open circuit voltage (V_{oc}). Therefore, the band gap of the polymer and the HOMO must be decreased in order to achieve the organic solar cells with high PCE. In this context, research efforts have been focused on the design and synthesis of new donor and acceptor materials with high carrier mobility and strong absorption in visible and near infrared region of solar spectrum [10–14], as well as device processing [15–18] fabrication [19–22] and architecture design [2,23–25].

A number of groups have investigated solution processed BHJ solar cells based on conjugated small molecules as donors and fullerene derivatives as acceptors. To date, the PCE ranging from 0.3% to 2.5% have been reported for the devices based on small molecules [26–31]. Recently, PCE of approximately 3.0% has been reported on solar cells based on low band gap small molecule blended with PCBM [32]. The efficiency based on small molecules is still low compared to either thermally deposited bi-layer small molecules solar cells [33–36], or polymer based solar cells. Despite of the low PCE attained by these solar cells, conjugated small molecules offer several advantages such as higher electron and hole mobilities due to better molecular ordering, over polymeric materials, making them promising materials for the solution processed solar cells. The most important advantage of conjugated small molecules is that they do not suffer from batch to batch variation, broad molecular weight distribution and difficult synthesis and purification methods, as it is for polymer counterpart.

In this investigation, we report the fabrication and characterization of single layer BHJ devices, based on conjugated alternating phenylenevinylene copolymer **P**:PCBM active layer with different weight ratio, deposited at different substrate temperatures. It was found that the optimum photovoltaic (PV) performance observed with the **P**:PCBM (1:3) deposited at 65 °C and PCE of ~1.14% which is further improved up to 1.28%, when the TiO_2 layer is incorporated in between the BHJ layer and the Al electrode. The PV device based on **P**:PCBM and **BTD-TNP**:**PPI** BHJs exhibits PCE about 2.68%, which has been further improved up to 2.91% when the TiO_2 layer was inserted between the active layer and the top Al electrode followed by thermal annealing. The increase in the PCE has been attributed to the improved photon absorption, better charge transportation in the device, induced by the incorporation of TiO_2 layer and thermal annealing. The PCE of thermally annealed single and bi-layer BHJ with TiO_2 layer is approximately 1.67% and 3.5%, respectively.

2. Results and discussion

2.1. Optical and electrochemical properties of materials

The synthesis of the conjugated alternating phenylenevinylene copolymer **P** [37], the small molecule **BTD-TNP** [38] and the perylene–pyrene bisimide (**PPI**) [39] has been reported elsewhere. Fig. 1 shows the chemical structures of these materials and PCBM.

Fig. 2 shows the UV–visible absorption spectra copolymer **P**, PCBM, **BTD-TNP** and **PPI** thin films. The copolymer **P** thin film shows a broad absorption band from 320 nm to 480 nm with absorption peak around 450 nm and onset around 620 nm. The small molecule **BTD-TNP** shows an absorption band from 600 to 680 nm and its absorption is extended up to 790 nm. The single layer films of copolymer **P**:PCBM, and **BTD-TNP**:**PPI** shows the absorption bands in different wavelength regions i.e. 420–560 nm and 550–750 nm for **P**:PCBM and **BTD-TNP**:**PPI**, respectively. The bi-layer blend film, however, showed continuous solar absorption spectra from 400 to 750 nm, arising from both BHJ layers.

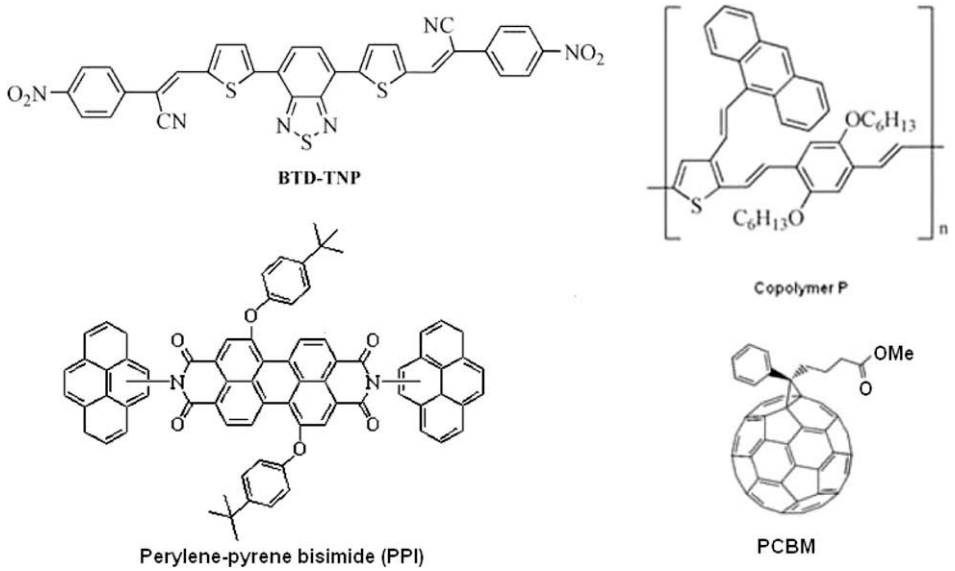

Fig. 1. Chemical structures of **BTD-TNP**, copolymer **P**, perylene–pyrene bisimide (**PPI**) and PCBM.

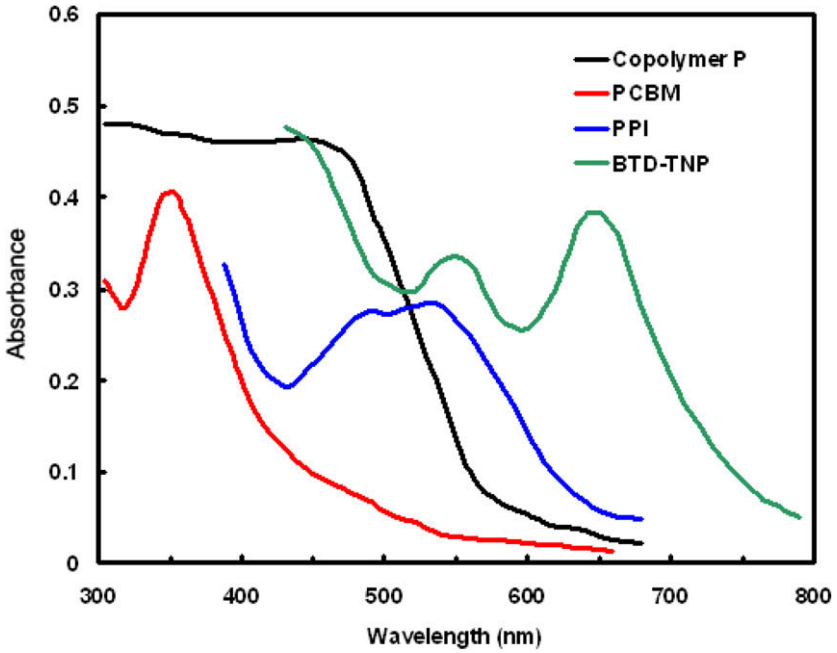

Fig. 2. UV–visible optical absorption spectra of copolymer **P**, PCBM, **PPI** and **BTD-TNP**.

The electrochemical cyclic voltammetry was performed to determine the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of **P**, **BTD-TNP**, PCBM and **PPI**. The HOMO and LUMO energy levels were calculated according to the following equations [40]:

$$E_{HOMO} = -(E_{ox} + 4.71)\text{eV}$$

and

$$E_{LUMO} = -(E_{red} + 4.71)\text{eV},$$

where E_{ox} and E_{red} are the onset oxidation and reduction potential vs. Ag/AgCl, respectively, observed in cyclic voltammogram. The potentials were internally calibrated using Ag/AgCl redox couple, which is estimated to have an oxidation potential of −4.71 eV vs vacuum. The values of HOMO and LUMO energy levels and the band gap of the above materials, estimated from the cyclic voltammetry (CV) data, are listed in Table 1.

Table 1
Estimated values of highest occupied molecular orbital and lowest unoccupied molecular orbital energy levels and band gap of materials from cyclic voltammetry data.

Material	E^{ox}_{onset} (V)	E^{red}_{onset} (V)	E_{HOMO} (eV)	E_{LUMO} (eV)	$E_g = E_{HOMO} - E_{LUMO}$ (eV)
Copolymer **P**	0.49	−1.71	−5.20	−3.00	2.20

*2.2. Photovoltaic properties of copolymer **P**:PCBM single layer BHJ device*

We have optimized the fabrication conditions of the device based on copolymer **P**:PCBM blend in terms of substrate temperature and blend ratio, before investigating the bi-layer BHJ PV device. Fig. 3a shows a schematic representation of a single layer BHJ solar cell based on a blend of **P** and PCBM. The energy level diagram for the materials involved in the single layer BHJ device is also shown in Fig. 3b. Since the HOMO and LUMO of **P** are by 1.2 and 1.0 eV higher than the corresponding energy levels of PCBM, the **P** and PCBM act as donor and acceptor, respectively. In view of interface morphology of thin BHJ films for solar cells, we have investigated the temperature effect on the performance for solar cells prepared by spin casting warm **P**:PCBM blend onto ITO/PEDOT:PSS substrates at different temperatures over 30–70 °C. Since the thickness of the photoactive layer affects the short circuit photocurrent of the device, we have kept the temperature of both blend solutions and substrate the same to slow down the evaporation rate, in order to control the film morphology. We have kept the thickness of all active layers almost constant to compare the PV properties of the devices. The thickness of the active layer deposited at different substrate temperatures was kept constant by controlling the viscosity of blend and spinning rate during the spin coating of the layer onto the substrate. The current–voltage (J–V) characteristics of the devices based on copolymer **P**:PCBM (1:3 weight ratio) under illumination intensity of 100 mW/cm^2 at different temperatures are shown in Fig. 4a. The variation of the PCE of the PV device with the substrate temperature is shown in the Fig. 4b. It seems from Fig. 4a that the

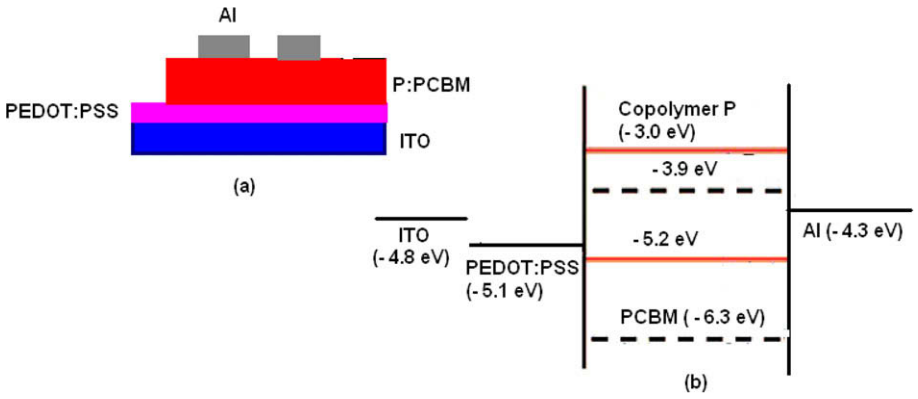

Fig. 3. A schematic representation of the device configuration (a) a bulk heterojunction solar cell based on copolymer **P**:PCBM and (b) the associated energy level diagram.

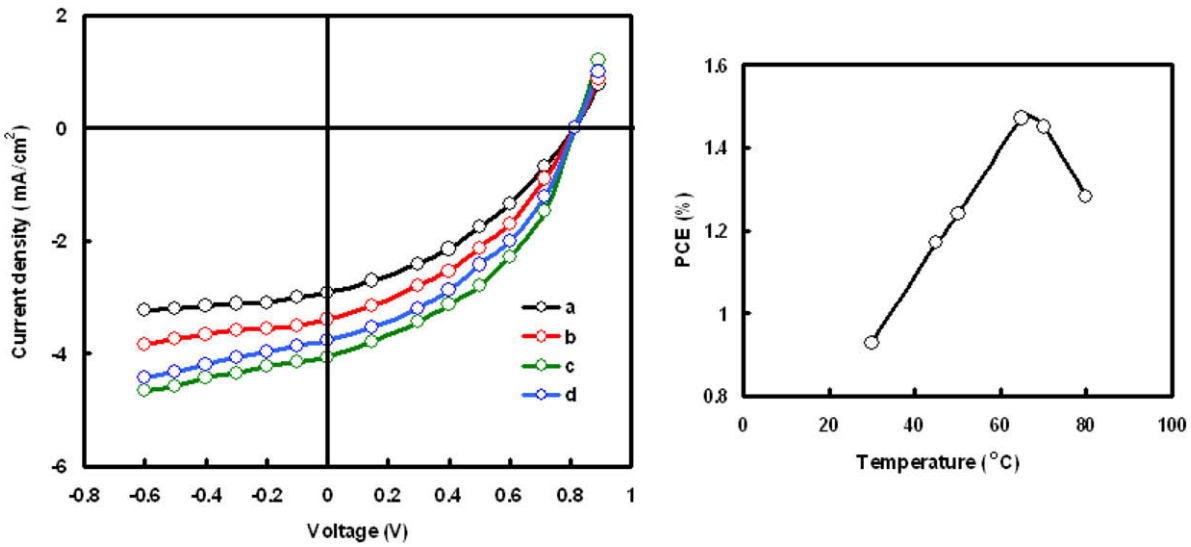

Fig. 4. (a) Current–voltage characteristics of ITO/PEDOT:PSS/Copolymer **P**:PCBM (1:3 by wt)/Al device at different substrate temperatures (a) 30 °C, (b) 45 °C, (c) 65 °C and (d) 80 °C. (b) Variation of power conversion efficiency (PCE) with substrate temperature.

substrate temperature affects mainly the J_{sc}, while the V_{oc} remains unchanged. Consequently the PCE increased continuously from 0.93% to 1.14% by increasing the substrate temperature from room temperature to 65 °C. Since copolymer **P** was spin cast from a warm DCB solution (70 °C), it could be crystallized quickly with defects upon contracting the substrate at lower temperatures. However, the copolymer **P** macromolecules in the bulk volume could take a long time to be crystallized during the slow film formation as the boiling point of DCB is as high as 180 °C. The defect rich copolymer **P** crystalline domains at the interface with ITO/PEDOT:PSS layer may act as trap site to reduce the overall hole mobility of **P** across the PV active film. The decrease in hole collection efficiency induced by the interfacial defects is proportional to the decrease in the substrate temperature. The observed decrease in PCE above 60 °C is probably due to the relatively faster evaporation of the solvent, which in turn, led to fast crystallization of **P** with introduced defects into the bulk film. Therefore, the optimized ITO substrate temperature for spin coating **P**:PCBM for a warm DCB solvent seemed to be 65 °C. All the devices described thereafter have been fabricated on the ITO/PEDOT:PSS substrate at 65 °C. Since the PCE of the device is maximum when the substrate temperature is about 65 °C, which is almost the same temperature of the warm blend solution, the change in PCE is only due the substrate temperature.

After optimizing the conditions for the device fabrication, we have further investigated the BHJ solar cells based on single layer copolymer **P**:PCBM blends with different weight ratio of 1:0.5, 1:1, 1:2, 1:3 and 1:4. The measured *J–V* characteristics (Fig. 5) show a strong dependence of the PV response on the copolymer **P**:PCBM wt. ratios. The observed increase in PCE with increasing **P**:PCBM wt. ratio results from an enhanced electron mobility associated with an increased PCBM content within the blend [41].

The decrease in PCE observed at 1:4 wt. ratio in **P**:PCBM blend is most probably due to the over suppressed hole transport induced by relatively nanoscale clusters of **P** in active layer and/or increased PCBM sites for charge recom-

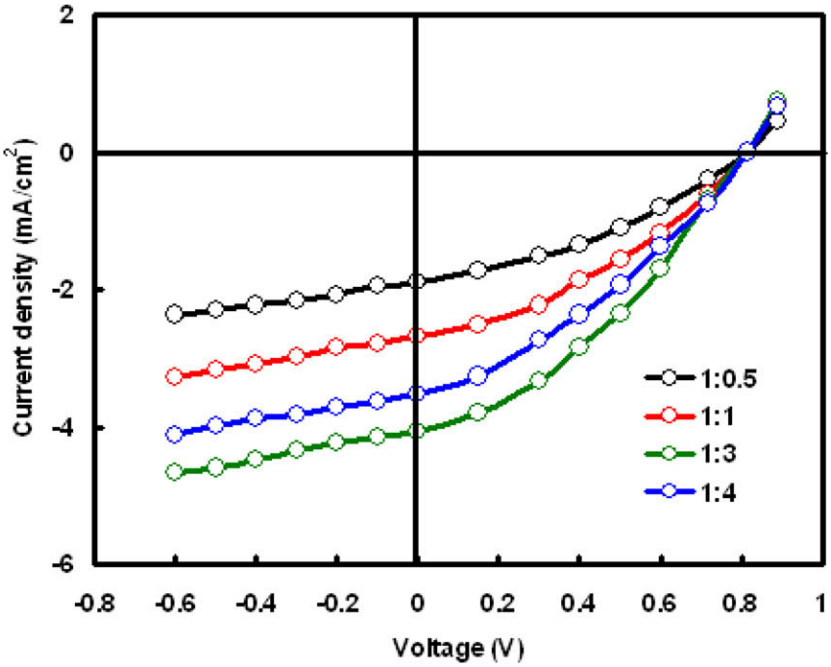

Fig. 5. Current–voltage characteristics of ITO/PEDOT:PSS/Copolymer **P**:PCBM/Al device with different weight ratio of Copolymer **P** to PCBM at substrate temperature 70 °C.

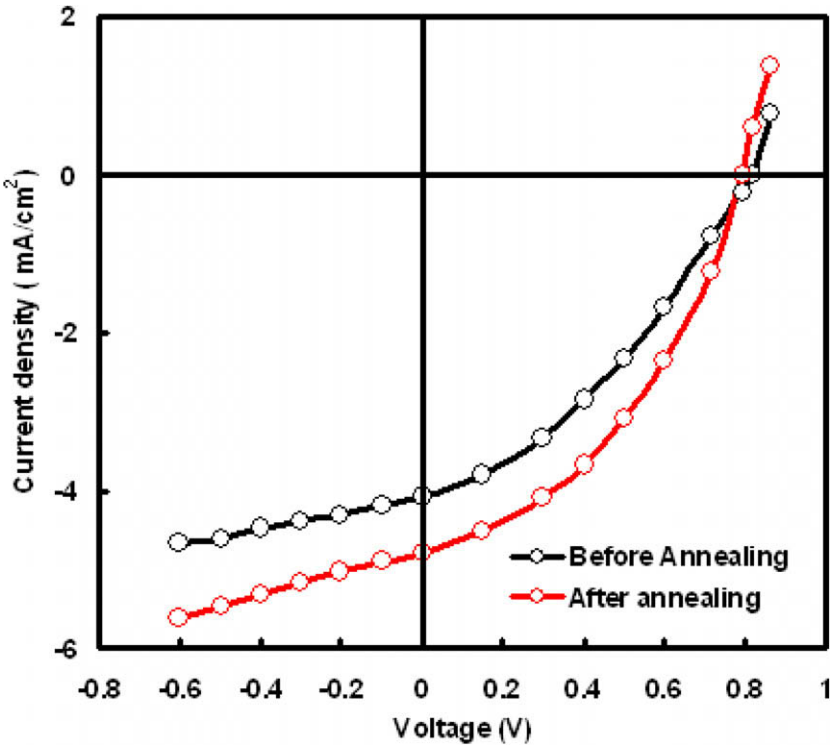

Fig. 6. Effect of thermal annealing on the current–voltage characteristics of ITO/PEDOT:PSS/Copolymer **P**:PCBM/Al device under illumination.

bination. The diluted solar absorption associated with the relatively reduced amount of copolymer **P** in the blend layer may also be contributing to the reduction in PCE. Therefore, we have used 1:3 weight ratio for **P** to PCBM deposited at substrate temperature of 65 °C for further investigation.

Fig. 6 shows the *J–V* characteristics for PV devices based on copolymer **P**:PCBM (1:3 wt. ratio) before and after thermal annealing at 100 °C for 20 min. It is found that the V_{oc} of ITO/PEDOT:PSS/**P**:PCBM/Al device remains almost unchanged while its J_{sc} slightly increased and fill factor (FF) significantly increased from 0.34 to 0.38 upon thermal annealing. In polymer solar cells, the FF is determined by the product of charge carrier lifetime and mobility. Therefore, the improved FF and J_{sc} is attributed to an enhanced charge transport due to the formation of large copolymer **P** crystalline domains in blend layer induced by thermal annealing. It is also found that the thickness of the blend film is decreased upon thermal annealing. This means that the molecular packing density of the as cast film is low. Therefore, all molecular interactions between the **P** domain, PCBM and **P**-PCBM domain are insufficient. Thermal annealing of the blend leads to an increase in the packing density, i.e. the distance between all molecules is narrowed and consequently, the efficiencies of exciton dissociation and charge transport are improved. Moreover, the annealing of the blend layer reduces the free volume and density of defects at the interface to facilitate the hole transport.

Charge carrier mobilities in donor/acceptor BHJ thin film play an important role on the performance of the organic PV devices [42,43]. We have fabricated the hole only device having structure ITO/PEDOT:PSS/**P**:PCBM/Au using the as cast annealed **P**:PCBM blends and the *J–V* characteristics in dark were measured. The hole mobility in the blend has been estimated using the SCLC model [42]. It is found that the hole mobility has been increased from 3.2×10^{-5} to 8.6×10^{-5} cm^2/V s upon the thermal annealing. The increase in the hole mobility also support our conclusion about the reduction in the free volume and density of defects at the interface. The enhancement in the photocurrent may also be attributed to the balanced charge transport in the device due to the improved hole mobility in copolymer **P** domain.

In addition to the enhanced hole transport, it is also essential to improve the electron transport in the PV device to achieve higher PCE. It has been already reported that the PCE has been improved, when a TiO_2 layer was inserted into the P3HT:PCBM blend in the PV device based on P3HT:PCBM [25]. This is due to the fact that the TiO_2 is a good electron transporting material, since its LUMO level is lower than that of PCBM and also very close to the work function of Al. We have also incorporated a thin TiO_2 layer into our copolymer P:PCBM devices. The *J–V* characteristics of the device are shown in Fig. 7a and the PV parameters are shown in Table 2. The as cast ITO/PEDOT:PSS/copolymer **P**:PCBM (1:3)/TiO_2/Al device showed a relatively enhanced PCE with respect to its counterpart without TiO_2. This was attributed to improved electron transport in the device with its LUMO level (−4.4 eV) lower than that of PCBM (−3.9 eV) (as shown in Fig. 7b). The subsequent thermal annealing also led to further enhanced performance with PCE about 1.67%, which once again is due to the formation of polycrystalline domains in the active layer.

To model the *J–V* characteristics of the copolymer **P**:PCBM solar cells, the BHJ of active layer of copolymer **P**:PCBM can be considered to be a single virtual semiconductor with HOMO and LUMO equivalent to those of **P** and PCBM, respectively, and having electron and hole mobilities equal to electron mobility of PCBM and hole mobility of **P**. When two electrode materials are brought to intimate contact with the active organic layer, the Fermi level alignment takes place and electron diffuse from the cathode to anode. Fig. 8a represents schematically the energy levels of the materials used in BHJ layer. Fig. 8b represents schematically the energy level diagram of the system

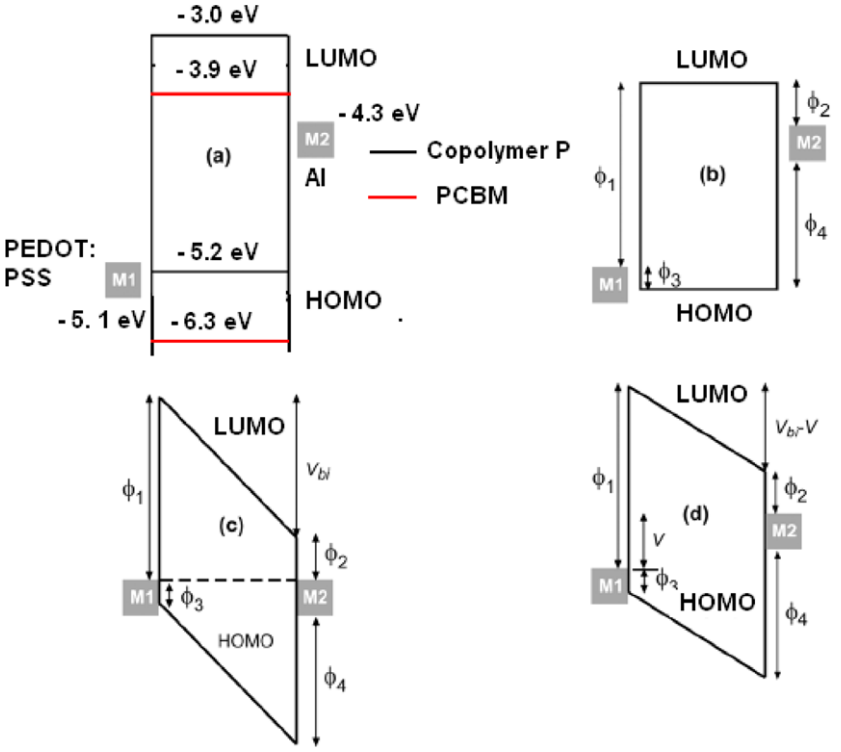

Fig. 8. Schematic energy diagrams (a) of the PEDOT:PSS/copolymer **P**:PCBM/Al device before the materials are brought to intimate contact, (b) of the virtual semiconductor (the blend of copolymer **P** and PCBM is assumed to be a single virtual semiconductor) before it is brought to intimate contact with electrodes, (c) of the system when the semiconductor is brought to intimate contact with electrode materials and (d) represents the situation when a forward bias voltage V is applied to the device.

with a virtual semiconductor before the intimate contact. Fig. 8c shows the situation when the virtual semiconductor has been brought to intimate contact with the contacting electrodes to formulate the device. The mathematical simulations show that in thermal equilibrium the electric field in the device is equal to V_{bi}/d, which reduces to $(V_{bi} - V)/d$, when forward bias of voltage V, is applied to the device. Fig 8d describes the situation when the forward bias is applied to the device.

We have calculated the J–V characteristics of the ITO/PEDOT:PSS/PPAT:PCBM/Al device in dark and under illumination using the model development by Kumar et al. [44] for BHJ devices. In this model they have solved the continuity equation including both drift and diffusion of charge carriers using a constant electric field in dark and under illumination and obtained the analytical expressions for J–V characteristics. The dark current in the device can be expressed as

$$J = \frac{q^2 D_n N_c (V_{bi} - V + JAR_s)\exp(-\phi_1/nkT)}{dnkT\left[1 - \exp\left(\frac{-q(V_{bi}-V+JAR_s)}{nkT}\right)\right]} \times \left(\exp\left(\frac{q(V - JAR_s)}{nkT}\right) - 1\right) + \frac{V - JAR_s}{R_p A}, \quad (1)$$

where n is the diode ideality factor, A is the cross section area, R_s and R_p are the series and parallel resistance, respectively, D_n is diffusion coefficient, N_c effective density

of state, ϕ_1 is the electron injection barrier at anode and d is the thickness of the organic layer.

Under illumination the J–V characteristics can be given as

$$J = \frac{q^2 D_n N_c (V_{bi} - V + JAR_s)\exp(-\phi_1/nkT)}{dnkT\left[1-\exp\left(\frac{-q(V_{bi}-V)+JAR_s}{nkT}\right)\right]} \times \left(\exp\left(\frac{q(V-JAR_s)}{nkT}\right)-1\right) + \frac{V-JAR_s}{R_p A} - J_{ph}(V), \qquad (2)$$

where J_{ph} is the photogenerated current. The photocurrent is determined by the light generated charge carriers due to the photon absorption by the active layer that reaches the appropriate electrodes with their lifetime (τ). The velocity of the charge carriers is determined by their mobility and internal electric field. At higher internal electric field all the generated charge carriers within the bulk of the device will contribute to the photocurrent, while at lower internal electric fields, only the generated charge carriers in the vicinity of the electrodes are collected by the electrodes.

Fig. 9 shows the comparison of the calculated and experimental J–V characteristics of the device. When a forward bias (negative at Al electrode) is applied to the device, electrons are injected into the LUMO of PCBM and holes are injected into the HOMO of copolymer **P**. In the copolymer **P**:PCBM BHJ, the copolymer **P** and PCBM form the different percolated paths for hole and electron, respectively, in which the electrons and holes transport easily towards the electrodes. Therefore, the electrons and holes move in PCBM and copolymer **P** channels, respectively. The two currents are added to each other in order to get the overall current in the device. The theoretical values of the current in dark and under illumination were estimated using Eqs. (1) and (2), respectively. The values of parameters used here are: $\phi_1 = 1.2$ eV, $\phi_2 = 0.9$ eV for holes $T = 300$ K, $\mu = 2.2 \times 10^{-5}$ cm^2/Vs, $R_s = 20\ \Omega$, $A = 25$ mm^2, $d = 100$ nm, $\varepsilon = 3.5$, $N_c = N_v = 10^{19}$ cm^3, $V_{bi} = 0.70$ V, and $R_p = 2.0 \times 10^4\ \Omega$ for dark and $R_p = 3.5 \times 10^3\ \Omega$ under illumination. As it can be seen from Fig. 9, the calculated J–V characteristics of the devices in both dark, as well as under illumination follow closely the experimental results. Therefore, we conclude that the model based on drift and diffusion current at constant electric field is valid for our BHJ device.

2.3. Photovoltaic properties of solar cells based on two bulk heterojunction layers

We have used copolymer **P**:PCBM and **BTD-TNP**:**PPI** BHJs for fabrication of solar cells. Fig. 10 shows the normalized optical absorption spectra of a bi-layer film of copolymer **P**:PCBM/**BTD-TNP**:**PPI**. The bi-layer film shows a continuous absorption from 350 nm to 780 nm arising from both BHJ layers.

In order to get more information about the photocurrent generation, we have measured the incident photon to current efficiency (IPCE) of the devices. The values of IPCE have been estimated using the following expression:

$$\text{IPCE}\ (\%) = 1240\, J_{sc}/\lambda P_{in}, \qquad (3)$$

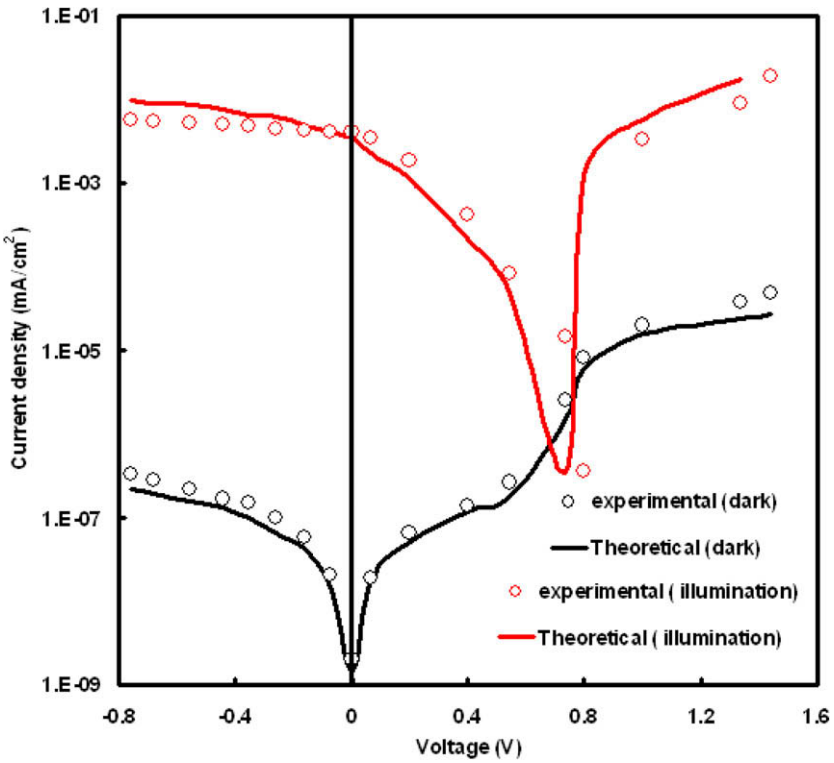

Fig. 9. Calculated and experimental J–V characteristics of an ITO/PEDOT:PSS/copolymer **P**:PCBM (1:3 wt. ratio)/Al device in dark and under illumination.

where J_{sc} (mA/cm^2) is the short circuit photocurrent, P_{in} mW/cm^2 and λ (nm) is the illumination intensity and wavelength of the monochromatic light. Fig. 11 shows the IPCE spectra of the PV devices employed with different active layers. It can be seen from the IPCE spectra of each device, that it closely resembles the absorption spectra of the blend used in the device. The bi-layer BHJ devices shows the improved IPCE in comparison to that the single

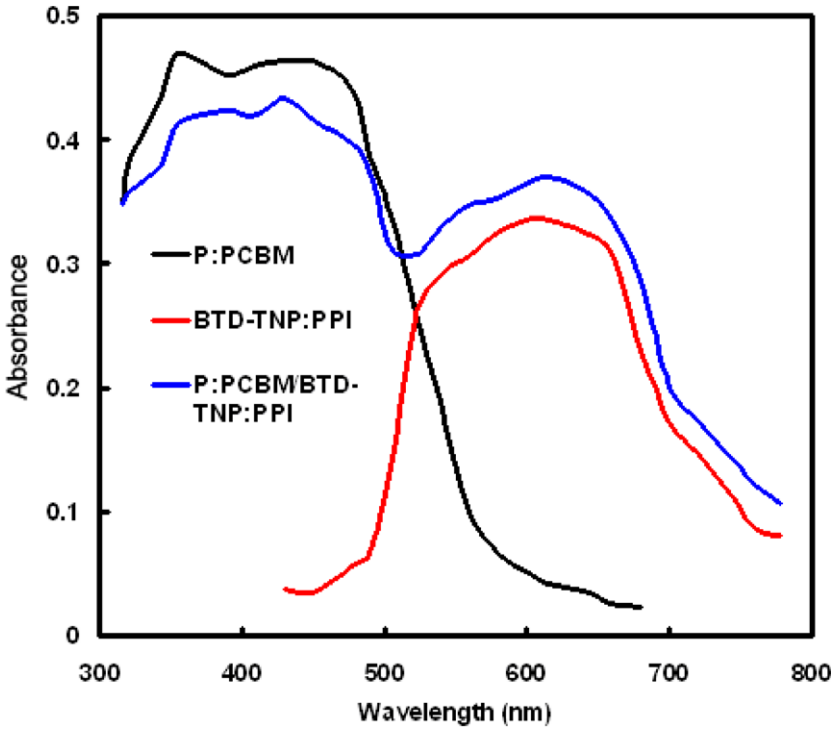

Fig. 10. Optical absorption spectra of copolymer **P**:PCBM, **BTD-TNP**:**PPI** and their bi-layer thin films.

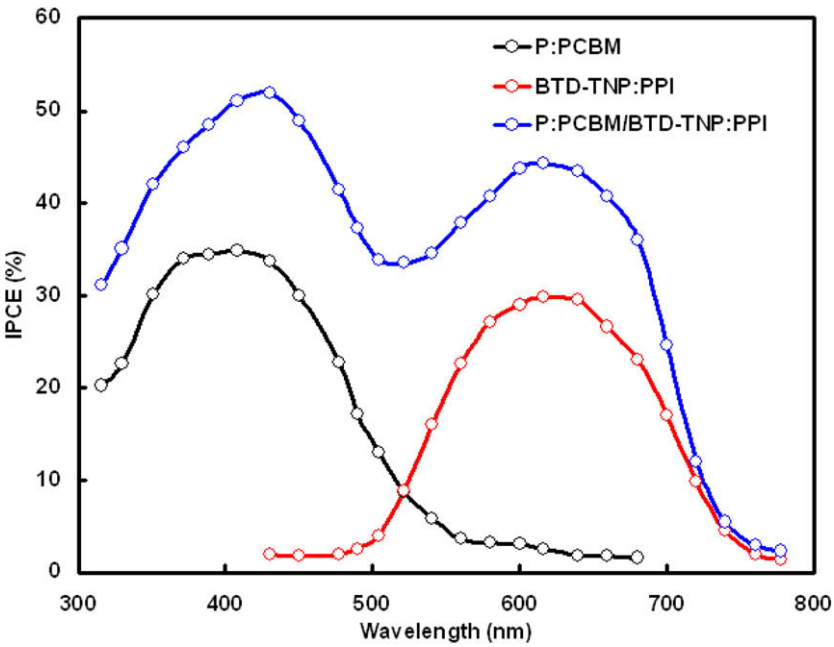

Fig. 11. IPCE spectra of photovoltaic devices using different photoactive layers.

layer BHJ devices. This increase in the IPCE was attributed to the improvement in the light harvesting and enhanced charge transport.

The *J–V* characteristics of ITO/PEDOT:PSS/**P**:PCBM/**BTD-TNP**:**PPI**/Al bi-layer heterojunction devices are shown in Fig. 12 and PV parameters are listed in Table 2. The single **P**:PCBM layer and bi-layer solar cells exhibit similar V_{oc} and bi-layer device showed a much higher J_{sc} and PCE. In general, the J_{sc} is determined by the product of photoinduced charge carrier density and the charge carrier mobility [1], as given by $J = nq\mu E$, where n is the charge carrier density, q is the electronic charge, μ is the mobility of charge carrier, and E is the electric field. The observed higher value of J_{sc} in the bi-layer BHJ device is attributable to the increased number of photo induced charge carriers by extended absorption to the solar photons in longer wavelength region. The schematic energy level diagram of the bi-layer BHJ solar cells fabricated from **P**:PCBM and **BTD-TNP**:**PPI** blend with and without TiO_2 layer is shown in Fig. 13. As the HOMO of **P** is at higher energy level than that of **BTD-TNP**, holes from the second layer can effectively pass through the first layer to the anode. The higher value of J_{sc} in bi-layer BHJ may also be due to the increased electric field induced by the additional electric forces related to the concentration gradient of charge carriers across the bi-layer heterojunction. This effect minimizes also the charge recombination.

The incorporation of TiO_2 layer between the active layer and Al electrode further increases the J_{sc} and PCE which is attributed to the increased electron transport in the device as we have discussed earlier. The formation of large polycrystalline domains of copolymer **P** in the first layer induced by the thermal annealing also increased the PCE of both devices with and without TiO_2 layer.

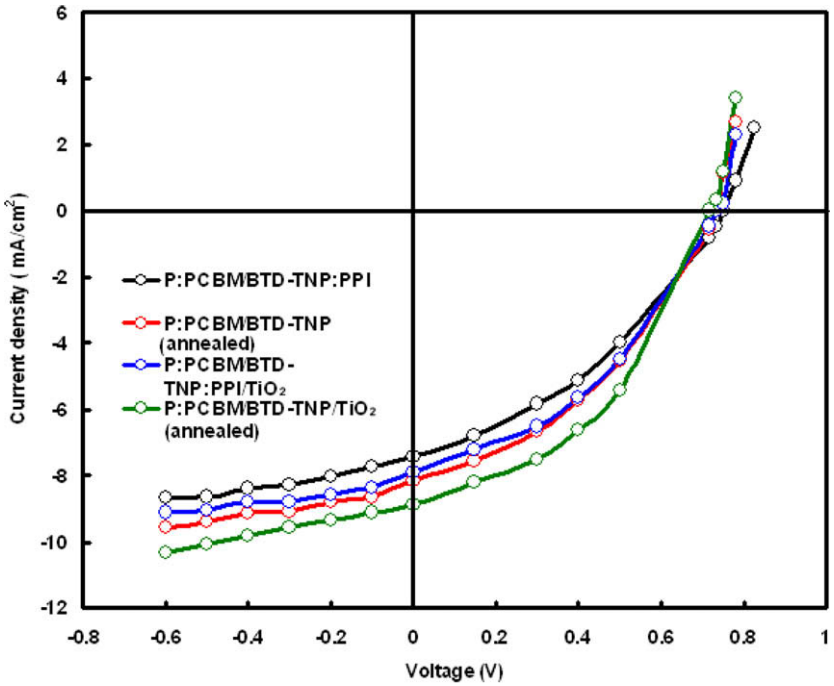

Fig. 12. Current–voltage characteristics of bi-layer BHJ photovoltaic devices with and without TiO_2 (as cast and annealed).

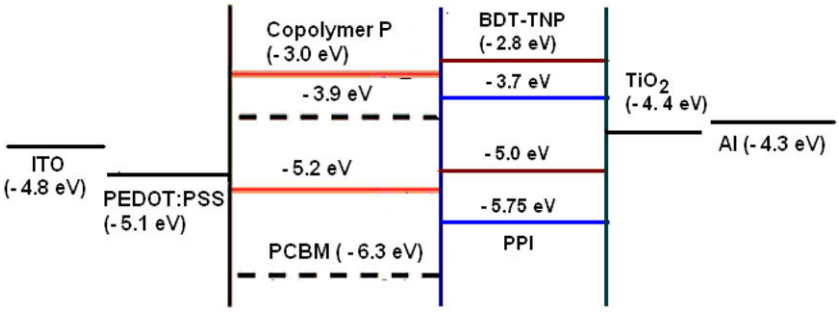

Fig. 13. Schematic energy band diagram of the bi-layer device based on two bulk-heterojunction layer with TiO_2 layer inserted before Al electrode.

In organic solar cells, the photocurrent generation is governed by two main factors [45]: (i) the fractional number of the absorbed photons in the active layer (relative to the total flux of photons from solar spectrum) and (ii) the incident photon to carrier collection efficiency defined as the fraction of collected carriers per absorbed photons. It is observed that in both single layer BHJ and bi-layer BHJ devices, the photocurrent increases when the TiO_2 layer is inserted between the active layer and the top Al electrode. The TiO_2 layer acts as an optical spacer and hole blocker [46] between the photoactive layer and the top Al electrode. The TiO_2 layer redistributes the light intensity within the active layer by changing the optical interference between the incident light and reflected light from Al electrode [47]. This mechanism leads to an increase in the fraction of light absorbed in active layer. In addition, the hole blocking feature of TiO_2 layer also enable the efficient electron collection without a significant increase in series resistance [46].

3. Conclusions

In conclusion, we have fabricated a single layer BHJ device with copolymer **P** and PCBM composites with different wt ratio of **P** to PCBM deposited at different substrate temperatures. It was observed that the single layer BHJ with 1:3 wt ratio shows the optimum PCE of about 1.14% which is further improved upon thermal annealing. The bi-layer BHJ PV device having structure ITO/PEDOT:PSS/**P**:PCBM/**BTD-TNP**:**PPI**/Al shows a PCE of approximately 2.68% which is further improved up to 2.98% upon thermal annealing. This increase was attributed to the enhancement in the hole transport due to the increased crystalline nature of copolymer **P** upon thermal annealing. The incorporation of TiO_2 layer into the active organic layer and the top Al electrode improves the PCE in both single and bi-layer BHJ devices. This increase in PCE is attributed to the enhanced photon absorption, due to the constructive optical interference between the incident light and the reflected light from the Al electrode and also to the hole blocking nature of TiO_2 layer that improves the electron transport. The increase PCE upon thermal annealing has been attributed to the improvement in the hole transport in the device.

4. Experimental

UV–visible spectra of the materials in thin film were recorded on a Beckman DU-640 spectrometer with spectrograde THF. The cyclic voltammetry of materials was performed on a potentiostat–Galvanostat (PGSTAT 30 Autolab, ECO-Chemie, Netherland) in acetonitrile solution (0.1 M) of 4-tert-butylpyridine (TBP) at room temperature. A glassy carbon electrode coated with a thin film of copolymer **P** or **BTD-TNP** or PCBM was used as the working electrode. Pt and Ag wire were used as the counter electrode and quasi reference electrodes, respectively.

All the devices were prepared on indium tin oxide (ITO) coated glass substrates. The substrates were cleaned with detergent, de-ionized water, acetone and isopropyl alcohol successively for 15 min and then dried in an oven. A thin film of PEDOT:PSS (40 nm) was spin cast onto ITO coated glass from aqueous solution. The substrates were dried at 80 °C for 20 min and then cooled up to room temperature. For single layer BHJ devices, the copolymer **P** and PCBM mixture was prepared by co-dissolving **P** and PCBM in 1,2-dichlorobenzene (DCB) at 65 °C. The thin films of copolymer **P**:PCBM blend with different weight ratio were prepared by spin coating a warm solution (60 °C) of blend onto ITO/PEDOT:PSS coated glass substrates and then dried at 60 °C in air. Al metal electrode was deposited on the top of **P**:PCBM blend film to complete the device having structure ITO/PEDOT:PSS/**P**:PCBM/Al. Likewise, another single layer BHJ devices based on **BTD-TNP**:**PPI** blends were prepared by same method as discussed above. The ITO/PEDOT:PSS/**P**:PCBM/TiO_2/Al device was fabricated by the deposition of TiO_2 paste on the top of **P**:PCBM layer before the deposition of Al electrode.

For the bi-layer BHJ devices, the **P**:PCBM (from dichlorobenzene solvent) layer was deposited on the top of ITO/PEDOT:PSS followed by drying at 60 °C for 1 h. The **BTD-TNP**:**PPI** (from chloroform solvent) was then spin cast on the top of **P**:PCBM layer and then dried again at 60 °C for 1 h. Finally, the Al electrode was deposited on the top of active layer by the thermal vacuum evaporation method. The device ITO/PEDOT:PSS/Copolymer **P**:PCBM/**BTD-TNP**:**PPI**/TiO_2/Al was fabricated the by inserting the TiO_2 layer before the deposition of Al electrode. The post-annealing of some devices was conducted by heating at 100 °C for 5 min followed by cooling up to room temperature.

The *J–V* characteristics of the devices in dark as well as under illumination intensity of 100 mW/cm^2, were obtained using a Keithley electrometer equipped with built in power supply. A 100 W halogen lamp was used as light source. The intensity of the illumination was measured with lux meter. The IPCE spectra of the device were calculated by illuminating the device with a halogen lamp using monochromator and measuring the resulting current with Keithley electrometer under short circuit conditions. The fabrication and characterization were performed under ambient conditions.

crystal, to overcome the conductivity mismatch problem of injecting spins from a metallic ferromagnet into a semiconductor [12,13].

Here we present, for the first time, FETs of 5,6,11,12-tetraphenylnaphthacene (rubrene, $C_{42}H_{28}$) single-crystals with high-quality, ferromagnetic Co electrodes and Al_2O_3 tunnel barriers, that can be used for carrier injection without spin randomization. Although the device layout, well-controlled interface, and choice of materials seem ideal for realizing the spin-valve effect, it has remained elusive in our devices so far. Possible reasons are discussed towards the end of the paper, and are expected to evoke both theoretical and experimental follow-up.

Fig. 2a is a photograph of one of our devices, showing the Co/Al_2O_3 electrodes (light bars) underneath a piece of rubrene single-crystal. Cobalt electrodes were chosen for two reasons. First, the reported workfunction of bare Co aligns favorably with the HOMO of rubrene [4], which should help in maximizing the amount of carriers injected from the electrodes into the semiconductor via tunneling (rather than thermal activation over a Schottky barrier). Second, technological processes are known, that allow the realization of a controlled and very thin Al_2O_3 layer on top of the Co film, acting at the same time as a well-defined tunnel barrier and as a protective layer against oxidation of the ferromagnet which is crucial, since CoOx is known to possess antiferromagnetic correlations, which would cause spin-flip scattering, randomizing the carrier spin during the injection. The Co electrodes (16 nm thick) are defined by photolithography on a highly doped Si/SiO_2 (300 nm) wafer and covered with a 2.5 nm Al_2O_3 tunnel barrier. The high-quality, pin-hole-free Al_2O_3 film is formed by plasma oxidation of Al evaporated on top of Co without breaking the UHV (10^{-10} Torr). This Al_2O_3 tunnel barrier prevents the Co electrodes from oxidation and helps to overcome the conductivity mismatch, as mentioned above. After lift-off with acetone, the electrodes are thoroughly cleaned in an oxygen plasma to ensure no resist is left. This is essential, as demonstrated by independent photon emission spectroscopy measurements [14]. Directly after this a rubrene single-crystal is electrostatically laminated on top of the electrodes. The lamination process yields uniform contact without air gaps, bubbles or interference fringes [6]. Similar single-crystal FET geometries were studied before in the case of non-ferromagnetic electrodes [6,8,9].

In order to verify the critical features of our device, we first performed the experiments described below. A Co/Al_2O_3/NiFe(permalloy) magnetic tunnel junction (MTJ [15], see inset of Fig. 1a) was used to check the quality of the Co/Al_2O_3 electrodes after exposure to air, acetone and oxygen plasma cleaning. To mimic the FET device fabrication process, the calibrated 2.0 nm thick Al film (resulting in a 2.5 nm thick layer of Al_2O_3) on top of the Co film (both grown in UHV) is first plasma oxidized for 10 min, exposed to air, covered with photoresist, cleaned by acetone and isopropanol, and oxidized again for 10 min to remove photoresist remnants and clean the bottom electrode. The MTJ is completed by evaporating the NiFe top electrode in UHV again. The magnetoresistance of a representative MTJ thus fabricated, is shown in Fig. 1a. We observe a clear hysteresis and a magnetoresistance (*MR*) of 16%, very close to the value of clean interfaces produced without breaking the vacuum (also shown in Fig. 1a), implying the good quality of the Al_2O_3 tunnel barrier (protecting the underlying Co from oxidation) and its robustness under our FET fabrication process. The realization of air-exposed FM electrodes in an organic spin-valve structure has been demonstrated before [16], but here an additional (and essential) cleaning step is used to remove any organic contaminations.

For spin valves, the ability to reverse the magnetization of the injector and detector electrodes independently is essential [1]. Therefore, the switching fields of both electrodes need to be sufficiently different. The magnetization of the 16 nm Co layer is in plane, and its switching field depends on the ratio between length and width. The switching fields H_{sw} of the Co/Al_2O_3 electrodes for different electrode widths d were determined from test samples with an ensemble of electrodes (see right inset of Fig. 1b), using the same fabrication procedure and substrate as for the FET devices. Hysteresis curves measured in a vibrating sample magnetometer (VSM) clearly reveal sharp switching fields, as shown in the left inset of Fig. 1b for the case of a test sample containing an ensemble

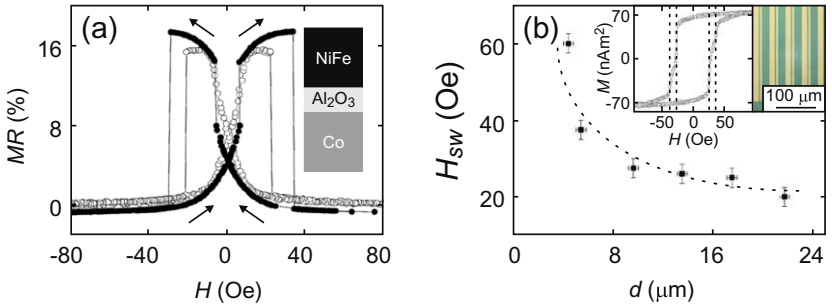

Fig. 1. Electrode characterization. (a) Magnetoresistance *MR* vs. magnetic field *H* for Co/Al_2O_3(~2.5 nm)/NiFe(15 nm) magnetic tunnel junctions (MTJs, inset). Data shown for a MTJ with 16 nm Co layer treated with photoresist, acetone and IPA (open circles) and an untreated one with a 8 nm Co layer (solid dots). *MR* is defined as $(R - R_P)/R_P$, with R_P the resistance for parallel magnetization of the Co and NiFe layers at large magnetic fields. Arrows denote the sweep directions. Different switching fields due to difference in Co layer thickness. (b) Switching field H_{sw} vs. electrode width d for Co/Al_2O_3 (16 nm/2.5 nm) electrodes. The dotted line is a guide to the eye. Left inset: Magnetization *M* vs. magnetic field *H* for electrodes with a width of 5.4 and 13.5 ± 0.4 μm. The switching field H_{sw} for the two widths is denoted by the dashed lines. Right inset: Ensemble of electrodes for H_{sw} measurements.

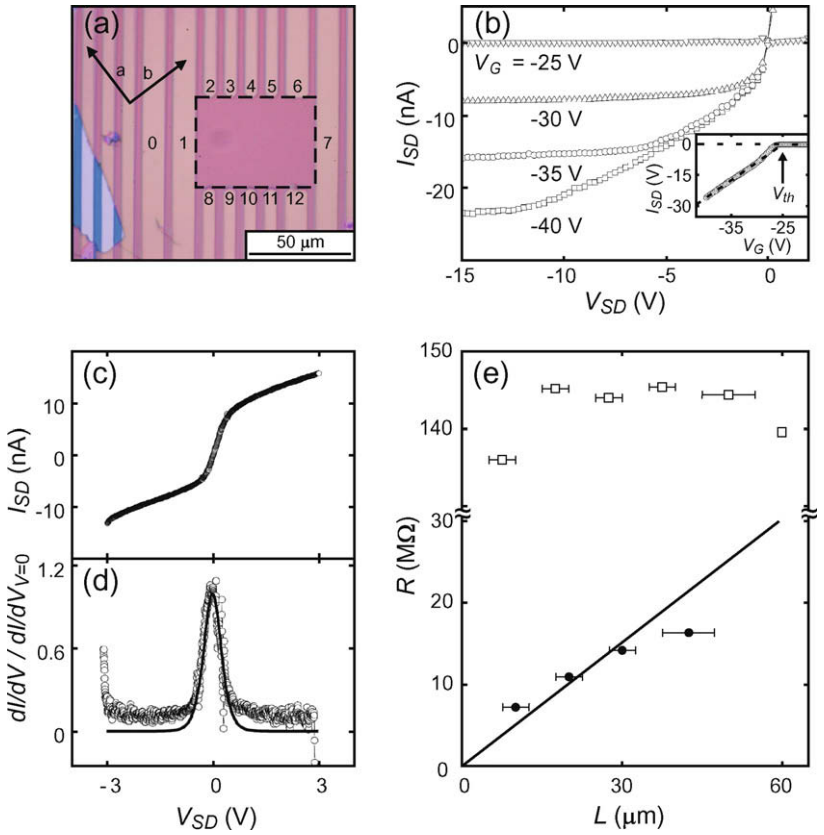

Fig. 2. Single-crystal FET device. (a) Photograph of the rubrene single-crystal (partly) overlapping with Co/Al_2O_3 electrodes (numbered 0–12; other electrodes not used). Electrodes 1, 6, 7 and 12 have 12 ± 0.4 μm width, 2–5 and 8–11, 6.5 ± 0.4 μm. The doped Si substrate is used as back gate. The active device area is denoted by the dashed rectangle, with channel length $L = 60$ μm and width $W = 50$ μm. The crystal axes *a* and *b* (the latter corresponding to the highest mobility) are denoted by the arrows. (b) Source–drain current I_{SD} vs. voltage V_{SD}(electrodes 1 and 7) for different gate voltages V_G. Inset: I_{SD} vs. V_G for $V_{SD} = -10$ V. The threshold voltage $V_{th} = -25$ V is indicated by the arrow. (c) Zoom-in around $V_{SD} = 0$ V($V_G = -40$ V) for the measurements in (b). (d) Normalized differential conductance $dI/dV / dI/dV_{V=0}$ vs. V_{SD}. The line is a fit to the derivative of Eq. (1). (e) Resistance *R* vs. channel length *L* for two-terminal measurements (open squares) for $V_{SD} = -1$ V and 4-terminal measurements (solid dots) for $I_{SD} = -1$ nA (linear regime, $V_G = -40$ V for all measurements). The solid line is a fit to Eq. (3).

of electrodes with two different widths (5.4 and 13.5 ± 0.4 μm). From these VSM measurements the switching field as a function of electrode width is derived, see Fig. 1b. H_{sw} strongly depends on electrode width for $d < 10$ μm, but saturates for wider electrodes.

The multi-terminal single-crystal device of Fig. 2a is characterized using different measurement configurations, and the main characteristics have been reproduced in multiple devices. The negative Si back gate voltage (used to induce holes) is expected to be screened by the Co/Al_2O_3 electrodes, i.e. the charge accumulation should be much lesser on top of the electrodes than at the crystal/SiO_2 interface in between the electrodes. To confirm this, a voltage of −10 V was applied between electrode 0 and 7 for a gate voltage of −40 V. No current larger than 10^{-11} A was measured. We conclude that, although current between adjacent electrodes can flow over the full crystal width, for non-adjacent electrodes there is only a current path through the non-contacted region (channel width $W = 50$ μm, channel length $L = 60$ μm) denoted by the dashed lines in Fig. 2a. Using electrodes 1–12, 2- and 4-terminal measurements are performed. The multi-terminal layout is also suitable for measuring spin accumulation in the so-called non-local geometry [17].

For 2-terminal measurements, the source–drain voltage V_{SD} is applied over electrodes 1 and 7, and the resulting current I_{SD} is measured using the same electrodes. Different contact combinations are discussed later on. I_{SD}–V_{SD} curves for different gate voltages V_G are shown in Fig. 2b. The typical gate leakage current in our devices is $I_{leak} < 10^{-11}$ A. The threshold voltage V_{th} is −25 V (inset of Fig. 2b), obtained from extrapolating the I_{SD}–V_G curves for large V_G (linear regime) to $I_{SD} = 0$. This value is relatively high, and might be related to hole trapping at the SiO_2/single-crystal interface or incomplete lamination of the crystal to the substrate.

The weak gate dependence around $V_{SD} = 0$ V implies that the device resistance is contact-dominated [8,9], as discussed in more detail below. The contact-dominated behavior is expected, since we have a tunnel barrier on top of the Co electrodes. The reasonable contact quality without a large hole injection barrier is demonstrated by

the linearity at $V_{SD} = 0$ V, as can be seen in Fig. 2c [18]. The overall non-linear shape around $V_{SD} = 0$ (see Fig. 2c) can be described by a back-to-back diode model [8]

$$I_{b-b} = I_0 \tanh\left(\frac{eV_{SD}}{2\eta k_B T}\right), \quad (1)$$

where I_0 is the saturation current, η the diode ideality factor, k_B the Boltzmann constant and T the temperature. The normalized differential conductance, obtained by numerical differentiation of the data, can be fitted by the derivative of Eq. (1), as shown in Fig. 2d. The small offset is explained by the fact that I_0 is weakly bias dependent, contrary to what is assumed in the derivation of Eq. (1). We obtain a value $\eta = 7.7 \pm 0.2$, as compared to $\eta = 1$ for an ideal Schottky diode. This high value demonstrates that although Schottky barrier formation plays a role in our devices, tunneling is important [19] and holes are indeed injected in the single-crystal through the tunnel barrier. Temperature-dependent measurements should give more insight into the height of the Schottky barriers.

In the linear regime, the usual FET relation applies

$$I_{SD} = \frac{W}{L}\mu C_i (V_G - V_{th}) V'_{SD}, \quad (2)$$

where C_i the capacitance of the gate insulator per unit area and μ the carrier mobility. Note that V'_{SD} is the voltage drop over the conducting channel, excluding the voltage drop over the electrodes. The channel resistance R_{ch} is determined from 4-terminal measurements. Current is driven between electrodes 1 and 7, the voltage drop is measured using the intermediate electrodes, to study the channel resistance as a function of length, see Fig. 2e (solid dots). Note that the square resistance $R_\square \sim 25\ \mathrm{M\Omega/\square}$ is $\sim 10^3$ times the quantum resistance. By rewriting Eq. (2), R_{ch} is given by

$$R_{ch} = \frac{L}{WC_i(V_G - V_{th})}\frac{1}{\mu}. \quad (3)$$

Fitting to Eq. (3), we extract a hole mobility of $0.25\ \mathrm{cm^2(Vs)^{-1}}$. The relatively low mobility is attributed to contaminations in the starting material (only one purification cycle is used) and the rather long period (∼weeks) between crystal growth and device fabrication. Although the crystals are stored in a nitrogen environment, oxidation cannot completely be ruled out [20]. Optimization of these factors has proven to result in typically 1–10 $\mathrm{cm^2\,(Vs)^{-1}}$ mobilities [21].

The 2- and 4-terminal resistance measurements are compared in Fig. 2e, where the difference is explained by the contact resistance. The normalized contact resistance R_cW of $0.28\ \mathrm{M\Omega\,cm}$ (used in 2D devices) dominates the 2-terminal resistance, as concluded before. This is much higher than contact resistances found for nickel oxide electrodes ($0.1 - 1\ \mathrm{k\Omega\,cm}$) [10] and cobalt oxide electrodes (10–200 $\mathrm{k\Omega\,cm}$) [8]. The high contact resistance in our devices can be explained by the Al_2O_3 tunnel barrier, and implies that charge is injected through the tunnel barrier, as intended.

In spite of the seemingly ideal choices for the spin injecting and detecting interfaces, we have not been able to unambiguously demonstrate a spin-valve effect in our FETs. This could have several reasons. First of all, the spin relaxation time τ_{sf} may be not as long as expected. Based on EPR studies [22], we have assumed a lower bound of 1 μs for τ_{sf}. Using $\lambda_{sf} = \sqrt{D\tau_{sf}}$, where λ_{sf} is the spin relaxation length, D the diffusion constant, and the Einstein relation $D = \mu k_B T/e$, gives $\lambda_{sf} > 1\ \mu\mathrm{m}$, comparable to the present device dimensions. Recently, even much larger values (∼ mm) were predicted for rubrene single-crystals [23]. However, if τ_{sf} is significantly shorter, we should make the channels shorter and/or use crystals with higher mobility. We cannot exclude that τ_{sf} is temperature dependent as well and is longer at lower temperatures. Devices similar to those demonstrated here, with shorter channel length, will provide a well-controlled experimental platform to investigate the conditions for the occurrence of spin injection in organic semiconductors.

In conclusion, we have succeeded to realize well-defined tunnel barriers between ferromagnetic electrodes and organic single-crystals. The high-quality tunnel barrier should allow for spin injection without randomization. This, in combination with the observed FET functionality, provides us with necessary conditions for demonstrating a spin-valve FET. Similar devices are also expected to shine light on the spin relaxation time in organic semiconductors and the underlying physical mechanisms.

sophisticatedly manufactured from a very fine capillary glass tube having a tip diameter of <1 μm.

In contrast to top-down process, Tessler et al. reported a bottom-up approach for conducting polymer patterning based on a hydrophobic SAM formed on a 80 nm thick TiO_2-covered substrate [12]. The SAM exposed to UV light through the photomask became hydrophilic due to the photocatalytic effect of TiO_2 in the exposed regions and enabled the solution-deposition of the conducting polymer via dewetting from the hydrophobic regions during subsequent spin-casting. However, this technique requires a thin TiO_2 layer for the photocatalytic reaction with SAM at a humidity of ca. 40%. Other dewetting techniques had hydrophobic regions defined by microcontact printing for ~3 μm patterning [13] and electron-beam lithography for a 500 nm transistor channel length [14]. However, it should be noted that electron-beam lithography is costly and time-consuming process for large-area applications.

In this work, we propose a hybrid process that combines conventional photolithography and local surface energy modification through hydrophobic treatment in order to fabricate the conducting polymer source/drain electrodes of poly(3-hexylthiophene) (P3HT) organic field-effect transistors (OFETs). This technique is then applied to the fabrication of nanoscale conducting polymer patterns using photoresist (PR) templates, where nanoscale resist features are produced by holographic lithography.

2. Experimental section

2.1. Selective surface energy treatment for microscale polymer patterning

The proposed fabrication process is shown in Fig. 1. In brief, a 50 nm thick silicon oxide (SiO_2) surface on a heavily doped n-type silicon substrate was successively cleaned with acetone, ethyl alcohol, and deionized water in an ultrasonic bath. For the initial hydrophilic surface modification, an oxygen plasma treatment was carried out at 300 W for 60 s. A positive tone PR (AZ-6612, Clariant) solution was spin-coated on the substrate at 2800 rpm for 30 s

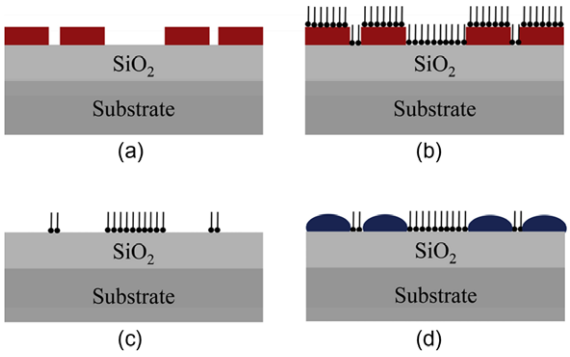

Fig. 1. Schematic of conducting polymer patterning using selective surface modification. (a) Photoresist patterns from conventional photolithography and the subsequent development process. (b) OTS attachment to the exposed substrate surface by self-assembly. (c) After removal of the PR patterns. (d) Conducting polymer solution dispersion; only hydrophilic regions are wet.

and then baked at 100 °C for 1 min. A UV light (λ = 365 nm) irradiated the PR film for 6.7 s through a clear-field photomask on which the desired patterns had been chromium-deposited. After development process, a gentle oxygen plasma treatment was performed at 100 W for 30 s in order to remove any residual PR layer under the trenches and generate hydroxyl groups at the exposed surfaces, which anchor the hydrophobic molecules during the SAM treatment.

The substrate with the PR patterns was immersed into an octadecyltrichlorosilane solution (OTS; 1.5 wt.% in toluene) for 5 min. At above 1.5 wt.%, aggregated OTS molecules were observed in all of the exposed regions. At less than 1.5 wt.%, the wettability contrast did not provide sufficient definition, especially for the 5 μm channel length, resulting in current leakage between the source and drain electrodes. During the OTS SAM coating, the head groups ($-SiCl_3$) reacted with the hydroxyl groups on the substrate surface in the trenches via siloxane linkage, and the alkyl chains underwent van der Waals interaction between each other with the hydrocarbon tail groups ($-CH_3$) exposed to the air, thereby rendering the surface hydrophobic nature. The substrate was then baked at 120 °C for 10 min to remove any residual toluene solvent. After PR pattern removal by acetone soaking for 5 min in an ultrasonic bath, the protected regions underneath the PR patterns remained hydrophilic during the photolithography process and the subsequent OTS treatment. Thus, a substrate with locally varied surface energies was achieved and subsequently utilized for spontaneous polymer patterning.

As a conducting polymer solution, we adopted the aqueous poly(3,4-ethylene-dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) polymer solution (1:2.5 by weight, 1 wt.% solid content, BAYTRON®, PH 500) due to its excellent processing ability, as well as its conducting, transparent, and thin film characteristics. Recent studies have shown that the conductivity of PEDOT:PSS can be dramatically increased with no loss in optical transparency through the addition of a small amount of diethylene glycol dopant [15,16]. In this experiment, diethylene glycol was mixed with PEDOT:PSS (1:10 by volume), and the solution was then dropped and dragged on the specially treated substrate using the doctor-blade method with a razor edge; there were no notable effects of blading direction relative to the feature geometries. The solution was dewetted by the hydrophobic regions and was thus spontaneously confined in the hydrophilic regions during spreading. Next, the sample was left in air for 2 min to allow the solvent to evaporate; at this time the polymer solution contracted, reducing the surface energy, which resulted in contours with sharp edges at the corners. Finally, the conducting polymer patterns were heated at 110 °C for 10 min to increase the conductivity for subsequent use as the source and drain electrodes of OFETs.

2.2. Nanoscale polymer patterning

Laser interference lithography (i.e., holographic lithography) was used to fabricate nanoscale periodic PR patterns because it can produce nanoscale features with ease. In brief, a diluted positive PR (AZ6612, Clariant) with

a thinner (AZ1500, Clariant) (volume ratio = 1:2) was spin-coated to a 150-nm thickness on a clean substrate that had previously been coated with hexamethyldisilazane (HMDS; above 98%, Fluka). Next, one-beam interference lithography method was utilized at an incident angle (θ) of 7.18 to fabricate repeated PR line patterns having a line-width of 290 nm at a 1.3 μm pitch size. A UV laser beam from the He–Cd ion laser (325 nm) was then passed through a spatial filter consisting of several lenses and a pin hole (10 μm diameter) in the end, where diffraction-limited beam enhancement occurs; this enhanced beam was projected onto the angle bracket where the sample holder and Lloyd mirror were placed perpendicular to each other. The PR was exposed to light for 50 s, equivalent to a dose of 30 mJ/cm^2, with a sinusoidal intensity owing to the constructive and destructive interference between the two split beams, one directly from the laser and the other reflected from the Lloyd mirror.

A specific pitch size was determined by $\Lambda = \lambda/2\sin\theta$, where θ is the incident angle, Λ is the pitch size of the pattern, λ is the laser wavelength, and the exposure time was optimized for the specific line width. After laser exposure, a developing process was performed by dipping the entire substrate into MIF 300 solution for 30 s and then rinsing with deionized water.

However, the solution-based SAM coating method used for microscale features did not work well for the nanoscale PR features due to the incomplete wetting to such confined areas caused by trapped air bubbles that prevented direct contact of the solution to the bottom of the exposed substrate surface between the PR features. Therefore, we applied a hydrophobic treatment in vapor phase using a tridecafluoro-1,1,2,2-tetrahydrooctyltrichlorosilane (Gelest Inc., CF_3–$(CF_2)_5$–$(CH_2)_2$–$SiCl_3$), which is commonly used as an anti-sticking material for the stamp surface treatment in nanoimprint lithography [17]. Perfluorocarbon-based trichlorosilanes have been reported to significantly decrease the stiction and friction of surfaces compared to hydrocarbon-based surface coatings [18].

A substrate with nanoscale PR features was loaded into a custom-built glass vacuum chamber and then pumped down to 10^{-3} torr. Then the pump was isolated from the chamber and the vapor of the hydrophobic material was then introduced into the chamber through a needle valve. The container of the hydrophobic agent solution was kept at 80 °C in order to maintain sufficient vapor pressure; this process was kept for 10 min at a static pressure of 0.3 torr. Next, the valve supplying the vapor of the hydrophobic material was closed and a second needle valve connected to a container partially filled with DI water was opened to allow water vapor into the chamber. The chamber was maintained for another 10 min at a total pressure of 0.8 torr in order to cross-link the neighboring attached molecules via a condensation reaction. Such a condensation reaction can produce a dense network within the monolayer on the substrate surface [19]. Finally, the chamber was again pumped down to a pressure 10^{-3} torr and the cycle was repeated twice more.

After removing the PR patterns with acetone, the polymer solution was cast on the substrate with locally different surface energies by using a multi-step spin-coating method; 1000 rpm for 10 s, 3000 rpm for 20 s, and 5000 rpm for 20 s.

3. Results and discussion

3.1. Surface energy measurement

To investigate the surface energy variation at each process step, the contact angle was measured with water at room temperature and then converted into surface energy using the Good–Girifalco–Fowkes–Young (G–G–F–Y) equation [20]:

$$(1+\cos\theta)\gamma_{LV} = 2(\gamma_{SV}\mathbf{V}_{LV})^{1/2}$$

where γ_{LV} is the surface tension of the test liquor (water; 72.8 dyne/cm), θ is the contact angle, and γ_{SV} is the surface energy of the medium of interest. Table 1 presents the results of contact angle measurements and their corresponding calculated surface energies at each step.

The initial surface treatment with oxygen plasma gas produced a very hydrophilic surface with a contact angle of 2.2°, equivalent to a high surface energy of 89.8 mN/m. The contact angle of the exposed substrate surface after development increased to a value of 14.2°. The surface became hydrophobic after application of the OTS SAM coating, attaining a contact angle of 97.7°, equivalent to a surface energy of 16.8 mN/m; this region was thermodynamically stable such that the surface is unlikely to react to other chemical elements.

The initial hydrophilic nature of the region under the PR pattern remained after PR removal, though the value increased to 26.8° due to the instability of the surface Si–OH groups with time. During the sequential processes for PR patterning and removal, the increase in contact angle is associated with a decrease in hydroxyl group coverage on the surface through the dehydration reaction between two neighboring hydroxyl groups, leading to the formation of a siloxane (Si–O–Si) bond [21]. The contact angle was 15° immediately after PR removal, and increased to 26.8° after 10 min in air. As such, polymer solution dispersion was completed within 10 min after PR removal. This selective surface engineering drives the spontaneous patterning of the conducting polymer solution, covering energetically unstable surfaces of hydrophilic regions with a high surface energy.

Table 1
Contact angle measurement and corresponding surface energy calculated at each step.

Experimental process		Contact angle (°)	Surface energy (mN/m)
Initial oxygen plasma treatment		2.2	89.8
Exposed area	After development	14.2	87.1
	After OTS treatment	97.7	16.8
Protected area	After PR pattern removal	26.8	80.5
On PEDOT:PSS film		7.6	19.7

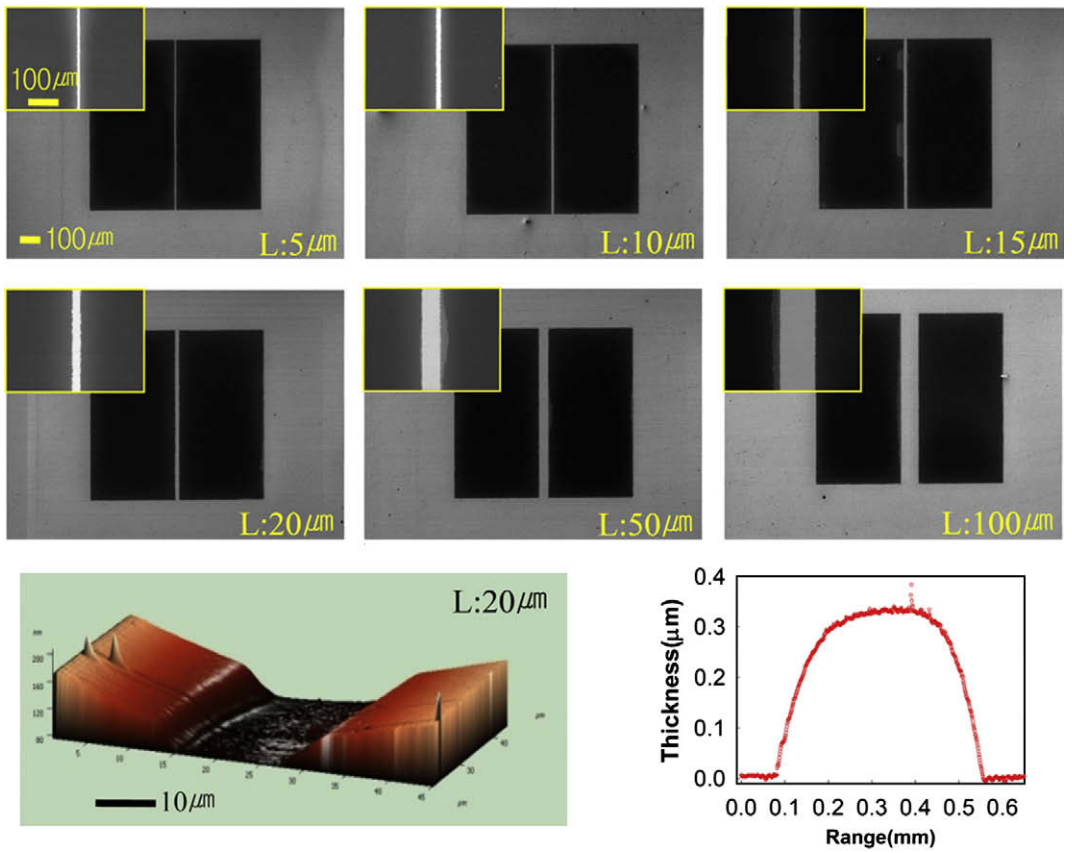

Fig. 2. (a) FE-SEM images of the conducting polymer source/drain electrodes with channel lengths from 5 to 100 μm. (b) AFM image of the surface morphology at the 20 μm gap. (c) Surface profile of a 500 μm wide conducting polymer electrode.

The contact angle of the DEG-PEDOT:PSS film deposited on the hydrophilic region was also measured using water. Water was dropped through a syringe and wet the DEG-PEDOT:PSS film at a contact angle of 7.6°, corresponding to a surface energy of 89 mN/m. This illustrates that the DEG-PEDOT:PSS solution has a high affinity to water, which is driving force for spontaneous wetting in the localized hydrophilic regions.

3.2. Results of microscale polymer patterning

Fig. 2a presents SEM images of conducting polymer patterns (500 μm × 1000 μm) at gaps ranging from 5 to 100 μm. The polymer patterns exactly reproduce the corresponding photomask patterns via the proposed patterning method. The solution wets the pre-determined hydrophilic areas. The significant outcomes are that the gap is clearly defined along the 1000 μm length even at 5 μm gap and that no cracks are observed within the polymer patterns.

Fig. 2b shows the AFM image of the surface morphology of the 20 μm gap, where it can be seen that the conducting polymer solution is well confined at the hydrophilic region at that resolution during dispersion. Fig. 2c represents the thickness profile of the polymer pattern measured by surface profiler (Alpha-Step IQ, KLA Tencor); the polymer electrode has a maximum thickness of 380 nm at the center. When a liquid interfaces with air, the molecules at the interface have a higher energy than that of the interior molecules; therefore, the eventual curvature of the thickness profile shown in the figure is formed to minimize the surface area and thereby reduce its surface energy.

These conducting polymer patterns were subsequently used as the source/drain electrodes in OFET devices. Using the four-point probe method, the conductivity of the conducting polymer pattern was measured to be ca. 400×10^2 S/cm. The polymer electrodes for the bottom contact OFETs (BC-OFET) were fabricated on top of a 50-nm thick gate insulating layer of silicon oxide that was grown on the heavily doped n-type silicon substrate. A prior study investigating the surface-treatment effects on the performance of OFETs indicated that OTS treatment of the gate dielectric layer increased the crystallinity of the semiconducting active material and hence carrier mobility [22]. In our case, as the exposed silicon oxide surface between the source/drain polymer electrodes was already coated with OTS during the selective hydrophobic treatment, 1 wt.% of P3HT solution in chloroform was spin-coated without further treatment and then baked at 125 °C for 20 min inside a nitrogen glove box.

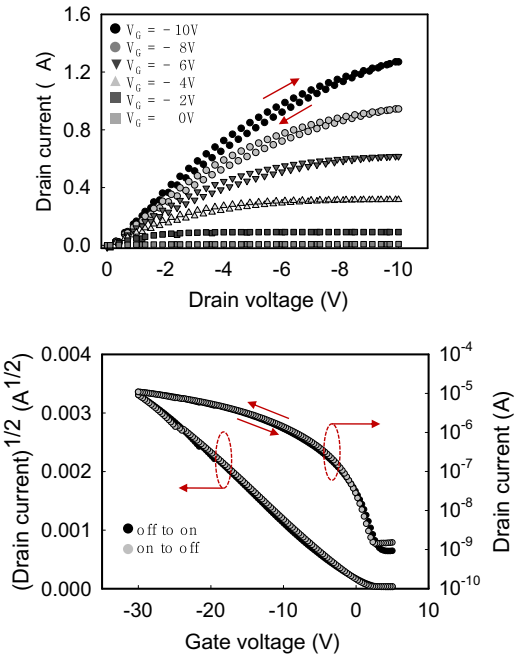

Fig. 3. (a) Output curves and (b) transfer characteristics, swept in both directions, of the P3HT OFFTs with the PEDOT:PSS source/drain electrodes fabricated using the selective surface engineering technique with channel width/length of 1000 and 5 μm, respectively.

Fig. 3a shows the typical transistor output curve at gate voltages from 0 to −10 V of BC-OFETs for a channel width/length of 1000 μm/5 μm. Fig. 3b shows the corresponding transfer characteristics in both forward and reverse scan and the calculated field-effect mobility and the threshold voltage are obtained from plots of the square root of $|I_D|$ in the saturation region at $V_D = -30$ V as a function of V_G (from +5 V to −30 V). All the measurements were performed in a nitrogen glove box. The output curves demonstrate a slight hysteresis phenomenon due to the hydroxyl groups at the surface of SiO_2 gate dielectric layer inherently remained after the selective surface treatment. The hydroxyl groups in the semiconducting materials or at the interface are reported to act as charge trapping sites, being negatively charged, and cause the hysteresis depending on the amount of hydroxyl groups [23]. Impurities such as moisture, oxygen and mobile ions also bring about large hysteresis in the device characteristics [24]. However, as the OFETs were fabricated and measured in dried nitrogen atmosphere in this experiment, the hysteresis was not noticeable, especially in transfer characteristics at the scan from $V_G = 5$ to −30 V and back to 5 V.

The charge carrier mobility in the saturation region is determined by the equation:

$$|I_D| = \frac{W}{2L}\mu C_i (V_G - V_T)^2$$

where C_i is the capacitance per unit area of gate insulator (50-nm thick silicon oxide, 69 nF/cm^2), W/L is the ratio of channel width to channel length, V_T is the threshold voltage, and μ is the charge carrier mobility of the OFET. For our device, the charge carrier mobility was calculated to be 1.4×10^{-3} cm^2/V s at a threshold voltage of 0.2 V and an on/off current ratio of 1.2×10^4. With increasing the channel length, the mobility was enhanced to 2.5×10^{-2} cm^2/V s ($L = 100$ μm) due to the reduced short channel effect.

Our device performance is comparable to other transistors with PEDOT:PSS conductive electrodes fabricated by different methods. For instance, Cho et al. reported transistors having ink-jet printed source/drain electrodes that were fabricated using a modified PEDOT:PSS solution (channel lengths from 25 to 150 μm) on P3HT film [25]. The devices had an average carrier mobility of 6.0×10^{-3} cm^2/V s in the saturation region regime ($V_d = -80$ V), V_T of 6 V, and on/off current ratio of 10^3. In addition, Azumi group demonstrated the microcontact printing of PEDOT:PSS solution as the source/drain electrodes for a channel length of 12 μm on P3HT film, with a carrier mobility of 1.7×10^{-3} cm^2/V s, and an on/off current ratio of 6.0×10^4 [26].

3.3. Nanoscale polymer line patterning

Fig. 4a shows the SEM image of separate PR line patterns after development with a linewidth of 290 nm, spacing of 1 μm, and a thickness of 120 nm, which was fabricated using an interference lithography technique. Its corresponding AFM image (Fig. 4b) illustrates a PR template ready for the local surface energy treatment.

After hydrophobic treatment in vapor phase, several trials using the doctor-blade method for polymer solution dispersion ended up with no polymer patterning at such a tiny scale; the solution covered the whole substrate because the generated solution film was too thick to be confined into the nanoscale hydrophilic line areas. Instead, a multi-step spin-coating method was utilized to produce nanoscale polymer patterns. Preliminary experiments with single-step casting at a low spin speed generated polymer coverage over the entire substrate similar to the doctor-blading results; at a high speed, all the polymer solution was spinned off before the substrate surface was wetted. Therefore, the spin speed was stepwise increased in order to provide a relaxation period to allow the polymer solution to equilibrate to the local surface energy.

Fig. 4c shows that the polymer line patterns are well matched with the feature size of the PR template; 292 nm wide lines at 1 μm spacing. However, some polymer residue can still be seen between the polymer lines in the AFM image (Fig. 4d). The cross-sectional surface profile (Fig. 4e) illustrates that 30 nm thick polymer nanolines were generated by using the multi-step spin-coating method.

4. Conclusions

In summary, a new process for conductive polymer patterning that combines conventional photolithography and self-assembly monolayer deposition of a hydrophobic material was proposed. As the regions protected by the

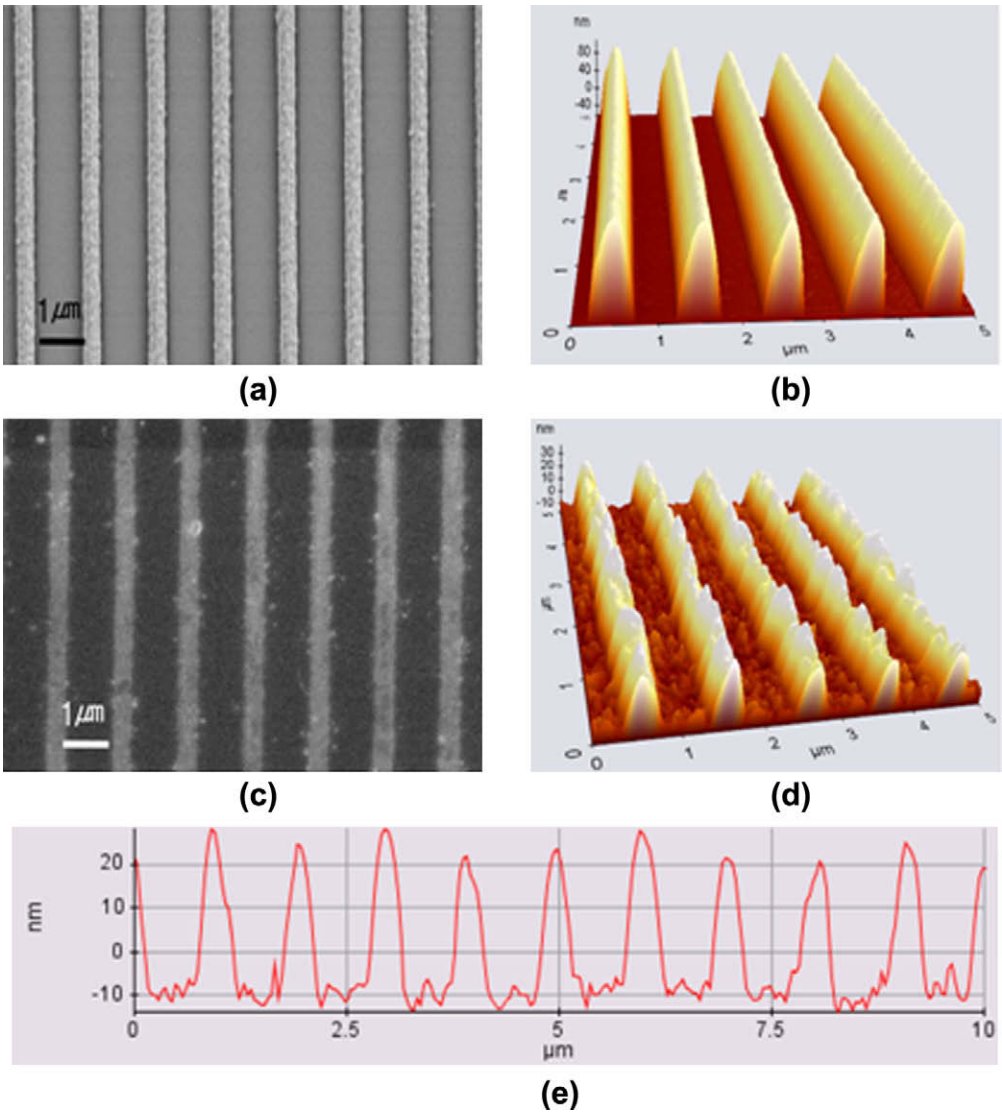

Fig. 4. (a) FE-SEM image of the nanoscale PR features produced by holographic lithography and (b) its corresponding AFM image. (c) FE-SEM and (d) AFM images of the nanoscale polymer line patterns with a width of 292 nm at 1 μm spacing produced by using the polymer template of (a). (e) Cross-sectional surface profile of the polymer line patterns.

photoresist patterns remained hydrophilic following the photoresist removal, a chemically patterned substrate with locally different surface energies was generated. Based on this process, we fabricated P3HT organic semiconducting field-effect transistors using the PEDOT:PSS source/drain electrodes formed by selective dewetting. The device showed a comparable transistor performance to previous devices: a field-effect mobility of 1.4×10^{-3} $cm^2/V\,s$; a threshold voltage of 0.2 V; and on/off current ratio of 10^4 at a 5 μm channel length. In addition, the polymer solution effectively wetted the nanoscale hydrophilic regions, predetermined by holographic lithography and subsequent selective hydrophobic treatment in vapor phase. As a result, nanoscale polymer lines with a linewidth of 292 nm at 1 μm spacing were reliably fabricated by the multi-step spin-coating method. In the near future, it is expected that this technique could be applied to solution-processible plastic electronics.

the versatile Suzuki coupling polymerization reaction, leading to fluorene-based polymers with additional functional components. To this end, various comonomers such as thiophene derivatives [7], benzothiadiazole [8], phenoxazine [9], triphenylamine [9,10], carbazole [11], quinoxaline, quinoline [12], triphenylamine-based hydrazone derivatives [13] and triazine, oxadiazole and cyano-substituted phenylene [14] have been incorporated into the polymer main chains or side chains. Although the addition of copolymerized monomer units can lead to a relatively large luminous efficacy, up to approximately 10 cd/A (see below), their role is not well understood [15]. It is generally agreed that their introduction can result in more "balanced" electron and hole contributions to the total current density [15]. However, it is still an issue of current debate whether their introduction then improves the recombination efficiency (as a result of more equal injected electron and hole current densities) or the light-outcoupling efficiency (as a result of a shift of the recombination profile to a region more close to the device centre where electrode quenching is less strong).

For the specific case of OLEDs based on fluorene-based polymers of the Sumation LUMATION™ blue series, containing copolymerized hole-transporting units (HTUs), Coehoorn et al. argued that the HTUs facilitate hole injection from the commonly used poly(3,4-ethylenedioxythiophene):poly(styrenesulphonic acid) (PEDOT:PSS) anode into the highest occupied molecular orbital (HOMO) states of the polymer [16]. Although this leads to more balanced electron and hole contributions to the total current density, the balance was still found to be voltage-dependent, resulting in a distinct maximum in the voltage dependence of the luminous efficacy and external quantum efficiency. From a device modeling study, it was argued that the efficiency maximum was predominantly due to a maximum in the recombination efficiency; the shape of the recombination profile was found to be only weakly dependent on the voltage. Similarly, Laquai and Hertel observed an efficacy maximum for OLEDs based on blue-emitting spirobifluorene polymers containing HTUs [17]. For the two concentrations of triarylamine HTUs studied, the maximum efficacy was found to be strongly different. In their analysis, the authors interpreted this as an effect of the different hole mobilities in these systems, affecting the position of the recombination zone within the light-emitting layer, and thereby the light-outcoupling efficiency.

So far, studies of the effects of the introduction of comonomers in blue light-emitting fluorene-based polymers on the OLED device performance have focused on materials containing one single type of comonomer [2–8,10–17]. In this paper, we present the results of a systematic study of OLEDs based on blue-emitting fluorene copolymers that contain *two different types of comonomers* with similar optical energy gaps but with different contributions to the hole mobility. This allows us to change the hole mobility either by changing the concentration of HTUs of one type, or by changing the ratio of HTUs of both types without changing the overall HTU concentration. The effect of the hole mobility can thus be studied in two independent ways. The luminous efficacies for some of the copolymers studied are shown to be high in comparison to those that were reported in the literature for devices based on other fluorescent fluorene-based OLED systems. Absolute measurements of the photoluminescence quantum efficiency (PLQE) of all examined materials are performed, which allows us to distinguish the effects on the luminous efficacy due to charge carrier mobility changes and due to changes of the radiative decay probability when varying the monomer concentration. As in the previous studies referred to above, again a maximum in the voltage-dependent efficacy is found. The position of the efficacy maximum and the efficacy at the maximum (corrected for the PLQE) are shown to be determined both by the hole mobility. By varying the hole mobility, it is therefore possible to tune the voltage dependence of the efficacy such that at the desired brightness the power conversion efficiency is optimal.

It is found that the observed voltage dependence of the efficacy can be understood well from a recently developed drift–diffusion device model [18]. The model takes advantage of recent developments in the field of OLED device physics, which have elucidated the roles of charge carrier diffusion [19,20], energetic disorder [21–23], and charge carrier injection [24]. It is considered more realistic than the drift-only device model used in Ref. [16], from which it was argued that the efficacy maximum is mainly due to the voltage dependence of the recombination rate (see above). The analysis shows that the presence of an efficacy maximum can already be explained from the voltage dependence of the light-outcoupling efficiency, but that the recombination efficiency also affects the shape of the efficacy curves, in particular at small voltages.

In Section 2, an overview is given of the copolymers studied and of the luminous efficacies measured for OLEDs based on these materials. The results of more in-depth studies of the energy level structure and of the PLQE are given in Section 3. In Section 4, current–voltage curves measured for separate unipolar (hole-only and electron-only) devices are presented and analyzed. An analysis of the composition dependence of the measured voltage dependence of the luminous efficacy using the results of device simulations is given in Section 5. Section 6 contains the conclusions. In the Appendix, details are given concerning the polymer synthesis, the device fabrication and the measurement methods employed in Sections 2 and 3.

2. Polymer structures and OLED device performance

The structure of the fluorene copolymers synthesized for this study is given in Fig. 1(a). The polymers consist of two different fluorene monomers, A and B, and two amine comonomers, C and D, with concentrations x_A = 50 - mol-%, $x_B = (50 - x_C - x_D)$ mol-%, x_C and x_D, respectively. The use of two different fluorene monomers increases the solubility and enhances the degree of structural disorder, so that the layers obtained from spin coating may be characterized as fully amorphous. The compositions of the 10 copolymers studied are given in Fig. 1(b). Details of the synthesis method, and of the device fabrication and optical measurements discussed below, are given in the Appendix.

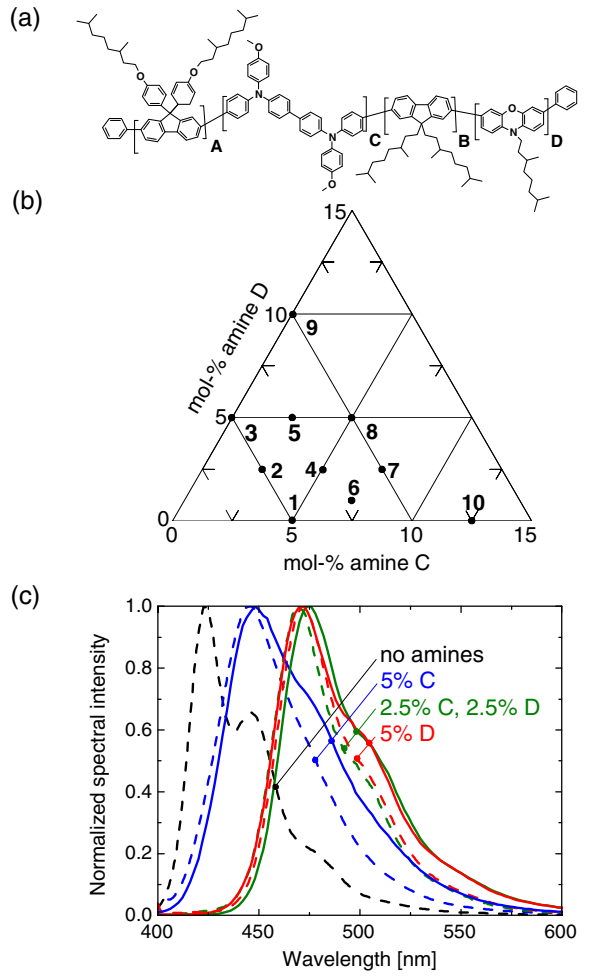

Fig. 1. (a) Structure of the fluorene copolymers described in this paper, comprising the fluorene monomers A and B and aromatic amine comonomers C and D (top). (b) Diagram showing the concentration of the comonomers C and D for the 10 copolymers studied. Horizontal lines connect points with equal values of x_D, from $x_D = 0$ (baseline, mol-% C axis) to $x_D = 0.15$ (top of the diagram). Lines parallel to the mol-% D axis connect points with equal values of x_C, from $x_C = 0$ at the mol-% D axis to $x_C = 0.15$ at the lower-right vertex of the diagram. (c) Normalized electroluminescence (EL) spectra (full, at $V = V_{max}$) and photoluminescence (PL) spectra (dashed) for copolymers **1**–**3**. Also the PL spectrum for a copolymer without amine co-monomers but with a random sequence of fluorene monomers A and B is included.

From a study of the electronic structures of the 10 copolymers using cyclic voltammetry, it follows that in all cases the hole mobility is due to hopping between the C and D guest monomers, whereas the electron mobility is due to hopping between conjugated polyfluorene segments. The ionization potentials were determined in solution and yielded estimated HOMO levels of 5.3 ± 0.1 eV with respect to the vacuum level. These values are comparable to those reported in the literature for comparable fluorene copolymers [6,25,26]. The ionization potential is smaller than in the polyfluorene host (5.8 eV). Previous studies by Doi et al. [2] and Spreitzer et al. [3] showed that incorporating guest sites with a reduced ionization potential into a host material with a (much) higher ionization

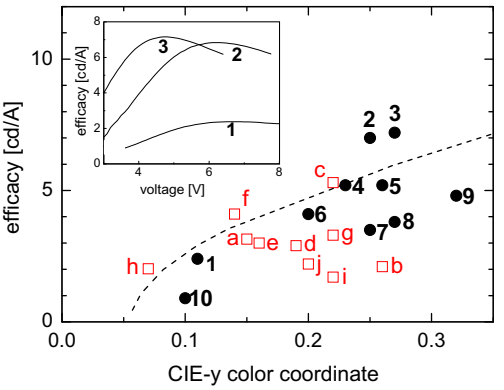

Fig. 2. Maximum luminous efficacy for the single layer OLEDs studied in this paper (full circles, see Fig. 1(b)) and for fluorescent fluorene-based copolymers, oligomers and/or single molecules, taken from the literature [3] (empty squares), as a function of the CIE(1931)-*y* coordinate. The dashed curve gives (in arbitrary units) the increase in luminous efficacy with increasing CIE-*y* coordinate which would be expected in the case of equal internal quantum efficiencies (see text). The inset shows the luminous efficacy of OLEDs based on fluorene copolymers **1**–**3** as a function of the applied voltage.

potential yields a critical guest concentration mobility below which the guest sites act as hole traps, and above which transport of holes proceeds predominantly via these sites. For all polymers investigated in this paper, with at least 5 mol-% of aromatic amines, the hole transport is in the second regime. The electron affinities were measured in film and gave estimated lowest molecular orbital (LUMO) levels of 2.1 ± 0.1 eV. The LUMO level coincides with the LUMO level of the polyfluorene host material, for which the single-particle HOMO–LUMO energy gap is known to be 3.6 ± 0.1 eV from X-ray photoelectron-spectroscopy and ultraviolet photoelectron-spectroscopy on poly(9,9-dioctylfluorene) [27].

For each copolymer studied a large number of nominally identical OLEDs were fabricated with the following stack structure: ITO (100 nm)/PEDOT:PSS (100 nm)/light-emitting polymer (LEP, 80 nm)/barium (5 nm)/aluminum (100 nm). Measurements of the perpendicular electroluminescence (EL) spectra showed a slight variation of the emission color, as shown in Fig. 1(c) for copolymers **1**–**3** (full lines). The color varies from blue for copolymers **1** and **10** containing only comonomer C to blue–green for copolymer **9**, containing the largest fraction of comonomer D. The small difference in optical gaps for amines C and D is within the error margin of the determination of the HOMO and LUMO energies. The difference may also be in part due to a slightly different exciton binding energy.

Measurements of the voltage dependence of the luminous efficacy, η_L, showed excellent reproducibility. For all polymers studied, η_L revealed a maximum, $\eta_{L,max}$, at a distinct value of the voltage, V_{max}. In Fig. 2, the full circles give for each copolymer $\eta_{L,max}$ as a function of the CIE-*y* coordinate of the EL spectrum measured at $V = V_{max}$. The CIE-*x* coordinate was almost equal for all polymers, *viz.* 0.14–0.15. For the LEP layer thicknesses studied (80 nm), almost no voltage dependence of the emission color was found, in all cases less than 0.01 CIE-*y* units. In the inset, the voltage

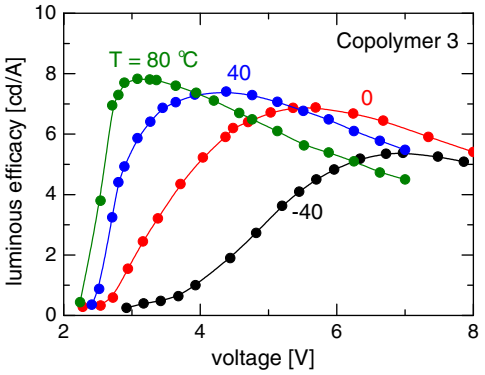

Fig. 3. Luminous efficacy of OLEDs based on copolymer 3 (5 mol-% amine D) as a function of the voltage, measured at various temperatures.

dependence of η_L is shown for the copolymers **1**–**3**. The figure shows that $\eta_{L,max}$ is strongly dependent on the amount and type of aromatic amine guest comonomer. For example, the value of $\eta_{L,max}$ of copolymer **3** is more than a factor of 2 larger than that of copolymer **8**, with essentially the same CIE-*y* coordinate. The variation can only in part be attributed to the varying eye-sensitivity to the EL spectrum, as may be concluded from a comparison with the trend shown by the dashed curve. The curve gives the effective eye-sensitivity (in arbitrary units) as a function of the CIE-*y* coordinate, based on a wavelength shifted EL spectrum of one selected material. The shape of the dashed curve was found to remain essentially identical when using the actual EL spectra of the copolymers **1**–**10**.

The luminous efficacy of the copolymers **2** and **3** may be considered high in comparison to the other copolymers studied here and to other fluorescent fluorene-based OLED systems that were reported in literature (open squares in Fig. 2, see figure caption). We note that higher efficacies, up to ~10.3 cd/A, were reported by Gohda et al. [28k]. However, in their study an additional 20 nm thick interlayer is included in between the PEDOT:PSS and the fluorene-based LEP layer which may be expected to positively affect the light-outcoupling efficiency by shifting the recombination away from the anode layer, thereby reducing electrode quenching. We find that the values of the maximum efficacy and of V_{max} show a significant temperature dependence, as shown in Fig. 3 for copolymer **3**. At 80 °C, $\eta_{L,max}$ has increased to almost 8 cd/A, observed at V_{max} = 3.0 V. A qualitatively similar temperature dependence of the efficacy curves was found for copolymer **2**. No (copolymer **2**) or only a weak (copolymer **3**) temperature dependence of the emission color in the maximum were observed. For copolymer **3**, the CIE-*y* coordinate decreased by 0.03 from −40 °C to +80 °C, whereas the CIE-*x* coordinate did not change. Therefore, the observed increase of the efficacy at $V = V_{max}$ can not be attributed to an increased eye-sensitivity to the emitted spectrum.

For all polymers studied, the observed ionization energies (5.3 ± 0.1 eV) are very close to the work function of PEDOT:PSS (~5.2 eV). Efficient hole injection is thus expected to take place for all devices studied. Therefore, the observed deviations of the maximum luminous efficacy from the variation in the eye-sensitivity, given by the dashed line in Fig. 2, are not related to differences in the injection efficiency. We demonstrate in this paper that the main factor which determines the voltage dependence of the luminous efficacy curves shown in Figs. 2 and 3 is the hole mobility. For that purpose, we first analyze in more detail in the next section the composition dependence of the external quantum efficiency.

3. Analysis of the external quantum efficiency

Fig. 4(a) shows in a way complimentary to Fig. 2 that the observed trends in the maximum luminous efficacy cannot be explained fully from the composition dependence of the eye-sensitivity to the EL spectrum. The figure gives the composition dependence of the external quantum efficiency (EQE, η_{EQE}) at $V = V_{max}$. The value of $\eta_{EQE,max}$ is largest for the copolymers **2** and **3**, with a 5 mol-% aromatic amine concentration, *viz.* up to 4.1 ± 0.2% for copolymer **2**. With increasing amine concentration, $\eta_{EQE,max}$ decreases. For copolymer **9**, with 10 mol-% of amine D, $\eta_{EQE,max}$ is lower by approximately 30%. And at comparable concentrations of amine C, $\eta_{EQE,max}$ has already dropped by a factor of ~3.

For fluorescent OLEDs, the EQE may be expressed as

$$\eta_{EQE} = \eta_{rec} \times \eta_S \times \eta_{rad} \times \eta_{oc}, \quad (1)$$

with η_{rec} the recombination efficiency, i.e. the fraction of injected charge carriers that actually recombine to form an exciton, η_S the fraction of singlet excitons formed upon recombination, η_{rad} the radiative decay probability of the singlet excitons, and η_{oc} the light-outcoupling efficiency. As a first step in our investigation of the cause of the variation of η_{EQE}, we study the photoluminescence quantum efficiency (PLQE, η_{PL}) of each copolymer in film.

The PLQE was measured using 80 nm polymer films spin coated on glass, using the integrating sphere method [29–31]. By carrying out the experiments for thin films on glass, instead of using the OLED devices, microcavity effects on the light absorption and emission related to the presence of metallic electrodes were avoided. Details are given in the Appendix. Examples of measured PL spectra are included in Fig. 1(c), for copolymers **1**–**3** and for a copolymer containing no HTUs but based on a random mixture of fluorene units as described in Section 2. A small red-shift is observed when going from copolymer **1** (5% C) to copolymer **2** (2.5% C, 2.5% D), corresponding to a photon energy difference of ~0.15 eV, similar to the shift observed in the EL spectra for these copolymers. We believe that the radiative decay of excitons in all copolymers (**2**–**9**) which contain amine D takes preferentially place at these amines, or from a charge transfer state involving these amines. As shown in Fig. 4(b), η_{PL} is found to be in between 42% and 59%. The systematic experimental error, predominantly in the system calibration, is approximately 5–10%. For a film of the reference fluorene homopolymer poly(9,9-dioctylfluorene) (PFO), spin coated from toluene (1% by weight solution), we measured η_{PL} = 52%. Ariu et al. reported η_{PL} = 53% for films of this material, spin coated from chloroform solution [32]. For comparison, Kanicki et al.

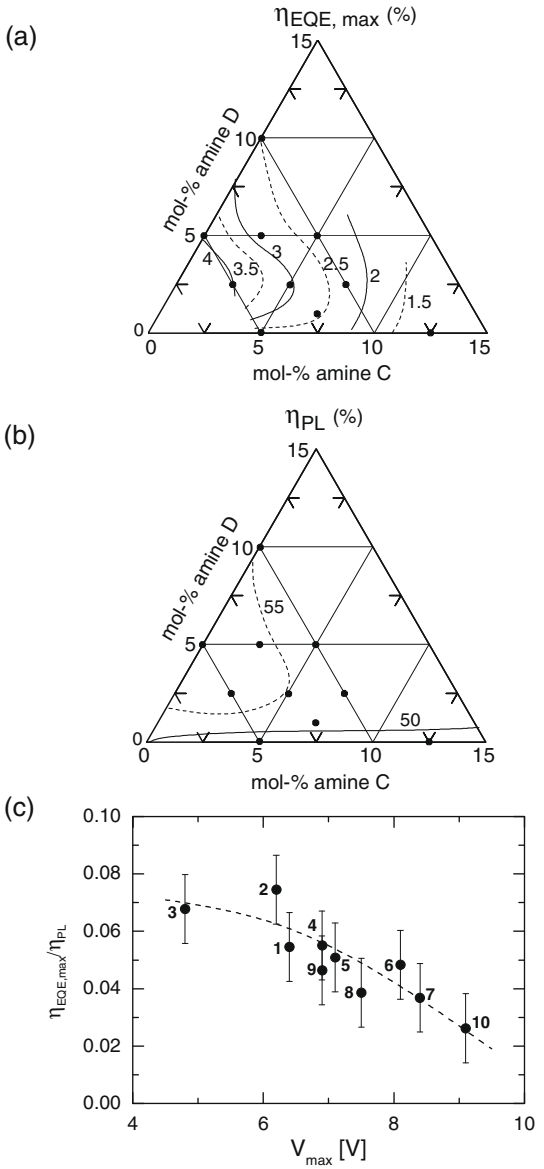

Fig. 4. (a) Composition dependence of the maximum EQE. (b) Composition dependence of the PLQE. (c) Ratio of the EQE the PLQE as a function of V_{max}, for copolymers **1**–**10**. The dashed line is a guide-to-the-eye. In figures (a) and (b), the contour lines are guides to the eye, and are based on data given in Table 1 (Appendix).

reported η_{PL} = 31% for a blue light-emitting polymer of the Dow Chemical Corp. [26] and Coehoorn et al. reported η_{PL} = 60% for a Sumation LUMATION™ blue series fluorene-based copolymer [16].

The effect on the PLQE of introducing the aromatic amine comonomers C or D into the fluorene backbone is, at the concentrations considered, at most 10%. The observation that in some cases the PLQE exceeds that of PFO may be a consequence of an increase in structural and/or energetic disorder, limiting the exciton diffusion length. The use of fluorene monomers of two different types (A and B) and the introduction of amine comonomers into the fluorene backbone is expected to reduce the quenching that Ariu et al. related to the ordered PFO β-phase [32]. Furthermore, the slightly smaller optical gap on amine D is also expected to impede exciton diffusion. At high amine D concentrations, their beneficial effect on the PLQE is reduced as a result of concentration quenching. Energy transfer to quenching sites is then facilitated by the small average distance between the amines. In the literature, also other mechanisms for concentration quenching have been described [33–36].

Neglecting microcavity effects, which can give rise to an enhancement of the radiative decay probability of singlet excitons (see e.g. Ref. [16]), we may employ η_{PL} as a first estimate of η_{rad}. It follows from Eq. (1) that the ratio η_{EQE}/η_{PL} will then reveal how in the absence of non-radiative decay processes in the polymer the EQE would vary with the composition and voltage. Interestingly, the value of η_{EQE}/η_{PL} at $V = V_{max}$ is found to be quite strongly related to the value of V_{max}, irrespective of the detailed composition, as may be seen from Fig. 4(c). We regard this as a key result obtained from this work. The figure shows that $\eta_{EQE,max}/\eta_{PL}$ decreases with increasing V_{max}.

A qualitatively similar result is obtained from the voltage dependence of the luminous efficacy at different temperatures, measured for all copolymers, when assuming that the PLQE is only weakly temperature dependent. In Fig. 3 the results for copolymer **3** were given. We have not measured the temperature dependence of η_{PL}, so that making a quantitative comparison with the results given in Fig. 4(c) is not possible. If η_{PL} would be temperature independent, the temperature dependent values of V_{max} and $\eta_{EQE,max}/\eta_{PL}$ as obtained using Fig. 3 would essentially coincide with the composition-dependent data points indicated in Fig. 4(c). However, we can presently not exclude that this agreement is somewhat fortuitous. First, η_{PL} may decrease slightly with increasing temperature, as has been observed for other organic semiconductors [37]. Second, the increase of $\eta_{EQE,max}$ with increasing temperature is for this specific polymer slightly (but at most a few percent) higher than that of $\eta_{L,max}$, in view of the small observed blue-shift of the emission (see Section 2).

4. Current density in unipolar devices

A subsequent step towards the understanding of the observed composition and temperature dependent systematics in the voltage dependence of the EQE is made by studying the *J*–*V* characteristics of selected unipolar devices. In Fig. 5, the current–voltage (*J*–*V*) characteristics of single-carrier hole-only (HO) and electron-only (EO) devices are shown for copolymers **1**–**3** (from top to bottom). For HO devices, a cathode consisting of thermally evaporated Pd (100 nm) was used instead of Ba–Al, to prevent electron injection. For EO devices the ITO/PEDOT:PSS anode was replaced with a thermally evaporated 30 nm thick Al layer. The *J*–*V* curves of the HO and EO devices were corrected for a small Ohmic leakage current and for the built-in voltage [16] ($V_{bi,h} \approx 1.0$ V and $V_{bi,e} \approx 0.65$ V, respectively). The figure shows that for all three polymers the *J*–*V* curves of the EO devices (dotted) are approximately

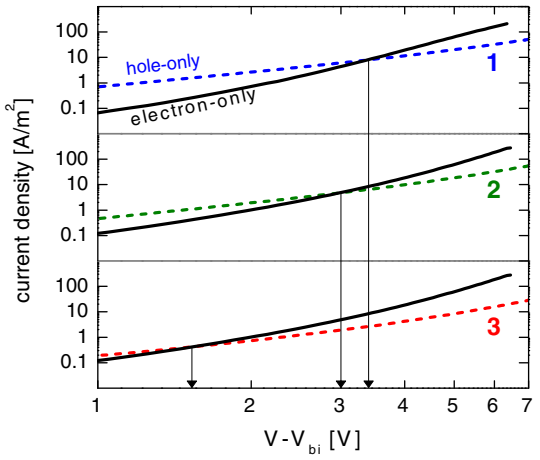

Fig. 5. Current–voltage characteristics of single-carier hole-only and electron-only devices with 80 nm layers of copolymers **1**–**3**, respectively. The arrows indicate the values of V_{cross}.

equal, but that at any voltage, the current density in the HO devices (dashed) decreases from polymer **1** to polymer **3**. The slopes of the EO curves are larger than those of the HO curves, but start off at a lower current density. As a consequence, the voltage at which the two built-in voltage corrected curves cross, V_{cross}, shifts from polymer **1** to polymer **3** to smaller values.

The strong composition dependence of the hole mobility is consistent with the role of the amines as hole-transporting units, in between which hopping takes place. The current density in HO devices depends therefore on the specific amine (C or D), as shown in Fig. 5. The figure also shows that this dependence is not necessarily gradual. The hole mobility decreases less strongly from copolymer **1** (only C) to copolymer **2** (2.5% C, 2.5% D) than from copolymer **2** to copolymer **3** (5% D). The current density measured at small voltages is indicative of a hole mobility difference of a factor ~4 between polymers **1** and **3**.

The relatively weak composition dependence of the current density in the EO devices is consistent with the point of view that the LUMO states are predominantly of a fluorene-character. Therefore, they are not or only weakly affected by copolymerization with the HTUs, of which the electron affinities are smaller than that of the polyfluorene host. The electron injection and mobility are thus expected to be only weakly dependent of the polymer composition.

5. Model for the voltage and composition dependence of the luminous efficacy

5.1. Composition dependence of the position of the efficacy maximum

Within a simplified picture of the transport, recombination and light-outcoupling processes, the voltage V_{cross} at which the current densities in HO and EO devices are equal might be used to estimate the voltage, V_{max}, at which in a double-carrier device the efficacy maximum is obtained. At that voltage, the hole and electron current densities are optimally balanced so that, as argued in the Introduction, the recombination efficiency and the light-outcoupling efficiency are expected to be quite optimal. Fig. 6(a) (closed circles) shows that this picture is very useful: the measured values of the voltage difference $V_{max} - V_{bi,dc}$ are surprisingly close to the measured values of the voltage V_{cross}. $V_{bi,dc}$, the built-in voltage for the double-carrier devices, is taken equal to 3 V for all three systems. We note that we regard the effective built-in voltages, used for obtaining V_{cross} for the single-carrier devices and used for obtaining the built-in voltage corrected voltage $V_{max} - V_{bi,dc}$, as relatively insensitive to the specific copolymer used, but that the uncertainty of each of the values of the built-in voltage used is several tenths of an eV. Therefore, the trend in the relative positions of the data points for the three copolymers is more significant than the close correspondence of the absolute values of V_{max} $V_{bi,dc}$ to those of V_{cross}. Furthermore, we note that the fact that in the double-carrier devices the onset of the emission is observed at voltages slightly below the voltage $V_{bi,dc}$ = 3 V (see the inset in Figs. 2 and 3) is consistent with the results of drift–diffusion OLED device modeling (see below).

The simple picture presented above explains why V_{max} increases with increasing hole mobility, but it does not yet explain why the EQE then tends to decrease (as shown in Fig. 4(c)). Also, it does not yet clarify the separate effects of the recombination efficiency and the light-outcoupling efficiency on the luminous efficacy. Furthermore, one might wonder why this picture appears to be so well applicable to the systems considered, as (i) the electron and hole mobility functions are expected to be quite different as a result of the different character of the intrinsic electronic states in between which hopping takes place, (ii) electron transport in large energy gap semiconducting polymers is often affected by the presence of (extrinsic) trap states [22,23], and (iii) an electron transport study for a similar system has revealed that there is a sizeable electron injection barrier (of at least ~0.5 eV [16]).

5.2. OLED device model

In order to develop a better understanding of the detailed shapes of the efficacy curves, including the trend in the luminous efficacy at $V = V_{max}$, we have carried out an exploratory device modeling study. The electron and hole mobility are assumed to be due to hopping in a Gaussian density of states. The mobility is then a function of the carrier density and the electric field, as described by Pasveer et al. [38]. To be specific, we have assumed widths of the Gaussian density of states equal to 0.13 eV (holes) and 0.07 eV (electrons). In addition, for electrons an exponential trap density of states with a width of 0.18 eV was assumed. The parameter choice was based on the results of a recent study of hole transport in a similar blue-emitting polyfluorene-based copolymer [21] and on the results of an electron transport study of the same material [23]. The electron and hole site densities were taken equal to 6×10^{26} m^{-3}, the electron trap density was taken equal to 1×10^{24} m^{-3}, and the electron injection barrier at the cathode was taken to be 0.7 eV. The voltage dependence of the current density and the recombination profiles were

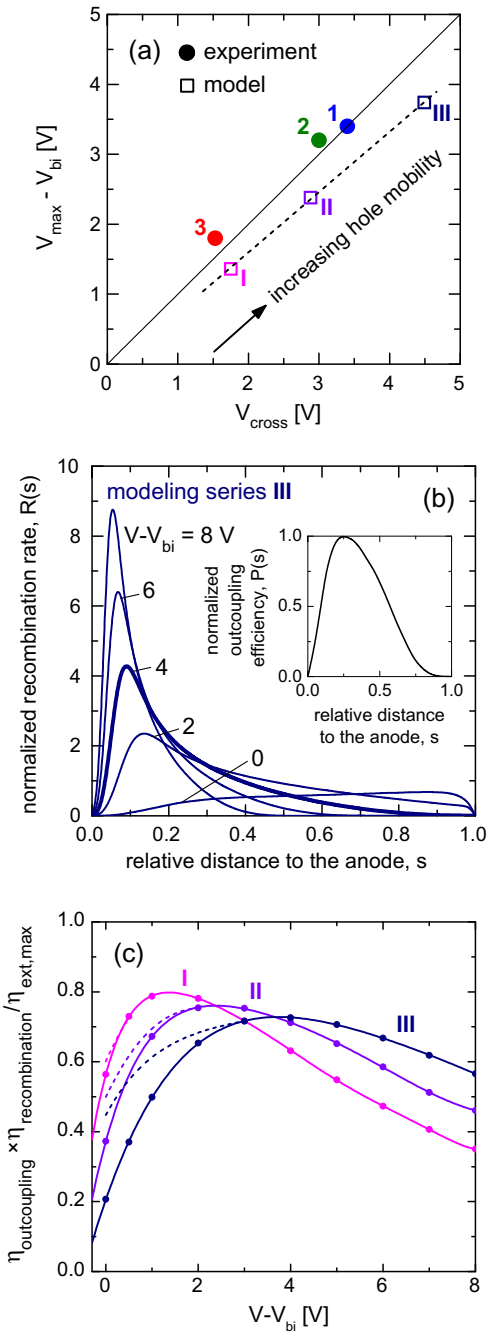

Fig. 6. Results of OLED device modeling. (a) Calculated voltages at which the EQE is maximal as a function of the voltage at which the current densities in the corresponding single-carrier devices cross (squares; both voltages are corrected for the built-in voltage), and the experimental results for copolymers **1**–**3** (spheres). (b) Calculated normalized recombination profiles for modeling series III and (inset) calculated normalized outcoupling efficiency as a function of the position in the device. (c) Calculated normalized product of the outcoupling and recombination efficiences for each modeling series (full curves, see Eq. (2)) and calculated normalized outcoupling efficiency (dashed curves).

calculated using a drift–diffusion-recombination model within which the electron and hole mobility functions are included as described above. The recombination is described as a bimolecular process, with a local recombination rate described by the (standard) Langevin formula. The calculations also include recombination of free holes with trapped electrons; however, for the systems and conditions studied the contribution from such processes is found to be only minor. Technical details concerning the method are given in Ref. [18]. The calculations were performed for L_{LEP} = 80 nm thick devices, with T = 298 K. We emphasize that the actual parameter values are expected to depend on the specific polymer, but that determining the precise composition dependence would be beyond the scope of this paper.

By taking appropriate values of the hole (electron) mobilities in the zero field and zero carrier density limits, $\mu_{0,h}$ ($\mu_{0,e}$), the device model leads to a similar crossing of the HO and EO current–voltage curves as shown in Fig. 5. In order to mimic the transport in devices containing polymers **1**–**3**, we have calculated the voltage dependence of the current density and of the recombination profiles for three different values of $\mu_{0,h}$, while keeping all other parameters fixed. The use of this simplified approach is motivated (i) by the clear indication obtained from Fig. 5 that a single composition-dependent parameter determines the device performance of all devices and (ii) by the results of the separate studies of hole and electron transport, discussed in Section 4, which indicate that the hole mobility constitutes this composition-dependent parameter. A first series of calculations (I) was carried out using a value of $\mu_{0,h}$ which led to crossing EO and HO curves at a voltage V^{I}_{cross} = 1.75 V above the built-in voltage, equal to the experimental value of V_{cross} for copolymer **3**. Two other series of calculations (II and III) were carried out for values of $\mu_{0,h}$ which were a factor 2.5 and 6.25 larger, leading to V^{II}_{cross} = 2.88 and V^{III}_{cross} = 4.49 V, respectively.

5.3. Model predictions of the voltage dependence of the luminous efficacy

For all three values of $\mu_{0,h}$ chosen, voltage-dependent normalized recombination profiles, $R(s, V)$ with $s \equiv x/L_{LEP}$, were calculated using the drift–diffusion-recombination model described in the previous subsection. The normalization is such that the integral is equal to the recombination efficiency, which may be defined as $\eta_{rec} \equiv (J_{h,anode} - J_{h,cathode})/J$. Here, $J_{h,anode}$ and $J_{h,cathode}$ are the hole current densities at the anode and cathode, respectively. As an example, Fig. 6(b) shows the normalized recombination profiles obtained for the modeling series III, calculated for values of $V - V_{bi,dc}$ ranging from 0 to 10 V. The figure shows that at small voltages, close to V_{bi}, the recombination profile is quite broad and most intense near the cathode. With increasing voltage the profile becomes narrower, with a peak which shifts to a location close to the anode. Qualitatively, this peak shift can be explained as a result of the steeper increase of the injected electron current density with increasing voltage, as compared to the increase of the hole current density.

In order to analyze the effect of the peak shift on the device efficiency, we make use of the position-dependent outcoupling efficiency curve, $P(s)$, as calculated for

blue-emitting polyfluorene–copolymer-based OLEDs with an equal layer stack structure, equal layer thicknesses and almost the same CIE emission color point as that of polymers **2** and **3** [16]. The calculations were performed using a well-established optical microcavity outcoupling model which includes the effects of exciton quenching and of the enhanced radiative decay rate near metallic electrodes [39]. The function $P(s)$ is normalized with respect to its peak value, and is given as an inset in Fig. 6(b). The product of the recombination efficiency and the outcoupling efficiency is then equal to

$$\eta_{rec} \times \eta_{oc} = \eta_{ext,max} \times \int_0^1 R(s,V)P(s)ds \quad (2)$$

where $\eta_{ext,max}$ is the external quantum efficiency which would be obtained if complete recombination would take place in a zone with infinitesimal thickness at the most optimal position in the device. The integral indicates to what extent the efficiency is less than the highest possible value for the device structure and emission spectrum considered, due to a non-ideal recombination efficiency and a non-ideal shape of the recombination profile. Fig. 6(c) shows for each modeling series the value of this integral as a function of the voltage, corrected for the built-in voltage (full curves). It also shows the ratio of this integral and the recombination efficiency ("normalized outcoupling efficiency", dashed curves), which gives the effect of the non-ideal shape of the recombination profile on the EQE. For each series of calculations we find that $\eta_{rec} = 1$ around and above V_{cross} (so that the full and dashed curves coincide) but that η_{rec} decreases at small voltages. The injected electron current density is then very small, so that not all injected holes recombine. Nevertheless, there is even some recombination at voltages below V_{bi}, resulting from the effects of charge carrier diffusion and energetic disorder [18]. The built-in voltage can therefore not be determined directly from the electroluminescence onset. For series III, the efficacy maximum is located at ~4 V above the built-in voltage. Fig. 6(b) shows that the corresponding recombination profile (thick curve) has its peak already quite close to the anode. As a result of the broad and asymmetric shapes of the outcoupling efficiency curve and the recombination profiles, the efficacy maximum is not located at the voltage at which the maximum of the recombination profile coincides with the maximum of the outcoupling efficacy curve.

The calculated voltage shift of the efficacy maximum with increasing hole mobility, shown in Fig. 6(c), is consistent with the experimental results. This may be seen from Fig. 6(a), within which the squares give the dependence of the calculated values of $V_{max} - V_{bi,dc}$ on the calculated values of V_{cross}. The effect of a change of the hole mobility on V_{cross} is found to be essentially equal to the effect on V_{max}. It is not surprising that there is no strict one-to-one correspondence between the calculated values of $V_{max} - V_{bi,dc}$ and V_{cross}, as this relationship is determined by the detailed values of the materials and device parameters, including the optical constants and thicknesses of the non-emissive layers. Furthermore, it may be seen from Fig. 6(a) that the experimentally observed difference between the peak voltages for polymers **1** and **3** (~1.6 V) can be understood as the result of a difference in the hole mobilities of approximately a factor of 4, in good agreement with the mobility difference estimated from the *J–V* curves (see Section 4). Studies of the current density in HO devices based on polymers **4**–**10** (not shown) confirm that the mobility increases with increasing monomer concentration, consistent with the picture discussed above that these units function as transport sites. It is then expected from the model that an increase of the monomer concentration results in an increase of V_{max}, as is indeed found experimentally (see Table 1).

Fig. 6(c) also provides answers to the questions posed in Section 5.1. It elucidates the separate roles of the light-outcoupling and recombination efficiencies and explains why the EQE tends to decrease with increasing V_{max}, i.e. with increasing hole mobility. For the three values of $\mu_{0,h}$ considered, the effect is due to a decrease of the degree of ideality of the shape of the recombination profile at $V = V_{max}$. For larger values of the hole mobility ($\mu_{0,h}$ at least a factor 5–10 larger than taken for modeling series III), it is expected that the EQE at V_{max} is also reduced as a result of a finite recombination efficiency. This might explain the rather fast decrease of the EQE with increasing V_{max} at large values of V_{max}, revealed by Fig. 4(c) and suggested (less directly) as well by Fig. 3.

The model discussed above was used in order to explain the observed trends. More quantitative modeling of the EQE would require making several refinements, such as a separate determination of the mobility functions for all materials and the use of separate optical outcoupling modeling for all materials (taking the (small) effects of the material dependence of the emission spectrum into account). Making such refinements is beyond the scope of this paper. It will then be possible to deduce the value of the fraction of singlet excitons formed. The experimental results presented in this paper do not indicate a strong dependence of η_S on the system studied.

5.4. Optimizing the luminous efficacy of OLEDs

From the analysis given above, it can be derived how blue-emitting fluorene polymers containing copolymerized hole-transporting amine monomers can be designed in a rational way for different OLED-applications. The

Table 1
Material parameters and OLED device properties of fluorene copolymers **1**–**10** (see Fig. 1(b) for the composition).

Copolymer	CIE-(x, y) (EL)	V_{max} V	$\eta_{L,max}$ cd/A	η_{PL} %	$\eta_{EQE,max}$ %

10	(0.15, 0.10)	9.1	0.9	42	1.1

copolymer which is most optimal for a certain application is the material for which the power efficiency is largest at the required brightness level. The brightness level is proportional to the current density times the reduction of the efficiency due to a non-ideal shape of the emission profile and recombination efficiency, given by the factor $f_1 \equiv \eta_{oc} \times \eta_{rec}/\eta_{ext,max}$ shown in Fig. 6(c). The power efficiency is proportional to the same factor, multiplied by the factor $f_2 \equiv V_{gap}/V$ which gives the power loss resulting from the use of a voltage which is larger than the voltage corresponding to the single-particle energy gap, V_{gap}.

In Fig. 7, the full curves show for the three series of calculations carried out above the dependence of the power efficiency on the brightness. The brightness was taken equal to $C \times f_1 J$, with a proportionality factor $C = 27.5$ cd/A as obtained in Ref. [16] for emission from for similar blue-emitting polyfluorene–copolymer-based OLEDs, i.e. assuming for calculating the light-outcoupling the same optical stack as in Section 5.3. The power efficiency is expressed with respect to the ideal power efficiency, obtained when $f_1 = f_2 = 1$, using $V_{gap} = 3$ V. The brightness scale obtained coincides well with the actually observed range of brightnesses at $V = V_{max}$, which varies from $\sim$100 cd/m^2 for copolymer **3** to $\sim$13,000 cd/m^2 for copolymer **10**. The figure reveals clearly that the optimal polymer composition depends on the required brightness. For small-brightness applications, within which the OLED is operated at a voltage not far above V_{gap} (such as in some lighting and signage applications), making use of a copolymer with a relatively small hole mobility is most optimal (series I). On the other hand, for high-brightness applications within which the OLED is operated at a voltage well above V_{gap} (such as in passive matrix displays) using a copolymer with a relatively large hole mobility is more optimal (series III).

The maximum possible power efficiency could be enlarged by further lowering of the hole mobility (e.g. by adapting the chemical nature of the HTUs), as may be seen from the dashed curve in Fig. 7. It shows the modeling results for a hole mobility which is a factor of 2.5 smaller than for curve I, all other modeling parameters being equal. The increase of the maximum is due to (i) a slight further increase of the maximum value of the ratio $f_1 \equiv \eta_{oc} \times \eta_{rec}/\eta_{ext,max}$, to approximately 0.85, and (ii) a further decrease of V_{max}, to approximately 0.8 V above V_{bi}. It is evident from the figure that this would only be useful when only very small brightnesses are needed. Upon further reducing the hole mobility, V_{max} approaches V_{bi}, so that the energy drop across the devices approaches the energies of the emitted photons. The device then approaches the thermodynamic limit, where device modeling should include not only recombination but also charge carrier generation. Although a theoretical model for the latter process has been developed recently [18], its application to the presently studied devices would be beyond the scope of this work. Lowering the hole mobility could be realized by adapting the chemical nature of the HTUs, but also by lowering their concentration. For the specific polymers studied, the maximum of the external quantum efficiency is obtained at the boundary of the composition range investigated. It is expected that for slightly smaller amine concentrations even slightly higher values of η_{EQE} are obtained, at smaller values of V_{max}. However, the brightness obtained at the maximum will then also decrease, limiting the practical applicability. We note that an enhanced power efficiency at higher brightnesses could be obtained by enhancing the hole and electron mobilities. An enhancement by the same factor would give rise to a shift of the brightness at which the power efficiency is highest by the same factor, without a change in shape of the curves.

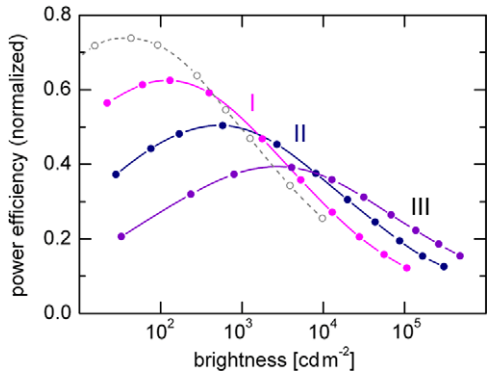

Fig. 7. Calculated dependence of the normalized power efficiency on the brightness, for OLEDs with hole mobilities which increase in steps of a factor 2.5 from small (dashed curve) to large (curve III). The $J(V)$ and efficiency data used for obtaining curves I–III have been calculated from the device simulations described in Section 5.3. The power efficiency is expressed with respect to the value that would be obtained for emission from the most optimal position in the emissive layer, at a voltage equal to V_{gap}. The approach used for obtaining an absolute brightness scale has been described in the text.

We have focused in this study on 80 nm LEP layer thicknesses, motivated by the observation of a maximum in the light-outcoupling efficiency close to this thickness as determined by microcavity interference effects (see e.g. Ref. [41]). This was confirmed by a study of the LEP layer thickness variation of the luminous efficacy carried out for devices based on copolymer **2**. With decreasing LEP layer thickness, the electron current density in single-carrier devices increases more rapidly than the hole current density, which is a well-known consequence of the presence of electron traps. As a result, V_{max} decreases. In principle, the higher current density at a given voltage and the smaller value of V_{max} could be used for obtaining a higher power efficiency at high brightnesses. However, reducing the LEP layer thickness to a value well below 80 nm, in order to accomplish this, is in practice hampered by the much smaller processing window, related to the occurrence of extrinsic defects.

6. Summary and conclusions

We have investigated the functioning of OLEDs based on blue and blue–green emitting fluorene polymers containing copolymerized aromatic amine comonomers which act as hole-transporting units and emitters. For that purpose, we have systematically synthesized and characterized a series

of 10 blue-emitting fluorene copolymers that contain two different types of comonomers (amines C and D) with similar optical energy gaps but with different contributions to the hole mobility. For all copolymers, the external quantum efficiency *versus* voltage curves are found to display a distinct maximum (at a voltage V_{max}). After correction for a small composition dependence of the radiative decay probability, an increase V_{max} is found to be accompanied by a decrease of the maximum efficiency. Also, V_{max} is found to increase systematically with increasing hole mobility. By making use of a numerical device model, it is shown that the voltage dependence of the efficiency curves can be understood as a result of a composition dependence of the hole mobility only. A voltage-dependent shift of the recombination profile across the emissive layer, leading to a voltage dependence of the light-outcoupling efficiency, is found to be the most important factor determining the shape of the efficiency curves.

