Multilayer emission region

ABSTRACT

We reported a highly efficient white organic light-emitting diode (WOLED) with a multilayer emission region made of sequentially evaporated host and guest layers. The singlet and triplet excitons were harvested in two separate channels. An external quantum efficiency of 16.3% photons/electron (~41 cd/A) was achieved with a good color rendering index (CRI) of 76, and a Commission Internationale de l'éclairage (CIE) coordinate of ($x = 0.38$, $y = 0.46$). At brightness of 100 and 500 cd/m^2, the external quantum efficiencies reached 11% and 10%, respectively. The performance of the WOLED is better than that fabricated by co-evaporation method due to an improved exciton capture and emission efficiencies. This work presents an alternative way of fabricating WOLED.

The tremendous developments of monochrome red, green and blue organic light-emitting diodes (OLEDs) since their first inception in 1987 [1] have paved the way for the recent advancement of the white organic light-emitting diode (WOLED). Various architectures have been applied to achieve efficient and color-balanced devices. The multiple emission layers architecture reported in the literature has been able to achieve the much desired saturated-white emission [2–5]. For multiple emission layers, the carrier recombination, carrier trapping, and exciton diffusion, the emission of red, green, and blue portion can be tuned appropriately to obtain desired color purity. This technique however suffers from a color-shift with an increase in current [3]. To eliminate color-shift, devices with a single emission layer doped with two or three dopants have been developed [6–9]. To balance red, green and blue emissions, the concentration of each dopant is carefully controlled. The highest efficiency is obtained for device that uses phosphorescent dopants [6]. Phosphorescence enables extraction of the forbidden triplet exciton to potentially increase the efficiency to unity. The architecture has been used to produce a WOLED with a high efficacy of 42 lm/W [6].

The blue-emitting phosphorescent molecule is unstable and has a relatively low operational lifetime. This resulted in color degradation with time, i.e. the blue portion reduces significantly. The device with three-phosphorescent dopants also suffers a large efficiency roll-off. Sun et al. showed that by harvesting the singlet and triplets into two different channels, the efficiency roll-off can be improved [10]. Previous study has shown that the diffusion length of the triplet is much longer than that of the singlet [11]. Sun et al. harvested the singlet (using fluorescent dye) near the exciton formation region and making use of the long diffusion length of triplet, harvested the triplet excitons at a distance from the formation region (using phosphorescent dyes). This structure also eliminates the need for high efficient blue phosphorescent materials, which are still relatively unstable and suffer a short lifespan when incorporated in WOLED. Similar method has been used to achieve WOLED with a power efficiency of 45 lm/W [12,13]. Recently WOLED with efficacy exceeding fluorescent tube has been reported [14].

The device reported by Sun et al. represents a clever technique to fully harvest the singlet and triplet excitons for white light creation. However despite of the high

doi:10.1016/j.orgel.2010.10.005

efficiency achieved, the performance somehow diminishes at low current injection, similar to fluorescent OLED. Fluorescent OLED normally uses a very small guest (dopant) concentration (with guest molecule spacing larger than the typical Förster radius) to reduce the aggregation and quenching effects [15,16]. At a low current (exciton) density, the spacing between the excitons is large, resulting in an incomplete energy transfer from the host to the guest. The device reported in Ref. [10] consists of doped and undoped regions where the excitons are harvested in the doped region. However due to the small doping concentration and thin doped region, the excitons was not fully extracted at low current density, resulting in a loss. As the current increases, the spacing between the excitons reduces. This increases the chance of exciton being captured by the guest molecules and improves the efficiency. Although the WOLED is normally operated at high current injection, for some application such as the tandem structure, the performance at low current density is still very important.

Another issue with the device reported in Ref. [10], or doped-OLED devices in general, is the uniformity of the device for large-area fabrication. Fabrication of high-efficiency WOLED (or in general OLED) involves co-evaporation of the guest and host materials with specified concentration [17,18]. Recently it has been shown that the thickness of the organic semiconductor can be controlled well with a variation of less than 3% for a large-area manufacturing [19]. However the current-efficiency of the device varies significantly throughout the regions. The large variation was attributed to the small variation of the doping concentration of the guest/host materials in the emission layer which can significantly influence the performance of the device. To control the doping concentration, thickness sensors are placed near the guest and host materials to monitor the deposition. However since the organic sources are placed at some distance from the substrate, where the layers are being deposited, the doping concentration of the organic materials may vary from region to region on the substrate. To have a better control of the organic deposition, one may place the thickness sensors near the substrate which render better control of the thickness uniformity of the film. However these sensors could not determine the doping concentration of the guest/host material. Therefore the control of the doping concentration for the large area device remains a problem.

Reineke et al. recently applied a rather different device architecture for OLED [20]. The emission region consists of a multilayer architecture, where the doped area is separated by a pure host repeatedly. This method has been used to improve the efficiency roll-off with the critical current density (current density when the efficiency drops to 50%) increased from 140 to 270 mA/cm^2 by confining the exciton within the guest molecule. In spite of the better roll-off performance, the device reported by Reineke et al. show a lower external quantum efficiency (EQE). We recently show that one can even further eliminate the requirement for doping [21], an OLED with a similar architecture was fabricated with the doped regions being replaced with pure guest layers. By carefully controlling the thickness of the guest and host layers, device with efficiency comparable to that fabricated by co-evaporation method was reported.

In this work, we utilized the multilayer structure to produce a highly efficient WOLED. The method to extract both the singlet and triplet follows that reported previously [10]. We showed that device with a multilayer design performs better compared to the device fabricated by the co-evaporation method. The maximum EQE of 16.3% photons/electron was achieved at a current density of 0.05 mA/cm^2. At high current injection, the EQE is comparable to that reported in Ref. [10]. At brightness of 100 and 500 cd/m^2, the EQE reach 11% and 10%, respectively. The multilayer approach is promising for tandem WOLED.

The OLED (or WOLED) was fabricated on ITO glass (50 Ω/square) which was earlier subjected to the standard cleaning procedure that involves ultra-sonication in acetone, ethanol, rinsing in de-ionized water and oxygen plasma treatment at 15 Pa for 3 min. Evaporation of organic materials and metals was carried out in a high vacuum condition of about 2×10^{-4} Pa with deposition rates of 0.5–4 Å/s. The quartz crystal microbalance thickness sensor was positioned near the ITO glass for better accuracy. For each run, up to four samples were fabricated simultaneously without breaking the vacuum, to ensure similar deposition condition. Electroluminescence (EL) spectra of the fabricated devices were measured with a calibrated PR650 Spectra Scan spectrometer. Current density–voltage characteristics were recorded by Yokogawa source measurement unit. We assumed the emission pattern was Lambertian, and calculated the EQE from the luminance, current density and EL spectrum [22]. All measurements were carried out at room temperature under ambient atmosphere without any encapsulation.

The efficiency of the guest–host OLED device is determined by two factors, the rate of energy transfer from the host to the guest molecules (exciton capture) and the efficiency of the guest molecules (exciton emission). Let's compare the rate of energy transfer of the following devices with the same emission region thickness. Device A with emission region consists of x nm (sub-monolayer) of guest and y nm of host, device B consists of two repeated $x/2$ nm of guest and $y/2$ nm of host layers and device C consists of k repeated x/k nm of guest and y/k nm of host layers, as shown in Fig. 1(a). If the intermolecular spacing in the planar guest layer of device A is r nm, guest spacing in devices B and C will be $\sqrt{2}r$ and $\sqrt{k}r$ nm, respectively. As the excitons diffuse toward the guest layer, some of them will be captured while some will escape. The rate of energy transfer (capture) of the exciton follows the Förster process [23] with a rate $\propto (r_F/r)^6$ for device A, while for devices B and C, the rates are $\propto 2(r_F/\sqrt{2}r)^6 = \frac{1}{4}(r_F/r)^6$ and $\propto k(r_F/\sqrt{k}r)^6 = \frac{1}{k^2}(r_F/r)^6$, respectively, where r_F is the Förster radius. This shows that exciton capture rate is higher for device with thicker guest layer (device A) than that with dispersed guest molecules (devices B and C). This is only so because the energy transfer follows Förster process. If the excitons were captured by impact (trapping), the rate would be proportional to the cross section of the guest molecules (r^{-2}), correspondingly, the capture rate

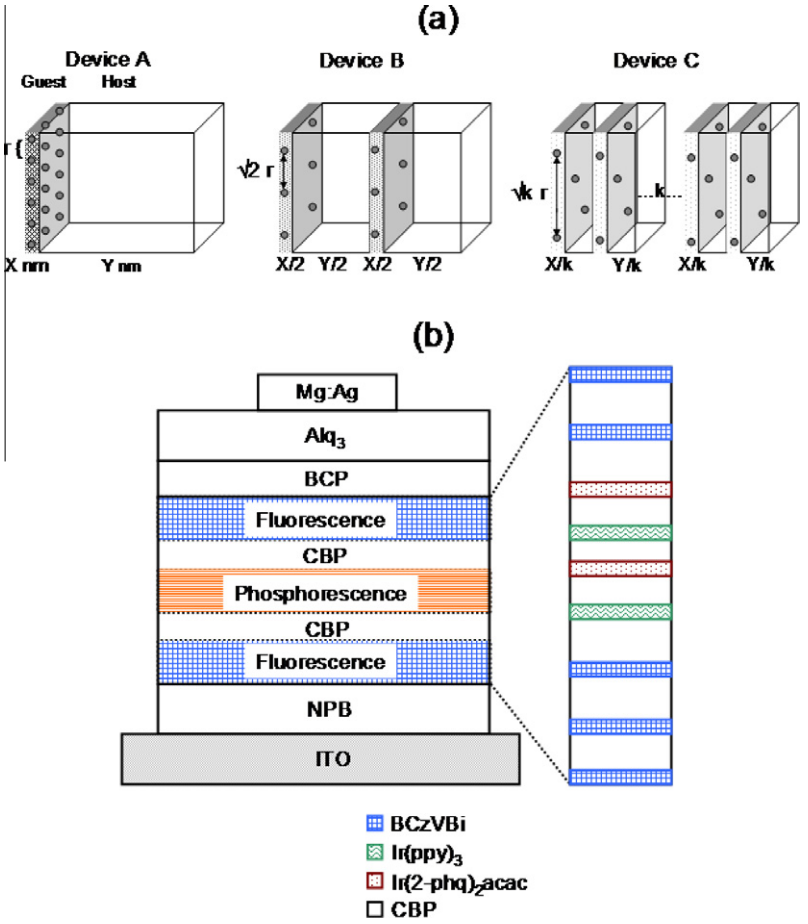

Fig. 1. (a) Illustration for devices with different doping (host/guest) architectures. (b) Schematic diagram of the WOLED with multilayered emission region.

would be the same for all devices. The second factor is the efficiency of the guest molecules. It has been recently shown that the efficiency of the guest molecules decreases significantly when the intermolecular spacing is less than certain quenching radius (~1–1.3 nm) [15]. However by using a very thin layer of guest layer (<1 nm), the intermolecular spacing in the planar guest layer is larger than this typical quenching radius. Assuming monolayer corresponds to 1 nm thickness with intermolecular spacing of 1 nm [24], device with 0.5 nm thick guest layer has an intermolecular spacing of approximately $\sqrt{2}$ nm which is larger than the typical quenching radius. Thus devices with multilayer architecture should out-perform those made of dispersed (co-evaporated) system.

Fig. 1(b) shows the schematic of the WOLED with multilayered architecture. NPB is *N*,*N*′-di(naphth-2-yl)-*N*,*N*′-diphenyl-benzidine used as the hole-transporting layer, CBP is 4,4′-bis(*N*-carbazolyl)biphenyl as the host, BCzVBi is 4,4′-bis(9-ethyl-3-carbazovinylene)-1–1′-bisphenyl as the blue-emitting fluorescent guest, $Ir(ppy)_3$ is tris(2-phenylpyridine) iridium(III) as the green-emitting phosphorescent guest, $Ir(2\text{-phq})_2(acac)$ is bis(2-phenylquinoline) (acetylacetonate) iridium(III) as the red-emitting phosphorescent guest, BCP is 2,9-dimethyl-4,7-diphenylphenanthroline as the hole blocking layer, and Alq_3 is tris-(8-hydroxyquinoline) aluminum as the electron transporting layer. The emission region consists of two separate parts for singlet and triplets harvesting. The singlet regions are placed near the interfaces of the heterojunctions, where most of the excitons are formed, while the triplet region is positioned in the middle of the emission layer. Instead of co-evaporating the guest and host molecules together, the singlet and triplet regions are formed by evaporating the guest and host molecules sequentially. The thickness ratio of the guest and host layers corresponds to the doping concentration of the co-evaporated system. Since the deposition thickness can be controlled very well throughout large-area [19], the uniformity of the device manufacturing should be improved.

Before constructing the WOLED, we studied the exciton (singlet and triplets) distribution in the device. To do this, we placed a thin layer of fluorescent and phosphorescent dye in various positions in the device. We used the BCzVBi and $Ir(2\text{-phq})_2(acac)$ to detect the distribution of the singlet and triplets exciton, respectively. The dye was deposited in two different positions inside CBP and NPB layers (Fig. 1). The structures are NPB (50 nm)/CBP (*x* nm)/dye (0.5 nm BCzVBi or 0.1 nm $Ir(2\text{-phq})_2acac$)/CBP (30-*x* nm)/BCP(20 nm)/Alq_3 (30 nm) for device with dye in CBP, and

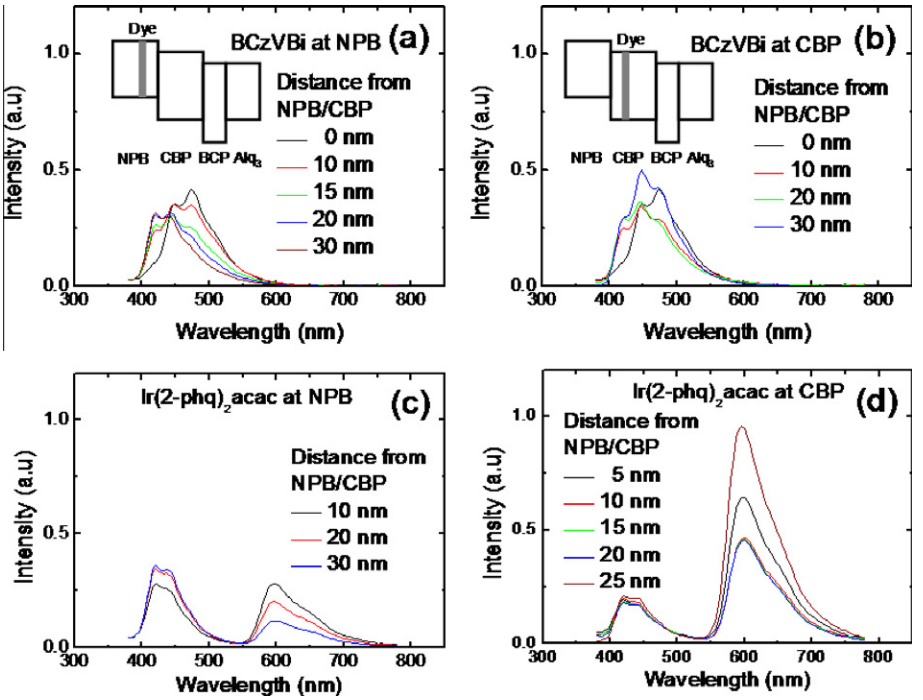

Fig. 2. Emission spectra for devices with a thin BCzVBi layer deposited in NPB (a) and CBP (b). Emission spectra for devices with a thin Ir(2-phq)$_2$acac layer deposited in NPB (c) and CBP (d).

NPB (50-y nm)/dye (0.5 nm BCzVBi or 0.1 nm Ir(2-phq)$_2$-acac)/NPB (y nm)/CBP (30 nm)/BCP (20 nm)/Alq$_3$ (30 nm) for device with dye in NPB, where x and y are the distances from NPB/CBP interface to dyes in NPB and CBP layers, respectively. Fig. 2(a)–(d) show the emission spectra for devices with a thin layer of BCzVBi and Ir(2-phq)$_2$acac deposited at various locations. Significant variation of the emission from the host and the dye can be seen. The host emission consists of that the NPB (peaking at 420 nm) [22] and CBP (peaking at 370 nm) [25]. Although the CBP emission peak is beyond our measurement range, the emission tail can still be seen at the wavelength of 380 nm. For devices with the dye deposited at the NPB (or CBP) side, only the NPB (or CBP) host varies significantly. The guest emission, on the other hand, reduces as the distance of the dye increases from the NPB/CBP or CBP/BCP interfaces. This signifies that the exciton formation is the largest at these interfaces.

Fig. 3 shows the intensities of the BCzVBi and Ir(2-phq)$_2$acac as a function of position in the device. It can be seen that the singlet and triplet excitons distributions are largest at the NPB/CBP or CBP/BCP interfaces. This can be understood since the interfaces have the largest accumulation of both electron and hole. The excitons are formed almost at the same rate at both the NBP/CBP and CBP/BCP interfaces.

The singlet exciton distribution at the NPB layer can be fitted with an exponential decay of $\exp(-y/L_{D(NPB)})$ with a diffusion length ($L_{D(NPB)}$) of 16 nm, where y is the distance from the NPB/CBP interface toward the NPB layer. The exciton distribution at the CBP layer can be fitted with the solution of the diffusion in a confined-space of $\lfloor n_1 \sinh(x/L_{D(CBP)}) + n_2 \sinh((L-x)/L_{D(CBP)}) \rfloor / \sinh(L/L_{D(CBP)})$ with diffusion length ($L_{D(CBP)}$) of 10 nm, where n_1 and n_2 are the exciton densities at CBP/BCP and NPB/CBP interfaces, respectively, L is the thickness of the CBP layer which is 30 nm and x is the distance from the NPB/CBP interface toward the CBP layer. Instead of being confined within the emission layer (CBP), it can be seen that the singlet leaks to the NPB layers.

From Fig. 2(c) and (d), it can be seen that the intensity of the phosphorescent dye in NPB side is much lower than in

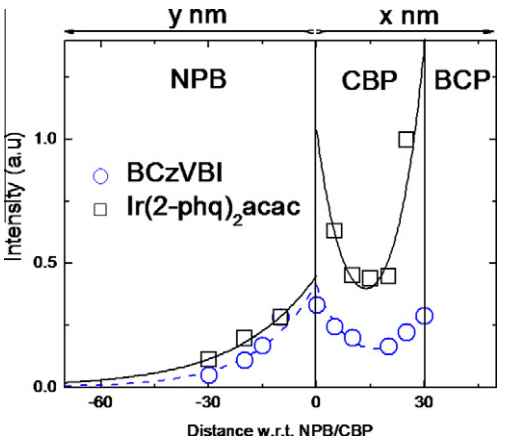

Fig. 3. The intensity of the fluorescent and phosphorescent dyes at various positions in the device.

CBP. Thus the phosphorescence emission in NPB layer is originated from the singlet exciton that leaks to the layer and transfers to the dye. Moreover the intensity profile of triplet exciton is similar to that of the singlet exciton in NPB as shown in Fig. 3. Therefore, it can be concluded that the triplets are well confined within the CBP emission layer. Similar with the case of the singlet exciton, the triplet exciton in CBP layer can be fitted with the same formula with a diffusion length $L^{T}_{D(CBP)}$ of 9 nm. Previously it has been reported that the triplet excitons have a larger diffusion length (~100 nm) [11] compared to the singlet excitons due to their long radiative lifetime. However here it seems the triplet distribution profile is similar to that of the singlet in CBP. This is probably because of the thin CBP layer (30 nm) used in the experiment, where Dexter [26] or Förster [23] processes still dominate the energy transfer besides diffusion.

We then deposited multilayer of BCzVBi near the NPB/CBP interfaces to harvest the singlet exciton. Since much of the singlet excitons are distributed in the NPB side, depositing the fluorescent dye at the hole-transporting layer seems a logical way to extract the singlet excitons. So we deposited the BCzVBi in the NPB layer. Two structures were fabricated, NPB (50 nm)/BCzVBi (0.5 nm)/CBP (30 nm)/BCP (20 nm)/Alq_3 (30 nm) with single guest layer at the interface, and NPB (30 nm)/[NPB (5 nm)/BCzVBi (0.5 nm)]$_4$/CBP (30 nm)/BCP (20 nm)/Alq_3 (30 nm) with four repeating host/guest layers. Fig. 4 shows the emission spectra of the two devices biased at the same current density. The inset of Fig. 4 shows the EQE of the devices. It can be seen that adding the BCzVBi layer at the NPB does not increase the EQE. The deposition of single BCzVBi layer at the interface prevents the excitons diffusion toward the NPB side, confining them in the CBP layer.

So we deposited the fluorescent BCzVBi dye in the CBP layer. The structure is NPB (50 nm)/[BCzVBi (0.5 nm)/CBP (7 nm)]$_p$ /CBP (40–7(p + q) nm)/[CBP (7 nm)/BCzVBi (0.5 nm)]$_q$ /BCP (20 nm)/Alq_3 (30 nm), where p and q are the numbers of repeating host/guest layers and varied from 1 to 3. Fig. 5(a) shows the emission spectra. The inset of Fig. 5(a) shows the external quantum efficiency (EQE) as a function of current density for devices with different

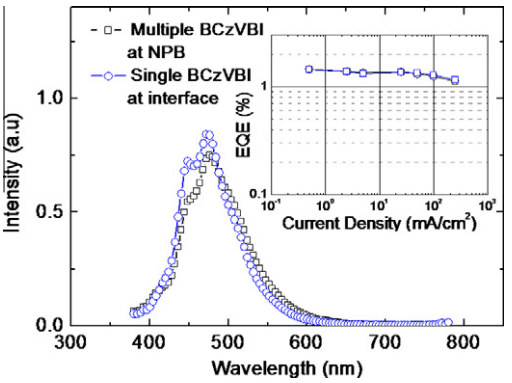

Fig. 4. Emission spectra for devices with singlet excitons extracted with single and multiple BCzVBi layers. Inset shows EQE as a function of current density of the corresponding devices.

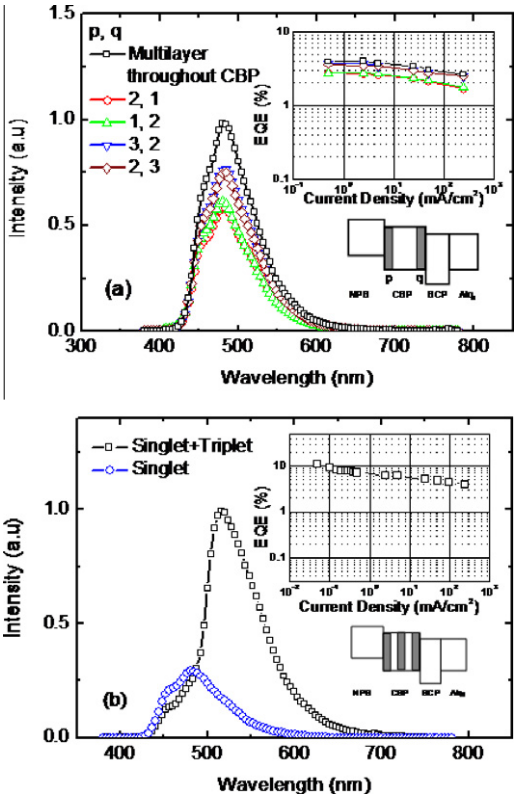

Fig. 5. Emission spectra for devices with p and q multiple BCzVBi layers deposited near the NPB/CBP and CBP/BCP interfaces, respectively, to harvest the singlet exciton (a). Insets in (a) and (b) shows the EQE as a function of current density of the corresponding devices.

numbers of BCzVBi layers, also shown in the figure is the EQE for device where the whole emission region was replaced by multilayer of BCzVBi and CBP. It can be seen that the EQE steadily increases as the numbers of BCzVBi layers increases. The maximum EQE for device with (p,q) = (3,2) is still 3.5%, which is slightly lower compared to the device with the whole emission region replaced by a multilayer of BCzVBi and CBP (3.9%). This shows that a small amount of singlet excitons still diffuse toward the middle region (escaping the BCzVBi layers), contributing to the loss. It can also be seen that there is no drop in EQE at low current density, unlike the conventional fluorescent OLED fabricated using the co-evaporation method [10]. This shows that the multilayered structure harvests the exciton better at low current density, due to a better capture and confinement of exciton by the thin layer of guest molecules.

The middle emission region was then added with green phosphorescent Ir(ppy)$_3$ layer. The structure of the device is NPB (50 nm)/[BCzVBi (0.5 nm)/CBP (7 nm)]$_3$/[Ir(ppy)$_3$ (0.5 nm)/CBP (6 nm)]$_2$/Ir(ppy)$_3$ (0.5 nm)/[CBP (7 nm)/BCzVBi (0.5 nm)]$_2$/BCP (20 nm)/Alq_3 (30 nm). Fig. 5(b) shows the emission spectrum of the corresponding devices. Also plotted in the figure is the emission spectrum for device without Ir(ppy)$_3$ [device in Fig. 5(a)]. It can be seen that

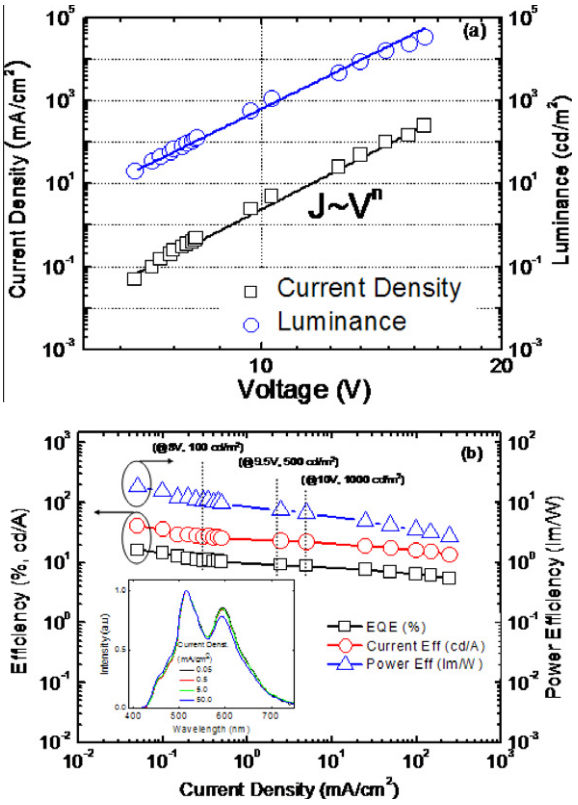

Fig. 6. Current density and luminance versus voltage for the WOLED device (a). The EQE, current and power efficiency as a function of current density for the WOLED [dotted lines @8V, 100 cd/m^2; @9.5V, 500 cd/m^2; and @10V, 1000 cd/m^2] (b). Inset in (b) shows emission spectrum of the WOLED at different current density.

the addition of Ir(ppy)$_3$ layer in the middle section of the emission layer reduces the BCzVBi emission by 40%, which indicates a significant energy transfer (enabled by the Förster process) from the singlet BCzVBi to the Ir(ppy)$_3$ molecule. In previous report, a CBP spacing region as thin as 4 nm was shown adequate to isolate the singlet exciton [10]. Here despite the large 7 nm CBP spacing region, we can still observed a significant energy transfer. This is understandable since the contribution of the molecules within the plane adds to the overall energy transfer, increasing the Förster transfer rate. From the intensity of the emission spectrum, it can be concluded that most of Ir(ppy)$_3$ emission is produced by the triplet exciton in the CBP layer. Direct energy transfer from the triplet of the BCzVBi to Ir(ppy)$_3$ is unlikely. Such a transfer can only occur via Dexter process which has limited range (~10 Å). The large CBP spacing (~7 nm) minimizes the direct energy transfer. The inset of Fig. 5(b) shows the EQE versus current density for the corresponding device. The EQE reaches a maximum of 11% at current density of 0.05 mA/cm^2. The EQE drops monotonously as the current increases, similar to the BCzVBi guest only device [Fig. 5(a)].

Finally we constructed a WOLED with a structure of NPB (50 nm)/[BCzVBi (0.5 nm)/CBP (7 nm)]$_3$/[Ir(ppy)$_3$ (0.5 nm)/CBP (6 nm)/Ir(2-phq)$_2$acac (0.1 nm)/CBP (6 nm)/Ir(ppy)$_3$ (0.5 nm) CBP (6 nm)/Ir(2-phq)$_2$acac (0.1 nm)/[CBP (7 nm)/BCzVBi (0.5 nm)]$_2$/BCP (20 nm)/Alq$_3$ (30 nm) (Fig. 1). Fig. 6(a) shows the current density and luminance versus the voltage for the device. It can be seen from the logarithmic plot that the current density versus voltage shows a power law relationship. The current density (J) can be written as $J \sim V^n$, where V is the voltage and n is equal to 9. This power law behavior is commonly observed in organic devices [27]. It can be seen that the operating voltage is larger than that reported previously which is due to the thick layer of organic semiconductor used in the device. The maximum luminance of >34,000 cd/m^2 was obtained.

Fig. 6(b) shows the EQE and power efficiency as a function of current density. The EQE, current and power efficiencies reach 16.3%, 41 cd/A and 18.5 lm/W at current density of 0.05 mA/cm^2, respectively. The EQE at low current density is much higher than that reported in Ref. [10]. At brightness of 100 and 500 cd/m^2, the EQE reaches 11% and 10%, respectively, comparable with that fabricated by co-evaporation method [10]. This shows that the multilayered emission layer architecture enables an efficient extraction of excitons.

The inset in Fig. 6(b) shows the emission spectra for the white OLED at different current densities. It can be seen that a good coverage of the visible spectrum is achieved. The color rendering index (CRI) reaches a reasonable value of 76 with Commission Internationale de l'éclairage (CIE) coordinate of (x = 0.38, y = 0.46). It can also be seen that variation of the emission at different current density is small.

The device structure has the potential for further optimization, such as the usage of LiF [28] or CsF [29] cathodes, electron-blocking layer [30], doped carrier-transporting layers [30], or corrugated substrate [31] in order to further reduce the operating voltage and increase the efficiency of the device.

In conclusion, we have shown that singlet and triplet excitons can be efficiently extracted from WOLED with a multilayered emission region. The performance of the WOLED is better at low current density and comparable to those fabricated by co-evaporation method at high current density. We also found that there is significant singlet exciton diffusion toward the hole-transporting layer. However the addition of a thin layer of BCzVBi at the NPB/CBP interface was able to confine the singlet exciton within the emission region (CBP). Triplet excitons were well confined within the emission region, enabling an efficient extraction. The method reported here is of significance to tandem WOLED operating at relatively lower current density.

Thiophene/phenylene co-oligomer

ABSTRACT

We have developed an ambipolar thiophene/phenylene co-oligomer (TPCO) by introducing the trifluoromethyl group and the methoxy group to molecular terminals of the parent (unsubstituted) TPCO molecule. The crystals of the compound exhibit the ambipolar carrier transport on the field-effect transistors with homogeneous Au electrodes and heterogeneous MgAg and Au electrodes. The latter device definitively emits the light by applying sinusoidal-wave and square-wave alternating-current (AC) voltages to the gate electrode. Time-dependent emission measurements indicate that major emissions take place twice during each period of the AC gate bias.

1. Introduction

Organic light-emitting field-effect transistors (OLEFETs) are currently attracting increasing attention as reliable devices that can combine signal transformation and its amplification, since a prototype device was proposed and developed [1]. Their device performance is based upon simultaneous injection of electrons and holes into the organic layer and their subsequent recombination. Several attempts were made to facilitate these processes. A typical example is a combination of n-type and p-type organic semiconductor materials. Muccini et al. investigated bi-layered structures [2] and blended films [3] composed of both the types of semiconductors. Recently, they demonstrated high external quantum efficiency (EQE) of 5% using trilayer heterostructure device composed of a light-emitting layer sandwiched between p-type and n-type layers [4]. To achieve the effective charge injection and transport, researchers developed a novel class of ambipolar organic semiconductors. Using poly(9,9-dioctylfluorene-*alt*-benzothiadiazole) (F8BT) [5,6], Sirringhaus et al. were successful in making an ambipolar OLEFET with a single-component semiconductor layer [7,8]. The morphology of amorphous films of F8BT, however, had to be optimized in order to achieve a good balance between charge transport and emission characteristics [8]. More specifically, the annealing temperatures of the processed F8BT were carefully set to prevent the films from forming polycrystalline morphology. Moreover, gold (source and drain) electrodes were modified with a self-assembled monolayer (SAM) to improve the ambipolar device operation [8]. Meanwhile, the ambipolar transport was attained in the OLEFETs using heterogeneous source and drain metal electrodes [9,10]. This is principally because electrons are hard to inject; very unstable metals such as calcium have to be used to improve their injection [9,10].

Thus organic semiconductors that ensure the steady ambipolar device operation are highly desired. With these circumstances as a background we have designed and developed a novel class of ambipolar organic semiconductors based on thiophene/phenylene co-oligomers (TPCOs)

[11]. The TPCOs consist of inline thiophene and phenylene rings with those rings suitably arranged at molecular level. The ambipolar TPCO materials pertinent to the present studies have *both* an electron donating group and an electron withdrawing group on molecular terminals. We have conceived this molecular design strategy on the basis of the fact that the modification of the molecular terminals with the electron donating (withdrawing) groups produces p-type (n-type) semiconductors [12]. Typical examples of them include a methoxy-substituted TPCO, 2,5-bis(4'-methoxybiphenyl-4-yl)thiophene (BP1T-OMe) [12], as the p-type material and a trifluoromethyl-substituted TPCO, 1,4-bis{5-[4-(trifluoromethyl)phenyl]thiophen-2-yl}benzene (AC5-CF_3) [12,13], as the n-type material. Notice that unmodified (i.e. unsubstituted) compounds are of p-type. An example is 2,5-bis(4-biphenylyl)thiophene (BP1T) [11], a parent molecule of BP1T-OMe. The compound we have particularly designed is 2-{4-[5-(4-methoxyphenyl)-2-thienyl]phenyl}-5-[4-(trifluoromethyl)phenyl]thiophene (henceforth abbreviated as AC5-1CF_3-12OMe); see Fig. 1 for the structural formula. We introduced the methoxy group and trifluoromethyl group to the molecular terminals of a parent molecule, 1,4-bis(5-phenylthiophen-2-yl) benzene, AC5 [11].

The devices based on a crystal of AC5-1CF_3-12OMe not only show the ambipolar carrier transport, but produce the characteristic light emission. The emission feature of the devices is probed by the recently-proposed novel operating method that is characterized by applying alternating-current (AC) biases to the gate electrodes [14,15]. For this purpose we have used both a sinusoidal-wave and a square-wave for the gate bias. In both the cases we successfully correlate the time-dependent light emission with the injection of carriers of both the types (i.e. holes and electrons).

2. Results

Fig. 2 depicts a schematic device structure. We used several combinations of metals for source and drain electrodes for the device to have homogeneous electrodes or heterogeneous electrodes (see Section 5.2.). Care should be taken with the electrodes designation according to whether the device is operated for the purpose of measuring the carrier mobility or performing the light-emitting experiments. When we determined the electron mobility on a device with heterogeneous electrodes of MgAg and Au, we solely designated the MgAg electrode as the electron-injection contact. This was because we obtained the higher electron mobility for this electrode designation than the reversed designation. For this measuring configuration we assigned the MgAg (Au) electrode to the source (drain) contact according to the convention [16]. With the hole-enhancement measurement, the electrode designation

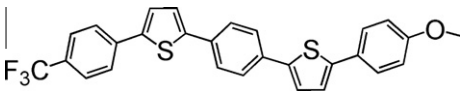

Fig. 1. Structural formula of AC5-1CF_3-12OMe.

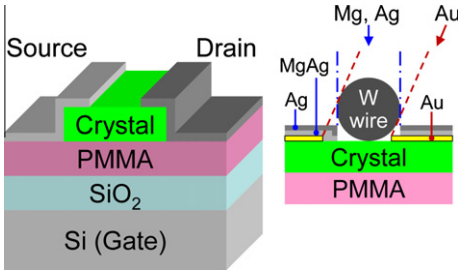

Fig. 2. Schematic structure of a single crystal field-effect transistor. Three combinations of metals of (MgAg, MgAg), (Au, Au), and (MgAg, Au) were used for source and drain electrodes. The former two cases are for the homogeneous electrodes and the last case is relevant to the heterogeneous electrodes. The inset shows an enlarged cross-sectional view of and near the channel of a device with the heterogeneous MgAg and Au electrodes. Care should be taken with the electrode designation according to whether the device is operated for the purpose of measuring the carrier mobility or performing the light-emitting experiments (see text).

was reversed. Regarding the light-emitting experiments we defined the source (drain) electrode as the electron (hole) injection contact. For this purpose the MgAg electrode was chosen as the electron-injection contact as well. A negative (positive) DC voltage with the same absolute value was routinely applied to the source (drain) contact.

The device with homogeneous MgAg electrodes showed typical n-type conduction. The field-effect electron mobility was estimated to be 1.9×10^{-4} $cm^2\,V^{-1}\,s^{-1}$ at the linear region. This device, however, did not show the hole transport (p-type) characteristic. For the device with homogeneous Au electrodes, on the other hand, we observed ambipolar transport feature. The electron and hole mobilities were estimated at the linear regions to be 3.4×10^{-5} and 5.1×10^{-5} $cm^2\,V^{-1}\,s^{-1}$, respectively. In this specific device, the hole mobility was slightly greater than the electron one. For a device with heterogeneous electrodes of MgAg and Au, the ambipolar transport is again evident. The output characteristics of the device were depicted in Fig. 3a for the electron-enhancement mode and Fig. 3b for the hole-enhancement mode. Notice once again that in Fig. 3a we designated the MgAg electrode as the source contact and that in Fig. 3b we assigned that same electrode to the drain contact. In the electron-enhancement mode (Fig. 3a) the drain currents started increasing in the region $V_{DS} \leqslant 10$ V. In the hole-enhancement mode (Fig. 3b) the drain currents rose up around $V_{DS} \approx -30$ V. In both modes, the drain currents were modulated with the gate voltages of $|V_G| \geqslant 60$ V. The electron and hole mobilities at the linear regions were 1.1×10^{-4} and 6.0×10^{-6} $cm^2\,V^{-1}\,s^{-1}$, respectively. The electron mobility is larger than the hole mobility, contrary to the device with homogeneous Au electrodes in the present studies and other unsubstituted TPCO-based ambipolar devices with heterogeneous electrodes [10,17].

Of the devices indicating the ambipolar characteristics, the current-injected light emission is clearly noted by eye under AC gate biases [14] for the device with the heterogeneous MgAg and Au electrodes. This is due to improved electron injection from the MgAg source electrode. Fig. 4a illustrates a micrograph of an unlit device and Fig. 4b represents that lighted in the dark under the AC gate bias

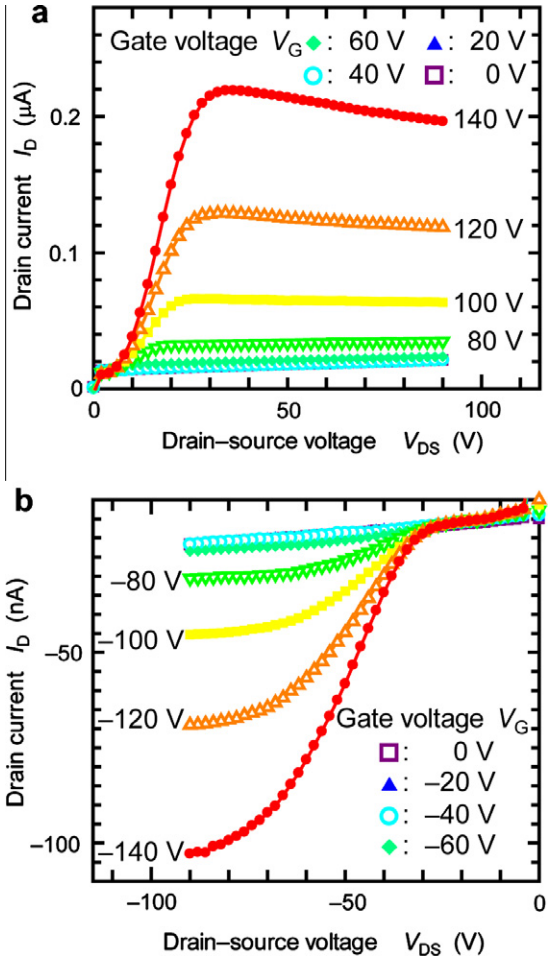

Fig. 3. Output characteristics of the device with heterogeneous MgAg and Au electrodes (a) in the electron-enhancement mode and (b) in the hole-enhancement mode.

application. For the latter, the green emission dominantly takes place from the channel region. Emissions near the source and drain contacts were noticed as well. In Fig. 4b direct current (DC) voltages of −100 and 100 V were applied to MgAg and Au electrodes, respectively (see Section 5.3.). We simultaneously applied a sinusoidal-wave AC gate voltage with an amplitude 120 V and frequency 500 Hz. Fig. 4c shows the emission spectrum taken under the AC gate bias application using another device. To record the emission spectrum, the device was operated by applying a square-wave AC gate voltage with its amplitude 120 V and frequency 20 kHz. A DC voltage of −100 (100) V was applied to the MgAg (Au) electrode. In Fig. 4c we compare the electrically-excited spectrum with an optically-excited one. Both the spectral profiles are closely related with the same peak position of the dominant line occurring at 538.40 nm. The full width at half maximum (FWHM) was 39.67 nm for the electrically-excited spectrum and 39.07 nm for the optically-excited spectrum.

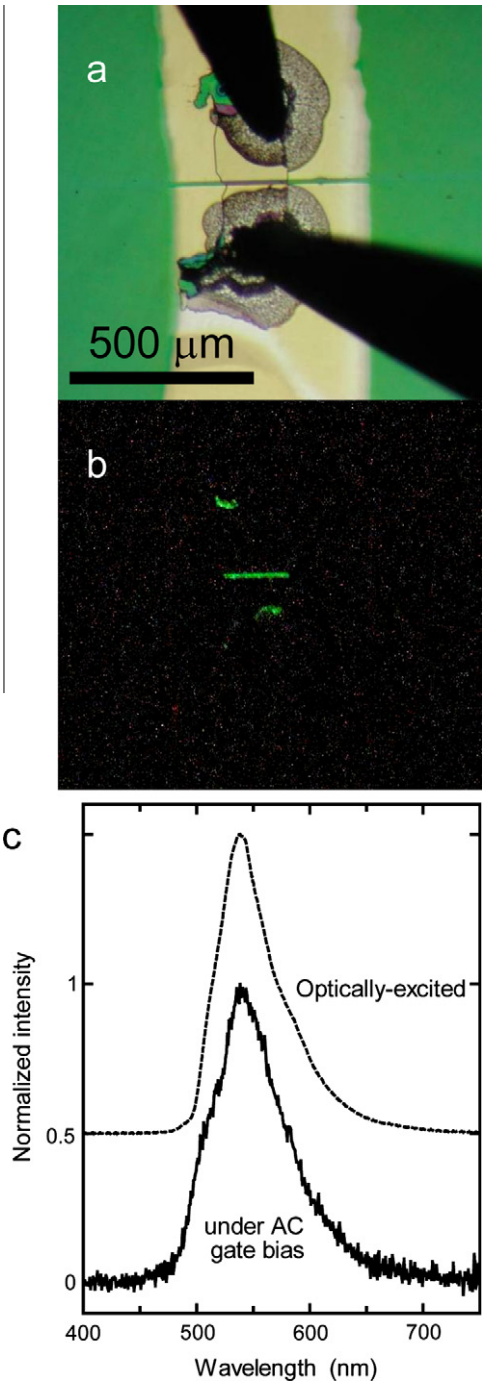

Fig. 4. (a) Micrograph of an AC5-1CF_3-12OMe single-crystal OLEFET. The two dark parts on the top and the right of the micrograph are tungsten needle microprobes. (b) Micrograph of the device lit in the dark under the application of a sinusoidal-wave AC gate bias. Green emissions were noted as a horizontal bar at the channel and as semicircles near the source and drain contacts. (c) Emission spectrum from the device operated under a square-wave AC gate bias. The spectrum is compared with an optically-excited emission spectrum from an AC5-1CF_3-12OMe crystal. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 5a and b compare the time-dependent emission intensity characteristics of the devices operated under the sinusoidal-wave AC gate bias and the square-wave gate bias. The temporal waveforms of the gate biases are indicated as a guide. In the sinusoidal-wave case we set the DC voltages and the amplitude and frequency of AC gate bias at values the same as the above. We observed emissions when both the maximum and minimum gate biases were reached (Fig. 5a). For the square-wave bias, in turn, we set DC voltages of the MgAg and Au electrodes at −70 and 70 V, respectively, and applied to the gate electrode an AC bias with an amplitude 90 V and frequency 5 kHz. Strong emissions clearly take place when the gate bias switches its polarity traversing 0 V. We stress that the maximum instantaneous intensity reaches several tens of times that recorded for the sinusoidal-wave case. Correspondingly the EQE for the square-wave device (Fig. 5b) was estimated at 0.16%. This number was higher by five times than 0.032% obtained for the sinusoidal-wave device (Fig. 5a). For both the sinusoidal-wave and square-wave cases, we have observed major emissions *twice* with each period (a 2π-phase change). This observation means that the moment the gate polarity is switched, electrons and holes are alternately injected through the source and drain electrode to produce the light emission. This provides a striking contrast to the results of our previous studies where BP1T was used for a device [14]. In that case we noticed a major emission only once with each period.

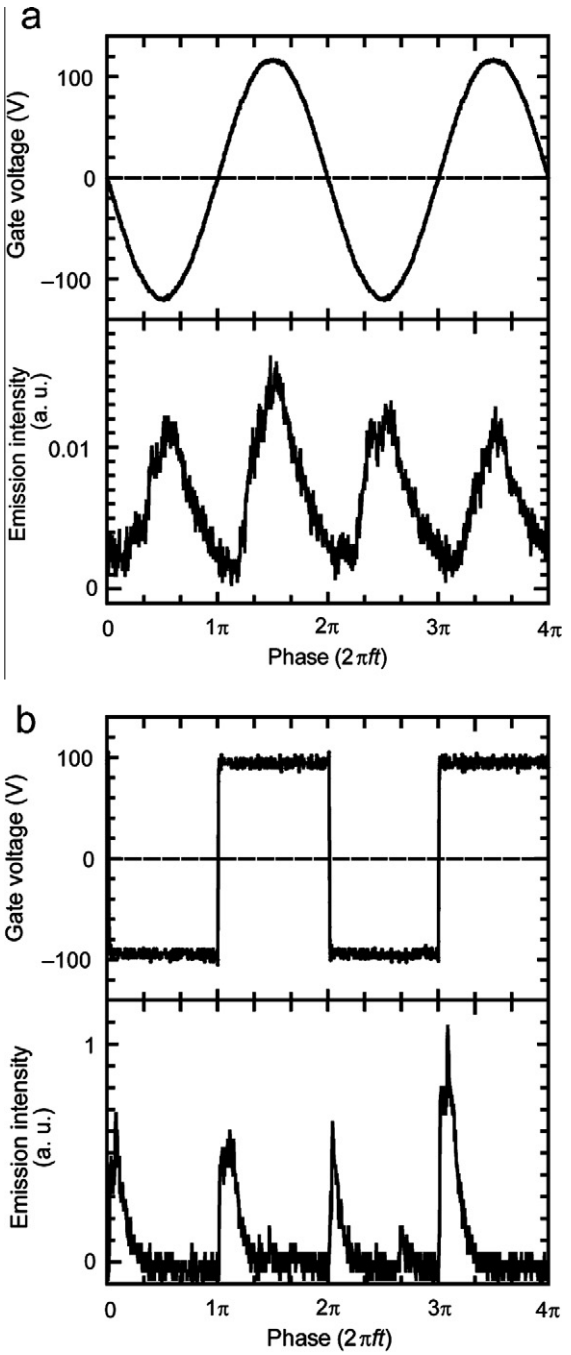

Fig. 5. Emission intensities of the devices as a function of phase. The devices were operated under (a) the sinusoidal-wave and (b) the square-wave AC gate biases. The temporal waveforms of the gate biases are indicated as a guide.

3. Discussion

Occurrence of the two major emissions is interpreted as follows: The electrons (holes) are injected from the source (drain) electrode when the gate bias is positive (negative). The injected carriers flow in the channel and are transported toward the opposite electrode. They recombine with carriers of the opposite polarity which are injected from that electrode when the polarity of the gate voltage is switched. This process evenly takes place twice during the individual period. The rapid polarity switching of the gate bias is responsible for the increase in the emission intensities, as previously observed in the devices with a p-type semiconductor such as BP1T [14,15]. The increased emission intensity is because principally of suppression of the depletion of carriers without the radiative recombination [15]. EQEs of the present studies are larger than those obtained for the BP1T thin film devices [14]. This results from the balanced injection and transportation of both the electrons and holes in the AC5-1CF_3-12OMe crystals.

Fig. 6a depicts an energy diagram where energy levels of the lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) for AC5-1CF_3-12OMe are indicated relative to Fermi levels of Au (−5.1 eV [18]) and Mg (−3.66 eV [18]). The LUMO and HOMO levels were −1.86 and −5.16 eV, respectively. The HOMO level is close to the Fermi level of Au. This is consistent with the observation that the homogeneous Au device indicates a good p-type characteristic. Meanwhile, the Au Fermi level is separated from the LUMO level by 3.24 eV. The n-type feature of the homogeneous Au device means that electrons can be injected from the Au electrode into the AC5-1CF_3-12OMe layer beyond the energy barrier of 3.24 eV. This number is exceptionally large and should be compared with a corresponding value of ∼1.8 eV for an ambipolar OLEFET device based on the F8BT thin film equipped with homogeneous Au electrodes [8].

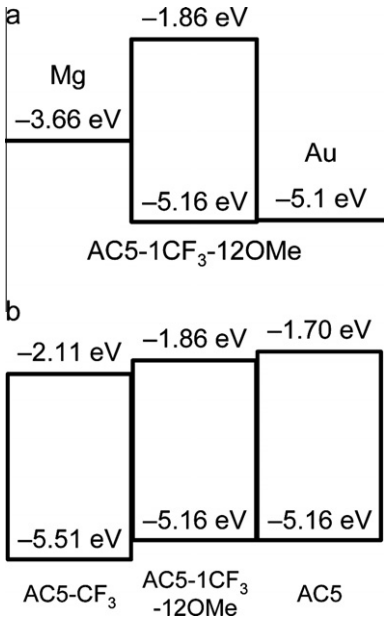

Fig. 6. (a) Energy diagram of the LUMO and HOMO levels of AC5-1CF_3-12OMe relative to Fermi levels of Mg and Au. The levels are indicated with respect to the vacuum level. (b) HOMO and LUMO levels of several TPCOs sharing the parent AC5 structure.

The Mg Fermi level, in turn, is located halfway between the LUMO and HOMO levels (Fig. 6a). Experimental results in the present studies again imply that electrons are easily injected from Mg beyond a barrier 1.80 eV into the AC5-1CF_3-12OMe layer. This is similarly the case with the AC5-CF_3 devices with homogeneous MgAg electrodes [13] to which the corresponding value is 1.55 eV; see Fig. 6b where we compare the HOMO and LUMO levels of several TPCOs sharing the parent AC5 structure. Of these, AC5-1CF_3-12OMe combines the superior abilities of the electron and hole injection. The energy diagram of Fig. 6 means that the hole injection barrier from Mg is 1.50 eV (1.85 eV) for AC5-1CF_3-12OMe (AC5-CF_3). These numbers are smaller than the above-mentioned electron injection barrier from Au into AC5-1CF_3-12OMe. This is indicative of the comparative difficulty in the hole injection from Mg [13]. The origin would therefore need seeking appropriately.

4. Conclusion

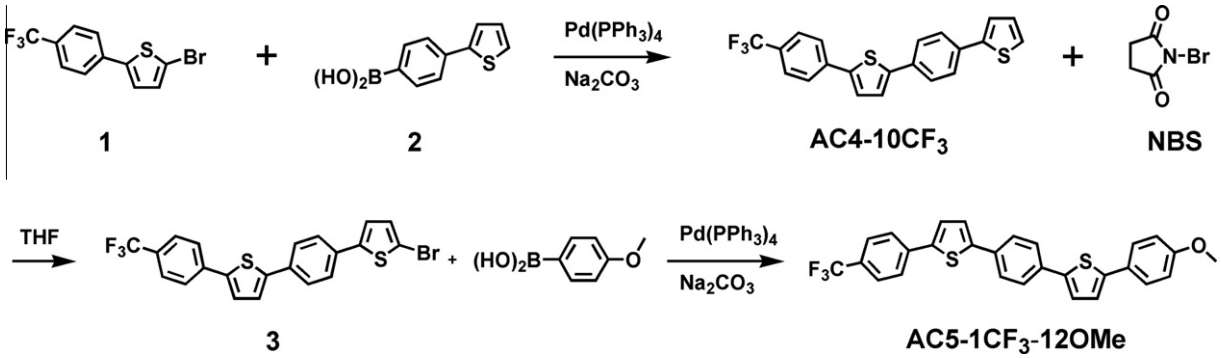
We have developed an ambipolar TPCO, AC5-1CF_3-12OMe, by introducing the trifluoromethyl group and the methoxy group to molecular terminals of the parent molecule AC5. The compound AC5-1CF_3-12OMe exhibits the ambipolar carrier transport on the FETs with the devices of homogeneous Au electrodes and heterogeneous MgAg and Au electrodes. Under the AC bias application to the gate electrode the device of the heterogeneous electrodes definitively shows the current-injected light emission. An EQE under square-wave gate bias was 0.16%. The time-dependent emission measurements obviously demonstrate that the major emissions take place twice during each period. This indicates that the moment the gate polarity is switched, electrons and holes are alternately injected through the source and drain electrodes to produce the light emission.

In combination with the AC gate bias operation method, the molecular design strategy in the present studies not only supports a platform display technology but also gives a powerful clue to exploring the charge injection and transport mechanisms associated with light emission.

5. Experimental details

5.1. Synthesis and characterization of AC5-1CF_3-12OMe

We show the synthetic route of AC5-1CF_3-12OMe in Scheme 1. The synthesis of AC5-1CF_3-12OMe is based on the Suzuki coupling reactions [19]. 2-Bromo-5-(4-trifluoromethylphenyl)thiophene [20] (**1**) and 4-(2-thienyl)phenylboronic acid [21] (**2**) were synthesized following the literature methods. Compounds **1** (6.1 g, 20 mmol), **2** (4.9 g, 24 mmol), and tetrakis(triphenylphosphine)palladium(0) [abbreviated as $Pd(PPh_3)_4$ in Scheme 1] (1.2 g, 1.0 mmol) were dispersed and dissolved in chlorobenzene (400 mL) and aqueous sodium carbonate (2.5 g, 24 mmol in 400 mL of water) at room temperature under a nitrogen environment. The mixture was warmed to 90 °C and stirred for 5 h. The reaction mixture was cooled to yield precipitates. The filtered precipitates were washed with cyclopentyl methyl ether and dried under reduced pressure to give



Scheme 1. Synthetic route of AC5-1CF_3-12OMe.

yellow crystals of 5.4 g (70%, 14 mmol) of 2-[4-(2-thienyl) phenyl]-5-(4-trifluoromethylphenyl)thiophene (AC4-10CF_3).

AC4-10CF_3 (3.9 g, 10 mmol) was dissolved in tetrahydrofuran (THF, 1000 mL). To this solution was added dropwise *N*-bromosuccinimide (abbreviated as NBS; 2.5 g, 14 mmol) at room temperature under a dry nitrogen environment and the mixture was stirred for 2 h. The resulting reaction solution was cooled to yield precipitates. The filtered precipitates were washed with THF and dried under reduced pressure to produce yellow crystals of 3.4 g (73%, 7.3 mmol) of 2-[4-(5-bromo-2-thienyl)phenyl]-5-(4-trifluoromethylphenyl)thiophene (**3**).

Compound **3** (2.8 g, 6.0 mmol) was dissolved in chlorobenzene (120 mL) and water (120 mL). To this solution, 4-methoxyphenylboronic acid (1.1 g, 7.2 mmol), sodium carbonate (0.8 g, 7.5 mmol), and $Pd(PPh_3)_4$ (0.3 g, 0.3 mmol) were added successively. The resulting solution was then warmed to 90 °C and stirred for 5 h. The reaction solution was cooled to produce precipitates. The precipitates were washed with cyclopentyl methyl ether and dried under reduced pressure to give 2.7 g (92%, 5.5 mmol) of AC5-1CF_3-12OMe as yellow crystals. m.p. 338 °C. ^{1}H NMR (400 MHz, THF-d_8, δ, ppm): 3.81 (s, 3H, methoxy protons), 6.95 (d, J = 8.8 Hz, 2H, phenylene protons), 7.27 (d, J = 3.8 Hz, 1H, thienylene proton), 7.42 (d, J = 3.8 Hz, 1H, thienylene proton), 7.49 (d, J = 3.8 Hz, 1H, thienylene proton), 7.57–7.60 (m, 3H), 7.67–7.71 (m, 6H), 7.87 (d, J = 8.1 Hz, 2H, phenylene protons). IR (KBr cm^{-1}): 3075 (w), 2941 (w), 1497 (m), 1453 (m), 1414 (w), 1331 (s), 1261 (m), 1129 (m), 1032 (m), 835 (m), 797 (vs). UV–vis (THF): λ_{max} = 384 nm. EIMS (m/z): 492 (M^+). Anal. To characterize AC5-1CF_3-12OMe, ^{1}H NMR spectra were measured on a Varian Mercury-400BB spectrometer (400 MHz) in a solution of deuteriotetrahydrofuran and chemical shifts were recorded in ppm (δ) relative to tetramethylsilane as an internal standard. IR spectra were taken on a JEOL JIR-6500 FT-IR spectrophotometer with finely pulverized samples dispersed and embedded in a potassium bromide matrix. Electron impact mass spectra were collected on a SHIMADZU GCMS-QP5000 mass spectrometer. Elementary analyses were performed with a J-Science Micro Corder JM10 and an Orion model 920A after two time purifications of the material by train sublimation technique [22]. UV–vis spectra were recorded on a HITACHI U-4100. Melting points were determined on a Seiko Instruments EXSTAR DSC 6220 thermal analysis system.