The analysis shows how blue-emitting fluorene polymers containing copolymerized HTUs can be designed in a rational way for OLEDs applied under different conditions. At small (high) brightness levels, the most optimal power efficiency is obtained by the use of polymers with small (high) hole mobilities. The model provides insight in the functioning of OLED materials studied earlier in the literature, such as the blue-emitting polyfluorene-based polymer of the Sumation LUMATIONTM blue series mentioned in the Introduction. For OLEDs with the same device structure as used here (data point *i* in Fig. 2), $V_{max} \approx 11$ V and $\eta_L = 3.3$ cd/A were found [16]. The analysis presented in this paper explains, at least in part, why for this material the maximum efficiency is smaller than for polyfluorene-based copolymers with a smaller hole mobility. We conclude that for the class of OLED materials studied the voltage dependence of the efficiency can be tuned such that the power efficiency at the required brightness level is optimized.

Appendix A. Experimental details

The fluorene copolymers were synthesized by the well-known Suzuki coupling method [40]. Into a toluene solution of $X-R-X$ (1 equiv), $Y-R'-Y$ (1 equiv), where R and R' are fluorene and/or arylamine segments and X and Y are halogen or boronate groups, catalytic amounts of $Pd(PPh_3)_4$ and a 20% aqueous solution of tetraethyl ammonium hydroxide were added. The copolymers were end-capped with (4,4,5,5-tetramethyl-1,3,2-dioxaborolyl)benzene. A schematic drawing of fluorene copolymer **2** is given in Fig. 1 with A 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolyl)-9,9-bis(4-[3,7-dimethyl-octyloxy]phenyl)fluorene, B 2,7-dibromo-9,9-bis(3,7-dimethyloctyl)-fluorene, C N,N′-bis(4-bromophenyl)-N,N′-bis(4-methoxyphenyl)-benzidine, and D 3,6-dibromo-N-(3,7-dimethyloctyl)phenoxazine. The reaction mixture was stirred at 110 °C overnight in an inert atmosphere (nitrogen flow). The organic layer was separated and washed with 2 wt-% NaCN aqueous solution to remove the catalyst residue. The organic layer was also washed with demi-water before drying with $MgSO_4$. The polymer was fractionated and precipitated in methanol. With a polydispersity in the range 1.4–2.4, the polymers have a weight-average molecular weight $\bar{M}_w$ in the range 130–680 kg/mol.

In order to estimate the HOMO and LUMO energy levels of the copolymers, cyclic voltammetry cycles were recorded in solution or in film. The cyclic voltammetry (CV) data were measured with a CHI 660A model from CH Instruments. The polymer films were deposited onto a platinum wire electrode and placed in an electrolyte solution of $TBAPF_6$ (0.1 M) in CH_3CN to measure the reduction potentials. For oxidation potential measurements in solution, the same configuration was used, however, the indicated compounds were dissolved (typically 0.1 mg) in dichloromethane as a solvent with 0.1 M of $TBAPF_6$. The potentials were measured relative to an Ag/Ag^+ reference electrode (scan rate was typically 0.1–1.0 V/s) and referenced to the first oxidation potential of Fc (~0.35 V). The oxidation potential of the Fc/Fc^+ relative to vacuum level was taken as 4.7 V [42]. The oxidation potentials of the copolymers were converted into ionization potentials using Fc/Fc^+ as the reference potential. The ionization potential (I_p) and electron affinity (E_a) were derived from the half-height oxidation and reduction potentials of the reversible scans and were related to the vacuum energy scale.

Light-emitting diodes were fabricated at Philips Research Laboratories in Eindhoven by spin coating polymers from toluene solution (1 wt-%) with film thicknesses of 80 ± 5 nm onto glass substrates under ambient conditions. Onto the OLED substrates with ~100 nm thick ITO (Indium–Tin–Oxide) coating a commercially obtained PEDOT:PSS dispersion (HC Starck, Baytron P VP AI 4083) was spin coated to yield approximately 100 nm thick films after drying. Barium and aluminum were thermally evaporated at reduced pressure to yield approximately 5 and 100 nm thick films, respectively. Following evaporation, the devices were hermetically sealed. The surface area of the pixels that were investigated was 9 mm^2. For single-carrier hole-only devices, a cathode consisting of thermally evaporated Pd (100 nm) was used. For electron-only devices the ITO/PEDOT:PSS anode was replaced with a thermally evaporated 30 nm thick Al layer.

The OLED layer thicknesses were derived from the geometric capacitance that was determined by dynamic capacitance measurements (Schlumberger gain/phase analyser 1260 SI) in the frequency range of 10 Hz–1 MHz and the bias range of −4 to 0 V. The AC variation on top of the

DC bias was 0.03 V. The dielectric constants of the different copolymers were determined by comparing the layer thickness of freshly prepared devices at 10–20 positions on the 6″ substrate with the geometric capacitance. The built-in voltages for the double-carrier and single-carrier hole-only devices were also determined by differential capacitance measurements in the frequency range of 100 Hz–10 kHz and the bias range of 0–3 V. The AC variation on top of the DC bias was 0.03 V. For the electron-only devices, the built-in voltage was taken from Ref. [16]. Photocurrent measurements were used to determine the built-in voltage.

Current (I) *versus* voltage (V) and luminance (L) *versus* voltage curves of 9 mm^2 OLED devices were measured using a Keithley Model 2400 general-purpose sourcemeter. Measurements at a high current density were carried out in a pulse-mode, in order to avoid heating of the devices. During the I–V–L cycle, the brightness was monitored by a calibrated photodiode, calibrated with a Konica Minolta LS-100 luminance meter, that was mounted orthogonally to the OLED that was connected to a Keithley Model 6517A electrometer/high-resistance meter. The EL spectra were measured using a spectroradiometer (Photo Research PR-705 camera), mounted orthogonally to the OLED plane. The EQE was then obtained by taking the ratio of the photon flux detected by the camera divided by the current density in the OLED, assuming that the brightness and spectral shape are independent of the viewing angle (Lambertian emission).

Solid-state fluorescence quantum yield measurements were determined using the integrating sphere method [29–31]. Thin polymer films with a thickness of 80 ± 2 nm were by spin coating from a toluene solution (1 wt-%) onto a glass substrate. The polymer films were excited under nitrogen flow with monochromatic light with a wavelength of 406 nm stemming from an ArKr laser (Beamlok 2080, Spectra-Physics Lasers Inc.). The fluorescence response in the wavelength range 350–800 nm was recorded by a Shamrock SR-163 spectrometer (Andor) that was linked to the integrated sphere by an optical fibre. The optical path from integrating sphere to CCD camera was calibrated by a DH-2000 Ocean Optics calibration lamp. Table 1 contains an overview of various device parameters for the 10 copolymers studied, obtained from the EL and PL experiments.

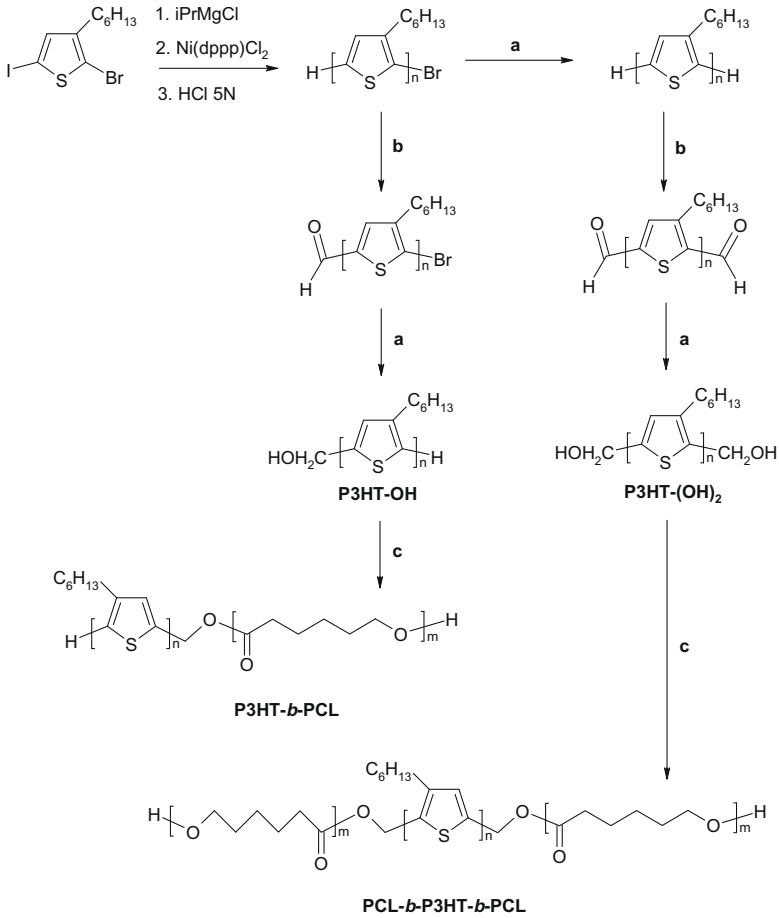
ring-opening metathesis, reversible addition fragmentation chain transfer and nitroxide mediated polymerizations [22–26]. Recently, the GRIM approach has been associated with the ring-opening polymerization (ROP) of D,L-lactide [27]. Extending this family of block copolymers with other lactones would yield interesting materials, especially by polymerizing ε-caprolactone (CL) onto RRP3HT segment since poly(ε-caprolactone) (PCL) is: (1) crystallizable (in contrast to other segments copolymerized with P3HT, such as poly(methacrylate)s [22]); (2) miscible with a number of other polymer compounds (such as poly(vinyl chloride), poly(ethylene chloride), poly(styrene-*co*-acrylonitrile),...); (3) removable by hydrolysis, and; (4) biocompatible. The capacity of PCL to be miscible blended with various commercial polymers over a wide range of composition (in contrast to polylactide blocks) opens the way for interesting compatibilization of a P3HT matrix by using P3HT/PCL block copolymers, whatever their topology. PCL is therefore a valuable partner for RRP3HT for improved compatibility and for potential bio-applications.

Here, we report on the stepwise synthesis of diblock and triblock copolymers by controlled polymerization of ε-caprolactone from (di)hydroxyl-terminated RRP3HT, see Scheme 1. Such copolymers are inherently expected to self-assemble in the solid-state; the resulting nanoscale morphologies in thin deposits are studied via atomic force microscopy (AFM) and correlated with the charge transport properties in field-effect transistor configuration.

2. Experimental section

2.1. Synthesis

α-bromo poly(3-hexylthiophene): Into a flask under a nitrogen atmosphere containing 2-bromo-3-hexyl-5-iodothiophene (1.18 g, 3.15 mmol), dry THF (15.0 mL) was added via a syringe, and the mixture was stirred at 0 °C. i-PrMgCl (2.0 M solution in THF, 1.08 mL, 3.15 mmol) was added via a syringe, and the mixture was stirred at 0 °C for 0.5 h. A suspension of Ni(dppp)Cl_2 (18 mg, 0.03 mmol) in THF (5.0 mL) was added to the mixture via a syringe at 0 °C, and then the mixture was stirred at room temperature. After the reaction mixture was stirred for 1 day, a 5 N HCl aqueous solution was quickly added to quench the reaction. The mixture was stirred for 0.5 h more, then precipitated in cold MeOH. The product was washed with MeOH yielding a purple solid, >98.5% rr-HT-P3HT. Yield = 69%; UV ($CHCl_3$, nm): 445; IR (cm^{-1}): 819 (C–H



Scheme 1. Comparative routes leading to diblock (P3HT-*b*-PCL) and triblock (PCL-*b*-P3HT-*b*-PCL) copolymers. Reagents a: $LiAlH_4$/HCl, b: 1. $POCl_3$/DMF, 2. CH_3COONa/H_2O, and c: CL/$SnOct_2$.

aromatic out-of-plane) and I_{sym}/I_{asym} = 6, characteristic of rr-HT-P3HT; ^{1}H NMR (300 Hz, $CDCl_3$): 6.98 (s, 1H), 2.80 (t, ^3J = 7.5 Hz, 2H), 1.71 (quint, 2H), 1.34 (m, 6H), 0.91 (t, ^3J = 6.4 Hz, 3H); GPC analysis: M_n = 4450 g/mol; PDI = 1.17. **Formyl-de-hydrogenation of α-bromo poly(3-hexylthiophene):** H-P3HT-Br (M_n = 3700, PDI = 1.17) (300 mg, 0.071 mmol) was dissolved in anhydrous toluene (80 mL) under N_2. N,N-Dimethylformamide (1 mL, 13 mmol) and $POCl_3$ (0.7 mL, 7.6 mmol) were added. The reaction was carried out first at 75 °C for 50 h. The solution was cooled down to room temperature, followed by the adding of a saturated aqueous sodium acetate solution. The reaction mixture was stirred for another 2 h. The polymer was precipitated in cold methanol and washed with water, then methanol. Yield = 94%; GPC analysis: M_n = 4800 g/mol; PDI = 1.17; ^{1}H NMR (300 Hz, $CDCl_3$): M_nNMR = 5400 g/mol. **Reduction of α-bromo, ω-formyl poly(3-hexylthiophene):** HOC-P3HT-Br (M_n = 3500, PDI = 1.23; 200 mg, 0.057 mmol) was dissolved in anhydrous THF (80 mL), under N_2. $LiAlH_4$ 1 M solution in THF (0.5 mL) was then added. The reaction was then kept stirring at room temperature for 1.5 h. HCl (1 N, 1 mL) was then added to quench the excess of $LiAlH_4$. The polymer was precipitated in methanol and washed with water then methanol. After drying in vacuum, 190 mg of CH_2OH-P3HT-Br was obtained. Yield = 95%; GPC analysis: M_n = 5100 g/mol; PDI = 1.22; ^{1}H NMR (300 Hz, $CDCl_3$): M_n NMR = 5400 g/mol. **Synthesis of poly(3-hexylthiophene)-*b*-poly(ε-caprolactone):** In a previously dried and nitrogen-purged 25 mL round-bottom flask equipped with a three-way stopcock and a rubber septum, 0.43 ml of CL (3.92 mmol) and 3.3 ml of dried toluene were added to freshly dried 0.5 g of hydroxyl-P3HT (0.098 mmol). The reaction mixture was gently heated to 110 °C until complete dissolution of P3HT before adding a 0.2 M solution of $Sn(Oct)_2$ (0.2 mL, 0.039 mmol, $[OH]_0/[Sn(Oct)_2]_0$ = 2.5, final concentration of CL = 1 M). After 15 h at 110 °C, the reaction was cooled down and stopped by adding dropwise an aqueous HCl solution (1 mol L^{-1}). The copolymer was then precipitated from cold methanol yielding a brown solid. Yield = 76% (m = 704 mg); ^{1}H NMR (300 Hz, $CDCl_3$): M_nPCL = 2300 g/mol; Conversion in PCL = 50.4% (M_n in PCL expected = 40 × 114 = 4560 g/mol); GPC analysis: M_nGPC = 6500 g/mol; PDI = 1.23. A detailed description of the materials, synthesis steps and characterization techniques is given in the Supporting information.

2.2. Atomic force microscopy

Sub-monolayer deposits were prepared by solvent casting on freshly-cleaved muscovite mica or silicon oxide substrates from dilute solutions (0.05–0.5 g L^{-1}); the solvent was slowly evaporated at room temperature in a solvent-saturated atmosphere. Thicker, homogeneous films were prepared by spin-coating the solutions onto silicon oxide or glass substrates (spinning speed from 2500 to 4000 rpm, solution concentration = 1.0 g L^{-1}). AFM studies were carried out in Tapping-Mode with Multimode Nanoscope IIIa or Nanoscope V microscopes (Veeco) operating in air at room temperature, using microfabricated silicon cantilevers with a spring constant of around 30 N m^{-1} (TESP, Veeco). Images of different areas of the samples were collected and Nanoscope image processing software was used for image analysis.

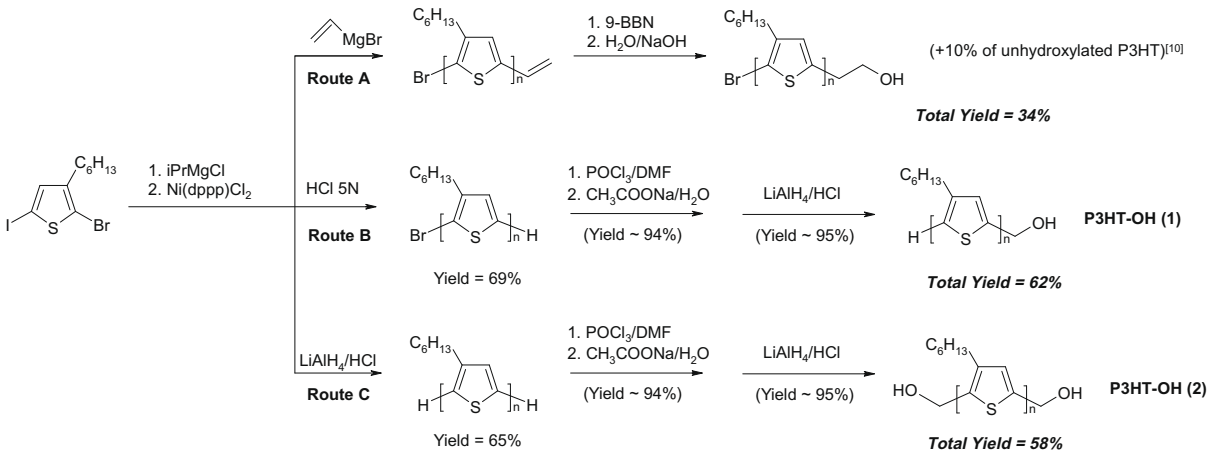
2.3. FET fabrication and characterization

The FET devices consist in a thermally-grown 200 nm-thick SiO_2 gate dielectric on top of a doped n^{++}-type Si gate electrode. Gold source and drain electrodes were used, and the devices were fabricated either in bottom-contact (100 nm-thick electrodes, channel length of 5 or 10 μm) or top-contact (channel length of 50 μm) configurations. Homogeneous thin films of the (co)polymers were prepared by spin-coating a 1.0 g L^{-1} solution (at 2500 rpm) onto the silicon oxide gate dielectrics. The devices were then tested in a glove box under nitrogen atmosphere and the electrical characteristics were measured on a probe station with a Keithley 4200 semiconductor parametric analyzer. The charge mobility has been estimated from the saturation regime (at source-drain voltage of −60 V), see the description in Refs. [35,40–44] for instance.

3. Results and discussion

3.1. Synthesis of (co)polymers

The key-step for the controlled generation of these novel architectures is the synthesis of perfectly controlled (di)hydroxyl-terminated regioregular P3HT. The first method considered for the synthesis of P3HT-OH consisted in the hydroboration/oxidation reaction of previously synthesized vinyl-terminated P3HT, as recently reported by McCullough et al. (Route A, Scheme 2) [28]. However, the expected P3HT-OH compound was systematically contaminated by ca. 10 wt.% of non-hydroxylated P3HT [23,29] (see Supporting information, SI) leading upon ring-opening polymerization of ε-caprolactone (CL) to a mixture of P3HT-*b*-PCL and P3HT and requiring intensive purification by fractionation. Comparatively, the formyl-dehydrogenation of the α-bromo P3HT protic end-group (Route B) was successfully performed by a Vilsmeier reaction leading to α-bromo, ω-formyl P3HT characterized by a recovering yield of 94% [23,29]. The evolution of the reaction was followed by MALDI-ToF analysis until complete transformation of the α-bromo P3HT to α-bromo, ω-formyl P3HT (Fig. S2) allowing us to recover a 100% formyl end-capped structure. After completion of the reaction, both the formyl and the bromide end-groups were reduced by $LiAlH_4$ yielding the expected P3HT-OH with a narrow molecular weight distribution (polydispersity index = 1.22) and a recovering yield of 95% (see SI, Fig. S3). It is worth noting that the global yield of the polymerization and the post-polymerization end-group modification processes reached 62%. Such a high yield, together with the fact that the recovered P3HT-OH is 100% functionalized by a hydroxyl group, represents a relevant progress in the field. Dihydroxyl-terminated P3HT (P3HT-$(OH)_2$) was also obtained by the same procedure but starting with a reduction reaction of α-bromo P3HT by $LiAlH_4$ (Total recovering yield: 58%,



Scheme 2. Comparative routes leading to (di)hydroxyl-terminated P3HT. Route A: hydroboration/oxidation of α-bromo, ω-vinyl P3HT [10]. Routes B and C: vilsmeier oxidation/reduction of (α-bromo) P3HT.

Route C, Scheme 2, Fig. S4). The molecular characterization of representative P3HT is described in Table 1.

These homopolymers were used as the starting materials for the synthesis of di- and triblock copolymers shown in Scheme 1. Tin(II)octoate ($Sn(Oct)_2$) was used to catalyze the controlled ROP of CL from the hydroxyl-end-groups(s) of P3HT macroinitiators [30]. Both P3HT-OH and P3HT-$(OH)_2$ were thus treated with $Sn(Oct)_2$ in toluene with an initial hydroxyl/Sn molar ratio of 2.5. CL was then added and the polymerization was carried out in toluene at 110 °C with an initial monomer concentration of 1 M and an initial $[CL]_0/[OH]_0$ molar ratio of 40. After a reaction time of 15 h, the copolymers were recovered by precipitation (see SI); the PCL molecular weights (M_n), as estimated from ^1H NMR, are 1900 and 3200 g/mol for P3HT-*b*-PCL and PCL-*b*-P3HT-*b*-PCL, respectively (Table 1). These values are in good agreement with the expected molecular weights taking into account the monomer conversion and initial monomer-to-initiator molar ratios. Size exclusion chromatography traces of the copolymers were all monomodal with polydispersity indices below 1.2 (Table 1 and SI).

3.2. Microscopic morphology in thin deposits

The micro- and nano-scopic morphology of thin deposits of the (co)polymers was investigated by atomic force microscopy (AFM) in intermittent-contact mode. Thin deposits have been prepared by drop-casting or spin-coating onto various substrates starting from good solvents for both P3HT and PCL blocks (e.g., tetrahydrofuran, toluene or chlorobenzene). Thin deposits of the studied compounds all show a fibrillar (nanowire-like) morphology (see AFM images in Fig. 1). This is observed for both sub-monolayer deposits (Fig. 1c and Fig. 1e, where the substrate surface appears dark) and for thicker deposits (Fig. 1a,b,d) prepared by drop-casting, in which the fibrils extend up to a few μm and arrange in lamellae. Films prepared by spin-coating from the same solvent (tetrahydrofuran) also show entangled fibrillar structures (Fig. 1f), indicative that the fibrillar assembly occurs even with a very rapid solvent evaporation process (spinning speed >2500 rpm). Indeed, this fibrillar morphology is typical from the (crystalline) assembly of RRP3HT into π-stacked assemblies, as observed and described for highly regioregular poly(thiophene)s and other conjugated (co)polymers thin deposits prepared with the same methods [31,32]. In these fibrils, P3HT molecules have extended conjugated backbones, with their long axis perpendicular to the π-stacking direction (the fibril axis). The fibrils arrange in lamellae due to interdigitation of alkyl groups perpendicularly to the backbone axis with a lamellar thickness of 1.7 nm, as observed using (Grazing Incidence) X-ray Diffraction measurements [33–34], which is in agreement with the fibril thickness measured here. This is further supported by the measured width of the fibrils, which

[d] Charge mobilities μ and current on/off ratios $I_{on/off}$ have been estimated from the transfer characteristics of top-contact FET devices.

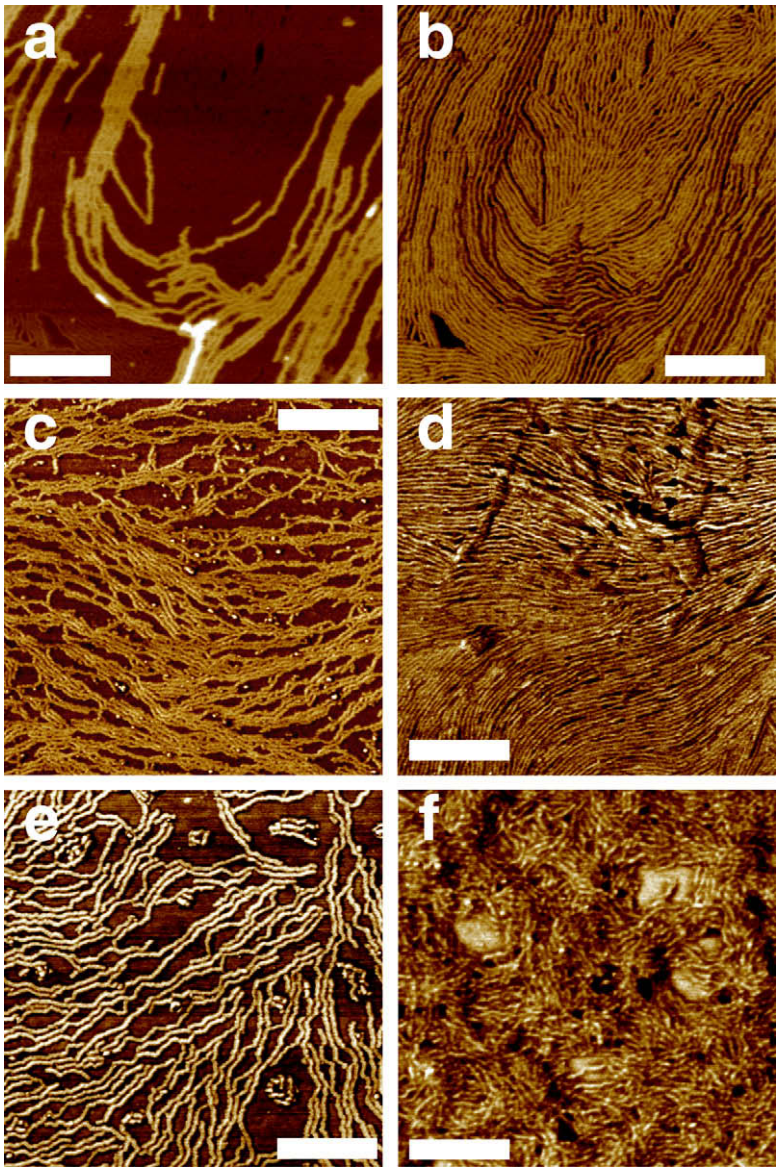

Fig. 1. AFM images of thin deposits from tetrahydrofuran of (a–b) P3HT-OH (a: height; b: phase); (c–d) P3HT-*b*-PCL (phase images, c: sub-monolayer deposit; d: thick film); (e–f) PCL-*b*-P3HT-*b*-PCL (phase images, e: sub-monolayer deposit; f: spin-coated film). The white scale bar is 250 nm-long.

correlates with the length of the P3HT conjugated backbone [35]: the measured widths are 11 ± 2 nm for P3HT-OH and 17 ± 2 nm for PCL-*b*-P3HT-*b*-PCL, while the estimated lengths of fully-extended P3HT backbones are 12.6 and 18.4 nm in average, respectively [36]. Note that, for the P3HT-*b*-PCL and PCL-*b*-P3HT-*b*-PCL block copolymers, adjacent fibrils (in bright) are close to each other, and appear to be separated by narrow dark bands in the phase images (for instance, compare Fig. 1b and Fig. 1e). This, together with the fact that the measured fibrils width is close to the length of the extended P3HT backbone, indicates that the PCL segments are very likely in a compact conformation in between the P3HT assemblies. Indeed, the PCL segments have a quite low degree of polymerization in these block copolymer structures (e.g. 20 monomer units in average in the diblock copolymer), which seems not sufficient to induce crystallization of PCL. If we consider a coiled conformation of the PCL segments, the estimated radius of gyration would be around 1.3–1.6 nm (in the di- and tri-block copolymers), i.e. around 3 nm in diameter [36]. All these results suggest that the self-assembly of the these block copolymers is driven by the ordering of the RRP3HT backbones (intra-lamellar π-stacking of conjugated backbones and inter-lamellar interdigitation between alkyl groups) rather than by the assembly of the PCL segments, which are very likely in a coiled configuration in between the P3HT fibrils [37].

3.3. Charge transport properties in field-effect transistors

Field-effect transistors (FET) were fabricated in bottom-gate configuration, with a gate dielectric layer made of SiO_2 on top of a heavily doped silicon (n^{++}) gate electrode. Thin films of the (co)polymers were deposited by spin-coating on the SiO_2 from chlorobenzene solutions because this deposition process leads to flat, homogeneous thin films suitable for FET fabrication (thickness $\sim 20 \pm 5$ nm and RMS roughness (over 1 μm^2) of about 2 nm, as measured with AFM). The devices were tested with gold source and drain electrodes either in top-contact or bottom-contact configurations, in the accumulation regime of hole transport (negative source-gate voltages) since holes are the major charge carriers in P3HT structures using this device architecture. Here we report results for top-contact FET devices, which show more reproducible FET characteristics using these preparation conditions [38]. Examples of transfer and output characteristics are shown in Fig. 2. For all (co)polymers, the output characteristics (source-drain current I_{ds} versus source-drain voltage V_{ds} at various gate voltages V_{gs}) show good saturation behavior, and the curves display typical characteristics of P3HT films using this preparation method [2,39]. From the transfer characteristics, we observe that the threshold voltages are close to 0 V, and the current on/off ratios are on the order of 10^3–10^4 (see Table 1). All these results show that the studied compounds behave as semiconducting polymers with low level of doping. The charge carrier mobilities μ, estimated in the saturation regime (i.e., from the slope of the plot of I_{ds} versus $V_{gs}^{1/2}$ at source-drain voltage $V_{ds} = -60$ V), are listed in Table 1. The μ values are in the range of 10^{-5}–10^{-3} $cm^2\,V^{-1}\,s^{-1}$; this is quite low compared to the highest mobilities reported for polymer FETs, which are on the order of 0.1–1 $cm^2\,V^{-1}\,s^{-1}$ for thiophene-based or thienothiophene-based polymers [40–42]. This difference can be attributed to the low molecular weight of the P3HT-based polymers studied here (maximum 7600 g/mol, corresponding to about 46 hexylthiophene units). Indeed, it has been shown that FETs made of low molecular weight fractions of P3HT show lower charge carrier mobilities: for $M_n < 10000$ g/mol, the charge mobility estimated in the same manner is $\sim 10^{-5}$–10^{-4} $cm^2\,V^{-1}\,s^{-1}$. For higher molecular weight fractions (10000 g/mol $< M_n <$ 40000 g/mol), μ is up to 10^{-2} $cm^2\,V^{-1}\,s^{-1}$. This difference has been attributed to the existence of charge transport pathways along longer chains connecting crystalline domains in the film and/or the more planar conformations in films of high molecular weight RRP3HT [43–44]. Surprisingly, we observe that the triblock copolymer film displays the highest value (around 0.5×10^{-3} $cm^2\,V^{-1}\,s^{-1}$), i.e. one order of magnitude higher than that of the corresponding P3HT homopolymer (0.6×10^{-4} $cm^2\,V^{-1}\,s^{-1}$) despite the fact that P3HT represents only about 60% by weight. This difference is not related to a molecular weight difference of the P3HT sequence, see Table 1. In our interpretation, it origi-

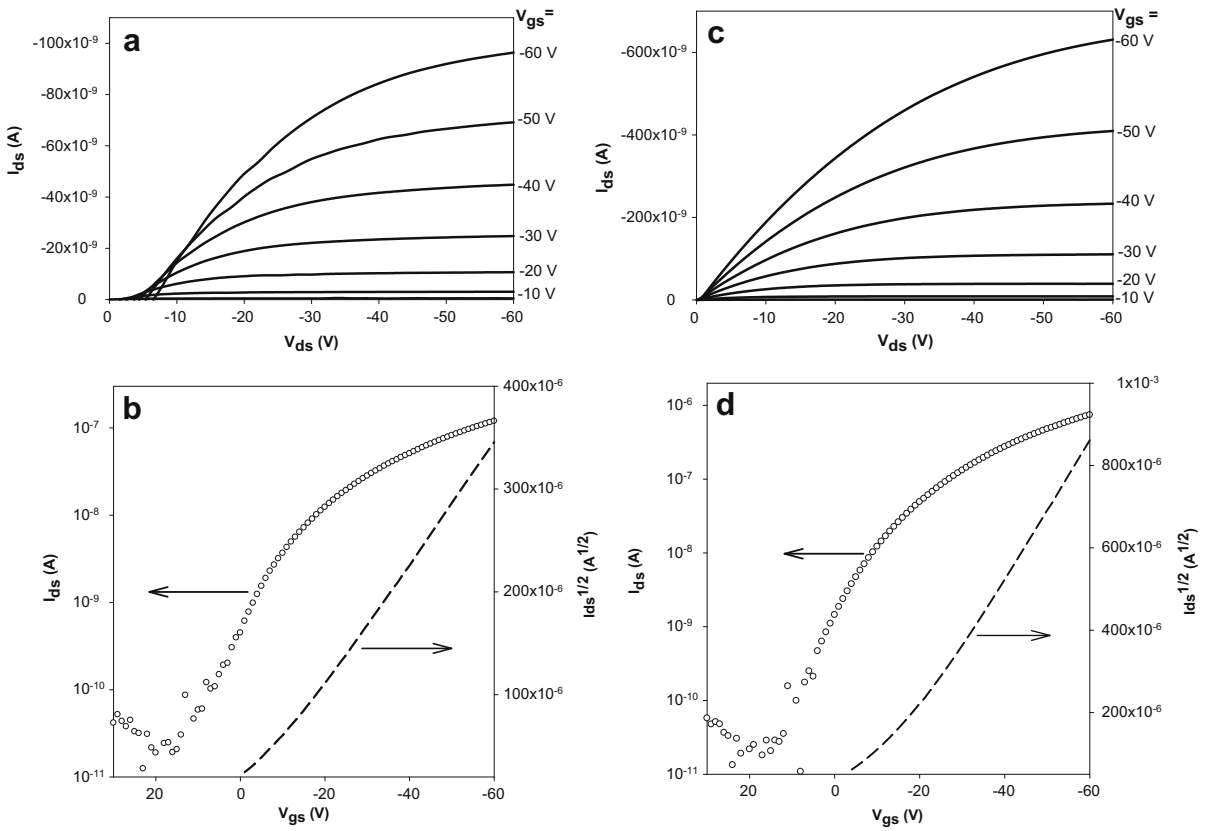

Fig. 2. Output (top) and transfer (bottom) characteristics of top-contact FET devices made of P3HT-$(OH)_2$ (a,b) and PCL-*b*-P3HT-*b*-PCL (c,d) as active layers.

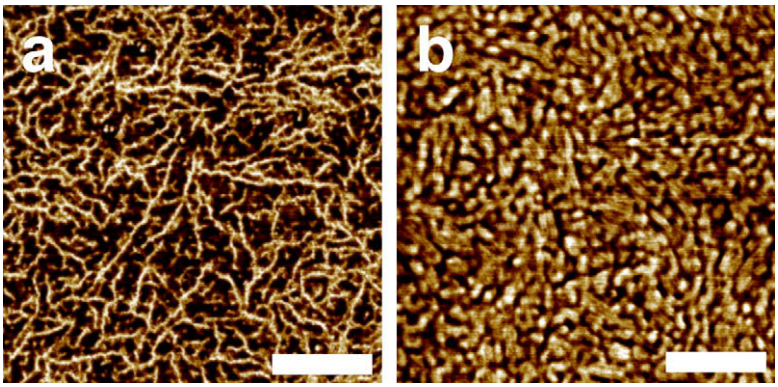

Fig. 3. AFM phase images of the active layer within the FET channel of (a) PCL-*b*-P3HT-*b*-PCL, and (b) P3HT-$(OH)_2$. The white scale bar is 250 nm-long.

nates from a difference in structural order within the thin films and/or interface with the electrodes. AFM measurements on the active layer in the channel of FET devices (see Fig. 3) reveal that films of PCL-*b*-P3HT-*b*-PCL show a higher degree of fibrillar order than pure P3HT-$(OH)_2$. The fibrils are relatively long in the case of PCL-*b*-P3HT-*b*-PCL (few hundreds nm-long) compared to the assemblies of P3HT-$(OH)_2$, which are confined in tens of nm-wide granular domains. In FET devices made of pure RRP3HT, it has been shown that films made of μm-long fibrillar structures lead to higher performances (i.e., charge mobility and current on/off ratio) than untextured, non-crystallized films, demonstrating that the fibrils act as efficient "conduits" for the charge transport in FET (in which the channel length is typically a few μm-long) [33]b,[35,39]. The higher degree of fibrillar order in PCL-*b*-P3HT-*b*-PCL spin-coated films is likely due to the tendency of this copolymer to phase-separate on the nanoscale, which probably forces the P3HT segments to be more in registry with each other and therefore leads to straight and long P3HT fibrils separated by small PCL domains. The higher charge carrier mobility observed here for the triblock copolymer also suggests that the charge transport is one-dimensional (along each fibril) rather than inter-fibrillar (bi-dimensional) in these materials [45], since in the case of the triblock copolymer film, the P3HT fibrils are surrounded by the PCL segments on each side, which are likely to insulate the π-conjugated systems of adjacent fibrils from each other.

4. Conclusions

In summary, we have described a well-controlled synthesis method for the design of poly(thiophene) block copolymers. Each reaction step has been carefully followed, making it possible to recover the target compounds in high yields without tedious purification steps. Regioregular P3HT homopolymers and P3HT-PCL block copolymers self-assemble into well-defined fibrillar structures. The charge transport properties of these (co)polymers have been characterized in FETs, showing characteristics of good quality organic semiconductors, with charge carrier mobilities in the range of 10^{-5}–10^{-3} $cm^2\,V^{-1}\,s^{-1}$. Interestingly, the copolymer PCL-*b*-P3HT-*b*-PCL shows higher charge mobility than the corresponding pure P3HT block, which is attributed to a higher degree of long-range fibrillar structures favored by nanophase separation. Since P3HT can be chemically doped after the self-assembly process and the lateral dimensions can be tuned by controlled synthesis of the polymer segments, these copolymers could be suitable materials for fabricating conducting nanowires insulated from each other. Moreover, the possibility of removing the PCL segments by hydrolysis shows potential for designing nano-sized pores (in between RRP3HT segments) [27] that could then be filled with electron acceptor molecules, which would be of interest for designing organic photovoltaic diodes with improved performances thanks to fine-control over the nanoscale morphology.

Acknowledgments

[36] The fully-extended length of RRP3HT chains is estimated by multiplying the average degree of polymerization N by the length of a monomer unit l (0.387 nm), taking into account the head-to-tail linkage of RRP3HT. The radius of gyration of the PCL coil is estimated with $R_g = l \times (N/6)^{1/2}$, with l being 0.85 nm in *trans-trans* conformation.
[37] Note that ultrathin deposits of pure PCL in the same conditions show dendritic structures with about 10 nm-thick crystalline lamellae (unpublished results). See also: V.H. Mareau, R.E. Prud'homme, Macromolecules 38 (2005) 398.
[38] When tested on several FETs, we observe that bottom-contact FETs show less reproducible properties than top-contact FETs (e.g. some of the output characteristics of bottom-contact FETs display discontinuities in the I–V curves). These differences between the two types of devices likely arise from different interface morphologies at the gold electrodes-semiconducting (co)polymer thin film.

between the donor and acceptor, which gives influence to exciton dissociation and charge transport and/or collection [10,14]. In order to control the blend morphology, various methods have been developed, among which thermal annealing [8,10,15–18], and vapor annealing [9,19,20] are frequently adopted. Although these fabrication protocols lead to an optimum morphology, it is challenging to apply these methods to practical fabrications. Thermal annealing is not compatible with the use of flexible substrates with low glass transition temperature, and solvent vapor annealing is not suitable for real roll-to-roll processes for the dangers of solvent vapor [21,22]. Recent years, several groups have devoted themselves to modifying the blend morphology by annealing-free approaches. One of these approaches is the addition of "unfriendly" solvents such as t-butanol, anisole and so on into the P3HT solution [23,24]. In mixed solution, P3HT chains tend to accumulate and form crystalline aggregates owing to the poor solubility. However the increased aggregate size of P3HT shortens the solution's shelf lifetime [25] and restrains the mixing of blends. Therefore, it is necessary to create new processing procedures for the development of flexible low-cost PSCs with high performance. Since the first report on additive to improve the device performance by Bazan and co-workers [26], lots of researches have focused their attention on this subject. Sariciftci and co-workers pointed out solar cells fabricated with additive shown red-shifted absorption and an increased optical absorption coefficient; meanwhile, the charge carrier mobility and carrier equilibrium mobility were also improved [27]. While Heeger and coworkers put their attention on investigating the mechanism of the modified morphology via introduction of a small concentration of additive, they interpreted that the modified morphology was attributed to the selective solubility as well as the difference of boiling points between host solvent and additive, such that the additive prevents isolated fullerene molecules from being dissolved throughout polymer phases and leaves more room for P3HT to undergo the crystallization process during the film-forming process [28,29]. However, the mechanism only concerns the role that the additive plays during the film-forming process and it gives no explanation on how the scale of phase segregation is tuned by the additive.

In this work, the role of the additive is revealed by combining the crystallization process of P3HT and the phase separation kinetics of P3HT/PCBM blends. Results show there are two different roles that the additive plays in the solution and during the film-forming process, respectively. First, the *n*-dodecylthiol improves the aggregation state of P3HT chains in the solution, which facilitates the coil-to-rod transformation, a premise condition for P3HT crystallization, and thus gives an enhancement of crystalline ability to P3HT. Secondly, *n*-dodecylthiol diminishes the influence of PCBM on the P3HT molecular interaction which benefits the P3HT crystallization, and the enhanced P3HT crystallinity reduces the PCBM amount resided in the amorphous regions of P3HT, then promotes the aggregation of PCBM which tunes the scale of phase segregation during the film-forming process. Thus, an increased P3HT crystallinity and a commensurate scale of phase separation balancing for exciton dissociation and charge transport and/or collection are finally obtained by adjusting the amount of additive, which results in an almost threefold increase in device efficiencies when the volume fraction of additive is 2.0% compared with reference devices without any additive in the photoactive layer as a consequence. Our conclusion suggests that an important characteristic of adding the additive is to promote the dispersion of P3HT in solution rather than the aggregation of P3HT, which gives rise to an increase of the solution's shelf lifetime and benefits the application of industrial mass production.

2. Experimental section

2.1. Materials

Regioregular HT-HT P3HT (>98.5%; HT: head-to-tail; Mw = 68 kDa) was purchased from Nichem Fine Technology Co. Ltd. PCBM (99.0%) was purchased from Solenne Co. Ltd. *n*-Dodecylthiol was purchased from Sigma–Aldrich Co. Ltd. Chlorobenzene was purchased from Beijing Chemical, China. All used as received.

2.2. Sample preparation

Samples for Dynamic light scattering analysis were prepared by dissolving P3HT in chlorobenzene to form a 10 mg ml^{-1} solution. The solution was sat for 12 h at r.t. Followed by blending with different volume fraction of *n*-dodecylthiol. Solutions for measurement were filtered with 450 nm PTFE membrane. The solution for spin-coating was prepared as followings: P3HT was first dissolved in chlorobenzene to make 10 mg ml^{-1} solution, followed by blending with *n*-dodecylthiol after 12 h, then PCBM (8 mg ml^{-1}) was added into the solution. The solution was stirring for 3 h prior to use.

2.3. Fabrication of solar cells

The solar cell devices used here were prepared on glass/ITO substrates. The substrates were cleaned by ultrasonic treating in detergent and deionized water then dried at 110 °C for 40 min. 40-nm-thick poly(ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, Baytron P4083) layer was spin-coated on the ITO glass and dried at 120 °C for 30 min. 90-nm-thick active layer was then deposited by spin-coating P3HT/PCBM blends under an inert atmosphere. Finally, the samples were transferred into an evaporator, 1-nm-thick LiF and 100-nm-thick Al electrodes were deposited by evaporation, respectively. The active surface area of typical device is 0.12 cm^2.

2.4. Characterization

UV–vis absorption spectroscopy (UV–vis): Solution and solid-state UV–vis absorption spectra were recorded with a Lambda 750 spectrometer (Perkin–Elmer, Wellesley, MA).

Grazing incidence X-ray diffraction (GIXD): GIXD patterns were obtained on Bruker D8 Discover Reflector (k = 1.78897 Å, Co source) under 40 kV and 40 mA tube

current. The X-ray profile was recorded from 3° to 30° with a step of 0.04° using automatic slits.

Atomic force microscope (AFM): The surface morphology of the films was characterized by SPA300HV equipped with a SPI3800N Probe Station (Seiko Instruments Inc., Japan) in tapping mode.

Transmission electron microscope (TEM): TEM was performed on JEOL JEM-1011 transmission electron microscope under 100 kV.

Dynamic light scattering (DLS): DLS of P3HT aggregates in solution was performed using a light scattering goniometer (BI200-SM, Brookhaven Instruments) equipped with a digital autocorrelator (BI-9000 AT, Brookhaven Instruments) and an Ar ion laser (Model 95, Lexel Laser, Inc.).

Viscosity measurement: Viscosity measurements were carried out with ARES G2 rotational rheometer. For all presented measurements, the P3HT/chlorobenzene (10 mg/ml) solution with and without *n*-dodecylthiol was fed into the cylinder rheometer and measured under constant angular shear frequency ($\omega = 1\ S^{-1}$) at 25 °C.

Photoluminescence spectroscopy (PL): PL emission spectrum was recorded with Hitachi F-4500 spectrophotometer equipped with a 150 W xenon lamp at room temperature.

Device parameter measurements: Current density–voltage (*J–V*) curves of the photovoltaic devices under white light illumination were measured using a computer-controlled Keithley 236 source meter.

3. Results and discussion

3.1. Modify the film morphology by the addition of n-dodecylthiol

The addition of *n*-dodecylthiol to P3HT/PCBM solution prior to spin-coating was found to significantly enhance the P3HT self-organization ability. The self-organization ability can be defined as the process of transformation from disorder to order, known as crystallizing, which can be divided into two mechanism-controlled processes: intrachain mechanism of coil-to-rod transformation to form lamellae, and interchain mechanism of lamellae stacking into ordered structure as suggested by Hotta and co-workers [30]. Thus, the self-organization ability could be viewed as the tendency of P3HT crystallizing into ordered structure. This enhanced self-organization ability led to improved P3HT crystallinity and intensified phase separation extent of P3HT/PCBM in films.

The enhanced self-organization ability of P3HT was confirmed by UV–vis absorption spectra. The UV–vis absorption spectra of the P3HT/PCBM blend films with and without *n*-dodecylthiol are shown in Fig. 1(A). Two bands of peaks are clearly indexed: one is the peak around 334 nm which corresponds to the absorption PCBM, the other is a broad peak consisting of a main absorption at 520 nm and two vibronic shoulder absorptions at 558 nm and 607 nm, which represents the contribution of P3HT. The shoulder mentioned above was not distinguishably observed for the as-produced film (without additive in solution). After adding of *n*-dodecylthiol, the two vibronic

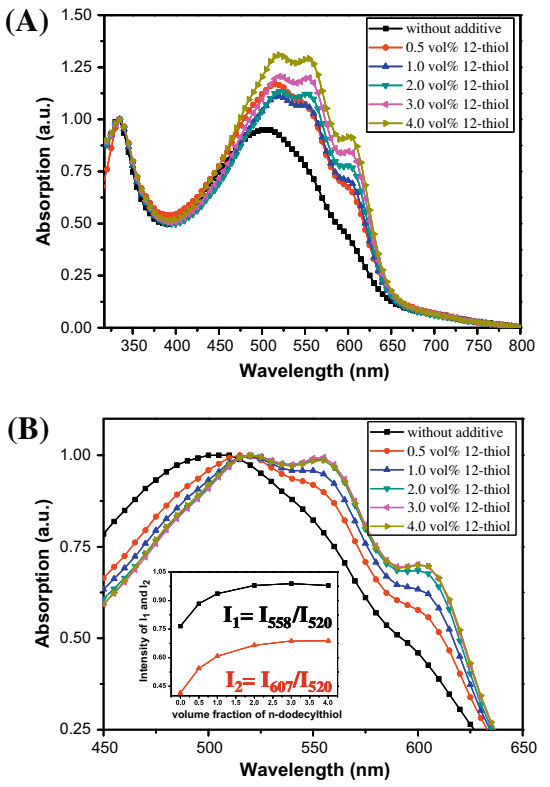

Fig. 1. (A) Absorption spectra for P3HT/PCBM blend films with different volume fraction (0.5%, 1.0%, 2.0%, 3.0% and 4.0%) of *n*-dodecylthiol. (B) Magnified image normalized at the maximum absorbance of the specified regions; Inset is the change trends of $I_1$and I_2, $I_1 = I_{558}/I_{520}$; $I_2 = I_{607}/I_{520}$; I_{520}, I_{558}, I_{607} represent the intensity of the peak located at 520 nm, 558 nm and 607 nm, respectively.

shoulder absorptions became visible. It is well known that the shoulder at 558 nm is attributed to the absorption of extended conjugation of P3HT in the solid-state [31] and the other one at 607 nm comes from the interchain stacking of P3HT [32]. Increasing the concentration of *n*-dodecylthiol from 0% to 4.0%, the ratios of peak intensity I_1 and I_2 (To quantitatively compare the aggregating state of P3HT, the spectra with different *n*-dodecylthiol content were normalized according to the peak intensity around 520 nm, and $I_1 = I_{558}/I_{520}$; $I_2 = I_{607}/I_{520}$; I_{520}, I_{558}, I_{607} represent the intensity of the peak located at 520 nm, 558 nm and 607 nm, respectively.) increased gradually as shown in the inset of Fig. 1(B). The change trends of I_1 and I_2 suggested the increased planarization and stabilization of P3HT chains, and the enhanced ordered packing of P3HT backbones resulted from the interchain π–π stacking, respectively [33]. At the same time, the intensity of the absorption band associated with P3HT also increased, which was attributed to the enhanced absorption coefficient of the film due to the growth of P3HT crystals promoted by the enhanced P3HT self-organization ability [18,34].

The enhanced P3HT self-organization ability after the addition of *n*-dodecylthiol aided the evolution of a well-ordered P3HT crystallite was also proved by the GIXD result

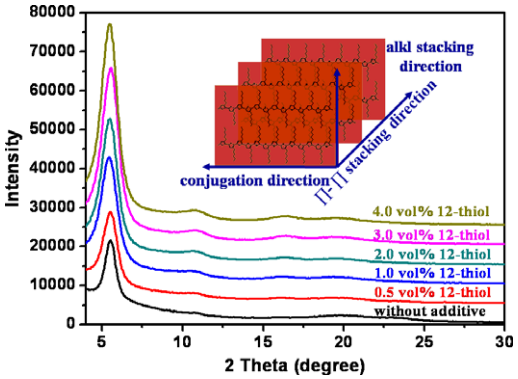

Fig. 2. GIXD spectra for P3HT/PCBM films deposited from different volume fraction of *n*-dodecylthiol. The inset shows the structure and orientation of the thiophene crystallites.

as shown in Fig. 2. All films showed an intense (1 0 0) diffraction peak at $2\theta = 5.4°$, corresponding to an ordered lamellar structure with an interlayer spacing, which was formed by parallel stacks of P3HT main chains that were separated by the alkyl side chains, as shown in the inset of Fig. 2 [22]. The intensity of the peak at $2\theta = 5.4°$ was proportional to the number of P3HT crystalline nanodomains and, in a certain view point, to the crystallinity of the investigated samples when the films had same area and thickness [35]. Judging from the increasing intensity of this peak with the amount of *n*-dodecylthiol, an increased crystallinity of P3HT could be traced, which resulted from the enhanced self-organization ability due to the addition of *n*-dodecylthiol. However, diffraction peaks caused by PCBM were barely seen in the diffractogram of the blend films both with and without *n*-dodecylthiol. Thus, adding of *n*-dodecylthiol only promoted the crystallization of P3HT but had little influence on the crystallization of PCBM.

Bright-field TEM which has been used to directly reveal the phase segregation in composite P3HT:PCBM films was used in our experiment. The TEM images of the P3HT/PCBM blend film were shown in Fig. 3. The dark areas of the images were thought to be PCBM-rich domains because of their relative higher electron scattering density as compared with P3HT [10]. As-produced film (Fig. 3(a)) was apparently homogeneous and the phase separation between P3HT and PCBM could hardly be distinguished. After the addition of *n*-dodecylthiol, fibrillar P3HT crystals, which were relatively brighter as compared to the background, became longer and its number also increased. In addition, the PCBM-rich domains grew up gradually, suggesting an intensified phase separation after adding *n*-dodecylthiol.

Based on the above observations, the conclusion that adding *n*-dodecylthiol to P3HT/PCBM blend system could improve the self-organization ability of P3HT to form crystallites and increase the scale of phase segregation was strongly confirmed. However, the thing we mostly care about is the mechanism behind these phenomena.

3.2. Mechanism for improving the P3HT crystallinity and enhancing the P3HT/PCBM phase separation extent

In this section, a proposed mechanism was put forward to explain the improved self-organization ability of P3HT and the enhanced scale of phase segregation. Experiments showed that these phenomena should be attributed to two functions of *n*-dodecylthiol in different stages: (1) reduced the P3HT chains entanglement in solution, which promoted the P3HT self-organization ability and thus benefited the crystallization of P3HT; (2) diminished the influence of PCBM on the P3HT molecular interaction, and promoted the aggregation of PCBM to form phase segregation during the film-forming process.

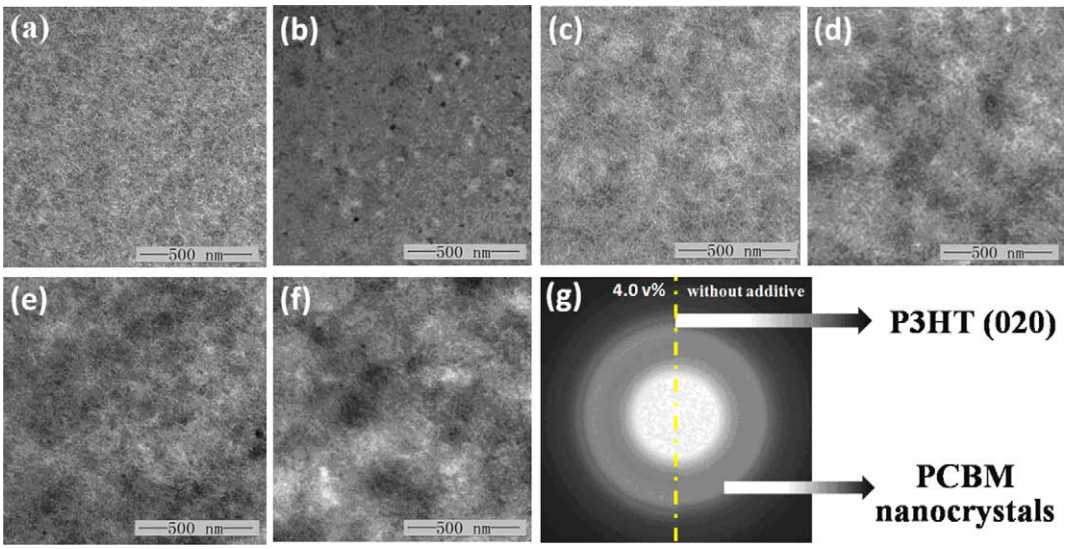

Fig. 3. TEM images of P3HT/PCBM blend films with different volume fraction of *n*-dodecylthiol: (a) 0.0%, (b) 0.5%, (c) 1.0%, (d) 2.0%, (e) 3.0% and (f) 4.0%. SAED patterns (g) obtained from P3HT/PCBM films with 0.0% and with 4.0% *n*-dodecylthiol.

3.3. Reducing the extent of entanglement among P3HT chains in solution

As is well known, it is not easy for P3HT to self-organize during the crystallizing process because of the strong chains entanglement [36]. Clarifying the effects of chains entanglement on aggregation and/or crystallization of P3HT is quite necessary for further understanding the mechanism of additive in this case. In order to exactly present the aggregation states of P3HT in solution, P3HT/chlorobenzene solution with and without additive were investigated by DLS and UV–vis. The DLS result of P3HT/clorobenzene solution showed two peaks in Fig. 4(A). The aggregation state of P3HT in solution has been investigated in recent years, the experimental results indicated the presence of two coexisting phases: P3HT in solution and P3HT in aggregates [30]. So the peak centered at 6.5 nm should be assigned to the scattering signal of P3HT single chain, the other one centered at 170 nm corresponded to the signal of P3HT aggregates. The aggregates were actually in amorphous state, because no absorption peak at 607 nm was observed in the combining UV–vis detection (Fig. 4(B)) [37]. After the addition of *n*-dodecylthiol, the dispersion of P3HT chains in chlorobenzene was improved. As shown in Fig. 4(A), the averaged size of P3HT aggregates reduced from 170 nm to 134 nm and 75 nm after adding 2.0% and 4.0% *n*-dodecylthiol, respectively. Whereas the peak position of single P3HT chains remained unchanged, but its intensity increased which hinted more single P3HT chains were obtained.

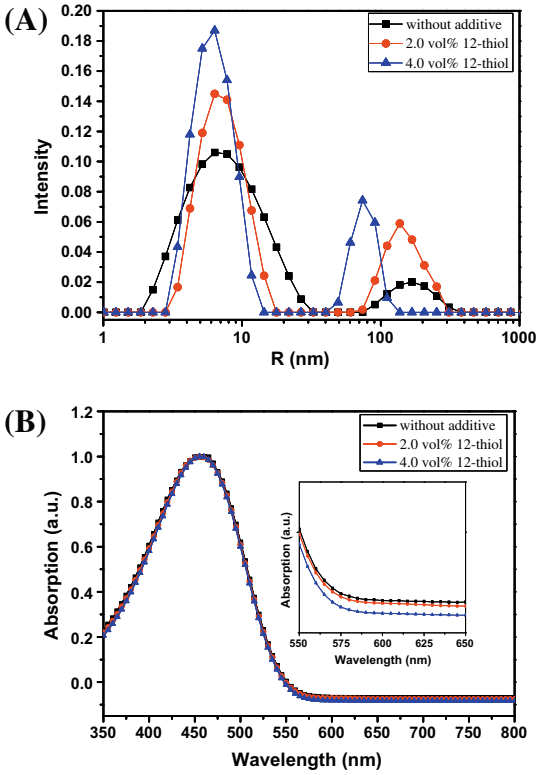

Fig. 4. (A) DLS spectra for P3HT/chlorobenzene solutions with different volume fraction of *n*-dodecylthiol. (B) Absorption spectra for P3HT/chlorobenzene solutions with different volume fraction of *n*-dodecylthiol. The insets show magnified images of the specified regions.

The influence of the additive on the solution viscosity was also investigated. The viscosity of P3HT/chlorobenzene solution is 1.12 cp, it reduced to 1.05 cp after the *n*-dodecylthiol (has higher viscosity than chlorobenzene) was added. The decrease amplitude was 6.25% (Table 1). As we know, the interaction among polymer chains affects the solution viscosity. A viscosity decrease of the solution means the physical cross-linking among the polymer chains reduced, i.e., the polymer coils have a tendency to not interact with each other [25]. After *n*-dodecylthiol was added, the entanglements among polymer chains became disentangled. As a result, some of P3HT chains escaped from the amorphous aggregates and randomly distributed as single molecule or smaller aggregate in the solution, which resulted in a reduced viscosity.

The changed states of P3HT in solution had a profound effect on the crystallinity of P3HT film. As we can see from Fig. 5(A), red-shifts in parallel with more pronounced vibronic peaks in P3HT film absorption spectra were observed after the addition of *n*-dodecylthiol, which was attributed to the enhanced self-organization ability of P3HT. As a result, P3HT formed crystallites more easily and thus resulted in a high absorption coefficient. Meanwhile, more intensive peaks in GIXD of P3HT films (Fig. 5(B)) also indicated higher crystallinity of P3HT after the addition of *n*-dodecylthiol. AFM height images of P3HT films with different amount of *n*-dodecylthiol were also shown in Fig. 5(C). The film casted from the solution contained *n*-dodecylthiol showed more fibrillar P3HT crystals running across the surface and had higher rms value. All these data demonstrated that the reduced P3HT aggregate size and the increased number of P3HT single chains after the addition of *n*-dodecylthiol in solution could enhance the crystallinity of P3HT.

It has been elucidated that the crystallization of P3HT is fundamentally driven by a single chain mechanism. A coil-to-rod transformation in P3HT main chain conformation followed by interchain π–π stacking is thought to be the precondition toward crystallization [30]. Consequently, rod-like rigid conformation of P3HT is quite necessary for production of crystallinity P3HT films. However, the chains entanglement certainly reduces the mobility of P3HT and thus hinders its coil-to-rod transformation. While *n*-dodecylthiol mixed with chlorobenzene could aid the dispersion of P3HT molecules. As a result, some of P3HT chains

Table 1
Viscosity of chlorobenzene (CB), *n*-dodecylthiol (12-thiol), P3HT/chlorobenzene solution (P3HT/CB, the concentration of P3HT was 10 mg/ml) and P3HT/chlorobenzene/*n*-dodecylthiol solution (P3HT/CB/12-thiol, the volume fraction of *n*-dodecylthiol was 4.0% and the concentration of P3HT was 10 mg/ml).

	CB	12-Thiol	P3HT/CB	P3HT/CB/12-thiol
Viscosity (25 °C cp)	0.73	2.53	1.12	1.05

The viscosity of chlorobenzene and *n*-dodecylthiol are from Handbook of Chemistry and Physics, 82th ed.

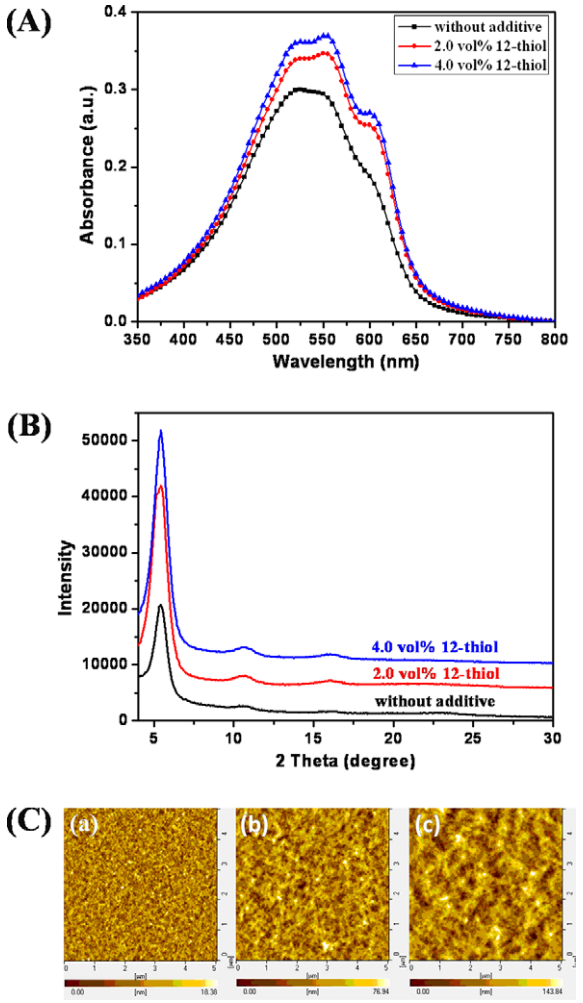

Fig. 5. (A) Absorption spectra and (B) GIXD spectra for P3HT films deposited from different volume fraction of *n*-dodecylthiol. (C) Tapping mode AFM height images of P3HT/PCBM blend films with different volume fraction of *n*-dodecylthiol: (a) 0.0%, (b) 2.0% and (c) 4.0%. The root-mean-square value is (a) 2.85 nm, (b) 13.22 nm and (c) 26.67 nm, respectively.

escaped from the amorphous aggregates and randomly distributed as single molecules or smaller aggregates in the solution. This speculation has been supported by DLS and in Fig. 4(A). Both the peak intensity of the aggregates and of the single chains were enhanced after adding *n*-dodecylthiol to solution, suggesting that some of the original larger-size aggregates transformed into more small aggregates and more single chains, which was also consist with the viscosity measurements. Due to the decreased extent of chains entanglement, P3HT single chains gained more freedom in rotation or motion, and also gave rise to the possibility of coil-to-rod transformation. In addition, with the evaporation of chlorobenzene, the fraction of *n*-dodecylthiol increased. Owning to the low solubility of P3HT in it (Table 2) (the solubility of P3HT and PCBM were obtained using the method depicted by Yang et al. [38]), P3HT would be promoted to aggregate to avoid the solvent.

Table 2
Boiling points, vapor pressure and P3HT, PCBM solubility of chlorobenzene and *n*-dodecylthiol.

Solvent	Boiling points (°C)	Vapor pressure at 25 °C (Pa)	S_{P3HT} (mg/ml)	S_{PCBM} (mg/ml)
Chlorobenzene	132	1573	>20.0	>20.0
n-Dodecylthiol	266–283	1	<0.2	1.8

Boiling points and vapor pressure are from Handbook of Chemistry and Physics, 82th ed.

During this process, the P3HT with rod conformation would get π–π stacking and then formed microcrystalline. The fraction of the polymer in the ordered aggregated phase is determined by the fraction of P3HT chains with rod conformation state at a given temperature [30]. Thus, the reduced entanglement extent among P3HT chains caused by the addition of *n*-dodecylthiol promoted the crystallinity of P3HT.

3.4. Diminishing the influence of PCBM and enhancing the phase segregation extent during the film-forming process

In P3HT/PCBM blend system, PCBM aggregation and phase separation extent during the film-forming process also played crucial role in energy conversion efficiency. In this case, *n*-dodecylthiol selectively dissolved PCBM and had a relative higher boiling point compared with chlorobenzene. These differences caused a change in phase separation kinetics of P3HT/PCBM blend system. The addition of *n*-dodecylthiol in P3HT/PCBM blend would enhance the discrepancy in precipitation sequence between P3HT and PCBM. During the film-forming process, chlorobenzene evaporated first, then P3HT precipitated prior to PCBM and formed aggregates. Due to the easiness of conformation transition and without the disturbance of PCBM, the P3HT crystallinity would be enhanced [34], i.e., the ratio of amorphous P3HT reduced. The Debye–Scherrer rings observed in the selected area electron diffraction (SAED) of P3HT shown in Fig. 4(G) confirmed the enhanced crystallinity of P3HT after the addition of *n*-dodecylthiol, which was consistent with the crystallinity change of P3HT after annealing treatment by Loos and co-workers [39]. While in P3HT/PCBM composite film, PCBM resided only in the amorphous P3HT domains [40]. So the enhanced P3HT crystallinity decreased the amount of PCBM in it after the addition of *n*-dodecylthiol, which resulted in a large scale of phase separation. When the volume fraction of *n*-dodecylthiol increased, this phenomenon was intensified and consequently a larger scale of phase separation was obtained.

3.5. Optimizing the n-dodecylthiol content for high performance photovoltaic devices

Photovoltaic devices based on P3HT/PCBM blend films with different *n*-dodecylthiol content were made according to standard ITO/PEDOT:PSS/P3HT:PCBM/LiF/Al architecture. The current density–voltage (*I*–*V*) curves of the devices are shown in Fig. 6(A). The open-circuit voltage

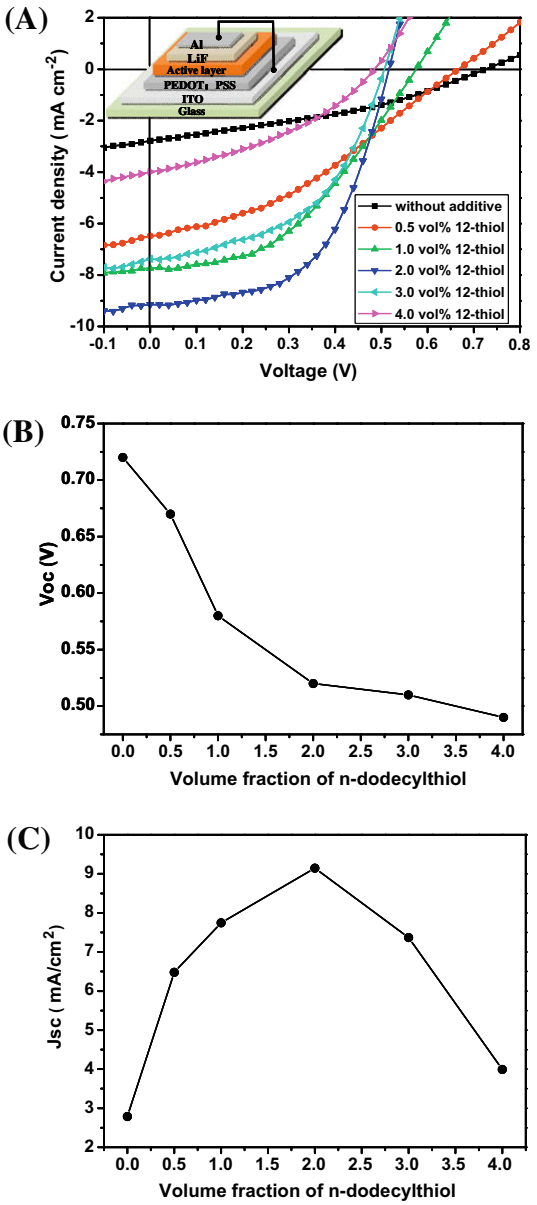

Fig. 6. (A) *I–V* curves for devices processed from P3HT/PCBM with different volume fraction of *n*-dodecylthiol under AM 1.5 illumination. Inset shows the structure of the organic solar cell. (B) Plot of V_{oc} and (C) J_{sc} vs. *n*-dodecylthiol content under AM 1.5G illumination.

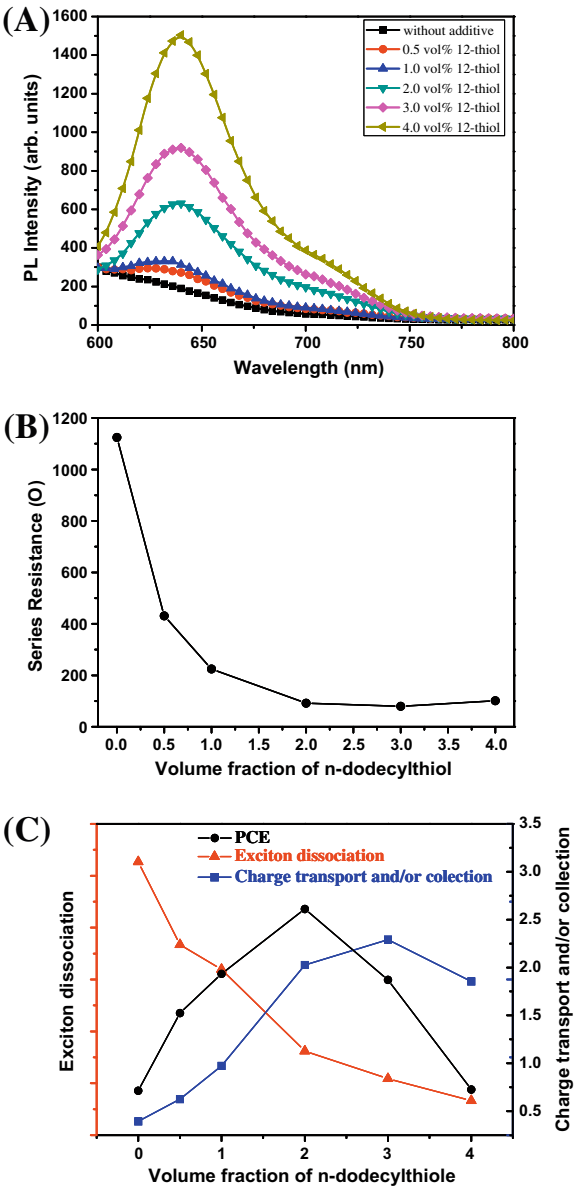

Fig. 7. (A) Photoluminescence (PL) quenching of P3HT/PCBM films with different volume fraction of *n*-dodecylthiol. Intensities of the spectra have been normalized according to the excitation at 520 nm. (B) Plot of series resistance vs. *n*-dodecylthiol content under AM 1.5G illumination. (C) Plots of exciton dissociation efficiency, carrier transport and/or collection efficiency, and PCE vs. *n*-dodecylthiol content under AM 1.5G illumination.

(V_{OC}) dropped monotonically with *n*-dodecylthiol content (Fig. 6(B)) from 0.68 V to 0.49 V. Generally, V_{oc} of polymer solar cells is dominated by the difference in energy levels between the HOMO of donor and the LUMO of the acceptor [20]. The addition of *n*-dodecylthiol increased the P3HT conjugation length on average, as a result decreased the HOMO energy level of P3HT, which resulted in decreasing in V_{oc} for the photovoltaic device. Unlike V_{oc}, the short-circuit current density (J_{sc}) presented a quite different changing mode against *n*-dodecylthiol content as shown in Fig. 6(C). An up-down mode with peak value of 9.1 mA cm^{-2} at 2.0% content was presented. A better fitting with solar emission spectrum and an improved charge transport after adding *n*-dodecylthiol may partially account for the improvement of J_{sc}. However, when the volume fraction of *n*-dodecylthiol beyond 2.0%, it would contaminate the J_{sc} for a large phase separation which was not suit for the exciton dissociation. To investigate the relationship between phase separation extent and exciton dissociation, photoluminescence was conducted

by exciting at 520 nm. The photoluminescence intensity increased with *n*-dodecylthiol as shown in Fig. 7(A), indicating that fewer excitons were able to diffuse to the interface before returning to base. In other view of point, the average interface distance between P3HT and PCBM turned out to be longer [41] as concluded above. The enhanced phase separation extent played a negative role for exciton dissociation, but benefited the charge transport and/or collection. The series resistance of the device calculated from the *I*–*V* curve in dark (Fig. 7(B)) decreased significantly after adding *n*-dodecylthiol, which is a signal of the efficiency of charge transport and/or collection [42]. A relative larger scale in phase separation would reduce the probability of charge recombination during charge transport and/or collection [20,43]. To establish the relationship between the device performance and the size of phase separation, plot of PCE vs. *n*-dodecylthiol content was made and shown in Fig. 7(C). Two other curves which represent exciton dissociation ability (the reciprocal of intensity of PL) and charge transport and/or collection ability (the reciprocal of series resistance), respectively, were also shown. At low volume fraction of *n*-dodecylthiol (<2.0%), corresponding to the small-scale phase separation, the PCE was limited by poor charge transport and/or collection, and charges were more likely to meet an opposite charge to recombine before reaching the electrode. While at high volume fraction of *n*-dodecylthiol (>2.0%), corresponding to large scale phase separation, exciton dissociation was impeded. When *n*-dodecylthiol was 2.0%, corresponding to intermediate-scale phase separation, an optimum balance between exciton dissociation and charge transport and/or collection was obtained, resulting in a PCE peak value of 2.61%, which was almost threefold increase in device efficiencies compared with reference devices without any additive in the photoactive layer as a consequence. This phenomenon is consistent with the dynamical Monte Carlo modelling of organic solar cells [44].

4. Conclusions

In this work, *n*-dodecylthiol was added to P3HT/PCBM solution to improve the P3HT crystallinity and enhance the P3HT/PCBM phase separation. It was shown that *n*-dodecylthiol played important role both in the solution and during the film-forming process. In solution, *n*-dodecylthiol reduced the P3HT chains entanglement which facilitated the P3HT coil-to-rod transformation and enhanced the P3HT crystallinity. During the film-forming process, due to the introduction of *n*-dodecylthiol, the P3HT crystallinity was enhanced, and it reduced the PCBM amount which dissolved in the amorphous regions of P3HT, then promoted the aggregation of PCBM, which contributed to the controlled scale of phase segregation. On these bases, an increased P3HT crystallinity and a commensurate scale of phase separation balancing for exciton dissociation and charge transport and/or collection were finally obtained by adjusting the amount of *n*-dodecylthiol, which resulted in an almost threefold increase in device efficiencies when the volume fraction of additive is 2.0% compared with reference devices without any additives in the photoactive layer as a consequence.

that this behavior is very different from that of a vacuum-deposited film of pentacene with no side chains, showing an increased behavior of the mobility with increasing T_a [10]. The annealing effect is found to suppress both the development of the cracks and the increase of the off-current with time in air under ambient pressure. It is suggested that the cracks act as trapping sites of moisture and/or oxygen for the off-current flow.

A top contact FET structure, shown in Fig. 1, was used in our study. A solution-processed polymer showing the low current leakage and negligible hysteresis, poly(4-vinylphenol) (PVP) mixed with methylated poly(melamine-co-formaldehyde) (MMF) of 125 wt.% as a cross-linker [11], was selected as a gate insulator. The PVP with MMF, dissolved in propylene glycol methyl ether acetate (PGMEA) in 10 wt.%, was spin-coated on the top of the pre-patterned ITO gate electrode, baked at 100 °C for 1 min to remove any residual PGMEA, and subsequently baked for 5 min at 200 °C to produce thermal cross-linking in the PVP layer. The thickness of the cross-linked PVP film was about 540 nm and the capacitance per unit area was 6.4 nF/cm^2. A solution of the TIPS-pentacene, dissolved in 1,2-dichlorobenzene (1,2-DCB) in 1.0 wt.%, was drop-casted on the top of the PVP insulator and was baked at 60 °C for 1 min to evaporate the 1,2-DCB solvent. The baking temperature of 60 °C is known to improve the crystallinity of the TIPS-pentacene film itself [6]. It should be noted that the cross-linked PVP layer is chemically inert against the 1,2-DCB solvent used for the TIPS-pentacene. The source and drain electrodes were prepared on the TIPS-pentacene film using gold (Au) at the deposition rate of 0.1 nm/s. The thickness of the Au electrode was 80 nm. The length (L) and the width (W) of the channel were 50 and 2000 μm, respectively. The fabricated TIPS-pentacene FETs were annealed up to 150 °C to examine the mobility enhancement, the crack development and the resulting morphological change, and the crystallinity in the TIPS-pentacene film. After thermal annealing, the TIPS-pentacene FETs were stored in air under atmospheric pressure for 4000 h to determine how the electrical properties of the TIPS-pentacene FETs change with time. The electrical measurements were carried out using a semiconductor parameter analyzer (HP4155A) at room temperature.

We first describe the crack development and the crystallinity of the TIPS-pentacene film prepared on the cross-linked PVP insulator as a function of the annealing temperature T_a. As shown in the optical microscopic (OM) images in Fig. 2, it is clear that no cracks were developed when annealed at temperatures below 60 °C. As T_a increases further beyond 60 °C, cracks were developed and more propagated. This may result from the inelastic stress built up during the thermal annealing above 60 °C. In contrast to a vacuum-deposited pentacene film [10], the cracks are naturally developed in the TIPS-pentacene film due to the existence of side chains irrespective of the mismatch in thermal expansion between the pentacene film and a gate dielectric layer. This is clear from the fact that no considerable difference between the cracks developed on a cross-linked PVP in our case and those on an inorganic SiO_2 [8] was observed although the thermal expansion coefficients of the two materials are much different (by a factor of 10) from each other [12]. Like other typical polymers with side chains [13,14], the side chains in the TIPS-pentacene are expected to be affected by the thermal treatment than the main backbone. This implies that the type of side chains is very important to suppress the development of cracks during thermal annealing and to increase the solubility of the pentacene derivatives in common organic solvents.

Fig. 2 shows that the X-ray diffraction (XRD) peak intensities along the (0 0 1) direction in the TIPS-pentacene films baked initially at 60 °C as a function of T_a. As T_a increases, the (0 0 1) diffraction peak increases and reaches a maximum at T_a = 60 °C and then decreases. Our XRD results indicate that the highest ordered state was obtained when the TIPS-pentacene film was annealed at 60 °C. This may result from the evaporation of any residual 1,2-DCB solvent and the relaxation of any mechanical strain in the TIPS-pentacene film, producing structurally more ordered arrangement of the TIPS-pentacene molecules, during the annealing process. The resultant high crystallinity is directly related to the large mobility of the TIPS-pentacene FET. The inset shows typical series of (0 0 l) diffraction peaks of the TIPS-pentacene film annealed at 60 °C, in which the well-defined and sharp diffraction peaks also represent the existence of highly ordered domains in the TIPS-pentacene film [7]. The decrease in the (0 0 1) diffraction peak for the TIPS-pentacene films annealed above 60 °C was accompanied by the crack development. Based on the crystallinity of the TIPS-pentacene film in relation to the crack development, the optimum value of T_a is determined to be 60 °C in this study.

We now examine how the electrical properties of our TIPS-pentacene FETs are influenced by the thermal annealing which is closely related to the crack development. Fig. 3a and b shows the output characteristic curves and

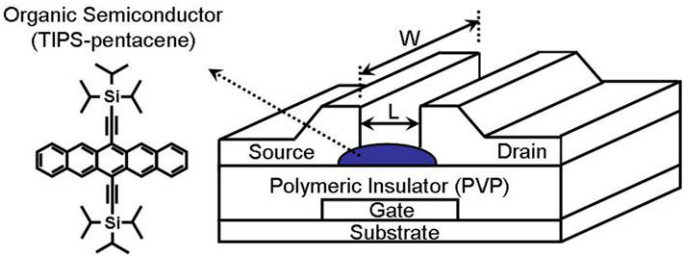

Fig. 1. The chemical structure of a soluble organic semiconductor, TIPS-pentacene, and the schematic diagram of our TIPS-pentacene FET with a solution-processed polymer insulator. The channel length and the channel width are denoted by L and W, respectively.

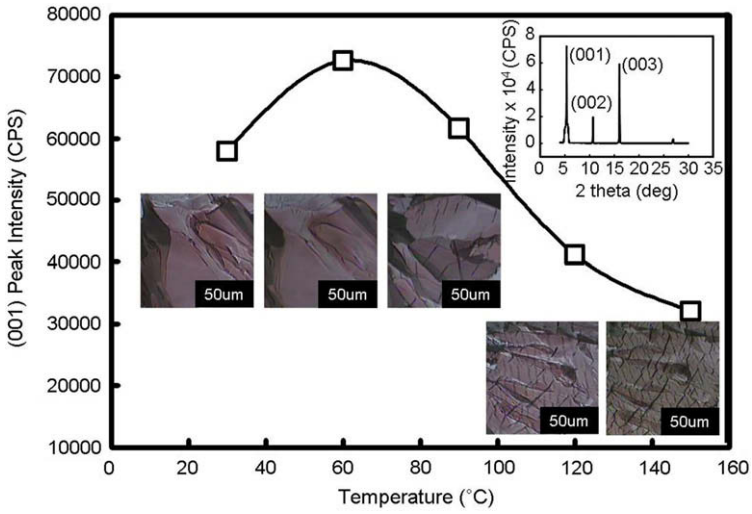

Fig. 2. The peak intensities of the X-ray diffraction along (0 0 1) and the corresponding optical microscopic images of the TIPS-pentacene films annealed at various temperatures. The inset shows typical series of the X-ray diffraction peaks observed in the TIPS-pentacene films annealed at 60 °C.

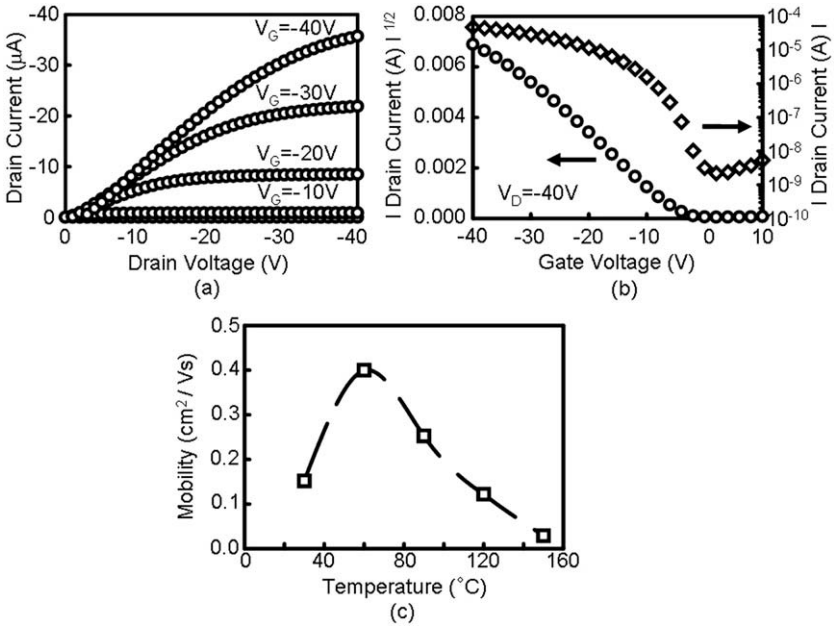

Fig. 3. (a) The output characteristic curves of our TIPS-pentacene FETs annealed at 60 °C, (b) the corresponding transfer characteristic curves, and (c) the field-effect mobility of each TIPS-pentacene FET as a function of the annealing temperature. The data at the drain voltage of −40 V were used for obtaining the mobility in each TIPS-pentacene FET.

the corresponding transfer characteristic curves of our TIPS-pentacene FETs annealed at the optimum value of T_a = 60 °C, respectively. From the characteristic curves, the field-effect mobility was determined to be 0.401 cm^2/V s. Note that without the help of an extra passivation layer and the optimization of the work function [6], and blending of the TIPS-pentacene [15], the high value of about 0.401 cm^2/V s has not been attained so far in a TIPS-pentacene FET fabricated on a solution-processed polymer gate insulator.

The annealing temperature (T_a) dependence of the field-effect mobility is shown in Fig. 3c. The mobility for the as-prepared TIPS-pentacene FET case was 0.152 cm^2/V s, and that annealed at T_a = 60 °C was 0.401 cm^2/V s. For T_a above 60 °C, the mobility decreases as low as 0.029 cm^2/V s at T_a = 150 °C due to the appearance of thermal cracks in the TIPS-pentacene film. This behavior does not exist in thermally-deposited films of pentacene with no side chains but a simple increased behavior is observed with

increase in the annealing temperature [10]. The on–off current ratio varies from 9×10^3 to 3×10^4 depending on T_a.

Let us investigate the thermal annealing effect on the stability of our TIPS-pentacene FETs in terms of the field-effect mobility and the off-current with time. Three different types of the TIPS-pentacene FETs (with no thermal treatment, annealed at 60 °C, and annealed at 150 °C) were studied at three different storage times of 0, 600, and 4000 h in air under atmospheric pressure. The OM images, taken after 4000 h, showing the morphology for each case were presented in Fig. 4a–c. In the non-annealed TIPS-pentacene FET, the cracks that did not exist initially were developed in time while in the annealed cases, no considerable change in the morphology was observed irrespective of the presence of the cracks. It is clear from Fig. 4d that after 4000 h, the mobility value for the non-annealed TIPS-pentacene FET decreases drastically by about 90% from 0.152 to 0.011 $cm^2/V\,s$ while the mobility values of the annealed cases decrease rather slowly by about 50% from 0.401 to 0.205 $cm^2/V\,s$ for $T_a = 60$ °C and from 0.029 to 0.016 $cm^2/V\,s$ for $T_a = 150$ °C. This implies that in relation to the cracks, the annealing effect plays a critical role in the stability of the TIPS-pentacene FETs. It is found that the thermal treatment at the optimum value of $T_a = 60$ °C avoids the crack development and enhances the crystallinity in the TIPS-pentacene film. This is why the TIPS-pentacene FET annealed at 60 °C exhibits the highest mobility (0.401 $cm^2/V\,s$) and the best stability in time among the three types of the TIPS-pentacene FETs we studied.

Fig. 4e shows both the relative change of the off-current and the resulting on–off current ratio with time for three different devices to address the temporal degradation in relation to the cracks. After 4000 h stored in air under atmospheric pressure, the values of the off-current for the TIPS-pentacene FETs with cracks shown in Fig. 4a and c increase as large as 80 times while the value for the TIPS-pentacene FET annealed at the optimum value of $T_a = 60$ °C, showing no cracks, increases by about a factor of 10. From the fact that the moisture and/or oxygen diffused into an organic semiconductor film deteriorate the electric properties of the FETs [16–18], it is reasonable to conclude that the physicochemical adsorption of air and/or moisture onto the cracks dictates primarily the long-term stability of the TIPS-pentacene FETs with time. After 4000 h, the on–off current ratio for the TIPS-pentacene FET annealed at the optimum value of $T_a = 60$ °C is on the order of 10^3, while that for the non-annealed case is below 10^2.

In summary, we demonstrate how the thermal annealing affects the mobility enhancement, the development of cracks and the resultant degradation mechanism of the electrical properties, and the temporal stability of the TIPS-pentacene FETs fabricated on a single, solution-processed polymer insulator. The annealing process at the optimum temperature of 60 °C results in the highest field-effect mobility of 0.401 $cm^2/V\,s$ among the TIPS-pentacene FETs we studied. Such high value has not been obtained so far in the TIPS-pentacene FET having a solution-processed polymer insulator without an additional buffer layer or a blending process. It is found the annealing effect suppresses both the development of the cracks and the increase of the off-current with time in the ambient environment. The cracks act as trapping sites of moisture and/or oxygen for the off-current flow and thus deteriorate the electrical performances of the TIPS-pentacene FET. Finally, further studies on the structural arrangement of side chains of the TIPS-pentacene in relations to the cracks as a function of temperature and the nature of the solvent used will provide a scientific platform for developing all solution-processed printed electronics.

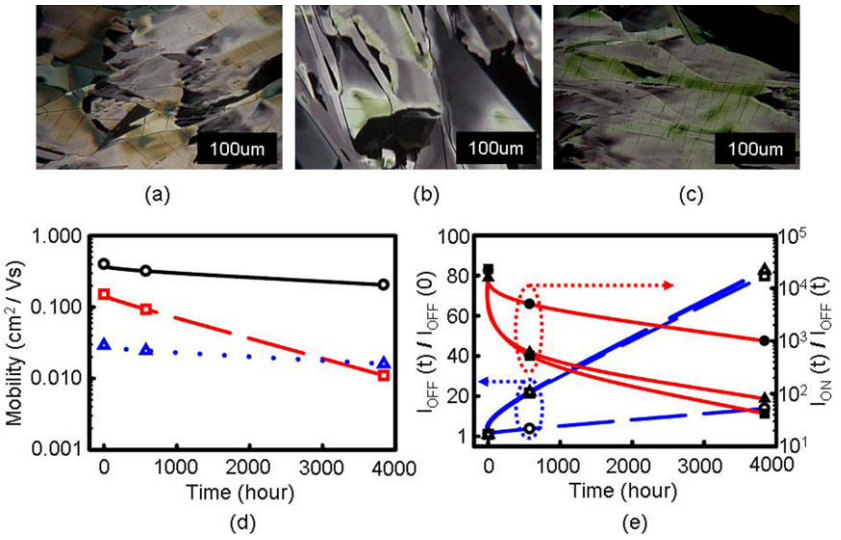

Fig. 4. The optical microscopic images, taken after 4000 h stored in air under atmospheric pressure, of the TIPS-pentacene film, (a) without the thermal treatment, (b) annealed at 60 °C, (c) annealed at 150 °C and (d) the field-effect mobility of each case as a function of the storage time. Open squares (dashed line), open circles (solid line), and open triangles (dotted line) represent the non-annealed case, the annealed case at 60 °C, and the annealed case at 150 °C, respectively, (e) the relative change of the off-current (open symbols) and the resulting on–off current ratio (filled symbols) of each case as a function of the storage time in the ambient environment.

fabricate a device of ZnO nanorod/semiconductor polymer heterostructure by a simple process, and ZnO EL with ultraviolet (UV) at 380 nm is detected under forward bias.

2. Experimental setup

The procedure for device fabrication is as follows. First, we cleaned the indium tin oxide (ITO) glass using acetone, ethanol, and deionized water sequentially. In the ZnO nanorod synthesis process, zinc acetate dehydrate solution was used as the seeding layer and spin-coated on the ITO glass substrate for subsequent growth of nanorods. Then, it was baked at 350°C for 20 min at ambient pressure. The hydrothermal reaction solution for ZnO nanorod fabrication was prepared by mixing 25 mM zinc nitrate hexahydrate ($Zn(NO_3)_2{\cdot}6H_2O$) and 25 mM hexamethylenetriamine ($C_6H_{12}N_4$) in 200 ml of deionized water in a glass beaker. During growth, the glass beaker was placed in an electrically heated thermostatic water bath and maintained at 92°C for 15 min. Subsequently, the sample was removed from solution and washed with ethanol and deionized water repeatedly and baked for 30 min at ambient pressure. A p-type polymer poly [2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) was dissolved in chloroform with a concentration of 5 mg/mL and then spin-coated on as-grown ZnO nanorod layers at a rotation speed of 1000 rpm (rotations per minute). This low rotation speed is intended to provide a smooth surface for subsequent thin film deposition. About 100 nm of Al film was deposited by thermal evaporation under high vacuum conditions at 2×10^{-4} Pa. A schematic diagram of the device and energy levels is shown in Fig. 1. In our experiment, a forward bias on the device denotes that the ITO is used as anode and Al as cathode. Device testing consists of measuring the EL spectrum at different DC bias voltages and of measuring the current–voltage–light power (*I–V–L*) characteristics with a system comprising an ACTON 150 CCD spectrometer, a Keithley 2410 electrometer and a Newport 1830-C Optical Power Meter Mainframe controlled by a computer. All of these tests were carried out at room temperature and in ambient atmosphere.

3. Results and discussion

The morphology of the ZnO nanorods was observed by field emission scanning electron microscopy (SEM). From the SEM pictures shown in Fig. 2(a), we can observe a ZnO nanorod array grown primarily aligned along the per-

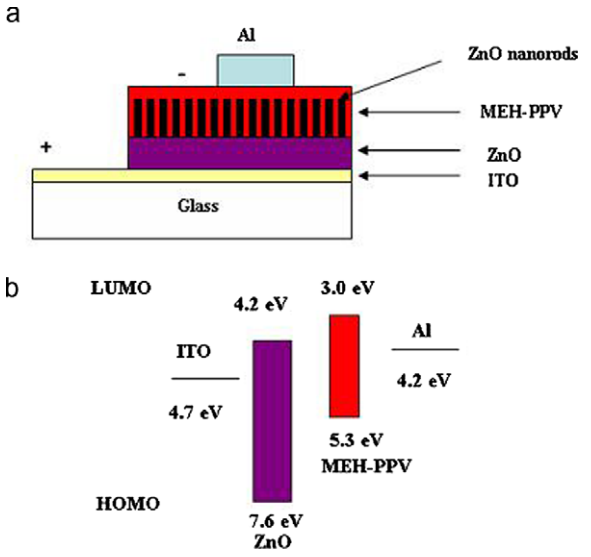

Fig. 1. Schematic diagram (a) and energy levels (b) of the ZnO nanorods/MEH-PPV heterostructure.

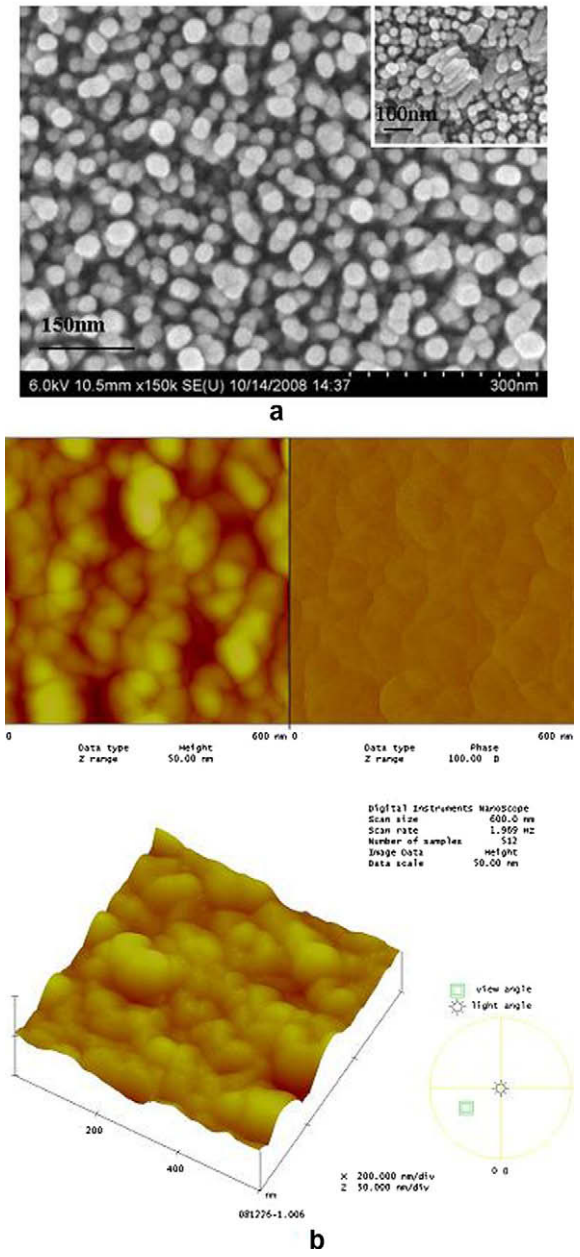

Fig. 2. (a) Top view of ZnO nanorods on ITO glass. Inset: top view of some fallen ZnO nanorods. (b) AFM picture of ZnO nanorods/MEH-PPV.

pendicular direction of the ITO substrate. The average height and diameter of the nanorods are about 130 nm and 30 nm, respectively. If the polymer layer of MEH-PPV is coated onto the nanorods as shown in Fig. 1, some MEH-PPV molecules should fill the space in between nanorods. It looks like the ZnO nanorods are encircled by MEH-PPV molecules. The thickness of MEH-PPV should be enough to cover all nanorods in order to prevent current leakage from ZnO nanorods to the Al electrode directly. This can be proved by atomic force microscopy (AFM) pictures as shown in Fig. 2(b). After coating with MEH-PPV, the roughness is a few nanometers and there is no phase separation according to the phase picture in Fig. 2(b). This means that all ZnO nanorods are completely covered with MEH-PPV.

Although the ultraviolet emission of ZnO excited by light has been detected, it is difficult to observe under an electric field. Even when it is observed, the intensity is very weak. The reason is that p-type doping of ZnO has remained a challenge. Nominally undoped ZnO typically exhibits n-type conductivity due to asymmetric doping limitations and the possibility of holes getting compensated by intrinsic donors, such as zinc interstitials and oxygen vacancies. So it is difficult to realise p-type ZnO doping with high quality and reproducibility. Now, different groups still continue their efforts in these researches to obtain more effective p-type ZnO. Hsu et al. reported that p-type ZnO can be prepared by a hydrothermal method by adjusting the properties of the seed layer [7]. Light emitting diodes based on n-GaN/p-ZnO have been fabricated and UV emission under forward bias was observed. In addition, devices based on p-ZnO/n-type organic materials were also prepared. The UV emission of ZnO is weak in these devices. The problem is that the stability of p-ZnO requires further study in this report. In order to obtain UV emission properties of ZnO, a lot of researchers have applied other p-type semiconductors, for example, Si, GaN, ZnTe, $SrCu_2O_2$, SiC, etc., to substitute p-ZnO to make the light emitting diodes. Only a few kinds of diodes have emitted UV light under a DC bias [11–13]. Meanwhile, some researchers use organic materials to prepare ZnO/polymer heterojunctions devices. Könenkamp et al. prepared a kind of LED with ZnO nanowires/polymer heterojuctions, and detected the electroluminescence at 384 nm [9,14]. Then Chang et al. also realised 383 nm electroluminescence in ZnO nanowires/polymer heterojuctions [10]. In these studies, the process for preparing the LED is almost the same. Firstly, a layer of organic insulator was spin-coated on a layer of ZnO nanowires or rods, and then the organic insulator was removed from the nanowires or rods. Afterwards, a p-type organic luminescence material was spin-coated. The UV emission of ZnO is weaker than defect emissions of ZnO in these reports. In our experiments, we fabricated ZnO nanorod/polymer heterostructure LEDs in which no insulator material is used to fill the space between nanorods. When the forward bias is 28 V, UV emission of ZnO at 380 nm is prominent and better than that of other similar reported LED devices [7,9,10,14]. All results of our experiments demonstrate that UV emission devices can be fabricated by a simple method based on ZnO nanorods/polymer heterostructures.

Fig. 3(A) shows the EL spectra of the ZnO nanorod/polymer heterostructure LED under different forward biases. When the forward bias is 22 V, the EL spectrum shows emission with multiple peaks at 380 nm, 580 nm, 610 nm, and 747 nm, respectively. When the DC bias voltage is increased, the EL intensity increases but the spectrum shape is not changed further. In order to make these emission peaks clearly distinguishable, the EL spectrum at 28 V is fitted to a Gaussian function, as shown in Fig. 3(B). It is clear that except for emissions at 380 nm, 580 nm, 610 nm, and 747 nm, there is a peak at around 640 nm. The emission at 380 nm is the band edge emission of ZnO nanorods and the emission at 580 nm with a shoulder at 610 nm is due to the exciton emission of MEH-PPV. According to the literature [9], emissions at 640 nm and 747 nm correspond to the defect emission of ZnO. With an increase in voltage, the intensity of the 380 nm line increases faster than other emissions along with increasing voltage. When the voltage reaches 28 V, the ZnO band edge emission becomes predominant and stronger than other emissions, and the full width at half maximum of this emission is 25 nm. In addition, defect emissions of ZnO nanorods is observed clearly at long wavelengths. To

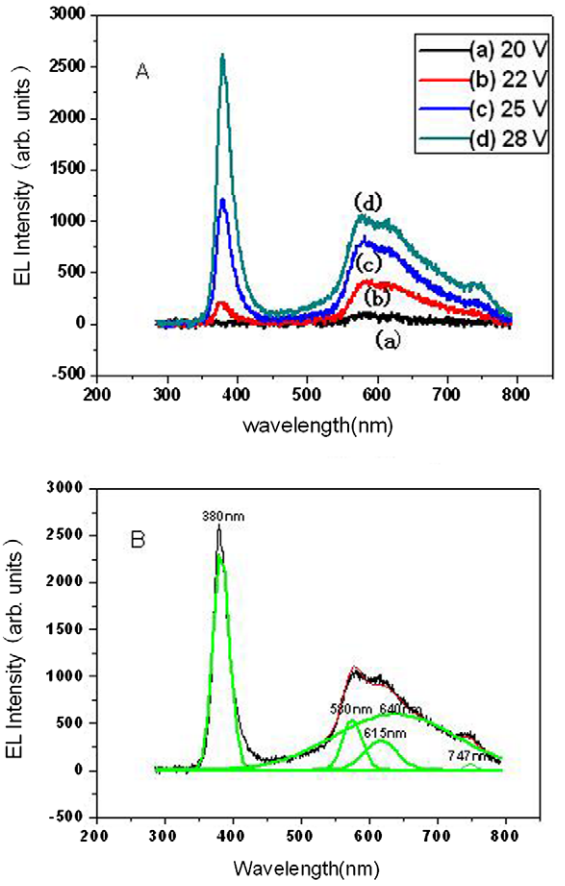

Fig. 3. (A) EL spectrum at different applied voltages of the ZnO nanorod/polymer heterostructure. (B) EL spectrum at 28 V after Gaussian fitting.

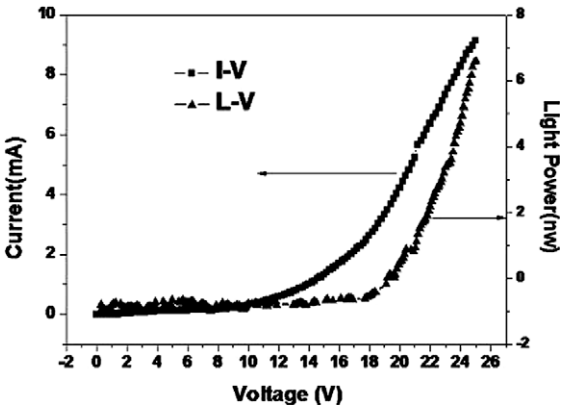

Fig. 4. Current–voltage–light power (380 nm) characteristics of the ZnO nanorod/polymer heterostructure.

summarise, the emissions of ZnO is stronger than that of MEH-PPV. However, under reverse bias no emissions are observed.

Fig. 4 shows the *I–V* characteristics of the ZnO nanorod LED. This structure demonstrates well-behaved and stable rectifying diode behaviour. According to the *I–L–V* characteristics, the luminescence increases faster than current at high voltages. It is concluded that the emission efficiency at high voltage is improved compared with the phenomenon at low voltage.

Fig. 1(b) shows the energy band structure of the device under forward bias. When the voltage is low, only the exciton emission of MEH-PPV is detected. As we know, the exciton emission of organic materials is due to carrier injection from both sides. The electron is injected from Al into the MEH-PPV layer and holes are injected from the ZnO nanorods. It has been reported that ZnO nanorods synthesised by hydrothermal methods display ambipolar charge transport [15]. Using bottom contact field-effect transistor structure, ZnO nanorods exhibit electron and hole mobilities up to 3.2 and 2.1$cm^2\ V^{-1}\ s^{-1}$, respectively. The hole mobility of ZnO nanorods is far larger than the electron mobility of MEH-PPV (about $10^{-5}\ cm^2\ V^{-1}\ s^{-1}$). So carriers recombine preferentially in the MEH-PPV layer at low applied voltage, and then excitons are formed in MEH-PPV and give the emission at 580 nm. Along with the increase of the applied voltage, band edge emission at 380 nm and defect emissions at 640 nm and 747 nm from ZnO nanorods are observed. But, at the beginning, the intensity at 380 nm is lower than that at 640 nm and 747 nm. Increasing the applied voltage results in band bending in MEH-PPV. So a carrier tunnelling process becomes possible. Electrons in the Al electrode tunnel through the MEH-PPV layer directly into the defect states of the ZnO nanorods under a relatively low electric field. Holes in the ITO electrode tunnel to the valence band of the ZnO nanorods. These holes recombine with electrons in defect states and give stronger defect emissions at a relatively low applied voltage. When the applied voltage is higher, the tunnelling of electrons and holes is more effective; in particular more electrons tunnel into the conduction band of the ZnO nanorods. The recombination of electrons in the conduction band and holes in the valence band give rise to band edge emission, which is enhanced faster than other emissions with increases in applied voltage. Moreover, the barrier between the valence band of ZnO and HOMO of MEH-PPV (as shown in Fig. 1(b) is enough to accumulate and confine holes in the ZnO nanorods. Therefore, the band edge emission of the ZnO nanorods is detected and competes with and exceeds other emissions. Again, this is proved by the *I–V–L* measurement. As seen from Fig. 4, the emission at 380 nm increases faster at high voltage than at low voltage. At the same time, although the exciton emission of MEH-PPV increases too, its enhancement is nevertheless lower than the ZnO nanorod emissions because of the fact that more electrons tunnel directly into ZnO nanorods from the Al electrode. So there are fewer carriers in MEH-PPV than in the ZnO nanorods.

Under reverse bias, no emission is observed. Although electrons and holes could be injected into the ZnO nanorods from the ITO electrode and into MEH-PPV from the Al electrode, they are confined within the ZnO nanorods and MEH, respectively, because of the barrier. The LUMO potential of MEH-PPV is higher than the conduction band potential of the ZnO nanorods, and the valence band potential of the ZnO nanorods is lower than that of HOMO of MEH-PPV. So it is difficult for electrons to transfer to a higher potential and holes to a lower potential under reverse bias. This results in a carrier imbalance in both ZnO and MEH-PPV. In such a case, exciton recombination emission of MEH-PPV or band edge emission of ZnO is difficult to realise in two layers.

4. Conclusion

In conclusion, a ZnO nanorod inorganic/organic heterostructure LED was prepared. A band edge ultraviolet emission peak at 380 nm, and defect emission from ZnO at 640 nm and 747 nm were detected. In addition, the typical exciton emission of MEH-PPV was measured. At low voltage, the emissions of MEH-PPV and defect emission of ZnO are clear and band edge emission is weak. At higher voltage, the band edge emission of ZnO is prominent and stronger than other emissions. The full width at half maximum of the 380 nm emission is 25 nm. Under high forward bias, the tunnelling of carriers results in stronger 380 nm emission. Under reverse bias, there is no emission. Because the ZnO nanorods were fabricated at low temperature, this ZnO-based LED offers a low-cost process in the field of UV LEDs.

of the long sublimation tube, it is essential to control the temperature gradient of the long sublimation tube very carefully for an efficient purification process.

With this technique, however, usually one cannot get a sufficient purity through just one purification process, and needs a couple of purifying processes to get a sufficiently high purity of target materials. Consequently, it consumes long time and a lot of source materials inefficiently [16,20]. After a couple of sublimation purification, one can get only 50% or less from the first source materials. These drawbacks become more serious problems in the view point of low cost devices which is one of the most important competitive merits of organic electronic devices. Therefore, the improvement of the purifying efficiency is urgently needed for the realization of low-cost and high-performance organic electronic devices.

Our research group has already reported a modified sublimation purification system using arrays of partitions [21]. By installing arrays of partitions in the sublimation tube, the HPLC purity of 1,3-bis[2-(2,2′-bipyridine-6yl)-1,2,4-oxadiazol-5yl] benzene (Bpy-OXD) was increased from 99.37% to 99.73%. This increase of purity resulted in lowering the driving voltage of EL device (for luminance of 1000 cd/m^2) as large as 1 V (from 4.7 V to 3.9 V), and increasing the lifetime of device 1.5 times longer (from 50 h to 79 h). In that system, however, some inherent problems exist and hinder us in commercializing as an efficient purification system. One is the difficulty of extracting the purified materials from the array of partition. Although the final yield was almost the same with that of a conventional method, it is very difficult and time-consuming to extract the purified materials deposited on the array of partition, especially on the junction parts between partitions. Another problem is the existence of undivided region by partitions – the surface of glass tube – which is almost the same state with the conventional method.

In this paper, we report a highly efficient sublimation purification system using baffles with orifices to solve those problems mentioned above. The purity and the effective yield of purified materials were improved simultaneously by introducing baffles with orifices in the sublimation glass tube.

2. Experimental

2.1. New purification system

The new sublimation purification system developed in this study was shown schematically in Fig. 1. There are two heaters; one is for the sublimation of materials and set on the high-temperature (T_h) region (Heater 1, 10 cm in length), and the other is for temperature gradient of long glass tube which is set on the low-temperature (T_l) region where purified materials are deposited (Heater 2, 20 cm in length). The sublimation tube is a 70 cm long quartz tube (40 mm in external diameter, 2 mm in thickness), and the pressure in the tube was controlled 1 Pa or 80 Pa with an Ar gas (99.9999%) flow.

Several pieces of baffles (32 mm in diameter) with orifices were inserted between inner glass tubes (32 mm in diameter), and they were attached each other tightly enough to prevent leakage of purified materials through joint chinks between inner tubes and baffles. Two groups of baffles were introduced separately in T_l region and T_h region, respectively. The number of baffles, hence the interval between baffles, was changed from 0 to 2 or 3 (20 mm and 10 mm intervals, respectively) in T_h region. The intervals between baffles in T_l region were also changed from 20 mm to 50 mm. Baffles were installed very carefully not to align orifices straightly between neighbored ones. A photograph of Fig. 1b shows the set of three pieces of baffles in T_h region and 50 mm interval in T_l region.

We have used mainly two kinds of baffles with different orifices; one has two orifices (10 mm in diameter) and another four (7 mm in diameter), as shown in Fig. 1c. We have also used two kinds of materials for the baffles; stainless steel (SS) and quartz. The percentage of open areas (orifices) is about 25%, and the thickness is 2 mm for all kinds of baffles.

We have also modified the source boat to be a similar shape with the inner glass tube having a narrow orifice on the rear side to prevent a reverse flow of sublimed materials as shown in Fig. 1a and b. Several pieces of glass tubes whose diameter is the same with the inner glass tube were installed on the rear of the source boat up to the gas

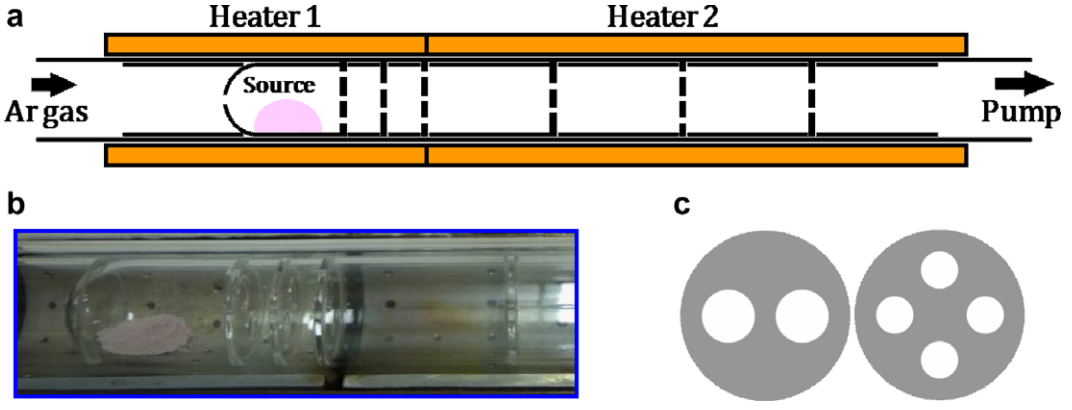

Fig. 1. (a) A schematic illustration of the new sublimation purification system where baffles with orifices are inserted between inner glass tubes. (b) An example of set-up of the new purification system; three pieces of baffles in T_h region and 50 mm interval in T_l region. 90° twisted installing of baffles by turns not to align orifices straightly between neighbored ones is worthy of notice. (c) Representative two kinds of baffles with two and four orifices.

inlet for the guidance of Ar gas into the source boat through a narrow orifice. Otherwise most of Ar gas flow outside of the source boat not into it because of a narrow orifice of the source boat, which resulted in two times longer sublimation time.

2.2. Evaluation of purification efficiency

For the evaluation of purification efficiency of a new purification system, we used three organic materials; bathocuproine (BCP, TCI, 97%), tris(8-hydroxyquinolinato) aluminum(III) (Alq_3, TCI, >95%) and 1,3-bis[2-(2,2′-bipyridine-6yl)-1,2,4-oxadiazol-5yl]benzene (Bpy-OXD, Hodogaya Chemical Co., Ltd., >99%), whose molecular structures are shown in Fig. 2. We have purified these materials under various conditions by changing the interval between baffles inserted in T_l region and/or by changing the number of baffles inserted in T_h region with various kinds of baffles described at the previous section, and compared the purification efficiency with that of conventional method.

As the factors for purification efficiency, we have evaluated and compared the purity (for BCP and Bpy-OXD) and the yield (for Alq_3 and BCP) of purified materials. For the evaluation of the purity factor, we have measured the melting point (T_m) of purified materials with the differential scanning calorimetry (DSC, Seiko Instruments, DSC6200, 2 °C/min heating condition). We have also compared the driving voltages to get 10 mA/cm^2 (V_{10J}) and 100 mA/cm^2 (V_{100J}) of EL devices whose structure is shown in Fig. 2d schematically; all of the materials used in this study are electron transport materials, and used as the electron transport layer (ETL) in the EL devices. In general, T_m goes up and driving voltage of EL device goes down as the purity is increased [7,19,22,23]. For Bpy-OXD, we have also checked the HPLC purity and compared with the results of T_m and driving voltages. The measurement condition of HPLC is as follow: column: Inertsil ODS-2 (5 μm, 4.6 × 250 mm), carrier: CH_3CN/0.05% TFA = 4/6, rate: 0.9–1.0 ml/min, temp.: 40 °C, det.: 254 nm. For the evaluation of the yield factor of purified materials, we have extracted carefully all of materials deposited at T_l region which is divided by a fixed length, and made it as the total yield. Among them, we have made the yield from a fixed section (50 mm length from the start of T_l region) as the effective yield. And then we have calculated the ratio of the effective yield (R_{EY}) by dividing the effective yield with the total yield.

3. Result and discussion

3.1. Yield

For the understanding of the effect of introducing baffles on yield, we have compared the total yield and the effective yield of purified BCP under various purification conditions, and some representative results are shown in Fig. 3, and summarized in Table 1. When we compared

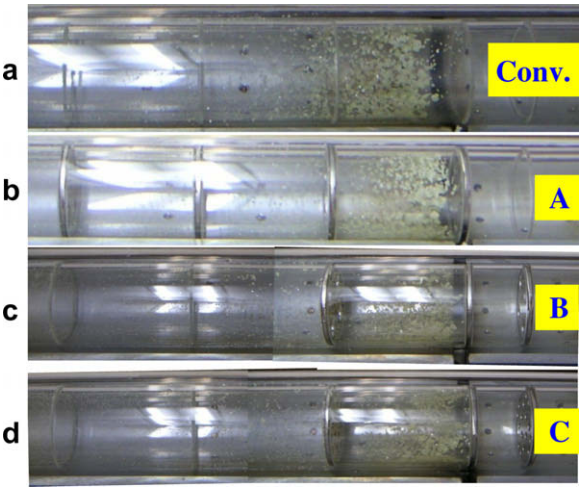

Fig. 3. Some representative results of purification of BCP under various purifying conditions; (a) a conventional method without introducing baffles, (b) introducing baffles only in T_l region, (c) introducing baffles with four orifices in both of T_h and T_l regions, and (d) the same setting with (c) except the number of orifices of baffles (16 orifices).

Molecular structures of (a) bathocuproine (BCP), (b) tris(8-hydroxyquinolinato) aluminum(III) (Alq_3), (c) 1,3-bis[2-(2,2′-bipyridine-6yl)-1,2,4-oxadiazol-5yl] benzene (Bpy-OXD) and (d) EL device structure used in this study. All of purified materials were used to make the electron transport layer (ETL).

Table 1
Summary of the yield data of purified BCP under various conditions which are shown in Fig. 3.

Condition	Total yield[a] (%)	Effective yield[b] (%)	R_{EY}[c] (%)
Conv.	86.49	**63.35**	**73.25**
A	84.58	**66.06**	**78.10**
B	86.72	**68.34**	**78.80**
C	87.09	**67.77**	**77.82**

[a] The quantity of BCP set in the source boat was 0.5 g.
[b] A yield from the first glass tube with 50 mm length.
[c] R_{EY} = (effective yield/total yield) × 100.

the total yield, we cannot get any relation between the total yield and the purification condition. In some conditions the total yield was increased compared with the conventional method, and in another conditions the yield was decreased. However, when we compared the effective yield – yield from the first glass tube with 50 mm length where is considered to collect the highest purity materials – it was found that the effective yield was increased by introducing baffles in all conditions. These increases became clearer by comparing R_{EY}, as shown in Table 1. In a conventional method, R_{EY} was about 73%, and it was increased up to about 78% by introducing baffles. If we consider that yields from the first baffle in T_l region were about 8% which are not concluded in the effective yields, these increases are much more meaningful.

This result strongly suggests that the purified materials are deposited more concentrated region by introducing baffles, which means that purified materials can be extracted from narrower region. This may be related not only to the efficiency of extraction but also to the purity of extracted materials since more pure materials can be deposited on narrower region.

To elucidate the effect of introducing baffles on the yield more clearly, we have changed the intervals between baffles in T_l region, and investigated whether there are any relations with the effective yield. The results with Alq_3 are summarized in Fig. 4 and Table 2. The intervals were controlled to be from 50 mm to 20 mm (Fig. 4b–e), and compared with a conventional method (Fig. 4a). At first, when we compare the effective yield from the marked region by two blue lines whose width is about 13 cm, it seems that there is not any relation between the intervals and the effective yield. However, when we look at the R_{EY}, it is clear that the R_{EY} is increased as the intervals are shortened. Considering 13 cm is quite broad region in this purification system, this clear relation between the intervals and the R_{EY} affords proof of the effect of introducing baffles on the yield mentioned above. When we compare the width of region where 50% yield was obtained, we can grasp this effect even more clearly. As shown in Fig. 4, yield 50% lines were shifted to T_h region as the intervals were shortened, which means that purified materials were deposited more compactly by introducing baffles and the deposition region was narrowed as the intervals was shortened.

In this section, it was clearly described that baffles introduced in T_l region make purified materials deposited on more concentrated region which was revealed with increased R_{EY} value.

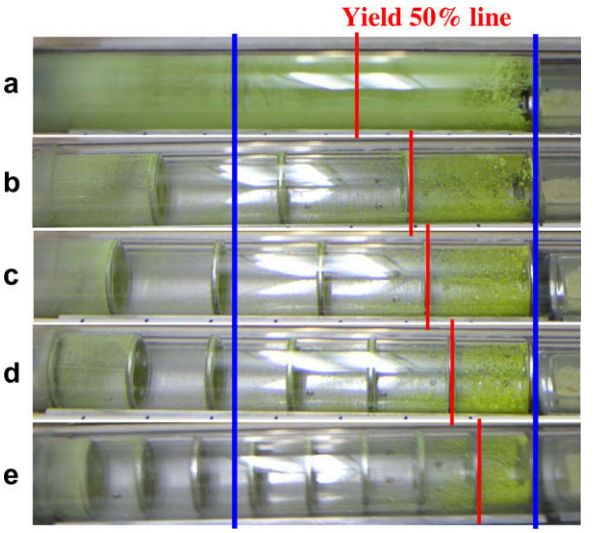

Fig. 4. Results of purification of Alq_3 (a) with a conventional method (without baffles), and (b–e) with the new system under different intervals between baffles; (b) 50 mm, (c) 40 mm, (d) 30 mm, and (e) 20 mm. The width of marked region by two blue lines is about 13 cm. Red lines represent the place to where 50% yield was extracted from the start. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table 2
Summary of the yield data of purified Alq_3 under various conditions with different intervals between baffles which are shown in Fig. 4.

Interval (mm)	Total yield[a] (%)	Effective yield[b] (%)	R_{EY}[c] (%)
No	74.88	71.92	**96.05**
50	73.43	70.65	**96.21**
40	72.33	69.90	**96.64**
30	77.88	75.48	**96.91**
20	74.64	72.73	**97.44**

[a] The quantity of Alq_3 set in the source boat was 1.0 g.
[b] A yield from the marked region of about 13 cm length.
[c] R_{EY} = (effective yield/total yield) × 100.

3.2. Purity

To evaluate the effect of introducing baffles on the purity clearly, we have used Bpy-OXD which is relatively easy to get HPLC purity data and to compare another data such as T_m and driving voltages of EL devices. It is also possible to compare this new purification system with the former one of our research group because it was also used in the former purification system.

All of results for Bpy-OXD were summarized in Table 3. We have used two kinds of baffles; QA has two orifices and QB four which are shown in Fig. 1c, and both of them are made of quartz. We have purified Bpy-OXD with introducing two or three baffles in T_h region – totally four kinds of sets; QA2, QA3, QB2, QB3 – and compared the purity data of them with those of non-purified (raw) one. We have also purified with a conventional method (without baffles, No or Conv.), and compared it with the above data. In all case, the purified materials were extracted from the first inner glass tube of T_l region with a length of 50 mm. The inter-

Table 3
Summary of the purity data of various Bpy-OXDs. The relations between T_m and the driving voltage, HPLC purity were also shown in Fig. 6 graphically.

Baffles	# of baffles	T_m (°C)	HWHM (°C)	V_{10J} (V)	V_{100J} (V)	HPLC purity (%)
Raw		**257.34**	1.76	**3.97**	**6.56**	**99.27**
No		**261.83**	1.32	**3.71**	**6.00**	**99.80**
QA	2	**262.43**	1.13	**3.29**	**5.53**	**99.95**
	3	**262.14**	1.22	**3.41**	**5.67**	**99.81**
QB	2	**262.40**	1.17	**3.52**	**5.74**	**99.95**
	3	**262.39**	1.25	**3.59**	**5.71**	**99.93**

vals of baffles in T_l region were also fixed as 50 mm. The yields of purified Bpy-OXD have shown the same tendency with those of mentioned in the former section, and are not mentioned in this section any more.

At first, we have checked the melting point (T_m) of purified materials with DSC, and the results were shown in Fig. 5. T_m was measured from a point of intersection of two tangent lines of DSC curves, as shown in Fig. 5. The value of half width at half maximum (HWHM) of the peak was also calculated. The right half parts of all peaks are almost the same with each other, and we calculated only the left part of HWHM. In general, T_m goes up and HWHM becomes narrow as the purity gets higher [22]. As summarized in Table 3, T_m was increased abruptly and HWHM also got narrow after purification. These behaviors show us that the material purity was increased by the purification process definitely. The most important thing is that all of the materials purified with introducing baffles have higher T_m and smaller HWHM than those of material purified by a conventional method even though the differences are not so remarkable.

We have also made EL devices of purified Bpy-OXDs with a device structure shown in Fig. 2, and compared their driving voltages to get 10 mA/cm^2 (V_{10J}) and 100 mA/cm^2 (V_{100J}). As shown in Fig. 6a together with T_m graphically, V_{10J} and V_{100J} show almost the same tendencies with T_m. These changes of V_{10J} and V_{100J} show us another strong evidence of increased purity by introducing baffles in T_h region.

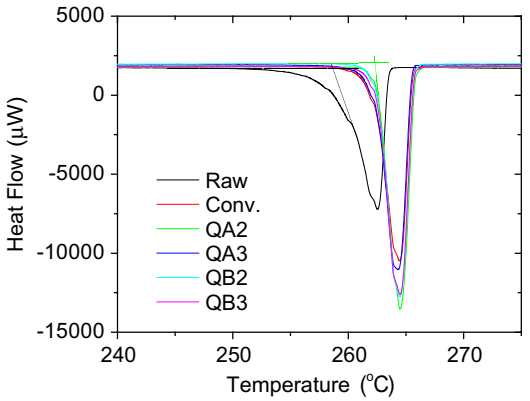

Fig. 5. DSC curves of purified Bpy-OXDs with various purifying conditions which are defined by the color of line. The detailed conditions are explained in the text. Two tangent lines for the raw material and QA2 were also shown by dotted lines with the same colors with the main curves, which were drawn for measuring T_m. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Finally, we have measured HPLC purity of all purified Bpy-OXDs. The purity of the raw material before purification is 99.27%. After purification with a conventional method, the purity is increased to 99.80%. By introducing baffles, the purity is increased more largely up to 99.95% (QA2 and QB2). This purity increase comes to be more obvious when we compare the decrement of the impurities; percentage of the decrease of impurity content after the purification against the raw material. For a conventional method, the decrement is 72.6% (from 0.73% to 0.20%). For the new system, the decrement is increased up to 93.2% (from 0.73% to 0.05%). This is very striking value because we can get only 92.5% value at the best after twice purifications by a conventional method even when we apply the same decrement for the second purification cycle. Generally, it becomes more difficult to eliminate impurities from purer materials, and we can expect the decrement value of the second purification cycle to be smaller than that of the first cycle. Consequently, the decrement value of 93.8% is even more meaningful and cannot be easily attained even we make purification twice with a conventional method. This value is also far better than that of the former purification system we have reported before although the purity of the starting material was somewhat different. The former system showed only 71.8% decrement (from 0.96% to 0.27%) [21]. This large difference can be a strong evidence that this new purification system has been improved greatly by solving the problems of the former system mentioned in Section 1. The main solution may be the full separation of deposition area of purified materials by introducing baffles.

It is also valuable to mention that the tendency of T_m (accordingly the driving voltage of EL devices) is almost the same with that of HPLC purity, as shown in Fig. 6b. This means that we can compare the purity of materials indirectly by comparing T_m and/or the driving voltages of EL devices instead of HPLC measurement. Because most of organic electronic materials are not easily soluble in general organic solvents, it is difficult to measure the purity directly by HPLC. In that case, we can estimate the purity of purified materials indirectly by comparing the T_m and/or the device performance made of it.

In this section, it was clearly described that the purity of purified materials was increased largely by introducing baffles in T_h region. The impurity decrement becomes 93.2% value by introducing baffles which is expected to be better than that of twice purified ones by a conventional method.

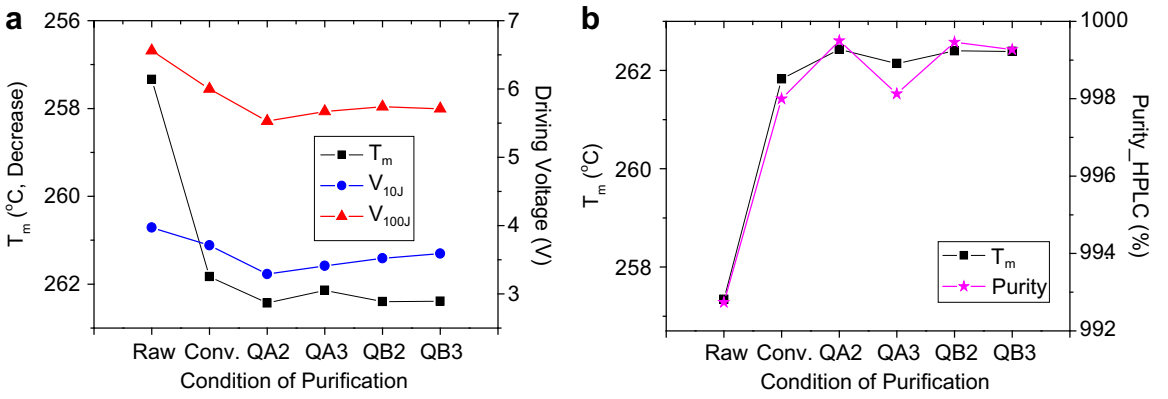

Fig. 6. Graphical summaries of (a) T_m and two driving voltages (V_{10J} and V_{100J}), and (b) T_m and HPLC purity. Note that the lines in graphics are just for visual guidance.

3.3. Comparison with a conventional method

As described in the previous two sections, the yield and the purity of the new purification system are enhanced largely comparing with a conventional method. It seems, however, that we need much more intuitive evidence for the enhancement of purification efficiency of this new system. For this purpose, we have repeated the purification of BCP three times with a conventional method, and compared its yield (from the first 50 mm glass tube) and purity with those of purified one just once by the new purification system (QB2 condition). The results are summarized in Table 4.

At first, the yield of purified BCP was decreased as the purification is repeated, and the final yield after repeating three times was 14.9%. This means that we can get just 0.15 g of purified BCP from 1 g source BCP after repeated purification three times. This result shows us that how serious the wasting materials is in repeating purification. On the other hand, the yield of the new system was 64.5%, and is reasonable value considering only 0.5 g BCP set in the source boat.

We have checked the driving voltages of EL devices made of purified BCPs. Surprisingly, the driving voltage was increased after the 2nd purification [24]. It was lowered again largely after the 3rd purification, but it was still higher than the value for purified one by QB2 condition. This result means that the purity of BCP purified three times by a conventional method is still lower than that of BCP purified just once by the new system. When we consider the yield simultaneously, this result shows us very clearly and intuitively how efficient this new purification system is. We can get at least four times larger quantity of purified materials – even the purity is much higher – by using this new purification system instead of a conventional method.

Table 4
Summary of the yield and the purity data of multiple purified BCP with a conventional method, and purified BCP with the new system under QB2 condition.

Condition	Yield (%)	Relative yield[a] (%)	V_{10J} (V)	V_{100J} (V)
Raw	–	–	**8.97**	**12.49**
1st	70.8[b]	–	**7.65**	**11.50**
2nd	57.8	37.8	**10.89**	**13.93**
3rd	47.9	**14.9**	**7.59**	**11.52**
QB2	**64.5**[c]	–	**7.45**	**11.03**

[a] Calculated against the BCP quantity set at the 1st cycle.
[b] Yield from about 1.0 g.
[c] Yield from about 0.5 g.

3.4. Discussion

It was clearly demonstrated that the purifying efficiency (both of the yield and the purity) has been improved in the new sublimation purification system. This improvement is definitely due to introducing baffles in the sublimation tube. In this section, we want to discuss what kinds of mechanisms work to improve the purifying efficiency by just introducing baffles with orifices.

At first, the dominant mass transport mechanism is diffusion in this system because the pressure is controlled to be 1 Pa or 80 Pa with an Ar gas flow. In this pressure condition, the mean free path (l) of sublimed materials will be from a few millimeters to several tens of micrometers [25,26]. Because both of the diameter of orifices in baffles and the intervals between baffles are larger than l, we do not need consider the effusion process. Actually, it is still unclear for the present what the exact role of baffles is, but at least three kinds of mechanisms are under consideration and acceptable quite reasonable ones.

The first is that the collision of sublimed materials with baffles can enhance the collapse of clusters into individual molecules which can result in promotion of impurity separation from target materials. In principle, materials are sublimed and deposited in a molecular state in sublimation purification method. However, it is well known that materials are diffused not only in a molecular state but also in a cluster form in a real purification system. If there is an impurity molecule in the cluster, that impurity will be deposited on the same region with target materials. In this new purification system, clusters can undergo frequent collision with baffles and glass tubes, and be collapsed into smaller clusters or even into individual molecules. These

collapses of clusters can promote the separation of impurities from the target material, and result in increase of the purity of deposited materials.

The second is that the travelling distance of sublimed materials unto deposition points can be extended by introducing baffles. Sublimed materials which may be directly diffused unto deposition region without baffles can collide with baffles and change its diffusion direction and result in the increase of travelling distance. Because there are a few baffles at least and the orifices are not aligned straightly each other, the collision of sublimed materials with baffles can be occurred very often, and the travelling distance may be increased very largely. This increase of travelling distance can lead to the enhanced separation of impurities from target materials.

The third is that baffles installed in T_l region can suppress the efflux of purified materials out of the extraction region. Some of purified target materials can be flowed out of the extraction region and grow far away from the sublimation region together with impurities, which is one of the serious causes of lowering the purification yield. Baffles installed in T_l region can block such efflux of purified materials and return them into the extraction region, which can increase the effective yield. Such a role of baffles installed in T_l region may be related not only to the effective yield but also to the purity of extracted materials as mentioned in Section 3.1.

4. Summary

We have developed a highly efficient sublimation purification system using baffles with orifices in the sublimation tube. It was described that baffles introduced in T_l region made purified materials deposited on more concentrated region which was revealed with increased R_{EY} value. It was also clearly demonstrated that the purity of purified materials was increased largely by introducing baffles in T_h region. The impurity decrement increased up to 93.2% by introducing baffles from 72.6% in a conventional method, which is expected to be better than that of twice purified ones by a conventional method. From the results of multiple purification of BCP by a conventional method, it was also proved that one can get at least four times larger quantity of purified materials – even the purity is much higher – by using this new purification system instead of a conventional method. This improvement of purifying efficiency by introducing baffles in the sublimation tube was discussed briefly with three kinds of possible functions of baffles; collapsing clusters into individual molecules, extending travelling distance, and suppressing the efflux of purified materials.

Acknowledgement

This work was supported by CLUSTER (the second stage) of Ministry of Education, Culture, Sports, Science and Technology, Japan. The authors would like to give special thanks to Mr. Norimasa Yokoyama and to whom it may concerned of Hodogaya Chemical Co., Ltd. for offering lots of Bpy-OXD and for measuring HPLC purities of various Bpy-OXD samples. This paper is dedicated to the first principal, Chotaro Harizuka, on the occasion of 100th anniversary of Faculty of Textile Science and Technology, Shinshu University.

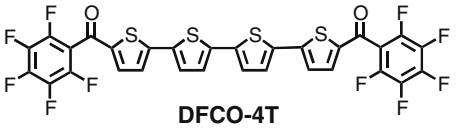
DP-DTT (**2**) exhibit excellent p-channel transport with hole mobilities of 0.42 cm^2/Vs [10a]. However, n-channel **DTT**-based semiconductors have been unknown until recently [11]. One approach to realizing electron transport in OTFTs is to functionalize p-channel semiconductors with strong electron-withdrawing and/or perfluorinated substituents, such as fluoro- [7a], perfluoroalkyl- [7b,12], perfluoroaryl- [7c,13], carbonyl- [14], cyano- [15], and trifluoromethylphenyl- [16] groups. Perfluorobenzoyl (COC_6F_5)-substituted quarter thiophenes (**DFCO-4T**) exhibit especially high electron mobilities of 0.45 cm^2/Vs for vapor-deposited films and 0.21 cm^2/Vs for solution-cast films [14a].



Following a similar molecular design strategy, we partly communicated synthetic approaches to several **DTT**-based compounds and their physicochemical properties [11]. Initial TFT results showed that two of these materials are n-channel semiconductors with electron mobilities of 10^{-3}–0.03 cm^2/Vs, and these were the first reports on **DTT**-based semiconductors. Although perfluorophenyl-substituted **DFP-DTT** (**3**) has been reported [17], its OTFT performance has not been explored. Herein, we report in full on the synthesis, characterization, and OTFT performance of **DTT**-based (**3**–**10**) organic semiconductors with appropriate electron-withdrawing groups, as shown in Fig. 1.

2. Experimental section

2.1. Materials and methods

All chemicals and solvents were of reagent grade and were obtained from Aldrich, Arco, or TCI Chemical Co. Solvents for reactions (toluene, benzene, ether, and THF) were distilled under nitrogen from sodium/benzophenone ketyl, and halogenated solvents were distilled from CaH_2. ^1H and ^{13}C NMR spectra were recorded on a Bruker 500, 300, or a Bruker DRX-200 instrument. Chemical shifts for ^1H and ^{13}C spectra were referenced to solvent peaks. ^{19}F NMR spectra were referenced to external $CFCl_3$. Differential scanning calorimetry (DSC) was carried out on a Mettler DSC 822 instrument, and calibrated with a pure indium sample at a scan rate of 10 K/min. Thermogravimetric analysis (TGA) was performed on a Perkin–Elmer TGA-7 thermal analysis system using dry nitrogen as a carrier gas at a flow rate of 40 mL/min. The UV–Vis absorption and fluorescence spectra were obtained using JASCO V-530 and Hitachi F-4500 spectrometers, respectively, and all spectra were measured in a specified solvent at room temperature. The IR spectra were obtained using a JASCO FT/IR-4100 spectrometer. Differential pulse voltammetry experiments were performed with a CH Instruments model CHI621C Electrochemical Analyzer. All measurements were carried out at a specified temperature with a conventional three-electrode configuration consisting of a platinum disk working electrode, an auxiliary platinum wire electrode, and a non-aqueous Ag reference electrode. The supporting electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$) in a specified dry solvent. All potentials reported are referenced to an Fc^+/Fc internal standard (at +0.6 V). Elemental analyses were performed on a Heraeus CHN–O-Rapid elemental analyzer. Mass spectrometric data were obtained with a JMS-700 HRMS instrument. Prime grade silicon wafers (p^+-Si) with ~300 nm (±5%) thermally grown oxide (from Montco Silicon) were used as device substrates. Preparation of **DTT** (**1**) and **TTA** (via one-pot [1 + 1 + 1] synthesis), **DFB-DTT** (**4**), **FBB-DTT** (**5**), **DB-DTT** (**6**), and **DT-DTT** (**9**) as well as X-ray crystal structure determinations of compounds **4**, **5**, and **6** see supporting information of Ref. [11].

2.2. Synthesis

2.2.1. One-pot [2 + 1] synthesis of dithieno[2,3-b:3′,2′-d]thiophene (DTT; 1)

Under nitrogen at −78 °C, 2.5 M *n*-BuLi (48 mL in hexanes, 0.12 mol) was slowly added to an ether solution

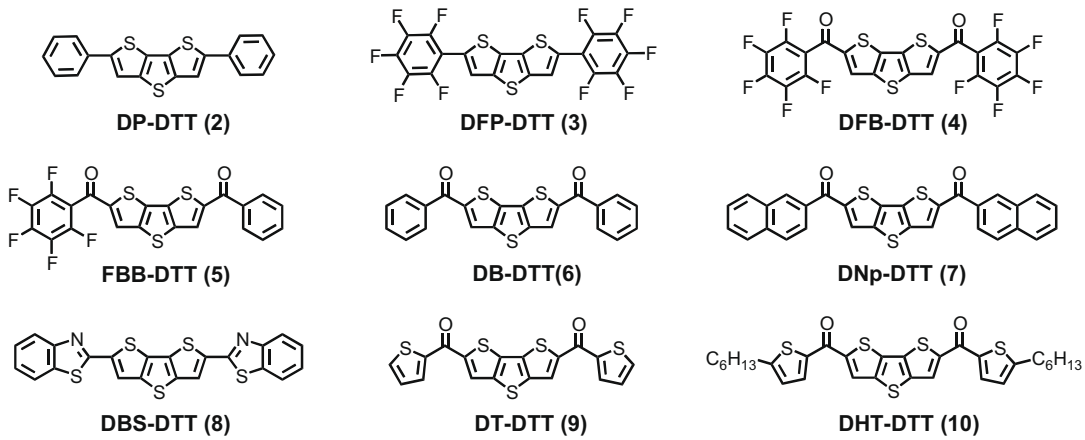


Fig. 1. Chemical structures of dithieno[2,3-b:3′,2′-d]thiophene (**DTT**) derivatives employed in this study.

(48 mL) of 3-bromothiophene (12 mL, 0.12 mol), and the mixture was stirred for 40 min. This solution was then warmed to 0 °C to vacuum remove C_4H_9Br, and then ether (48 mL) was added. (Note: without removing C_4H_9Br, 3-butyl-S-thiophene will be generated as a major side product after the S addition in the next step.) At −78 °C, sulfur (1.92 g, 0.06 mol) was added into this ether solution, stirred for 30 min, warmed to 0 °C, and stirred for another 30 min. p-Toluenesulfonyl chloride (TsCl, 11.42 g, 0.06 mol) was added to this solution at 0 °C, stirred for 30 min, then warmed up to 40 °C for 4 h. Next, at 0 °C, 2.5 M *n*-BuLi (52.8 mL in hexanes, 0.132 mol) was slowly added to this mixture, stirred for 30 min, and then refluxed for 1 h. $CuCl_2$ (18.32 g, 0.138 mol) was added to this mixture at 0 °C, stirred for 1 h, warmed to room temperature, and stirred overnight. Solids were removed by filtration, and the organic + ether portion was collected, and then chromatographed (silica gel; hexanes as the eluent). The **DTT** product was recrystallized from hexanes as light-yellow powder to give a total of 2.94 g in a yield of ~25.0%. ^{1}H NMR ($CDCl_3$): δ 7.36 (*d*, *J* = 5.4 Hz, 2H, 2,6-CH), 7.29 (*d*, *J* = 5.1 Hz, 2H, 3,5-CH).

2.2.2. One-pot [1 + 1 + 1] synthesis of pentathienoacene (PTA) [5a]

Follow the one-pot [1 + 1 + 1] synthetic procedure [11], 3-bromothieno[3,2-b]thiophene [18] was employed to give pentathienoacene (**PTA**) [5a] as yellow–orange powder in 12% yield. ^{1}H NMR (300 Hz; DMSO-d_6): δ 7.68 (*d*, *J* = 5.1 Hz, 2H, *CH*), 7.43 (*d*, *J* = 5.1 Hz, 2H, CH).

2.2.3. Synthesis of DP-DTT(2) [10a] and DFP-DTT (3) [19]

Under nitrogen at 0 °C, *n*-BuLi (2.5 M, 0.87 mL in hexanes, 2.18 mmol) was added to a 20 mL ether solution of **DTT** (0.195 g, 0.99 mmol) and the mixture was stirred at this temperature for 1 h. Tri-*n*-butylstannyl chloride (0.60 mL, 2.18 mmol) in 10 mL ether was then added into the mixture and stirred for 30 min at 0 °C. The mixture was then stirred at room temperature for 12 h. Ether was next removed under vacuum and 10 mL toluene solution of dry bromopentafluorobenzene (0.30 mL, 2.11 mmol) as well as 20 mL toluene solution of tetrakis(triphenylphosphine)palladium (50 mg, 0.04 mmol) were added and the mixture was refluxed for 24 h. Water was added to quench the reaction and the solid product was collected/filtered and was washed with hexanes, which was further purified by gradient sublimation at a pressure of $<10^{-4}$ Torr, giving a bright-yellow solid **DFP-DTT** (**3**; 259 mg) in a yield of 49.2%. ^{1}H NMR ($CDCl_3$): δ 7.77, ^{19}F NMR ($CDCl_3$): δ −139, −154, and −161.

DP-DTT (2) [10a] was prepared ~50% yield via similar procedure except using C_6H_6Br in the coupling reaction.

2.2.4. Synthesis of DNp-DTT (7)

Under nitrogen, $AlCl_3$ (6.47 g, 47.8 mmol) was added to a 100 mL CS_2 solution of **DTT** (0.939 g, 4.78 mmol) and 2-naphthalenecarbonyl chloride (2.03 g, 10.5 mmol), and the mixture was stirred at 40 °C for 3 days. Water was then added to quench the reaction, and the solid product was washed with ether and ethyl acetate, which was then purified by gradient sublimation at a pressure of $<10^{-4}$ Torr, giving a bright-yellow solid (0.736 g) in a yield of 30%. ^{1}H NMR ($CDCl_3$): δ 8.46, (s, 1H), 8.02–7.94 (m, 4H), 7.98 (s, 1H), 7.66–7.62 (m, 2H), 7.55–7.52 (m, 2H). ^{13}C NMR ($CDCl_3$): not sufficiently soluble to obtain a spectrum. Anal. calcd. for $C_{30}H_{16}O_2S_3$: C, 71.40; H, 3.20; S, 19.06. Found: C, 71.58; H, 2.98; S, 19.38. Orange crystals of the title compound suitable for X-ray diffraction were obtained by slow diffusion of hexanes into CH_2Cl_2 solution. The molecular structure of **7** has been confirmed by X-ray diffraction as shown in Fig. 4 (cif file of **7** is in SI).

2.2.5. Synthesis of DBS-DTT (8)

Under nitrogen, 3 eq. of 2-aminothiophenol (0.25 g, 1.96 mmol) was added to a 50 mL C_6H_5Cl solution of **DTT**-$(COCl)_2$ (0.21 g, 0.65 mmol, generated from **DTT**-$(COOH)_2$ with $SOCl_2$) and the mixture refluxed for 3 days. The desired solid product was collected by filtration, washed with ether, and then purified by gradient sublimation at pressures of $<10^{-4}$ Torr, giving a bright-yellow solid (0.13 g) in a yield of 42%. ^{1}H NMR ($C_2D_2Cl_4$): not sufficiently soluble to obtain a spectrum. Anal. calcd. for $C_{22}H_{10}N_2S_5$: C, 57.11; H, 2.18; N, 6.05, S, 34.65. Found: C, 56.55; H, 2.25; N, 5.96, S, 34.19. MS (FAB) *m*/z) calcd. for $C_{22}H_{10}N_2S_5$: 462 (M^+). Found: 462.

2.2.6. Synthesis of DHT-DTT (10)

Under nitrogen, a CH_2Cl_2 solution of **DTT**-$(COCl)_2$ (0.35 g, 1.1 mmol), 2-hexylthiophene (0.39 g, 2.3 mmol), and $AlCl_3$ (1.47 g, 11.0 mmol) was stirred at room temperature for 2 days. Water was added to quench the reaction and the solvent was removed under vacuum. The solid product was collected by filtration and washed with ether. The product was purified by gradient sublimation at pressures of $<10^{-4}$ Torr, giving a bright-yellow solid (0.22 g) in a yield of 35%. ^{1}H NMR ($CDCl_3$): δ 8.12 (s, 2H), 7.81 (d, *J* = 3.9 Hz, 2H), 6.91 (*d*, *J* = 3.9 Hz, 2H), 2.90 (*t*, *J* = 7.5 Hz, 4H), 1.75 (m, 4H), 1.42 – 1.30 (m, 12H), 0.90 (*t*, *J* = 7.5 Hz, 6H) Anal. calcd. for $C_{30}H_{32}O_2S_5$: C, 61.60; H, 5.51; S, 27.41. Found: C, 61.8; H, 5.82; S, 27.11. MS (EI) *m*/z) calcd. for $C_{30}H_{32}O_2S_5$: 584(M^+). Found: 584.

2.3. X-ray crystal structure determinations of compounds 3 and 7 [20]

The chosen crystal was mounted on a glass fiber. Data collection for compound **3** was carried out on a Bruker Smart Apex CCD diffractometer and compound **7** on a Nonius Kappa CCD diffractometer with Mo radiation (λ = 0.71073 Å) at 100(2) K and 200(2) K, respectively. After data collection, the frame was integrated and absorption correction was applied. The initial crystal structure was solved by direct methods, the structure solution was expanded through successive least-squares cycles, and the final solution was determined. All of the non-hydrogen atoms were refined anisotropically. Hydrogen atoms attached to carbon atoms were fixed at calculated positions and refined using a riding mode. Crystal data, data collection, and refinement parameters are summarized in Table S1.

2.4. Film deposition and characterization

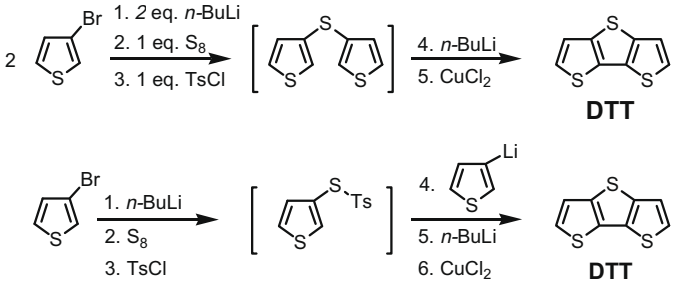
All p^+-Si/SiO_2 substrates were cleaned via sonication in absolute ethanol for 3 min and then by oxygen plasma treatment for 5 min (20 W, 0.5 Torr). For the SiO_2 coating layer, –$SiMe_3$ groups were introduced using hexamethyldisilazane (HMDS) and were deposited by placing the clean SiO_2 substrates in a N_2-filled chamber saturated with HMDS vapor for 48–72 h. All of the semiconducting materials were vacuum deposited at $\sim 6 \times 10^{-6}$ Torr ($\sim$500 Å, 0.2–0.3 Å/s) at the preset deposition temperatures (T_D). Thin films of organic semiconductors were analyzed by atomic force microscopy (AFM) (JEOL-5200 Scanning Probe Microscope) in the tapping mode, scanning electron microscopy (Hitachi S-4800 FE-SEM), and wide angle θ–2θ X-ray diffraction (XRD) (Rigaku ATXG) using monochromated Cu K_α radiation. For TFT device fabrication, top-contact electrodes ($\sim$70 nm) were deposited by evaporating gold ($\sim 1 \times 10^{-6}$ Torr) through a shadow mask with a channel length (L) of 100 μm and a channel width (W) of 5000 μm.

3. Results and discussion

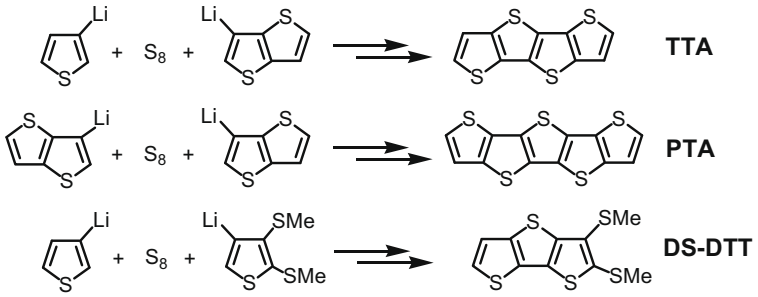
3.1. Synthesis

Since the key building block is the **DTT** core, a convenient, efficient, and cheap one-pot [2 + 1] synthesis of **DTT** was explored. Our new route from inexpensive, commercially available materials dispenses with the requirement for expensive bis(phenylsulfonyl)sulfide, and results in **DTT** in a much shorter synthetic time [21]. For this one-pot [2 + 1] synthesis, 3-bromo-thiophene (2 eq.) was first lithiated with *n*-BuLi (2 eq.), followed first by S_8 (1 eq.) and then by TsCl (1 eq.) additions, as shown in Scheme 1. Without isolating the product, the crude mixture was dilithiated with *n*-BuLi and ring closure was achieved with $CuCl_2$. Finally, **DTT** was isolated in a yield of about 25%. An alternative one-pot [1 + 1 + 1] synthesis of **DTT** was also achieved and offered a higher yield (about 30%). The former [2 + 1] route is simpler, but the latter [1 + 1 + 1] route enables the synthesis of fused thiophenes with more rings (e.g., pentathienoacene (**PTA**) was obtained in 12% yield) [5a] and asymmetric fused thiophenes (e.g., **DS-DTT**) that are not feasible using previous methods, as shown in Scheme 2 [11].

The synthesis of functionalized dithieno[2,3-b:3′,2′-d]thiophene was achieved and is shown in Schemes 3–6. Perfluorophenyl and perfluorobenzoyl functionalization of the **DTT** core should result in good candidates of n-channel semiconductors **3** (**DFP-DTT**) [17] and **4** (**DFB-DTT**). Since the electronic performance of **3** has not been examined, it was explored via the Stille coupling of the **DTT** core with C_6F_5Br in $\sim$49% yield as shown in Scheme 3, which is comparable to the Suzuki coupling method. For comparison **DP-DTT** (**2**) [10a] was also achieved via similar synthetic route. Preparation of **4** was explored using three different routes shown in Scheme 4. Route I, via the double deprotonation of **DTT** and then double acylation, provided the most efficient path to **4** (36% yield). Route II, via the thermal acylation of **DTT**, produced the double acylation product **4** in a yield of <30% with a considerable amount of mono-acylated **FB-DTT**



Scheme 1. One-pot [2 + 1] and [1 + 1 + 1] syntheses of the **DTT** core.



Scheme 2. One-pot syntheses of tetrathienoacene (**TTA**), pentathienoacene (**PTA**) and asymmetric **DTT**.

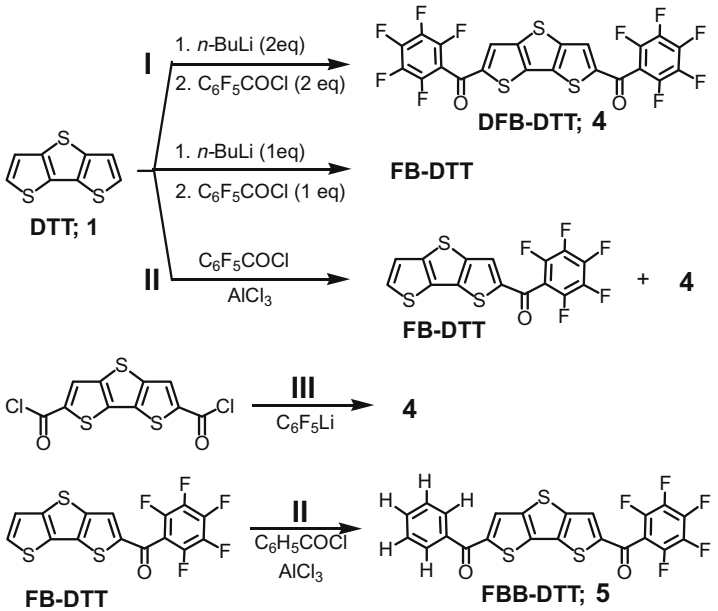

Scheme 4. Synthetic routes to **DFB-DTT** (**4**) and **FBB-DTT** (**5**).

side product, even after refluxing for one week. Presumably, compound **4** could also be generated from route III**,** the reverse of route I; however, a yield of less than 10% was obtained. Unprecedentedly, since mono-acylated **FB-DTT** could also be obtained as the major product (>80%) via mono-deprotonation of **DTT** with 1 eq. of *n*-BuLi and then mono-acylation with 1 eq. C_6F_5COCl, asymmetric **FBB-DTT** (**5**) was developed from the thermal mono-acylation of **FB-DTT** with benzoyl chloride via route II in a yield of 57% as shown in Scheme 4. Benzoyl-, 2-naphthylcarbonyl (Np-), and 2-thienoyl-substituted derivatives **6**, **7**, and **9** were also obtained in good yields via Route II (shown in Scheme 5). **DBS-DTT** (**8**) and **DHT-DTT** (**10**) can be obtained from refluxing **DTT**-$(COCl)_2$ [22] with 2-aminothiophenol and 2-hexylthiophene in a yield of ~40%, as shown in Scheme 6.

3.2. Thermal and optical properties

For these DTT derivatives, differential scanning calorimetry (DSC) scans exhibit a sharp endotherm above 214 °C, and thermogravimetric analysis plots demonstrate weight loss (5%) only on heating above 241 °C, as summarized in Table 1. For compounds **4**–**6**, lower melting points and lower weight loss temperatures were observed for **DTT** derivatives with a greater number of perfluorophenyl groups, which indicates a higher volatility contributed by the F-substituents, as reported in the literature [23]. Similar trend was observed for **DFP-DTT** (**3**) compared to its non-fluorinated derivative **DP-DTT** (**2**) [10a].

The optical absorption spectra of **DTT**s **2**–**10** in *o*-$C_6H_4Cl_2$ are significantly red-shifted compared to **1** (λ_{max} ~300 nm), as shown in Fig. 2, and the **DTT**s with the

carbonyl substituents exhibit further red-shifted absorptions (λ_{max} >400 nm) than those without carbonyl substituents **DP-DTT** and **DFP-DTT** (λ_{max} ~360 nm). For compounds **4**–**6**, note that the absorption is slightly red-shifted in the compound having the greater number of F atoms. This result is in line with established substituent group directing effects [6c,24]. Compared to benzoyl-substituted **6**, more π-electron delocalization is observed for the 2-naphthylcarbonyl (**7**), and 2-thienoyl-substituted thienyl (**9**/**10**) or benzothiazolyl (**8**) substituted compounds, giving the latter the lowest energy gap among the compounds in this study. This result indicates delocalization extending from the **DTT** core to the two benzothiazolyl substituents. The HOMO–LUMO energy gaps calculated from the onset of the optical absorption (2.6–3.1 eV) increase in the order: **8** < **9** ≈ **10** < **4** < **7** < **5** < **6** < **2** < **3**, as shown in Table 1.

The photooxidative stability of the **DTT** derivatives was investigated by monitoring the absorbance decay at λ_{max} of **2**–**10** in aerated $CHCl_3$ solutions exposed to white light (fluorescent lamp) at room temperature. Under these conditions for 4–5 days, no decomposition is observed for any of these compounds, demonstrating the favorable stability of these materials.

3.3. Electrochemical characterization

Differential pulse voltammograms (DPVs; using ferrocene/ferrocenium as internal standard at +0.6 V) of **DTT**s **2**–**10** were recorded in dichlorobenzene at 25 °C, and the resulting reductive and oxidative potentials are summarized in Table 1 [25]. As expected, the non-carbonyl substituted **DTT**s exhibit the largest band gap of all the compounds in this study revealing relatively small -electron delocalization. Furthermore, the electron affinity increases with an increase in the number of fluoroaryl rings, where fluoroaryl substitution in **DFP-DTT** (**3**) strongly lowers both the HOMO and LUMO energies compared to those in **DP-DTT** (**2**). Similar trend was observed for **DFB-DTT** (**4**) compared to its non-fluorinated derivative **DB-DTT** (**6**) and half fluorinated asymmetric **FBB-DTT** (**5**). The HOMO–LUMO energy gaps obtained from the DPV data are 2.97 eV for **DFB-DTT**, 3.07 eV for **FBB-DTT**, and 3.08 eV for **DB-DTT** (Fig. 3; assuming ferrocene/ferrocenium oxidation at 4.8 eV) and the ordering is consistent with that obtained by optical absorption data. Compared to compound **6**, the HOMO and LUMO energies of the 2-naphthylcarbonyl (**7**), thienyl- (**9**) and hexylthienyl- (**10**) substituted compounds showed no significant change. In contrast, the benzothiazolyl substitution in compound **8** strongly shifts both the HOMO and LUMO levels to higher values, causing the compound to exhibit the most extensive π-electron delocalization among the **DTT** series with the smallest band gap (about 2.93 eV) [26]. Overall, the electrochemically-derived HOMO–LUMO energy gaps are ranked in the order **8** < **4** < **9** ≈ **10** < **7** < **5** < **6** < **2** < **3** (Table 1), which is consistent with the values obtained from optical spectroscopy.

3.4. Crystal structure

The diffraction-derived crystal structures of compounds **3** and **7** are shown in Figs. 4 and 5, and the crystal structure data are summarized in Table S1 [27]. Similar to **DFCO-4T** [14], compound **3** with F-substituents on both ends exhibits intramolecular and intermolecular ortho-F (perfluorophenyl)-H (DTT core) contacts [28], as shown in Fig. 4A and B. Like other non-carbonyl diaryl substituted DTTs [10], compound **3** exhibits typical herringbone packing with an interplanar angle of ~43.7° and the perfluorophenyl groups are only slightly deviated at angles of ~11° to the DTT core (Fig. 4B). The distances between the planar DTT cores are ~3.60 Å (Fig. 4B) with the shortest sulfur–sulfur distance of ~3.48 Å (Fig. 4C). Similar to compounds **4**, **5**, and **6**, the functionalized 2-naphthylcarbonyl moieties in compound **7** are not coplanar with the **DTT** cores, but are with a less acute torsional angles of about 36.4° (Fig. 5C) [29]. However, without the H–F intermolecular interactions, the molecular packings are considerably different for compound **7** (compared to **4** and **5**). Compound **7** exhibits typical herringbone structure (Fig. 5D) and adopt an edge-to-face packing motif [30] with an smaller interplanar angle of ~23.0° for **7** (Fig. 5E) [31] with the shortest sulfur–sulfur distance of ~3.25 Å (Fig. 5D). Comparing the carbonyl substituted DTT derivatives **4**–**6**, the distances

between the planar DTT cores and the shortest S–S distances among DTT cores are **5** (~3.50 Å) < **6** (3.68 Å) < **4** (3.74 Å) and **5** (3.20 Å) < **6** (3.23 Å) < **4** (3.42 Å), respectively, demonstrating the tightest molecule-packing of **5** in the solid state, which is in accord with the OTFT device performance trends (*vide infra*).

3.5. Thin-film transistor characterization

Top-contact/bottom gate OTFT devices were fabricated by vacuum deposition (5×10^{-6} Torr) of each compound on bare and HMDS-treated SiO_2/p^+-Si substrates at preset deposition temperatures (T_D). Gold source and drain contacts were patterned by thermal evaporation using shadow masks that gave a channel length of 100 μm and a width of 5000 μm. The TFT properties were tested under positive or negative gate bias under vacuum to explore the major charge carrier types and device performance. TFT data are summarized in Table 2, and representative transfer and output plots are shown in Fig. 6.

Devices fabricated with **DTT**-based compounds all exhibit TFT activity, with compounds **3–5** performing as n-channel semiconductors, and the rest of the compounds performing as p-channel semiconductors. Derived field-effect mobilities of the **DTT** derivatives strongly depend upon both the dielectric surface treatment and the deposition temperature (T_D). In general, enhanced device performance is observed at higher deposition temperatures and on HMDS-treated SiO_2 substrates. Compounds **3–5** exhibit electron mobilities as high as 0.07, 0.002 and 0.03 cm^2/Vs, respectively. Compound **4** is active both under vacuum ($\mu = 3 \times 10^{-5}$–0.002 cm^2/Vs) and under ambient conditions ($\mu = 1 \times 10^{-4}$ cm^2/Vs), exhibiting high current on/off ratios of 10^5–10^6. Compounds **3** and **5**, on the other hand,

Table 2
Majority charge carrier types, field-effect mobilities (μ, cm^2/Vs),[a] current on/off ratios (I_{on}/I_{off}), and threshold voltages (V_T, V) for thin-film OTFTs fabricated by vacuum deposition of compounds **3–10** on bare and HMDS-treated p^+-Si/SiO_2 substrates at the indicated deposition temperatures (T_D, °C). Device performance measured under vacuum unless otherwise indicated.

[a] Device performance is the averaged value of at least four samples. (Standard deviation between devices is <10%.)
[b] Measured in ambient.

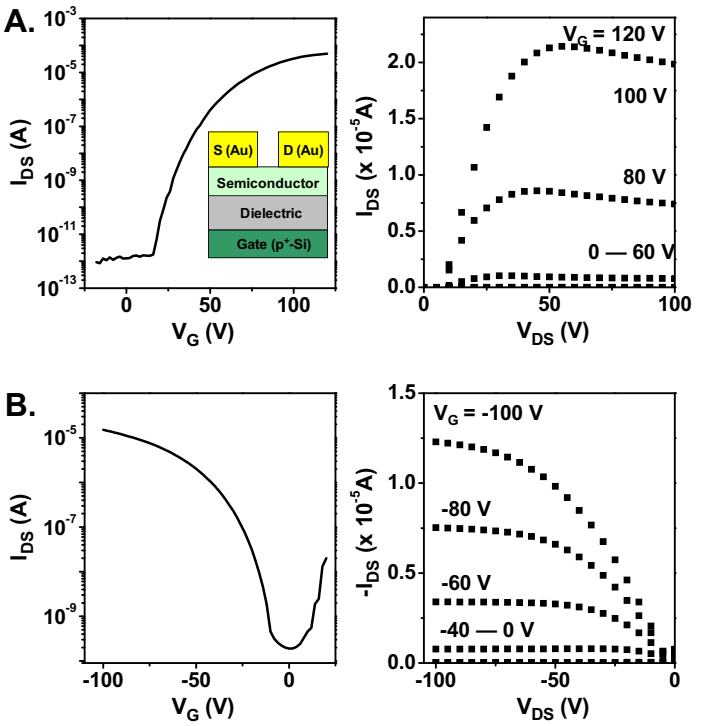

Fig. 6. OTFT plots of devices fabricated with compounds **3** and **8** on HMDS-treated SiO_2 substrates. (A) Transfer (V_{DS} = 100 V) and output plots of **3** (T_D = 25 °C), (B) transfer (V_{DS} = −100 V) and output plots of **8** (T_D = 90 °C). The general OTFT device structure (inset).

are only active under vacuum. Compound **3** exhibits the highest electron mobility, 0.07 cm^2/Vs, of all the **DTT** derivatives on HMDS-treated SiO_2 substrates (T_D = 25 °C) with an I_{on}/I_{off} of ~10^7 (Fig. 6A). The end-substitution with electron-withdrawing perfluorophenyl groups promotes majority carrier sign inversion in this family, as previously demonstrated for other materials [13]. The non-fluorinated **DTT** derivatives **6**–**10** exhibits p-channel transport with hole mobilities of 4×10^{-6}–0.01 cm^2/Vs. Among the p-channel **DTT**-based compounds, **6** and **8** exhibit relatively high mobilities, up to 0.01 cm^2/Vs, with I_{on}/I_{off} of 10^5–10^7 on HMDS-treated SiO_2 substrates (Fig. 6B). For these compounds, there is a clear correlation between μ and T_D, which is also evident in the XRD and AFM characterization data (*vide infra*). The other **DTT** (**7**, **9**, and **10**) derivatives exhibit relatively low hole mobilities of 4×10^{-6}–0.004 cm^2/Vs and I_{on}/I_{off} of 10^3–10^7.

3.6. Thin-film microstructure and morphology

Vacuum-deposited film crystallinity and morphology are known to affect TFT performance. Thin-film microstructures and morphologies for this new class of materials were studied by θ–2θ XRD, AFM, and SEM. X-ray diffraction experiments provide useful information to understand the crystallinity of the semiconductors as thin films and the molecular orientation relative to the substrate surface. In general, high crystallinity and preferential alignment of the π-conjugated core (perpendicular to the dielectric surface) are beneficial to efficient charge transport between the source and drain electrodes. In this study, conventional $\theta/2\theta$ scans were utilized to obtain out-of-plane *d*-spacings in the vacuum-deposited thin films on HMDS-treated Si/SiO_2 substrates at various T_Ds. The thicknesses of all films were determined to be 50–70 nm by profilometry. Representative XRD scans are shown in Fig. 7, and the data are presented in Table 3.

The $\theta/2\theta$ out-of-plane XRD scans show that all of compounds except **4** and **10** were highly textured and exhibit high intensities with multiple reflections (Fig. 7). For all of the films except compound **6** (*vide infra*), a single set of diffraction peaks is observed without the presence of any reflections corresponding to π–π stacking distances, and *d*-spacing values are estimated from the nominal (1 0 0) reflection peaks as 18.2–24.4 Å, suggesting the presence of a crystalline polymorph where the majority of the molecules have an edge-on orientation with respect to the substrate surface, with the π–π stacking direction roughly parallel to the substrate surface. This molecular orientation promotes in-plane charge transport from the source to the drain. Compounds **3**–**8** (except **4**) exhibit strong XRD peak intensities and multiple reflections, consistent with good TFT mobility, as described above. Compound **10** with poor TFT mobility exhibits only a single Bragg reflection, indicating low film texturing. This low texturing is possibly due to hindered molecular packing by the *n*-hexyl side groups. Interestingly, films of compound **4**, having reasonable carrier mobility (⩽0.002 cm^2/Vs), also exhibits only a single reflection and modest peak intensity. This indicates the presence of an interface mismatch between the HMDS-

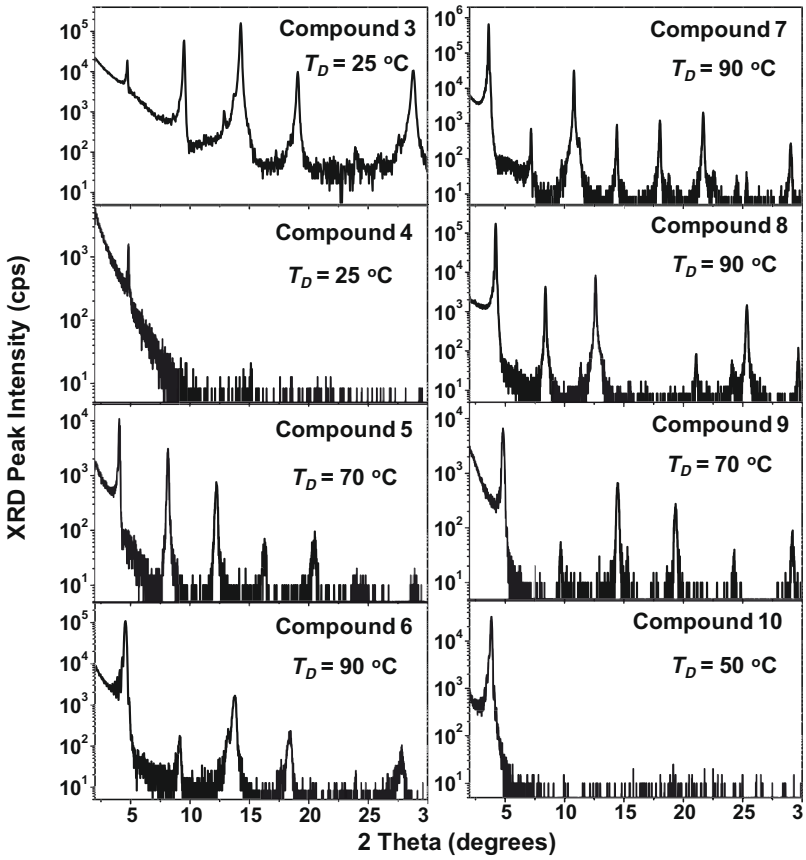

Fig. 7. Representative θ–2θ XRD scans on a logarithmic scale of **DTT** (**3**–**10**) films vapor-deposited at the indicated T_Ds on HMDS-treated SiO_2 substrates.

Compound	Reflections	T_D (°C)	2θ (°) (1 0 0)	*d*-spacing (Å)
3	100–600	25, 50	4.70	18.8
4	100	25	4.84	18.2
5	100–700	25, 70	4.06	21.7
6	100–600	25–90	4.57	19.2–19.5
7	100–800	25, 90	3.61	24.4
8	100–700	25–90	4.20	21.0
9	100–600	25, 70	4.80	18.4
10	100	25, 50	3.83	23.0

treated SiO_2 dielectric and the fluorinated semiconductor layers, which prevents ordered crystal growth in the semiconductor layer. Similar results have been observed for end-fluorinated perylene- and naphthalene-based compounds [1c,32].

Since the TFT performance for several compounds is quite sensitive to the deposition temperature (*vide supra*), T_D-dependent XRD patterns were also examined. Fig. 8A shows field-effect mobilities and XRD data for films of compound **8** on HMDS-treated substrates at various T_Ds. As shown, there is a clear correlation between mobility values and XRD peak intensity. Note that XRD peak position for compound **8** films does not change at different T_Ds. Similar behavior is also observed for compound **5**-based TFTs (not shown). Interestingly, compound **6**-derived films show somewhat different XRD patterns. As the T_D increased, the XRD peak intensity for compound **6** films decreases slightly (Fig. 8B). However, the XRD peak position shifts to slightly higher angle, from $2\theta = 4.53°$ to 4.60°, at higher T_D values, suggesting some structural reorganization (from 19.5 to 19.2 Å of *d*-spacing). Enhanced mobility at higher T_D values for compound **6**-based TFTs appears to be associated with this reduced *d*-spacing.

Since microstructure characterization at the dielectric-semiconductor interface, where charge transport in TFTs occurs, is challenging by conventional techniques, we studied the morphology of the semiconductor surfaces via AFM and SEM, assuming that the microstructure at the surface conveys information about the underlying microstructure at the interface. From the film morphologies, it is clear that the film growth patterns depend significantly on the substrate temperature and surface treatment, which are strongly correlated with the device performance (*vide supra*). Figs. 9 and S1 show representative surface morphologies of the films of compounds **3**–**10**. For example, films exhibit ribbon-like grains (compounds **4** and **5** at 25 °C), plate-like faceted films (**3**, **5**–**8** at high T_D), or small grains (compounds **9** and **10**).

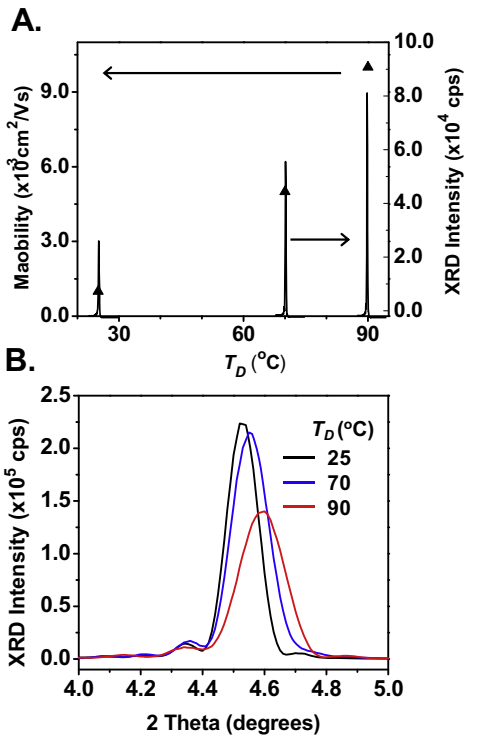

Fig. 8. (A) Field-effect mobilities and XRD ($\theta/2\theta$ scan; $2\theta = 3–6°$) data for compound **8**-based TFTs on HMDS-treated SiO_2 substrates at the indicated T_Ds. (B) XRD ($\theta/2\theta$ scan) data ($2\theta = 4–5°$) for compound **6**-derived films on bare SiO_2 substrates grown at the indicated T_Ds.

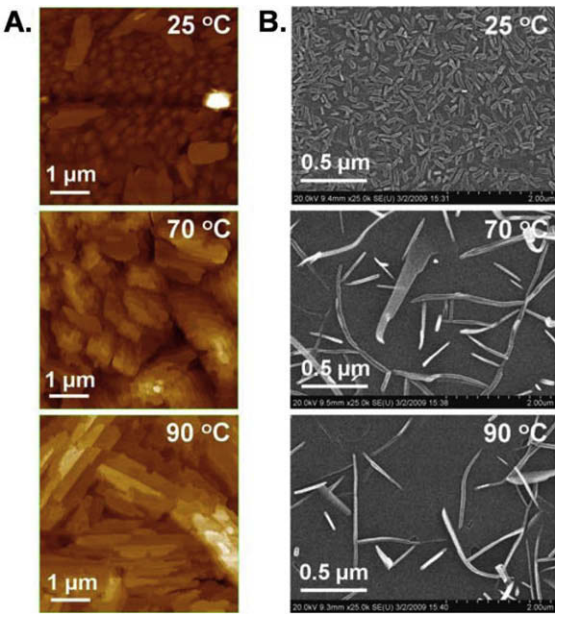

Fig. 9. (A) AFM images ($5 \times 5\ \mu m^2$) of films from compound **6** on bare SiO_2 substrates grown at the indicated T_Ds. (B) SEM images of films from compound **8** on HMDS-treated SiO_2 substrates grown at the indicated T_Ds.

Similar to the XRD patterns, AFM images also show a strong dependence of film morphology on the T_Ds and a correlation with the device performance. Fig. 9A and B shows AFM and SEM images of the films from compounds **6** and **8**, respectively, grown at different T_Ds. The films from compound **6** on bare SiO_2 substrates exhibit small grains with a few plate-like grains at $T_D = 25$ °C, but much larger, well-faceted grains are observed at higher T_Ds, as assessed by AFM (Fig. 9A). Films from compound **8** on HMDS-treated SiO_2 substrates show similar behavior, with lower T_D samples having small grains at $T_D = 25$ °C, but large crystal-like grains protruding from the film surface at higher T_Ds. The large highly-crystalline surface microstructural features exhibited by both compounds at the higher deposition temperature correlates well with the enhanced TFT performance. Similar T_D-dependent morphological change is also observed for compounds **3**, **5**, and **7** (Fig. S1).

4. Conclusions

Convenient, efficient, cost-effective, one-pot [2 + 1] and [1 + 1 + 1] synthesis of DTT were achieved that enables the efficient realization of a new **DTT**-based semiconductor series for organic thin-film transistors (OTFTs). Perfluorophenyl and perfluorobenzoyl substitutions are found to be effective in promoting n-channel transport. Diperfluorophenyl **DFP-DTT** (**3**), diperfluorobenzoyl **DFB-DTT** (**4**), and asymmetric **FBB-DTT** (**5**) films exhibit n-type transport with mobilities as high as 0.07 cm^2/Vs [33]. Compared to **DFCO-4T** [14a], the lower mobilities can be ascribed to the larger interplanar π–π separation distances (3.74 Å for **4** and 3.56 Å for **5** vs. 3.5 Å for **DFCO-4T**) caused by non-negligible F···H interactions in compounds **4** and **5** [34]. Interestingly, the intermolecular H···F interactions in asymmetric compound **5**, the compound having the shortest interplanar DTT core distances in this study, reveal the potential utility of this asymmetric design for other n-channel systems. In contrast, the non-fluorinated aryl carbonyl substituted **DTT** derivatives exhibit exclusively p-type transport, with the greatest hole mobility of 0.01 cm^2/Vs, observed for **DB-DTT** (**6**) and **DBS-DTT** (**8**). The carrier mobilities are found to be strongly dependent on the substrate deposition temperatures and surface treatments, and these **DTT**-based OTFTs exhibit excellent ambient stability over many months (near 1 year). These results provide new information about the structural characteristics of **DTT**-based semiconductors and the advantages of using this stable core for designing more soluble derivatives.

[33] Ambipolar transport in these **DTT** materials was not observed.
[34] In addition to the larger intermolecular core distance, the less conjugation of **DTT**s may be responsible for the lower mobilities.

the semiconductor thickness. This finding showed that the charge transport in these systems takes place mainly in the first two monolayers close to the insulator/semiconductor interface [3].

While those crystalline vacuum-deposited oligothiophene films are well-established, well-studied model systems showing highly ordered layer-by-layer growth and high charge carrier mobilities [4–6], low-cost production requires semiconductors which are soluble in solvents and can therefore be fast and easily processed by methods like drop-casting, spin-coating, dip-coating or printing. These requirements are fulfilled by several polymers of the thiophene material class, the polythiophenes. One of the best-known materials of this class is regio-regular poly-(3-hexylthiophene) (rr-P3HT), which is soluble in several solvents, therefore processable wet-chemically, and shows comparably high charge carrier mobility [7].

Unlike the above-mentioned small oligothiophene molecules deposited by evaporation in vacuum, the long polythiophene chains processed from solution do not show such high ordering [8,9]. Several studies have been performed on the dependence of the charge carrier mobility on the P3HT film thickness [10–13]. They were performed on silicon substrates with the silicon serving as common gate electrode and a silicon oxide layer serving as gate insulator on which source and drain electrodes as well as the P3HT were deposited. Contrary to this bottom-gate setup, a top-gate structure with spin-coated gate insulator on top of the P3HT layer is often used in plastic devices, where the insulator thus serves also as encapsulation of the P3HT layer, which otherwise shows rapid degradation of its electric qualities within minutes or hours.

Increasing mobility μ with increasing P3HT layer thickness was found for thin layers in bottom-gate transistors on silicon substrates. Sandberg et al. presume that because of interfacial strain, thin layers/monolayers are poorly ordered whereas the presence of a highly ordered bulk in thicker films causes an ordering effect in the interfacial layer [12]. This reordering is obviously completed at a thickness of ca. 20 nm, where Wang et al. found a constant charge carrier mobility after a strong increase with thickness for thinner layers [13]. Further deposition of the polymer to even higher thickness does not have a big effect on the interface layers any more. As the charge transport takes place mainly in the part of the semiconductor adjacent to the gate insulator, the charge carrier mobility remains fairly constant with further increased thickness.

The interface between semiconductor and insulator is known to play a crucial role in OFET performance [14]. In OFETs fabricated on silicon substrates P3HT is processed on the smooth surface of silicon oxide. In our devices however, the interface between insulator and semiconductor, at which the charge transport is presumed to take place, is the one between the upper side of the P3HT layer and the organic insulator deposited on top of it. Thus possible changes in the P3HT surface roughness, e.g. with increasing layer thickness, would directly affect the charge transport properties. Knipp et al. showed that in bottom-gate pentacene OFETs the charge carrier mobility of a device with a rough surface of the gate dielectric was more than one order of magnitude lower than in a film deposited on a smooth surface, while all other parameters remained the same [15]. In a more quantitative study, also on evaporated pentacene layers, Steudel et al. investigated the relation between the rms value of the SiO_2 surface and the charge carrier mobility in OFETs produced on this surface and also found a strong mobility decrease with increasing rms value [16]. A similar result was found by Jung et al. [17] with spin-coated polythiophenes on SiO_2 and could be related to the grain size variation with surface roughness. Therefore, the thickness dependence of the P3HT charge carrier mobility determined in silicon-based bottom-gate devices cannot be transferred to the top-gate device setup and was investigated in the present study with the organic insulator poly(methyl methacrylate) (PMMA).

As typical for disordered systems, P3HT shows non-constant, gate-voltage dependent mobility. This manifests itself in the linear regime by a non-linear shape of the transfer curves. Nevertheless in most studies, charge carrier mobilities are determined by linear fits in a very limited voltage range, often at extreme voltages, to obtain larger mobility values. Mobilities obtained in this way are difficult to compare since the selected voltage regime matters. Furthermore, valuable physical information is lost, as the exponent of the gate-voltage dependence of the charge carrier mobility reflects the width of the density of localized states, in which the charge transport takes place via hopping from one state to another. Therefore, in this study the transfer curves are fitted according to the Vissenberg–Matters model [18], allowing us to use the complete transfer curves over the entire measurement range and to extract the threshold voltage, the charge carrier mobility at a certain gate-voltage and the exponent of its variation with the gate-voltage, which allows us to calculate the width of the exponential density of states.

2. Experimental

The organic field-effect transistors (OFETs) were produced on poly(ethylene terephtalate) (PET) foils. The transistors were built in a bottom-contact configuration with top-gates. The setup is shown in the upper left of Fig. 1. 30 nm thick gold source and drain electrodes were structured by optical (UV) lithography. Each sample contained 45 transistors, among them 12 transistors with equal geometry, i.e. a channel length L of 20 μm and a channel width W of 20 mm. These transistors were used for the statistical analysis presented here.

As organic semiconductor, regio-regular poly-(3-hexylthiophene) (rr-P3HT, Fig. 1, lower left) from BASF, Germany with a molecular weight of 40,000 g/mol and a regioregularity of 94% was used. It was spin-coated onto the samples at 2000 rpm from solutions in chloroform ($CHCl_3$) filtered through a 450 nm filter. Solutions with different concentrations of P3HT, ranging from 0.02 wt.% to 2.0 wt.%, were taken for spin-coating to obtain different film thicknesses. After one minute of heating at 90 °C, the gate insulator was spin-coated on top. Poly(methyl methacrylate) (PMMA, Fig. 1, lower right) from Evonik industries, Germany, with a molecular weight M_w of 1250 kD

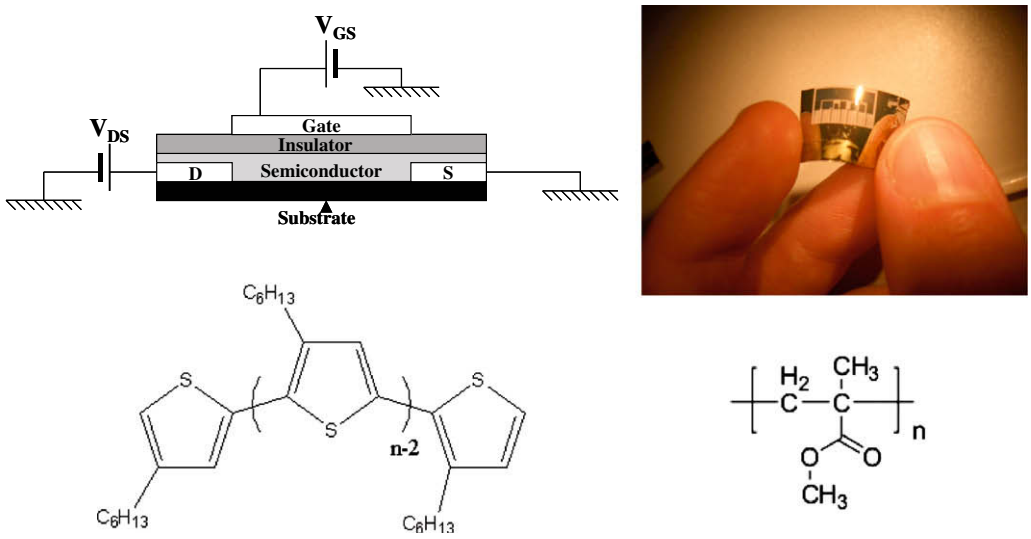

Fig. 1. Top: schematic view (left) and photo of OFET in bottom-contact and top-gate configuration produced on flexible and transparent plastic substrates; bottom: chemical structure of regio-regular poly-(3-hexylthiophene) (rr-P3HT, left) and poly(methyl methacrylate) (PMMA, right).

was used in a 5 wt.% solution in methyl-ethyl-ketone and spin-coated at 2000 rpm, yielding a layer of (860 ± 10) nm thickness. Remaining solvents were baked out during 5 min at 60 °C. The top-gate electrodes of gold (thickness (50 ± 5) nm) were deposited through a shadow mask in an argon sputter coater. Transfer and output curves were taken by measurements in darkness in ambient air (21 °C, 34% relative humidity) in a probe station where the source, drain and gate electrodes were contacted by needles. The thickness of the P3HT semiconductor layers was measured by a *Dektak* profilometer and confirmed by atomic force microscopy (AFM). Exemplary capacitance measurements with two gold rectangles produced on the same sample templates on the source/drain and on the gate level, respectively, confirmed the thickness measurements. The layer thicknesses were determined to be 3, 10, 12, 17, 21, 39, 53, 88, and 216 nm.

Exemplary transfer (taken in the linear regime at $V_{DS} = -1$ V) and output curves of the transistor devices can be seen in Fig. 2. Hardly any hysteresis is observed at all. The shape is typical for polymeric transistors, with a power law dependence of the mobility on the gate-voltage [19]. This results in an increasing slope with higher, i.e. more negative, gate-source voltage, which cannot be described by a simple linear fit consistent with the standard gradual channel approximation. Therefore, we used the Vissenberg–Matters model for charge transport in highly disordered systems [18]. It assumes charge transport to take place via variable range hopping between localized states in the tail of an exponential density of states (DOS)

$$N(E) = \frac{N_t}{\sigma} \exp\left(\frac{E}{\sigma}\right) \quad \text{for } E \leqslant 0 \tag{1}$$

with the total number of tail states N_t and the width of the DOS σ. For one given temperature T, the charge carrier mobility μ is then related to the gate-voltage V_{GS} in an exponential correlation:

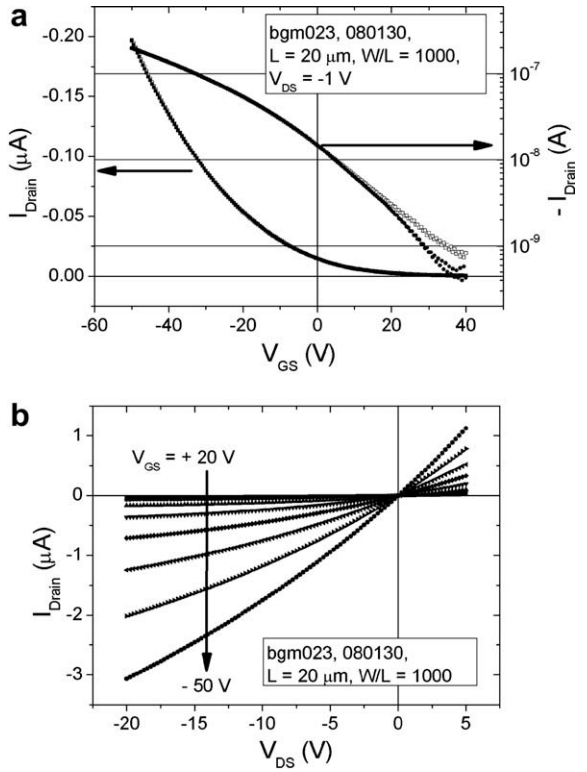

Fig. 2. Transfer curve (a) and output curves (b) taken from a transistor with a P3HT layer thickness of 21 nm. The mobility increases by a power law with the gate-source voltage. The exponent is found to be 2.4, the threshold voltage V_{th} is 44 V. Filled symbols show the forward measurements (from positive to negative voltage), open symbols the reverse measurements.

$$\mu = \mu_0 \left(\frac{V_{GS} - V_{th}}{V_{aa}}\right)^{\gamma} \tag{2}$$

μ_0 is the charge carrier mobility at $V_{GS} - V_{th} = V_{aa}$, where V_{aa} is an adequately chosen constant. According to the Vissenberg–Matters model, the exponent γ of the gate-voltage dependence is directly related to the width of the exponential DOS σ and thus to the disorder of the system by

$$\gamma = 2\left(\frac{\sigma}{k_B T} - 1\right) \quad (3)$$

where k_B is Boltzmann's constant. Data analysis in this way contains thus additional physical information compared to linear fits in a limited voltage range, the data obtained are clearly defined and allow for easier comparison with other data. The fits reproduce the whole transfer curves over the entire voltage range measured, as can be seen in Fig. 3.

Highest charge carrier mobilities of up to 1×10^{-2} cm^2/(Vs) are observed, which are high values for P3HT transistors for the given induced carrier density in the channel. Publications report of mobilities beyond 0.1 cm^2/(Vs) on e.g. silicon substrates determined at high gate-voltages (60 V) and oxide thickness of 200 nm or less [20,21], which corresponds to an electric field of 5 MV/cm, for higher carrier densities than are used in the present study. Our gate-source voltage of −50 V at 860 nm insulator thickness corresponds to a reasonable electric field of around 500 kV/cm. Applications at operation voltages of 10 V or lower would then require a reasonable insulator thickness below 170 nm.

When exposed to air, P3HT field-effect transistors usually show a rapid decrease in device performance. The charge carrier mobility μ decreases within minutes and falls by an order of magnitude after one day only. This makes not encapsulated P3HT OFETs inappropriate for most applications. In our devices, however, the P3HT layer is encapsulated by the insulator layer and therefore protected against air and humidity. No decrease of charge carrier mobility has been observed even for transistors produced more than four months ago. This shows that PMMA encapsulation is suitable for the protection of P3HT layers.

Fig. 4a shows the average values and standard deviation of the charge carrier mobility μ_0 for the $L = 20\mu$m transistors of nine different samples with nine different P3HT

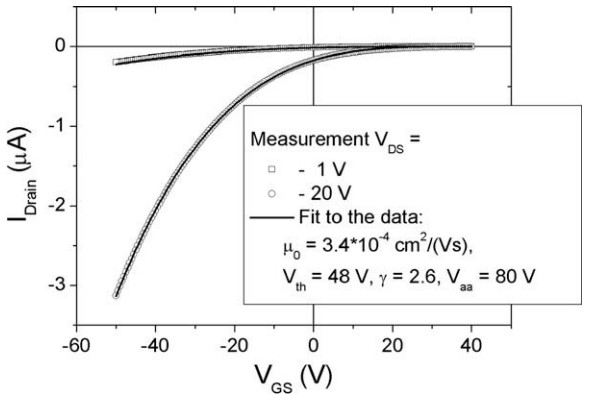

Fig. 3. Fits according to the Vissenberg–Matters model to transfer curves from the same transistor as in Fig. 2. The fits reproduce the curves over the entire voltage range which was measured, V_{GS} from +50 to −50 V, in the linear regime (V_{DS} = −1 V) as well as at V_{DS} = −20 V.

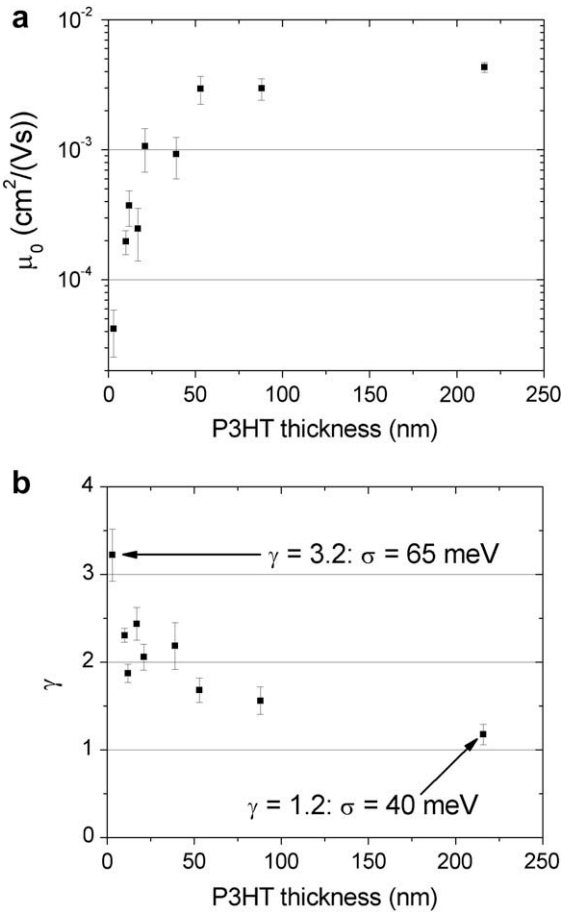

Fig. 4. (a) Charge carrier mobilities μ_0 (at V_{aa} = 80 V) and (b) exponent γ obtained for the L = 20 μm transistors, plotted over the thickness of the P3HT semiconductor layer. Each data point represents the average and standard deviation of 12 transistors with the same device geometry on the same substrate. The overall number of transistors shown is thus 108.

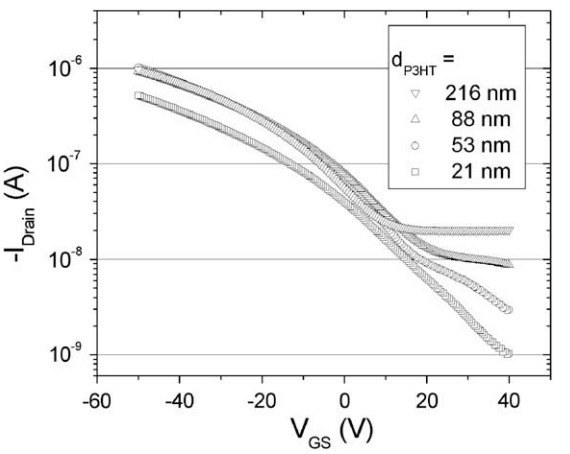

Fig. 5. Comparison of logarithmically plotted transfer curves of devices with different P3HT thickness depicting the constant on-current but increasing off-current in devices with more than 50 nm thickness.

layer thicknesses between 3 and 216 nm. As experiments with P3HT transistors processed by dip-coating have shown, a single monolayer of P3HT corresponds to a thickness of about 2 nm [11,22]. While for the smallest thickness of 3 nm, obtained by spin-coating a 0.02 wt.% solution, a low charge carrier mobility of just $\mu_0 = (4.2 \pm 1.7) \times 10^{-5}$ cm^2/(Vs) was obtained, at a film thickness of 21 nm the mobility increased by more than one order of magnitude to $\mu_0 = (1.1 \pm 0.4) \times 10^{-3}$ cm^2/(Vs). For films with thicknesses higher than 50 nm, a saturation of the mobility value at 3×10^{-3} cm^2/(Vs) was observed. In devices with thicker active layer, like the ones with 88 and 216 nm P3HT thickness, no significant increase of on-current and mobility is observed any more. The devices even show worse quality in the sense that the off-current is increased by more than one order of magnitude with further growing layer thickness as seen in Fig. 5. This is due to the fact that the positive voltage applied at the top-gate can only deplete a thin layer next to the interface whereas not entirely depleted regions still enable bulk current flow in the thicker films due to the residual doping level. Hence there is an optimum active layer thickness just below 50 nm in our top-gate transistors, which combines high charge carrier mobility with low off-currents.

Part (b) of Fig. 4 shows the average and standard deviation of the mobility exponent γ in dependence of the semiconductor thickness. The exponent strongly decreases from 3.2 at 3 nm thickness down to less than 2 in thicknesses above 40 nm. For even bigger thickness, the change is much less dramatic. While from these values of γ the width of the exponential density of states was determined to be 40 meV ($\gamma = 1.2$) for the thickest film, it increases up to 65 meV ($\gamma = 3.2$) in the thin films of 3 nm thickness. The reduced mobility in these thin films can thus directly be related to higher electronic disorder.

Phase contrast AFM measurements were taken to verify if the observed electronic disorder is related to the structural order of the film. Fig. 6 shows exemplarily the phase contrast images (3×3 μm^2) of a 10 nm thick film spin-coated from 0.05 wt.% solution in chloroform and of a 50 nm thick film spin-coated from 0.7 wt.% solution. Indeed, it is observed that the thicker film is much more ordered, exhibiting larger grain sizes. According to Fourier transformation of the data, the average correlation length in the phase contrast image of the thicker film is ca. 150 nm compared to 80 nm in the left image of the thinner film.

3. Conclusion

P3HT transistors in top-gate configuration with PMMA as gate insulator were successfully produced on flexible and transparent plastic foils as substrate. The electrical characteristics were analyzed according to the Vissenberg and Matters model for charge transport in disordered systems taking into account the gate-voltage dependence of the charge carrier mobility, which is directly related to the width of the DOS and thus the disorder of the system. High charge carrier mobility μ of up to 10^{-2} cm^2/(Vs) was obtained at $V_{GS} = -50$ V for a 860 nm insulator. Due to the encapsulation of the P3HT semiconductor by the insulator, the device performance remained stable during months. Low operation voltages of 10 V are expected with decrease of the insulator thickness. This active layer thickness dependence study shows a strong mobility increase with thicker P3HT layer in the regime of a few nm, up to a saturation around 50 nm. Further increase in thickness does not improve the mobility, but deteriorates the device performance by increasing the off-current. The mobility increase is accompanied by a decrease of the exponent γ of the gate-voltage dependence of the mobility. The observed thickness dependence of the mobility is thus explained by poor ordering in very thin films and improved ordering at 40–50 nm, while further increase of thickness does not affect the film order. Phase contrast AFM images confirm the better ordering of thicker P3HT films.

core [9]. It was found that the "bricklayer" structure showed much better TFT performance than the "slipped-stacked" structure, and that the bulkiness of the substituents (relative to the molecular size) which produced the bricklayer structure was required to fall within a narrow range; If the size of the substituents was too large or too small, a "slipped-stacked" or "herringbone" structure occurred, which showed poorer TFT performance. Based on this strategy, many small molecules yielding promising TFT performances have been developed [10–12].

In 2007, our group reported the development of promising *TIPS* anthracene derivatives (*TIPSAnts*) using the anthracene moiety in place of pentacene [13]. Anthracene is much more stable with respect to Diels–Alder reactions, and this stability prevents butterfly dimer decomposition, improves processability, and yields high crystallinity [14–16]. Small molecules containing *TIPSAnt* showed promising optical, electrochemical, and crystalline properties that resulted in moderate charge-carrier mobilities. However, to achieve higher TFT performances, further improvements were required. Because *TIPSAnt* contains dibromo moieties, it can serve as a soluble oligomer core for aromatic coupling reactions. The synthetic functionalities of *TIPSAnt* led to the development of a variety of new *TIPSAnt*-based small molecules.

Recently, we reported single crystal TFT performances of *TIPSAnt* derivatives by incorporating naphthalene and bithiophene moieties as counterparts of *TIPSAnt* [17]. Device performance was increased by increasing the molecular surface area available for π-stacking overlap. However, *TIPSAntNa* and *TIPSAntBT* single crystals showed only a "slipped-stacked" structure.

In this paper, we report three new small molecules based on *TIPSAnt*, 2,6-bis(thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (*TIPSAntT*), 2,6-bis(benzo[b]thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (*TIPSAntBeT*), and 2,6-bis(5′-phenyl-thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (*TIPSAntPT*). We systematically designed these new small molecules to elucidate the relationship between thin-film structure and TFT device performance for aromatic end-capped *TIPSAnt* derivatives. Thiophene, benzothiophene, and phenyl thiophene were used as end cappers for the *TIPSAnt* series. Two structural factors were considered: (1) the increase in the rigidity caused by fusing the aromatic rings, and (2) the increase in the effective π-stacking area of the "bricklayer" structure. We performed a comparative study to investigate the relationship between the molecular structures and TFT performances by measuring the thermal, optical, electrochemical, crystalline, and morphological properties of these molecules. This study demonstrated, for the first time, that the preparation of a "bricklayer" stacking structure using a *TIPSAnt* derivative yields high TFT performance.

2. Experimental

2.1. Instruments and reagents

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AVANCE 400 spectrometer with tetramethylsilane as an internal reference. For the NMR measurements, chloroform-d ($CDCl_3$) was used as the solvent for the materials except *TIPSAntBeT* (1,1,2,2,-tetrachloroethane-d_2). Elemental analysis was performed using EA-1110-FISONS elemental analyzer. UV–vis spectra were measured by using a Jasco V-530 UV/vis Spectrometer. Thermogravimetric analysis (TGA) measurement was performed under nitrogen atmosphere at a heating rate of 10 °C/min using TA Q500 instrument, and the differential scanning calorimetric (DSC) measurement was made using TA Q100 instrument operated under nitrogen atmosphere. Cyclic voltammetry (CV) measurement was performed on an AUTOLAB/PGSTAT12 at room temperature with a three-electrode cell in a solution of 0.1 M tetrabutylammonium tetrafluoroborate (TBABF4) in anhydrous acetonitrile at room temperature under nitrogen gas with a scan rate of 50 mV/s. The working electrode was the oligomer coated platinum, the counter electrode was a platinum wire, and the reference electrode was $Ag/AgNO_3$ (0.10 M) which was separated by a diaphragm. The measurements were calibrated using ferrocene as a standard. The single crystal for X-ray analysis was typically grown from hexane and chlorobenzene. Analyses were performed on a Bruker SMART Apex II X-ray Diffractometer. Data have been submitted as .cif files. AFM (Multimode IIIa, Digital Instruments) operating in tapping-mode was used to image surface morphology of our semiconductor. Synchrotron X-ray diffraction analyses of PAT4 films were performed at the 10C1 beam line (wavelength ≈1.54 Å) of the Pohang Accelerator Laboratory (PAL). Top-contact OTFTs were fabricated on a common gate of highly n-doped silicon with a 300 nm thick thermally grown SiO_2 dielectric layer. Substrates were modified with octyltrichlorosilane from a toluene solution for 2 h at room temperature. Films of organic semiconductor were spin-coated at 2000 rpm from 0.7 wt.% chloroform or chlorobenzene solution, with nominal thickness 45 nm. Gold source and drain electrodes were evaporated on the top of semiconductor (100 nm). For all measurements, we used channel lengths (L) of 150 μm and channel widths (W) of 1500 μm. Electrical characteristics of the TFTs were measured in air using both Keithley 236 source/measure units. The carrier mobility was calculated in the saturation regime from the slope of a plot of the square root of the drain current versus gate voltage (V_G) by fitting the data to the following equation: $I_{DS} = (WC_i/2L)\mu(V_G - V_T)^2$, where I_{DS} is the drain current, μ is the carrier mobility and V_T is the threshold voltage. For single crystal TFTs, saturated chlorobenzene solution of the small molecules was slowly evaporated at room temperature on OTS-modified SiO_2 substrates. After 1 or 2 days, well-defined rod-type single crystals were obtained and gold electrode was patterned onto the single crystals by thermal evaporation with thickness of 100 nm. Width and length of the channels were calculated from optical microscopy (OM) images. The thickness of single crystals was measured using an alpha stepper (Alpah Step 500, Tencor).

Chemical reagents were purchased from Aldrich Chemical Co. and were used without further purification. Solvents with analytical-grade were used during the whole experiments, and all chemicals were used without further purification. 2,6-Dibromo-9,10-bis-(triisopropylsilylethy-

nyl)anthracene (*TIPSAnt*) [13], 2-pinacolborylthiophene (1a) [18], and 2-(4′,4′,5′,5′-tetramethyl-1′,3′,2′-dioxaborolane)benzo[b]thiophene (1b) [19], 5-phenyl-1-tributyl stannyl thiophene (1c) [20] were synthesized according to the reported procedures.

2.2. Synthesis

2.2.1. Synthesis of 2,6-Bis(thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (TIPSAntT)

Into 150 mL two-neck flask were added *TIPSAnt* (1 g, 1.43 mmol) and 2-pinacolborylthiophene (1a) (0.66 g, 3.16 mmol) in 15 mL of anhydrous toluene. Catalytic amount of tetrakis(triphenyl phosphine)palladium(0) was transferred into the mixture in dry box. Subsequently, (2 M Na_2CO_3) sodium carbonate (0.76 g, 7.21 mmol) deaerated for 30 min and the phase transfer catalyst, Aliquat®336 (0.29 g, 0.72 mmol) in toluene purged under nitrogen for 1 h was transferred via cannula. The reaction mixture was stirred at 90 °C for 3 days and cooled to room temperature. Then, the reaction mixture was poured into saturated sodium bicarbonate solution and extracted with EA. The organic layer was washed with brine, and then dried over anhydrous $MgSO_4$. The crude product was column chromatographed with hexane and MC mixture as the eluent, and then crystallized from hexane and MC to yield *TIPSAntT* (0.72 g, 71.0%) as bright orange crystal. ^{1}H NMR ($CDCl_3$, ppm) δ = 8.84 (d, 2H), 8.60 (d, 2H), 7.87 (dd, 2H), 7.53 (d, 2H), 7.37 (d, 2H), 7.14 (dd, 2H), 1.31 (m, 42H). ^{13}C NMR ($CDCl_3$, ppm) δ = 144.31, 132.57, 132.49, 132.19, 128.25, 127.92, 125.79, 125.72, 123.99, 122.97, 118.53, 105.28, 103.10, 19.00, 11.55. Anal. calcd for $C_{44}H_{54}S_2Si_2$: C, 75.15%; H, 7.74%; S, 9.12%. Found: C, 74.73%; H, 7.58%; S, 8.99%.

2.2.2. Synthesis of 2,6-bis(benzo[b]thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (TIPSAntBeT)

Into 150 mL two-neck flask were added *TIPSAnt* (1 g, 1.43 mmol) and 2-(4′,4′,5′,5′-tetramethyl-1′,3′,2′-dioxaborolane)benzo[b] thiophene (1b) (0.86 g, 3.31 mmol) in 20 mL of anhydrous toluene. Catalytic amount of tetrakis(triphenyl phosphine)palladium(0) was transferred into the mixture in dry box. Subsequently, (2 M Na_2CO_3) sodium carbonate (0.76 g, 7.21 mmol) deaerated for 30 min and the phase transfer catalyst, Aliquat®336 (0.29 g, 0.72 mmol) in toluene purged under nitrogen for 1 h was transferred via cannula. The reaction mixture was stirred at 90 °C for 3 days and cooled to room temperature. Then, the reaction mixture was poured into saturated sodium bicarbonate solution and extracted with MC. The organic layer was washed with brine, and then dried over anhydrous $MgSO_4$. The crude product was column chromatographed with hexane and MC mixture as the eluent, and then crystallized from chlorobenzene to yield *TIPSAntBeT* (0.63 g, 55.1%) as bright orange crystal. ^{1}H NMR (1,1,2,2-tetrachloroethane-d_2 at 100 °C, ppm) δ = 9.06 (s, 2H), 8.74 (d, 2H), 8.05 (d, 2H), 7.93 (d, 2H), 7.86 (d, 2H), 7.83 (s, 2H), 7.41 (m, 4H), 1.44 (m, 42H). ^{13}C NMR (1,1,2,2-tetrachloroethane-d_2 at 100 °C, ppm) δ = 144.34, 141.05, 140.35, 133.07, 132.98, 132.83, 128.25, 126.00, 124.85, 124.84, 124.77, 123.89, 122.46, 121.02, 119.35, 106.50, 103.41, 19.10, 12.01. Anal. calcd for $C_{52}H_{58}S_2Si_2$: C, 77.75%; H, 7.28%; S, 7.98%. Found: C, 77.24%; H, 7.02%; S, 7.68%.

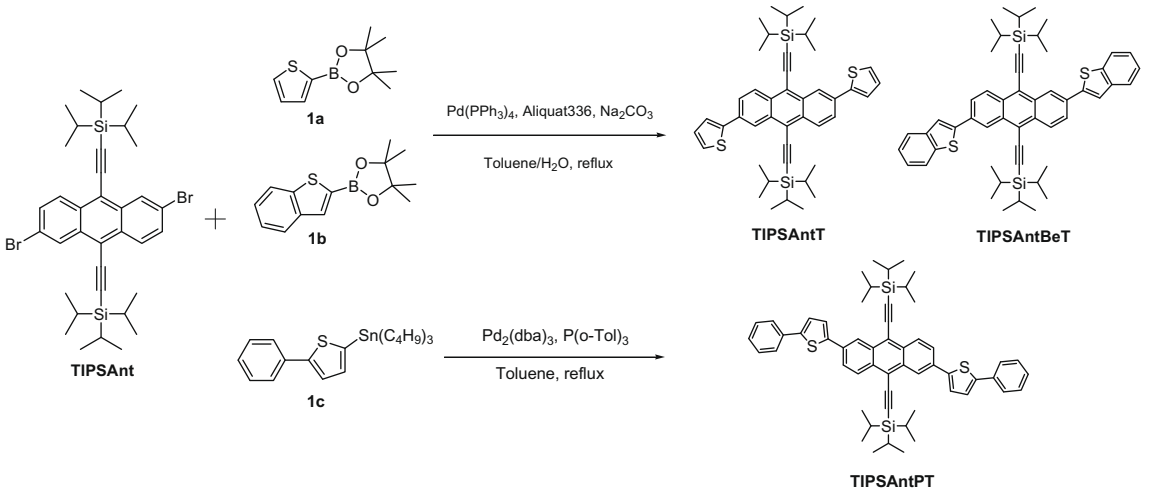
2.2.3. Synthesis of 2,6-bis(5′-phenyl-thiophene-2′-yl)-9,10-bis(triisopropylsilylethynyl)anthracene (TIPSAntPT)

To a 150 mL two neck round-bottom flask equipped with a stir bar under N_2 was added *TIPSAnt* (0.60 g, 0.86 mmol) and 5-phenyl-1-tributylstannyl thiophene (1c) (1.16 g, 2.58 mmol). Tris(dibenzylideneacetone)dipalladium (0.016 g, 0.017 mmol) and tri-o-tolyphosphine (0.021 g, 0.069 mol) was transferred into the mixture in dry box. Subsequently anhydrous toluene (20 mL) was added and purged under nitrogen for 30 min. The reaction mixture was stirred at 120 °C for 3 days and cooled to room temperature. Then, solvent was evaporated with rotary evaporator and dried at vacuum. The crude product was column chromatographed with hexane and MC mixture as the eluent, and then crystallized from hexane and chlorobenzene to yield *TIPSAntPT* (0.56 g, 75.7%) as bright orange crystal. ^{1}H NMR ($CDCl_3$, ppm) δ = 8.86 (d, 2H), 8.59 (d, 2H), 7.91 (dd, 2H), 7.66 (dd, 4H), 7.49 (d, 2H), 7.41 (t, 4H), 7.35 (d, 2H), 7.30 (t, 2H), 1.32 (m, 42H). ^{13}C NMR ($CDCl_3$, ppm) δ = 144.39, 143.44, 134.24, 132.60, 132.35, 132.22, 128.99, 127.90, 127.67, 125.58, 125.28, 124.94, 124.23, 122.79, 118.51, 105.29, 103.13, 19.04, 11.61. Anal. calcd for $C_{56}H_{62}S_2Si_2$: C, 78.63%; H, 7.31%; S, 7.50%. Found: C, 78.52%; H, 7.28%; S, 7.52%.

3. Results and discussion

3.1. Synthesis of the small molecules

The soluble oligomer core, *TIPSAnt*, was synthesized according to procedures developed previously [13]. The bromo groups of *TIPSAnt* enabled coupling of the molecules to a variety of borolanylaryl or stannylaryl molecules, for example, acene, thiophene, or fluorene derivatives. In the present work, we chose thiophene, benzothiophene, and phenyl thiophene for *TIPSAntT*, *TIPSAntBeT*, and *TIPSAntPT*, respectively, as counterparts of *TIPSAnt*. Aromatic end cappers (1a–1c) were easily synthesized via well-known lithiation methods. *TIPSAntT* and *TIPSAntBeT* were synthesized via a Suzuki coupling reaction, and *TIPSAntPT* was synthesized via a Stille coupling reaction with high yields, as shown in Scheme 1. To achieve high purity, we purified the molecules by column chromatography, followed by several consecutive recrystallizations. The products were bright orange highly crystalline solids. The relative solubilities of the resulting products were as follows: *TIPSAntT* > *TIPSAntPT* > *TIPSAntBeT*. *TIPSAntT* showed good solubility in common organic solvents, such as THF, toluene, and chloroform, whereas *TIPSAntBeT* was soluble only in hot chlorobenzene. *TIPS* groups improved the solubility of the π-conjugated rings, but as the molecular size and rigidity increased, the solubility of the molecules decreased. The compounds were characterized by ^{1}H NMR, ^{13}C NMR, and elemental analysis.



Scheme 1. Syntheses of the small molecules.

3.2. Thermal properties

The thermal stabilities of the small molecules were characterized by thermogravimetric analysis (TGA) under a nitrogen atmosphere. *TIPSAntT* exhibited good thermal stability, with a decomposition temperature, based on 5% weight loss (T_{d5}), of 355 °C, whereas *TIPSAntBeT* and *TIPSAntPT* exhibited excellent thermal stabilities, showing a T_{d5} of 416° and 420 °C, respectively. The larger molecular weights of *TIPSAntBeT* and *TIPSAntPT* may have contributed to their improved thermal stabilities. The thermal transitions of the small molecules were studied by differential scanning calorimetry (DSC) under a nitrogen atmosphere. *TIPSAntT* exhibited liquid crystalline properties, with the first endothermal peak at 173 °C and the second endothermal peak at 290 °C, and corresponding exothermal peaks at 140 °C and 220 °C. *TIPSAntBeT* and *TIPSAntPT* exhibited similar transition behavior, with major melting endotherms at 209 and 304 °C, and corresponding crystallization exotherms upon cooling at 206 and 262 °C. All peaks were significant and reversible, without the presence of additional thermal transitions. From these thermal responses, we concluded that the small molecules were highly crystalline and should form well-ordered thin films when deposited onto a substrate. DSC results are shown in Fig. 1.

3.3. Optical properties

The UV–vis absorption spectra of the small molecules were recorded both in solution (chlorobenzene) and in film states, as shown in Fig. 2. The UV–vis data for the small molecules is summarized in Table 1. All small molecules showed good absorption properties, with vibronic structures in both solution and film states. In both the solution and film states, the absorption spectra of the small molecules showed relative red-shifts as follows: *TIPSAntT* < *TIPSAntBeT* < *TIPSAntPT*. The largest red-shift in the absorption spectrum of *TIPSAntPT* suggested the presence of increasing electron delocalization along the main chain due to more extensive conjugation. The lowest energy transitions in the film states were more red-shifted (18–37 nm) than those in solution states for all small molecules (see Δ2nd Max in Table 1). The intensities of the lowest energy transitions were also larger in the film states compared to the intensities in the solution states. The red-shifts and increased intensities demonstrated extended π-conjugation and substantially more intermolecular ordering within the 2D stacking of the small molecules in the film state. The most striking red-shift, observed for *TIPSAntPT* (37 nm), indicated that this molecule has the strongest intermolecular interactions. The existence of strong interactions between the π-conjugated systems of neighboring molecules in the solid state is desirable for good TFT device performance.

3.4. Electrochemical properties

To investigate the electrochemical stability and the charge transport properties of the small molecules, we carried out cyclic voltammetry (CV) measurements on thin films of the small molecules, summarized in Table 2. The small molecules showed reversible waves for both p-doping and n-doping processes. The oxidation potentials E_{ox} (p-doping) for *TIPSAntT*, *TIPSAntBeT*, and *TIPSAntPT* were 0.99, 1.13, and 0.96 V, respectively. The relatively high oxidation potentials for *TIPSAnts*, compared to *TIPS* pentacene (380 mV), [21] resulted in better oxidation stability of the materials. The highest occupied molecular orbital (HOMO) levels of *TIPSAntT*, *TIPSAntBeT*, and *TIPSAntPT* were estimated to be −5.39, −5.53, and −5.36 eV, respectively, using the previously reported empirical equation [22]. The observation that *TIPSAntBeT* had the lowest HOMO was attributed to reduced delocalization along the backbone through the introduction of a fused aromatic unit, benzothiophene. The delocalization of electrons from the benzothiophene unit onto the backbone was less favorable than from a single thiophene and benzene ring, due to the larger resonance stabilization energy of the fused ring [23]. It is worth noting that among the three materials, the

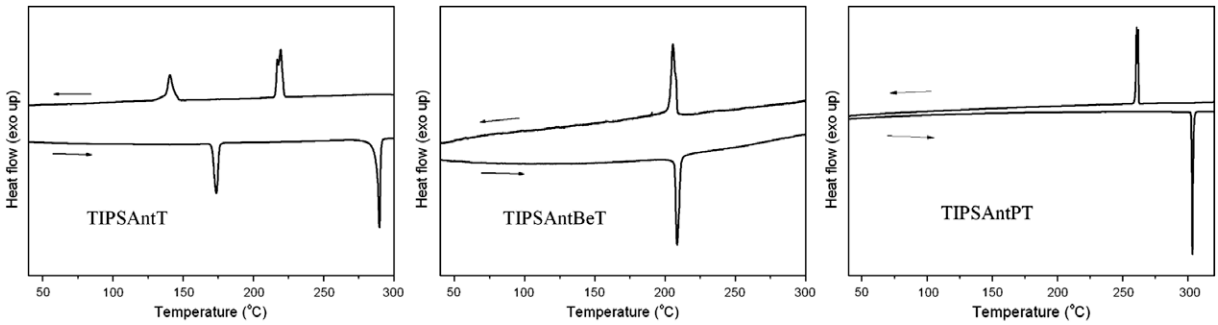


Fig. 1. DSC scans of the small molecules.

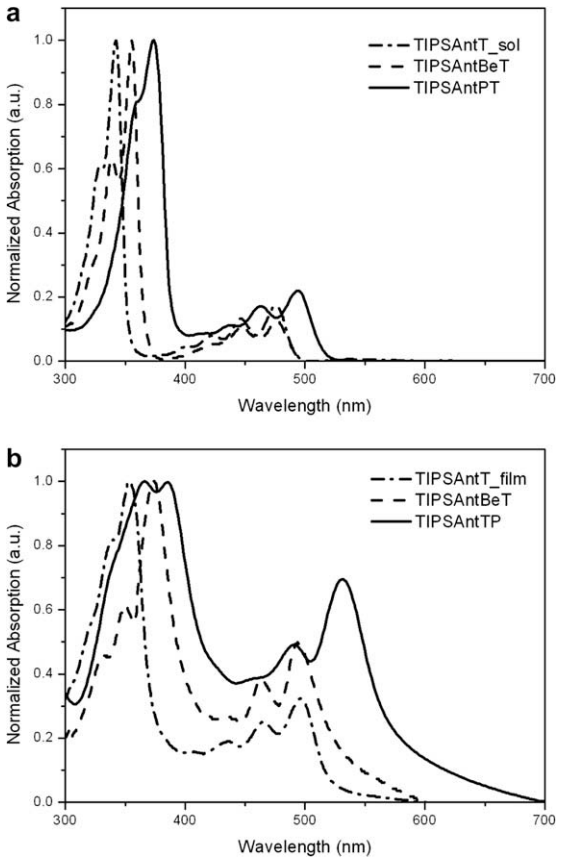

Fig. 2. UV–vis absorption of the small molecules. (a) In a chlorobenzene solution (b) in the spin-coated film state.

HOMO level of *TIPSAntPT* provided the best match to the work function of gold metal [24]. As a result, hole injection from the gold source electrode in p-type thin-film transistors composed of *TIPSAntPT* was expected to be the most efficient among the three materials. In contrast, the lowest lying HOMO level of *TIPSAntBeT* would be expected to increase the hole injection barrier between the gold electrodes and the *TIPSAntBeT* film. The relative band gaps of *TIPSAnts*, calculated from CV measurements and the onset of absorption in the film states, decreased in the order *TIPSAntT* > *TIPSAntBeT* > *TIPSAntPT*, as summarized in Table 2.

Table 1
UV–vis absorption properties of the small molecules.

λ_{max}	UV_sol[a]	UV_film[b]	Δ1st Max[c]	Δ2nd Max[d]
TIPSAntT	342, 475	353, 496	11	21
TIPSAntBeT	357, 476	373, 494	16	18
TIPSAntPT	373, 494	366, 531	−7	37

[a] In chlorobenzene solution.
[b] Spin-coated thin film from chlorobenzene solution.
[c] The 1st maximum peak difference between solution and film states around 340–370 nm.
[d] The 2nd maximum peak difference between solution and film states around 470–530 nm.

The low band gap of *TIPSAntPT* was attributed to the extended conjugation system of the material, which benefited from the long conjugation length of the main chain, as described in Section 3.3.

3.5. X-ray crystallography

Crystallographic analysis allows for the rapid screening of potential OTFT materials. Single crystals of small molecules, easily grown from hexane and chlorobenzene, were analyzed by X-ray crystallography.

Fig. 3 shows the π-stacking structures of the small molecules in single crystals. All of the molecules showed face-to face molecular interactions similar to our previous results [13]. The interplanar distances in the three molecules were almost identical: 3.54, 3.55, and 3.54 Å for *TIPSAntT*, *TIPSAntBeT*, and *TIPSAntPT*, respectively. Single crystals of *TIPSAntT* and *TIPSAntBeT* showed "slipped-stacked" structures similar to that previously reported for *TIPSAnts* [13,17], as shown in Fig. 3b and d. However, single crystals of *TIPSAntPT* showed a "bricklayer" structure, as shown in Fig. 3f. How the *TIPSAnt* columns interdigitate determines whether a "slipped-stacked" or "bricklayer" structure is formed. When *TIPSAntT* of *TIPSAntBeT* columns packed together, each conjugated core in one column adjoined two TIPS groups in an adjacent column to form a "slipped-stacked" structure, as shown in Fig. 3a and c. For *TIPSAntPT*, by contrast, the bulky phenyl groups prevented the conjugated cores of the *TIPSAntPT* molecules in one column from adjoining the two *TIPS* groups in an adjacent column. As a result, the conjugated cores of *TIPSAntPT* molecules in one column adjoined the conjugated cores of molecules in

Table 2
Electrochemical properties of the small molecules.

	E_{ox} (mV)[a]	E_{red} (mV)[a]	HOMO (eV)[b]	LUMO (eV)[b]	E_g (eV)	E_{g_opt} (eV) [c]

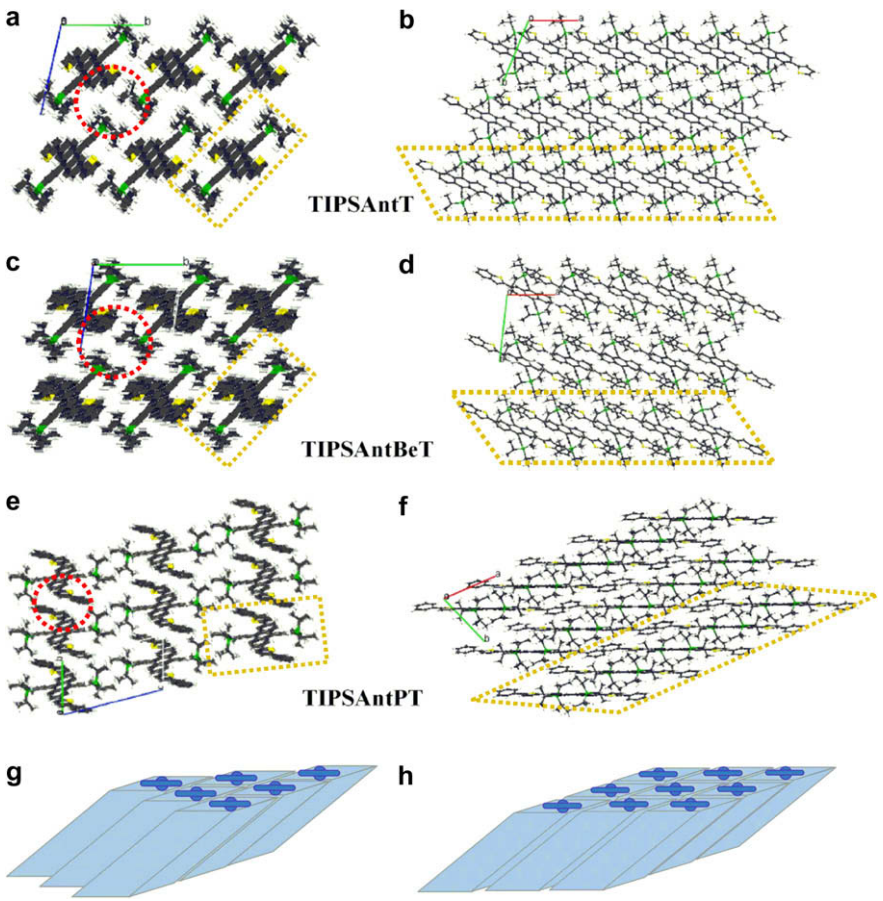

Fig. 3. Single crystal structures of (a and b) *TIPSAntT* and (c and d) *TIPSAntBeT*, which show "slipped-stacked" structures, and (e and f) *TIPSAntPT*, which shows a "bricklayer" structure. (a, c and e): view down crystallographic *a* axis, (b, d, and f): view down crystallographic *c* axis. Schematic figures of columns of *TIPSAnts* stacks: (g) for *TIPSAntT* and *TIPSAntBeT*, and (h) for *TIPSAntPT*. Yellow dotted squares indicate columns of *TIPSAnts* stack and red dotted circles indicate adjoining areas between adjacent columns. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

adjacent columns, resulting in a "bricklayer" structure, as shown in Fig. 3e. *TIPSAntPT* is the first *TIPSAnt* derivative to yield a "bricklayer" stacking structure. In Fig. 3g and h, the *TIPSAnt* columns and the adjoining areas between adjacent columns are indicated by yellow and red dotted lines, respectively.

Fig. 4 shows the area of π-overlap between a molecule and above adjacent molecules of *TIPSAnt* derivatives. (The area of π-overlap with below adjacent molecules was omitted for clarity.) When bulkier substituents were incorporated into the conjugated core, the area of π-overlap increased. As a result, *TIPSAntBeT* had a larger π-overlap area than *TIPSAntT*. Only *TIPSAntPT* showed an additional area of π-overlap with adjacent molecules due to the "bricklayer" stacking structure. This additional area of π-overlap significantly improved the charge-carrier mobility.

3.6. TFT performances

Top-contact OTFTs were fabricated on a common gate of highly n-doped silicon with a 300 nm thick thermally grown SiO_2 dielectric layer. Substrates were modified with

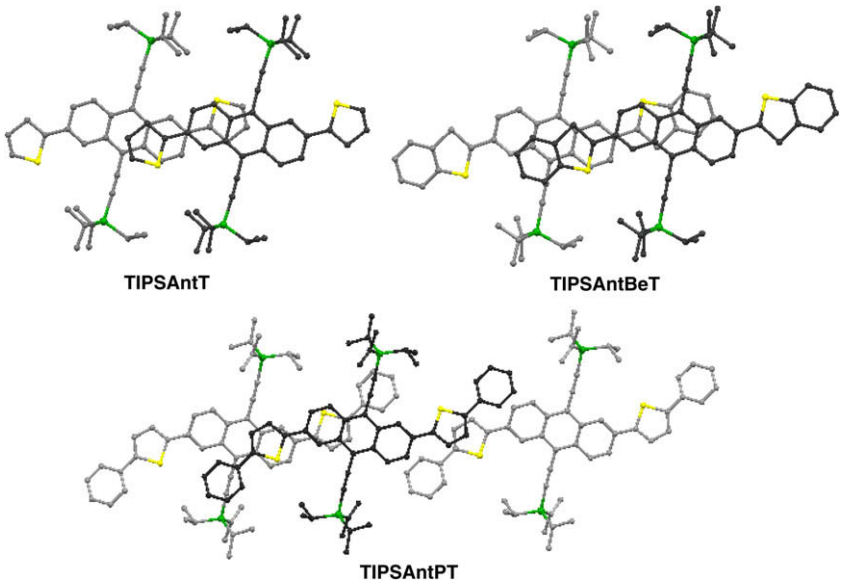

Fig. 4. Overlap of the molecules (dark-shaded molecules) along with their closest neighbors in the plane above the molecule (light-shaded molecules).

octyltrichlorosilane (OTS) by incubation in a toluene solution of OTS for 2 h at room temperature. Films of the organic semiconductors were spin-coated at 2000 rpm from a 0.5 wt.% chloroform solution of *TIPSAntT* and *TIPSAntPT*, and chlorobenzene for *TIPSAntBeT*, due to solubility limitations. All of the TFT results were obtained in ambient air condition and the devices did not show any unstable problems. As shown in Fig. 5, the TFT devices of all molecules showed typical p-channel responses and good saturation behavior. The TFT performances of *TIPSAnts* are summarized in Table 3. *TIPSAntPT* showed the most improved TFT performance among the three molecules, with an average mobility of 0.063 cm^2/Vs, on/off ratio of 4×10^5, and threshold voltage (V_T) of −4.0 V. *TIPSAntPT* showed an order of magnitude larger charge-carrier mobility than *TIPSAntT*, most likely because of the "bricklayer" structure of the film. *TIPSAntBeT*, however, showed a lower mobility than *TIPSAntT*. Although a larger area of π-overlap was observed, as shown in Fig. 4, *TIPSAntBeT* exhibited decreased mobility on account of its poorer solubility and higher crystallinity arising from the rigid benzothiophene. In addition, high crystallinity increased the number of hole-trapping sites at the interface between the OTS monolayer and the *TIPSAntBeT* film. If there were too many hole-trapping sites, a very large negative gate bias would be required to swing the polymer into hole accumulation mode, by inducing a high threshold voltage, V_T. The low HOMO level of *TIPSAntBeT* also produced a hole injection barrier. As a result, V_T of *TIPSAntBeT* (−28.7 V) was much larger than V_T for the other small molecules. The trend in TFT performance among the three small molecules corresponded with the morphological properties, which are discussed in the next section.

Single crystal TFTs based on the small molecules were fabricated because single organic crystals allow the facile investigation of the intrinsic material parameters that determine charge transport efficiency [25,26]. In particular, single crystals of functionalized pentacene reportedly yielded high mobilities because they were largely free from grain boundaries and molecular disorder, and, thus, overlap of the π-orbitals was enhanced [27]. A saturated chlorobenzene solution of the small molecules was slowly evaporated at room temperature onto OTS-modified SiO_2 substrates. After 1 or 2 days, well-defined rod-type single crystals were obtained, and gold electrodes were patterned onto the single crystals by thermal evaporation. The width and length of the channels were calculated from optical microscopy (OM) images. OM images of single crystal TFTs and a schematic device structure are shown in Fig. 6 The mobility trend for single crystal devices was the same as that of the film devices (*TIPSAntBeT* < *TIPSAntT* < *TIPSAntPT*). As expected, the highest TFT performances, showing a mobility of 0.12 cm^2/Vs, were achieved from one-dimensional (1D) single crystalline *TIPSAntPT* microribbons. The improved performance arose from the highly efficient π-orbital overlap of the "bricklayer" structure of the *TIPSAntPT* single crystals. *TIPSAntT* also grew as 1D single crystalline microribbons, resulting in a high mobility, but the less efficient π-orbital overlap of the "slipped-stacked" arrangement of *TIPSAntT* single crystals resulted in a lower mobility than was observed for *TIPSAntPT* single crystals. In contrast, *TIPSAntBeT* grew as three-dimensional (3D) polyhedron single crystals with a larger thickness than *TIPSAntPT*. (The thickness of single crystals was 80 and 200 nm for *TIPSAntPT* and *TIPSAntBeT*, respectively, measured with an Alpha Step 400, Tencor.) In single crystal TFTs, 1D or 2D microrods showed much higher TFT performance than 3D polyhedra because 3D polyhedra have difficulties contacting the gold electrodes [28,29]. As a result, the mobility of *TIPSAntBeT* single crystals was poor. TFT results of single crystals of the *TIPSAnt* derivatives are summarized in Table 3. We are currently working on improving device performances including operational stability and we will publish the results elsewhere.

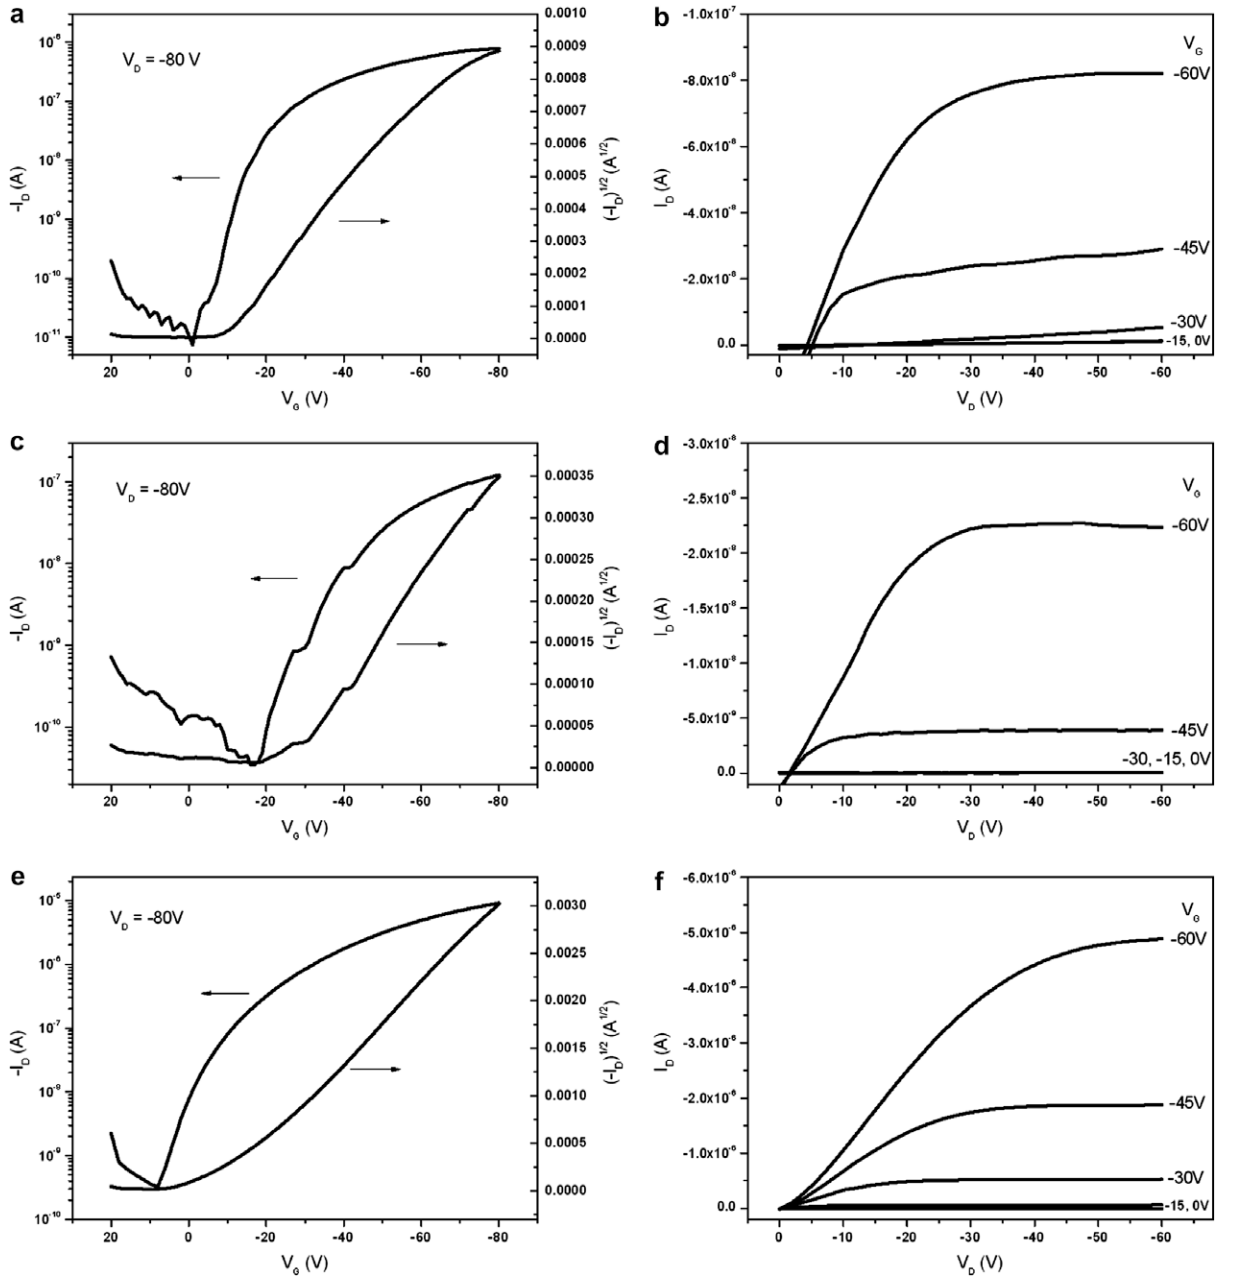

Fig. 5. Transfer characteristics and output characteristics of *TIPSAntT* (a and b), *TIPSAntBeT* (c and d), and *TIPSAntPT* (e and f).

3.7. Morphological properties

We performed atomic force microscopy (AFM) measurements to further investigate the relationship between molecular alignment in films and device performance as AFM provides the thin-film morphologies in micrometer scales to hundreds of nanometer scales. As shown in Fig. 7c, *TIPSAntPT* showed film morphologies dominated by 2D growth after spin-casting, due to the strong electronic interactions in the "bricklayer" π-stacking structure. Each crystalline domain connected smoothly in the as-cast film, yielding devices with high TFT hole mobilities based on *TIPSAntPT*. In contrast, *TIPSAntT* and *TIPSAntBeT* underwent 3D film growth, as shown in Fig. 7a and b, due to the limited π-overlap in the "slipped-stacked" structures. *TIPSAntBeT*, especially, showed poor substrate coverage, with the needle-like crystallites produced due to poor solubility. The high crystallinity also led to a very low mobility and high V_T. The rotational invariance of the fused benzothiophene in the backbone facilitated the adoption of a low energy backbone conformation, promoting the formation of highly ordered crystalline domains.

Out-of-plane and in-plane mode X-ray diffraction (XRD) spectra of films of the molecules were measured,

Table 3
TFT performances of the small molecules.

	Film			Single crystal		
	Mobility (cm^2/Vs)	I_{on}/I_{off}	V_T (V)	Mobility (cm^2/Vs)	I_{on}/I_{off}	V_T (V)
TIPSAntT	0.0039	6×10^4	−11.2	0.059	5×10^3	−24.1
TIPSAntBeT	0.0013	7×10^3	−28.7	0.0067	3×10	−8.5
TIPSAntPT	0.063	4×10^5	−4.0	0.12	2×10^2	−6.1

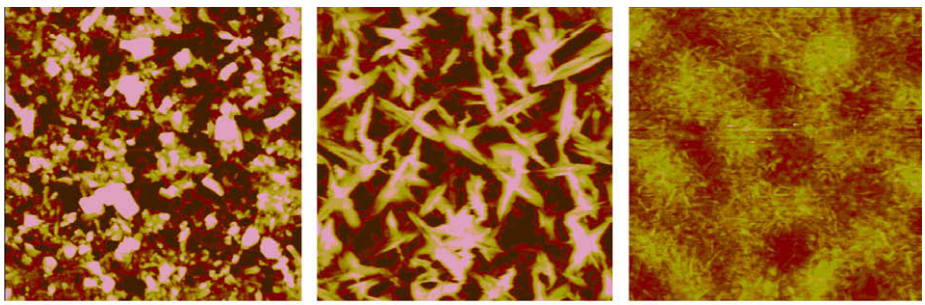

Fig. 7. AFM images (5μ × 5μ).

as shown in Fig. 8. The *TIPSAntT* film showed the lowest degree of crystallinity, exhibiting no specific ordering in the peaks of the out-of-plane mode XRD. Although a (0 1 0) peak was observed in the in-plane mode XRD of the *TIPSAntT* film, the interlayer spacing *d* was 4.28 Å, which is the largest spacing measured among the three molecules, indicating less effective intermolecular π-stacking. In contrast, *TIPSAntBeT* films showed highly crystalline properties, with (1 0 0), (2 0 0), and (3 0 0) reflections in the out-of-plane mode XRD indicating well-organized intraplanar lamella-like structures oriented normal to the substrate. The molecular length of the *TIPSAnt* derivatives along the *TIPS* axis was 16.7 Å, as determined by X-ray crystallography. The *d* spacing of the (1 0 0) peak was 14.9 Å, which implied that *TIPSAntBeT* molecules were aligned perpendicular to the substrate, with respect to

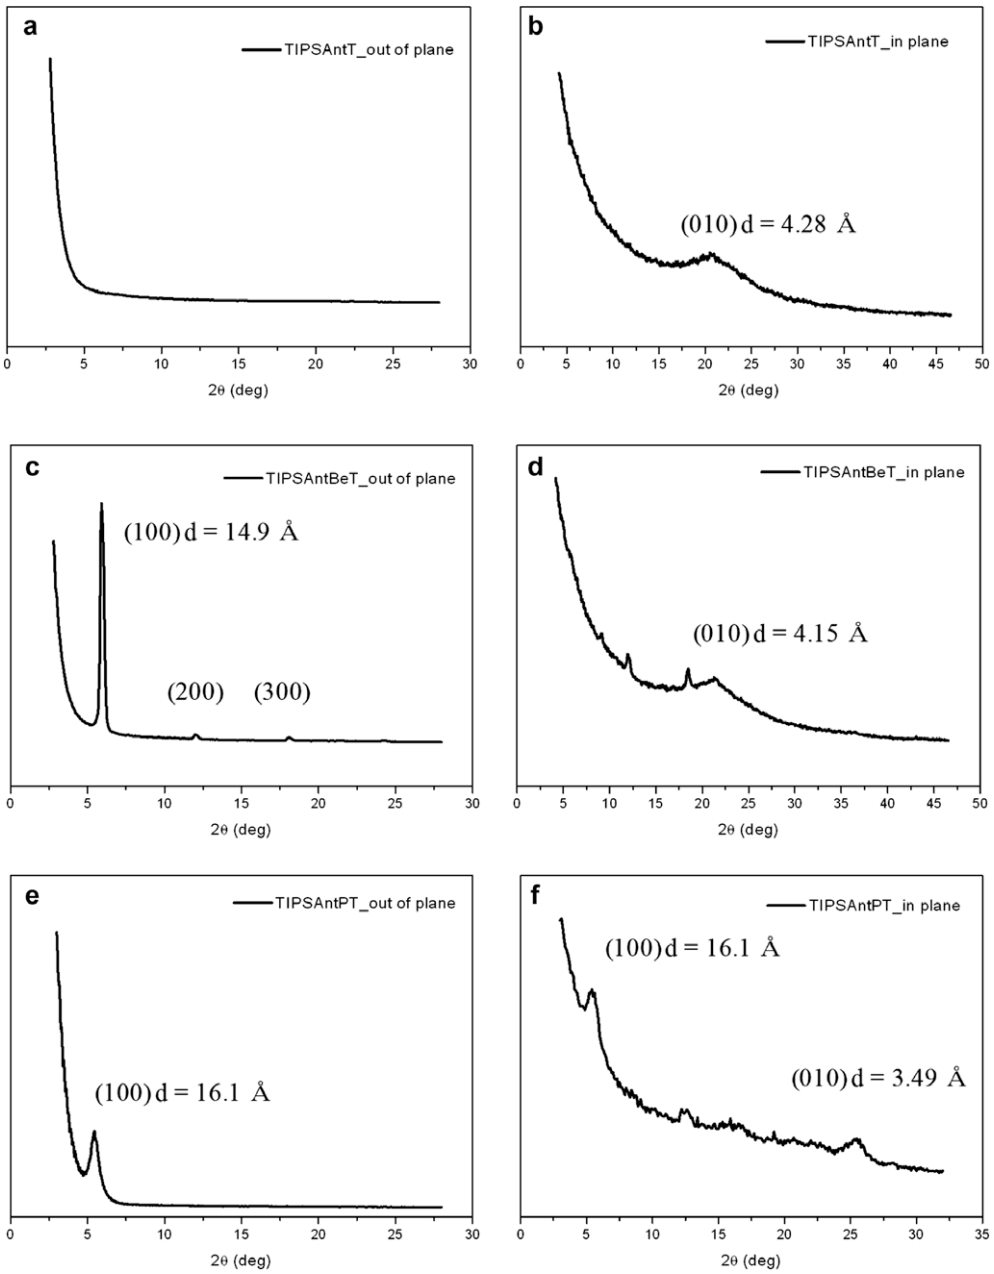

Fig. 8. XRD patterns (a) *TIPSAntT*_out of plane, (b) *TIPSAntT*_in-plane, (c) *TIPSAntBeT*_out of plane, (d) *TIPSAntBeT*_in-plane, (e) *TIPSAntPT*_out of plane, and (f) *TIPSAntPT*_in-plane.

the *TIPS* axis, with a tilt angle of 27°. Although the (0 1 0) peak in the in-plane mode XRD of the *TIPSAntBeT* films showed a closer interlayer *d* spacing of 4.15 Å, the high crystallinity of the *TIPSAntBeT* films resulted in poorer device performances than *TIPSAntT*. The high crystallinity of the *TIPSAntBeT* probably arose from a π-overlap area that was larger than that of *TIPSAntT*, as expected from X-ray crystallography. *TIPSAntPT* films showed the most promising XRD results in both out-of-plane and in-plane mode XRD experiments. The *d* spacing of the (1 0 0) peak was 16.1 Å, implying that *TIPSAntPT* was aligned more perpendicularly to the substrate along the *TIPS* axis than was *TIPSAntBeT*, with a smaller tilt angle of 15°. When the molecules were aligned perpendicular to the substrate, the π-overlap between adjacent molecules was maximized, and carrier transport could occur more effectively. In-plane XRD of *TIPSAntPT* showed a (0 1 0) peak that indicated the interlayer *d* spacing of 3.49 Å. This value was very close to the interplanar distances (3.54 Å) determined by X-ray crystallography measurements, indicating highly effective π-orbital overlap due to the "bricklayer" structure.

4. Conclusions

We synthesized three new *TIPSAnt* derivatives and carried out comparative studies among these three molecules to investigate the relationship between the molecular structures and TFT performances. Only *TIPSAntPT* showed a "bricklayer" stacking structure that resulted in a high charge-carrier mobility of 0.063 cm^2/Vs in the film state and 0.12 cm^2/Vs in the single crystal state. This result agreed well with the AFM and XRD findings. Although the rigidity of the substituents and large area of π-overlap resulted in high crystallinity for the *TIPSAntBeT*, the lack of solubility and the needle-like crystalline films reduced the device performance. These results provide valuable insight into the design of new small molecules for solution-processable OTFTs.

also applied as etch resist to pattern silver [4–6], copper [7–10], and palladium [11]. The first implementation of microcontact printing in organic electronics was presented by Rogers and coworkers [12]. Microcontact printing allows for the realization of radio frequency identification tags and flexible displays [13]. The use of a standard gold etching solutions (e.g., potassium iodide/iodine solution, KI/I_2) is not possible, since the thiol SAMs cannot withstand the standard etching solution.

The major advantage of using printed thiol SAMs as etch resist is that the method can be applied to pattern microstructure over large areas. However, the method exhibits also some disadvantages. Only thin metal films can be patterned by the method since the etching solution exhibits a relatively poor selectivity between the thiol SAM and the metal film. Furthermore, the etching solution (ferri/ferrocyanide) is not compatible with standard chemicals used in semiconductor processing. Thus, an alternative and environmental friendly approach was developed, which allows for patterning of thicker coinage metals with a good selectivity while being environmental friendly and compatible with etching solution commonly used in semiconductor processing. The developed approach is based on using thiol self-assembled monolayers as a selective dewetting agent rather than an etch resist. A basic introduction to microcontact printing of self-assembled monolayers is given in Section 2. The use of thiol based self-assembled monolayer was dewetting agents is described in Section 3. The process was used to pattern gold electrodes of organic thin-film transistors. The device fabrication and characterization is discussed in Section 4, before summarizing the work in Section 5.

2. Microcontact printing of thiol self-assembled monolayers

A solution of an eicosanethiol (ECT, $CH_3(CH_2)_{19}SH$) SAM was used as "ink" for the surface engineering of the gold films. Thiol molecules like ECT consist of a radical or alkyl group, which is terminated with a thiol (–SH) group. The head group of the thiol molecules forms a bond with the cleaned gold surface, i.e., S–Au bond. Prior to deposition of the gold films, the substrates were cleaned by isopropanol. The gold films were prepared on oxidized silicon wafers, flexible polyethelene terephthalate (PET) foils and glass substrates. The gold films were deposited by electron beam evaporation. To improve the adhesion of the gold films on the substrates a 3 nm titanium layer was deposited prior the evaporation of the gold films. The regions covered by the ECT SAMs are hydrophobic, whereas the unexposed regions stay hydrophilic. The surface wetting behaviours of the two regions were characterized by water contact angle measurements. Complete wetting is observed in the hydrophilic areas, whereas the hydrophobic regions exhibit contact angles in the range of 110–114°. Such patterned SAMs cause a physicochemical modification of the gold surface, and allows the surface properties of the material to be controlled independently from the bulk properties. The presence of the long radical chains allows the SAM to be used as a surface wetting agent.

3. Thiol self-assembled monolayers as dewetting agents

The use of a ferri/ferrocyanide as an etching solution does not comply with standard chemicals used in semiconductor processing. To avoid using such a hazardous etching solution a new and environmental friendly patterning method was developed. The route to pattern is shown in Fig. 1.

In this case the thiol self-assembled monolayer is used as a selective wetting agent rather than an etch resist or etch mask. In the first step the thiol SAM is microcontact printed on a cleaned gold surface. An elastomeric stamp is used to print alkyl thiol SAMs over gold or silver films on flexible and rigid substrates. The stamps were prepared by casting an elastomeric material, polydimethylsiloxane (PDMS), against a relief structure (master). Afterwards the elastomer was cured at 70 °C for 2 h and removed from the master. Prior to microcontact printing the gold surfaces were cleaned by using a NH_4OH solution and UV/ozone treatment, respectively. An ~2 mM solution of eicosanethiol, ECT ($CH_3(CH_2)_{19}SH$) in acetone was used as "ink" for the printing process. Before printing the self-assembled molecules on the metal surfaces, the alkyl thiol molecules were spin coated on the PDMS stamp at 1000 rpm for 1 min. During the printing process, the stamp was brought in conformal contact with the substrate, so that the self-assembled molecules are transferred from the stamp to the substrate in the regions of contact. The printing of the SAMs was carried under ambient conditions in a clean room. The surface properties of the metal films were characterized by water contact angle measurements.

The area covered with the thiol SAMs turns hydrophobic, whereas the uncovered areas stay hydrophilic. Such patterned surface modification allows for selective wetting of polymers or resists over the prepatterned surfaces [14]. The polymer wets the hydrophilic regions of the substrates, whereas the hydrophobic regions remain uncoated. In the study, poly-methyl methacrylate (PMMA) was used to selectively wet the gold surface. The polymers were either dip or spin coated. The polymers form a film in the hydrophilic region of the substrate, whereas the hydrophobic regions stay uncoated. Subsequently, the dried patterned polymers were used as etch mask to pattern the gold film by potassium iodide/iodine (KI/I_2) etching solution (3:10 of KI/I_2:H_2O etching solution). The KI/I_2 solution etches away the gold film together with the SAMs. The SAM does not have to be removed by a UV ozone treatment or oxygen plasma. The titanium film was removed by a sulphuric acid solution, after patterning the gold film.

The electrodes were patterned on oxidized silicon wafers and glass. Structures down to 500 nm were patterned by this approach. The resolution was limited by the dimensions of the elastomeric stamp used for the microcontact printing process, which was patterned by optical lithography. The use of electron beam lithography should allow for patterning of stamps with smaller features. A titanium layer was used as adhesion layer for the gold film. The titanium film was used to improve the adhesion of the gold film on the glass substrates and the silicon wafers. Since the KI/I_2 solution does not attack the resist pattern the pat-

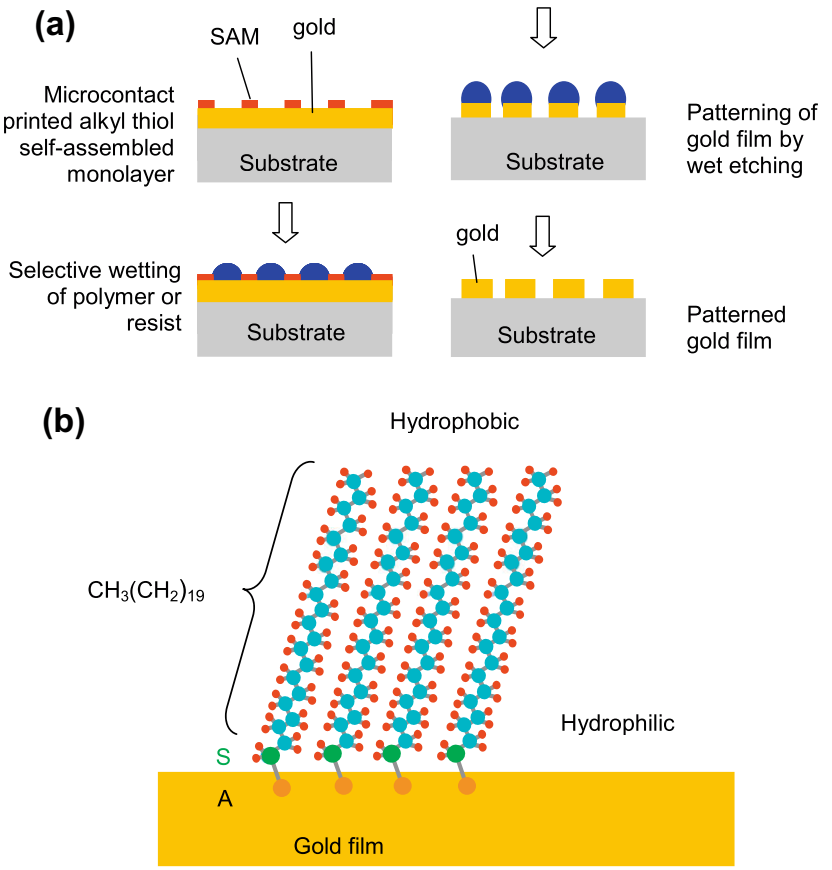

Fig. 1. Patterning of gold by microcontact printing of thiol based SAMs. The thiol based SAMs acts as selective surface wetting agent for a polymer or resist. The gold or silver films were patterned by a potassium iodide/iodine (KI/I_2) etching solution.

terning process is not limited to thin metal films. The same patterning experiments were repeated for silver electrodes which are typically used as electrodes in thin-film solar cells [15,16]. The results of the experiments were comparable to the results on gold surfaces.

The same patterning procedure was also applied to pattern gold structures on flexible plastic foils. Patterned gold structures on a 2 cm × 2 cm large polyethylene terephthalate (PET) plastic foil are shown in Fig. 2.

Therefore, the method allows for combining the advantages of a low cost printing process with the advantages of conventional semiconductor processing. In the following section the approach was used to fabricate drain and source electrodes of organic thin-film transistors (OTFTs). The cross section of the thin-film transistor is shown in Fig. 3b. Atomic force microscope images of pentacene films prepared on gold electrodes are shown in Fig. 4. The electrodes prepared by contact printing (b) and optical lithography (a). The pentacene crystals are large in the channel region (brown region) and distinctly smaller on top of the gold electrodes (yellow region). The edges of the electrodes are clearly visible in the AFM images. A comparison of the resolution between the electrodes patterned by optical lithography (a) and microcontact printing (b) shows that the resolution of the microcontact printing process is comparable to optical lithography.

4. Organic transistors with printed drain and source electrodes

The cross section of an organic thin-film transistor is shown in Fig. 3b. The OTFTs were fabricated on highly doped silicon wafers. Transistors with channel lengths down to 2 μm were realized by the patterning approach. The insulator of the transistors consists of 100 nm silicon oxide. Before depositing the organic semiconductor, pentacene, the silicon oxide gate dielectric and the gold electrodes were treated by hexadimethylsilazane (HMDS). The organic semiconductor layer, pentacene (Fig. 3a), was deposited by organic molecular beam deposition (OMBD) [17]. The organic film has a deposited at a deposition rate of 0.5 Å/s resulting in thickness of 30 nm and the film. The source material was two times sublimation purified before depositing the molecules at a base pressure of 5×10^{-6} Pa. The films were prepared at a constant substrate temperature of 70 °C. The source temperature was kept constant at 275 °C while depositing the pentacene films. The pentacene films consist of pentacene crystals with an average diameter of 1 μm. The diameter of the crystals is typical for pentacene films prepared on a HMDS treated silicon oxide film [17].

The transfer characteristic of a pentacene transistor is shown in Fig. 5. The length and width of the transistor

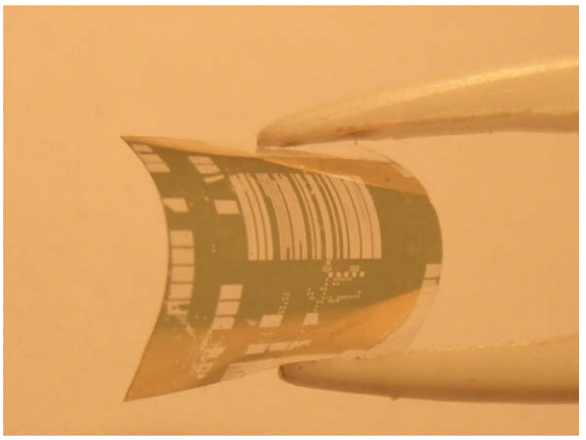

Fig. 2. Patterned gold test structures on a 2 cm × 2 cm large polyethelene terephthalate (PET) plastic foil. The structures were patterned by a combination of microcontact printing of an eicosanethiol SAMs, selective surface wetting/dewetting and wet chemical (KI/I_2 solution) etching. The dark regions represent the patterned gold region, whereas the bright regions exhibit the plastic foil.

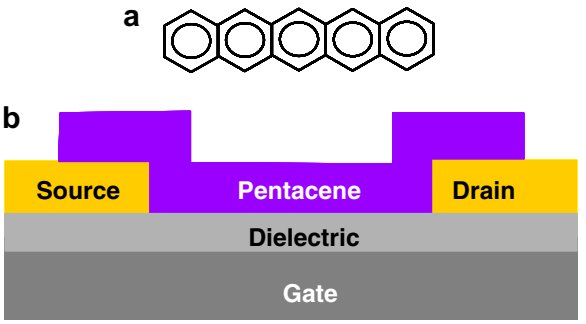

Fig. 3. Molecular structure of pentacene (a) and schematic cross section of a pentacene thin-film transistor (b). The source and drain electrodes were patterned by microcontact printing of an eicosanethiol SAMs, selective surface wetting/dewetting and wet chemical (KI/I_2 solution) etching.

channel were 60 μm and 4000 μm. The transistor exhibits a carrier mobility of 0.3 $cm^2/V\,s$ and threshold voltage of −1.0 V. The on/off ratio is $\sim 10^6$ at a gate voltage of −10 V and the subthreshold slope is 0.3 V/decade.

For transistors with shorter channel length the charge charier mobility drops down to 0.05 $cm^2/V\,s$. The drop of the charge carrier mobility is caused by the influence of contact effects that limit the charge carrier mobility for short channel behaviour [17–19]. Such behaviour is common for short channel organic thin-film transistors. The drain current of a thin-film transistor in the linear region is described by

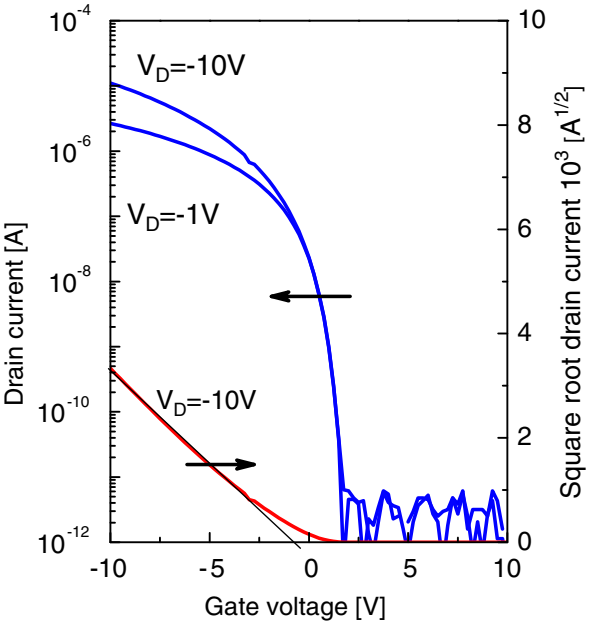

Fig. 5. Transfer characteristics of a pentacene TFT with drain and source contacts fabricated by a combination of microcontact printing of an eicosanethiol SAMs, selective surface wetting/dewetting and wet chemical (KI/I_2 solution) etching. The length and width of the transistor channel were 60 μm and 4000 μm.

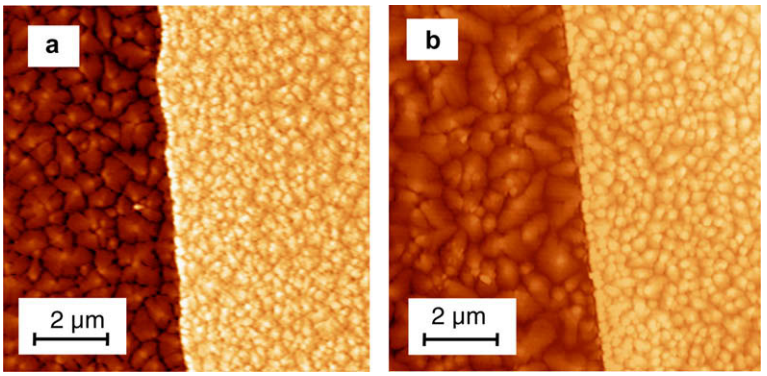

Fig. 4. Atomic force microscope (AFM) image of pentacene films prepared on a silicon dioxide dielectric treated with a hexamethyldisilazane (HMDS) self-assembled monolayer (SAM) and a gold drain/source electrode (yellow region). The drain/source electrodes were patterned by optical lithography (a) and microcontact printing (b). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Measured transistor parameters and device parameters determined by using a transistor model that includes the contact resistance. The parameters are listed for transistors with printed drain and source electrodes (bottom) and transistors with electrodes patterned by optical lithography (top). The device parameters listed on the left (right) side were determined for device operation in the linear (saturation) region.

		Extracted device parameters		
		Charge carrier mobility ($cm^2/V\,s$)	Threshold voltage (V)	Contact resistance ($k\Omega\,cm$)
Transistor with electrodes patterned by optical lithography	Measurement	0.4/0.42	−1.2/−1.0	–
	Transistor model incl. contacts	0.41/0.42	−2.4/−1.1	0.93/1.3
Transistor with electrodes patterned by microcontact printing	Measurement	0.33/0.30	−2.5/−1.0	–
	Transistor model incl. contacts	0.35/0.32	−3.0/−1.5	2.0 / 3.2

$$I_D = \frac{W}{L} C_G \cdot \mu_{dev} \cdot V_D \cdot \left(V_G - V_T - \frac{V_D}{2} \right) \quad (1)$$

where W and L are the width and the length of the channel. C_G is the gate capacitance per unit area, and V_G, V_D and V_T are the gate, drain and threshold voltages, respectively. μ_{dev} is the device charge carrier mobility. The transistor operates in the linear region if $V_D < V_G - V_T$.

In order to account for the influence of the contacts on the drain current the drain voltage V_D and gate voltage V_G, in Eq. (1) are replaced by $V_D - I_D(R_D + R_S)$, and $V_G - I_D R_S$, where R_D and R_S are the drain and source contact resistances, which are expected to be equal. The term "$V_D - I_D(R_D + R_S)$" represents the actual voltage drop across the channel of the transistor. Thus, the drain current can be described by

$$I_D = \frac{W}{L} C_G \mu_0 \frac{L}{L + C_G \mu_0 r_C \left(V_G - V_T - \frac{V_D}{2} \right)} V_D \cdot \left(V_G - V_T - \frac{V_D}{2} \right) \quad (2)$$

where μ_0 is defined to be the intrinsic charge carrier mobility of the transistor and r_C the normalized contact resistance, $r_C = W(R_D + R_S)$. In the following the modified transistor model was used to determine the intrinsic charge carrier mobility, the threshold voltage and the normalized contact resistance of the pentacene thin-film transistor patterned by microcontact printing and optical lithography. The extracted device parameters are listed in Table 1. The parameters were determined for the linear region of operation (listed on the left side) and the saturation region (listed on the right side). The performance of the transistors with printed drain and source contacts is comparable to values published in literature [17–19].