5.2. Device fabrication

Crystals of AC5-1CF_3-12OMe (of 240–1040 μm in size and 225–1920 nm in thickness) were grown according to the literature method [23] under nitrogen gas flow (35–50 mL/min). The AC5-1CF_3-12OMe crystals were laminated on a poly(methyl methacrylate) (PMMA) layer (143–330 nm in thickness) that was spin-coated with its 5 wt.% toluene solution on an Si substrate (as the gate contact) covered with a 300-nm thick SiO_2 layer (see Fig. 2). The devices were completed as the top-contact and bottom-gate configuration by depositing metal electrodes in vacuum (~10^{-3} Pa). These metal electrodes were deposited on top of the AC5-1CF_3-12OMe crystal over a tungsten wire in close contact with the crystal. For the electrodes we chose three different combinations of metals either homogeneous or heterogeneous: (i) MgAg (100-nm thick), (ii) Au (50 nm), and (iii) MgAg (30–40 nm) and Au (30 nm). The homogeneous MgAg electrodes were formed first by co-depositing Mg and Ag (15 nm) and depositing Ag (85 nm) subsequently. For the fabrication of heterogeneous MgAg and Au electrodes, the Au (30 nm) was first evaporated obliquely relative to the channel (see the inset of Fig. 2). The Mg and Ag were successively evaporated from directly above the channel; the MgAg layers were formed by co-depositing Mg and Ag (20 nm) and subsequently depositing Ag (10–20 nm) such that the total thickness of the resulting heterogeneous electrodes was 60–70 nm. Note that the innermost parts of the electrodes (i.e. either Au or MgAg) determine the carrier injection (see the inset of Fig. 2). The channel length and width of the devices ranged from 8.3–11.2 μm and 0.16–1.53 mm, respectively.

5.3. Device operation and spectroscopic measurements

For the purpose of estimating the carrier mobility, we routinely operated the device in vacuum (~10^{-3} Pa) in either the electron-enhancement or hole-enhancement mode [13]. For the emission measurements, AC biases were applied to the gate contact. We used either a sinusoidal-wave or a square-wave form with various AC voltage amplitudes and frequencies according to the purposes of experiments.

The experimental setups for the light-emitting experiments and spectroscopic measurements were similar to those employed in our previous studies [14,15]. The device was mounted on a sample stage in a vacuum chamber (~10^{-3} Pa). The emissions occurring from the device were collected with an OLYMPUS SZ61 stereo microscope through a glass window of the vacuum chamber. The emission spectra were recorded in a manner similar as before [14,15]. The optically-excited emission spectrum was measured using the setup and method identical to those used in the previous study [24] except a sharp cut filter was not used in the present studies.

5.4. Quantum chemical calculations

We carried out molecular orbital (MO) calculations of AC5-1CF_3-12OMe. The density functional theory (DFT) calculations were performed to optimize the geometry and estimate the HOMO and LUMO energies at the B3LYP/6-31G(d) level using Gaussian 03 program [25]. We also calculated the energy levels for the parent material AC5 [26] and a homogeneously substituted material AC5-CF_3.

ABSTRACT

We report successful realization of workable polarized phosphorescent organic light-emitting devices (OLEDs) by combining a recently developed mesogenic phosphorescent Pt(II) complex and a mesogenic oligofluorene host to form the corresponding mesogenic host–guest emitting system. In the host–guest film, the mesogenic Pt(II) complex tends to aggregate and self-assemble into the columnar stacking arrangement, exhibiting metal–metal-to-ligand charge transfer (MMLCT) emission of the Pt(II) complex. Both the host molecules and guest aggregates in the host–guest films were successfully aligned by using the rubbed conducting polymer as the alignment layer. With such aligned host–guest films, polarized red-emitting OLEDs were successfully implemented, showing an EL polarization ratio of ~2, a maximal brightness exceeding 2000 cd/m^2, and a cd/A efficiency up to 2.4 cd/A. Due to the particular alignment mechanism of guest aggregates and the unique MMLCT emission mechanism, the polarized OLED exhibiting stronger electroluminescence perpendicular to the rubbing direction than along the rubbing direction.

1. Introduction

The polarization control of light is of particular importance for optical information processing devices, such as displays, optical storage, and stereoscopic imaging systems etc. [1,2]. For instance, linearly polarized electroluminescence (EL) devices would be useful for backlights of liquid–crystal displays (LCDs) [3,4]. With polarized backlights, the displays can be made "greener" (i.e. more power-efficient) and simplified by removing polarizers needed for conventional non-polarized backlights and the optical losses it induced. As such, there had been substantial efforts in developing polarized organic light-emitting devices (OLEDs) [5–19]. Among them, linearly polarized OLEDs adopting mesogenic polyfluorenes/oligofluorenes together with appropriate molecular alignment techniques are some distinctive examples [5–11]. S.H. Chen et al. also reported the use of liquid–crystalline oligofluorenes as hosts to guide molecular orientation of guest emitters, forming the polarized host–guest emitting systems [7–10]. The previous efforts in polarized OLEDs were mainly on fluorescent OLEDs. Yet, the development of OLEDs in recent years has largely shifted toward phosphorescent OLEDs [20,21], since phosphorescent OLEDs could effectively utilize both singlet and triplet excitons and realize ideally 100% internal quantum efficiencies [22,23]. As such,

doi:10.1016/j.orgel.2010.09.020

it is of both scientific and technical importance to explore the possibility of achieving polarized phosphorescent OLEDs.

In this paper, we report an initial attempt to realize workable and functional polarized phosphorescent OLEDs by using a recently developed mesogenic phosphorescent metal (Pt(II)) complex, which is combined with a mesogenic oligofluorene host to form the corresponding mesogenic host–guest emitting system.

2. Experiments

2.1. Materials

Fig. 1 shows the mesogenic materials, a Pt(II) complex N200, $Pt(N^{\wedge}N)_2$ [*N* = 2-(3-(3,4,5-trihexyloxyphenyl)-1H-pyrazol-5-yl)pyridine], and a fluorene oligomer F(MB)5, penta[9,9-bis(2-methylbutyl)fluorene], used in this work. The Pt(II) complex N200 adopts the distinctive pyridyl azolate as ligands, which are known to form strong chelate bonding with Pt ions and render the molecule a square-plannar geometry, affording distinctive emission (phosphorescent) properties [24–26]. Indeed, the Pt(II) complex N200 exhibits rather efficient green phosphorescence at room temperature in dilute solutions [26]. Further attaching alkyloxyphenyl groups onto the ligands gives certain flexibility to the molecular core and mesomorphic characteristics, thereby yielding luminescent metallomesogens [26–30]. As studied by polarizing optical microscopy and differential scanning calorimetry, the Pt(II) complex N200 shows liquid–crystalline properties within a rather wide temperature range. Upon heating of the bulk crystalline samples, a transition from the solid to the hexagonal columnar mesophase (as verified by X-ray diffraction [26]) and a transition from the mesophase to the isotropic liquid occurs around 98 °C and 340 °C, respectively. The details of syntheses and basic material properties of the Pt(II) complex N200 had been reported elsewhere recently [26].

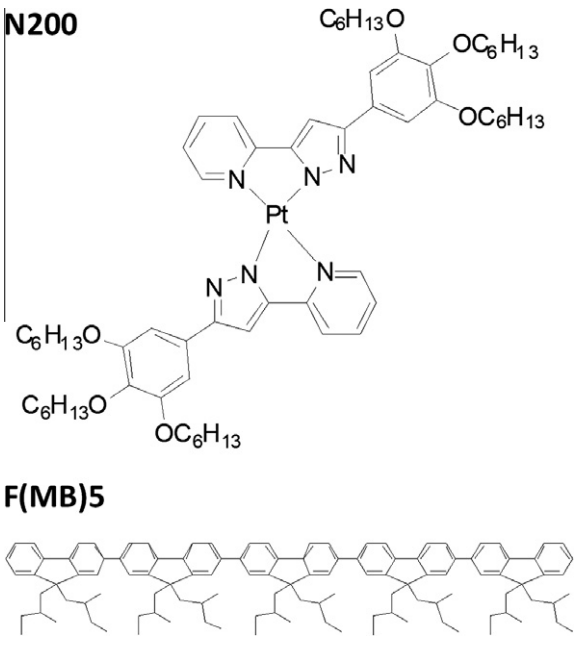

Fig. 1. Molecular structures of N200 and F(MB)5.

On the other hand, the fluorene oligomer F(MB)5 consists of five fluorene units on the backbone and two 2-methylbutyl substituents on C9 atoms [8,9]. F(MB)5 belongs to the class of glass-forming nematic oligofluorenes, that is, materials that exhibit the nematic mesophase at elevated temperatures and yet also the stable glass phase at room temperature [7–10]. As studied by polarizing optical microscopy and differential scanning calorimetry, F(MB)5 exhibits a glass transition (Tg) at ~89 °C and a nematic-to-isotropic transition at 167 °C. It had been demonstrated that liquid–crystal glass of F(MB)5 could be formed by freezing its mesophase down to room temperature without crystallization, and that the aligned glassy nematic film of F(MB)5 could be formed by utilizing mesophase-mediated alignment (e.g. assisted by the rubbed polyimide alignment layer) at elevated temperatures [8,9]. F(MB)5 is also an efficient fluorescent blue emitter with a thin-film quantum yield of >50% [8,9]. Detailed Syntheses and characterizations of F(MB)5 could be found in previous publications [8].

2.2. Molecular alignment

To conduct and study molecular alignment of the Pt(II) complex N200 for polarized emission, different sample structures and alignment approaches were tested: (1) In the first scheme, the active thin films under investigation were spin-coated onto the quartz substrates and then were uniaxially rubbed with a dustless cloth for surface alignment. (2) In the second scheme, a conducting polymer Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) was used as the alignment layer. PEDOT:PSS was spin-coated onto quartz substrates, dried at 130 °C in air, and uniaxially rubbed with the dust-free cloth. The active thin films under investigation were then spin-coated onto the rubbed PEDOT:PSS for surface alignment. In (1) and (2), the active layer to be aligned could be a neat film of the Pt (II) complex N200 or a F(MB)5:N200 host–guest film. To induce mesophase mediated molecular alignment, after sample preparation, the neat N200 films and the F(MB)5:N200 mixture films were further annealed at 150 °C and 120 °C, respectively, for 1 h.

2.3. Photophysical characterization

The UV–visible absorption spectra were measured on a spectrophotometer. Photoluminescence (PL) spectra were measured on a luminescence spectrometer with a liquid-nitrogen cooled charge coupled device (CCD) coupled to a monochromator, using the 325-nm line of He-Cd laser as the excitation [31,32].

The polarized PL spectra of the aligned samples were measured with a polarizer inserted between the sample and the spectrograph. The polarizer and the rubbing/alignment orientation was set at 45° relative to the entrance-slit/grating orientation of the spectrograph, so that the

polarization dependence of the detection system (e.g. effects of slit orientation, diffraction gratings etc.) can be avoided and the intensities of PL parallel and perpendicular to the rubbing direction could be directly compared. The polarized UV–visible absorption spectra of the aligned samples were measured with a polarizer inserted between the lamp source and the sample.

2.4. Device fabrication and characterization

The OLED device on the glass substrates was composed of multiple organic layers sandwiched between the transparent bottom indium-tin-oxide (ITO) anode and the top aluminum (Al) cathode. In general, the layer structure of the polarized OLED in sequence consisted of: ITO/rubbed PEDOT:PSS (30 nm)/F(MB)5:25 wt.% N200 (55 nm)/TPBi (45 nm)/LiF (0. 5 nm)/Al (150 nm). The ITO-coated glass substrate was cleaned by sequential ultrasonication in detergents and in organic solvents, followed by UV ozone treatments. The uniaxially rubbed PEDOT:PSS (30 nm) was used as the hole injection layer (HIL) and also as the alignment layer [7–10]. F(MB)5:25 wt.% N200 was spin-coated on top of the rubbed PEDOT:PSS layer as the emitting layer (EML). Before deposition of subsequent functional layers, the film of F(MB)5:25 wt.% N200 was annealed at 120 °C for 1 h. Then, 1,3,5-tri(phenyl-2-benzimidazoly)-benzene (TPBi) [33–35], thin lithium fluoride (LiF) (0.5 nm) [36], and Al were deposited as the electron transport layer (ETL), the electron injection layer (EIL), and the cathode, respectively. TPBi, LiF, and Al were deposited by thermal evaporation in a vacuum chamber with a base pressure of $<10^{-6}$ torr. The evaporation system permitted the fabrication of the complete device structure in a single pump-down without breaking vacuum.

The current–voltage-brightness (I–V-L) characterization of the light-emitting devices was performed with a source-measurement unit and a Si photodiode calibrated with the Photo Research PR650 spectroradiometer. The electroluminescence (EL) spectra of devices were collected by a CCD spectrograph. For polarized EL spectra, the measurement was conducted in a way same as the polarized PL measurements.

3. Results and discussions

3.1. Photophysical properties

Fig. 2 shows the absorption and PL spectra of N200 in the dilute CH_2Cl_2 solution (5×10^{-6} M) at 298 K, the absorption and PL spectra of the spin-coated N200 neat film at 298 K, and the PL spectra of the N200 neat film at 77 K.

Based on photophysical properties of previously reported Pt(II) complexes possessing cyclometalating chelates and previous quantum chemical calculations [37–43], the absorption spectrum of N200 in solution can be ascribed to several domains in terms of the absorption wavelength and intensity. The intense absorption bands in the higher-energy region (<300 nm) mainly originate from the ligand-centered transitions, as supported by the similar

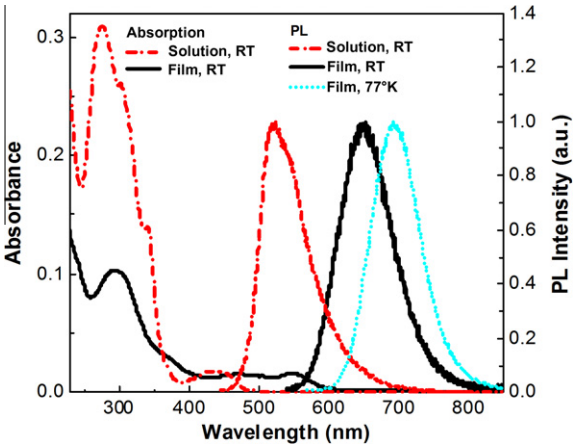

Fig. 2. Absorption and emission spectra of N200 in CH_2Cl_2 solution and in thin films.

transition documented for the free anionic ligands [44,45]. The much weaker lower-energy absorption bands around 380–480 nm can be assigned to the metal-to-ligand charge transfer band (MLCT) [46,47]. In the CH_2Cl_2 solution at 298 K, the Pt(II) complex N200 shows intense green luminescence with a peak wavelength of about 520 nm. The 520-nm phosphorescence band appears to be a mirror image of the lowest absorption band, suggesting it be monomeric MLCT emission from the molecules in the dilute solution.

In sharp contrast with absorption and PL spectra of N200 in the dilute solution, the absorption of the N200 neat film extends to a much longer wavelength of ~600 nm (and shows a lowest-energy peak around 550 nm), together with a significant red shift of the room-temperature PL to red emission peaking around 650 nm. Spectral properties of the spin-cast films suggest N200 molecules exhibit strong ground-state intermolecular interactions (instead of simply excited-state interaction, like excimers) and they tend to self-assemble to form aggregates in films. Previous luminescence characterization of bulk samples of these Pt(II) complexes revealed that they exhibited red emission only in the columnar mesophase, while monomer-like green emission was observed in the isotropic liquid state or in the crystalline state (in which N200 molecules are packed in an antiparallel format) [26]. Thus the appearance of red emission in N200 samples appears to be a good indication of columnar-mesophase-like molecular packing. Due to the columnar mesomorphic nature of N200 and the resemblance of photophysical properties in spin-cast films to those of bulk samples in the liquid crystal phase [26], presumably the square-planar N200 molecules also pack into a one-dimensional columnar stacking arrangement in spin-cast films. The extension of the absorption to longer wavelengths (lower energies) and red emission in neat films can then be reasonably assigned to metal–metal-to-ligand charge transfer (MMLCT) transitions that are associated with the intermolecular interaction between the Pt(II) metal cores [46,47]. As such, the further red shift in PL of N200 films at the lowered temperature (77 K, Fig. 2) can

be attributed to metal–metal bond shortening and thus enhanced intermolecular interaction at lowered temperatures [48–50]. Such temperature dependence of luminescent properties is very different from (i.e. opposite to) that originating from excited-state interaction (e.g. excimers), but is a typical behavior for the metal–metal-stacked compounds and further supports such supramolecular packing and interaction mechanisms [48–50].

Fig. 3 shows the PL spectra of the spin-cast F(MB)5:N200 mixture films with different N200 weight ratios, compared to that of a neat N200 film. It is seen that for the N200 concentrations shown, the emission is more or less comprised of a deep blue emission and a red emission, with the relative intensities depending on the N200 ratios. The deep blue emission can be unambiguously assigned to contribution from F(MB)5 [8,9], while the red emission resembles N200 MMLCT emission in the neat N200 film. It suggests in the spin-cast F(MB)5:N200 mixture films, N200 molecules also aggregate and self-assemble into the column-like stacking arrangement during the casting process, thereby exhibiting MMLCT emission of the Pt(II) complex. The PL spectra also indicate excited-state energy transfer from F(MB)5 to aggregates of N200. The energy transfer increases with the N200 ratios and the aggregate MMLCT emission becomes dominant when the N200 ratio is >20 wt.%.

3.2. Molecular alignment and polarized transitions

With an aim to construct polarized phosphorescent OLED using the mesomorphic N200 complex, we first tried the use of the rubbed PEDOT:PSS film to align the neat N200 film spin-cast onto it, since PEDOT:PSS was to be used as the conductive alignment layer in the polarized OLED. Fig. 4 shows the PL spectra of the annealed N200 film on the rubbed PEDOT:PSS, measured with the polarization parallel with the rubbing direction ($PL_{//}$) and with the polarization perpendicular to the rubbing direction ($PL_{\perp}$). Both show the characteristic MMLCT red emission of N200. $PL_{//}$ and $PL_{\perp}$ spectra are basically of the same

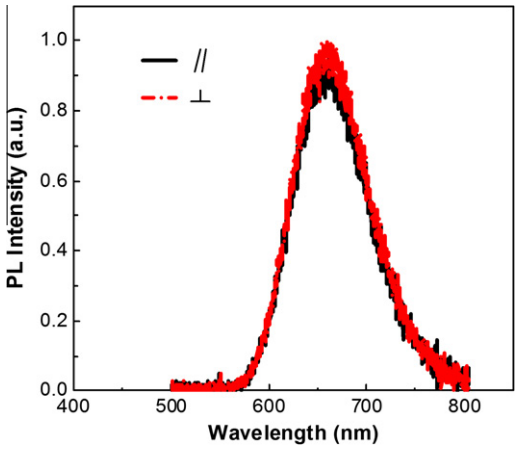

Fig. 4. PL spectra of the annealed N200 film on the uniaxially rubbed PEDOT:PSS layer, measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction.

intensity, indicating that N200 cannot be effectively aligned using the rubbed PEDOT:PSS layer beneath.

We then further studied alignment of the N200 neat films via directly rubbing the surface of the cast N200 film, followed by annealing. Fig. 5 shows the PL and absorption spectra of the uniaxially rubbed N200 film, measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction. With this alignment scheme, now both PL and absorption show distinctive polarization dependence (i.e. polarized transitions), indicating alignment of N200 molecules. In PL, $PL_{\perp}$ shows a larger intensity than $PL_{//}$ and the PL dichroic ratio $PL_{\perp}/PL_{//}$ is about 3. The dichroic phenomena in absorption are more complicated and depend on the wavelength ranges. For the higher-energy ligand-centered transition region (e.g. ~300 nm), the absorption along the rubbing direction is stronger than that perpendicular to the rubbing direction. For the low-energy MMLCT transition region (e.g. 520–600 nm), however, the situation is reversed; the absorption along the rubbing direction is

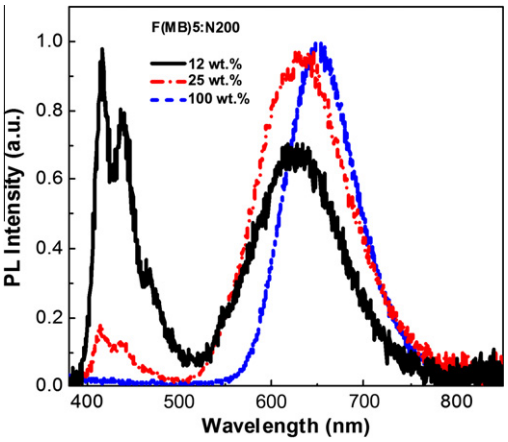

Fig. 3. PL spectra of the F(MB)5:N200 mixture films with different N200 weight ratios.

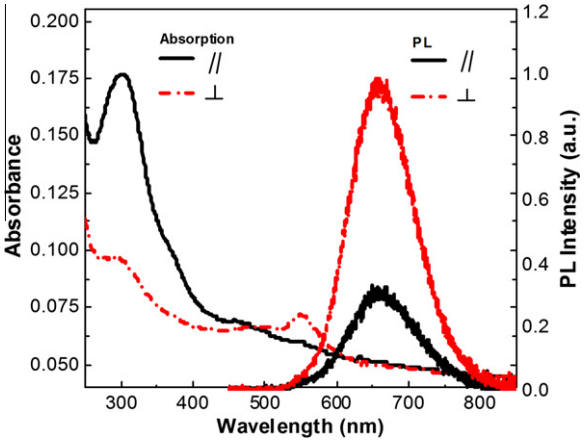

Fig. 5. PL and absorption spectra of the uniaxially rubbed N200 neat film, measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction.

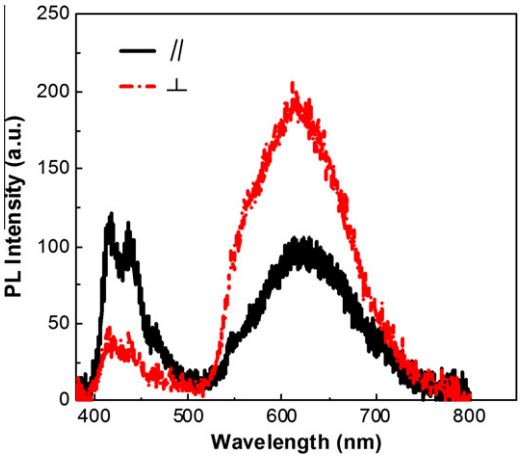

Fig. 6. PL spectra of the annealed F(MB)5:N200 (25 wt.%) mixture film coated onto the rubbed PEDOT:PSS layer, measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction.

weaker than that perpendicular to the rubbing direction. From the polarized absorption in the higher-energy ligand-centered transition region in Fig. 5, one concludes that the pyridyl azolate ligands with alkyloxyphenyl groups are roughly aligned with the rubbing direction. From the consistency of polarized absorption in the low-energy MMLCT transition region and polarized PL (Fig. 5), one can conclude that the axis of the columnar stack of N200 molecules in aggregates is more or less perpendicular to the rubbing direction, since the MMLCT transition is typically along the chain of the metal cores [51–53].

Although polarized emission of N200 was successfully achieved by directly rubbing the N200 neat film, yet the attempt to construct polarized OLEDs using the directly rubbed N200 neat film failed, due to the roughness and damages caused by the mechanic rubbing mechanism. Thus, we next investigated the alignment of the F(MB)5:N200 mixture films. It had been reported that mesomorphic oligofluorenes similar to F(MB)5 can be effectively aligned with a rubbed PEDOT:PSS at elevated temperatures [8–9]. Thus it was hoped that F(MB)5 in F(MB)5:N200 mixture films can also be aligned by the rubbed PEDOT:PSS layer coated beneath and at the same time guide (align) the orientation of N200 molecules in the F(MB)5 host. Fig. 6 shows the PL spectra of the annealed F(MB)5:N200 (25 wt.%) mixture film coated onto the rubbed PEDOT:PSS layer, measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction. Both deep blue emission of F(MB)5 and MMLCT red emission of N200 show polarization dependence (i.e. polarized emission), indicating both F(MB)5 and N200 could be aligned by this configuration. For the F(MB)5 emission, the emission along the rubbing direction is stronger than that perpendicular to the rubbing direction. For N200 MMLCT emission, however, the situation is reversed; the emission along the rubbing direction is weaker than that perpendicular to the rubbing direction, with a PL dichroic ratio $PL_{\perp}/PL_{//}$ of about 2.

For the F(MB)5:N200 mixture film, from the polarized F(MB)5 emission and the polarized N200 MMLCT emission in Fig. 6, it is induced that the oligofluorene backbone are roughly aligned with the rubbing direction and that the axis of the columnar stack of N200 molecules in aggregates is more or less perpendicular to the rubbing direction, similar to the case in Fig. 5. With overall considerations of the mesomorphic characteristics, photophysical characteristics, and polarized transitions of these materials in various states and compositions, a proposed schematic representation of the morphologies and molecular alignments in the aligned F(MB)5:N200 mixture (host–guest) film is shown Fig. 7. Although more advanced characterizations may be needed to further elucidate details of the morphologies (e.g. dimensions and packing parameters of the N200 aggregates in the mixture etc.), it is worthy of mentioning that this

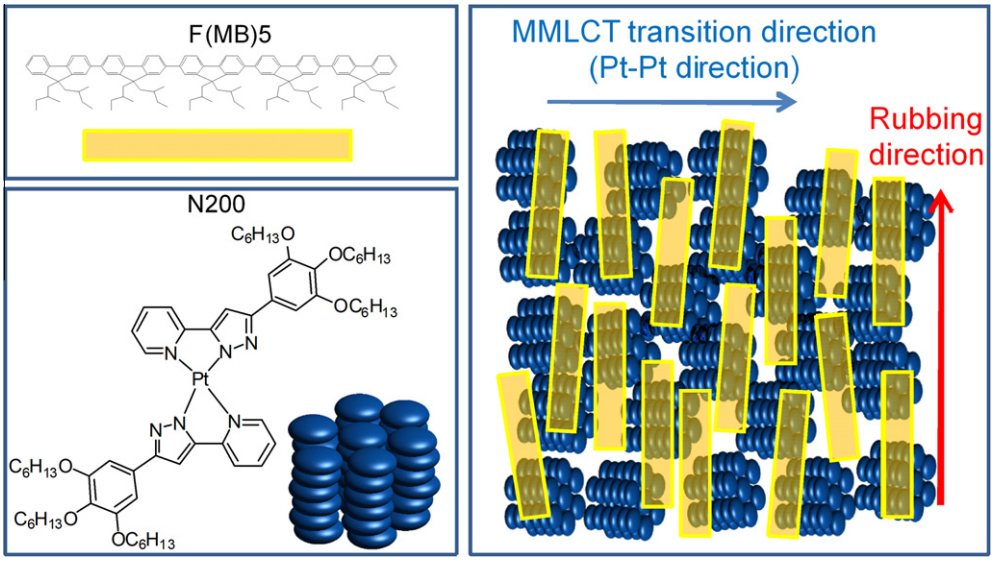

Fig. 7. The schematic representation of the morphologies and molecular alignments in the aligned F(MB)5:N200 mixture (host–guest) film.

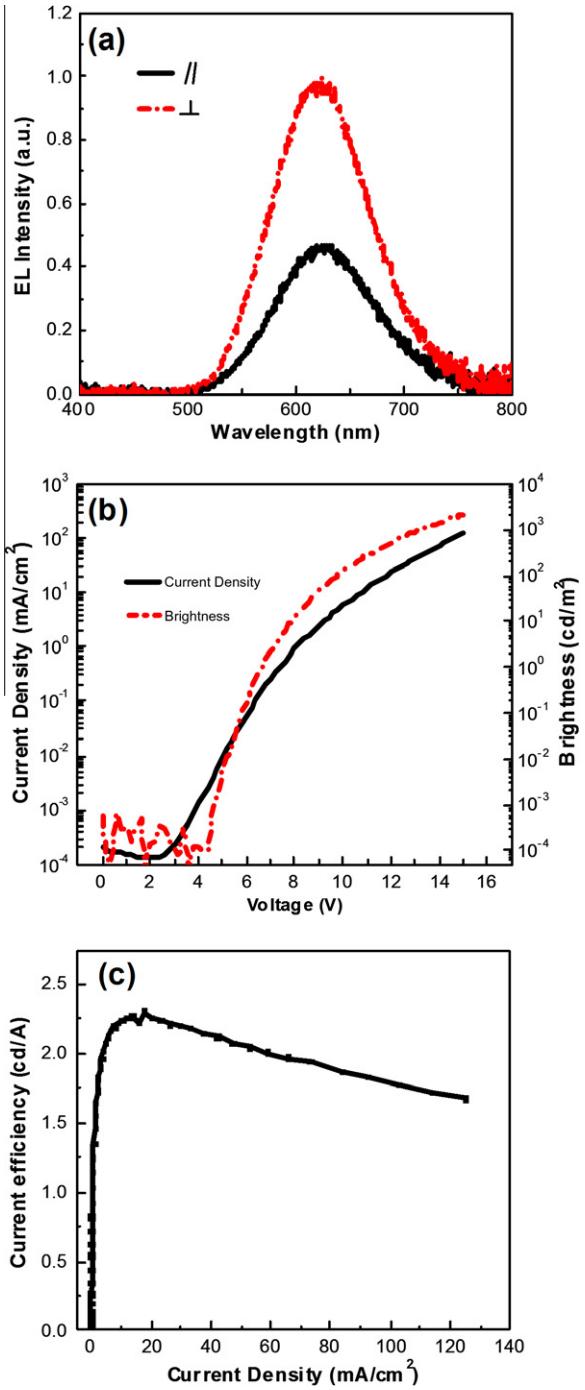

Fig. 8. EL characteristics of the polarized OLEDs: (a) EL spectra measured with the polarization parallel with (//) and perpendicular to (⊥) the rubbing direction; (b) I–V-L characteristics; (c) cd/A efficiency.

proposed picture is rather consistent with all the physical and photophysical characterizations conducted.

3.3. Characteristics of polarized OLEDs

Fig. 8(a) shows the EL spectra of the polarized OLED: ITO/rubbed PEDOT:PSS (30 nm)/F(MB)5:25 wt.% N200 (55 nm)/TPBi (45 nm)/LiF (0. 5 nm)/Al (150 nm), measured with the polarization parallel with ($EL_{//}$) and perpendicular to ($EL_{\perp}$) the rubbing direction. Different from the PL of the F(MB)5: N200 mixture film in Fig. 3 and Fig. 6 [that show emission from both F(MB)5 and N200], EL of the device shows purely N200 MMLCT emission, indicating carrier trapping and direct recombination of holes and electrons on N200 guest molecules (in addition to energy transfer) play important roles in EL [54]. Similar to N200 MMLCT emission in PL of the aligned mixture film (Fig. 6), EL perpendicular to the rubbing direction ($EL_{\perp}$) is stronger than that along the rubbing direction ($EL_{//}$), with an EL dichroic ratio $EL_{\perp}/EL_{//}$ of about 2. For comparison, a control OLED with the same layer structure but no rubbing on PEDOT:PSS (thus no alignment) shows no polarization dependence in EL. It is interesting to note the EL polarization of the present polarized OLED (roughly perpendicular to the rubbing direction) is very different from that of many previously reported polarized (fluorescent) OLEDs (i.e., parallel with the rubbing direction) [5–11], mainly due to the unique emission mechanisms in the present polarized OLED.

Fig. 8b and c show the I–V-L and the efficiency characteristics of the polarized OLED. The red-emitting polarized OLED exhibits a turn-on voltage of 3–4 V, a maximum brightness exceeding 2000 cd/m^2, and a maximum cd/A efficiency of 2.4 cd/A. The EL efficiency achieved for the polarized OLED may not be impressive compared to the state-of-art phosphorescent OLEDs nowadays, but it is worthy of mentioning that this work represents an initial attempt to realize workable polarized phosphorescent OLEDs.

4. Conclusions

In summary, we have successfully realized workable polarized phosphorescent OLEDs by combining a recently developed mesogenic phosphorescent metal (Pt(II)) complex and a mesogenic oligofluorene host to form the corresponding mesogenic host–guest emitting system. In the host–guest film, the mesogenic Pt(II) complex tends to aggregate and self-assemble into the columnar stacking arrangement, exhibiting MMLCT emission of the Pt(II) complex. Both the host molecules and guest aggregates in the host–guest films were successfully aligned by using the rubbed conducting polymer PEDOT:PSS as the alignment layer. With such aligned host–guest films, polarized red-emitting OLEDs were successfully implemented, showing an EL polarization ratio of ~2, a maximal brightness exceeding 2000 cd/m^2, and a cd/A efficiency up to 2.4 cd/A. Due to the particular alignment mechanism of guest aggregates and the unique MMLCT emission mechanism, the polarized OLED exhibiting stronger EL perpendicular to the rubbing direction than along the rubbing direction.

Transparent conductive film

ABSTRACT

We report a conductive hybrid material composed of single-walled carbon nanotubes (SWCNTs) and poly(3,4-ethylenedioxythiophene) (PEDOT). The hybridization of SWCNT and PEDOT was achieved by the use of poly(ionic liquid) (PIL), specifically poly(1-vinyl-3-ethylimidazolium) salt as the bridging molecules between the two conductive components. The use of PIL not only allows the formation of effective 3D network of SWCNT bundles in the PEDOT matrix, but also enables the resulting SWCNT-PIL:PEDOT hybrid material to be suspended selectively in water or organic solvents. Thin films of SWCNT-PIL:PEDOT were more conductive as compared to the PEDOT-based films, demonstrating the surface resistivity of 6.2×10^4 Ω/sq and optical transparency of 85.5% at a 0.2 wt.% SWCNT loading. The composites were also found to be thermally stable, showing less change in surface resistivity as compared to PEDOT-based films.

1. Introduction

Electrically conducting nanocomposites with interconnected 3D network of carbon nanotubes (CNTs) in polymer matrix have attracted widespread scientific and technological interests as robust and highly conductive material [1–4]. The macroscopic electrical conductivity of a CNT-based composite material is strongly dependent on the CNT loading in the polymer matrix, which is described by the percolation threshold [5–8]. Sufficient high loadings of CNTs are generally required to form electrical pathways within composites and thus enable percolation. In order to use CNTs efficiently as conductive fillers and achieve lowest percolation threshold, there are several considerations to be addressed. For example, CNTs are held together in bundles by strong van der Waals interactions and thus difficult to disperse individually in polymer matrix unless dispersing agents (i.e. electrically insulating surfactant molecules) are incorporated [9–11]. The tendency of CNTs to agglomerate in the composites results in diminished electrical properties as compared to theoretical predictions yielded of individual CNTs. In addition, the presence of electrically insulating tube-to-tube junctions compromise overall conductivity of the composites, and this often generates limitations in most proposed applications [12,13]. Therefore, in the specific case of CNT-based composites, the major challenge is to achieve high conductivity at low percolation by dispersing individual CNTs into polymer matrix with reduced junction resistance across the tubes.

For this purpose, the use of intrinsically conducting polymers as the polymer matrix for CNTs has been explored in the hopes of improving the electrical properties. For example, the enhancement of electrical properties has been shown to be more pronounced for CNT-based composites when conducting polymer was utilized as matrix polymer [14–17]. However, a simple mixture of CNTs and conducting polymers may be segregated into individual components due to limited miscibility, which prevents the fine dispersion of CNTs in conducting polymer matrix. Considerable efforts have been made to efficiently disperse individual CNTs in a conducting polymer matrix. One can modify

either the conducting polymer to enhance interaction with the π-system of CNT walls or modify the CNT surface via functionalization [18–22]. It is also possible to use a third component to assist the effective coupling of CNTs and conducting polymers, and thus achieve effective 3D network of individual CNTs within the conducting polymers by improving miscibility between the two. For example, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) has been combined with CNTs to produce composites with conductivities of up to $\sim 7.0 \times 10^4$ S/m. However, it is basically processed from aqueous phase since this method is based on the use of water soluble PSS [23,24].

Here, we have employed poly(ionic liquid) (PIL), a polymer from ionic liquid (IL) monomer, to combine single-walled carbon nanotubes (SWCNTs) with PEDOT. In addition to an effective association of SWCNTs and PEDOT, the use of PIL allows the resulting SWCNT–PEDOT composites to be processed in both aqueous and organic solvents. Recently, PIL, specifically of poly(1-vinyl-3-ethylimidazolium) salt has been proposed as a functional molecule to hybridize SWCNT with PEDOT. The hybrid material (here referred to as SWCNT-PIL:PEDOT) could be an attractive alternative for practical applications using CNT-based composites, since their selective suspension in water or organic solvent is expected to be achievable by a simple chemistry such as anion exchange of PIL [25]. In an extension of our previous work, we report here our progress toward tuning the electrical properties of SWCNT-PIL:PEDOT composites. By modifying the synthetic procedure of the SWCNT-PIL:-PEDOT hybrid composites, we show that these composite films could be more conductive than the ones that are not hybridized. Finally we show that these materials are thermally stable, displaying much lower change in surface resistivity at high temperature, as compared to PIL-modified PEDOT film.

2. Experimental

2.1. Materials

SWCNTs were purchased from Carbon Solutions Inc. under the trade name P3-SWCNT. (1-vinyl-3-ethylimidazolium bromide) (ViEtIm$^+$Br$^-$) was synthesized according to literature method [26]. EDOT monomer was provided from H.C. Starck. All other reagents and solvents were purchased from Aldrich and used as received.

2.2. Synthesis of SWCNT-PIL:PEDOT hybrid materials

Modification of SWCNTs with PIL was carried out according to previous literature [27]. Briefly, the P3-SWCNTs were further oxidized in HNO_3–H_2SO_4 (3:1, v:v) mixture for 3 h at 80 °C. After cooling to room temperature, it was washed with DI water and dried under vacuum at room temperature for 24 h. Acid-treated SWCNTs (30 mg) were suspended in water (80 ml), with polymerizable IL monomer, i.e. (1-vinyl-3-ethylimidazolium) bromide (ViEtIm$^+$Br$^-$) (3.0 g) in ethanol (30 ml). Polymerization of IL was carried out by adding a solution of azobis(2-methylpropionitrile) (AIBN) (30 mg of AIBN in 10 mL ethanol) dropwise to the suspension and stirring at 70 °C for 10 h under N_2 atmosphere. To terminate the reaction, an excess amount of acetone was poured into the suspension, which causes the gel formation of PIL-modified SWCNT (SWCNT-PIL) at the bottom of the flask. The SWCNT-PIL in a gelatinous form was then obtained by filtration through a polycarbonate (PC) membrane and re-suspended in water.

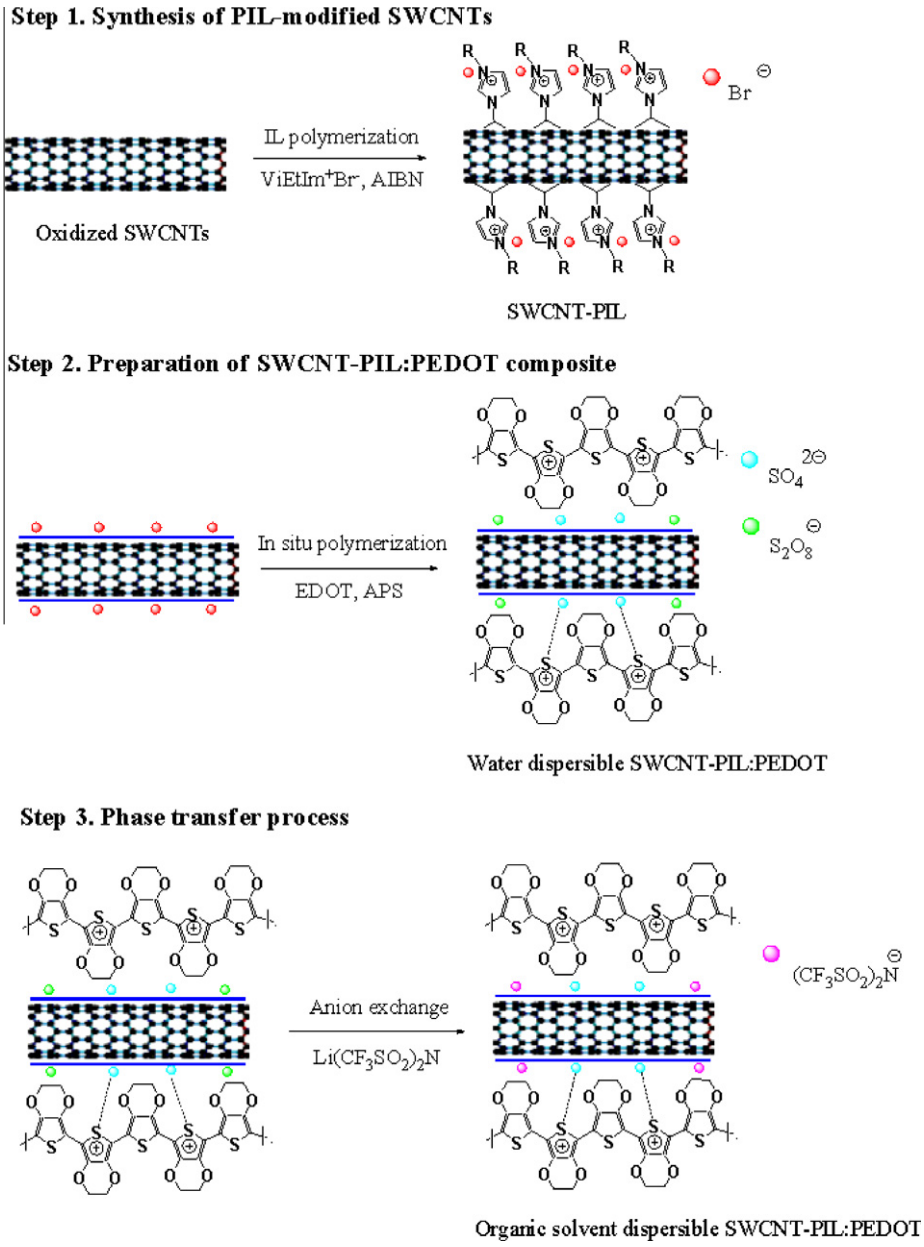
In a typical experiment, the hybrid materials of SWCNT and PEDOT were prepared by adding EDOT monomer (0.2 g) into the aqueous suspension of SWCNT-PIL (0.25 g in 80 ml H_2O) with a dropping of an aqueous solution of APS (0.3 g in 20 ml H_2O). The mixture was then vigorously stirred for 48 h at room temperature, which resulted in an aqueous suspension of SWCNT-PIL:PEDOT hybrid material (hydrophilic SWCNT-PIL:PEDOT). An aqueous suspension of the hydrophilic SWCNT-PIL:PEDOT was then subjected to a phase transfer process in which an aqueous solution of lithium bis(trifloromethanesulfonyl)amide ($Li^+NTf_2^-$) was added into the suspension (1.2 equiv. of NTf_2^- with respect to the repeating units of PIL cations). The addition of $Li^+NTf_2^-$ leads to an immediate replacement of hydrophilic and water soluble anions in the PILs with hydrophobic and water-immiscible NTf_2^- anion, which resulted in the precipitation of the product in water. Due to the increased hydrophobicity, as-produced SWCNT-PIL:PEDOT hybrid became readily dispersible in a range of organic solvents such as acetone, propylene carbonate (PC), dimethylformamide (DMF), acetonitrile, *N*-methyl-pyrollidone (NMP), nitromethane (NM), methyl ethyl ketone (MEK). For comparison, the PIL-modified PEDOT (without any SWCNTs) (PEDOT:PIL) sample was also prepared separately under same condition.

2.3. Characterization and instrumentation

The IR spectrum was measured using a FT-IR spectrometer (Avatar 320, Nicolet) with KBr pellets. X-ray photoelectron spectroscopy (XPS) measurements were performed with ESCA2000 (VG Microtech) system using a monochromatized aluminum Kα anode. The zeta potential was measured in aqueous solution by electrophotoretic light scattering spectrophotometry (ELS-8000, Otsuka). Thermal gravimetric analysis (TGA) was carried out on a NETZSCH STA 409 PC/PG instrument with a heating rate of 10 °C min^{-1} under nitrogen. XRD data were collected on a Rigaku D/Max Ultima II Powder X-ray diffractometer. Scanning electron microscopy (SEM) images were recorded using a JEOL JSM-6700F instrument. AFM image was obtained on a AFM XE-100 (Park system) equipped. High resolution transmission electron microscope (HR-TEM) was conducted on a TECNAI 20 microscope operated at 200 kV. The surface resistivity was obtained using a CMT series JANDEL four-point probe at room temperature.

3. Results and discussion

A suspension of SWCNT-PIL:PEDOT composites in organic solvent was obtained through a three-step procedure (Scheme 1). The first step involved the PIL modification of the acid-treated SWCNT surfaces. In this step, solution of



Scheme 1. Schematic illustration of synthetic process for the SWCNT-PIL:PEDOT composites.

(1-vinyl-3-ethylimidazolium) (IL) monomer in ethanol was introduced into an aqueous suspension of the acid-treated SWCNTs, followed by the in situ polymerization of IL with AIBN to form PIL-modified SWCNTs. The SWCNT-PIL in water phase was then collected as gelatinous form by pouring an excess amount of acetone into the suspension, as shown in the photo (Fig. 1(a)). In Fig. 1(b), scanning electron microscope (SEM) image showed the PIL is coated on SWCNT surfaces with an increase in the diameter of individual SWCNT, and the resulting SWCNT-PIL are interlocked with one another in the gelatinous matrix. Transmission electron microscopy (TEM) images of the SWCNT-PIL shows untangled and individualized SWCNTs embedded in PIL matrix (Fig. 1(c)) and also confirm the presence of thin PIL layer on the SWCNT surface (Fig. 1(d)). The decoration of PIL on the SWCNT surface was also evidenced by the zeta potential measurement. The value of the zeta potential from the SWCNT suspension in water was −4.04 mV due to the negatively charged carboxylic acid on the SWCNTs. In contrast, the introduction of PIL into the SWCNT suspension resulted in the reversal of zeta potential with the value of 8.77 mV. These results indicate that the negatively charged carboxylic groups on SWCNTs were covered with the positively charged polycations in PIL, which suggests a noncovalent functionalization of PILs o the graphitic structure of SWCNTs through

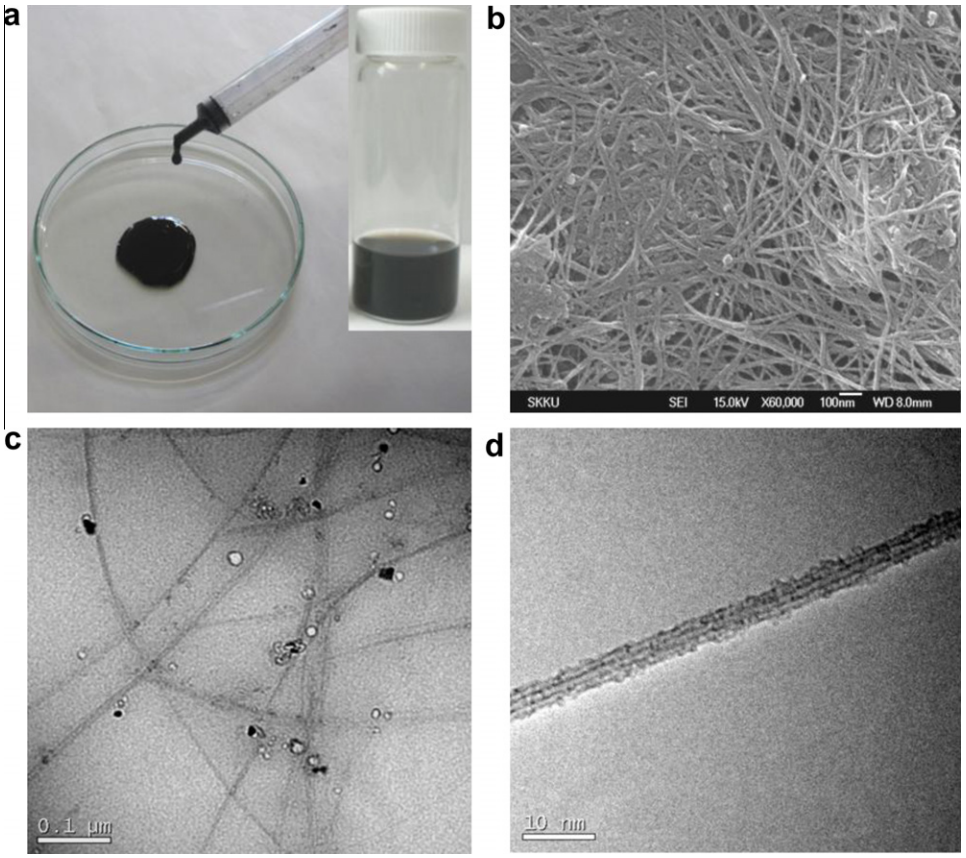


Fig. 1. (a) Photograph of PIL-modified SWCNTs (SWCNT-PIL) in a gelatinous form and its aqueous solution (inset photo). (b) The SEM image and (c and d) TEM images of SWCNT-PIL.

possible interactions may include the $\pi-\pi$ interactions or an electrostatic interaction between SWCNT and PILs [22,28]. The conductivity value of this SWCNT-PIL sample was measured as 0.68 S/cm.

In the second step, gelatinous SWCNT-PIL was re-dispersed in water via mild sonication, and EDOT monomer was added with ammonium persulfate (APS), an oxidizing agent. It is noteworthy that the addition of APS into the SWCNT-PIL suspension immediately led to an exchange of anions (Br^-) in PIL with persulfate anion, which effectively initiates the polymerization of EDOT along the PIL chains on the SWCNT. Therefore, the growth of PEDOT mainly takes place in the vicinity of SWCNT by PIL-mediated polymerization, and the PIL functions to provide a linkage between PEDOT and SWCNT to form a SWCNT-PIL:PEDOT hybrid materials, as shown in Scheme 1. We also note some portion of PILs are intact by PEDOT chains and contains hydrophilic anions such as bromide and persulfate, which preserves the good dispersion of the resulting SWCNT-PIL:PEDOT in water. In the next step, a phase transfer of the SWCNT-PIL:PEDOT from water to organic solvent was carried out by substituting the hydrophilic anions ($S_2O_8^-$ and Br^-) in PIL with hydrophobic anions with details described in the experimental section. As-produced SWCNT-PIL:PEDOT hybrid materials are readily dispersed in organic solvents such as dimethylformamide (DMF), propylene carbonate (PC), and acetonitrile (AN) by mild sonication. These suspensions remained stable for more than 3 months.

A successful hybridization of PEDOT and SWCNTs with the aid of PIL was confirmed by a FT-IR, X-ray photoelectron spectroscopy (XPS) and electron microscopy. Fig. 2 shows the IR spectra of SWCNT-PIL (red curve[1]) and SWCNT-PIL:PEDOT (blue curve). For SWCNT-PIL, the IR peak at 1720 cm^{-1} corresponds to carboxylic acid group in SWCNT, while the multiple peaks at 3130, 3080, 2990, 2880, and 1550 cm^{-1} arise from cation in the PIL and the peak centered at 3430 cm^{-1} was assigned to bromide anion in the PIL [29]. In the case of SWCNT-PIL:PEDOT hybrid, the IR spectrum shows additional characteristic peaks assigned to PEDOT (C–C stretching in the thiophene ring, 1355 cm^{-1}; vibration modes of the ethylenedioxy group, 1200, 1138, 1095 and 1050 cm^{-1}; S–O stretches, 980 and 932 cm^{-1}). The chemical composition of the SWCNT-PIL:PEDOT composites was also investigated by XPS analysis. For SWCNT-PIL (Fig. 2(b)), the C 1s XPS spectrum can be deconvoluted into three main components corresponding to carbon atoms in different functional groups: the non-oxygenated ring C (285.08 eV), the C in C–N bonds (286.55 eV) and the carbonyl C (C=O, 288.20 eV). The

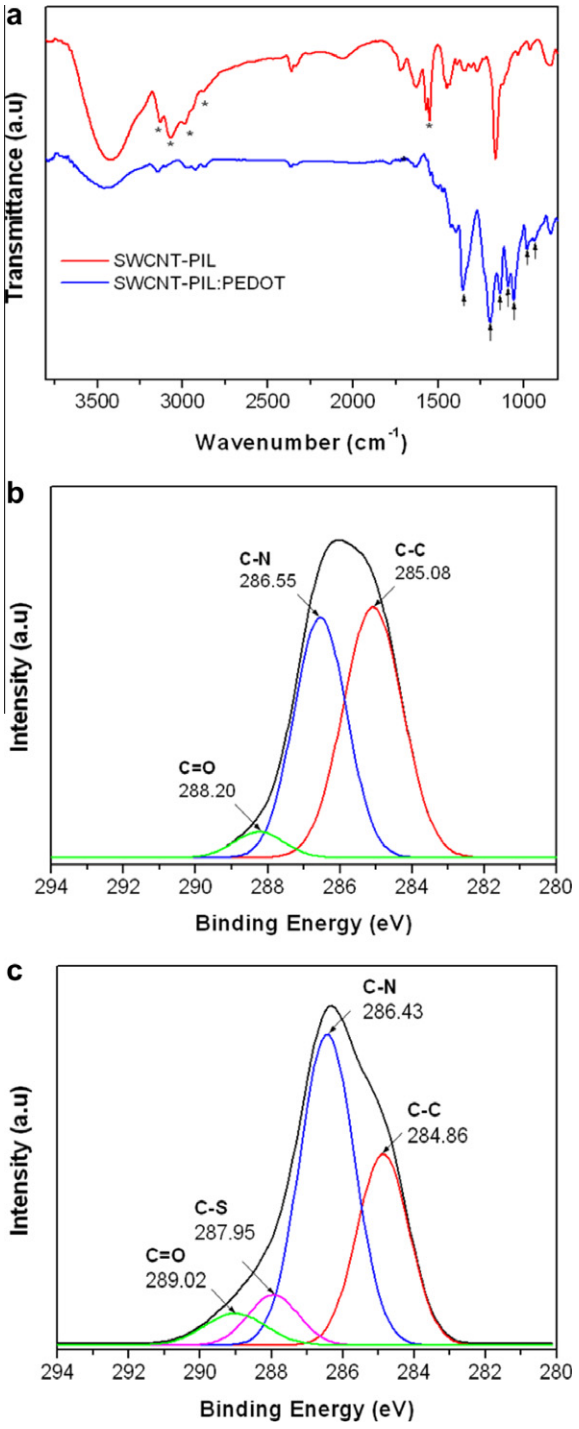

Fig. 2. (a) FT-IR spectra of SWCNT-PIL and SWCNT-PIL:PEDOT composites. (b) C 1s XPS spectra of SWCNT-PIL, and (c) C 1s XPS spectra of SWCNT-PIL:PEDOT composites (with NTf_2^- anions in PIL).

C 1s XPS spectrum of SWCNT-PIL:PEDOT composite (with NTf_2^- being anions of PIL) also exhibited the same functionalities that have been assigned for SWCNT-PIL. However, there is an additional peak at 287.95 eV assigned to the C–S bonds of PEDOT, indicating a creation of SWCNT-PIL:PEDOT hybrid material. The S 2p, O 1s, N 1s XPS spectra (Fig. S1) and XRD data (Fig. S2) in the Supporting information (SI) also support a successful hybridization of SWCNT and PEDOT with the use of PIL as interlinking functional molecules.

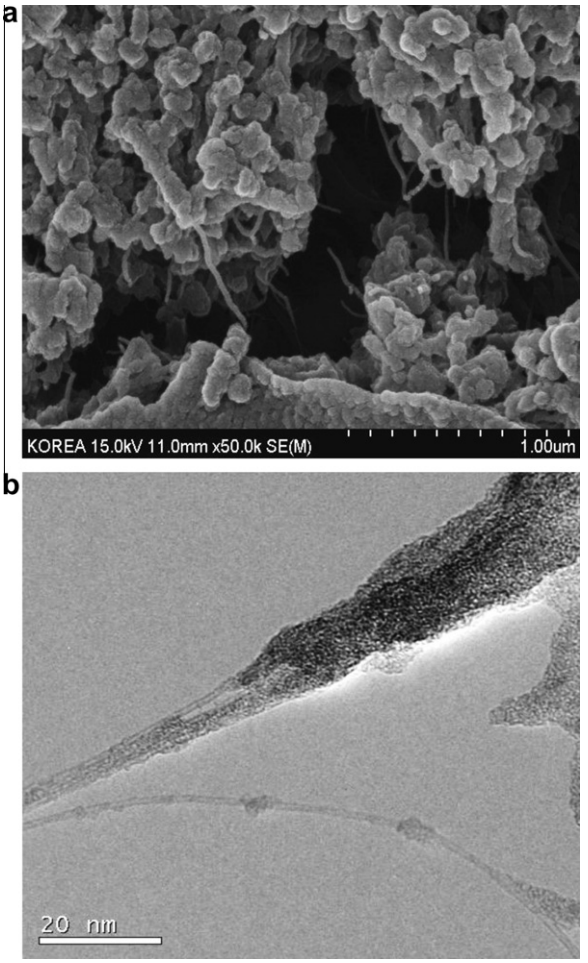

Fig. 3. (a) SEM image on the crack-section of SWCNT-PIL:PEDOT composite film. (b) TEM images of SWCNT-PIL:PEDOT composites.

Based on scanning electron microscopy (SEM) observations (Fig. 3(a)), a good homogeneity of SWCNTs was achieved in the crack-section of composites film; we could also see the SWCNTs bundles bridging the crack faces in the wake. An AFM image showed the SWCNTs randomly distributed on the small particulates of PEDOT matrix (Fig. S3). In addition, the TEM image (Fig. 3(b)) of selected parts confirms the presence of a PEDOT layer adsorbed onto the SWCNT surface, suggesting that PIL is effective to interlink SWCNTs and PEDOT for their hybridization.

The electro-conductive properties of organic solvent dispersible SWCNT-PIL:PEDOT composites were evaluated by measuring electrical conductivity of the composite film (Fig. 4). While the control PIL-modified PEDOT sample (exclusive of SWCNTs) showed a conductivity of 0.083 S/cm, SWCNT-PIL:PEDOT hybrid composite showed increasing conductivity values of up to 1.68 S/cm with increasing

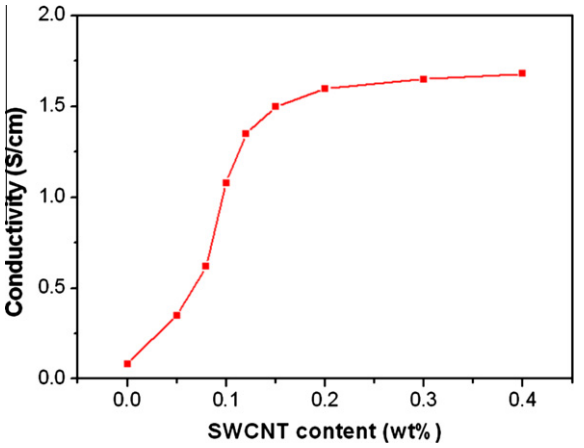

Fig. 4. The electrical conductivity of SWCNT-PIL:PEDOT composite films as a function of SWCNTs content in the composite.

SWCNT contents in the composites in the ranges up to 0.4 wt.%. As in the figure, the conductivity of the composite film increases sharply with increasing SWCNT loading level up to 0.2 wt.% (showed a conductivity of 1.62 S/cm) and then saturated with higher SWCNT concentration, which gives an estimation that a percolation threshold is in the proximity of 0.11 wt.%. This percolation threshold value is comparable to or even lower than the values previously reported in SWCNT nano-composites with PEDOT:PSS matrices [30,31]. This could be explained by means of enhanced inter-tubular charge carrier transfer due to the improved contact between the SWCNTs. The tube-to-tube junction resistance could be reduced by a conductive PEDOT on the SWCNTs, which enhances a charge carrier hopping rate. It should be noted that the conductivity of water dispersible sample with 0.2 wt.% of SWCNTs content was 1.05 S/cm, which was little lower than those of organic solvent dispersible sample. We thought that a difference in conductivity values of the two film samples may come from several factors including solvent-induced morphological changes.

In order to evaluate the possible application of SWCNT-PIL:PEDOT composites as a transparent, flexible, and conductive film, we have fabricated thin films of SWCNT-PIL:PEDOT on polyethylene terephthalate (PET) and investigated their optical and electrical properties. A suspension of SWCNT-PIL:PEDOT (in a mixture of propylene carbonate/ethanol, inset of Fig. 5(a)) was applied on PET films using draw-down bar method and dried at 80 °C to form a homogeneous conductive composite film with a thickness of ~1 μm (Fig. 5(a)). We note that a suspension of SWCNT-PIL:PEDOT in solvent mixture of PC:EtOH (8:2 v:v) resulted

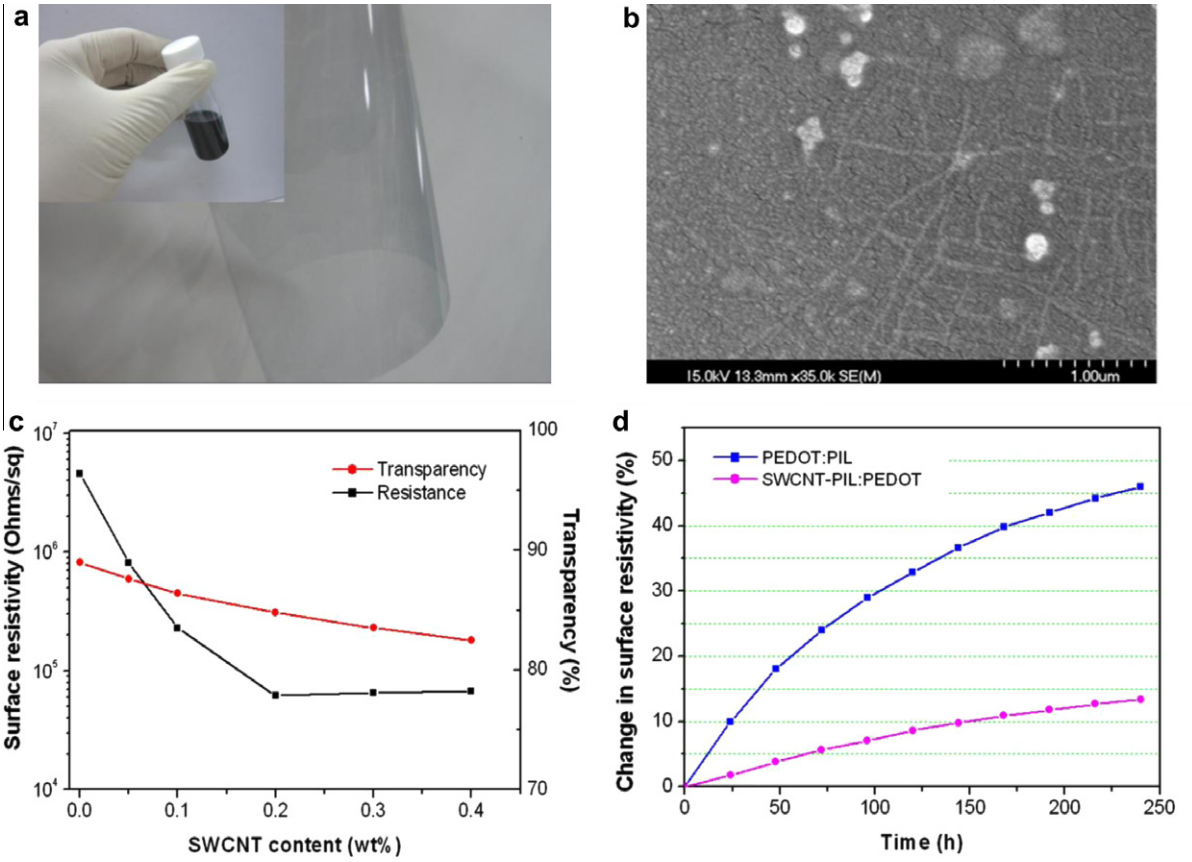

Fig. 5. (a) A hybrid composite film of SWCNT-PIL:PEDOT on the PET substrate. Inset photograph shows a suspension of SWCNT-PIL:PEDOT in organic solvent. (b) SEM image of the hybrid composite film. (c) Surface resistivity and optical transparency vs. SWCNTs concentration in the composite film. (d) Plot of a change in surface resistivity over aging time.

in the most uniform coating on PET film, while other organic solvents such as PC, DMF, THF, NMP, and MEK can be used in the suspension. Fig. 5(b) shows a SEM image of uniform coating of SWCNT-PIL:PEDOT on a PET substrate. It can be seen that the conductive nanotubes channels are formed in PEDOT matrix, which is valuable for achieving reduced overall surface resistivity and thus effective charge transport in the films. Fig. 5(c) shows the surface resistivity and optical transmission of the films as a function of SWCNT concentration in the composite films. For comparison, the control PIL-modified PEDOT film was also tested and it shows a surface resistivity of $4.6 \times 10^6\ \Omega$/sq with an optical transmittance of 87.8% (at 550 nm wavelength). On the other hand, the SWCNT-PIL:PEDOT composite film shows a decrease in the surface resistivity by an order of 2, as the SWCNT concentration in the composite increases up to 0.2 wt.%. This result indicates that the hybridization of SWCNT with PEDOT can effectively reduce the surface resistivity of the film. However, the SWCNT-PIL:PEDOT composite films also show a decrease in the transmittance from 87.8% to 82.5%, which is proportional to the weight percentage of the SWCNT in the composite. The lowest surface resistivity of $6.2 \times 10^4\ \Omega$/sq at optical transmittance of 85.5% was achieved with 0.2 wt.% SWCNT loading, and then increases slightly at loading levels in exceed of 0.2 wt.% due to increase tube-to-tube junction resistance of SWCNTs. The transparent and conductive properties of the present film are consistent with other reports involving CNT/polyethylene composites film [32], PMMA/CNT composites [33], PEDOT–PSS/SWNT composites [34], and lower than that of the SWCNTs films only [35,36]. However, the homogeneous conductive composites relatively low percolation threshold of expensive SWCNTs showed their good adhesion to the plastic substrate with large scale. This feature makes the composites practically easier in industrial approach.

These composite films were subjected to a further testing for thermal stability. Fig. 5(d) shows a change in surface resistivity of the composite films over aging time, while the films were kept at a constant temperature of 80 °C. As it can be seen, the surface resistivity of the control PEDOT film increases over time, while the SWCNT-PIL:PEDOT composite film displays much lower change in surface resistivity. This is indicative of an improved thermal stability of SWCNT-PIL:PEDOT, which is supported by thermal gravimetric analysis (TGA) data (Fig. S4). These results also suggest that the coupling of SWCNT and PEDOT could delay the thermal degradation of PEDOT chains due to a specific interaction between SWCNT and PEDOT, which needs to be in need of further investigation.

4. Conclusions

In this work, a hybrid material of SWCNT and PEDOT was prepared by poly(ionic liquid)-mediated coupling method. Poly(ionic liquid) (PIL) functions to tightly bind exfoliated SWNTs together with PEDOT with enhanced miscibility, and thus generates a uniformly interconnected 3D network of SWCNTs in a PEDOT matrix. This organic solvent dispersible SWCNT-PIL:PEDOT hybrid composites show excellent transparency, electrical conductivity, and thermal stability holds great potential for application in variety of optoelectronic devices where these properties together with room temperature fabrication technologies are required.

ABSTRACT

This paper reports a highly efficient organic light-emitting diode (OLED) with high-quality white emission that employs a deep blue-emitting beryllium complex bis(2-(2-hydroxyphenyl)-pyridine)beryllium ($Bepp_2$) doped with a wide-bandwidth orange-emitting fluorescent dye 4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4-*H*-pyran (DCM) through incomplete energy transfer from the blue host to the orange dopant. The two-component WOLED exhibits ideal and stable CIE coordinates (0.334 ± 0.002, 0.337 ± 0.007) with a high color rendering index equal to 79–81 upon variation in brightness from 10 to 10,000 cd m^{-2}. As an all-fluorophore-doped white OLED, it yields very high EL efficiencies with the peak luminescence efficiency. The peak value of luminescence efficiency (LE), power efficiency (PE), and external quantum efficiency (EQE) is 14.0 ± 0.35 cd A^{-1}, 9.2 ± 0.25 lm W^{-1}, and 5.6 ± 0.15%, respectively.

1. Introduction

White organic light-emitting diodes (WOLEDs) have attracted considerable attention in recent years due to their potential applications in next-generation, full-color, flat-panel displays, and solid-state lighting sources [1]. Due to the limited spectral bandwidth of organic molecules, however, single-molecular species cannot provide white-light emission. Therefore, high-quality white light is generally achieved by mixing several materials that give rise to the three primary colors (blue, green, and red) or two complementary colors (cyan and orange) by stacking multiple emitting layers [2] or by co-doping (blending for polymers) several compounds (one host and two emitters at least) [3] in a single emitting layer. However, each of these approaches suffers from some drawbacks such as complicated device fabrication, high driving voltages, and driving voltage-dependent Commission Internationale de L'Eclairage (CIE) coordinates. Another problem with multiple-component systems is that the CIE coordinates of white-light emission change over time for either all-phosphor or fluorophore/phosphor systems due to the limited stability of blue triplet emitters and the different operational lifetimes between singlet and triplet emitters. Therefore, the strategy of using less emitting layers and dopants based on conventional and relatively inexpensive fluorescent materials in multiple-color band architecture should be reconsidered and adopted. The goal is to generate highly efficient white EL emission and to retain ideal and stable CIE coordinates with a high CRI (Color Rendering Index).

Recently, many fluorescent WOLEDs with simple emitting layers containing one blue host and one yellow (or orange) dopant [4] or only one blue emitter that forms an excimer (or exciplex) at longer wavelengths [5] have been developed. However, their performance remains unsatisfactory due to issues such as high turn-on voltage, moderate efficiency, and undesired white CIE coordinates. This paper employs the deep-blue-emitting material bis(2-(2-hydroxyphenyl)-pyridine)beryllium ($Bepp_2$) [6] as the host, which is lightly doped with the wide-bandwidth orange-emitting 4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4-*H*-pyran (DCM) as the two-component

doi:10.1016/j.orgel.2010.10.006

emitting layer, in order to obtain a highly efficient WOLED. This WOLED results from an incomplete energy transfer from $Bepp_2$ to DCM which currently shows the highest EL performance as an all-fluorophore WOLED together with high-quality white emission. The peak value of luminescence efficiency (LE), power efficiency (PE), and external quantum efficiency (EQE) is 14.0 ± 0.35 cd A^{-1}, 9.2 ± 0.25 lm W^{-1}, and $5.6 \pm 0.15\%$, respectively. White light has CIE coordinates (0.334 ± 0.002, 0.337 ± 0.007) which are close to those of the ideal equal-energy white (0.33, 0.33) and remains almost constantly bright (from 10 to 10,000 cd m^{-2}). This chromaticity-stable WOLED also yields a high CRI of 79–81 and a Correlated Color Temperature (CCT) of about 5500, which is appropriate for white-light illumination [1a].

2. Experimental section

2.1. Instrumentation

Photoluminescence spectra were recorded on a Perkin–Elmer LS 55 spectrophotometer, whereas UV–visible spectra were recorded on a Shimadzu UV-2550 PC spectrometer. Electrochemical measurements were performed in anhydrous CH_2Cl_2 with a BAS 100 W bioanalytical electrochemical work station, using Pt as the working electrode, platinum wire as the auxiliary electrode, and a porous glass wick Ag/Ag^+ as the reference electrode. It was standardized against a ferrocene/ferrocenium couple with a scan rate of 100 mV s^{-1}. Elemental analyses were performed on a Flash EA 1112 spectrometer. The EL spectra, brightness, CIE coordinates, and current–luminance–voltage characteristics of the devices were measured with a rapid scan system using a Photo Research PR650 spectrophotometer combined with a computer-controlled, programmable direct-current (DC) source (Keithley 2400).

2.2. Materials and OLED fabrication

The chemical structures and proposed energy diagram of the emitting materials ($Bepp_2$ and DCM) are shown in Fig. 1. Prior to deposition, all organic materials were purified by sublimation. The devices were grown on a glass substrate pre-coated with an indium tin oxide (ITO) anode having a sheet resistance of 20 Ω per square. The ITO substrate was routinely cleaned via ultrasonic treatment in detergent solutions, followed by rinsing with acetone, boiling in isopropanol, rinsing in methanol, and finally rinsing in de-ionized water. The substrate was dried in a vacuum oven between each cleaning step. The devices were fabricated by successive vacuum deposition of organic materials onto the substrate. A very thin layer of LiF can enhance electron injection from the aluminum cathode. A shadow mask with 2×3 mm^2 openings was used to define the cathodes.

3. Results and discussion

3.1. Absorption and photoluminescent (PL) properties

The UV absorption of DCM and the PL spectrum of $Bepp_2$ are shown in Fig. 2. Due to a perfect overlap between the absorption spectrum of DCM and the emission spectrum of $Bepp_2$, the energy transfer from $Bepp_2$ to DCM is possible and efficient. The PL spectra of the $Bepp_2$:DCM co-deposited films with different concentrations prove this point. As shown in Fig. 2, the reduction of $Bepp_2$ emission intensity (with a peak of about 450 nm) in the doped films is notable along with an increase in the concentration of DCM. When the DCM concentration reaches or exceeds 1 wt.%, complete quenching of $Bepp_2$ is achieved. For the DCM doped film with 0.5 wt.% concentrations, the simultaneous emission from $Bepp_2$ to DCM (with a peak of about 560 nm) with comparable emission intensity is achieved, indicating a broad band covering the range of 400–650 nm. These phenomena suggest that the $Bepp_2$:DCM system is well suited as a white EL emitter potentially through the incomplete energy transfer from $Bepp_2$ to DCM.

3.2. EL properties

To examine the EL properties, three organic EL devices (I, II, and III) were fabricated. The compound 4,4-bis(*N*-(1-naphthyl)-*N*-phenylamino)biphenyl (NPB) was employed

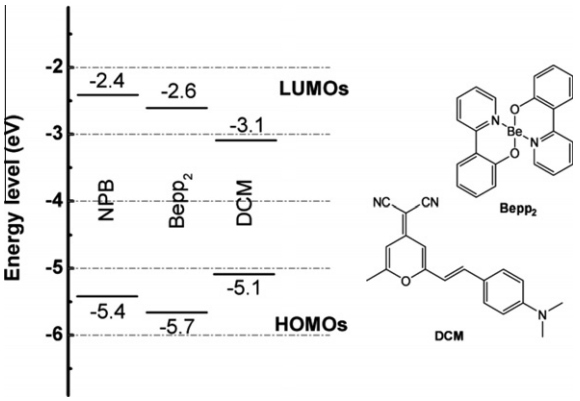

Fig. 1. Proposed energy diagram of the materials used in OLED (left) and the chemical structures of the emitting materials (right).

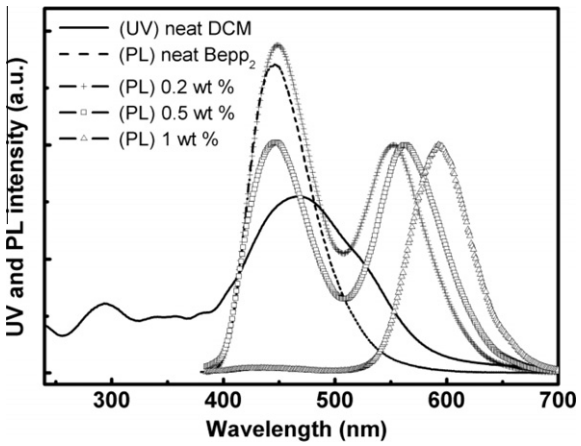

Fig. 2. UV absorption of the DCM film and PL spectra of $Bepp_2$ and $Bepp_2$:DCM co-deposited films with different concentrations.

as a hole-transporting layer (HTL), and DCM-doped $Bepp_2$ with different concentrations was used as the emitting layer (EML) and electron-transporting layer (ETL). The device structures are shown below:

Device I: ITO/NPB (400 nm)/$Bepp_2$:DCM (1 wt.%, 45 nm)/LiF (1 nm)/Al.
Device II: ITO/NPB (400 nm)/$Bepp_2$:DCM (0.5 wt.%, 45 nm)/LiF (1 nm)/Al.
Device III: ITO/NPB (400 nm)/$Bepp_2$:DCM (0.2 wt.%, 3 nm)/ $Bepp_2$:DCM (0.5 wt.%, 42 nm)/LiF (1 nm)/Al.

Fig. 3 top displays the EL spectra of devices I (inset) and device II (normalized). When the concentration of DCM in the emitting layer was 1 wt.% (device I), a dominant emission with a peak at λ_{max} = 580 nm together with a slight emission at the wavelength of about 450 nm was observed at the brightness of 10,000 cd m^{-2}. This was due to an almost complete energy transfer from $Bepp_2$ to DCM. This is also consistent with the PL spectral characteristics shown in Fig. 2. When the doping concentration of DCM decreased to 0.5 wt.% (device II), a broad white emission band with two major emissions at 450 nm (from $Bepp_2$) and 570 nm (from DCM) was obtained. However, with an increase in blue-emission intensity, brightness-dependent

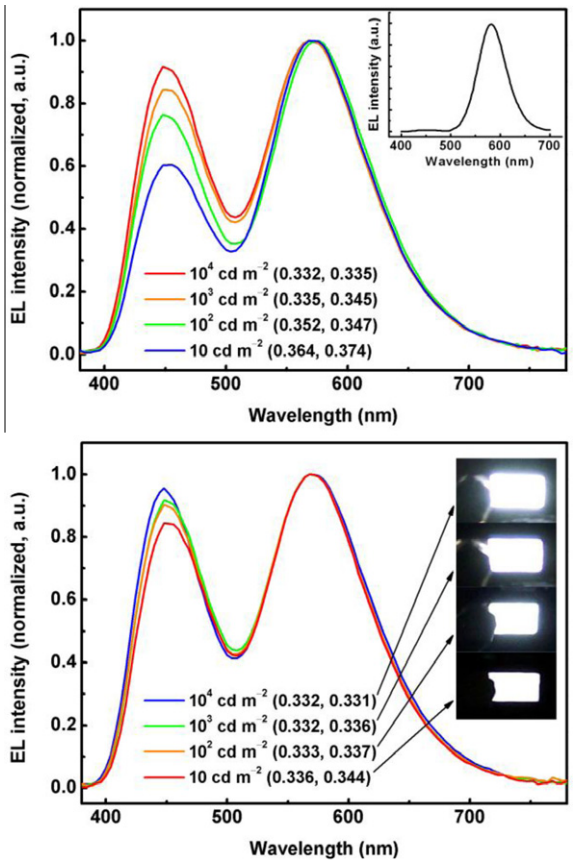

Fig. 3. EL spectra and CIE coordinates of devices II (top) and III (bottom) at brightness of 10, 100, 1000, and 10,000 cd m^{-2}. Inset (top): EL spectrum of device I at brightness 10,000 cd m^{-2}. Inset (bottom): images of device III at brightness of 10, 100, 1000, and 10,000 cd m^{-2}.

(corresponding to voltage dependence) EL spectra became more obvious than the orange dopant as the brightness increased. The CIE coordinates of this cell at brightness 10, 100, 1000, and 10,000 cd m^{-2} were all in the white light region. The EL of device II originated from the uniformly doped layer, so the relative change in EL intensity for blue and orange emissions was partly attributed to the requirement of higher energy excitation for blue light. Moreover, the competition between efficient energy transfer from the blue host to the orange dopant and exciton formation on the orange dopant (DCM) by charge trapping [7] due to a higher HOMO and a lower LUMO of DCM than those of $Bepp_2$ (Fig. 1) would also have a considerable effect on the relative emission intensity.

Due to the similar device structures and comparable EL properties between $Bepp_2$ and Alq_3 [6a,b], the dominant mobile carriers in the diamine (NPB) layer are holes and the emission zone in the doped emitting layer is adjacent to the HTL/EML interface within 5 nm for devices I and II, which is similar to a previously reported doping of NPB/Alq_3 (tris-(8-hydroxyquinoline)aluminum):DCM [8]. To further improve the color stability of the WOLED used, device III was fabricated and designed by decreasing the doping concentration from 0.5 to 0.2 wt.% within 3 nm of EML adjacent to the HTL/EML interface and by maintaining the total thickness of the doped EML at 45 nm.

Fig. 3 bottom summarizes the normalized EL spectra of device III at brightness 10, 100, 1000, and 10,000 cd m^{-2}. The WOLED with the ideal CIE coordinates (0.334 ± 0.002, 0.337 ± 0.007) exhibited better color stability than that of device II within the whole range of diving voltages. This result strongly supports another hypothesis that the recombination zone should be located mainly within the region where the doping concentration is 0.2 wt.% at low driving voltages. The very low concentration effectively decreased orange emission by suppressing the charge trapped on the orange dopant and increased the ratio of blue emission in the mixed EL spectra due to incomplete energy transfer. This led to more pure white CIE coordinates [(0.336, 0.344) and (0.333, 0.337)] in device III than the coordinates [(0.364, 0.374) and (0.352, 0.347)] of device II at brightness 10 and 100 cd m^{-2}, respectively. The similarity between the EL spectra of devices II and III at high diving voltages (corresponding to a high brightness of more than 1000 cd m^{-2}) suggests that the recombination zone in device III extends to the region with a doping concentration of 0.5 wt.% similar to that of device II. Both incomplete energy transfer and charge trapping contribute to the EL emission of device III. The balanced emission of blue and orange with ideal and stable white CIE coordinates in both devices II and III at high brightness (exceeding 1000 cd m^{-2}) also suggests that the saturation of orange-emission sites occurs in the gradually broadened recombination zone as the current increases. The images of device III at brightness 10, 100, 1000, and 10,000 cd m^{-2} shown in the inset of Fig. 3 bottom presents the color stability of the white emission intuitively. This wide EL emission from device III effectively covered the visible spectral region and largely enriched the color rendering capability with a CRI as high as 79–81 and a CCT between 5400 and 5600 which are required for high-quality white-light illumination.

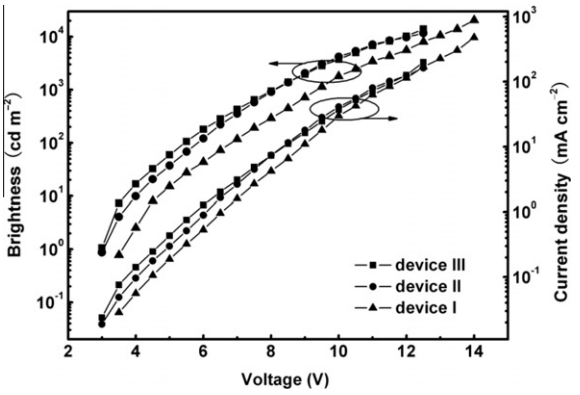

Fig. 4. Brightness–voltage and current density–voltage curves of devices I, II, and III.

The brightness–current density–voltage characteristics of devices I, II, and III are plotted in Fig. 4. Device III exhibited the lowest turn-on voltage of 3.0 V (recorded at 1 cd m^{-2}), and the maximum brightness of 14,010 cd m^{-2} was reached at 12.5 V. Brightness increased linearly with current density, indicating a highly efficient WOLED. The trend of reduction in driving voltage with the doping levels decreased from device I to device III due to DCM in the $Bepp_2$ layer which acted as trapping sites for holes and electrons in terms of the proposed energy diagram (Fig. 1). The almost superposed characteristics of the brightness–voltage and current density–voltage curves in the region of high driving voltage also suggests that a similar EL process should be existent in both devices at high voltages for devices II and III.

Fig. 5 shows the LE, PE, and EQE of the devices as functions of current density. device III exhibited a slightly higher efficiency than device II, and a decrease in efficiency as the concentration increased from 0.5 wt.% (device II) to 1 wt.% (device I) indicated that significant concentration quenching occurred in device I. The highest EL performance was realized in device III. Here, the maximum LE of 14.0 ± 0.35 cd A^{-1} and the maximum EQE of 5.6 ± 0.15% were obtained at brightness 180 cd m^{-2} (6 V), whereas the maximum PE of 9.2 ± 0.25 lm W^{-1} was obtained at brightness 20 cd m^{-2} (4 V). The EL efficiencies of device III remained as high as 12 cd A^{-1} (for LE) and 5.0% (for EQE) upon a variation in brightness from 20 to 2000 cd m^{-2}, indicating the good operational stability of device III. Notably, the EL efficiencies (LE, PE, and EQE) at the practical brightness of 100 cd m^{-2} remained at 14.0 cd A^{-1}, 8.2 lm W^{-1}, and 5.6%, respectively. For lighting applications, the light emitted from all sections of the substrate can, in principle, be redirected to the forward direction via certain lighting fixtures applied to the forward viewing efficiencies by a factor of 1.7–2.3 [1a,9]. Therefore, the total values of LE, PE, and EQE of device III at 100 cd m^{-2} can reach 23.8–32.2 cd A^{-1}, 13.9–18.9 lm W^{-1}, and 9.7–13.1%, respectively. These are comparable to that of an incandescent light bulb (12–17 lm W^{-1}) [1a]. Overall, the values demonstrate high EL efficiencies for a WOLED based on fluorescent materials and illustrate the high potential of an all-fluorophore host/guest doped system for the development of WOLEDs.

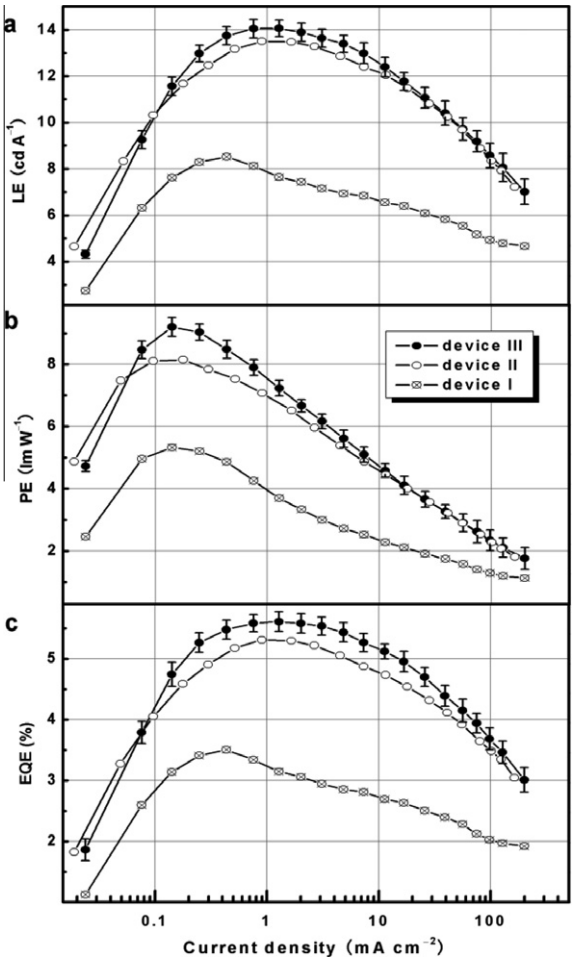

Fig. 5. Luminescence efficiency-current density (a), power efficiency–current density (b), and external quantum efficiency–current density (c) curves of devices I (forks and circles), II (open circles), and III (filled circles). Data are Mean ± SD (standard deviation) values of three experiments in the measurement of device III; the SD falls within the size of the symbol.

4. Conclusion

Using two commercial fluorescent emitting materials, deep-blue beryllium complex $Bepp_2$ (host) and orange organic dye DCM (dopant), a two-component all-fluorophore-doped WOLED was successfully demonstrated. This WOLED yielded a high CRI of 79–81 and stable CIE coordinates close to those of the ideal equal-energy white (0.33, 0.33) at brightness from 10 to 10,000 cd m^{-2}. As a WOLED based on typical fluorescent materials, this device also presented high EL performance not only with a peak efficiency of 14.0 ± 0.35 cd A^{-1} for LE, 9.2 ± 0.25 lm W^{-1} for PE, and 5.6 ± 0.15% for EQE but also high LE and EQE values such as 12 cd A^{-1} and 5.0%, respectively, upon a variation in practical brightness from 20 to 2000 cd m^{-2}. Considering the potential of improved out-coupling, the total PE value

can reach the general efficiency of an incandescent light bulb. The high-efficiency and high-quality white emission of the WOLED, together with inexpensive fluorescent emitters, makes this device a promising candidate for low-cost flat-panel displays and solid-state lighting sources. However, further measurements of the lifetime of encapsulated devices are needed.

ABSTRACT

We have demonstrated an organic photodetector (PD) which can detect 808 nm radiation in near infrared (NIR) region. The photodiode has a hybrid planar-mixed heterojunction structure: ITO/CuPc (10 nm)/CuPc:F16CuPc (1:2, 30 nm)/F16CuPc (20 nm)/LiF (1 nm)/Al. Here, CuPc and F16CuPc denote copper–phthalocyanine and hexadecafluoro–copper–phthalo-cyanine complexes, respectively. The photodiode behaves a response time of 80 ns and a bandwidth of 14 MHz, which are higher than those of recent reports. At the same time, the response waveband of the photodiode covers longer wavelength in NIR comparing to the PD reported. It is conjectured that the high detection performance is due to high electron-mobility of F16CuPc, the large band edge offset between D/A molecules as well reasonable design of the diode structure. The detail working mechanism is also augured.

1. Introduction

Organic photodetectors (PDs) have been the subject of extensive research in the past decade due to several inherent advantages such as large-area detection, wide selection of materials and low-cost fabrication on flexible substrates [1–4]. Except for ultraviolet and visible PDs, organic near-infrared (NIR) PDs also have tremendous potential in industrial and scientific applications, especially commercial and military field including night vision, tomography and so on. Communication applications also need to extend organic PD sensitivity to the NIR waveband [5–8]. It is considered that the more the NIR absorption of an organic compound is, the stronger the PD response is in NIR spectral region. However, the photo-response spectrum of the reported NIR PDs were almost apart from NIR waveband [5–7], even a photo-response spectrum covered some red light radiation [6,7]. Campbell et al. have reported a photoconductive type NIR PD, but its response bandwidth was too low (only 3 kHz) [8]. Image generation demands periodic read-out of a detector signal, hence the frame rate for image generation is dependent on the response speed of a PD [9]. It has been recognized that upon optical excitation of an organic material, localized Frenkel or charge-transfer excitons are generated, then energy level offsets at heterojunctions are essential to separate excitons because of the fundamental nature of the photogeneration process in organic materials [10].

We note that a CuPc derivative, hexadecafluoro–copper–phthalocyanine (F16CuPc) complex, presents two absorption peaks, 725 and 808 nm in the NIR spectral region, and is used as an electron acceptor in solar PV cells [11]. In addition, the complex behaves the highest occupied molecular orbital (HOMO) of −6.3 eV and lowest unoccupied molecular orbital (LUMO) of −4.9 eV [12]. In light of above spectral and electrical behaviors of F16CuPc and well-known hole transporting property of CuPc, in this letter CuPc and 16FCuPc will be used as the electron donor and acceptor of the PD, respectively. The photocurrent response peak of

doi:10.1016/j.orgel.2010.09.015

the fabricated photodiode lies at 808 nm in the NIR waveband and it behaves fast response speed which could satisfy some special applications, such as medical back-check [13], etching technique [14].

2. Experimental

The NIR PD has the three-layer structure, ITO/CuPc (10 nm)/CuPc:16FCuPc (1:2, 30 nm)/F16CuPc (20 nm)/LiF (1 nm)/Al (200 nm), which is called as an organic hybrid planar-mixed heterojunction (H-PMHJ), that is, the blend of CuPc and 16FCuPc is sandwiched in between two layers. The advantage of this PD structure is that two diodes with planar heterojunction and mixed heterojunction, respectively, can be combined into a single device by stacking their high-efficiency regions in the H-PMHJ diode.

F16CuPc is purchased from Suzhou-Nakai Sunatech Inc., and other materials were commercial materials which were not further purified before use. The photodiodes were fabricated on cleaned indium tin oxide (ITO) coated glass substrates with a sheet resistance of 25 Ω/sq in vacuum chamber and the device active area is $2 \times 2\ mm^2$. The organic layers were deposited at a rate of 2 Å/s, and the evaporating rate of LiF and Al cathode were controlled to be 0.5 and 10 Å/s with the thickness of 1 and 200 nm, respectively. All the vacuum chambers were also controlled at a pressure of 5×10^{-4} Pa and deposition rates and thickness of the layers were monitored using oscillating quartz monitors. Absorptions of films and photocurrent spectral responses of the PDs were measured with a Shimadzu UV-3101 PC spectrophotometer and a Hitachi F-4500, respectively. Current–voltage (I–V) characteristics of the PD devices were recorded in dark and under illumination of 808 nm NIR light with different intensities and through the ITO side. NIR light source was provided by an LD-009 infrared laser diode with 808 nm radiation which was powered by a Keithley 2400 SMU. Transient response was measured and the output signal was displayed on a 500 MHz digital oscilloscope (TDS 3052, Tektronix). The LUMO and HOMO levels of CuPc were cited from Ref. [15]. All the measurements were carried out at room temperature under an ambient condition.

3. Results and discussion

Fig. 1a depicts schematic energy level diagram at the interface of CuPc/F16CuPc and the LUMO level difference between CuPc and F16CuPc is 1.4 eV. This indicates that

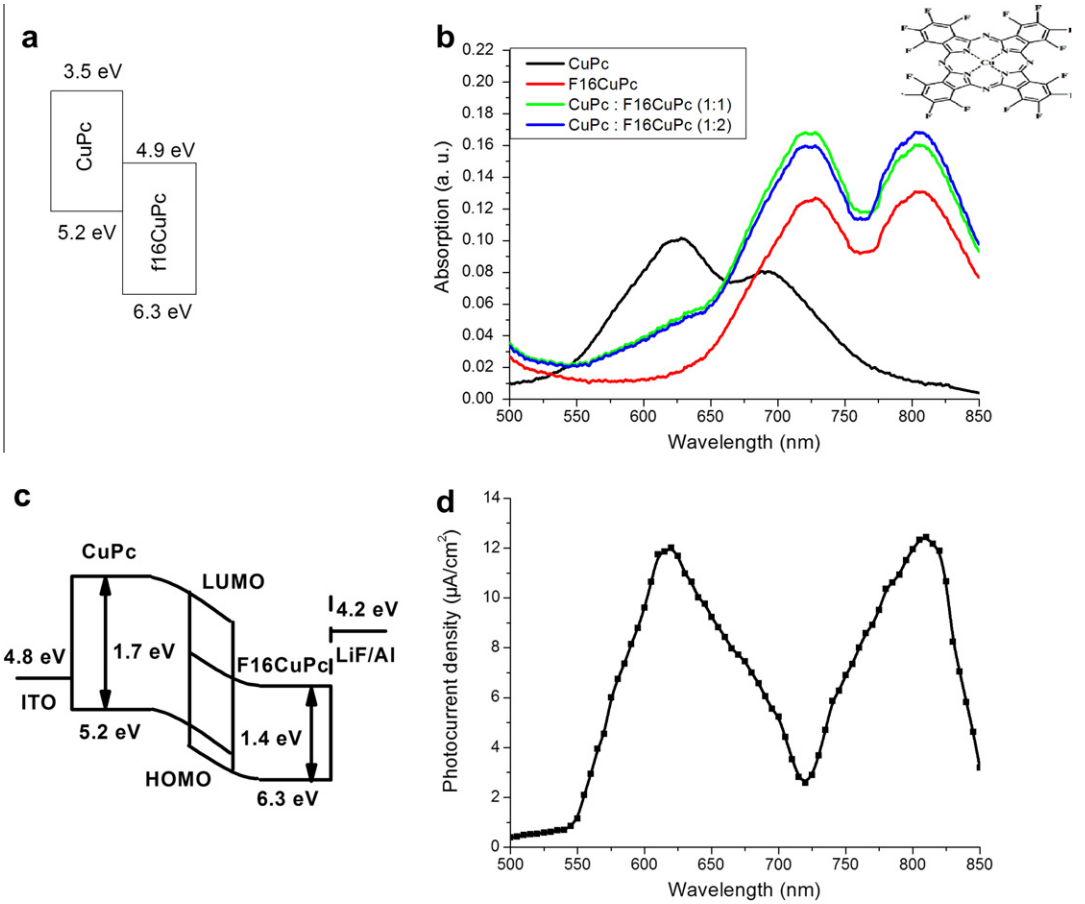

Fig. 1. (a) Schematic energy level diagram at the interface of CuPc/F16CuPc. (b) The solid state absorption spectra of neat films of CuPc and F16CuPc as well blend films of CuPc:F16CuPc with 1:1 and 1:2 ratios by weight, respectively, inset: chemical structure F16CuPc. (c) The schematic level diagram corresponding to the H-PMHJ structure PD. (d) The photocurrent response as a spectrum at zero bias.

at such a DA interface the charge separation of the photo-generated excitons easily occurs because 1.4 eV is markedly larger than the coulombic force of the binding electron and hole pair (exciton) [16]. Fig. 1b illuminates the solid state absorption spectra of the neat films of CuPc and F16CuPc as well the blend films of CuPc:F16CuPc with 1:1 and 1:2 by weight ratio, respectively. From Fig. 1b it can be seen that the neat F16CuPc film shows the two absorption bands which locate at 725 and 808 nm, respectively, in NIR range and the longer waveband can be extended out to 1000 nm. We also note that both the two blend films have higher absorption intensity over the neat F16CuPc film at the NIR spectral region and the 808 nm absorption intensity of the 1:2 blend film is considerably higher than that of the 725 nm peak.

In terms of above the absorption properties of the blend films and energy level alignment between CuPc and F16CuPc, the 1:2 blend film was used to construct a PD which has H-PMHJ structure with ITO/CuPc (10 nm)/CuPc:F16CuPc (1:2, 30 nm)/F16CuPc (20 nm)/LiF (1 nm)/Al. The schematic level diagram of the photodiode is described in Fig. 1c can offer a maximum photocurrent response of about 12.5 μA/cm^2 at 808 nm peak, while 725 nm absorption peak (see Fig. 1b) does not almost contribute to the response, as showed in Fig. 1d. It is surprised that there is a wave-trough at 720 nm which response is around 5.7 times lower than response for 808 nm. Thus, an organic PD with pure 808 nm NIR photo-response could be realized by using a cut-off filter (see the latter of the text).

In order to understand the photo-response feature, we used the 808 nm NIR laser diode with continuous work mode and the monochromatic light source to determine the photo-response. Fig. 2a illuminates the current–voltage (I–V) characteristics of the photodiode. From Fig. 2a we can speculate a rectification ratio of 10^4 at ±10 V biases. Power conversion efficiency (PCE) of 0.2% was obtained under 808 nm laser illumination. The device showed an external quantum efficiency (EQE) of 9.22% at −9 V under illumination with 808 nm radiation. The photodiode figure of merit is the noise equivalent power (NEP), i.e., the minimum impinging optical power that a detector can distinguish from the noise can be shown by the formula (1)

$$\mathrm{NEP} = (A\Delta f)^{1/2}/D^* \tag{1}$$

where A is the effective area of the photodiode in cm^2, Δf is the electrical bandwidth in Hz, and D^* is the detectivity measured in units of Jones. The detectivity can be

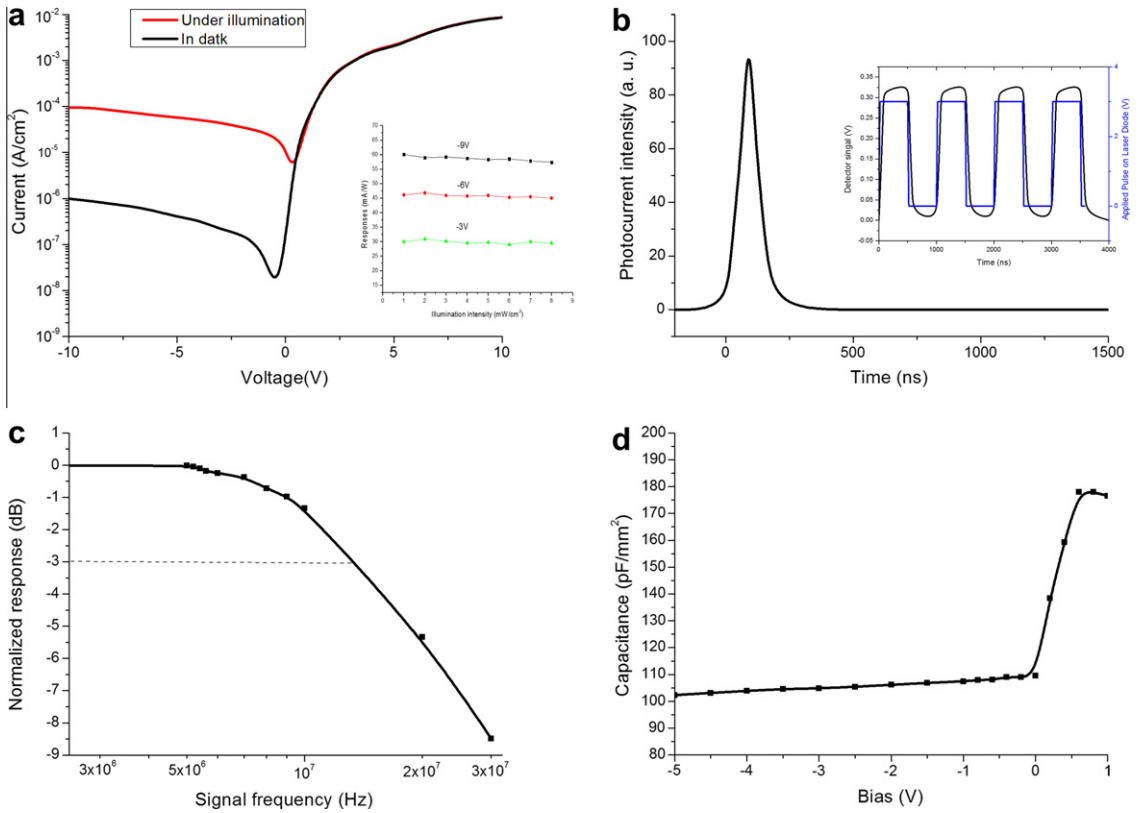

Fig. 2. (a) I–V characteristics of the photodiode in the dark and under 808 nm laser radiation with an intensity of 3 mW/cm^2. Inset: the photocurrent response of the NIR PD at different biases. (b) Photocurrent response of the photodiode based on the structure of ITO/CuPc/CuPc:F16CuPc/F16CuPc/LiF/Al under 808 nm stimulation with 100 ns pulse-width, inset: time response of the same detector to a train of light pulses at a wavelength of 808 nm and with a 1 MHz repetition frequency. (c) Frequency response of the photodiodes with a device area of 2 × 2 mm^2. (d) Capacitance–voltage measurements at frequency of 10 kHz.

expressed as reported by Refs. [17,18], D^* is shown by the formula (2)

$$D^* = R/(2qJ_d)^{1/2} \quad (2)$$

where R is the response (as shown in Fig. 2a inset), q is the absolute value of electron charge (1.6×10^{-19} C) and J_d is the dark current. At zero bias the calculated detectivity using Eq. (2) is, respectively, $D^* = 4.6 \times 10^{10}$ Jones at −9 V and 5.2×10^{10} Jones at −6 V for our NIR photodiode under illumination of 808 nm NIR laser with an intensity of 3 mW/cm^2. Fig. 2b displays the photocurrent response of the photodiode under 808 nm NIR stimulation with 100 ns pulse-width, and inset is the time response of the same detector to a train of light pulses at a wavelength of 808 nm and with a 1 MHz repetition frequency. From Fig. 2b both the rise and fall times of 80 ns were obtained. Fig. 2c indicates the frequency response of the photodiode with an area of 2×2 mm^2, it has been attained that at this area a bandwidth is about 14 MHz at −9 V bias. According to Fig. 2a and c using Eq. (1), a NEP of 1.7×10^{-12} W was calculated. Capacitance of the PD was almost independent of reverse bias by capacitance–voltage measurements in Fig. 2d, which was in contrast to the p-i-n or Schottky-barrier PDs made of inorganic semiconductors. Thus, fast response could be achieved even at zero or low biasing voltage.

In light of the data shown in Fig. 2, we concluded that our 808 nm NIR PD behaved more fast response speed and wider response bandwidth than those of reported NIR PDs [5–9]. At the same time, the spectral peak of our NIR detector focuses on 808 nm which was also much longer than those of reported NIR PDs [5–8], though the EQE at 808 nm needs to be improved further.

The achievement of so good NIR detection performance can be understood as bellow. One of main reasons is the higher hole mobility of 7×10^{-4} cm^2/V s for CuPc [15] and electron mobility of 4.2×10^{-4} cm^2/V s for 16FCuPc which were measured in our lab; another is that the larger band edge offsets between DA molecules [11] is beneficial to exciton dissociation. The response time of planar heterojunction device was 80 ns, which also thanked to adoption of H-PMHJ structure which favoured the efficient exciton dissociation and charge-carrier generation throughout the blend layer as well at the interfaces between the mixed and two adjacent homogeneous layers in the NIR PD. So, excitons had higher probability to reach at DA interfaces prior to recombination. By adding the charge transport layers at two sides of the blend layer, a higher efficiency for extraction of photogenerated charges from and through the blend layer was obtained because the intermolecular distances in D:A blend extent were significantly shorter than that of corresponding charge collection length at either built in field or in addition of the reverse bias. The higher hole and electron mobilities would be in favor of balancing the charge carrier transports in order to collect charge carriers generated.

In addition, we noted that the photocurrent response spectrum of our NIR photodiode also covered visible region from 400 to 700 nm. If the PD is required to detect the NIR waveband, we could use a filter – IPG-700T2 filter to block visible light so that only the NIR radiation can enter into the PD. The photocurrent response of the diodes with the filter is shown in Fig. 3. It is seen that the NIR waveband response is unchanged.

4. Conclusion

In conclusion, CuPc and 16FCuPc with high carrier mobilities act as the D and A species were used in the NIR photodiode and its photocurrent response spectral peak focused on 808 nm. The photodiode having H-PMHJ structure offered a response time of 80 ns and a response bandwidth of 14 MHz, respectively, which were higher than the recent reported results, though the EQE needed to be further improved. The high performance of a PD would be ascribed to larger energy edge offsets of CuPc and F16CuPc, balance of free carrier transport forwards to the two electrodes and stronger absorption at the NIR waveband of the F16CuPc,

as well skillfully diode design. If the PD is asked to only detect NIR waveband, the photo-response at the visible spectral region must be reduced by selecting such DA materials having no visible absorption.

ABSTRACT

A charge transfer (CT) model is introduced for strong acceptors like A = F4TCNQ that are ionized on surfaces at low coverage θ. Each A forms a CT dimer with a surface state S. Dipole–dipole repulsion grows as $\theta^{3/2}$ up to $\theta = 1$ in a full monolayer. Electron transfer $\rho(\theta)$ within dimers is found self-consistently and decreases with increasing coverage. The surface dipole and work function shift $\Delta\Phi$ are proportional to $\theta\rho(\theta)$. The CT model has implications for photoemission and accounts for $\Delta\Phi(d)$ profiles of F4TCNQ films of thickness d on Cu(1, 1, 1) or on hydrogenated diamond (1, 0, 0). The CT model also describes $\Delta\Phi(\theta)$ of organic donors on metals and is contrasted to previous treatments of dipoles on a surface.

1. Introduction

F4TCNQ (tetrafluorotetracyanoquinodimethane) is a powerful π-electron acceptor (A), even stronger than TCNQ. TCNQ forms mixed stacks with π-donors (D) and an extensive series of salts with segregated stacks of A^- or $(A_2)^-$anion radicals and closed-shell cations between stacks [1,2]. As reviewed by Chen et al., [3] recent interest in F4TCNQ films has been in the context of organic electronics [4–6] and promoting hole injection [7] by modulating the work function via surface dipoles. Initial adsorption of F4TCNQ on semiconductors or metals is as A^- anion radicals as shown by two diagnostic electronic states, E_1 and E_2, separated by ~ 1.2 eV in photoemission [8,9]. Adsorption beyond a monolayer (ML) involves neutral molecules A with photoemission at higher binding energy E_3 and suppression of E_1 and E_2. Indeed, surface dipole [3] and other data [10] indicate that A^- coverage saturates below a ML. There is broad agreement about the principal features of F4TCNQ films. There are different estimates of the saturation coverage of A^-, however, or how adsorption evolves from A^- to A. Moreover, agreement about A^- on surfaces does not extend to cations D^+ when the adsorbed molecule is a donor. Photoemission evidence is much less accessible because D^+ has higher binding energy than D. Nevertheless, initial adsorption of D = TTF (tetrathiafulvalene) on Au(1 1 1) is also as D^+ leading to ordered sub ML structures that were attributed to dipole–dipole repulsion [11].

Metal-organic (m-O) interfaces have been extensively studied in connection with organic electronics applications, as reviewed by Ishii et al. [12] and Hwang et al. [13]. A major advance has been to identify surface dipoles $\Delta(d)$ that are formed or almost formed at film thickness $d = d_{ML}$. By contrast, interfaces between metals and wide band inorganic semiconductors show band bending over a length scale that is an order of magnitude longer. There is a fundamental difference between metal-semiconductor and m-O interfaces. Possible physical origins of Δ have been discussed [12,13]. Density functional theory (DFT) and quantum chemical calculations have mainly addressed the magnitude of $\Delta \sim \Delta(d_{ML})$. The evolution of $\Delta(d)$ with $d \leqslant d_{ML}$ has not been modeled in general, to the best of our knowledge. In this paper, we model $\Delta(d)$ profiles of sub ML F4TCNQ films by a method that is applicable to any m-O interface with weak nonspecific bonding. Profiles yield information about the charge of adsorbed species and discriminate among possible contributions to surface dipoles.

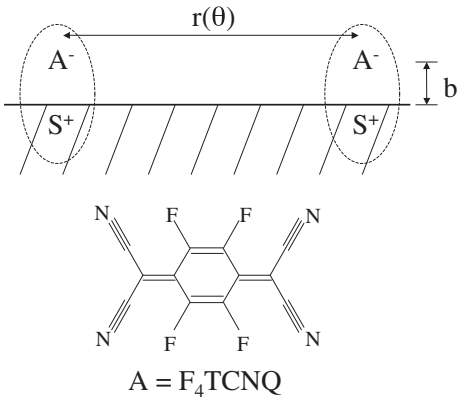

Fig. 1. Schematic representation of adsorbed F4TCNQ molecules on a surface separated by r(θ) at coverage $\theta \leqslant 1$. Each A forms a charge transfer (CT) dimer with a surface state S.

The phenomenological model of $\Delta(d)$ profiles is presented in Section 2. Here we introduce the principal ideas. As sketched in Fig. 1, we suppose that each adsorbed molecule A forms a charge transfer (CT) dimer with a surface state S of the metal. Following Mulliken's treatment of DA dimers, the wave function is a linear combination of a neutral state $|AS\rangle$ and an ionic state $|A^-S^+\rangle$ with dipole $\mu_0 < 0$ normal to the surface. The coefficient $\rho(\theta)^{1/2}$ of the ionic state gives the fraction $\rho(\theta)$ of transferred charge. The separation $r(\theta)$ between adsorbed molecules decreases with increasing $\theta = d/d_{ML} \leqslant 1$, and dipole–dipole repulsion reduces $\rho(\theta)$. Collective CT refers to the self-consistent treatment of dimers on an infinite surface. We follow previous CT studies of organic crystals [14,15] or molecular aggregates [16,17]. The energies of the two states are $E(AS)$ and $E(A^-S^+)$ when the CT integral is $t = 0$. Although t is small by hypothesis, strong mixing is possible when $E(AS) \sim E(A^-S^+)$ are nearly degenerate, as required for neutral-ionic transitions or crossovers [15,17].

In addition to surface dipoles, m-O interfaces typically have an induced density of interfacial states (IDIS) as shown by deviations from the Schottky–Mott limit [12,13]. Induced states are consistent with CT. Weak nonspecific bonding is thought [13] to describe m-O interfaces in contrast to covalent bonds in MLs of alkanethiols on Au or at chemically modified surfaces. Chemisorption also involves strong interactions with $t > 1$ eV in the Newns model [18]. While there is no sharp boundary between weak and strong interactions, CT models assume small t and emphasize electron correlation. DFT or direct calculations are more detailed but less correlated descriptions. Quite generally, dipoles have been associated with atoms or molecules adsorbed on metals, semiconductors or insulators, and qualitative aspects of interfaces are well known. Dipole models have also been criticized and are best for weak interactions.

The Topping model also describes nonspecific bonding that can be applied to $\Delta(d)$ profiles [19,20]. The model assumes a fixed dipole p_0 and polarizability α for every adatom. The dipole field $F(\theta)$ at coverage θ is found self-consistently for induced dipoles $\alpha F(\theta)$ that reduce the net dipole to $p(\theta)$. An example of a quantitative fit [19] is the $\Delta(d)$ profile of Cs on Si(1, 1, 1). Fixed p_0 and depolarization is quite different from variable dipoles and dipole–dipole repulsion in the CT model. But the sharp mathematical difference is less sharp physically since both polarization and CT involve charge redistribution. The models describe work function shifts that cannot uniquely be partitioned into CT and polarization. Since different profiles are predicted, however, observed shifts may point to either model. CT is the natural starting point for F4TCNQ films in view of evidence for ions at $\theta \sim 0$ and molecules at $\theta \sim 1$. We are applying [21] the CT model to published $\Delta(d)$ profiles with CT from molecule to metal and find equally good agreement for D^+ ions at $\theta \sim 0$.

The CT model of interacting dimers is presented in Section 2. Its parameters are $\rho(0)$ and $\rho(1)$, the initial and final degree of CT. Alternatively, the parameters are $E(A^-S^+)$–$E(AS)$ and dipole–dipole repulsion V, both in units of $t = 1$. Two scale factors enter the work function shift $\Delta\Phi(d)$, the ML thickness d_{ML} and the shift Φ_0 of an ionic ($\rho = 1$) ML. Section 3 has applications to F4TCNQ films. Calculated $\Delta\Phi(d)$ profiles are compared to work function shifts of F4TCNQ films on hydrogenated diamond (1, 0, 0) and Cu(1, 1, 1) surfaces. The Discussion contrasts the Topping and CT models and comments briefly on direct approaches to m-O interfaces. We mention extensions of the CT model and emphasize its phenomenological nature.

2. Collective CT model of submonolayers

An isolated A on the surface is modeled as a CT dimer with a localized surface state S whose precise nature is left open. The neutral state $|AS\rangle$ has energy $E(AS)$ and dipole μ_N that we neglect for simplicity. The ionic singlet state $|A^-S^+\rangle$ has energy $E(A^-S^+)$ and large dipole $\mu_0 = -eb$ normal to the surface with $b \sim 3.5$ Å for a planar conjugated molecule in the prone position. The energy difference is $2\Gamma(0) = E(A^-S^+)$–$E(AS)$ in the limit $t = 0$. The two states are coupled by a small CT integral $t = \langle A^-S^+|H|AS\rangle/\sqrt{2}$ that does not perturb the electronic structure of A and A^- significantly. The ground state (gs) of this 2×2 configuration interaction (CI) problem is [14].

$$|\psi(0)\rangle = \sqrt{1-\rho(0)}\,|AS\rangle + \sqrt{\rho(0)}\,|A^-S^+\rangle \tag{1}$$

The ratio $t\sqrt{2}/\Gamma(0) = \tan 2\gamma$ and $\rho(0) = \sin^2\gamma$ determines the relative neutral and ionic contributions. Without loss of generality we set $t = 1$ as the unit of energy and obtain

$$\varepsilon(0) = -2\sqrt{2\rho(0)(1-\rho(0))} + 2\rho(0)\Gamma(0) \tag{2}$$

for an isolated dimer. The parameter $\Gamma(0)$ fixes $\rho(0)$, with $\Gamma(0) < 0$ for $\rho(0) > 1/2$.