5. Summary

A universal patterning approach was proposed that combines the advantages of a low cost printing process with the advantages of conventional semiconductor processing. The approach combines microcontact printing of thiol SAMS with selective surface dewetting/wetting. The printed regions turn hydrophobic, while the unprinted regions stay hydrophilic. The hydrophilic/hydrophobic patterns were used to selectively deposit polymers or resists on the substrates. Subsequently, the patterned polymer is used as etch resist and the bare regions of the gold films were patterned or etched by a KI/I_2 etching solution. The patterning method is environmental friendly as compared to commonly used microcontact printing approaches that apply ferri/ferrocyanide etchants. Furthermore, the method also allows for patterning of thick metal films, which is not possible by using thiol SAMs as etch resist. The method allows for patterning of electrodes over large area and flexible substrates. Organic thin-film transistor with electrodes fabricated by the method showed a performance comparable to transistors fabricated with conventional lithography. Similarly, the method can also be applied for patterning of electrodes of other organic or inorganic electronic devices on rigid or flexible substrates.

In case (2), polymer gate insulators generally give a clockwise hysteresis from a more complex origin. By introducing a cooperative hydrophilic/hydrophobic dielectric bilayer structure, it was pointed out that hysteresis with polymer gate insulator was bulk related rather than interface related, which was quite different from SiO_2 dielectric [15]. The positive shift of the threshold voltage in clockwise hysteresis loop is probably due to the negatively trapped charges inside the gate dielectric, which were injected from the gate electrode [16]. The bulk trapped electrons induce extra holes in the channel and result in larger drain current during the bias sweep loop, contributing to clockwise hysteresis [7]. To provide solid evidence for gate electron injection mechanism, various thickness SiO_2 buffer layer was added in between polymer insulator and gate electrode, which was effective to block electrons [9]. As the SiO_2 thickness increased, the clockwise hysteresis decreased, disappeared, and finally changed to anti-clockwise direction. This concluded the co-existence of bulk and interface effects. The bulk effect dominated first when SiO_2 thickness was not enough to block electron injection from the gate. As the SiO_2 layer was grown to a certain thickness, bulk and interface effects offset each other, showing non-visible hysteresis. When the thickness was enough to block all the electron injection from the gate, the interface effect dominated and anti-clockwise hysteresis appeared.

Case (3) is caused by the slow polarization in the bulk of the organic dielectric. Polar groups inside the dielectric can reorient and make the drain current lap the bias sweep, resulting in a clockwise hysteresis [6,8,10,17]. Under a negative gate bias, migration of impurity ions in the polymer can make a similar effect [18].

Polar group is believed to be responsible for the hysteresis behavior [7,8]. Many research groups tried to reduce the concentration of polar groups in polymer films by using thermal and photo curing process [19,20]. Various cross-linking reactions have been proposed and some of them are proved to be efficient to diminish hysteresis loop [7,8,19].

Low-operating voltage OFET is another concern during recent years. Reduction in the operating voltage of organic transistors is important for successful implementation in low-power electronics [21,22]. To achieve low-voltage operation, one method is to increase the dielectric constant of the gate insulator. A great deal of attention has been focused on high-*k* inorganic/smooth organic bilayer structures in recent years [23,24]. A second way to achieve low-voltage operation is to make ultrathin dielectric, like self-assembled monolayer [21,25] and multilayer [26]. It was also demonstrated that ion-gel could be used as a gate insulating material for OFETs [27]. A single organic layer dielectric through a solution process at a comparably low temperature such as spin coating or printing is desirable to reduce the processing cost [28]. Only a dielectric with very low leakage and high dielectric strength can be used for ultra thin dielectric for low-voltage operation.

In this report, we used cross-linkable polyacrylate copolymer (PA) as a gate insulator. Various curing temperatures on dielectrics were investigated and hysteresis free metal–insulator–semiconductor (MIS) capacitors and OFETs were tested. By downscaling the thickness of the dielectric, an OFET was tested for low-voltage operation.

2. Experimental

The cross-linkable solution was made with a co-solvent of methyl-3-methoxy propionate (MMP, 30%) and methyl ethyl diglycol (MEDG, 60%) and 10 wt% PA (MW ~ 9000, sample name: PB-174-binder, supplied by LG Chem. Co. Ltd.). The molecular structures and related molar ratio of each repetitive units of the random copolymer PB-174-binder were displayed in Fig. 1a. The film was spin-coated with the solution onto piranha cleaned p-type (for MIS capacitors) and n-type heavily doped (for metal–insulator–metal structures and OFETs) silicon wafers at 3000 rpm for 1 min inside the high purity Ar-filled glove box. And then the film was baked in an annealing furnace for 30 min at various temperatures of 170, 200, and 230 °C to study the temperature effects on the film properties and device performance. The unbaked and baked films were correspondingly referred to as PA, PA170, PA200, and PA230. It was expected that cross-linking reaction as shown in Fig. 1b occurred during the bake. Pentacene, which was purchased from Aldrich Chemical Co., was deposited onto the gate dielectric using an organic molec-

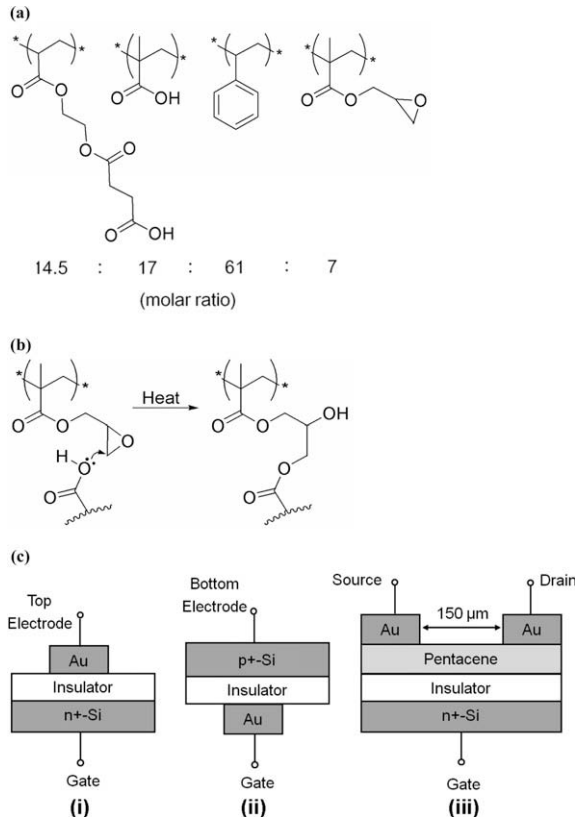

Fig. 1. (a) Repetitive units in PA copolymers and the corresponding molar ratios, (b) mechanism of cross-linking reaction between functional groups and (c) schematic of the device geometries of (i) Au/PA/n+-Si MIM structure, (ii) Au/PA/p−Si MIS capacitor and (iii) top-contact/bottom-gate OFET.

ular beam deposition system at a rate of 0.2–0.3 Å/s and at a substrate temperature of 50 °C. The thickness of the pentacene layer was 60 nm for OFETs and for morphology study with AFM. For metal–insulator–metal (MIM) structures and MIS capacitors, Au top electrode was deposited with evaporation through a shadow mask to make a circular dot area of 8.02×10^{-4} cm^2. For OFETs, Au electrodes were deposited in an evaporator and patterned by a shadow mask with a channel width of 1500 μm and a channel length of 150 μm. The device geometries of Au/insulator/n+Si (MIM structure), Au/insulator/p−Si (p−Si MIS capacitor), and top-contact pentacene OFETs are shown in Fig. 1c.

Fourier Transform Infrared (FT-IR) (Nicolet 700) spectra of the solid films were recorded in a transmission mode. Contact angle measurements were conducted using a contact angle goniometer (Model DSA-10, Krüss Co. Ltd.). Thickness was measured using a Woolham Co. VASE32 ellipsometer. Capacitance–voltage (*C–V*) characteristics of the MIS capacitors were measured to study the hysteresis behavior, using HP 4284A Precision LCR meter (Agilent Tech.) at 1 MHz. To study the roughness of the dielectric surface as well as pentacene morphology, atomic force microscopy (AFM), Dimension™ 3100 microscope (Digital Instruments) was used. The in-plane X-ray diffraction (XRD) was carried out at the 3C2 X-ray scattering beam line of the Pohang Light Sources (PLS), Pohang Accelerator Laboratory (PAL). The electrical performance of MIM structures and OFETs were characterized with a HP5270A (Agilent Tech.).

3. Results and discussion

3.1. Properties of PA and pentacene films

FT-IR absorption spectra were recorded to monitor the progress of the cross-linking reaction. In Fig. 2a, the bands centered at 3530 and 2940 cm^{-1} were attributed to OH and CH_x groups, respectively, and the broad peak between 3500 and 3000 cm^{-1} was from COOH groups. The reduction in COOH broad absorption peak and the emerging of OH peaks suggested a successful cross-linking reaction with the mechanism demonstrated in Fig. 1b. The reduction of CH_x peak intensity in baked films showed the removal of the residue solvent from the film. In Fig. 2b, bands at low wave numbers were assigned to C–O vibration peaks from COOR (1162 cm^{-1}), secondary C–OH (s-COH, 1112 cm^{-1}) and primary C–OH (p-COH, 1030 cm^{-1}). The increase of p-COH and s-COH intensity at elevated temperatures suggested more intense reaction. p-OH and s-OH are major and minor products of the reaction as demonstrated in Fig. 1b. Due to the bulk hindrance effect, the acid groups tended to attack the less substituted side of epoxide in the nucleophilic substitution reaction, and thus s-COH product was preferred to p-COH groups. The COOR peak (C–O–C) intensity reduction from PA (untreated) to cured dielectrics indicated removal of the solvent.

Surface energy of the dielectric surface, which was reported to affect the pentacene crystallinity and mobility of OFETs [29], was determined from the contact angle measurements using distilled water and diiodomethane as a probe liquid. As shown in Fig. 3, the contact angles with polar probe liquid of water were 81.6°, 76.8°, 77.0° and 78.1° on PA, PA170, PA200 and PA230 films. The high contact angle on PA might be from the residual solvent which is less polar. With the residual solvent, aging effect might also drive the polar functional group into the dielectric bulk under the force of surface energy reduction [30]. Contact angles with non-polar probe liquid of diiodomethane showed a more obvious trend, with the values of 32.0°, 35.0°, 36.1° and 36.5° on PA, PA170, PA200 and PA230 films. Surface energy values were then calculated from the contact angles of the two probe liquids, as displayed in Table 2. Among the dielectric films, the lowest surface energy of the PA230 film was possibly because the reaction removed more COOH group as confirmed with FT-IR. The surface roughness was very small as shown in Fig. 4 and its contribution to the contact angle may be negligible.

AFM images of the insulator surface were captured to understand if the insulator surface has a significant influence on the growth mode of pentacene. Smooth dielectric films were obtained in all cases with root-mean-square (RMS) roughness of dielectrics all less than 0.5 nm (see Fig. 4a–d), which was negligible to affect the pentacene deposition mode [19]. Fig. 4e–h show AFM images of

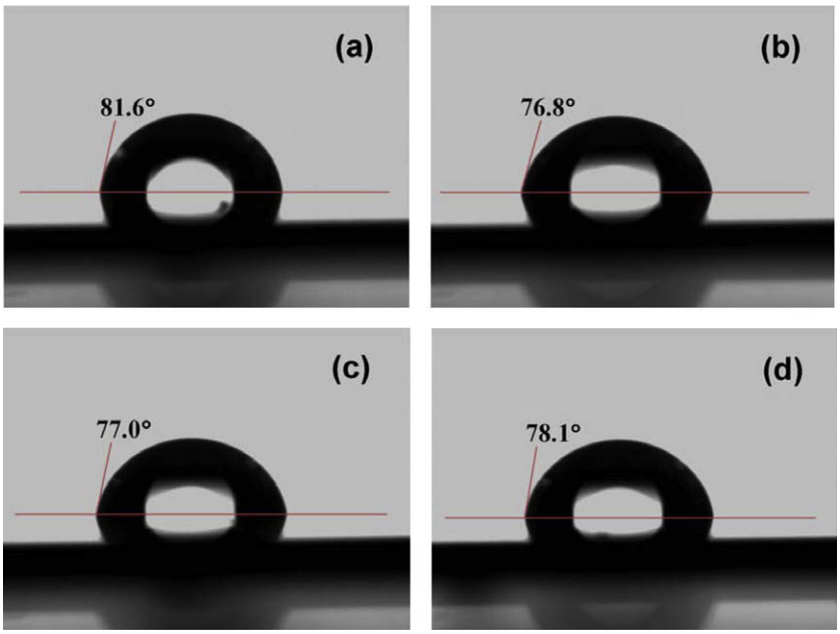

Fig. 3. Images of water drops on (a) PA, (b) PA170, (c) PA200 and (d) PA230.

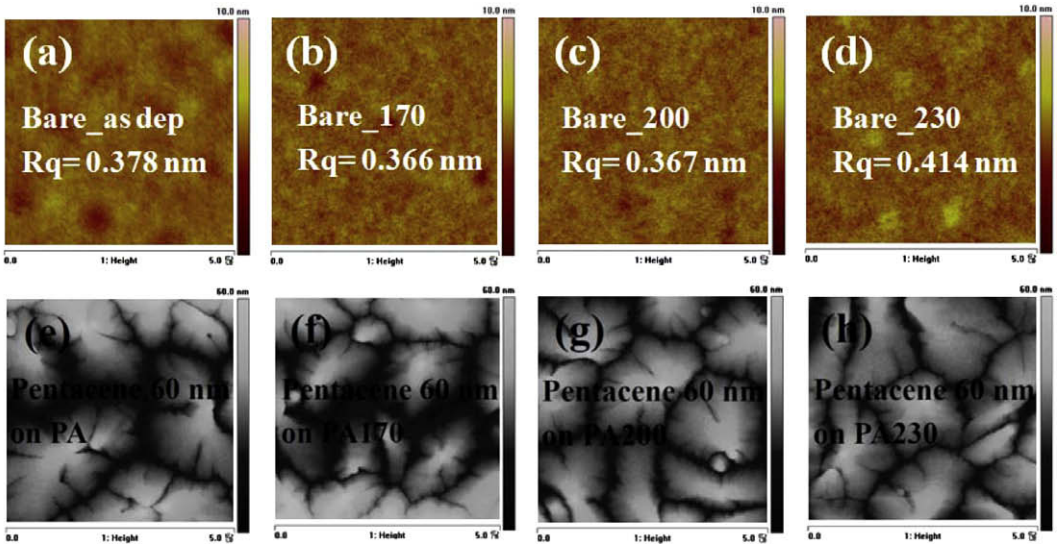

Fig. 4. AFM images (5×5 μm^2) of dielectric surfaces of (a) PA, (b) PA170, (c) PA200 and (d) PA230, and 60 nm pentacene films grown on (e) PA, (f) PA170, (g) PA200 and (h) PA230.

60 nm pentacene films, which were deposited on PA, PA170, PA200 and PA230, respectively. The pentacene grains are compactly stacked on PA200 and PA230, while wide and deep gaps emerged between grain boundaries in PA and PA170, as shown in the dark areas in Fig. 4e–h. The grain boundaries are thought to be interfacial trap sites which can disrupt the charge transport in the organic semiconductors [31]. The RMS roughness of the pentacene films, which was from the difference in peak-to-valley depth, showed values of 11.8, 10.3, 8.71 and 7.16 nm for PA, PA170, PA200 and PA230, indicating that a flatter topology could be obtained with PA cured at a relatively higher temperature.

Fig. 5 shows the XRD patterns of 60 nm pentacene films deposited on top of various polymer gate dielectrics at a moderate deposition temperature of 50 °C. In the spectra, first pentacene peak (0 0 1) at $2\theta = 5.74°$ represents thin film phase, while triclinic bulk phase peak is not visible in our spectra. This diffraction angle corresponds to the vertical periodicity of the 15.4 Å layer-by-layer spacing [32], indicating that the molecules were standing nearly perpendicular to the substrate and formed perfectly

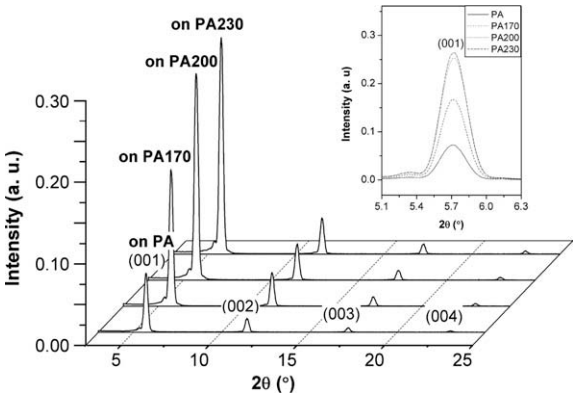

Fig. 5. XRD patterns of 60 nm pentacene films deposited on the gate dielectric of PA, PA170, PA200 and PA230 (bottom), and an overlap of (0 0 1) peaks (up).

packed structure. Because of the anisotropy in the electrical transport in pentacene domains, it is important to know how the crystalline regions are oriented relative to the substrate. To more accurately compare the crystallinity of the pentacene layer, the full width at half maximum (FWHM) values as well as the peak intensity was obtained. The peaks showed a quite similar FWHM value of ~0.26°, but quite different peak intensities. The (0 0 1) peak intensity of PA, PA170, PA200 and PA230 was inserted in Fig. 5. Since the FWHM was nearly the same for all samples, intensity of XRD peaks represented the crystallinity. It was reported that higher μ is closely related to the (0 0 1) plain crystallinity [33], while the best crystallinity was observed in the pentacene thin film on PA230.

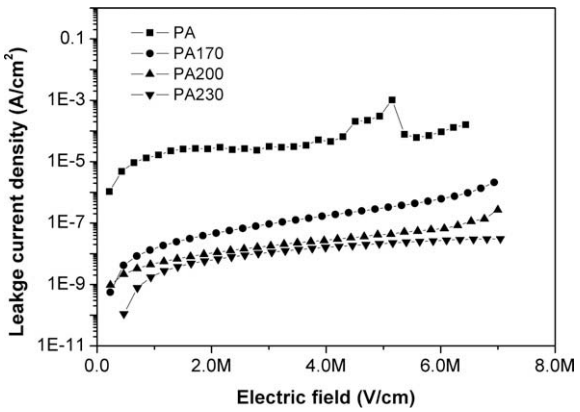

Fig. 6. Current density–electric field (J–E) characteristics of Au/PA/n+Si MIM structures.

3.2. I–V characteristics of MIM structures

An important concern with the gate dielectric material is the dielectric strength and the gate leakage. Fig. 6 displays the leakage current density through the dielectric layer as a function of the applied electric field. Under the low electric field, there are free ions that can be accelerated by the field and induce a current, which will be saturated after a certain voltage and give a constant current, as shown in the linear region of the curves. An increase in the leakage current in a higher electric field is caused by ion avalanche, which is generally explained by the Townsend discharge mechanism. Except PA, breakdown was not observed below ~7 MV/cm, and the PA230 showed the lowest leakage $\sim 5 \times 10^{-9}$ A/cm^2 at the electric field of 1 MV/cm. Table 1 compares the leakage current density values of existing cross-linked polymeric, hybrid, and inorganic dielectrics [4,20,22,34–41]. Pure polymeric gate insulators always give high leakage current density and low dielectric strength, and thereafter not listed in the table. PA230 showed desirable dielectric strength and low leakage, superior to most organic dielectrics and comparable to inorganic dielectrics such as Al_2O_3 ($E_{BD} \sim 7.9$ MV/cm). Note that ~7 MV/cm is the upper limit of our equipment, and no dielectric breakdown was observed under this electric field. The high dielectric strength may attribute to the linear chain structure and the soft side groups of PA polymer, which may contribute to a dense film with less air in the free volume, and reduce the possibility to dielectric breakdown. Curing is also an essential process for the use of polymers as gate dielectrics if a high breakdown field and a low gate leakage current are to be achieved [20]. The process further reduces the free volume

Table 1

[a] k is dielectric constant under 1 MHz if not specially indicated.
[b] E_{BD} is the abbreviation of break down electric field of a gate insulator or dielectric strength.
[c] J represents the leakage current density value at 1 MV/cm.
[d] SC is the abbreviation of spin coating.
[e] TG is the abbreviation of thermal growth.

in which ionized molecules can migrate. Organic polymers are especially prone to this partial discharge breakdown mechanism, because high temperature in the discharges readily causes degradation to carbon and gaseous products, and the process is often accelerated by the reaction of ozone and other active species formed in the gaseous discharges. Since the dielectric strength of PA polymer is very high and there was not a breakdown in the electrode, possibilities of thermal breakdown and electromechanical breakdown were excluded.

3.3. C–V characteristics of MIS capacitors

Typical *C–V* scans from depletion (positive gate bias) to accumulation region (negative gate bias) were carried out using Au/PA/p−Si MIS capacitors with various dielectrics, and the gate bias was swept back to check the amount of hysteresis originating from the bulk or interface charge trapping, as shown in Fig. 7. The negative shift of the depletion region could be explained by the positive fixed charge on the insulator/semiconductor interface as demonstrated by the following equation

$$V_{FB} = \phi_{MS} - \frac{Q_{SS}}{C_i}, \quad (1)$$

where ϕ_{MS} is the metal–semiconductor work function difference and Q_{SS} is the equivalent fixed oxide charges [42]. The defects and dangling bonds on p−Si wafer surface could induce positive fixed charge, which is responsible for the negative shift of the flat band voltage as indicated in Eq. (1). Since the fixed charge does not change with the gate voltage sweep, it just horizontally shifts *C–V* curve without changing its shape, and thus has little effect on the hysteresis behavior.

For a negative bias on the gate, two phenomena can happen (1) hole from the semiconductor can be injected into the oxide giving rise to a negative flat band voltage shift ($-\Delta V_{FB}$) and (2) electrons from the gate electrode can be injected into the oxide, giving rise to a positive shift (ΔV_{FB}) [43]. The clockwise hysteresis ($+\Delta V_{FB}$) is thus correlated with the electron injection from the gate. Electron

injection from the gate and trapping in the dielectric is responsible for the hysteresis behavior under negative gate bias as was observed in many other polymeric gate dielectrics. Hysteresis characterized by flat band voltage shift (ΔV_{FB}) was calculated to be 30.4, 12.8, 6.5 and 1.7 V for PA, PA170, PA200 and PA230 capacitors, respectively. The difference in the flat band voltage is due to the trapped charges in the gate capacitor with a capacitance/area equal to C_i [42].

$$\Delta V_{FB} = -\frac{\Delta Q_{SS}}{C_i}. \tag{2}$$

If the trapping sites are evenly distributed in the dielectric film, the amount of hysteresis caused by electron trapping can be expressed as

$$\Delta V_{FB} = -\int_0^{t_i} \frac{\rho}{\varepsilon_0 \varepsilon} x \mathrm{d}x, \tag{3}$$

where ρ is the electron trap density across the dielectric layer, ε_0 is permittivity in vacuum, and ε is permittivity of the dielectric [44]. If the OH or residue carboxylic acid groups act as a electron trap, positive voltage shift during the *C*–*V* scan should be linearly decreased with the decrease in the density of the charge traps, and it matches well with the maximum amount of charge trapping, as evaluated in the later part with inverse subthreshold slope (*SS*). Linear relationship has been found between OH contents and hysteresis gap in the *C*–*V* curve [44]. Cross-linking reaction proved to be an efficient tool for hysteresis removal [19]. Compared with the calculated trapping density in the latter part, electron injection and trapping could be a major factor for hysteresis, while evidence for dipole reorientation and mobile ions were less obvious.

The maximum capacitance (C_{max}) values were 20.1, 16.2, 15.2 and 14.5 pF for PA, PA170, PA200 and PA230 capacitors and the *k* values were calculated to be 4.39, 3.27, 3.05 and 2.88 for each sample from

$$C_{max} = \varepsilon_0 A \frac{k}{t}. \tag{4}$$

Here, *k* is the dielectric constant, *t* is the thickness of the dielectric film and *A* is the capacitance area, and ε_0 is the permittivity in vacuum. Smaller amount of polar groups, such as COOH, made *k* and C_{max} smaller [45]. After annealing, capacitance can increase due to the decrease in the film thickness from 155.3 nm (PA) to 142.0 nm (PA230) but this effect was small.

3.4. Organic field-effect transistors

Top-contact pentacene OFETs were fabricated utilizing PA, PA170, PA200 and PA230 as a gate dielectric on n+-Si wafer. Their transfer and output characteristics are shown in Fig. 8 and Fig. 9, respectively. μ of the OFET was calculated in the saturation regime from a plot of the square root of the drain current versus V_G by fitting data to the equation [19],

$$I_{D,sat} = \frac{W}{2L} \mu C_i (V_G - V_{th})^2. \tag{5}$$

Here, $I_{D,Sat}$ is the drain current in the saturated regime, *W*/*L* is the channel width/length, V_G is the gate voltage, and V_{th} is the threshold voltage.

Table 2 displays the electrical data of OFETs with as deposited and cured PA dielectrics under an operating voltage of −20 V. PA230 device exhibited the best performance, with μ of ~0.60 $cm^2/V\,s$, $I_{on}/I_{off} \sim 10^5$, and a low SS of 1.22 V/dec. The relatively better μ might attribute to the effective curing of the film to reduce polar groups as monitored by FT-IR results. This enabled pentacene to

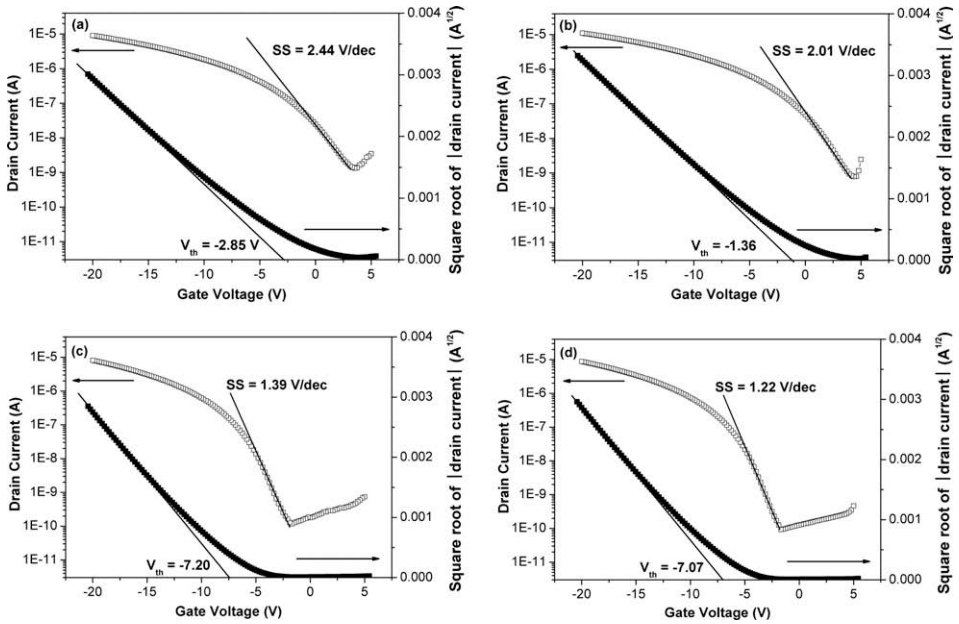

Fig. 8. Transfer characteristics of OFETs with different dielectrics (a) PA, (b) PA170 (c) PA200 and (d) PA230.

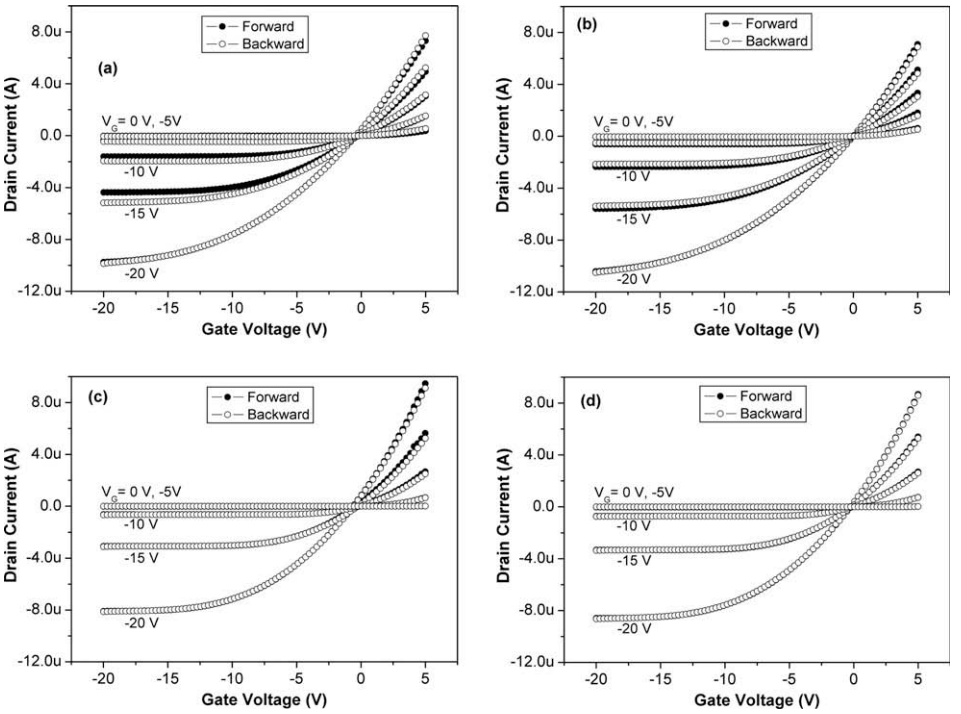

Fig. 9. Output characteristics of OFETs with (a) PA, (b) PA170 (c) PA200 and (d) PA230.

deposit under a layer-by-layer mode (as evidenced by XRD result) to form a dense film, in which the π–π conjugation made more effective hole transport. At the same time, the cross-linking reactions could provide the dielectric films with better insulating properties and devices with higher I_{on}/I_{off}. Optimized cross-linking condition also eliminated the charge traps inside and on the surface of the gate insulator, permitting the sharpest SS. The SS controls the voltage swing required for a transistor to turn from off to on, and it should be as low as possible [28]. High SS is a drawback of organic transistors, resulting from a combination of low gate-dielectric capacitance, low breakdown voltage, and high parasitic capacitances at the insulator/semiconductor interface.

The μ, I_{on}/I_{off} and SS were 0.56 $cm^2/V\,s$, 6×10^4, 1.39 V/dec for PA200 device, 0.37 $cm^2/V\,s$, 10^4, 2.01 V/dec for PA170 device, and 0.32 $cm^2/V\,s$, 5×10^3, 2.44 V/dec for PA transistor. As can be seen in Table 1, better cross-linked dielectric film could contribute to a better electrical performance, and significant improvement was observed for PA170 to PA200 OFETs. However, only slight enhancement in electrical property was observed from PA200 to PA230 devices, suggesting that the curing condition was optimized.

Fig. 9 shows that the saturation source–drain current is −8 to −10 μA under an operating voltage of −20 V. Although the PA and PA170 devices showed relatively higher output current of ∼−10 μA, the unreliable behavior of the hysteresis loop made the devices less attractive.

We estimated the density of the trapped charges in the device using

$$N_{trap}^{max} \approx \left[\frac{qS\log(e)}{kT} - 1\right]\frac{C_i}{q} \quad (6)$$

$$N_{trap} \approx \frac{C_i \Delta V_{th}}{q}, \quad (7)$$

where q is electronic charge, S is the (reciprocal) SS in V/dec, k is Boltzmann's constant and C_i is the capacitance/area of the gate dielectric. Eq. (6) estimates an upper limit of trapped charges [46]. In Eq. (7), the threshold voltage shift was due to the trapped charges in the gate capacitor [28].

The significant improvements in SS can be attributed to the decreased charge trap density at the pentacene/dielectric interface. Using Eq. (6), we estimate an upper limit of the trapped charge density to be $4.15 \times 10^{12}\,cm^{-2}$, $3.12 \times 10^{12}\,cm^{-2}$, and $2.23 \times 10^{12}\,cm^{-2}$ for PA, PA170, and PA200 devices, respectively. Using Eq. (7), we estimated the trapped charge density in PA, PA170, and PA200 to be $2.02 \times 10^{11}\,cm^{-2}$, $1.37 \times 10^{11}\,cm^{-2}$, and $2.8 \times 10^{10}\,cm^{-2}$, respectively. The consistency of ΔV_{FB}, trapped charge density and upper limit of charge trapping confirms the charge injection and trapping as the major origin of hysteresis. PA230 device showed least trapped charge density of $1.6 \times 10^{10}\,cm^{-2}$ (N_{trap}) and $1.96 \times 10^{12}\,cm^{-2}$ (N_{trap}^{max}), which shows that the trap states have been significantly reduced by cross-linking reaction at 230 °C. The hysteresis of the output curves was also diminished with annealing at an elevated temperature as shown in Fig. 9. There was a large difference between forward and backward output curves with PA, while the difference became negligible with PA230.Because of the high dielectric strength, the 230 °C baked thin PA film (∼89 nm) could

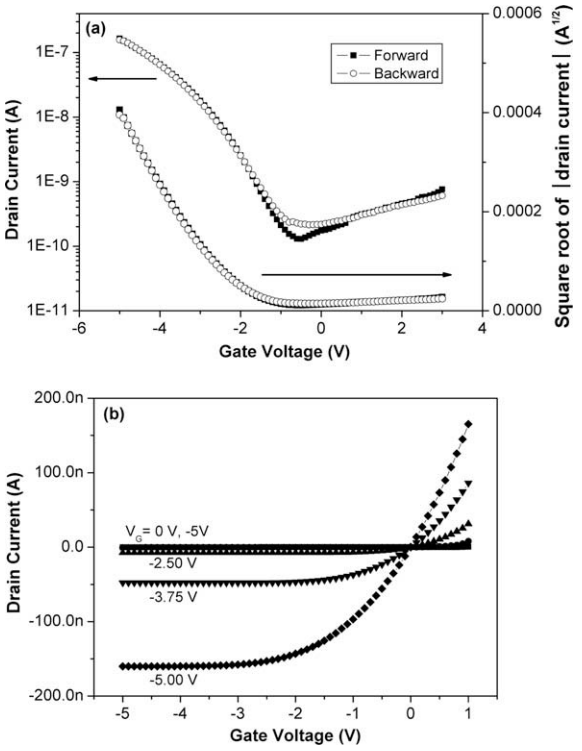

Fig. 10. (a) Transfer and (b) output characteristics of PA230–OFET operated at −5 V.

be used as a dielectric in OFET to improve C_i and to make low-voltage operation possible. Transfer and output characteristics are displayed in Fig. 10. Under −5 V operation, the device gave a drain current of −0.2 μA. The μ, I_{on}/I_{off} and SS were ~0.2 cm^2/V s, 10^3, 0.87 V/dec. Note that the W/L ratio is 10, and output current could be further improved by modifying W/L ratio.

4. Conclusions

We have reported newly fabricated hysteresis-free pentacene field-effect transistors with a polyacrylate copolymer gate insulator, and the effect of the cross-linking temperature was investigated. An elevated temperature of 230 °C enabled an effective cross-linking reaction in PA, and produced a high dielectric strength thin film and negligible hysteresis behavior was achieved in device operation. μ of 0.6 cm^2/V s, on/off current ratio of ~10^5, and inverse subthreshold slope as low as 1.22 V/dec were obtained with −20 V drain voltage. High dielectric strength made it possible to downscale the dielectric thickness, and a thin PA–OFETs could be operated at a low voltage of −5 V.

Acknowledgments

This research was supported by the Korea Science and Engineering Foundation (KOSEF) through the National Research Laboratory Project and Polymer Gel Cluster group of the Korean government. The author Wentao Xu is grateful to the Pohang Accelerator Laboratory for providing the synchrotron radiation source at the 3C2 beamlines used in this study, and Hyunjin Park, researcher at NCNT for supporting AFM analysis.

of donor unit and the bulkiness of side group of the acceptor unit. Although several research groups have synthesized TQ-based low-bandgap copolymers and reported the photovoltaic properties of those copolymers, the molecular weights of the copolymers were very low because of the lack of solubility, and therefore the power conversion efficiencies were below 0.7% [17,20–23].

Herein we report the synthesis and characterization of a new class of donor–acceptor alternating copolymers comprising 3-hexylthiophene (3HT) unit and TQ derivatives as electron-donating and electron-withdrawing unit, respectively. The optical and electrochemical properties of the copolymers and the performance of the copolymers/PCBM BHJ solar cells are reported.

2. Experimental

2.1. Materials

All reagents were obtained from Aldrich unless otherwise specified and used as received. Tetrahydrofuran (THF) was dried over sodium/benzophenone under nitrogen and freshly distilled before use. Hexane was dried over calcium hydride under nitrogen and freshly distilled before use. 5,6-Diamino-4,7-di(4-hexylthien-2-yl)-2,1,3-benzothiadiazole (**2**), 6,7-dimethyl-4,9-di(4-hexylthien-2-yl)[1,2,5]-thiadiazolo[3,4-*g*]quinoxaline (**3b**), and 6,7-dimethyl-4,9-di(5′-bromo-(4-hexylthien-2-yl))[1,2,5]-thiadiazolo[3,4-*g*]quinoxaline (**4b**) were synthesized by following the literature method [24]. [6,6]-Phenyl-C_{61}-butyric acid methyl ester (PCBM) was obtained from Nano-C. Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) (Baytron P VP AI 4083) was purchased from H.C. Stark and passed through a 0.45 μm PES syringe filter before spin-coating.

2.2. Synthesis

2.2.1. 2,5-Bistrimethylstannyl-3-hexylthiophene (*1*)

3-Hexylthiophene (5.0 g, 0.03 mol) and tetramethylethylenediamine (TMEDA) (13.5 ml, 3.0 equiv) were added into 150 ml of anhydrous hexane. After cooled to −78 °C with isopropanol/dry ice bath, *t*-BuLi (52.4 ml, 3.0 equiv) was added dropwise to the solution over 30 min. After the cooling bath was removed, the reaction mixture was stirred at room temperature for 48 h under nitrogen atmosphere. Then the reaction mixture was cooled back down to −78 °C, and the reaction solution was stirred overnight at room temperature after 92.0 ml of trimethyltinchloride solution (3.0 equiv) was added. The product mixture was washed with saturated solution of $NaHCO_3$, water, and brine, then dried over anhydrous $MgSO_4$ and filtered. After evaporation of the solvent under reduced pressure, the residue was further purified by flash chromatography on silica gel (99:1 hexane/triethylamine as eluent), yielding viscous light yellow liquid as a product. Yield: 12.44 g (85%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 7.21 (t, 1H), 2.56 (t, 2H), 1.60 (t, 2H), 1.52–1.41 (m, 6H), 0.86 (t, 3H), 0.43–0.30 (m, 18H). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 151.88, 143.79, 137.82, 137.61, 32.77, 32.19, 31.55, 29.48, 22.08, 13.73, −8.18. Anal. Calcd for $C_{16}H_{32}S_1Sn_2$ (%): C, 38.91; H, 6.48; S, 6.50. Found (%): C, 38.92; H, 6.47; S, 6.49.

2.2.2. 6,7-Diphenyl-4,9-di(4-hexylthien-2-yl)[1,2,5]-thiadiazolo[3,4-g]quinoxaline (*3a*)

To a suspension of 5,6-diamino-4,7-di(4-hexylthien-2-yl)-2,1,3-benzothiadiazole (0.815 g, 1.64 mmol) in 80 ml of acetic acid, 1,2-diphenyl-1,2-ethanedione (0.862 g, 4.1 mmol) was added in one portion. When the mixture was stirred at room temperature for 8 h, green-colored precipitate was obtained. The precipitate was filtered, washed thoroughly with methanol, and then dried in vacuum to afford green powder as product. Yield: 1.01 g (92%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 8.86 (d, 2H), 7.83 (d, 4H), 7.44 (m, 6H), 7.30 (d, 2H), 2.80 (t, 4H), 1.78 (m, 4H), 1.48–1.35 (m, 12H), 0.93 (t, 6H). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 153.11, 152.12, 143.23, 138.37, 135.80, 135.38, 135.04, 130.94, 130.79, 129.87, 128.27, 121.53, 32.01, 29.82, 29.37, 28.90, 22.91, 14.07. Anal. Calcd for $C_{40}H_{40}N_4S_3$ (%): C, 71.41; H, 5.95; N, 8.33; S, 14.31. Found (%): C, 71.14; H, 5.96; N, 8.30; S, 14.55.

2.2.3. 6,7-Diphenyl-4,9-di(5′-bromo-(4-hexylthien-2-yl))-[1,2,5]-thiadiazolo[3,4-g]quinoxaline (*4a*)

The compound **3a** (0.890 g, 1.32 mmol) was dissolved in 40 ml of THF, to which *N*-bromosuccinimide (NBS) (0.483 g, 2.71 mmol) was added in the dark. After stirring the mixture at room temperature for 3 h, the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel (1:3 chloroform/hexane as eluent) to yield the dark-green product. Yield: 0.804 g (74%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 8.79 (d, 2H), 7.70 (d, 4H), 7.45 (m, 6H), 2.80 (t, 4H), 1.78 (m, 4H), 1.50–1.35 (m, 12H), 0.93 (t, 6H). ^{13}C NMR (75 MHz, $CDCl_3$): δ (ppm) 153.02, 150.77, 141.79, 137.45, 135.22, 134.29, 134.03, 130.85, 129.44, 127.69, 119.78, 118.25, 31.87, 29.88, 29.59, 28.71, 22.66, 13.89. Anal. Calcd for $C_{40}H_{38}N_4S_3Br_2$ (%): C, 57.83; H, 4.58; N, 6.75; S, 11.59. Found (%): C, 57.98; H, 4.65; N, 6.52; S, 11.79.

2.2.4. Poly(3-hexylthiophene-alt-6,7-diphenyl-4,9-bis-(4-hexylthien-2yl)-[1,2,5]thiadiazolo[3,4-g]quinoxaline (P(3HT-PhTDQ))

Under nitrogen atmosphere, monomer **1** (102.0 mg, 0.206 mmol) and **4a** (171.3 mg, 0.206 mmol) were dissolved in 10 ml of anhydrous 1,2-dichlorobenzene. The solution was flushed with N_2 for 20 min, and then 7.2 mg of $Pd(PPh_3)_2Cl_2$ was added. After the reaction mixture was stirred at 130 °C for 48 h, the polymer was precipitated by addition of 70 ml of methanol. The crude product was filtered through a Soxhlet thimble, and then subjected to Soxhlet extraction with methanol, hexane, acetone, and chloroform. The polymer was recovered from the chloroform fraction by rotary evaporation as dark green solid. Yield: 107.7 mg (63%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 9.18–8.80 (m, 2H), 7.75 (s, 4H), 7.33 (d, 6H), 7.20–6.93 (m, 1H), 3.01–2.54 (m, 6H), 1.98–1.60 (m, 6H), 1.58–1.21 (m, 18H), 0.98–0.65 (m, 9H). Anal. Calcd for $C_{50}H_{52}N_4S_4$ (%): C, 71.75; H, 6.22; N, 6.70; S, 15.34. Found (%): C, 71.46; H, 6.22; N, 6.67; S, 15.41.

2.2.5. Poly(3-hexylthiophene-alt-6,7-dimethyl-4,9-bis-(4-hexylthien-2yl)-[1,2,5]thiadiazolo[3,4-g]quinoxaline (P(3HT-MeTDQ))

The polymerization process was the same as that of P(3HT-PhTDQ), except that the monomer **4b** was used instead of **4a**. Yield: 62.5 mg (55%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 9.10–8.71 (m, 2H), 7.36–7.02 (m, 1H), 3.04–2.49 (m, 12H), 1.98–1.66 (m, 6H), 1.58–1.33 (m, 18H), 1.02–0.68 (m, 9H). Anal. Calcd for $C_{40}H_{48}N_4S_4$ (%): C, 67.39; H, 6.74; N, 7.86; S, 18.01. Found (%): C, 67.35; H, 6.78; N, 7.75; S, 17.96.

2.3. Measurement

The chemical structures of materials used in this study were identified by ^{1}H NMR and ^{13}C NMR (Avance DPX-300). Elemental analysis was performed on EA1110 (CE Instrument) elemental analyzer. Molecular weight and its distribution were measured by gel permeation chromatography (PL-GPC 50 Integrated GPC System, Polymer Laboratories) equipped with a refractive index detector using THF as eluent, where the columns were calibrated against standard polystyrene samples. The optical absorption and photoluminescence spectra were obtained by UV–vis–NIR spectrophotometer (Lambda 850, Perkin-Elmer) and fluorescence spectrometer (814, Photon Technology International), respectively. Cyclic voltammetry experiments were carried out on potentiostat/galvanostat (Model 273 A, EG&G Princeton Applied Research) in an electrolyte solution of 0.1 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in dichloromethane. Three-electrode cell was used for all experiments. Platinum wires (Bioanalytical System Inc.) were used as both counter and working electrodes, and silver/silver ion (Ag in 0.1 M $AgNO_3$ solution, Bioanalytical System Inc.) was used as a reference electrode.

2.4. Fabrication of photovoltaic devices

Polymer solar cells were fabricated on ITO glass cleaned by stepwise sonication in acetone and IPA, followed by O_2 plasma treatment for 10 min. The substrate was spin-coated with PEDOT:PSS at 4500 rpm for 1 min and annealed at 120 °C for 30 min to yield 40 nm thick film. A mixture of polymer and PCBM were dissolved in anhydrous chlorobenzene (30 mg/ml), and spin-coated on the top of the ITO/PEDOT:PSS film at 800 rpm for 60 s. The typical thickness of the active layer was 70–80 nm. LiF (0.5 nm) and Al (100 nm) were evaporated under vacuum lower than 10^{-6} Torr on the top of active layer through a shadow mask. The effective area of one cell was ca. 4 mm^2. The current–voltage (J–V) curve of the device was obtained on a computer-controlled Keithley 4200 source measurement unit under AM 1.5G (100 mW/cm^2) simulated by an Oriel solar simulator (Oriel 91160A). The light intensity was calibrated using a NREL-certified photodiode prior to each measurement. The external quantum efficiency (EQE) was measured using a Polaronix K3100 IPCE measurement system (McScience) where the light intensity at each wavelength was calibrated with a standard single-crystal Si cell.

3. Results and discussion

3.1. Synthesis and characterization

We synthesized alternating copolymers for preparation of low-bandgap polymers. The synthetic routes for preparation of the monomers and polymers are shown in Fig. 1. We used the palladium-catalyzed Stille coupling reaction to synthesize alternating copolymers of 3HT and TQ derivatives which are electron-donating and electron-withdrawing unit, respectively. At first, 3HT was dilithiated with 3 equiv amount of t-BuLi and TMEDA, followed by reaction with trimethyltin chloride to yield 2,5-bistrimethylstannyl-3-hexylthiophene (**1**). In a separate experiment, the comonomer **4a** was synthesized by condensation reaction of diamino compound with 1,2-diphenyl-1,2-ethanedione, followed by bromination with NBS in THF. Stille coupling of **1** with **4a** or **4b** resulted in the corresponding polymers, P(3HT-PhTDQ) and P(3HT-MeTDQ), with moderate yield. The polymers are highly soluble in common organic solvents, such as chloroform, toluene, and THF at room temperature. The number-average molecular weight (M_n) and polydispersity index (PDI) of P(3HT-PhTDQ) are 7200 and 1.6, respectively, and those of P(3HT-MeTDQ) are 11,100 and 1.5, respectively.

3.2. Optical properties

The optical absorption spectra of the two polymers in chloroform solutions and films on glass substrate are shown in Fig. 2a and b, respectively. Both of two polymers have broad absorption from visible to infrared region. The lower energy absorption peaks of P(3HT-PhTDQ) and P(3HT-MeTDQ) in solution are 784 nm and 703 nm, respectively. As expected, the broad and longer wavelength absorption of the polymers is attributed to the intermolecular charge transfer induced by the donor–acceptor structure of the 3HT and TQ units. When the maximum absorption of polymers in solution is compared with that in solid state (Fig. 2a vs. b), it reveals that the maximum absorption wavelengths (λ_{max}) of the two polymers are red-shifted in solid state by 76 nm and 30 nm, respectively, indicating that polymer chains are associated in solid state. The optical bandgaps (E_g(opt)) as determined from the onset of the absorption spectra of P(3HT-PhTDQ) and P(3HT-MeTDQ) are 1.02 eV and 1.35 eV, respectively. Particularly, the bandgap of P(3HT-PhTDQ) is lower than that of P(3HT-MeTDQ) because the electron-withdrawing phenyl group in P(3HT-PhTDQ) makes the TQ unit more electron-deficient while the electron-donating methyl group in P(3HT-MeTDQ) weakens the electron-withdrawing power of TQ unit. Since it has generally been accepted that the strong electron-withdrawing power of acceptor unit results in a decrease of bandgap for alternating copolymer, our results are very consistent with the prediction and other reports [11,25].

Fig. 3 compares photoluminescence (PL) spectra of P(3HT-MeTDQ) and P(3HT-MeTDQ)/PCBM composite in solid state. P(3HT-MeTDQ) shows strong PL with a maximum at 990 nm whereas P(3HT-PhTDQ) does not show

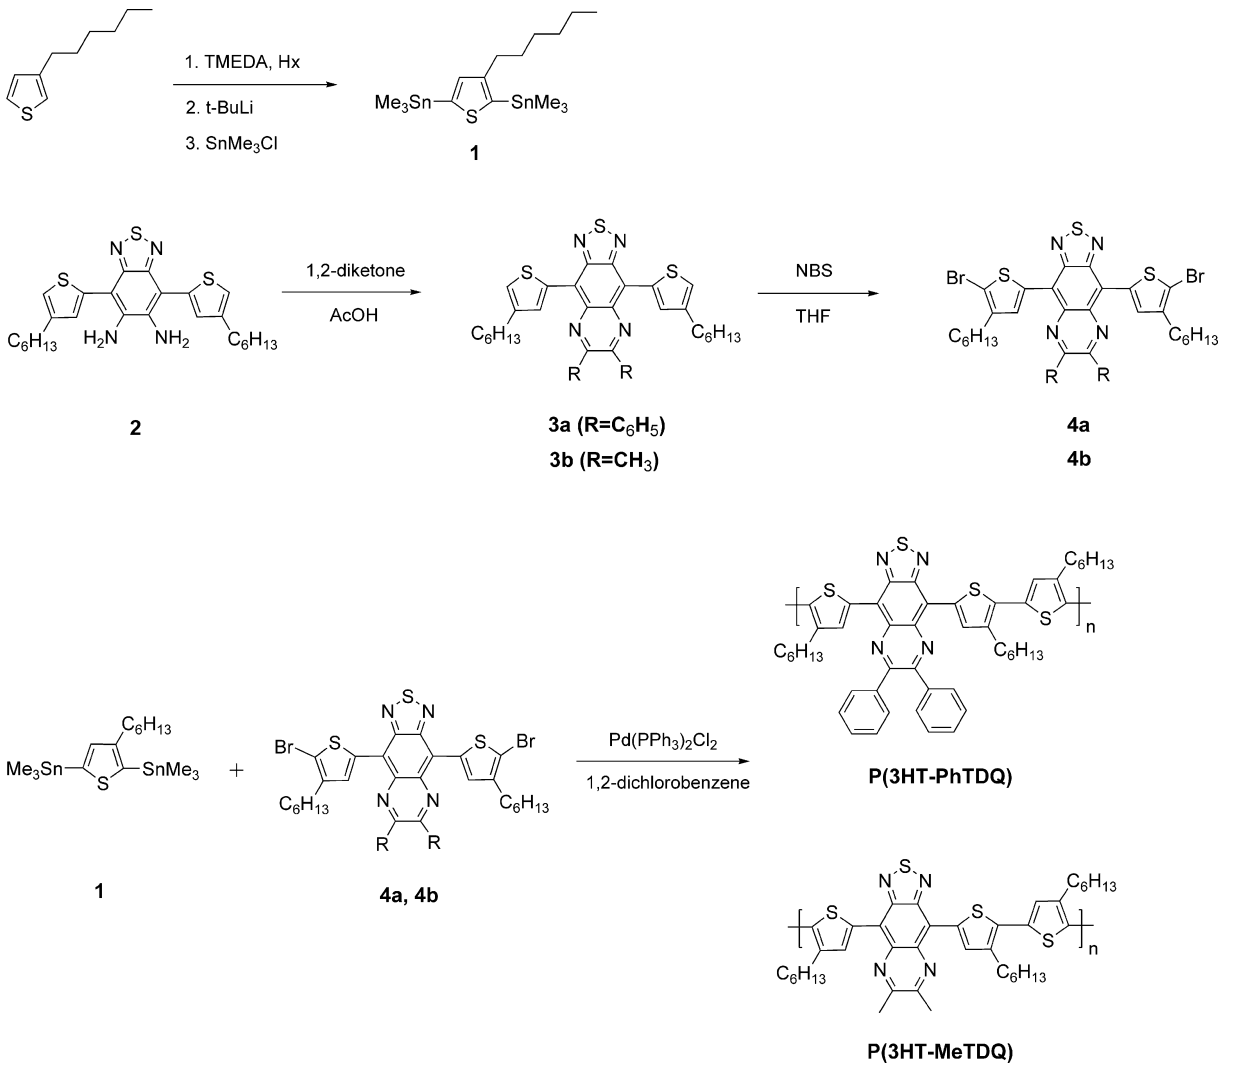

Fig. 1. Synthetic route of alternating copolymers.

PL below 1000 nm wavelength. The PL intensity of P(3HT-MeTDQ) is largely quenched by addition of PCBM, indicating that the charge transfer takes place effectively from the polymer to PCBM.

3.3. Electrochemical properties

The electrochemical data of all the polymers were obtained from the oxidation and reduction cyclic voltammograms, as shown in Fig. 4, and are summarized in Table 1. The onset oxidation and reduction potential of P(3HT-PhTDQ) are 0.38 eV and −0.48 eV (vs. Ag/Ag^+), respectively, and those of P(3HT-MeTDQ) are 0.52 eV and −0.65 eV (vs. Ag/Ag^+). The HOMO energy levels of the polymers can be calculated using the equation: HOMO = $-[E_{ox} - E_{1/2}(\text{ferrocene}) + 4.8]$ V, where E_{ox} is the onset oxidation potential of polymer and $E_{1/2}$(ferrocene) is the onset oxidation potential of ferrocene vs. Ag/Ag^+. The LUMO energy levels can be estimated by using the equation: LUMO = $-[E_{red} - E_{1/2}(\text{ferrocene}) + 4.8]$ V, where E_{red} is the onset reduction potential of polymer. The calculated HOMO and LUMO energy levels of P(3HT-PhTDQ) are −4.82 eV and −3.94 eV, and those of P(3HT-MeTDQ) are −4.96 eV and −3.79 eV, respectively, from which the electrochemical bandgaps (E_g(ec)) for each polymer can be determined. It is noted that the E_g(ec) values of the copolymers are smaller than their corresponding values of E_g(opt). It has generally been accepted that a LUMO–LUMO offset of 0.3–0.4 eV is necessary for efficient electron transfer from polymer to PCBM [26]. Since the LUMO energy level of PCBM has the value ranging between −4.0 and −4.3 eV [27,28], the LUMO–LUMO offset between P(3HT-MeTDQ) and PCBM is larger than 0.3 eV and therefore it is expected that exciton can be easily dissociated at the interface between P(3HT-MeTDQ) and PCBM, whereas the LUMO–LUMO offset between P(3HT-PhTDQ) and PCBM is small, and thus the charge separation is difficult to occur. Furthermore, the HOMO energy level of P(3HT-PhTDQ) is

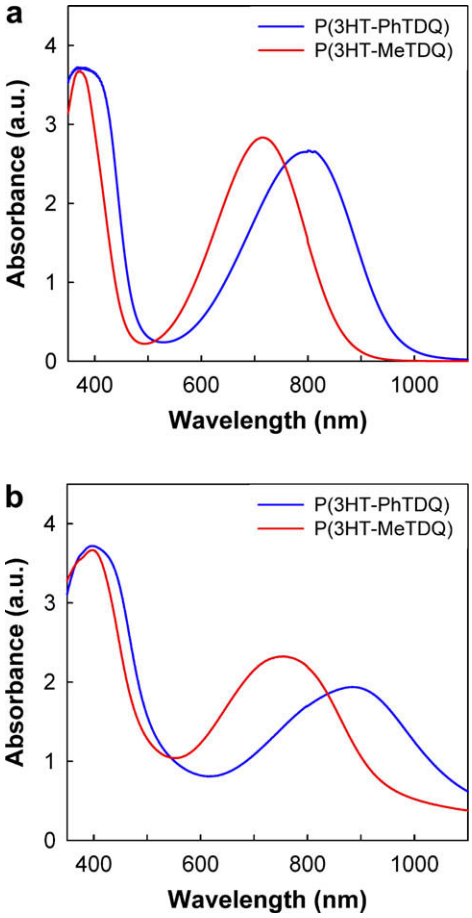

Fig. 2. UV–vis–NIR absorption spectra of the copolymers in chloroform (a) and in film (b).

higher than that of PEDOT:PSS (−5.0 eV), while the HOMO energy level of P(3HT-MeTDQ) is almost the same as that of PEDOT:PSS, indicating that holes can be easily transported from P(3HT-MeTDQ) to PEDOT:PSS whereas holes can be trapped at the interface between P(3HT-PhTDQ) and PEDOT:PSS. Consequently, it can be expected that P(3HT-MeTDQ) is better candidate for active material in photovoltaic device.

3.4. Photovoltaic properties

The polymer solar cells were fabricated with layered configuration of glass/ITO/PEDOT:PSS/polymer:PCBM/LiF/Al. The current–voltage characteristics of photovoltaic devices with two different polymers, P(3HT-PhTDQ) and P(3HT-MeTDQ), are shown in Fig. 5, and the photovoltaic parameters of open circuit voltage (V_{oc}), short circuit current (J_{sc}), fill factor (FF), and power conversion efficiency (PCE) are summarized in Table 2. When the PCEs of P(3HT-MeTDQ) are compared with those of P(3HT-PhTDQ), it reveals that the PCEs of P(3HT-MeTDQ) are higher than those of P(3HT-PhTDQ). It should be noted here that P(3HT-MeTDQ) device reaches 0.48% of PCE at the mixing ratio of 1:2 (polymer:PCBM) with V_{oc} = 0.58 V, J_{sc} = 1.58 mA/cm^2, and FF = 0.53. The values of V_{oc} and FF of P(3HT-MeTDQ) are comparable to or slightly higher than those of other TQ-based polymer solar cells [17,20–23], while the J_{sc} value is lower than others. When the external quantum efficiencies (EQE) of P(3HT-PhTDQ) and P(3HT-MeTDQ) are compared (Fig. 6), P(3HT-MeTDQ) exhibits 7.3% efficiency at 700 nm while P(3HT-PhTDQ) shows very low efficiency. This can be explained by the small offset of LUMO levels of P(3HT-PhTDQ) and PCBM, which implies that only a small fraction of the absorbed photons is dissociated at the polymer/PCBM interface.

It is important to optimize the morphology of active layer for achieving high efficiency. The AFM image of P(3HT-MeTDQ):PCBM blend film shows smooth and homogeneous film surface without exhibiting any characteristic feature of phase separation, as can be seen in Fig. 7a and b. This homogeneous morphology may cause low current density because it does not provide the pathway for charge carriers to pass through. It has recently

been reported that the morphology of active layer can be effectively modified by the use of specific additives [29–32]. Peet and coworkers [29] have demonstrated that addition of 1,8-octanedithiol (ODT) to polymer:PCBM composite induces phase separation of active layer and thereby improves the PCE of BHJ solar cells. Accordingly, when we add 5 vol.% of ODT to chlorobenzene solution of P(3HT-MeTDQ):PCBM (1:2 w/w), the morphology of active layer shows a phase-separated structure, as shown in Fig. 7c and d. When the surface roughness and phase morphology of film with addition of ODT are compared with those of film without ODT, as shown in Fig. 7, it is realized that the surface roughness of film with ODT is larger than the film without ODT and that the film morphology with ODT exhibits more phase-separated structure as compared to the film without addition of ODT.

Table 2
Photovoltaic parameters of devices testing under standard AM 1.5G conditions.

Polymer	Polymer:PCBM	Solvent	V_{oc} (V)	J_{sc} (mA/cm²)	FF	PCE (%)
P(3HT-PhTDQ)	1:1	CB	0.46	0.39	0.32	0.06
	1:2	CB	0.47	0.85	0.36	0.14
	1:3	CB	0.51	0.56	0.43	0.12
	1:4	CB	0.52	0.46	0.42	0.10
P(3HT-MeTDQ)	1:1	CB	0.59	0.89	0.54	0.28
	1:2	CB	0.58	1.58	0.53	0.48
	1:3	CB	0.63	1.03	0.51	0.33
	1:4	CB	0.59	1.06	0.44	0.28

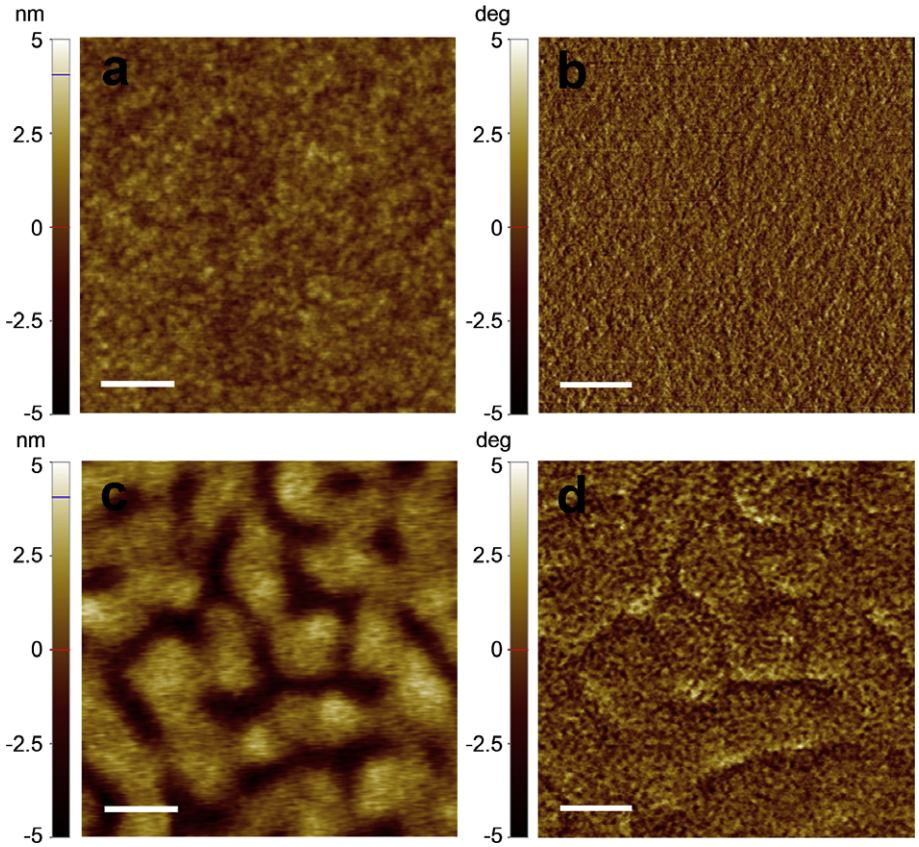

Fig. 7. AFM images of P(3HT-MeTDQ):PCBM (1:2 weight ratio) thin films cast from chlorobenzene (a, height; b, phase), and chlorobenzene with 1,8-octanedithiol as an additive (c, height; d, phase). Scale bars are 150 nm.

To investigate the effect of phase-separated morphology on the charge transport property, we measured hole and electron mobilities from the space charge limited current (SCLC) J–V curve obtained in the dark for hole-only device (ITO/PEDOT:PSS/P(3HT-MeTDQ):PCBM/Au) and electron-only device (Al/P(3HT-MeTDQ:PCBM)/Al) (Fig. 8). The SCLC behavior can be analyzed using the Mott–Gurney law [33]: $J = (9/8)\varepsilon\mu(V^2/L^3)$, where ε is the static dielectric constant of the medium, μ is the carrier mobility, $V = V_a - V_{bi}$ (V_a, the applied bias; V_{bi}, the built-in potential due to the difference in electrical contact work functions), and L is the layer thickness. When the hole and electron mobilities of the device with ODT, determined from the slope of plot of $J^{1/2}$ vs. V, are compared with those of the device without ODT, it is found that both the hole and electron mobilities of the device with ODT are enhanced compared to those of the device without ODT: the hole mobility increases from 6.37×10^{-6} to 2.30×10^{-5} cm^2/Vs; the electron mobility increases from 1.10×10^{-5} to 3.60×10^{-5} cm^2/Vs. This can be attributed to effective formation of phase-separated structure induced by the addition of ODT, which leads to better connectivity of each phase.

Fig. 9 compares J–V curves of devices with and without ODT, from which V_{oc}, J_{sc}, FF, and PCE are determined (Table 2). The PCE of the device with ODT (1.27%) is much higher than that of device without ODT (0.48%). Particularly, the addition of ODT causes a large increase in J_{sc}, because polymer/PCBM composite is phase-separated in nanometer scale as ODT is added, which provides effectively the pathway for charge carriers to pass through the active layer. On the other hand, the photovoltaic performance of P(3HT-PhTDQ) device is not improved by addition of ODT, indicating that the low PCE of the device is attributed mainly to the small difference between LUMO energy levels of the polymer and PCBM.

4. Conclusion

We have synthesized two types of 3-hexylthiophene-thiadiazoloquinoxaline alternating copolymers via the Stille coupling polymerization. Introduction of three hexyl side groups in a repeating unit results in highly soluble polymers with moderate molecular weight. The copolymers exhibited a wide range of optical absorption up to near-IR region. The device fabricated with P(3HT-MeTDQ) shows the PCE of 1.27%, one of the highest values among the TQ-based copolymers, when a small amount of ODT is added to polymer/PCBM composite. Our results demonstrate that P(3HT-MeTDQ) is a potential candidate for application of near-IR absorbing polymer solar cells.

but it is not sufficient for large area applications. The conductivity of 1000 S/cm has been reported for the case of PEDOT by using vapor phase polymerization [12]. However, the process is not suitable for printing process.

As a deposition method of PEDOT:PSS for S/D electrodes ink jet printing has been considered to be an appropriate technology due to its efficient material usage. But its resolution is limited to 20–50 μm due to the statistical variations of droplets positioning and the spreading of droplets on the substrate [13]. This is not sufficient in defining S/D electrodes for the practical applications of OTFTs.

Especially, on a hydrophobic dielectric layer such as polyvinylphenol (PVP) it is difficult to define a fine and continuous pattern with the aqueous PEDOT:PSS because the hydrophilic PEDOT:PSS aggregates on the hydrophobic PVP. Thus, the aqueous PEDOT:PSS layer needs to be heated on substrate during the printing process in order to prevent aggregation of PEODT:PSS droplets on the PVP. However, the heating can result in the shrinkage of the plastic substrate, inducing alignment errors. Moreover, the droplets, which were dropped on the wrong positions, were immediately dried by heating and thus it was difficult to obtain fine patterns. Therefore, an alternative method of ink jet printing needs to be developed for patterning the aqueous PEDOT:PSS on the hydrophobic PVP layer that can be carried out at room temperature. The oxygen plasma process was frequently applied to change the surface energy of hydrophobic film [14]. For instance oxygen plasma was applied to define 5 μm channel length by etching polyimide film and changing surface energy of glass substrate [15]. However, the articles about patterning of the aqueous PEDOT:PSS ink on the hydrophobic PVP were rarely found.

In this work, we developed ink jet printing process for PEDOT:PSS for S/D electrodes of OTFTs. As an appropriate organic compound glycerol was chosen to enhance conductivity of PEDOT:PSS, and a controlled amount of glycerol was figured out to maximize the conductivity as well as to adjust the ink viscosity suitable for ink jet printing. As a result the conductivity of PEDOT:PSS was drastically enhanced to be suitable for S/D electrode of OTFTs. Additionally to avoid the aggregation problems of the aqueous PEODT:PSS on the hydrophobic PVP an ink jet printing technology was also developed by combining oxygen plasma treatment instead of heating. Moreover, the pattern shape was improved when a leveling agent was added. Finally, it was found that the electrode resistance, corresponding to sum of the contact resistance and the series resistance of electrode itself, of the modified PEDOT:PSS to pentacene was comparable to that of Au electrode. It implies that the expensive Au vacuum process can be replaced by the ink jet printing with the PEDOT:PSS.

2. Experimental procedure

The glycerol (from Aldrich) was mixed with PEDOT:PSS (from Bayer AG, Baytron ph 500) and the solution was stirred for 3 h. It is named by G-PEDOT:PSS for convenience. The amount of glycerol was controlled to maximize the conductivity and to make ink viscosity suitable for ink jet printing simultaneously. The surface tensions of the inks were measured by using K9ET (Kruss, Gremany). The curing temperature and time were also optimized to obtain high conductivity by measuring the resistivity with various temperatures and times. The resistivity was measured by a four-point-probe (CMT-Series, AIT). The solvent damage test on the G-PEDOT:PSS film was performed by putting it into various solvents for 5 min, such as water, acetone, anisole, chloroform, which are frequently used as solvents for the soluble semiconductors.

In order to overcome the aforementioned problem, such as the discontinuity in the PEDOT:PSS line that appeared when patterned on the PVP dielectric, the hydrophobic surface of a specific area on PVP was changed to be hydrophilic by treating the area with oxygen plasma. The plasma process was carried out under various conditions, and finally figured out the suitable parameters such as the oxygen flow rate being 3 sccm and the inductively coupled plasma power being 100 W for 5 min. The specific area was defined by the photolithography process. The photoresist was stripped off after the oxygen plasma treatment, and then PEDOT:PSS ink was dropped on the area by ink jet nozzle with a diameter of 50 μm. The geometrical characteristics were examined by a 3-Dimensional (3D) profiler (NV-E1000 Nano system). Several leveling agents were also tested to completely fill the area right up to the corners with the ink.

Test chips, which contained thirty-six OTFTs with the various channel length, were fabricated to investigate the electrical properties of the G-PEDOT:PSS ink for S/D electrodes. Test chips using Au and the pristine PEDOT:PSS electrode were also made for comparison. The bottom gate and bottom S/D contact structure were employed. PVP was used for gate dielectrics and pentacene for semiconductors. The details of the process can be found in other studies [16,17]. All of the processes were carried out in class 1000 clean room in order to minimize the particle contamination. The transfer and output characteristics of OTFTs were measured by a semiconductor parameter analyzer (Keithley SCS-4200). The series resistance of electrodes and the contact resistance were also measured and compared to that of the Au electrodes.

3. Results and discussion

The conductivity of the PEDOT/PSS was strongly dependent on the properties and structure of the additive organic compounds. Among the various organic compounds, glycerol was chosen, which is believed to act as a plasticizer and increased the chain mobility of the polymer. The addition of glycerol helped in not only improving the conductivity and surface wetting properties, but also in avoiding any nozzle clogging problems and in improving the reliability of ink jet printing due to its high boiling point [18].

The resistivity strongly depended on the amount of glycerol, as shown in Fig. 1a, in which the G-PEDOT:PSS film was cured at 120 °C for 20 min. The pristine PEDOT:PSS produced resistivity of 12.9 Ω cm. The resistivity of the G-PEDOT:PSS drastically decreased as the amount

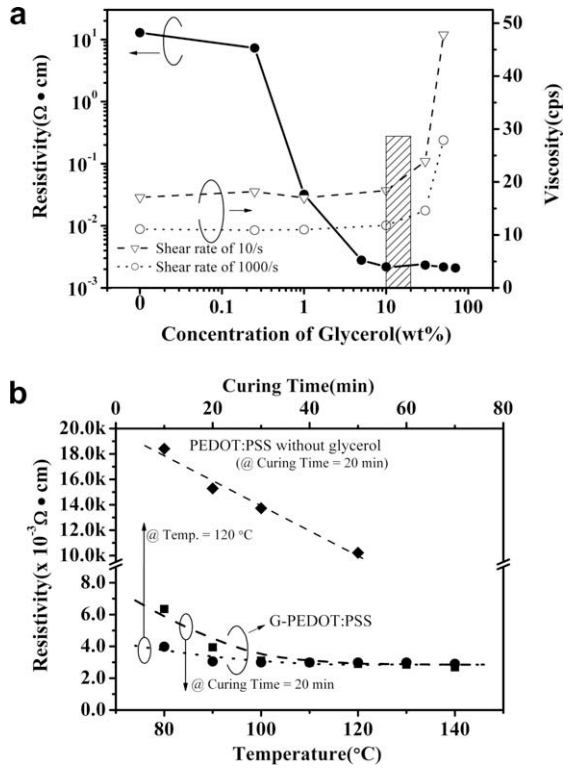

Fig. 1. (a) The resistivity and the viscosity variation of PEDOT:PSS according to the amount of glycerol, (b) The resistivity variation of the G-PEDOT:PSS, which was mixed with glycerol, according to the curing temperature and curing time.

of glycerol increased, and it reached the minimum value of about $2.2 \times 10^{-3}\ \Omega$ cm at 10 wt.% of glycerol.

The viscosity of the G-PEDOT:PSS also changed with the amount of glycerol, as shown in Fig. 1a. The viscosity rapidly increased when the amount of glycerol increased to above 20 wt.%. The viscosity needed to be <20 cps for reliable jetting to occur without any nozzle clogging problems [19]. Therefore, the optimum amount of glycerol was found to be about 10–20 wt.%, as shown in the shaded range in Fig. 1a. This leads to resistivity of $2.2 \times 10^{-3}\ \Omega$ cm, which corresponded to 450 S/cm, and changed the viscosity of the ink to be <20 cps.

The resistivity also varied with the curing temperature and time as well, as shown in Fig. 1b. It decreased as the temperature and the time increased, where it reached the minimum value of $2.2 \times 10^{-3}\ \Omega$ cm at 120 °C and 20 min. In addition the G-PEDOT:PSS film exhibited strong chemical resistance against the organic solvents such as acetone, anisole, and chloroform, which are frequently used as solvents for soluble semiconductors. The resistivity of G-PEDOT:PSS was not changed even after immersing it into the solvents for 5 min. Therefore, the subsequent semiconductor process, which uses strong solvents, can be performed on the G-PEDOT:PSS S/D electrodes.

In order to define S/D electrodes, the G-PEDOT:PSS ink was dropped on the plasma-treated PVP area, as shown in Fig. 2b. The channel length of 10 μm was well defined.

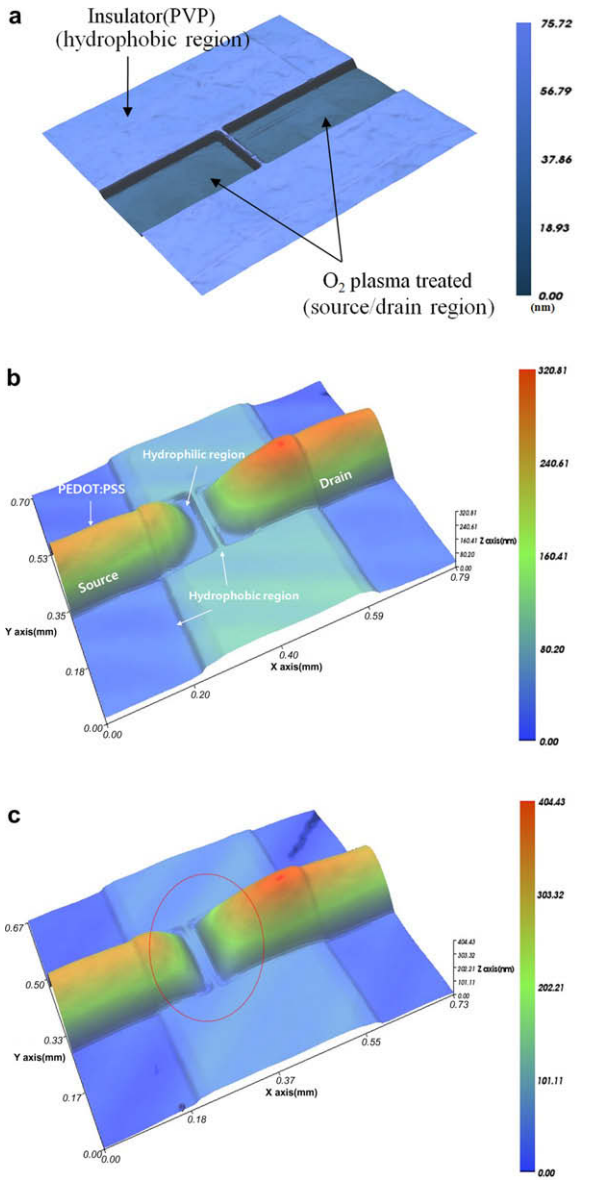

Fig. 2. (a)The 3D image of S/D electrode area on PVP dielectric treated by oxygen plasma; the S/D area was slightly etched off by 30 nm depth, (b) the 3D image of S/D electrode using the G-PEDOT:PSS without, and (c) with a leveling agent. By adding a leveling agent the ink was well spread up to the corners, forming a good shape.

The droplets that were dropped outside of the defined area due to the statistical variation of droppings moved and were confined into the area due to the surface energy difference between the plasma-treated and the non-treated area. In addition, the plasma-treated area was slightly etched off by ~30 nm, as shown in Fig. 2a, and it acted as a kind of bank to tightly keep the ink inside of the area, and thus the confinement was more enhanced.

However, the G-PEDOT:PSS did not completely fill the area right up to the corners, as shown in the 3D profiler image of Fig. 2b, even though the surface property changed after the oxygen treatment. After screening a wide range

of ink recipes, we found that additives of low surface energy solved the current problem. We chose poly(dimethylsiloxane)-based leveling agent (EFKA 3030, Ciba Co.), which is able to effectively reduce the surface energy and help the spreading of the ink in aqueous system. As expected, the modified ink decreased the surface tension significantly from 70.2 to 49.6 mN/m. It is generally known that fluorinated compounds also lower surface energy, but none of this kind was found to be suitable in our case. After ink jet printing, surface energy modified ink spreads uniformly to the corners of the designated area, as shown in Fig. 2c. From this, we can say that surface energy of the ink needs to be modified in ink jet printing and that uniform spreading can be achieved by selecting a proper additive.

The transfer and output characteristics of OTFTs, with the G-PEDOT:PSS, as well as the pristine PEDOT:PSS and the Au S/D electrodes are depicted in Fig. 3 for comparison. The performance parameters, such as field effect mobility and threshold voltage, were extracted from the transfer curves by comparing it with the following equation in the saturation region, and are summarized in Table 1:

$$I_{DS} = \frac{W}{2L}\mu C_G (V_G - V_T)^2 \quad (1)$$

where I_{DS} is the saturation drain current, W is the channel width, L is the channel length, μ is the field effect mobility, C_G is the capacitance of the PVP gate dielectric, V_G is the gate voltage, and V_T is the threshold voltage. The capacitance of the PVP gate dielectric that was measured at 1 MHz was 9.1 nF/cm^2, which was used to extract the parameters.

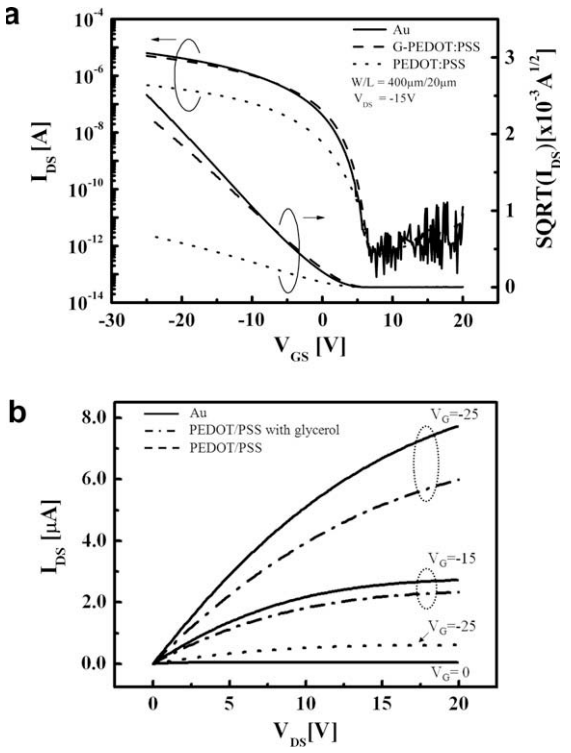

Fig. 3. (a) The transfer characteristics and (b) the output characteristics of pentacene OTFTs using the various S/D electrodes such as the pristine PEDOT:PSS (without glycerol) and the G-PEDOT:PSS (with glycerol) and Au as well (W = 400 μm and L = 20 μm).

Table 1
The performance parameters of pentacene OTFTs with the various S/D electrodes.

Parameter	PEDOT/PSS (without glycerol)	G-PEDOT/PSS (without glycerol)	Au
Mobility (cm^2/Vs)	0.01	0.13	0.16
Threshold voltage (V)	1.9	2.3	1.0
Subthreshold slop (V/dec)	0.98	0.58	0.83
I_{on}/I_{off} current ratio	7.8×10^5	5.6×10^6	1.6×10^7
Off state current (pA/μm)	0.002	0.002	0.003

According to Table 1, the performance of OTFTs that used the pristine PEDOT:PSS without glycerol was worse than the other two OTFTs that used the G-PEDOT:PSS and Au electrodes. The field effect mobility of the pristine PEDOT:PSS was about 0.01 cm^2/V s, which was 10× smaller than the others. Meanwhile, the field effect mobility of the G-PEDOT:PSS electrodes was similar to that of the Au electrodes, which was about 0.1 cm^2/V s. Such field effect mobility difference seems to be originated from the resistance of materials that were used for S/D electrodes. However, in Eq. (1), the resistance was not considered, so that the field effect mobility of the three OTFTs that were extracted from Eq. (1) was different from each other, even though they should have been equal because they used the same semiconductor and dielectric.

The resistance effect is especially clear in the high drain current region, as shown in Fig. 3a, where I_{on} at $V_{GS} = -25$ V of the pristine PEDOT:PSS was 10× smaller than the other two materials. In the output characteristics of Fig. 3b in the small V_{DS} region near 0 V, the drain current linearly increased with V_{DS}, reflecting an ohmic contact.

Let's consider the resistance that is associated with the electrode materials. The total resistance of OTFTs, where R_T consists of three components, is like the following:

$$R_T = (R_S + R_C) + R_{CH} = R_E + R_{CH} \quad (2)$$

where R_S is the series resistance of the electrode itself, R_C is the contact resistance between the electrode and pentacene, and R_{CH} is the channel resistance of pentacene. Here we define a new term electrode resistance R_E, which corresponds to the sum of R_S and R_C, to consider the large series resistance. In transfer length method (TLM) [20], which is frequently applied to extract the contact resistance, the measured R_C is actually equal to the above R_E because R_S is not separated from R_C but included into the measured R_C. For the case of metal electrodes the R_E can be assumed to be equal to R_C because R_S is negligible. However, for PEDOT:PSS with a non-negligible R_S the measured R_C should be considered to be the R_E instead of R_C alone.

The electrode resistance R_E and the channel resistance R_{CH} of the OTFTs in Fig. 3, where the channel width W was equal to 400 μm and the channel length L to 20 μm, were extracted by TLM measurement and compared in Fig. 4. The R_{CH} and the R_E of all OTFTs decreased as the gate

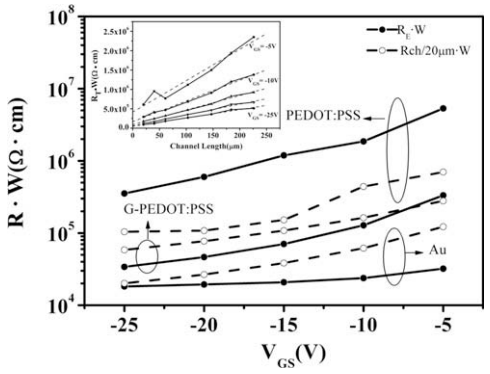

Fig. 4. The comparison of the normalized electrode resistance R_E W, corresponding to sum of contact R_C and series resistance R_S of electrode, and channel resistance $R_{CH}{\cdot}W$ (L = 20 μm) of S/D electrode using Au, G-PEDOT:PSS, and PEDOT:PSS. The inset is $R_T{\cdot}$W of G-PEDOT:PSS.

voltage increased toward negative bias direction since the channel carrier density became larger and the carrier injection enhanced as the gate voltage increased.

The R_{CH}'s were expected to be equal because the OTFTs used the same semiconductor material but they exhibited somewhat difference. We estimated that the difference was caused by the experimental variation as well as the different process history, where Au electrode was fabricated by lift-off meanwhile PEDOT:PSS meanwhile G-PEDOT:PSS electrode were treated by oxygen plasma.

The R_E's produced severe difference depending on the electrode materials. For PEDOT:PSS the R_E was much larger than its R_{CH} so that R_E limited the drain current. It was the cause of small current as mentioned previously. For G-PEDOT:PSS and Au the R_{CH} was larger than their R_E's so that R_{CH} limited current. However, the R_E's were not negligible comparing with R_{CH}'s. Especially, for Au it was equal to its R_{CH} at $V_{GS} = -25$ V. Therefore, the R_E's were also important factors to limit the currents.

The effect of the R_E on drain current will be clear by comparing the injection efficiency as figure-of-merit. The contact injection efficiency η is expressed by Eq. (3) [21] and depicted in Fig. 5 with respect to channel length and gate voltage as well

$$\eta = \frac{R_{CH}}{R_{CH} + R_E} \tag{3}$$

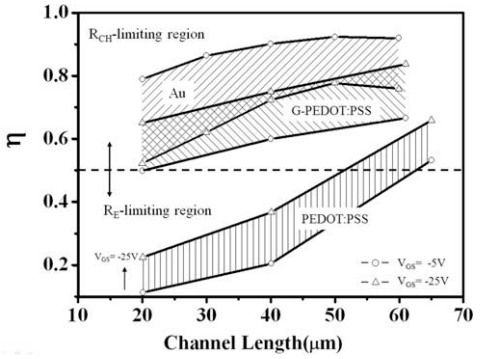

Fig. 5. The comparison of contact injection efficiency $\eta = \frac{R_{CH}}{R_{CH}+R_E}$ of S/D electrode using Au, G-PEDOT:PSS, and PEDOT:PSS.

The η was varied with channel length and gate voltage. The η of PEDOT:PSS was much smaller than the other two devices by exhibiting <0.5 in the most of channel length, meaning that R_E limited current; R_E-limiting electrode. For G-PEDOT:PSS and Au the η was larger than 0.5 in all channel length, meaning that R_{CH} limited current; R_{CH}-limiting electrode as a good contact. The η of G-PEDOT:PSS was overlapped with that of Au in a certain gate voltage region, implying that the injection efficiency of G-PEDOT:PSS is comparable to Au in the gate voltage region. However, at L = 20 μm and $V_{GS} = -25$ V the η of both electrodes approached to 0.5, and expected to be <0.5 when L was smaller than 20 μm and V_{GS} larger than −25 V, entering into R_E-limiting region. In Fig. 3a three OTFTs were in the R_E-limiting region when biased at $V_{GS} = -25$ V. Therefore, the R_E was also an important factor to limit the drain current along with the R_{CH} at $V_{GS} = -25$ V.

As shown in Eq. (2) the R_E consists of R_S and R_C. The series resistance R_S of the pristine PEDOT:PSS electrode was about 2 MΩ/□, which is about $10^4\times$ larger than that of the G-PEDTO:PSS (290 Ω/□) and $10^7\times$ larger than that of the Au electrode (0.3 Ω/□). Thus, the voltage drop on R_S of the pristine PEDOT:PSS electrode became non-negligible so that the R_S would be the main reason of $10\times$ smaller current of PEDOT:PSS than the others. Therefore, the R_E of PEDOT:PSS is mostly determined by the large R_S in the case of PEDOT:PSS.

The R_E of G-PEDOT:PSS was about 30 kΩ cm at $V_{GS} = -25$ V as shown in Fig. 4, which was $10\times$ smaller than that of the article [22], where it was 360 kΩ cm at $V_{GS} = -80$ V for polymer semiconductors. By the way the R_E was comparable to R_E = 20 kΩ cm of Au although the R_S of G-PEDOT:PSS was $10^3\times$ larger than that of Au. The reason can be found in the contact resistance R_C. The R_C determines the injection property of carriers from the electrodes into the semiconductors, which was parameterized by an energy barrier ϕ_B at the contact interface. According to articles [23], the energy barrier of PEDOT:PSS is 0.25 eV, which is smaller than 0.85 eV of Au. Especially, it has been reported that PEDOT:PSS formed a p-doped interface layer, resulting in a low energy barrier [22,24–26]. If it is true for G-PEDOT:PSS, the small energy barrier of G-PEDOT:PSS results in a smaller R_C than that of Au. Therefore, the electrode resistance R_E of G-PEDOT:PSS consists of the larger R_S and the smaller R_C than Au, resulting in the slightly larger than or comparable to that of Au, which has the smaller R_S and the larger R_C than that of G-PEDOT:PSS, as shown in Fig. 4.

According to Fig. 5 the R_E of G-PEDOT:PSS should be reduced further for the application to short channel <20 μm, resulting in the η to be larger than 0.5 as a good contact. There might be two ways to reduce R_E, such as selection of the proper organic additives to reduce R_S or surface treatment employing dipole layer to reduce R_C [27–29].

4. Conclusion

A solution process for the S/D electrodes of OTFTs was developed by using the polymer PEDOT:PSS as a material and ink jet printing for patterning. The conductivity of the PEDOT:PSS was improved to 450 S/cm by adding a con-

trolled amount of glycerol, 10–20 wt.%, which also made ink jet printing suitable in terms of viscosity, which was <20 cps. The ink was patterned on S/D electrode area, which was predefined by photolithography and oxygen plasma, in order to make the area more hydrophilic distinguishing from the other hydrophobic area. The shape of the G-PEDOT:PSS electrode improved with the addition of a leveling agent. The OTFTs with the G-PEDOT:PSS electrodes produced the electrode resistance of 30 kΩ cm at $V_G = -25$ V and the field effect mobility of 0.13 cm^2/V s, which were similar to those of the Au electrodes. However, for short channel applications the electrode resistance need to be further reduced.

[16–18]. The solid-state electron affinity (EA) of $Mo(tfd)_3$ is 5.6 eV [18], which is large enough to *p*-dope a number of hole-transport materials including pentacene, which has the solid-state ionization energy (IE) of 5.1 eV [19]. Within Koopmans' approximation, EA is the difference between vacuum level (E_{vac}) and the lowest unoccupied molecular orbital (LUMO) energy level, whereas IE is the difference between vacuum level and the highest occupied molecular orbital (HOMO) level. In other words, the LUMO level of $Mo(tfd)_3$ is 0.5 eV lower in energy than the HOMO of pentacene, making an electron transfer from a pentacene molecule to the molecular dopant energetically favorable.

Top-contact OFET device structures with Au source/drain electrodes and large channel lengths (25–200 μm) are used in this study. Effects of channel length scaling are studied in devices with doped contacts and undoped (with only a 50 nm pentacene layer) reference OFETs. In contrast to most previous studies where pristine dopant films were deposited with the control of lateral [11] or vertical [14] position of the dopant layer, in our study, a 10 nm co-evaporated (1:1 ratio, from different crucibles) layer of $Mo(tfd)_3$ and pentacene was deposited under the metal electrodes and above the 50 nm pentacene layer for the selective doping in OFETs. $Mo(tfd)_3$ doping in the OFETs resulted in improved μ and V_{TH} values as well as a significant reduction in contact resistance.

2. Device fabrication and electrical characterization

OFETs were fabricated on heavily doped *n*-type silicon substrates (also serving as gate electrodes) with 200 nm thick thermally grown SiO_2 as the gate dielectric in a top contact configuration. Ti/Au (10 nm/100 nm) metallization on the backside of the substrate was carried out to further enhance the gate electrical contact. First, the substrates were cleaned by O_2 plasma for 3 min to make the SiO_2 surface hydrophilic. Surface treatment with octadecyltrichlorosilane (OTS) (5 mM in toluene) was performed by soaking the substrates in the OTS solution for 17 h in a N_2-filled glove box. The substrates were then rinsed with toluene and annealed at 60 °C for 5 min. The capacitance density of the OTS-treated SiO_2 was measured and found to have a value of 16.2 nF/cm^2. Pentacene (Sigma–Alrich), purified using gradient zone sublimation, was deposited (50 nm) on the substrates by vacuum sublimation without any active substrate heating. For doped devices, a 10 nm-thick layer of a 1:1 mixture of $Mo(tfd)_3$ (synthesized according to the literature [20]) and pentacene was co-evaporated, followed by deposition of 60 nm Au, through a shadow mask to define the source/drain electrodes. For undoped reference devices, Au was directly deposited on top of the pentacene layer. Devices were not exposed to normal ambient after loading in the glove box for OTS treatment. Fig. 1(a) shows the cross-sectional device structure of a standard OFET with a single pentacene layer. Such devices are referred to as reference OFETs. Fig. 1(b) shows the cross-sectional device structure of OFETs in which an additional co-evaporated layer (pentacene + $Mo(tfd)_3$, ratio 1:1) was deposited on top of the pentacene layer through the same shadow mask used to deposit the top electrodes. Such devices are referred to as contact-doped OFETs. The chemical structures of pentacene and $Mo(tfd)_3$ are also shown in Fig. 1.

The samples were transferred in an air-tight vessel, without being exposed to atmospheric conditions, into another N_2-filled glove box (O_2, H_2O < 0.1 ppm) for electrical testing. The electrical measurements were performed using an Agilent E5272A source/monitor unit. Output (I_{DS} vs. V_{DS}) and transfer (I_{DS} vs. V_{GS}) characteristics were measured for the devices, and μ and V_{TH} were measured in the saturation regime from the highest slope of $|I_{DS}|^{1/2}$ vs. V_{GS} plots using the saturation region current equation for standard transistors. For the study of stability under a constant bias, the time-dependent decay of I_{DS} was tested in the saturation regime ($V_{GS} = V_{DS} = -30$ V) for 1 h.

3. Results and discussion

Devices with channel width $W = 1000$ μm and various channel lengths ($L = 25$, 50, 100, and 200 μm) were characterized to obtain values of the hole mobility in saturation (μ_{sat}), V_{TH}, current on/off ratio (I_{on}/I_{off}), and sub-threshold

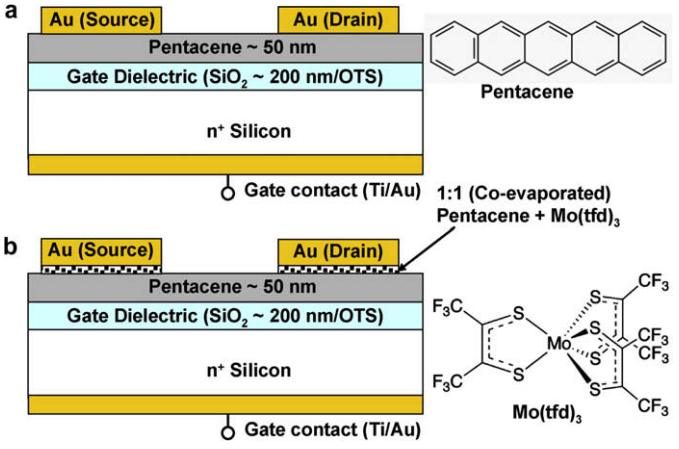

Fig. 1. Device structures of a reference top-contact pentacene OFET (a) and that of a device in which the contact region under the source and drain electrodes has been doped with $Mo(tfd)_3$ (b); chemical structures of pentacene and $Mo(tfd)_3$ are shown on the right.

slope (*SS*). Table 1 summarizes the performance parameters with $W = 1000$ μm and $L = 25$, 50, 100 and 200 μm for a total 13 reference devices and 14 contact-doped devices with μ, V_{TH} and $I_{on/off}$ averaged over 3 or 4 devices for each device geometry. Fig. 2(a) and (b) shows the comparison of output and transfer characteristics of contact-doped vs. reference devices for $W/L = 1000$ μm/200 μm, whereas Fig. 2(c) and (d) shows the same comparison for the smallest L in our study ($W/L = 1000$ μm/25 μm). Fig. 2(e) and (f) shows the plots for the comparison of μ_{sat} and V_{TH}. As can be seen from the results, I_{DS} in the contact-doped devices increases by 28% for devices with $W/L = 1000$ μm/200 μm and 50% for devices with $W/L = 1000$ μm/25 μm. On the other hand, the values of the *SS* and $I_{on/off}$ decrease in the contact-doped devices. The drop in $I_{on/off}$ is essentially due to the increase in I_{off} in the devices, which is higher for the devices with smaller channel L ($\sim 10^{-10}$ A for 1000 μm/200 μm, and $\sim 10^{-9}$ A for 1000 μm/25 μm). The $I_{on/off}$ is on the order $\sim 10^4$ or higher in the contact-doped OFETs in the studied range ($L = 25$–200 μm), which indicates that this technique can be suitable for applications where higher drive currents are desired at the cost of a moderate increase in power dissipation in the "off" state. Apart from the changes in the electrical parameters such as μ, V_{TH} $I_{on/off}$, and *SS*, the next important parameter to look at is contact resistance (R_C).

As explained in the literature [14], carrier injection from the Au contact to the semiconductor in the contact region can be separated into two processes: interface charge injection from the metal contact to the semiconductor and the vertical charge transport through the pentacene film to the channel. Hence, the contact resistance R_C is generally divided into two parts: a contribution from the interface resistance (R_{int}), and a contribution from the vertical bulk resistance (R_{bulk}) which results from the transport region between the electrode interface and the conduction channel near the semiconductor/gate dielectric interface [14]. Selective doping near the electrode interface is expected to mainly decrease R_{int} due to a reduction in the energy barrier height for carrier injection from the metal electrode to the semiconductor due to the band bending associated with the doping near that interface.

To better understand the effect of doping on R_C, the R_C values for each type of device were extracted using a transmission line method (TLM) based on the dependence of the current–voltage characteristics on L. A set of devices with L ranging from 25 μm to 200 μm and a fixed $W = 1000$ μm was used to calculate the R_C at a low V_{DS} of −3 V for V_{GS} values ranging from −15 V to −30 V. In the linear regime, the overall device resistance R_{on} can be considered to be the sum of the channel resistance R_{ch} and the total contact resistance R_C, as already explained in the literature [21–23]. The width-normalized contact resistance ($R_C W$) was estimated by extrapolating $R_{on}W$ to $L = 0$ μm using the y intercept of plots of $R_{on}W$ vs. L, which are shown in Fig 3(a) and (b) for reference and contact-doped OFETs, respectively. The $R_C W$ for different V_{GS} for both types of devices are plotted in Fig. 3(c). The $R_C W$ for contact-doped

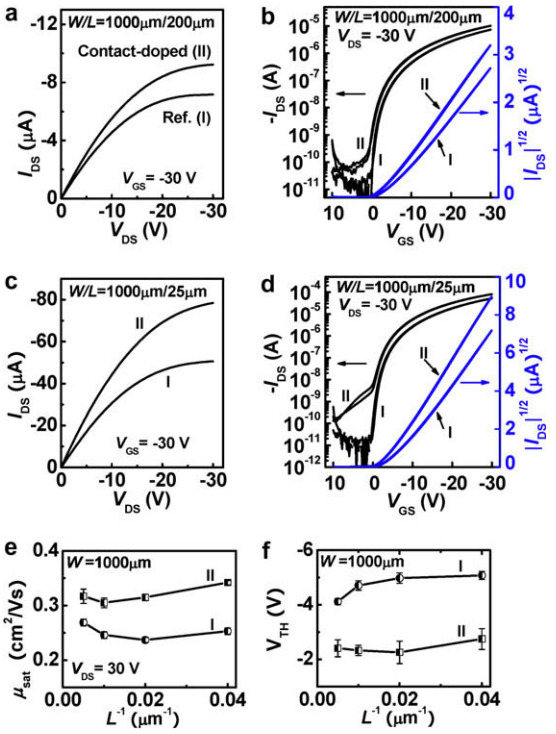

Fig. 2. Comparison of output and transfer characteristics of reference (I) and contact-doped (II) pentacene OFETs with $W/L = 1000$ μm/200 μm (a and b), and with $W/L = 1000$ μm/25 μm (c and d); (e) dependence of μ_{sat} on L^{-1}; and (f) dependence of V_{TH} on L^{-1} for both types of OFETs.

Table 1
Summary of the electrical parameters of reference (13 devices) and contact-doped OFETs (14 devices) with $W = 1000$ μm and $L = 25$, 50, 100, and 200 μm. Average values and standard deviations for devices were obtained by averaging over three or four devices with identical geometry fabricated on the same substrate.

Device (W/L)	μ (cm^2/Vs)	V_{TH} (V)	$I_{on/off}$	*SS* (V/dec)
Reference (13 devices)				
1000 μm/25 μm (3 dev.)	0.253 (±0.004)	5.1 (±0.2)	5×10^6	0.59 (±0.04)
1000 μm/50 μm (3 dev.)	0.237 (±0.005)	5.0 (±0.2)	2×10^6	0.58 (±0.02)
1000 μm/100 μm (4 dev.)	0.246 (±0.006)	4.7 (±0.2)	1×10^6	0.49 (±0.04)
1000 μm/200 μm (3 dev.)	0.269 (±0.006)	4.1 (±0.1)	7×10^5	0.36 (±0.07)
Contact-doped (14 devices)				
1000 μm/25 μm (3 dev.)	0.342 (±0.004)	2.8 (±0.4)	2×10^4	1.43 (±0.13)
1000 μm/50 μm (4 dev.)	0.315 (±0.006)	2.3 (±0.4)	1×10^4	1.59 (±0.07)
1000 μm/100 μm (4 dev.)	0.305 (±0.009)	2.3 (±0.2)	1×10^4	1.46 (±0.06)
1000 μm/200 μm (3 dev.)	0.317 (±0.013)	2.4 (±0.3)	2×10^5	0.73 (±0.02)

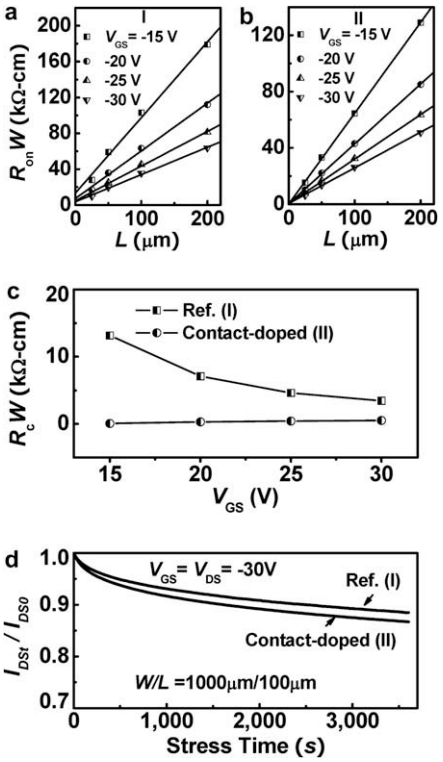

Fig. 3. Values of $R_{on}W$ obtained at various values of V_{GS} for different channel lengths for reference (I) (a), and contact-doped (II) (b) OFETs; (c) plot of R_CW as a function of V_{GS} for both types of devices; (d) decay of drain-source current for $V_{GS} = V_{DS} = -30$ V measured continuously over a period of 1 h.

devices is significantly lowered compared to reference OFETs. In the strong accumulation regime ($V_{GS} = -30$ V), it is lowered from ~3.4 kΩ-cm for reference to ~0.5 kΩ-cm for contact-doped devices.

Fig. 3(d) shows the time-dependent decay of I_{DS} under a continuous dc bias stress with $V_{GS} = V_{DS} = -30$ V measured over 1 h for both types of devices with the geometry $W/L = 1000\ \mu m/100\ \mu m$. The decay of the current measured in these experiments is nearly identical for the two types of devices. The current decays to 90–85% of its initial value after one hour. These results show that the reduction in R_C in contact-doped OFETs could be achieved without compromising the electrical stability under a continuous bias stress, which is very important for the reliable operation of organic devices and circuits.

4. Summary and conclusion

In summary, the electrical performance of *p*-channel pentacene OFETs could be improved by selectively doping the organic semiconductor region beneath the source/drain electrodes with $Mo(tfd)_3$. The doping with $Mo(tfd)_3$ yielded a small increase in μ, a reduction in V_{TH}, and a significant reduction in R_CW (from 3.4 kΩ-cm to 0.5 kΩ-cm at $V_{GS} = -30$ V). In contrast to previous studies performed in short channel OFETs [13,14], these improvements in electrical performance were achieved while maintaining large current on/off ratios and good electrical stability under continuous bias stress. These advances are important for the design of future backplanes for displays and other organic-based circuits.

These compounds were found to exhibit a high external quantum efficiency of 4.6% and a pure deep blue emission with CIE coordinates (0.154, 0.078) [29]. In other research in this area, Yamashita's group used an indenopyrazine derivative, difluoro-diindeno[1,2-b;1′,2′-e]pyrazine-6,12-dione, as the channel material in an n-type OTFT, with excellent results (mobility, 0.17 cm^2/Vs; on/off ratio, 10^7) [30]. Indenopyrazine is therefore gaining recognition in optoelectronics as a potentially useful core structure for a new family of organic functional materials. However, if indenopyrazine derivatives with enhanced performance suitable for diverse optoelectronics applications are to be developed, more systematic studies of their structures and properties must be conducted.

In a previous study, we hypothesized that the π–π^* stacking of molecules in the thin-film state due to the plate-like molecular structure of indenopyrazine would give rise to a reduction in its fluorescence yield and a bathochromic effect on its emission wavelength. To remove this effect, we introduced short alkyl groups at the 6- and 12-positions of indenopyrazine and a bulky *m*-terphenyl side group at positions 2 and 8. An OLED device based on the resulting molecule was found to exhibit excellent characteristics, with high efficiency and a pure deep blue color [29]. In this study, we investigated the effects on the optical and electroluminescence properties of varying the substitution position of the side groups (Scheme 1). In particular, we examined the bulky *m*-terphenyl substitution positions 2 and 8 (*meta* positions), 1 and 7 (*ortho* positions), and 3 and 9 (*para* positions).

Although varying the substitution positions of side groups on emitting cores offers important information about the intrinsic properties of the molecules, it is difficult to change the side group substitution positions for most emitting cores (*e.g.* fluorene, bifluorene and anthracene) [9–28]. In this study, however, varying the substitution pattern was facilitated by the use of bromo-indanones with Br substituted at positions 4, 5, and 6 as the starting compounds. This procedure enabled the facile synthesis of three compounds in which *m*-terphenyl is substituted at the *ortho*, *meta*, and *para* positions: 6,6,12,12-tetraethyl-1,7-bis-[1,1′;3′,1″]terphenyl-4′-yl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (*o*-TP-EPY), 6,6,12,12-tetraethyl-2,8-bis-[1,1′;3′,1″]terphenyl-4′-yl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (*m*-TP-EPY), and 6,6,12,12-tetraethyl-3,9-bis-[1,1′;3′,1″]terphenyl-4′-yl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (*p*-TP-EPY).

2. Experimental

2.1. Synthesis of o-, m-, and p-TP-EPY

The compounds *o*-, *m*-, and *p*-TP-EPY were synthesized following literature procedures [29]: to 2,8-dibromo-6,6,12,12-tetraethyl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (1 g, 1.9 mmol) and 4,4,5,5-tetramethyl-2-[1,1′;3′,1″]terphenyl-4′-yl-[1,3,2]dioxaborolane (1.49 g, 4.19 mmol) in a 500 mL round-bottomed flask under a nitrogen atmosphere were added $Pd(OAC)_2$ (0.042 g, 0.19 mmol), tricyclohexylphosphine (0.053 g, 0.19 mmol) and toluene. The temperature was then increased to 50 °C, and tetraethylammonium hydroxide (13.5 mL, 19.0 mmol, 20 wt.% in water) was added. Stirring was continued at this temperature and the reaction was monitored by TLC. When the reaction was complete, the product was extracted with water and toluene. The organic extract was dried over anhydrous $MgSO_4$ and filtered, after which the solvent removed in vacuo. The resulting crude mixture was passed through a short column of silica with THF as the eluent and then recrystallized from THF to obtain *m*-TP-EPY as a white solid. The purification method of *o*- and *p*-TP-EPY was same as *m*-TP-EPY.

2.1.1. Synthesis of 6,6,12,12-tetraethyl-1,7-bis-[1,1′;3′,1″] terphenyl-4′-yl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (o-TP-EPY)

The final yield was 1.06 g, 68%. ^{1}H NMR (500 MHz, $CDCl_3$): δ (ppm) 8.00–7.99 (d, 2H), 7.74–7.72 (m, 6H), 7.59 (d, 2H), 7.48–7.45 (t, 4H), 7.41–7.36 (m, 12H), 7.16–7.14 (m, 4H), 7.08 (s, 2H), 2.10 (m, 2H), 1.85 (m, 2H), 1.74 (m, 2H), 1.62 (m, 2H), 0.27–0.20 (m, 6H), −0.51 to −0.60 (m, 6H). ^{13}C NMR (500 MHz, $CDCl_3$): 162.7, 152.5, 145.4, 141.5, 141.1, 140.9, 139.0, 138.4, 134.1, 131.7, 130.7, 129.6, 129.1, 128.2, 127.8, 127.4, 126.9, 126.5, 125.0, 120.4, 56.2, 30.6, 30.1, 8.9, 8.8, 7.8. FT-IR (KBr cm^{-1}): 3056, 2961, 2928, 2873, 1599, 1486, 1469, 1456, 1400, 1367, 1291, 1244, 1204, 1182, 1103, 1076, 1030, 776, 755, 742, 698. HRMS Calcd for $C_{62}H_{53}N_2$ $(M+H)^+$, 825.4209, found: 825.4229.

2.1.2. Synthesis of 6,6,12,12-tetraethyl-3,9-bis-[1,1′;3′,1″] terphenyl-4′-yl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (p-TP-EPY)

The final yield was 0.89 g, 57%. ^{1}H NMR (500 MHz, THF-d_8): δ (ppm) 8.09–7.76 (s, 2H), 7.76–7.75 (m, 8H), 7.71–7.69 (d, 2H), 7.46–7.43 (t, 4H), 7.35–7.34 (t, 2H), 7.27–7.22 (m, 6H), 7.19–7.15 (m, 6H), 7.04–7.03(d, 4H), 2.47–2.28 (m, 4H), 2.06–1.99 (m, 4H), 0.38–0.36 (t, 12H). ^{13}C NMR (300 MHz, $CDCl_3$): 162.9, 152.4, 148.0, 141.7, 141.3, 140.9, 140.7, 140.6, 139.8, 139.5, 131.7, 131.3, 130.2, 129.4, 129.0, 128.0, 127.6, 127.3, 126.8, 126.3, 122.4, 122.2, 53.8, 31.3, 8.8. FT-IR (KBr cm^{-1}): 3055, 3025, 2962, 2919, 2874, 2853, 1599, 1486, 1462, 1442, 1317, 1288, 1233, 1178, 1124, 895, 826, 763, 748, 697, 486, HRMS Calcd for $C_{62}H_{53}N_2$ (M+H)$^+$, 825.4209, found: 825.4214.

2.1.3. Synthesis of 1,7-dibromo-6,6,12,12-tetraethyl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]-pyrazine (1c)

2.1.3.1. 4-Bromo-2,3-dihydro-2-(hydroxyimino)indene-1-one (1a). The yield was 79%. ^{1}H NMR (300 MHz, acetone-d_6): δ (ppm) 11.90 (s, 1H), 7.95–7.92 (d, 1H), 7.79–7.76 (d, 1H), 7.50–7.45 (t, 1H), 3.76 (s, 2H).

2.1.3.2. 1,7-Dibromo-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (1b). The yield was 56%. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 8.17–8.15 (d, 2H), 7.65–7.63 (d, 2H), 7.45–7.42 (d, 2H), 4.02 (s, 4H).

2.1.3.3. 1,7-Dibromo-6,6,12,12-tetraethyl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (1c). The yield was 38%. ^{1}H NMR (500 MHz, $CDCl_3$): δ (ppm) 8.08–8.05 (d, 2H), 7.58–7.56 (d, 2H), 7.32–7.29 (t, 2H), 2.72–2.55 (m, 4H), 2.37–2.29 (m, 4H), 0.27–0.24 (t, 12H). ^{13}C NMR (500 MHz, $CDCl_3$): 163.0, 152.2, 145.9, 142.5, 142.3, 134.1, 133.9, 129.4, 129.3, 128.5, 120.4, 120.2, 119.8, 57.5, 57.4, 28.3, 8.8. Fab$^+$-MS *m*/*e*: 526.

2.1.4. Synthesis of 3,9-dibromo-6,6,12,12-tetraethyl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]pyrazine (3c)

2.1.4.1. 6-Bromo-2,3-dihydro-2-(hydroxyimino)indene-1-one (3a). The yield was 77%. ^{1}H NMR (300 MHz, acetone-d6): δ (ppm) 11.83 (s, 1H), 7.89–7.85 (m, 2H), 7.64–7.61 (d, 1H), 3.82 (s, 2H).

2.1.4.2. 3,9-Dibromo-6,12-dihydrodiindeno[1,2-b:1,2-e]pyrazine (3b). The yield was 53%. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 8.37–8.36 (s, 2H), 7.64–7.60 (d, 2H), 7.54–7.38 (d, 2H), 4.04 (s, 4H).

2.1.4.3. 3,9-Dibromo-6,6,12,12-tetraethyl-6,12-dihydro-diindeno[1,2-b;1′,2′-e]-pyrazine (3c). The yield was 63%. ^{1}H NMR (500 MHz, CDCl3): δ (ppm) 8.23–8.21 (s, 2H), 7.58–7.56 (d, 2H), 7.33–7.26 (d, 2H), 2.33–2.28 (m, 4H), 2.06–2.02 (m, 4H), 0.38–0.33 (t, 12H), ^{13}C NMR(300 MHz, CDCl3): 163.1, 151.8, 148.5, 141.1, 132.3, 124.9, 124.6, 121.7, 54.1, 31.2, 8.7. Fab$^+$-MS *m*/*e*: 526.

2.2. Measurements

The structures of the synthesized compounds were characterized by using NMR, FT-IR, and fast-atomic bombardment (FAB) mass spectrometry. ^{1}H and ^{13}C NMR spectra were recorded on Bruker Avance 300 and Avance 500 spectrometers. The FT-IR spectra were recorded on a Thermo Electron Nicolet IR-200 spectrometer. FAB-mass spectra were recorded on a JEOL, JMS-AX505WA, HP5890 series II. The melting temperatures (T_m), glass-transition temperatures (T_g), crystallization temperatures (T_c), and degradation temperatures (T_d) of the compounds were measured by carrying out differential scanning calorimetry (DSC) under a nitrogen atmosphere with a DSC2910 (TA Instruments) and thermogravimetric analysis (TGA) with a SDP-TGA2960 (TA Instruments). The optical absorption spectra were obtained with a HP 8453 UV–Vis–NIR spectrometer. A Perkin Elmer luminescence spectrometer LS50 (xenon flash tube) was used for photo- and electroluminescence spectroscopy. The redox potentials of the compounds were determined with cyclic voltammetry (CV) by using a WBCS 3000 system with a scanning rate of 100 mV/s. We used a synthetic material coated ITO as the working electrode, a saturated Ag/$AgNO_3$ reference electrode, and acetonitrile (AN) with 0.1 M tetrabutylammonium perchlorate (TBAP) as the electrolyte. Ferrocene was used for potential calibration and for reversibility criteria.

2.3. Fabrication of the OLEDs

All organic layers were deposited under 10^{-6} Torr, with a rate of deposition of 1 Å/s to give an emitting area of 4 mm^2. In these devices, 4,4′,4″-tris(N-(2-naphthyl)-N-phenyl-amino)-triphenylamine [2-TNATA] was used as the hole injection layer, N,N′-bis(naphthalen-1-yl)-N,N′-bis(phenyl)benzidine [NPB] and 4,4′,4″-tri(N-carbazolyl)triphenylamine [TCTA] were used as the hole transporting and exciton blocking layers, respectively, and 8-hydroxyquinoline aluminum [Alq_3] was used as the electron transporting layer [31]. The LiF and aluminum layers were continuously deposited under the same vacuum conditions. The device structures were ITO/2-TNATA (30 nm)/NPB (10 nm)/TCTA (10 nm)/*o*- or *m*- or *p*-TP-EPY (30 nm)/Alq_3 (30 nm)/LiF (1 nm)/Al (200 nm). The current–voltage (I–V) characteristics of the fabricated EL devices were obtained with a Keithley 2400 electrometer. Light intensity was obtained with a Minolta CS-1000A.

2.4. Computational details

The HOMO and LUMO energy levels of the indenopyrazine derivatives were optimized by using the DMol^3 program of Materials Studio 4.3®, which carries out quantum mechanical calculations with density functional theory (DFT). The Perdew, Burke and Ernzerhof (PBE) functional and double numeric polarization basis set was used in the calculations. The structures were optimized by using delocalized internal coordinates; to confirm that each optimized conformation was the minimum structure we performed numerical frequency analysis.

3. Result and discussion

3.1. Synthesis and characterization

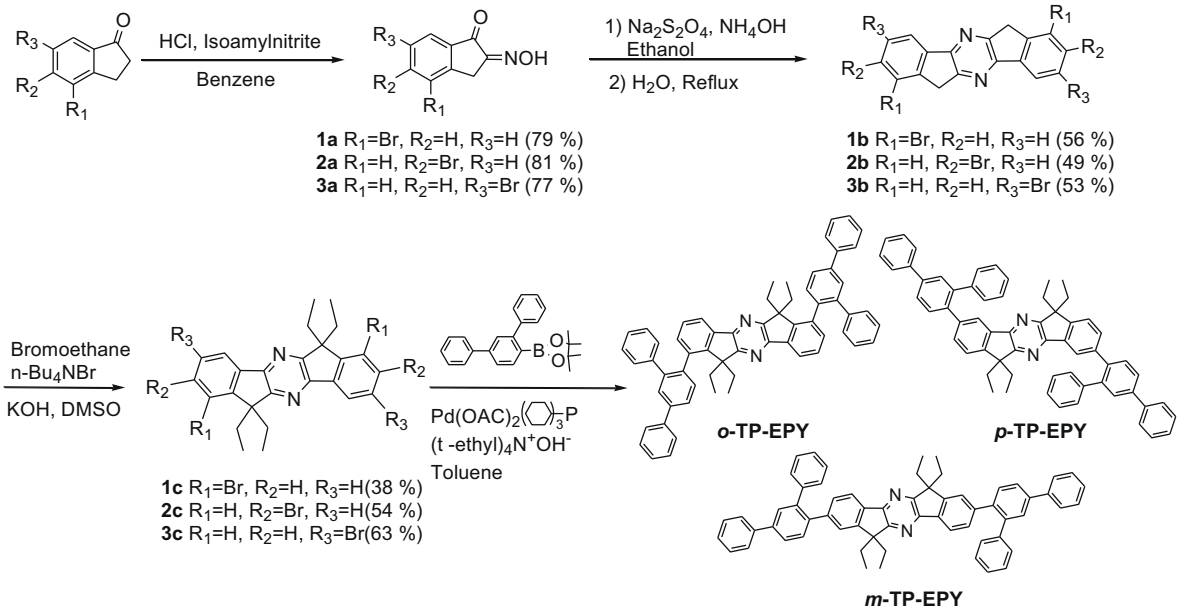
The indenopyrazine derivatives were synthesized according to literature procedures [29]. As shown in Scheme 2, we used bromo-indanones with Br substituted at positions 4, 5, and 6 as the starting compounds. In the first step, the oximes (1a, 2a, 3a) were synthesized via the reaction with isoamylnitrile dropped in under acid conditions. The oximes were then cyclized to synthesize the key intermediate dibromo-indenopyrazines (1b, 2b, 3b) with bromine present at the *ortho*, *meta*, and *para* positions in high yield (overall yield approximately 40%). Since the 6- and 12-position carbons of the synthesized dibromo-indenopyrazines are acidic, these carbons were capped with four ethyl groups (1c, 2c, 3c), and then the tetraethylated dibromo-indenopyrazines were coupled with a borated *m*-terphenyl group by carrying out Suzuki Ar–Ar coupling reactions. This procedure enabled the facile synthesis of *o*-, *m*-, and *p*-TP-EPY, in which *m*-terphenyl is substituted at the *ortho*, *meta*, and *para* positions respectively. The structures of the synthesized compounds were characterized by using NMR, FT-IR, and FAB-mass analysis.

3.2. Optical and electrochemical properties

The UV–visible absorption (Abs) spectra and photoluminescence (PL) spectra for the solution states of *o*-, *m*-, and *p*-TP-EPY are shown in Fig. 1, and the spectral features are summarized in Table 1. The PL quantum yields of the solution states of *m*-TP-EPY, *p*-TP-EPY, and *o*-TP-EPY were determined to be 73%, 61%, and 42%, respectively. As shown in Fig. 1, *the Abs peaks* of *o*-TP-EPY and *p*-TP-EPY were found to be blue-shifted 17 and 15 nm with respect to that of *m*-TP-EPY. In the PL spectra, the maxima for *o*-TP-EPY (411 nm) and *p*-TP-EPY (415 nm) were blue-shifted 26 and 22 nm, respectively with respect to that of *m*-TP-EPY at 437 nm, thereby moving these spectra from the blue region to the violet region. These findings suggest that changing the substitution position alters the intrinsic optical properties of the molecule.

These phenomena were also observed for the thin-film states, as shown in Fig. 2: *the Abs peaks* of *o*-TP-EPY (389 nm) and *p*-TP-EPY (390 nm) are blue-shifted 19 and 18 nm with respect to that of *m*-TP-EPY (408 nm), and the PL spectra maxima of *o*-TP-EPY (418 nm) and *p*-TP-EPY (426 nm) are blue-shifted 25 and 17 nm, respectively with respect to that of *m*-TP-EPY at 443 nm. Moreover, the minute differences of 6–11 nm between the PL spectral values of the solution and thin-film states for each derivative indicate that the short alkyl chains (ethyl) at carbon positions 6 and 12 of indenopyrazine and the *m*-terphenyl side groups on the aromatic rings effectively suppress the π–π^* stacking of the molecules regardless of whether the substitution pattern is *ortho*, *meta*, or *para*. In addition, the full widths at half maximum (FWHMs) of the PL spectra for the thin-film state are 43 nm for *o*-TP-EPY and *p*-TP-EPY, but 54 nm for *m*-TP-EPY. The sharper spectra of *o*-TP-EPY and *p*-TP-EPY probably arise because these molecules have fewer electron transition states than *m*-TP-EPY.

The energy bands, and the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of *o*-, *m*-, and *p*-TP-EPY were estimated with cyclic voltammetry (CV) and through absorption edge analysis by using a plot of ($h\nu$) vs. $(\alpha h\nu)^2$, where α, h, and ν are the absorbance, Planck's constant, and the frequency of light; the results are summarized in Table 1 [23]. The HOMO levels of *o*-TP-EPY and *p*-TP-EPY are 6.13 and 6.07 eV, respectively, which are slightly lower by 0.10



Scheme 2. Synthetic routes for *o*-, *m*-, and *p*-TP-EPY.

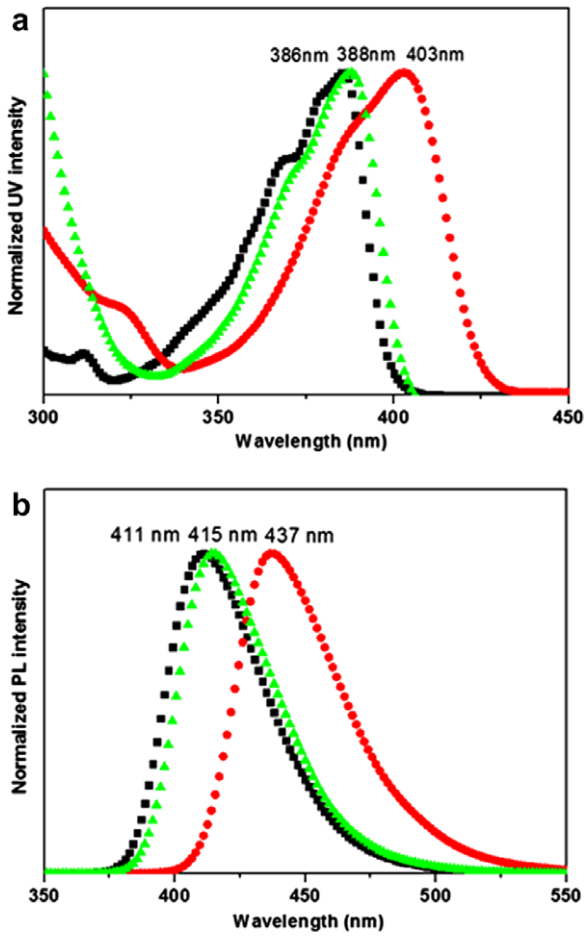


Fig. 1. Normalized UV and PL spectra of *o*-TP-EPY (■), *m*-TP-EPY (●), and *p*-TP-EPY (▲) in $CHCl_3$ (1.00×10^{-5} M) solution.

and 0.04 eV, respectively than the HOMO level of *m*-TP-EPY at 6.03 eV. The band gaps of *o*-TP-EPY and *p*-TP-EPY were found to be 0.21 and 0.24 eV wider, respectively than that of *m*-TP-EPY.

3.3. Theoretical calculations

In an attempt to theoretically explain the observed variations in the optical and electronic properties of the indenopyrazine core system with the substitution position of the *m*-terphenyl side group, we performed frontier molecular orbital calculations to determine the electron density distributions of ethyl indenopyrazine (EIP-core), and *o*-, *m*-, and *p*-TP-EPY (Fig. 3). The structures of the indenopyrazine derivatives were optimized by using the DMol[3] program of Materials Studio 4.3®, which carries out quantum mechanical calculations with density functional theory (DFT). The Perdew, Burke and Ernzerhof (PBE) functional and double numeric polarization basis set was used in the calculations [32–34]. The most remarkable result obtained from the molecular orbital analysis is that the lobe of the orbital at the junction points of the *ortho* and *para* positions of the EIP-core and side groups is smaller than the lobe of the orbital at the junction point of the *meta* position, in both the HOMO and LUMO as shown in Fig. 3. In particular, a node was found at the junction points of the *ortho* and *para* positions for the HOMO and the LUMO. Therefore, whereas there is an extension of the conjugation in *m*-TP-EPY from the EIP-core to the *m*-terphenyl group, the nodes observed for *o*-TP-EPY and *p*-TP-EPY indicate that these molecules are less conjugated than *m*-TP-EPY. This difference in conjugation means that the energy gaps decrease in the order *o*-TP-EPY > *p*-TP-EPY > *m*-TP-EPY, as shown in Table 1. In addition, this trend explains the spectral phenomena shown in Fig. 1, such as the larger blue shift in the *Abs* and PL spectra induced by substitution of the *m*-terphenyl group at the *ortho* and *para* positions, and the wider band gaps. These findings establish that the π-conjugation of the indenopyrazine derivatives can be adjusted by placing side groups at the node or lobe of the electron distribution of the indenopyrazine core system (Fig. 3(a)). Thus, in efforts to develop optoelectronics devices based on π-conjugated molecules, physical characteristics such as their optical and electronic properties can be systematically controlled according to the electron density distribution of the orbital at the position where the side group attaches to the molecular core.

3.4. Thermal properties

The thermal properties of the synthesized substances were determined by using thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The results are summarized in Table 2. The T_m values of the synthesized *o*-, *m*-, and *p*-TP-EPY derivatives were found to be 365, 338, and 317 °C, respectively, which are more than 110 °C higher than the T_m of the commercial blue luminous material 4,4′-bis(2,2-diphenylvinyl)-1,1′-biphenyl (DPVBi),

Table 1
Optical and electrical properties of the synthesized compounds.

	UV_{max}[a] (nm)	PL_{max}[a] (nm)	Q.Y[b] (%)	UV_{max}[c] (nm)	PL_{max}[c] (nm)	FWHM[c]	HOMO (eV)	LUMO (eV)	ΔE_{exp}[d] (eV)	ΔE_{cal}[e] (eV)

which is 204 °C. The T_g values of *m*-TP-EPY and *p*-TP-EPY are 129 and 127 °C, respectively, which are approximately twice as high as that of DPVBi, 64 °C [29]. In the case of a thin-film of *m*-TP-EPY, the average surface roughness (R_a) measured with atomic force microscopy (AFM) was found to undergo almost no change in comparison to that of a DPVBi film after storage at 65 °C for 24 h [29]. Improved lifetimes of the synthesized substances in OLED devices are anticipated [35].

3.5. Electroluminescence properties

To determine whether the changes with substitution position in the intrinsic molecular properties are reflected in OLED (a representative optoelectronics device) performance, non-doped OLED devices were fabricated with the synthesized compounds as the emitting material layer (EML). The results are summarized in Table 3 and Fig. 4. The most important observation is that the electroluminescence (EL) spectra of *o*-TP-EPY and *p*-TP-EPY have maxima at 419 and 423 nm, respectively, which are blue-shifted 21 and 17 nm with respect to the peak for *m*-TP-EPY at 440 nm (see Fig. 4). This trend in the EL spectra is

Table 2
Thermal properties of *o*-, *m*-, and *p*-TP-EPY.

	T_g (°C)	T_c (°C)	T_m (°C)	T_d (°C)
o-TP-EPY	–	–	365	403
m-TP-EPY	129	167	338	441
p-TP-EPY	127	165	317	442

in good agreement with the shifts from the blue region to the violet region observed in the PL spectra of the thin-films. In addition, the EL spectra of *o*-TP-EPY and *p*-TP-EPY are sharper than the *m*-TP-EPY EL spectrum, as reflected in the FWHMs (43 and 42 nm for *o*-TP-EPY and *p*-TP-EPY, respectively, compared to 47 nm for *m*-TP-EPY). Such narrow emission spectra can result in pure colors, which is advantageous for emitting materials. In terms of the Commission Internationale de l'Eclairage (CIE) coordinates, the *y*-axis values of *o*-TP-EPY and *p*-TP-EPY are 0.068 and 0.063 that is, closer to the violet region than the value of 0.078 for *m*-TP-EPY. These CIE coordinates show that adjusting the π-conjugation by varying the junction position of the side group attached to the indenopyrazine core system changes the optical and electronic properties, and that such changes can be exploited in OLEDs. The EL devices were found to exhibit power efficiencies and external quantum efficiencies (EQE). in the ranges 0.16–0.9 lm/W and 1.2–4.6%, respectively, at 10 mA/cm^2 (see Table 3). The EQE of the *m*-TP-EPY device

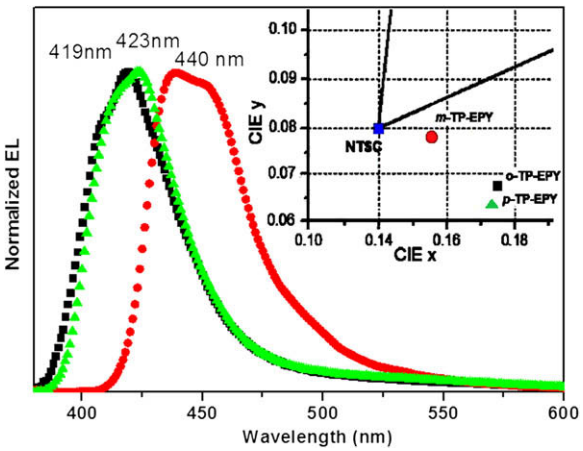

Fig. 4. EL spectra of *o*-TP-EPY (■), *m*-TP-EPY (●), and *p*-TP-EPY (▲) in OLED devices. The inset shows the CIE (*x*, *y*) coordinates of the *o*-, *m*-, and *p*-TP-EPY devices.

was 4.61%, which is 3.6 and 2.4 times the values for *o*-TP-EPY (1.27%) and *p*-TP-EPY (1.88%), respectively. This difference can be explained by the following two factors. First, *m*-TP-EPY has a higher PL quantum yield (73%) compared to *o*-TP-EPY (42%) and *p*-TP-EPY (61%). Second, *o*-TP-EPY and *p*-TP-EPY exhibit wider band gaps (3.11 and 3.08 eV) than *m*-TP-EPY (2.87 eV), making carrier injection difficult in OLED devices based on *o*-TP-EPY and *p*-TP-EPY. These factors caused the EL efficiency of *o*-TP-EPY and *p*-TP-EPY to be lower than that of *m*-TP-EPY. The EQE for *p*-TP-EPY, 1.88%, is superb; the excellent violet emitting materials presented previously, F_2PA and CBP, have EQE values of 1.95% and 1.25%, respectively [36,37].