F4TCNQ covers $A_0 \sim 100$ Å^2 in Fig. 1, so that a ML has $\sim 10^{14}$ acceptors/cm^2. We consider decreasing electron transfer $\rho(\theta) < 1$ with increasing θ due to dipole–dipole repulsion. The nearest-neighbor separation scales as $r(\theta) = r_0\theta^{-1/2}$ for an invariant surface structure. The model Hamiltonian for $0 < \theta \leqslant 1$ is

$$H(\theta) = \sum_p h_p + \frac{1}{2}\sum_{pp}{}' V_{pp'}\rho_p(\theta)\rho_{p'}(\theta) \tag{3}$$

where h_p describes an isolated dimer and $V_{pp'} = \mu_0^2/r_{pp'}^3$ is the dipole–dipole interaction. We introduce a BCS-type trial function for $N_d = N\theta$ dimers at coverage θ

$$|\psi(\theta)\rangle = \prod_{p=1}^{N_d}(\sqrt{1-\rho(\theta)} + \sqrt{\rho(\theta)}\, b_p^+)|N\rangle. \quad (4)$$

$|N\rangle$ is a product of $N\theta$ neutral dimers whose interactions with the surface or with each other are neglected. The operator b_p^+ acts on the pth dimer to generate the singlet $|A_p^- S_p^+\rangle$. The trial function contains all possible distributions of $|AS\rangle$ and $|A^-S^+\rangle$ states on the surface, and it is strongly peaked at $\rho(\theta)$. CI mixing $\rho(\theta)$ is the same for all dimers by construction. As in BCS, there is perfect correlation of two states ($k\alpha$, $-k\beta$ there, electron–hole excitation of dimers here) and a mean-field approximation otherwise.

The gs expectation value of $|\psi(\theta)\rangle$ is

$$E(\theta) = N_d\varepsilon(\theta) + \rho(\theta)^2 {\sum_{pp'}}' V_{pp'}/2. \quad (5)$$

The first term is Eq. (2) with $\rho(\theta)$ instead of $\rho(0)$. The second term contains sums over $1/r_{pp'}{}^3$ that scale as $\theta^{3/2}$

$$\sum_{p,p'} V_{pp'} = 2kN_d\mu_0^2\theta^{3/2}/r_0^3 \equiv 2V_0\theta^{3/2}N_d. \quad (6)$$

Topping [20] evaluated the sum accurately and obtained $2k \sim 9$ per unit area of either a hexagonal or square planar lattice. $2V_0$ is the repulsion per dimer in a ML with $\rho(1) = 1$. Minimization of $E(\theta)$ with respect to $\rho(\theta)$ gives the self-consistency condition

$$\frac{1-2\rho(\theta)}{\sqrt{2\rho(\theta)(1-\rho(\theta))}} = \Gamma(0) + V\theta^{3/2}\rho(\theta) \equiv \Gamma(\theta) \quad (7)$$

with $V = V_0/t$. A dimer with $\rho(0) > 1/2$ and $\Gamma(0) < 0$ at $\theta = 0$ becomes less ionic with increasing θ. The states are degenerate at θ_1, where $\rho(\theta_1) = 1/2$, $\Gamma(\theta_1) = 0$ and

$$V\theta_1^{3/2} = -2\Gamma(0) \quad (8)$$

The relation between V and $\Gamma(0)$ is independent of t. Alternatively, the model's two parameters may be taken as $\rho(0)$ and $\rho(1)$, the initial and final CT in Eq. (7).

The surface dipole is $\mu_0\theta\rho(0)$, linear in coverage for $V = 0$. Repulsion $V > 0$ gives nonlinear profiles and superlinear $\theta^{3/2}$ may even produce a $\theta\rho(\theta)$ maximum. The derivative

$$\mu'(\theta) = \mu_0\rho(\theta)\left(\frac{(2+\Gamma(\theta)^2)^{3/2} - V\theta^{3/2}/2}{(2+\Gamma(\theta)^2)^{3/2} + V\theta^{3/2}}\right) \quad (9)$$

vanishes at the $\theta\rho(\theta)$ maximum. Since $\Gamma(\theta_1) = 0$, we have $\Gamma(0) = -2\sqrt{2}$ and $\rho(0) = 0.9476$ when $\mu'(\theta_1) = 0$. The maximum shifts to $\theta < \theta_1$ for $\Gamma(0) < -2\sqrt{2}$ and to $\theta > \theta_1$ for $\Gamma(0) > -2\sqrt{2}$. There is no maximum when the numerator of Eq. (9) is positive at $\theta = 1$.

The surface dipole is $b\sigma_-(\theta)$, with charge density $\sigma_-(\theta) = -e\theta\rho(\theta)/A_0$. The change of electrostatic potential across the acceptor layer is $-4\pi eb\sigma_-(\theta)$. The work function shift is

$$\Delta\Phi(\theta) = -4\pi eb\sigma_- \equiv \Phi_0\theta\rho(\theta). \quad (10)$$

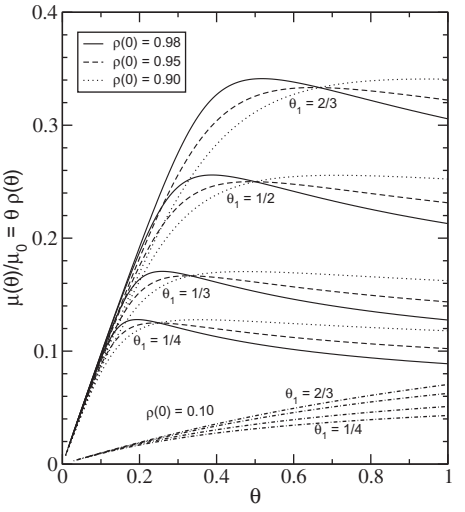

Fig. 2. Surface dipole $\mu(\theta)/\mu_0 = \theta\rho(\theta)$, Eq. (10), at coverage $\theta \leqslant 1$. The dipole $\mu_0\rho(0)$ of isolated dimer decreases to $\mu_0/2$ at θ_1 due to repulsion V in Eq. (7); increasing V decreases θ_1 in Eq. (8). Maxima of $\theta\rho(\theta)$ are given by Eq. (9). Small $\rho(0) = 0.10$ surface dipoles with the same θ_1 are nearly linear in θ.

The prefactor $\Phi_0 = -4\pi e\mu_0/A_0$ is the shift a full ML of A^- ions with $\mu_0 = -eb$. Comparison with experiment requires Φ_0 and d_{ML}. First we consider the CT model itself. Fig. 2 shows $\theta\rho(\theta) = \mu(\theta)/\mu_0$ for the indicated θ_1 and $\rho(0) \sim 1$. Curves with $\rho(0) > 1/2$ cross at θ_1. Increasing θ_1 amounts to decreasing dipole–dipole repulsion V in Eq. (8). The surface dipole is $\sim\mu_0\theta_1/2$ over a broad range with a maximum at $\theta = \theta_1$ for $\rho(0) = 0.95$ as expected from Eq. (9) and at $\theta < \theta_1$ for $\rho(0) = 0.98$. Saturation at $\sim\theta_1/2$ is sudden because the repulsion $\theta^{3/2}$ in Eq. (6) is superlinear. The change becomes more collective with increasing $\rho(0)$.

Fig. 2 also shows $\theta\rho(\theta)$ for largely neutral dimers with $\Gamma(0) \to -\Gamma(0)$, and hence $\rho(0) \to 1-\rho(0) = 10\%$, and unchanged repulsion V based on θ_1. The surface dipole is small and nearly linear, with little indication of cooperative behavior at $\rho(0) = 10\%$ and even less for $\rho(0) < 10\%$. We have neglected the dipole μ_N of $|AS\rangle$ compared to μ_0. The model is readily generalized to include μ_N as another parameter. It is then convenient to redefined $\mu_0 \to \mu_0 - \mu_N$ and the self-consistent analysis holds with minor changes. Our reasons for setting $\mu_N = 0$ are that there are other contributions to $\Delta(d)$ and that CT addresses CI while μ_N reflects local bonding.

3. F4TCNQ on metals or semiconductors

F4TCNQ films have been discussed in terms of ions A^- on the surface and molecules A in thick films. The growth mode is not known, but a full ML or a thick film surely has more adsorbed molecules than the ~20% coverage of A^- inferred from $\Delta\Phi$ shifts. [3,7,10,22,23] CT dimers are linear combinations of A^- and A according to $|\psi(\theta)\rangle$ in Eq. (4), with $\rho(\theta)$ found self-consistently via Eq. (7) to yield the profile $\Delta\Phi(\theta)$ in Eq. (10). There are several ways to compare with experiment: (1) the magnitude of $\Delta\Phi(d)$

for films of thickness d; (2) $\Delta\Phi(d)$ profiles as a function of d with $d_{ML} \sim 4$ Å for F4TCNQ; (3) photoemission spectra or other probes that identify surface species; (4) the surface roughness of sub ML films, which is open at present. The generality of the CT model invites comparison with sub ML films of any m-O interface.

Fig. 3 shows published $\Delta\theta(d)$ profiles to $d = 10$ Å for F4TCNQ on Cu(1, 1, 1) from Fig. 2 of [22] and for the surface dipole contribution on hydrogenated diamond (1, 0, 0) from Fig. 3.5b of [3]. To calculate profiles, we took $\Phi_0 = -4\pi e\mu_0/A_0 = 6.3$ eV in Eq. (10) with $A_0 = 100$ Å^2 and $\mu_0 = -eb$ with b = 3.5 Å. Such inputs pertain to the interface rather than the model. The calculated profiles have $\rho(0) = 0.50$ and $\rho(1) = 0.09$ in Eq. (7), a five fold decrease in the ML, or alternatively $\Gamma(0) = 0.0$ and $V = 22.5$. The shift $\Delta\Phi(d_{ML}) = \Phi_0\rho(1)$ gives an estimated $\rho(1)$. The initial slope of $\Phi_0\rho(0)/d_{ML}$ is an estimate of $\rho(0)$. Shifts beyond $d = d_{ML}$ are small (~0.10 eV), comparable to experimental uncertainties, and not modeled. The fit demonstrates the viability of the model. Moreover, F4TCNQ/Ag(1, 1, 1) has [23] $\Delta\Phi \sim 0.65$ eV and the larger $\Delta\Phi = 1.3$ eV on a passivated Si surface, [9] comparable to diamond (1, 0, 0), was not resolved into surface dipole and band bending. Similar $\Delta \sim \Delta(1)$ for F4TCNQ on different surfaces points to nonspecific bonding.

Photoemission indicates $TCNQ^-$ or $F4TCNQ^-$ on surfaces. Grobman et al. [8] assigned $TCNQ^-$ photoemission at energy E_1 to ionization of the anion's singly occupied HOMO, the neutral molecule's LUMO. The next emission at E_2 was assigned to a "relaxed HOMO" level, perturbed by the partially filled LUMO. This assignment is regrettably still current, [3,22] long after Masuda et al. [10] pointed out the proper interpretation of E_2. Photoemission of an anion generates the electronic spectrum of the neutral molecule. The final state for E_2 emission is the lowest triplet of TCNQ or F4TCNQ. The same MOs give a singlet excited state at higher binding energy. With resolution limited to ± 0.1 eV at best, the reported values of $E_2 - E_1$ for F4TCNQ are 1.3 eV on graphite, [10] 1.4 eV on passivated [9] Si, 1.0 eV on polycrystalline [7] Au, 1.2 eV on [2] Ag(1, 1, 1), 1.0 eV on hydrogenated diamond [3] (1, 0, 0), and 0.9 eV on Na-doped [24] Al_2O_3. Density functional theory (B3LYP) with the reasonably large 6–311++G** basis in the GAUSSIAN 03 program [25] returns 1.09 eV for the vertical triplet state of F4TCNQ.

Photoemissions E_1 and E_2 indicate $F4TCNQ^-$ at sub ML coverage, while E_3 indicates neutral molecules. The three features sometimes coexist, [9,24] with E_3 gaining and E_1, E_2 losing intensity with increasing film thickness. The CT model assumes weakly perturbed A or A^- in the trial function $|\psi(\theta)\rangle$ at least for the π-MOs that are mixed by CI. The electronic spectrum of the model at any θ is a superposition of an ionic fraction $\rho(\theta)$ and a neutral fraction $1-\rho(\theta)$. The CT model implies the coexistence of A^- and A at sub ML coverage, a point whose confirmation is a matter of resolution.

4. Discussion

The CT fit in Fig. 3 of vacuum level shifts is preliminary for several reasons. First, more accurate $\Delta\Phi$(d) data are assured if profiles become the focus rather than the existence and magnitude of Δ. Second, there may be better interface inputs such as d_{ML} or A_0. Third, the CT model can be generalized if warranted by good fits. The principal conclusion is that initial adsorption has considerable ionic character with $\rho(0) \sim 0.5$ that decreases to $\rho(1) \sim 0.1$ in a full ML. The precise value of $\rho(\theta)$ may change on considering other contributions. Since $\Delta\Phi$(d) is linear in coverage for noninteracting dipoles, deviations from linearity indicate $V > 0$ in the CT model or a depolarization field in the Topping model. Profiles with large deviation from linearity bring out differences.

Most m-O interfaces have $\Delta < 0$ and electron transfer from molecule to metal. The vacuum level shifts [26] of α-NPD on Au are shown in Fig. 4 up to $d = 20$ Å. D = α-NPD (N,N′diphenyl-N,N′bis(1-naphthyl)-1,1′biphenyl-4,4′diamine) is not planar and its orientation on the surface is not known. Its molecular volume is almost twice that of F4TCNQ, but the estimated $d_{ML} = 11$ Å gives a similar A_0 and larger $\Phi_0 = -12.0$ eV. A flat $-\Delta\Phi(d)$ profile following

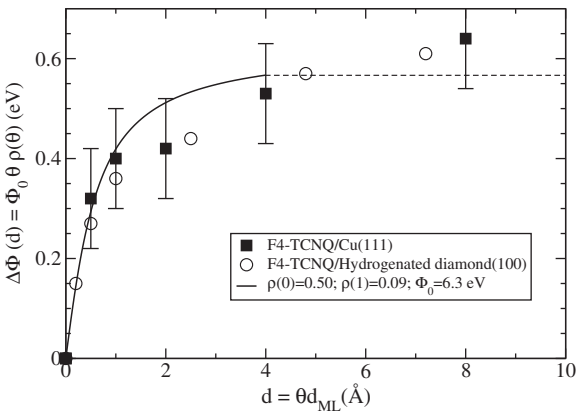

Fig. 3. Work function shift $\Delta\Phi(d)$ of F4TCNQ films. The Cu and diamond data are from Fig. 2 of [22] and Fig. 3.5b of [3], respectively. The curve is Eq. (10) with the $d_{ML} = 4$ Å, $\Phi_0 = 6.3$ eV and the indicated $\rho(0)$ and $\rho(1)$.

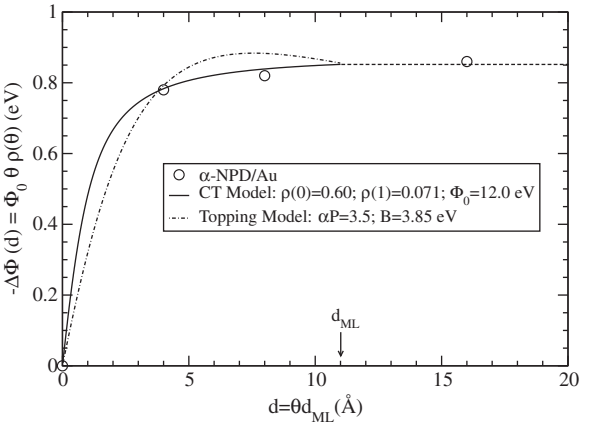

Fig. 4. Work function shift $-\Delta\Phi(d)$ of α-NPD films from [26]. The CT fit is Eq. (10) with the indicated $\rho(0)$, $\rho(1)$ and Φ_0. The Topping fit is Eq. (11) with $\alpha P = 3.5$ and $B = 3.85$ eV.

a steep initial increase is typical of other m-O interfaces [12,13,27] and points to strong repulsion. The CT model fits the profile with $\rho(0) = 0.60$ and $\rho(1) = 0.071$ for μ_0 = eb and b = $d_{ML}/2 + 1.5$ Å for the atomic radius of Au. Larger b and smaller A_0 increases dipole–dipole repulsion in Fig. 1. CT in the ML is about nine times less than at $\theta \sim 0$.

The Topping model works well for adatoms on semiconductors. [19] Its parameters are the dipole p_0 and polarizability α of an adatom on the surface. Topping [20] first scaled the surface structure in Fig. 1 as $r(\theta) = r_0\theta^{-1/2}$. The depolarization field $F(\theta)$ is found self-consistently for induced dipoles $\alpha F(\theta)$. The net dipole $p(\theta)$ and hence $\Delta\Phi_T(\theta)$ is [19]

$$\Delta\Phi_T(\theta) = -B\theta/(1 + \alpha P\theta^{3/2}) \tag{11}$$

where P contains the sum over r^{-3} in Eq. (6) and $B = -4\pi ep_0/A_0$. The dashed line in Fig. 4 has $\alpha P = 3.5$ and $B = 3.85$ eV in Eq. (11). It does not produce an extended flat region. The shift clearly goes as $\theta^{-1/2}$ when αP is large, and $\alpha P < 2$ is required to avoid a maximum at $\theta < 1$. Although $\Delta\Phi_T(\theta)$ with $\alpha P < 2$ differs from the CT profile, small differences from linearity call for accurate profiles. The CT model's $\Gamma(\theta)$ in Eq. (7) has a similar $V\theta^{3/2}$ factor, but its increase is limited by decreasing $\rho(\theta)$. Rearrangement of Eq. (7) with $\Gamma(0) = 0$ immediately shows that $\theta\rho(\theta)$ is constant for large V up to small corrections in $\rho(\theta) << 1$. Hence $\Delta\Phi(d)$ profiles can in principle discriminate among models.

As noted in the Introduction, $\Delta\Phi(\theta)$ profiles indicate charge redistribution but not the origin of surface dipoles. The present model invokes CT, the Topping model invokes polarizability, the pillow effect [28,13] invokes the compression of the metal's electron density on adsorption. Since the pillow contribution is always $\Delta < 0$, the surface dipole of F4TCNQ films contains a larger $\Delta > 0$ contribution. Also, local compression implies a linear profile while the observed profiles in Fig. 3 or Fig. 4 require interactions between adsorbed molecules. The $\Delta(d)$ profiles of all published m-O interfaces [12,13,27] are nonlinear to some extent. The pillow effect for p_0 plus a depolarization field amounts to a Topping model with p_0 due to compression.

In principle, the polarizability tensor α of an adsorbed molecule can be added to variable dipoles $\mu_0\rho(\theta)$ in the CT model. The CT dimer has polarizability α_d normal to the surface. An electric field F along μ_0 changes $E(A^-S^+)$ by $-ebF$ and leads to $\rho(F)$. Charge redistribution within a dimer gives [29]

$$\alpha_d = eb\left(\frac{\partial\rho}{\partial F}\right)_0 = \frac{e^2b^2}{2(\Gamma^2+2)^{3/2}} \tag{12}$$

with $\Gamma(\theta)$ defined in Eq. (7). The α_d contribution depends on θ and is largest at $\Gamma(\theta_1) = 0$ where CT is most sensitive to F. The remainder $\alpha' = \alpha - \alpha_d$ is due to charge redistribution that is beyond a CT dimer. The same logic applies to organic molecular crystals with anisotropic α tensors. Fractional atomic charges [30] yield α_C, which is part of $\alpha = \alpha_C + \tilde{\alpha}$, and the remainder $\tilde{\alpha}$ is associated with atomic polarizability; α_C is typically large and may even exceed [31] α, in which case $\tilde{\alpha} < 0$. In contrast to independent molecular computation of α, however, the polarizability of an adsorbed molecule is a model parameter. We may or may not choose CT to represent charge redistribution. Once the choice is made, however, the depolarization factor in Eq. (11) becomes $\alpha' = \alpha - \alpha_d$ instead of α and the shift $\Delta\Phi(\theta)$ in Eq. (10) is multiplied by $1/(1 + \alpha' P\theta^{3/2})$.

The CT model is phenomenological. It gives a two-parameter expression for the surface dipole $\mu(\theta) = \mu_0\theta\rho(\theta)$ that is nonlinear in the coverage $\theta \leqslant 1$. The parameters $\Gamma(0)$ and V in Eq. (7) lead to $\rho(0)$ and $\rho(1)$ for the initial and final CT. Direct evaluation $\Gamma(0)$ or t requires explicit consideration of both molecules and surfaces. Related models of ion-radical or CT salts [1,14,15] or of molecular aggregates [16,17] are based on small t. The present model is designed for D or A that are ionized on surfaces at low coverage. Large dipoles μ_0 are generated in systems with quite different bonding. Some approximations, less important ones, are readily relaxed. Small μ_N and depolarization can be included at the cost of extra parameters. Charges at finite b can be used instead of point dipoles. Films thicker than one ML can be considered. The $\theta^{3/2}$ dependence of dipole–dipole repulsion is required, but not the magnitude of V or $\Gamma(0)$ or t.

Detailed analysis of m-O interfaces is possible using DFT or quantum chemistry. Theoretical interest in surface dipoles has focused on the magnitude [13] of Δ, the pillow effect, [28] induced density of interface states [32] and cluster calculations [33]. Some studies have considered both [23,34] $\theta = 1/2$ and $\theta = 1$ or variable [35] θ in sub MLs with constrained structures. Direct modeling is limited to one interface at a time and starts with an optimized ML structure that is either retained for $\theta < 1$ or optimized again at $\theta = 1/2$. Direct modeling is more appropriate, indeed mandatory, for strong adsorption with the formation of covalent bonds. The results sometimes [34–36] map into $\Delta\Phi_T(\theta)$ in Eq. (11) with *derived* rather than model parameters. CT dimers and related solid-state models focus on small t and on collective properties as discussed above. Some shared challenges are noted below.

Rangger et al. [23] studied F4TCNQ bonding on Au(1, 1, 1) and Ag(1, 1, 1) at $\theta = 1$ and $\sim 1/2$ and on Cu(1, 1, 1) at $\theta \sim 1/2$ using DFT and supercells. They report backbonding at CN groups that accounts for significant deviations from planar F4TCNQ and hence generates a dipole μ_N (their "molecular contribution", ΔE_{vac}) normal to the surface. The μ_N contribution is opposite to their CT contribution and reduces it by almost a factor of two. Such DFT analysis of σ-bonds is complementary to the CT model with $\mu_N = 0$ and weakly coupled π-electronic states. But correlated models with small t are used precisely where DFT or MO methods have difficulties. The DFT transfer [23] of 1.8 π-electrons leads to $F4TCNQ^{1.8-}$ that in our opinion is not consistent with either E_1, E_2 evidence for $F4TCNQ^-$ anions or for extensive solid-state spectra that point to radical ions rather than dianions, even in stacks with σ-bonded $TCNQ^-$ that are not planar. [37] DFT with on-site repulsion U should limit transfer to one π-electron without major changes in σ-bonding.

In a computational study, Natan et al. [34] analyzed reconstructed Si surfaces at coverage $\theta = 1/2$ and 1 by p-substituted phenyls with the formation of Si–C σ-bonds. They find a linear dependence of the surface dipole on

the gas-phase dipole p_0. They emphasize the collective nature of dipole formation and find good agreement with Eq. (11) with $\alpha P \sim 0.9$ for the calculated α. They conclude that CT or other contributions to surface dipoles are small in these systems. Without disagreeing with the conclusion, we note such small deviations from linear $\Delta(d)$ profiles can be fit with the CT model, and that CT may be appropriate in some contexts.

Romaner et al. [35] studied depolarization and dielectric constants in self-assembled monolayers of 4′substituted 4-mercaptobiphenyl derivatives using DFT and related their results to Eq. (11). The ML structure is accurately known: polar molecules of length b are standing on the surface with a small tilt angle and are tightly packed with separation $r_0 < b$. The point dipole approximation of Eq. (11) requires modification, [35] as expected, for $b > r_0$ and the issue comes up whenever r_0 and d_{ML} are comparable. They assumed that sub ML structures retain erect molecules while scaling $r(\theta)$ as $r_0\theta^{-1/2}$. Scaling is a convenient fiction when covalent bonds are formed on adsorption, especially for standing molecules. Nevertheless, the dependence of polarization or other properties on b/r_0 or on θ can be extracted from such conceptual studies. Surface structure is a general concern in sub ML films.

In summary, we have modeled sub ML films of F4TCNQ in terms of CT dimers with surface states of the metal, as shown in Fig. 1. Small t mixes the neutral and ionic states and leads to variable electron transfer $\rho(\theta)$ due to dipole–dipole repulsion that is treated self-consistently. Collective CT accounts for having both A^- and A on the surface of F4TCNQ films and provides a general approach to profiles of work function shifts or surface dipoles. The model is phenomenological, well suited for modeling $\Delta\Phi(d)$ profiles of m-O interfaces. It is closely related to quantum cell models of donors and acceptors in π-radical solids.

ABSTRACT

Hybrid organic–inorganic complementary inverters were demonstrated on a flexible polyethersulfone (PES) substrate with vertically stacked *p*-channel pentacene and *n*-channel amorphous indium gallium zinc oxide thin-film transistors (TFT). Al_2O_3 layers grown by atomic layer deposition were used as top- and bottom-gate dielectric layers. Common-gate top-contact *p*- and bottom-contact *n*-channel TFTs showed saturation mobility values of 0.3 ± 0.02 and 5.3 ± 0.2 cm^2/Vs and low threshold voltage values. Complementary inverters yielded high gain values of 61 V/V with high and balanced noise margins at a low supply voltage of 5 V. The independent control of the thickness of the gate dielectric layer used for each transistor in this proposed vertically stacked geometry, allows for the realization of high-density low-power complementary circuits with high gain and balanced noise margins.

1. Introduction

Thin-film transistors recently have attracted considerable attention as an emerging technology for unique consumer markets that will allow the development of microelectronic circuits on flexible substrates, over very large-areas and potentially at a very low cost. Organic and oxide-based TFTs are two technologies that offer advantages over *n*-channel amorphous silicon TFTs technologies in that these materials are capable of larger mobilities, can be processed at lower temperatures [1–4] and if combined, they could lead to complementary electronic circuits. To date, most complementary inverters used two-dimensional (2D) geometries. Recently a vertically stacked organic TFT-based inverter was demonstrated using two *p*-channel transistors on a glass substrate [5]. This vertical inverter with two pentacene TFTs stacked on top of one another yielded a maximum gain of 13.4 V/V and a switching threshold voltage of −11 V with noise margin low and high values of 9.4 and 6.6 V, respectively, at a supply voltage of 20 V. However, practical electronic devices are expected to use *p*- and *n*-channel TFT-based complementary inverters to operate with low power consumption, high gain, high noise margins, and on flexible substrates.

Organic materials provide a natural framework for the development of complementary technologies, since *n*-channel or *p*-channel TFTs can readily be fabricated. However, they tend to be more susceptible to degradation in air and have lower mobilities than metal oxide semiconductors. On the other hand, transistors based on oxide semiconductors that can be processed at low temperatures with high mobility values operate mainly as *n*-channel transistors [3,6,7]. Hence, hybrid complementary structures comprising *p*-channel organic and *n*-channel metal oxide TFTs are particularly attractive to realize complementary circuit designs because they benefit from the intrinsic advantages of these two material systems.

Most hybrid TFT-based complementary inverters use horizontally distributed *n*- and *p*-channel semiconductor layers with a bottom-gate geometry [8–10] with a shared gate dielectric layer. Recently, we demonstrated organic–inorganic hybrid complementary inverters with high gain

values of 130 V/V and high and balanced noise margins employing *n*-channel *a*-IGZO and *p*-channel pentacene TFTs horizontally distributed on flexible substrates [10]. Here, we report on a novel flexible hybrid organic–inorganic vertically stacked complementary inverter geometry in which a *p*-channel pentacene TFT is stacked on top of an *a*-IGZO *n*-channel TFT. This geometry shown in Fig. 1 has the following advantages. The potential damage to the organic semiconductor layer associated with the deposition of gate dielectric materials and further fabrication steps of the *n*-channel TFT is avoided by employing a *p*-channel organic TFT on the top of a burried *n*-channel oxide TFT. Furthermore, the thickness of each of the gate dielectric layer used for the *n*- and *p*-channel TFTs can be controlled independently which is an important design parameter to achieve complementary circuits with high gain and balanced noise margins. In this study, a 100 nm-thick Al_2O_3 was used as top-gate dielectric for the *n*-channel oxide TFT and a 75 nm-thick Al_2O_3 was used as bottom-gate dielectric for the *p*-channel organic TFT. In both cases, atomic layer deposition was used to grow the Al_2O_3 layers. Balanced "*on*-currents" at the same operating voltages were obtained by independently controlling the size and width of the *n*- and *p*-channels, and by adjusting the thickness of the Al_2O_3 layers.

2. Device fabrication and electrical characterization

Hybrid organic–inorganic complementary inverters with vertically stacked TFTs were fabricated on a flexible polyethersulfone (PES) substrate. A bottom-gate top-contact *p*-channel TFT was fabricated on the top of a top-gate bottom-contact *n*-channel TFT by sharing the gate electrode, as shown in Fig 1(a). First, Ti/Au (6 nm/50 nm) electrodes were deposited using electron-beam (e-beam) at room temperature on a glass substrate through a shadow mask to define the source and drain electrodes for the top-gate *n*-channel TFT. A 30 nm-thick *a*-IGZO (Ga_2O_3:In_2O_3:ZnO = 1:1:1 mol%) layer was then deposited by radio frequency (rf) sputtering without intentional substrate heating using a power of 125 W, a working pressure of 3 mTorr, and an O_2/Ar (2/98) atmosphere through a shadow mask. Then, a 100 nm-thick Al_2O_3 gate dielectric layer was deposited by atomic layer deposition (ALD) system (Savannah100, Cambridge Nanotech Inc.) on top of the *a*-IGZO to form a TFT with a top-gate geometry. The Al_2O_3 films were deposited at 110 °C using alternating exposures of tri-methyl-aluminum ($Al(CH_3)_3$) and H_2O vapor at a deposition rate of approximately 0.1 nm per cycle. Each deposition cycle (one monolayer) lasted 25 s, yielding a total deposition time of 7 h and 20 min for 1000 cycles [11]. Al_2O_3 layers deposited by ALD had a dielectric constant of nine, which yielded highly conformal and defect-free gate dielectrics with high capacitance densities [12,13]. A 50 nm-thick Al electrode was fabricated by thermal evaporation through a shadow mask to serve as a common gate electrode. Then, another 75 nm-thick Al_2O_3 was deposited by ALD on the top of the *n*-channel *a*-IGZO TFT to serve as the gate dielectric for the pentacene TFT. A 50 nm-thick layer of pentacene was deposited through a shadow mask using thermal evaporation at a substrate temperature of 25 °C and an initial pressure of 2×10^{-8} Torr. Prior to its thermal evaporation, pentacene was purified using gradient zone sublimation. Finally, Au (100 nm) source/drain electrodes were deposited through a shadow mask over the pentacene channel. Here, a small offset, of around 400 μm, was introduced along the channel width direction to allow independent access to the source and drain electrodes of the top and bottom TFTs. This offset is not necessary but was use to facilitate the individual characterization of both TFTs. The samples were then transferred into a nitrogen-filled glove box (O_2, H_2O <0.1 ppm) for electrical testing. Gold was used as source and drain electrodes because it provides a similar charge-injection energy barrier of 0.6 eV for the injection of holes into pentacene and electrons into *a*-IGZO [14,15]. In these complementary inverters with a vertical stacked

geometry, further optimization of the injection characteristics can easily be achieved by separately selecting suitable metals for the source and drain electrodes of each channel. Complementary inverter circuits with the structure shown in Fig. 1(b) were fabricated using *p*-channel pentacene and *n*-channel *a*-IGZO TFTs with a channel length of $L_p = L_n = 180$ μm. A channel width of $W_p = 4000$ μm was used for the *p*-channel TFT and $W_n = 400$ μm for the *n*-channel TFT. The *n*- to *p*-channel ratio $W_p/W_n = 10$ and the different thicknesses of the top- and bottom-gate dielectric layers were optimized to compensate for: (1) differences in hole (μ_h) and electron mobility (μ_e) in the pentacene and
a-IGZO transistors; and (2) differences in the threshold voltages of the two transistors. The selected choice of the relative channel widths and gate dielectric thicknesses allowed the *n*- and *p*-channel TFTs to achieve balanced on-currents at comparable operating voltages. To test the inverter characteristics of these vertically stacked TFTs, the drain electrodes of the top and bottom TFTs were connected by using a single probe at the region of overlap. The common gate electrode for both *n*- and *p*-channel TFTs served as the input voltage (V_{IN}) of the inverter circuit.

The dielectric properties of parallel plate capacitors with a geometry PES/Ti/Au/Al_2O_3 (100 nm)/Al/Al_2O_3 (75 nm)/Au fabricated on the same flexible substrate were measured in capacitors of various areas ranging from 1 to 5 mm^2. Measurements of the leakage current and capacitance were performed by first, grounding the Ti/Au bottom electrode (floating top Au electrode) and applying a voltage ranging from −25 to 25 V to the Al electrode, biasing the 100 nm-thick Al_2O_3 layer. Then, the experiment was repeated by grounding the top Au electrode (floating bottom Ti/Au electrode) and applying a voltage ranging from −20 to 20 V to Al electrode, biasing the 75 nm-thick Al_2O_3 layer. Very low leakage current densities, below 10^{-7} A/cm^2 at 2.0 MV/cm were measured. High capacitance density of 81 ± 1 and 108 ± 2 nF/cm^2, with a dielectric constant value of $\varepsilon_r = 9$, were measured for the 100 nm-thick and the 75 nm-thick Al_2O_3 layers, respectively. Variations of the capacitance density smaller than 2% were observed for frequencies ranging from 1 to 100 kHz and electric fields between −2.5 and 2.5 MV/cm. The properties of these Al_2O_3 layers deposited by ALD are consistent with our previous reports [11,12]. The combined dielectric properties of these layers are indicative of a low defect concentration [16].

The current–voltage characteristics of the vertically stacked, bottom-gate *p*-channel and top-gate *n*-channel TFTs with channel widths ($L_p = L_n = 180$ μm) and lengths ($W_p = 4000$ μm and $W_n = 400$ μm) are shown in Fig 2(a and d). The output characteristics (drain current I_{DS} vs. drain–source voltage V_{DS} at multiple constant gate–source voltages V_{GS}) and transfer characteristics (I_{DS} vs. V_{GS} at fixed V_{DS}) of the TFTs were measured using an Agilent E5272A medium-power source/monitor unit connected to a probe station. Hysteresis-free transfer curves and leakage cur-

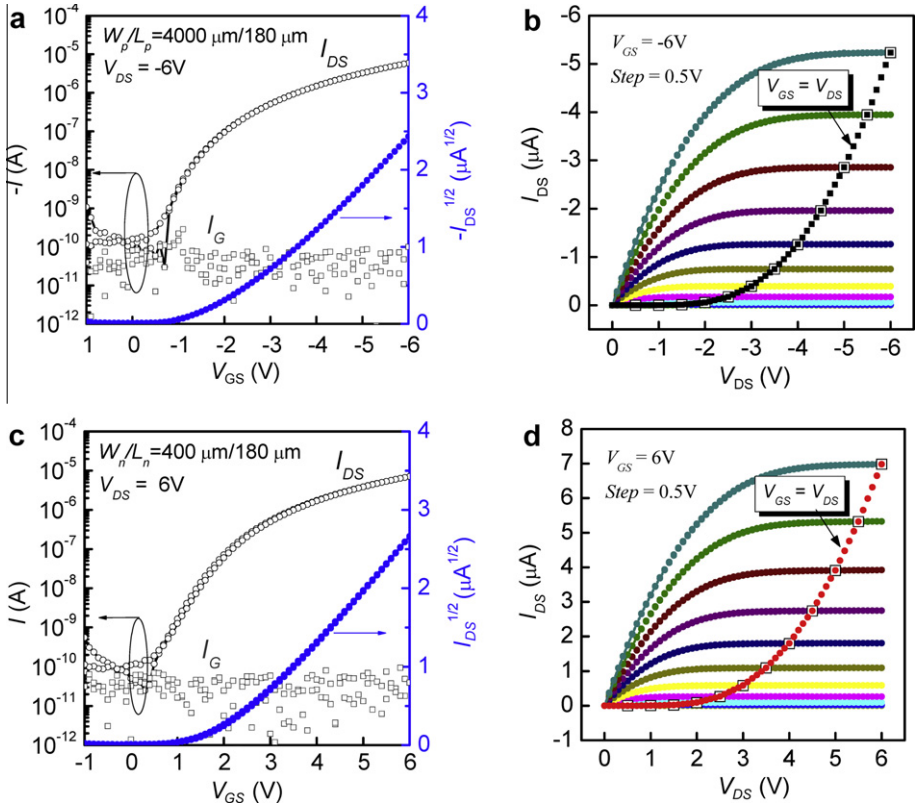

Fig. 2. Representative (a) hysteresis transfer and (b) hysteresis output characteristics of pentacene TFTs with $L = 180$ μm and $W_p = 4000$ μm. Representative (c) hysteresis transfer and (d) hysteresis output characteristics of *a*-IGZO TFTs with $L = 180$ μm and $W_n = 400$ μm.

rents measured for both forward and reverse gate biases are shown in Fig. 2(a) (*p*-channel) and Fig. 2(c) (*n*-channel). Saturation mobility values of 0.3 ± 0.02 and 5.3 ± 0.2 cm^2/Vs and threshold voltage values of −2.0 ± 0.2 and 2.1 ± 0.2 V were obtained for the *p*-channel pentacene and *n*-channel *a*-IGZO TFTs, respectively. Higher mobility values have been obtained from bottom-gate geometry *a*-IGZO TFTs because differences in processing conditions are expected to yield *a*-IGZO films with a slightly different stoichiometry than previously obtained [12,17]. Higher mobility values are expected upon further optimization of the deposition process. The hysteresis output curves shown in Fig. 2(b) (*p*-channel) and Fig. 2(d) (*n*-channel) exhibit good linearity at low drain-to-source voltage (V_{DS}) despite the relatively large energy barrier for charge injection and show no hysteresis.

3. Vertically stacked organic–inorganic hybrid complementary inverters

The static performance of an inverter is evaluated by its static gain and noise margin values, both extracted from the measured voltage transfer characteristics (VTCs). Achieving high and balanced noise margin values is necessary for reliable circuit operation in complex logic circuits such as ring oscillators. Noise margin values are defined by low noise margin ($NM_L = V_{IL} - V_{OL}$) and noise margin high ($NM_H = V_{OH} - V_{IH}$), where V_{IH}, V_{IL}, V_{OH}, and V_{OL} are input (V_{IN}) and output (V_{OUT}) voltages at high and low levels of a given inverter VTCs. The noise margin is limited by the steepness ($\Delta V_{IN} = V_{IH} - V_{IL}$) of the transition, where ΔV_{IN} is the difference of input voltages at high and low levels, and by the position of the switching threshold voltage ($V_M = V_{IN} = V_{OUT}$). High and balanced noise margins are found when the ideal condition $V_M = 0.5V_D$ is met, hence when $V_M = V_{IN} = 0.5V_D = V_{OUT}$. However, the value of V_{IN} at which this transition occurs is generally not $0.5V_D$. A complementary inverter can be modeled as two series-connected voltage-dependent variable resistors. In general, for a given supply voltage, V_D, V_M corresponds to the input voltage where the resistance of the *n*-channel TFT ($R_n = V_{DS}/I_{DS}$) is equal to that of the *p*-channel TFT ($R_p = -V_{DS}/-I_{DS}$). The conventional analytical equation used to find V_M, derived from the MOSFET square law model, assumes that the mobility and threshold voltage remain constant during operation [18,19]. However, in organic or oxide TFTs, this analytical approach may not always hold true. Therefore, an accurate calculation of V_M would require a fitting procedure to get the functional dependence of the mobility and threshold voltage as a function of V_{GS} and V_{DS}. Recently, we have proposed a method that does not require any fitting parameters, such as the carrier mobility or the threshold voltage, and in principle requires just a pair of measurements of R_n and R_p, which can be extracted from the output characteristics of independent TFTs, as a function of $V_{GS} = V_{DS}$ (as shown in Fig. 2(b) and (d)) [10]. Note, that testing at different V_D values is not really necessary once the output characteristics are measured for a large enough range of $V_{GS} = V_{DS}$. This is because the values of I_{DS} and consequently R_n and R_p can be interpolated from the measured output characteristics of the *n*-channel and *p*-channel TFTs. The absolute values of the difference of R_n and R_p, $R_d = |R_n - R_p|$, can be estimated for arbitrary values of V_D. Here, the value of V_M is given as the $V_{GS} = V_{DS}$ value where R_d reaches a minimum value.

Fig. 3(a) shows absolute values of R_d. Fig. 3(b) shows the corresponding hysteresis VTCs and static gain (dV_{OUT}/dV_{IN})

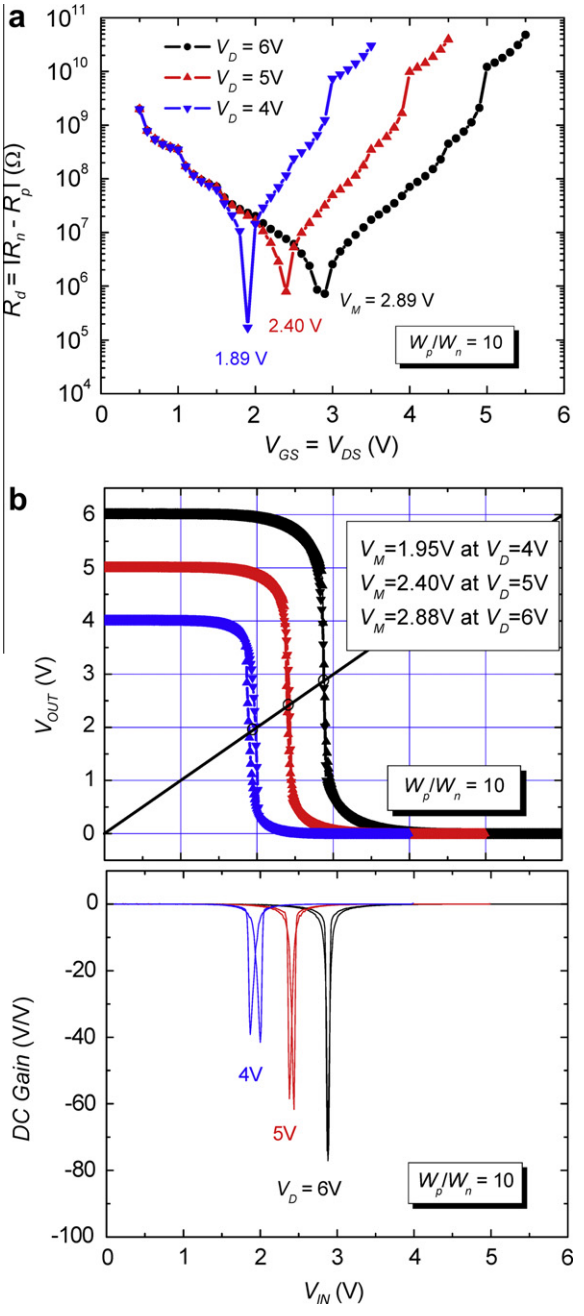

Fig. 3. (a) Absolute values of the differences of total resistances of pentacene *p*-channel and *a*-IGZO *n*-channel TFTs at $V_{GS} = V_{DS}$ by sweeping V_{GS} from 0 to ±4 V, ±5 V, ±6 V (positive for *n*-channel TFT, negative for *p*-channel TFT); (b) their corresponding voltage transfer characteristics and static gains of the hybrid complementary inverters for $W_p/W_n = 10$ at different supply voltages of 4, 5, and 6 V.

Table 1
Performance of an inverter using vertically stacked *p*-channel (pentacene) TFT on the top of an *n*-channel (*a*-IGZO) TFT.

W_p/W_n (μm/μm)	V_D (V)	*Maximum* dV_{OUT}/dV_{IN}	NM_L (V)	NM_H (V)	ΔV_{IN} (V)	V_M (measured) (V)	V_M (calculated) (V)	$R_p = R_n$ (MΩ)
4000/400	4	−42	1.57	1.72	0.39	1.95	1.89	24
	5	−61	1.87	2.07	0.47	2.41	2.40	11
	6	−78	2.17	2.46	0.62	2.88	2.89	5.8

values of the inverters for V_D = 4, 5, and 6 V. As expected from the comparison of the V_M extracted as the minimum value of R_d, at the optimum value of V_D, a reasonably centered V_M with high and balanced noise margins was achieved. Note that hysteresis-free VTCs of the inverter are desirable for stable circuit operations. Negligible hysteresis of the inverters for forward and reverse input biases can be attributed to the hysteresis-free current voltage characteristics, a necessary but not sufficient condition to assure the long-term operational stability of inverters. While this inverters show good short-term stability, under continuous prolonged operation we would expect variations of the threshold voltage, due to deep trapping events at the semiconductor/gate dielectric interfaces, to affect the long-term stability of these inverters. However, this geometry offers a clear path for the optimization of the long-term operational stability because it allows independent passivation of the interfaces of each individual TFT. The performance of this complementary inverter is summarized in Table 1. The maximum static gain value at V_D = 5 V was −61 V/V at V_M = 2.41 V. The corresponding value of NM_L and NM_H are 1.87 and 2.07 V with the steepness of ΔV_{IN} = 0.47 V (9.4% of max V_{IN}). At the switching threshold voltage values, $R_p = R_n$ was found to be 11 MΩ. Further reduction of the operating voltage and size of the TFTs could be achieved without significant degradation of performance because the high quality of the dielectric layers produced by ALD will allow increasing the capacitance density of the gate dielectrics by reducing the thicknesses of the top- and bottom-gate Al_2O_3 layers. Furthermore, the low temperature process of the ALD method makes the proposed geometry and fabrication method also compatible with the use of all-organic semiconductors.

4. Conclusion

In summary, we demonstrated a novel hybrid flexible organic–inorganic complementary inverter geometry with vertically stacked *p*-channel and *n*-channel TFTs. To implement this geometry a pentacene *p*-channel TFTs was stacked on top of an *a*-IGZO *n*-channel TFT. The complementary inverters used *n*- and *p*-channel TFTs with channels having different aspect ratios and dielectric layers with a different thickness to achieve high and balanced noise margins with high static gains. Al_2O_3 layers grown by atomic layer deposition were used as bottom- (100 nm) and top-gate (75 nm) dielectric layers for the *n*-channel *a*-IGZO and *p*-channel pentacene TFTs, respectively. These layers had a high capacitance density of 81 ± 1 and 108 ± 2 nF/cm^2, respectively. With a shared common gate electrode positioned in between two gate dielectric layers, bottom source/drain contact *n*- and top source/drain contact *p*-channel TFTs showed saturation mobility values of 0.3 ± 0.02 and 5.3 ± 0.2 cm^2/Vs and threshold voltages of −2.0 ± 0.2 and 2.1 ± 0.2 V, respectively. Complementary inverters showed voltage transfer curves with negligible hysteresis due to hysteresis-free transfer and output characteristics of the individual TFTs. Hybrid complementary inverters yielded a high gain of 61 V/V and high and balanced noise margins with low and high noise margin values of 1.87 and 2.07 V, respectively. These values correspond to 75% and 83% of their theoretical maximum, with high steepness of 0.47 V at a low voltage of 5 V. Balanced "*on*-currents" during inverter operations could be obtained because this geometry allows for independent control of the channel widths, the *n*- to *p*-channel ratios, as well as separate control of the thickness of the gate dielectric layers. The use of vertically stacked *p*- and *n*-channel TFTs in complementary circuits is a promising way to realize higher packing density and higher interconnectivity with low power by the reduction of the interconnection lengths and parasitic resistances.

ABSTRACT

Quantum chemical method was used to investigate the geometrical structures, electronic properties, absorption and phosphorescent mechanism of four Pt(II) complexes 6-phenyl-4-(*p*-R-phenyl)-2′,2-bipyridyl (C^N^N)Pt(II)Cl, (R = Me, (**1a**); COOMe (**1b**), $P(O)(OEt)_2$ (**1c**), and 6-phenyl-4-(*p*-Me-phenyl)-2′,2-bipyridyl (C^N^N)Pt(II) C≡CPh (**2a**). The geometrical structures and electronic properties of **1a**–**1c** are insensitive to the variation of substituents, because of their longer distance to Pt(II) center. However, changes are significant for **2a** with respect to **1a** due to the direct connection of C≡CPh group with phosphorescent Pt(II) center. The oscillator strengths of the lowest energy absorptions for **1a**–**1c** are small, and this intensity for **2a** gets a remarkable enhancement due to the increase of electronic delocalization on the acetylide and Pt(II). More importantly, different phosphorescent quantum yields of these complexes are compared, especially between **1a** and **2a**. It is believed that the higher e_g^*-like Pt d-orbital, the larger ^{3}MC–^{3}MLCT energy gap as well as the deeper potential energy surface (PES) of **2a** than **1a** are the main reasons accounting for its higher efficiency of **2a**. In addition, the potential as light-emitting layer materials of these complexes are investigated.

1. Introduction

Phosphorescent d^6 and d^8 transition-metal complexes have been attracting an increased interest for the design and synthesis of new functional molecular materials. Due to the strong spin–orbit coupling effect, these complexes produce bright emission from excited states with an increased contribution from the metal-to-ligand charge transfer (MLCT) character, which effectively breaks down the spin-selection rule, facilitating a change in multiplicity and the subsequent radiative transition from the triplet state to the ground state [1]. The potential applications of these complexes include the chromophores for promoting photoinduced charge separation in artificial photosynthesis [2]. High-efficiency Ir(III) and Os(II) complexes represent the examples of phosphorescent transition-metal complexes with d^6 electronic configuration [3]. Because they generally possess an octahedral geometry, which can efficiently prevent the triplet–triplet annihilation arising from strong bimolecular interactions of phosphor, such that the respective emission can be produced in a rather effective manner: high phosphorescent quantum yield and short lifetime. Pt(II) complexes are typical phosphorescent materials with d^8 electronic configuration. The dsp^2 hybridization determines the square-planar structure of these complexes which can facilitate electron delocalization and thus lead to various charge transfer states, such as MLCT, ligand-to-ligand charge transfer (LLCT), or intraligand charge transfer (ILCT). Furthermore, similar to octahedral geometry,

doi:10.1016/j.orgel.2010.10.011

square-planar structure is also in favor of electron–hole creation and separation, therefore, these complexes are ideal candidates in OLEDs fabrication and related super-molecular devices.For Pt(II) complexes, the presence of low-lying metal-centered (MC) dd excited states are often used to account for the nonemissive behavior, as the potential-energy minima of its dd excited states is markedly displaced from that of the ground-state structure, and thus efficient nonemissive decay pathways are provided. A general strategy for promoting emission over nonemissive behavior has emerged, namely to ensure that dd excited states involving the population of the strong antibonding $d_{x^2-y^2}$ orbital are not thermally accessible to either the MLCT or ligand-centered (LC) excited state for emission quenching. The key to increase the energy of the dd nonemissive decay is to introduce strong-field ligands. Yip et al. [4] have shown that the introduction of electron-releasing substituents at the 4′-position of the terpyridine ligand in [Pt(tpy)Cl$^-$] leads to emission in fluid solution at room temperature with lifetimes of microseconds. However, only coordination of transition metal ion with strong-field ligand is not enough. Simple modification of the electronic properties of ligands and changes of substituents were expected to perturb the relative energies of MLCT, LLCT or dd excited states, and consequently the phosphorescent quantum yields and lifetimes. For instance, Pt(II) complexes containing tridentate ligands, 6-phenyl-4-(*p*-R-phenyl)-2′,2-bipyridyl (C^N^N)Pt(II)Cl, (R = Me, (**1a**); COOMe (**1b**), and P(O)(OEt)$_2$ (**1c**)) [5], the phosphorescent efficiency changes from 0.066 to 0.035, and lifetime changes from 580 to 385 ns, respectively. If Cl group in **1a** is replaced by acetylide (**2a**) [6], the phosphorescent quantum yield can be improved to 0.073 in CH_2Cl_2 solution. In this case, it is expected that the dd excited states splitting would be increased and the resultant dd excited states raise to higher energies with respect to MLCT states. Therefore, an in-depth understanding of the effect of substituents and coordinating ligand on the photophysical behavior is desirable for rational syntheses of highly emissive phosphorescent materials. In this paper, DFT and time-dependent DFT (TDDFT) calculations have been performed to rationalize the reasons resulting in the different phosphorescent properties and provide a further insight into the spectroscopic origins of this class of complexes.

2. Computational details

The ground-state and the lowest-lying triplet excited-state geometries were optimized by DFT [7] with Becke's LYP (B3LYP) exchange-correlation functional [8] and the unrestricted B3LYP (UB3LYP) [9] approach, respectively. There were no symmetry constraints on these complexes. At the respective optimized geometries of ground and excited states, TDDFT/B3LYP [10] calculations associating with the conductor polarized continuum model (CPCM) [11] in dichloromethane (CH_2Cl_2) media were carried out in order to obtain the vertical excitation energies of singlet (S_n) and triplet (T_n) states. Recent calculations with TDDFT method for transition-metal complexes have supported its credibility and gave good agreement with experimental spectra [12]. Spin–orbital coupling (SOC) causes mixture of singlet and triplet states, and the latter is allowed to participate in both absorption and emission; however, no SOC factor is included in current TDDFT calculation under G03 software. Su and co-workers explored the SOC effect on the excited energy of Re complexes [13]. The results revealed that SOC has a tiny effect on transition and it provides available spectral features for transition-metal Re complexes.

In the calculation, the quasi-relativistic pseudo-potentials of **Pt** atoms proposed by Hay and Wadt [14] with 16 valence electrons were employed, and a "double-ξ" quality basis set LANL2DZ was adopted. 6-31G(d) was used for nonmetal atoms. All calculations were performed with Gaussian 03 software package [15].

3. Results and discussion

3.1. Geometries in the ground and the lowest-lying triplet excited states

The sketch map for the four complexes is presented in Chart 1 and the optimized ground-state structure of **1a** is shown in Fig. 1. The main structural parameters are summarized in Table 1 together with the X-ray crystal structures data of **1a** [5]. For **1a**–**1c**, the main bond lengths and bond angles are insensitive to the variation of substituents, i.e., nearly the same for the three complexes, as shown in Table 1. The Mulliken atom charges on the related atoms of **1a**–**2a** are presented in Fig. S1 (Supporting Information). Fig. S1 indicates that charge is influenced locally, mostly from the atoms to which the substituents are attached. Therefore, the Mulliken charges on Pt(II) and its surrounding atoms are insensitive to the variation of substituents, which leads to the similar bond lengths among **1a**–**1c**. Our conclusions are in good agreement with the results reached by Tong and Che recently [16], who reported a series of platinum complexes similar to systems in this paper. Table 1 indicates that the optimized bond lengths of **1a** are in general agreement with the experimental values [5]. The largest discrepancies are Pt–N2 bond and C2–C3–C4–C5 dihedral angle, which deviate from the measured data of about 0.08 Å and 37.3°, respectively. This is due to the fact that the optimized **1a** is a free molecule in the gas phase, while the measured condition is in the tight crystal lattice. As shown in Fig. 1, the repulsion between H1 and H2 distorts the complex in the gas phase. Moreover, there is π-stacking (∼3.33 Å) of bipyridyl parts of C^N^N ligands between adjacent molecules. This is because the π-accepting ability of pyridine ring is stronger than the cyclometalated phenyl ring, and the co-planar structure of the pendant phenyl ring with the cyclometalated portion of two C^N^N ligands results from the crowded intermolecular stacking. For **1a**–**1c**, Pt–N1 bond (1.978 Å) is ca. 0.21 Å longer than Pt–N2 (2.188 Å). This can be attributed to the fact that side pyridine is localized *trans* to the phenyl ring, which has strong *trans* effect and weakens the metal–nitrogen interaction.

Compared with **1a**, the replacement of Cl group with acetylide in **2a** causes the elongation of Pt–C and Pt–N distances, especially for Pt–N1 bonds. In **2a**, Pt–C6 bond is ca. 0.03 Å shorter than Pt–C1 bond. This is due to the fact that

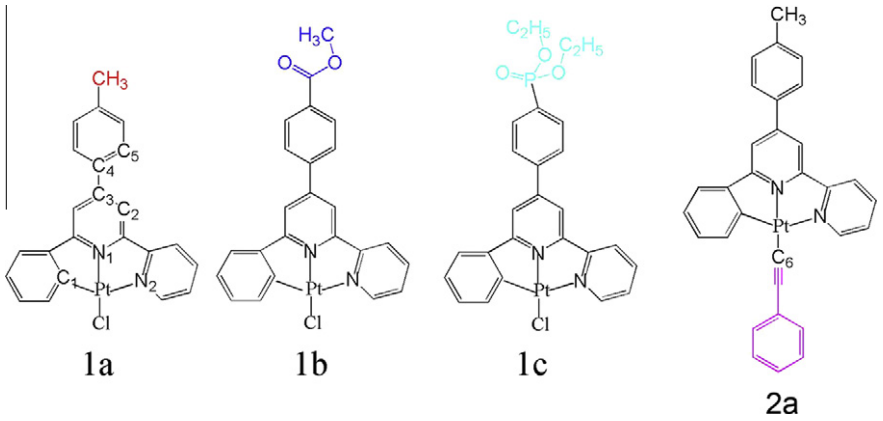

Chart 1. Schematic structures of the investigated complexes.

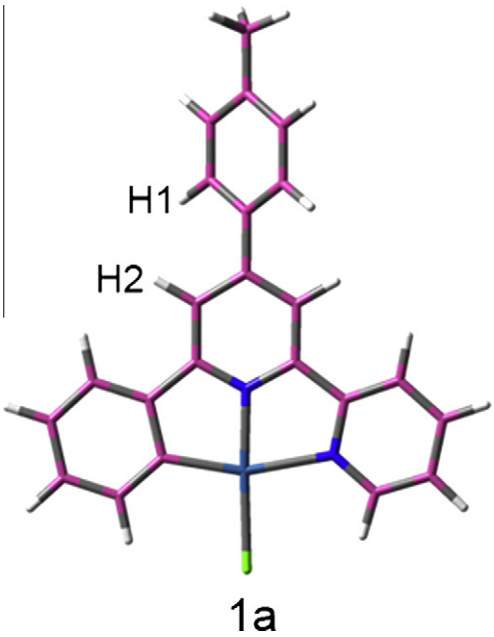

Fig. 1. Optimized structure of 1a in the ground states at DFT/B3LYP level.

phenyl ring in acetylide exhibits a stronger conjugating effect on the C≡C bond, thus leads to higher negative electron density on C6(−0.365 |e⁻|) than C1(−0.241 |e⁻|) and results in shorter Pt–C6 bond than Pt–C1 bond. This substituent effect of phenyl ring on ligand has been observed previously [17]. Moreover, we noted that Pt–N1 bond is elongated significantly with respect to that in **1a**. This indicates that the strong σ donation of Pt–C_{ethyne} bond resulting in the elongation of Pt–N1 bond at its *trans* position.