4. Conclusions

New indenopyrazine derivatives with bulky *m*-terphenyl side groups substituted at the *ortho*, *meta*, or *para* junction positions were successfully synthesized. There are larger blue shifts in the *Abs* and PL spectra of *o*-TP-EPY and *p*-TP-EPY than in those of *m*-TP-EPY for both the solution and thin-film states, resulting in violet PL emission. These findings are consistent with the results of our molecular calculations, which indicate that the side group position on the indenopyrazine core, in particular whether the side group coincides with a node or lobe in the orbital structure, affects the π-conjugation of the molecule and hence alters the optical properties. These changes in optical properties are reflected in the behavior of the non-doped OLED devices fabricated using the synthesized compounds. In particular, the device containing *p*-TP-EPY (high T_g, 127 °C) was found to exhibit excellent properties: an EL spectrum with a peak at 423 nm for violet emission at CIE coordinates (0.173, 0.063) and an EQE of 1.88%.

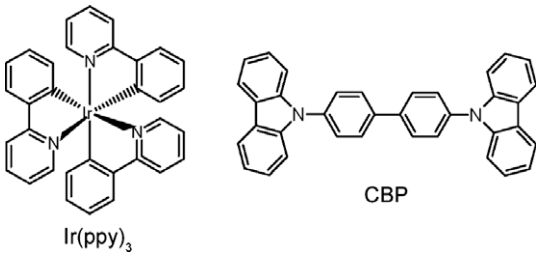

Fig. 1. The chemical structures of $Ir(ppy)_3$ and CBP.

as indicated below, injection of holes from the MoO_x film is quite significant and we can still observe well-defined transistor output characteristics.

Fig. 2a shows the output characteristics of a TFT with 100% of $Ir(ppy)_3$ at room temperature (292 K). Well-defined *p*-type current–voltage curves can be observed. Applying the standard expressions of

$$I_D = \frac{W}{L}\mu_{LIN}C_i\left[V_D(V_G - V_T) - \frac{V_D^2}{2}\right] \quad (1)$$

$$I_D = \frac{W}{2L}\mu_{SAT}C_i(V_G - V_T)^2 \quad (2)$$

one can extract the hole mobility of $Ir(ppy)_3$ [15]. In Eqs. (1) and (2), W (=9 mm) and L (=50 μm) are the channel width and length, respectively; C_i is the capacitance of gate dielectric per unit area; V_T is the threshold voltage; V_G and V_D are the gate bias and the potential difference across the *S*/*D* electrodes, respectively; μ_{LIN} and μ_{SAT} are the field effect (FE) mobility extracted from the linear and saturation regions, respectively. The results are $\mu_{LIN} = 9.5 \times 10^{-6}\ cm^2\ V^{-1}\ s^{-1}$, and $\mu_{SAT} = 1.7 \times 10^{-5}\ cm^2\ V^{-1}\ s^{-1}$. These values fall into the range of mobility values that are typical for an amorphous organic hole transporter for OLED applications. For example, when NPB, one of the most widely used amorphous organic hole transporters in OLEDs, was measured with the same method, a FE mobility of $2.4 \times 10^{-5}\ cm^2\ V^{-1}\ s^{-1}$ was obtained in the saturation region [10]. Judging from the values of the hole mobility, one can also view $Ir(ppy)_3$ as a rather good organic hole transporter.

Fig. 2b shows the output characteristics of pristine film of CBP. Despite the rather large HOMO value of CBP (~5.8 eV), one can still observe well-behaved output characteristics of a typical TFT. The result is consistent with recent reports that MoO_x films possess a work function approaching 6 eV and thus facilitate the injection of holes into the CBP film [16]. Using the same analysis as outlined for $Ir(ppy)_3$, we obtained $\mu_{LIN} = 1.2 \times 10^{-5}\ cm^2\ V^{-1}\ s^{-1}$, $\mu_{SAT} = 1.5 \times 10^{-5}\ cm^2\ V^{-1}\ s^{-1}$ for CBP in the linear and saturation, respectively.

In a POLED, $Ir(ppy)_3$ is most often present as a dopant in CBP rather than a host [5–7]. Therefore, it would be interesting to study a film of $Ir(ppy)_3$-doped CBP film. The TFT characteristics of such a film consisting of 20% $Ir(ppy)_3$ doped into CBP is shown in the inset of Fig. 3. Compared to the pristine (100%) $Ir(ppy)_3$ film, the output current I_D

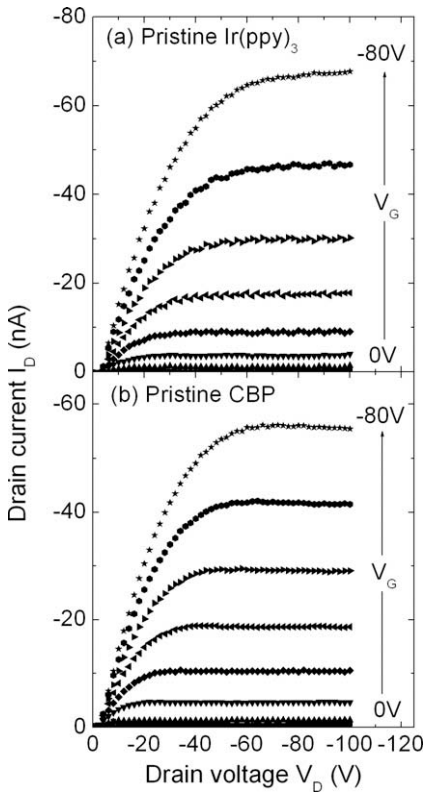

Fig. 2. Output characteristics of top contact OTFTs with 100 nm of (a) $Ir(ppy)_3$ and (b) CBP at 292 K. The gate voltages increase in steps of −10 V starting from 0 V to −80 V.

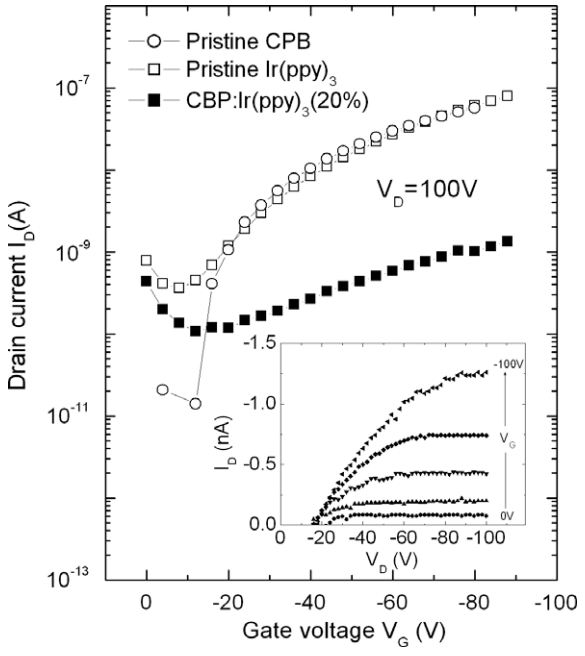

Fig. 3. Transfer characteristics of OTFT with 100 nm of pristine $Ir(ppy)_3$ (□), CBP:$Ir(ppy)_3$ (20%) (■) and pristine CBP (○). The inset shows the output characteristics of a TFT with CBP:$Ir(ppy)_3$ (20%).

for the doped film is substantially lowered. The extracted FE mobility in the saturation region is $\mu_{SAT} = 1.7 \times 10^{-7}\,cm^2\,V^{-1}\,s^{-1}$. The value is two orders of magnitude smaller than the pristine Ir(ppy)$_3$ film. Due to the large HOMO difference between CBP and Ir(ppy)$_3$, it is unlikely that holes can be injected into the CBP molecules directly. Instead, holes are expected to be directly injected to the dopant molecules Ir(ppy)$_3$ from the source electrode. Once injected, holes are expected to hop among the dopant molecules rather than the host. So, it is expected the hole mobility will decrease if the doping concentration is reduced. Following this line of thought, we doped the CBP film with lower concentrations (e.g. 10%) of Ir(ppy)$_3$. However, the signals were barely detectable and no reliable mobility values can be obtained. Fig. 3 is a summary of the room temperature transfer characteristics of the samples used in this study. Pristine films of Ir(ppy)$_3$ or CBP have well-defined transfer characteristics. In contrast, when Ir(ppy)$_3$ acts as a dopant in CBP, the output hole current is substantially reduced.

Having established Ir(ppy)$_3$ all by itself is a good hole transporter, we explore its conductivity mechanism further by measuring the temperature dependent characteristics. The results were then analyzed by the Gaussian disorder model (GDM) that is widely employed to describe hopping conduction in amorphous organic materials [17]. In the GDM, an amorphous organic material is treated as an ensemble of transporting sites for hopping conduction. The carrier mobility is field and temperature dependent. The GDM can be described as follows [17]:

$$\mu(F,T) = \mu_\infty \exp\left[-\left(\frac{2\sigma}{3kT}\right)^2\right] \exp\left\{CF^{\frac{1}{2}}\left[\left(\frac{\sigma}{kT}\right)^2 - \Sigma^2\right]\right\} \quad (3)$$

F, T, and k are the applied electric field, the absolute temperature and the Boltzmann constant; μ_∞ is the high temperature limit of mobility, and C is a constant. The energetic disorder σ can be interpreted as the width of Gaussian distribution of DOS of energy for the transporting sites; the positional disorder Σ describes the geometric randomness of the material. At low field ($F \to 0$), the second exponential term in Eq. (3) approaches 1, and thus, $\mu(0,T) \sim \exp[-4/9(\sigma/kT)^2]$. So, a semi-log plot of low field mobilities vs $1/T^2$ should yield a straight line. The slope of this line can be used to extract σ. Following this idea, we plot the FE mobilities extracted in low field region, i.e. the linear region in Fig. 2a. The results are shown in Fig. 4 as hollow squares. The solid line is the best fit to the TFT data. The extracted σ for Ir(ppy)$_3$ in an OTFT is 88 meV. The result is quite comparable to the data obtained from the FE mobility measurements of other amorphous organic hole transporters, such as phenylamine compounds (e.g. NPB) [10,11,18]. In those cases, the extracted σ are in the range 80–90 meV.

Beside pristine Ir(ppy)$_3$, we have, in addition, studied the temperature dependent transport of pristine CBP and Ir(ppy)$_3$-doped CBP (20%). The results are shown in Fig. 4. The extracted σ and μ_∞ of pristine CBP are 95 meV and $7.3 \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$, respectively. The extracted μ_∞ for Ir(ppy)$_3$-doped CBP is substantially reduced by two orders of magnitude to about $5.0 \times 10^{-5}\,cm^2\,V^{-1}\,s^{-1}$. The reduction in μ_∞ indicates the increase in charge hopping distance in the Ir(ppy)$_3$-doped CBP film.

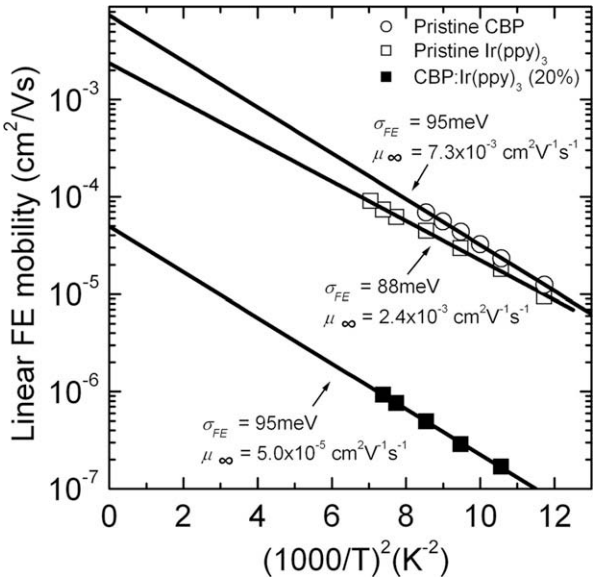

Fig. 4. Linear FE mobilities vs $(1/T)^2$ for Ir(ppy)$_3$ (□), CBP (○) and CBP:Ir(ppy)$_3$ (20%) (■). The energetic disorder and the high temperature limit of mobilities can be extracted from the plot. The straight lines are the best fits to the data.

The present report describes the hole transport behaviors of Ir(ppy)$_3$ and Ir(ppy)$_3$-doped CBP. However, it has direct relevance for explaining device operation and optimization. As Ir(ppy)$_3$ possesses significant hole mobility, it can potentially act directly as hole transporting component in a POLED. Furthermore, due to its relatively small HOMO value of ~5.2 eV, it can either function as a hole injection material itself and/or the target for hole injection from the anode. One recent demonstration shows, indeed, it is possible to have direct hole injection from the anode into Ir(ppy)$_3$-doped CBP [19,20]. With this realization, one can eliminate the hole-injection layer in a POLED and simplify device structure.

Finally, we want to emphasize the advantage of using TFT technique to study carrier transport in amorphous organic electronic materials. In principle, only a few monolayers (~10 nm) are required to form a complete conducting channel in an organic TFT [10]. In contrast, much thicker organic films are needed for other experimental techniques, e.g., time-of-flight or admittance spectroscopy [21–23]. Thus, TFT technique can provide a powerful platform for mobility determination when the material under investigation is in limited quantity.

characteristics. A built-in potential has been found and evaluated to describe the charge distribution at the p–p junction interface. Finally, the interface electronic structure was depicted to explain the ambipolar charge transport behavior.

Oxotitanium phthalocyanine (TiOPc) is an intrinsic molecular semiconductor that has a special electrical behavior depending on measuring ambient, which is electron-type in inert ambient and hole-type in air [11]. This trait makes it to be an excellent probe-molecule to investigate charge-carrier transport behavior in organic semiconductor. Copper phthalocyanine (CuPc) is a classical semiconductor defined as hole-type material, which possesses high chemical and thermal stability that are attractive for practical application [12]. Moreover, they belong to the same phthalocyanine family holding good molecular compatibility that is especially important for bilayer heterojunction devices. Based on the above reasons, we prepared organic p–p junction composed of CuPc/TiOPc.

2. Experiment

OFET devices with top contact were fabricated according to the following procedure (Fig. 1a). Heavily doped n-type silicon wafers (0.01–0.15 Ω cm) were acted as gate electrode and substrate. A layer of silicon dioxide (SiO_2) film with unit capacitance of 10 nF/cm^{-2} was served as gate insulator by thermal oxidation covered on the substrate. The OTS thin film acts as the modified layer covered on the surface of SiO_2 by inserting the substrate to OTS solution (chloroform as solvent, 2 mM) for 1 day. The wafers were ultrasonically cleaned with acetone, isopropyl alcohol, and ultra purified water, respectively. TiOPc with 5 nm and CuPc with 15 nm were deposited in succession at a base pressure of $(4–5) \times 10^{-4}$ Pa at a rate of 1 Å s^{-1} (it is recorded by quartz crystal oscillate), while the substrates were held at 200 °C. Subsequently to prepare the source/drain electrodes, 15 nm Au and 30 nm Al films were evaporated through shadow masks defining channel width of 3800 μm and length of 180 μm, respectively. The introduction of Al film could effectively protect Au layer from measured probe. Furthermore, organic metal–oxide–semiconductor (MOS) structures (Fig. 1b) and diodes were also fabricated and held with the same conditions described above. All organic source samples were purchased from Sigma–Aldrich without further purification. *IV* and *C–V* characteristics were performed at room temperature in air by Agilent 4155C and E4980A, respectively.

3. Results and discussion

OFET devices with top contact and the corresponding organic metal–oxide–semiconductor (MOS) structures were fabricated according to the description in experimen-

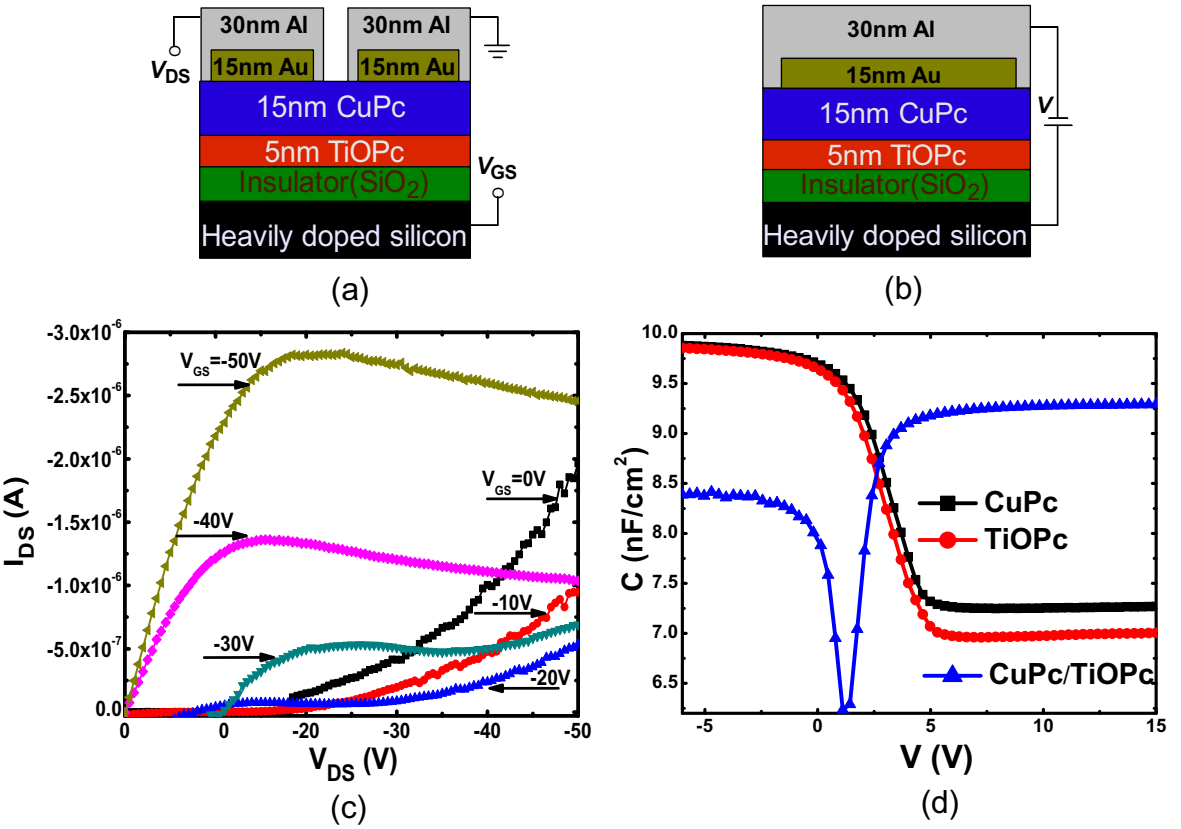

Fig. 1. Schematic cross-section of CuPc/TiOPc heterojunction. (a) FETs and (b) MOS structures. (c) Ambipolar characteristics of CuPc/TiOPc FETs. (d) Capacitance as a function of gate voltage for TiOPc, CuPc, and CuPc/TiOPc MOS structures at 1 kHz.

tal section shown in Fig. 1a and b. Gold with high work function (i.e., 5.1 eV) and Aluminum with low work function (i.e., 4.3 eV) were deposited to act as source/drain electrodes so that both electron and hole can be injected to organic semiconductors. Furthermore, the added Al thin film can effectively avoid damage by measuring probe because it is harder than Au film. The double active layers were prepared by combination TiOPc and CuPc, TiOPc deposited as the bottom layer and CuPc as the upper layer. In this case, CuPc actually also act as a prevent layer to protect TiOPc from air. Fig. 1c shows the output curves of CuPc/TiOPc-based transistors. By applying gate voltage (V_{GS}) from 0 to −20 V, the source-drain current (I_{DS}) displayed a drop step by step by scanning drain voltage (V_{DS}) from 0 to −50 V. It was attributed to electron-current, which was depleted by continuously increasing V_{GS}. The device show diode like curves at the low V_{GS}, which presents a typical ambipolar FET feature [13]. A current inversion appeared when V_{GS} was −30 V, and linear and saturation regions were observed at V_{GS} from −30 to −50 V. This indicated hole current has emerged and simultaneously electron-current has been full depleted. As a result, typical ambipolar behavior has been observed in FET.

For further clarifying bi-carrier transport, *C–V* characteristics of MOS structures were presented in (Fig. 1d). The applied frequency was 1 kHz. Note that the *C–V* properties of MOS have an apparent dependence on measuring frequency. When applying a low frequency region (i.e., <100 Hz), interface state will result in inversion phenomenon and decreased accumulation capacitance. Therefore, high frequency (1 kHz) should be used during *CV* measurement for excluding interface state effects. Furthermore, *CV* curves of single-layer TiOPc and single-layer CuPc were inserted for comparison. Firstly, single hole-only charge process was found in single-layer TiOPc and single-layer CuPc MOS structures by scanning bias from −6 to +15 V. Accumulation and depletion regions for hole current may be clearly observed at negative and positive bias, respectively. This represented holes dominated in TiOPc or CuPc and the inversion mode was not appeared. In respect of double-layer junction MOS, holes were firstly accumulated at the bias range of −5–0 V, then it were gradually depleted in the bias range of 0–1 V, finally an inversion region emerged that meant electron-current has dominated and accumulated in diode. Moreover, the capacitance of junction diode at hole accumulation region was smaller than that of single-layer devices. It is probably due to the accumulated holes at the CuPc layer, the introduction of TiOPc has formed double gate insulators that resulted in a low capacitance. It may be described by $C_h = \varepsilon\varepsilon_0 S/d$, assuming to be the same ε (dielectric constant) for TiOPc and SiO_2, in this case the increase of thickness of insulator led to lower capacitance [12]. Here, ε_0 and d are the vacuum permittivity, and dielectric layer thickness, respectively. As a result, two kinds of current types including holes and electrons have been demonstrated from p–p type CuPc/TiOPc junction.

For further ascertaining the electrical structures of junction interface, the corresponding diode characteristics were provided (Fig. 2a), the inset is diode configuration. To single-layer diodes (TiOPc or CuPc), symmetrical current at forward and reverse bias implied two electrodes (Heavily doped Si and Au) have a good contact behavior with TiOPc or CuPc for charge injection and extraction. However, the rectifying characteristic (rectifying ratio is 20) was found from the CuPc/TiOPc junction diode. This result revealed that the rectification came from the interface of two semiconductors and a built-in electric field (E_{bi}) was existence. From the rectifying direction, E_{bi} directed from CuPc to TiOPc. Fig. 2b shows the resistance–voltage curves of CuPc/TiOPc diode, in which diode resistance (R_d) represented bulk resistance (R_b) for single-layer TiOPc and CuPc devices in contrast to R_d represented a sum of R_b and junction resistance (R_j) for double-layer CuPc/TiOPc device. Considering junction diode, the R_d was 0.82 kΩ at forward bias and 17 kΩ at reverse bias. Under reverse bias, the applied bias mainly dropped at the interface and R_j dominated in R_d. In this case, E_{bi} was gradually strengthened with the increase of bias that led to an increase of R_j. The R_d reached a saturate value of 17 kΩ at a reverse bias of −0.3 V. As applying forward bias, the R_d was sharply decreased at a bias range from 0 to 0.47 V due to the E_{bi} was gradually weakened. The R_j was counteracted when applied bias was larger than 0.47 V. At this time, R_j fully represented R_b with 0.82 *k*Ω.

Moreover, the *C–V* Properties of diodes were presented to clarify the above *I–V* results. Fig. 2c shows the *C–V* characteristics of junction diode in the frequency of 1 kHz. A peak capacitance was observed when the applied voltage reached 0.47 V. This value revealed that the built-in potential (V_{bi}) was approximately 0.47 V that shows good consistent with *IV* measuring result deduced by Anderson's model equations [14,15]:

$$C_j = A\sqrt{\frac{q\varepsilon_s N_A N_D}{(N_A + N_D)}}(V_{bi} - V)^{-\frac{1}{2}} \quad (1)$$

where q is the electronic charge, ε_s is the dielectric constant of semiconductors. N_D and N_A are the doping densities of in TiOPc and CuPc, respectively. V_{bi} and V are built-in electric voltage and applied voltage. From this equation, the capacitance (C_j) exhibits a peak value when V_{bi} is equal to V. Moreover, charge transport mechanism in organic junction was studied by simulating *IV* characteristics using the following equation:

$$I = I_0\left[\exp\left(\frac{qV}{nkT}\right) - 1\right] \quad (2)$$

where I_0 refers to reverse bias the saturation current, k is the Boltzmann constant, T is the temperature. n is an ideality factor for general Shockley theory. By setting n was 13.2, we can observed that the simulation results are well match for the experiment results (Fig. 2d). It herein needs to point out that the ideality factors have a strong dependence on temperature that is inconsistent with the conventional Shockley theory [15].

Based on *IV* and *CV* analysis, we depicted the energy level diagram of CuPc/TiOPc as shown in (Fig. 3a). Their Fermi levels are aligned when put TiOPc and CuPc together under thermal equilibrium condition. The highest occupied molecular orbit (HOMO) of CuPc bends upward to accumulate holes and the lowest unoccupied molecular orbit

(LUMO) of TiOPc bends downward to accumulate electrons, which cause ambipolar transport behavior in FETs. Thus an E_{bi} is formed with direction from CuPc to TiOPc. ΔE_{HOMO} and ΔE_{LUMO} were the band offsets for two semiconductors, respectively. The V_{bi} is a sum of V_{D1} and V_{D2}, which is also equal to the difference of bulk Fermi levels between two semiconductors. The HOMO and LUMO data for CuPc and TiOPc can be found from elsewhere [16]. Finally, schematic diagrams of charge distribution were provided to describe the transformation of carriers' distribution from two single-layer films to an organic p–p junction shown in Fig. 3b. It should be noted that all unique characteristics for organic junction come from charge migration by the alignment of Fermi level. Based on the above analysis, we can deduce the accumulated charge are transported in different layers that electron and hole is flowed in TiOPc and CuPc layer, respectively. In this case, hole-transport in CuPc should be influenced by TiOPc film morphology. The film roughness of bottom layer and crystalline structure match of two films play key roles for ambipolar transport. In current work, both TiOPc and CuPc has phthalocyanine ring as ligand that possess similar crystalline growth mode, which result in good film compatibility. As a result, we believe that the match of interface electric structure and film morphology are two important respects to realize ambipolar transport.

Recent progress displayed that organic semiconductors have native capability for transport both electron and hole [17]. The key factor is how to offer proper interface for both electron and hole accumulation at a single device. Moreover, localized states at the interface often acts as charge trap to impede the form of conductive channel in OFET. Therefore, the functional interface should be introduced to develop ambipolar devices. Several effective methods including of modifying gate insulator or using polymer insulator (i.e., PVA) with OH-group have been proved to easily realize for ambipolar transport [18,19]. Therefore, organic heterojunction may also be considered to offer a

new interface for the accumulation of either electron or hole. In respect of organic heterojunction, the film quality of bottom layer including of surface roughness, surface energy, chemical properties, crystalline structure etc. will influence on charge-type and transport capability.

4. Conclusion

In summary, ambipolar charge transport has been demonstrated in CuPc/TiOPc junction by *IV* and *CV* FET measurements. A built-in electric field was confirmed by diode analysis. Its direction and electric potential were also addressed. All results indicated that both electrons and holes are located at the interface of p–p junction and can be driven by external electric field. Therefore, bi-carrier transport may be realized based on two conventional defined p-type materials. Current studies will be helpful for fundamental comprehensions on the charge transport in organic junction.

2. Experimental

2.1. Materials

1-Iodo-2-bromobenzene, *n*-butyllithium (n-BuLi), chlorodiphenylphosphine, *N*-bromosuccinimide, naphthalene-1-boronic acid, tetrakis(triphenylphosphine)palladium(0), potassium carbonate, 2,7-dibromo-9-fluorenone were purchased from the Aldrich Chem. Co. and used without further purification. Hydrogen peroxide was obtained from the Duksan Sci. Co. and used without further purification. Tetrahydrofuran (THF) was distilled over sodium and calcium hydride.

2.2. Synthesis

The synthetic route of SPPO21 is shown in Scheme 1. The synthesis of 1-(2-bromophenyl)naphthalene (**1**) and 2,7-dibromospiro[fluorene-7,11′-benzofluorene] (**2**) was described in a previous work [9].

2.3. 2,7-Bis(diphenylphosphino)spiro[fluorene-7,11′-benzofluorene] (*3*)

2,7-Dibromospiro[fluorene-7,11′-benzofluorene] (0.97 g, 1.85 mmol) was dissolved in THF. The solution was cooled to −78 °C and n-BuLi (10 M in hexane, 0.46 mL) was slowly added dropwise. The solution was stirred for 3 h and then a solution of chlorodiphenylphosphine (1.02 g, 4.62 mmol) was added under an argon atmosphere. The resulting mixture was gradually warmed to ambient temperature and quenched with methanol. The mixture was extracted with dichloromethane, and the combined organic layers were dried over magnesium sulfate, filtered and evaporated at a reduced pressure. The white powder that was obtained was purified using column chromatography.

2.4. 2,7-Bis(diphenylphosphoryl)spiro[fluorene-7,11′-benzofluorene] (SPPO21)

A mixture of 2,7-bis(diphenylphosphino)spiro[fluorene-7,11′-benzofluorene] (0.845 g, 1.14 mmol), dichloromethane (10 mL), and 2 mL of 30% hydrogen peroxide was stirred overnight at room temperature. The organic layer was separated and washed with dichloromethane and water. The extract was dried through evaporation to produce a white solid, which was further purified using column chromatography with a final yield of 0.74 g.

SPPO21 yield 83%. T_g 135 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.75–8.71 (d, 1H), 8.34–7.30 (d, 1H), 7.95–7.84 (m, 3H), 7.70–7.41 (m, 15H), 7.35–7.20 (m, 12H), 7.13–7.06 (d, 2H) 6.73–6.69 (d, 2H). MS (FAB) *m/z* 767 [(M+1)+].

2.5. Characterization

The ^{1}H nuclear magnetic resonance (NMR) was obtained using a Varian 200 (200 MHz) spectrometer. The photoluminescence (PL) spectra were recorded on a fluorescence spectrophotometer (HITACHI, F-7000), and the ultraviolet–visible (UV–vis) spectra were obtained using a UV–vis spectrophotometer (Shimadzu, UV-2501PC). The transition temperature measurements for SPPO21 were carried out using a differential scanning calorimeter (DSC, Mettler DSC 822) at a heating rate of 10 °C/min under a nitrogen atmosphere. The low and high resolution mass spectra were recorded using a JEOL, JMS-AX505WA spectrometer in the FAB (fast atom bombardment) mode. The energy levels were measured using cyclic voltammetry (CV). Atomic force microscopic (AFM) measurements were performed on the evaporated SPPO21 film in order to study the morphological stability of the film.

2.6. Device fabrication

A basic device configuration of indium tin oxide (ITO, 150 nm)/N,N′-diphenyl-N,N′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/N,N′-di(1-naphthyl)-N,N′-diphenylbenzidine (NPB, 20 nm)/4,4′,4″-tris(N-carbazolyl)triphenylamine (TCTA, 10 nm)/SPPO21: iridium(III) bis(2-phenylquinoline) acetylacetonate ($Ir(pq)_2acac$, 30 nm, ×%)/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, 5 nm)/tris(8-hydroxyquinoline) aluminum (Alq_3, 20 nm)/LiF(1 nm)/Al(200 nm) was used for the device fabrication. Various doping

concentrations of 1% (device I), 2% (device II), 3% (device III), 5% (device IV) and 10% (device V) were used for the red emitting layer. The device structures of the red PHOLEDs are shown in Fig. 1. The photoluminescence (PL) measurements were carried out for $Ir(pq)_2acac$ doped SPPO21 using a fluorescence spectrophotometer. $Ir(pq)_2acac$ doped solid films with the same doping concentration as the red devices were fabricated for the PL measurements. The current density–voltage–luminance and electroluminescence (EL) characteristics of the red PHOLEDs were measured using a Keithley 2400 source measurement unit and a CS 1000 spectroradiometer. The external quantum efficiency was calculated from the EL spectra, luminance and current density. Lambertian distribution of the light emission was assumed in the calculation of the quantum efficiency and the light emission in the forward direction was measured.

3. Results and discussion

SPPO21 was synthesized through the phosphonation reaction of dibromospirobenzofluorene with chlorodiphenylphosphine. Dibromospirobenzofluorene was effectively prepared through the reaction of dibromofluorenone with 2-bromobiphenyl followed by lithiation and dehydration [9]. The synthetic yield of SPPO21 was 83%, and after purification using column chromatography, the purity of SPPO21 was over 99%. The synthetic scheme of SPPO21 is shown in Scheme 1. SPPO21 was fully characterized using ^1H NMR, high performance liquid chromatography, differential scanning calorimetry and high resolution mass spectrometry.

SPPO21, containing a spirobenzofluorene unit and two diphenylphophine units, was used as the electron transporting host material for the red phosphorescent dopant. The spirobenzofluorene moiety has good thermal and morphological stability because of its rigid benzofluorene unit [9]. Additionally, the spirobenzofluorene unit has a triplet bandgap of 2.4 eV, and can be applied as a molecular backbone for the host in red PHOLEDs. The phosphine oxide group isolates the core structure and has electron withdrawing characteristics because of its polarity [10,11]. Therefore, the electron transport properties of the molecule were enhanced by the phosphine oxide group and SPPO21 was an efficient electron transport type host material. Additionally, the energy levels of SPPO21 were effectively managed by the two electron withdrawing phosphine oxide units for efficient electron injection.

Fig. 2 shows the UV–vis and PL spectra of SPPO21. The PL spectra were obtained at both room temperature and 77 K in order to measure the triplet bandgap of SPPO21. SPPO21 exhibited strong absorption peaks at 297 and 340 nm, which corresponded to the absorption of the spirobenzofluorene unit. On the other hand, the diphenylphosphine oxide group did not greatly contribute to the optical absorption. A bandgap of 3.55 eV was calculated for SPPO21 using the absorption edge of the UV–vis spectrum. A PL emission peak was observed at 417 nm because of the wide bandgap of SPPO21. A low temperature PL spectrum was also obtained at 77 K, and the triplet emission peak of SPPO21 was detected at 533 nm with a triplet bandgap of 2.32 eV.

The CV measurements showed that SPPO21 had a HOMO level of 6.12 eV, and a lowest unoccupied molecular orbital (LUMO) of 2.57 eV as well a triplet bandgap of 2.32 eV, which was suitable for transferring energy to red emitting $Ir(pq)_2acac$ (triplet bandgap of 2.2 eV). Therefore, SPPO21 can be used as the host in the $Ir(pq)_2acac$ doped device.

SPPO21 had a spirobenzofluorene core structure with a twisted fluorene and benzofluorene backbone, which was advantageous for amorphous and thermally stable film formation. Additionally, the diphenylphosphine oxide unit that was connected to the spirobenzofluorene backbone structure also improved the thermal stability because of the polar phosphine oxide group and the phenyl group that was attached to the phosphine oxide unit. Therefore, SPPO21 had a high glass transition temperature of 135 °C.

The surface morphology of the evaporated SPPO21 film was analyzed using AFM in order to study the film stability of SPPO21. The AFM measurements were carried out for a pristine SPPO21 film and an SPPO21 film that was thermally treated at 100 °C for 2 h. The AFM images of SPPO21 are shown in Fig. 3. SPPO21 formed a stable amorphous film with a surface roughness of 0.12 nm. The surface morphology of the SPPO21 film did not change even after thermal treatment at 100 °C for 2 h, and the surface roughness of the SPPO21 film baked at 100 °C was 0.14 nm. Therefore, SPPO21 can effectively be used as a thermally stable host material in organic light-emitting diodes. The stability of the amorphous film was caused by the twisted structure

of the spirofluorene–benzofluorene core and the two diphenylphosphine oxide units.

The device performances of the red PHOLEDs were studied with respect to the doping concentration of Ir(pq)$_2$acac in order to evaluate the performance of SPPO21 as a host material for red PHOLEDs. Fig. 4 shows the current density–voltage–luminance curves of the red PHOLEDs with different doping concentrations. The current density of the red PHOLEDs increased as the doping concentration increased, and the highest current density was obtained for the red PHOLED with the highest doping concentration. SPPO21 had a HOMO/LUMO level of 6.12/2.57 eV, whereas the HOMO/LUMO of Ir(pq)$_2$acac was 5.2/3.0 eV in the energy level diagram (Fig. 1), corresponding to a HOMO/LUMO level difference of 0.92/0.43 eV between the SPPO21 and Ir(pq)$_2$acac. The large HOMO level gap between SPPO21 and Ir(pq)$_2$acac induced significant hole trapping by the dopant, and electrons were also trapped by the dopant because of the LUMO level gap of 0.43 eV [12]. Therefore, the charge trapping was critical to the current density, and the intermolecular hopping between the dopant materials dominated the charge transport behavior of the SPPO21 device, resulting in high current densities in the highly doped devices.

The luminance of the SPPO21 red PHOLEDs was high at a doping concentration of 3% despite the low current density, indicating a high recombination efficiency in device III. The low luminance of devices I and II was caused by their low current densities. Additionally the luminance of devices IV and V was low because of the low recombination efficiency of the holes and electrons.

Fig. 5 shows the quantum efficiency and current efficiency of the SPPO21 based red PHOLEDs. Device II exhibited the highest quantum efficiency at high luminance (>400 cd/m^2), whereas the quantum efficiency of device I

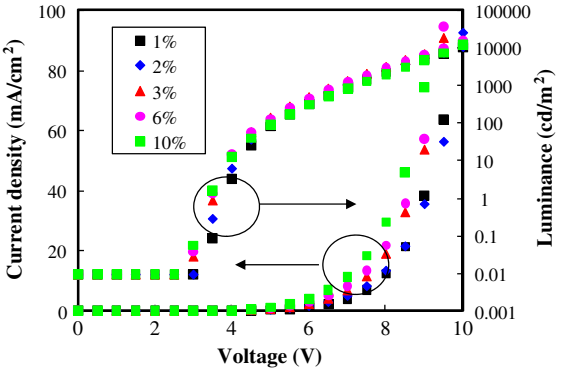

Fig. 4. Current density–voltage–luminance curves of the red PHOLEDs with the SPPO21 host according to the doping concentration of the Ir(pq)$_2$acac.

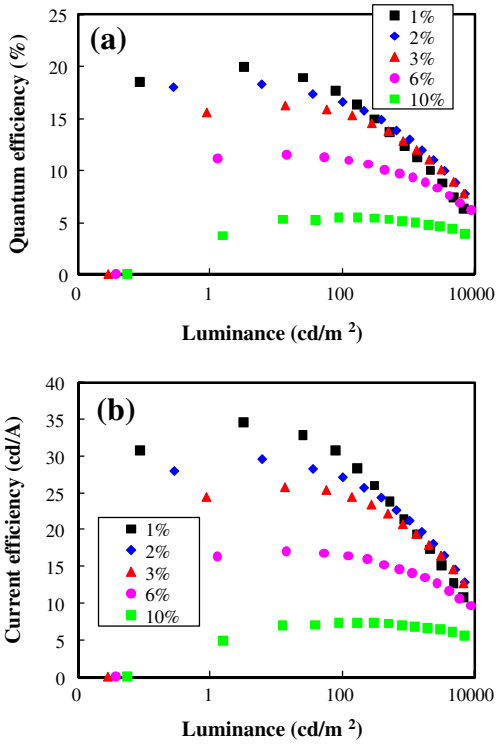

Fig. 5. Quantum efficiency (a) and current efficiency (b) of the red PHOLEDs with the SPPO21 host according to the doping concentration of the Ir(pq)$_2$acac.

was higher than the other devices at low luminance (<400 cd/m^2). The maximum quantum efficiencies of devices I and II were 20% and 18.3%, respectively, whereas the quantum efficiencies at 1000 cd/m^2 were 12.1% and 13.1%, respectively. The quantum efficiency of the SPPO21 device was higher than the SPPO2 that was reported earlier [13]. The external quantum efficiency of device I was the same as the theoretical external maximum quantum efficiency of 20%. However, the quantum efficiency was significantly reduced in devices IV and V. The maximum quantum efficiencies of devices IV and V were only 11.5% and 5.4%, respectively. The quantum efficiency of the SPPO21 based red PHOLEDs was optimized at a very low doping concentration of 1% or 2%. The current efficiency showed the same tendency. However, the reason for this observation was unknown. Therefore, the PL spectra of the Ir(pq)$_2$acac doped SPPO21 films and the EL spectra of the fabricated red PHOLEDs were examined at various doping concentrations.

Fig. 6 shows the PL spectra of the Ir(pq)$_2$acac doped SPPO21 films at different doping concentrations of Ir(pq)$_2$acac. The PL emission of the pure SPPO21 film was observed at around 400 nm with a maximum peak at 405 nm, and the Ir(pq)$_2$acac PL emission was detected at 605 nm. The Ir(pq)$_2$acac doped SPPO21 films exhibited PL peaks for both SPPO21 and Ir(pq)$_2$acac at doping concentrations below 6%, whereas the Ir(pq)$_2$acac doped SPPO21 films exhibited only the Ir(pq)$_2$acac emission at higher doping concentrations above 6%. Therefore, the energy transfer from the SPPO21 host to Ir(pq)$_2$acac was not complete at low doping concentrations. At 6% doping the SPPO21 emission was completely absorbed by Ir(pq)$_2$acac. However, the PL intensity of Ir(pq)$_2$acac was not as strong in the 6% doped SPPO21 film as the others despite the complete energy transfer from SPPO21 to Ir(pq)$_2$acac. The PL intensity of the emitter doped film is affected by the luminescence concentration quenching, which is governed by the doping concentration [14–16]. The concentration quenching rate constant was dependent on R^{-6}, where R is the average distance between dopant molecules. The average distance between Ir(pq)$_2$acac decreased according to the following relationship, $R = [(\text{molecular density in film}) \times (\text{mol\% of the dopant in a film})]^{-1/3}$ [16], and R decreased below 3.0 nm in the 3% doped film. The Förster radius of the phosphorescent emitter doped film was estimated to be below 3 nm [16–18]. Therefore, the concentration quenching was serious above a doping concentration of 3%, resulting in a decrease in the PL intensity. The highest PL intensity was obtained at a doping concentration of 2% because of the small concentration quenching, even though the SPPO21 emission was not completely quenched by the dopant. The low PL intensity at 1% doping was caused by the incomplete energy transfer, whereas the low intensity at 3% doping was caused by the concentration quenching.

The PL intensity of the film was well correlated with the quantum efficiency of the red PHOLEDs. The high efficiency was obtained for device II at a 2% doping concentration, and the efficiency decreased as the doping concentration increased. Even though other factors affected the quantum efficiency of the EL devices, these results proved that the PL emission was critical to the quantum efficiency of the SPPO21 based red PHOLEDs.

Fig. 7 shows the EL spectra of the SPPO21 based red PHOLEDs. The red PHOLEDs exhibited main emission peaks at around 600 nm and the emission peaks were red-shifted at higher doping concentrations because of the intermolecular dipole–dipole interaction that was caused by the short distance between the dopant molecules at high doping concentrations. The main emission peak shifted from 596 nm at 1% doping to 612 nm at 10% doping.

Comparing the PL spectra of the films and the EL spectra of the devices, device I did not show any host emission in the PL spectrum of the 1% doped film. All of the SPPO21 emissions were not absorbed by the 1% doped Ir(pq)$_2$acac in the PL excitation, but the host emission disappeared in the EL emission because of the hole and electron trapping by the Ir(pq)$_2$acac in the energy level diagram of the host and dopant. The excitons were generated not only in the host but also in the dopant because of the charge trapping caused by the large energy level difference between the host and dopant materials. Both the excitons that were formed in the host through the transfer of energy to the dopant and the excitons that were generated in the dopant directly emitted. Therefore, both the energy transfer and the charge trapping were parts of the main mechanism for the light emission in the SPPO21 based red PHOLEDs. The contribution of the charge trapping on the light emission was significant in the highly doped device, but the concentration quenching had a negative effect on the

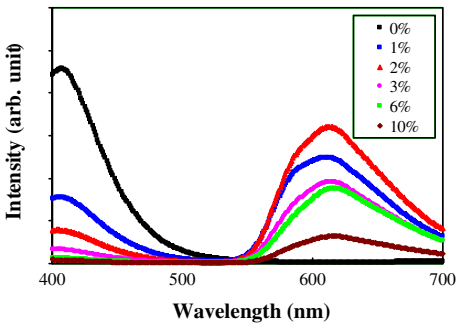

Fig. 6. Photoluminescence spectra of the SPPO21: Ir(pq)$_2$acac film according to the doping concentration of the Ir(pq)$_2$acac.

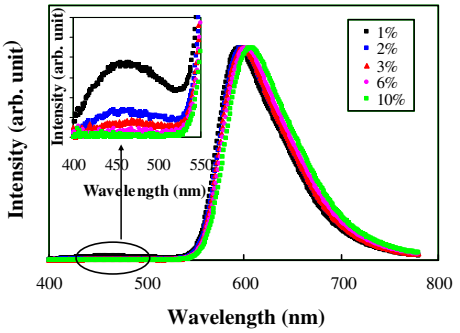

Fig. 7. Electroluminescence spectra of the red OLEDs with the SPPO21 host according to the doping concentration of Ir(pq)$_2$acac.

quantum efficiency. On the other hand, the energy transfer dominated the light emission and the charge trapping compensated for the incomplete energy transfer in the devices with low doping concentrations. Therefore, a high quantum efficiency over 20% was achieved in the SPPO21 based red PHOLEDs.

Even though SPPO21 did not exhibit an emission at 405 nm, a weak emission was detected at 465 nm in the EL spectra of the red PHOLEDs at low doping concentrations. The intensity of the emission weakened at higher doping concentrations and was not observed in device V. An expanded image of the emission peak is shown in Fig. 7 as an inset. This emission peak was caused by the exciplex of TCTA and SPPO21, which was confirmed by the PL emission of the mixed film of TCTA and SPPO21. The electron donating aromatic amine group in TCTA and the strong electron withdrawing phosphine oxide group combined to make the excited complex [19,20]. The TCTA hole transport layer and the SPPO21 host formed the exciplex at the interface, which emitted a weak peak at 465 nm. The exciplex formation was facilitated by the electron accumulation and overflow at the interface between the SPPO21 host and TCTA. Fewer electrons were trapped by the dopant in the red PHOLEDs with lower doping concentrations, leading to better electron transport through the SPPO21 emitting layer. Therefore, more electrons accumulated at the interface and were injected into the TCTA layer in device I, resulting in a relatively strong exciplex emission. The exciplex emission was responsible for the large efficiency roll-off in the red PHOLEDs with low doping concentrations in Fig. 5. A previous report showed that the charge leakage is critical to the efficiency roll-off, and confirming the results that were obtained in this work [21]. The efficiency roll-off decreased as the intensity of the 465 nm peak decreased.

4. Conclusions

The device performances of the red PHOLEDs with the phosphine oxide based SPPO21 host were studied, and a high external quantum efficiency of 20% was achieved. The device performances were optimized at a low doping concentration because of the little concentration quenching, energy transfer and charge trapping. SPPO21 exhibited a high quantum efficiency and low optimum doping concentration making it an effective host material for red PHOLEDs, and therefore, the SPPO21 host material exhibited potential for use in future display and lighting applications.

luminescence efficiency of organic semiconductors with the high electron mobility of inorganic oxides.

In this context, recent work by Glezos et al. [11] has shown that a member of the class of polyoxometalates (POMs) [12], a class of soluble inorganic molecular oxides whose diverse chemistry allows for facile tuning of their structural, optical and electronic properties [13], exhibits a high electron mobility of $\sim 4 \times 10^{-3}$ cm^2/V s (in PMMA at 1:1 w/w) [11] and has a low lying conduction-band edge located at ≈4.0 eV (taking into account solid-state polarization effects and assuming an exciton binding energy of ≈0.3 eV) [14,15]. In addition, electron transport studies in polyoxometalate layers showed efficient electron transport in very thin structures [16]. These characteristics make it a very appealing candidate for use as an EIL in HyLEDs. Furthermore, its hydrophilic nature, in contrast to the hydrophobic character of the conjugated emissive polymer layer, allows its facile spin-casting from water or alcohol-based solvents without disrupting the emissive layer morphology.

Here we report *for the first time* the use of a commercially available, solution-processable inorganic anionic polyoxometalate (POM) molecular oxide (namely, the Keggin structure phosphotungstic acid $(PW_{12}O_{40})^{3-}$) [11] as a novel EIL in HyLEDs. A thin-POM layer, with a LUMO level lying between that of the emissive polymer and the Fermi level of Al, provides an intermediate step for facilitating and enhancing electron injection from Al to the polymer LUMO, when inserted between the emissive layer and Al. This results in a lowered turn-on voltage and a significant decrease of the operating voltage as well as a significant increase in the maximum current density and luminance, improving the overall performance of the HyLEDs.

2. Experimental

Both reference and HyLEDs were fabricated on oxygen plasma-cleaned indium tin oxide (ITO) coated glass substrates. Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, obtained from Aldrich) was used as an anode interfacial layer to improve hole injection. The ~70 nm thick PEDOT:PSS layer was spin-cast from an aqueous solution and then annealed in air at 130 °C for 15 min. Next, an ~70 nm thick layer of the light-emitting green-yellow (YE) polyfluorene copolymer poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(1,4-benzo-{2,1′,3}-thiadiazole)] (ADS233YE, obtained from American Dye Source Inc.) was spin-cast on PEDOT-PSS from a 8 mg/ml chloroform solution. Prior to spin-coating, the polymer solution was filtered using a 0.20 μm PTFE filter. After spin-coating, the emissive layer was annealed at 85 °C for 10 min in air. In order to enhance electron injection, a thin-POM layer was deposited from a methanol solution on the polymer film to serve as the EIL in the HyLED configuration. Note that methanol is an orthogonal solvent with regard to the polymer (no dissolution of the polymer film was observed). By varying the concentration of the POM solution from 0.2–1 wt.%, the thickness of the EIL varied between ~2 and 10 nm. Finally, a 150 nm thick Al layer was deposited by thermal evaporation (at $\sim 5 \times 10^{-5}$ mbar) through a shadow mask (defined active area of 12.56 mm^2). The thickness of the polymer and the POM films was measured with an Ambios XP-2 profilometer and a M2000 Woolam ellipsometer, respectively. Current density–voltage characteristics were measured with a Keithley 2400 source-measure unit. Luminance and electroluminescence (EL) spectra were recorded with an Ocean Optics USB 2000 fiber optic spectrophotometer, assuming a Lambertian emission profile (for luminance measurements). Photovoltaic mode measurements were recorded under ~70 mW cm^{-2} solar light illumination simulated from a Hg–Xe lamp and a AM 1.5G filter. Surface morphology and structure of POM, YE and YE/POM bilayer films was investigated with a Veeco atomic force microscope (AFM). All measurements were carried out in air at room temperature.

3. Results and discussion

The Keggin structure of the anionic $(PW_{12}O_{40})^{3-}$ tungsten polyoxometalate (POM) along with the device architecture of a representative HyLED studied in this work and its corresponding energy diagram are shown in Fig. 1a and b and c, respectively. The device configuration is ITO (100 nm)/PEDOT-PSS (70 nm)/YE (70 nm)/POM (*x* nm)/Al (150 nm), where POM is used as a thin EIL and ETL to modify the YE/Al interface. Reference devices without POM were also fabricated for direct comparison. Fig. 2 shows atomic force microscopy (AFM) surface morphology images of (a) a 20 nm thick POM film (b) a 70 nm thick YE film (c) a YE(70 nm)/POM(2 nm) bilayer film and (d) a YE(70 nm)/POM(10 nm) bilayer film, all deposited on quartz glass substrates. POM forms an inhomogeneous and nanostructured film surface with an RMS roughness of ~5 nm and some features extending up to 40 nm in height (even larger than the nominal film thickness). In contrast, the surface of the YE polymer film is amorphous and relatively smooth with an RMS roughness of ~0.6 nm and very few features up to a few nm in height (peak to peak difference of 6 nm). The surface of the polymer/POM bilayer film, exhibits a POM solution concentration dependent number of rather well-defined nanorod-type features up to 15 nm high (shown as bright nanorod domains protruding from the surface with a diameter between 10 and 100 nm), more likely attributed to the presence of POM nanoparticle clusters spontaneously growing and regularly distributed on the polymer surface. This behavior is not unexpected if we consider that POM nanoparticles have a diameter of ~1 nm [11], thus deeming unlikely the formation of a continuous homogeneous film of POM in the thickness range between 1 nm and a few nm by spin-coating from very low concentration solutions (<1 wt.%) in polar solvents. An interesting aspect though is that these nanocluster domains grow in size (both in diameter and height) and also increase in number, therefore increasing the polymer film coverage, with an increase of the POM concentration solution. The mean POM nanocluster diameter is calculated to be ~50 nm. Moreover, the surface RMS roughness of the bilayer films is increased up to ~1.5 nm. This picture is supported by SEM imaging coupled with EDX-analysis (data not shown here)

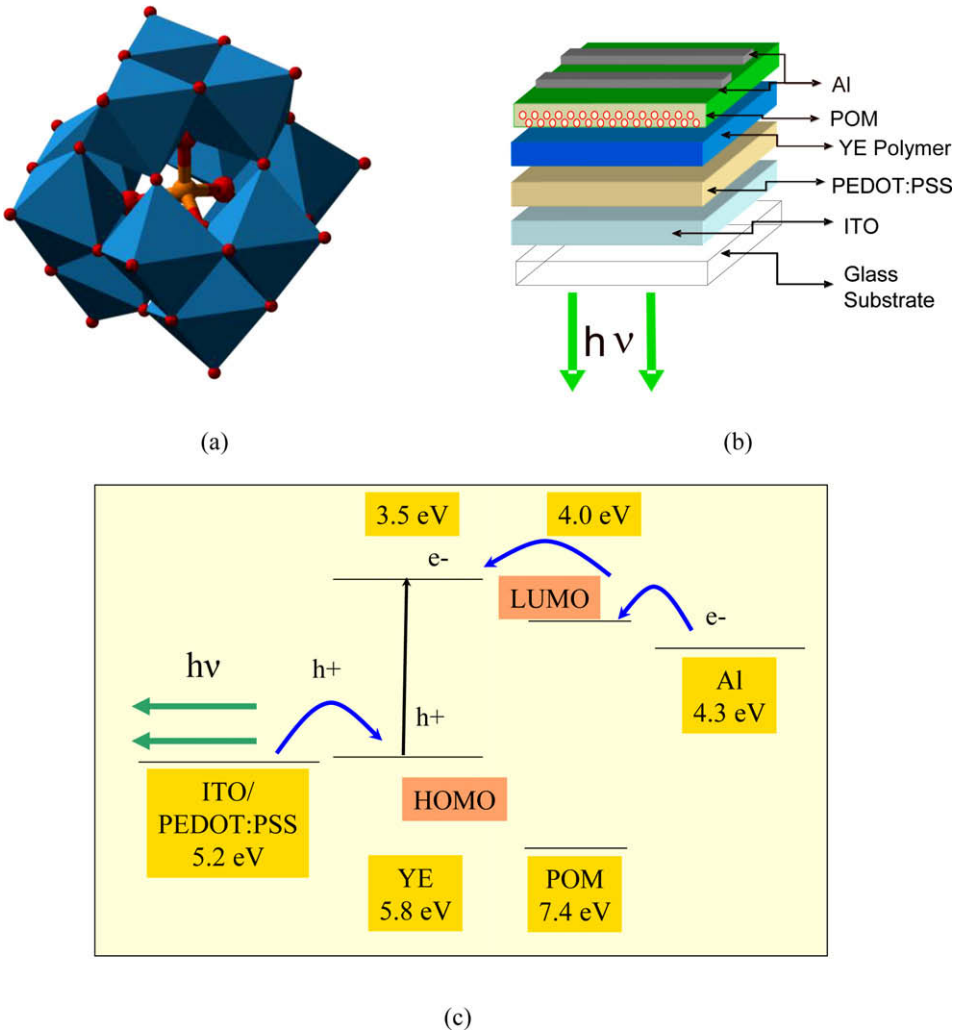

Fig. 1. (a) Keggin structure of the $(PW_{12}O_{40})^{3-}$ tungsten polyoxometalate (POM). The P atom occupies its center while the W atoms occupy the centers of the regular polyhedra and the O atoms are at the vertices. (b) Schematic architecture of the fabricated HyLED and (c) corresponding energy diagram.

which also indicate that POM nanoclusters with variable diameter and height are rather randomly distributed across the YE surface.

The difference in the surface topography and coverage between the POM film on glass and the POM onto the YE polymer film as well as the inhomogeneities present in either case as seen upon comparing Figs. 2a, c and d, respectively, may be a result of the different wetting conditions of this polar hydrophilic molecule on the two surfaces. We note however that although the heterogeneous coverage of POM on the YE film surface may contribute to an increased leakage current flow, the increased interfacial nanostructured area of POM with Al – as a result of the nanocluster presence – is expected to be beneficial for charge injection due to the high local electric field present in the vicinity of these surface POM domains.

The influence of the POM EIL and, in particular, its thickness on the current density versus voltage (J–V) and luminance versus voltage (L–V) characteristics of the YE-based PLEDs is shown in Figs. 3 and 4, respectively. A detailed description of the device performance characteristics is shown in Table 1. Reference PLEDs exhibit a turn-on voltage (for $L \approx 10$ cd m^{-2}) of 5.5 V, reach a luminance of ~1000 cd m^{-2} at 7.5 V and a maximum current density and luminance of ~1350 A m^{-2} and ~4150 cd m^{-2}, respectively, at 13 V. The maximum luminous current and power efficiency are 3.2 cd A^{-1} and 1 lm W^{-1} at ~3500 cd m^{-2}, typical of single-layer polyfluorene-benzothiadiazole (F8BT) based PLEDs with an Al cathode [17]. HyLEDs with a 2 nm thick POM EIL turn-on at 4 V (~1.5 V lower than the reference PLEDs), reach 1000 cd m^{-2} at 6.5 V and also exhibit a decrease in their maximum operating voltage as they reach a maximum current density and luminance of ~4400 A m^{-2} and ~5300 cd m^{-2}, respectively, at 12 V. An increase of the maximum current density by a factor of ~2.5 is demonstrated, with a smaller increase in the maximum luminance, which indicates a substantial increase of electron injection and the corresponding electron current (as also suggested by the steep exponential rise of the HyLED J–V–L characteristics above the turn-on voltage).

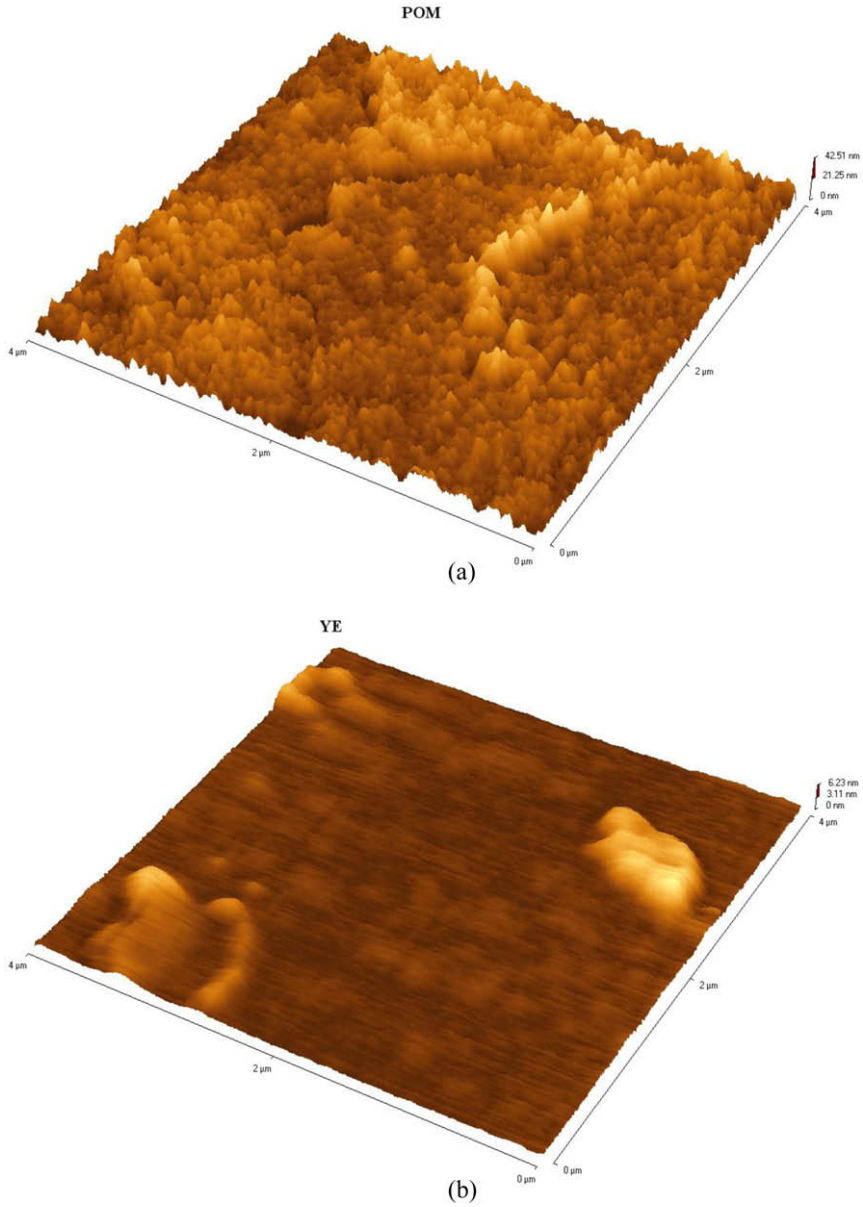

Fig. 2. 4 × 4 μm 3D AFM topographic images of (a) a 20 nm thick POM film on glass (b) a 70 nm thick YE film and (c) and (d) YE/POM bilayer films with a POM thickness of 2 and 10 nm, respectively. A larger interfacial contact area with increased surface roughness was observed when POM was inserted at the YE/Al interface.

Note that the inset of Fig. 3 shows the *J–V* characteristics plotted on a logarithmic scale (for the current) from where the presence of leakage current below the turn-on voltage can be identified. Both reference PLEDs and HyLEDs show high leakage current, regardless of the POM thickness that may be attributed to film heterogeneities. However, it appears than the insertion of a POM layer somewhat reduces the leakage current and that the use of a very thin-POM nanoclustered layer results in the lowest leakage current and a better diode behavior.

The maximum luminous current and power efficiency of the HyLEDs reach ~1.7 cd A^{-1} and 1.2 lm W^{-1} at ~120 and 10 cd m^{-2}, respectively. The small decrease in the HyLED current efficiency suggests that the charge balance in the reference devices is not improved upon insertion of the POM EIL. This is mainly attributed to the predominantly electron transporting character of the YE copolymer which results in electrons being the majority carriers in single-layer F8BT-based PLEDs [18–20]. However, the maximum power efficiency of the HyLED is slightly enhanced due to the significant lowering of its operating voltage. Upon increase of the POM thickness to ~10 nm, a slight increase of both the turn-on voltage to 4.5 V and the operating voltage (for $L \approx 1000$ cd m^{-2}) to 7.3 V is ob-

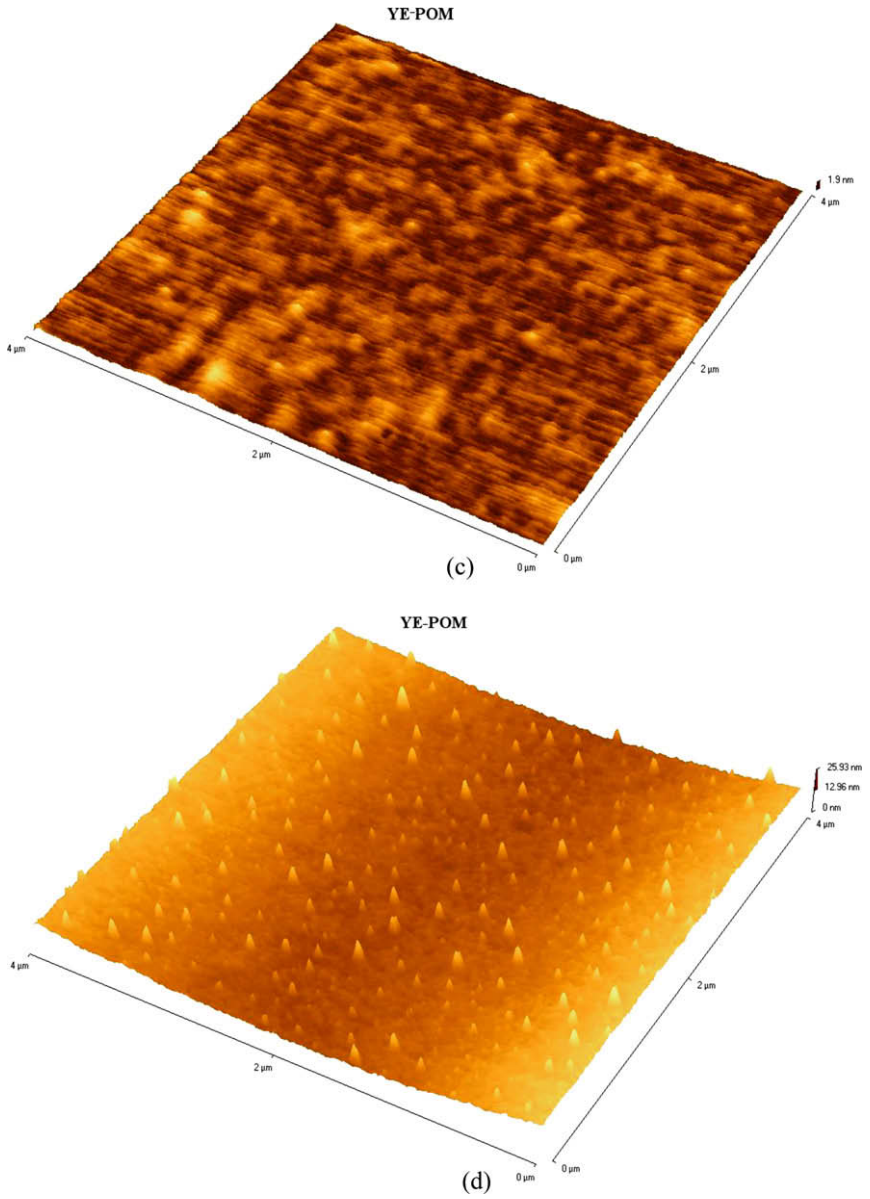

Fig. 2 (*continued*)

served (compared to 4 and 6.5 V, respectively, for the 2 nm thick EIL HyLED). Both values are still slightly lower though than those of the reference PLED. The maximum current and power efficiency reach 1 cd A^{-1} and 0.4 lm W^{-1}. Their decrease compared to those of the ~2 nm thick EIL-modified HyLED may be attributed to interference effects as a result of the increased distance of the recombination/emission zone from the cathode or to increased leakage current flow through the thicker EIL. Note that no appreciable change in the reference PLED EL spectrum was found upon insertion of the POM EIL layer. Green-yellow emission with a peak at ~540 nm, characteristic of F8BT [17] was observed, which indicates that charge recombination and exciton formation takes place inside the emissive layer, most likely away from the YE/POM interface due to the high electron mobility of the YE polymer and the electron-dominated character of the HyLEDs [21]. The relatively independent HyLED performance on the EIL thickness suggests that most of the applied electric field drops across the emitting layer and that the electron conductivity of POM is not a limiting factor in device performance, at least for thin EILs. Therefore, key limiting step for low voltage operation is the electron injection at the Al/YE interface. As the anode interface has the same structure, these improvements clearly indicate that an increased electron injection is responsible for the improved device operation of the thin-POM EIL-modified HyLEDs. The introduction of a thin-POM EIL reduces the turn-on

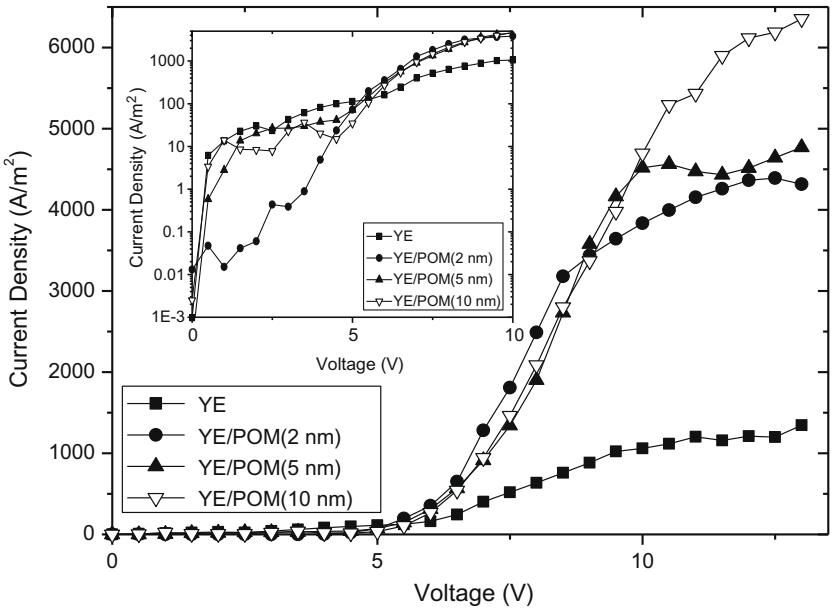

Fig. 3. Current density–voltage (J–V) characteristics of reference and HyLEDs for different POM thicknesses. A notable increase in the current density is demonstrated upon using a very thin-POM layer as EIL. The inset shows log(J)–V characteristics where the presence of leakage current, below the turn-on voltage, is seen.

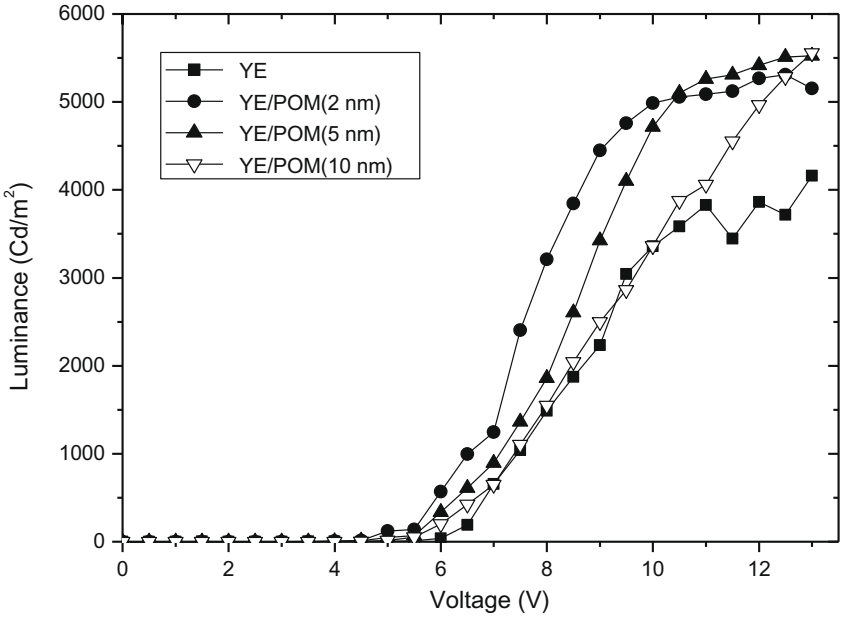

Fig. 4. Luminance–voltage (L–V) characteristics of reference and HyLEDs as a function of the POM layer thickness. Also, a notable increase in the luminance is demonstrated upon using a very thin-POM layer as EIL.

and operating voltage and enhances the maximum current density, luminance and luminous power efficiency (for a thin EIL), at the expense though of a decrease in the luminous current efficiency. The enhanced device operation is primarily attributed to the favorable position of the LUMO of POM that is situated at ≈4.0 eV, between the LUMO of YE (≈3.5 eV) [17] and the Al Fermi level (≈4.3 eV), thus acting as an intermediate step to reduce the energetic barrier height at the YE/Al interface and facilitate electron injection to the LUMO of YE. The nanostructured YE/POM surface and the high electron mobility of POM is also expected to further enhance the HyLED performance. n-Type

Table 1
Device performance characteristics of both reference PLEDs and HyLEDs with various POM thicknesses.

POM thickness (nm)	Turn-on voltage (V) (at 10 cd m^{-2})	Voltage (V) (at 100 cd m^{-2})	Voltage (V) (at 1000 cd m^{-2})	Maximum current density (A m^{-2}) (at voltage [V])	Maximum luminance (cd m^{-2}) (at voltage [V])	Maximum luminous current efficiency (cd A^{-1}) (at luminance [cd m^{-2}])	Maximum luminous power efficiency (lm W^{-1}) (at luminance [cd m^{-2}])
0	5.5	6.2	7.5	1348 (13)	4161 (13)	3.2 (3500)	1.0 (3500)
2	4.0	5.2	6.5	4366 (12)	5267 (12)	1.7 (120)	1.2 (10)
5	4.5	5.3	7.1	4771 (13)	5525 (13)	1.2 (5416)	0.6 (336)
10	4.7	5.7	7.3	6355 (13)	5556 (13)	0.9 (5556)	0.4 (202)

doping of POM upon spontaneous electron transfer from Al may also contribute in reducing the contact resistance and improving injection. Enhanced electron injection followed by facile transfer to the polymer LUMO results then in increased current flow as well as faster electron–hole recombination rate. Note that although the POM interlayer may act as a hole blocking layer (due to the very large Δ(HOMO) offset at the YE/POM interface) reducing hole leakage current, it may also increase electron leakage current, due to its nanostructured surface and increased roughness, thus contributing to the much higher current densities observed in the HyLEDs.

To further support the argument that the origin of the improved device performance is mainly related to changes in the energetics at the polymer/Al interface upon modification with the POM EIL, photovoltaic measurements were carried out to determine the open circuit voltage (V_{oc}). Its value reflects the built-in potential upon contact with the electrodes (for Ohmic contacts, it will be equal to the difference between the work-functions of PEDOT:PSS and Al). J–V curves were recorded under AM 1.5 G solar illumination (~70 mW cm^{-2}) and are presented in Fig. 5. The comparison of the V_{oc}'s of the devices with and without the POM EIL shows that a significant increase to ~1.27 V (compared to ~0.87 V for the reference device) is noted when a thin (<10 nm) POM film is used as an EIL. Attributing the ~0.4 V increase in V_{oc} to an enhanced built-in potential is also supported by the corresponding dark J–V characteristics where a higher 'compensation' voltage of ~0.3 V (defined as the voltage at which the internal field is cancelled by the external field) is observed for the HyLED (not shown here). This ~0.4 V increase of the built-in potential is suggestive of either pinning of the Fermi level of Al close to the LUMO of POM or decrease of the Al effective work-function. It is also noted that the high surface polarity of POM could lead to a favorable surface potential and further enhance electron injection as previously suggested for a ZnO modified ITO-F8BT interface [22]. The enhanced built-in field present in the HyLED results in a lowering of the effective electron injection barrier and therefore in an increased electron injection and charge recombination rate with a corresponding decrease of the operating voltage and an increase of both the maximum current density and luminance. Finally we note that, although POM is an n-type inorganic molecular oxide that could non-radiatively quench YE excitons due to its larger electron accepting ability and affinity, the similar short circuit photocurrent of the POM-modified HyLED with that of the YE PLED suggests otherwise. This observation along with the similar photoluminescence intensities measured for both YE and YE/POM films (not shown here) strongly suggests that no significant charge generation, due to exciton quenching (electron transfer to POM), takes place at the YE/POM interface. This is in contrast to other oxide/polymer interface based HyLEDs (for example, F8BT/TiO_2 based HyLEDs) where exciton quenching at this interface has been identified as a key exciton loss mechanism [22]. However, we have observed POM composition dependent PL and EL quenching in blends of YE and POM (data not shown here) suggestive of photoinduced electron transfer from the polymer excited state to the LUMO of POM and charge (electron) transfer between the two components that reduces exciton confinement in the polymer phase, respectively, and we will report these results in a future publication.

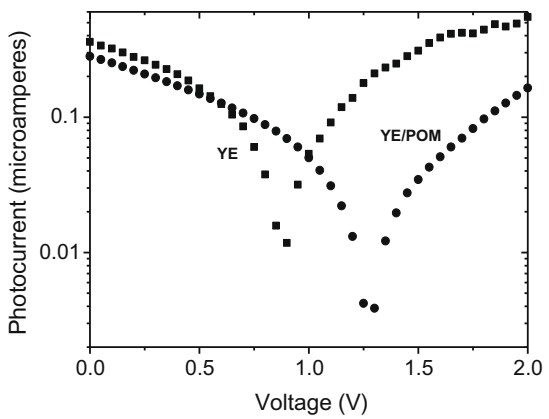

Fig. 5. Photocurrent density–voltage (AM1.5G, 70 mW cm^{-2}) characteristics of a reference and a HyLED. Photovoltaic open circuit voltage (V_{oc}) measurements reveal an increased built-in potential and, therefore, a reduced electron injection barrier height when POM is inserted at the YE/Al interface.

4. Summary

In summary, we have reported the use of a water soluble polyoxometalate (POM) inorganic molecular oxide for the formation of a novel thin (<10 nm), efficient electron injection layer (spin-cast from methanol, an orthogonal solvent with regard to the polymer layer underneath) be-

tween the emissive polymer layer and an Al cathode, and demonstrated improved performance HyLEDs based on the yellow-green emitting poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(1,4-benzo-{2,1′,3}-thiadiazole)] (YE) copolymer. Upon inserting this layer, a reduced turn-on and operating voltage combined with a significant increase in the maximum attainable current density and luminance were obtained in the HyLEDs. The superior electron injection characteristics was primarily attributed to the reduced effective electron injection barrier height at the POM-modified YE/Al interface, as suggested by the increased built-in potential directly measured with photovoltaic open circuit voltage measurements. This proof-of-concept demonstration elucidates polyoxometalate compounds as a versatile, emerging new class of efficient electron injection/transport molecular materials for high performance air-stable HyLEDs.

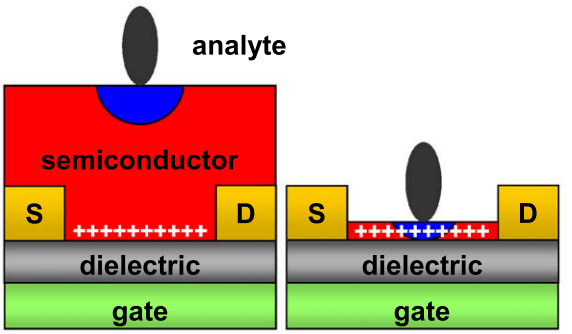

Fig. 1. Schematic representation of the operation principle of a SAMFET sensor. The transistor consists of an organic semiconductor, a source and drain electrode, a gate dielectric and a gate. A conducting channel is formed at the semiconductor gate dielectric interface. On the left side, analyte molecules are absorbed on top of a thick semiconductor layer. The current modulation is limited by the thickness of the semiconductor. The electrostatic interactions are stronger when the distance between the analyte and the channel is decreased. Hence a monolayer thick semiconductor (right) yields the ultimate sensing performance.

detection of NO. The operation principle is elucidated in Fig. 1. The left side shows a standard organic field-effect transistor consisting from top to bottom of an organic semiconductor, a source and drain electrode, a gate dielectric and a gate. Upon applying a bias to the gate, charge carriers are accumulated at the gate dielectric-semiconductor interface. A conducting channel is formed with a thickness of approximately 1–2 nm [12]. Analyte molecules absorbed on top of the semiconductor can modulate the charge transport in the channel by electrostatic interactions. However, it has been demonstrated by Huang et al. [13] that the sensitivity of such a sensor is dependent on the thickness of the active layer. The response of organic transistors to nerve agent simulants increased dramatically with decreasing layer thickness, due to the strong distance dependence of the electrostatic interactions. Torsi et al. [14] have reported chiral sensors and argue that the sensing is restricted to the conducting channel. The sensitivity did not increase with decreasing layer thickness but this could be due to the granular nature of the semiconducting films. Finally, sensitivity enhancement of up to an order of magnitude has been reported in transistors by using ultra thin semiconducting films [15]. Hence a semiconductor of only one monolayer thickness should yield the most sensitive gas sensor, as shown in Fig. 1 on the right.

A SAMFET has recently been reported by Smits et al. [16]. The monolayer consists of molecules with a semiconducting quinquethiophene core and an aliphatic spacer that is attached to the gate dielectric with a monofunctional anchoring group. The chemical structure of chloro[11-($5''''$-ethyl-$2,2':5',2'':5'',2''':5''',2'''':5''''$-quinque thien-5-yl)undecyl]dimethylsilane is shown in the inset of Fig 2. The SAMFETs were fabricated on heavily doped *n*-type Si wafers, acting as common gate electrode, with a 1000 nm thermally oxidized SiO_2 layer as gate dielectric. Gold source and drain electrodes were defined by conventional photolithographic methods, resulting in ring transistors with a channel length of 10 μm and a width

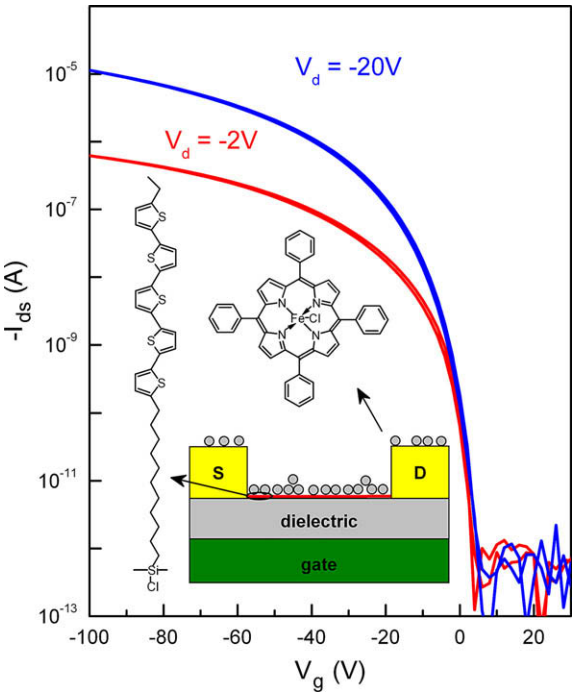

Fig. 2. Transfer characteristics of a typical SAMFET in vacuum with a 1 μm SiO_2 gate dielectric in the linear and saturated regime. The device exhibited *p*-type behavior with a pinch off voltage around 0 V. The inset shows a schematic cross-section of the SAMFET sensor. The chemical structures of the SAM molecule (left) and the NO receptor Fe(TPP)Cl (above) are shown.

of 2500 μm. Semiconducting monolayers were self-assembled from a toluene solution on a HF activated SiO_2 dielectric, as described previously [16]. The SAMFETs were annealed in vacuum at 110 °C for one hour to remove residual water and solvents. Electrical measurements were performed under vacuum using an Agilent 4155B semiconductor parameter analyzer. Possible gate bias stress effects in the electrical measurements were prevented by using a short integration time of less than 1 ms per step. A typical transfer curve is presented in Fig. 2. The mobility is about 0.01 cm^2/Vs and the current modulation six decades, in good agreement with previous reports.

The response of the SAMFETs was measured by admitting small amounts of NO, diluted in nitrogen carrier gas, to the closed chamber. The gas pressure in this static system was used to calculate the partial NO concentration at 1 bar. The response of the SAMFET itself to NO is indistinguishable from random drift of the threshold voltage. To make the SAMFET specific for NO, a porphyrin receptor was used. Porphyrins are known to bind NO in *e.g.* biological systems [17]. Here we used iron^{III} tetraphenylporphyrin chloride (Fe(TPP)Cl, Sigma Aldrich), that was previously used to detect NO in solution with a molecular controlled semiconductor resistor [18]. In the ideal case this receptor is grafted on, or incorporated into, the monolayer. Here, to demonstrate the concept, we used a thin spin coated film. The porphyrin receptor was dissolved in toluene, 1.6 mg/ml, and thin layers were spin coated at 800 rpm. The films

are only 10 nm thick and they contain a lot of pinholes. Therefore the diffusion of the nitric oxide is not limiting the detection rate. The addition of porphyrin on the SAMFET had no significant influence on the performance of the SAMFET. The chemical structure and the device layout are schematically depicted in the inset of Fig. 2.

The transfer curve of the SAMFET with the porphyrin shifts upon exposure to NO. We observe that the field-effect mobility remains unaffected; the only effect is a change in the threshold voltage towards positive gate bias. This clearly points to an increase of fixed negative interface charges upon exposure to NO. However, the reaction is not instantaneous, the threshold voltage shifts with time. A typical example is presented in Fig. 3. A possible reason might be the slow supply of negatively charged minority carriers needed to convert NO into NO_x^-, an effect that is presently under study. The threshold voltage shift takes about half an hour to saturate. Hence, in order to arrive at a dose response curve, the transfer curves were measured 30 min after NO exposure. To exclude any influence of competing charging effects, the threshold voltage of the SAMFET was monitored in the absence of NO. This measurement did not reveal a change of threshold voltage in time. The response to NO of the SAMFET without porphyrin was also investigated. These reference measurements are shown in Fig. 3. Only the combination of the SAMFET and the receptor in NO atmosphere yields a shift in threshold voltage.

We made many sensors and investigated the response to NO. Fig. 3 discussed above showed a typical measurement for 2.7 ppm NO. Concentrations in the ppm regime can reproducibly be detected. In exceptional cases however a much higher sensitivity has been measured. An example is presented in Fig. 4 where the transfer curves measured in the linear regime are presented on a linear scale as a function of the NO concentration. The transfer

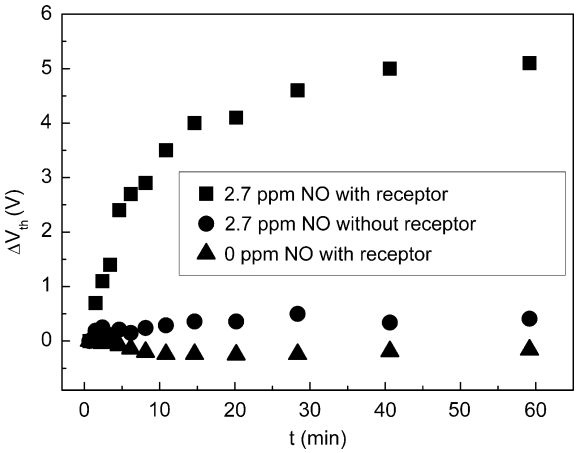

Fig. 3. The response of the SAMFET sensor as a function of time for a fixed NO concentration (2.7 ppm). The threshold voltage shifts towards more positive voltages and saturates after approximately 30 min. Reference measurements of the SAMFET without the porphyrin in NO (2.7 ppm) and the SAMFET with porphyrin in absence of NO are included. Only the combination of the SAMFET and the receptor in NO shows a threshold voltage shift that stands out over random drift.

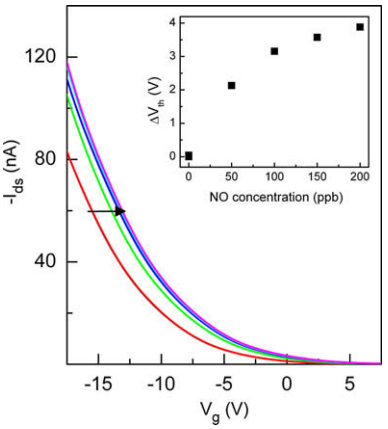

Fig. 4. Linear plot of the transfer characteristics of the SAMFET sensor. The measurements performed in vacuum and nitrogen were identical. The transfer curve measured 30 min after exposure is shifted towards positive values for increasing NO concentrations. The inset shows the threshold voltage shift as a function of NO concentration. The detection limit is as low as sub 100 ppb NO.

curve systematically shifts to positive gate biases with increasing NO content. The relative threshold voltage shift, ΔV_{th}, was determined by taking the gate biases yielding a fixed source drain current of 60 nA, as indicated by the arrow in Fig. 4. The shifts are used to construct a dose response curve. The inset shows the threshold voltage shift as a function of the NO concentration. The dose response curve shows that with the SAMFET sensor ppb concentrations of NO can be detected. The achieved sensitivity compares favorably with an earlier reported detection limit of an NO sensor based on a field-effect transistor [19].

The magnitude of the shift and the functional dependence such as the apparent saturation at high NO content are not yet quantitatively understood. Various operation mechanisms have been reported. For instance Fe(TPP)Cl has been attached to functionalised GaAs surfaces [18]. The current was measured upon exposure to NO in aqueous buffer solution. The current did increase with NO content. The change in current was explained as originating from a change in dipole moment of the Fe(TPP)Cl complex. However a threshold voltage shift in a field-effect transistor cannot be explained with only a change in surface dipole moment [20]. A different reaction mechanism was proposed by Lin and Farmer [21]. In solution NO forms a complex with Fe(TPP), NO–Fe(TPP). Catalytic reaction of this nitrosyl-complex with free NO then yields amongst others NO_2 which is known to cause a shift in threshold voltage [22] presumably by formation of negative surface charges. Recently, ZnO chemiresistors have been functionalised with a comparable iron(III)porphyrin, *viz.* ferriprotoporphyrin IX chloride [23]. NO could be detected down to the ppm range. The operation is reported to be due to electron transfer from ZnO to the receptor. In summary, iron porphyrins could selectively react towards NO, but the microscopic mechanism is unknown.

The selectivity of the SAMFET sensor versus other vapors was investigated. Preliminary experiments show that the sensor is not sensitive to a variety of gases. No threshold

voltage shift was observed for non-oxidizing agents as toluene (8 ppm), methanol (%) and ammonia (2 ppm). Even for oxidizing agents as O_2 and SO_2 the threshold voltage shift is negligible showing the selectivity of the porphyrin towards these gases. Reversibility of the sensor after NO detection was also examined. Full recovery of the sensor is achieved by annealing under vacuum conditions at 110 °C for 1 h. Under those conditions the threshold voltage returns to its pristine value. Our explanation is that the threshold voltage shift upon NO exposure is due to the formation of NO_x^-. At elevated temperature the equilibrium shifts to neutral nitrogen oxides that subsequently desorb from the surface. This could explain the full reversibility. A major problem still to be resolved is that a significant spread in the NO response was found for the numerous investigated SAMFET sensors. The differences can be due to imperfections in the monolayer, variations in the porphyrin converter deposition, or parasitic reactions with residual water. The latter becomes more important at lower NO content. The parameter spread is the focus of current research.

In summary, the response of a field-effect sensor is dominated by the electrostatic interactions between analyte and the conducting channel. In a self-assembled monolayer field-effect transistor the semiconductor is only one molecule thick, making it highly suited for sensing applications. SAMFETs sensors were fabricated using iron porphyrin as a specific receptor for the biomarker NO. The transfer curve systematically shifts to positive gate biases with increasing NO content. Dose response curves were obtained by plotting the threshold voltage shift as a function of NO concentration. High sensitivity was demonstrated by detecting parts per billion concentrations NO.

the performance of OSCs based on other high performance electron donor materials [12,13]. These results may have been obtained due to unsatisfactory phase separation between the polymer donor and the fullerene acceptor, or due to the relatively low bulk charge carrier mobility of PQT-12. Recently, several selenium analogs of polythiophenes have been reported for optoelectronic applications, with higher mobilities than their sulfur analogs. For example, regioregular poly(3-hexylselenophene) (P3HS) [14], poly(9,9′-*n*-dioctylfluorene-alt-biselenophene) (F8Se2) [15], and poly(5,5′-bis(3-dodecylthiophene-2-yl)2-2′-biselenophene) (PDT2Se2) [16] revealed an order of magnitude larger field-effect mobility than their analogs, P3HT, poly(9,9-dioctylfluorene-co-bithiophene) (F8T 2), and PQT-12, when used as active layers in OFETs. Photovoltaic performance was also reported for the P3HS:PCBM blend [15]. In those reports, although the system was not optimized, high photovoltaic performances similar to those of a P3HT:PCBM device under identical conditions were obtained, indicating enhanced electron donor characteristics for the selenophene analogs.

In this paper, we describe the use of a selenium analog of PQT-12, PDT2Se2, blended with PCBM, as an electron donor material for BHJ photovoltaic cells. The blend ratio was optimized, yielding a PCE of 1.4% under AM 1.5 G illumination, 100 mWcm^{-2}, for a blend ratio of 1:4 w/w PDT2Se2:PCBM. This PCE is higher than the PCE reported for the PQT-12:PCBM system. A variety of structural and morphological analysis techniques were employed to predict the optimal fabrication conditions for this system. In addition, the space charge limited current (SCLC) behavior of both PDT2Se2 and PQT-12 sandwiched cells was characterized at several temperatures.

2. Results and discussion

The charge transport characteristics of PDT2Se2 and PQT-12 polymer thin films were compared by measuring the temperature-dependent SCLC behavior of the films. For hole-only currents, ITO/PEDOT:PSS/polymer/Au devices were fabricated. Fig. 1 shows the experimental *J–V* characteristics of hole-only devices made from PQT-12 and PDT2Se2 (film thickness, L = 120 nm) at several temperatures. SCLC behavior is described by the Mott–Gurney equation: [17]

$$J = \frac{9}{8}\varepsilon\varepsilon_0\mu\frac{E^2}{d} \tag{1}$$

where, J is the current density, ε_0 is the permittivity of a vacuum, ε is the relative permittivity of the polymer, μ is the mobility, E is the electric field, and d is the thickness of the layer. By fitting the experimental *J–E* curves to this equation and extrapolating to $E = 0$, we obtained the zero-field mobility, μ_0, and the temperature dependence of μ_0, as shown in Fig. 1. Although this law describes *J–V* characteristics at the low electric field limit, in the presence of larger electric fields it is generally observed that the value of J tends to be larger than is predicted by the above equation (Fig. 1). In such cases, the charge carrier mobility, μ, is not constant for a given electric field, but rather is described by the Poole–Frenkel equation [18],

$$\mu = \mu_\infty \exp\left(\frac{E_A}{k_T}\right)\exp(\gamma(T)\sqrt{E}) \tag{2}$$

where, μ_∞ is the mobility in the limit $T \to \infty$ and $E \to 0$, E_A is the activation energy, k is the Boltzmann constant, γ is the electric field coefficient for mobility, and E is the applied electric field. The dependence of the mobility on the electric field is generally observed for doped polymers, conjugated polymers, and organic glasses [19,20]. Therefore, we required a new *J–E* relationship that includes the effect of a non-constant field-dependent μ. Combining Eqs. (1) and (2), we obtained a relation for $J/E^{1/2}$ vs. $E^{1/2}$, which describes a linear relationship between log $(J/E^{1/2})$ and log $(E^{1/2})$ with coefficient γ:

$$\frac{J}{E^2} = \frac{9\epsilon\epsilon_0}{8d}\exp\left(-\frac{E_A}{kT}\right)\exp(\gamma(T)\sqrt{E}) \tag{3}$$

Fitting the experimental data to this combined equation yielded the electric field coefficients, γ, and the temperature dependence of these quantities for PQT-12 and PDT2Se2. The obtained values are plotted in Fig. 2, using the value of μ_0 obtained previously (Fig. 1). These results show that the substitution of a selenophene in place of a

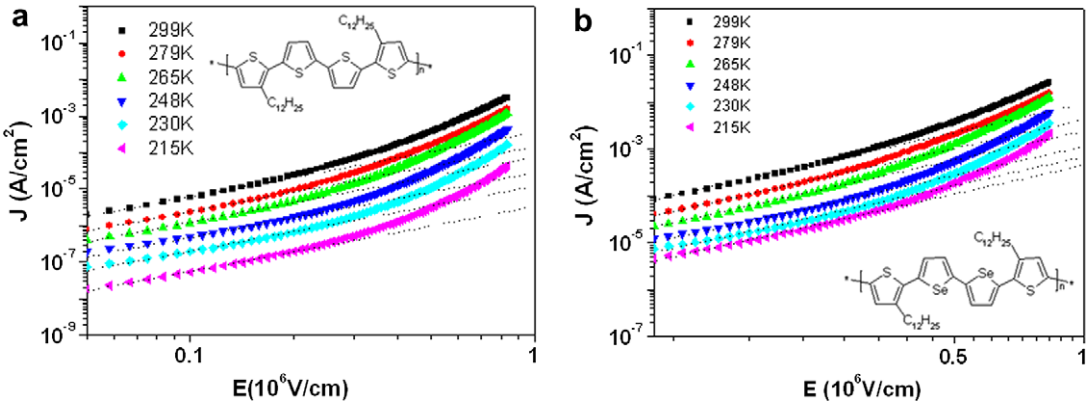

Fig. 1. Temperature-dependent *J–V* characteristics of (a) PQT-12 and (b) PDT2Se2 hole-only devices. The dashed line indicates the prediction of the SCLC model. The chemical structures of PQT-12 (a) and PDT2Se2 (b) are shown in the inset.

polythiophene increased the (zero-field) mobility by an order of magnitude and decreased the temperature dependence of the mobility, or activation energy, which was determined by the trap distribution (E_A = 140 meV for PQT-12 and 92 meV for PDT2Se2). Likewise, both the field- and temperature-dependence of the mobility, γ, were lower in PDT2Se2 than in PQT-12. This behavior could be explained by Bässler's charge carrier hopping model in disordered organic semiconductors [21,22]. Systems with a large degree of energetic disorder have high energy barriers between adjacent hopping cites. High energy barriers create mobilities that are strongly dependent on the electric field, because the electric field can compensate for the energy barrier along the direction of charge carrier hopping. The temperature dependence of γ is also related to the energetic disorder, because the energy barrier between adjacent hopping cites may be difficult to overcome at lower temperatures. This behavior would be maximized in highly disordered systems. Therefore, the higher mobility and lower field dependence, activation energy, and temperature dependence of γ in PDT2Se2, relative to PQT-12, imply a lower degree of energetic disorder in PDT2Se2. Lower energetic disorder arises, structurally, from more effective interchain π–π overlap in PDT2Se2, generated by the introduction of the electron-rich selenophene. The values obtained for the activation energy and γ of PDT2Se2 were similar to those reported previously for poly(*p*-phenylene vinylene) derivatives [23,24].

To take advantage of the relatively high mobility and efficient π–π overlap in PDT2Se2, we fabricated photovoltaic cells by blending this polymer with PCBM and compared the results with those of PQT-12. Fig. 3 shows the UV–Vis absorption and photoluminescence spectra of the spin-coated films of homo PDT2Se2 and blended films. The absorption spectra of both films showed a maximum at 565 nm and a shoulder around 620 nm, indicative of a well-ordered inter-molecular packing structure. A trailing edge appeared in the near-IR region of the spectrum, resulting in an optical band gap of approximately 1.85 eV, which was slightly lower than the band gaps for P3HT and PQT-12 [1,10]. The electrochemical measurements revealed HOMO and LUMO levels of −5.1 eV and

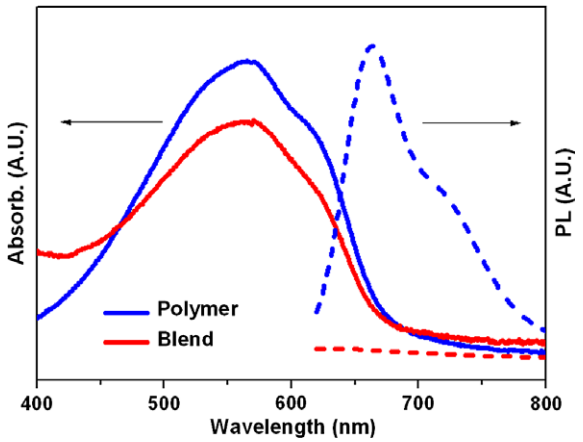

Fig. 3. UV–Vis absorption and PL spectra of spin-coated films of the PDT2Se2 homopolymer and a blend with PCBM.

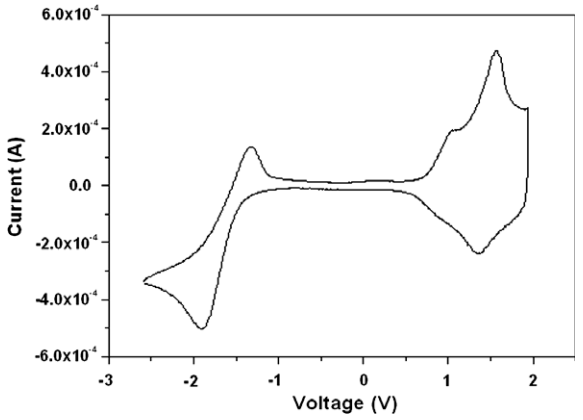

Fig. 4. Cyclic voltammogram of the spin-coated PDT2Se2.

−2.95 eV, respectively, yielding an electrochemical band gap of 2.15 eV (Fig. 4). The HOMO of PDT2Se2 was shifted slightly to lower values, by 100–200 meV, relative to that

of P3HT. Because there is a linear relationship between the donor-HOMO and acceptor-LUMO energy differences and the open circuit voltage (V_{OC}) of the bulk heterojunction devices [25], larger values of V_{OC} for PDT2Se2-based cells were expected. Efficient charge separation at the donor–acceptor interface requires an offset of ~0.3 eV between the donor-LUMO and acceptor-LUMO levels [26]. This energy level matching was present in the PDT2Se2:PCBM blend. Photoluminescence measurements on several films showed the effective quenching of PDT2Se2 emission due to the presence of PCBM in the film (Fig. 3). Quenching was attributed to a sufficient LUMO level difference between the donor and acceptor and the optimal morphology of the phase separation in blended films.

The *J–V* characteristics of the PQT-12:PCBM and PDT2Se2:PCBM blend (ratio from 1:1 to 1:4)-based photovoltaic cells are shown in Fig. 5, and the device performance parameters are summarized in Table 1. The best photovoltaic performances were obtained from blend ratios of 1:4 for both PQT-12 and PDT2Se2 cells, with a V_{OC} of 0.66 V, short circuit current (I_{SC}) of 2.7 mA cm^{-2}, fill factor (FF) of 29%, PCE of 0.53% for PQT-12:PCBM and with a V_{OC} of 0.69 V, short circuit current (I_{SC}) of 4.3 mA cm^{-2}, fill factor (FF) of 47%, PCE of 1.4% for PDT2Se2:PCBM, respectively. In accordance with the expectations from the HOMO level of PDT2Se2, a relatively large V_{OC} was obtained compared with those of PQT-12. (The V_{OC} of P3HT-based cells was <0.65 V. [26]) Although these photovoltaic parameters were still very low compared to conventional P3HT:PCBM based solar cells, it clearly shows that PDT2Se2 is much better electron donor material for photovoltaic cell than PQT-12, [13] Structural analyses were carried out to understand much better performances of PDT2Se2 compared to PQT-12 and their blend ratio dependence, by employing XRD recorded in grazing-incidence geometry. Fig. 6 shows out-of-plane XRD patterns of both homo polymers and polymer:PCBM blends with various ratios. Interestingly, diffraction spectra of both polymers are shifted to lower angle by blending with PCBM compared to their homo polymers. This inter-molecular expansion can be attributed to intercalation of the PCBM molecules between the side chains of the polymers [2]. One of the notable differences between two polymers is that PDT2Se2 shows significant decrease in the Bragg peak intensity by adding PCBM, while PQT-12:PCBM blend still shows intense peaks even for blend ratio of 1:4. In the case of PDT2Se2, no signatures of crystalline were observed for blend ratios of 1:3 and 1:4, implying the presence of a highly amorphous polymer lamellar structure. This means that the presence of excess fullerene effectively suppressed the crystallization of PDT2Se2 while PQT-12 could retain high crystalline nature. This structural difference can be attributed to two points. First, the molecular interactions for PDT2Se2-PCBM and PQT-12-PCBM are different. The surface energy of PCBM (34.2 mJ/m^2) is similar to that of PDT2Se2 (35.97 mJ/m^2) rather than that of PQT-12 [27]. (37.85 mJ/m^2) Therefore, more similar surface energies of PDT2Se2–PCBM resulted in rather homogeneous blends and low crystalline well-mixed films. Second, PQT-12 has highly interdigitated structure while PDT2Se2 does not have such highly interdigitated structure as can be shown from XRD results. The interlamellar backbone spacing in PDT2Se2 was determined from the Bragg equation to be 2.28 nm, which is longer than the spacing in PQT-12, 1.85 nm. Considering that the side chain length of C12 is about 1.6 nm, it is clear that the side chain of PDT2Se2 has lower degree of interdigitation than that of PQT-12. Therefore, crystalline structure of PDT2Se2 can be more easily disturbed by PCBM addition, leading to homogeneous state in blend system. Structural difference was also reflected in the morphology as shown in Fig. 7. Excellent miscibility between PDT2Se2 and PCBM was observed for

Table 1
Effects of PCBM content on I_{SC}, V_{OC}, FF and PCE of PQT-12:PCBM and PDT2Se2:PCBM blends.

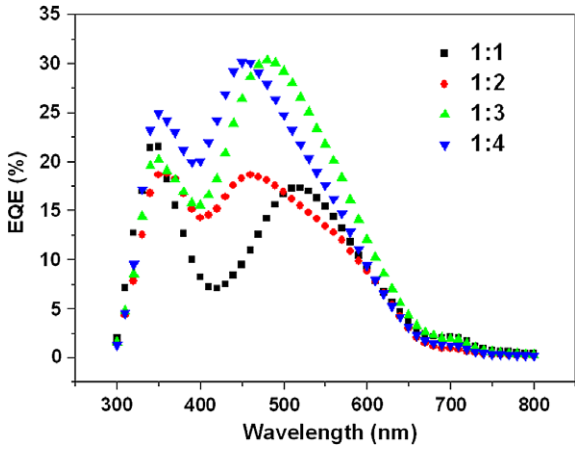

Fig. 8. IPCE spectra of PDT2Se2:PCBM devices with blend ratios of 1:1, 1:2, 1:3, and 1:4.

blend ratio of 1:4, with a low r.m.s. roughness of <0.3 nm while all the PQT-12:PCBM blends (Fig. 7(a) and (b)) and PDT2Se2:PCBM 1:1 blend (Fig. 7(c)) show large-scale phase separation with r.m.s roughness of >0.7 nm. Nanostructures that are optimized for efficient photovoltaic effects should fulfill two criteria: first, the phase separation should be small, comparable to the exciton diffusion length of 10 nm [28,29], to ensure charge separation at the donor–acceptor interface; second, a percolating pathway for both hole and electron charge carriers must exist for the transport of carriers to the respective harvesting electrode [24]. In other words, PDT2Se2:PCBM with blend ratio 1:4 has the domain sizes comparable to the exciton diffusion length (~10 nm), enabling sufficient donor–acceptor interfacial area. Formation of effective morphology by adding excess fraction of PCBM in PDT2Se2:PCBM system can also be observed by IPCE spectra as shown in Fig. 8. The spectral response extends from about 300 nm to 700 nm, indicating that both donor and acceptor contribute to the photocurrent. In terms of EQE, PDT2Se2:PCBM blend film with excess fraction of PCBM showed high EQE over 30%, showing good coincidence with previously obtained photovoltaic parameters, especially with J_{SC}. Therefore, we can see that the use of an excess weight fraction of PCBM in the PDT2Se2:PCBM BHJ system effectively suppress the domain size of the crystalline PDT2Se2 and generate homogeneous nanoscale phase separation, resulting in better photovoltaic performance compared to PQT-12:PCBM BHJ system. Unlike the P3HT:PCBM blend system, in which thermal annealing could be used to optimize the morphology, thermal annealing of the both PQT-12:PCBM and PDT2Se2:PCBM blend system at temperatures above 100 °C induced macrophase separation and a remarkable decrease in the photovoltaic performance. This behavior resulted from increased diffusive motion of the PCBM molecules within the polymer matrix, due to the significantly larger interchain spacings of both polymers, as described earlier [30].

3. Conclusion

PDT2Se2 blended with PCBM was investigated as an electron donor material for BHJ OSCs. This blend showed a higher bulk mobility and lower energetic disorder, as confirmed by temperature-dependent SCLC analysis. In contrast with P3HT:PCBM devices, PDT2Se2:PCBM devices showed optimum performances when an excess of PCBM was used, due to the large free volume present between the side chains of the polymer backbone. The PCE of an OSC composed of a blend of PDT2Se2 and PCBM (1:4, w/w) reached 1.4% under A.M. 1.5 G illumination, 100 mW cm^{-2}. This PCE was higher than those achievable using the PQT-12:PCBM system. Because the photovoltaic performance of this blend was much lower than the performance of P3HT:PCBM, further optimization is required.

4. Experimental

PDT2Se2 and PQT-12 were synthesized via Stille and oxidative coupling, as described previously [16]. PCBM (99%) used in this study was obtained from Aldrich. The PDT2Se2:PCBM blend solutions (weight ratios of 1:1, 1:2, 1:3, 1:4) were prepared in chlorobenzene at a concentration of 20 mg/mL. After cleaning the pre-patterned ITO-coated glass, PEDOT–PSS (Baytron P TP AI 4083, Bayer AG) was spin-coated to a thickness of 30–50 nm and annealed at 120 °C (for 60 min) in air. The active layer was spin-coated onto the PEDOT:PSS layer for 60 s to a thickness of 100 nm. Finally, lithium quinolate (Liq.) (0.6 nm)/Al (100 nm) cathodes were thermally deposited. The current density–voltage (*J–V*) characteristics were measured using Keithley 4200 source/measure units in the dark and under AM 1.5 G solar illumination (Oriel 1 kW solar simulator) with respect to the reference cell PVM 132 (calibrated at the National Renewable Energy Laboratory, NREL, at an intensity of 100 mW/cm^2).

UV–Vis and photoluminescence (PL) measurements were carried out on a UV–Vis–NIR spectrophotometer (Cary 5000: Varian Co. and FR 6500, JASCO CO.). Cyclic voltammetry measurements of the polymer films were performed on a BAS 100 B/W electrochemical analyzer in acetonitrile, with 0.1 M tetrabutylammonium perchlorate (Bu_4NClO_4) as the supporting electrolyte, at a scan rate of 100 mV/s. The potentials were measured against an Ag/AgCl reference electrode with ferrocene as the internal standard. The onset potentials were determined from the intersection of the tangents to the rising current and to the background current of the cyclic voltammogram. GIXD studies were performed using the 4C1 and 4C2 beam lines at the Pohang Accelerator Laboratory (PAL). The measurements were carried out with a sample-to-detector distance of 136 mm. Data were typically collected for ten seconds using an X-ray radiation source of λ = 0.138 nm with a 2D charge-coupled detector (CCD) (Roper Scientific, Trenton, NJ, USA). X-ray diffraction analysis for the one-dimensional diffraction pattern was performed at the 10C1 beam line (wavelength ~1.54 Å) at the (PAL).

AFM (Multimode IIIa, Digital Instruments), operated in tapping mode, was used to image the surface morphology of the photoactive layer.

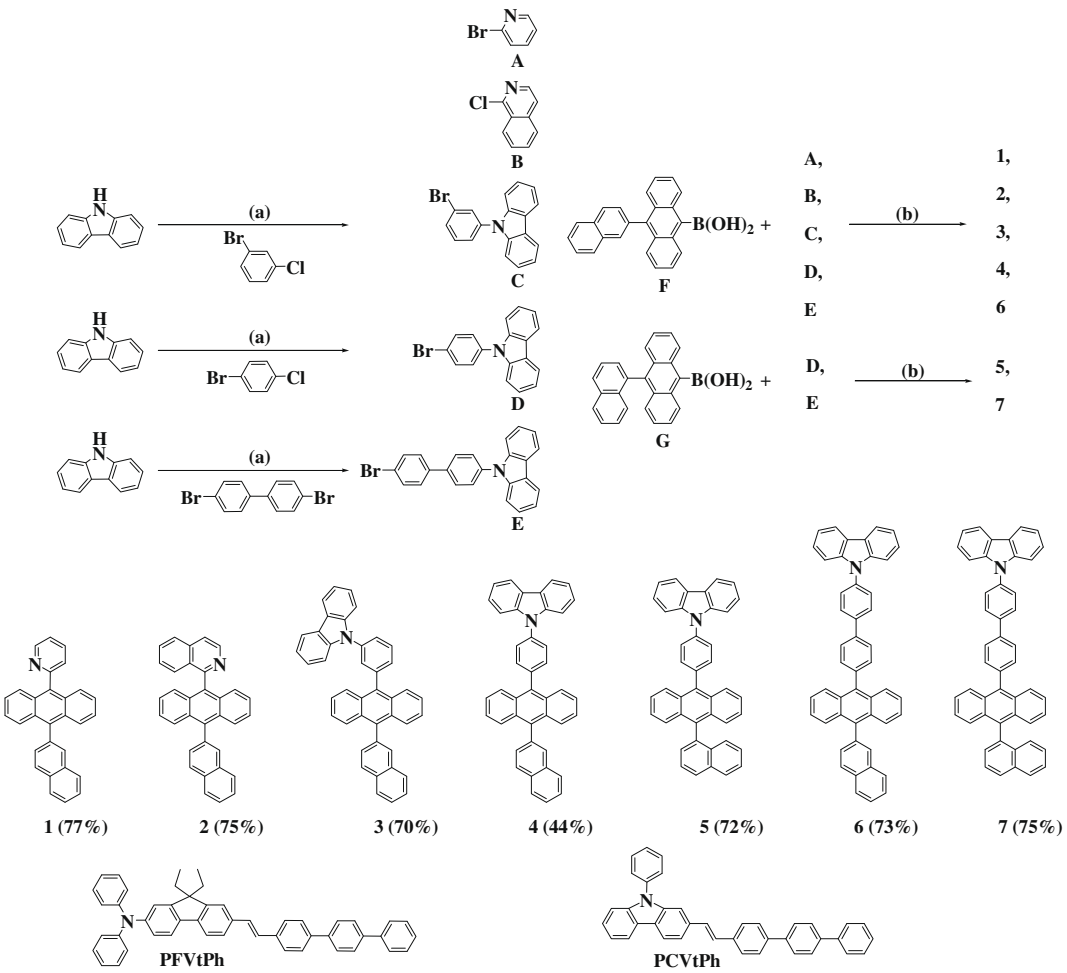
oligoquinoline derivatives [12] have been developed and subsequent attempts made to improve their EL properties. Among them, many researchers continuously strive to develop new, high efficient blue emitters because such derivatives provide excellent thermal- and electrochemical stabilities, as well as desirable photoluminescent properties [6]. For example, Park et al. have reported anthracene derivatives bearing bulky side groups with an excellent external quantum efficiency (EQE) of 7.18% and CIE coordinates of (0.156, 0.088) [13]. Additionally, anthracene derivatives bearing non-planar diarylsilyl groups with high EQE (6.3%) and good CIE coordinates (0.142, 0.149) have been reported by Char and coworkers [14]. In these studies, the bulky substituents provide steric hindrance that prevents intermolecular interactions and reduces self-quenching effects, leading to improved electroluminescent (EL) performance. These studies, as along with others [15], suggest that the structural features of the emitting materials are an important factor in EL performance. Meanwhile, the charge balance in the emitting layer is also a crucial factor towards improving EL performance. However, there have been few systematic studies on blue-emitting materials based on anthracene derivatives with different electronic properties and thus, charge transporting properties.

In this paper, we report highly efficient blue light-emitting materials based on the 10-naphthylanthracene core unit containing heteroaromatic moieties with different electronic properties: 2-(10-(naphthalen-2-yl)anthracen-9-yl)pyridine (**1**); 1-(10-(naphthalen-2-yl)anthracen-9-yl)isoquinoline (**2**); 9-(3-(10-(naphthalen-2-yl)anthracen-9-yl)phenyl)-9H-carbazole (**3**); 9-(4-(10-(naphthalen-2-yl)anthracen-9-yl)phenyl)-9H-carbazole (**4**); 9-(4-(10-(naphthalen-1-yl)anthracen-9-yl)phenyl)-9H-carbazole (**5**); 9-(4′-(10-(naphthalen-2-yl)anthracen-9-yl)biphenyl-4-yl)-9H-carbazole (**6**); 9-(4′-(10-(naphthalen-1-yl)anthracen-9-yl)biphenyl-4-yl)-9H-carbazole (**7**) (Scheme 1). In materials **1**–**4** and **6**, electron-withdrawing groups such as pyridine [16] and isoquinoline [17], and electron-donating groups such as carbazolylphenyl and carbazolylbiphenyl [18,19] were introduced into the 10-(naphthalen-2-yl)anthracene core to test the effects of anthracene side groups with different electronic properties on EL perfor-



Scheme 1. Molecular structures and synthetic routes of new host materials (**1–7**). *Conditions*: (a) Cu, 18-Crown-6, K_2CO_3, 1,2-Dichlorobenzene, reflux, 24 h; and (b) $Pd(PPh_3)_4$, 2.0 M Na_2CO_3, toluene/EtOH, reflux, 4 h.

mance. Blue materials **5** and **7** bore a 10-(naphthalen-1-yl)anthracene core, instead of 10-(naphthalen-2-yl)anthracene, to study the differences in the EL performances between the 1- and 2-naphthylanthracene derivatives.

To investigate the EL properties of materials **1**–**7**, multilayered OLEDs were fabricated using these blue materials as the emitting layer (non-doped) and host material for 4′-[2-(2-diphenylamino-9,9-diethyl-9H-fluoren-7-yl)-vinyl]-*p*-terphenyl (**PFVtPh**) [20] and 3-(N-phenylcarba zol)vinyl-*p*-terphenyl (**PCVtPh**) [21] (doped). As will be demonstrated below, devices using materials **1**–**7** exhibited highly efficient blue emissions.

2. Experimental details

2.1. Materials and measurements

Carbazole, 1-bromo-3-iodobenzene, 1-bromo-4-iodobenzene, 4,4′-dibromobiphenyl, 2-bromopyridine (**A**), and 1-chloroisoquinoline (**B**) were used as received from Aldrich (City, State, Country) or TCI (City, State, Country). The 9-(3-bromophenyl)-9H-carbazole (**C**) [22], 9-(4-bromophenyl)-9H-carbazole (**D**) [23], 9-(4′-bromobiphenyl-4-yl)-9H-carbazole (**E**) [24], 9-(2-naphthyl)anthracene-10-boronic acid (**F**) [25], 9-(1-naphthyl)anthracene-10-boronic acid (G) [25], 4′-[2-(2-diphenylamino-9,9-diethyl-9H-fluoren-7-yl)vinyl]-*p*-terphenyl (**PFVtPh**) [20], and 3-(N-phenylcarbazol)vinyl-*p*-terphenyl (**PCVtPh**) [21] were synthesized as reported previously. All solvents were dried using standard procedures and all reagents were used as received from commercial sources, unless otherwise stated. All reactions were performed under a N_2 atmosphere.

The ^{1}H- and ^{13}C-NMR were recorded on a Varian Unity Inova 300Nb spectrometer. All FT-IR spectra were recorded using a Bruker VERTEX70 FT-IR spectrometer. Elemental analysis (EA) was measured using an EA 1108 spectrometer. Low- and high-resolution mass spectra were measured using a Jeol JMS-600 spectrometer in the EI mode and a JMS-T100TD (AccuTOF-TLC) in the positive ion mode.

2.2. General procedure for the Suzuki cross-coupling reaction

The 10-(naphthalen-2-yl)anthracen-9-yl-boronic acid (1.2 mol) or 10-(naphthalen-1-yl)anthracen-9-yl-boronic acid (1.2 mol) and the corresponding aryl halide derivatives (1.0 mol), $Pd(PPh_3)_4$ (0.04 mol), aqueous 2.0 M Na_2CO_3 (10.0 mol), ethanol, and toluene were mixed in a flask and refluxed for 4 h. After the reaction finished, the reaction mixture was extracted with ethyl acetate and washed with water. The organic layer was dried with anhydrous $MgSO_4$ and filtered with silica gel. The solution was then evaporated and the crude product re-crystallized from CH_2Cl_2/EtOH.

2.2.1. 2-(10-(Naphthalen-2-yl)anthracen-9-yl)pyridine (1)

Yield: 77%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.94 (d, J = 4.5 Hz, 1H), 8.07–7.90 (m, 5H), 7.71 (d, J = 8.4 Hz, 2H), 7.62–7.53 (m, 6H), 7.47 (td, J = 1.2, 6.2 Hz, 1H), 7.37–7.23 (m, 4H). ^{13}C-NMR (75 MHz, $CDCl_3$) [δ ppm]: 158.8, 150.5, 138.2, 136.8, 136.6, 135.6, 133.6, 133.0, 130.5, 130.4, 130.2, 130.0, 129.9, 129.6, 128.5, 128.4, 128.3, 128.2, 128.1, 127.4, 127.1, 126.7, 126.5, 126.4, 125.8, 125.4, 122.7. FT-IR [ATR]: ν = 3050, 1739, 1586, 1468, 785, 762, 748 cm^{-1}. MS(EI$^+$) m/z 381 (M$^+$). Anal. calcd for $C_{29}H_{19}N$: C 91.31, H 5.02, N 3.67; found: C 91.23, H 5.02, N 3.72.

2.2.2. 1-(10-(Naphthalen-2-yl)anthracen-9-yl)isoquinoline (2)

Yield: 75%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: .8.86 (dd, J = 1.1, 5.9 Hz, 1H), 8.12–7.88 (m, 6H), 7.77–7.68 (m, 3H), 7.65–7.57 (m, 3H), 7.43–7.21 (m, 8H). ^{13}C-NMR (75 MHz, $CDCl_3$) [δ ppm]: 160.5, 143.3, 138.5, 136.8, 136.7, 136.6, 133.6, 133.0, 130.7, 130.6, 130.4, 130.3, 129.9, 129.7, 128.6, 128.5, 128.4, 128.3, 128.2, 128.1, 128.0, 127.9, 127.5, 127.2, 126.7, 126.5, 126.0, 125.4, 120.7. FT-IR [ATR]: ν = 3015, 1738, 1585, 1500, 761, 744 cm^{-1}. MS(EI$^+$) m/z 431 (M$^+$). Anal. calcd for $C_{33}H_{21}N$: C 91.85, H 4.91, N 3.25; found: C 91.73, H 4.95, N 3.19.

2.2.3. 9-(3-(10-(Naphthalen-2-yl)anthracen-9-yl)phenyl)-9H-carbazole (3)

Yield: 70%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.14 (d, J = 7.8 Hz, 2H), 8.06 (dd, J = 4.2, 5.4 Hz, 1H), 8.02–7.96 (m, 2H), 7.90–73 (m, 8H), 7.64–7.57 (m, 6H), 7.42 (t, J = 7.7 Hz, 4H), 7.35–7.29 (m, 4H). ^{13}C-NMR (75 MHz, $CDCl_3$) [δ ppm]: 141.2, 140.8, 138.1, 137.6, 136.6, 136.5, 136.0, 133.5, 132.9, 130.4, 130.3, 130.2, 130.1, 130.0, 129.8, 129.6, 129.5, 128.4, 128.3, 128.2, 128.1, 128.0, 127.4, 126.8, 126.6, 126.4, 126.2, 126.1, 125.7, 125.4, 123.7, 120.5, 120.3, 110.0. FT-IR [ATR]: ν = 3060, 1739, 1598, 1478, 763, 747 cm^{-1} MS(EI$^+$) m/z 545 (M$^+$). Anal. calcd for $C_{42}H_{27}N$: C 92.45, H 4.99, N 2.57; found: C 92.19, H 5.03, N 2.51.

2.2.4. 9-(4-(10-(Naphthalen-2-yl)anthracen-9-yl)phenyl)-9H-carbazole (4)

Yield: 44%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.22 (d, J = 7.8 Hz, 2H), 8.09 (d, J = 8.4 Hz, 1H), 8.05–8.01 (m, 2H), 7.95–7.92 (m, 1H), 7.86 (t, J = 9.0 Hz, 4H), 7.76 (t, J = 8.3 Hz, 4H), 7.69 (d, J = 8.1 Hz, 2H), 7.66–7.60 (m, 3H), 7.52 (td, J = 1.2, 7.8 Hz, 2H), 7.45 (td, J = 1.4, 7.6 Hz, 2H), 7.38–7.33 (m, 4H). ^{13}C-NMR (75 MHz, $CDCl_3$) [δ ppm]: 141.0, 138.4, 137.5, 137.2, 136.6, 136.3, 133.6, 133.0, 132.9, 130.4, 130.3, 130.1, 129.6, 128.3, 128.2, 128.1, 127.4, 127.1, 126.9, 126.6, 126.4, 126.2, 125.6, 125.4, 123.7, 120.6, 120.3, 110.1. FT-IR [ATR]: ν = 3062, 1739, 1598, 1479, 771, 749 cm^{-1}. MS(EI$^+$) m/z 545 (M$^+$). Anal. calcd for $C_{42}H_{27}N$: C 92.45, H 4.99, N 2.57; found: C 92.25, H 5.04, N 2.58.

2.2.5. 9-(4-(10-(Naphthalen-1-yl)anthracen-9-yl)phenyl)-9H-carbazole (5)

Yield: 72%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.22 (d, J = 7.5 Hz, 2H), 8.09 (d, J = 8.1 Hz, 2H), 8.04 (d, J = 8.1 Hz, 2H), 7.89 (d, J = 9.0 Hz, 2H) 7.86–7.82 (m, 2H), 7.80–7.69 (m, 4H), 7.60 (d, J = 6.6 Hz, 1H), 7.55–7.48 (m, 5H), 7.44 (d, J = 6.3 Hz, 1H), 7.40 (d, J = 5.1 Hz, 1H), 7.35 (d, J = 7.5 Hz, 1H), 7.30–7.22 (m, 4H). ^{13}C-NMR (75 MHz, $CDCl_3$) [δ ppm]: 141.1, 138.5, 137.4, 136.9, 135.8, 134.0, 133.8, 133.1, 130.9, 129.5, 128.5, 128.4, 127.5, 127.2, 127.0, 126.9, 126.6, 126.3, 125.9, 125.7, 125.6, 123.8, 120.7, 120.4, 110.2. FT-IR [ATR]: ν = 3061, 1597, 1479,

781, 740 cm^{-1}. MS(EI^+) m/z 545 (M^+). Anal. calcd for $C_{42}H_{27}N$: C 92.45, H 4.99, N 2.57; found: C 92.55, H 5.00, N 2.43.

2.2.6. 9-(4′-(10-(Naphthalen-2-yl)anthracen-9-yl)biphenyl-4-yl)-9H-carbazole (6)

Yield: 73%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.19 (d, J = 7.8 Hz, 2H), 8.10 (d, J = 8.7 Hz, 1H), 8.03–8.00 (m, 4H), 7.97–7.95 (m, 3H), 7.86–7.83 (m, 2H), 7.77–7.73 (m, 3H), 7.67–7.56 (m, 6H), 7.54(s, 1H), 7.48 (dd, J = 1.2, 6.9 Hz, 2H), 7.43 (dd, J = 1.2, 7.2 Hz, 1H), 7.40–7.31 (m, 6H). FT-IR [ATR]: v = 3058, 2360, 1600, 1479, 815, 741 cm^{-1}. MS(FAB^+) m/z 621 (M^+). HRMS-TOF (M^++H) Anal. calcd for $C_{48}H_{32}N$ 622.2535: found: 622.2508. Anal. calcd for $C_{48}H_{31}N$: C 92.72, H 5.03, N 2.25; found: C 92.52, H 5.03, N 2.25.

2.2.7. 9-(4′-(10-(Naphthalen-1-yl)anthracen-9-yl)biphenyl-4-yl)-9H-carbazole (7)

Yield: 73%. ^{1}H-NMR (300 MHz, $CDCl_3$) [δ ppm]: 8.20 (d, J = 7.8 Hz, 2H), 8.09 (d, J = 7.8 Hz, 1H), 8.05–8.01 (m, 2H), 8.00–7.92 (m, 3H), 7.87 (d, J = 8.7 Hz, 2H), 7.76–7.73 (m, 3H), 7.71–7.66 (m, 2H), 7.60 (d, J = 6.0 Hz, 1H), 7.56–7.53 (m, 3H), 7.50–7.45 (m, 4H), 7.41–7.38 (m, 2H), 7.35 (d, J = 6.9 Hz, 2H), 7.30 (d, J = 7.8 Hz, 2H), 7.26–7.22 (m, 2H). FT-IR [ATR]: v = 3047, 1626, 1453, 819, 746 cm^{-1}. MS(FAB^+) m/z 621 (M^+). HRMS-TOF (M^++H) Anal. calcd for $C_{48}H_{32}N$ 622.2535: found: 622.2522. Anal. calcd for $C_{48}H_{31}N$: C 92.72, H 5.03, N 2.25; found: C 92.66, H 5.03, N 2.21.

2.3. Physical measurements

The UV–Vis absorption and photoluminescence spectra of the newly designed host materials were measured in a CH_2Cl_2 solution (10^{-5} M) using a Shimadzu UV-1650PC and an Amincobrowman series 2 luminescence spectrometer. Fluorescent quantum yields were determined in the CH_2Cl_2 solution at 293 K against 9,10-diphenylanthracene as the standard (Φ = 0.90) [26]. The ionization potentials (or highest occupied molecular orbital (HOMO) energy levels) of the compounds were measured with a low-energy photo-electron spectrometer (Riken-Keiki, AC-2). Lowest unoccupied molecular orbital (LUMO) energy levels were estimated by subtracting the energy band gap from the HOMO energy levels. The energy band gap was determined by the on-set absorption energy from the absorption spectra of the materials. Thermal properties were measured using thermogravimetric analysis (TGA) (DTA-TGA, TA-4000) and differential scanning calorimeter (DSC) (Mettler Toledo; DSC 822) under N_2 at a heating rate of 10 °C/min. A heat-cool-heat method was used with an initial heating rate of 10 °C/min and rapidly quenched-cooled into liquid nitrogen and a final heating rate of 10 °C/min.

2.4. OLED fabrication and measurement

For fabricating OLEDs, indium-tin-oxide (ITO) thin films coated on glass substrates were used, which were 30 Ω square of the sheet resistivity and 100 nm thick. The ITO-coated glass was cleaned in an ultrasonic bath by the following sequence: acetone, methyl alcohol, distilled water, and stored in isopropyl alcohol for 48 h and dried with a N_2 gas gun. The substrates were treated by O_2 plasma under 2.0×10^{-2} torr at 125 W for 2 min [27]. All organic materials and metals were deposited under high vacuum (5×10^{-7} torr). The OLEDs were fabricated in the following sequence: ITO/4,4′-bis(*N*-(1-naphthyl)-*N*-phenylamino) biphenyl (NPB) (50 nm)/Blue-emitting materials (**1–7**) (30 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen) (30 nm)/lithium quinolate (Liq) (2 nm) /Al (100 nm), NPB as the hole-transporting layer, Bphen as the electron-transporting layer, and Liq:Al as the composite cathode. The current density (J), luminance (L), luminous efficiency (LE), and CIE chromaticity coordinates of the OLEDs were measured with a Keithly 2400, Chroma meter CS-1000A. Electroluminance was measured using a Roper Scientific Pro 300i.

3. Results and discussion

3.1. Thermal properties

The thermal properties of **1–7** were measured by thermogravimetric analysis (TGA) and differential scanning calorimeter (DSC), and are listed in Table 1. The decomposition temperatures (T_d; corresponding to 5% weight loss)

Table 1
Optical properties of new host materials (**1–7**).

of all compounds were between 320 and 461 °C, indicating that thermal stability increases relative to the size of the substitution groups at the 10-position of the anthracene molecules. Moreover, **4** and **6**, having *para*-positioned carbazole and 2-naphthalene, exhibited a T_d higher than **3**, **5**, and **7** with *meta*-positioned carbazole or 1-naphthalene. Notably, the T_d of **6** was 60 °C higher than that of **4**. The glass temperatures (T_g) were observed for compounds **1**–**7** at 95, 127, 129, 153, 154, 157, and 158 °C, respectively, with DSC in the second heating scans. These results clearly reveal that compounds **4**–**7** possess good thermal stability, very desirable characteristic for OLEDs stability. Additionally, most compounds showed melting temperatures higher than 270 °C.

3.2. Optical properties

The optical properties for all compounds are summarized in Table 1. Fig. 1a shows the emission spectra of the blue materials (**1–7**), with the maximum emission peaks ranging from 418 to 431 nm in the deep-blue region. There was a slight blue-shift in the PL spectra of **5** and **7** compared to **4** and **6,** as well as **2** and **3** compared to **1** and **4**, respectively. This is likely due to a decrease in the π-conjugation length through the steric hindrance between 1-naphthalene and anthracene. Their full width at half maximum (FWHM) values ranged from 52 to 59 nm. The overall quantum yields of all compounds, with the exception of **2**, were high values (Φ = 0.70–0.78). As such, these compounds make excellent candidates for use as efficient blue-emitting materials in OLEDs. As shown in Fig. 1b, the emission spectra in the thin films of **1**–**7** are red-shifted compared to those in the CH_2Cl_2 solution, owing to the solid-state effect [28].

From the spectra overlap between the absorption of **PFVtPh** and the emission of materials **1**–**7**, as shown in Fig. 1a, sufficient energy transfer from **1**–**7** to **PFVtPh** through a Förster energy transfer was expected, indicating that materials **1**–**7** acted as good host materials in OLED devices using **PFVtPh** as a dopant.