The calculated geometrical parameters of the lowest-lying triplet excited states for **1a**–**2a** are also listed in Table 1. For all the four complexes, Pt–C1 bond elongates in T_1 states compared with those in S_0 states, while all the other metal–ligand interaction becomes strengthened in T_1 states. This indicates that under higher energy excitation, Pt–C1 bond will be broken first due to its anbibonding combination with Pt d-orbital. In T_1 states, there is negligible change of C1–pt–N1 angle, while N1–pt–N2 bond angles increase about 1° for all the four complexes, which results from the contraction of Pt–N1 and Pt–N2 bonds. In addition, the distortion between phenyl ring and C^N^N moiety significantly reduced for **1a**–**1c** because of the decrease of C2–C3–C4–C5 dihedral angles. However, this change for **2a** is much smaller. Furthermore, bite

angles (C1–pt–N2) of the chelating ligands play an important role in determining the photophysical properties of Platium(II) complexes [18]. Decrease in bite angle usually indicates faster non-radiative decay via MC states. The optimal bite angle for maximum orbital overlap would be 180° to offer sufficient ligand field strength. However, the calculated bite angles for **1a**–**1c** are around 160°, these small bite angles result from the binding to large transition metal ion. We noticed that the bite angles slightly increase in T_1 states for all the complexes, which is favorable to improve the phosphorescent quantum yield.

3.2. Frontier molecular orbital properties

It is well understood that the photophysical properties are strongly dependent on the character of frontier orbitals and the resulting HOMO–LUMO energy gap, which in turn are governed by their basic skeletal arrangement and the electronic properties of substituents anchored to these chelating chromophores. Frontier molecular orbital (FMO) compositions for **1a**–**2a** are given in Tables S1–S4 (supporting information). The HOMO and LUMO distribution, energy levels and energy gaps are plotted in Fig. 2.

For **1a**, the HOMO is composed of the mixture of Pt d-orbital (42%), Cl p-orbital (21%) and phenyl ring moiety of C^N^N ligand (37%), and Pt is antibonding combination with both moieties. We noticed negligible participation of phenyl ring connected to the central pyridine of C^N^N ligand in HOMO. Therefore, one can anticipate that attaching different substituents on this phenyl ring will not cause a significant difference in orbital distribution and energy levels for **1b** and **1c**, as shown in Tables S1–S3 and Fig. 2. HOMO−1 of **1a** has similar composition with HOMO and is calculated only 0.04 eV lower than HOMO. Thus, HOMO and HOMO−1 is a couple of nearly degenerate orbitals. HOMO−2, localized at about 0.19 eV lower than HOMO−1, has large composition from Cl group (47.6%) and with the remaining mainly distributed over Pt d-orbital ($31.3d_{xy}$) and C^N^N ligand. HOMO−3 lying at −6.06 eV is dominantly composed of 91% Pt d-orbital ($71.6d_{z^2}$ + $1.5d_{xy}$) and HOMO−4 is mainly localized on C^N^N ligand.

Comparing **2a** with **1a**, the replacement of Cl with acetylide causes significant differences in composition and energy levels, in which HOMO is controlled by acetylide ligand mixed with some contribution from Pt d-orbital as shown in Table S4. HOMO−1 has increased participation from C^N^N moiety, which is different from that of HOMO, and this can be used to account for the large energy gap between HOMO and HOMO−1.

Due to the stronger electron accepting ability of pyridine than phenyl ring, LUMO for the four complexes is predominantly arising from the bipyridines moiety of C^N^N ligand. Since the substituents and ancillary ligands are not connected directly to C^N^N moiety, thus LUMO distribution and energy levels are not pertured much. In **1b**, the slightly lower LUMO energy and the increased participation from phenyl ring result from the electron-withdrawing effect of –COOH group. There is a large energy gap between LUMO+1 and LUMO for **1a**–**2a**, because the orbital composition extends greatly to phenyl ring moiety in the LUMO+1. Other unoccupied orbitals with higher energy tend to localized on both the phenyl ring and C^N^N ligand across, with the exception of LUMO+2 in **1a** and **2a**.

The dd state is usually regarded as the intrinsic reason for the nonemission of square-planar Pt(II) complexes in solution. Therefore, destabilizing and deactivating the dd excited state is of great significance in experiments. In the calculation, the calculated e_g^*-like orbitals are localized at 0.03, −0.08, −0.06, and 0.54 eV, which are higher than HOMO about 5.58, 5.58, 5.59, and 5.30 eV for **1a**–**2a**, respectively, and are much larger than MLCT, LLCT and ILCT energies.

Fig. 2 shows that the replacement of Cl with acetylide increases the HOMO energy level more markedly than that of the LUMO and results in the narrow HOMO–LUMO gap (ΔE_{H-L}) than **1a**–**1c**. Moreover, for **2a**, the energy gaps between HOMO and HOMO−1, LUMO and LUMO+1 are large. These large energy gaps may demonstrate the difficulty of electron transition from HOMO−1 or lower occupied MOs to LUMO+1 or higher unoccupied MOs. This implies that HOMO–LUMO transition may be dominant for the lowest singlet excited states.

3.3. Absorption spectra

Starting from the ground-state geometries, singlet and triplet excited states of **1a**–**2a** were calculated by TDDFT/B3LYP method with CPCM in CH_2Cl_2 media, thus allowing the simulation of absorption spectra up to 280 nm. The calculated transition states, oscillator strength, and assignment for singlet and triplet excited states are listed in Table 2 and Table S5 (Supporting Information), respectively.

As shown in Table 2, for **1a**–**1c**, the calculated lowest energy absorption follows the order **1b** > **1c** > **1a**, which is consistent with the variation rule of energy gaps because HOMO–LUMO transition configurations are predominantly $S_0 \rightarrow S_1$ transition. As a result of the negligible intensity in the range 0.0012–0.0022, the $S_0 \rightarrow S_1$ transition is probably forbidden and would be practically absent in the absorption spectra. However, for **2a**, the transition intensity of S_1 state (0.2716) is significantly improved compared with **1a**–**1c**. The calculated transition dipole moments for **1a**–**2a** are 0.1844, 0.1377, 0.1520 and 2.1241 a.u., respectively. The increased intensity in **2a** originates from the increased transition dipole moments, which is defined as the transition density weighted by the distance of the atom from the center of the gravity [19]. The co-planar molecular structure of C≡CPh and C^N^N moieties is most favorable to achieve an enlargement of the absorption intensity and transition dipole moment. From the above discussion on FMO, the calculated 470, 478 and 475 nm transitions for **1a**–**1c** can all be described as {[d(Pt) + π(Cl + trph) → π*(trph)]} transition with characters of MLCT, LLCT, ILCT. For **2a**, the charge transfer (CT) transition of MLCT and LLCT {[d(Pt) + π(C≡Cph) → π*(trph)]} contributes to S_1 excitation as shown in Table 2.

For **1a**–**2a**, the lower lying distinguishable absorption bands in experiment do not appear in the singlet excited states calculation, which indicates that they are singlet-to-triplet in nature as shown in Table S5. The measured 436, 440 and 439 nm triplet absorptions for **1a**–**1c** all

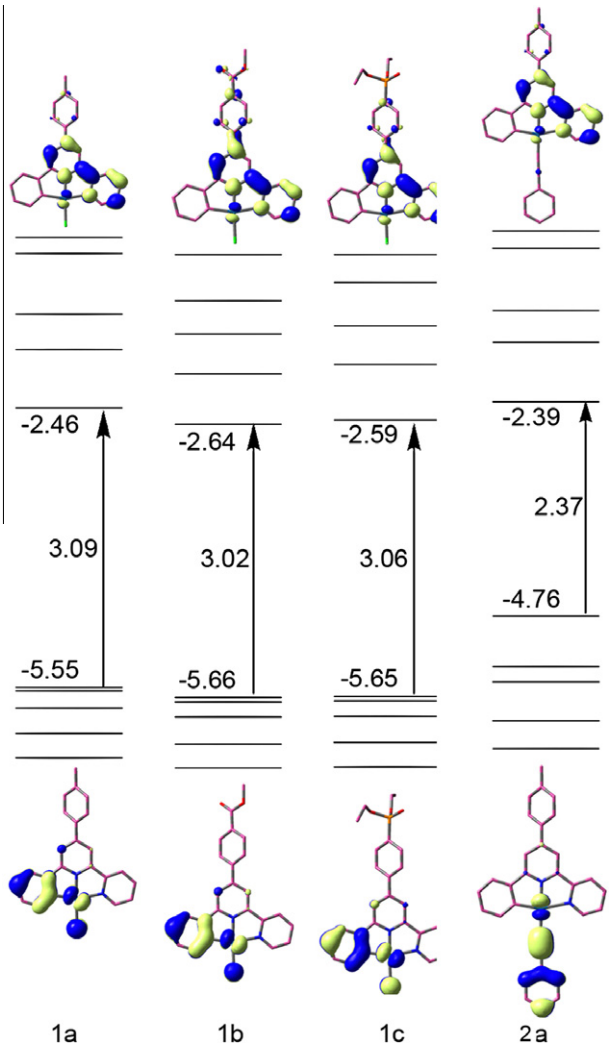

Fig. 2. Energy levels, energy gaps (in eV) and orbital composition distribution of HOMO and LUMO for the four complexes.

correspond to MLCT, LLCT and ILCT characters. For **2a**, the calculated 463 and 444 nm triplet absorptions correspond to the 461 and 448 nm measured values in experiment, respectively, which also have MLCT, LLCT and ILCT characters.

The first distinguishable lower energy absorption bands appear at around 370 nm for the four complexes, and transition with the largest oscillator strengths localized at 352, 352, 350 and 362 nm for **1a**–**2a**, respectively. For **1a**, the Pt d-orbital to trph π^*-orbital transition (MLCT) is the main character, and for **1b** and **1c**, ligand-based transition dominants the 352 and 350 nm absorption. In **2a**, mixed transition characters of MLCT, LLCT and ILCT from Pt d-, C≡Cph and trph π-orbital to trph-based π^*-orbital is predominantly for the 362 nm absorption. The observed strongest absorptions in experiment localized at higher energy region are 291, 288, 285 and 283 nm for **1a**–**2a**, respectively. With the exception of **1a**, the other three complexes appear to be composed of a series of transitions, and each is dominated by two more intense excitations as shown in Table 2. The 291 nm absorption for **1a** is mainly contributed by transition configuration of HOMO−3 → LUMO+1(92%) with MLCT excitation to ph and trph π^*-orbital. The 288 and 283 nm shoulders for **1b** and **2a** appear to be composed of mixed π–π^* and MLCT transitions also with ph-and-trph-based π^*-orbital as arrival orbital. For **1c**, the calculated 298 and 293 nm absorptions compose the 285 nm shoulder, which are both π–π^* transitions in characters.

The calculated results agree with the experimental observations that MLCT component is more remarkable in lower energy region and triplet excitation is appearance in the absorption spectra, which indicates that spin-selection rules are not strictly obeyed for heavy third-row transition-metal complexes. Though the participation of MLCT is weak, it is an efficient process to collect light and therefore enhances the luminescence quantum yields. The selection of substituents with electron-donating properties or ancillary ligand with large π-conjugation planar can also improve the light absorption efficiency.

3.4. Phosphorescence

On the basis of the optimized lowest triplet excited-state structures, TDDFT method was used to calculate emission energies. The calculated results are listed in Table 3 and the molecular orbital compositions related to emission are listed in Table 4. The transition responsible for the emission is simulated in Fig. 3.

Table 3 shows that the calculated lowest energy emissions of the four complexes are localized at 619, 629, 621, and 761 nm, respectively. The calculated Stokes shifts between the ^{3}MLCT absorption and the lowest energy emissions are in the range of 0.32–0.41 eV for **1a–2a**, and they are comparable with our investigation of Ir complexes [20]. These larger Stokes shifts indicate that the lowest-lying emissions for **1a–2a** will be in a larger mixture of ^{3}MLCT and ligand-based $^3(\pi \rightarrow \pi^*)$ transitions [21]. Our calculated results agree with the experimental observations that the measured emission spectra give structured emission with several shoulders [5]. Because emission bands from ^{3}MLCT states are generally broad and featureless, while $^3(\pi \rightarrow \pi^*)$ states typically give highly structured emissions [21].

For **1a–1c**, the predicted emissions deviate from measured values by 42, 55 and 48 nm, respectively, which is comparable with the results reported recently [22]. However, the calculated absolute emission of 761 nm for **2a** deviates largely from the measured result of 595 nm [6]. One reason is that the excited-state geometry we used here was optimized in the gas phase, and another reason is the limited dimensions of the basis set. Table 3 and Fig. 3 show that the 619, 629 and 621 nm emissions for **1a–1c** are all nearly evenly contributed by HOMO → LUMO and HOMO-1 → LUMO transition configurations, and the three complexes have similar orbital compositions. In Table 4, the HOMO−1 of **1a–1c** is localized on Pt d-orbital, Cl p-orbital, phenyl ring and center pyridine moieties of C^N^N ligand, which covers the whole molecule across. The HOMO is mainly the anbibonding combination of Pt d-orbital with C^N^N moiety. Therefore, the 619, 629 and 621 nm emissions can be described as {[d(Pt) + π(Cl + ph + trph)]→[π*(ph + trph/trph)]} transition with MLCT, LLCT and ILCT characters, and {[d(Pt) + π(trph)]→[π*(ph + trph/trph)]} transition with MLCT and ILCT characters. As expected, the 761 nm emission of T_1 state for **2a** arises mainly from HOMO → LUMO transition and has the

characters of MLCT, LLCT and ILCT {[d(Pt) + π(trph)]→[π*(trph)]} as shown in Fig. 3.

In experiment, the measured phosphorescent quantum yields for **1b** and **1c** are lower than **1a**, however, the replacement of Cl with acetylide group in **1a** increases the quantum yield in **2a**. From the experimental quantum yields (Φ) and lifetime (τ) data, we obtained the k_r (radiative decay rate) and k_{nr} (non-radiative decay rate) values and the results are listed in Table 5, in which $k_r = \Phi/\tau$ and $k_{nr} = (1 - \Phi)/\tau$. Obviously, Φ can be affected by the competition between k_r and k_{nr}, namely, $\Phi = k_r/(k_r + k_{nr})$. Therefore, to increase the quantum yield, k_r should be increased and k_{nr} should be decreased simultaneously or respectively [23]. As shown in Table 5, the k_r values for **1a–2a** are found to be 3.6–7.9 times larger than k_{nr} values, probably, represent the main factor for regulating the luminescence behavior of these complexes. For **1a–1c**, the calculated k_r values decrease in the order **1a** → **1b** → **1c** and the k_{nr} values increase also in the order **1a** → **1b** → **1c**. According to the above expression, the resulting Φ values decrease in the order **1a** → **1b**→**1c**. The increased k_{nr} values for **1b** and **1c** than **1a** may result from the

Table 5

2a	1.510	0.190	0.073	485

electron-withdrawing effect of COOH and $PO(OC_2H_5)_2$ groups relative to CH_3, which can slightly decrease the metal–ligand interaction as reported previously for Ir complexes with COOH groups, though there no obviously bond lengths difference was observed [24]. The weakened metal–ligand interaction will facilitate the nonemissive transition decay. For **2a**, the larger k_{nr} value than **1a** results from the slightly weakened metal–ligand interaction as shown in Table 1. In addition, according to energy gap law, non-radiative rates increase for longer wavelength emission [25]. The larger Φ of **2a** than **1a**–**1c** can be ascribed to the increased k_r value, which is resulting from the increased light absorption section due to the presence of phenyl ring. It can increase the transition dipole moment of **2a** than **1a**–**1c**, which reflects the transition probability from the ground state to the excited states. The higher transition probability to the excited states means the larger emission probability and higher phosphorescent quantum yields [26].

The excited-state decay in these complexes can be attributed to a balance between activated decay via ^{3}MC state and non-radiative decay. Therefore, in this section, to gain insight into the nature of different phosphorescent quantum yields, the orbital diagram of triplet excited states, energy difference between ^{3}MC and ^{3}MLCT states, ground- and excited-states potential energy surface (PES) for **1a** and **2a** are represented in Fig. 4 by elongating and selectively freezing Pt–C bonds. The choice of Pt–C bond is due to the fact that Pt–C distance shows elongation on going from S_0 to T_1 minima. As shown in Fig. 4(a) and (b), along with the Pt–C bond stretching, the e_g^* -like Pt d-orbital is stabilized and rapidly become more accessible for the occupied orbitals, and the energy separation between ^{3}MC and ^{3}MLCT is significantly reduced for both complexes (Fig. 4(c)). The LUMO+2 for **1a** and LUMO+4 for **2a** are the lowest virtual orbitals receiving electron density in ^{3}MC states as Pt–C distance longer than 2.40 Å, and the ^{3}MC–^{3}MLCT energy separation for **1a** is smaller than that in **2a** as shown in Fig. 4(c). It is generally believed that far separation between metal-center ^{3}MC and the responding emissive state of ^{3}MLCT/$^3(\pi \rightarrow \pi^*)$ plays a key role to reduce non-radiative transition. In this case, the smaller ^{3}MC–^{3}MLCT energy separation in **1a** will facilitate non-radiative from ^{3}MC state. The T_1-PES was calculated by using the constrained geometry optimization method at UB3LYP level when the variations in Pt–C bond lengths changed in the range 1.80–2.40 Å. Then SCF energies of T_1 and S_0 states were calculated based on the T_1 optimized geometries. For S_0 and T_1 PES, the vertical axis indicates the SCF energy relative to the optimized ground-state geometry. As shown in Fig. 4(d) and (e), both S_0 and T_1 states become less stable in energy when Pt–C distance becomes shorter and longer. In addition, the T_1-PES for **2a** is slightly deeper than **1a**, which indicates larger energy barrier to its surrounding state. Furthermore, we noted that in **2a**, the T_1–S_0 energy separation increased when Pt–C distance is longer than 2.40 Å, which means that less surface crossing and radiationless transition from ^{3}MC take place in **2a** than in **1a**. These calculated results may also account for the measured slightly higher phosphorescent quantum yields of **2a** than **1a**.

3.5. Electroluminescent (EL) properties

Due to the bright phosphorescent emission of these complexes in CH_2Cl_2 solution and in the solid state, we are very interested in the EL properties of the complexes as light-emitting layer materials in OLED. In this section, ionization potentials (IPs), electron affinities (EAs), reorganization energy (λ), hole and electron extraction potential (HEP and EEP) are calculated, and the results are listed in Table 6. The details for these definitions can be obtained from our previous work [20,24]. For photoluminescent materials, a smaller IP value means easier hole injection ability and a larger EA value will facilitate electron injection.

The IP value for **2a** (6.08 eV) is much smaller than **1a**–**1c** (6.99–7.11 eV), which is consistent with the measured oxidation potentials of 0.94 V for **2a** and 1.10–1.14 V for **1a**–**1c** [5,6]. This also implies that the difficulties of hole injection from hole-transporting layer (HTL) to these complexes gradually decrease in the order **1c** → **1b** → **1a** → **2a**. By analysis of EA values, **1b** and **1c** can more easily accept an electron than **1a** and **2a** due to the slightly increased electron-withdrawing effect of COOH and $PO(OC_2H_5)_2$ substituents.

According to Marcus/Hush model [27], the charge (hole or electron) transfer rate k can be expressed by the following formula:

$$\kappa = \left(\frac{\pi}{\lambda \kappa_b T}\right)^{1/2} \frac{V^2}{\eta} \exp\left(-\frac{\lambda}{4\kappa_b T}\right) = A \exp\left(-\frac{\lambda}{4\kappa_b T}\right) \quad (1)$$

where T is the temperature, κ_b is the Boltzmann constant, λ is the reorganization energy, and V is the coupling matrix element between the ions and molecules which is dictated by the overlap of orbitals. As shown in Eq. (1), two factors, λ and V determine the k. Due to the limited intermolecular charge transfer range in solid-state, the mobility of charges has been demonstrated dominantly related to the internal reorganization energy λ for OLEDs materials [28], and the expression of λ can be obtained from previous reports [20,24]. Emitting layer materials need to achieve hole and electron injection and transport balance, and the lower reorganization energy is necessary for an efficient charge transport process. As shown in Table 6, the reorganization energy for hole (λ_{hole}) of the four complexes are all smaller than that of electron ($\lambda_{electron}$), which indicates the better hole than electron transfer abilities. After careful analysis, we noted that both the hole and electron reorganization energy values, together with the energy difference between $\lambda_{electron}$ and λ_{hole} for **2a** are smaller than **1a**–**1c**. This can be rationalized by the replacement of Cl atom with C≡Cph group, which is co-planer with the molecular framework. The extended planer structure is in favor of electron–hole creation and separation than **1a**–**1c**. In addition, the confinement of recombination zone within the light-emitting layer has been claimed to play a major role in the long-term stability of the phosphorescent device [29]. In a doped system, unequal carrier trappings were expected if the corresponding trap depths are different [30]. The traps characterizing the electron transport in the material are as the states in which the injected electron

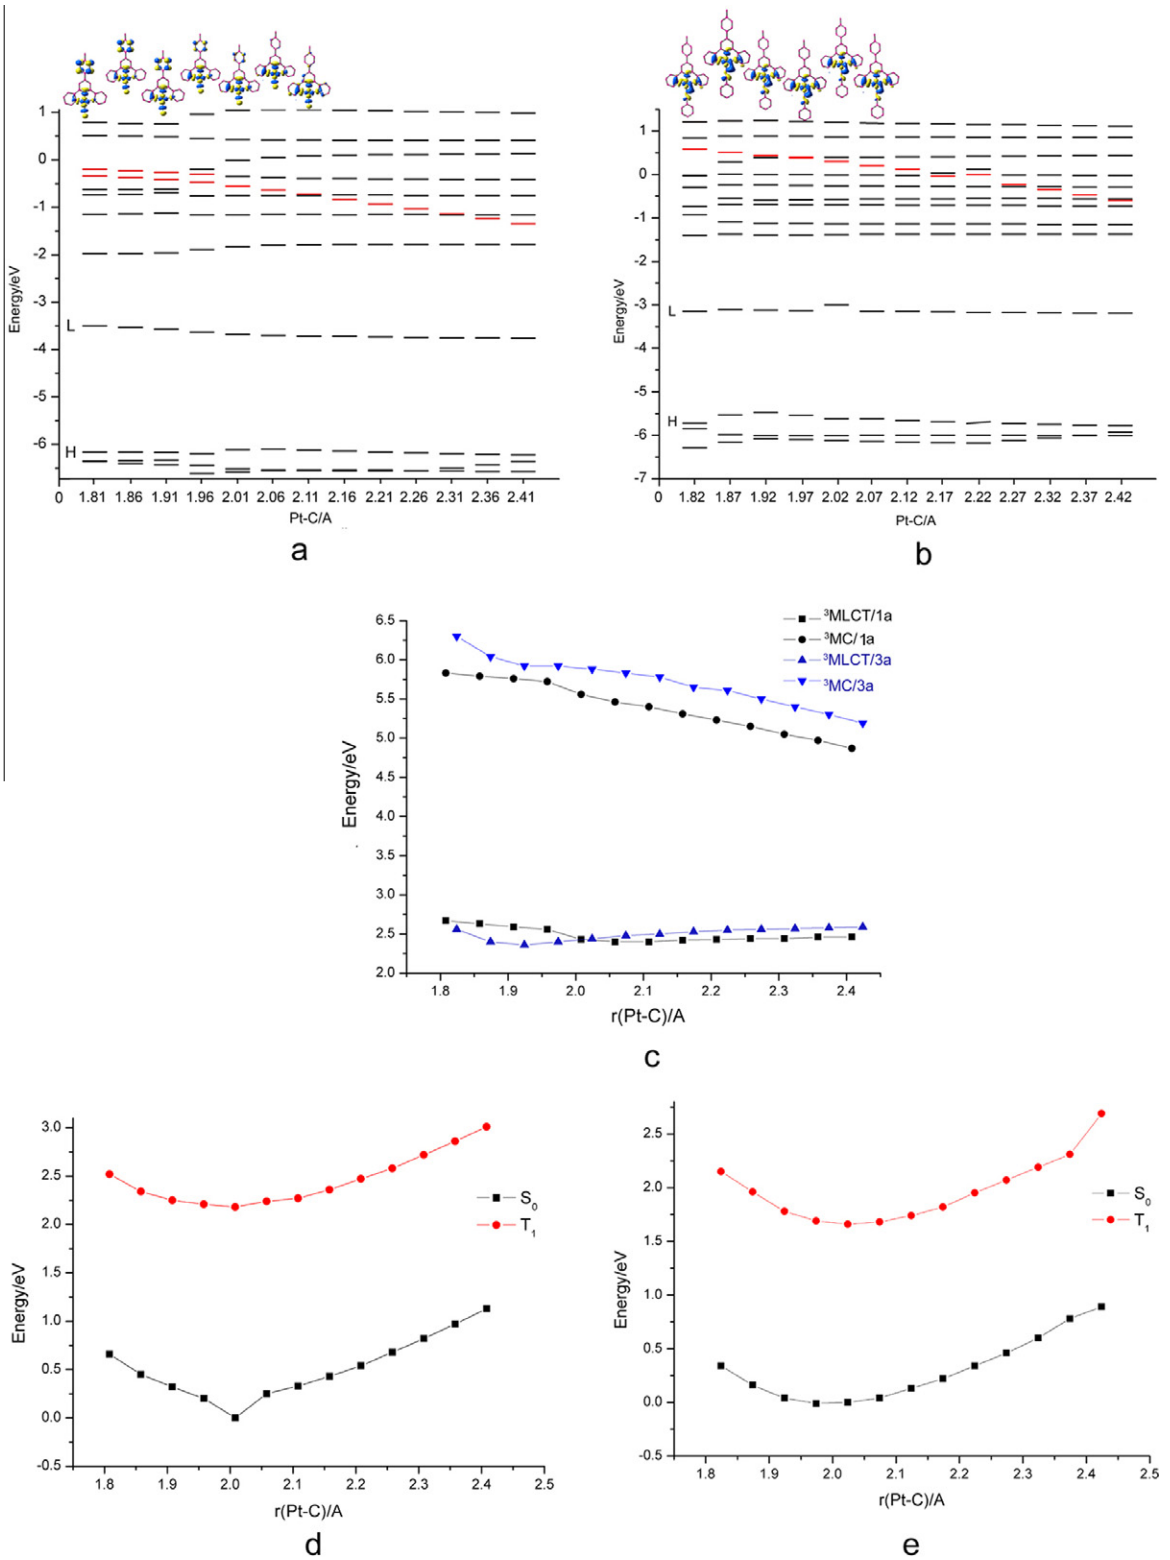

Fig. 4. The partial e_g^*-like orbitals (red lines in a (**1a**) and b (**2a**)), ^{3}MC–^{3}MLCT energy gaps (eV) and potential energy surface (PES) for **1a** (d) and **2a** (e). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 6
Ionization potentials (IP), electron affinities (EA), extraction potentials (HEP and EEP), stabilization energy (SPE) and internal reorganization energies for the investigated complexes (eV).

	IP(v)	IP(a)	HEP	SPE(h)	λ_{hole}
1a	6.99	6.88	6.80	0.11	0.19
1b	7.09	6.98	6.90	0.11	0.19
1c	7.11	6.96	6.87	0.15	0.24
2a	6.08	6.01	5.90	0.07	0.18
	EA(v)	EA(a)	EEP	SPE(e)	$\lambda_{electron}$
1a	1.14	1.29	1.43	0.15	0.29
1b	1.39	1.57	1.72	0.18	0.33
1c	1.33	1.51	1.67	0.18	0.34
2a	1.19	1.29	1.43	0.10	0.24

is self-trapped in an individual molecular accompanied by structure relaxation. However, such a procedure provides an estimate of exciton trap energy rather than that of the injected electrons [31]. In Table 6, **2a** has smaller SPEs for both the hole and electron than **1a**–**1c**. Moreover, the much higher HOMO energy level of **2a** than other three complexes can provide a more stable potential well for hole trapping. The λ and SPE values for **2a** are comparable with recently reported highly efficient phosphorescent and electroluminescent Iridium complexes based on C^N═N ligands [32–34]. Therefore, among the four complexes, **2a** may be ideal candidate as light-emitting material in OLED devices.

4. Conclusions

We investigated the electronic structures, absorption, phosphorescent and electroluminescent mechanism of four Pt(II) complexes 6-phenyl-4-(*p*-R-phenyl)-2′,2-bipyridyl (C^N^N)Pt(II)Cl, (R = Me, (**1a**); COOMe (**1b**), $P(O)(OEt)_2$ (**1c**), and 6-phenyl-4-(*p*-Me-phenyl)-2′,2-bipyridyl (C^N^N)Pt(II) C≡CPh (**2a**). The similar geometrical structures and electronic properties of **1a**–**1c** result from the longer distance between different substituents and central Pt(II) ion, making them insensitive to the variation of substituents. However, for **2a**, the C≡CPh group connects directly to the Pt(II) center and causes significant difference in electronic properties from **1a** to **1c**. The oscillator strength of lowest lying absorptions for **1a**–**1c** are much smaller than **2a**, due to the presence of the extended π-delocalization between C≡CPh and Pt(II) center in **2a**. Highly important, different phosphorescent quantum yields between **1a** and **2a** are investigated. The calculated results reveal that the higher e_g^*-like Pt d-orbital, the larger ^{3}MC–^{3}MLCT energy gap as well as the deeper potential energy surface (PES) for **2a** than that in **1a** are the main reasons resulting in the higher efficiency of **2a**. In addition, the electroluminescent properties of these complexes were reported, and the results indicate that **2a** is more suitable as light-emitting materials in OLED device than **1a**–**1c**.

Distributed feedback organic laser
π-Conjugated polymer-composite
Free-standing membrane

ABSTRACT

A free-standing organic composite membrane distributed feedback (DFB) laser template-patterned by a commercially-available blank digital versatile disk (DVD) is demonstrated. This laser operates at room-temperature and ambient atmosphere and is based on a specifically designed composite incorporating a recently introduced organic semiconductor polymer system, green light-emitting π-conjugated poly[2,5-bis(2′,5′-bis(2″-ethylhexyloxy)phenyl)-*p*-phenylene vinylene] (BBEHP-PPV), as the gain element. This flexible organic membrane laser oscillates around 521 nm above a 1.1 mJ/cm^2 threshold. Optical gain characteristics of the composite material are also reported. The approach represents a step towards viable low-cost, even 'disposable' organic solid-state lasers.

1. Introduction

Since the realization of organic light-emitting diodes (OLEDs) [1,2], great effort has been put into the investigation of light amplification in organic materials for laser applications [3–8]. Attractive features of organic compounds for the fabrication of lasers and other active photonic devices include the potential for low-cost, high-throughput processing and the possibility to obtain 'plastic-like', mechanically flexible structures that have desired amplifying characteristics [9–11]. Such structures could be employed in conformal photonic devices and integrated circuits for a range of potential applications [9–17] in fields as varied as flexible displays, lighting, sensors and bio-sensing/monitoring. If their fabrication can be made cost-effective enough and their lifetime under typical operating conditions extended, they could also form the backbone for a range of 'disposable' visible laser sources [18]. In this study, we report a simple and potentially cost-effective way to produce all-organic flexible composite membrane lasers that operate under photo-pumping in air and at room-temperature. They are made of a specifically designed surface-patterned composite incorporating a recently introduced semiconducting polymer as the gain element.

Conjugated semiconducting polymers have been identified as a promising class of materials for laser applications owing to their high-emission efficiency, large cross sections for stimulated emission and wide spectral coverage [8]. Among these π-conjugated polymers, poly(*p*-phenylene vinylene) (PPV) and its derivatives, including BuEH-PPV, BCHA-PPV, MEH-PPV, M3O-PPV, TOP-PPV and DOO-PPV, have demonstrated high-gain and low laser oscillation threshold [8,19–22]. Recently, the synthesis of poly[2,5-bis(2′,5′-bis(2″-ethylhexyloxy)phenyl)-*p*-phenylene vinylene] (BBEHP-PPV) has been reported for laser chemo-sensing applications [23]. This green-emitting material has potential for a range of applications due in part to its low

doi:10.1016/j.orgel.2010.09.021

stimulated emission threshold and improved photo-stability compared to other organic materials. A further, complementary, way to improve the stability of organic-based amplifying devices, and in turn make them relevant for real-world applications, is to incorporate the active elements into a transparent host matrix [24–28]. In such a configuration, the polymer matrix effectively protects the gain medium from degradation by isolating it from the ambient environment [26–29]. The resulting material benefits from the combination of its constituents and can be tailored to obtain desired optical and mechanical characteristics. Doing so, it is possible to obtain a photo-polymerized sheet that can emit and amplify light. Other functionalities – such as thermal and/or photo-initiated crosslinking – can also be added to the composite to further extend its processability.

In this paper we use this approach to demonstrate laser action in a surface-structured free-standing composite membrane based on BBEHP-PPV. A light-emitting free-standing membrane is obtained by depositing a layer of composite solution on a substrate, photo-curing and subsequent peeling-off of the solidified composite. Because the refractive index of the composite is higher than air, emitted light is effectively confined within the membrane, which acts as a waveguide. By exciting the active element of the composite – BBEHP-PPV – the generated light can then, in principle, be amplified. In order to trigger laser oscillation a feedback mechanism to re-circulate the amplified light needs to be added. For this membrane geometry, a distributed feedback (DFB) grating is ideally suited. In our case, the DFB is inherently integrated to the membrane at the fabrication stage. To this end, an exposed standard commercial blank digital versatile disk (DVD) is used as the substrate/template, in effect transferring its sub-micron scale grating structure onto one of the membrane surfaces. Blank DVDs consist of repeating tracks – in fact a very long spiral on the disc – with a pitch, Λ, of 740 nm. As we will see in Section 3, this pitch can correspond to a higher Bragg reflection order for green wavelengths and therefore enables resonant feedback in our composite. Compared with custom-made DFB grating structures, the use of mass-produced blank DVDs has the advantage of simplicity and low-cost [8,30]. By casting the film on a mass-produced substrate we show the potential for simple low-cost fabrication.

In Section 2, the optical characterization of neat BBEHP-PPV and of the composite, including optical gain, is reported. The fabrication and demonstration of the free-standing membrane laser based on this specifically-tailored material are then detailed in Section 3.

2. Gain measurements

2.1. Optical gain in pure BBEHP-PPV neat film

In this work, BBEHP-PPV was first synthesized following the method described in [23]. Results of the optical characterization of a 250-nm thin film of pure BBEHP-PPV, including absorption, photoluminescence (PL) and amplified spontaneous emission (ASE) are summarized here. For more details the reader is referred to the Section 5. Two obvious vibrational modes can be identified [23] in the PL spectrum (Fig. 1) at around 496 nm (0–0 transition) and 528 nm (0–1 transition), respectively. The solid-state PL quantum yield (PLQY) of the neat film is 86%. For ASE measurements, the film was excited by a 4-ns-pulsed pump beam shaped as a stripe and the full-width at half-maximum (FWHM) of the emission spectrum and the relative output power as a function of the pump intensity were both monitored from the edge of the sample (Fig. 2). It is seen that the FWHM of the edge-emitted PL narrows from 20 nm to 6 nm when pumping above a pump energy density of 1.1 $\mu J/cm^2$. Optical loss measurements suggest a very low loss coefficient of 0.83 cm^{-1} in the neat film (Fig. 3 and Table 1). The net gain coefficient at 535 nm was found to be $g = 19\ cm^{-1}$ for a pump energy density of 12 $\mu J/cm^2$ (Fig. 4 and Table 2). At higher pump energy densities the gain coefficient no longer increases because of gain saturation in the polymer film.

2.2. Optical gain in BBEHP-PPV/CHDV composite

For the composite, as-synthesized BBEHP-PPV material was incorporated into a UV transparent polymerisable host

matrix, 1,4-cyclohexanedimethanol divinyl ether (CHDV) (Sigma–Aldrich, Inc.). A UV initiator (the 'photo-acid generator' or PAG) for cationic polymerization, *para*-octyloxy-functionalized diphenyliodonium hexafluoroantimonate (Gelest, Inc.), was added to trigger the photo-crosslinkable behavior via the vinyl ether moieties [31]. This crosslinking process is achieved when the vinyl ether moieties polymerize, and a carbon-based backbone with associated vinyl ether groups is produced [29,31]. In the experiment, BBEHP-PPV was incorporated at a 10 mg/ml concentration into CHDV monomer solution, with 0.2 wt.% of PAG to trigger the polymerization process. The uncured composite solution was drop-cast onto a smooth planar substrate and cured under UV light forming a 25-μm solid film for gain measurements.

Optical characterization, including absorption, PL and ASE measurements (threshold, gain and loss), was conducted on such a plane composite film. Both absorption and PL features (Fig. 5) are slightly blue-shifted (6 nm for absorption and 8 nm for PL on average) compared to the results from the pure BBEHP-PPV neat film (Fig. 1). This small shift is similar to other cases of doping organic light-emitting materials into a CHDV matrix [26,27,29,31]. The PLQY of the composite material is measured to be 61%, which is lower than in the case of neat BBEHP-PPV. This indicates that some quenching of the radiative transition occurs when BBEHP-PPV is incorporated into CHDV and that some of this effect comes from added non-radiative recombination. Nevertheless, ASE measurements on such a film demonstrate that stimulated emission can be achieved, with a 4 mJ/cm^2 threshold and ~9-cm^{-1} propagation loss coefficient (Figs. 6 and 7 and Table 3). Because the thick membrane supports many transverse optical modes, it is difficult to directly compare results with those of the thin film characterization. However, net gain at saturation is found to be ~19 cm^{-1} at 33 mJ/cm^2 excitation density (Fig. 8 and Table 4) similar to a neat film of BBEHP-PPV (Fig. 4 and Table 2). Measurements were also done on membranes with higher BBEHP-PPV concentrations (20 and 40 mg/ml). Gains at saturation were found to be lower at 13 cm^{-1} (20 mg/ml) and 11 cm^{-1} (40 mg/ml), respectively. For photostability characterization, we photo-pumped a 50-μm thick BBEHP-PPV/CHDV (10 mg/ml) film sample in ambient atmosphere for about an hour while monitoring the PL peak intensity from the sample edge. The result shows no obvious degradation for about an hour (~3.5×10^4 pump pulses) at the pump fluence of about 1.0 mJ/cm^2.

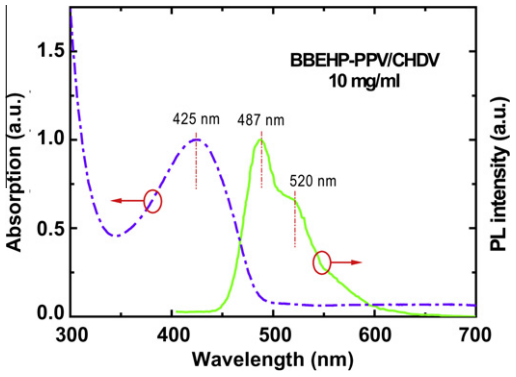

Fig. 5. Absorption and PL spectrum of BBEHP-PPV/CHDV film on a plane glass substrate. The absorption measurement was conducted by Cary 50 UV–Vis spectrophotometer. The PL measurement was conducted under the photo-pumping with a GaN-based cw laser (374 nm).

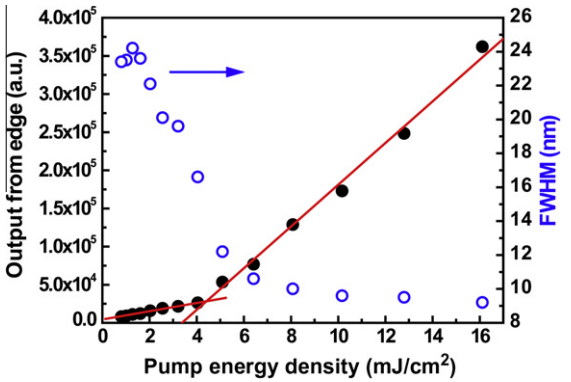

Fig. 6. Output intensity and full width at half maximum (FWHM) versus the pump energy density for a (10 mg/ml) BBEHP-PPV/CHDV membrane. The ASE threshold of BBEHP-PPV/CHDV membrane is found to be 4.6 mJ/cm^2 in this sample.

3. Laser action in BBEHP-PPV/CHDV composite

The uncured composite solution was drop-cast onto a blank DVD with exposed track under UV light. The solidified composite was then gently peeled-off from the DVD substrate resulting in a free-standing membrane with the DVD nanopatterns replicated onto one of its surfaces. The sample preparation process and morphology can be seen in Fig. 9, of which details can be found in the Section 5.

A crude but straightforward way to check the uniformity of the replicated grating structure on a surface-patterned membrane is to look at the as-prepared sample from different angles to see whether there exists any effect of diffraction caused by the grating. Here, we simply used a

camera to take photographs of the DVD-patterned membrane under white-light illumination. Photographs taken at several different angles are shown in Fig. 9c. Changes in the recorded colours indicate that regular structure is indeed present on the membrane surface. In order to examine details at the micron-scale, we used scanning electronic microscopy (SEM) to study a piece of the membrane and also scanned a sample of blank DVD for comparison. The SEM images in Fig. 9d clearly show that the two patterns are complementary, confirming the accurate replication of the grating structure from the blank DVD substrate (Fig. 9d1) to the as-prepared membrane laser (Fig. 9d2). Atomic force microscopy (AFM) was also applied to analyze the membrane surface profile (Fig. 9e), suggesting that the modulation depth of the DFB-textured surface is about 130 nm (Fig. 9e2 and e3), which is suitable to provide sufficient feedback for laser action in a DFB laser structure [32,33]. The thickness of the polymer membrane was estimated from the optical image of the membrane's cross-section profile to be about 50 μm.

In our experimental demonstration, we photo-pumped the membrane laser on its textured side with a stripe at 355 nm (pulse width: 5 ns, repetition rate of 10 Hz and averaged spot size on the membrane: ~0.1 × 2.9 mm^2) incident at about 45° and measured the edge and vertical emission simultaneously (Fig. 10). The results show that, when pumping above a certain energy, a laser peak emerges at 521.3 nm in the edge direction while only normal PL is recorded in the vertical direction (Fig. 10b) at the same time. The edge laser emission was projected onto a paper screen placed about 5 cm away, showing a bright green spot (~5 mm in size) in Fig. 10c. Above the threshold, the laser peak linewidth reaches the resolution limit

of our spectrometer (~0.2 nm). One can also see corrugation in the spectrum with a ~1.9-nm separation (close to the dominant peak) formed by non-lasing transverse modes. The size and shape of the pump stripe on the membrane limits to a certain extent the number of lateral modes but there are still several transverse modes that can potentially oscillate. Given the thickness (~50 μm) of the membrane, one would expect the spectral separation between consecutive transverse modes to be around 1.9 nm, which correspond to the observations. The evolution of the laser emission behavior under different pumping energy was investigated (Fig. 11a). Results show a laser threshold at around 1.1 mJ/cm^2. It can also be seen in the inset of Fig. 11a that there is a 1.5-nm blue-shift of the spectral peak (i.e. the gain maximum) between low pumping levels and threshold.

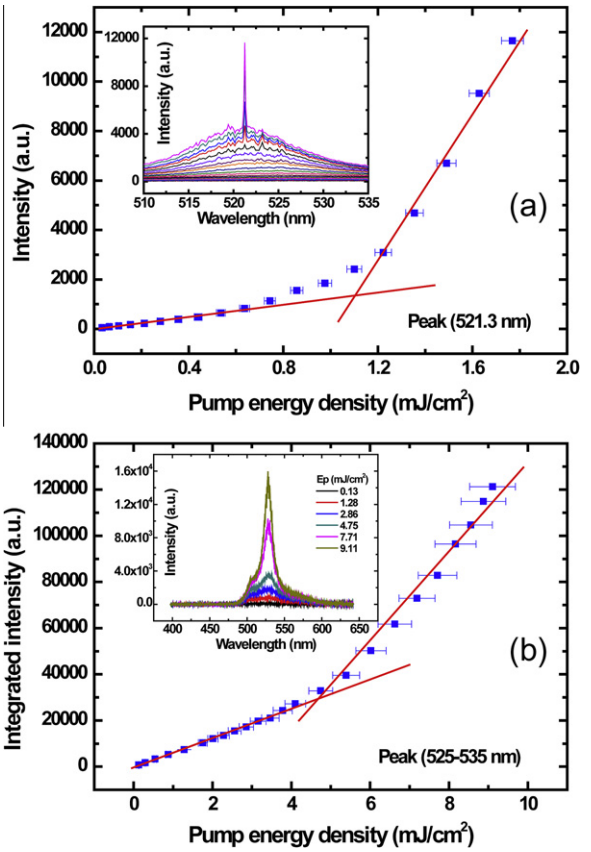

Fig. 11. (a) Laser threshold curve derived from (inset) the evolution of the sample (membrane with grating pattern) edge emission spectra under various pump energy densities. (b) ASE threshold curve and (inset) typical spectra evolution of the plane membrane (no grating pattern) at various pump energy densities.

A similar membrane but prepared on a flat substrate, i.e. with no embedded grating on its surface, was pumped under the same conditions. In that case, no laser oscillation signature was observed but only ASE (Fig. 11b) with a 4.6 mJ/cm^2 threshold. These measurements indicate that the emergence of the laser mode is enabled, or at least facilitated, by the surface grating. In a DFB grating, the in-line resonant feedback is realized when propagating waves fulfill the Bragg condition [8]:

$$m\lambda_{Bragg} = 2n_{eff}\Lambda \quad (1)$$

where n_{eff} is the effective refractive index of the mode in the gain medium, Λ is the period of the grating structure as seen by the propagating mode, and m is the diffraction order. For our composite membrane, at this wavelength, the refractive indices of BBEHP-PPV and CHDV are approximately $n_{\text{BBEHP-PPV}} \approx 1.7$ [23] and $n_{\text{CHDV}} = 1.472$ (Sigma–Aldrich, Inc.), respectively. Given the low concentration of BBEHP-PPV (10 mg/ml in CHDV) in the composite

and the rather thick membrane, the effective refractive index can be taken to be close to the matrix index for lower order transverse modes. Because the period of the grating is 740 nm, it is probably the 4th order diffraction that provides the resonant feedback. For $m = 4$ and a wavelength of 521.3 nm, corresponding to the observed laser emission, one obtains $n_{eff} \sim 1.41$. This is slightly below the composite index and indicates that higher order transverse modes are probably favoured due to a higher modal overlap with the grating.

4. Conclusion

In summary, we have demonstrated a green-emitting free-standing membrane DFB laser that uses a novel guest–host organic composite with π-conjugated BBEHP-PPV as the chromophore. The composite approach protects the light-emitting elements to a certain extent and benefits from improved processability. The composite membrane itself acts as an amplifying waveguide for the light it generates under optical excitation and the feedback is obtained by a grating embedded onto its surface. This surface-grating is directly formed at the fabrication stage and in this case was obtained by template-patterning the membrane with a commercially-available blank DVD. The resulting membrane laser operates at room-temperature and ambient atmosphere. Such a technique is easy to implement, and promising for the fabrication of low-cost and even 'disposable', green-emitting organic lasers.

5. Experimental methods

5.1. ASE measurements

BBEHP-PPV was synthesized according to the literature [23]. For the pure material (BBEHP-PPV), neat films of 250-nm thickness were made by spin-coating from 25 mg/ml Chlorobenzene solutions at 2800 rpm for 60 s on quartz substrates for absorption, photoluminescence and ASE characterization. For the BBEHP-PPV/CHDV composite, membrane samples on plane glass substrates were prepared with concentration of 10, 20 and 40 mg/ml for optical gain and loss measurements. In the ASE measurements, the film or membrane samples were located in a vacuum chamber with a pressure of approximately 10^{-5} mbar. The excitation light was generated by a Nd:YAG laser pumped optical parametric oscillator (OPO) with 4-ns output pulses at a repetition rate of 20 Hz. The pump wavelength was selected to be 425 nm which is close to the absorption maximum (431 nm, see Fig. 1) of BBEHP-PPV. Calibrated neutral density filters were inserted in the beam path to adjust the pump intensity incident on the samples. A cylindrical lens was used to shape the excitation beam into a narrow stripe with a width of approximately 0.046 cm and a length of 0.35 cm. The edge emission from the film was collected and recorded with a fibre-coupled grating spectrograph and a charge coupled device (CCD) detector.

To measure the waveguide loss coefficient, α, the pumped stripe on the film was moved away up to 0.8 cm from the edge of the sample without changing its length. The pump stripe was fixed in the loss measurements to be 0.47 cm $\times$ 0.046 cm. The emission from the edge should then be given by [8]:

$$I = I_{pump} e^{(-\alpha x)} \tag{2}$$

where x is the distance between the end of the pump stripe and the sample edge.

For gain measurements, the output intensities were recorded as a function of excitation length for a range of pump intensities. The pump stripe was able to vary in the range of 0.01 cm to 0.25 cm controlled by an adjustable aperture. In theory, when ASE occurs the output intensity from one end of the pump stripe is given by [8]:

$$I(\lambda) = \frac{A I_{pump}}{g(\lambda)} (e^{g(\lambda) l} - 1) \tag{3}$$

where l is the length of the pump stripe.

5.2. Membrane laser preparation

BBEHP-PPV was incorporated into the CHDV monomer to form a composite solution (BBEHP-PPV concentration of 10 mg/ml). A 0.2 wt.% of PAG, to act as a UV initiator for later polymerization, was also added to the solution [26,27,29]. To ensure the BBEHP-PPV is properly dissolved, the overall mix was stirred in an ultrasonic bath for 30 min. A layer of this BBEHP-PPV composite was then drop-coated onto a piece of standard blank DVD substrate ($\sim$3 cm $\times$ 3 cm). Prior to this over-coating, the DVD substrate was left in an ultrasonic bath of methanol for 30 s in order to remove the protective coating and expose the grating tracks. The composite spread to form a uniform layer due to its low viscosity. The next step was to use a UV lamp ($\sim$370 nm and power density: $\sim$200 mW/cm^2) to cure (30 s) the BBEHP-PPV/CHDV composite layer [27]. Finally, the cured composite layer (thickness: $\sim$50 μm) was peeled off from the DVD substrate. The resulting free-standing membrane was mechanically flexible and one of its surfaces was embossed with the negative of the DVD surface tracks. As a control experiment, a set of BBEHP-PPV/CHDV membrane samples on plane glass substrates were prepared with concentration of 10, 20 and 40 mg/ml. The optical characterizations of ASE threshold, gain and loss measurements on these samples were conducted in the ASE setup described above. PLQY measurements were made on a 10 mg/ml membrane (25 ± 5 μm thick) using an integrating sphere, following the method of Greenham et al. [34], with excitation at 442 nm from a He-Cd laser for excitation. The thicknesses of the membranes were measured using a DekTak 150 Surface Profiler.

5.3. Laser demonstration

The static PL measurement on the BBEHP-PPV/CHDV film was conducted under photo-pumping by a GaN-based cw laser (peak: λ_m = 374 nm, power: 15 mW and spot size: $\sim$3 mm in radius). For laser action, photo-pumping of the composite membrane was done in air with a frequency-tripled Q-switched Nd:YAG laser system yielding 5-ns pump

pulses at a repetition rate of 10 Hz and an excitation wavelength of 355 nm. The membrane was pumped at an angle of about 45°. A cylindrical lens was used to shape the pump beam as a stripe resulting in a 0.1×2.9 mm^2 pump area on the membrane surface. Both edge and vertical emission of the sample were collected by a lens-optical fibre combination, which was fed into a spectrometer (Avantes) for analysis.

ABSTRACT

A silane-containing triazine derivative (NSN) with ultrawide bandgap and excellent thermal stability was used as electron acceptor for organic ultraviolet photodetectors. Poly (9,9-dihexylfluorene-2,7-diyl) (PFH), 4,4′,4″-tris(3-methylphenylphenylamino)-triphenylamine (*m*-MTDATA), 2,7-bis(3′,5′-diphenylphenyl)-9,9-diphenylfluorene (PFP) and poly(*N*-vinylcarbazole) (PVK) were applied as electron donors and respectively combined with NSN to construct planar heterojunction devices: indium tin oxide (ITO)/poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS)/donor/NSN/LiF/Al. Under illumination through the ITO electrode, though all the devices exhibit near-ultraviolet (NUV) response, the cutoff wavelength can be well tuned by selecting donors with different bandgaps. If a semitransparent Al cathode is applied for the incidence of light, the response region can be further extended to deep-ultraviolet (DUV) region. Particularly for PFP/NSN and PVK/NSN based devices, quasi-solar-blind response can be realized by combining home-made NUV-blocking organic filters. As a result, the devices are capable of NUV and DUV-selective response for radiation, respectively from ITO and Al sides. The study shown here may provide a useful guideline to achieve low-cost organic detectors with spectral selective response.

1. Introduction

During the past two decades, organic semiconductors have attracted much attention and found lots of applications in optoelectronic devices such as solar cells, light-emitting diodes, transistors and so on [1–5]. They are also proved to be candidates for ultraviolet (UV) photodetection [6–20]. For example, Li et al. reported efficient organic UV photodetectors using 4,4′,4″-tris(3-methylphenylphenylamino)-triphenylamine (*m*-MTDATA, as donor) and 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)-benzene (as acceptor) and Lin et al. succeeded in applying wide-bandgap triaryldiamine and oxadiazole-containing oligoaryls for UV detection [10,19]. Conjugated polymers like poly(3,6-(*N*-(2-ethylhexyl))carbazole) were also employed as the active materials by Cao et al. [21].

For UV detection, materials with wide-bandgap are generally preferable to ensure the device visible-blind [22]. Since deep-ultraviolet (DUV, with wavelength shorter than 300 nm) can be hardly found in the solar radiation that comes into the aerosphere, device with DUV-selective response is especially attractive. With those devices, detection of weak UV emitters in full sunlight can be realized, which has lots of applications [23]. Nevertheless, almost all the organic UV detectors reported show the response cutoff wavelength round or beyond 400 nm. Though Li et al. succeeded in shifting the response peak to 280 nm by filtering part of near-ultraviolet (NUV) in the incident light, the cutoff wavelength round 400 nm is unchanged [16]. So much work is still needed to tune the spectral response of organic UV detectors.

In this article, we synthesized a silane-containing triazine derivative (NSN) with strong DUV absorption and employed it as electron accepter for organic ultraviolet photodetectors. Poly (9,9-dihexylfluorene-2,2-diyl) (PFH), *m*-MTDATA, 2,7-bis(3′,5′-diphenylphenyl)-9,9-diphenylfluorene (PFP) and poly(*N*-vinylcarbazole) (PVK) were applied as electron donors to combine with NSN to construct planar heterojunction devices: indium tin oxide (ITO)/poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS)/donor/NSN/LiF/Al. Due to the different bandgaps of the donors, NUV response with varied cutoff wavelengths was achieved for ITO side illumination and the response region was further extended to DUV region by employing the semitransparent counter electrode for the light incidence. Moreover, in PFP/NSN and PVK/NSN based devices, by combining home-made organic filters, quasi-solar-blind response was also realized.

2. Experimental

2.1. Materials

2-Chloro-4,6-diphenyl-1,3,5-triazine (**1**) [24], diphenyl-[4,4′-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolane-2-yl)diphenyl]silane (**2**) [25], (3,5-diphenylphenyl)boronic acid (**3**) [26], 2,7-dibromo-9,9-diphenylfluorene (**4**) [27], 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene perchlorate (FM1) and chlorinated derivative of FM1 (FM2) [23,28] were synthesized according to the literatures. All other chemicals were purchased from commercial suppliers and used as received. The synthesis routes to bis(4-(4,6-diphenyl-1,3,5-triazine-2-yl)phenyl)diphenylsilane (NSN) and 2,7-bis(3,5-diphenylphenyl)-9,9-diphenylfluorene (PFP) are shown in Scheme 1. The organic UV filters for DUV detection were prepared as follows: first FM1, FM2 or their blend was dissolved in water solution of polyvinyl alcohol (PVA), then the solution was poured into a mould and evaporated slowly at room temperature [23]. After drying, a transparent film with thickness of round 0.1 mm was obtained, which can be placed in front of the devices to filter the NUV in the incident light.

2.2. Synthesis of NSN

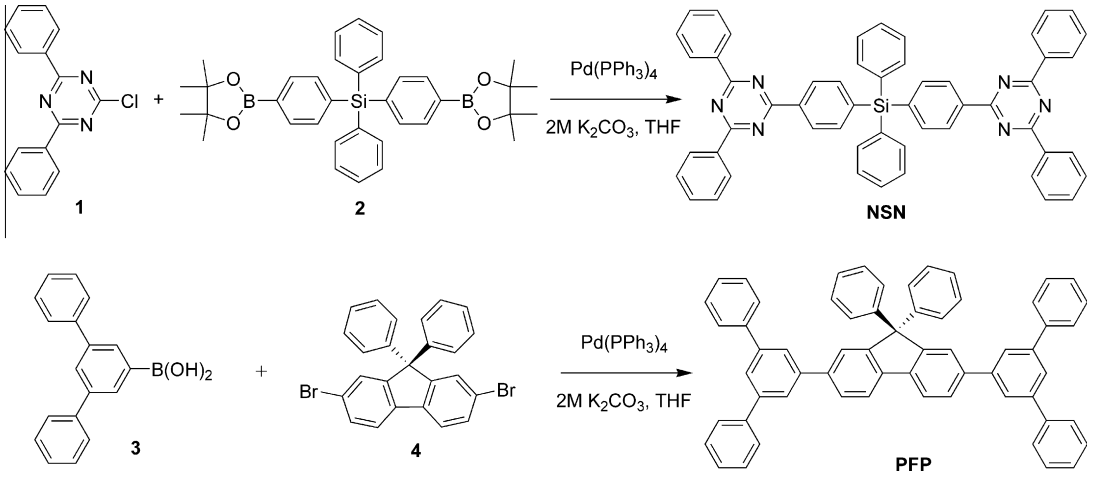
A mixture of **1** (0.59 g, 2.2 mmol), **2** (0.59 g, 1 mmol), 15 mg $Pd(PPh_3)_4$, 25 mL tetrahydrofuran (THF) and 5 mL 2 M K_2CO_3 aqueous solution was stirred at 65 °C for 24 h under nitrogen atmosphere. The resulting mixture was cooled to room temperature and then poured into water. The organic layer was extracted with ethyl acetate and dried over $MgSO_4$. The crude product was purified by chromatography using petroleum ether and dichloromethane (4:1, v/v) as eluent. Yield: 0.54 g (68%). FT-IR (in KBr) υ cm^{-1}: 3066, 3028 (CH_{ar}), 1587, 1562, 1520, 1446, 1428 ($C{=}C_{ar}$). ^1H NMR (300 MHz, $CDCl_3$, δ ppm): 8.79 (m, 12H), 7.86 (d, 4H), 7.68 (d, 4H), 7.55–7.64 (m, 12H), 7.41–7.52 (m, 6H). Anal. Calcd. for $C_{54}H_{38}N_6Si$: C, 81.17; H, 4.79; N 10.52. Found: C, 81.43; H, 4.91; N 10.02.

2.3. Synthesis of PFP

A mixture of **3** (0.48 g, 1.76 mmol), **4** (0.38 g, 0.8 mmol), 30 mg $Pd(PPh_3)_4$, 30 mL THF and 5 mL 2 M K_2CO_3 aqueous solution was stirred at 65 °C for 24 h under nitrogen atmosphere. The resulting mixture was cooled to room temperature and then poured into water. The organic layer was extracted with ethyl acetate and dried over $MgSO_4$. The crude product was purified by chromatography using petroleum ether and dichloromethane (5:1, v/v) as eluent. Yield: 0.4 g (65%). FT-IR (in KBr) υ cm^{-1}: 3056, 3030 (CH_{ar}), 1593, 1575, 1476, 1454 ($C{=}C_{ar}$). ^1H NMR (300 MHz, $CDCl_3$, δ ppm): 7.92 (d, 2H), 7.71–7.79 (m, 10H), 7. 69 (d, 8H), 7. 49 (t, 8H), 7.30–7.44 (m, 8H), 7.18–7.30 (m, 6H). Anal. Calcd. for $C_{61}H_{42}$: C, 94.54; H, 5.46. Found: C, 93.64; H, 5.43.

2.4. Characterization

^1H NMR spectra were recorded on a 300 MHz Varian spectrometer in $CDCl_3$. FT-IR spectra were recorded using a Brucker VII FT-IR spectrometer. Element analysis results were obtained on ThermoFinnigan Flash EA1112. UV–vis absorption spectra were taken on a Cary Bio 100 spectro-



Scheme 1. Synthetic routes for NSN and PFP.

photometer. The thermogravimetric analysis (TGA) was performed under a nitrogen atmosphere on a PE Pyris 1 TGA at heating rates of 20 °C min^{-1}. Cyclic voltammetry (CV) measurements were conducted in a 0.1 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) acetonitrile solution at room temperature using a CHI 660C electrochemical workstation at a scan rate of 50 mV s^{-1}. A saturated calomel electrode (SCE), a platinum wire and a platinum disk were used as the reference electrode, counter electrode and working electrode, respectively.

2.5. Device fabrication and performance characterization

For the device fabrication, glass plates covered with patterned ITO were used as substrates. They were first ultrasonically cleaned in detergent and a series of organic solvents (isopropanol, ethanol and acetone) and then precoated with a buffer layer (40 nm) of PEDOT:PSS. Then, organic layers were deposited. For small molecules (*m*-MTDATA, PFP, NSN), thermal evaporation in vacuum chamber at 5×10^{-4} Pa was used, while for polymers (PFH, PVK), spin-coating was applied. The thickness of every organic layer is 30 nm. Finally, LiF (0.5 nm) and aluminum (12 nm) film was evaporated through a mask onto the active layers under high vacuum (about 10^{-4} Pa) as the top electrode.

The photoresponse studies were made with a Keithley 236 Source-Measure Unit under the excitation of a high pressure mercury lamp (CHG-200) filtered by 365 or 340 nm bandpass filters. For spectral response measurement, a 500 W Xenon lamp and a grating monochromator were used. The beam was chopped at 23 Hz and the photocurrent was measured using Stanford Research Systems (USA) SR830 DSP lock-in amplifier. The radiant power was calibrated with a standard silicon photodetector for the calculation of responsivity. Both the spin-coating of the films and photoresponse measurement of the devices were conducted at room temperature in ambient conditions.

3. Results and discussion

3.1. Synthesis and characterization of electron acceptor

NSN was synthesized by palladium-catalyzed Suzuki coupling of **1** and **2**. The structure was confirmed by ^1H NMR spectroscopy and elemental analysis. Though there are two triphenyltriazine (TTA) units in the molecule, they are not conjugated due to the interruption of silicon atom. Thus, the effective conjugation scale for NSN is close to that of TTA, while the thermal stability of NSN shall be much improved due to its larger molecular size and the silane moiety included [29]. According to TGA analysis, the 5% weight loss temperature is as high as 490 °C. Fig. 1 shows the absorption spectra of NSN. In THF, NSN exhibits strong absorption in the region below 300 nm with a peak at 276 nm, indicating that this material may be good for DUV detection. For NSN film, the peak of absorption redshifts to 282 nm and the onset is round 323 nm, from which a bandgap of 3.84 eV can be obtained. Such wide bandgap may facilitate the response cutoff wavelength control in device fabrication. Due to the presence of electron-withdrawing triazine moieties, NSN is expected to work as an electron acceptor and its lowest unoccupied molecular orbital (LUMO) level is round 3.0 eV according to the CV measurement.

3.2. Structure and absorption of electron donors

In order to construct heterojunction, four materials were selected as electron donors to combine with NSN. The chemical structures of the donors are shown in Scheme 2a. Among them, PFP is newly synthesized by Suzuki coupling of **3** and **4** (Scheme 1), while the other three materials are commercial hole-transporting materials. Fig. 2 shows the absorption spectra of corresponding films of the donors. Due to the difference in conjugation scale, the absorption onset for PFH, *m*-MTDATA, PFP and PVK decreases in sequence with a value of 420, 400, 370 and 360 nm, respectively. On the above films, NSN was then further deposited and the absorption spectra of the obtained bilayer films were also measured. As shown in Fig. 3, the absorption is simply the summation of that of the two single layers without additional absorption peaks. Besides, the absorption onsets of all bilayer films keep the same as that of the corresponding donor due to the much wider bandgap of NSN than the donors. Thus, by applying those molecules as donors to construct heterojunction with NSN, we may realize UV photoresponse with different cutoff wavelengths.

3.3. J–V curves and spectral response

By employing the above-mentioned bilayer films as active layers, UV photodetectors with planar heterojunction structure were fabricated. The device structure and the energy level diagram of the materials are shown in Scheme 2. Energy levels for PFH, *m*-MTDATA and PFH are quoted from the literatures [19,30,31], while those for PFP and NSN are obtained by CV measurement. Charge transfer between the

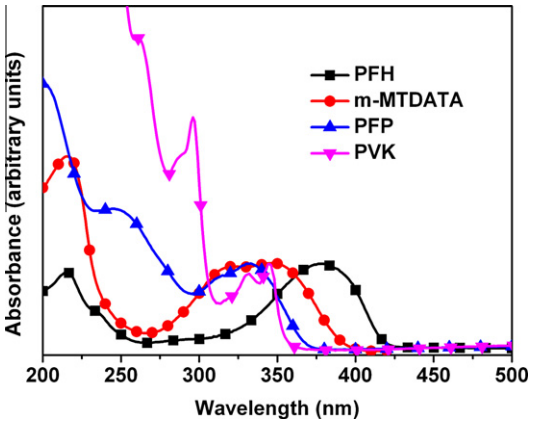

Fig. 2. Absorption spectra of the films of PFH, *m*-MTDATA, PFP and PVK.

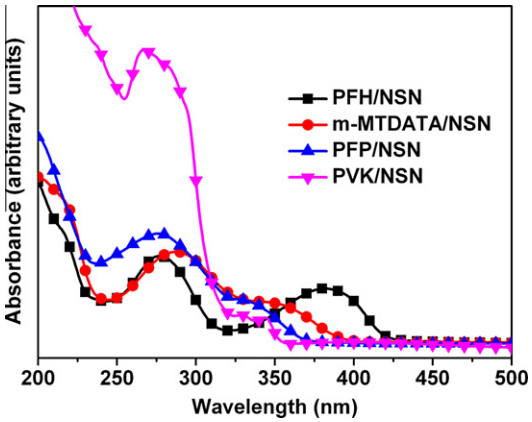

Fig. 3. Absorption spectra of the bilayer films of PFH/NSN, *m*-MTDATA/NSN, PFP/NSN and PVK/NSN.

donors and NSN can be expected from the relative energy level alignment. Fig. 4 shows the *J*–*V* curves for ITO/PEDOT:PSS/PFH/NSN/LiF/Al. Under illumination of 1 mW/cm^2 UV light at 365 nm through ITO-coated substrate, the device presents a high open-circuit voltage of round 2 V, which shall be attributed to the large gap between the highest occupied molecular orbital (HOMO) level of PFH (5.6 eV) and LUMO level of NSN (3.0 eV). However, the short-circuit current is relative small. This is reasonable if we consider the charge transporting ability of NSN. Since the conjugation scale of NSN is small, and the film is amorphous due to the nonplanar molecule structure, the electron mobility of NSN shall be low. As a result, under

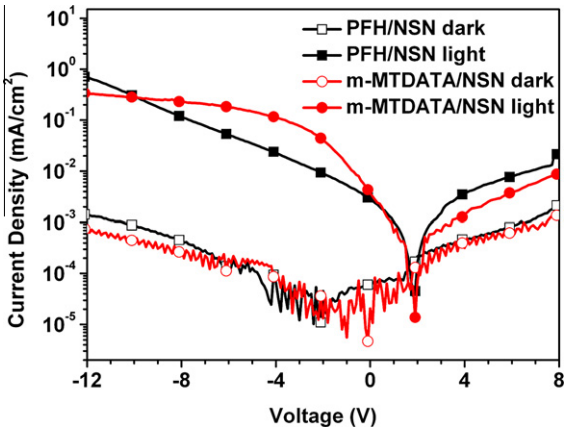

Fig. 4. Semi-log plot of *J–V* curves in the dark and under illumination of 1 mW/cm^2 UV light at 365 nm through ITO electrode for ITO/PEDOT:PSS/PFH/NSN/LiF/Al and ITO/PEDOT:PSS/*m*-MTDATA/NSN/LiF/Al.

build-in electric field, the separated charge carriers from the interface may be unable to be efficiently transported out before recombination. This problem can be solved by applying a reverse bias to facilitate the charge transportation. As shown in Fig. 4, the current density increases quickly with the increase of reverse bias. At −12 V, the photocurrent reaches 0.697 mA/cm^2, while the dark current is 1.4 μA/cm^2. Accordingly, the responsivity and the photo-to-dark current ratio under this bias are 0.696 A/W and 498, respectively. It is found that the quantum yield is over unity, the origin of which is still debatable [15,32–36]. Fig. 4 also shows the results for *m*-MTDATA/NSN based device. *m*-MTDATA is a well-known hole-transporting material widely used in organic light-emitting diode (OLED) and also in ultraviolet photodetectors [19]. Though its conjugation scale is a little lower than that of PFH, the photovoltaic performance is comparable and the responsivity at low reverse bias is even better (Fig. 4). At high reverse bias, the photocurrent tends to saturate and reaches 0.334 mA/cm^2 at −12 V.

The *J–V* curves for devices with PFP/NSN and PVK/NSN heterojunctions were also investigated. Due to the larger energy gaps, the absorption of PFP and PVK at 365 nm is small, so UV light at 340 nm was employed for the photoresponse study. As shown in Fig. 5a, under illumination of 0.5 mW/cm^2 UV light at 340 nm, the photocurrent at −12 V for the PFP/NSN heterojunction is 0.124 mA/cm^2 and the photo-to-current ratio is round two orders of magnitude. After correcting the photocurrent with the dark current, a responsivity of 0.245 A/W can be obtained. As for the PVK/NSN heterojunction, though the photocurrent is a little higher, the dark current is also large, especially at high reverse bias, leading to a poor photo-to-current ratio. For this device, operating at lower bias may be more preferable, though the responsivity will be lower.

According to the above results, the four devices exhibit different *J–V* characters, which may be related to different charge transporting properties of the donors. Nevertheless, the response is all quick. Take PFP/NSN based device for example, as shown in Fig. 5b, the current increases quickly

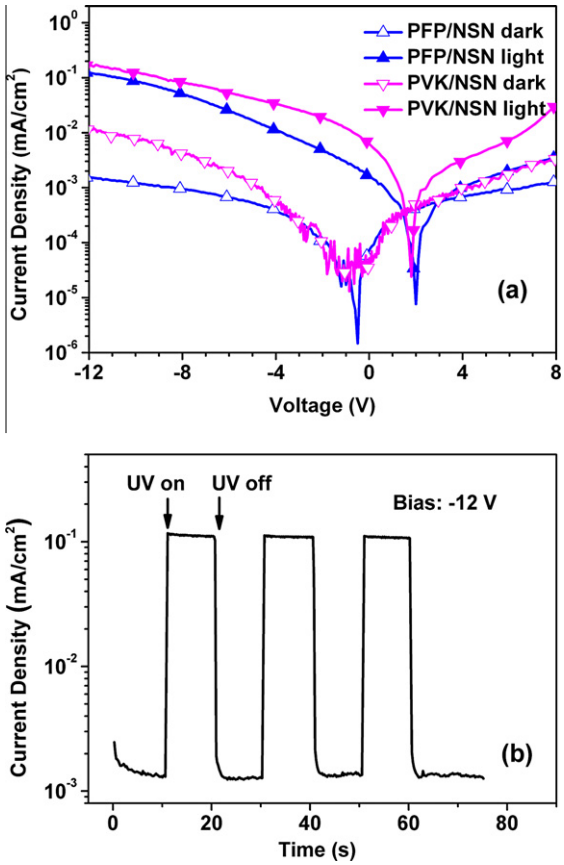

Fig. 5. (a) Semi-log plot of *J–V* curves in the dark and under illumination of 0.5 mW/cm^2 UV light at 340 nm through ITO electrode for ITO/PEDOT:PSS/PFP/NSN/LiF/Al and ITO/PEDOT:PSS/PVK/NSN/LiF/Al. (b) The transient response curve for ITO/PEDOT:PSS/PFP/NSN/LiF/Al at −12 V.

as the light is illuminated and recovers to its original level once the light is removed. The response is stable and reproducible, which is beneficial for UV detection.

The photocurrent response spectra of the four devices under ITO side illumination are integrated in Fig. 6 for comparison. Due to the absorption of ITO substrates, DUV in the incident light can hardly reach the active layers. As a result, only NUV detection can be realized. The response peak for PFH, *m*-MTDATA, PFP and PVK based devices is at 375, 345, 340 and 330 nm, respectively. Moreover, the response cutoff at longer wavelength is also different. In consistent with the optical absorption, the response cutoff blue-shifts sequentially from PFH, *m*-MTDATA, PFP to PVK with a value of 425, 410, 375 and 370 nm, respectively. So, by selecting donors with different bandgaps to combine with NSN, the response cutoff wavelength can be well tuned. In particular, the PFP/NSN and PVK/NSN based devices can be applied as visible-blind UV photodetectors.

3.4. Realization of DUV detection

Since the ITO substrate can block the UV light with wavelength below 300 nm, a semitransparent Al electrode

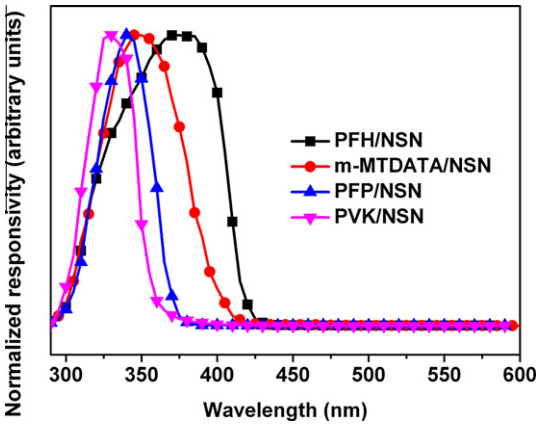

Fig. 6. Normalized photocurrent response spectra of ITO/PEDOT:PSS/donor (PFH, *m*-MTDATA, PFP and PVK)/NSN/LiF/Al for illumination through ITO side.

with thickness of 12 nm was thus employed for the purpose of DUV detection. Fig. 7a shows the response spectrum for illumination through Al side in the PFP/NSN based device. Due to the permission of DUV transmission by Al electrode, the response spectral covers 200–375 nm, which can be further restricted within the DUV region only by filtering the NUV part of the incident light. The UV filter can be simply prepared by doping dyes in PVA film [23]. The structure and absorption of the dyes applied are shown in Fig. 8a. Both FM1 and FM2 exhibit a strong absorption peak in the NUV region but retain a transmission window in the DUV region. The transmittance spectra shown in Fig. 8b indicate that filters based on FM1 and FM2 can respectively block the light in the region of 290–350 and 310–375 nm. Considering the response cutoff wavelength of PFP/NSN based device mentioned above, FM2-based filter seems especially appropriate to block the NUV that can excite this device. In order to further widen the block region of the filter, the doping concentration and final thickness can be increased. However, the transmittance in the DUV region will be also reduced. Alternatively, adding a small amount of FM1 in the FM2-based filter can also extend the blocking region to the lower wavelength. As shown in Fig. 8b, for a filter based on blend of FM1:FM2 (1:8, by weight), UV light in the region of 300–375 nm can be totally blocked. Meanwhile, a transmittance of 45% can still be obtained at 270 nm. With this filter put in front of the semitransparent

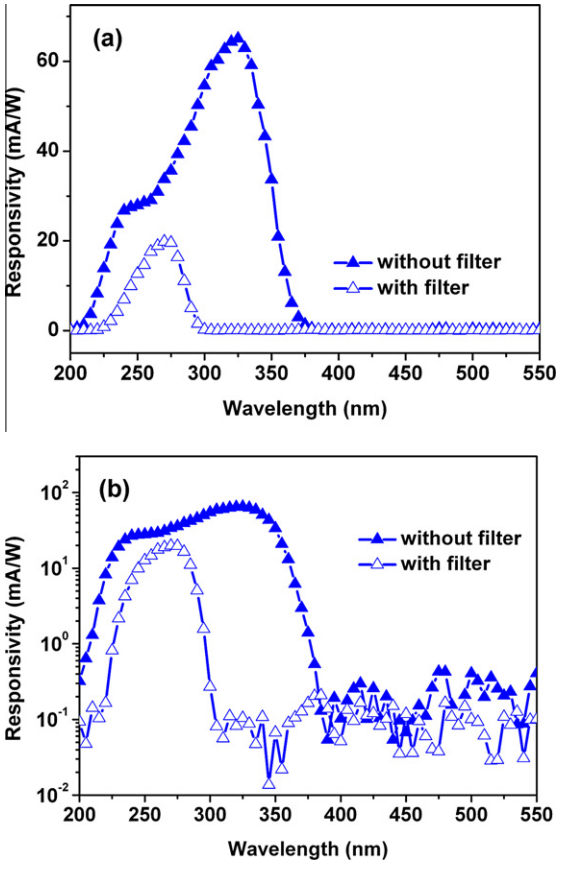

Fig. 7. Photocurrent response spectra of ITO/PEDOT:PSS/PFP/NSN/LiF/Al (a) in linear scale and (b) in semi-log scale for illumination through Al side. The applied bias is −9 V. Both curves with and without UV filter applied are given.

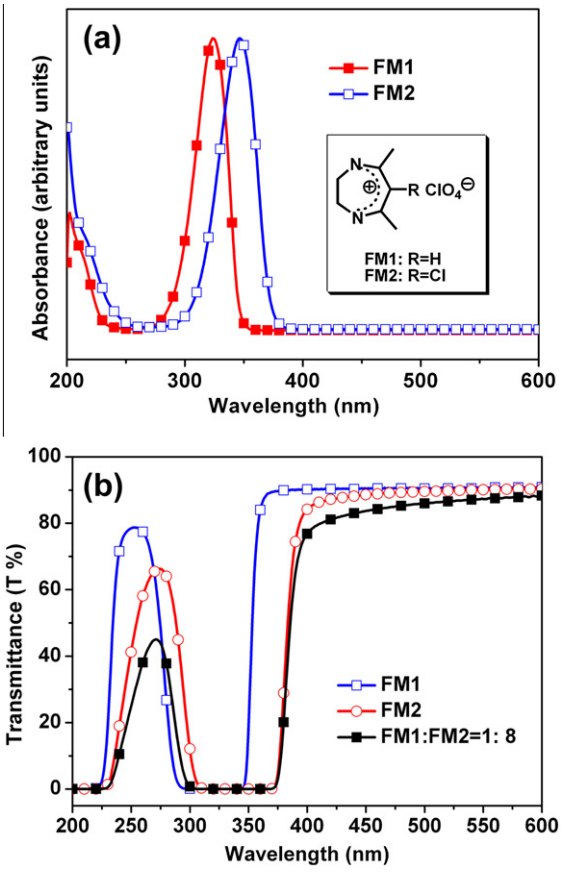

Fig. 8. (a) Absorption spectra of FM1 and FM2 in methanol. The structures for FM1 and FM2 are also shown in the inset. (b) Transmittance spectra of the home-made UV filters.

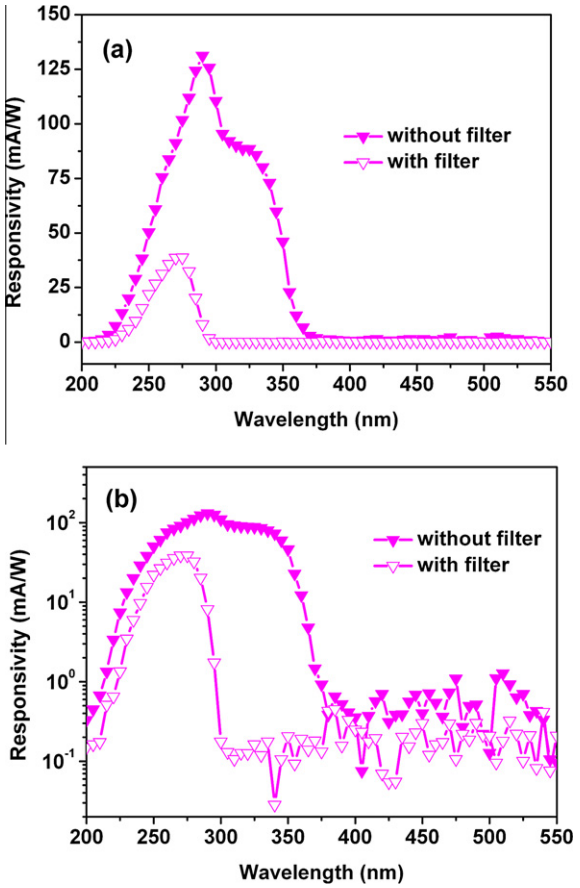

Fig. 9. Photocurrent response spectra of ITO/PEDOT:PSS/PVK/NSN/LiF/Al (a) in linear scale and (b) in semi-log scale for illumination through Al side. The applied bias is −9 V. Both curves with and without UV filter applied are given.

Al electrode, the response cutoff shifts to 300 nm just as expected and a peak responsivity of 19.87 mA/W can be obtained round 270 nm under reverse bias of −9 V (Fig. 7a). From the semi-log plot shown in Fig. 7b, it is observed that the cutoff at 300 nm is very sharp. As a result, quasi-solar-blind response is realized. Since the intrinsic cutoff wavelength for the PVK/NSN based device is even lower, similar effect can be achieved. As shown in Fig. 9, by combining the above-mentioned filter, the device only responses to the UV light in the region of 200–300 nm and the peak responsivity round 275 nm is 38.76 mA/W. To achieve more efficient devices, there are at least two routes. One is developing organic filters with higher transmittance in DUV region and also excellent blocking ability in NUV or even visible region to broaden the selection space of the active materials. The other is applying wide bandgap semiconductors with higher carrier mobility for the devices.

Though the good blindness to NUV of the present devices is not intrinsic, the applied filters can be easily fabricated and will not increase the cost too much. Moreover, the filters are flexible and can be easily integrated with the device during encapsulation. Contrarily, as to the reported solar-blind detectors based on wide-bandgap inorganic semiconductor such as MgZnO and AlGaN, the fabrication is rather complicated and the cost is high [37,38]. Thus, the study shown here may provide a useful guideline to achieve low-cost organic detectors for DUV-selective detection. Besides, by combining the organic NUV filter, the devices based on PFP/NSN and PVK/NSN heterojunctions are also capable of dual-band UV detection. In practical application, the devices can respectively response to NUV and DUV radiating through ITO side and Al side, which facilitates distinguishing complicated UV signals.

4. Conclusion

Organic ultraviolet photodetectors based on a wide bandgap acceptor of triazine derivative (NSN) and four different donors (PFH, *m*-MTDATA, PFP and PVK) were fabricated with device structure of ITO/PEDOT:PSS/donor/NSN/LiF/Al. The devices present NUV response to the radiation from ITO side with varied response cutoff wavelengths due to the different energy gaps of the donors. By employing semitransparent Al electrode for the light incidence, the response region was further extended to DUV region. Specifically, in PFP/NSN and PVK/NSN based devices, by combining home-made organic NUV filters, quasi-solar-blind response was also realized. Since those devices can not only detect NUV radiation from the ITO side, but also give sensitive response to the DUV radiation from the Al side, they may be applied as low-cost NUV/DUV dual-band photodetectors.

Vertical transistor
Space–charge-limited current

ABSTRACT

The vertical mobility of a polymer film prepared on a textured substrate is enhanced from 10^{-5} cm^2/Vs to 10^{-3} cm^2/Vs by a slow drying process which is unattainable in planar substrate. Highly ordered structure is observed for polymer film treated with high-boiling-point solvent and slow solvent annealing. The enhanced vertical mobility enables the polymer space–charge-limited transistor (SCLT) capable of outputting current density as high as 100 mA/cm^2 while maintaining good current gain and on–off ratio. Such vertical transistor is able to drive high-power devices or mechanical actuator in large-area and flexible array.

1. Introduction

Flexible electronics based on solution-processed semiconductors is an exciting emerging technology with the potential applications with very large areas. It enables displays and sensor arrays to cover the surfaces of clothes, buildings, robots, and cars [1,2]. In such large-area array, the pixel size may be over one centimeter and transistors need to drive high-power devices in the pixel as an organic light-emitting diode with high luminance or a motor and other mechanical actuator in robotic applications. For current output over 100 mA it is difficult to achieve using polymer field-effect transistors. Indeed for a channel length of 50 micron typically made by shadow mask the drain current is only 4 mA for channel width as long as 100 cm, given the carrier mobility of 0.1 cm^2/Vs, drain bias of 20 V, and capacitance of 10 nF/cm^2. In principle, the 100 cm channel width can be made by 50 pairs of 1 cm long inter-digited source and drain fingers, resulting in a 1 cm by 1 cm active area. Nevertheless in addition to the insufficient current output, the fabrication of this structure is fragile because any defect would break the entire finger. Furthermore, the operation voltage of organic field-effect transistor is usually over 20 V, so the Joule heating and power consumption will be a major problem for high-current applications. Polymer field-effect transistor is therefore not suitable for the driving of high-current load in the large-area flexible arrays.

Organic vertical transistors offer another approach to this requirement [3–10]. It has intrinsically low operation voltage and the current is directly proportional to its surface area for easy scaling up. One of the most successful vertical transistors is the space–charge-limited transistor (SCLT) which is a solid-state version of vacuum tube triode, with a metal grid embedded in an organic diode to control its vertical current [7–10]. SCLT shows low-operation voltage, below 1 V, and has a robust fabrication using self-assembled sub-micron plastic spheres as the shadow mask [9]. However, so far its current density (J_C) is only 1 mA/cm^2 due to the poor vertical mobility of the polymer. While the field-effect mobility of P3HT and some other polymers is over 0.1 cm^2/Vs, the vertical bulk mobility is only 10^{-5} cm^2/Vs. The surface treatment for the gate dielectric enhances the chain alignment near the interface but not in the bulk. Besides, the high carrier density at the interface also increases the mobility by filling the traps.

doi:10.1016/j.orgel.2010.09.023

In this work we demonstrate that the polymer vertical mobility can be greatly enhanced by a slow drying process using high-boiling-point solvent, i.e. solvent annealing, in a textured surface with 200 nm scale defined by the grid. The vertical columns promote the chain alignment of P3HT during the slow solvent annealing and result in an ordered structure unattainable in planar substrate. The vertical mobility is raised from 4×10^{-5} cm^2/Vs to 2×10^{-3} cm^2/Vs and the SCLT can deliver output current density as high as 100 mA/cm^2 while maintaining good current gain and on–off ratio. With such high current density, 100 mA current out-put can be delivered by a 1 cm^2 active area which is very easy to fabricate with high reliability. With this grid-induced crystallinity SCLT solves the problem of power transistor for large-area flexible electronics.

2. Experimental

The SCLT is fabricated on an ITO glass substrate. Cross-linkable poly(4-vinyl phenol) (PVP) of 210 nm is spin coated and cross-linked on the ITO substrate. Poly (melamine-co-formaldehyde) methylated is utilized as a cross-linking agent for PVP. After treating the PVP surface with 50 W O_2 plasma, the substrate is then submerged into 200 nm positively charged polystyrene spheres (Merck, K6-020) dilute ethanol solution with 0.8 wt.% for 3 min. The substrate is transferred into a beaker with boiling isopropanol solution for 10 s, and then blown dry immediately. Forty nanometer Al and 50 nm SiO are sequentially evaporated as metal base electrode and upper insulating layer. After removing the polystyrene spheres by an adhesive tape (Scotch, 3 M), the PVP at sites without base electrode coverage is removed by 13 min 150 W O_2 plasma treatment. Three hundred and fifty nanometer P3HT is then deposited with or without solvent annealing. For the device prepared by spin coating, P3HT in chlorobenzene or dichlorobenzene is spin coated on the substrate until the film dried. As for the device prepared by dichlorobenzene solvent annealing, P3HT in dichlorobenzene (2.5 wt.%) is spin-coated at 450 rpm for 30 s and then 1200 rpm for 1.2 s to form a P3HT wet film. The wet film is then holding still in the glove box until the film dried. The P3HT film is annealed at 140 °C for 10 min. Finally, the Al collector is deposited to complete the SCLT with active area as 1 mm^2. Transistor characteristics are recorded using an Agilent E5270B modular parameter analyzer. SEM image is obtained with a field-emission SEM (JEOL JSM-7401). XRD pattern is obtained with high resolution X-ray diffractometer, D1, Bede.

3. Results and discussions

Diodes and SCLTs with P3HT thickness of 350 nm are prepared from chlorobenzene (b.p. ~130 °C) and dichlorobenzene (b.p. ~180 °C) to understand the influence of solvent and drying process on the characteristics of devices. Because of the high boiling point of dichlorobenzene, the drying time is 7 s for spin coating P3HT chlorobenzene solution while it is 4 min for spin coating P3HT dichlorobenzene solution. Longer drying time about 20 min is achieved by a solvent annealing procedure which is the first spin coat P3HT dichlorobenzene solution for a short time then letting P3HT dichlorebenzene wet film dry slowly in the glove box. The drying time is visually judged by the change in film color. Diode structure and characteristics are shown in Fig. 1a. The output current density (J) of the P3HT diode prepared by spin coating chlorobenzene is higher than the one prepared by spin coating dichlorobenzene. With dichlorobenzene solvent annealing, J is enhanced but still inferior to the one achieved by chlorobenzene spin coating. The mobility, deduced from J follows space–charge-limited current (SCLC), of the diode prepared by spin coating P3HT chlorobenzene solution is therefore the highest one among various diodes as shown in Fig. 1b. The influence of the solvent and drying process on the SCLT is, however, not in the same trend as in diode as shown in Fig. 1e–h. The structure of SCLT is shown in Fig. 1c and d. The active layer of SCLT is fabricated by spin coating P3HT chlorobenzene solution (SCLT-A), spin coating P3HT dichlorobenzene solution (SCLT-B), and spin coating P3HT dichlorobenzene solution for a while then letting wet film dry slowly (SCLT-C). The ITO emitter is commonly grounded and the Al collector is negatively biased at collector-to-emitter voltage (V_{CE}). J_C is obtained by dividing output current by device active area of 1 mm^2. The grid-to-emitter voltage (V_{GE}) is varied to modulate J_C. As the transistor is turned on with $V_{GE} = -0.9$ V, J_C of SCLT-C (shown in Fig. 1f) is higher than the one of the SCLT-A (shown in Fig. 1e) for over one order of magnitude. Besides, as shown in Fig. 1h, J_C is 36 mA/cm^2 for SCLT-B ($V_{GE} = -1.1$ V and $V_{CE} = -4.5$ V) while 52 mA/cm^2 for SCLT-C ($V_{GE} = -1$ V and $V_{CE} = -4.5$ V). J_C of the SCLT fabricated by dichlorobenzene is higher than the one fabricated by chlorobenzene. The SCLT fabricated with dichlorobenzene solvent annealing can output higher current than the one fabricated with spin coating. As a whole, high-boiling-point solvent and long drying time enhance the output current. Furthermore, for SCLT-C, J_C of 104 mA/cm^2 is achieved when V_{CE} is −9.5 V as shown in Fig. 1h. With operation voltage below 10 V, this transistor is able to delivered 100 mA output current by a 1 cm^2 area which could drive

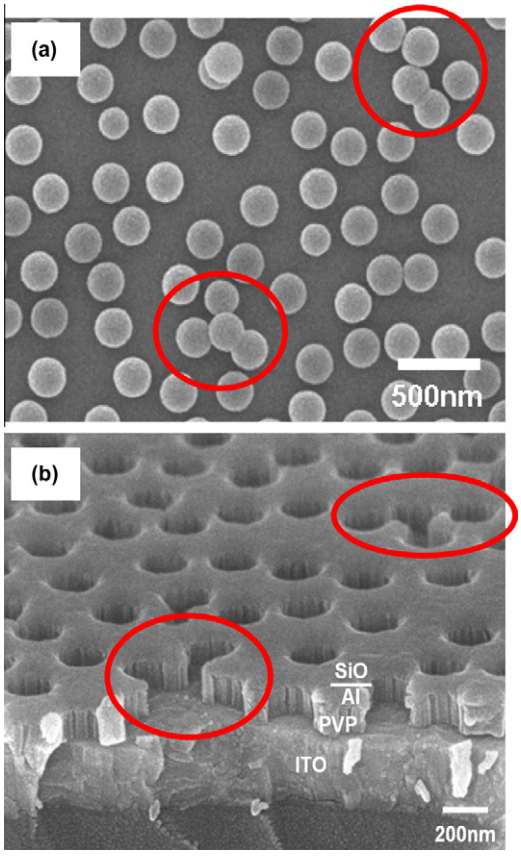

Fig. 2. Scanning electron microscopic images. (a) Top view of polystyrene spheres on poly(4-vinyl phenol). (b) The openings form at sites without Al grid.

high-current load in the large-area flexible arrays. As the SCLT is turned off, the off current of SCLT-C is still higher than SCLT-B and SCLT-A. The output current of SCLT is enhanced no matter in on state or off state. However, on/off ratios of these SCLTs are in the same order of 10^4. As shown in Fig. 1g the gird current density (J_G) is in the order of 10^{-4} to 10^{-3} mA/cm^2 and hence the current gain $|J_C/J_G|$ is as large as 10^4 to 10^5.

The reason why on and off current of SCLT-C are higher than other devices can be understood from scanning electron microscopy (SEM) images at difference phase of device fabrication. Top view of polystyrene spheres on poly(4-vinyl phenol) (PVP) is shown in Fig. 2a. The openings form at sites without Al grid is shown in Fig. 2b. Although most polystyrene spheres are separate to each other, aggregates contain more than two spheres can still be observed. Large openings will occur at sites with these randomly occurred aggregates. The grid control of the current is strong near the edge of the grid. The vertical carrier channel in the region far away from the grid can not be effectively modulated by grid. As large openings occur, the grid control on the current far away from the grid is small. Despite the on current is benefit from the slow drying process enhanced carrier mobility, the off current can not be suppressed by V_{GE} since the grid control on the current in the region away from the grid is less. The off current of SCLT is higher than J_G.

The mobilities of SCLTs are shown in Fig. 1b. Since the current channel is formed only at the openings, the device active area is recalculated according to the amount of openings for estimating the current density and the mobility. Mobilities deduced form SCLTs are higher than those from diodes except the one of SCLT-A. The highest mobility attainable in SCLT-C is 2×10^{-3} cm^2/Vs. With high-boiling-point solvent and solvent annealing process, P3HT can be self-organized into semicrystalline lamellar and yield high carrier mobility [11]. The carrier mobility is different in diode and SCLT which can be explained as vertical channel columns induced chain alignment of P3HT during the slow solvent annealing. To understand the reason why mobility increases in SCLT, atomic force microscopy (AFM) images of P3HT surface on textured surface are shown in Fig. 3a–c. The root mean square roughness of 13.6 nm is achieved for spin-coated film from chlorobenzene solution. The roughness increases to 15.3 nm when high boiling point dichlorobenzene is used. As dichlorobenzene solvent annealing process is used, the roughness is further increased to 22.2 nm. It has been demonstrated that polymer

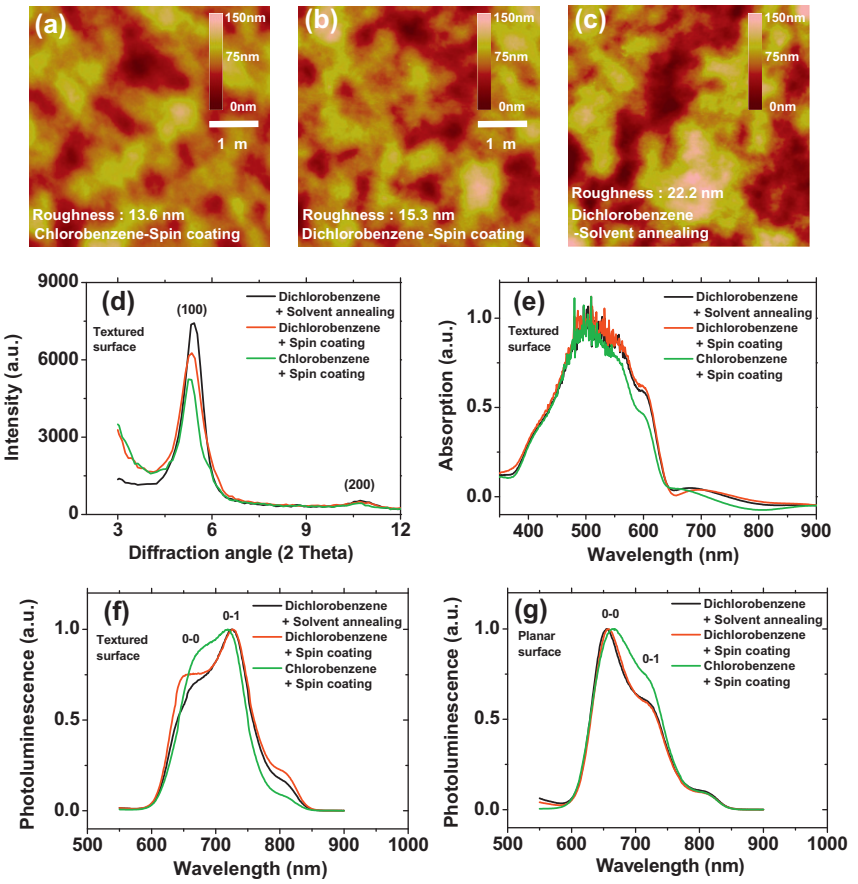

Fig. 3. (a–c) Atomic force microscopy images of P3HT surfaces on textured surface. (g) Photoluminescence spectroscopy of P3HT film prepared from three processes on planar surface.

film with high surface roughness indicates polymer organization [12]. The increased mobility in SCLT may come from the enhanced degree of the polymer chain alignment. To confirm this, grazing incidence X-ray diffraction (GIXRD), UV–visible absorption spectroscopy, and photoluminescence spectroscopy are utilized to get more in-depth information inside the film since AFM images represent only film surface condition. From out-of plane GIXRD spectra shown in Fig. 3d, stronger reflection of the (100) layer can be observed at $2\theta = 5.4^\circ$ for film prepared with dichlorobenzene solvent annealing [13]. All P3HT films show well-organized intra plane structure which means P3HT self-organizes into two-dimensional π-stacked lamellar structures. The intensity increases when using dichlorobenzene and solvent annealing process. Crystallinity of P3HT is indeed improved by using high boiling point dichlorobenzene and solvent annealing process as illustrated in Fig. 1c and d. Besides, from UV–visible absorption spectra shown in Fig. 3e, prominent vibronic features can be observed at 600 nm for film prepared from dichlorobenzene. Previous work demonstrated that the enhanced vibronic absorption peak indicates strong interchain interactions and enhanced P3HT ordering [14]. This represents the utilization of high boiling point dichlorobenzene helps to induce ordered film with strong inter chain interactions. The influences of π-stacked polymer chains on photoluminescence spectra are shown in Fig. 3f. The 0–0 to 0–1 peak intensity ratio, S_R, is usually used as an effective probe for disorder [15,16]. The 0–0 peak is forbidden by symmetry in disorder-free aggregates. As disorder occurred the symmetry is broken and the 0–0 emission is allowed. The S_R is high as P3HT is spin-coated from chlorobenzene; however, as dichlorobenzene is used as the solvent, the S_R is decreased and reached the lowest value when solvent annealing process is used. This indicates that, on the textured surface, the P3HT film prepared from dichlorobenzene solvent annealing has less disorder while the one prepared from chlorobenzene spin coating has lots of disorder. The mobility is therefore high in P3HT film prepared from dichlorobenzene solvent annealing. Longer drying time may attribute to well-ordered lamellar structure. However, on the planar surface, the film prepared from dichlorobenzene solvent annealing is most disorder while the film prepared from chlorobenzene spin coating is less disorder as shown in Fig. 3g. The difference in photoluminescence spectra of P3HT on textured surface and planar surface reveal the level of disorder and may be used to explain the difference in device performance as shown in Fig. 1. With this grid-induced crystallinity, SCLT treated with dichlorobenzene solvent annealing can output high current which is suitable for large-area flexible electronics. The improved P3HT ordering in grid structure can be explained by improved π-π stacking due to nanoconfinement-induced chain alignment. The nanostructure-induced crystallinity in P3HT was also reported by several other groups [17–19]. Coakley et al. reported that P3HT nanopillars with diameters ranged from 20 to 75 nm have larger hole mobility than P3HT neat film. For pore diameter above 75 nm, the hole mobility falls off and approaches the mobility value for a neat film [17]. In our experiment, with pore diameter as 200 nm, hole mobilities in P3HT nanopillars are still higher than those in neat film. The discrepancy may come from the influences of solvent, drying method, and the pore sidewall properties. The nanostructure-induced crystallinity, however, is a clear phenomenon in all these works.

4. Conclusion

In conclusion, the SCLT capable of outputting current density as high as 100 mA/cm^2 is realized while maintaining good current gain and on–off ratio. The slow drying process using high-boiling-point solvent is utilized to enhance the polymer vertical mobility. The vertical columns promote the chain alignment of P3HT during the slow solvent annealing and result in an ordered structure unattainable in planar substrate. Such vertical transistor can be used to drive high-power devices or other mechanical actuator in large-area and flexible array.

ABSTRACT

The optical features of the internal dipole radiation have major impact on the emission pattern and overall device efficiency of organic light-emitting diodes (OLEDs). We provide some general directives on how the OLED layered stack should be designed in order to enable precise measurements of the *active* optical properties of the emissive material (namely internal electroluminescence spectrum, profile of the emission zone and dipole moment orientation) by radiation pattern analyses. We discuss a model layered system and deduce universal emitter positions most suitable for the determination of the particular OLED internal features of interest. Furthermore, we evaluate the real benefit of conducting radiation pattern analyses utilizing a substrate index-matched glass-hemisphere.

1. Introduction

In the past two decades considerable progress has been achieved in improving the lifetime and efficiency of organic light-emitting diodes (OLEDs) as well as in studying the basic physics of such devices. However, one factor still limiting the overall device performance is the rather low light extraction efficiency. This is due to the fact that the energy of an excited emitter can be radiated into different optical channels and only a small fraction of the light energy is finally extracted from the device. In order to perform comprehensive optical analysis and optimization of the OLED layered system, which promise improved device efficiency, the optical features of both the internal dipole radiation and the layered stack need to be known.

The radiation pattern of an OLED is generated by the interplay of the *active* optical properties of the emissive material (which are the internal electroluminescence (EL) spectrum, the profile of the emission zone, the orientation of the transition dipole moments and the internal luminescence quantum efficiency) and the *passive* optical properties of the layered system (which are the material refractive indices and the layer thicknesses). While the *passive* optical properties, material dispersions and thin film thicknesses, can be measured utilizing standard spectroscopic methods [1–3], the *active* optical properties of the emissive system are difficult to access. Frequently, photoluminescence (PL) experiments are performed to determine the spectrum of the emissive material [4] as well as the molecular dipole orientation [3–6]. However, PL experiments generally suffer from the fact that the initially photo-generated excited states are not necessarily identical to the excited states in EL operation [7]. Consequently, *in situ* investigations of OLEDs are desirable, and a promising approach is based on measurements of the optical far-field of OLEDs in electrical operation and subsequent optical reverse simulations. A variety of methods utilizing the full angular, spectral and polarization resolved radiation pattern or some essential aspects of these have been proposed, allowing conclusions to be drawn to the profile of the emission zone [8–12] as well as the orientation of the emissive dipoles [13]. However, in order to observe the internal features of the dipole radiation in the OLED far-field accurately, devices with well-adapted layered systems are needed to optically enhance the feature of interest. Although this is a crucial point, the potential of adapted devices to OLED characterization has not been investigated yet.

In this paper we provide some general principles concerning the design of the OLED layered stack in order to enable for precise measurements of the *active* optical properties of the emissive material, namely the internal EL spectrum, the profile of the emission zone and the dipole moment orientation. Starting from basic considerations of the dipole radiation characteristics, we discuss a model layered system with sufficient detail to be meaningful for discussions of most real OLED configurations. We utilize the fact that the emitter–cathode distance is the most crucial factor in enhancing or suppressing certain dipole contributions to the optical far-field. Additionally, for the reverse simulation we take advantage of the fact that perpendicular dipoles only contribute to transverse-magnetic polarized light emission. Moreover, we evaluate the real benefit of conducting radiation pattern analyses utilizing an index-matched glass-hemisphere to access the substrate internal pattern. Finally, broadly suitable emitter positions are deduced, which allow the internal features of particular interest to be determined with greatest accuracy and in a manner almost independent of the other *active* properties of the emissive material.

2. Method

2.1. Optical modeling

In OLEDs, the electroluminescent emissive process can be considered as a dipole transition from an excited molecular state into the ground state. The emissive dipole transition moment at position z in the emissive material has a defined orientation φ, where φ denotes the internal angle between dipole moment and layered system normal. The angular (θ, angle to the layered system normal) and spectral (λ, wavelength) radiant intensity $I^{class}(\theta,\lambda,z,\varphi)$ of an emitter inside the OLED stack is simulated assuming a classical, continuously oscillating dipole source, yielding the emitted power $P^{class}(\theta,\lambda,z,\varphi)$ per solid angle $\mathrm{d}\Omega$ and wavelength $\mathrm{d}\lambda$ interval:

$$I^{class}(\theta,\lambda,z,\varphi)=\frac{\mathrm{d}^2P^{class}(\theta,\lambda,z,\varphi)}{\mathrm{d}\Omega\mathrm{d}\lambda}. \tag{1}$$

In the following discussion, all power values of classical dipoles are normalized with respect to the total irradiated power of a corresponding dipole in the homogeneous infinite emitter medium. The electromagnetic dipole fields in the system are evaluated using a transfer-matrix formulation of the well-known Green's function model [14]. For further details on the generation of the dipole fields see Ref. [15] and references therein.

The classical emission pattern of an arbitrarily oriented dipole can be decomposed into contributions of three orthogonal dipoles ($\|$TE, $\|$TM, $\perp$ TM) [16]:

$$\begin{aligned}I^{class}(\theta,\lambda,z,\varphi)=\sin^2(\varphi)\cdot[I^{class}_{\|\mathrm{TE}}(\theta,\lambda,z)+I^{class}_{\|\mathrm{TM}}(\theta,\lambda,z)]\\+\cos^2(\varphi)\cdot[I^{class}_{\perp\mathrm{TM}}(\theta,\lambda,z)].\end{aligned} \tag{2}$$

These orthogonal dipoles are specified according to their orientation with respect to the interfaces of the layered system (parallel "$\|$", perpendicular "$\perp$") and the corresponding polarization of the emitted radiation (transverse-electric "TE", transverse-magnetic "TM").

In order to ensure normalization of power emitted from the dipole in the layered system, we utilize the equivalence between the probability for spontaneous emission of a photon via a dipole transition and the radiated power of a classical dipole source in the corresponding layered system [17]:

$$I(\theta,\lambda,z,\varphi)\propto\frac{1}{\Gamma_{rel}(q,z,\varphi)}I^{class}(\theta,\lambda,z,\varphi), \tag{3}$$

where $\Gamma_{rel}(q,z,\varphi)$ denotes the emission rate of the dipole at position z with orientation φ in the cavity normalized to the emission rate in the infinite emitter medium. By this means, the influence of the OLED stack on the rate of emission, the so-called microcavity effect, is taken into account. For all rate calculations performed in this study, a representative internal luminescence quantum efficiency of $q = 0.7$ was assumed. Although the q-value has a major impact on the overall efficiency of OLEDs, it has very minor quantitative impact on the considerations we address here. For a more detailed discussion of the q-value see for example Refs. [17–20].

At this point it is worth noting that although the applied optical model is similar to the simulation tools established by other groups and discussed elsewhere [18,21–24], all calculations are performed with a self-developed, in-house software tool [25]. Each layer within the OLED stack is assumed to have smooth, parallel interfaces and a certain thickness. The interaction between materials and radiation is considered by the wavelength dependent complex refractive index ($n + i\kappa$, with refractive index n and extinction coefficient κ), and the light propagation through the multilayer system is simulated utilizing a transfer-matrix method [26].

In real OLED devices the emissive material can be treated as an ensemble of incoherent radiators. Distributions in (i) emitter location z, (ii) dipole orientation φ, and (iii) wavelength dependent spectral intensity account for (i) the profile of the emission zone $N(z)$, (ii) the distribution of emitter orientation $g(\varphi)$, and (iii) the internal EL spectrum $S(\lambda)=(hc/\lambda)\cdot\hat{s}(\lambda)$, respectively. The internal EL spectrum takes the photon energy hc/λ into account, where h denotes the Planck constant and c the speed of light in vacuum. The integrals of all distributions are normalized to one: $\int N(z)\mathrm{d}z=1$, $\int g(\varphi)\sin\varphi\mathrm{d}\varphi=1$, and $\int\hat{s}(\lambda)\mathrm{d}\lambda=1$. By this means, the integrated distribution weight yields a single emissive event in total and $\int S(\lambda)\mathrm{d}\lambda$ yields the mean photon energy with respect to the spectral distribution $\hat{s}(\lambda)$. The emission pattern from the OLED layered system $I^{LS}(\theta,\lambda)$ can be obtained by an incoherent superposition of all contributions [27]:

$$\begin{aligned}I^{LS}(\theta,\lambda)&=S(\lambda)\int_z\int_\varphi N(z)g(\varphi)\frac{I^{class}(\theta,\lambda,z,\varphi)}{\Gamma_{rel}(q,z,\varphi)}\sin\varphi\mathrm{d}\varphi\mathrm{d}z\\&=S(\lambda)\left\langle\frac{I^{class}(\theta,\lambda,z,\varphi)}{\Gamma_{rel}(q,z,\varphi)}\right\rangle_{\varphi,z}.\end{aligned} \tag{4}$$

Hence, $I^{LS}(\theta,\lambda)$ includes only optical effects due to the layered system. Electrical phenomena, like charge carrier

injection and recombination, are excluded from this investigation. Consequently, it is this quantity which should be considered for optical analyses. It is related to the experimentally accessible spectral radiant intensity of a device $I(\theta,\lambda)$ by the formula:

$$I(\theta,\lambda) = (I_{inj}/e)\cdot\gamma\cdot\eta_{S/T}\cdot q\cdot I^{LS}(\theta,\lambda). \quad (5)$$

Eq. (5) also includes the number of injected charge carriers I_{inj}/e, where I_{inj} denotes the current applied to the device and e denotes the elementary charge. Furthermore, the radiant intensity is limited by (i) the probability of charge carrier recombination and subsequent exciton formation γ, and (ii) by the generation of excited singlet as well as triplet states according to spin statistics, where allowed and forbidden transitions are regarded by the singlet/triplet-factor $\eta_{S/T}$. Additionally the internal luminescence quantum efficiency q of the emissive system limits the radiant intensity.

The fraction of photons emitted from a device $\eta_{out}^{LS} = 2\pi\cdot\int_\lambda\int_\theta I^{LS}(\theta,\lambda)/(hc/\lambda)\mathrm{d}\theta\mathrm{d}\lambda$, with respect to the infinite emissive material, yields a measure of how the number of emitted photons is influenced by the presence of the layered system. It defines the overall device efficiency, represented by the well-known external quantum efficiency:

$$EQE = \gamma\cdot\eta_{S/T}\cdot\langle q_{eff}\cdot\eta_{out}^{class}\rangle_{\varphi,z} = \gamma\cdot\eta_{S/T}\cdot q\cdot\eta_{out}^{LS}, \quad (6)$$

giving the number of emitted photons per injected charge. The middle term of Eq. (6) is well established: in any microcavity the quantum efficiency of excited state luminescence is system dependent due to near field effects, represented by the effective quantum efficiency q_{eff}, and only a fraction of the internally generated light can leave the structure, taken into account by the classical outcoupling-factor η_{out}^{class}. In this notation, however, q_{eff} accounts for the variation of the emissive rate due to the surrounding layered system, and the outcoupling-factor η_{out}^{class} is calculated by classical theory. Thus, both quantities, q_{eff} and η_{out}^{class}, depend on the emitter position z within the system as well as on the emitter orientation φ, a fact which is often disregarded. In order to transform q_{eff} to an emissive system specific constant, the internal luminescence quantum efficiency q is introduced into Eq. (6) on the right hand side, with the advantage that the material dependent quantities $(\gamma,\eta_{S/T},q)$ are separated from the layered system specific effects (η_{out}^{LS}).

2.2. Optical reverse simulation or the inverse outcoupling problem

Eqs. (4) and (6) illustrate the fundamental reason why optical reverse simulation from external device measures is not straight forward: externally measured device outputs are necessarily an average of all single emitter contributions. Starting from *EQE* measurements it is almost impossible to estimate features of the internal dipole radiation, since it is also an integral over all angular and spectral components. Furthermore, the other factors in Eq. (6) have to be known precisely in order to deduce meaningful results from the measured *EQE*. By contrast, angular, spectral and polarization resolved measurements of the radiation pattern are more likely to allow for conclusions about the *active* optical properties of the emissive sites. However, in order to separate the contributions from emitters with distinct locations or orientations [see Eq. (4)], two ideas are fundamental: (i) According to Eq. (2), parallel dipoles emit TE and TM polarized radiation, whereas perpendicular dipoles contribute to TM polarized radiation only. Consequently, investigations of the internal EL spectrum and the emission zone can be performed independently of the dipole orientation distribution in the emissive material by analyzing TE polarized radiation only. Although straight-forward, this consideration has not been utilized in recent studies [9,11,12]. However, by subsequently analyzing TM polarized radiation, the emitter orientation remains the only unknown parameter, which can be adjusted to match TM experiment and simulation. (ii) The emitter–cathode distance mainly determines the interference conditions at the position of the emissive sites and is most crucial to enhance or suppress certain dipole contributions to the OLED far-field. Thus, the device architecture should be well adapted in order to optically enhance the feature of interest.

Solving the inverse outcoupling problem is based on performing a least-squares fit to the measured angle, wavelength and polarization dependent radiant intensity of a device. In order to circumvent the complexity of absolute measurements and the consideration of absolute factors [like in Eq. (5)], a non-absolute reverse simulation based on Eq. (4) is usually performed. Commonly, a number of discrete emitter positions within the emissive layer are assumed, each with identical internal spectrum $S(\lambda)$ and orientation distribution $g(\varphi)$. Some investigations are conducted considering a single dipole at a single position within the emissive layer [18,19]. Other studies take an extended emission zone into account, assuming a parametric distribution $N(z)$ deduced from electrical considerations [9–11,13] with numerically reasonable emitter position discretizations of e.g. ~10 nm [10] and ~20 nm [11]. However, applying a parametric distribution $N(z)$ is intrinsically limited, since the resulting emission zone is always within the frame of the electrical model. Consequently, the results derived are as open to debate as is the underlying electrical model. This is especially relevant for investigations considering the emission from positions very close to interfaces [10,11]. Unfortunately, optical reverse simulations based on a large number of discrete emitter positions without assuming a distribution $N(z)$ fail, because the radiation patterns of the emissive sites are not sufficiently distinct and not linearly independent. Regarding the orientation of the emissive sites, it is impossible to measure the detailed orientation distribution $g(\varphi)$, but rather the fraction of parallel and perpendicular dipole contributions generating the radiation pattern. This has been shown by experiments using both optical [6] and electrical [13] excitation. However, knowledge of the detailed emitter orientation distribution is not necessary for optical evaluations and information on the ratio of parallel to perpendicular dipole contributions is sufficient [see Eq. (2)].