3.3. Estimation of the HOMO and LUMO energy levels

The HOMO energy levels of these materials were estimated by an AC-2 photoelectron spectrometer, indicating a HOMO energy level variation of −5.73 to −5.98 eV for **1**–**7**. The lowest unoccupied molecular orbital (LUMO) energy levels calculated by subtraction of the optical band gaps from the HOMO energy levels were between −2.67 and −2.87 eV, as shown in Fig. 2.

The optical energy band gaps (E_g) of **1–7** ranged from 3.06 to 3.11 eV, as determined from the absorption spectra. These compounds possessed higher energy band gaps than those of **PFVtPh** (2.82 eV) and **PCVtPh** (3.10 eV), implying that energy transfer from materials **1**–**7** to **PFVtPh** and **PCVtPh** through a Förster energy transfer was expected, indicating them as good host materials in OLED devices using **PFVtPh** as a dopant. Furthermore, employment of cyclic voltammetry (CV), using a three-electrode cell with ferrocene as the internal standard, allowed for estimation of the electrochemical behavior of **1** and **4**. During the anodic scan in acetonitrile, **4** exhibited a reversible oxidation process at 0.92 V $\left(E^{OX}_{1/2}\right)$, with an onset potential of 0.88 V. Upon the cathodic scan, a reversible reduction potential $\left(E^{red}_{1/2}\right)$ of −2.19 V, together with an onset potential of −2.08 V, was detected. However, **1**, with the electron-deficient pyridine moiety, exhibited an irreversible oxidation process with an $\left(E^{OX}_{onset}\right)$ value of 0.81 V, while the reversible reduction process indicated values of $\left(E^{red}_{1/2}\right)$ of −2.18 V, respectively. These observations demonstrated that introduction of an electron-rich carbazole unit in **4** moderately increased the oxidation potential, while only slightly changing its reduction potential. On the basis of the onset potentials of oxidation, the respective HOMO levels of **1** and **4** could be estimated to be 5.61 and 5.68, with regard to ferrocene (4.80 eV below vacuum). The electrochemical results are consistent the estimation of HOMOs energy levels by an AC-2 photoelectron spectrometer.

Interestingly, among materials **1**–**7**, material **1**, with the pyridine moiety (−5.73 eV), had the highest HOMO energy

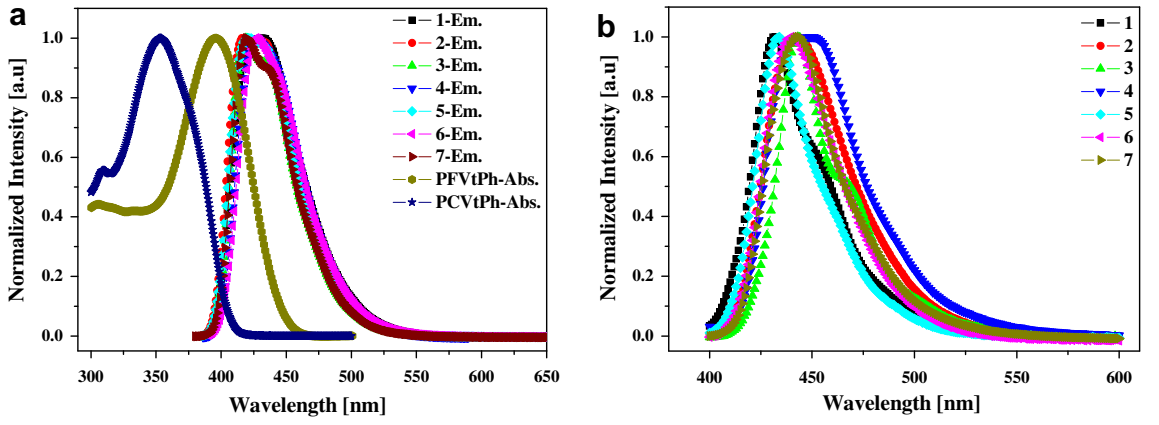

Fig. 1. (a) Emission spectra of host materials (**1**–**7**) and absorption spectra of dopant materials (**PFVtPh** and **PCVtPh**) in CH_2Cl_2; and (b) Emission spectra of **1**–**7** in thin film.

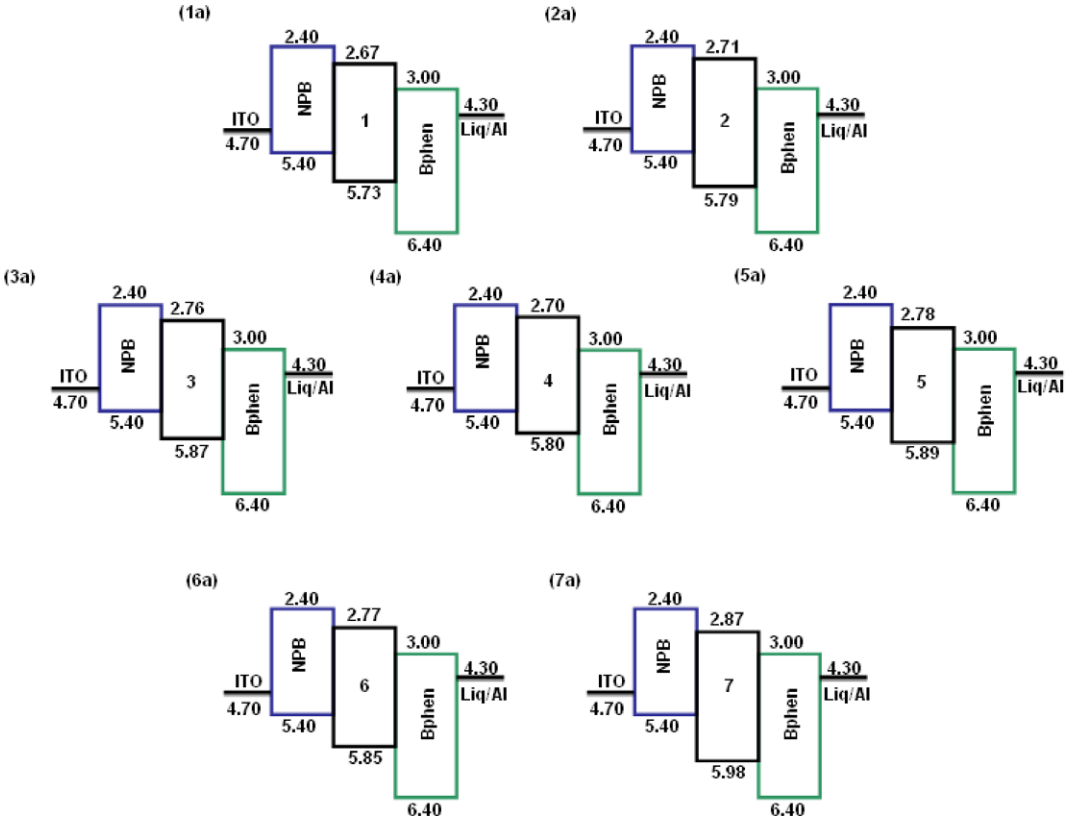

Fig. 2. Energy diagrams of non-doped devices **1a–7a**.

level. In order to investigate the origin of this observation, materials **1–4** were calculated using DFT calculations with a 6-31G* basis set level [29]. The respective highest occupied molecular orbital (HOMO) energy levels of **3** and **4** (both −5.211 eV) were lower than **1** (−5.101 eV) and **2** (−5.129 eV). This discrepancy can be explained by the HOMO shapes. The electron distributions of the HOMOs are shown in Fig. 3. In the HOMOs for **3**, **4**, the electrons are distributed over the anthracene, carbazole, and phenyl moieties, while in HOMOs **1** and **2**, the electrons are relatively localized over the anthracene moiety. Accordingly, the HOMOs for **3** and **4** show more delocalized electrons compared with **1** and **2**, and as such, the HOMO energies of **3** and **4** are lower than those of **1** and **2**.

3.4. Electroluminescence properties

The EL spectra of devices **1a–7a** showed deep-blue emissions with respective peaks at 441–454 nm, Fig. 4.

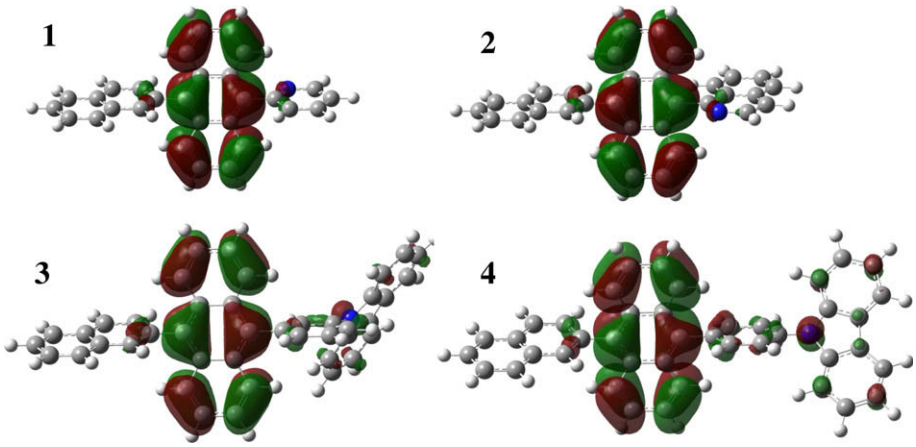

Fig. 3. The B3LYP/6-31G* calculated HOMOs for **1–4**.

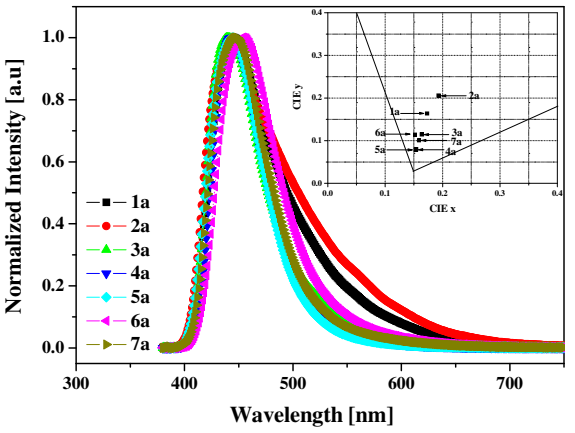

Fig. 4. EL spectra and the CIE coordinates at 8.0 V of non-doped devices **1a–7a**.

Interestingly, the EL spectra of devices **3a–7a**, using emitting materials with an electron-donating group (*N*-arylcarbazole), showed a narrower full-width at half maximum (FWHM) (ca. 16–34 nm) over devices **1a–2a**, using emitting materials with an electron-withdrawing group (pyridine, isoquinoline). Assumedly, in devices **3a–7a**, excimer and exciplex formations involving emitting materials are reduced since the *N*-aryl carbazole-substituted naphthylanthracene derivatives prevent intermolecular interactions. The red-shift emissions observed in devices **1** and **2** may not only be due to the excimer from the intermolecular interactions, but also derived from the exciplex in the device interfaces due to the miss-matched energy levels. Moreover, the CIE *x* and *y* coordinates of devices **3a** (0.164, 0.115), **4a** (0.154, 0.080), **5a** (0.153, 0.079), **6a** (0.152, 0.114), and **7a** (0.159, 0.101) were lower than devices **1a** (0.173, 0.164) and **2a** (0.193, 0.206) because of the narrow FWHM. In particular, the CIE coordinates of device **5a** (0.153, 0.079) were very close to the NTSC blue standard of (0.14, 0.08).

Fig. 5 shows the luminance–voltage–current density (*L–V–J*), luminous efficiencies (LE), power efficiencies (PE), and external quantum efficiencies (EQE) of devices **1a–7a**, respectively. The EL properties of devices **1a–7a** are summarized in Table 2, with all devices showing low turn-on voltages no greater than 4.5 V. The molecular structure and electronic properties of the blue materials can be correlated with device performances. First, devices **3a–7a**, using emitting materials with an electron-donating group (*N*-arylcarbazole), showed improved EL efficiencies, compared with devices **1a–2a** using emitting materials with an electron-withdrawing group (pyridine, isoquinoline). In devices **1a–2a**, excimer and exciplex formations involving emitting materials, appeared as shown in the EL spectra in Fig. 4. Presumably, these would contribute

to the reduced EL properties of devices **1a–2a** by a self-quenching effect. Interestingly, the EL performances of device **2a** are much worse than those of device **1a**. In the EL spectra in Fig. 4, the FWHM of device **2a** was wider than that of device **1a**. This observation indicates that excimer and exciplex formations in device **2a** are severe and thus, lead to the reduced EL efficiencies of device **2a**, as compared with device **1a**. In addition, the lower quantum yield of material **2** relative to material **1** could partially contribute to the reduced EL efficiencies of device **2a**, as compared with device **1a**.

Among devices **3a–7a** with an electron-donating group (*N*-arylcarbazole), device **6a** exhibited excellent EL performances; its luminous efficiency, power efficiency, and external quantum efficiency reached 4.40 cd/A, 4.31 lm/W, and 3.83% (3.40 cd/A, 1.92 lm/W, and 3.20% at 20 mA/cm^2), respectively. The EL efficiencies of device **6a** were twice as high as the common blue host material MADN. Compared to device **6a**, using emitting material **6** with a 2-naphthyl group at the 9-position of the anthracene core, device **7a**, using emitting material **7** with a 1-naphthyl group at the 9-position of the anthracene core, showed reduced EL efficiencies. Material **7** had HOMO and LUMO energy levels lower than material **1**, as shown in Table 1. These data imply that the hole-injection into the emitting layer of device **7a**, using **7**, was less effective than device **6a**, using **6**, because of the smaller barrier between the NPB (−5.4 eV) and **6** (−5.85 eV) than **7** (−5.98 eV). However, electron-injection into the emitting layer of device **7a**, using **7**, was more effective than device **6a**, using **6**, because of the smaller barrier

between the Bphen (−3.0 eV) and **7** (−2.87 eV) than **6** (−2.77). Presumably, the higher hole-injection barrier of device **7a** could play a crucial factor in the reduced EL efficiencies of device **7a**, due to the larger energy differences in the HOMO energy levels (0.14 eV) than the LUMO energy levels (0.10 eV) between **6** and **7**. In addition, compared to devices **6a**, devices **3a–5a** possessed reduced EL efficiencies. In these cases, there are no significant differences between the HOMO–LUMO energy levels, the quantum efficiencies, and the degree of molecular aggregation between materials **6** and **3–5**. Presumably, the changes of carrier mobility and carrier recombination rate in the emitting layers of the devices by subtle structural changes in emitting materials, would play important roles in variation of the EL efficiencies of devices.

In order to enhance EL efficiencies, these host materials (**1–7**) were doped with blue dopant materials (**PFVtPh** and **PCVtPh**) at 8% in the same device structure, respectively. The EL properties of devices **1b–7c** are summarized in Table 3. Notably, the EL efficiencies of the **b** devices, using

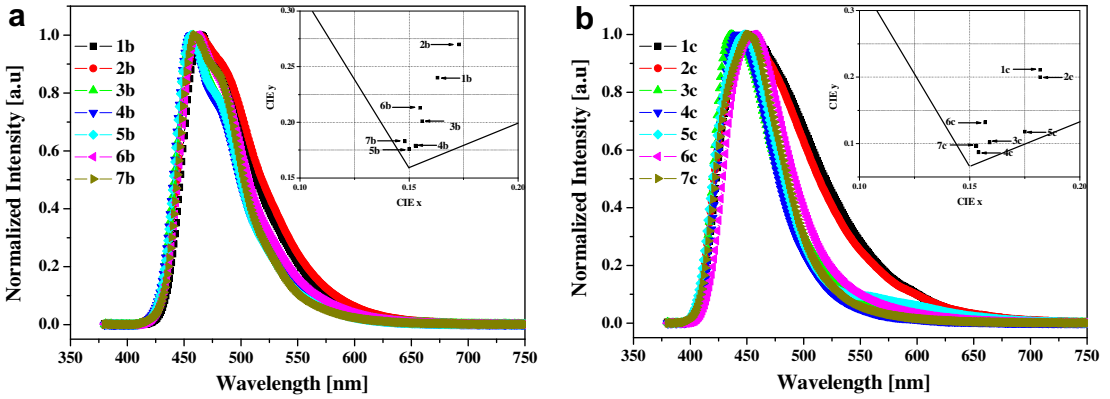

Fig. 6. EL spectra and CIE coordinates at 8.0 V of the doped devices; (a) **1b–7b**; and (b) **1c–7c**.

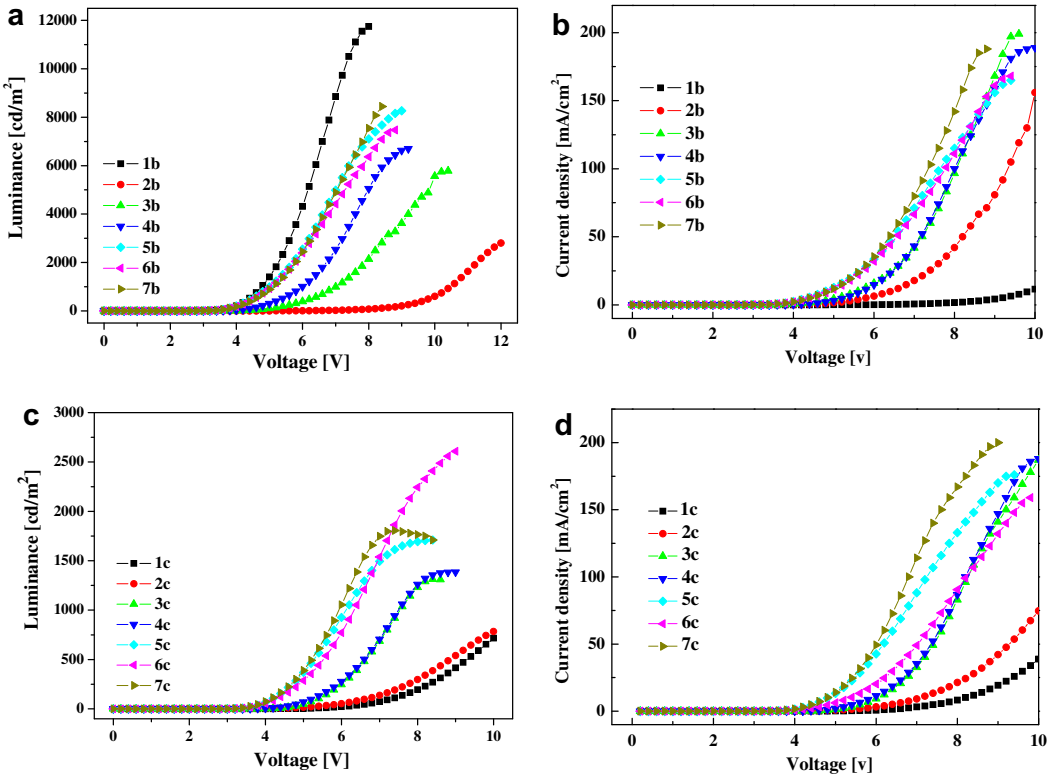

Fig. 7. *L–V–J* characteristics of the doped devices; (a) and (b) **1b–7b**; (c) and (d) **1c–7c**.

PFVtPh as a dopant, were more effective than those of the **c** devices that employed **PCVtPh** as a dopant. The electroluminescence in the host-dopant system can occur by the Förster-type energy transfer from the host to dopant [9]. It can be seen from Fig. 1a that the emission spectra of the host materials (**1–7**) overlapped better with the absorption spectra of **PFVtPh** than those of **PCVtPh**, demonstrating that **PFVtPh** can effectively accept energy from the host materials (**1–7**) by a Förster-type energy transfer and lead to improved EL efficiencies.

Fig. 6 shows the EL spectra of the **b** (8 wt.% **PFVtPh**-doped) and **c** devices (8 wt.% **PCVtPh**-doped). When dopant-doped, the devices using **3–7** also showed narrow bandwidths, as well as reduced CIE *x* and *y* coordinates when compared with the devices using **1** and **2**. The luminance–voltage–current density (*L–V–J*), luminous efficiencies, external quantum efficiency and power efficiency of the doped devices (**1b–7c**) are shown in Figs. 7 and 8, respectively. Compared to the corresponding non-doped devices, all **b** devices using **PFVtPh** as a dopant showed much improved EL efficiencies, while the CIE-coordinates were red-shifted. This indicates that the EL emissions of the **b** devices originate from the emissions of dopants **PFVtPh** by a Förster-type energy transfer between the dopant and the corresponding hosts. The variation of the CIE coordinates would contribute to the differences in the solvation state in solid-state devices using different hosts. Among the devices, **1b** with the CIE coordinates (0.160, 0.240) had an excellent EL performance; its luminous efficiency, power efficiency, and external quantum efficiency reached 10.35 cd/A, 8.77 lm/W, and 5.70% (10.24 cd/A, 6.06 lm/W, and 5.66% at 20 mA/cm^2), respectively. In addition, the maximum EQE of devices **5b–7b** were greater than 5%, a known theoretical limit. The CIE coordinates of devices **5b–7b** were (0.150, 0.176), (0.155, 0.213), and (0.148, 0.183), respectively. Thus, devices **1b**, **5b**, **6b**, and **7b** exhibited highly efficient sky-blue emissions. Intriguingly, performances of the **b** devices showed the complicated correlation with molecular structure of the blue hosts in the emitting layer. Presumably, in devices **b**, the various host materials would affect carrier balance in the emitting layers of the devices, which play important roles in EL efficiencies of the devices [30]. These effects would lead the variation of the EL efficiencies of devices **b**, there are no the significant differences in the quantum yields, HOMO–LUMO energy levels, and the overlap of the absorption spectra of **PFVtPh** with emission spectra of hosts **1–7**.

Devices **c** showed deep-blue emissions in spite of the lower EL efficiencies, compared with devices **b**. Particularly, devices **4c**, **6c**, and **7c** exhibited efficient deep-blue emissions with a maximum EQE of 2.96, 3.60, and 3.33%, respectively. The CIE coordinates of devices **4c**, **6c**, and **7c** were (0.154, 0.087), (0.157, 0.132), and (0.153, 0.097), respectively. In the **c** devices, the energy transfer from hosts to dopant **PCVtPh** was inefficient, as shown in Fig. 1. In these systems, the inefficient confinement of the

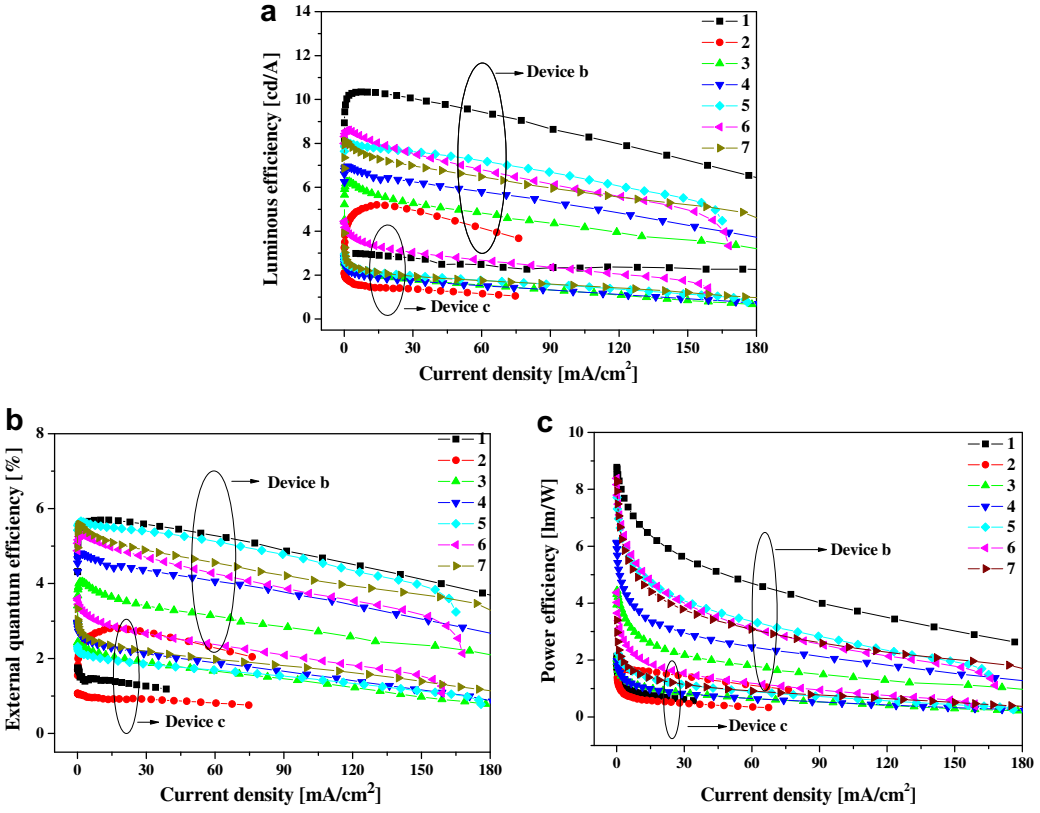

Fig. 8. (a) Luminous efficiencies; (b) external quantum efficiencies; and (c) power efficiencies as a function of current density for the doped devices (**1b–7c**).

excitons in dopant **PCVtPh** was due to the ineffective energy transfer between hosts and dopant **PCVtPh** [31]. Thus the **c** devices exhibited not only an emission of dopant **PCVtPh,** but also hosts **1**–**7**. This notion could be supported from the similar trend in the EL efficiencies between non-doped **a** devices and **PCVtPh**-doped **c** devices. For example, among the **c** devices, device **6c** exhibited the best EL efficiencies. Additionally, devices **3c–7c** showed improved EL efficiencies when compared with devices **1c–2c**. In addition, compared to device **6c** and **1c**, device **7c** and **2c** showed improved EL efficiencies, respectively. However, in contrast to the **c** devices, there were no clear correlations with the EL efficiencies between devices **a** and **b** as shown above. These observations indicate that the EL emissions of the hosts themselves would contribute to the emissions of the **c** devices. In addition, the contribution of the exciplexes between hosts **1**–**7** and dopant **PCVtPh,** to the emissions of the **c** devices cannot be excluded [32].

4. Conclusion

In conclusion, a series of new blue-emitting materials based on 10-naphthylanthracene derivatives with attached side-groups of varying electronic properties have been designed and synthesized *via* a Suzuki cross-coupling. We have demonstrated that the physical and electroluminescent properties are affected by the introduction of electron-withdrawing (pyridine, isoquinoline) and electron-donation groups (*N*-arylcarbazole) into the 10-naphthylanthracene core. Device **6a** (non-doped OLEDs) exhibited excellent electroluminescent performance (4.40 cd/A, 4.31 lm/W, and 3.83%), nearly twice that of MADN. In particular, device **5a** showed an efficient deep-blue emission with a maximum external quantum efficiency of 2.61% and CIE coordinates of (0.153, 0.079), very close to the NTSC blue standard of (0.14, 0.08). Using **1** as a host material for the **PFVtPh** blue dopant material, device **1b** showed high EL efficiencies with 10.35 cd/A, 8.77 lm/W, and 5.70% (10.24 cd/A, 6.06 lm/W, and 5.66% at 20 mA/cm^2). Moreover, using **4** as a host for the **PCVtPh** blue dopant, device **4c** exhibited efficient deep-blue emissions with a maximum external quantum efficiency of 2.96% and CIE coordinates of (0.154, 0.087), very close to the NTSC blue standard of (0.14, 0.08). This study demonstrates that these blue-emitting materials with the 10-naphthylanthracene core have sufficient potential for OLED display or lighting applications.

encountered serious problems in that phase-mixing and/or small grains become heavy in film growth on a metal electrode. Thus, investigation of the electrical properties of PbPc thin films is a challenge from the viewpoint of both film growth and measurement technique.

In the present study, we examine nano-scale current–voltage (I–V) characteristics of monoclinic single-phase PbPc films using two recently developed methods: top-contact nanometre-spaced electrodes (nano-gap) fabricated by angle-controlled shadow-masking method [16] and point-contact current-imaging atomic force microscopy (PCI-AFM) [17–21]. The results indicate low resistivity at low electric field and space-charge limited-current (SCLC) behaviour at high electric field. These properties are different from those obtained by long-distance measurements using conventional micrometre-spaced electrodes (micro-gap).

2. Methods

Configurations of the thin films and electrodes for I–V measurements with micro-gap, nano-gap and PCI-AFM are illustrated schematically in Fig. 1a–c, respectively. The micro-gap, which is a commonly used method for I–V measurements, has two planar top-contact electrodes separated by a gap of d_{micro} = 60 μm formed by the conventional mask technique. As the gap is two orders greater than the grain size of PbPc thin films prepared in this experiment, the electrical properties would involve grain boundary effects. In contrast, as shown in Fig. 1b, the distance of nano-gap electrodes d_{nano} = 45 nm is one order smaller than grain size, and so I–V measurement using the nano-gap could considerably eliminate grain boundary effects. Despite the discriminating capability of the nano-gap method, it is less well utilised for I–V measurements due to the requirement that the nano-gap electrodes should be fabricated without degradation of organic layers. Indeed, conventional nano-fabrication methods, including electron-beam lithography and/or resist processes, cause serious deterioration and are not suitable for organic materials. In our experiments, the requirements are satisfied by angle-controlled shadow evaporation using specially designed apparatus with sample support at a distance of 500 mm from the evaporator to reduce thermal radiation [16].

As mentioned above, the nano-gap is a useful method to reduce the grain boundary effect. The results, however, still reflect only averaged data including large numbers of grains due to the long line edges of the electrodes. To determine the intrinsic electrical properties of PbPc, the AFM-based method is necessary for spatially-resolved conduction measurement. For this purpose, contact-mode operation with a conductive cantilever is typically adopted for current mapping. The contact-mode is a simple method but has problems of sample degradation because organic and/or nano-scale materials are easily damaged by lateral scanning during tip-sample contact. In contrast, intermittent contact-mode (so-called tapping mode) can reduce sample damage, but is inadequate to make sufficient electrical contact between the tip and sample to measure I–V characteristics.

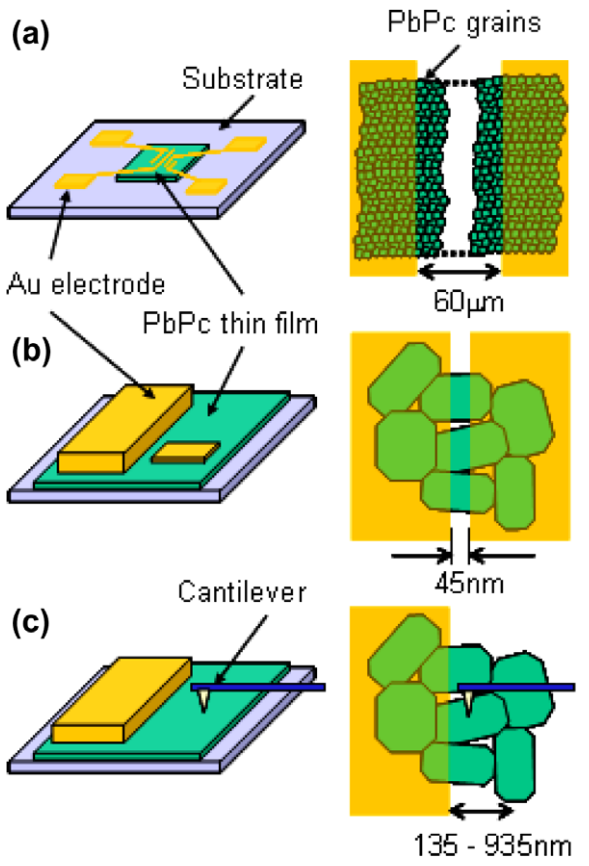

Fig. 1. Electrode configurations. Schematic illustrations of electrodes used to obtain I–V characteristics. (a) The micro-gap electrode is placed on PbPc thin films with top-contact geometry. Two planar Au electrodes are apposed in parallel with a gap distance of d_{micro} = 60 μm and edge length of 3 mm. The gap distance and edge length are far greater than the grain size of both monoclinic (500 nm) and amorphous (80 nm) thin films. Accordingly, the electrical properties measured using the micro-gap electrode are influenced by the grain boundary. (b) The configuration of the nano-gap electrode is similar to that of the micro-gap electrode except for the dimensions. The gap distance is d_{nano} = 45 nm and edge length was 5 μm. The gap distance is less than the grain size of PbPc thin films but the edge length is far greater than the grain size. Thus, the effects of grain boundary on electrical measurements are markedly reduced but still not fully excluded. (c) PCI-AFM measurements are conducted using a planar Au electrode half-covering a surface of PbPc ultra-thin film. The edge length is 10 mm, which is equivalent to the size of the sample substrate. The other electrode is a Pt-coated tip mounted on an AFM cantilever. By choosing the tip position, I–V measurements through a single-grain of PbPc crystal could be performed. The distance between the planar electrode edge and the tip apex is variable in the range from 135 nm to 935 nm for current mapping and I–d analysis.

Point-contact current-imaging atomic force microscopy (PCI-AFM) provides a solution to those problems in current mapping for delicate nano-materials without degradation. PCI-AFM is a combination of tapping-mode scan for topographic observation and point-contact for I–V measurements [17]. The tapping-mode scan is interrupted at preset pixels and the tip is then contacted to the sample with well-controlled loading force without lateral motion.

This procedure achieves simultaneous acquisition of topographic and current images with complete spatial conformity while scanning of a frame. The *I–V* measurement using PCI-AFM is a two-probe measurement between a planar electrode and a PtIr-coated tip. Accordingly, the measured *I–V* characteristics involve contact resistance. The contact resistance, however, can be estimated by analysis of numerous *I–V* data at each pixel with various distances between the tip and electrode [18]. As a result, PCI-AFM measurements can reveal intrinsic electrical properties of single-grain PbPc nano-crystals without contact resistance.

3. Experimental

3.1. PbPc thin film preparation and analysis

Substrates used were two-sided polished sapphire (0 0 0 1) (Shinkosha) and the surfaces of the substrates were prepared with Ar+ sputtering (bias potential, 500 V; ion current, 8.6 mA; Ar pressure, 9×10^{-2} Pa; 3 min) to eliminate contamination and scratches from polishing. PbPc powder (80% dye content) (Sigma–Aldrich) was purified by sublimation three times under a vacuum (10^{-4} Pa). The purified PbPc was deposited on the substrate by thermal evaporation using a shutter-equipped Knudsen-cell at 250–300 °C under a background pressure of 10^{-6} Pa during deposition, and the substrates were heated at 150 °C using a tungsten heater with monitoring using a thermocouple in contact with the substrate surface. The deposition rate and film thickness, which were determined using a quartz crystal microbalance, were 1 nm/min and 25 nm, respectively. The deposited PbPc thin films were stored in air under desiccant condition for two weeks before *I–V* measurements. This period is long enough to saturate carrier doping with oxygen because the conductivity increase was observed only within several hours from the breaking the vacuum after the film deposition.

The crystal structure of the PbPc thin film were examined by $\theta-2\theta$ X-ray diffraction using an X-ray diffractometer (X'Pert-Pro MRD; Philips) with Cu Kα line (0.154 nm). The X-ray beam was induced at 45 kV and 40 mA, and an X-ray mirror, which was assembled by grades shaped parabolic, was used as an incident beam conditioner. The divergence slit was fixed at 1/8° to maintain a beam width of 375 μm.

The surface morphology of the films was observed by atomic force microscopy (SPA-300HV; Seiko), with tapping mode, in air at room temperature. The force constant of the cantilever (SI-DF20; Seiko) was 4.5 N/m and resonant frequency was about 142 kHz.

3.2. Micro-gap electrode fabrication

Micro-gap electrodes were fabricated by thermal evaporation under a background pressure of 10^{-5} Pa. Au (99.95%) was deposited on the PbPc film with a metal (SUS 304) mask (Fuji Seimitsu Co.). The thickness of the mask was 100 μm and the width and length of slits were 6 μm and 3 mm, respectively, and the interval of the slits was 6 mm.

3.3. Nano-gap electrode fabrication

Nano-gap electrodes were fabricated by angle-controlled shadow-masking thermal deposition using a homemade chamber under a vacuum pressure of 10^{-7} Torr. Sample substrate was put in place at a distance of 500 mm from evaporation source to prevent heating of the sample surface by thermal irradiation. The Au layer must be deposited at a slow speed of 0.15–0.3 nm s^{-1} to avoid particle generation and surface diffusion. Such careful procedures contribute to reduction in the degradation of PbPc thin films and realize light effect of contact resistance to the total resistance. In fact, the contact resistance can be estimated less than 0.1 MΩ by the results of PCI-AFM measurements (see Section 3 in Supplementary material).

The fabrication procedure of the nano-gap consisted of two steps of Au deposition. First, the Au layer was deposited on the sample surface half-hidden by a small piece of Si(1 0 0) wafer. The wafer edge cleaved along a crystal axis is extremely sharp and enables fabrication of a sharp edge on the Au electrode. A second opposite electrode (second Au layer) was deposited with a metal mask, which had a pattern of lines and pads for electrical connections. The edge length (width of line) of the nano-gap was 5 μm. In the second deposition, the direction of the deposition angle was controlled to be oblique against the first-layer to form a shadow. The nano-gap distance dnano was estimated as:

$$d = h(1/\tan\theta_2 - 1/\tan\theta_1),$$

where h was the height of the first-layer electrode, and θ_1 and θ_2 were the angle of the first-layer electrode and the oblique deposition angle of the second-layer electrode, respectively. Using this equation, gap distance was controlled by changing the thickness of the first-layer electrode and the oblique angle in the fabrication process of the second-layer electrode. The thicknesses of the first- and second-layer electrodes were 80 and 30 nm, respectively, as measured with a quartz thickness monitor. The oblique angle for second-layer deposition was set to 30°. The nano-gap distance between the first- and second-layer electrodes was measured as 45 nm. These two electrodes are not equivalent due to the difference of contact condition. However, this nonequivalence is not so large that the electrical asymmetry has little influence on the analysis of *I–V* characteristics (see S1 in Supplementary data). A detailed description for nano-gap fabrication was reported previously [16].

3.4. Electrical measurement

The *I–V* measurements for micro- and nano-gap junctions were performed in air using a semiconductor characterisation system (4200; Keithley) at a delay and hold time of 0.5 s and 0.1 s, respectively. The scan ranges and steps were from −10 to 10 V in 0.5-V steps for micro-gap junctions, from −5 to 5 V in 0.05-V steps and from −15 to 15 V in 0.5-V steps for nano-gap junctions of monoclinic

and amorphous films, respectively. In the case of measurement of monoclinic films in nano-gap junctions, narrow scan range and slow scan rate were required to prevent field-induced migration and leakage generation. In all *I–V* measurements, hysteresis induced by the charging effect and irreversible structure changes were not observed. The detail of time response on *I–V* measurements are discussed in the Section 3 of Supplementary data.

3.5. Point-contact current-imaging atomic force microscopy (PCI-AFM)

PCI-AFM measurement was performed in air by a scanning probe microscope (JSPM-4200; JEOL) equipped with two function generators (WF1946; NF Corporation). Platinum-coated cantilevers (NSCS-12/Pt; MikroMasch) were used for current detection, and their force constant and resonant frequency were 4.5 N/m and about 150 kHz, respectively. A gold electrode was deposited on half of the area of a monoclinic PbPc ultra-thin film surface using the same apparatus that was used for nano-gap electrode. Topographic and current images were obtained simultaneously. In the tapping-mode scan, the feedback was active and the cantilever was oscillated at a resonant frequency of 150 kHz. When the tip met the preset positions for *I–V* measurements, the lateral scan was interrupted and the feedback was frozen. During the time when the feedback system was deactivated, the cantilever excitation stopped, and the tip was proceeded to make an electric contact with a preset loading force. The applied bias voltage was then swept and the *I–V* characteristics were stored in the memory. The time response of *I–V* measurement was enough fast to avoid transient effect (see Section 3 in Supplementary data). After *I–V* curve acquisition, the tip-sample separation was re-set to the former position, the feedback system was reactivated, and tapping-mode scan was restarted. These alternate operations were performed continuously, and both the topographical data and the *I–V* data were obtained at 128 points lengthwise and crosswise (total: 16,384 points). Current images were formed by extracting current data at a chosen bias voltage from *I–V* curves corresponding to each pixel. For analysis of the *I–V* curve, the current–voltage characteristic at the tip-electrode distance was the average of over 10 data points, which were extracted from a PCI-AFM current image at the points of the same tip-electrode distance. For *I–d* analysis, the current data were obtained by averaging the values at over 30 points with the same tip-electrode distance for noise reduction at large *d* (low current condition). The detailed experimental procedure was reported previously [17].

4. Results and discussion

4.1. Micro- and nano-gap measurements

Using the methods described above, the electrical properties of PbPc thin films are investigated on the nanometre scale. For this purpose, the growth of highly-ordered single-phase monoclinic-crystalline PbPc thin films is achieved by thermal deposition at 150 °C on an Ar^+-sputtered sapphire (0 0 0 1) substrate with well-optimised conditions [22]. Fig. 2a shows the molecular arrangement in the monoclinic PbPc crystal. The PbPc molecule has a quadrangular pyramidal structure and its central Pb atom is out of the molecular plane. Due to this asymmetrical structure, the PbPc molecules form a monoclinic crystal with a large unit cell that includes four columns oriented in alternate directions. The X-ray diffraction pattern of the PbPc film shows only (2*l*, 0, 0) peaks for monoclinic PbPc crystals, as shown in Fig. 2b. This result indicates that the films were grown with their *a*-axis normal to the substrate surface as a single-phase and formation of the triclinic phase was completely suppressed. This *a*-axis orientation of monoclinic PbPc crystal is also obvious from the AFM observation in Fig. 2c. This AFM image indicates Frank-van der Merwe type growth with the step of 1.3 nm in height corresponding to the half unit cell dimension of the monoclinic PbPc crystal along the *a*-axis.

To clarify the effects of electrode distance on observed electrical properties, conventional micro-gap methods are used for *I–V* curve measurements. Fig. 3a shows AFM topography and an *I–V* curve (inset) for monoclinic PbPc thin films. The average grain size of this film is 500 nm, which is two orders smaller than the distance between micro-gap electrodes. For this sample, the *I–V* characteristics indicate a featureless linear relationship with $\rho_{micro} = 1.1 \times 10^5\ \Omega m$, where ρ_{micro} is apparent resistivity involving the effect of grain boundaries, contact resistance at electrodes and any other imperfections. This value is of the same order as those reported for Zn phthalocyanine [23] and Cu phthalocyanine crystalline films [6,24].

To examine the influence of crystallinity and morphology on the electrical properties, amorphous PbPc thin films are also studied in comparison with monoclinic samples. The amorphous PbPc thin films prepared by deposition at room temperature show no peaks on X-ray diffraction analyses (not shown) and consist of small spherical grains 80 nm in diameter, as shown in Fig. 3b. Although amorphous PbPc thin films show markedly different crystallinity and morphology from monoclinic films, the *I–V* characteristics of the amorphous PbPc (inset in Fig. 3b) also shows a featureless linear relationship similar to the monoclinic samples, and the apparent resistivity of $8.8 \times 10^5\ \Omega m$ was only one order higher than that of monoclinic films.

The nano-gap method brings a marked change to observed *I–V* characteristics. Fig. 4a and d shows non-linear *I–V* curves for both monoclinic and amorphous PbPc thin films obtained by the nano-gap method. These non-linear characteristics are quite different from the linear relationship observed by micro-gap measurements. This difference may be attributable to the strong electric field applied by narrow-spaced nano-gap electrodes. Furthermore, the nano-gap measurement is also effective in eliminating the number of grain boundaries, which is a causal factor of the potential drop between electrodes. In fact, whereas the micro-gap spacing of 60 μm is much greater than the grain sizes of both monoclinic and amorphous PbPc films (500 nm and 80 nm, respectively), the 45-nm separation of the nano-gap is shorter than the both grain sizes. Thus,

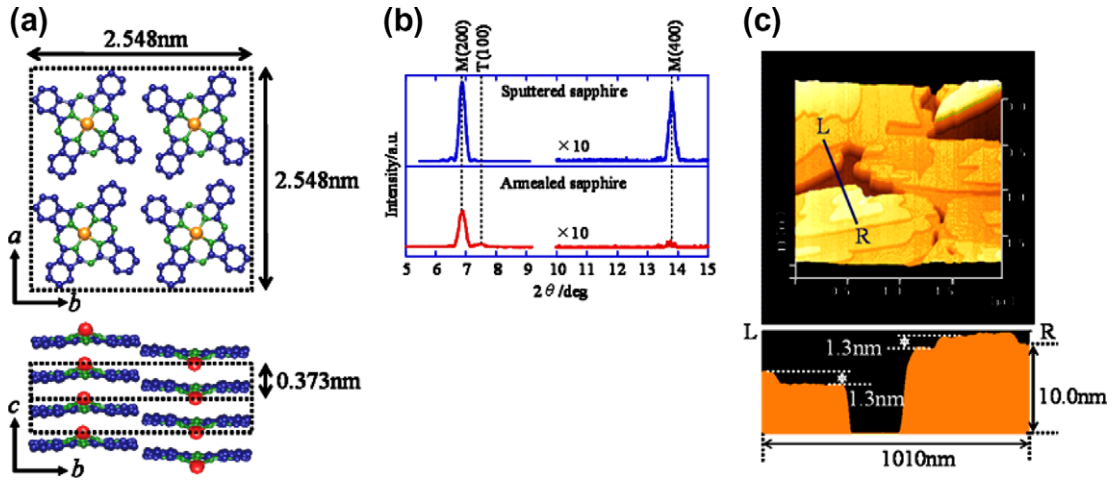

Fig. 2. Single-phase monoclinic PbPc thin film. (a) Molecular arrangement in the monoclinic PbPc crystal. The PbPc molecule has a quadrangular pyramidal structure and its central Pb atom is out of the molecular plane. Due to this asymmetrical structure, the PbPc molecules form a monoclinic crystal with a large unit cell including four columns oriented in alternative directions. (b) The X-ray diffraction pattern of the PbPc films. M and T indicate monoclinic and triclinic phases, respectively. In comparison with the growth on an annealed sapphire (0 0 0 1) surface, the films grown on Ar^+-sputtered sapphire (0 0 0 1) shows only (2*l*, 0, 0) peaks for monoclinic PbPc crystals indicating that the crystal has an orientation with the *a*-axis normal to the substrate surface as a single-phase and the formation of the triclinic phase is completely suppressed. (c) AFM image and line profiles of monoclinic PbPc film surface. The image indicates Frank-van der Merwe type growth with steps of 1.3 nm corresponding to the half unit cell dimension of the monoclinic PbPc crystal along the *a*-axis.

the electrical field affecting each grain in nano-gap measurement is far stronger than that in micro-gap measurement. Therefore, analysis based on various field functions was attempted for the non-linear *I*-*V* characteristics. To examine conduction mechanisms exhibiting non-linear electrical properties, the *I*-*V* data in Fig. 4a and d are analysed as shown in Fig. 4b and c for monoclinic PbPc thin films and Fig. 4e and f for amorphous films.

Fig. 4b shows two distinct regions in log *I*–log *V* plots for a monoclinic PbPc thin film. At low voltages, the slope was 1.0 indicating a linear relationship. The apparent resistivity of $\rho_{nano} = 1.9 \times 10^3\ \Omega m$ found in this region is two orders of magnitude lower than that obtained by the micro-gap method. This suggests that the resistivity obtained by micro-gap measurements reflects electrical properties not of the intrinsic monoclinic PbPc crystal but of the grain boundaries. With increasing bias voltage, the slope in Fig. 4b changes to 5.3 signifying the power law with a distinct transition bias at 3.0 V. Such behaviour is often observed in sandwich junctions of organic semiconductors and can be explained by the space-charge limited-current (SCLC) mechanism with an exponential distribution of trap levels [25,26].

In contrast to monoclinic films, the log *I*–log *V* plot for the amorphous film does not exhibit any meaningful relationship, as shown in Fig. 4e. Thus, neither linear relationship at low field nor SCLC mechanism at high electric field is appropriate for amorphous PbPc and another conduction model should be considered. Poole–Frenkel conduction model is often applied to non-linear electrical behaviour for amorphous semiconductors [27]. To examine the adequacy of this model for amorphous PbPc thin films, a log (I/E)–$E^{1/2}$ plot is shown in Fig. 4f. The plot shows the linear relationship for amorphous PbPc film throughout the whole bias region suggesting relevance of the Poole–Frenkel model. This result implies that electrical conduction is dominated by the field-assisted thermal excitation of localised carriers [28] reflecting the presence of a large numbers of trap sites around the Fermi level in the amorphous PbPc thin films.

As mentioned above, the nano-gap method clarifies the difference in electrical properties between monoclinic and amorphous PbPc thin films, despite the lack of remarkable differences on analysis using micro-gap methods. Moreover, the resistivity measured by the nano-gap method at low electric field is two or three orders of magnitude lower than that obtained by the micro-gap method. These results suggest that the presence of grain boundaries between electrodes obscures the observation of intrinsic electrical properties. Accordingly, it is a logical conclusion that the electrical measurement for a single-grain is required to obtain essential electrical properties of monoclinic PbPc crystals.

4.2. Point-contact current imaging

Electrical measurements of single-grain monoclinic PbPc crystals are conducted by PCI-AFM for ultra-thin PbPc films. For single-grain measurement, it is necessary that the sample is thin enough to avoid layered accumulation of multiple grains. The samples used here satisfy this requirement, as shown by AFM topography in Fig. 5 where the bare surface of the substrate can be seen behind the grains with an average thickness of 10 nm. A perpendicular stack of PbPc grains is rarely observed in such ultra-thin films. In this sample, certain grains are contiguous to a gold electrode placed at the left side in the image. Such grains are included in the scan areas of PCI-AFM measurements to obtain single-grain *I*–*V* characteristics, as represented by the dashed line in the AFM image. In addition, the scan-

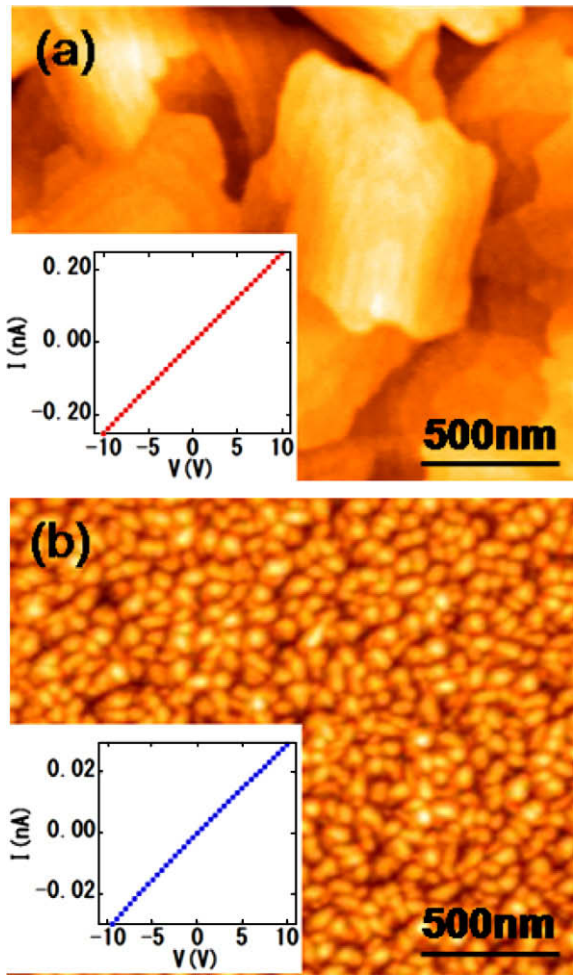

Fig. 3. Surface morphology and micro-gap *I–V* characteristics. (a) AFM topography of monoclinic polycrystalline PbPc thin film. The grain size is ca. 500 nm. The *I–V* curve of this monoclinic PbPc thin film obtained using the micro-gap electrode is shown in the inset. The *I–V* curve for the monoclinic PbPc shows linear characteristics with apparent resistivity of $\rho_{micro} = 1.1 \times 10^5\ \Omega m$. (b) AFM topography of amorphous PbPc thin film. Spherical grains 80 nm in diameter are shown in the image. The *I–V* curve of this amorphous PbPc thin film obtained with the micro-gap electrode is shown in the inset. The *I–V* curve for amorphous PbPc shows linear characteristics similar to that of the monoclinic sample, but the apparent resistivity is $\rho_{micro} = 8.8 \times 10^5\ \Omega m$, which is one order higher than that in the case of monoclinic PbPc.

ning area is at least 50 nm from the edge of the planar gold electrode to prevent Au atom migration under the high electric field between the tip and electrode. The actual closest tip-electrode distance during the scan is estimated to be ca. 135 nm.

Simultaneously obtained topography and current image of a PbPc thin film are shown in Fig. 6a and b, respectively. The current image is obtained with a bias voltage of 5.0 V. In comparison with topography, the current image gives sharp contrast and is sensitive to the surface conditions of the tip and sample. While topography retains constant smoothness and resolution for the whole scan area, the current image shows discontinuity around the centre due to abrupt changes in noise level. This may be attributable to removal of insulating contamination at the tip surface during the scan.

The line profiles of the topography and the current image are shown in Fig. 6c and d along lines A and B, respectively. Between the points p and q on line A (Fig. 6c), there are no PbPc grains and the insulating substrate surface is exposed. In this region, the line profile of the current image indicates constant values around 10^{-2} nA in a position-independent manner. These observations imply that the value indicates the noise level of PCI-AFM measurement using this apparatus. The following analyses are based upon this detection limit. The profile along line B (Fig. 6d) shows the effect of the grain boundary on electrical conduction. A distinct drop is observed in the current profile at point *r*, where a grain boundary can be seen in the topographic image (Fig. 6b). This is direct evidence why nano-gap measurements provide different electrical properties from those of micro-gap measurements.

4.3. Distance-dependent electrical characteristics

As mentioned above, the presence of the grain boundary is captured by PCI-AFM. Therefore, measurements using only the inside region of single-grain PbPc crystals are suitable for quantitative analysis of position-dependent electrical characteristics. Fig. 7a shows the electrical properties of single-grain PbPc crystals at tip-electrode distances of $d = 135$, 204, 286 and 443 nm. The observed *I–V* curves can be divided into two regions by analysis based on log *I*–log *V* plots: a low bias region showing a slope of 1.0 indicating a linear *I–V* relationship, and a high bias region above 0.6 V showing an increase in upward curvature with increasing bias voltage reflecting higher-order *I–V* characteristics. This behaviour, which is the transition from linear to SCLC conduction with increasing electric field, is consistent with the results of nano-gap measurements. Furthermore, in Fig. 7b, log *I*–log *d* plots at a bias voltage of 5.0 V clearly show a power law with the order of −2.79 demonstrating the adequacy of SCLC-type conduction [26].

On the basis of the simple theory that the transition voltage from linear to SCLC reflects field strength in the material, the transition voltage in PCI-AFM measurement with the distance range of $d = 135$–443 nm should be larger than that of nano-gap measurement with $d = 65$ nm. However, in actual measurements, the transition in PCI-AFM measurement occurs only around 0.6 V, which is quite low in comparison with the transition voltage of 3 V in nano-gap measurements. This anomaly can be attributed to the difference in trap density between the two methods. In the case of nano-gap measurement, many grain boundaries between electrodes and the trap site at the boundary should be filled by charge before the transition from linear to SCLC conduction. In contrast, such trap levels in PCI-AFM measurements are lower in comparison with those of nano-gap measurement because PCI-AFM can be used to determine the electrical properties for single-domain crystals. As a result, the low transition voltage in single-grain measurement by PCI-AFM reflects the pri-

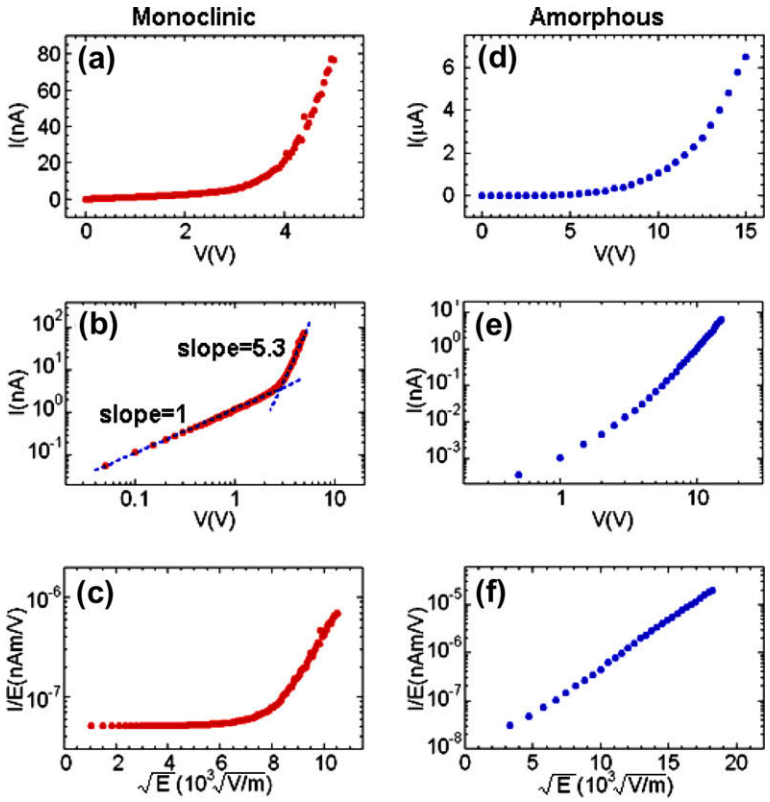

Fig. 4. Nano-gap *I–V* characteristics. (a) The *I–V* curve representing the non-linear relationship for monoclinic PbPc thin films obtained using the nano-gap electrode at room temperature. (b) The log *I*–log *V* plot shows two distinct linear regions with a distinct transition at 3.0 V. At low voltages, the slope is 1.0, indicating a linear *I–V* relationship with apparent resistivity of 1.9×10^3 Ωm. At high bias voltages, the slope is 5.3 signifying the power law of a space-charge limited-current (SCLC) mechanism. (c) The log (I/E)–$E^{1/2}$ plot shows a non-linear curve indicating that the Pool–Frankel model is inadequate for monoclinic PbPc thin films. (d) The *I–V* curve indicates a non-linear relationship for amorphous PbPc thin films obtained with the nano-gap electrode at room temperature. (e) The log *I*–log *V* plot shows the non-linear relationship without any distinct transition. SCLC or other models based on power law are inappropriate for amorphous PbPc thin films. (f) The log (I/E)–$E^{1/2}$ plot shows a linear curve indicating that the Pool–Frankel model is adequate for amorphous PbPc thin films.

mary change from linear to SCLC conduction with low trap site density.

Position-dependent electrical measurements of single-grain crystals by PCI-AFM provide further insight into nano-scale conduction. Fig. 7c shows a resistance–distance (*R–d*) curve plot at $V = 0.16$ V. At such a low bias voltage, the *I–V* characteristics are linear as shown in Fig. 7a. In general, a linear *I–V* curve indicates ohmic conduction, which in turn indicates a linear increase in resistance with increasing tip-electrode distance. However, Fig. 7c shows that the resistance increases at an accelerating pace with increasing tip-electrode distance. This distance dependence implies that the electron transport at low voltages is not ohmic. The *R–d* curve can be fitted by $R(d) = R_0 + A\exp(d/d_0)$, where R_0 is the sum of contact resistances at the interfaces between the electrodes and PbPc crystal. From the fitting, R_0 is 0.5 MΩ that is so small as to not affect the resistivity analysis. This exponential distance dependence suggests that there is a great deal of randomness for electron transport even in a single-grain crystal because only the hopping conduction through periodic and isopotential sites allows linear distance dependence [29].

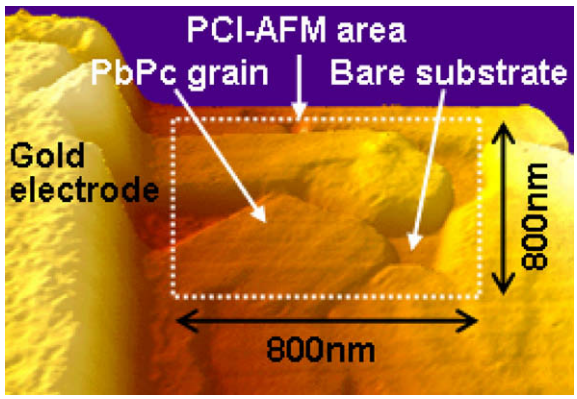

Fig. 5. Ultra-thin PbPc film for single-grain PCI-AFM measurements. AFM topography of ultra-thin monoclinic polycrystalline PbPc film used for single-grain PCI-AFM measurements. The image shows the bare surface of the substrate behind the grains. The PbPc layers are only 10 nm in thickness. A perpendicular stack of PbPc grains is rare and unexpected accumulation of multiple grains is inhibited in the ultra-thin film. Grains connected to the Au electrode are included in the scan areas of PCI-AFM measurements to obtain single-grain *I–V* characteristics, as represented by the dashed line. The scanning area is kept 135 nm from the edge of the planar gold electrode to prevent Au atom migration under the high electric field between the tip and electrode.

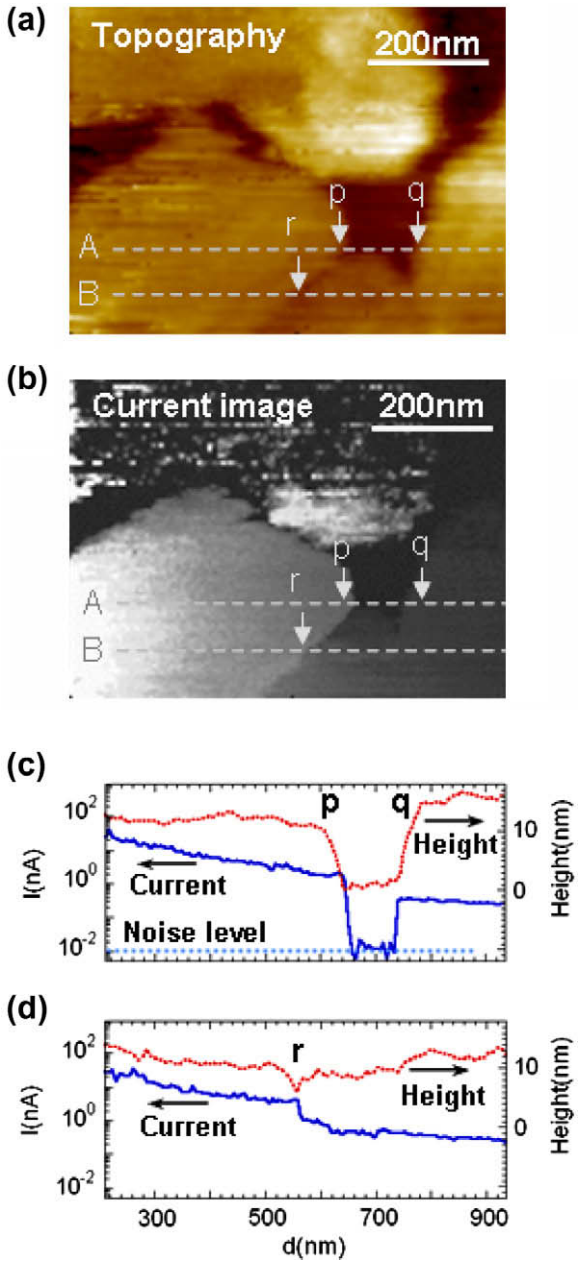

Fig. 6. Spatially-resolved electrical properties of single-grain PbPc by PCI-AFM. (a) Topography of monoclinic polycrystalline PbPc ultra-thin films obtained by PCI-AFM observation. (b) Current image corresponding to the topography. This current image is constructed from the current data at 5.0 V extracted from the *I*–*V* spectra acquired during the topography scan. The bright contrast in the grayscale figure indicates high current. The current is reduced from left to right side reflecting the location of the Au planar electrode on the left outside of the figure. (c) Line profiles of the topography and the current image along line A. Between points p and q on line A, there are no PbPc grains and the insulating substrate surface is exposed. In this region, the line profile of the current image shows a constant value of 10^{-2} nA with no position dependence. This value indicates a noise level (detection limit) of the PCI-AFM apparatus. (d) Line profiles of the topography and the current images along line B shows the effect of the grain boundary on electrical conduction. A distinct drop is observed in the current profile at point r, where a grain boundary could be seen in the topographic image.

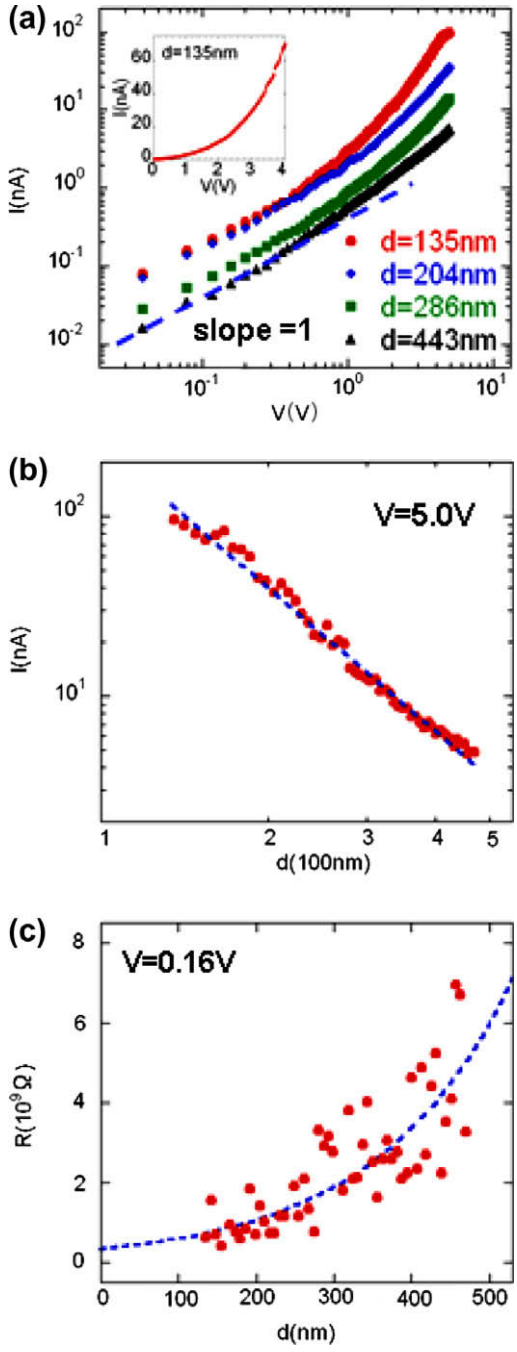

Fig. 7. Distance-dependent electrical characteristics of single-grain PbPc. (a) The *I*–*V* curve at electrode-tip distance d = 204 nm shows a non-linear curve for the overall voltage region (see inset). The log *I*–log *V* curve at d = 135–443 nm. At low voltages of less than 1 V, the slopes are 1.0 indicating a linear *I*–*V* relationship, regardless of d. The slopes became steeper with increasing voltage above 1 V, suggesting the transition from linear conduction to SCLC. (b) The log *I*–log d curve at bias voltage of 5.0 V. The plots indicate that the current is proportional to the −2.79 power of the distance over the full electrode-tip distance range indicating the SCLC mechanism. (c) *R*–d curve at V = 0.16 V shows non-linear behaviour where the resistance increased at an accelerating pace with increasing tip-electrode distance. The resistance–distance plots can be fitted by $R(d) = R_0 + A\ \exp(d/d_0)$, where R_0 is contact resistance at the interfaces between electrode and PbPc crystal.

Despite the considerable randomness mentioned above, distance-differential resistivity on the nano-scale is quite low in comparison with apparent resistivity values measured by other methods. The distance-differential resistivity $\rho_{diff} = 1 \times 10\,\Omega m$ is determined by PCI-AFM measurement at $d = 200$ nm, whereas the apparent resistivities obtained by other methods are considerably higher as follows: $\rho_{nano} = 1.9 \times 10^3$ and $\rho_{micro} = 1.1 \times 10^5\,\Omega m$ for nano-gap and micro-gap measurements of monoclinic thin films, respectively, and $\rho_{bulk} = 10^2\,\Omega m$, where ρ_{bulk} is for bulk single-crystal measurements. The high resistivity for thin films can be attributed to the presence of the grain boundary as discussed above. In particular, it is notable that ρ_{diff} taken by PCI-AFM measurement for single grains is lower than ρ_{bulk} using bulk crystal. This result implies that the resistivity on the nano-scale cannot be estimated using Ohm's law on the basis of bulk crystal measurement.

5. Conclusion

Here, we have demonstrated the reduction of nano-scale resistivity for PbPc monoclinic polycrystalline films using two recently developed nano-scale measurement techniques: nano-gap electrodes and PCI-AFM. These measurements, where electrode distances are narrower than the PbPc grain size, show quite different electrical properties from the results obtained by conventional micro-gap measurements. The comparison of micro-gap and nano-gap measurements indicates that the conduction in PbPc thin films is highly limited at the grain boundary and current-imaging by PCI-AFM exposed the potential drop at the grain boundary directly. These results indicate distinct advantages of the nano-gap and PCI-AFM methods. In particular, detailed analysis of current–distance characteristics using PCI-AFM provides new insight into nano-scale conduction for single-grain PbPc crystals, in which the low distance-differential resistivity indicates the potential of nano-structured organic materials for electrical applications.

film characteristics, and correlate the material properties with MFM device performance. These results demonstrate that through careful film processing this material may be a promising solution for a non-volatile memory element for flexible electronics.

2. Experimental

Metal–Ferroelectric–Metal capacitors were fabricated as follows. P(VDF-TrFE) copolymer powder with 70/30 mol ratio (Hisense Electronics Co., China) was dissolved in 2-butanone without further purification as 3 and 4 wt.%, respectively. Chromium and gold (10/100 nm) were e-beam evaporated on a silicon substrate with a Si_3N_4 buffer layer as the bottom contact, and patterned using photolithography. Copolymer films (154 and 210 nm) were then spin-coated on the Cr/Au contact from the 3 and 4 wt.% solutions, followed by drying and annealing at 65 °C, 118 °C, 133 °C, 144 °C and 156 °C (T_m is approximately 148 °C) for 2 h in a vacuum oven (pressure was approxi-

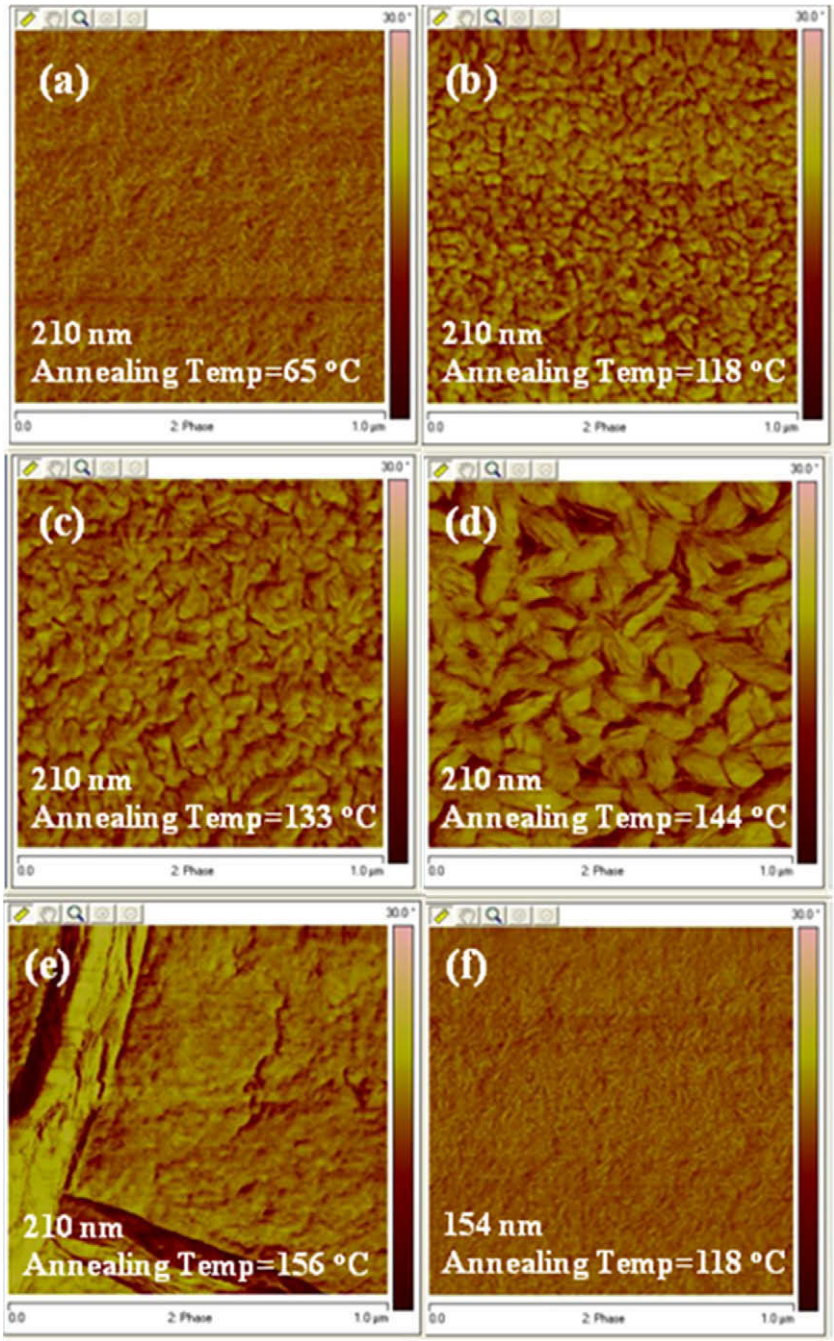

Fig. 1. (a)–(e) AFM phase images of 210 nm P(VDF-TrFE) films annealed from 65 °C to 156 °C and (f) shows 154 nm film annealed at 118 °C for comparison.

mately 20 Torr). All the samples were then left in the vacuum oven to slowly cool down to room temperature in order to maximize their grain size. Gold was thermally evaporated and photolithography patterned on the copolymer film as the top contact. The area of the MFM capacitors ranged from 0.0003 cm^2 to 0.0025 cm^2. The electrical performance was characterized using Capacitance–Voltage (HP4284, Agilent), Displacement Current–Voltage (Keithley 4200 semiconductor parameter analyzer), and Displacement Charge Density–Voltage (virtual ground circuit, RT66B, Radiant Technology). Film thicknesses were determined using a profilometer (Dektak), surface morphology was studied using Atomic Force Microscopy (AFM, DM09 Veeco), crystallinity was measured using thin film X-ray diffraction (XRD, Rigaku), and molecular bonding and orientation were characterized using Fourier-transform infrared reflection–absorption spectroscopy (FT-IR, Magna-IR 560, Nicolet). The ferroelectric β phase increases with annealing temperature. We demonstrate that high polarization and low leakage current can be achieved by annealing at, or slightly above T_c, whereas annealing at higher temperature, but below the melting temperature increases leakage current.

3. Results and discussions

To correlate the film's physical and chemical characteristics with device performance, P(VDF-TrFE) films were studied before top electrode deposition. We studied the microstructure, surface morphology, crystallinity and molecular phase configuration. Fig. 1a–e shows the AFM phase images (tapping mode) of 210 nm films annealed at temperatures ranging from 65 °C to 156 °C. Films annealed at 65 °C, below the Curie temperature (T_c = 118 °C), show a smooth surface with relatively small grain size (Fig. 1a). As the annealing temperature increases near, and above T_c (Fig. 1b and c), the polymer grain size increases, as expected. Films annealed at 144 °C (just below T_m = 148 °C) show the largest grain size (approximately 180 nm long) (Fig. 1d). Annealing at temperatures above T_m at 156 °C, results in films with a completely different morphology. This is due to film re-crystallization during cooling [11,16]. We also compare 154 nm (Fig. 1e) with 210 nm films (Fig. 1b) annealed using the same conditions. While the thinner films follow the same trend as thicker films (Fig. 2a), it can be seen that the thinner film shows smaller grains, even though the films are annealed using the same conditions and temperature. This indicates that P(VDF-TrFE) crystallization is a function of not only the annealing temperature, but also film thickness, and demonstrates that annealing has to be optimized for each film thickness. The evolution of film roughness as a function of annealing temperature and film thickness is shown in Fig. 2b. It is well known that P(VDF-TrFE) copolymer is a polycrystalline material, and that its ferroelectric response is attributed to the β phase (all-trans), which shows a rod-like shape with a relatively rough surface [15]. Fig. 2b shows a clear increase in the Root-Mean-Square (RMS) roughness as a function of annealing temperature, suggesting the presence of the β phase. Although higher annealing temperature favors

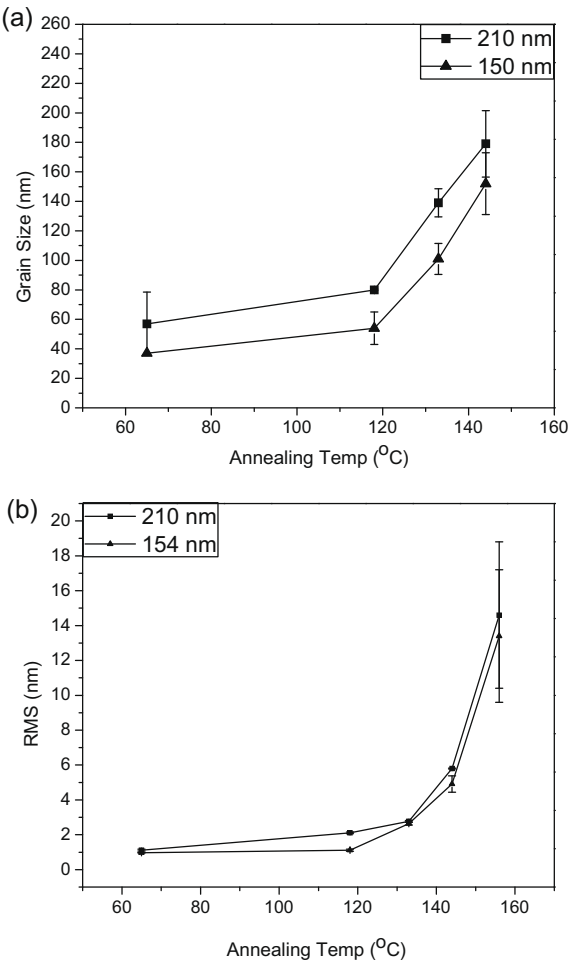

Fig. 2. (a) Average β phase crystallite grain size of 210 nm and 154 nm film at different annealing temperature treatment below T_m. (b) Surface roughness (RMS) of 210 nm and 154 nm films at different annealing temperatures.

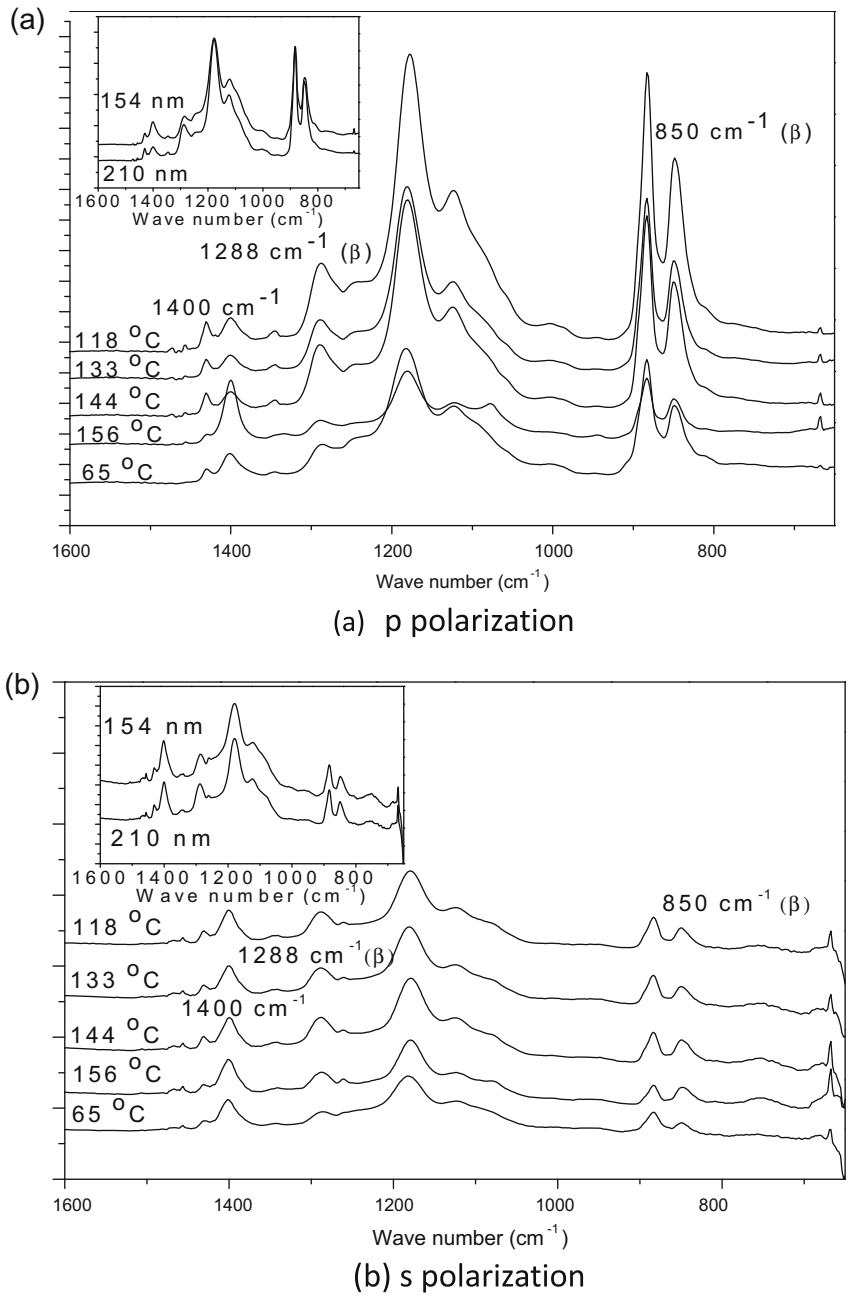

Fig. 4. (a) p Polarization (for molecular dipole interaction with direction perpendicular to substrate) and (b) s polarization (for molecular dipole interaction with direction parallel to substrate) of FT-IR of 210 nm P(VDF-TrFE) films annealed at different temperatures. Inset shows both of the 210 nm and 154 nm films annealed at 118 °C.

larger crystallites, it also increases surface roughness, which could result in increased leakage current. The RMS roughness increases from 1.1 nm to 14.6 nm for 210 nm films and from 1.0 nm to 13.4 nm for 154 nm films, as shown in Fig. 2.

Fig. 3 shows XRD results for the 210 nm films annealed at different temperatures. The sharp peak at $2\theta = 19.9°$ is assigned to the (1 1 0) and (2 0 0) orientations, and is attributed to the ferroelectric β phase. The diffraction angle of this peak does not change with the annealing conditions, indicating similar inter-chain spacing for all the annealing conditions [17]. The inter-planar distance was calculated to be approximately 4.5 Å, in agreement with an earlier report [10]. Higher annealing temperatures, but below T_m, produces more intense diffraction peaks, indicating a higher degree of crystallinity. Annealing above T_m causes a dramatic reduction in the peak intensity for the (1 1 0) and (2 0 0) peaks, which suggests a change in the crystalline

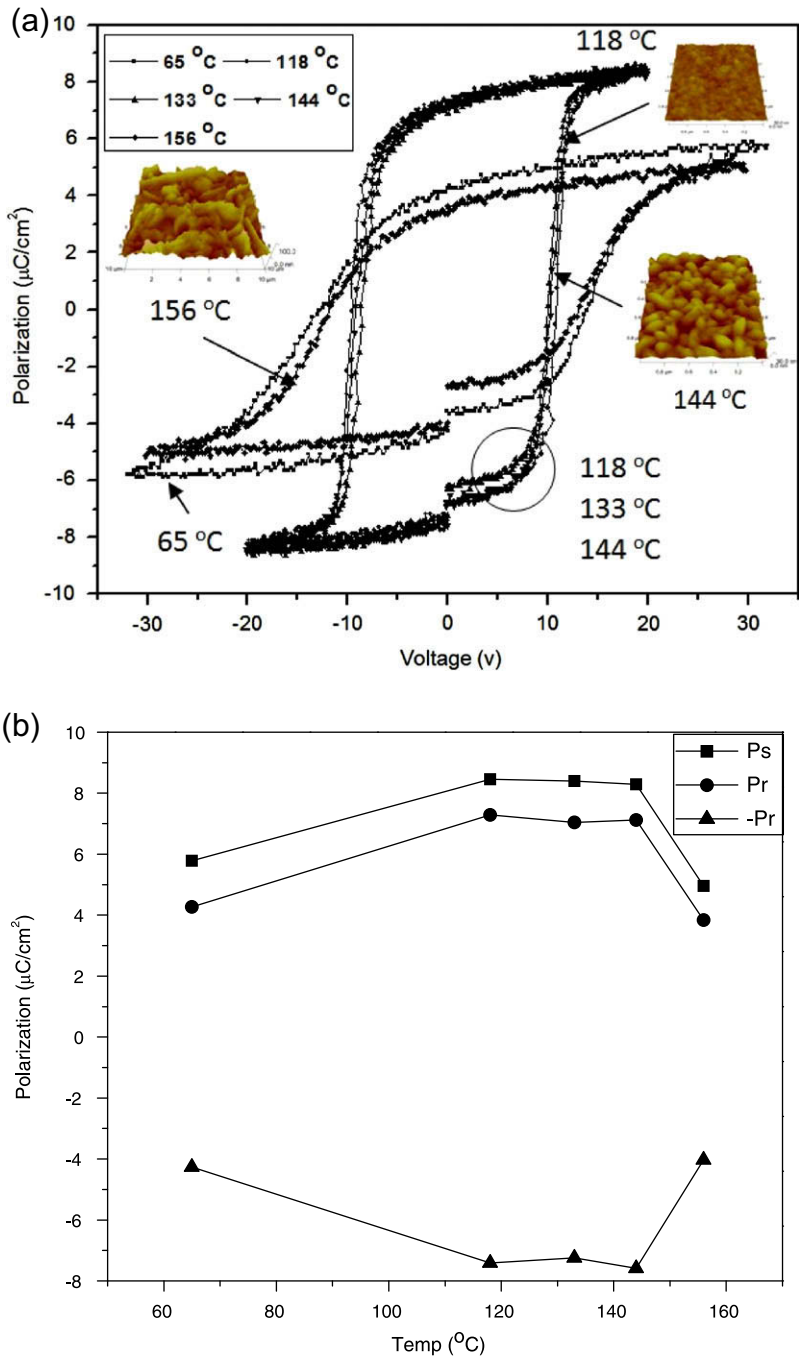

Fig. 5. (a) Hysteresis loops of 210 nm P(VDF-TrFE) copolymer films annealed at different temperatures. Inset AFM images show the morphologies of corresponding temperature annealed devices. (b) Saturation and remanent polarizations at different temperatures.

characteristics of the films, with a likely reduction in the ferroelectric β phase. The 154 nm films follow a similar trend. The 210 nm film shows a higher degree of crystallinity, as shown in the inset of Fig. 3.

Polarized FT-IR is used to characterize the localized chain orientation and configuration of the P(VDF-TrFE) films. We use the fact that the different P(VDF-TrFE) phases have different responses to the external electromagnetic field associated with FT-IR spectroscopy [18]. The large dipoles in P(VDF-TrFE) strongly interact with the applied IR electric field when the field is perpendicular to the dipole direction. Fig. 4a shows the FT-IR results (from 1600 cm^{-1} to 650 cm^{-1}) for 210 nm thick films annealed at different temperatures. IR with the electric field component parallel to the plane of the substrate (p polarization) is used for this measurement. The 1288 cm^{-1} and

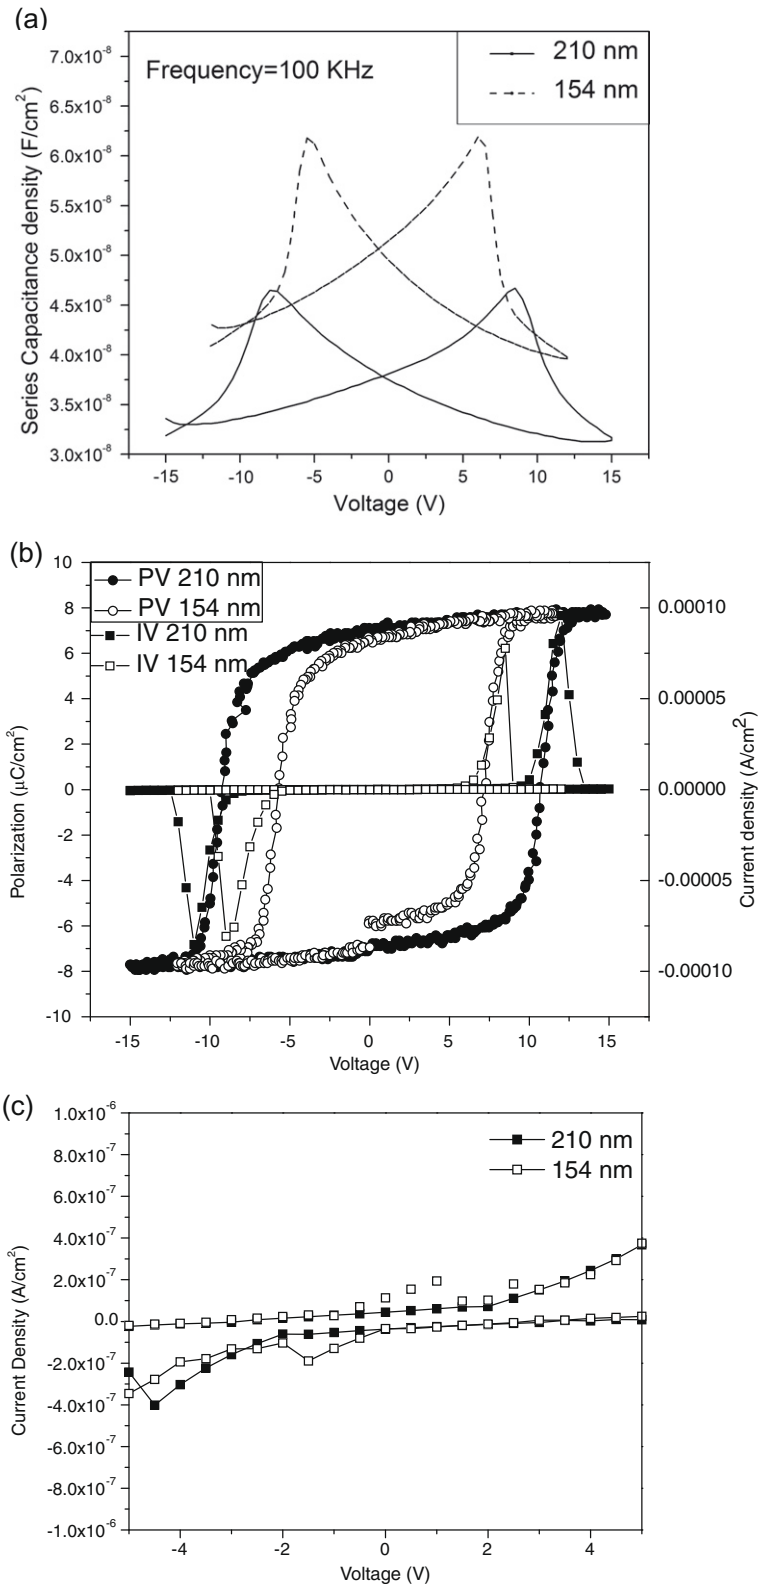

Fig. 6. (a) *C–V* measured at 100 kHz, (b) *P–V* and *I–V* data and (c) Leakage current for low voltage sweep for 210 nm and 154 nm P(VDF-TrFE) MFM devices annealed at 118 °C.

850 cm^{-1} bands are assigned to CF_2 symmetric stretching characteristics of the β phase, with three or more trans sequence of isomers [19]. These IR absorption bands indicate transition dipole moments μ parallel to the polar *b* axis [9]. For samples annealed at 118 °C, 133 °C and 144 °C, these two absorption bands can be clearly seen, indicating that the *b* axis of the copolymer film is perpendicular to the substrate. For the samples annealed at 65 °C and 156 °C, these two bands are relatively weak, indicating that the *b* axis is tilted away from the direction normal to the surface. Moreover, the 1400 cm^{-1} band (the wagging vibration of CH_2), which has μ parallel to the polymer chain *c* axis, increases for the film annealed above T_m, indicating that a significant portion of the copolymer chain tilts vertically, which is undesirable for vertical polarization [20]. In contrast, s polarized (the electric field component is perpendicular to the substrate) IR spectra of samples annealed at low temperature (Fig. 4b) show a large absorption ratio between 1400 cm^{-1} and 1288 cm^{-1} bands, indicating the strong wagging vibration of CH_2 along the *c* axis, and confirming that most of the copolymer chains are oriented parallel to the substrate when the films are annealed below T_m.

The electrical performance of the devices with area of 0.0005 cm^2 was evaluated after fabrication as a function of annealing conditions and film thickness. The Polarization–Voltage (*P*–*V*) hysteresis loops (1 Hz) for 210 nm MFM devices with different annealing temperatures measured at room temperature are shown in Fig. 5a. For devices annealed at 65 °C, PV shows a saturation polarization (P_s) of 5.8 μC/cm^2 and a remanent polarization (P_r) of 4.3 μC/cm^2 with a coercive voltage (V_c) of approximately 13.3 V (corresponding to a coercive field E_c = 0.63 MV/cm). These data are for a voltage sweep from −32 V to 32 V (*E* field of −1.52 MV/cm to 1.52 MV/cm). The low polarization and high V_c are consistent with a low concentration of the ferroelectric β phase, as confirmed by the AFM, FT-IR and XRD results. When the annealing temperature is increased to 118 °C, the polarization increases sharply, with a concurrent decrease of V_c. The *P*–*V* loops show a typical square shape with P_s, P_r and V_c of 8.5 μC/cm^2, 7.4 μC/cm^2 and 10.2 V, respectively. This corresponds to an E_c of approximately 0.5 MV/cm (measured at ±20 V for a field of ±0.95 MV/cm). These results are in agreement with previous reports [21]. The polarization saturates and the hysteresis loops remain almost constant as the annealing temperature increases to 133 °C and 144 °C. This saturation demonstrates that, although the grain size is different for each of these temperatures, annealing these films at 118 °C is enough to achieve acceptable ferroelectric performance. As the annealing temperature increases above T_m to 156 °C, P_s and P_r decrease, while V_c increases. This indicates the tilted chain orientation and a reduction of the ferroelectric β phase. This is also in agreement with changes in morphology seen with AFM, XRD and FT-IR. The discontinuities at the origin of the hysteresis loops are due to non-switchable polarization, as reported in Ref. [22].

P_s, P_r and $-P_r$ for the different annealing temperatures are plotted in Fig. 5b. While most of the polarization of P(VDF-TrFE) originates from the β phase, the β phase crystal orientation also impacts polarization [20]. The data suggest that annealing at temperatures equal to or slightly above T_c is sufficient to align the β phase dipole moment (μ) perpendicular to the substrate, which is the requirement for high P_s and P_r and low V_c. Although annealing at temperatures higher than T_c, but below T_m favors a higher degree of crystallinity with larger grains, the increased film roughness (Fig. 2) might be an issue for leakage current. The high surface roughness will cause a non-uniform electric field, with the concomitant increase in leakage current in the film. This will result in devices with lower electrical stability. Therefore, the best annealing temperature is at, or just above T_c.

Fig. 6 shows the *C*–*V*, *P*–*V* and *I*–*V* plots for 210 nm and 154 nm films annealed at 118 °C. Hysteresis was measured at ±15 V and ±12 V, respectively. Fig. 6a shows peak capacitance densities of 47 nF/cm^2 (210 nm) and 62 nF/cm^2 (154 nm), measured at 100 kHz. The dielectric constants of the films with the two thicknesses show similar values, between 7.8 and 11 depending on the measurement voltage, slightly higher than the value reported in the literature [21], probably due to the improved annealing treatment. The polarizations were measured to be 7.7 μC/cm^2 and 7.0 μC/cm^2 for P_s and P_r with a peak switching current of approximately 85 μA/cm^2 (Fig. 6b). The leakage current is lower than 5×10^{-7} A/cm^2 before the electric field reaches E_c (Fig. 6c). The maximum polling slope (d*P*/d*V*) of the two thicknesses of the devices shows similar values and the coercive field is consistent, indicating similar switching behavior. This indicates that film orientation might be more important that grain size. For the same annealing conditions, thicker films show larger grains, but the electrical performance of the films is similar for different thicknesses.

4. Conclusion

The transition of the β phase crystallite and the rearrangement of the molecular chain orientation to favor vertical ferroelectric polarization can be achieved with thermal annealing at or just above T_c. The polarization of the MFM devices after bias tends to saturate as annealing temperature increases. Higher annealing temperature (but below T_m) results in films with larger grains, higher degree of crystallinity and increased roughness, but less effect on molecular chain orientation. Annealing above the T_m, results in a shift of molecular chain orientation, degraded β phase crystallization and decreased polarization. Thicker films produce larger grains and a higher degree of crystallinity, however, the polarization does not increase because it is more related to molecular orientation. When reducing the thickness of the film, the annealing process needs to be optimized to reach high polarization as well as smooth surface morphology. We conclude that annealing at or slightly above T_c for the P(VDF-TrFE) copolymer is optimal to achieve maximum polarization and low leakage, and is compatible with low temperature substrates for flexible electronics applications.

ordered structure of the active layer [10–12]. The composition of the P3HT:PCBM active layer, i.e. the relative ratio of each polymer, also influences the microstructure of the active layer and consequently the performance of the OSCs [9,12]. Several research groups have reported that the optimized morphologies and photovoltaic (PV) performances occurred at a 1:1 ratio of the P3HT:PCBM (50 wt.% of P3HT) composites [11,13]. Recently, reports have shown that the use of a low composition (1:0.8–0.7 ratio of P3HT:PCBM) of PCBM resulted in a PCBM cluster free structure and thermally stable devices [1,14]. Although there have been several reports about the effect of the composite ratio on the performance of the OSCs mostly with the optical and electrical properties [9,12–14], further studies are required in order to understand the relationship between the properties and the microstructure of the active layer associated with phase separation depending on the ratio of P3HT:PCBM and the OSCs performance.

In this study, the effect of the P3HT:PCBM composition in the active layer was studied by varying the composite ratio of P3HT from 20 to 80 wt.%. The optical properties and microstructure of the active layer and the correlation with the device performance were explored.

2. Experimental

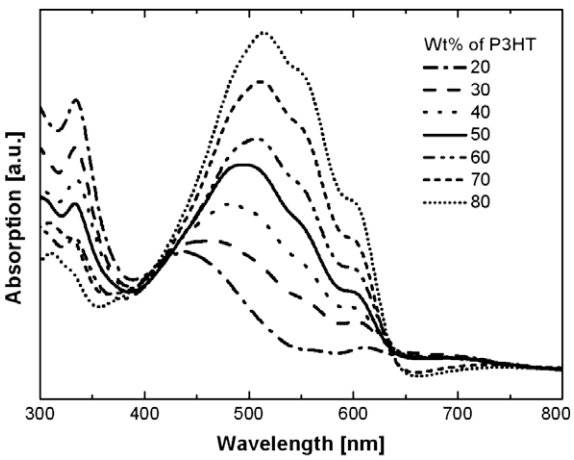
Regioregular P3HT (Rieke Metals, Inc.) and PCBM (Nano-C) were used for the active layer as purchased without any further purification. P3HT and PCBM were separately dissolved in chlorobenzene (30 mg/ml for each solution) and stirred at 60 °C for 1 h. These solutions were mixed with different weight ratios of: 20, 30, 40, 50, 60, 70, and 80 wt.% of P3HT. The substrate for the OSCs, the indium tin oxide (ITO; 10 Ω/square) coated glass substrate, was cleaned in an ultrasonic bath with deionized water, acetone and isopropyl alcohol for 15 min each, and then cleaned with UV–ozone for 10 min. The poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS; Baytron P VP AI 4083, H.C. Stark), used as an anodic buffer layer, was spin coated at 6000 rpm for 10 s and baked at 130 °C for 10 min. The P3HT:PCBM photoactive layer was spin coated on the PEDOT:PSS at 4000 rpm for 5 s. The thicknesses of the buffer and active layers were 30 nm and 70 nm, respectively, as measured using a surface profiler (alpha-step 500). The Al (100 nm) cathode was thermally evaporated through a shadow mask defining active area of 0.1 cm^2. Thermal annealing was conducted at 150 °C in an oven for 10 min under ambient N_2. The entire fabrication process was conducted in an air environment except for thermal annealing.

An UV/visible spectrophotometer (Shimadzu UV-1601) was used to characterize the absorption properties of the P3HT:PCBM layer. The crystallization of the active layer was analyzed using X-ray diffraction (XRD; Mac Science, Cu Kα wavelength of 1.54056 Å). The phase separation and resulting microstructure were observed using optical microscopy and field-emission transmission electron microscopy (FE-TEM; JEM-2100F, JEOL). For the TEM analysis, the specimens were prepared by floating the active layers onto the deionized water and then picking them up with a Cu grid. The current density versus voltage (J–V) characteristics were measured with a Keithley 236 source measurement unit and a solar simulator (Yamashita denso) under an AM 1.5 G (100 mW/cm^2) irradiation intensity. The total incident light intensity was calibrated with a pyranometer (Eko MS-802) and a standard reference silicon solar cell.

3. Results and discussion

Fig. 1 shows the UV/visible absorption spectra of the P3HT:PCBM active layer with different concentration ratios. A previous reports showed that the maximum absorption wavelengths (λ_{max}) of PCBM molecules are almost constant regardless of the amount of the PCBM composite or ordering of the active layer [9,15,16]. In this study, the intensity of the PCBM absorption spectra (~330 nm) increased without any shift in the wavelength as the composition of PCBM increased. On the other hand, as the composition of P3HT increased, the absorption spectra of P3HT between 450 and 650 nm gradually increased, was broader as well as more vibronic, and red-shifted. The λ_{max} of the P3HT peak were at 437, 461, 482, 495, 507, 512 and 515 nm for 20, 30, 40, 50, 60, 70 and 80% of P3HT, respectively. The shift of absorption peaks to higher energy indicates an increasing density of conformational defects, equivalent to non-plarnarity, and causes loss of conjugation [17]. Moreover, the absorption shoulder at ~610 nm which is assigned to interchain interactions became bigger and more pronounced. Since the thickness of the active layer was kept the same (~70 nm) for the all of the samples, the increased, broadened, red-shifted and pronounced absorption peaks of P3HT were attributed not only to the increased composite ratio but also to the closer chain packing of P3HT which resulted from strong interchain interactions [9,12,17,18].

The XRD analysis in Fig. 2 depicted the crystallization of P3HT, which was represented by the peak intensity and the



Wt% of P3HT [%]	20	30	40	50	60	70	80
P3HT λ_{max} (nm)	437	461	482	495	507	512	515

Fig. 1. UV/visible absorption spectra of the active layer with various composite ratios of P3HT:PCBM after thermal annealing at 150 °C for 10 min in a N_2 flow oven.

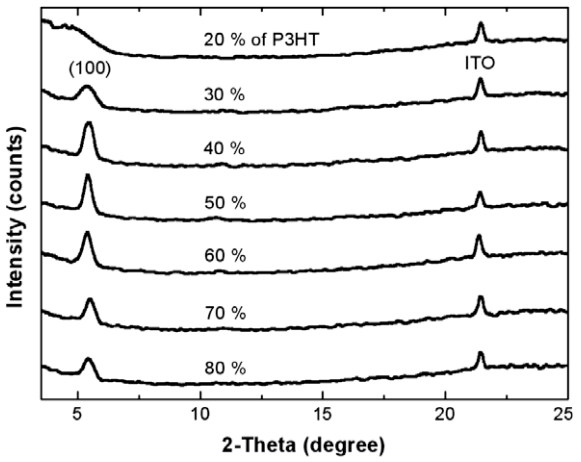


Fig. 2. XRD pattern of the active layer with various composite ratios of P3HT:PCBM.

full width at the half maximum (FWHM) intensity of the peak. The peak intensity of P3HT (100) gradually increased with increasing P3HT composition from 20% to 50%. One remarkable observation was that further increase of the P3HT composition exceeding 60% results in a gradually reduced peak intensity. The size of the crystallites was calculated from the broadening of a peak in the diffraction pattern with Scherrer's equation;

$$\tau = \frac{K\lambda}{\beta \cos\theta}$$

From the XRD peak intensity results, the calculated sizes of the crystallites gradually increased with increasing P3HT composition from 20% to 50%, and further increasing the P3HT composition above 60% reduced the crystallite size.

Comparing the absorption and XRD data, the absorption of P3HT continually increased and red-shifted with increasing P3HT composition which indicated closer chain packing at higher compositions. On the other hand, the diffraction peak of the P3HT (1 0 0) phase increased until 50 wt.% of P3HT and then decreased upon further increase of the P3HT composition. The results of the XRD denote the volume fraction of the π-conjugated planes of P3HT (1 0 0) with lamella oriented normal to the substrate [12,18]. Therefore, both results can be summarized as follows. The interchain packing of P3HT within the crystallized phase improved with increasing P3HT composition, but the volume fraction of the P3HT (1 0 0) phase normal to substrate increased until a P3HT composition of 50% and decreased at higher compositions.

The phase separation and microstructure of the active layer was directly characterized by optical microscopy and TEM. The phase contrast optical microscopy images in Fig. 3 show the macroscopic morphology of the active layer. Overgrown clusters resulting from local diffusion and crystallization of PCBM were observed in the active layers with P3HT compositions of 20, 30, and 40%, and their size and density reduced as the composition of P3HT increased. No PCBM clusters were found at higher P3HT compositions. Previous reports showed that the thermal annealing of the P3HT and PCBM composite film leads to the formation of overgrown PCBM clusters when the PCBM composition exceeds 50% [16,19,20].

Fig. 4 shows the FE-TEM images of various ratios of the P3HT:PCBM layer. For 20% of P3HT in Fig. 4(a), the P3HT rich (bright domains) and PCBM rich (dark domains) regions were barely distinctive compared to the higher compositions of the layer. For the layer with 30–50% of P3HT in Fig. 4(b–d), the phase separation was clear, and P3HT formed a fiber structure embedded in the PCBM matrix. The difference in the microstructures of the phase separated P3HT and PCBM was minimal though the composition varies from 30 to 50% in these TEM images. The TEM images were believed to be obtained in the regions without any PCBM overgrown clusters as shown in the optical micrographs. Therefore it was concluded that almost the same fraction of P3HT and PCBM formed the similar phase separated morphologies and the remaining PCBM formed overgrown clusters. The phase separated microstructure noticeably became blurred and eventually randomized

without clear fiber phases when increasing the P3HT composition above 60% in Fig. 4(e–g), which was in accordance with the XRD results. A previous report showed that the pure P3HT molecules form fibrillar structures even at room temperature [4]. Therefore, the disordering of P3HT in Fig. 4(e–g) was evidently caused by the small amount of PCBM molecules added to the P3HT matrix. Yang et al. suggested that the PCBM molecules deteriorate the ordering of P3HT by disrupting the chain packing and also by reducing the conjugation length of the polymer [12]. For the high P3HT composition regime in Fig. 4(e–g), the PCBM molecules did not likely crystallize because of the small amount of them present, which led to a lower probability of the molecules meeting for crystallization to take place in the given annealing conditions. Rather, the PCBM molecules hindered the crystallization of the P3HT phases because they were dispersed in the P3HT phases. As a result, a less ordered phase separated structure formed in the high P3HT composition layer.

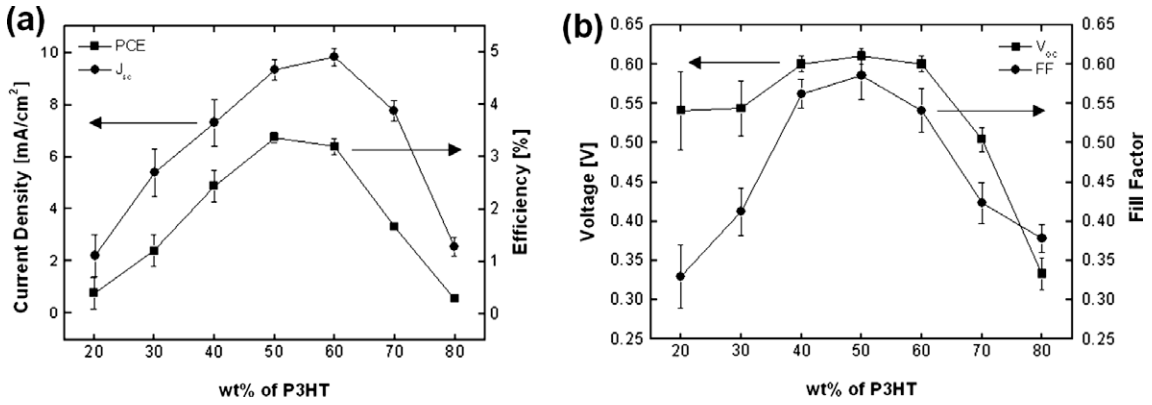

Fig. 6. Statistical data for the device parameters derived from each type of device with various composite ratios of the P3HT:PCBM active layer; (a) J_{sc} and PCE, (b) V_{oc} and FF.

Table 1
Summary of the statistical data for the device parameters derived from each type of device with various composite ratios of the P3HT:PCBM active layer.

Wt% of P3HT	20	30	40	50	60	70	80
J_{sc} (mA/cm^2)	2.21	5.40	7.33	9.35	9.84	7.78	2.56
V_{oc} (V)	0.54	0.54	0.6	0.61	0.60	0.50	0.33
FF	0.33	0.41	0.56	0.59	0.54	0.42	0.38
PCE (%)	0.40	1.20	2.44	3.37	3.20	1.66	0.29

Fig. 5 shows the current density–voltage (J–V) characteristics of the OSCs with various composite ratios of the P3HT:PCBM active layer. More than ten individual devices were fabricated and measured at each P3HT:PCBM composition. Fig. 6 and Table 1 show the statistical data of the device parameters. The device with 20% of P3HT exhibited very poor PV performances with a short circuit current density (J_{sc}) of 3.23 mA/cm^2, fill factor (FF) of 0.34, open circuit voltage (V_{oc}) of 0.58 V, and PCE of 0.63%. Moreover, the devices at this composition had a large variation in the device-to-device performance due to the large amount of PCBM overgrown clusters present (see Fig. 3). The PV performances depending on the P3HT:PCBM composition agreed well with the ordering of the P3HT phase and the phase separation as discussed in the XRD and TEM results. The J_{sc}, FF, PCE, and Voc all remarkably increased as the composition of P3HT increased from 20% to 50% because of the improved absorption of the incident light and the charge transportation property of the highly ordered P3HT fibers. Further increasing the P3HT composition from 60% to 80% degraded the PV performances even with the increased absorption at the high P3HT composition layer. This degradation in the PV performance was caused by degraded ordering of P3HT, the deficient PCBM molecules that accepted the generated electrons, and the deteriorated phase separation of the blurred heterojunction. Finally, the best PCE of 3.4% was obtained with reproducible performances from the device with the 50% P3HT composition layer.

4. Conclusion

The effect of the composite ratio of P3HT and PCBM on the PV performance of the OSCs was investigated in the BHJ structure. The UV/visible absorption and XRD results denoted that the interchain packing of crystallized P3HT improved with increasing P3HT composition, while the volume fraction of the P3HT (1 0 0) phase that was normal to the substrate increased until a P3HT composition of 50% and decreased at higher compositions. From the TEM analysis, P3HT and PCBM formed a heterojunction with the P3HT fiber structures as well as the PCBM overgrown clusters through phase separation when the PCBM composition exceeds 50 wt.%. Uniform phase separation, which formed P3HT fibers in the PCBM matrix without overgrown clusters, was obtained at a 50% P3HT and 50% PCBM composition. As the P3HT composition exceeded 50%, the fibril structures of P3HT were collapsed by the PCBM molecules, which hindered the crystallization of the P3HT phase. The optimized PV performance of the OSCs was achieved at an active layer composition of 50% P3HT and 50% PCBM with a maximum PCE of 3.4%.

able improvement of the conductivity and work function of the material. Furthermore, efforts have also been made to modify the PEDOT:PSS by low-electron energy [18] and adding anionic surfactants [19]. Recently, a simpler and efficient way for the electronic property modification of the material has been achieved using a UV–ozone treatment at ambient conditions [20–22]. This method showed a significant increase in the work function and enhancement of electrical conductivity of the PEDOT:PSS. Surprisingly, the potential of this easy and versatile method for the improvement of fluorescent OLEDs has not yet been investigated in detail. The present study therefore focuses on investigating the role of device architecture and duration of the UV–ozone exposure required for work function tuning to achieve balanced charge injection and optimum power efficiency in fluorescent OLEDs.

In this study, the fluorescent OLEDs selected to study the effect of UV–ozone exposure on the device efficiency are two green-emitting fluorescent devices of the following configuration; Device I – Indium tin oxide (ITO)/PEDOT:PSS (38 nm)/*N*,*N*-di(naphthalene-1-yl)-*N*,*N*′-diphenylbenzidine [α-NPD] (50 nm)/tris(8-quinolinolato) aluminum [Alq_3] (40 nm)/CsF (1 nm)/Al (100 nm); and Device II – ITO/PEDOT:PSS (38 nm)/α-NPD (40 nm)/Alq_3:1% C545T (30 nm)/Alq_3 (30 nm)/CsF (1 nm)/Al (100 nm). In both Devices I and II, the PEDOT:PSS layer was exposed to UV–ozone treatment from 0 min to 12 min in two minute intervals. The efficiency of the OLEDs whose PEDOT:PSS layer are treated by UV–ozone exposure are compared with the OLEDs fabricated without the UV–ozone exposure (control). Furthermore, the effect of the UV-exposure time on physical and/or chemical modification of the polymer related to charge injection and the device efficiency is discussed in relation to the device physics of charge injection.

2. Device fabrication

A cross section of the OLEDs (Device I and Device II) and the materials utilized as hole-transporting and emissive layers in device fabrication are shown in Fig. 1. As an anode, ITO (20 Ω/) on a glass substrate was used. In the first step, the ITO/glass substrate was cleaned by a detergent followed by ultrasonic bath in acetone and isopropanol. Following the wet cleaning, the sample was dried with nitrogen gas and exposed to UV–ozone dry cleaning for 20 min. Then, an aqueous solution of PEDOT:PSS (Baytron P VP AI 4083) was filtered using a 0.2 μm syringe filter and subsequently spin-coated at 3000 rpm onto a precleaned substrate. After the PEDOT:PSS spin coating, the film was annealed at 120 °C under ambient conditions for 10 min to remove water from the polymer film. The thickness of the dry PEDOT:PSS film is ∼ 38 ± 5 nm. Next, the PEDOT:PSS layer was exposed to UV–ozone (PSD-UV, Novascan, IA, USA) for time ranging from 0 to 12 min. Following the PEDOT:PSS deposition, the organic materials were deposited by resistive evaporation.

The organic layers, α-NPD and Alq_3, were deposited at a deposition rate of ∼2 Å/s. The source materials were purified by sublimation before deposition. To improve a better electron charge injection or device performance of the OLEDs, a 1 nm CsF was deposited after the deposition of the electron transport layer, Alq_3. The cathode realized by shadow mask deposition of aluminum without breaking the vacuum. The cathode thickness and pixel area is 100 nm with 0.04 cm^2, respectively. The resulting OLEDs electroluminescence characteristics were measured using Hamamatsu Photonic C9920-22 system containing a Keithley 2400 source-meter, an integrated sphere and a multichannel analyzer PMA-12. The electroluminescent

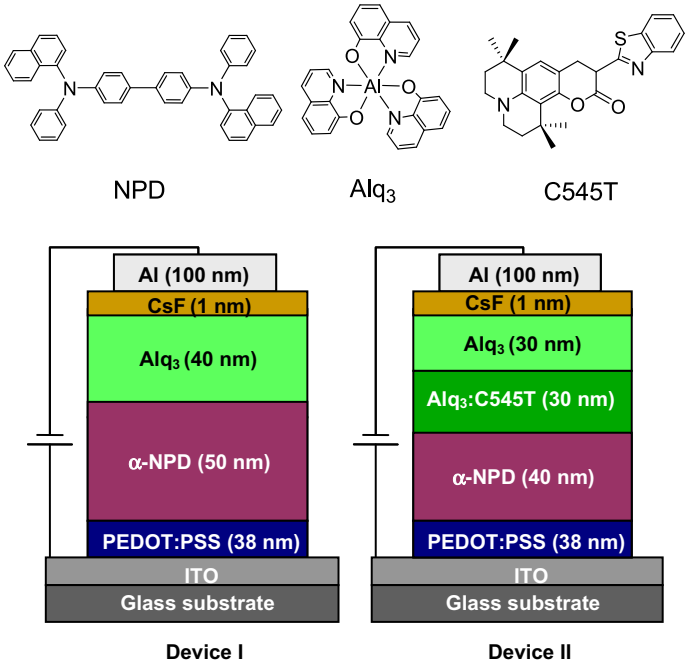

Fig. 1. Molecular structure of the transport and emitting layers used for the device fabrication (top), and the architectures of Device I and Device II (bottom).

characterizations were made in glove box under nitrogen atmosphere so as to protect the device degradation by oxygen or moisture.

3. Results

First, the effect of the UV–ozone exposure on surface property of the PEDOT:PSS was studied. PEDOT:PSS was spin-coated onto a silicon wafer substrate, which displays low surface roughness compared to ITO–glass substrate. To maintain the consistency of the process, the wafer was cleaning, spin-coated and treated with UV–ozone exactly in the same way used for the ITO substrate used in device fabrication. Fig. 2 presents the surface profilometry characterization of the PEDOT:PSS on a silicon wafer exposed to 8 min UV–ozone vs. the un-exposed, which was

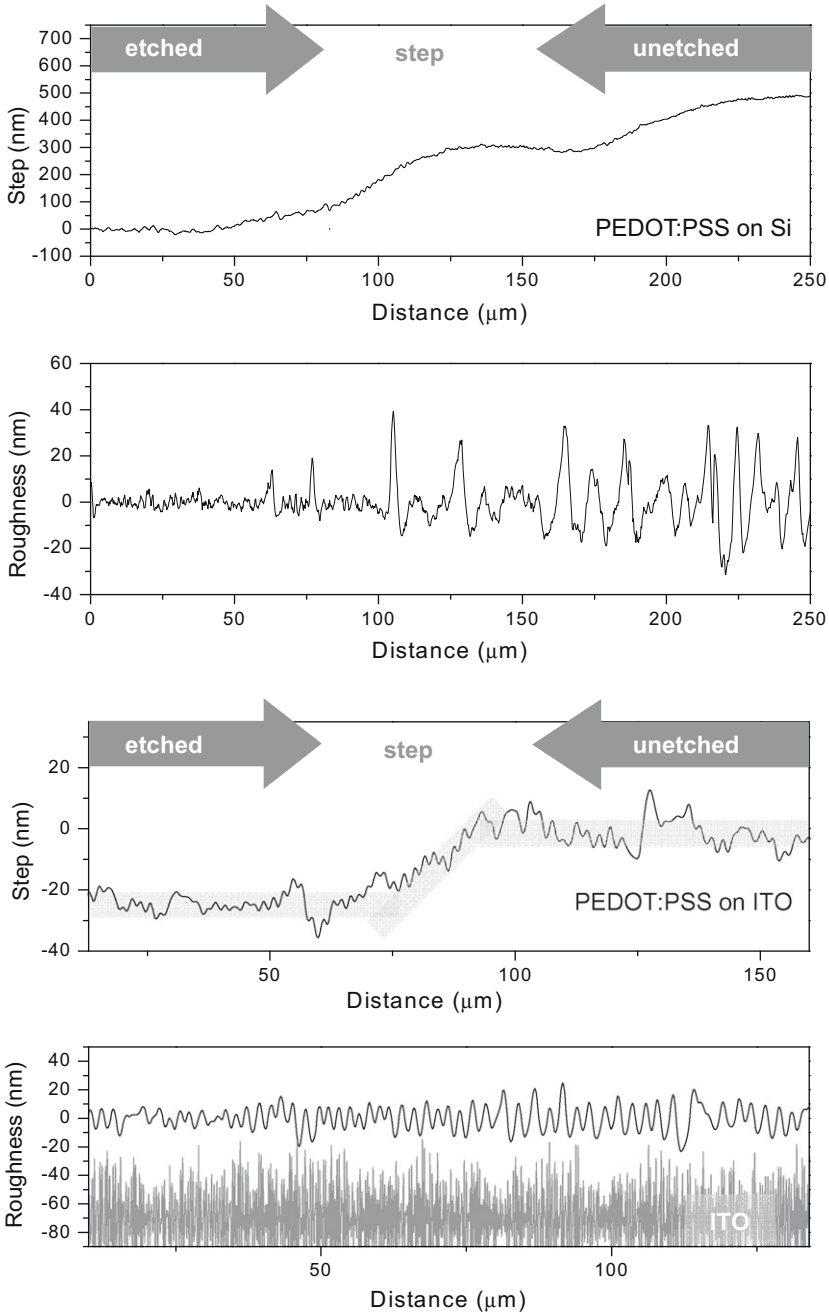

Fig. 2. Surface profilometry measurements of PEDOT:PSS on a silicon wafer (top and second panels) and PEDOT:PSS on an ITO-covered glass (third and bottom panels). Top panel: The step between the etched (left) and unetched (right) region (covered by a shadow mask) indicates approx. 150 nm of etching. Second panel: The etched regions shows lower surface roughness compared to the un-etched film. Third panel: the step between the etched (left) and unetched (right) region (covered by a shadow mask) indicates approx. 17 nm of etching. Bottom: The etched region shows lower surface roughness compared to the un-etched film, both regions show lower surface roughness than the ITO-covered glass substrate.

covered by a shadow mask during the UV–ozone treatment. The UV–ozone exposure resulted with two obvious changes, etching and decreased roughness of the polymer film. The scanning surface profilometry measurements across the exposed and un-exposed regions on of the polymer film showed a clearly observable step in the polymer thickness due to etching. For example, the UV–ozone exposure of the PEDOT:PSS on the silicon wafer for 8 min resulted in reduction of the thickness of the polymer film from 316 nm to ~155 nm, which corresponds to approx. 50% etching. Furthermore, the average roughness of the film was decreased from ~20 nm without the exposure to ~10 nm after the 8 min exposure. Similar effect was also observed for exposures shorter than 8 min, however, with a smaller effect on film thickness and roughness. Similarly, it is expected that both effects, etching and decreased surface roughness, will be observed for UV–ozone exposed PEDOT:PSS film on ITO substrate. On the ITO substrate, the PEDOT:PSS film deposited in the exactly same manner was only 37–39 nm thick. This is presumed to be due to the different wettability of the silicon vs. ITO. Here, the step from 37–39 nm to 20–22 nm after 8 min. of treatment, which corresponds to approx. 46% reduction in the PEDOT:PSS thickness, was observed.

The study of the etching effect and roughness was done using a silicon wafer rather than ITO because the roughness of the ITO is close to the thickness of the polymer film, which precludes accurate observation of the surface features. Unfortunately, the difference in surface chemistry of the silicon wafer vs. ITO and the attendant differences in surface energy and polymer–substrate interaction result also in a large difference of the polymer film thickness and compactness. Thus, the known conditions used to deposit a 38 ± 5 nm thick PEDOT:PSS film on ITO yield a ~310 nm film on a Si wafer. Importantly, the PEDOT:PSS is etched more on Si than on ITO, presumably as a result of a different ozone penetration depth and the fact that the wafer reflects the UV light used for etching. The etching study on Si is presented here only to illustrate the two factors that we believe are universal for the UV–ozone process: The etching and decrease in the surface roughness.

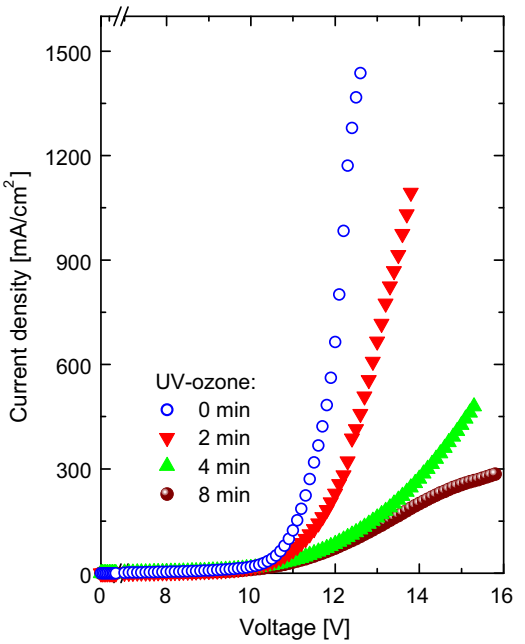

Fig. 3. Current density–voltage (*J–V*) characteristics of a fluorescent OLED utilizing PEDOT:PSS treated with UV–ozone for 0, 2, 4 and 8 min. The configuration of the Device II is ITO/PEDOT:PSS (38 nm)/α-NPD (40 nm)/Alq_3:1% C545T (30 nm)/Alq_3 (30 nm)/CsF (1 nm)/Al (100 nm).

Secondly, the effect of UV–ozone treatment on fluorescent OLEDs performance and its potential applicability to fabrication of the devices were performed by characterization of the OLED devices fabricated at different time of UV–ozone exposure of PEDOT:PSS (HIL) from 0 to 12 min. The electrical properties of the OLEDs were studied together with the optical characteristics. Fig. 3 shows the current density–voltage (*J–V*) characteristics of OLEDs (Device II) using PEDOT:PSS treated with UV–ozone for 0, 2, 4 and 8 min. As one can see, the UV–ozone exposure has a significant effect on charge injection, which decreases with extended UV–ozone exposure. Similar trend in the *J–V* characteristics was also observed for OLEDs regardless of the changes in the configuration. Because the treatment affects the hole injection from the PEDOT:PSS anode, the injection efficiency [3] was studied using a hole-only device with configuration of ITO/PEDOT:PSS (38 nm)/ α-NPD (70 nm)/CsF (1 nm)/Al (100 nm). The data from the hole-only device show that the injection efficiency dramatically decreases, e.g. at 8 V from 0.014 for untreated anode to 0.001 at 8 min of UV–ozone exposure, which corresponds to a thirteen-fold decrease.

In addition to the effect of the UV–ozone exposure on the thickness of the polymer film and the charge injection of the polymer by the exposure, we have also studied the potential effect of UV–ozone exposure time on the shape of the electroluminescent spectra of the devices. Fig. 4 shows that there is no appreciable change in the shape of the EL spectra as a result of the UV–ozone treatment.

Fig. 5a shows the external quantum efficiency (EQE) vs. current density dependence recorded for Device I. It shows that the use of UV–ozone treatment of the PEDOT:PSS layer has a positive effect on the electroluminescence characteristics of the device as well as the duration of exposure required for optimal performance. The EQE of the device improved from 1.15% to 1.55% for the duration of UV–ozone treatment from 0 min to 4 min. After 4 min of the treatment, the EQE drops off significantly. To get a more detailed insight into the phenomenon, the power efficiency of the improved devices by UV–ozone exposure were compared with the control device wherein the HIL was left untreated.

Fig. 5b shows the corresponding power efficiency vs. current density characteristics of the devices for 0, 2 and 4 min of UV–ozone exposure and the resulting increase in the device power efficiencies, which was found to increase from 1.05 lm/W at 0 min to 2.7 lm/W after a 4 min exposure with a maximum luminance of 37,000 cd/m^2. Thus, the maximum power efficiency of the devices was improved by more than 100%. Similarly to the EQE, the power efficiency decreases with a UV–ozone treatment

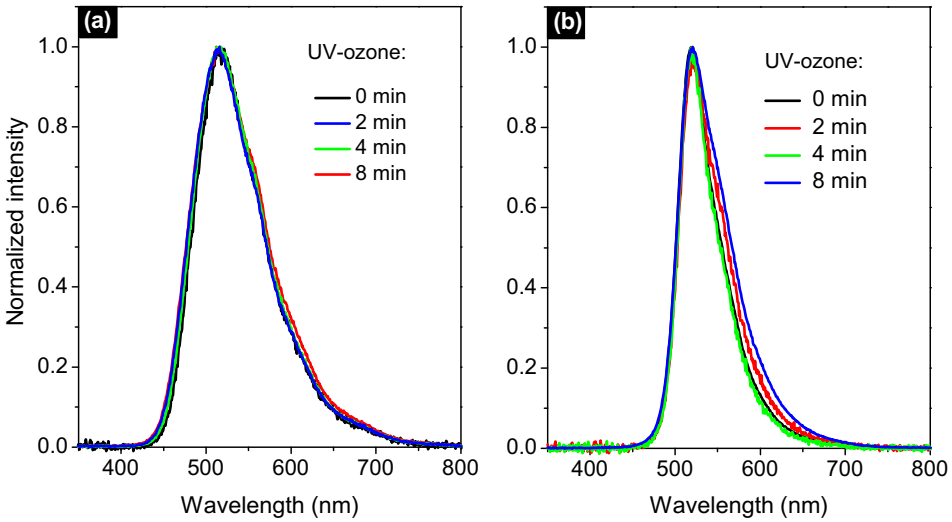

Fig. 4. Electroluminescence spectra of Device I (a) and Device II (b) at 0 min, 2 min, 4 min and 8 min of UV–ozone exposure.

prolonged beyond 4 min. Both the EQE and power efficiency measurements of Device I show that the optimal performance is achieved at 4 min of UV–ozone treatment.

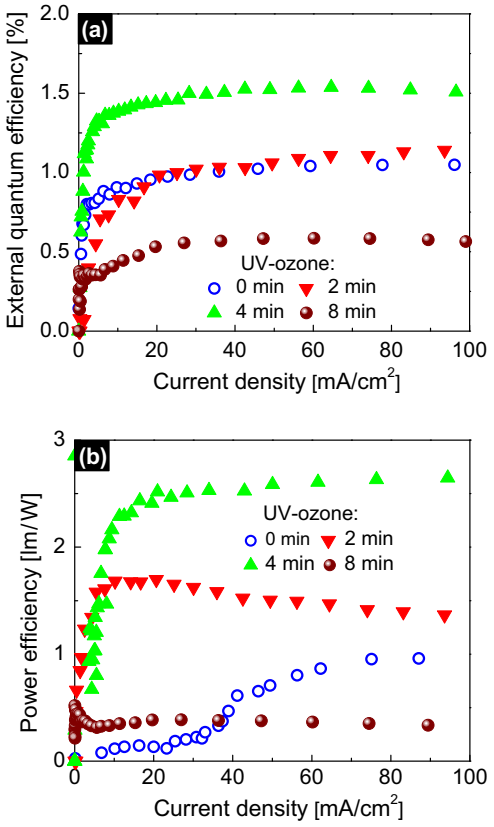

Fig. 5. EQE–current density (a) and power efficiency–current density (b) characteristics of Device I at 0 min, 2 min, 4 min and 8 min of UV–ozone exposure.

It was also observed that the corresponding current efficiency of the device has peaked at 4 min of the treatment with 4.6 cd/A that increased from 3.1 cd/A at 0 min. The UV–ozone treatment affects the turn-on voltage of the device from 3.5 V for the control device with untreated PEDOT:PSS layer to 2.6 V of for the 4 min of the UV–ozone exposure.

The UV–ozone treatment method was also tested to Device II with optimized emissive layer comprising highly emissive dopant C545T (fluorescence quantum yield ~0.95) in the emissive layer. Due to the strongly emitting dopant (quantum yield of C545T is more than twice higher, compared to the neat Alq_3 in Device I) even in the unoptimized HIL, Device II displays a relatively high performance [14]. The electroluminescence characteristics of the Device II are shown in Fig. 6. Fig. 6a shows the dependence of EQE on current density. Here, the use of UV–ozone exposure increases the EQE, which reached its maximum at 8 min and a further increase in the UV–ozone exposure of the PEDOT:PSS tends to reduce the performance of the device. The EQE of the Device II is improved from 4.0% for the untreated (control) device to 5.5% at 8 min exposure. Importantly, the control device reached 4.0% EQE at very high current density (>50 mA/cm^2) while the optimized Device II (8 min treatment) reached its maximum EQE at a low current density of 0.4–0.8 mA/cm^2. Similarly, the power efficiency of Device II was also improved, Fig. 6b. Specifically, the power efficiency of Device II increased from 4.10 lm/W for untreated (control) device to 8.24 lm/W fabricated using the UV–ozone treated PEDOT:PSS layer for 8 min. Once again, this corresponds to a 100% improvement in power efficiency. The maximum power efficiency in Device II with 8 min UV–ozone treatment was achieved at current density of 0.4–0.8 mA/cm^2, which corresponds to a respectable luminous output of 66–140 cd/m^2. The corresponding maximum current efficiency of the device increased following a similar trend and increased from 14.5 cd/A at 0 min to 19.5 cd/A at 8 min.

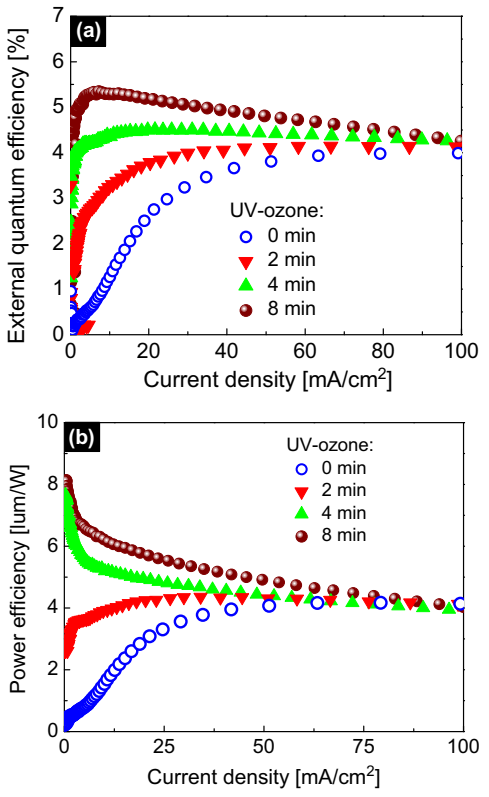

Fig. 6. EQE–current density (a) and power efficiency–current density (b) characteristics of Device II at 0 min, 2 min, 4 min, and 8 min UV–ozone exposure.

In both types of devices, it was observed that the value of maximum luminance is reduced with the increased UV–ozone exposure. For example, in Device II, the maximum luminance was 74,000 cd/m^2 for the untreated (control) device and 22,100 cd/m^2 for 8 min of UV–ozone treatment. However, upon UV–ozone treatment Device II achieves maximum luminous efficiency at significantly lower overall charge carrier density in the device available for recombination. Here, it is important to note that the luminance in either Device I at 4 min or Device II at 8 min satisfies the device requirement in display application while showing improved device efficiency. Thus, from the devices characterization results, a general comparable device efficiency improvement was observed for both Device II and Device I alike.

In addition to the electroluminescence characteristics of the OLEDs, we have also investigated the effect of changing the order of the process steps of UV–ozone exposure and annealing the PEDOT:PSS on the morphology of the polymer film and devices performance. The standard fabrication process utilizes spincoating, drying, annealing and UV–ozone treatment. The performance of these devices fabricated using the reversed order of the annealing and UV–ozone steps was found comparable to the devices fabricate using the standard process and no further improvements in the resulting devices were observed. Note, that all the devices described here were fabricated by the standard process based on the annealing of the PEDOT:PSS followed by UV–ozone exposure.

4. Discussion

The improvement of the electroluminescence efficiency of OLEDs by improving and balancing of charge injection is a crucial factor for fabrication of efficient devices. In particular, the PEDOT:PSS, a HIL material deposited by solution method at ambient condition is important material in the OLEDs, organic photovoltaics (OPVs) and other organic–electronic devices. Hence, the development of methods for tuning its electrical properties is highly desirable. In the realm of OLEDs, the requirement on the HIL is high work function, reduced charge trapping defects and smoother surface (reduced roughness) with low occurrence of pinhole defects [20]. The data obtained in this study show that UV–ozone exposure imparts such properties to the PEDOT:PSS HIL. Particularly, the surface profilometry measurements indicate that the surface roughness is dramatically reduced as a result of the UV–ozone treatment. Furthermore, when compared to the control devices fabricated without the UV–ozone treatment, the increase of the OLED performance suggests that the UV–ozone treatment improved balanced charge injection has been achieved. The study also indirectly proves the change in work function of the polymer film by UV–ozone exposure. This finding is in agreement with recent studies carried out using X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy, which indicated that the use of UV–ozone exposure results in an increase in the work function by at least 0.2 eV [20] and at most 0.25 eV [21] with enhancement of electrical conductivity of the material. This increase in conductivity originates from a decrease in the number of the charge trapping related defects and the formation of linear or expanded polymer chain coil conformation [21]. Thus, the increase in the PEDOT:PSS layer work function, which resulted in better utility of injected charges, seems to be the main reason for the improved device efficiency of the OLEDs with UV–ozone treated PEDOT:PSS layer.

Our measurements indicate that an optimum UV–ozone exposure is required for the best device efficiency. The efficiency of the device first increases with prolonged UV–ozone exposure up to a certain critical time (i.e., 4 min and 8 min for Device I and Device II, respectively), after which the charge injection efficiency decreases. The decrease in charge injection efficiency seems to have originated from the UV–ozone induced increase in the work function of the polymer. The change in the performance of the OLEDs for different time of the UV–ozone exposure indicates that balanced charge injection of the HIL is dependent on the exposure time of the PEDOT:PSS. This is presumably due to the different composition of the emissive layers, which each require different PEDOT:PSS work function to achieve the balance in charge injection and optimal charge recombination in the respective emissive layers. The change in work function as a function of the time of UV–ozone exposure has two regimes: First,

the work function increases with time and then it saturates at a certain critical time [20]. Thus, we believe the untreated (control) devices showed a reduced performance simply due to its low (native) work function, as compared to the exposed cases. Similarly, the low performance in the devices that fabricated using the PEDOT:PSS treated for duration lower than critical time would be due to the insufficient increase in the work function and perhaps also due to insufficient time for complete oxidation of the material to induce an effective balanced charge injection. The change of the work function saturates after a certain critical time of UV–ozone exposure. Based on the device performance results, the work function seems to reach saturation after 4 min, as Device II showed performance improvement at 8 min, which indirectly showed that there is an increase of the work function after 4 min. Also, the improved performance of the device might have come from the reduced surface roughness and possible enhanced interface compatibility between the PEDOT:PSS (HIL) and α-NPD (HTL) as a result of the UV–ozone exposure. Furthermore, due to a mild erosion of the HIL surface and possible changes to HIL–HTL adhesion cannot be excluded. However, we reason that changes in the PEDOT:PSS surface, either chemical (oxidation) and or physical (reduced roughness), are not likely the main reason for the OLED performance improvement. This is because such changes would uniformly affect both the Device I and Device II as they have the same interface of injection, i.e., PEDOT:PSS/α-NPD. In other words, while the roughness of the polymer film is improved at 8 min than at 4 min, the best device performance is at 4 min for Device I while it is at 8 min for Device II, and this difference in time of exposure is related to the charge balanced issue which is controlled by the UV–ozone induced tuning or shift of the work function. Thus, the improvements in the device efficiency of the devices by the UV–ozone exposure, related to the change/increase in the work function, seems to be mainly originated from the oxidation and/or oxygenation of the PEDOT:PSS. The increase in the work function accompanied by decreased surface roughness is a significant factor in device performance improvement. It could be argued that the improved performance might be due to the change in polymer film thickness (5–10 nm) upon etching. However, a study by Zhou et al. [23] on PEDOT:PSS layer thickness in a device architecture similar to Device I indicates that the OLEDs employing different thicknesses of the HIL exhibited very similar performance. Thus, the variation in the PEDOT:PSS thickness due to UV–ozone exposure is not the reason for such a marked improvement in the performance of the devices. However, it should be noted that a UV–ozone exposure prolonged beyond a critical time increases the chance of creating pinhole defects due to excessive etching and device failure, while the change in work function saturates and does not provide further benefit.

We believe that the present easy-to-do inexpensive method that allows for improvement in device efficiency offers a promising avenue for improving low-cost devices for practical applications and is complimentary to the previous efforts made in enhancing the efficiency of the fluorescent OLEDs [14–16].

5. Summary

The application of a mild UV–ozone treatment of PEDOT:PSS HIL in the controlling of balanced charge injection and the device efficiency improvement of fluorescent OLEDs were investigated. Comparative measurements of the device characteristics with and without UV–ozone treated PEDOT:PSS layer were carried out. The study shows that the use of UV–ozone treatment of PEDOT:PSS improves the OLEDs power efficiency by at least 100%. It has also been found that the performance of OLEDs is dependent on the UV–ozone exposure time and that the exposure to achieve maximum device performance varies with the device configuration. The improved efficiency is due to the controlled increase in the work function and reduced roughness of the PEDOT:PSS as a result the UV–ozone induced oxidation of the material. Using the UV–ozone treatment of the PEDOT:PSS, the power efficiency of the Alq_3-based Device I was improved from 1.05 lm/W without the treatment to 2.7 lm/W at 4 min. Device II, which utilizes green coumarin C545T dopant and Alq_3 as a host for the emissive layer was improved from 4.1 lm/W without the treatment to 8.24 lm/W at 8 min. The improved efficiency of the devices is mainly obtained through the efficient balanced charge injection as a result of tuning the work function of the HIL brought about by the UV–ozone exposure. The surface profilometry study confirms that the UV–ozone oxidation etching of the PEDOT:PSS layer change the morphology or roughness of the PEDOT:PSS layer. Therefore the method addresses the two important conditions in the device fabrication, improved roughness and enhanced work function, and an impact on device performance improvements. In summary, this simple and versatile method can be used to improve the performance of OLED devices without a need for further instrumentation or advanced device architectures. As such, this method could be useful in fabrication of inexpensive large scale OLEDs without significant impact to the overall cost.

with an agate mortar to obtain a corresponding sample with a smaller average grain size. Samples for photoluminescence (PL) measurements were prepared by pressing powder of the materials into aluminum cans to form tablets of 4 mm in diameter and 1 mm in thickness. Special cares have been devoted to make the powder in the tablets as densely packed as possible. Nevertheless, it is expected that due to the different crystal sizes and shapes, the packing densities of samples can be slightly different. Intensities of the UCL spectra so measured are thus not straightly quantitative. Hence, when comparing the absolute PL intensities of different samples, there can be small variations due to different packing densities.

XRD spectra were measured using a Siemens D5005 diffractometer with Cu-Kα radiation (λ = 1.5418 Å). Field emission scanning electron microscopy (FE-SEM) was carried out on a Hitachi S-4800 electron microscope. UCL spectra were measured under excitation of continuous 980 nm semiconductor laser with a maximum power of 2 W at an area of 0.01 cm^2. A Spectrometer with Spex 1403 photomultiplier with a boxcar averager was used to record the spectra. Conventional single photon PL spectra of crystalline samples under continuous 325 nm He–Cd laser were recorded by a UV-Laboratory Raman Infinity (n°9/35 INF, made by Jobin Yvon Company) with a resolution of 2 cm^{-1}. For comparison, PL measurements were also carried out on spin-coated thin film of polymethylmethacrylate (PMMA) doped with 0.1 wt.% rubrene and 0.5×10^{-3} M rubrene chloroform solution. The PL decay curves were measured by a two channel TEKTRONIX TDS-3052 oscilloscope and a Spectrometer with Spex 1403 photomultiplier under excitation of a 980 nm OPO laser and a 355 nm YAG:Nd^{3+} laser. The response time of the measurement system is about 30 ns and the lifetime shorter than 100 ns could not be exactly measured and overestimated with an error about several tens nanoseconds.

Fig. 1 shows X-ray diffraction (XRD) spectra of the four different rubrene powder samples. The main peaks in the XRD spectrum of Ru-1 can be indexed to the (0, 0, 2) and (0, 0, 6) planes of orthorhombic rubrene crystal [17]. Intensities of the (0, 0, 4) and the (0, 0, 8) peaks are much lower than those of (0, 0, 2) and (0, 0, 6). Besides the (0, 0, 2n) peaks, XRD spectra of Ru-2 and Ru-3 also show peaks corresponding to the (2, 0, 0), (2, 2, 0), (3, 1, 1), and (4, 2, 0) planes of a face-centered cubic (FCC) structure. It can also be seen that the (0, 0, 2) peak of the orthorhombic phase in Ru-2 and Ru-3 not only have lower relative intensities, but also be widened. The XRD results suggest that Ru-1 contains pure orthorhombic phase with a highly preferred orientation, while both Ru-2 and Ru-3 consist of orthorhombic and FCC phases. XRD spectrum of Ru-4 is virtually the same as that of Ru-1 which confirms that the grinding did not change the crystal structure. In addition, through comparing the intensities and widths of the diffraction peaks, it is concluded that Ru-1 and Ru-3 have the highest and the lowest crystallinity, respectively.

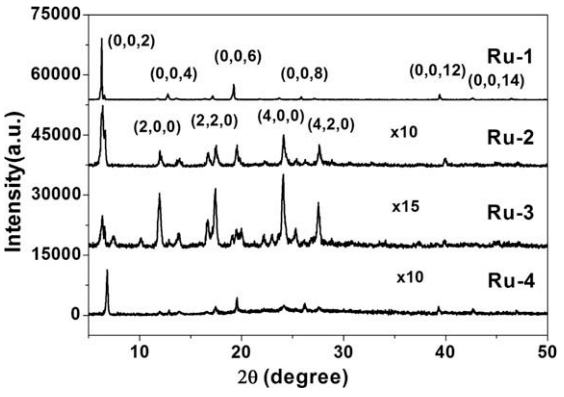

Fig. 1. XRD patterns of crystalline samples Ru-1, Ru-2, Ru-3, and Ru-4.

SEM images of the four crystalline samples are shown in Fig. 2. It can be seen that these samples have distinctly different crystal shapes and crystal sizes, which are about 40 μm, 15–30 μm, 10–20 μm, and 20 μm for Ru-1, Ru-2, Ru-3, and Ru-4, respectively. Crystalline features (sharp angles and edges, etc.) can be clearly observed in all samples. From SEM photographs, we can see that Ru-4 and Ru-1 have similar morphologies. It appears that the grinding of Ru-1 has broken the longer crystals into particles of smaller aspect ratios. On the other hand, Ru-2 and Ru-3 are respectively dominated by plate-like and short-rod crystals.

Fig. 3 shows UCL spectra of the four samples at room-temperature (RT) under the illumination of 980 nm laser. It can be seen that Ru-1 and Ru-3 give the highest and lowest UCL intensities, respectively. As mentioned in the experimental section, possible differences in packing densities of four samples might influence UCL intensities. However, when the conventional PL spectra (Fig. 4) of the four samples (which are exactly the same samples used for the UCL measurements) are compared, it can be seen that Ru-1 has lower PL intensity than Ru-2 and Ru-3. These results suggest that the possible packing density differences should not be a dominating factor on the relative UCL and conventional PL intensities of Ru-1, Ru-2, and Ru-3. On the other hand, as shown in Fig. 1, Ru-1 has a strong (0, 0, 2) texture. Hence, the highly preferred (0, 0, 2) orientation might be a possible cause for the highest UCL intensity. To check this, UCL intensities of Ru-1 were measured again upon tilting the samples to different angles with respect to the incident beam. No obvious change in UCL intensity has been observed. This suggests that the crystal orientation should not influence the UCL intensity.

Fig. 1 shows that Ru-1 consists purely orthorhombic phase, while Ru-2 and Ru-3 are mixtures of orthorhombic and FCC phases. The UCL intensity increases with the ratio of orthorhombic phase to FCC phase. Under the hypothesis that the orthorhombic phase gives the higher UCL intensity than the FCC phase, the UCL intensity order of Ru-1 > Ru-2 > Ru-3 can be consistently explained. Furthermore, Ru-1 has higher UCL (Fig. 3) and conventional PL (Fig. 4) intensities than Ru-4. This suggests that a larger grain size should increase both the UCL and conventional PL. One possible reason for this is stronger scattering effect in the sample with smaller grain size. It should also be pointed out that the UCL peak position of Ru-3 (594 nm) differs obviously from that (610 nm) of the other three samples, and the reasons are not clear.

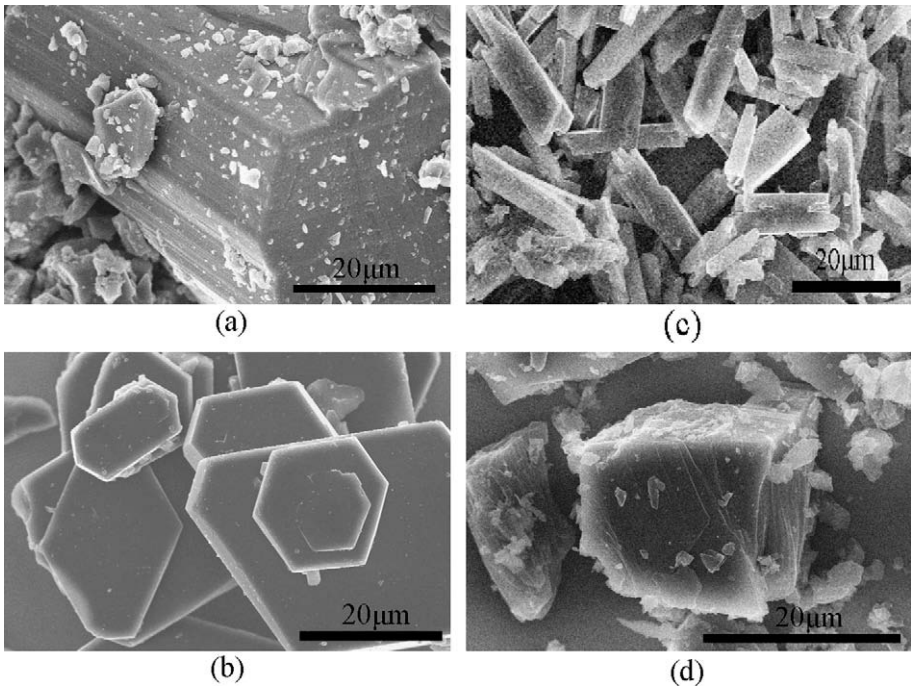

Fig. 2. SEM photographs of Ru-1 (a), Ru-2 (b), Ru-3 (c), and Ru-4 (d) samples.

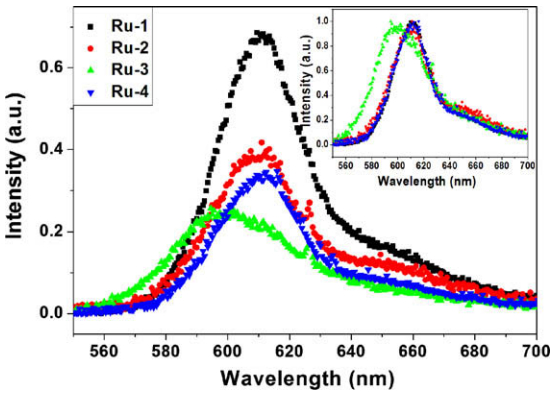

Fig. 3. UCL spectra of Ru-1, Ru-2, Ru-3, and Ru-4 at RT. Inset: Unitary UCL spectra of all samples at RT.

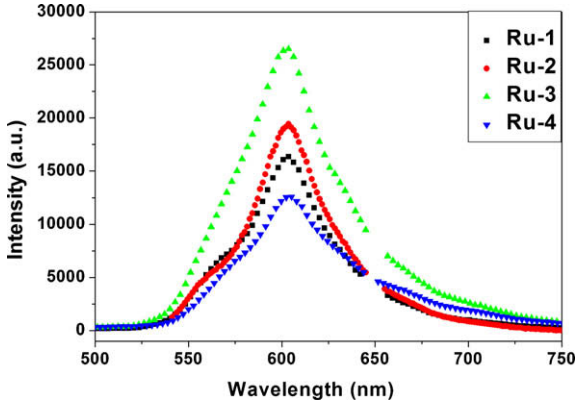

Fig. 4. Single photon emission spectra of samples Ru-1, Ru-2, Ru-3, and Ru-4 (λ_{ex} = 325 nm). Since the intense 650 nm laser line of He–Cd laser overlapped in the spectra, the spectra were drawn after the subtraction of 650 nm line.

Besides the influence of crystal phases and grain size on the difference of UCL intensities at RT, chemical impurities, structural defects, and reabsorption of fluorescence were also taken into account because these factors are related to the luminescence properties of crystal materials [18]. In our work, all samples were sublimed twice at 10^{-6} torr, so that the effect of chemical impurity could be ignored. The samples with lower crystallinity (Ru-2 and Ru-3) and the grinded sample (Ru-4) must have more structural defects than Ru-1. On the other hand, the blue-shift of photo-absorption and the red-shift of the emission peak of rubrene single crystal comparing with Rubrene solution were observed [19], which will lead to the suppression of reabsorption of fluorescence and the increase of fluorescence intensity. Therefore, quasi-single sample Ru-1 shows the highest UCL intensities at RT.

Fig. 5 shows the UCL spectra of the four samples at 77 K. It can be seen that the relative intensities of the samples are similar to those at RT (Fig. 3). One major difference from RT spectra is that the emission bands in all samples shift to shorter wavelength. At low temperature the oscillation of molecular crystal lattice mitigates so that the emission bands shift to higher energy [20].

Fig. 6 shows the dependence of the integral UCL intensity of Ru-1 on the excitation power density at RT and 77 K. At both temperatures, the UCL integral intensities show

power law relationships to the excitation power density. The slopes of the fitted straight lines for RT and 77 K are 1.67 and 1.88, respectively, indicating that the UCL of rubrene crystal belongs to TPA process [21].

We also have measured UCL of 0.1 wt.% rubrene dispersed in PMMA film by spin-coated from their chloroform solution and 0.5×10^{-3} M rubrene chloroform solution under excitation of 980 nm laser. However, no UCL was observed; while the film and solution show conventional yellow PL around 550 nm upon illumination of 325 nm laser (Fig. 7). The distance between rubrene molecules in crystalline materials is expected to be much closer so that a stronger intermolecular interactional force produces. It is considered that the interaction between rubrene molecules in crystal is much stronger than that of dispersed rubrene molecules in solid matrix or in solution [19,22]. In other word, there should be no excitonic state corresponding to UCL emission level (610 nm) in rubrene film or solution [19]. Therefore, rubrene dispersed PMMA film or solution samples could not give UCL emission under excitation of 980 nm laser, but isolated rubrene molecules can be excited by 325 nm UV light, as shown in the right of Fig. 8.

In order to deeply investigate the mechanism of UCL process, we measured the decay curves of UCL and conventional PL of crystalline rubrene, and fitted the two lifetimes according to the equation: $y = A_1 * e^{-x/t_1} + A_2 * e^{-x/t_2}$. The results were t_1 = 68 ns (A_1 = 0.80346), t_2 = 472 ns (A_2 = 0.07556) and t_1 = 43 ns (A_1 = 9.99468), t_2 = 506 ns (A_2 = 0.02116) for up-conversion and conventional PLs, respectively. Considering the spectra of up-conversion and conventional PLs, we attribute the shorter lifetime and the longer lifetime to 610 nm emission and 650 nm emission, respectively, because the longer lifetime component presents a little proportion. The 650 nm emission is attributed to the emission of rubrene crystals which exist in small amounts in rubrene samples and this emission is the result of molecular interactions that is similar to the 610 nm emission [22]. Meanwhile, when excited by pulse laser, we can not capture the spectra of up-conversion

and conventional emissions of crystalline rubrene using our spectral measurement system even though we can see the bright light with our eyes, therefore the 610 nm emission should be less than the response time of our system (30 ns). That is, the lifetime of UCL is similar to that of single photon emission. The spectra in Figs. 3–5 were obtained under excitation of continuous 980 nm semiconductor laser and 325 nm He–Cd laser.

Considering that the lifetime of UCL through TTA is far longer than that of single photon emission, we think that the UCL process of crystalline rubrene would be arisen from TPA rather than from TTA. Under excitation of 980 nm infrared laser, as there are no sensitizers in the system, there must be a virtual state with a short lifetime (of the order of a few femto-seconds) playing a very important role in TPA process. As infrared light passes through crystalline rubrene molecules, the virtual state may form and exist for a very short duration [23–25]. If a second photon arrives before this virtual state decayed, TPA can result. The probability of TPA scaling with the square of the light intensity leads to a highly localized photon excitation. Therefore, TPA involves the concerted interaction of both photons that combine their energies, and then produces an electronic excitation similar to that conventionally caused by a single photon of a correspondingly shorter wavelength. Differing from single-photon absorption, the probability is squarely proportional to the incident intensity, as proved by Fig. 5 [23]. In crystalline rubrene, the second photon arriving level, also named as the final level (E_f), lies at 2.51 eV. After absorbed two 980 nm photons, UCL occurs through energy transfer from E_f to UCL level (2.03 eV), as shown in the left of Fig. 8. More detail mechanism for our UCL system is under studying.

UCL of crystalline rubrene samples under excitation of 980 nm infrared laser was demonstrated. It is interesting that it needs no assistance of any sensitizing materials. The UCL intensity increases as the proportion of orthorhombic crystal phase increases. Up-conversion quantum efficiency up to 0.19% was observed at RT in a sample with high phase purity of orthorhombic crystal. A large grain size appeared to have positive influences, while crystal orientation was observed to have little influence on the UCL intensity. UCL was not observed in all non-crystalline rubrene samples. The UCL is attributed to the excitonic state via stronger intermolecular interaction in the crystalline rubrene. It is well-known that most reported organic up-conversion lasers were in solutions which can limit certain applications [26], therefore, this special UCL system could be used to design new up-conversion optical systems.

resistance of 12 Ω/□. The substrates were ultrasonically cleaned in acetone, ethanol and de-ionized water, by which most of the ITO surface organic contaminants were removed. The surface of ITO gate electrode was then treated in an Ar plasma prior to depositions of the insulating layer. A radio frequency (r.f.) capacitively-coupled plasma (CCP) with a pressure of 0.1 Torr, Ar flow rate of 10 sccm, and r.f. main power of 100 W was used for surface treatment of the ITO gate electrode. Without breaking vacuum after the plasma surface treatment, plasma polymerized methyl methacrylate (ppMMA) insulting layer was then deposited, where a MMA monomer (Sigma–Aldrich Co.) was used. Plasma polymerization of the ppMMA dielectric layers was done again using the r.f. CCP equipment. Details of the plasma polymerization equipment were described elsewhere [10]. The ppMMA was deposited under following experimental condition: main power of 200 W, bias power of 20 W, system pressure of 0.5 Torr, Ar flow rate of 30 sccm, and deposition time of 10 min. The thickness of the ppMMA film was measured by field emission-scanning electron microscope (FE-SEM; Hitachi, S-4300) and found to be about 100 nm. A 60 nm-thick-pentacene (Sigma–Aldrich Co.) active channel layer, and 100 nm-thick-Au source/drain electrodes layer were then deposited using thermal evaporation technique. The Au source/drain electrodes were patterned on pentacene layer through a shadow mask. The OTFT devices had inverted staggered structures of Au/pentacene/ppMMA/ITO.

Film composition, surface morphology, and electrical properties of the ppMMA were investigated using Fourier transform infrared spectroscopy (FTIR; Bruker Optics, Vertex 80v) in vacuum, contact angle measurements (Erma Inc.), X-ray diffraction (XRD; Rigaku, D/Max 2200V/PC), atomic force microscope (AFM; Digital instrument, Nanoscope Mutimode IVa) and capacitance–voltage analysis (*C–V*, Keithley 590), respectively. For investigating performance of the OTFTs, current–voltage (*I–V*) characteristics according to applied voltage change were measured by a source measurement unit (Keithley 236) combined with another source measurement unit (Keithley 2400).

Fig. 1a shows FTIR spectrum for the ppMMA thin film. The FTIR spectra of the ppMMA and conventional spin-coated poly methyl methacrylate (PMMA) are consistent with similarly processed materials in Ref. [7], which identifies chemical similarities and dissimilarities of the two materials. Functional groups such as C–O, C=O, and CH are observed. The ppMMA thin film exhibits strong bands at 1730 cm^{-1} corresponding to the poly dimethylketene-like vinyl ester structure. Additionally, the C=C and CH stretches at 1460 and 1386 cm^{-1} are also evident. In the ppMMA, plasma polymer was formed in a cross-linked 3D network which is typical in plasma polymerization. This is indicated by the differences between the characteristic absorption peaks of ppMMA and solution processed PMMA, suggesting significant amount of fragmentation and rearrangement in the plasma deposition process. Inset in the Fig. 1a is AFM image of the surface of ppMMA gate dielectric. The surface roughness of a 100 nm-thick-ppMMA on ITO-coated glass was characterized and showed good root mean square roughness of about 0.24 nm. Fig. 1b shows a cross-sectional SEM image of the OTFT device. The surface energy of the ppMMA dielectric was about 45 mJ/m^2, which was similar to that of pentacene (42–48 mJ/m^2), which suggests that it might be possible to develop more efficient OTFTs channel by matching the surface energy of the ppMMA dielectric and the pentacene [11,12].

Fig. 2 shows the reflective XRD patterns and AFM image of 60 nm-thick-pentacene layer grown on ppMMA dielectric. XRD and AFM experiments were performed in order to investigate the effects of the surface properties of the gate dielectric on the surface morphology of pentacene. The structure of pentacene layer was elucidated by XRD in reflection mode at 20 kV, 20 mA and Cu Kα radiation (λ = 1.5406 Å) with a coupled (θ–2θ) scans configuration. The corresponding XRD pattern contains a series of sharp (0 0 k) peaks indicating that the pentacene film is highly ordered. The first peak at 5.7° (the thin-film phase) corresponds to a lattice parameter of 15.6 Å. The AFM images of pentacene layer on ppMMA reveal a dendritic structure

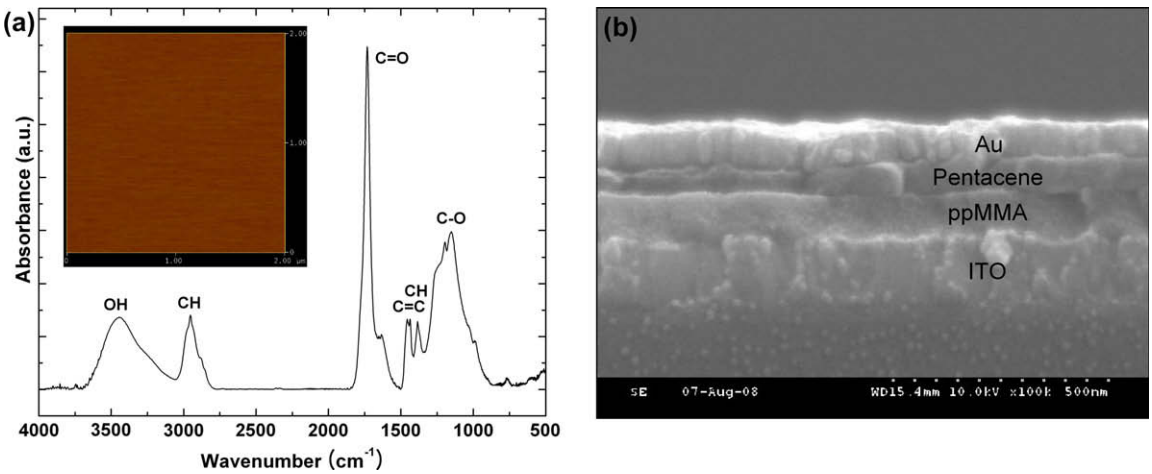

Fig. 1. (a) FTIR spectrum of ppMMA. Inset: AFM image (2 μm × 2 μm) of the surface of ppMMA gate dielectric. (b) SEM image of the OTFT device on a side view.

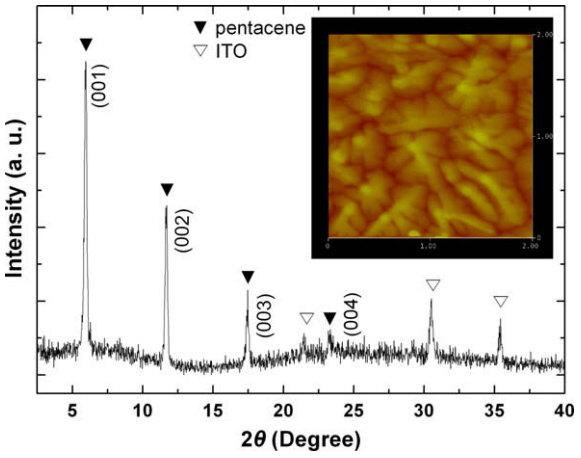

Fig. 2. X-ray diffraction pattern of the pentacene deposited on a ppMMA dielectric. Inset: the AFM image (2 μm × 2 μm) of the pentacene grown on a ppMMA dielectric.

with a grain size of ~1 μm. The data suggest a robust and pinhole-free ppMMA film, where the growth morphology of pentacene was similar to those prepared on other polymer substrates [13].

One of the main problems of OTFT devices is the occurrence of hysteresis. Although they are very often ignored in the literature, Gu et al. [14] described hysteresis effect for MIS capacitors based on pentacene and attributed them to carrier trapping or migration of dopants [15]. Fig. 3a shows the *C*–*V* characteristics (100 kHz) of a MIS device with a 100 nm-thick ppMMA in dark at room temperature. The normalized capacitance (C/C_{MAX}) was ranged to be within 1.00 and 0.80 when voltage was applied from −20 to 20 V. *C*–*V* characteristics in accumulation–depletion region were investigated using the MIS structure, and gate bias was swept back to check the amount of hysteresis origination from bulk or interface charge trapping. Very small hysteresis was observed in the *C*–*V* curves, which is due to low carrier trapping in MIS capacitor by non-solvent process and cross-linked polymerization deposition [16,17]. Dielectric constant *k* of the ppMMA layer was obtained with the following equation: [18]

$$k = C\frac{d}{\varepsilon_0 A}$$

where *C* (1.37 nF) is capacitance of the ppMMA dielectric, *d* and *A* are the ppMMA thickness (100 nm) and the dot area (0.04 cm^2), ε_0 is permittivity in vacuum (8.85×10^{-14} F cm^{-1}), respectively. According to the calculation, we obtained a higher dielectric constant ($k = 3.86$) for the ppMMA in an ITO–ppMMA–Au (MIM) sandwich structure, in contrast to the conventional PMMA layers ($k = 2.5$–2.9) in Ref. [3]. Jang et al. [4] described a correlation between device field-effect mobility and permittivity of dielectric materials. The higher field-effect mobility for dielectrics with higher dielectric constants may be due to increases the number of hole carriers at the semiconductor–dielectric interface. To investigate the potential of ppMMA as gate dielectric, we checked whether their leakage current density is sufficiently low by testing the corresponding ITO–ppMMA–Au (MIM) devices. Fig. 3b shows the current density–electric field (*J*–*E*) curve of the ppMMA insulator on ITO, and in particular the leakage behavior of the ppMMA dielectric. The ppMMA appeared to have quite a good dielectric strength of ~2 MV/cm based on a minimum leakage current density of $\sim 10^{-8}$ A/cm^2 even though its total thickness was only 100 nm. This might be caused by the pinhole-free ppMMA dielectric with highly cross-linked structure. Fig. 4 shows *I*–*V* characteristics of the

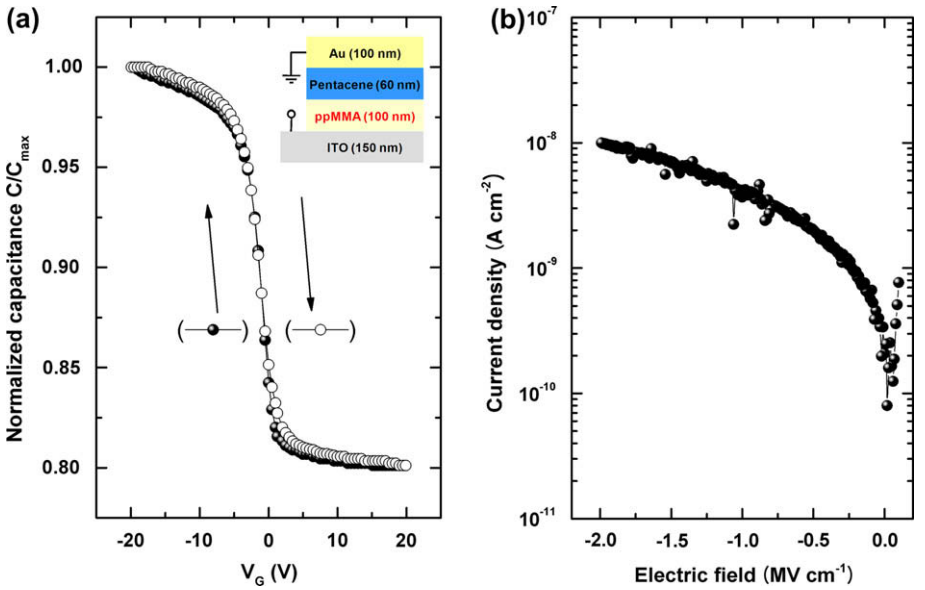

Fig. 3. *C*–*V* and *J*–*E* characteristics: (a) *C*–*V* characteristics of ITO–ppMMA–pentacene–Au (MIS) capacitor at ac signal frequency (100 kHz). The bias voltages were swept from −20 to +20 (○) and from +20 to −20 (●). Inset: schematic cross-section of the MIS device. (b) *J*–*E* characteristics of ITO–ppMMA–Au (MIM) device.

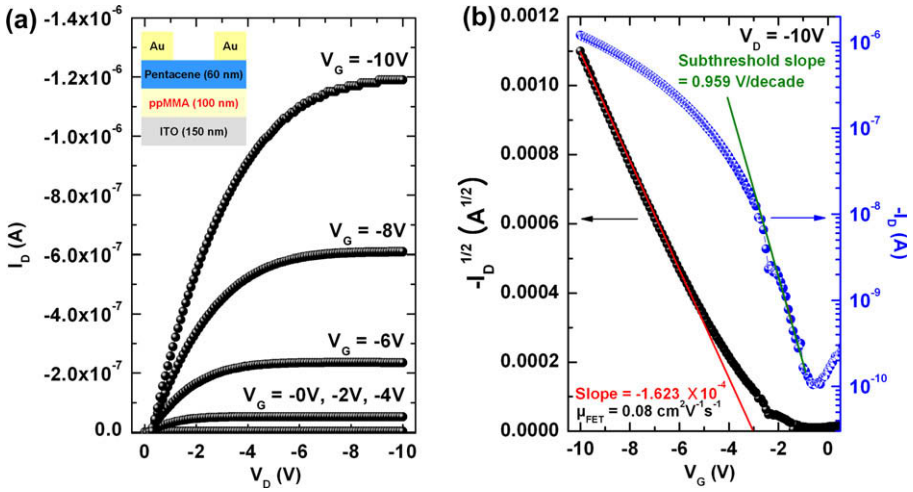

Fig. 4. Current–voltage (I–V) characteristics of OTFT device with inverted staggered structure of ITO/ppMMA/pentacene/Au: (a) drain current–drain voltage (output) characteristics of OTFT devices. Inset: schematic cross-section of the OTFT device; (b) drain current–gate voltage (transfer) characteristics of OTFT devices.

OTFT device with a 100 nm-thick-ppMMA layer in dark at room temperature: (a) typical output I_D–V_D curve at applied step gate voltages (−2 V); (b) transfer I_D–V_G curve at fixed −10 V drain voltage. The I–V characteristics were measured for the OTFT device with channel length of 100 μm and channel width of 2000 μm. From these data, average field-effect mobility was calculated in the saturation current regime (V_D = −10 V) by equation which are derived in threshold voltage V_{TH} and field-effect mobility μ: [18]

$$I_{Dsat} = \frac{W}{2L} C_i \mu (V_G - V_{TH})^2$$

where W and L are channel width and length, C_i is capacitance per unit area of the ppMMA insulators, V_G and V_{TH} are gate and threshold voltage, and μ is field-effect mobility. The OTFT devices with the ppMMA insulator was found to have a field-effect mobility of 0.08 ± 0.02 $cm^2\,V^{-1}s^{-1}$ in the saturation region, a lower threshold voltage of −3 ± 0.15 V, a lower sub-threshold slope of 0.959 ± 0.05 V/decade, and an on/off current ratio (I_{on}/I_{off}) of 1.0×10^4 ± 0.10, respectively. This combination of favorable properties demonstrated that the OTFT can be operated successfully at voltages ~10 V.

An OTFT device with inverted staggered structure of Au/pentacene/ppMMA/ITO was fabricated. Proposed plasma polymerization method could be applied to a completely dry process for the OTFT fabrication, which offers a one-step and compatible process with conventional methods. The OTFT with the ppMMA dielectric could be operated with a lower operation voltage of −10 V. It was demonstrated in this report that the 100 nm-thick-ppMMA dielectric thin film could be used to obtain an OTFT device with favorable electrical properties and performance of the OTFT device could be significantly improved. Plasma polymerization method has the benefits of polymer gate dielectrics including potentially high capacitive coupling, and shadow mask patterning and in situ dry processing with large-area flexible substrates.

polymers under AM 1.5G illumination, a maximum PCE of 1.9% was achieved in an OPV cell with an active layer composition of 1:8 in PGREEN: $PC_{60}BM$ ([6,6]-phenyl-C61 butyric acid methyl ester) blends.

Here, we report on several pathways to improve and optimize the key device parameters including short-circuit current (J_{SC}), open-circuit voltage (V_{OC}) and fill factor (*FF*) via the use of $PC_{70}BM$ (to increase the J_{SC}), bis-$PC_{60}BM$ (to increase the V_{OC}), and MoO_3 interlayer (to increase the *FF*). Three different active layers consisting of blends of PGREEN with $PC_{60}BM$, $PC_{70}BM$, and bis-$PC_{60}BM$ sandwiched between an ITO anode and a LiF/Al cathode were used in this study. In addition, MoO_3 is introduced as an anode interlayer to replace the commonly used poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT-PSS) anode interlayer. Fig. 1 shows the repeat unit structure for the polymer employed and the energy level diagram of the solar cell components used in this study.

To fabricate OPV cells with a PEDOT:PSS interlayer, a thin layer (30 nm) of PEDOT:PSS was spin coated on top of a pre-cleaned ITO coated glass substrate. For cells with a MoO_3 interlayer, a thin film (10 nm) of MoO_3 was thermally evaporated on the ITO substrate under a vacuum of 10^{-6} torr. For the PEDOT:PSS cell, a 115 nm thick bulk-heterojunction active layer was spin-casted from a solution of PGREEN and $PC_{60}BM$ (1:8) prepared using chlorobenzene as the solvent. Subsequently, the active layer was annealed at 70 °C for 45 min, and a LiF/Al cathode (1/100 nm) was thermally evaporated onto the active layer material. The annealing temperature (70 °C) used for all devices reported in this work. Each device has an active area of 0.04 mm^2. The current density was measured as a function of voltage with a 150 W ozone free Newport xenon arc lamp in conjunction with a Keithley 4200 semiconductor parameter analyzer. Solar measurements were done under AM 1.5G, 1000 W/m^2 illumination conditions. External quantum efficiency of OPV cells as a function of wavelength were measured using a calibrated silicon photodiode in conjunction with a lock-in amplifier.

Fig. 2a shows the current density–voltage (*J–V*) characteristics of the PGREEN devices with different fullerene acceptors and different interfacial layers, measured under simulated solar illumination. First, we investigate the effect of $PC_{70}BM$ on the performance of the PGREEN cell. We found that the optimum blend composition (PEDOT:PSS/PGREEN:$PC_{70}BM$/LiF-Al) has a PGREEN:$PC_{70}BM$ blend ratio of 1:6; higher in polymer content when compared to the $PC_{60}BM$-based cells [16]. The device exhibits a J_{SC} value of 7.01 mA/cm^2, a V_{OC} value of 0.8 V and a *FF* value of 51%. Compared to the PEDOT:PSS cell with $PC_{60}BM$ as an acceptor, a 52% enhancement in PCE (Table 1) was observed. The major enhancements in the $PC_{70}BM$ cell are due to enhancements in short-circuit current and fill factor. The external quantum efficiencies of the PGREEN-

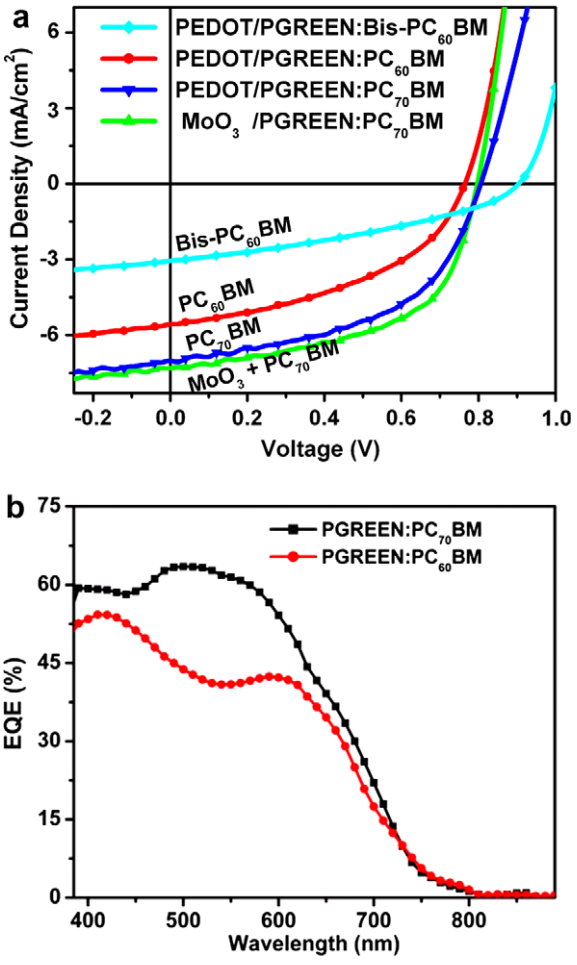

Fig. 2. (a) The *J–V* curve of a PGREEN polymer solar cell under AM 1.5 conditions and (b) external quantum efficiency (EQE) of PGREEN/$PC_{60}BM$ and PGREEN/$PC_{70}BM$.

Table 1
Photovoltaic parameters of PGREEN solar cell devices.

PV devices	J_{SC} (mA/cm^2)	V_{OC} (V)	*FF* (%)	PCE (%)	R_S (Ω cm^2)
PEDOT/PGREEN:$PC_{60}BM$/LiF-Al	5.56	0.77	44	1.90	24.52
MoO_3/PGREEN:$PC_{60}BM$/LiF-Al	5.38	0.77	51	2.12	15.88
PEDOT/PGREEN:$PC_{70}BM$/LiF-Al	7.01	0.80	51	2.89	22.78
MoO_3/PGREEN:$PC_{70}BM$/LiF-Al	7.32	0.79	56	3.22	14.64
PEDOT/PGREEN:bis-$PC_{60}BM$/LiF-Al	3.05	0.90	37	1.01	57.47

fullerene films with $PC_{70}BM$ and $PC_{60}BM$ are shown in Fig. 2b. Here, the $PC_{70}BM$ cell exhibits only one broad absorption band with a maximum at 475 nm whereas the $PC_{60}BM$ cell exhibits two broad-band absorptions with two absorption maxima. In addition, we also observed that the color of the $PC_{70}BM$ cell is brown as opposed to the asparagus green ($PC_{60}BM$ device)[16] due to the strong absorption of $PC_{70}BM$ in the blue-green region. Here, the absorption of $PC_{70}BM$ fills the transmission window of the PGREEN polymer [16,17] leading to the single broad absorption band. The external quantum efficiency (EQE) of the PGREEN-$PC_{70}BM$ device resembles its absorption spectrum, yielding a maximum value of 60% at 570 nm. This value is 11% higher than that of the $PC_{60}BM$ cell and illustrates the importance of the $PC_{70}BM$ phase in both light absorption and transport.

Next, we examine the effect of bis-$PC_{60}BM$ on the BHJ PGREEN OPV cells (PEDOT:PSS/PGREEN:bis-$PC_{60}BM$/LiF-Al). Bis-$PC_{60}BM$ has a higher lying LUMO energy [12] and is expected to give a larger V_{OC} value. Here, we found that an optimum blend ratio for the PGREEN:bis-$PC_{60}BM$ photoactive layer is 1:8, identical to that found for $PC_{60}BM$. As shown in Fig. 2, we do observe the overall V_{OC} enhancement in the bis-$PC_{60}BM$ cells to 0.90 V, as compared to 0.77 V for the $PC_{60}BM$ cells [12]. It should be noted that despite this increase in $V_{OC,}$ the overall performance of the OPV cells decreases due to significant reduction in J_{SC} and *FF*, resulting in a PCE of 1.01%.

To study the anode interface effect, first we replaced the anode interface layer PEDOT:PSS by MoO_3 for the PGREEN:$PC_{60}BM$ device with the optimum blend composition of 1:8. We observe the fill factor and PCE increase from 44% to 51%, and 1.90% to 2.12%, respectively (Table 1). The enhancement in fill factor is mainly due to a decrease in the series resistance (R_S) (Table 1) of the MoO_3 cell. Similar effects have been observed previously for other polymer and small molecule based devices [15–18]. To understand the effect of the MoO_3 interlayer, we have previously reported on the interface electronic structure of the MoO_3 interlayer by photoelectron spectroscopy, and observed that the MoO_3 interlayer exhibits an *n*-type alignment [18,19] (Fig. 1). Recently, the same behavior (*n*-type) of MoO_3 was also reported by Kröger et al. [20]. Furthermore, there is a 2 eV shift in the vacuum level resulting in band bending at the MoO_3/electroactive layer interface [18]. The resulting built-in electric field leads to an enhancement in hole extraction from the electroactive layer to the anode, leading to a reduction in the cell series resistance (Table 1).

The PGREEN:$PC_{70}BM$ PV cell with a MoO_3 interlayer exhibits the highest PCE of 3.22% and the corresponding cell has a J_{SC} value of 7.32 mA cm^{-2}, a V_{OC} value of 0.79 V and a *FF* value of 56% at an optimized blend composition of 1:6. This corresponds to a 69% enhancement in PCE compared with the $PC_{60}BM$ cell with a PEDOT:PSS interlayer. Relative to the PEDOT:PSS cell, the PCE's of both of the $PC_{60}BM$ and $PC_{70}BM$ cells having the MoO_3 interlayer were enhanced by 12% due to an enhancement in the fill factor.

In order to gain insight into the mechanisms behind the enhancement in EQE and short-circuit current, we carried out charge carrier transport studies on hole-only carrier devices. Here, the hole-only device has the following device structure: ITO/PEDOT/Active Layer/Pd [21] with either a pristine PGREEN or a PGREEN-$PC_{70}BM$ or $PC_{60}BM$ blend as the active layers at their optimum ratios (Fig. 3) reported above. Space-charge limited (SCL) currents were observed in these devices. From the current density–voltage (*J*–*V*) results, we determine that the hole mobility of the neat PGREEN polymer is $\sim 10^{-7}$ cm^2 V^{-1} s^{-1} which is low compared with the electron mobility in the PCBM ($\sim 10^{-3}$ cm^2 V^{-1} s^{-1}) [22]. This difference in electron and hole mobilities results in unbalanced charge transport in the BHJ photovoltaic cells. On the other hand, blending the copolymers with an optimized large proportion of PCBM leads to a significant increase in hole current as shown in Fig. 3 leading to an enhancement of hole mobility (4×10^{-5} cm^2 V^{-1} s^{-1}) in the polymer blend. The better charge balance leads to a higher short-circuit current, higher fill factor, and hence higher power conversion efficiency in these devices. Blending PGREEN with $PC_{70}BM$

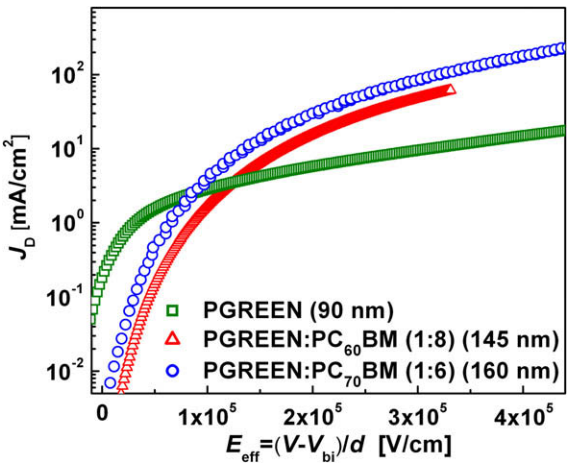

Fig. 3. The current densities for hole-only devices (ITO/PEDOT/Active Layer/Pd) of PGREEN, PGREEN:$PC_{60}BM$ and PGREEN:$PC_{70}BM$ as a function of the effective electric field.

leads to further enhancement of hole mobility of $9 \times 10^{-5}\,cm^2\,V^{-1}\,s^{-1}$. $PC_{70}BM$ also gives rise to enhanced light absorption in the visible window (480–550 nm) which fills the transmission window of the PGREEN polymer. The improved absorption and enhanced hole mobility of the PGREEN/$PC_{70}BM$ polymer blend, along with the enhanced hole extraction attributed to the MoO_3 interlayer, results in a 69% overall improvement in the OPV power conversion efficiency relative to the standard device which employs PEDOT/PSS with $PC_{60}BM$.

In conclusion, we have demonstrated a 69% improvement in the performance of PGREEN PV device using the electron acceptor $PC_{70}BM$ along with MoO_3 interface layer. The enhanced device performance is attributed to the combined effect of improved light absorption, enhanced charge transport in the active layer and efficient charge collection at the interface layer. While a significant enhancement of open-circuit voltage was observed in the bis-$PC_{60}BM$ cells, the overall power conversion efficiency decreases due to substantial decrease in short-circuit current and fill factor.

violet (UV) curing of the gate dielectric will result in hysteresis-free OTFTs [18].

In this study, thermal cross-linking of the reactive –OH groups with an organosilane, p-tolyltrimethoxysilane (TTMS), is used to eliminate the presence of –OH groups; the TTMS serves as the thermal cross-linking agent. Our earlier studies showed that a thermally cross-linked PVP film was unable to serve as the dielectric because it was not chemically compatible when the subsequently deposited materials used to form the other OTFT device layers. UV cross-linked PVP-*co*-PMMA combined with a thermally cross-linked polysiloxane top layer and gold electrodes along with regioregular polythiophene used as the semiconductor has been reported to increase the on/off ratio by about two orders of magnitude [19].

In this work, the thermal cross-linking of a single layer of PVP-*co*-PMMA by the new agent TTMS is shown to yield a dielectric film that results in a significantly higher on/off ratio, i.e., on the order of 10^6. The material systems studied include bis(triisopropylsilylethynyl) (TIPS), PVP-*co*-PMMA and conductive ink that are chemically and mechanically compatible and are solution processable using traditional graphic arts printing (e.g. screen, gravure, flexography).

2. Experiment – processing

Polyimide film was used as the substrate. The gate was formed from 50 nm thick aluminum deposited by E-beam evaporation. Solutions of the dielectric were prepared with the cross-linking agent TTMS in TTMS/PVP-*co*-PMMA at ratios of 0.1/1, 0.25/1, 0.5/1, 1/1, 1.5/1, and 2/1 by weight; TTMS was added into basic solutions having 20% (wt.%) PVP-*co*-PMMA in 1-methoxy propanol acetate (PMA). The dielectric solution was spin-coated onto the substrate. The coated film was cured at 200 °C for 1 h in a convection oven. Source and drain electrodes were deposited on the cross-linked dielectric film by screen printing using silver (Ag) conductive ink, followed by curing of the Ag electrodes at 100 °C for 15 min in an oven. Finally, 2% (wt.%) TIPS in toluene solution was deposited in the channel between the source/drain (S/D) by drop casting. The channel length and channel width for the OTFT devices were 100 and 5000 μm, respectively.

The electrical characteristics of the OTFTs were measured at room temperature using a Keithley 4200 Semiconductor Characterization System when placed in a dark box purged with nitrogen. Thermogravimetric analysis (TGA) (CAHN TG-131) was used to examine the thermal properties of the solutions having different ratios. Cross-sectional views of the resulting devices and the thickness of the dielectric film were studied with scanning electron microscopy (SEM; JEOL JSM-6320F). X-ray photoelectron spectroscopy (XPS) was performed to investigate the chemical composition of the dielectric surface using a Kratos AXIS-165 with a monochromatic Al Kα (1486.6 eV) X-ray source.

3. Results and discussion

Fig. 1 shows the capacitance of films formed from solutions prepared with different TTMS/PVP-*co*-PMMA ratios.

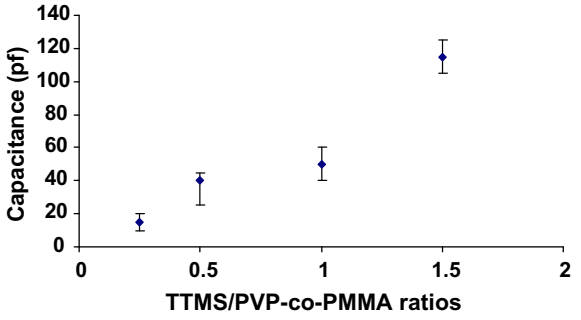

Fig. 1. Capacitance data for the OTFT devices fabricated with different TTMS/PVP-PMMA ratios of 0.25/1, 0.5/1, 1/1, and 1.5/1 by weight.

Increasing TTMS/PVP-*co*-PMMA ratios are shown to yield films with increasing capacitance. This is indicative of decreasing film thickness, because thinner films are made with lower viscosity solutions; thinner films are achieved when more TTMS is added, while keeping the spin coating conditions constant. However, there are two notable exceptions. In the cases of the TTMS/PVP-*co*-PMMA ratio being of 0.0/1 and 0.1/1, the leakage current between the gate electrode and the S/D electrodes was excessive and, therefore, no capacitance data was obtained. The leakage current of the noncross-linked PVP-*co*-PMMA film is apparently the result of dielectric film dissolution by the metal ink solvent used for fabrication of the S/D electrodes. It appears that the dielectric film underneath the electrodes was chemically modified by the solvent in the metal ink used for the printed source and drain which subsequently resulted in shorting to the gate electrode (Fig. 2a). Indeed, when assessing the OTFT device fabricated with a noncross-linked film, no dielectric layer was observed; the entire dielectric film was apparently dissolved as shown in Fig. 2a. The SEM image of the cross-section of the device with TTMS/PVP-*co*-PMMA ratio of 0.1/1 shows the source and drain penetrating the dielectric film at several locations (Fig. 2b) since the amount of TTMS is not sufficient to obtain optimal cross-linking of the PVP-*co*-PMMA. In comparison, Fig. 2c shows that the dielectric film resulting from the TTMS/PVP-*co*-PMMA ratio of 1/1 has a uniform thickness. On the other hand, for the film formed from a TTMS/PVP-*co*-PMMA ratio of 2/1, excess TTMS appears to have created pinholes as it evaporated during the thermal cross-linking process in the oven. The printed S/D electrodes are found to short with the gate electrode through those pinholes and therefore no capacitance values were recorded.

Fig. 3 shows the transfer characteristics of OTFTs with dielectric cross-linked films and different TTMS/PVP-*co*-PMMA ratios. Gate voltage sweeps were performed from +20 to −60 V at a bias voltage of −40 V. The field-effect mobility (μ) can be calculated from the transfer curve in the saturated regime, and it was calculated to be between 0.002 and 0.003 cm^2/V s. The threshold voltage is found to be between the range of 0 and 10 V; the highest threshold voltage of ~10 V was obtained with the device made by using the 1.5/1 TTMS/PVP-*co*-PMMA ratio. This device also had the lowest on-current, e.g., below 10^{-7}, compared to those of the other transistors made with TTMS/PVP-*co*-

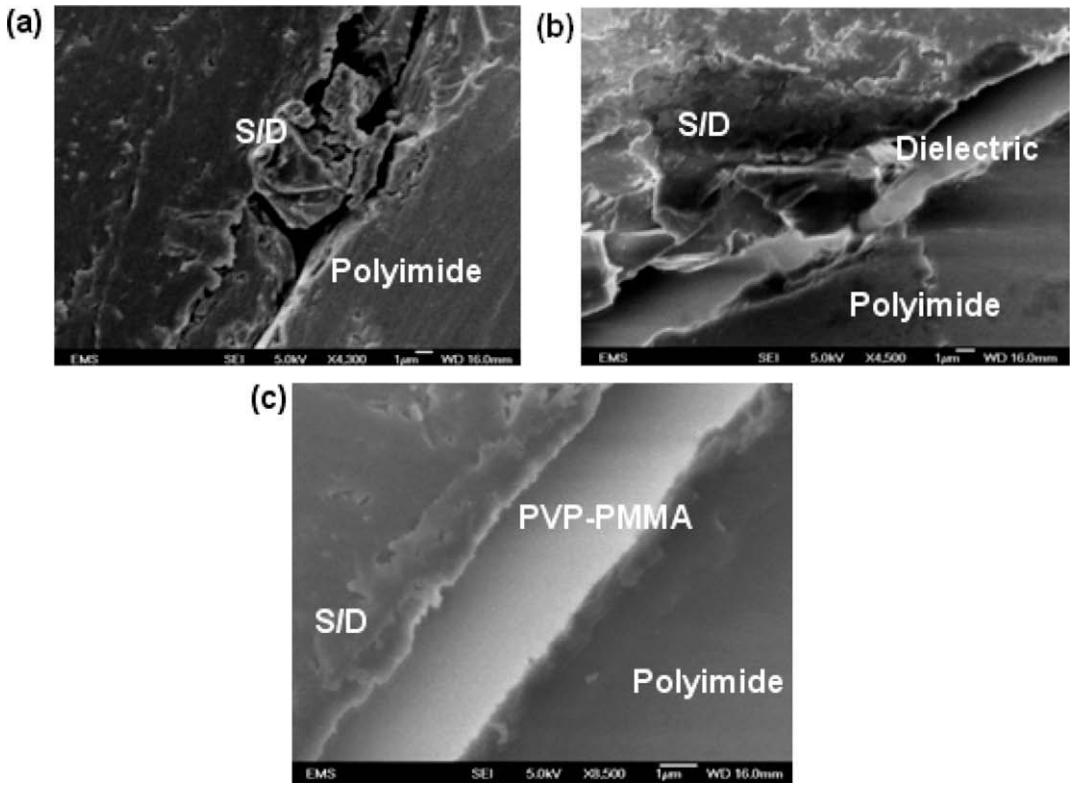

Fig. 2. SEM images of cross-sections of OTFT devices with dielectric layers formed using different ratios: (a) TTMS/PVP-*co*-PMMA: 0/1, i.e., uncross-linked dielectric film; (b) TTMS/PVP-*co*-PMMA: 0.1/1; (c) TTMS/PVP-*co*-PMMA: 1/1.

PMMA ratios of 0.25/1, 0.5/1, and 1.0/1. Also, the surface morphology of the dielectric with TTMS/PVP-*co*-PMMA ratio of 1.5/1 appeared to have greater roughness than those of the others which could be attributed to greater evaporation of TTMS during the device fabrication (Fig. 4). The coarser surface may provide increased nucleation sites for the semiconductor crystal which results in more grain boundaries in the film. Several studies have concluded that device performance deteriorates when organic semiconductors have high populations of grain boundaries [20–25].

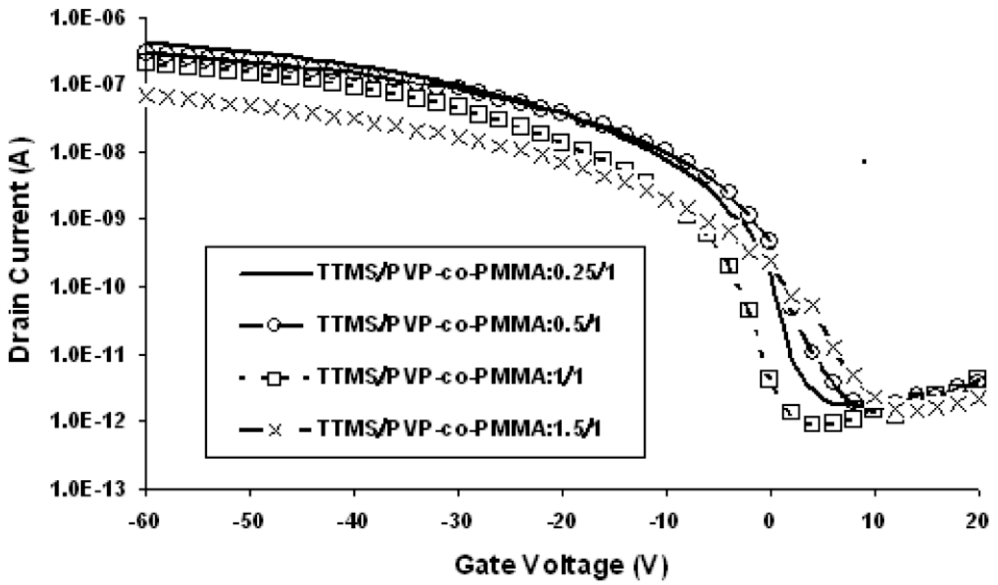

Fig. 3. Transfer curves for the OTFTs with the dielectric film cross-linked with TTMS at different ratios of TTMS/PVP-*co*-PMMA from 0.25/1 to 1.5/1.

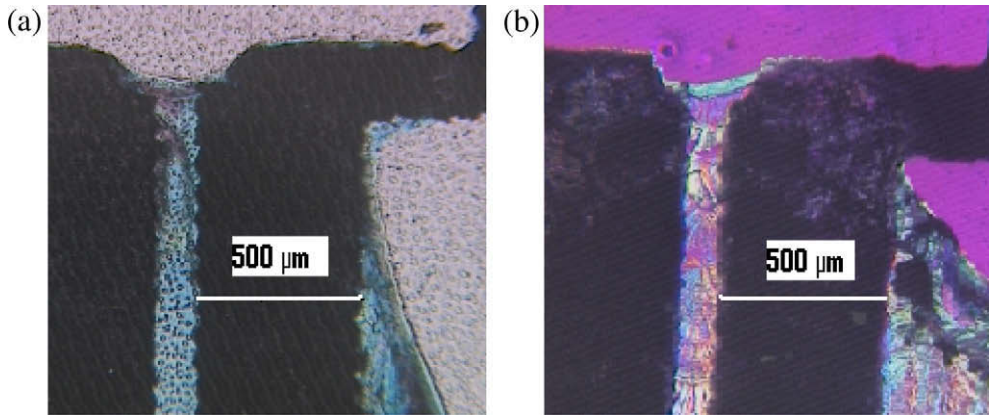

Fig. 4. Optical images of the top view of a bottom contact OTFT, *S* and *D* width is 500 μm, channel length is 100 μm, (a) dielectric with the TTMS/PVP-*co*-PMMA ratio of 1.5/1; (b) dielectric with the TTMS/PVP-*co*-PMMA ratio of 0.5/1.

TGA analyses of pure PVP-*co*-PMMA and TTMS show that the decomposition point for PVP-*co*-PMMA is above 300 °C, while TTMS evaporates at about 200 °C (Fig. 5a and b). Therefore, during thermal cross-linking at 200 °C, noncross-linked PVP-*co*-PMMA would remain in the film while the excess TTMS would begin to evaporate. Moreover, TGA studies for dielectric films with different TTMS/PVP-*co*-PMMA ratios indicate that the mass of the dielectric remains constant during thermal cross-linking at 200 °C (Fig. 5c). Thus, our TGA results shown in Fig. 5 suggest that higher amounts of TTMS should be added into the dielectric solution in order to assure optimal cross-linking

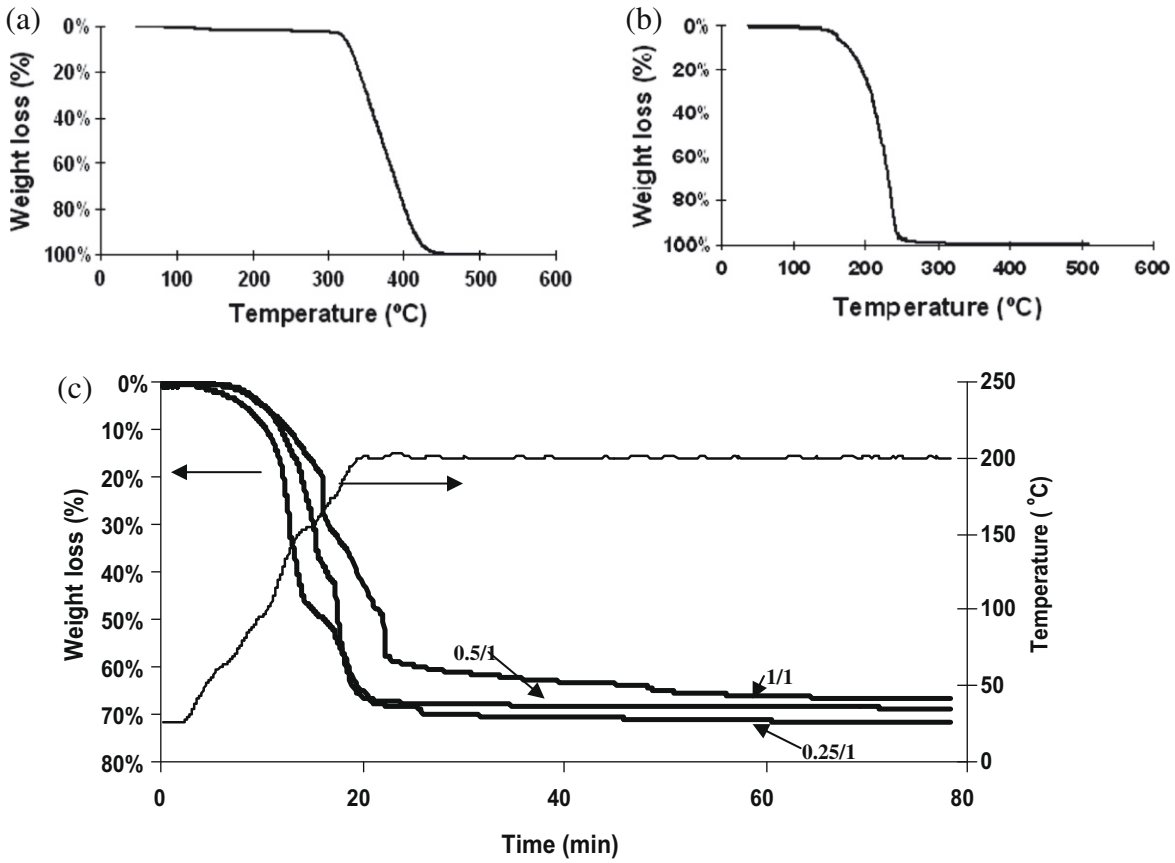

Fig. 5. TGA analyses for (a) pure PVP-*co*-PMMA; (b) pure TTMS; (c) dielectric solutions with TTMS/PVP-*co*-PMMA ratios of 0.25/1, 0.5/1, and 1/1, respectively, in (a) and (b), weight loss is recorded by increasing temperature to 500 °C, in (c), weight loss is recorded by increasing temperature to 200 °C first, then temperature is kept at 200 °C for 1 h.

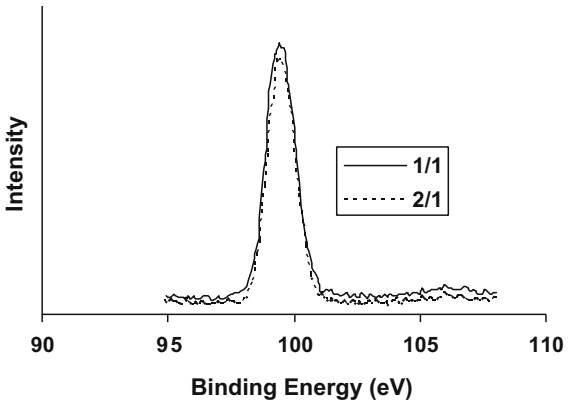

Fig. 6. XPS characterization for Si 2p of the dielectric with the TTMS/PVP-*co*-PMMA ratios of 1/1 and 2/1, respectively.

of the resulting dielectric film. The rough surface of the dielectric film formed with TTMS/PVP-*co*-PMMA ratio of 1.5/1 (Fig. 4a) indicates that higher roughness of the dielectric surface is caused by greater TTMS evaporation. Therefore, the proposed optimal TTMS/PVP-*co*-PMMA ratio window for these systems is 0.25/1–1.0/1.

XPS characterization was used to provide chemical information for the surface of the dielectric films. Data in Fig. 6 includes Si 2p XPS spectra that suggest dielectric films with TTMS/PVP-*co*-PMMA ratio of 1/1 have similar chemical composition to that with a ratio of 2/1, at least within the 6–8 nm from the surface that can be probed with XPS, although the latter samples have twice as much TTMS in the solutions used and the silicon peak contribution is only provided by TTMS. Therefore, the similar chemical composition of TTMS/PVP-*co*-PMMA samples manifested at two distinctly different ratios of TTMS and PVP-*co*-PMMA suggests that there is an optimal ratio for the reaction between TTMS and PVP-*co*-PMMA, while excess TTMS is removed via evaporation.

4. Summary – conclusions

In order to eliminate –OH groups in the final processed dielectric film, thermal cross-linking of PVP-*co*-PMMA is proposed. It was demonstrated that PVP-*co*-PMMA could be thermally cross-linked with a new cross-linking agent, TTMS, and that the OTFT field-effect mobility was similar to that of OTFTs fabricated with UV cross-linked PVP-*co*-PMMA. The optimal TTMS/PVP-*co*-PMMA ratio was found to be in the range of 0.25/1–1.0/1. Moreover, the thermally cross-linked dielectric film was chemically and mechanically compatible with the metal ink formulation used to fabricate the screen printed source and drain. The results of this study demonstrate that OTFTs can be fabricated using all-solution processed materials on a flexible polymeric substrate with sufficient electrical performance for a variety of applications e.g., displays, sensors, and memories.

methods since the solvent can damage the organic semiconductor [16].

In this work, we introduce an external pressure sensible organic thin film transistor (OTFT) by soft-contact lamination. After forming two bottom electrodes and one roof electrode separately on the bridge-structured PDMS mold by thermal deposition of gold (Au), two bottom electrodes of the mold were used as source and drain electrodes in OTFT structure via soft-contact lamination. Then, the roof electrode between source and drain electrodes could play a role to control the effective channel length of OTFT through the PDMS deformation by the external pressure. Since the device performance was similar to the piezoelectric effect, the output current could be controlled through the pressure applied to the device.

2. Experimental

2.1. Overall device structure

The overall structure of the laminated OTFT is shown in Fig. 1. Pentacene was used as an organic semi-conducting layer, and a PDMS mold was replicated from a silicon master mold. Au electrodes were then deposited onto the PDMS mold by thermal evaporation through a shadow mask. Subsequently, the PDMS mold containing the Au electrodes was laminated on the substrate, which was composed of the gate electrode, dielectrics, and pentacene as shown in Fig. 1(a).

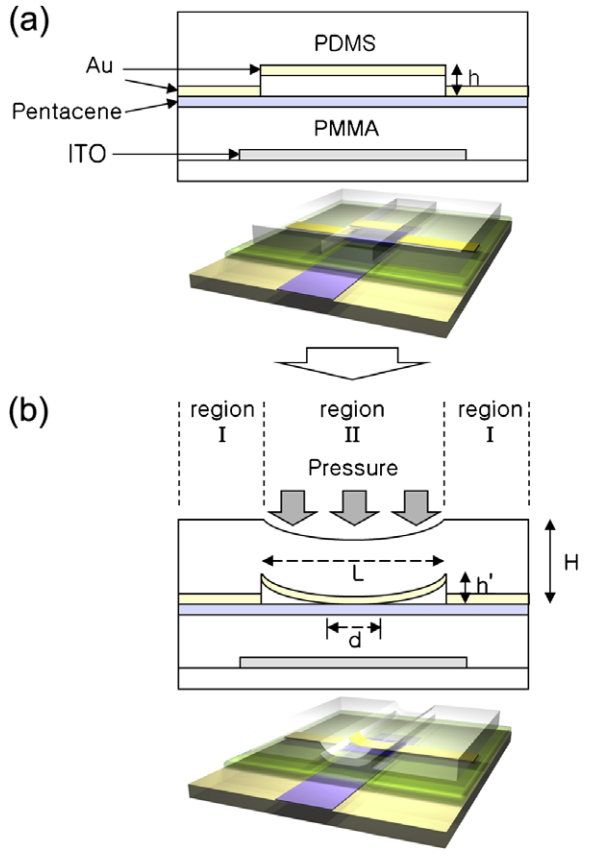

Fig. 1. Schematic illustrations of the soft-contact laminated OTFTs (a) without the external load and (b) with the external load. Under the external load, the area over which the pressure was applied was divided into two regions (region I and region II).

2.2. Preparation of Au electrode on the PDMS mold

Silicon master mold with a long protruding line, which was 35 μm high and 1 mm wide, was prepared. Polydimethylsiloxane (PDMS) (Sylgard 184, Dow Corning) prepolymer and its curing agent were mixed at a weight ratio of 10:1. The PDMS mixture was then poured onto the silicon master mold and thermally cured at 60 °C in a vacuum oven for 2 h. After thermal curing, the cured PDMS mold was peeled off from the master mold, and a shadow mask with a 1 mm wide line was aligned perpendicularly to the channel of the PDMS mold. An Au electrode (70 nm) was thermally evaporated onto the sample at the speed of 15–20 Å/s.

2.3. Preparation of the substrate

Transparent ITO coated glass was successively cleaned by sonication in acetone and isopropyl alcohol. An ITO film was then patterned by photography and a wet etching process. Onto ITO patterned glass, 10 wt.% of poly(methylmethacrylate) (PMMA) in toluene was spin-coated at a speed of 3000 rpm for 30 s. The PMMA-coated sample was moved to a hot plate and annealed at 100 °C for an hour on a hot stage. A pentacene film (100 nm) was then deposited onto the PMMA-coated substrate at a speed of 0.5–1 Å/s by thermal evaporation. All the processes, except for the thermal evaporation of pentacene, were done in an air environment.

2.4. Performance measurement

Pressure was applied onto the OTFT by a push–pull gauge with a rectangular tip (1 × 1 cm). Electric sources from a semiconductor parameter analyzer were connected to the ITO electrode and Au electrodes on the OTFT with probe tips. The characteristic curves of the devices were measured by a semiconductor parameter analyzer (Keithely Instruments Inc., 4200-SCS), and the capacitances of dielectrics were measured using an LCR meter (Agilent 4980A).

3. Results and discussion

Typical OTFT characteristics were observed after laminating the Au-deposited PDMS mold onto the pentacene-deposited substrate. If gate bias was not applied, no output current could be observed between the source–drain electrodes because the Au line on the PDMS mold was disconnected by anisotropic metal evaporation as shown in Fig. 1(a). Due to the low Young modulus and the elastic properties of PDMS, the roof of the PDMS mold was deformed by the external load when pressure was applied on the PDMS mold. If the external load on the PDMS mold was high enough, the Au line on the deformed roof of the PDMS mold reached the pentacene inside the channel.

The contact length, d, increased as the external pressure on the PDMS increased, and the output current also increased as the contact length increased. Contact between the Au line and the pentacene layer due to the external force contributed to the increase in the output current through the channel because of the conducting properties of Au. Consequently, it could be expected that this contact between the Au line and the pentacene layer reduced the active section of pentacene, from which electrons were transferred through. Electrons were transported more efficiently through the Au than the pentacene layer because of the relatively less electric resistance of Au. In other words, the actual channel length of pressed OTFT became $L - d$ because the potential difference between both the ends of the contacted Au line is negligible compared with the potential drop along the channel.

To investigate this contact effect more clearly, an additional experiment was performed. An Au line that was 1 mm in width was deposited on a flat PDMS substrate through a shadow mask. Then, to insert the Au line between the source–drain electrodes of OTFT, it was laminated on the complete OTFT structure which had a channel length of 2 mm. No external pressure was applied after the insertion of the Au line inside the channel. In this case, since the conformal contact between the OTFT and the PDMS substrate could be achieved without any external pressure via soft-contact lamination method, the actual channel length of 1 mm and the 2-fold of output current compared to the OTFT with the channel length of 2 mm were expected. Consequently, the output current of the device with the inserted Au line was increased by 90% compared to that with the 2 mm channel length, and it showed that the metal line when in contact with the pentacene layer was charged with an electric current. This result clearly demonstrated that electrons moved through the contacted Au electrode on the semi-conducting layer when the laminated device was pressed.

Fig. 2 shows the field-effect transistor characteristics of the laminated OTFT under various external pressures. As shown in Fig. 2(a) and (b), the gate voltage was scanned from +20 V to −120 V with −1 V step at a fixed source–drain voltage of −120 V. When the external pressures of 0, 0.2, 0.4, and 0.6 N/mm^2 were applied to the laminated OTFT device, the values of the on-current were 5.1, 10.3, 25.1, and 56.2 μA, whereas the values of the off-current were 1.5, 1.7, 0.9, and 0.6 nA, respectively. Besides the on- and off-currents, the values of the threshold voltage were 20.2, 20.1, 22.1, and 25.4 V, respectively. Fig. 2(c) and (d) also shows the drain current versus source–drain voltage at a fixed gate voltage at external pressures of 0 and 0.6 N/mm^2, respectively. Most notable was the increase in the on-current of OTFT as the external pressure was increased, while significant changes were not observed in the off-current and the threshold voltage. In the same manner, the values of the on/off ratio also increased as the external pressure was increased.

In OTFTs, if contact resistance is negligible, the drain current can be typically expressed as

$$I_D = \frac{WC_i}{2L}\mu_e(V_G - V_T)^2 \quad (1)$$

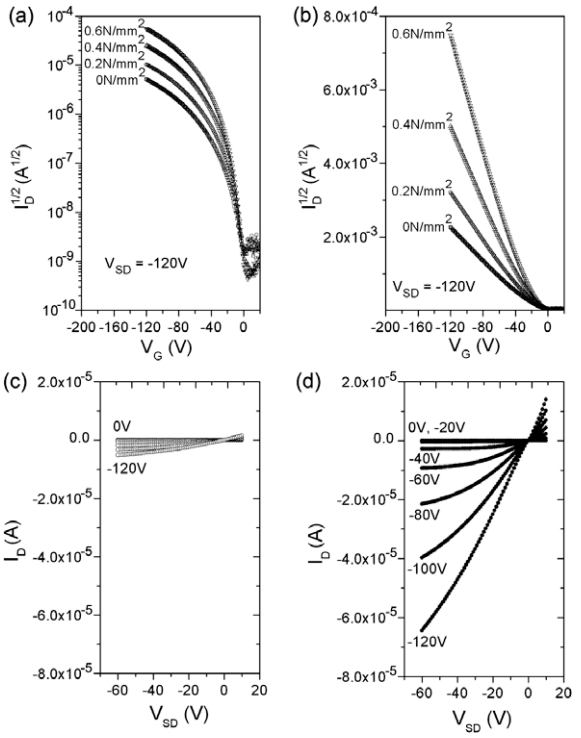

Fig. 2. Characteristics of the laminated OTFT under various external loads (from 0 to 0.6 N/mm^2). Transfer characteristics of the device at a fixed source–drain voltage of −120 V (a) in log scale and (b) in square-root scale. Output characteristics of the device with the external pressures of (c) 0 N/mm^2 and (d) 0.6 N/mm^2, respectively.

where I_D is the drain current, W and L are the channel width and length, respectively, μ_e is the effective mobility, C_i is the capacitance per unit area, V_G is the gate voltage, and V_T is the threshold voltage. In this work, OTFT characteristics were obtained from the same device, and the plot of total resistance of the device versus channel length which is measured by a microscope is nearly linear. It is known that the channel resistance is more dominant than the contact resistance when the channel length is over 10 μm [17], and the contact resistance of OTFT with the soft-contact laminated electrodes is more than an order of magnitude smaller than that with the evaporated Au electrodes [13]. In this experiment, contact resistance exists when holes move from pentacene to Au and from Au to pentacene across the interface between pentacene and Au. However, the channel lengths measured by microscope were much longer than 10 μm and the plot of total resistance of the device versus channel length which is measured by a microscope is nearly linear. Therefore, the constant charge carrier mobility of pentacene could be expected regardless of the external pressure, and it is assumed that the contact resistance between the pentacene and the Au layer containing the channel is negligible. Based on the assumption that the charge carrier mobility of pentacene does not change in the saturated region when the device is pressed, the effective channel length, L_{eff}, can be calculated from the experimental values of I_D and V_G. Without any external pressure, this OTFT device pro-

vided a charge carrier mobility of 0.27 $cm^2 V^{-1} s^{-1}$ as calculated through Eq. (1), because the values of L, W, and C_i of the device were 0.1 cm, 0.1 cm, and 3.8 nF cm^{-2}, respectively. The values of L_{eff} under the external pressures of 0.2, 0.4, and 0.6 N/mm^2 can be calculated using this constant charge carrier mobility and the experimental characteristics as shown in Fig. 3. The values of L_{eff} were determined to be 495, 127, and 82 μm under the external pressures of 0.2, 0.4, and 0.6 N/mm^2, respectively. Therefore, the theoretical values of the contact length between the Au line and the pentacene layer under the external pressures of 0.2, 0.4, and 0.6 N were 505, 803, and 918 μm, respectively.

While the laminated devices were pressed with an external pressure, the area over which the external pressure was applied can be divided into two regions (region I and region II), as shown in Fig. 1. During the application of an external pressure, the height of the posts, which support the roof of PDMS mold, h, was compressed to a height, h', in region I, and the roof of the PDMS mold was bent in region II using a uniform external force. Assuming that deformations in region I and region II are independent and there was no lateral expansion of the PDMS when the PDMS mold was exposed to the external pressure, a simple model describing the contact length can be considered. If it is assumed that the compression in region I and the bending in region II occur independently, the value of h' in region I can be easily calculated. A stable silicone rubber has a unique flexibility ($G \sim 1$ MPa = 1 N/mm^2) at room temperature. For simple extension and uni-axial compression, the rubber-elastic stress–strain relation can be expressed as follows [18]:

$$F_{ce} = A_R G\left(\delta - \frac{1}{\delta^2}\right) \tag{2}$$

where F_{ce} is the applied compressive or extensive force, A_R is the area of the rubber on which the force is applied, and δ is the rubber's extension ratio $\left(\delta = 1 + \frac{h-h'}{h}\right)$. Considering that $P = F_{ce}/A_R$, Eq. (2) can be rearranged as follows:

$$G\delta^3 - P\delta^2 - G = 0 \tag{3}$$

and the values of δ, which vary according to the external pressure, can be calculated by Eq. (3). By using these calculated values of δ, the values of h' can also be obtained.

As shown in Fig. 1, the bending of the PDMS bridge, which was supported by the compressed posts, occurred in region I. If it is assumed that the compression of PDMS is negligible in region II, a simply supported beam model with a uniform load [19] can be applied to region II. The moment of inertia can be set as $I = \frac{zy_1^3}{12}$ and

$$y(x) = -\frac{u}{24EI}\left(x^4 - 2Lx^3 + L^3x\right) \tag{4}$$

where u is the uniform load on the bridge, z is the width of the bridge and E is Young's modulus of PDMS. Considering that $u = P \cdot z$ and $y_1 = H - h$, Eq. (4) can be simplified to $y(x) = -\frac{P}{2E(H-h)^3}(x^4 - 2Lx^3 + L^3x)$. To calculate the value of x_1 such as $y(x_1) + h' = 0$, Eq. (4) can be also simplified as follows:

$$2h - h\delta - \frac{P}{2E(H-h)^3}\left(x^4 - 2Lx^3 + L^3x\right) = 0 \tag{5}$$

The contact length can be defined as the distance between x_1 and x_2, which intersects the pentacene layer as illustrated in Fig. 3(a). By considering the symmetric deformation of the PDMS roof, the contact length, d, becomes $L - 2 \cdot x_1$. Therefore, the value of the contact length, d, which varies according to the external pressure, can be obtained using Eqs. (3) and (5).

In this study, the experimental values of h, L, H, G, and P were 0.035 mm, 1 mm, 1 mm, 0.7 MPa, and 0.7 MPa, respectively. From these values, the contact length, d, versus the external pressure can be plotted as shown in Fig. 3(b). At an external pressure of 0.14 N/mm^2, the roof of the PDMS mold was initially brought into contact with the pentacene layer, and the contact length was then increased dramatically up to an external pressure of 0.3 N/mm^2. If the external pressure exceeded this range, the increasing rate of the contact length versus the external pressure decreased. The contact lengths measured by the inverted microscope (open circle), and calculated from the output current data using Eq. (1) (solid symbol) are shown in Fig. 3(b). The graph calculated from Eqs. (3) and (5) (solid line) was also compared to the data obtained from the experiments.

The external pressure sensing on a real time scale is shown Fig. 4. Each point was scanned at the stated intervals of 1 s, and various external pressures, which depended on time, were applied to the laminated OTFT. Due to the elastic property of the PDMS, the laminated OTFT returned to its initial shape after the external pressure was released.

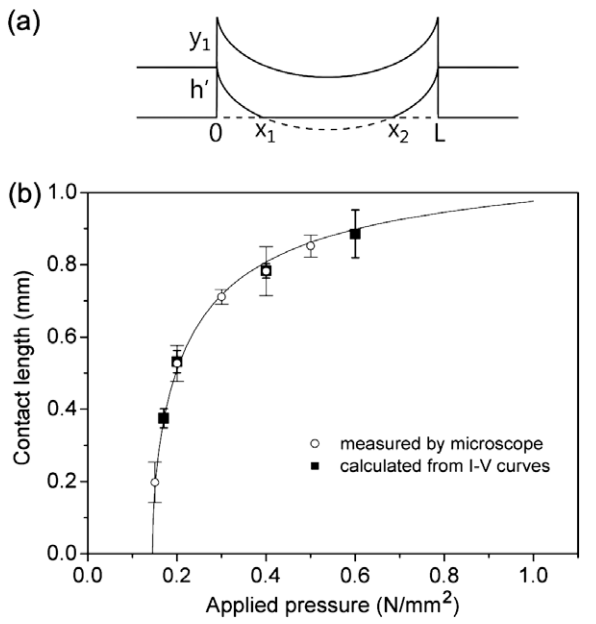

Fig. 3. (a) Schematic illustration of the contact length, which was defined as the distance between x_1 and x_2 and intersects the pentacene layer. (b) Three different types of PDMS deformation, which were the inverse operated values obtained from the output data using Eq. (1) (solid symbol), the calculated values by simple modeling from Eqs. (3) and (5) (solid line) and the experimentally measured values from the microscope (open circle). The sizes of error bars are ±5% for both solid symbols and the open circles.

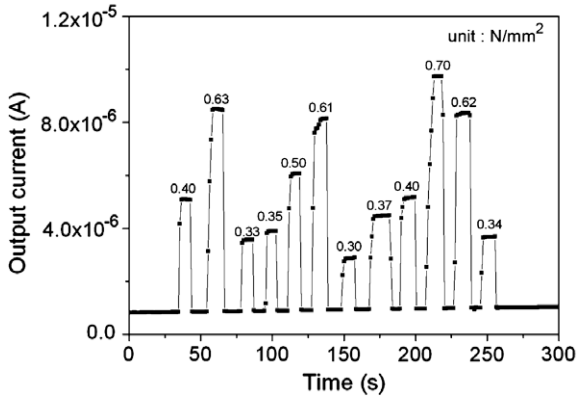

Fig. 4. Sensing of the external load on a real time scale. Source–drain voltage and gate voltage were −40 V and −50 V, respectively. The numbers in the figure means pressure applied onto the device and the output currents of the device under 0.4 N/mm^2 at different times were almost same.

The current output increased when an external pressure was applied, and the current was in proportion with the magnitude of the external pressure. Furthermore, the output currents of the device, which was exposed to the same external pressure of 0.4 N/mm^2 at different times, were almost same as shown in Fig. 4. The first and the second output currents were 5.10 and 5.16 μA, respectively. When the pressures are 0.33, 0.35, and 0.34 N/mm^2, output currents were 3.56, 3.89, and 3.68 μA, respectively. Therefore, these results suggest that the output current, which depends on the magnitude of the external pressure, and the laminated OTFT also have reversibility that restores the output current to the non-contact condition after the external pressure was released. Although the sensitivity of the device was low, it can be improved by controlling the thickness of the laminating mold or the Young modulus of the mold. A further study would be required to enhance the pressure sensitivity.

4. Conclusions

In conclusion, a pressure dependent output current-controllable OTFT was fabricated by soft-contact lamination. Soft-contact lamination provided OTFT with a new functionality, and the source–drain currents were controllable by changing the contact area of the electrodes on the semi-conducting layer, which corresponded to the external pressures applied to the device, without changing any of the semi-conducting material properties. As the external pressure on the device was varied from 0 to 0.6 N/mm^2, the source–drain current increased by 11-fold, from 5.1 to 56.1 μA, whereas the off-current and threshold voltage were almost fixed. Comparing the contact lengths calculated by three different methods, which were (a) the inverse operation from the output current data using Eq. (1), (b) the simple beam modeling using Eqs. (3) and (5), and (c) the experimental measurement by the microscope, the results obtained were very similar to each other. Reversible and time-durable operations of the device could also be achieved. Consequently, a new functionality was added to OTFTs via soft-contact lamination due to the elastic properties of the PDMS molds. Furthermore, these pressure dependent devices, which have an OTFT structure, hold a great promise for their use in fabricating novel piezoelectric-like devices or in various applications such as touch screens and flexible devices in the display field.

they have received particular attention as in the context of bulk-heterojunction solar cells. For example, Morin and co-workers described the synthesis of a variety of new poly(2,7-carbazoles) [14]. In a later effort, the first photovoltaic device derived from poly(*N*-alkyl-2,7-carbazole), which has a power conversion efficiency (PCE) of 0.6%, was described by Müllen and co-workers [15].

In recent years, considerable interest has grown in the area of low-band gap polymers owing to their applications in organic solar cell devices as an active layer for light absorption and charge generation [16–18]. High power conversion efficiencies (PCEs) are key goal for solar applications since these values determine how much electrical energy is produced by absorbed photons. One strategy to improve PCE is to employ well designed and readily synthesized low-band gap polymers, which have improved overlap of the polymer absorption spectrum with the standard solar spectrum under AM 1.5G. One successful approach that has been used to design these polymers takes advantage of vinylene linkages in π-conjugated systems. Based on this design principal, a number of polymers have been prepared which, in comparison to conventional π-conjugated polymers, have low the band gaps in the range of 0.3–0.5 eV [19]. Another advantage arising from the introduction of vinylene units is that it serves as a good method to create planar molecules with extended π-conjugation lengths. This is a consequence of the relatively small dihedral angle that exists between vinylene and aryl groups that leads to an increase in the absorption maxima of the material [20]. Finally, different monomer units can be easily introduced into the polymer in order to fine tune electronic properties.

We have previously described the preparation of novel vinylene based, π-conjugated polymers, including the alkyloxyphenoxy and 1,3,4-oxadiazole-substituted PPVs, poly(9,9-dioctylfluorenyl-2,7-vinylene) (PFV), PFV-*co*-MEH-PPV, highly luminescent poly(*m*-SiPh-PV) derivatives, highly branched poly(PDOT-PV), poly(PDOT-PV-*co*-*m*-SiPh-PV), poly($3OC_1OC_{10}$-PV), and poly($3OC_1O$-C_{10}-PV-*co*-*m*-SiPh-PV) [21–27].

In this effort, repeating vinylene units were introduced between the 2- and 7-positions of the carbazole main chain by using the Gilch polymerization procedure [28]. The substances prepared in this effort include poly(*N*-(3,4-bis(decyloxy)phenyl)carbazolyl-2,7-vinylene) (PCzV) and its copolymer with MEH-PPV segment, poly[*N*-(3,4-bis(decyloxy)phenyl)carbazolyl-2,7-vinylene)-*co*-{2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene}] [PCzV-*co*-MEH-PPV]. These polymers possess many attractive properties, such as high molecular weights, low polydispersities and ready purification. To enhance the solubilities and electronic properties of the derived poly(carbazolyl-2,7-vinylene), a meta and para bis-decyloxyphenyl groups were incorporated on the carbazole nitrogen atoms. The addition of vinylene units along the 2,7-carbazole backbone is expected to tune the highest occupied molecular orbital (HOMO) level of π-conjugated polymers as well as improve the electro-optical properties. The preparation of these polymers along with an analysis of their thermal, optical, electrochemical, and photovoltaic properties are described below.

2. Experimental

2.1. General information

^{1}H NMR spectra were recorded on a Varian Mercury Plus 300 MHz spectrometer and the chemical shifts were recorded in ppm units with chloroform as the internal standard. UV–visible and the emission spectra were recorded with a JASCO V-570 and Hitachi F-4500 fluorescence spectrophotometers. Measurements of solid state emissions were carried out by supporting each film on a quartz substrate, which was mounted to receive front-face excitation at an angle of less than 45°. Each polymer film was excited with several portions of the visible light from a xenon lamp. The molecular weight and polydispersity of the polymer were determined by using gel permeation chromatography (GPC) using a PLgel 5 μm MIXED-C column on an Agilent 1100 series liquid chromatography system with THF as an eluent and calibration with polystyrene standards. Thermal analyses were carried out on a Mettler Toledo TGA/SDTA 851, DSC 822 analyzer under N_2 atmosphere at a heating rate of 10 °C/min. Cyclic voltammetry (CV) was carried out in a 0.1 M solution of tetrabutylammonium hexafluorophosphate ($TBPAPF_6$) in benzene:acetonitrile (1.5:1 v/v) [29] using a CHI600C voltammetric analyzer at a potential scan rate of 100 mV/s. Each polymer film was applied to a Pt disc electrode (0.2 cm^2) by dipping the electrode into the polymer solution. A platinum wire was used as the counter electrode, and $Ag/AgNO_3$ electrode was used as the reference electrode.

2.2. Materials

Sodium nitrite, copper cyanide, potassium cyanide, catechol, iodine, iodic acid, copper powder, RED-Al, methanesulfonyl chloride, triethylamine, potassium *tert*-butoxide, 4-*tert*-butylbenzyl bromide, tetrahydrofuran (THF), and *N*,*N*-dimethylacetamide were purchased from Aldrich Co. and used without further purification unless otherwise noted. Solvents were dried and purified by fractional distillation over sodium/benzophenone and handled in a moisture-free atmosphere. Column chromatography was performed using silica gel (Merck, 250–430 mesh).

2.3. Synthesis of 2,7-dicyanocarbazole (**4**)

To a solution of 2,7-diaminocarbazole (**3**) (2 g, 10 mmol) and hydrochloric acid (10 mL) in distilled water (100 mL) was added dropwise an aqueous solution of sodium nitrite (1.66 g, 24 mmol). The resulting solution was stirred for 2 h at 0 °C. Aqueous sodium carbonate was added at 0 °C to bring the pH to 7 (solution A). To a solution of copper cyanide (3.63 g, 40.56 mmol) in distilled water was added a solution of potassium cyanide (2.64 g, 40.56 mmol) in distilled water at room temperature (solution B). To this mixture in an ice bath was added solution A at 0 °C. After being stirred overnight at room temperature, the formed precipitate was removed by filtration. The precipitate was washed with distilled water before being

repeatedly triturated with acetone. The triturate was concentrated in vacuo to give a solid which was dissolved in ethyl acetate. Filtration followed by concentration of the filtrate gave a crystalline solid which was recrystallized from ethanol to give 0.54 g. Yield: 25%, ^{1}H NMR (acetone-d_6, δ ppm): 11.3 (br, 1H), 8.46–8.43 (d, 2H, aromatic protons), 8.06 (s, 2H, aromatic protons), 7.62–7.59 (d, 2H, aromatic protons). ^{13}C NMR (acetone-d_6, δ ppm): 141.01, 126.10, 123.48, 123.16, 120.16, 116.85, 110.75.

2.4. Synthesis of 1,2-bis(decyloxy)benzene (**5**)

To a solution of catechol (15 g, 135 mmol) in 1-bromodecane (83.7 mL, 404.7 mmol) and DMF (150 mL) was added potassium carbonate (74.58 g, 539.6 mmol). The mixture was stirred at 60 °C for 24 h. and concentrated in vacuo to give a residue which was subjected to flash chromatography on silica gel using ethyl acetate:hexane (1:10) as an eluent. This yielded 50.6 g (96%) of **5**. ^{1}H NMR ($CDCl_3$, δ ppm): 6.92 (s, 4H, aromatic protons), 4.05 (t, 4H, α-protons of decyloxy position), 1.93–1.78 (m, 4H, β-protons of decyloxy position), 1.61–1.25 (br, 28H, aliphatic protons), 0.92–0.89 (m, 6H, aliphatic protons). ^{13}C NMR ($CDCl_3$, δ ppm): 149.25, 121.02, 113.97, 69.21, 32.07, 29.68, 29.47, 26.20, 22.84, 14.24.

2.5. Synthesis of 1,2-bis(decyloxy)-4-iodobenzene (**6**)

To a solution of 1,2-bis(decyloxy)benzene (**5**) (20 g, 52 mmol) in acetic acid (600 mL) was added water (200 mL) at 40 °C. Sulfuric acid (16 mL) and iodine (6.768 g, 26.67 mmol) were added and the resulting mixture was stirred at 44 °C. Iodic acid (1 g, 5.68 mmol) was added three times during a 40 min period. After cooling, the mixture was extracted with diethyl ether, washed with aqueous sodium carbonate and saturated brine, dried over anhydrous $MgSO_4$ and concentrated in vacuo to give a the crystalline residue which was recrystallized from ethanol to yield 18.65 g (71%) of **6**. ^{1}H NMR ($CDCl_3$, δ ppm): 7.20–7.12 (s, 2H, aromatic protons), 6.64–6.60 (d, 1H, aromatic protons), 3.97–3.88 (t, 4H, α-protons of decyloxy position), 1.83–1.75 (m, 4H, β-protons of decyloxy position), 1.60–1.27 (br, 28H, aliphatic protons), 0.91–0.86 (m, 6H, aliphatic protons). ^{13}C NMR ($CDCl_3$, δ ppm): 149.80, 129.86, 123.68, 122.54, 115.64, 82.63, 69.45, 32.07, 29.52, 29.17, 26.10, 22.86, 14.31.

2.6. Synthesis of 9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-dicarbonitrile (**7**)

To a solution of 2,7-dicyanocarbazole (**4**) (1 g, 5 mmol) and 1,2-bis(decyloxy)-4-iodobenzene (**6**) (7.13 g, 13.8 mmol) in *N*,*N*-dimethylacetamide (60 mL) was added copper powder (2 g, 31 mmol) and potassium carbonate (2.1 g, 15 mmol) under a N_2 atmosphere. The mixture was stirred at 160 °C for 12 h, diluted with distilled water, and extracted with methylene chloride. The methylene chloride extracts were dried over anhydrous $MgSO_4$ and concentrated in vacuo giving a residue, which was subjected to flash chromatography on silica gel using chloroform as an eluent. This gave 0.56 g (20%) of **7**. ^{1}H NMR ($CDCl_3$, δ ppm): 8.26–8.23 (d, 2H, aromatic protons on carbazole), 7.68 (s, 2H, aromatic protons on carbazole), 7.61–7.58 (d, 2H, aromatic protons on carbazole), 7.13–7.08 (d, 1H, aromatic proton on benzene), 7.02–6.96 (dd, 1H, aromatic proton on benzene), 6.94–6.91(d, 1H, aromatic proton on benzene), 4.16–4.11 (dt, 4H, α-protons of decyloxy position), 1.97–1.80 (m, 4H, β-protons of decyloxy position), 1.57–1.22 (br, 28H, aliphatic protons), 0.92–0.83 (m, 6H, aliphatic protons). ^{13}C NMR ($CDCl_3$, δ ppm): 149.81, 148.05, 141.09, 135.71, 127.53, 122.84, 120.77, 116.91, 116.80, 114.08, 112.82, 105.59, 98.32, 69.48, 32.05, 29.61, 29.30, 26.26, 22.73, 14.30.

2.7. Synthesis of 9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-dicarboxylic acid (**8**)

A mixture of 9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-dicarbonitrile (**7**) (2 g, 3 mmol) in ethanol (50 mL) containing sodium hydroxide (30%, 30 mL) was stirred at 110 °C for 24 h. After hydrochloric acid was added to bring the pH below 7, a portion of the water and ethanol were removed by concentration in vacuo. The resulting mixture was stirred at 120 °C for 3 h, cooled and filtered. The precipitate was dried under reduced pressure to yield 1.99 g (94%) of **8**. ^{1}H NMR (DMSO-d_6, δ ppm): 8.43–8.40 (d, 2H, aromatic protons), 7.91–7.87 (d, 4H, aromatic protons), 7.27–7.21 (t, 2H, aromatic protons), 7.16–7.12 (d, 1H, aromatic proton), 4.12–3.96 (dt, 4H, α-protons of decyloxy position), 1.83–1.65 (m, 4H, β-protons of decyloxy position), 1.52–1.09 (br, 28H, aliphatic protons), 0.91–0.0.81 (q, 6H, aliphatic protons). ^{13}C NMR (DMSO-d_6, δ ppm): 177.60, 162.22, 149.53, 147.48, 141.97, 137.67, 130.18, 121.41, 114.56, 109.57, 108.64, 103.25, 96.12, 71.66, 38.16, 28.33, 25.82, 22.58, 18.64, 13.62.

2.8. Synthesis of (9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-diyl)dimethanol (**9**)

To a solution of 9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-dicarboxylic acid (**8**) (2 g, 3 mmol) in benzene (90 mL) was added sodium bis(2-methoxyethoxy)aluminum hydride (RED-Al) (18.7 mL, 62.2 mmol). The mixture was stirred at 100 °C for 24 h. Ice-water was added after hydrochloric acid was added to make the solution acidic. Extraction with chloroform gave an extract that was dried over anhydrous $MgSO_4$ and concentrated in vacuo to give a residue which was subjected to flash chromatography on silica gel using chloroform:ethyl acetate (9:1) as an eluent. This gave 1.30 g (68%) of **9**. ^{1}H NMR ($CDCl_3$, δ ppm): 8.11–8.09 (d, 2H, aromatic protons on carbazole), 7.34 (s, 2H, aromatic protons on carbazole), 7.29–7.26 (d, 2H, aromatic protons on carbazole), 7.05–7.04 (m, 2H, aromatic protons on benzene), 6.99–6.98 (d, 1H, aromatic proton on benzene), 4.83–4.81 (d, 4H, $-CH_2OH$), 4.13–3.94 (dt, 4H, α-protons of decyloxy position), 1.94–1.77 (m, 4H, β-protons of decyloxy position), 1.58–1.19 (br, 28H, aliphatic protons), 0.92–0.83 (q, 6H, aliphatic protons). ^{13}C NMR ($CDCl_3$, δ ppm): 167.88, 162.92, 161.15, 142.61, 139.19, 124.08, 122.54, 120.06, 119.12, 112.50, 109.43, 94.32, 66.48, 65.18, 32.10, 29.55, 29.04, 26.15, 22.92, 14.33.

2.9. Synthesis of 9-(3,4-bis(decyloxy)phenyl)-2,7-bis(chloromethyl)carbazole (**10**)

To a solution of (9-(3,4-bis(decyloxy)phenyl)carbazole-2,7-diyl)dimethanol (**9**) (1 g, 2 mmol) in methylene chloride (100 mL) was added methanesulfonyl chloride (0.50 mL, 6.48 mmol) and triethylamine (0.90 mL, 6.48 mmol). The resulting mixture was stirred for 48 h at room temperature, diluted with water and extracted with chloroform. The extracts were dried over anhydrous $MgSO_4$ and concentrated in vacuo giving a residue which was subjected to flash chromatography on silica gel using chloroform as an eluent to yield 0.51 g (48%) of **10**. ^{1}H NMR ($CDCl_3$, δ ppm): 8.12–8.09 (d, 2H, aromatic protons on carbazole), 7.387.26–8.09 (m, 4H, aromatic protons on carbazole), 7.11–7.08 (q, 2H, aromatic protons on benzene), 7.0 (s, 1H, aromatic proton on benzene), 4.80–4.67 (s, 4H, CH_2Cl), 4.14–3.97 (dt, 4H, α-protons of decyloxy position), 1.93–1.82 (m, 4H, β-protons of decyloxy position), 1.57–1.19 (br, 28H, aliphatic protons), 0.99–0.86 (q, 6H, aliphatic protons). ^{13}C NMR ($CDCl_3$, δ ppm): 150.11, 149.02, 142.04, 135.71, 129.66, 122.84, 120.85, 120.77, 119.80, 114.08, 112.82, 110.29, 69.49, 47.33, 32.08, 29.63, 29.31, 26.26, 22.86, 14.31.

2.10. Synthesis of poly[N-(3,4-bis(decyloxy)phenyl)-carbazolyl-2,7-vinylene)-co-{2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene}] [PCzV-co-MEH-PPV] (**13**)

A potassium *tert*-butoxide solution (1.84 mL of a 1.0 M solution in THF) was added dropwise by using a syringe pump over a 15 min period to a 0 °C solution of 9-(3,4-bis(decyloxy)phenyl)-2,7-bis(chloromethyl)carbazole (**10**) (100 mg, 0.15 mmol) and 1,4-bis(chloromethyl)-2-(2-ethylhexyloxy)-5-methoxybenzene (**12**) (51 mg, 0.15 mmol) in freshly distilled THF (12 mL) under N_2 atmosphere. The solution was stirred at 0 °C for 50 min and cooled. End capping was performed by the addition of 3–4 drops of 4-*tert*-butylbenzyl bromide followed by stirring for 15 min at room temperature. The solution was poured into methanol and the precipitate was removed by filtration. After carrying out successive Soxhlet extractions, the polymer was obtained by pouring the solution into methanol. The resulting product 13 (49 mg, 38%) was obtained by drying reduced pressure. ^{1}H NMR ($CDCl_3$, δ (ppm): 8.19–6.70 (br, 13H, aromatic and vinylic protons), 4.26–3.29 (br, 9H, α-protons of alkoxy position), 2.03–0.86 (br, 53H, aliphatic protons). Anal. Calcd. for PCzV-*co*-MEH-PPV: C, 78.72; H, 9.32; N, 0.21. Found: C, 75.70; H, 9.13; N, 0.17.

The homopolymer, poly(*N*-(3,4-bis(decyloxy)phenyl)-carbazolyl-2,7-vinylene) (PCzV) was synthesized by using a method that is similar to that used to prepare PCzV-*co*-MEH-PPV.

PCzV: 1H NMR ($CDCl_3$, δ ppm): 8.12–7.94 (br, 2H, aromatic protons), 7.57–7.36 (br, 4H, aromatic protons), 7.18–6.79 (br, 5H, aromatic and vinylic protons), 4.23–3.48 (br, 4H, α-protons of decyloxy position), 1.95–0.68 (br, 38H, aliphatic protons). Anal. Calcd. for PCzV: C, 82.85; H, 9.21; N, 2.42. Found: C, 77.96; H, 9.12; N, 2.22.

2.11. Solar cell fabrication and measurements

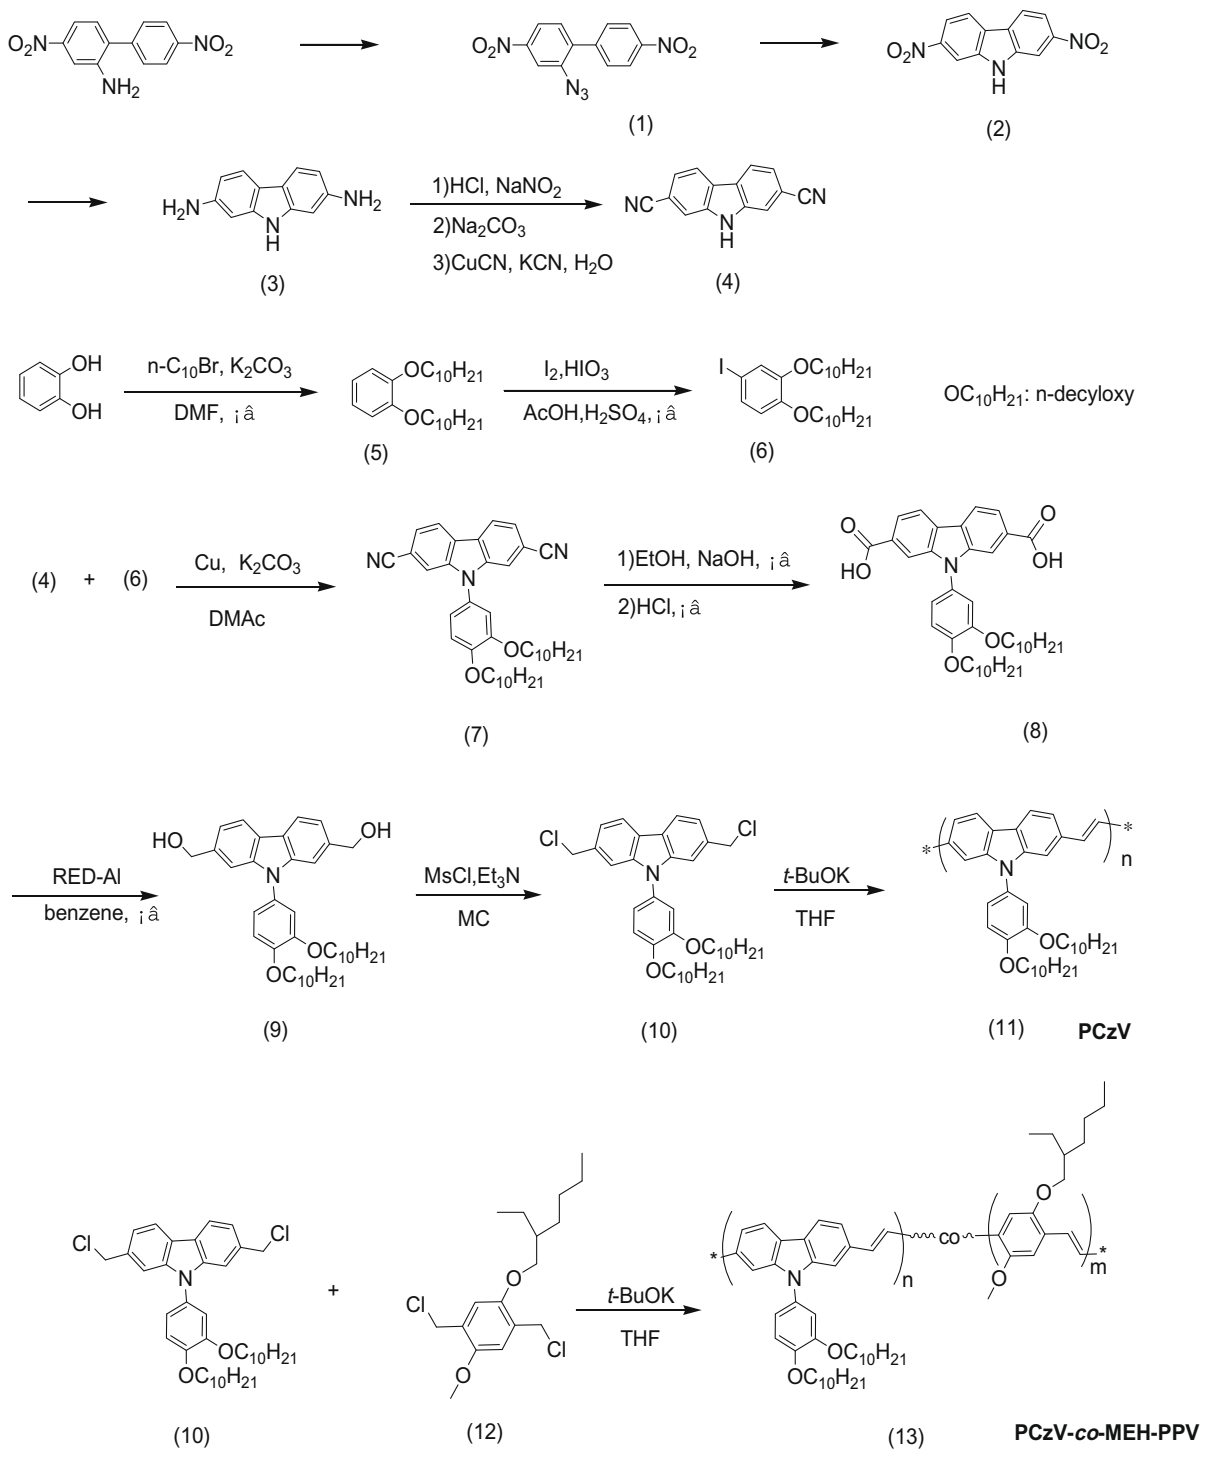
Bulk-heterojunction solar cells used to measure photovoltaic properties were constructed as follows. Each glass substrate was coated with a transparent ITO electrode (110 nm thick, 10–20 Ω/sq sheet resistance). The ITO-coated glass substrates were ultrasonically cleaned with detergent, deionized water, acetone, and isopropyl alcohol. The layer of 40 nm thick PEDOT:PSS (H.C. Stack, PH500) was spin-coated onto the pre-cleaned and UV-ozone treated ITO substrates. The spin-coated film was baked in air at 150 °C for 30 min. For fabrication of the active layers composed of interconnected networks of electron donor and acceptor, 1,2-dichlorobenzene and chloroform (1:1 wt.%) solutions of the synthesized polymer (10 mg/mL) and $PC_{61}BM$ (15 mg/mL) were shaken at room temperature for 12 h. The polymer and $PC_{61}BM$ blends was then prepared by mixing the two solutions and subsequent shaking for 12 h. Filtration using a 0.45 μm PTFE (hydrophobic) syringe filter gave the polymer blends with a ratio of the electron donor to the $PC_{61}BM$ as an electron acceptor of 1:3, 1:4, 1:5, and 1:6 wt/wt, respectively. The TiO_x precursor solution (1 wt.%) was spin-casted (4000 rpm) onto the active layer with thickness of *ca.* 10 nm and heated at 80 °C for 10 min in air. After being subjected to vacuum (5×10^{-6} Torr), the Al electrodes with thickness around 100 nm were deposited. The top metal electrode area, comprising the active area of the solar cells, was found to be 4 mm^2. Performance of the solar cells were measured using a AM 1.5G solar simulator (Oriel 300 W) at 100 mW/cm^2 light illumination after adjusting the light intensity using Oriel power meter (model No. 70260 which was calibrated using laboratory standards that are traceable to the National Institute of Standards and Technologies, USA). Current density–voltage (*I–V*) curves were recorded using a standard source measurement unit (Keithley 236). All fabrication steps and characterization measurements were performed in an ambient environment without a protective atmosphere. Thickness of the thin films was measured using a KLA Tencor Alpha-step IQ surface profilometer with an accuracy of ±1 nm.

3. Results and discussion

3.1. Synthesis and characterization

The synthetic routes used for preparation of the monomer and the polymers are shown in Scheme 1. Syntheses of the poly(carbazolyl-2,7-vinylene) derivatives, although not often straightforward [30], were accomplished starting with 4,4′-dinitro-2-biphenylamine and employing a sequence involving the known intermediates 4,4′-dinitro-2-azidobiphenyl (**1**), 2,7-dinitrocarbazole (**2**), and 2,7-diaminocarbazole (**3**) [31].

In order to introduce chloromethyl units into the 2- and 7-position of carbazole, the dicyano derivative **4** is generated by using a diazotation-cyanide substitution route. To improve the processibility of the poly(carbazolyl-2,7-vinylene) derivatives, the bulky didecyloxyphenyl pendant group is introduced at the nitrogen atom of carbazole



Scheme 1.

backbone. For this purpose, the ortho-hydroquinone derivative **5** is produced by using the Williamson ether synthesis method through reaction of *n*-decyl bromide and catechol. Iodination of **5** yields the iodo-arene **6**, whose coupling reaction with carbazole **4** produces **7**, which contains two decyloxy groups at the *m*- and *p*-positions of the *N*-phenyl position. Hydrolysis of the dicyano compound (**7**) affords the dicarboxylic acid **8**, which undergoes reduction with RED-Al in benzene to yield diol **9**. The corresponding dichloride **10** is then produced from **9** by treatment with

methane sulfonyl chloride. PCzV and PCzV-*co*-MEH-PPV are synthesized by using the Gilch polymerization method. Homopolymerization of 9-(3,4-bis(decyloxy)phenyl)-2,7-bis(chloromethyl)carbazole (**10**) and copolymerization with 1,4-bis(chloromethyl)-2-(2-ethylhexyloxy)-5-methoxybenzene (**12**) [32] are carried out with an excess of potassium *tert*-butoxide in dry THF under a N_2 atmosphere. This is followed by the addition of 3–4 drops of 4-*tert*-butylbenzyl bromide in order to end-cap the polymer chain. The polymers, formed in this manner, were found to be completely soluble in organic solvents such as chloroform, 1,2-dichlorobenzene, and THF. The high solubility of these polymers is an important requirement for device fabrication. To improve photovoltaic performance, the resulting polymers were purified by using Soxhlet extraction with different solvents, including methanol, acetone and finally chloroform, in order to remove the unreacted monomers, impurities, and oligomers.

Implementation of this procedure results in the production of highly purified and the narrowly polydispersed polymers. Molecular structures of the monomer and the resulting polymers were characterized by using ^{1}H-, and ^{13}C NMR spectroscopy, and elemental analysis. The chloromethyl protons of monomer **10** at 4.80–4.67 ppm disappear during the polymerization reaction and new vinylic proton resonances appear at 7.18–6.79 ppm together with the carbazole protons in PCzV and PCzV-*co*-MEH-PPV. The composition ratio of PCzV-*co*-MEH-PPV is calculated from the integration ratios of the 8.19–6.70 ppm and 4.26–3.29 ppm peaks in the ^{1}H NMR. ^{1}H NMR peak area calculations show that the actual composition of PCzV-*co*-MEH-PPV is 30:70 wt.%. Table 1 contains a summary of the polymerization results in the form of molecular weight, polydispersity, and thermal characteristics of PCzV and PCzV-*co*-MEH-PPV.

The weight-average molecular weight (M_w) and the polydispersity of the PCzV and PCzV-*co*-MEH-PPV were found to be 38,600, 1.60 and 79,900, 2.05, respectively.

Table 1
Polymerization results, thermal and electro-optical properties of PCzV and PCzV-*co*-MEH-PPV.

		PCzV	PCzV-*co*-MEH-PPV
$M_w \times 10^4$[a]		3.86	7.99
PDI[a]		1.60	2.05

PL (nm)	Solution	467,492	556,596
	Film[d]	482,510	585,631
E_g[e] (eV)		2.50	2.07

[a] M_w and PDI of the polymers were determined by GPC using polystyrene standards.
[b] Determined by DSC at a heating rate of 10 °C/min under N_2 atmosphere.
[c] TGA was measured at temperature of 5% weight loss for the polymers.
[d] Measured in the thin film onto the quartz substrate.
[e] Band gap estimated from the onset wavelength of the optical absorption.

3.2. Thermal, optical and electrochemical properties of the polymers

The thermal behaviors of the polymers were investigated by using DSC and TGA thermograms. PCzV and PCzV-*co*-MEH-PPV have glass transition temperatures (T_g) of 95 and 78 °C, respectively, and these polymers have good thermal stabilities with a 5% weight loss temperature at 407 and 377 °C under N_2 atmosphere. PCzV exhibits a higher thermal stability than the PCzV-*co*-MEH-PPV and both polymers have higher thermal stabilities than dialkyloxy-substituted PPVs or poly(9,9-dialkylfluorene)s [33,34]. The high T_g values and thermal stabilities of PCzV and PCzV-*co*-MEH-PPV indicate that these polymers can be used for the fabrication of bulk-heterojunction solar cells without complications associated with deformation or degradation during operation of the solar cells.

Fig. 1 is shown the normalized UV–visible absorption spectra (Fig. 1a) of the PCzV and PCzV-*co*-MEH-PPV in chloroform solutions and in thin films. The absorption spectrum of the PCzV contains two broad peaks at 381 nm and 403 nm in the solution state and at 386 nm and 417 nm in the thin film state. The peaks at *ca.* 400 nm correspond to the carbazole chromophore. The absorption spectrum of the PCzV-*co*-MEH-PPV has a maximum at 489 nm in the solution state and at 499 nm in the thin film state. Both absorption bands in thin film states are slightly red-shifted by *ca.* 10 nm compared to the solution state owing to interactions between the polymer chains. The optical band gaps (E_g), calculated from the onset of the absorption of the PCzV and PCzV-*co*-MEH-PPV, are 2.50 eV and 2.07 eV, respectively. The wavelength of the absorption peaks and the optical band gaps of the PCzV and PCzV-*co*-MEH-PPV are summarized in Table 1. Photoluminescent (PL) spectra of PCzV in chloroform solution and in the thin film state are shown in Fig. 1b. The spectrum of homopolymer PCzV has PL peaks at *ca.* 467 nm and 492 nm in the solution state and at 482 nm and 510 nm in the thin film state. The PL spectrum of the PCzV-*co*-MEH-PPV has maxima at 556 nm and 596 nm in the solution state and at 585 nm and 631 nm in the thin film state. The disappearance of PL emission from PCzV in the PCzV-*co*-MEH-PPV copolymer indicates that efficient energy transfer takes place from the wide band gap PCzV segment to the small band gap MEH-PPV segment. Thus, the transfer of exciton energy from the PCzV segment to the MEH-PPV segment occurs mainly along the polymer chain and intermolecular energy transfer occurs in the PCzV-*co*-MEH-PPV.

To investigate the charge injection and transport properties of PCzV and PCzV-*co*-MEH-PPV and to determine the energies of their highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbitals, redox measurements were carried using CV. The HOMO energies of PCzV and PCzV-*co*-MEH-PPV for the standard ferrocene/ferrocenium (4.8 eV) are found to be 5.29 eV and 5.34 eV, respectively. The respective LUMO energies, calculated based on the HOMO energies and the band gaps determined by using UV spectroscopic analysis spectra, for PCzV and PCzV-*co*-MEH-PPV are found to be 2.79 eV and 3.27 eV, respectively. The energy band diagrams of PCzV, PCzV-*co*-

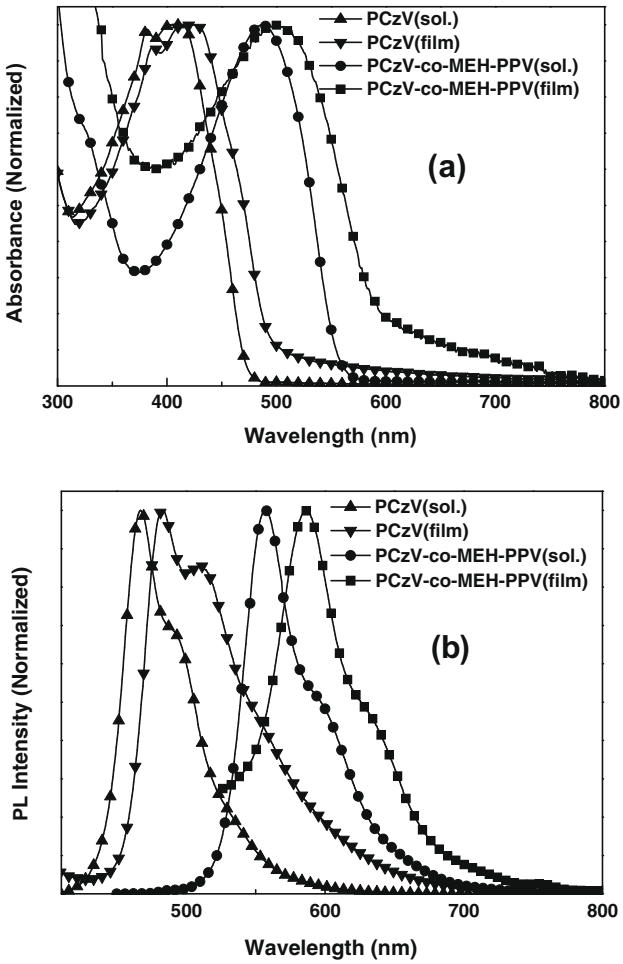

Fig. 1. UV–visible absorption (a) and PL emission (b) spectra of PCzV and PCzV-*co*-MEH-PPV.

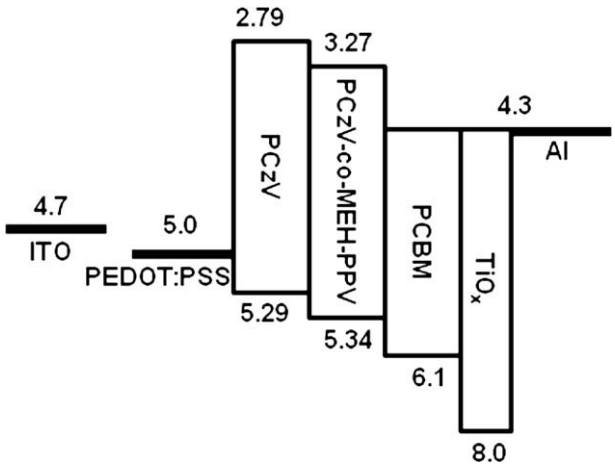

Fig. 2. Energy level diagram of the components of the bulk-heterojunction solar cell.

MEH-PPV and PCBM are shown in Fig. 2. The energies of these electron donors are well-matched to those of $PC_{61}BM$ as an electron acceptor. Photogeneration of charge in most of π-conjugated polymers is not very efficient since there recombination of two charge carriers is always involved. However, a consideration of the high LUMO energies of

PCzV and PCzV-*co*-MEH-PPV and the corresponding low HOMO energy level of $PC_{61}BM$ leads to the prediction that charge transfer will take place at the interface of these materials.

3.3. Solar cell properties of the polymers

Bulk-heterojunction solar cells were fabricated using PCzV and PCzV-*co*-MEH-PPV as electron donors and $PC_{61}BM$ as an electron acceptor. The photovoltaic cell structures are as follow: ITO/PEDOT:PSS/polymer:$PC_{61}BM$/TiO_x (10 nm)/Al (100 nm). We also used solution processable TiO_x [35–37] between the active layer and the metal cathode as a hole blocking and electron transporting layer [38,39]. The energy level of TiO_x matches the work function of Al well. Many research groups have obtained best photovoltaic performances through optimization of the ratios of electron donor polymers to the electron acceptor $PC_{61}BM$ [40,41]. The charge balance generally depends on the thickness of the active layer and the amount of $PC_{61}BM$ in the polymer blended active layer. In this effort, we probed the effect of the ratios of PCzV and $PC_{61}BM$ on photovoltaic performance using a 1,2-dichlorobenzene and chloroform mixed solvent system. The current density–voltage (*J*–*V*) characteristics of solar cells, fabricated with 1:3, 1:4, 1:5 and 1:6 ratios of polymer to $PC_{61}BM$, under AM 1.5G illumination, are shown in Fig. 3 and summarized in Table 2.

Fig. 3a is shown the *J*–*V* characteristics of PCzV with different ratios of $PC_{61}BM$. Open-circuit voltages (V_{oc}) of bulk-heterojunction solar cells are closely related to the energy difference between the HOMO level of the electron donor and the LUMO level of the electron acceptor. The V_{oc} of all solar cells we constructed are almost identical, but higher short-circuit current densities (J_{sc}) and a higher fill factors (FF) are observed with increasing $PC_{61}BM$ content in the blended active layer. The best photovoltaic performance of 0.57% was seen for a solar cell fabricated using a 1:6 ratio of PCzV:$PC_{61}BM$. For reference, the PCE of a cell made using a 1:3 ratio of PCzV:$PC_{61}BM$ (1:3 wt/wt) is 0.26%.

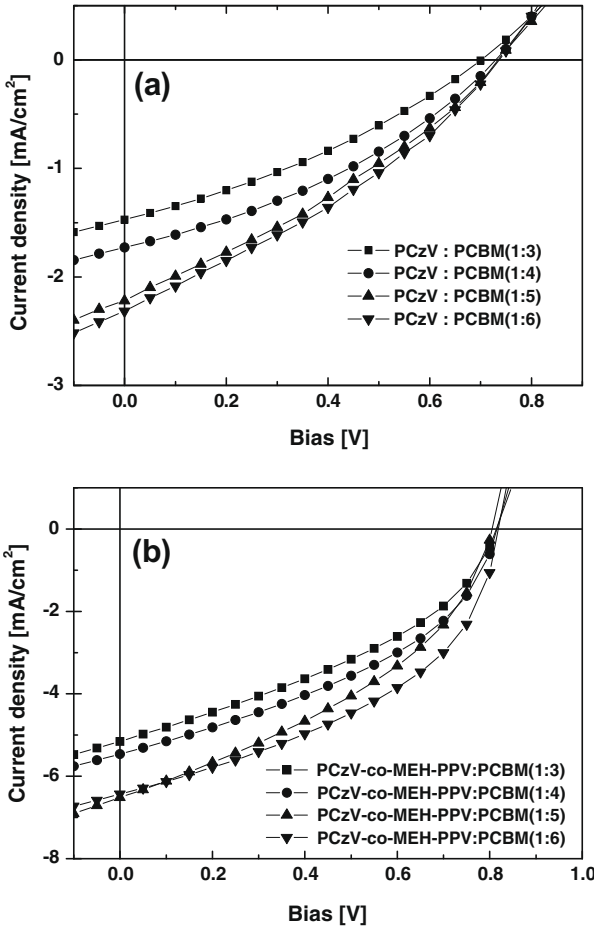

Fig. 3. Current density–voltage characteristic of PCzV (a) and PCzV-*co*-MEH-PPV (b) bulk-heterojunction solar cells containing different ratios of $PC_{61}BM$.

Table 2
Solar cell performance of PCzV and PCzV-*co*-MEH-PPV as electron donor sand $PC_{61}BM$ as the electron acceptor in ITO/PEDOT:PSS/polymer:$PC_{61}BM$/TiO_x/Al devices.