A glass-hemisphere or -prism is frequently attached to the OLED substrate [11,12,18,28] in order to cancel the

total internal reflection at the substrate–air interface. Thus the radiant intensity in the OLED substrate $I^{sub}(\theta^s, \lambda)$, where θ^s denotes the propagation angle in the substrate with respect to the system normal, is accessed and an extended fraction of the internally generated angular radiation pattern is investigated. However, attaching a glass-hemisphere to the OLED substrate using an index-matched oil considerably increases the difficulty of experiments. In the following, we conduct our analyses for both cases, i.e. the emission pattern in air, $I^{LS}(\theta, \lambda)$ and in the substrate, $I^{LS,sub}(\theta^s, \lambda)$, in order to evaluate the real benefit of hemisphere measurements for accessing OLED emitter properties by radiation pattern analyses.

2.3. Model layered system

The basic considerations in this study are illustrated by monochromatic analyses (λ = 550 nm) of an artificial OLED system (see Fig. 1). Conventional OLED substrates are about 1 mm thick and exhibit refractive indices around n = 1.5 with negligible absorption. An indium–tin–oxide (ITO) layer of about 100 nm thickness is typically utilized as transparent anode, covered by a hole transport layer (HTL) of either several 10 nm or around 200 nm thickness. However, the anode-side part of the OLED stack has a minor impact on the basic effects we address. In this study, we have adjusted the HTL thickness to 60 nm, corresponding approximately to an optimized radiation into air. An electron transport layer (ETL) performs as the optical spacer between the emissive sites and the opaque metallic cathode of, in our case, silver. The organic materials and ITO utilized in conventional OLED systems have refractive indices around n = 1.8 at λ = 550 nm accompanied by, for our considerations, negligible absorption [1,13,17]. The optical properties of silver were taken from Ref. [29].

We believe that the proposed configuration (Fig. 1) adequately represents most real OLED systems. It is apparently very similar to bottom emitting structures based on small-molecule materials, where charge carrier injection and blocking layers have refractive indices around n = 1.8 as well. Top emitting OLEDs could be reproduced by inverting the whole structure without the substrate and exchanging the ITO layer by a thin (~20 nm) metal layer. However, in such a system the distance between the emissive sites and the semi-transparent metal has to be carefully adjusted as well, in order to observe the effects we address later in this paper. Typical polymeric OLEDs have a combined emissive and electron transport layer and a rather broad emission zone [30]. Nevertheless, for the purpose of optical analyses it is meaningful to divide the origin of this emission into single, discrete sheets. Furthermore, polymeric OLEDs can exhibit a confined emission zone at the anode-sided interface of the emissive layer (EML) if the charge transport inside the emissive material is electron dominated [10]. Consequently, this case is included by an association of the real polymeric EML with a combination of ETL and emissive sites in the model system. In summary, we believe that the proposed model system matches most real OLED systems well enough to describe the experimental aspects addressed in this contribution.

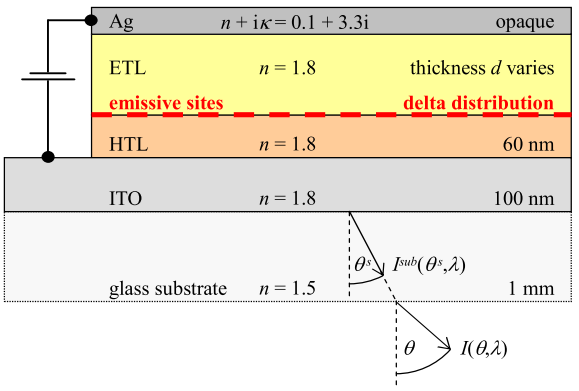

Fig. 1. Model OLED stack as used in the present considerations. Attaching an index-matched, macroscopic glass-hemisphere to the substrate additionally, allows investigation of the substrate radiation pattern $I^{sub}(\theta^s, \lambda)$.

3. Results and discussion

3.1. TE polarization: determination of internal EL spectrum and emission zone

As mentioned above, only TE polarized radiation has to be considered, if an investigation of the internal EL spectrum and/or emission zone is intended. To illustrate the following reasoning, Fig. 2(a) depicts the dependence of the normalized radiant flux ($\Phi_{TE} = 2\pi \cdot \int I^{LS}_{TE}(\theta, 550\,\text{nm}) \sin\theta \mathrm{d}\theta$) of TE polarized radiation from the model device into air on the emitter cathode distance d. In this context the radiant flux from a device can be interpreted as a measure of the optical efficiency of an OLED. An optically optimized device architecture ensures the emissive sites are placed at a distance of about d = 65 nm to the cathode (roughly corresponding to a quarter wavelength distance $\lambda/4n$, n = 1.8, shifted additionally by the non-ideal phase change upon reflection at the non-ideal cathode mirror). The emission into air is enhanced at this distance due to constructive interference of light emitted directly into the substrate direction with that reflected at the metal cathode. For an ETL thickness of about 140 nm (corresponding to about a half wavelength distance $\lambda/2n$) radiation from the emissive sites experiences destructive interference and emission into air is suppressed. Note that the behavior of the TE radiant flux represents the characteristics of the overall radiant flux from a device as well.

The shape of the angular radiation pattern is related to the interference conditions at the position of the emissive site. Fig. 2(b)–(k) shows the TE angular radiation pattern in air [$I^{LS}_{TE}(\theta, 550\,\text{nm})$ according to Eq. (4)] for some representative ETL thicknesses. The characteristics shown in Fig. 2(b)–(d) and (h)–(k) correspond to emissive sites located at values of emitter–cathode distance in the first and second maximum of the normalized TE polarized radiant flux into air, respectively. The angular pattern is nearly Lambertian like for these cases and all characteristics are very similar to each other due to the constructive interference conditions for moderate emission angles around

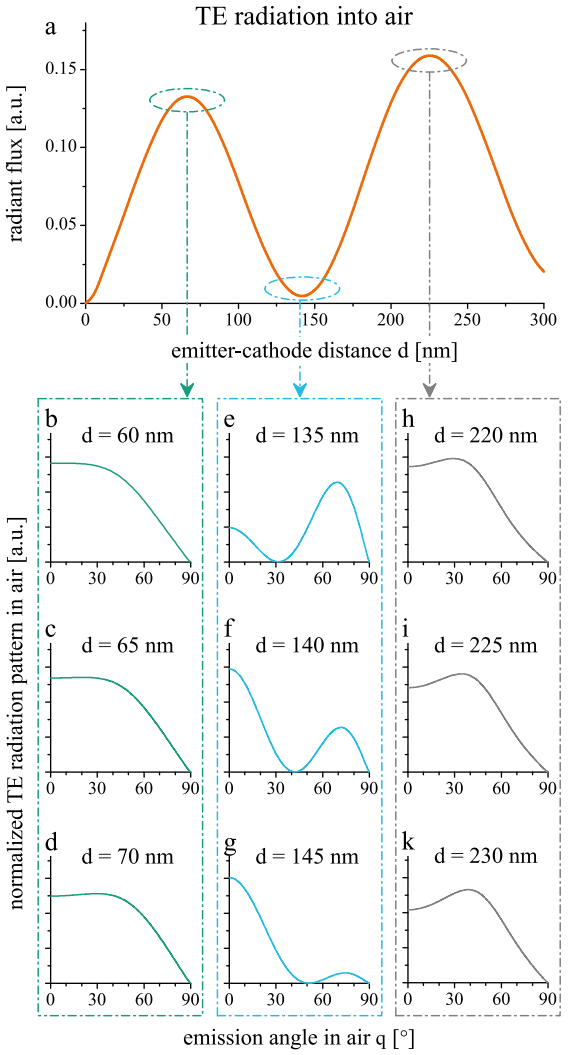

Fig. 2. As a measure for the optical efficiency of the model OLED stack, the normalized TE polarized radiant flux into air for $\lambda = 550$ nm is shown (a). The normalized TE polarized angular radiation patterns for discrete emitter positions around the first maximum (b)–(d), the minimum (e)–(g), and the second maximum (h)–(k) are plotted as well.

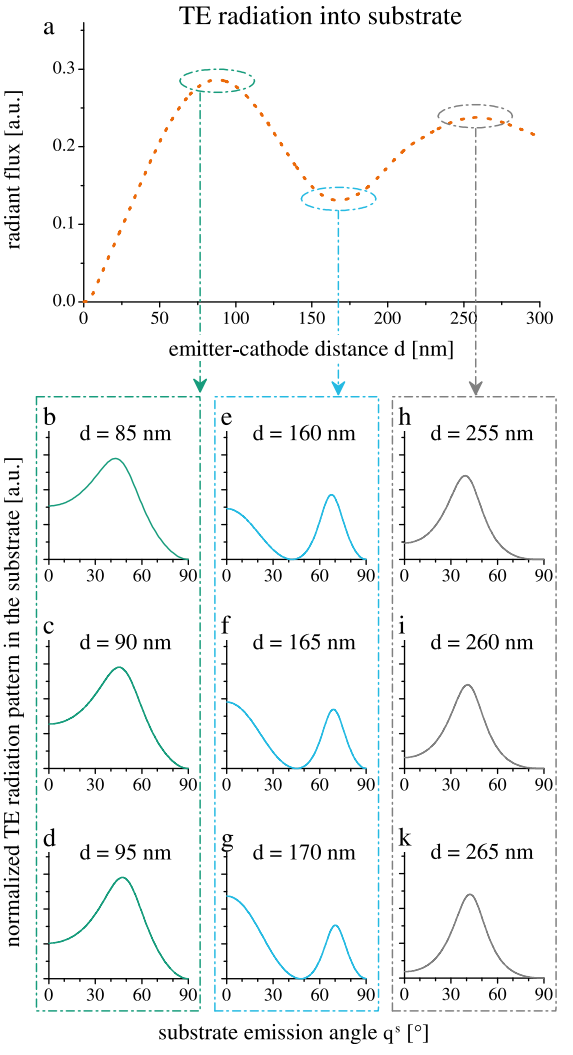

Fig. 3. The normalized TE polarized radiant flux into the substrate for $\lambda = 550$ nm is shown (a). The normalized TE polarized angular radiation patterns for discrete emitter positions around the first maximum (b)–(d), the minimum (e)–(g), and the second maximum (h)–(k) are plotted as well.

these positions. By contrast, the angular characteristics of emissive sites around the minimum of the normalized TE polarized radiant flux into air [Fig. 2(e)–(g)] are significantly modulated, deviating strongly from a Lambertian emission pattern. Furthermore, the absolute emission intensity is considerably reduced due to destructive interference. Surprisingly, it can be seen that the angular characteristics vary considerably for emitters displaced by just a few nanometers. For emissive sites at a distance $d \approx 140$ nm to the cathode, there is destructive interference for emission into oblique angles of $\theta \approx 40°$. This condition shifts significantly towards lower or higher emission angles upon moving the emissive sites closer to or further from the cathode, causing a variation of the balance between radiation into normal or oblique angles.

Fig. 3 illustrates the same characteristics as Fig. 2, but for radiation into the OLED substrate. The normalized TE polarized substrate radiant flux [Fig. 3(a)] consists of an extended fraction of the internally generated angular radiation pattern and is less modulated than the radiant flux into air. All angular patterns from emitter–cathode distances corresponding to maxima of the normalized TE polarized radiant flux into the substrate Fig. 3(b)–(d) and (h)–(k) exhibit enhanced radiation into larger substrate angles, yielding a higher flux due to solid angle considerations. Their characteristics deviate from a Lambertian emission significantly and are very similar to each other. The angular characteristics of emissive sites around the minimum of normalized TE polarized radiant flux into the substrate [Fig. 3(e)–(g)] are again significantly modulated and the absolute emission intensity is considerably reduced. However, compared to the data minimum of the normalized TE polarized radiant flux into air in

Fig. 2(e)–(g), there is much less effect of the emitter–cathode distance on the radiation pattern shape.

In order to quantify the variation of angular radiation pattern due to the emitter–cathode distance, we introduce the parameter

$$V_\theta(d) = \int_{\theta=0^\circ}^{90^\circ} \left| \frac{I^{LS}_{\mathrm{TE},d_{(-)}}(\theta, 550\ \mathrm{nm})}{\Phi_{\mathrm{TE},d_{(-)}}} - \frac{I^{LS}_{\mathrm{TE},d}(\theta, 550\ \mathrm{nm})}{\Phi_{\mathrm{TE},d}} \right| \cdot \frac{\sin\theta \mathrm{d}\theta}{\Delta d}, \tag{7}$$

where $I^{LS}_{\mathrm{TE},d}(\theta, 550\ \mathrm{nm})$ denotes TE polarized radiation emitted into the angle θ in air from an emissive site at a distance d to the cathode. $d_{(-)}$ denotes the next distance closer to the cathode, depending on the discretization $\Delta d = |d - d_{(-)}|$ of the emitter–cathode distances chosen for the calculation of $V_\theta(d)$. In Eq. (7), normalization with respect to the radiant flux at the particular distance to the cathode is important to distinguish the desired relative variation of the shape of the angular pattern from a variation of the absolute emitted power. In other words, all radiation patterns are normalized to the same area in terms of solid angle and only the relative variation of the characteristics is considered. By this means, $V_\theta(d)$ provides a measure of how distinguishable are the radiation pattern shapes of two neighboring positions, $d_{(-)}$ and d, in the device. Replacing $I^{LS}_{\mathrm{TE}}(\theta, 550\ \mathrm{nm})$ by the TE radiation pattern in the substrate as a function of the substrate angle θ^s and normalizing to the radiant flux in the substrate in Eq. (7) yields the corresponding variation of angular radiation pattern in the substrate as a function of emitter–cathode distance.

The angular radiation pattern variation $V_\theta(d)$ versus emitter–cathode distance is shown in Fig. 4 for both radiation in air and in the substrate. It can be seen that $V_\theta(d)$ is low for almost all emitter–cathode distances, including the case of optically optimized devices, apart from emission from around the radiant flux minimum. The latter feature can be explained by the destructive interference conditions for emission into certain oblique angles, which considerably modulates the angular radiation pattern, as discussed above. Surprisingly, analyzing the substrate radiation pattern yields only little more information, to the emission in air. The radiation in air exhibits even better contrast to the exact emission origin, if the emissive sites are placed around the radiant flux minimum. This might be surprising at first, because one might expect the substrate radiation, containing an extended fraction of the OLED-internal radiation pattern, to yield much more information than the radiation into air. However, the suggested approach is based on observing radiation pattern changes, and the substrate pattern variations are largest at small emission angles. This sensitive interval is expanded in air, because the transition from the substrate into air restricts the observed fraction of the OLED-internal radiation pattern. Hence, the qualitative impression from the shape of the angular emission patterns [Figs. 2(b)–(k) and 3(b)–(k)] is confirmed by the quantitative measure $V_\theta(d)$.

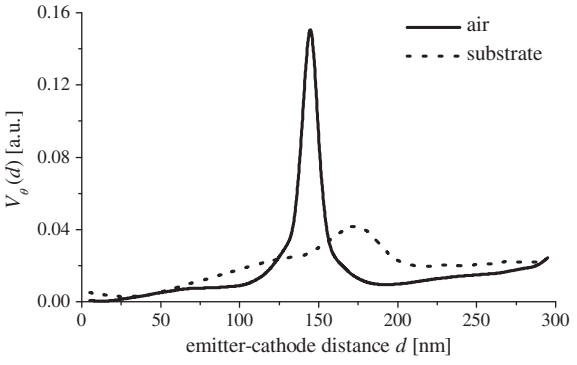

Fig. 4. The variation of the TE polarized angular radiation pattern for $\lambda = 550$ nm in air and in the substrate, respectively, is plotted according to Eq. (7). Maxima of $V_\theta(d)$ correspond to minima of optical outcoupling [see Figs. 2(a) and 3(a)]. Thus, placing the emissive sites around $d \approx 140$ nm and $d \approx 165$ nm, for emission into air and in the substrate, respectively, enables for an accurate determination of the exact emission origin.

Of course, when designing an experiment to measure the internal EL spectrum of a material, relatively weak changes of the interference conditions are desired in order to minimize the influence of the actual position of the emissive sites on the result. Consequently, the emissive sites should be placed around a maximum for optical outcoupling which additionally ensures a high outcoupling intensity.

By contrast, the radiation pattern is most sensitive to the position of the emissive sites at the minimum of optical output where destructive interference conditions apply. We take as an example the following experiment: the EML of a small-molecular device has a width of 10 nm and the exact emission origin is of particular interest. In this case, the ETL thickness should be adjusted in order to match the efficiency minimum in air (corresponding to 140 nm for the present model system). Even analyzing the angular radiation pattern in air in a purely qualitative manner provides information about how the emission zone is balanced. If the angular emission pattern is larger at larger angles, the origin of the emission is at the cathode side of the EML, whereas a larger emission in the perpendicular direction provides evidence for anode-side emission [see Fig. 2(e)–(g)]. Of course, quantitative reverse simulations using an extended spectral range promise even more accurate results.

These monochromatic considerations can be extended in a straightforward manner to the case of real emissive materials for OLEDs with a spectral width of typically about 100 nm, where the layered stack should be designed to match the desired criterion for maximum or minimum outcoupling at the mean wavelength of the spectrum under investigation. As can be seen from Fig. 4, the interference conditions do not change significantly with emitter–cathode distance around the quarter wavelength distance, which implies that the interference conditions do not change significantly with wavelength as well. Consequently, for emitters around the optical maximum the determination of the internal EL spectrum is almost independent of the actual position of the emissive sites, as discussed above. For the profile of the emission zone one would expect to gather more information if the investigated spectral range is extended. However, the condition showing good contrast on the emitter position, corre-

sponding to the $V_\theta(d)$ maximum, is wavelength dependent. This is potentially a positive feature when analyzing extended emission zones but yields no benefit when investigating rather confined emission zones.

The problematic case of measuring the emission profile of broad emission zones, which are typical for polymeric systems, is now discussed. It is essentially critical for such experiments that, in general, positions with good extraction efficiency and thus high far-field contribution possess low sensitivity to the emission origin, as indicated by a low $V_\theta(d)$. By contrast, positions featuring a high sensitivity to the emission origin have only weak contributions to the far-field. In other words, radiation from positions around the efficiency minimum might not be visible in the far-field of the OLED, because it is much weaker than the brighter signal from positions around the efficiency optimum. Although there have been extensive studies on measurements of the profile of the emission zone in polymeric OLEDs recently, this general and problematic issue has not been considered yet [10–12].

3.2. TM polarization: determination of dipole emitter orientation

As discussed above, parallel dipole moments contribute to both TE and TM polarized radiation, whereas perpendicular moments contribute to the TM polarized radiation only [see Eq. (2)]. One basic idea for a dipole orientation measurement is to analyze the TE polarized radiation first and determine the contribution from parallel dipoles to the radiation pattern. Subsequently analyzing TM polarized radiation, the emitter orientation can be adjusted to match TM experiment and simulation.

In order to detect perpendicular dipoles in the TM polarized optical far-field of an OLED, their contributions to the radiation pattern must be sufficiently large compared to the TM polarized contributions arising from parallel dipoles. As a measure of the far-field contribution, the normalized radiant flux ($\Phi_{\mathrm{TM}} = 2\pi \cdot \int I^{LS}_{\mathrm{TM}}(\theta, 550\,\mathrm{nm}) \sin\theta \mathrm{d}\theta$) at $\lambda = 550$ nm of the two TM dipoles embedded in the model OLED stack was calculated as a function of the emitter–cathode distance (see Fig. 5) for radiation into air and in the substrate. Evidently, the emission from parallel and perpendicular emissive sites is governed by opposite interference conditions, discussed in detail in Ref. [13]. A comparison with Figs. 2(a) and 3(a) reveals that emission from ∥TM dipoles shows the same characteristics as emission from ∥TE dipoles.

To quantify the visibility of perpendicular emitters in the TM polarized OLED radiation pattern, we introduce the parameter

$$V_\perp(d) = \frac{\Phi_{\perp\mathrm{TM},d}}{\Phi_{\parallel\mathrm{TM},d} + \Phi_{\perp\mathrm{TM},d}}, \tag{8}$$

giving the relative fraction from ⊥ TM dipole contributions to the overall TM polarized emission in air and in the substrate, respectively, for a given emitter–cathode distance d. The dependence of the $V_\perp(d)$-parameter on the emitter–cathode distance is plotted in Fig. 6. Positions close to the cathode are not suitable for any optical experiment, because they suffer from strong coupling to the surface plasmon mode and the overall outcoupling efficiency is very weak. However, the interference conditions around the optical maximum enhance radiation from parallel dipoles and suppress light from perpendicular emitters. Consequently, the distribution of the dipole moment orientation is almost impossible to obtain using standard, efficient OLED geometries which are optimized for maximum emission, because almost all light generated by perpendicularly oriented emitters is trapped inside the OLED stack. This holds for both the emission in air and in the substrate. By contrast, changing the emitter–cathode distance to the minimum of optical outcoupling yields a large far-field contribution from perpendicular dipole moments accompanied by weaker outcoupling of the radiation from parallel dipoles, which is the desired case for an emitter orientation analysis. Again, this is valid for both, air and substrate emission. Measurements using a glass-hemisphere will yield more information for very large emitter–cathode distances ($d > 150$ nm) only, but offer no benefits compared to an emitter orientation investigation

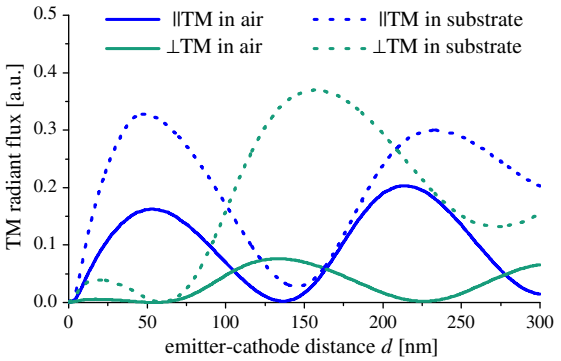

Fig. 5. The normalized TM polarized radiant flux of the two TM dipoles is shown for radiation in air and in the substrate, respectively, as a measure of their far-field contributions. Radiation from parallel and perpendicular dipoles experiences opposite interference conditions, enabling a measurement of the dipole emitter orientation.

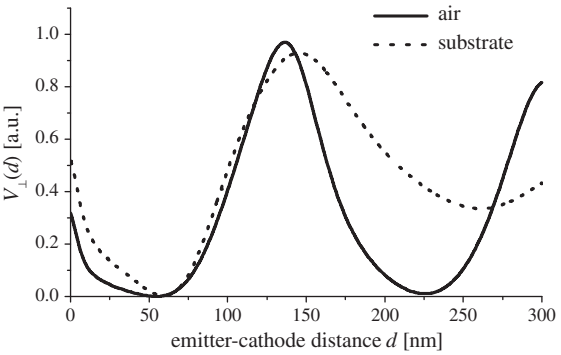

Fig. 6. The contribution of radiation from perpendicular dipoles ($\Phi_{\perp\mathrm{TM},d}$) to the overall TM polarized far-field ($\Phi_{\parallel\mathrm{TM},d} + \Phi_{\perp\mathrm{TM},d}$) in air and in the substrate, respectively, according to Eq. (8) for $\lambda = 550$ nm is shown versus the emitter–cathode distance d. Maxima of $V_\perp(d)$ correspond to minima of optical outcoupling [see Figs. 2(a) and 3(a)]. Thus, positions around $d \approx 140$ nm are favorable for a measurement of the dipole orientation.

based on the radiation pattern in air utilizing a well-adapted OLED stack.

4. Conclusions

In summary, we have proposed general strategies for accessing OLED emitter properties by radiation pattern analyses. Taking advantage of the fact that perpendicular dipoles contribute to TM polarized light emission only, one should analyze TE polarized radiation only if an investigation of internal EL spectrum or emission zone is intended. Provided the OLED layered stack is designed carefully, subsequently analyzing TM polarized radiation yields information about the orientation of the emissive sites.

We have shown that the OLED layered stack design is important for the successful characterization of the emissive sites from radiation pattern measurements. Consequently, well-adapted devices have to be utilized to enable an accurate determination of the *active* optical properties of emissive materials used in OLEDs. In this context, the distance from the emissive sites to the metallic cathode plays a decisive role, as it alters the interference conditions in the device. To illustrate our reasoning, we consider the emitter–cathode distance in terms of device efficiency. Then, placing the emissive sites at a position:

(i) around the emission maximum and analyzing TE polarized radiation allows a determination of the internal EL spectrum,
(ii) around the emission minimum and analyzing TE polarized radiation allows an accurate determination of the emission zone, and
(iii) around the emission minimum and analyzing TM polarized radiation allows a determination of the orientation of the emissive dipoles,

almost independent of the other *active* optical properties, respectively. These rules apply very well to systems where the emissive sites are relatively well confined and the emitter–cathode distance is easily adjustable. Consequently, small-molecular emissive materials can be analyzed in the proposed way. However, the strategies developed are also valid for polymeric materials, where extended emission zones can reduce the contribution of the desired feature to the OLED far-field and thus potentially reduce the quality of the measurement. Considering white OLEDs, the red, green, and blue emissive sites should be analyzed separately, using device architectures adapted to the particular color. However, without loss of generality different molecular moieties can be modeled as a superposition of an appropriate number of emissive species with different emission spectra, emission zones and orientation distributions. Provided the emission spectra are sufficiently distinct, the presented approaches can be extended to analyze all emitters individually. For this purpose additional OLED stacks, featuring ETL thicknesses adapted to the particular color, might be required.

Additionally, we have demonstrated that investigations utilizing a substrate index-matched glass-hemisphere to access the substrate radiation pattern are not necessarily superior to analyses of the emission pattern in air. Glass-hemisphere measurements yield slightly more information only when analyzing extended emission zones, which are problematic in general.

Finally, it is worth underlining again that the proposed concepts are based on adapted OLED stack designs which might differ significantly from common, electrically and optically optimized devices. Hence, one needs to ensure that the emitter properties are unchanged when varying the layered system in order to obtain results which are also meaningful for optimized devices. It has been shown that such an assumption is valid for examples of both polymeric and small-molecular emissive sites [17,19,20].

[27] At this point it is worth noting that Eq. (4) supports different types of ensemble-averaging methods regarding the orientation of the dipole transition moment φ, where the particular character of the emissive species is accounted in the detailed calculation of $\Gamma_{rel}(q,z,\varphi)$ [16]. In this contribution, we assume the orientation of the dipole transition moment φ to be fixed during the process of emission. However, applying different ensemble-averaging methods typically results in small quantitative differences only, which have no qualitative impact on the considerations we present.

ABSTRACT

A near-ultraviolet light emitting diode (LED) consisting of ZnO nanorods/MEH-PPV heterostructure and a layer of ZnS as the modification buffer layer is reported. Specially, the ZnO nanorods are grown on the ZnS hole-injecting buffer layer by hydrothermal method. Then the devices of ITO/ZnS/ZnO/ZnOnanorods/MEH-PPV/Al are prepared. Under forward bias, not only strong near-ultraviolet (N-UV) electroluminescence (EL) at 380 nm of ZnO band edge emission and weak defect-related emissions of ZnO nanorods at 410, 510 and 760 nm are observed, but also the exciton emission of MEH-PPV at 580 nm is detected. Along with increasing the thickness of ZnS film, the emission at 580 nm strengthens. Compared with the device ITO/ZnO/ZnOnanorods/MEH-PPV/Al we have reported in the past, the experimental results show that the suitable insertion of a ZnS thin layer can enhance the N-UV EL. Under the same voltage, the light intensity can be increased up to 10 times more than that of the device without a ZnS layer. Moreover, the turn-on voltage is reduced remarkably. The effect of ZnS as the hole-injecting buffer layer with different thickness on the EL of ZnO nanorods/MEH-PPV heterostructure is investigated.

1. Introduction

Zinc oxide is a promising semiconductor that has a wide direct band gap of 3.37 eV and a very large exciton binding energy of 60 meV at room temperature. Thus, ZnO materials have been regarded as very attractive candidates for the next generation of UV light emission [1]. However, as we known, the *p*-type doping ZnO is always a bottleneck since wide band gap materials usually show a poor doping efficiency. It is an important problem for the application of ZnO based UV LEDs [2,3]. Thus, the *p*-n heterostructures consisting of *n*-type ZnO as the active layer and other *p*-type materials have been introduced, but still lack high efficiency [4–6].

Recently, great focus has been placed on the research of ZnO nanostructures to realise UV light emission. A few studies have been reported on LEDs by using ZnO thin film [7–10], ZnO nanowires [4,11,12], ZnO nanorods [5,6,13,14], or ZnO nanoparticles [15]. Among these studies, low-dimensional nanostructural ZnO has attracted great interest because of its unique physical and chemical properties [16]. For example, ZnO or other semiconductor nanowires or nanorods can offer additional advantages for optoelectronic device applications due to the increased junction area, enhanced polarization dependence, and improved carrier confinement in one dimension [17]. Hsu et al. reported that the *p*-type undoped ZnO nanorods could be obtained by hydrothermal method through adjusting the properties of the seed layer [18]. Light emitting diodes have been created by using this simple and useful fabrication method. However, the electroluminescence of these diodes is weak, particularly the lower UV intensity than that of the visible emission. In order to realise UV electroluminescence, we have reported a device based on ZnO nanorods/MEH-PPV heterostructure in which the polymer MEH-PPV was used as the electron

doi:10.1016/j.orgel.2010.09.018

injection layer. Under DC bias, the N-UV electroluminescence of ZnO at 380 nm was detected [14]. But the intensity of N-UV is weak. In order to enhance N-UV electroluminescence, a layer of ZnS as the modification layer was introduced to the ZnO nanorods/MEH-PPV heterostructure. ZnO nanorods were grown on the ZnS buffer layer by hydrothermal method. The as-grown ZnO nanorods were then used to fabricate the devices of ITO/ZnS/ZnO/ZnOnanorods/MEH-PPV/Al. Under forward bias, these devices emitted a relatively strong N-UV light at 380 nm and weaker visible light. This is a developmental approach in the synthesis of ZnO nanorods on the substrates, and this method shows an innovative feature in the ZnO nanostructure LED field [19,20].

2. Experimental setup

The process of the device preparation is as follows. The indium tin oxide (ITO) glass substrates were cleaned in an ultrasonic cleaner with acetone, ethanol, deionised water sequentially, and then were dried with nitrogen for later use. ZnS thin films with varying thicknesses from 2 to 8 nm were deposited on the ITO substrates (3×3 cm) by thermal evaporation in a high vacuum condition of 2.5×10^{-3} Pa. The ZnO nanorods were grown using a two-step hydrothermal method at low temperature. Firstly, to facilitate the nucleation of ZnO nanorod growth, a seeding layer, prepared with Zinc acetate dehydrate solution, was spin-coated on the substrates. Then, they were annealed at 360 °C for 20 min in ambient atmosphere. The hydrothermal reaction solution for ZnO nanorod fabrication was prepared by mixing 25 mM zinc nitrate hexahydrate ($Zn(NO_3)_2{\cdot}6H_2O$) and 25 mM hexamethylenetriamine ($C_6H_{12}N_4$) in 200 ml of deionised water in a glass beaker. During the growth of ZnO nanorods, the glass beaker was placed in an electrically heated thermostatic water bath and maintained at 92 °C for 15 min. Subsequently, the samples were removed from the solution and washed with ethanol and deionised water repeatedly and annealed for 30 min in ambient atmosphere. A *p*-type polymer poly [2-methoxy-5-(2-ethylhexyloxy)-1, 4-phenylene vinylene] (MEH-PPV) was dissolved in chloroform with a concentration of 5 mg/ml, then spin-coated on as-grown ZnO nanorod layers with a rotation rate of 1200 rpm (rotations per minute). This specific rotation rate was used in order to cover the top of the ZnO nanorods with a thin MEH-PPV layer, and provide a smooth surface for subsequent thin film deposition. About 150 nm thick Al film was deposited by thermal evaporation in a high vacuum condition of 2×10^{-4} Pa. Finally, four devices with different ZnS thicknesses of 2 nm (device 1), 4 nm (device 2), 6 nm (device 3) and 8 nm (device 4) were prepared for comparison. In this experiment, the forward bias on the device indicated that the ITO is anode and Al is cathode. The schematic diagram and energy band structure of the device under forward bias is given in Fig. 1. The morphology of the ZnO nanorods was observed by using field emission scanning electron microscopy (FE-SEM, S-4800). The device testing consisted of measuring the EL spectrum of the devices under different forward bias, and the current–voltage (I–V)

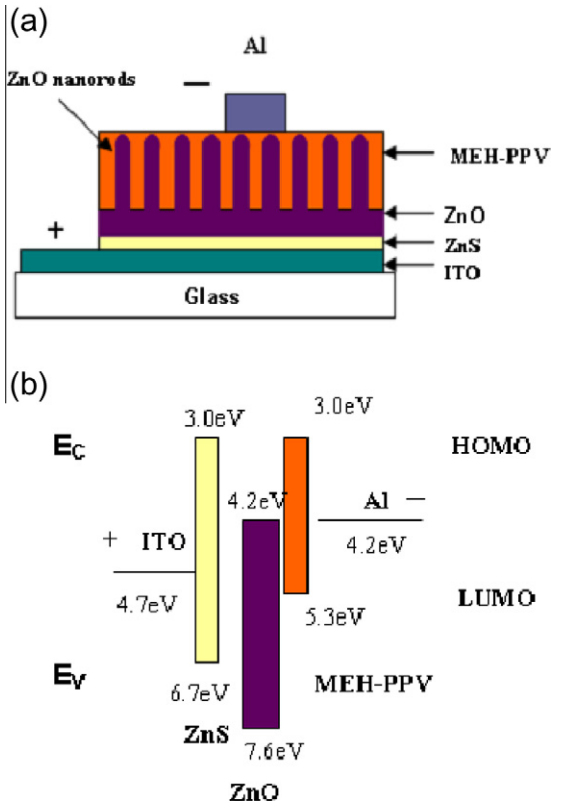

Fig. 1. (a) Schematic diagram of the device (b) Energy band diagram of the device.

and EL characteristics were measured by a system of an ACTON 150 CCD spectrometer, a Keithley 2410, and a Newport 1830-C Optical Power Meter Mainframe controlled by a computer. The photoluminescence (PL) of ZnO nanorods was measured by a fluorolog-3 spectrophotometer. The crystallinity of ZnO nanorods was carried out by X-ray diffraction (XRD) system. All of these tests were carried out at room temperature and in ambient atmosphere.

Device 4: ITO/ZnS(8 nm)/ZnO/ZnOnanorods/MEH-PPV/Al

3. Results and discussion

Fig. 2(a) and (b) present the top-view and cross-sectional SEM of ZnO nanorods grown on the substrate with a 2 nm ZnS layer. It can be observed that ZnO nanorods were compact, and primarily aligned along the perpendicular direction of the substrate. The average diameter and height of the nanorods was about 30 and 100 nm, respectively. The seed layer was about 50 nm thick. Fig. 2(c) and (d) show the top-view and cross-sectional SEM images

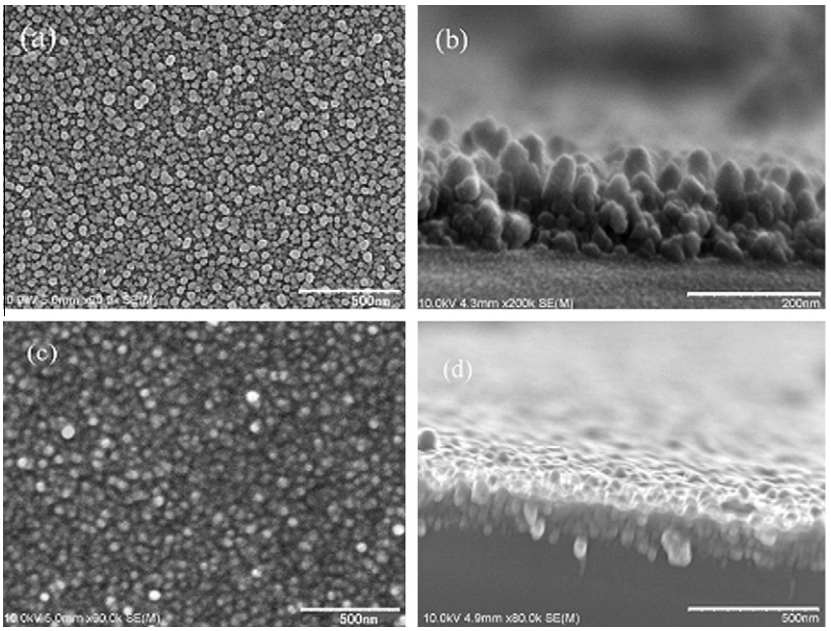

Fig. 2. Top-view (a) and cross-sectional (b) SEM of ZnO nanorods grew on the substrate with 2 nm ZnS layer; Top-view (c) and cross-sectional (d) SEM of ZnO nanorods grew on the substrate with 2 nm ZnS layer after covered by MEH-PPV thin film.

of as-grown ZnO nanorods after being coated with an approximately 30 nm MEH-PPV layer at a rotation rate of 1200 rpm. Moreover, the MEH-PPV layer on the top of every nanorod must be thin (less than 5 nm), which is optimal to allow the electrons to tunnel to the ZnO nanorods and recombine with the holes. However, MEH-PPV should cover ZnO nanorods completely to avoid carrier leakage from ZnO nanorods to the Al electrode directly and form the ZnO nanorods/MEH-PPV *p*-n junction. Unlike the more common process, in these experiments no insulator material was used to fill the interspaces of nanorods.

Fig. 3(a), (b), (c) and (d) show the EL spectra of devices 1, 2, 3, and 4 under different forward biases. From Fig. 3(a) and (b), strong N-UV EL at 380 nm of ZnO band edge emission was observed. The full width at half maximum of this emission was only 25 nm. The turn-on voltage for N-UV electroluminescence was about 14 V for device 1. This value was lower than that reported in reference [14]. In addition, a wide emission with a peak at 510 nm and a weak emission at 760 nm were detected under higher voltage, and regarded as defect-related emissions of ZnO nanorods. In order to make these emission peaks distinguishable, the Gaussian fitting EL of device 1 under 22 V is shown in Fig. 3(e). Another defect-related emission at 410 nm of ZnO and an exciton emission of MEH-PPV at 580 nm were observed. However, there was no MEH-PPV emission detected under low forward bias. Thus, this device was suitable for pure N-UV emission under low bias. Along with the increased voltage, the N-UV light intensity increased faster than other emissions.

Compared with the device with no ZnS as the modification layer [14], the following conclusions can be made: (1) the turn-on voltage of N-UV electroluminescence was reduced from 22 to 14 V. Fig. 1(b) shows the energy band structure of the device under forward bias. From this diagram, it can be seen that the ZnS thin film can lower the hole-injecting barrier by laddering it, and thus the turn on voltage can be reduced. In addition, the thinner MEH-PPV film at the top of ZnO nanorods allowed the electrons to tunnel into the ZnO nanorods more easily, which might also have contributed to the reduction of the turn-on voltage. (2) The MEH-PPV exciton emission at 580 nm couldn't be observed when the voltage was low. The MEH-PPV film was considered sufficiently thin. Most of the electrons could quickly tunnel to the ZnO nanorods even under low bias and recombine with holes. Thus, there was no obvious emission at 580 nm. (3) There were two more defect-related emissions at 410 and 510 nm, which was not reported in reference.

Fig. 4 shows the XRD pattern of the ZnO nanorods grown on the substrate, both with and without 2 nm ZnS thin film (the process of growing ZnO nanorods is same as described above). Only a high intensity of (0 0 2) diffraction peak was detected and implied that ZnO nanorods have a typical wurtzite structure and grow along a c-axis direction perpendicular to the substrate well. However, the diffraction peak of the ZnO nanorods directly grown on the substrate was higher than that grown on the substrate on which a 2 nm ZnS layer had been deposited. This suggests that a ZnS layer affects the vertical alignment and the crystallinity of the ZnO nanorods, and may cause defects in ZnO nanorods [21].

Fig. 5 shows the normalized PL spectrum of as-grown ZnO nanorods. The emissions at 410 and 510 nm were enhanced by the ZnO nanorods grown on the ZnS layer. Thus, it can be confirmed that the insertion of a ZnS thin layer caused the defect-related emissions at 410 and 510 nm of ZnO nanorods.

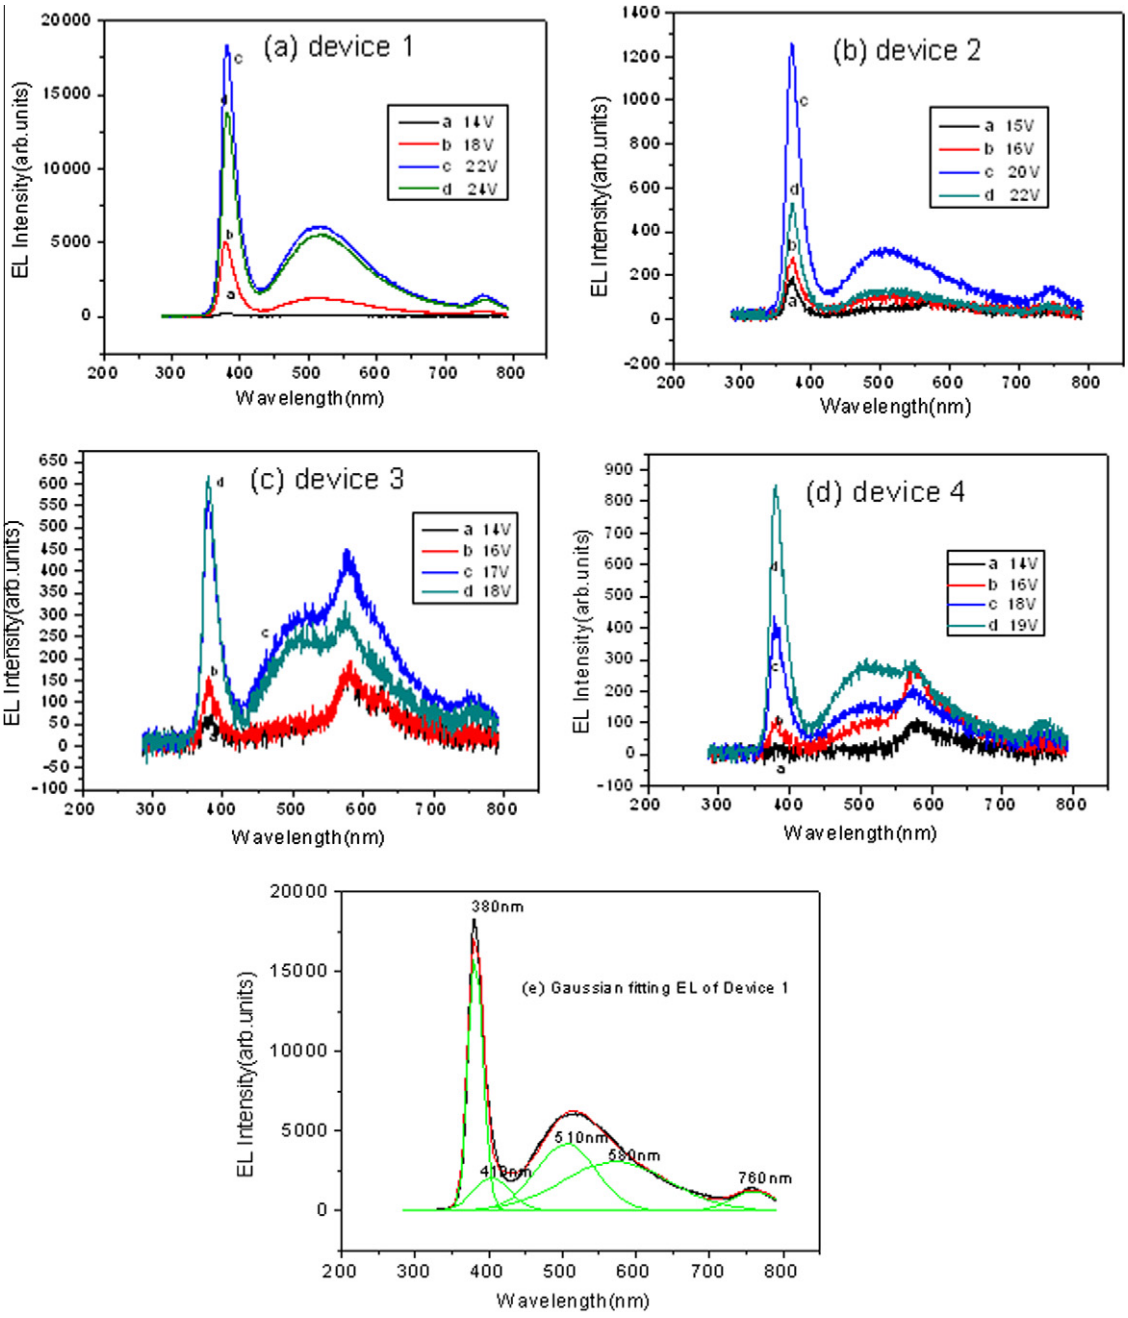

Fig. 3. EL spectra of (a) device 1, (b) device 2, (c) device 3 and (d) device 4 under different forward biases; (e) Gaussian fitting EL of device 1.

From Fig. 3(c), (d) and (e), it can be seen that the exciton emission of MEH-PPV at 580 nm strengthened as the thickness of ZnS film increased. This can be explained as followed: As the thickness of ZnS film increased, a larger portion of applied voltage was dropped on the ZnS/ZnO nanorods. Correspondingly, the portion of applied voltage dropped on the MEH-PPV layer reduced. Thus, the tunnelling probability of electrons decreased. Fewer electrons tunnelled into the conduction band of the ZnO nanorods, and more electron hole recombination occurred in the MEH-PPV layer. In addition, the hole mobility of ZnO was larger than the electron mobility of MEH-PPV. Thus, holes reached the organic layer more quickly compared with devices 1 and 2. As a result, the emission at 580 nm strengthened as the ZnS thickness increased.

Fig. 6(a) and (b) show the I–V characteristics and EL power of devices 1, 2, 3 and 4, respectively. Fig. 6(a) shows that the devices exhibited stable rectifying diode behaviour. The series resistance of device 1 was relatively small, as concluded from its I–V characteristic. When ZnS film

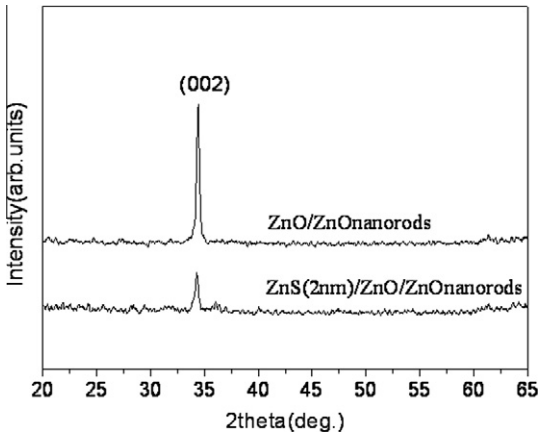

Fig. 4. The XRD pattern of the ZnO nanorods grew on the substrate with and without 2 nm ZnS.

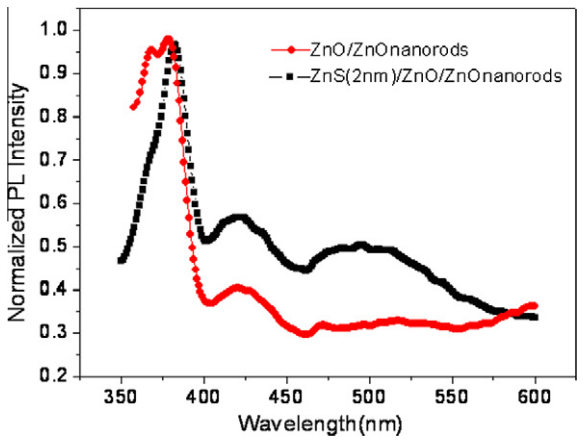

Fig. 5. The normalized photoluminescence spectrum of the ZnO nanorods grew on the substrate with and without 2 nm ZnS (Excitation wavelength is 320 nm).

became thicker, the series resistance of the devices increases. It means that with the increased thickness of ZnS layer, the devices have a decreased current injection. That may be due to the fact that thicker ZnS films resulted in defects in ZnO nanorods and high series resistance in the devices. Under the same forward bias, device 1 had the maximum brightness and the EL intensity could be increased up to 10 times more than that of a device without a ZnS layer. Moreover, the turn-on voltage was reduced remarkably [14]. It was demonstrated that the ZnS buffer layer laddered the hole-injecting barrier, increased the hole injection, and balanced the carrier concentration in the emission layer, all of which contributed to more exciton emission in the ZnO nanorods region. Meanwhile, the intensity of the device weakened as the ZnS thickness increased. From this, it can be acknowledged that excessively thick ZnS film is disadvantageous to the EL of the devices. In addition, the turn-on voltages of devices 2, 3, and 4 were a little higher than that of device 1, which would also be attributed to the excessively thick ZnS film.

4. Conclusions

In summary, it was shown that the suitable insertion of a ZnS modification buffer layer can significantly enhance the N-UV EL of ZnO nanorods/MEH-PPV heterostructure and reduce the turn-on voltage, which can be attributed to a decrease of the hole-injecting barrier and more electron hole recombination in the ZnO nanorods region. When ZnS film is 2 nm thick, the devices ITO/ZnS/ZnO/ZnOnanorods/MEH-PPV/Al show a strong N-UV EL at 380 nm of ZnO band edge emission under DC bias. In addition, not only defect-related emissions at 410 nm, 510 nm and a weak emission at 760 nm of ZnS nanorods were detected under higher voltage, but also an exciton emission of MEH-PPV at 580 nm was observed. However, there was no MEH-PPV emission detected under low forward bias. Also, the exciton emission of MEH-PPV at 580 nm was strengthened when the thickness of ZnS film was increased. The experiment results show that the vertical alignment and crystallinity of the ZnO nanorods grown on ZnS modification layer becomes poor. This affected the EL and I–V characteristics of ITO/ZnS/ZnO/ZnOnanorods/MEH-PPV/Al. The method in this study is a first attempt to improve

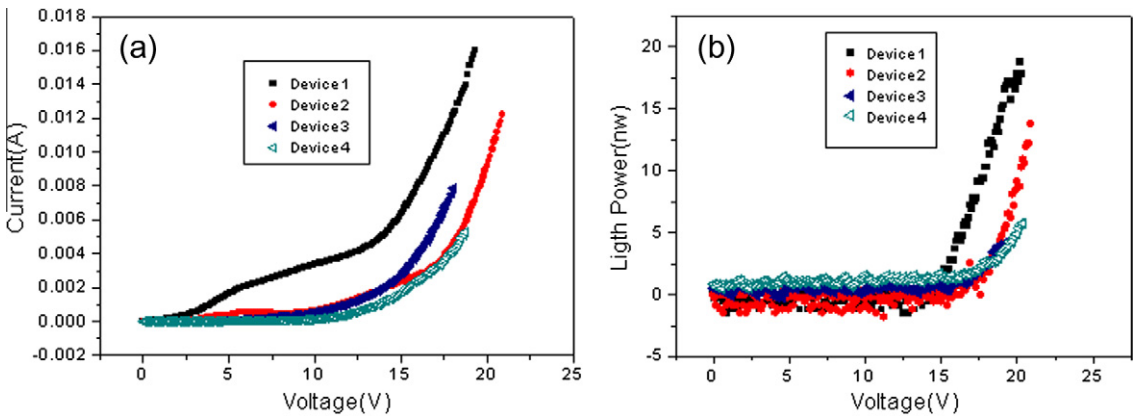

Fig. 6. The I–V characteristics (a) and EL power (b) of devices 1, 2, 3 and 4.

the N-UV EL of ZnO nanorods/MEH-PPV heterostructure and is valuable in the development of growth of ZnO nanorods on the buffer layer, as well as in the improvement of ZnO nanostructure based LED.

ABSTRACT

We present a one-step route for micropatterning a thin ferroelectric poly(vinylidene fluoride-*co*-trifluoroethylene) (PVDF-TrFE) film with both molecular and microstructural crystal control over a large area. The method is based on the static mechanical shearing and subsequent detachment of a film spin coated on pre-patterned Al which has been lithographically prepared on a SiO_2 substrate under appropriate thermal conditions. Selective detachment of the film in contact with the SiO_2 substrate gave rise to micropatterns of PVDF-TrFE film positioned only on the Al regions. Further, the PVDF-TrFE film showed 25-nm-thick crystalline lamellae aligned perpendicular to the shear direction, wherein the *c* axis of the crystals was globally ordered parallel to the shear direction. The sheared and patterned PVDF-TrFE thin films are readily incorporated into non-volatile memory units of metal/ferroelectric/metal capacitors and bottom gate-top contact field effect transistors, leading to arrays of memory devices with enhanced performance.

1. Introduction

Non-volatile memories fabricated from ferroelectric polymers such as poly(vinylidene fluoride) (PVDF) and its copolymers with trifluoroethylene (TrFE) are of great interest among various organic non-volatile memory technologies such as flash [1,2] and resistive type ones [1,3] for potential use in organic information storage, one of the most essential technologies for realization of full organic electronic devices [4–6]. Solution-processed thin ferroelectric polymer films are easily incorporated into both destructive and non-destructive memory elements of metal/ferroelectric/metal (MFM) capacitors and ferroelectric field-effect transistors (FeFETs), respectively [4–12]. The macroscopic polarization of a ferroelectric film is attributed to the cooperative dipole moments pointing from fluorine to hydrogen in the ferroelectric polymer molecules, which are in turn hierarchically self-assembled into the characteristic crystalline structures. Non-volatile switching of the polarization is accomplished by rotating the polymer backbone around the chain axis upon exposure to a large polarization-opposing electric field [5].

There are, in our opinion, two main issues for realizing organic memories based on thin PVDF-TrFE films. First of all, in order to optimize ferroelectric properties such as remanent polarization, operating voltage, retention, fatigue and so on, the degree of crystallinity needs to be maximized. In addition, the effective crystal orientation in the *b* axis should be favorably aligned parallel to the electric field of the PVDF-TrFE [13–15]. Secondly, micropatterning of thin ferroelectric films should be possible

doi:10.1016/j.orgel.2010.10.007

such that microarrays of the memory elements are readily fabricated without harming the intrinsic properties of the PVDF-TrFE.

A globally oriented PVDF-TrFE thin film with effective crystal orientation has been achieved via various techniques which rely on the ability to couple an externally applied field to some molecular and/or supermolecular feature in the polymer. These techniques include crystallographic matching on a surface known as epitaxy [16,17], using a localized thermal gradient [18], directional solvent evaporation [19] and the employment of mechanical fields [20–22]. We have recently demonstrated two approaches for producing highly-ordered crystalline structures of ferroelectric polymer thin films spin coated onto substrates suitable for memory device architecture: high throughput epitaxy of a thin PVDF-TrFE film on a friction transferred poly(tetrafluoroethylene) (PTFE) surface [23] and global orientation of the film by static shear [24]. In particular, the static shear turned out to be very effective for centimeter scale orientation of the ferroelectric polymer without requiring an additional interlayer, which significantly increases the operating voltage.

Although photolithography with subsequent dry and wet etching processes, available in the current semiconductor industry, is the most common and is powerful for micropattern fabrication, it is, in general, not applicable to PVDF-TrFE patterning because the polymer is significantly damaged or suffers alteration of its intrinsic properties under the harsh patterning conditions. Great care should be taken when fabricating patterned structures of PVDF-TrFE using the conventional etching process [25]. Thus, there is a need for a new non-invasive method based on printing technologies. Several techniques have been demonstrated for micropatterning ferroelectric polymers, including microimprinting [26,27], capillary molding [28] and microcontact printing [19]. Ferroelectric blend layers have also been micropatterned by solid state transfer methods in which a thin blend film floated on a water/air interface was deposited onto metal-coated poly(dimethylsiloxane) pre-patterned mold, and, subsequently, both the ferroelectric and metal layers were directly transferred to another metal electrode surface, resulting in arrays of MFM capacitors [29]. A recent work by Sekitani et al. successfully demonstrated printed non-volatile ferroelectric memory for communication system based on solution processes including ink-jet printing [30].

Most of the previous works, including our approaches, are, however, limited to the fabrication of patterned ferroelectric polymers without successful control of crystal orientation in the patterned films. In other words, the micropatterns have semi-crystalline ferroelectric domains that are randomly oriented. It would be ideal to develop a non-invasive printing technique which is able to simultaneously control both the molecular structure and the microstructure of the ferroelectric crystals. Furthermore, the method would ideally have industrial potential when combined with the spin coating process, one of the most desirable methods for large area uniform polymer film formation.

In this study, we demonstrate a new one-step micropatterning technique which allows us not only to fabricate micropatterns of thin PVDF-TrFE films but also to control both the molecular and microstructural orientations of the ferroelectric crystals in the patterned regions. Our method is based on the static-shearing of a PVDF-TrFE film spin-coated onto a lithographically defined Al pre-pattern, followed by selective detachment of the film. Our shear and detachment process allows for the fabrication of a globally ordered crystalline structure of a PVDF-TrFE film on the pre-patterned Al regions in which the crystalline lamellae are globally oriented perpendicular to the shear direction. Furthermore, facile formation of thin patterned ferroelectric films on metallic surfaces with ordered crystalline structure enables us to fabricate arrays of both MFM capacitors and bottom-gate FeFET devices with enhanced memory performance.

2. Experimental section

2.1. Al patterned substrate preparation

Conventional photolithography was used to prepare various Al pre-patterns on SiO_2 substrates. First, a positive photoresist was spin-coated onto a 200-nm-thick SiO_2 grown wafer that had been chemically cleaned. After soft-baking to eliminate residual solvents, the photoresist was exposed to ultraviolet light through a photomask for development. Subsequently, an ~80-nm-thick layer of Al was deposited onto the patterned photoresist by thermal evaporation under a pressure of 10^{-6} mB at room temperature with a deposition rate of ~0.1 nm/s. The photoresist was then completely removed by lift-off. Finally, Al micropatterns with a variety of shapes and sizes were produced on the SiO_2 substrate, including 1.5-μm- and 5-μm-wide lines with periodicities of 5 and 10 μm, respectively, and 2 and 5 μm squares arrayed into a 4 mm symmetry. Hexagons with 2 μm sides were also prepared and arrayed into a 6 mm symmetry. For non-volatile memory devices, alternating Al lines 300 and 700 μm in width with a periodicity of 1500 μm were prepared on SiO_2 substrate through a shadow mask by thermal evaporation under the same conditions as described above.