Active layer (polymer:$PC_{61}BM$)	V_{oc} (V) [a]	J_{sc} (mA/cm^2)[b]	FF (%)[c]	PCE (%)[d]
PCzV:$PC_{61}BM$ (1:3 wt/wt)	0.70	1.47	25	0.26
PCzV:$PC_{61}BM$ (1:4 wt/wt)	0.73	1.72	24	0.30
PCzV:$PC_{61}BM$ (1:5 wt/wt)	0.73	2.22	31	0.51
PCzV:$PC_{61}BM$ (1:6 wt/wt)	0.73	2.31	34	0.57
PCzV-*co*-MEH-PPV:$PC_{61}BM$ (1:3 wt/wt)	0.81	5.16	38	1.60
PCzV-*co*-MEH-PPV:$PC_{61}BM$ (1:4 wt/wt)	0.81	5.46	41	1.81
PCzV-*co*-MEH-PPV:$PC_{61}BM$ (1:5 wt/wt)	0.80	6.52	39	2.04
PCzV-*co*-MEH-PPV:$PC_{61}BM$ (1:6 wt/wt)	0.82	6.43	44	2.31

[a] V_{oc}, open-circuit voltage.

[d] PCE, power conversion efficiency.

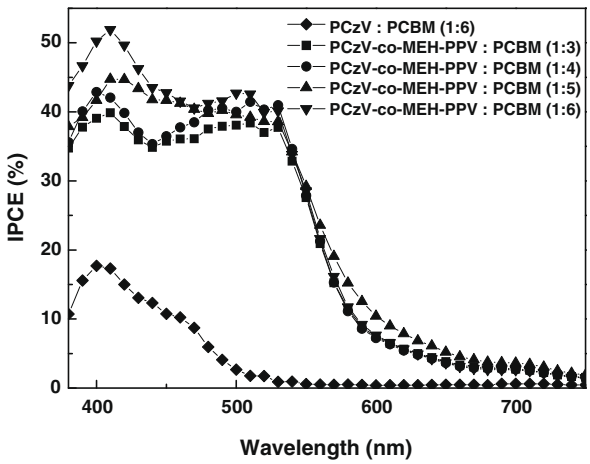

Fig. 4. IPCE spectra of PCzV and PCzV-*co*-MEH-PPV bulk-heterojunction solar cells containing different ratios of $PC_{61}BM$.

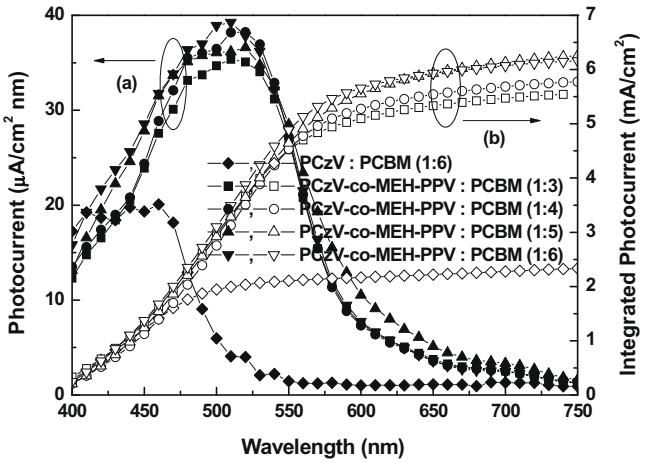

Fig. 5. (a) Photocurrents obtained using data from Fig. 4. (b) The total solar photocurrent obtained by integrating the curves shown in plots a.

Owing to the higher energy difference (1.04 eV) between the HOMO of PCzV-*co*-MEH-PPV and LUMO of $PC_{61}BM$ relative to that of PCzV and $PC_{61}BM$ (0.99 eV), the V_{oc} of PCzV-*co*-MEH-PPV:$PC_{61}BM$ solar cells are higher than those of the PCzV:$PC_{61}BM$ solar cells. The PCzV-*co*-MEH-PPV:$PC_{61}BM$ derived solar cells have similar photovoltaic performances as the PCzV:$PC_{61}BM$ cells (see Fig. 3b). The solar cell fabricated with 1:6 ratio of PCzV-*co*-MEH-PPV and $PC_{61}BM$, with TiO_x with V_{oc} of 0.82 V, J_{sc} of 6.43 mA/cm^2, FF of 44%, and PCE of 2.31%, displays the highest photovoltaic performance when compared with the solar cells arising from PCzV and $PC_{61}BM$.

Incident photon to current conversion efficiency (IPCE) spectra of the bulk-heterojunction solar cells fabricated with PCzV-*co*-MEH-PPV and $PC_{61}BM$ as active layers, recorded in the wavelength region between 380 nm and 750 nm, are shown in Fig. 4. In IPCE spectra of bulk-heterojunction solar cells, the shape of peak around 400 nm was enhanced with increasing amount of the $PC_{61}BM$. In order to easily understand, we measured absorption spectra of the PCzV-*co*-MEH-PPV, $PC_{61}BM$ and PCzV-*co*-MEH-PPV:$PC_{61}BM$ solutions (see Fig. S1). $PC_{61}BM$ showed a strong absorption peak at 340 nm and small peaks located at 400–600 nm. However as increasing the blending ratio of $PC_{61}BM$ content in PCzV-*co*-MEH-PPV and $PC_{61}BM$ solutions, the strong absorption peak of $PC_{61}BM$ showed at 340 nm and the absorption peak of PCzV-*co*-MEH-PPV was gradually reduced. It should be indicated that this makes it possible for the $PC_{61}BM$ molecules to penetrate into the PCzV-*co*-MEH-PPV polymer chains. Thus, the peak in IPCE spectra around 400 nm arises from the absorption of $PC_{61}BM$ and PCzV-*co*-MEH-PPV. As increasing the $PC_{61}BM$ content, more $PC_{61}BM$ molecules are embedded into the PCzV-*co*-MEH-PPV polymer chains, which was in favor of the generation and transport of charge carriers in the $PC_{61}BM$ phase. A maximum IPCE of 17% was observed in the case of the pristine PCzV homopolymer bulk-heterojunction solar cell at a wavelength of 410 nm. As increasing the MEH-PPV content in PCzV-*co*-MEH-PPV copolymers, IPCE also increases considerably and reaches a maximum of 52% at 410 nm and broadened up to 650 nm for a bulk-heterojunction solar cell comprised of a 1:6 ratio (wt/wt) of PCzV-*co*-MEH-PPV:$PC_{61}BM/TiO_x$. This finding may be a result of an increase of the charge-carrier mobility in the active layer and, thus, an increase in light absorption in the solar cell active layer promoted by a high amount of $PC_{61}BM$. This factor also contributes to the increased PCE of PCzV-*co*-MEH-PPV:$PC_{61}BM$ solar cells.

Integrated photocurrent curves were obtained by integrating IPCE spectra in the wavelength region between 400 nm and 750 nm (see Fig. 5). The J_{sc} value, determined from the overlap integral of the IPCE curve and the standard AM 1.5 G solar emission spectrum, is in excellent agreement with the measured photocurrent density. The error of J_{sc} and the integrated photocurrent is 5–7%, which is in the 5–10% range often seen in these values [42]. Therefore, a negligible spectral mismatch exists between the solar simulator used in this study and standard AM 1.5 G sunlight.

4. Conclusions

A new class of high molecular weight poly(*N*-(3,4-bis(decyloxy)phenyl)carbazolyl-2,7-vinylene) (PCzV) and its copolymers with an MEH-PPV have been prepared by using the Gilch polymerization procedure. PCzV and PCzV-*co*-MEH-PPV exhibit high glass transition temperatures and are easily spin casted onto the ITO substrates. Bulk-heterojunction solar cells with ITO/PEDOT:PSS/polymer:$PC_{61}BM/TiO_x$/Al configurations were fabricated with PCzV and PCzV-*co*-MEH-PPV as electron donors and $PC_{61}BM$ as the electron acceptor. The solar cells are comprised of 1:3, 1:4, 1:5 and 1:6 ratios of polymer to $PC_{61}BM$. The PCE values of the solar cells were found to increase with increasing $PC_{61}BM$ content and a maximum PCE of 2.31% (J_{sc} = 6.43 mA/cm^2, V_{oc} = 0.82 V, FF = 44%) is observed for the cell prepared from a 1:6 ratio (wt/wt) of PCzV-*co*-MEH-PPV:$PC_{61}BM$.

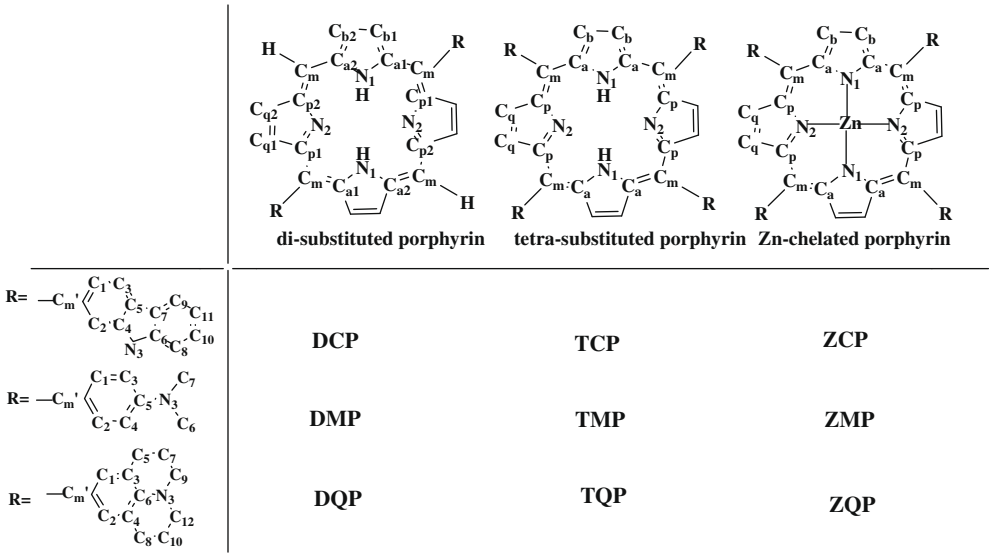
excited states properties of this type of porphyrin derivatives. The moieties of C (carbazole), M (N,N-dimethyl-phenyl), and Q (2,3,6,7-tetrahydro-1H,5H-pyrido[3,2,1-*ij*]quinoline) are chosen as energy transfer donors because of their wide application in red OLEDs [16,17,1]. Moreover, their emission peaks are in the region of 300–350 nm (predicted by TDDFT/B3LYP/6-31G(d) using Turbomole suite [18] in Table 1), which are similar with the fluorescence spectra of fluorene arms [11]. Accordingly, these moieties are linked to meso-sites of the porphyrin ring, that is, 5,15-di(R)porphyrin, 5,10,15,20-tetra(R)porphyrin, and Zn-5,10,15,20-tetra(R)porphyrin, namely, DCP, TCP, and ZCP (where R = C); DMP, TMP, and ZMP (where R = M); DQP, TQP, and ZQP (where R = Q), as shown in Scheme 1. The main aim of this work is twofold: (1) to testify if these porphyrin derivatives have TB energy transfer features; (2) to reveal the origin of their improved efficiency as red light-emitting materials. In addition, the experimental synthesized compounds such as tetraphenylporphyrin (TPP), 5,15-difluorenylporphyrin (DFP), 5,10,15,20-tetrafluorenylporphyrin (TFP), and Zn-5,10,15,20-tetrafluorenylporphyrin (FPZ) [15] will be used for comparative studies. This work is expected to provide valuable insight into the structure–photophysical property relationship for designing efficient red emitters with TB energy transfer features.

2. Computational methods

Recent studies [20–22] had confirmed that DFT theory can predict relatively accurate electronic structure for porphyrins derivatives. So, the DFT-B3LYP [23–25] level of theory with 6-31G(d) basis set was employed to optimize the ground-state geometries of 5,15-di(R)porphyrin, 5,10,15,20-tetra(R)porphyrin, and Zn-5,10,15,20-tetra(R)porphyrin, where R = carbazole, N,N-dimethyl-phenyl, and 2,3,6,7-tetrahydro-1H,5H-pyrido[3,2,1-*ij*]quinoline, as well as their ions structures. The free based porphyrin (FBP), Zn porphyrin (ZnP), and di-substituted porphyrins (DCP, DMP, and DQP) were optimized with D_{2h}, D_{4h}, and C_i symmetry constraint, respectively. Tetra-substituted porphyrins (TCP, TMP, TQP, and TPP) and Zn-chelated porphyrins (ZCP, ZMP, and ZQP) were restricted with C_{2h} point group constraint. On the basis of these optimized geometries, the ionization potentials (IP), electron affinity (EA), hole extraction potentials (HEP), electron extraction potentials (EEP), and reorganization energy (λ) [26] were calculated by the method as described in Refs. [15,27]. On the basis of the optimized ground-state geometries, the absorption spectra of these compounds were predicted by the TD-DFT//B3LYP/6-31G(d) method. This kind of calculation level had been proven to be reliable for porphyrin derivatives [15,23,24].

In order to facilitate the computation for large molecules, the lowest singlet excited-state (S_1) geometries of studied complexes were optimized by singlet configuration interaction CIS [28] with 3-21G(d) basis sets, which had been proved to be suitable for model the excited states of porphyrin derivatives [29]. Based on our previous report



Scheme 1. The studied porphyrin derivatives: 5,15-di(R)porphyrin, 5,10,15,20-tetra(R)porphyrin, and Zn-5,10,15,20-tetra(R)porphyrin, namely, DCP, TCP, and ZCP (where R = carbazole); DMP, TMP, and ZMP (where R = N,N-dimethyl-phenyl); DQP, TQP, and ZQP (where R = 2,3,6,7-tetrahydro-1H,5H-benzo[*ij*]puinolizine), together with the schematic structures of porphyrins fragment and meso-substitutions.

[15], it was found that the TDHF/6-31G(d) method, in combination with the CIS level, was suitable for predicting the emission spectra of the type of porphyrin derivatives. Therefore, the emission spectra were obtained by TD-HF/6-31G(d) at the excited-states structures. All these calculations were performed on the SGI origin 2000 server, using Gaussian 03 program package [30].

3. Results and discussions

3.1. Ground-state geometry properties

The optimized geometries of porphyrin derivatives are illustrated in Fig. 1, and the labeling schemes are depicted in Scheme 1. The main optimized geometric parameters of studied compounds in the ground state are summarized in Table 2 (see Table S1 in Supporting information for details).

Fig. 1(b) illustrates that the porphyrin rings in studied compounds are essentially planar, while the meso-arms are not coplanar with the porphyrin rings. As shown in Table 2(a), the inter-ring dihedral angle $\alpha(C_{a1}–C_m–C_{m'}–C_1)$ between meso-arms and porphyrin ring is quite large (62.6° for DCP, 59.2° for DMP, and 59.9° for DQP). This may ascribe to the steric repulsions between two hydrogen atoms bound to the carbon atoms C_{b1} (or C_{q2}) and C_1 (or C_2). It is noteworthy that the large inter-ring dihedral angle preserves respective character of donor and acceptor, which is the typical structure feature of energy-transfer systems [31]. In addition, Table 2(a) also collects the main geometries of di-substituted porphyrins (DCP, DMP, and DQP) are similar with the experimentally synthesized compound DFP [15]. For example, the $C_{a1}–C_{b1}$, $C_{a1}–N_1$, $C_{a1}–C_m$, and $C_{p1}–C_m$ bond lengths of DCP, DMP and DQP deviate only by 0.001 Å from DFP, except for the $C_{m'}–C_m$ bond length. The natural bond orbital (NBO) analyses for these complexes give us a good explanation for the above results. According to the NBO analyses, the charge population of C, M, Q, and fluorenyl moieties is 0.0163, 0.033, 0.0354, and 0.0148 a.u. [15], respectively. Obviously, the electron-donation abilities of M and Q are better than those of C and fluorenyl groups. So, the bond length $C_{m'}–C_m$ of DMP and DQP are shortened by 0.004 Å from those of DCP and DFP.

Similarly, as given in Table 2(b), the main geometric parameters of tetra-substituted porphyrins and Zn-chelated porphyrins are consistent with referenced compounds TFP [15] and FPZ [15], respectively. Comparing with the tetra-substituted porphyrins, the $C_a–C_b$ and $C_p–N_2$ bond lengths of Zn-chelated porphyrins are elongated by 0.011 Å, while the $C_p–C_q$ bond length of Zn-chelated porphyrins is contracted by ca. 0.015 Å. The inter-ring dihedral angle $\alpha(C_a–C_m–C_{m'}–C_1)$ is 68.6°, 65.6°, 66.5°, 69.6°, 66.8°, and 67.6° for TCP, TMP, TQP, ZCP, ZMP, and ZQP, respectively. It is obvious that all the studied compounds have the typical structure feature of energy-transfer systems [31]. As shown above, there are small geometrical differences between theoretical design and experimentally synthesized molecules. It indicates that DCP, DMP, DQP, TCP, TMP, TQP, ZCP, ZMP, and ZQP should have similar electronic and optical properties with reference compounds [15].

3.2. Geometry properties of ionic-state molecules

According to our previous report [15], the internal reorganization energy (λ) for hole transfer can be calculated as followings:

$$\lambda_{hole} = \lambda_+ + \lambda_1 = [E^+(A) - E^+(A^+)] + [E(A^+) - E(A)] \quad (1)$$

E^+ and E represent the energies of the cation and neutral species in their lowest energy geometries, respectively, while (A^+) and (A) denote the structures of them. As shown in Eq. (1), the λ couples with the structure changes in the ionization process. Herein, all the ionic and neutral geometries of studied compounds are optimized by DFT//B3LYP/6-31G(d) method. And the calculated bond lengths of them are listed in Table S1 in Supporting information. Table S1 clearly shows that the largest variations between the ionic and corresponding neutral structures of DCP, DMP, and DQP are similarly with each other. Similarly, for tetra-substituted porphyrins and Zn-chelated porphyrins, the largest variations between the ionic and corresponding neutral compounds do not change with the changes of meso-substituents. Therefore, we only take DCP, TCP, and ZCP as examples. The deviations of bond lengths between their ionic and neutral geometries are depicted in Fig. 2. As shown in Fig. 2, the localizations of structural change mainly focus on porphyrin ring. Take DCP as an example, the $C_m–C_{m'}$ (labeled 15) bond length has remarkable change in the cationic state, while the $C_{a1}–C_m$ (labeled 5), $C_{p2}–N_2$ (labeled 11), and $C_{p1}–C_m$ (labeled 13) bond lengths change significantly in the anionic state. In addition, as depicted in Fig. 2, the bond lengths in meso-substituents change remarkably in the ionization process. As given in Table S1, the change of bond length $N_3–C_5$ is 0.023, 0.021, 0.025, 0.019, 0.019, and 0.016 Å for DMP^+, DMP^-, TMP^+, TMP^-, ZMP^+, and ZMP^-, respectively. And the bond length $N_3–C_6$ changes 0.027, 0.017, 0.020, 0.013, 0.020, and 0.013 Å for DQP^+, DQP^-, TQP^+, TQP^-, ZQP^+, and ZQP^-, respectively. Apparently, the involved meso-substituents can influence the internal reorganization energy, which will be further testified in Section 3.5.

3.3. Frontier molecular orbitals

Gouterman's four orbitals (HOMO−1, HOMO, LUMO, and LUMO+1 orbitals) [32] has been used as an essential standard on explaining the abundance chemistry properties of porphyrins. The plots of HOMOs of studied compounds are drawn in Fig. 3. And the energies and symmetries of the frontier molecular orbitals of these compounds are shown in Fig. 4 (detailed data are listed in Table S2 in Supporting information). The local density of states (LDOS) of porphyrin ring and meso-substituents are shown in Fig. 5. In addition, according to the LDOS analysis, the contribution of C_m to HOMO in studied compounds is listed in Table 3.

Recently, Otsuki and co-workers [33] have demonstrated that the Dexter-type energy transfer can explain the major parts of TB energy transfer, whereas the Förster-type energy transfer process accounts for only minor part of TB energy transfer. The Dexter mechanism can be

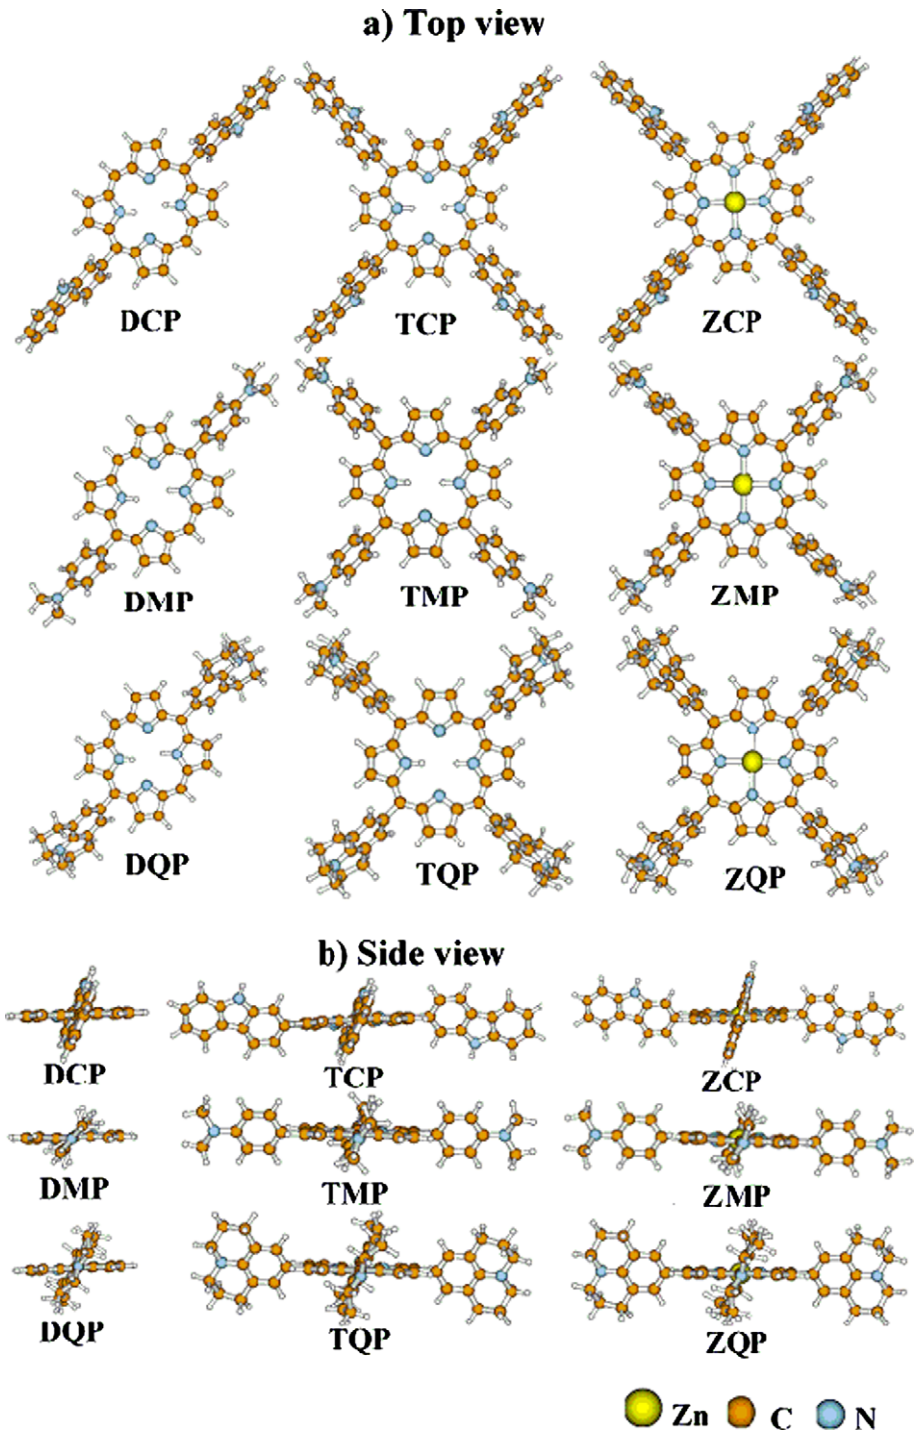


Fig. 1. (a) Front view and (b) side view of the optimized structures of studied compounds obtained by DFT//B3LYP/6-31G(d).

considered as an electron exchange process [34], thus the rate of Dexter-type energy transfer is sensitive to the nature of frontier orbitals. As a guiding principle [34], a stronger electronic interaction between the donor (meso-substituent) and acceptor (porphyrin) is acknowledged when HOMO is heavily populated at the C_m (as C_m is the connection bridge of donor and acceptor), whereas a weaker interaction is expected when HOMO has virtually no electron density at the C_m. As shown in Fig. 3, the HOMO of FBP with b_{3u} symmetry is heavily populated at the C_m, while the HOMO of ZnP is node on the C_m. After meso-substituents are added, the HOMOs of di- (a_u symmetry),

tetra- (b_u symmetry), and Zn-chelated porphyrins (b_u symmetry) have large electron density on the C_m. It indicates that our studied compounds have strong electron interaction, that is, the Dexter-type energy transfer process dominates in our designed compounds. Furthermore, as listed in Table 3, the contribution of C_m to HOMO of di-substituted porphyrins decreases as: DCP(49.12%) > DMP(39.32%) > DQP(33.73%). Similarly, the contributions of C_m to HOMO of TCP and ZCP are larger than those of TQP, TMP, ZQP, and ZMP. It is evident that the C moiety has importantly influence on the character of HOMOs, indicating that the Dexter-type energy transfer can easily occur in DCP, TCP, and ZCP. Consequently, we can predict with some confidence that DCP, TCP, ZCP would have higher efficiency than the others as red light-emitting materials, which will be further testified in Section 3.5.

Brédas et al. experimentally estimated the HOMO and LUMO energies by using an empirical formula based on the onset of the oxidation and reduction peaks measured by cyclic voltammetry [35]. The preliminary hole/electron injection properties of the materials are usually estimated by the values of HOMO/LUMO, in accord with the work function values of cathode/anode. Normally, the hole-transport materials with the higher value of HOMO should lose their electrons more easily, while the electron-transport materials with lower value of LUMO should accept electrons more easily. In this study, the calculated HOMO and LUMO energies obtained by DFT/B3LYP/6-31G(d) are

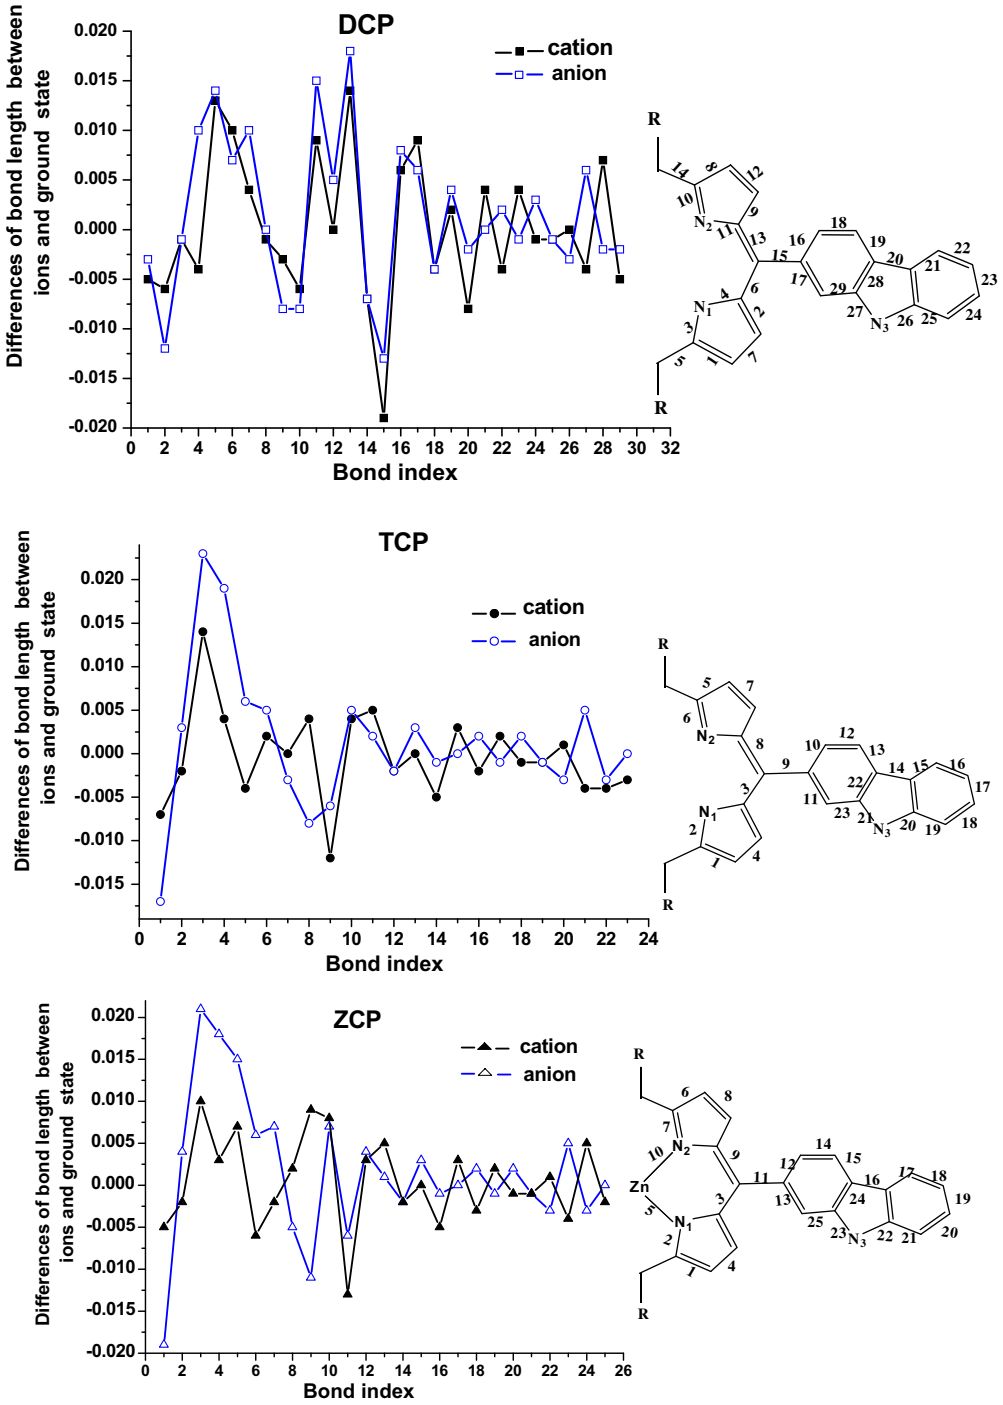

Fig. 2. The bond lengths deviates between the ionic and neutral structures of DCP, TCP, and ZCP. The atom numbers of studied compounds are labeled in Scheme 1.

listed in Table S2. As listed in Table S2, the HOMO and LUMO levels for TCP, DMP, TMP, ZMP, DQP, TQP, and ZQP are −4.79 and −2.13, −4.58 and −1.97, −4.30 and −1.76, −4.39 and −1.69, −4.50 and −1.94, −4.23 and −1.71, and −4.31 and −1.64 eV, respectively. Obviously, they are higher than the HOMO and LUMO energy levels of FBP (εHOMO, −5.15 eV and εLUMO, −2.24 eV), ZnP (εHOMO, −5.21 eV and εLUMO, −2.14 eV), TPP (εHOMO, −4.91 eV and εLUMO, −2.20 eV) DFP [15] (εHOMO, −4.94 eV and εLUMO, −2.24 eV), TFP [15] (εHOMO, −4.83 eV and εLUMO, −2.17 eV), and FPZ [15] (εHOMO, −4.91 eV and εLUMO, −2.10 eV). It suggests that the hole injection

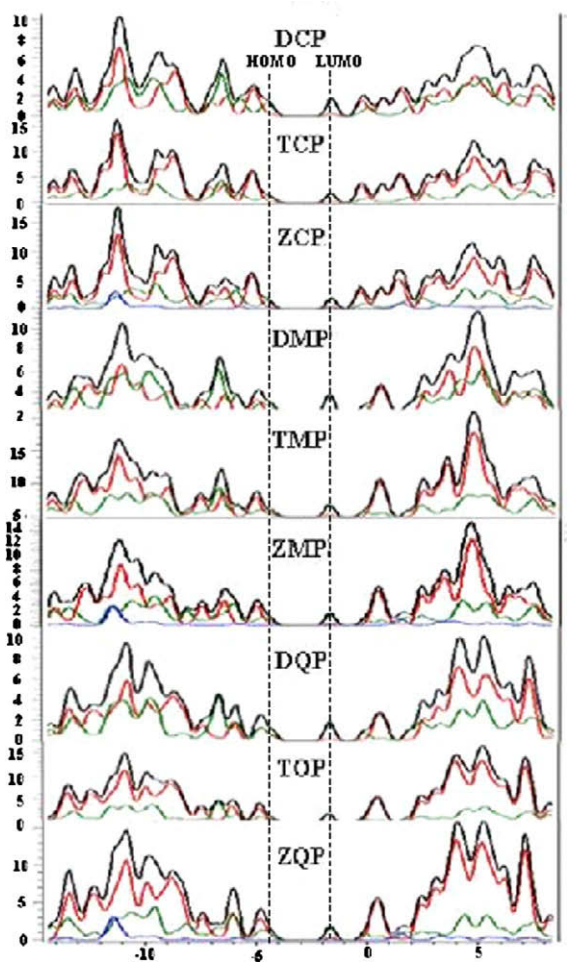

Fig. 5. The density of states (DOS) of all studied porphyrins. The black, red, green, blue lines stand for the local density of states (LDOS) of the total, meso-substitutions, porphyrin, and Zn (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.).

abilities of porphyrin derivatives are effectively enhanced by introducing these meso-substitutions. Furthermore, the HOMO energies of DCP, TCP, ZCP match well with the work function values of ITO (−4.8 eV), again indicating that these compounds have good hole injection ability [36].

The frontier MOs of these porphyrin derivatives are not entirely consistent with the common Gouterman four-orbital model. As drawn in Fig. 4, the LUMOs and LUMO+1s of studied molecules are nearly degenerate, and they are well separated from other unoccupied orbitals. However, the HOMOs and HOMO−1s of them are not degenerate any more, and the energy gaps between the HOMO−1s and other occupied orbitals become narrow. Take the $\Delta E_{(\mathrm{HOMO}-2)-(\mathrm{HOMO}-1)}$ energy gap for example, it is 0.45, 0.50, 0.49, 0.13, 0.20, 0.25, 0.05, 0.07, and 0.09 eV of DCP, TCP, ZCP, DMP, TMP, ZMP, DQP, TQP, and ZQP, respectively. The examination on the local density of states (LDOS) of different regions in studied molecules gives some clues for this phenomenon. As plotted in Fig. 5, the HOMO−1s, LUMOs and LUMO+1s of these porphyrin derivatives are mainly contributed by P-rings (drawn in red[1] line) with more than 80% compositions (except for HOMO−1 of DQP), however, the HOMOs of them are dominantly composed of the meso-substituents and P-rings. Clearly, their HOMOs energies are more sensitive to the meso-substituents than those of LUMOs. Similarly, as drawn in Fig. 5, the meso-substituents contribute near 90% to theirs HOMO−2s, HOMO−3s, HOMO−4s, and HOMO−5s, leading to narrow energy gaps between these inner occupied orbitals and corresponding HOMO−1s.

3.4. Absorption and fluorescence spectra analysis

TDDFT//B3LYP/6-31G(d) has been employed to investigate the absorption spectra of studied compounds in this work. Based on the calculated results (the absorption wavelength spectra, excitation energy, oscillator strength, and main configurations are listed in Table S3 in Supporting information), simulated electronic absorption spectra plots of porphyrin derivatives are shown in Fig. 6.

As depicted in Fig. 6, a shoulder peak at the high energy region (250–350 nm) has been observed in these porphyrin derivatives. Furthermore, the fluorescence spectra of these donors (C–H, M–H, and Q–H) are in the region of 300–350 nm, as listed in Table 1. Obviously, there is good overlap between the absorption band of energy transfer acceptors (DCP, DMP, DQP, TCP, TMP, TQP, ZCP, ZMP, and ZQP) and the fluorescence peak of corresponding donors (C–H, M–H, and Q–H). Thus, from the point of view of Förster-type energy transfer mechanism, the TB energy transfer process can easily occur in studied compounds.

Interestingly, as listed in Table S3(a), the Q bands for FBP are composed of two weak absorption peaks (oscillator strengths (f) < 0.0001 for 543.8 nm and oscillator strengths (f) < 0.0001 for 507.2 nm). And Table S3(b) also shows that ZnP has relative weak Q band (oscillator strengths (f) = 0.0008 for 510.2 nm). Now, we will take ZnP as an example to explore the reasons of its weak Q bands. For ZnP, the Q band at 510.2 nm is assigned to the two lowest excitation energy states (S_1 and S_2). The S_1 state is constructed by two transitions of (−0.50) $a_{1u} \rightarrow e_g$ and (0.51) $a_{2u} \rightarrow e_g$. And S_2 state consists of the (−0.50) $a_{2u} \rightarrow e_g$ and (0.51) $a_{1u} \rightarrow e_g$ transitions. It is obviously that the Q bands are expressed by sign-reversed superposition of two configurations and the weights of the configuration are equal. Consequently, the transition dipole moment is canceled out, which results in very weak intensity in Q bands. After introducing the meso-substitutions, as listed in Table S3(c)–(k), the oscillator strength (f) of the Q bands for these compounds are intensified. Take ZMP as an example (listed in Table S3(h)), the S_1 state consists of the superior (0.59) $b_u \rightarrow b_g$ and inferior (−0.40) $a_u \rightarrow a_g$ transitions, while S_2 state is descripted by two configurations, (0.58) $b_u \rightarrow a_g$, and (0.42) $a_u \rightarrow b_g$ transitions. Obviously, there is less complete cancellation of the transition dipole moments, so the Q bands of ZMP are intensified [37]. In addition to the

intensified oscillator strength, the slight red-shifts of the absorption spectra compared with corresponding bands of FBP and ZnP have been observed, which are caused by reducing energy of one-electron transition from the meso-substitutions. In addition, as listed in Table S3, inner occupied molecular orbitals (energies lower than the energy of HOMO) are involved in one-electron transitions for the B bands of studied compounds. It agrees with the analyses of molecular orbital energy in Section 3.3.

Our previous work [15] found that the TDHF method can successfully predict the fluorescence spectra of porphyrin derivatives in contrast to the corresponding experiments. Thus TDHF/6-31G(d) method has been employed to simulate the fluorescence spectra in this work. The obtained emission wavelengths, oscillator strengths, and main configurations for all the studied compounds are listed in Table 4. It is found that the fluorescence spectra of DCP, DMP, and DQP are similarly with each other. And for tetra- and Zn-chelated porphyrins, their fluorescence spectra are hardly influenced by introduced different substituents. But, as listed in Table 4, the fluorescence spectra of di-, tetra-, as well as Zn-chelated porphyrins are significantly different from each other. Taking DCP, TCP, and ZCP for examples, the fluorescence spectrum of TCP is 735.01 nm, while the fluorescence spectra of DCP and ZCP blue shift about 10 and 60 nm from that of TCP, respectively, which are in good agreement with the tendency of the fluorescence spectra of DFP, TFP, and FPZ [15]. The examination of the main orbital transitions associated with these emission wavelengths will give reasonable explanation for this phenomenon. As listed in Table 4, the main orbital transitions of all these emission wavelengths are from HOMO to LUMO. Fig. 4 shows the HOMO–LUMO gaps (ΔE_{H-L}) of DCP, TCP, and ZCP are 2.71, 2.66, and 2.83 eV, respectively. Clearly, the ΔE_{H-L} decreases as: ZCP > DCP > TCP, so the fluorescence wavelength of them increases as ZCP < DCP < TCP.

3.5. Charge injection and transport properties as well as exciton binding energy

The charge injection and transport rate, and balance as well as exciton confinement in the device are the main factors in determining the operating voltage and luminance efficiency of OLEDs. Normally, the lower IP value indicates a higher ease of injection of holes from ITO to hole-transport layer (HTL); and the higher EA value corresponds to the better ease of electron injection from cathode to electron-transport layer (ETL). Thus, in this report, IP and EA are employed to evaluate the energy barrier of injection holes and electrons, respectively.

The motilities of hole and electron are investigated by reorganization energy (λ) based on the Marcus theory [26], which has been widely applied to assess the ability of charge mobility [15,27,38]. Usually, smaller λ and more balance hole and electron reorganization energy (λ_{hole} and $\lambda_{electron}$) will result in higher efficient charge transport.

For OLEDs, the first phase is to inject electrons and holes into the organic functional film from the cathode and anode, respectively, which is also the key stage. Take TPP as an example, although it has smaller λ_{hole} and $\lambda_{electron}$ values (0.10 and 0.21 eV, as listed in Table 5), the fluorescence quantum yield of TPP is still low (0.12) [39]. The poor injection abilities of electrons and holes for TPP (its higher IP and lower EA values) may be the main factors. Hence, it is essential to evaluate the energy barrier for injection holes and electrons. The calculated IP and EA values of studied compounds are listed in Table 5, together with referenced compounds [15]. Table 5 shows that M- (DMP, TMP, and ZMP) and Q-substituted porphyrins (DQP, TQP, and ZQP) display improved IP values, which are lower than referenced compounds (DFP, TFP, and FPZ) and two widely-used hole materials in OLEDs (4,4′-bis(1-naphthylphenylamino) biphenyl (NPB) [40] and 4,4′-bis(phenyl-m-tolylamino) biphenyl (TPD) [40]). And the IP values of the compounds with same meso-substituents decrease as: di-substituted porphyrins > Zn-chelated porphyrins > tetra-substituted porphyrins. Consequently, the hole injection abilities increase in the following sequence: ZnP > FBP [15] > DFP [15] > DCP > FPZ [15] > ZCP > TFP [15] > TCP > DMP > DQP > ZMP > TMP > ZQP > TQP. In addition, Table 5 also shows DCP, TCP, and ZCP have similar EA values with referenced compounds [15]. And the values of EA are increased as ZCP < DCP < TCP, which suggests that ability of accepting an electron increase in the same sequence.

The next stage of OLEDs is electron and hole transport in the light-emitting layer. As listed in Table 5, though FPZ has much better charge transfer balance than that of TPP, the

Alq_3 [41]						0.276		

fluorescence quantum yield of FPZ (0.05) [11] is still smaller than TPP (0.12) [39]. This is maybe due to the lower charge transfer rate of FPZ than that of TPP. Obviously, fast transfer rates are very important to practical OLEDs. Therefore, the λ_{hole} and $\lambda_{electron}$ of studied compounds are computed and shown in Table 5. As listed in Table 5, the values of λ_{hole} of C-substituted porphyrins (DCP, TCP, and ZCP) are much smaller than those of M- and Q-substituted porphyrins, suggesting that the hole transport rates of C-substituted porphyrins are higher than those of M- and Q-substituted porphyrins. Table 5 also shows that the $\lambda_{electron}$ of TCP, TMP, and DQP is 0.15, 0.18, and 0.19 eV, respectively, which is much smaller than that of tris(8-hydroxyquinoline) aluminum (Alq_3) [41] ($\lambda_{electron}$ = 0.276 eV, which is conventional electron-transport materials). Hence, these studied compounds are expected to be good electron-transport materials from the standpoint of λ. Furthermore, as the λ_{hole} increases, the $\lambda_{electron}$ values of studied compounds increase by the same magnitude. Thus the balance of the charge carriers is enhanced in studied compounds. It will effectively increase the probability of confined excitons in the light-emitting layer. It is noteworthy that DCP, TCP, and ZCP have the almost same rates in the transportation between hole and electron transport as DMP, TMP, ZMP, DQP, TQP, and ZQP. Consequently, DCP, TCP, and ZCP are anticipated to be highly efficient red emitters with great commercial potential.

In addition, as reported in our previous work, the carrier transport rate and transport balance of DFP are better than TFP, however, the fluorescence quantum yield of DFP (0.17) is smaller than TFP (0.24). Besides that, DFP has worse charge injection ability than TFP. The exciton binding energy (E_b), the energy required to destroy a exciton, should be another important factor responsible for the fluorescence efficiency. Very recently, E_b has been investigated by our group and computed by the following formula [38] (in eV):

$$E_{Flu} = \Delta E_{H-L} - E_b \quad (2)$$

where E_{Flu} is the excitation energy and ΔE_{H-L} is the energy differences of the HOMO and LUMO. Accordingly, the E_b values of studied compounds are computed and given in Table 5. Table 5 shows the value of E_b of TFP is smaller than that of DFP, indicating that TFP is easier to destroy the hole–electron excitions than DFP, thus the fluorescence quantum yield of TFP is higher than that of DFP. Table 5 also shows the E_b of all studied compounds are smaller than that of TPP, especially for TMP, ZMP, DQP, and ZQP, which indicates these compounds are easy to destroy the hole–electron excitons. Taking into account the changes

of IP, EA, λ and E_b, it is found that TCP and ZCP have faster carrier injection and transport rate, better transport balance, and relatively smaller exciton binding energy than other molecules. Therefore, our calculations predict that TCP and ZCP would be very promising red emitting materials with high fluorescence quantum yield, which is agree with the analysis in Section 3.3.

4. Conclusions

Our B3LYP calculations predict the electronic and photophysical properties of porphyrins derivatives with energy transfer donors at meso-positions. The calculated results show that the TB energy transfer character from fragments C, M, and Q to corresponding acceptors, has been detected in some extent by the three following properties: (1) the large inter-ring dihedral angles $\alpha(C_a–C_m–C_{m'}–C_1)$, which preserves the respective character of donor and acceptor; (2) heavily electron density populated at the C_m atoms in theirs HOMO orbitals, which indicates that these compounds should have strong electron interaction; (3) large overlap of the absorption band of studied compounds and the fluorescence emission peak of corresponding donors. Furthermore, the compounds with TB energy transfer characters have higher HOMO energies and smaller ionization potentials (IP) than these properties of referenced compounds (DFP, TFP, and FPZ). And the HOMO energies of DCP, TCP, ZCP well match with the work function values of ITO (−4.8 eV). And TCP and ZCP have faster carrier injection and transport rate, better carrier transport balance, and relatively smaller exciton binding energy than other molecules in the studied molecules, rendering great potential of these red emitting materials with high fluorescence quantum yield in the development of red OLEDs. Thus, if TCP and ZCP can be prepared and isolated, we predict that they will be proven to be highly efficient red light-emitting materials.

significantly degraded by directly depositing organic semiconductor onto the NPs, due to the improper alignment and undesirable orientation of the organic molecules subsequently grown on the dielectric/NPs surfaces. This condition can be improved by introducing a self-assembled monolayer (SAM) of thiol molecules onto the metal NPs before the deposition of the organic semiconductor layer [9]. It has been observed that pentacene thin films deposited on bare gold NPs tend to crystallize with the long molecular axes lying parallel to the substrate, whereas those deposited on thiol-modified gold substrates tend to crystallize with the long molecular axis of pentacene oriented vertically on the substrates [14].

In this work, we demonstrate, for the first time, that the memory window of pentacene OFET-based organic memory device can be significantly enhanced by adjusting the location of silver NPs embedded in the pentacene layer. In contrast with the conventional structure where the nanoparticles are placed directly onto the dielectric [9], we applied a sandwiched structure by placing the Ag NPs in between two pentacene layer. The memory window (i.e. shifting of the threshold voltage) can be controlled by varying the location of Ag NPs. Our findings show that the memory windows of the devices increase with the increasing thickness of the first pentacene layer, and a maximum memory window of 90 V is obtained in the pentacene (15 nm)/Ag NPs(5 nm)/pentacene (25 nm) configuration. The current device can be performed *in situ* in a single run, thus eliminating the process of thiol molecules SAM for metal NPs deposition and permits more reproducible device preparations.

2. Experimental

The schematic of the bottom-gate memory device structure used in this work is shown in Fig. 1(a). The devices were fabricated on highly-doped *n*-type Si substrates, with 300-nm thick thermally-grown SiO_2 as the gate dielectric. Substrates were cleaned by regular substrate cleaning procedures, including sonication under DI water with soap, followed by cleaning in DI water, acetone, isopropanol, acetone and isopropanol. After that, the substrates were exposed to an ozone plasma for 15 min and immediately functionalized with a self-assembled monolayer of octadecyltrichlorosilane (OTS) by immersing the substrate in OTS/hexane solution (1:500 v/v%).

Pentacene thin films, silver NPs and silver drain–source contacts were thermally evaporated at a base pressure of 1×10^{-7} Torr. Transistor devices with three types of structures were fabricated in this work (listed in Table 1). For type A devices, 40 nm of pentacene thin films were thermally evaporated on OTS-treated substrates, followed by the deposition of 50-nm thick silver drain–source electrodes through a mechanical shadow mask. For type B devices, OTS treatment was done after the deposition of nominally 5-nm thick Ag layers on the substrates, followed by the growth of 40 nm pentacene thin films and electrodes. For type C devices, the device configuration was in the form of pentacene/Ag NPs/pentacene. The thickness of the first and the second pentacene layers were varied such that the total thickness of the pentacene layers was 40 nm. Here, OTS treatment was done before the first pentacene layer in order to align the pentacene molecules vertically on the substrate, which is different from the thiol molecule SAM for the metal NPs as described in Refs. [9,15]. The Ag layers among type B and type C devices were maintained at a nominal thickness of 5 nm. It has been confirmed by the scanning electron microscopy (SEM) images that the as-deposited 5-nm silver films were discontinuous and isolated NPs were formed, as shown in Fig. 1(b) and (c). The channel lengths (L) and widths (W) of all devices were 50 μm and 1000 μm, respectively. The

output and double-sweep transfer characteristics of the transistors were measured by two LabVIEW-controlled Keithley 2400 sourcemeters under dark and ambient conditions.

3. Results and discussion

The output and transfer characteristics for devices A, B and C15 (referring to pentacene (15 nm)/Ag NPs (5 nm)/pentacene (25 nm)) are shown in Fig. 2(a)–(f). For device A, the output curves are measured with the gate voltage (V_g) varied from 0 V to −60 V (Fig. 2(a)). The output curves exhibit a typical p-channel field-effect transistor behavior, and the field-effect mobility (μ) in the saturation region is obtained by the following equation [16]:

$$I_{ds} = \frac{\mu W C_i}{2L}(V_g - V_{th})^2 \quad (1)$$

I_{ds} is the drain–source current, C_i is the capacitance per unit area of the dielectric layer, and V_{th} is the threshold voltage. The threshold voltage of a device is determined by the x-axis intercept of the tangent of $I_{ds}^{0.5}$ against V_g curve. The carrier mobility for device A is measured to be 0.3 cm^2 V^{-1} s^{-1}, as listed in Table 1. With the drain–source voltage (V_{ds}) maintained at −60 V, when the gate bias sweeps between +60 V and −100 V with either increasing or decreasing V_g, an on/off ratio of 10^4–10^5 is measured and very small hysteresis is obtained (Fig. 2(b)). The hysteresis effect in the type A device can be attributed to the defects at the interface between the SiO_2 and pentacene [17,18]. It is important to mention that all of the measurements were performed in dark at ambient conditions, shortly after the devices were taken out of the thermal evaporation chamber. These procedures helped to minimize potential degradation effects.

For type B device where the Ag NPs were deposited at the interface between the SiO_2 and pentacene, I_{ds} drops significantly as compared with device A (Fig. 2(c)). The lower I_{ds} value is possibly due to the altered morphology of the pentacene thin film by the NPs, which leads to a reduced mobility [3,15]. On the other hand, if a 15-nm thick pentacene is deposited before the deposition of the Ag NPs (device C15), the I_{ds} (Fig. 2(e)) is almost two orders higher than that in device B. It suggests the first few monolayers of pentacene, which dominates on the transport properties of the OFET, are largely unaffected by the deposition of silver NP layer [19]. The hysteresis properties of type B and C devices were investigated by cyclic sweeping of V_g (i.e. from positive to negative and then back from negative to positive). The memory window of the device is defined as the difference of the threshold voltages in the two V_g sweeping direction, i.e. $\Delta V_{th} = V_{th1} - V_{th2}$. For type B device, with Ag NPs embedded at the SiO_2/pentacene interface, a memory window of 30 V is obtained (Fig. 2(d)). In contrast, if Ag NPs are located between two pentacene layers, a memory window as high as 90 V for the C15 device is achieved (Fig. 2(f)), which is three times higher compared with device B. The dependence of ΔV_{th} on V_{ds} is investigated by varying V_{ds} from −5 V to −60 V, and the results are plotted in Fig. 2(g). It can be noted that the memory window remains constant when V_{ds} is varying, which agrees with the observations in Ref. [4]. The carrier mobility of the memory device is also an important parameter, because it governs the operation speed of the memory device. The mobility in the saturation region for C15 device is 0.100 cm^2 V^{-1} s^{-1}, which is almost 20 times higher than that for type B device (0.005 cm^2 V^{-1} s^{-1}), suggesting the good performance of C15 device while comparing with the type B device.

To further investigate the hysteresis phenomena in type C devices, we varied the position of silver NPs by changing the thickness of the bottom pentacene layer while maintaining the total thickness of the pentacene. As summarized in Table 1, the memory window of the type C devices increases with thicker bottom pentacene layer, from 55 V for device C5 to 90 V for device C15. The enhancement of the memory window is attributed to the increasing charge trap density, as the deposited Ag atoms can penetrate into the pentacene layer, forming dopant-like traps [20,21]. To test this hypothesis, the morphology of silver NPs in device B and C15 are shown in Fig. 1(b) and (c), and the areal densities of Ag NPs as evaluated by image processing in MATLAB are 1.2×10^{11} cm^{-2} and 3.3×10^{11} cm^{-2}, respectively. The areal density of Ag NPs can be compared with the number of trapped charges Δn, which can be calculated by [22],

$$\Delta n = \frac{\Delta V_{th} \cdot C'}{e} \quad (2)$$

Because the Ag NPs was deposited above the bottom pentacene layer, so the capacitance of the pentacene should be considered. Therefore, the capacitance per unit area in the current device was obtained by $\frac{1}{C'} = \frac{1}{C_{SiO_2}} + \frac{1}{C_{pen}}$, C_{SiO_2} and C_{pen} are the capacitance per unit area of the SiO_2 and pentacene, respectively. As shown in Table 1, the charge trap density increases with thicker bottom pentacene layer, which agrees with the larger Ag nanoparticle densities observed in the SEM images. For device C15, the number of trapped charges is 6.24×10^{12} cm^{-2}, which represents each Ag NP contributes to around 20 trap states. The trap densities in the current OFET memory devices are comparable to that in inorganic ZnO thin-film transistor

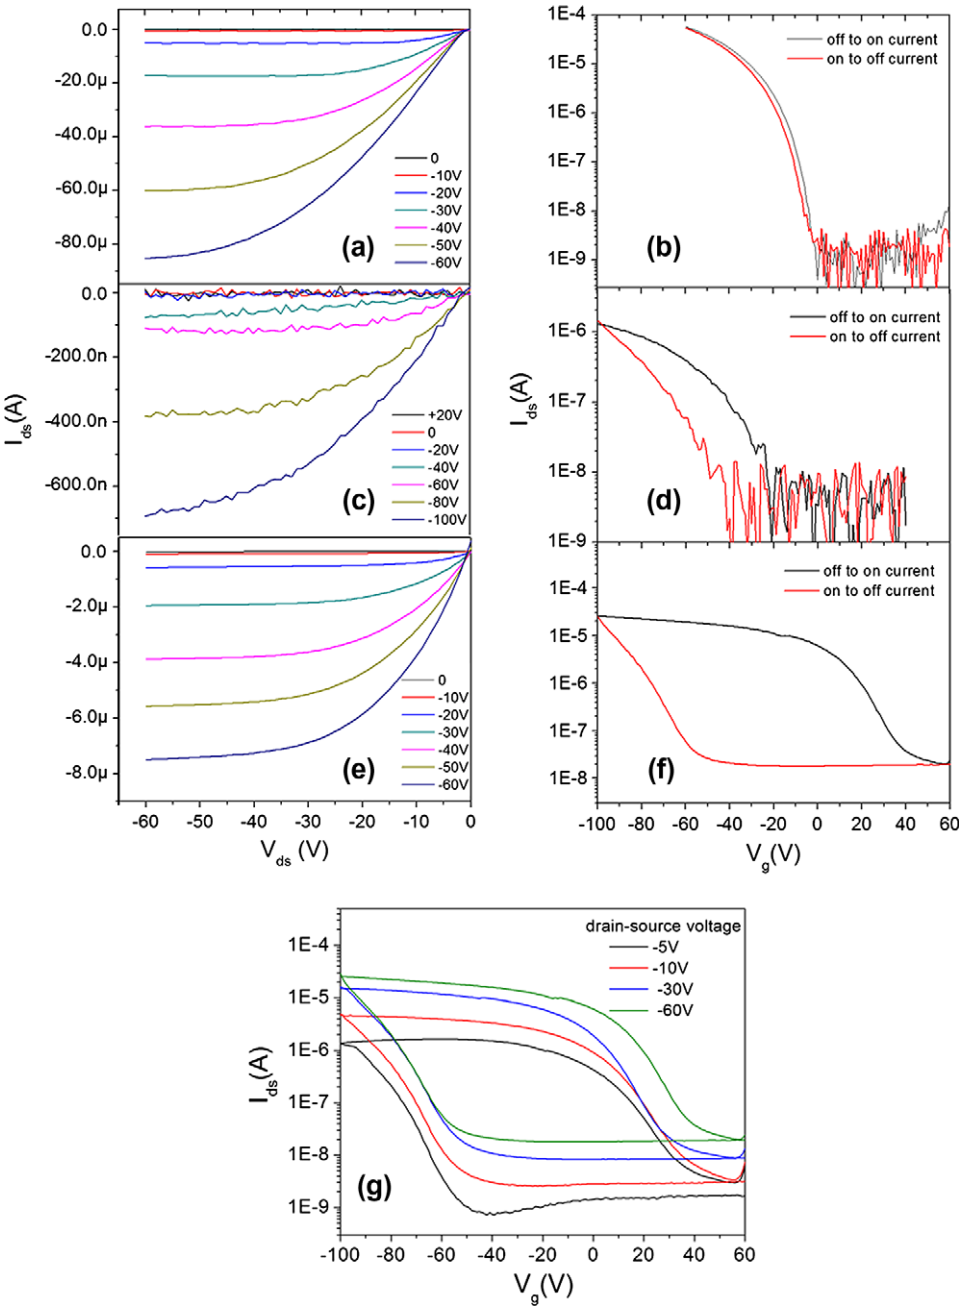

Fig. 2. Output characteristic curves (left column) and transfer curves (right column) for type A device [(a) and (b)], type B device [(c) and (d)] and C15 devices [(e) and (f)]; (g) shows the memory windows of device C15 under different source–drain voltage and no significant variation in the memory windows can be observed.

memory with Ag NPs embedded in the gate insulator/ZnO interface [23].

The memory effect obtained in the current devices is due to the trapping and detrapping of charges. It has been shown that these traps can either be electron or hole traps [24–26]. In order to identify the nature of the traps in our devices, drain current–time measurements are performed in device C15, and the results are shown in Fig. 3(a). During the measurements, the gate voltage is kept at different initial values V_{g0} (−20 V and −40 V) for 100 s, and is switched to $V_g = -30$ V for another 100 s. V_{ds} is maintained at −30 V throughout the whole measurement, and the value of I_{ds} is monitored. To ensure that the device starts at the same initiate state for each measurement, an initialization routine is conducted with $V_g = +60$ V for 60 s at the beginning of each measurement before V_{g0} is imposed on the device. As shown in Fig. 3(a), when the gate voltage is switched from a more negative value ($V_{g0} = -40$ V) to

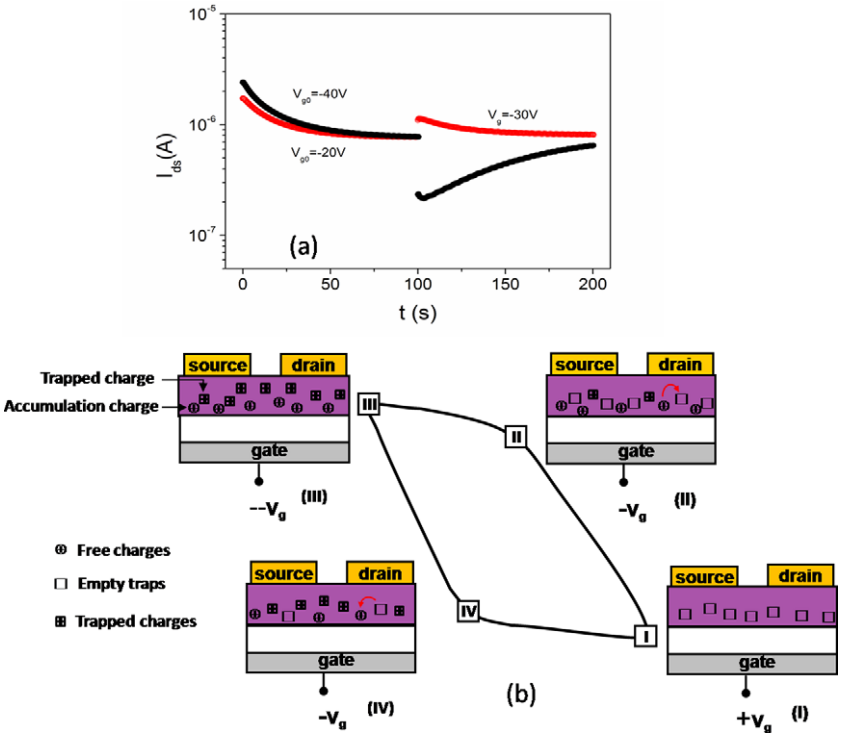

Fig. 3. (a) Current–time measurement with different V_g. (b) schematics for different trap states at different V_g sweeping directions ((⊕) free holes; (□) empty traps; (⊞) trapped holes; red arrow indicate charge trap and detrap directions).

−30 V, the current does not stay constant but increase with time. However, when the gate voltage is switched from a less negative value (−20 V) to V_g = −30 V, the current decreases with time. This response of the I_{ds} under different bias condition provide evidence that the traps in the current memory devices are predominantly hole traps. When V_g switches from −40 V to −30 V, the increasing current is due to the release of the trapped holes which can only be held at more negative V_g [16,27,28]. If electron traps dominate the observed hysteresis, I_{ds} should stay constant because the traps are emptied at more negative gate value, and no electrons can be released after switching to a less negative V_g [29].

A potential mechanism which explains the measured memory effect is provided as follows. When a large negative V_g is applied, holes are injected into the traps, and these trapped charges generate an internal electric filed opposite to the applied gate voltage, causing the screening effect. Therefore a higher negative V_g is required to turn on the device, resulting in a shift of threshold voltage to a more negative value [30,31]. Similarly, when a large positive V_g is applied, holes would be detrapped from the trap centers. Such trapping and detrapping processes result in the shift of transistor threshold voltage, hence forming the memory window. The drain–source current at different V_g sweeping directions are further explained by the schematic diagram as shown in Fig. 3(b). At the beginning of the sweeping cycle, a large positive gate bias is applied to the device and the traps are emptied (state I). During the positive to negative sweep direction (from state I to II), more and more holes would be trapped at the trap centers. When the trapped centers are filled up by the holes, the screening effect will become important and further increase the magnitude of V_g would not cause a significant increase of free holes and the drain–source current (state II–III). During the negative to positive sweep (from state III to IV), the trapped holes would released slowly and more holes are still in trap centers [18,27,29], therefore the drain–source current contributed from the free holes decrease significantly (state IV).

4. Conclusions

In summary, we demonstrated a novel OFET-based memory devices based on the Ag NPs embedded into pentacene layers. By varying the location of the Ag NPs, the memory effect was adjustable and the maximum memory window of 90 V has been obtained, which is a 300% improvement compared with the conventional structure where Ag NPs are directly deposited on silicon dioxide. The increased memory effect results from different trap densities induced by the Ag NPs, and hole trap mechanism is found to dominate the hysteretic behavior. By comparing the deposited Ag NPs density on the pentacene, it can be estimated that each nanoparticle contributes to around 20 traps states. This structure demonstrates potential for memory applications in organic thin-film transistors and integrated circuits.

when an inorganic gate insulator is applied. For example, it was observed in the pentacene/SiO_2 interface where hydroxyl (OH) group was proved to provide electron traps [23]. Ambient moisture diffusion into the interface between the pentacene and the gate dielectric [24] layer along with impurities, defects as well as grain boundaries in semiconductor [25,26] also act as charge traps. A clockwise hysteresis is also associated with a polymeric gate insulator, and is often induced by the charge injection from the gate electrode and trapping inside the dielectric [27]. The dielectric bulk trapped electrons induce more holes in the channel and result in larger drain current during the bias sweep loop, contributing to clockwise hysteresis [28]. Lee et al. added SiO_2 buffer layer in between polymer insulator and gate electrode and proved the evidence of the electron injection from the gate electrode into the dielectric [21]. Additionally, residual dipole or mobile ions cause slow polarization in the bulk of the organic dielectric. The dipole reorientation process makes the drain current fall behind the bias sweep and a clockwise hysteresis appears [29]. Under a negative gate bias, migration of ions from internal impurities in polymer can also induce a similar effect [30].

Another advantage of the polymeric insulator is its flexibility [6] and flexible OFETs have been reported by many groups on a polymer substrate such as poly ethylene terephthalate (PET) and poly ethylene naphthalate (PEN) with a conductive organic electrode (PEDOT:PSS) and a polymer insulator (PVP, PVA, PS) [31–33]. On the other hand, stainless steel substrate is one of the flexible substrates with high corrosion resistance, high conductivity and thermal stability [34,35]. Its excellent thermal conductivity as a metal is helpful for the thermal management of the organic device. Through chemical mechanical polishing (CMP) process, a stainless steel substrate can have smooth enough surface to serve as a gate electrode [36].

In this report, OFETs were fabricated using a cross-linkable high-*k* CEP/PMMF blend with various mixing ratios as a dielectric to achieve OFETs with low voltage, low hysteresis operation with high μ and steep inverse subthreshold slope (SS). Stainless steel substrate was studied as a gate electrode and as a substrate to fabricate flexible devices. Electrical performance of OFETs on N+Si and stainless steel were also compared and bending effect on the device performance was studied.

2. Experimental

Fig. 1a and b shows the molecular structure of CEP (cyanoethylated pullulan) and PMMF [poly(methylated melamine-co-formaldehyde)] and the structure after cross-linking. Fig. 1c shows the schematic of MIM (metal–insulator–metal) structure, MIS (metal–insulator–semiconductor) capacitor and a top-contact pentacene OFET. The cross-linkable solution was prepared in a co-solvent (*N*,*N*′-dimethylformamide:acetonitrile 1:1) with 5 wt.% CEP ($M_w \sim 489{,}000$, Shin Etsu Chemical Co.) and various amount of PMMF (Aldrich, $M_n \sim 511$). PMMF/CEP ratios were set at 10%, 30%, 50%, and 70% to study the effect of the cross-linker content on the film properties and device performances. The solid films were formed with spin coating on piranha cleaned p-type (for MIS capacitors) or heavily doped n-type (for MIM structures and OFETs) silicon wafers at 3000 rpm for 1 min inside the high purity Ar-filled glove box. The film was annealed for 1 h inside a vacuum oven at 200 °C. The baked films were referred to as CEPM10, CEPM30, CEPM50 and CEPM70 for each PMMF content. After forming the dielectric, a 60 nm thick pentacene active layer (Aldrich Chemical Co., without purification) was deposited in a thermal evaporator with a deposition rate of 0.2–0.3 Å/s at a substrate temperature of 50 °C. Then 70 nm thick Au source and drain electrodes were deposited through a shadow mask, using the thermal evaporator; the device channel length and width are 150 and 1500 μm, respectively. For MIM structures and MIS capacitors, Au top (or bottom) electrodes were deposited with evaporation through a shadow mask to make a circular dot area of 8.02×10^{-4} cm^2.

Fourier Transform Infrared (FT-IR) spectra of solid films were recorded in a transmission mode with Nicolet 6700. Contact angle measurements were conducted using Model CA-A face contact angle meter (Kyowa Kaimenkagaku Co., Ltd.). Ultraviolet photoelectron spectroscopy (UPS) was used to calculate the work functions of the gate electrodes. The thickness of CEPM films were measured by ellipsometry. Capacitance–voltage (*C*–*V*) characteristics of the MIS capacitors were measured using HP 4284A Precision LCR meter (Agilent Tech.) at 1 MHz. The electrical characteristics of the pentacene FETs were measured using HP 5270A (Agilent Tech.) in a dark box under ambient conditions. To study the roughness of the dielectric surfaces, as well as pentacene morphology, atomic force microscopy (AFM) was adopted using a Dimension™ 3100 microscope (Digital Instruments). The in-plane X-ray diffraction (XRD) was carried out at the 3C2 X-ray scattering beamline of the Pohang Light Sources (PLS) at Pohang Accelerator Laboratory (PAL).

3. Results and discussion

3.1. Properties of CEPM and pentacene films

FT-IR spectra of the solid film in Fig. 2 were recorded in a transmission mode to monitor the chemical changes in the cross-linking reaction as demonstrated in Fig. 1b. The observed band between 3100 and 2800 cm^{-1} was assigned to the C–H (CH_x) stretching vibrations. As the PMMF content increased, slightly thicker film was obtained from higher material concentration, giving more intense CH_x peak. In contrast, O–H stretching vibration peak intensity centered at 3480 cm^{-1} decreased from the OH group removal through cross-linking. The contact angle of deionized water on the film surface was measured as summarized in Table 1 [37].

AFM images of the insulator surface were obtained as shown in Fig. 3a–d. The film became rougher when more PMMF content was added with root-mean-square (RMS) roughness from 0.35 to 1.27 nm, which affected pentacene morphology. AFM images of 60 nm thick pentacene films on different dielectrics are displayed in Fig. 3e–h. The pentacene grain size showed decreasing trend from CEPM10 to CEPM70 because the surface roughness becomes a more

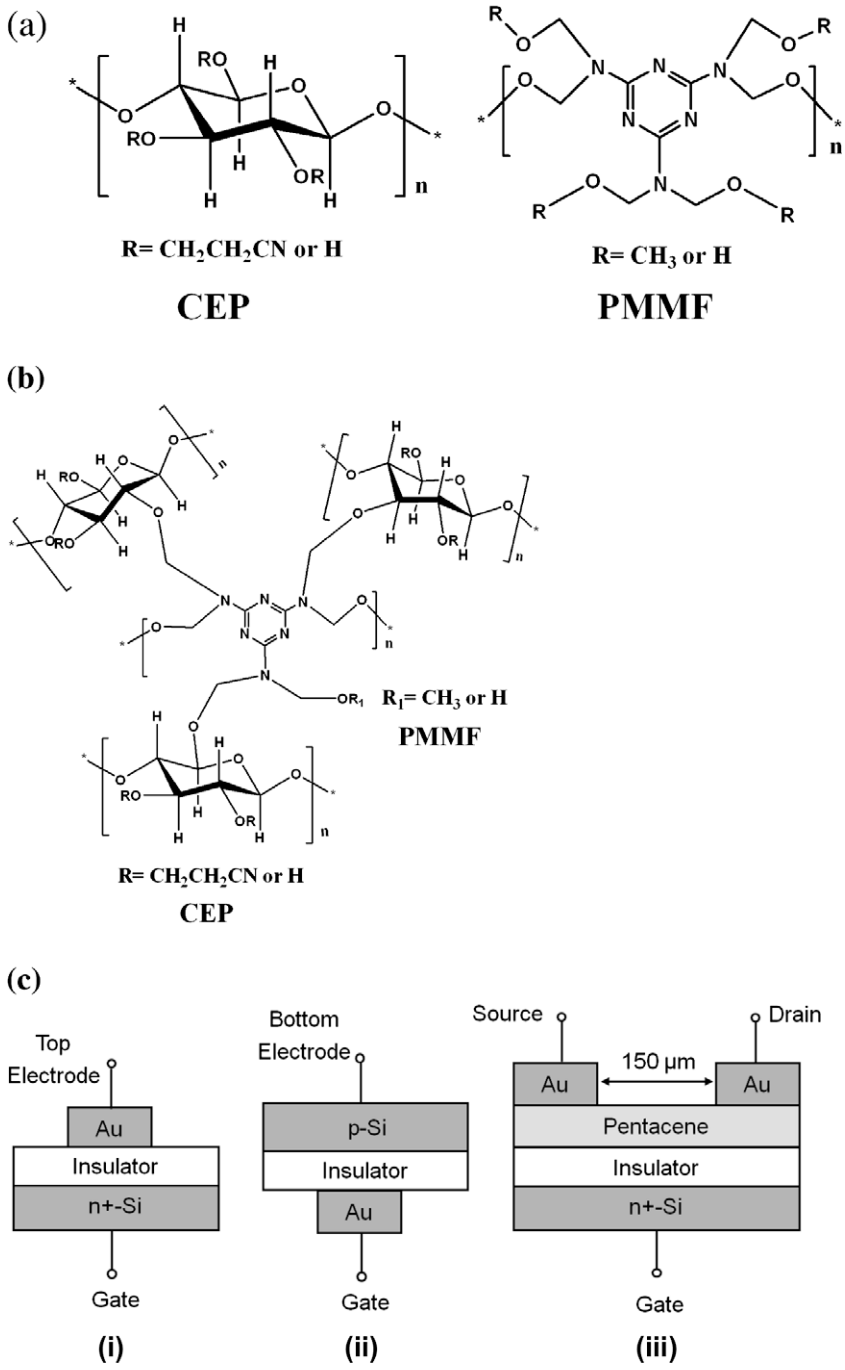

Fig. 1. (a) Chemical structures of CEP and PMMF, (b) structure formed by cross-linking CEP polymer with PMMF, and (c) schematic of the device geometries of (i) Au/CEPM/n+-Si MIM structure, (ii) Au/CEPM/p-Si MIS capacitor and (iii) top-contact/bottom-gate OFET.

effective factor than surface polarity. Although pentacene morphology would be affected, the RMS roughness below 1.51 nm was reported to have little effect on other gate dielectric properties such as capacitance and surface polarity, and so on μ [38].

XRD peak was recorded for 60 nm pentacene film to investigate the molecular ordering in a symmetric reflection coupled θ–2θ arrangement with a synchrotron radiation X-ray source. Fig. 4 exhibits a series of XRD patterns corresponding to the (0 0 l) planes of the thin-film phase of pentacene, and indicates that the ordering of layered structure of pentacene depends on the PMMF contents, which may determine μ of OFET devices [39]. Vacuum evaporated pentacene thin films typically consist of two

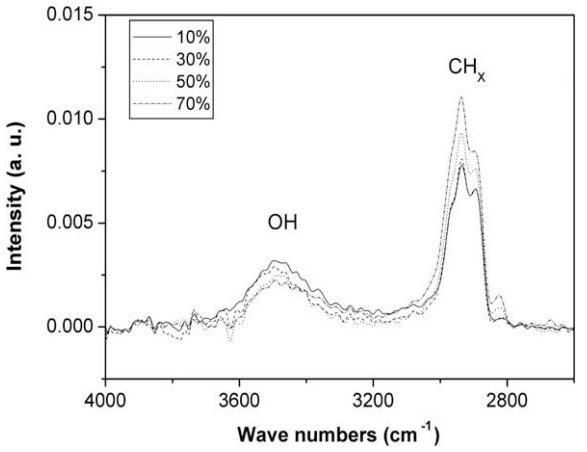

Fig. 2. FT-IR spectra of dielectrics in transmittance mode for CEPM10, CEPM30, CEPM50, and CEPM70.

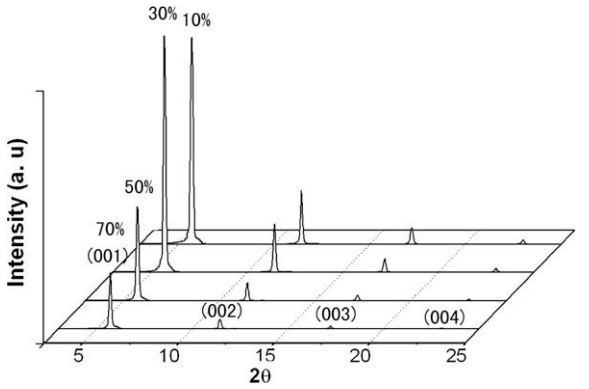

Fig. 4. XRD patterns of 60 nm pentacene films deposited on the gate dielectric of CEPM10, CEPM30, CEPM50, and CEPM70.

crystallographic phases, single crystal phase (bulk phase) and thin-film phase. Dimitrakopoulos et al. found the new pentacene phase with d_{001} of 15.4 Å, which is different from the well-known single crystal phase ($d_{001} \sim 14.1$ Å) [40]. Since pentacene molecules stand vertically on a substrate in thin-film phase, better charge transport and higher mobility can be expected. The surface polarity dependent crystallinity of pentacene on CEPM30 (high contact angle) vs. that of CEPM10, CEPM50, and CEPM70 (low contact angles) correlates well to the improvement in μ of OFETs with CEPM30 vs. other dielectrics as will be discussed in the later part of this paper.

Table 1
Thickness, contact angles, and parameters extracted from *C–V* characteristics.

PMMF/CEP (%)	Thickness (nm)	C.A. (°)	C_i (nF/cm^2)	k	ΔV_{FB} (V)

30	211.2	68.0	52.5	13.4	0.3
50	224.6	64.4	42.3	11.9	0.3
70	251.4	63.0	35.5	10.7	0.5

3.2. MIM structures and MIS capacitors

The leakage current density and gate voltage (*J–V*) characteristics of CEPM dielectrics are presented in Fig. 5. The

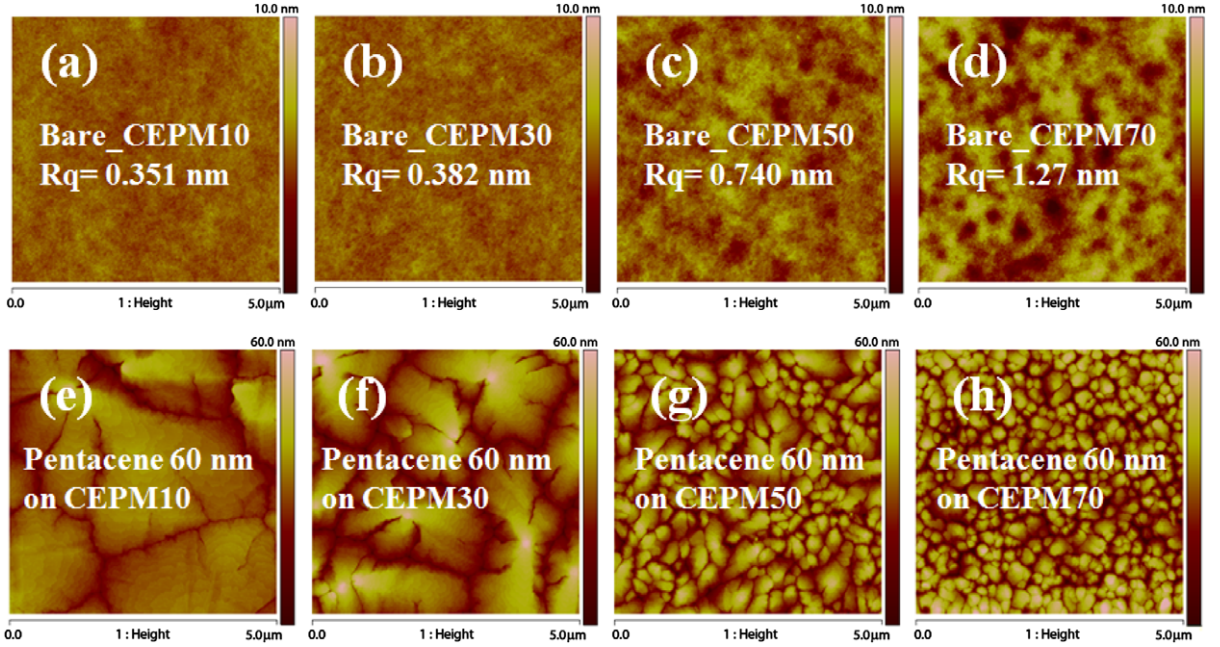

Fig. 3. 5 × 5 μm^2 AFM images of dielectric surface, (a) CEPM10, (b) CEPM30, (c) CEPM50, and (d) CEPM70, and 60 nm pentacene films grown on (e) CEPM10, (f) CEPM30, (g) CEPM50, and (h) CEPM70.

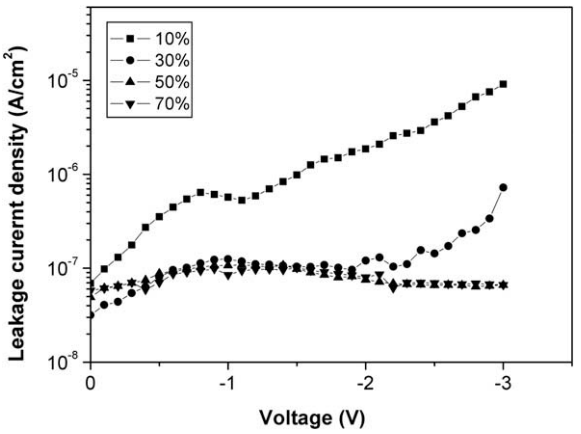

Fig. 5. *J–V* characteristics of Au/CEPM/n+-Si MIM structures with CEPM10, CEPM30, CEPM50, and CEPM70.

leakage current density of CEPM10 is as high as 10^{-5} A/cm^2 at an applied voltage of -3 V, while CEPM50 shows the leakage current density by more than two orders of magnitude lower to 5×10^{-8} A/cm^2. The significant reduction in the leakage current density from CEPM10 to CEP50 is likely from a better-formed net structure via a more effective cross-linking reaction. The tiny increase of leakage in CEPM70 indicates an excess of curing agent amount, and extra cross-linking agent might negatively affect on the film robustness, since PMMF itself cannot form a smooth film.

C–V characteristics of the Au/CEPM/p-Si MIS capacitors were measured to comparably study the hysteresis behavior at 1 MHz, and parameters are summarized in Table 1. The MIS capacitors with CEPM30 and CEPM50 showed negligible hysteresis behavior as measured by ΔV_{FB}, as shown in Table 1. This might attribute to effective removal of charge traps in the dielectrics, as will be discussed in a later part in this paper. The capacitance density (C_i) are 60.9, 52.5, 42.3, and 35.5 (nF/cm^2) for CEPM10, CEPM30, CEPM50, and CEPM70, respectively. The capacitance density is related to *k* value and the thickness of the dielectric, as indicated in the following equation [7],

$$C_i = \varepsilon_o \frac{k}{t} \quad (1)$$

In this equation, *k* is dielectric constant, *t* is thickness of the dielectric film, and ε_o is the permittivity of vacuum. Both thicker films from 206.9 nm for CEPM10 to 251.4 nm for CEPM70, and the lower *k* values from 15.2 to 10.7 lowered the capacitance. The change in *k* values attributes to the addition of different amount of low-*k* component PMMF, as expected from the following power–law relationship [41],

$$k^\beta = k_1^\beta + (1-\varphi)k_2^\beta \quad (2)$$

where *k*, k_1, and k_2 are the dielectric constants of cross-linked film and that of the two components, respectively. φ is the volume fraction of component one and β is a parameter representing the shape and orientation of the filler, which is in the range of [−1, 1] [42]. CEP/PMMF system possessing more low-*k* PMMF component tends to give lower *k* value.

3.3. Organic field-effect transistors

Top contact OFETs were fabricated by sequentially evaporating pentacene and Au through shadow masks

onto the cross-linked dielectrics. As can be observed from the device characteristics in Fig. 6, high quality devices with operating voltages as low as −2 V were achieved by employing the CEPM dielectrics. Electrical parameters are extracted from the following equations [31,43], and summarized in Table 2.

$$I_{D,sat} = \frac{W}{2L}\mu C_i (V_G - V_{th})^2 \quad (3)$$

$$S \equiv dV_G/d(\log I_{SD}) \quad (4)$$

Here, $I_{D,Sat}$ is the drain current in the saturated regime, W/L is the channel width/length, μ is the mobility, V_G is the gate voltage, and V_{th} is the threshold voltage. Also S is the inverse subthreshold slope (SS) and I_{SD} is the current between source and drain at a given gate voltage.

OFET-CEPM30 shows the highest μ of 2.16 cm^2/V s under a 2 V operation. OFET-CEPM30 showed on/off current ratio (I_{on}/I_{off}) of 2.4×10^3, SS of 0.163 V/dec, and V_{th} shift (ΔV_{th}) of 0.10 V. Although an relatively high μ value has been achieved with OFET-CEPM30, the other electrical parameters are not as good as OFET-CEPM50, which has a μ of 1.83 cm^2/V s $I_{on}/I_{off} \sim 5.0 \times 10^4$, a low SS of 0.117 V/dec, and small ΔV_{th} of 0.01 V. The improvement of the I_{on}/I_{off} using 50% PMMF is from the decrease in leakage current density as shown in Fig. 5.

The significant SS difference attributes to a decreased charge trap density at the pentacene/dielectric interface and inside the insulator. We estimated the upper limit of the charge trap density in the devices using Eq. (5) [44]

$$N_{trap}^{max} \approx \left[\frac{qS\log(e)}{kT} - 1\right]\frac{C_i}{q} \quad (5)$$

Here q is the electronic charge, k is Boltzmann's constant, and C_i is the capacitance/area of the gate dielectric. Using Eq. (5), we estimate an upper limit of trapped charge (N_{trap}^{max}) to be $9.55 \times 10^{11}/cm^2$, $5.57 \times 10^{11}/cm^2$, $2.48 \times 10^{11}/cm^2$, and $2.51 \times 10^{11}/cm^2$ for CEPM10, CEPM30, CEPM50, and CEPM70 devices, respectively. The consistency of charge traps and contact angle measurements strengthens the arguments that the origin of the hysteresis is from charge injection and trapping, which can be minimized by suitable amount of cross-linking agent. The SS change is also in consistency with the ΔV_{th}, which is another measure of trap states (N_{trap}), as compared in Fig. 7c and Table 2.

OFET-CEPM10 exhibits μ of 0.78 cm^2/V s, I_{on}/I_{off} of 1×10^3, a SS of 0.212 V/dec, and ΔV_{th} of 0.17 V. One factor for the low μ was high polarity of the dielectric surface as measured by contact angles of deionized water, which interacted with pentacene modules when growing film. Another very important reason was the high leakage (recorded with transfer characteristic, 1.44×10^{-7} A at −2 V) of the polymer film, which is almost one third of the on current (4.72×10^{-7} A), causing significant degradation of μ.

Fig. 8d shows the comparative trends of dielectric constant and on current of the transfer curves. Higher dielectric constant generally gives higher capacitance, which might generate a higher on current, while the low on current of OFET-CEPM10 is because of the high leakage current density and low μ.

All the above trends were observed more clearly under 3 V operation, as summarized in Table 2. Especially, the OFET-CEPM50 showed high I_{on}/I_{off} of 3×10^5, ΔV_{th} as low as 0.01 V and very sharp SS value of 0.066 V/dec, which might be the lowest SS value with polymer gate insulator to date. This exceeded our previous report approaching the theoretical minimum of 0.057 V/dec [20].

3.4. Flexible devices and lower voltage operations

To probe the possibility of utilizing CEPM-OFETs in flexible displays, stainless steel substrate was used as a gate substrate. The bending test was conducted with the device bended along the channel direction by attaching the substrate on the out-surface of a glass arc, whose diameter was 4.5 cm. Electrical characteristics were obtained with the bended device. The process has been described in detail in another paper [36]. As shown in Fig. 8a and b, only a slight degradation in μ and I_{on}/I_{off} was observed during the bending test showing a good mechanical robustness of the polymeric cross-linked gate insulator. By comparing the curves from stainless-OFET and N+Si-OFET, a positive V_{th} shift was observed. In this sense, stainless steel substrate not only provides flexibility, but also improves the V_{th}. As can be observed in Fig. 8a, stainless-OFET-CEPM50 gives higher on current, and better I_{on}/I_{off}, which attributes to the positively shifted V_{th}. UPS spectra of bare N+-Si and stainless steel substrate gates were taken to calculate work functions, as shown in Fig. 9. The work function data were obtained from the following equation [45,46],

$$\phi = h\upsilon(= 21.2\ \text{eV}) - E_{cutoff} + E_{Fermi} \quad (6)$$

where ϕ, E_{cutoff}, and E_{Fermi} are the work function, secondary electron cutoff and Fermi level, respectively. The photon

energy of the UPS light source (helium I irradiation) is 21.2 eV. The work function increase from 4.29 to 4.53 eV

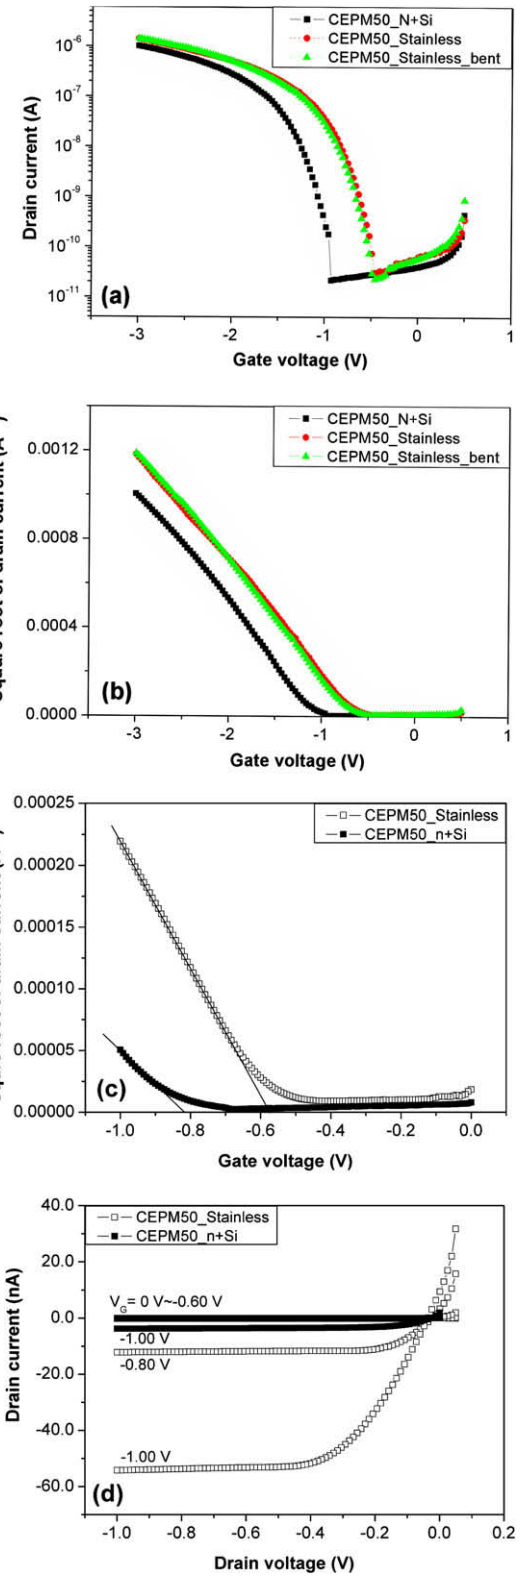

Fig. 8. Electrical characteristics of low-voltage operated OFETs on N+-Si and stainless steel substrate, (a) comparison of transfer curves, (b) square root of drain current vs. gate voltage, (c) V_{th} shift with 1 V operation and (d) output characteristics comparison with 1 V operation.

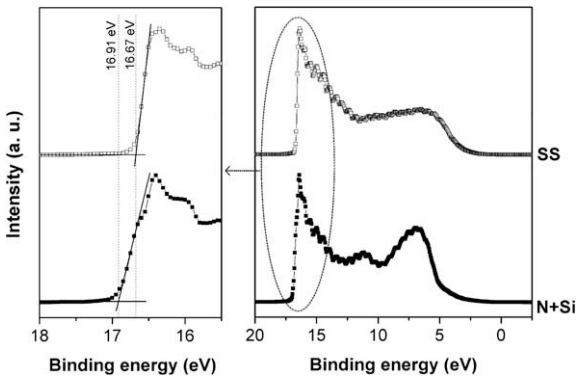

Fig. 9. UPS spectra of N+Si and stainless steel substrates surfaces.

for N+-Si and stainless steel substrate gives comparably positive V_{th} shift, as has been discussed in detail in some literature [47–49].

The slight positive V_{th} shift may have negligible effect if the operating voltage is high, while in a low-voltage operation, the effect would be quite obvious to improve the output current. In the case of low-voltage operation, if the V_{th} is too close to the maximum of the gate voltage sweep, the device cannot be operated well. The improvement in V_{th} becomes essential to improve the drain current. Fig. 8c and d show significant improvement in V_{th} and output curves for -1 V operation by changing N+Si to stainless steel substrate. The lower μ in N+Si device was caused by the very small difference between V_{th} (-0.83 V) and the maximum of the gate voltage sweep range (-1 V).

4. Conclusions

OFETs were fabricated using spin-coated CEP/PMMF blend at various ratios as a gate dielectric. The high-k polymer CEP was thermally cured at 200 °C by the cross-linking agent PMMF. The highest μ was obtained using OFET-CEPM30, while the best I_{on}/I_{off}, SS and reliability with the smallest hysteresis were obtained with OFET-CEPM50. The electrical performance was improved with the low surface wettability, low leakage current density of dielectric films, as well as the good crystallinity of pentacene thin films. In low-voltage operation of 1 V, devices on stainless steel substrate showed much better electrical performance than on an N+-Si substrate. It was due to the V_{th} shift, which resulted from the higher work function of the stainless steel gate electrode. The thin-film devices showed good electrical properties even with bending at considerable angles. These results indicate that cross-linked high-k dielectric is a promising candidate for low cost, low power consumption, reliable and flexible electronics.

of the metal complex emitter in the polymer host must be improved.

Chemical modification of the phosphorescent green iridium(III) complex *fac*-tris(2-phenylpyridyl)iridium(III) [Ir(ppy)$_3$], which has been shown to have a high photoluminescence efficiency and relatively short radiative lifetime, has led to some improvement in the solubility. For example, methylation of Ir(ppy)$_3$ on the ligand phenyl ring at the position *para* to the ligand pyridyl ring, i.e. tris[2-(4-tolyl)pyridyl]iridium(III), [Ir(mppy)$_3$], enhances the solubility. However, although the solubility is improved, this approach still does not fully prevent the aggregation of the emissive molecules. This is due to Ir(mppy)$_3$ still having only poor to at best moderate solubility in organic solvents commonly used for processing polymer hosts such as toluene and chlorobenzene. The range of concentrations that the complex is used as a guest in a polymer host in which a uniform dispersion is achieved is therefore quite limited. Moreover, the low solubility of Ir(mppy)$_3$ makes it difficult to accurately control the doping concentrations and the long mixing time required for dissolution makes the fabrication process rather time-inefficient.

Dendrimer OLEDs offer the advantages of combining the high efficiency of small molecule OLEDs and the solution processing properties of polymer OLEDs [5,6]. High efficiency dendrimer OLEDs have been achieved when the dendrimer layer has been deposited by spin-coating, and an evaporated electron-transport layer has been used [7–9]. Lately, blade coating has shown potential as an alternative processing method to spin-coating and ink-jet printing. It also opens up the possibility of multi-layer OLEDs, in which all the layers are deposited by solution processing [10] without the use of post UV-cured polymerization of soluble cross-linkable precursors [11]. In general multi-layer structures are required to balance electron and hole currents for achieving highly efficient OLEDs.

In this Letter we use highly soluble dendrimers, p-G1-Ir and m-G1-Ir, as the light-emitting guest (chemical structures shown in Fig. 1c). The host is a mixture comprised of poly(9-vinylcarbazole) (PVK), and charge-transport materials, *N,N′-diphenyl-N,N′*-[bis(3-methylphenyl)]-[1,1′-biphenyl]-4,4′-diamine (TPD) and 2-(4-biphen-4′-yl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD) [12]. The p-G1-Ir and m-G1-Ir dendrimers consist of a *fac*-tris(2-phenylpyridyl)iridium(III) [Ir(ppy)$_3$] core, first generation biphenyl-based dendrons, and 2-ethylhexyloxy surface groups [13,14]. The synthesis of the dendrimers has been previously reported [15]. As shown in Fig. 1c, the difference between p-G1-Ir and m-G1-Ir is that p-G1-Ir has the dendron attached on the ligand phenyl ring *para* to the pyridyl ring whereas m-G1-Ir has the dendron attached on the ligand phenyl ring *meta* to the pyridyl ring [7,15,16]. Unlike most phosphorescent emitters based on small molecules, the phosphorescent dendrimers have superb solubility in common organic solvents due to the surface groups attached to the distal ends of the dendrons. In addition, the dendrons act as rigid spacers that reduce the intermolecular interactions of the emissive cores that can cause luminescence quenching [5,6,17]. Indeed, there is dramatic difference in solubility between the dendrimers used and Ir(mppy)$_3$. The solubility of p-G1-Ir is more than

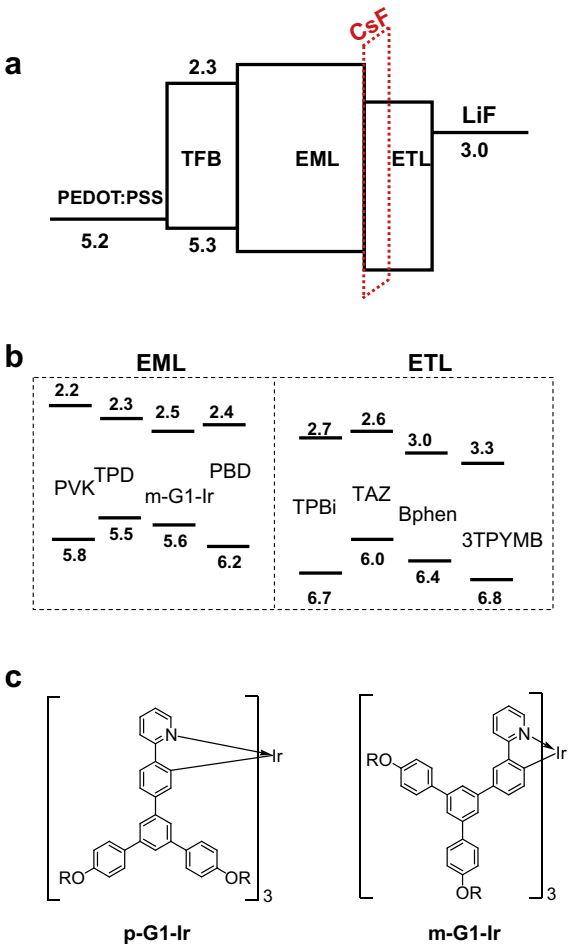

Fig. 1. (a) Schematic diagram of the OLED structures employed. The cathodes are CsF/Al for the devices without the ETL and LiF/Al for those with the ETL. (b) Energy diagram of the materials in this work, the numbers are in eV. (c) Structures of p-G1-Ir and m-G1-Ir.

10 wt.% both in toluene and chlorobenzene, whereas Ir(mppy)$_3$ is less than 0.5 wt.% in chlorobenzene and it is virtually insoluble in toluene. Bi-layer OLEDs with CsF/Al cathode and tri-layer OLEDs with an electron-transport layer (ETL) and a more stable LiF/Al cathode were fabricated with the dendrimers as the guest in a PVK:TPD:PBD blend host. The electron transport materials were deposited by a newly developed blade-coating method to avoid dissolution [10]. The ETL materials studied included 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBi), 3-(4-biphen-4′-yl)-4-phenyl-5-(4-*tert*-butylphenyl)-1,2,4-triazole (TAZ), 4,7-diphenyl-1,10-phenanthroline (Bphen), and tris-[3-(3-pyridyl)mesityl]borane (3TPYMB). High efficiencies were achieved for dendrimer weight concentrations of up to 33% with easy concentration control and instant dissolution during fabrication. An efficiency of 38 cd/A (at 5 V) and luminance of 27,000 cd/m^2 (at 14.5 V) were obtained in the bi-layer devices prepared by blade coating. Although direct comparison is not possible as different host materials have different solubility for the studies, current device efficiencies are higher than

those previously reported for similar bi-layer device fabricated from spin-coating [18]. In addition, the amount of dendrimer used in the emissive layer is less than that of previous reports, making the blade-coating fabrication more cost effective.

2. Experimental

Fig. 1 shows the OLED device structures used in the study. To fabricate the OLEDs, the indium-tin-oxide (ITO) substrate was first precleaned in deionized water with detergent, which was purchased from Alconox, and then UV–ozone treated. In order to use the blade-coating technique it was necessary to have large ITO substrates (7 cm × 8 cm). A 50 nm poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS, CLEVIOS™ P VP AI 4083) was then spin-coated onto the ITO substrate and annealed at 100 °C for 40 min in vacuum. To improve hole injection in the devices [19,20], poly[(9,9-dioctylfluorenyl-2,7-diyl)-*co*-(4,4′-{*N*-[4-*s*-butylphenyl]}diphenylamine)] (TFB) in toluene (1 wt.%) was blade-coated on top of the PEDOT:PSS and spin-rinsed with toluene after annealing at 180 °C for 40 min in vacuum to leave a TFB layer with thickness of about 5 nm. The light-emitting solution was prepared by mixing host solution, PVK:PBD:TPD in chlorobenzene (2 wt.%), and dendrimer guest solution, dendrimer in toluene (2 wt.%), and then blade-coated onto the TFB layer to give a 70 nm thick 'light-emitting' film. In the blend system, dendrimer:PVK:TPD:PBD, the ratio of TPD:PBD was fixed at 9:24 and the ratio of dendrimer:PVK was tuned. The ratios of p-G1-Ir:PVK were 1:66, 2:65, 6:61, 13:54, and 33:34. The ratios of m-G1-Ir:PVK were 2:65, 6:61, 13:54, and 33:34. The emissive layer was annealed at 80 °C for 60 min in vacuum. To complete the devices without an electron-transport layer, a 2 nm layer of CsF was deposited, followed by a 100 nm capping layer of Al. The latter two layers were deposited using thermal evaporation at a pressure of 10^{-6} Torr. For the devices with electron-transport layers, TPBi, TAZ, Bphen, and 3TPYMB, were dissolved in *n*-butanol (0.5 wt.%) and blade-coated on top of the emissive layer (dendrimer:TPD:PBD:PVK with a ratio of 6:9:24:61) to give thicknesses of order 20 nm [12]. Dissolution between the ETL and emissive layer was avoided by using the newly developed blade-coating method with *n*-butanol as the solvent. A thin (≈1 nm) layer of LiF was evaporated under the pressure of 10^{-6} Torr and covered with a 100 nm of Al to form the cathode and complete the devices. The active area of each pixel was 4 mm^2. *I–L–V* characteristics were measured with a Keithley 2400 source meter with the light output integrated with a PR650 photometer. PVK with a molecular weight (M_w) of 1,100,000 was purchased from Sigma–Aldrich. TPD, PBD, TPBi, TAZ, BPhen, and 3TPYMB were obtained from Luminescence Technology Corp, and TFB was purchased from American Dye Source.

3. Results and discussion

Figs. 2 and 3 show the bi-layer device characteristics and emission spectra based on p-G1-Ir and m-G1-Ir, respectively, and using CsF/Al as cathode. In general, the

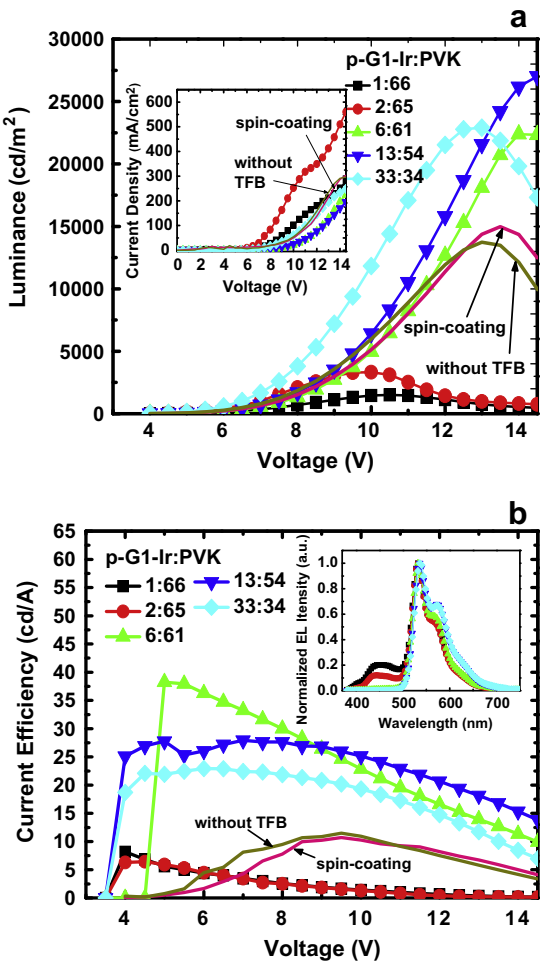

Fig. 2. Device performance of p-G1-Ir:PVK:TPD:PBD. (a) The luminance and the inset is the current density *versus* voltage. (b) The current efficiency *versus* voltage and the inset shows the electroluminescent spectra at 1000 cd/m^2. The ratio of TPD:PBD was fixed at 9:24. The performance of the device without TFB layer is indicated by dark yellow line, while the performance of the device fabricated by spin-coating instead of blade coating is indicated by pink line. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

luminance and efficiency were not high at low dendrimer doping concentrations in the PVK (i.e. 1:66 and 2:65 with a fixed ratio of TPD:PBD of 9:24). This could be due to the fact that there were not enough emitters in the host to harvest the excitons, which is supported by the emission spectra where there is blue emission from the host (Fig. 2b). The blue emission at the wavelengths near 400 nm can be attributed to the TPD or PVK host while the broad emission peaking at 470 nm may originate from the $(TPD + PBD-)^*$ exciplex [12]. Interestingly, the blue emission from m-G1-Ir based devices is not as obvious as those of p-G1-Ir at the same doping concentration (2:65) (Fig. 3). Given that the two dendrimers have exact the same molecular weights and the same dendrimer doping concentrations, the smaller amount of blue emission from the (2:65) device could be due to the different shape of the dendrimers. The different shape results from the dendrons

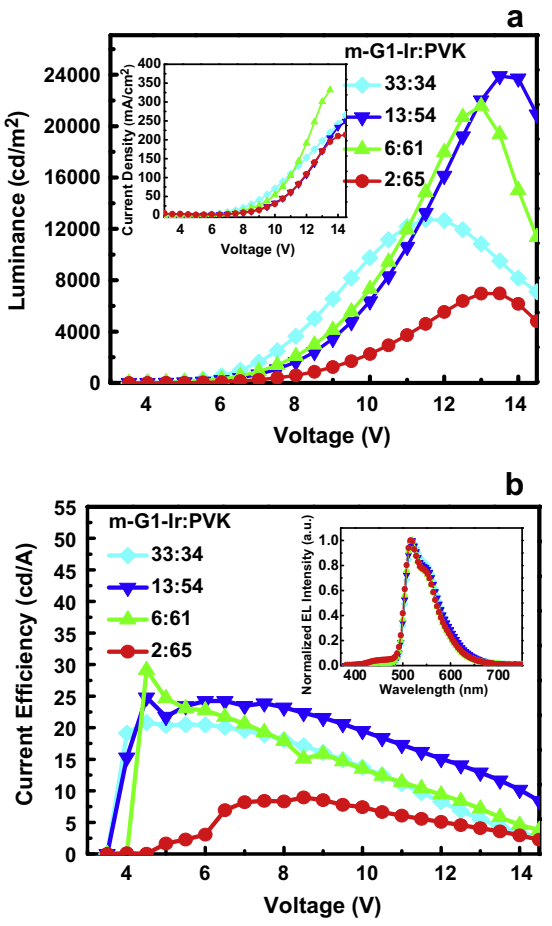

Fig. 3. Device performance of the m-G1-Ir:PVK:TPD:PBD. (a) The luminance and the inset shows the current density *versus* voltage. (b) The current efficiency *versus* voltage and the inset is the electroluminescent spectra at 1000 cd/m^2. The ratio of TPD:PBD was fixed at 9:24.

being attached to different positions on the ligand phenyl ring of the emissive core, which in turn could give rise to a different film morphology. The fact that m-G1-Ir has a larger effective hydrodynamic radii is evidence of the difference in shape between the two materials [15].

Both the luminance and efficiency significantly increased as the dendrimer concentrations increased above the ratio of 6:9:24:61 [dendrimer:TPD:PBD:PVK (TPD:PBD:PVK = host)]. The peak luminance of 22,900 cd/m^2 (at 13 V), 27,000 cd/m^2 (at 14.5 V), and 22,380 cd/m^2 (at 14 V) was achieved for p-G1-Ir:PVK with blending ratios of 33:34, 13:54, and 6:61, respectively. The current efficiency was around 22–38 cd/A for the mixing ratios of dendrimer:PVK between 33:34 and 6:61, showing that the dendrimers can be used in rather high blending concentrations due to the uniform distribution in the emissive layer with less aggregation and self-quenching. The highest external quantum efficiency is 10.2% at 5 V with a brightness of 50.1 cd/m^2 for p-G1-Ir:PVK at ratio of 6:61. Such excellent dispersion in the polymer host is attributed to the good solubility of the dendrimers in comparison to small molecule iridium(III) complexes.

While the efficiency of device with a p-G1-Ir:PVK ratio of 6:61 reaches up to 40 cd/A, it drops rapidly as the voltage increases. In contrast, the devices with a p-G1-Ir:PVK ratio of 13:54 keeps a high efficiency at high luminance. In fact the ratio 13:54 of dendrimer:PVK was found to be the optimum ratio for both dendrimers in the host. For OLEDs with higher dendrimer concentrations, although the dispersion is still good, some level of self-quenching sets in causing a slight reduction in the efficiency.

The significance of the blade-coating method can be understood from the performance of the device fabricated by spin-coating. The concentration ratio of p-G1-Ir:PVK is 6:61. As shown in Fig. 2, the luminance and current efficiency are low for the device fabricated by spin-coating. The peak luminance of 14,980 cd/m^2 was achieved at 13.5 V, and the maximum current efficiency of 10.7 cd/A was achieved at 9.5 V. This inferior performance may result from the layer-to-layer dissolution while using spin-coating technique or due to a completely different film morphology being formed. The layer-to-layer dissolution can be prevent by adopting the blade-coating technique as described in previous work [10]. The need for the TFB layer is

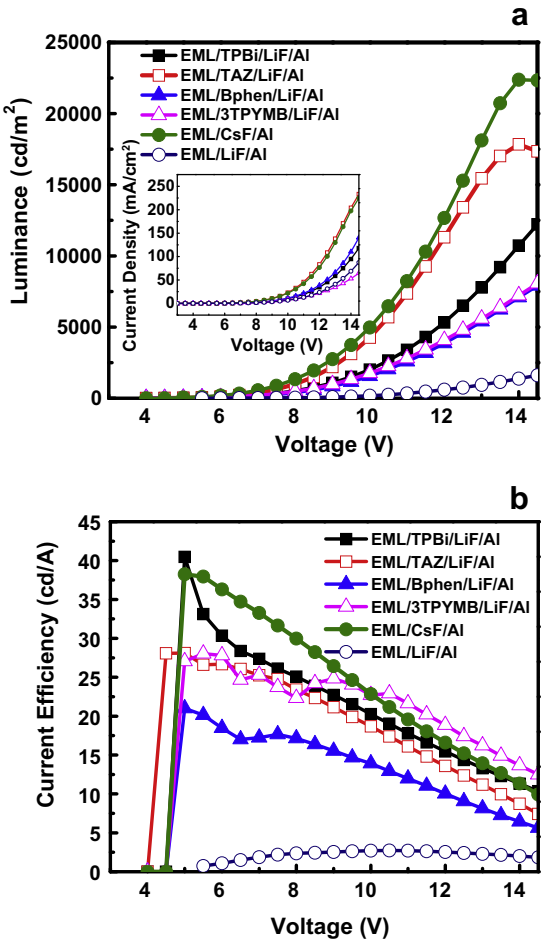

Fig. 4. The results of the multi-layer p-G1-Ir:PVK:TPD:PBD devices with ETL materials, TPBi, TAZ, Bphen, and 3TPYMB. (a) The luminance and the inset is the current density *versus* voltage. (b) The current efficiency *versus* voltage.

also shown in Fig. 2. For the device without TFB hole-transporting and electron-blocking layer, the peak luminance of 13,730 cd/m^2 was achieved at 13 V, and the maximum current efficiency of 11.5 cd/A was achieved at 9.5 V. The superior performance of the device with TFB layer results from the fact that more holes can be injected.

Fig. 4 shows the performance of the devices with TPBi, TAZ, Bphen, and 3TPYMB as the electron-transport layers and p-G1-Ir as the emitter. The ratio of dendrimer:TPD:PBD:PVK was 6:9:24:61. The results were compared with those without the electron-transport layer. Of the tri-layer devices, the device with TAZ shows the highest luminance as it and PBD have highest electron affinities [most stable Lowest Unoccupied Molecular Orbital (LUMO) energies] and this leads to more efficient electron injection into the light-emitting layer. However, the overall efficiency of TAZ devices is slightly lower than those containing TPBi. The device that had a LiF/Al cathode had a maximal efficiency of 40 cd/A (at 5 V with external quantum efficiency = 10.8% and brightness of 19 cd/m^2) and maximal luminance of 17,840 cd/m^2 (at 14 V). This difference probably arises from the fact that while the TAZ has the higher electron affinity it is a poorer hole blocking material than TPBi (see energy diagram Fig. 1b). In general the electron-transport layer in combination with LiF/Al cathode shows similar performance to devices with CsF/Al cathode but the latter devices tend to be less stable to the moisture. Without the electron-transport layer, the LiF/Al cathode has poorer electron injection capability and this may be due to a poor metal/organic interface leading to relatively low efficiencies (Fig. 4). The blade-coated layer of the electron transport materials therefore has a similar effect as with the equivalent vacuum deposited layers. Importantly, there is no dissolution of the emissive layer observed while blade coating the electron-transport layer.

4. Conclusion

In conclusion, we demonstrate that the good solubility of phosphorescent dendrimer emitters allows the formation of a dispersion of the dendrimers in a polymer host. The uniform dispersion enabled OLEDs with high efficiency and luminance to be achieved with a wide range of emitter concentrations because of low level of intermolecular quenching of the phosphorescence. The good compatibility of the phosphorescent dendrimers and the polymer host indicates that it is crucial to add functional groups to enhance the solubility when designing solution processable triplet emitters for use in blends. Importantly, all solution processed multi-layer OLEDs without layer-to-layer dissolution can be fabricated using the blade-coating technique. Blade-coating phosphorescent dendrimers show promise for the development of large-area and low-cost lighting emitting applications.

Our research	32.8	Systematic variation of the thickness of the ITO and the organic layer, and the location of emission zone

the OCEs of the conventional OLEDs, the microcavity structure has not been systematically varied to cover all possible states such as the position of the emission zone and the thicknesses of the ITO and organic layers. The analyses were done with either fixed thicknesses of both the ITO and organic layers [1,4,9] or with a fixed ITO thickness [6,7,10,11]. Especially, the thickness of the ITO layer was fixed in all the analyses because the effect of the thickness of the ITO layer on OCEs has not been considered in previous works.

In this paper, we systematically varied the location of the emission zone and the thicknesses of the organic layer and the ITO layer independently to calculate the maximum OCE in bottom emission OLEDs. This analysis will demonstrate that maximum outcoupling efficiencies over 27% and 30% are achievable if thin ITO layers in the range of 50–70 nm and 50–100 nm are used for blue and green phosphorescent OLEDs, respectively. Even higher efficiencies of 29% for blue and 31.6% for green can be obtained if we use thicker organic layers supporting two antinodes suggesting that phosphorescent OLEDs can have much higher external quantum efficiency than 20%.

To investigate the OCE of bottom emission OLEDs, a few assumptions are made. First, the device has a layered structure and is modeled as a simple one dimensional (1D) weak microcavity consisting of a thick reflective cathode, an organic layer, an ITO layer and a semi-infinite glass as shown in Fig. 1. Most efficient OLEDs have multiple organic layers consisting of the hole injection, hole transporting, emitting, electron blocking, electron transporting and electron injection layers. Accounting for all the layers in the calculation of the OCE requires too much computational time and is not necessary because the refractive indices of organic semiconductors are not significantly different for the materials commonly used in the devices. Therefore, the simplification of the multiple layers by a single emission layer does not degrade this optical calculation at all. Second, the dipole radiators are

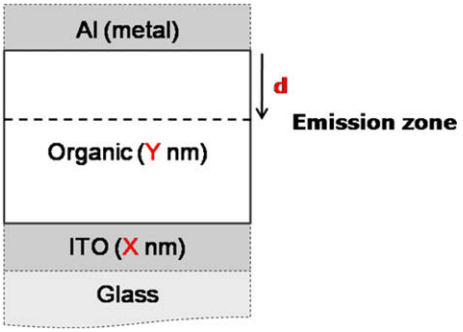

Fig. 1. Schematic diagram of the device structure for optical modeling. Parameters of x, y, and d are the thickness of ITO and the organic layer, and the position of emission zone, respectively.

imbedded in the layered structure as a sheet and their orientations are randomly distributed. Random distribution of the dipoles is in good agreement with experimental results for amorphous small molecular systems [13,14,19–23,28]. The sheet dipole approximation is also not a limitation of this calculation. Any distribution of excitons in a real device can be easily accounted for by the weighted integration of the calculated OCEs based on the sheet dipole approximation. Third, the intrinsic PL quantum yields of the phosphorescent dyes are assumed to be 100%. This assumption is reasonable for Ir(p-py)$_3$ in CBP or Firpic in mCP [1,29].

In the classical theory of radiation, the normalized damping rate of oscillating electric dipoles is proportional to the dissipated power of the dipoles [30]. Therefore, we calculated the normalized damping rate of the dipole radiators in the 1D microcavity as a function of the wavelength, the thicknesses of the organic and ITO layers, and the position of the emission zone. The total radiated power from the dipole radiators at each wavelength is described in detail elsewhere [17–19,22] and is given by

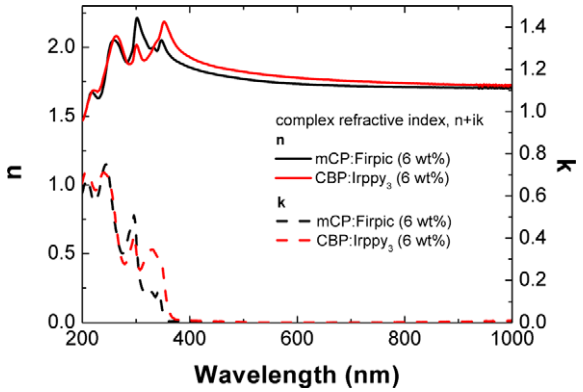

Fig. 2. Complex refractive indices spectra of Firpic doped mCP layer for blue (black line), and 6 wt.% Ir(ppy)$_3$ doped CBP for green (red line). Refractive indices were measured by a spectroscopic ellipsometer. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

$$R(\lambda, y, d) = \int_0^{\infty} \mathrm{Re}[S(u, \lambda, x, y, d)]du \tag{1}$$

where $R(\lambda, t, d)$ is the radiated power from a dipole radiator which is a function of the wavelength λ, the ITO thickness x, the thickness of organic layer y and the distance of the emission zone from the cathode d. S is the electric field which is affected by an optical environment. Re[S] is the real part of S, representing the normalized damping rate, and u is the parallel component of the wavenumber k to the emissive layer. Detailed procedure of the derivation of Re[S] can be found in Refs. [21–23,26].

The electric field coupled to various optical modes can be classified by the parallel component of the wavenumber u. If $0 \leqslant u \leqslant k_{air}$ the electromagnetic field will be coupled to the radiation mode escaping to the air where k_{air} is the wavenumber of the air. The outcoupling efficiency or the light extraction efficiency, η_{out}, which is defined as the ratio of the surface emitted light to the total emitted light from the dipole radiators is described as follows:

$$\eta_{out}(x, y, d) = \frac{\int_{400}^{700} I_{PL}(\lambda) \int_0^{k_{air}} \mathrm{Re}[S(u, \lambda, x, y, d)]du d\lambda}{\int_{400}^{700} I_{PL}(\lambda) d\lambda} \Bigg/ \frac{\int_{400}^{700} I_{PL}(\lambda) \int_0^{\infty} \mathrm{Re}[S(u, \lambda, x, y, d)]du d\lambda}{\int_{400}^{700} I_{PL}(\lambda) d\lambda} \tag{2}$$

where I_{PL} is the PL spectrum of the emissive layer under consideration in free space.

We selected the blue and green PhOLEDs for the analyses where iridium(III) bis[(4,6-difluorophenyl)pyridinato-N,C$^{2'}$]picolinate (Firpic) doped in *N*,*N*′-dicarbazolyl-3,5-benzene (mCP) and *fac*-tris(2-phenylpyridine) iridium

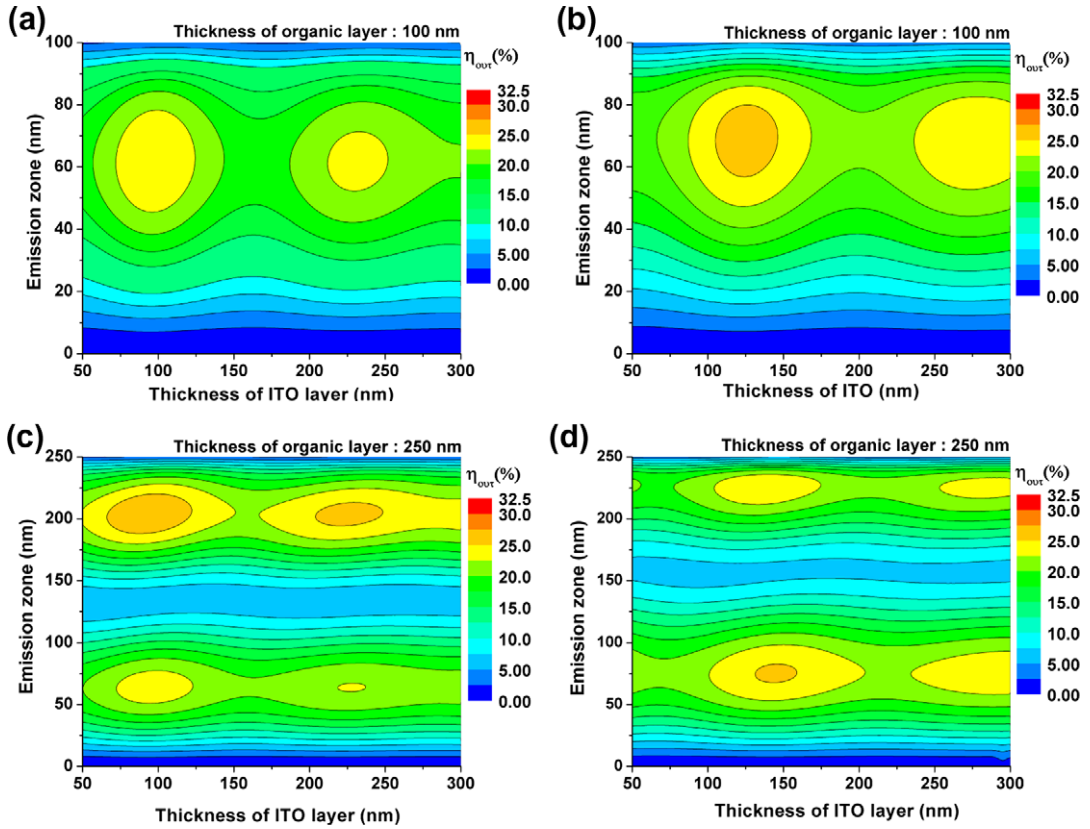

Fig. 3. Contour plots of outcoupling efficiency as a function of thickness of ITO and emission zone for selective thickness of organic layers: (a) 100 nm for blue, (b) 100 nm for green, (c) 250 nm for blue and (d) 250 nm for green. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

($Ir(ppy)_3$) doped in *N*,*N*′-dicarbazolyl-4–4′-biphenyl (CBP) were used as the emitting layer, respectively. Both dopants are known to have almost 100% PL quantum yield [1,28]. Doping concentration was 6 wt.% in the organic layers. The complex refractive indices of the organic layers for the simulation were measured by a spectroscopic ellipsometry and are shown in Fig. 2 [31]. The refractive index of $Ir(ppy)_3$ in CBP is larger than Firpic in mCP in the visible region. The refractive indices of ITO layer and Al were taken from Refs. [32–34].

The calculated OCEs of the OLEDs are represented as contour plots in Fig. 3 as functions of ITO thickness and the location of emission zone for the blue and green OLEDs with two different thicknesses of the organic layers. The OCEs are significantly changed as the location of the emission zone changes. The OCEs increase from zero at $d = 0$ due to the quenching by the metal layer to the maximum at the antinode position of the electric field coming from the interference effect. Further movement of the emission zone from the metal cathode reduces the OCE due to the reduced electric field and increased interaction with ITO. If the organic layer is much thicker to support the second antinode as shown in Fig. 3(c) and (d), the distribution of OCEs has two peaks now. Proper selection of the thickness of the organic layers will result in higher OCEs at the second antinode than the first antinode because it is farther apart from the metal electrode to reduce the dipole-metal interaction.

The OCEs are also affected by the thickness of the ITO even though it is less extent than the position of the emission zone. The OCEs oscillate from 20% to 25% with increasing ITO thickness when the emission zone is located at the antinode position. This oscillation is coming from the interference effect of the reflected light from the ITO layer. The effect of the ITO thickness is less than the effect of the position of the emission zone because the reflection by the ITO layer is smaller than the reflection of the metal cathode. The maximum OCEs are obtained when the structure satisfies the resonance condition of the emitted light. When the thickness of the organic layer is 100 nm, which is a thickness commonly used in OLEDs, the maximum OCEs are 25.6% and 26.1% for blue and green OLEDs, respectively. It is worthwhile to note that maximum OCEs are obtained when the thicknesses of the ITO layer are 95 and 125 nm for blue and green OLEDs, respectively, if the thickness of the organic layer is 100 nm. The thicknesses are thinner than the widely used thickness of 140–160 nm in OLEDs. OLEDs with a 100 nm thick organic layer and 140–160 nm thick ITO layers result in maximum OCEs of 20 ± 2% for blue and 22 ± 2% for green which are consistent with previous theoretical results [1,15].

The maximum OCE for a given ITO thickness and an organic layer thickness can be obtained by varying the emission zone in the device. By repeating the procedure for different thicknesses of the ITO and organic layers, we can now get the contour plots of the maximum OCEs as functions of the thickness of the ITO layer and the thickness of the organic layer shown in Fig. 4(a) and (b) for the blue and green PhOLEDs, respectively. These figures clearly show that the OCEs in normal bottom emission OLEDs can be as high as 30% in green OLEDs and 27% in blue OLEDs if the first antinode is used, e.g., when the thickness of the organic layer is thinner than 200 nm. OCEs over 30% can be achieved with an ITO layer thinner than 100 nm for the green OLED. The blue OLEDs require a thinner organic and ITO layer than the green OLEDs as expected. The ITO layer must be thinner than 80 nm to get the OCE over 26% from the blue OLED. The EQEs can be even higher if the emission zone is located in the second antinode in the thicker OLEDs because of the smaller coupling to surface plasmon polariton mode and evanescent field. EQEs of 29% and 31.6% are possible for the blue and green OLEDs, respectively. The parameters that achieve the maximum OCEs are summarized in Table 2. It must be noted that the high efficiencies are obtained by using much thinner ITO layers and thicker organic layers than normally used in OLEDs. In fact, most recent high efficiency

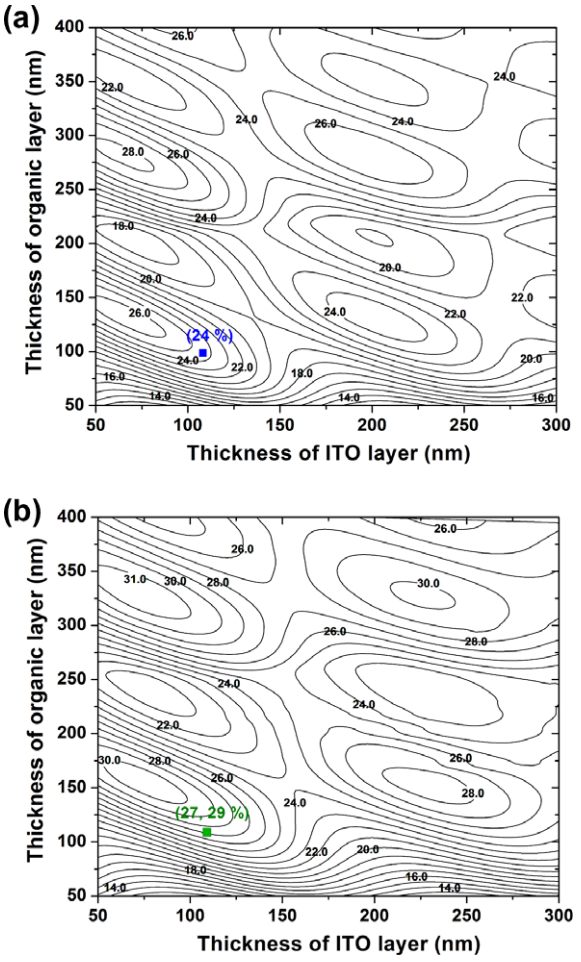

Fig. 4. Contour plot of the maximum outcoupling efficiency as a function of thickness of the organic and ITO layers where the position of the emission zone is varied within the organic layer to get the maximum outcoupling efficiency at given thicknesses of the organic and ITO layers: (a) blue and (b) green PhOLEDs [*Note:* The scatters in figures are the external quantum efficiencies referenced from published papers; Ref. [24] (green square in (b) (29% of EQE)), Ref. [25] (blue square in (a), and green square in (b) (27% of EQE))]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 2
The values of the parameters achieving the maximum outcoupling efficiency for blue and green devices.

	1st antinode		2nd antinode	
	Blue	Green	Blue	Green
	27.3	30.4	28.9	31.6
Organic layer thickness (nm)	132	155	285	330
ITO thickness (nm)	67	75	65	75
Emission zone (nm)	68	75	207	242

OLEDs have adopted thinner ITOs ranging from 70 to 110 nm [24,25,27]. The EQEs of recent high efficiency OLEDs are compared to the calculated results in the figures. The experimental EQEs are very close to the maximum OCEs predicted by the analysis. These results indicate that the devices are well designed to satisfy the optical conditions for the location of the emission zone and the electron–hole balance.

Variation of the maximum OCEs through altering the thicknesses of the ITO layers can be easily understood by analyzing the coupling ratio of the dissipated power of the emitted light to various optical modes shown in Fig. 5 which are calculated along the ridge line of the first antinode in Fig. 4. There are discontinuities in the graphs when the ITO layer begins to support the waveguide mode (critical thickness for waveguiding in the ITO layer) so that the power dissipated in the organic and ITO layers shows rapid change at the expense of the surface plasmon polaritons mode at the thicknesses. It is clear that coupling to the glass substrate is almost constant if the ITO layer is thinner than the critical thickness of the ITO layer for waveguiding. Therefore, the variation of the OCEs is originated from the variation of the power dissipation to the organic, ITO and metal layers with the thickness of the ITO layer.

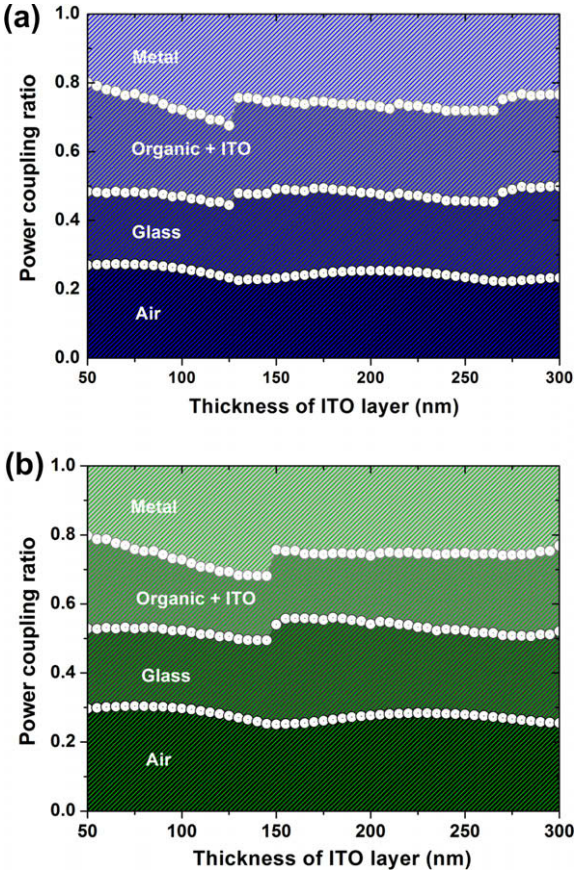

Fig. 5. Power coupling ratio of the dissipated power from emissive dipoles coupled to various optical modes for (a) blue and (b) green phosphorescent OLEDs. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