2.2. Thin film preparation

The PVDF-TrFE with 27.5 wt% TrFE employed in our study was kindly supplied by MSI Sensor, PA. The melting (T_m) and Curie (T_c) temperatures of the polymer were 150 and 80 °C, respectively. PVDF-TrFE solutions in methylethylketone (MEK) with concentrations ranging from 1 to 5 wt% were spin-coated at a spin rate of 2000 rpm for 1 min to form thin polymer films on the micropatterned Al substrates.

2.3. Static shearing process

The same shearing process was applied for the current experiments as were used in our previous experiment [24]. A poly(methylsiloxane) (PDMS) pad 100 μm in thickness and $1.0 \times 1.0\ cm^2$ in size was placed onto the PVDF-TrFE film on a pre-patterned Al substrate. Then, the

samples were fixed onto the bottom heating plate of our lab-made apparatus, were heated above the melting temperature for 30 min, and were then cooled to 140 °C. The sample was subsequently pressurized to approximately 10^5 Pa using a pressure controller, and a lateral force of about 1 N was applied. The resulting shear stress ($\sim 10^4$ Pa) caused the immediate elastic distortion of the PDMS pad and subsequently gave rise to a slow linear displacement from the viscous shear flow of the PVDF-TrFE. The static shear field was also combined with thermal treatments of PVDF-TrFE thin films spin coated and covered with PDMS pad on Al substrate as described in our previous work [21]. A PVDF-TrFE film was heated over its melting temperature during 30 min and subsequently cooled down to 135 °C at which shear force begins to be exerted on the sample with the pressure applied. All shearing experiments were performed within 2 h, and the maximum displacement in our experimental setup was approximately 2 mm with a velocity of 1.0 mm/h. The translation velocity after shear stress was measured to be approximately 300 nm s^{-1}, and the shear rate became 2 s^{-1} with a 150-nm-thick film. The shear field direction was varied with respect to the pattern geometry.

2.4. Ferroelectric property characterization

MFM capacitors were prepared by depositing Al top electrodes 200 μm in diameter onto the sheared PVDF-TrFE thin films previously prepared with alternating 300 and 700 μm Al lines by thermal evaporation under a 10^{-6} mB pressure with a deposition rate of ~0.1 nm/s. Ferroelectric polarization–voltage measurements were performed using a virtual ground circuit (Radiant Technologies Precision LC units).

For the FeFET memory elements, a pentacene active channel and source/drain Au electrodes were sequentially deposited through a shadow mask onto the sheared, patterned PVDF-TrFE thin film on the alternating Al lines for MFM elements at room temperature by thermal evaporation in a vacuum chamber at a base pressure of 9.0×10^{-7} torr. The deposition rates were fixed at 0.2–0.3 Å/s for the pentacene and at 1 Å/s for the Au electrodes. The pentacene and Au films were 60 and 100 nm in thickness, respectively. The pentacene channel length and width were 100 and 200 μm, respectively. The electrical properties of the devices were recorded using semiconductor systems (E5270B, HP4284A, Agilent Technologies). All measurements were performed in a metallic shielded box at room temperature in air.

2.5. Microstructure characterization

The microstructures of the sheared PVDF-TrFE thin films were characterized by field emission scanning electron microscopy (FESEM) (Jeol 2000) and tapping mode atomic force microscopy (TM-AFM) (Nanoscope IV, Digital Instrument). The molecular ordering of the PVDF-TrFE crystals was investigated by two-dimensional (2D) grazing-incidence X-ray diffraction (GIXD). The GIXD was performed on the 4C2 beam line at the Pohang Accelerator Laboratory in Korea (incidence angle: 0.09–0.15°). The samples were mounted onto X and Y axes goniometers. Monochromatized X-rays ($\lambda = 0.1608$ nm) under vacuum were used, and the full range of available incidence angles were employed. The scattered beam intensity was recorded with an SCX: 4300–165/2 CCD detector (Princeton Instruments). Two-dimensional GIXD patterns were obtained in the range of $0 < q_z < 2.33$ Å^{-1}, $0 < q_{xy} < 2.33$ Å^{-1} ($q = 4\pi \sin\theta/\lambda$, with Z perpendicular to and XY parallel to the substrate).

3. Results and discussion

Fig. 1 illustrates the procedure of our patterning technique in which the crucial steps for the successful patterning with the controlled crystalline structure lie in the static shear of a PVDF-TrFE film covered by a PDMS layer and in the selective detachment of the PVDF-TrFE film after shearing. In our previous work [24], good adhesion between PVDF-TrFE and PDMS gave rise to an excellent crystal ordering over a large area under the proper conditions, i.e., a Weissenberg number, the dimensionless product of a characteristic relaxation time and the shear rate, $W_e = \dot{\gamma}\tau > 1$. Additionally, a firm interface should be formed in order to avoid the possible slipping of PVDF-TrFE at the interface with a solid substrate, frequently resulting in mechanical deformation and tearing of the film without proper crystal orientation [24]. The work of adhesion given by $W_{12} = 4\{(\gamma_1^d\gamma_2^d/(\gamma_1^d + \gamma_2^d)) + (\gamma_1^p\gamma_2^p/(\gamma_1^p + \gamma_2^p))\}$ can be a gauge for evaluating the interfacial strengths between 1 and 2 materials, where γ^p and γ^d correspond to the polar and dispersion contributions to the surface energy. The surface tension of a PVDF-TrFE film was obtained from the equation based on the geometric-mean method, described by $(1 + \cos\ \theta_t\ )\ \gamma_t = 2\{(\gamma_t^d\gamma_s^d)^{1/2} + (\gamma_t^p\gamma_s^p)^{1/2}\}$ [31], where θ is the contact angle of a testing liquid on the PVDF-TrFE surface, and γ_t and γ_s are the surface energies of the testing liquid and the solid surface, respectively. Water and ethylene glycol were chosen as the test liquids to measure the contact angle on the surface. The resulting $\gamma^d_{\text{PVDF-TrFE}}$ and $\gamma^p_{\text{PVDF-TrFE}}$ of the PVDF-TrFE film calculated from the contact angle measurement were 35.5 and 1.5 mJ/m^2, respectively, slightly lower values compared to the 38.6 and 2.6 mJ/m^2 of the PVDF [32].

We employed various substrates (metals, oxides and polymers) to investigate adhesion with PVDF-TrFE, as shown in Table 1. The surface energies of those substrates were obtained either from the literature or from experiments, similar to that performed for PVDF-TrFE. Both the surface energies and the calculated adhesion values for the PVDF-TrFE surface are summarized in Table 1. As shown, most metallic substrates have adhesion values close to that of a homogeneous interface between two PVDF-TrFE layers (~75 mJ/m^2). Recalling that excellent orientation of the crystalline PVDF-TrFE lamellae was achieved on an Al surface in our previous work [24], good adhesion of PVDF-TrFE with a solid substrate is essential for the shear-induced ordering of the ferroelectric crystals. In order to confirm this, we also sheared several hundred-nanometer-thick PVDF-TrFE films on both Ag and Au substrates and again observed excellent crystal orientation

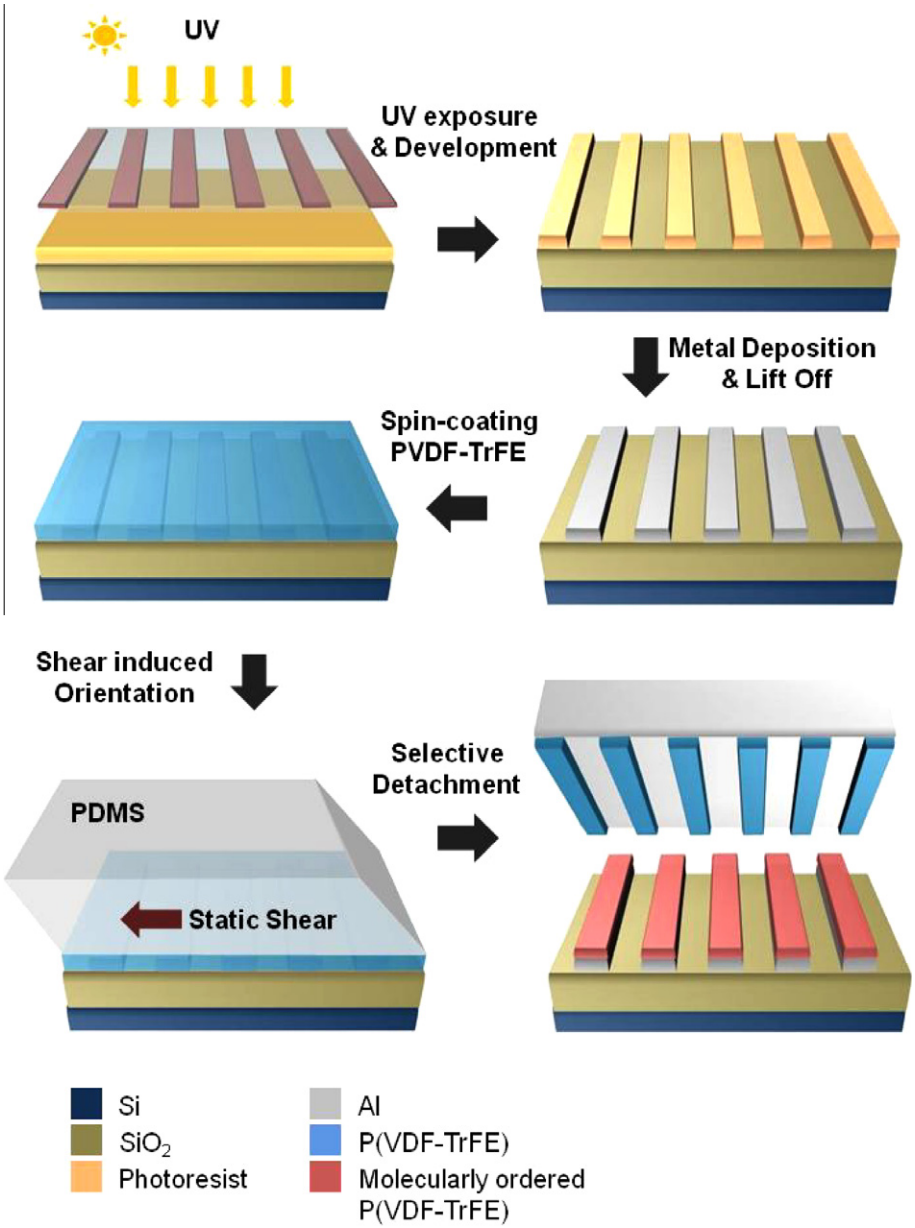

Fig. 1. (a) A schematic diagram of a one-step micropatterning process of a thin PVDF-TrFE film by selective shear and detachment. A thin PVDF-TrFE film is spin-coated onto an Al micropattern defined on SiO_2 substrate by conventional photolithography and lift-off. The static shear of the film with a PDMS pad and subsequent removal of the pad result in a micropatterned PVDF-TrFE selectively on the pre-patterned Al regions in which crystalline PVDF-TrFE lamellae are highly aligned perpendicular to the shear direction, with the *c*-axis of the crystals parallel to the shear field.

over a large area, confirmed by both electron micrographs and GIXD results (see Supporting Information). The edge-on crystalline lamellae of the PVDF-TrFE were well aligned perpendicular to the direction of the shear field on both the Au and Ag substrates. On the other hand, other substrates including SiO_2, Al_2O_3, ITO and PVP have relatively lower adhesion values with thin PVDF-TrFE films. In particular, SiO_2, which has the lowest adhesion value, gave rise to a significantly deformed and torn film with randomly ordered crystals after static shear, implying that the shear field generated from the PDMS layer was not effectively transferred to the PVDF-TrFE film due to slippage of the film on the substrate.

The different shearing behaviors of the PVDF-TrFE film, which depended on the surface properties of the substrates, prompted us to introduce a patterned substrate composed of two different materials having extremely different adhesions with PVDF-TrFE. For instance, alternating periodic lines of Al were prepared on a SiO_2 substrate by conventional lithography. A PVDF-TrFE thin film was spin-coated over the entire pre-pattern, and a shear field was subsequently applied using the PDMS

pad. Thereby, we envisioned that the shear field would effectively be exerted onto the pre-patterned Al regions, while the films on the SiO_2 regions would selectively detach from the surface after shearing. Our process thus allows for the one-step fabrication of a micropatterned PVDF-TrFE in which both the molecular structure and the microstructure were precisely controlled by shear direction, as shown in the schematic of Fig. 1.

Micropatterned PVDF-TrFE films were successfully obtained on a 5 μm Al line patterned substrate by our one-step shear and detachment process, as shown in an optical microscopy image in Fig. 2a. A cross-polarized image in the inset exhibits highly birefringent periodic lines of PVDF-TrFE, arising from its crystalline domains. The TM-AFM topography image in Fig. 2b clearly displays highly oriented crystalline lamellae of approximately 25 nm in width aligned perpendicular to the shear direction. We also confirmed the crystal orientation by GIXD, as shown in the inset, in which there are two distinguishable diffraction peaks at 13.5 nm^{-1} (i.e., ≈4.6 Å), on the meridian of the diffraction pattern, and 60° from the meridian. As described in our previous work, these two reflections resulted from the PVDF-TrFE crystal phase having an orthorhombic lattice where (2 0 0) and (1 1 0) have nearly equal spacings. This also indicates that the *c*-axis of the PVDF-TrFE crystals is predominantly parallel to the shear direction. Combined with our previous results on a flat Al substrates [24], the schematic in Fig. 2c depicts the molecular and microstructural orientations of PVDF-TrFE lamellae on an Al pattern after the one-step shear and detachment process.

A SEM image of the patterned PVDF-TrFE film in Fig. 2d again shows the global orientation of the PVDF-TrFE crystalline lamellae perpendicular to the shear direction, which occurs only at the Al lines. There is almost no residual PVDF-TrFE over the large area SiO_2 region, as shown the inset of Fig. 2d. Our patterning technique works well even when the width of an Al line was reduced to 1.5 μm, as shown in Fig. 2e. AFM images both in height (Fig. 2e) and phase contrast (the inset of Fig. 2e) clearly exhibit well aligned crystalline PVDF-TrFE lamellae on Al line patterns with a periodicity of 5 μm. In this case, however, the line edge became slightly irregular, possibly due to the non-uniform detachment of the film along such a narrow line. The confined crystalline lamellae look very straight and perpendicular to the line (Fig. 2e) compared to those in the larger line pattern in Fig. 2d which appear a little wavy. We also employed a two-dimensionally patterned Al substrate consisting of hexagons, with a 2 μm inside length, arrayed into a 6 mm symmetry, as shown in Fig. 2f. Micropatterned PVDF-TrFE thin films were also developed on Al patterned regions by a one-step shear and detachment process. A magnified image of an individual hexagon in the inset of Fig. 2f shows highly ordered crystalline lamellae aligned perpendicular to the shear direction and confined in the hexagon. In this case, the edges of the hexagon are not perfectly defined due to inhomogeneous detachment of the film in the SiO_2 regions.

Our micropatterning technique illustrated very effective control of the orientation of the PVDF-TrFE crystals with respect to the geometry of the pre-pattern, since the static shear, which always results in the crystalline lamellae being oriented perpendicular to the shear direction, can be easily applied in any direction regardless of the pattern geometry. For instance, the static shear direction was readily changed to be either parallel to or perpendicular to the line axis of the periodic line pre-pattern, as shown in Fig. 3a and b. It is apparent that the ordered crystalline lamellae were formed perpendicular to the line edge when shear was applied along the patterned line axis in Fig. 3a, while the ordered lamellae were all aligned parallel to the line edge upon shearing perpendicular to the line axis in Fig. 3b. The control of the lamellae orientation in the patterned domains was successfully achieved with 2D square-shaped pre-patterns in Fig. 3c and d. When the shear was applied parallel to the side of the square patterns 5 μm in the length, as indicated with an arrow in Fig. 3c, the crystalline lamellae were well oriented parallel to the two sides of the square patterns and, at the same time, perpendicular to the other two sides, as shown in the inset of Fig. 3c. Interestingly, the shear field applied diagonal to the direction of the square pattern, i.e., tilted 45° to each side of the square pattern, gave rise to the lamellae of PVDF-TrFE aligned with the 45° tilted direction against all sides of the square pattern, as shown in the inset of Fig. 3d. Highly birefringent individual patterned domains of Fig. 3d indicate the existence of ordered PVDF-TrFE thin films on the Al patterned regions after our process. It should be noted, however, that there are some crystalline lamellae grown from the edges of 2D hexagons or squares, as evidenced in Fig. 2f and d, respectively, possibly due to the nature of the highly defective pattern edge between Al and SiO_2 at which PVDF-TrFE may trans-crystallize with the directionally grown crystals.

Although the oriented PVDF-TrFE and PVDF crystals were achieved via confinement of the crystals in either micron or nanometer scale templates, the facile control of the crystal orientation of PVDF-TrFE with respect to the geometry of a micropattern by the direction of the static shear field has only rarely been demonstrated. The orientation of the polymer crystals confined into micron or nanoscale templates mainly depends upon the interfacial interaction

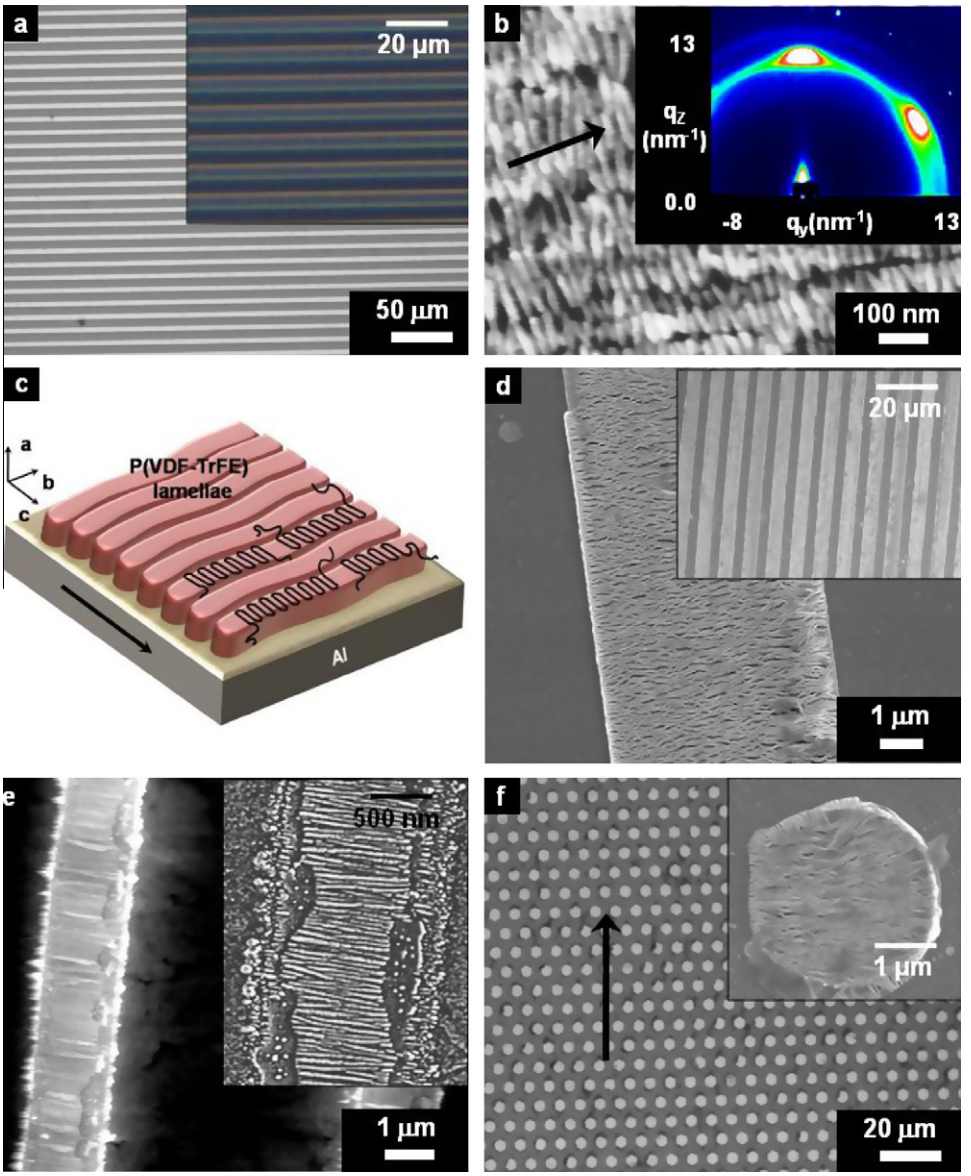

Fig. 2. (a) An optical microscopy image of a PVDF-TrFE film sheared at 140 °C on 5-μm-wide Al lines patterned on a SiO_2 substrate. The inset shows a cross-polarized image of the sample. (b) A TM-AFM image in height contrast of the sheared and micropatterned PVDF-TrFE on a pre-patterned Al substrate where the semi-crystalline PVDF-TrFE lamellae 25 nm in width are highly ordered. A 2D GIXD pattern from a sheared PVDF-TrFE thin film is shown with the incident angle parallel to the shear direction in the inset of (b). (c) A schematic illustration of a PVDF-TrFE film ordered by static shear on an Al surface. The crystalline lamellae and the *c* axis of the crystals are oriented perpendicular and parallel to the shear direction, respectively. (d) A FESEM image of the sample in (a). The inset of (d) exhibits the patterned PVDF-TrFE over a large area. (e) A TM-AFM topography image shows highly ordered PVDF-TrFE produced by the shear field on Al line patterns 1.5 μm in width. An AFM image in phase contrast of the sample is also shown in the inset. (f) A bright field optical microscopy image of a PVDF-TrFE sheared and micropatterned on hexagonal Al pre-pattern. An individual hexagon with the highly ordered crystalline lamellae of PVDF-TrFE is shown in the inset of (f).

between the template surface and the polymer crystal. In general, the polymer crystals tend to grow from a specific unit cell surface preferential to the template surface. For example, the PVDF crystalline lamellae were always aligned parallel to the pore direction of the anodic aluminum oxide (AAO) when they were confined and re-crystallized from the melt state [36]. In our previous work, we also achieved crystalline PVDF lamellae aligned perpendicular to the line pattern when the crystals were molded by capillary printing [37]. As noted, it would be difficult to change the crystal orientation with respect to the pattern geometry without further chemical modification of either the polymer crystals or the template surface. Our shear and detachment process can be one effective way to overcome this issue.

The highly ordered crystalline domains of PVDF-TrFE preferentially formed on a patterned metallic Al surface were readily incorporated into non-volatile ferroelectric

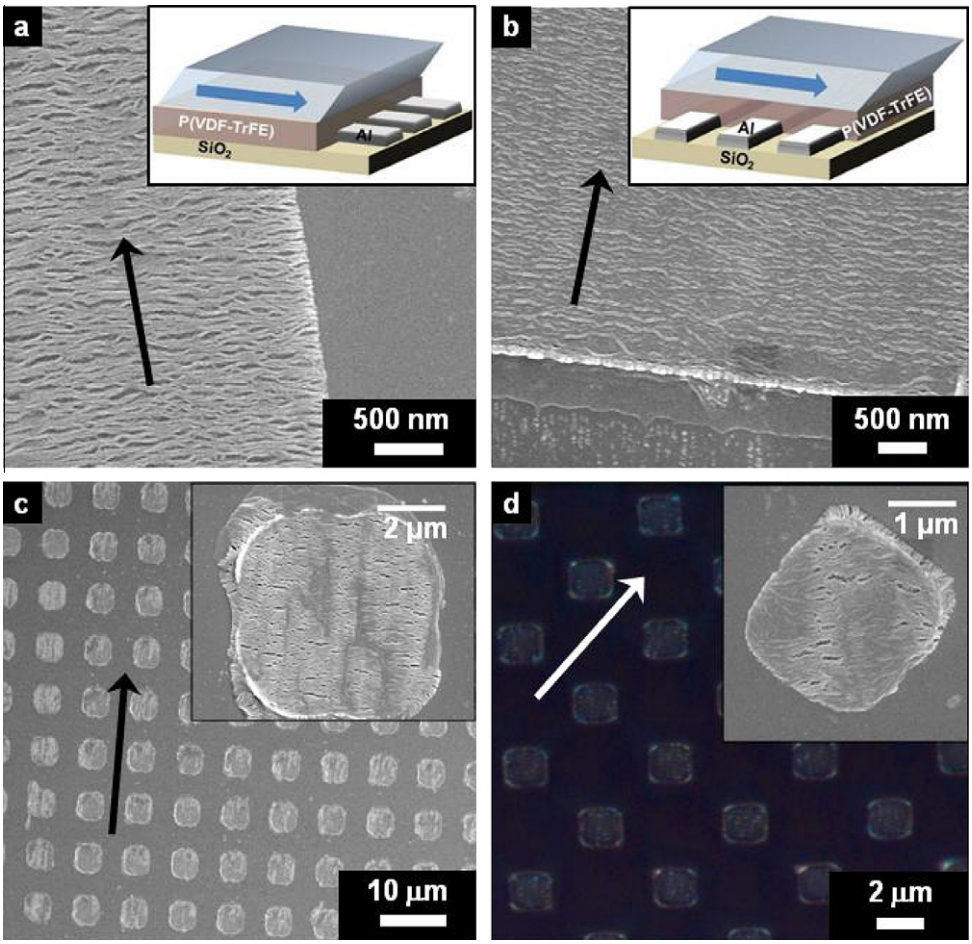

Fig. 3. FESEM images of thin PVDF-TrFE film sheared with the direction (a) parallel and (b) perpendicular to pre-patterned Al lines. The inset of (a) and (b) exhibit the schematics of shear direction with respect to the orientation of the Al lines. (c) An FESEM image of a micropatterned PVDF-TrFE film sheared in the direction indicated with an arrow on 5 μm Al squares. An individual domain highlighted with the ordered crystalline lamellae is shown in the inset. (d) A cross-polarized OM image of a micropatterned PVDF-TrFE film on 2 μm square pattern when the shear field was applied diagonal to the square, as indicated with an arrow. An individual domain with ordered crystalline lamellae is shown in the inset. The crystalline PVDF-TrFE lamellae are always aligned perpendicular to the shear direction regardless of the geometry of the pre-pattern.

memory unit devices such as metal/ferroelectric polymer/metal (MFM) capacitors and bottom gate ferroelectric field effect transistors (FeFETs). Our method allowed for the fabrication of arrays of both devices containing controlled crystalline PVDF-TrFE domains, as shown in Fig. 4a and c. First of all, arrays of Al/ordered PVDF-TrFE/Al capacitors were formed on alternating Al line patterns of 300 and 700 μm on SiO_2 substrate by our one-step shear and detachment method, as shown in Fig. 4a. The static shear on a spin-coated PVDF-TrFE film was applied in the line direction, and Al top electrodes 200 μm in diameter were subsequently deposited by thermal evaporation. Since there was no PVDF-TrFE on the SiO_2 substrate remaining after the shear process, the ferroelectric capacitors were formed in only the regions of the Al bottom electrodes on which the crystalline PVDF-TrFE lamellae were well aligned perpendicular to the shear direction.

Fig. 4b exhibits two different ferroelectric hysteresis loops as determined by polarization-voltage measurements obtained from two different sets of capacitors fabricated on Al bottom electrode at the same time: one with 150 nm thick sheared PVDF-TrFE and the other with non-sheared PVDF-TrFE. MFM capacitors with non-sheared PVDF-TrFE were prepared from the area of a spin-coated film not in contact with the PDMS pad during shearing at appropriate thermal conditions. At sufficient voltage sweep between ±20 V, the remanent polarization (P_r) of 6.49 μC/cm^2 and the coercive voltage (V_c) of 7.91 V, which corresponds to coercive field of approximately 50 MV/m, were obtained from the capacitor measurement with the sheared film. On the other hand, the capacitor with the non-sheared film showed a lower P_r of 2.94 μC/cm^2 with a similar V_c of 7.9 V. The higher P_r value of the sheared PVDF-TrFE arose from the orientation of the crystalline lamellae, as reported in our previous work [13]. Since the PVDF-TrFE thin films in all of our samples were pre-melted before shearing at 140 °C, the thin PVDF-TrFE film without the shear field generally consisted of face-on lamellae whose *c* and *b* axes were aligned normal and parallel to the substrate, respectively [22]. The ineffective orientation

(b) Polarization P vs. applied voltage V hysteresis loops of Al/PVDF-TrFE/Al capacitors from the sheared region and the outside (not-sheared) region, with a thickness of approximately 160 nm. (d) I_{SD}–V_G transfer curves of the FeFET with highly ordered PVDF-TrFE (square) and the outside (circle) region on an Al gate substrate. The drain voltage V_D, channel length L, and width W are −5 V, 100 and 200 μm, respectively. (e) Data retention of a FeFET memory with pentacene measured with the ON state drain current taken per second. The currents were detected at zero gate voltage with the continuous drain voltage of −5 V after single voltage pulse of −35 V for ON current.

of the b axis with respect to the electric field resulted in a low P_r in the non-sheared sample. In contrast, the sheared PVDF-TrFE film with the oriented edge-on lamellae effectively rotated its permanent dipoles upon exposure to an electric field, leading to the high P_r.

For the fabrication of the arrays of FeFETs with patterned and sheared PVDF-TrFE films, a 300-nm-thick ferroelectric film was spin-coated onto a 700-μm-wide Al line pattern in order to prevent gate leakage between the gate and drain electrodes. Each Al line pattern, on which ferroelectric PVDF-TrFE crystalline lamellae were oriented, served as a bottom gate, as shown in Fig. 4c. The subsequent thermal deposition of semi-conducting pentacene as an active channel and Au as the source and drain electrodes was performed using shadow masks on micropatterned PVDF-TrFE films on the Al line pattern. The photograph and optical microscopy images of Fig. 4c and the inset in Fig. 4c represent the arrays of FeFETs and the top view of an individual device, respectively. The fabricated FeFET exhibits a characteristic hysteresis arising from the bistability of the ferroelectric PVDF-TrFE film in the current between the source and drain when the gate voltage was applied, as shown in Fig. 4d. As the gate voltage was increased, holes accumulated at the interface between the pentacene and the oriented PVDF-TrFE, after which, the On state was achieved when I_{DS} increased to

1×10^{-8} A as indicated by an arrow in Fig. 4d. Although the gate voltage was zero, I_{DS} still remained in the On state due to the remanent ferroelectric polarization of the PVDF-TrFE. When sufficient positive voltage was applied to rotate the dipole of the PVDF-TrFE, the device turns to the Off state. The On/Off bistability of the FeFET increases with programming gate voltage sweep and was maximized of approximately $10^{2.6}$ under ambient conditions with a gate voltage sweep of ±35 V. Further increase of program voltage sweep did not significantly change the value. In order to examine retention properties of On state of a FeFET device, we measured I_{DS} of written On state under zero gate bias with a constant V_{DS} of −5 V after programming at 35 V. On current taken per second is not significantly altered even after period longer than 4000 s as shown in Fig. 4e. It should be noted that our retention measurement last approximately an hour due to air-sensitive pentacene active channel in our FeFETs without additional passivation. Extrapolation of the current with time allows us to expect long time data retention capability of our device as long as the chemical and physical properties of pentacene are preserved without environmental degradation.

Our FeFET with the sheared PVDF-TrFE film operated at gate voltage sweep of ±35 V even without an additional interlayer, which helped to reduce the gate leakage [38]. We also compared the device performance of FeFET containing the sheared film with that of a non-sheared film. The *I*–*V* characteristics of FeFET with non-sheared PVDF-TrFE exhibited notably worse device performance in which the On/Off bistability ratio was approximately $10^{1.4}$, or ten times less than that of the device with the sheared film, as shown in Fig. 4d. Due to many structural defects and large surface roughness arising from semi-crystalline grain–grain mismatch, pinholes and residual solvent trapped in the film, a thick ferroelectric gate insulator is often required to minimize the electric leakage, resulting in high operating gate voltage. Most of previous studies suggest insertion of various interlayers between gate electrode and ferroelectric layer including SiO_2 [39], poly(vinyl phenol) [29,40], and poly(styrene-random-methylmethacrylate) copolymer [38]. For low voltage operation of a device, one should design an interlayer as thin as possible with high capacitance. Our shear and detachment method seems beneficial for reducing surface roughness of a film because a PVDF-TrFE film was flattened out under a PDMS mold during shearing process. In fact, surface of a sheared film is lower in roughness than that of non-sheared one. Highly aligned crystalline domains by shear method may be also efficient for reducing leakage current possibly due to fewer structural defects. The performances of memory devices with sheared and non-sheared films are summarized in Table 2.

Table 2
Device performances of MFM capacitors and FeFETs with PVDF-TrFE films, based on shearing and non-shearing process.

Region	P_r (μC/cm^2)	V_c (V)	ON/OFF	Memory window
Sheared	6.4	7.9	400	26
Non-sheared	2.9	7.9	25	17

All device performances were based on the mean value from three different sets of samples.
Each set of samples was made from the same batch.

4. Conclusions

We developed a facile one-step micropatterning technique for ferroelectric PVDF-TrFE film in which each patterned domain has highly oriented crystalline lamellae of PVDF-TrFE due to selective static shear and detachment. The proper choice of pre-patterned surfaces based on the adhesion with PVDF-TrFE allowed us to orient the crystalline lamellae perpendicular to the shear direction, with the *c* axis of the crystals preferentially oriented parallel to the shear direction on good adhesive regions. At the same time, the film selectively detached from poorly adhesive regions, leading to a micropatterned PVDF-TrFE with controlled molecular structures and microstructures. Our method is also beneficial because the orientation of crystalline lamellae is able to be readily controlled regardless of the micropattern geometry simply by changing the shear direction with respect to the geometry of the prepattern. Arrays of non-volatile MFM and FeFET memory units with patterned and sheared PVDF-TrFE thin films exhibited excellent device performances with both high P_r and On/Off bistability ratio in MFM and FeFET, respectively, compared to those with non-sheared PVDF-TrFE. Our patterning capability in a few micron level can potentially make it possible to realize higher density memory than other state-of-art printing techniques of ink-jet and screening printing.

ABSTRACT

A detailed method for air-processed, inverted Organic Photovoltaic (OPV) devices using lamination of the metal electrode with a doped conducting polymer adhesive is presented. A poly(3-hexylthiophene) (P3HT) - [6,6] phenyl C_{61} butyric methyl ester (PCBM) bulk heterojunction is used, with a solution-processed ZnO electron collection layer. The top contact consists of modified polyethylene dioxythiophene:polystyrene sulfonate (PEDOT:PSS) that is spin-coated onto a Ag electrode, and the entire structure is laminated onto the active layer. Lamination produces devices with 3.19% power conversion efficiency at 1 sun illumination, which is higher than the value for control devices produced with the standard sequential process with an evaporated top metal electrode. The laminated interface yields an ohmic contact, as shown by the high fill factor and low series resistance of the laminated devices compared to devices with a thermally evaporated top metal electrode. We examine the lamination parameters and their effect on device performance, and we identify the treatment of the adhesion layer to be one of the more important parameters to control for efficient devices. The optimized protocol described here allows one to fabricate efficient inverted OPV devices in air, without the need for an expensive, high quality evaporation chamber for top contact deposition.

1. Introduction

Recent progress on materials optimization for organic photovoltaics (OPV) has resulted in efficiencies exceeding 8% [1]. While these advances bring the technology closer to commercialization, there is also strong motivation to improve the processing techniques for the fabrication of these devices. Of particular concern is compatibility with large-area manufacturing on flexible substrates and encapsulation for mechanical robustness and stability against degradation [2]. Due to the nature of the polymeric materials involved in OPV, unconventional methods of fabrication that encompass these traits become possible. One of these methods is the simple lamination (“gluing”) of two parts of the device to finish the final OPV structure, as was shown over a decade ago for polymer–polymer bilayers [3] and was recently demonstrated for polymer-fullerene bulk heterojunctions [4,5]. In contrast to lamination of inorganic PV that is performed to encapsulate a finished device, the OPV lamination process brings two active elements of the device into contact with the goal of forming a functioning charge-collecting interface, as shown in Fig. 1.

In this paper we report on OPV devices fabricated in-air with a hot press lamination process. Lamination as a method to fabricate OPV has several potential advantages over conventional bottom-up fabrication. First, the processing step of thermal evaporation of a metal onto the active layer is eliminated, as the metal electrode is now deposited onto a bare substrate. Thermal damage of the active layer has been proposed to occur during conventional metal evaporation, and high parasitic resistances have been measured

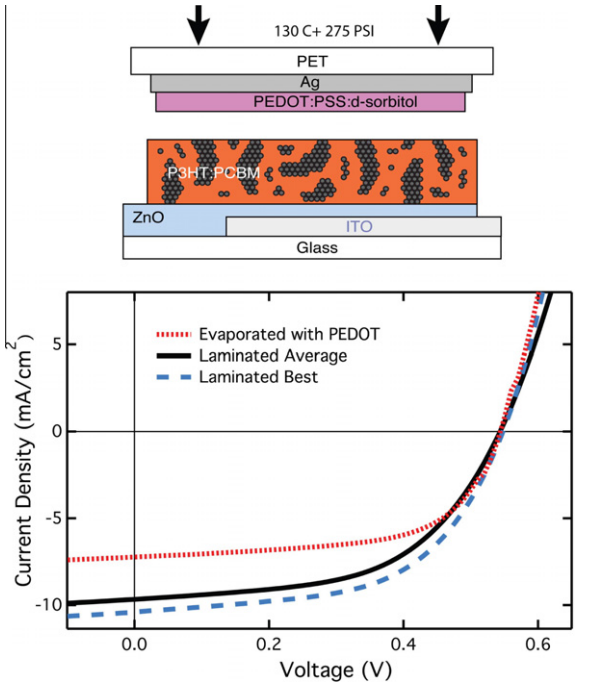

Fig. 1. The laminated device structure and typical *J–V* curves of inverted OPV devices made by hot press lamination (solid black) compared to ones with thermally evaporated top contact (dotted red). The best performing laminated device is also shown (dashed blue). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this paper.)

in evaporated metal-organic interfaces, compared to laminated ones [6]. It has been shown that the rate of metal evaporation onto a polymer:fullerene active layer is an important determining factor for the efficiency of the device [7]. Therefore, unless one has access to a high quality (and potentially expensive) thermal evaporation system that allows precise control of the evaporation rate, the fabrication of consistently performing inverted OPV devices may be problematic. As we will show, lamination enables the in-air fabrication of devices with power conversion efficiencies equivalent to evaporated contact devices fabricated in parallel. Second, lamination produces a self-encapsulated device that is mechanically protected on both sides. Utilization of flexible substrates with good oxygen and moisture barrier properties should also result in enhanced lifetimes of laminated devices. Third, the methodology presented here allows one to prepare, optimize and characterize two parts of the device independently before bringing them to contact. The method is compatible with roll-to-roll processing on flexible substrates and with solution-processed metal electrodes [8]. Finally, lamination provides a method to bring organic materials to device-grade electrical contact that can be applied to various Organic Electronic devices beyond OPV.

To demonstrate hot press lamination we use the prototypical poly(3-hexylthiophene) (P3HT) – [6,6] phenyl C_{61} butyric methyl ester (PCBM) bulk heterojunction in an inverted geometry, [7,9–11] using a solution-cast Zinc Oxide (ZnO) underlayer as the electron collecting contact and a laminated polyethylene dioxythiophene:polystyrene sulfonate (PEDOT:PSS)/Ag layer as the hole collecting top electrode. The device structure is shown in Fig. 1. The devices reach 3.19% power conversion efficiency at 1 sun, and their high fill factors (typically over 0.55) relative to evaporated devices indicate good electrical contact between the laminated layers. We present studies of the effect of various parameters of lamination on device performance as well as demonstrate the processing steps that are important and must be carefully controlled in order to consistently obtain efficient devices.

The two parts of the device, one on glass and the second on a flexible polyethylene terephthalate (PET) substrate, are fabricated in air as follows. A glass slide with patterned ITO is sonicated in acetone and isopropyl alcohol, then treated with an oxygen plasma for 5 min. Zinc oxide (ZnO) is deposited from zinc acetate solution followed by thermal conversion at 300 °C in air [7]. The active layer is 320 nm thick and it is spun from a 1:1 weight ratio of P3HT:PCBM dissolved in chlorobenzene with 2% dibromooctane added to promote phase separation without the need for solvent or thermal annealing [12,13]. On the PET film, 100 nm of silver is thermally deposited, followed by a 40 nm spin-coated film of PEDOT:PSS. For the best devices the PEDOT:PSS was doped with 10% by weight d-sorbitol [14], unless otherwise stated. The PET substrate is then annealed at 115 °C for varying annealing times as discussed below. The two parts of the device are then placed in contact as shown in Fig. 1, and placed in a hydraulic hot press for lamination. Both top and bottom plates of the press are preheated to 130 °C (verified within 2%) and the sample is pressed with 1.9 MPa (275 psi) of pressure for 5 min. Control devices were fabricated in parallel with evaporated top Ag contacts by spin coating PEDOT:PSS on top of the P3HT:PCBM active layer and annealing at 130 °C, followed by thermal evaporation of 100 nm Ag. To facilitate adhesion of the PEDOT:PSS layer in this case, the active layer was exposed to a mild oxygen plasma treatment.

Current–voltage (*J–V*) curves are measured on an AM 1.5G solar simulator with a Xenon lamp calibrated to 1 sun intensity. The device area of 0.11 cm^2 defined by the electrode geometry is inaccurate because of the high conductivity of the doped PEDOT:PSS layer, so an aperture was used to define a device area of 0.0517 cm^2 [15,16]. It was verified that the external quantum efficiency (EQE) of devices integrated with the AM 1.5G spectrum reproduces the short circuit current density with a 10% accuracy. Although an aperture is unnecessary for evaporated contact devices, the evaporated contact control devices were apertured to .0401 cm^2 for a more accurate comparison to the laminated contact devices. Aperturing evaporated contact devices to 0.0401 cm^2 from 0.11 cm^2 decreases their open circuit voltages (V_{OC}) and increases fill factors (*FF*) while keeping the short circuit current (J_{SC}) constant. The efficiency is consistent within error of the measurements.

Typical *J–V* curves of laminated devices and comparison to devices with a thermally evaporated top contact with a PEDOT:PSS hole transport layer are shown in Fig. 1. The device performance parameters are summarized in Table 1, where the average and standard deviation of performance

Table 1
Performance characteristics of laminated contact devices compared to evaporated contact ones. The control and laminated devices were made during this study, while the best evaporated device data was taken from previous work [7].

parameters taken from six laminated devices is also shown. As we will discuss below, optimizing the annealing step of the PEDOT:PSS layer impacts both the efficiency and the reproducibility of the devices. The best laminated device has an efficiency of 3.19% and was achieved when the zinc acetate precursor solution was prepared fresh, stirred overnight at room temperature, then spun just before device fabrication. As documented in previous work, inverted devices benefit from aging in air, with efficiencies gradually improving due to change of the work function of the top Ag electrode [17]. This phenomenon is also observed in the laminated inverted devices presented here, but to a lesser extent. The best efficiencies are reached 5–7 days after the fabrication of the device, but the overall improvement is around 20% over the performance immediately after fabrication. During that period the devices were stored in the dark in ambient conditions. We note that the time evolution during storage in air of inverted OPV devices using ZnO has been shown to result in more dramatic changes (up to 67%) in efficiency over 9 days [17]. It has been suggested that evolution of the ZnO layer also plays a role in the aging of inverted OPV devices. During traditional fabrication the devices are exposed to various environments, including high vacuum for top contact deposition that may cause metastability of the ZnO layer. In this work the part of the device that contains the ZnO remains in ambient conditions throughout fabrication and characterization, therefore we do not expect ZnO evolution to play a major role in device performance.

Compared to the best ZnO-based inverted device presented by White et al. [7] laminated devices have similar V_{OC} of 549 mV and much higher *FF* of 56%. The J_{SC} of the laminated device is lower at 10.3 mA/cm^2, but efficiency is still improved compared to evaporated contact devices. As can be seen from Table 1, the presence of PEDOT:PSS between the active layer and the Ag top contact improves the fill factor of the devices, resulting in values consistently over 54%.

The performance of OPV devices fabricated with hot press lamination is critically affected by the composition and thermal treatment of the PEDOT:PSS layer. Fig. 2 demonstrates the significance of the PEDOT:PSS layer and the d-sorbitol additive on the performance of laminated devices. These samples were fabricated at the same time under conditions that allowed us to compare different compositions of the laminated contact. The best laminated device of the series contained d-sorbitol additive (10% by liquid weight) and had an efficiency of 2.67%. This differs from the 3.19% laminated device since the other parameters mentioned in the study had not yet been optimized.

With no PEDOT:PSS interlayer, the devices have poor efficiency with very low V_{OC} of 173 mV, and J_{SC} of

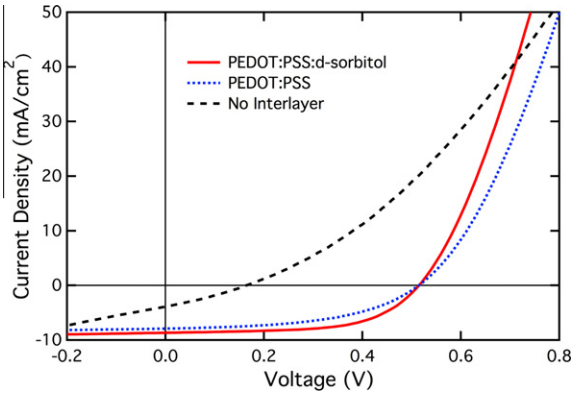

Fig. 2. *J–V* curves under 1 sun illumination of devices using various layers at the lamination interface. The black dashed line shows performance from a device laminated without an interlayer between the bulk heterojunction and the Ag on PET. The blue dashed line has a PEDOT:PSS interlayer, and the solid red line has a PEDOT:PSS:d-sorbitol interlayer. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this paper.)

3.9 mA/cm^2. This indicates the presence of a barrier for charge collection at the laminated (hole collecting) side of the device in the absence of PEDOT:PSS. The low *FF* of 29%, and high series resistance of ca. 200 Ω, measured from the inverse slope of the curve at 1 V indeed suggests poor electrical contact at the laminated interface, also evidenced by structural failure of the devices under mild mechanical stress. The presence of a PEDOT:PSS interlayer drastically improves the device performance: V_{OC} is 506 mV, J_{SC} is 8.1 mA/cm^2, series resistance drops to 50 Ω, and *FF* increases to 52%. These observations verify that the PEDOT:PSS is providing an ohmic contact for hole extraction [4,14]. The addition of d-sorbitol to the PEDOT:PSS interlayer further increases the J_{SC} to 8.7 mA/cm^2 and the *FF* to 58%. In some cells, the fill factor is over 60%, and the series resistance is reduced to 35 Ω. The decreased series resistance and increased *FF* are consistent with increased conductivity of the PEDOT:PSS:d-sorbitol. The d-sorbitol doped films exhibit much enhanced adhesion, and devices from these films are made more physically robust during the lamination process. About 25% of the undoped PEDOT:PSS devices delaminated when the plates of the press were pulled apart, while none of the doped PEDOT:PSS devices failed in this manner.

Sublimation of d-sorbitol occurs at 120 °C at atmospheric pressure and is responsible for the increase in the conductivity of the PEDOT:PSS film [18]. The enhanced mechanical robustness of laminated devices that incorporated

d-sorbitol (as discussed above) indicates that at least some d-sorbitol remains in the film after lamination at 130 °C. The d-sorbitol treatment also alters the work function from 5.1 to 4.8 eV in PEDOT:PSS films deposited on glass [18]. However, in the devices shown in this work, the V_{OC} is relatively unchanged between PEDOT:PSS with and without d-sorbitol. This is in contrast to what is seen in non-inverted devices, in which formulating the PEDOT:PSS with sorbitol results in a decrease in V_{OC} [19]. We also note that the V_{OC} of inverted devices using a thermally evaporated Ag top contact has been seen to correlate with the work function of the Ag [17]. That the behavior of this laminated electrode is different suggests that either the chemical potential at the laminated interface is decoupled from the work-function of the electrode, presumably due to a lack of Fermi level pinning, or that it is the Ag in the PEDOT:PSS:d-sorbitol/Ag that is dominating the chemical potential. Further studies into this issue are underway.

During annealing of the PEDOT:PSS:d-sorbitol layer a balance needs to be achieved between removing water from the film, while maintaining levels of d-sorbitol at the lamination interface until an electrical connection is made. Careful control of the annealing conditions of the PEDOT:PSS:d-sorbitol layer is one of the most important parameters for efficient and reproducible laminated devices. Fig. 3 shows the effect of different pre-lamination treatments of the PEDOT:PSS:d-sorbitol interlayer on device performance. The error bars correspond to the standard deviation between six devices on the same substrate. The following types of treatment were used: (i) drying in ambient conditions, (ii) a 10 min vacuum step without heat and (iii) an annealing step on a hot plate in-air set to 115 °C. In treatment (iii) the time on the hot plate was varied between 2 and 10 min. Annealing above 115 °C leads to delamination during fabrication and poor reproducibility. Fig. 3 shows that both the J_{SC} and the *FF* of devices increase and become more consistent when the samples are heated, while the V_{OC} is relatively unchanged. We conclude that annealing the PEDOT:PSS:d-sorbitol layer at 115 °C for 10 min increases both the performance and reproducibility of laminated devices. Note that the efficiency of the optimized devices in Fig. 3 is ca. 2.4%, lower than the 3+% reported above. The results shown in Fig. 3 are taken from devices measured shortly after the lamination process without allowing them to age, which improves their efficiency.

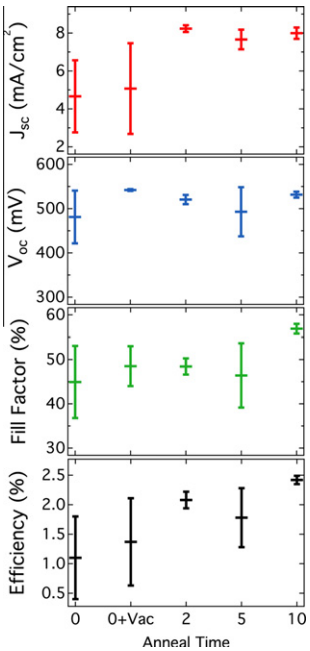

Fig. 3. Device performance parameters for different pre-lamination treatments of the PEDOT:PSS:d-sorbitol interlayer. "0" represents drying the layer in ambient conditions, and "0 + Vac" represents drying the layer in vacuum of 10^{-1} torr at room temperature for 10 min. The other points correspond to annealing the layer at 115 °C in-air for 2, 5, and 10 min.

Additional parameters were explored and were found to have less effect on device performance. Lamination pressure was varied from 0.7 to 2.4 MPa (100–350 psi) with a broad performance peak between 1.31 and 2.07 MPa but with small variations outside that range. Lamination time was varied from 0.5 to 30 min with devices laminated 2 min or less showing poor reproducibility, and devices annealed longer than 5 min showing no significant improvement. Thickness of the active layer was varied from 230 to 560 nm, with thicker layers showing higher J_{SC} and lower *FF* values. The optimum thickness was near 320 nm, the same as reported in evaporated devices [7].

In summary, we demonstrate that lamination of the Ag contact can produce inverted OPV devices with efficiencies higher than devices made in parallel with thermal evaporation of the top contact. This approach greatly reduces the cost of the equipment required for fabrication as devices are processed in air without the need for a high quality evaporation chamber for metal contact deposition. This will allow research groups to investigate other, more novel OPV materials without the need for extensive financial investment into vacuum deposition equipment. It also opens pathways for low cost deposition of electrode materials, such as solution cast electrodes. The processing parameters that are important in the fabrication process are the presence of a PEDOT:PSS:d-sorbitol interlayer at the lamination interface, the pre-lamination treatment of that layer. If these parameters are adequately controlled, devices with a P3HT:PCBM active layer routinely achieve efficiencies over 3%.

ABSTRACT

An inverted polymer solar cell was fabricated on a polyethylene terephthalate (PET) substrate. The cell structure was ITO/amorphous titanium oxide (TiO_x)/[6,6]-phenyl C_{61} butyric acid methyl ester (PCBM): regioregular poly(3-hexylthiophene) (P3HT)/poly(3,4-ethylenedioxylenethiophene):poly(4-styrene sulfonic acid) (PEDOT:PSS)/Au (TiO_x cell). It was achieved using low boiling point diethyl amine (DEA) as a Ti^{4+} complexing agent, and high boiling point 1,2,3,4-tetrahydronaphthalene (Tetralin) containing 2 vol.% 1,8-octanedithiol (ODT) as the solvent for PCBM:P3HT film preparation. With heat treatment at 100 °C, the use of DEA and Tetralin:ODT made it possible to prepare a TiO_x electron collection layer and PCBM:P3HT photoactive layer, respectively. Fabricating the TiO_x cell on the thin PET film was possible, as PET did not warp at 100 °C. The power conversion efficiency (PCE) of the TiO_x cell fabricated on PET was 2.43%, under AM1.5G conditions. When fabricated on glass, the PCE was 2.76%. When [6,6] diphenyl C_{62} bis(butyric acid methyl ester) (bis-PCBM) was instead used as the electron acceptor in the photoactive blend layer, the flexible air-stable cell provided a PCE of 2.81%.

1. Introduction

Much attention has recently been given to polymer solar cells, as candidates for the next generation of solar cells. They are expected to provide a low-cost, environmentally friendly, flexible, easily scaled up and lightweight alternative to the silicon solar cells currently in widespread use [1–3]. The organic active layer of polymer solar cells typically consists of a *p*-conjugated polymer donor and fullerene derivative acceptor, and is prepared by wet-processes such as spin-coating or roller-printing. The power conversion efficiency (PCE) of polymer solar cells has recently achieved 6–7%, which has arisen from the development of new *p*-conjugated polymers [4–7] and fullerene derivatives [8,9]. The *p*-conjugated polymers such as copolymers of benzodithiophene and thienothiophene absorb at long wavelengths and may also possess a low energy HOMO level. Studies investigating their commercial viability (e.g. durability improvement, cost effective production of large-scale flexible cells) are also of great interest and importance, in addition to those investigating their efficiency enhancement. We have been developing air-stable inverted polymer solar cells. Such inverted cells are comprised of a multilayered structure and have a reverse geometry compared with that of a normal cell. Both cell geometries are depicted schematically in Fig. 1. In a normal solar cell, the back Al electrode effectively collects electrons because of its low work function. However, its performance is quickly degraded when Al surface deposition is not carried out under ultrahigh vacuum [10]. High durability can be obtained for the inverted solar cell geometry because the transparent metal oxide (e.g. amorphous titanium oxide (TiO_x) or zinc oxide (ZnO)) provides a non-corrosive electron collection electrode. We previously reported that the performance of an unsealed inverted polymer solar cell with the structure ITO/TiO_x/PCBM:P3HT/PEDOT:PSS/Au (denoted as TiO_x cell) was maintained

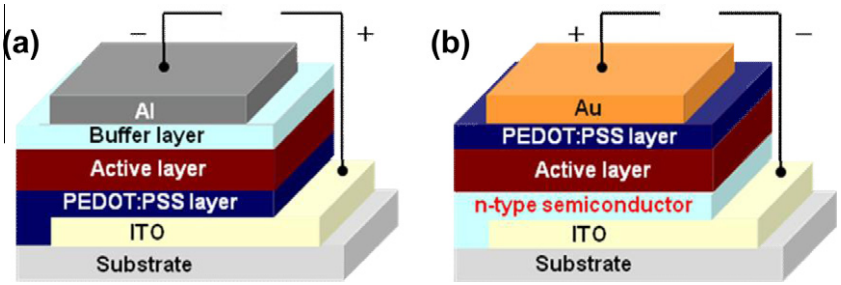

Fig. 1. Schematic illustrations showing the structures of normal (a) and inverted (b) polymer solar cells.

under continuous light irradiation for 100 h in an ambient atmosphere [11]. This structure is a promising candidate for further studying polymer solar cell durability improvement [12–14].

Preparing robust, light weight, flexible polymer solar cells is important for encouraging their widespread use. Several papers have reported the fabrication of polymer solar cells on flexible substrates [15–21]. Krebs et al. fabricated modules from PET-ITO/ZnO nanoparticles/PCBM:P3HT/PEDOT:PSS/Ag cells using a roll-to-roll process [22], and showed that the PCE reached 2.33% from a working area of 4.8 cm^2. Flexible inverted polymer solar cells containing ZnO nanoparticles as an electron collection layer [22,23], or Cs_2CO_3 as a buffer layer [24], have been reported by other research groups. However, such solar cells containing TiO_x films have not been reported, because the PET substrate easily warps during heat treatment. In the current study, we report a flexible TiO_x cell fabricated on a PET substrate, with a photoactive area of 1 cm^2. This cell exhibited a maximum PCE of 2.8% under AM1.5G conditions.

2. Experimental section

2.1. Materials

Titanium (IV) isopropoxide ($Ti(OCH(CH_3)_2)_4$), acetylacetone (AA) ($CH_3C(O)CH_2C(O)CH_3$), diethylamine (DEA) ($CH_3CH_2NHCH_2CH_3$), regioregular P3HT (Mw 87,000), PEDOT:PSS 1.3 wt.% dispersion in water, polyoxyethylene tridecyl ether (PTE), chlorobenzene (CB), o-dichlorobenzene (DCB), 1,2,3,4-tetrahydronaphthalene (Tetralin) and 1,8-octanedithiol (ODT) were purchased from Sigma–Aldrich Chemical Co., Inc. PCBM was purchased from Frontier Carbon Corporation. Bis-PCBM was purchased from ATR Company. All chemicals were used as received. Glass-ITO substrates (sheet resistance = 10 Ω/sq.) and Au wires were purchased from the Furuuchi Chemical Corporation. PET-ITO substrates (sheet resistance = 30 Ω/sq., thickness of PET sheet = 125 μm) were obtained from Nakai Industrial Co., Ltd.

2.2. Preparation of TiO_x layers

TiO_x precursor solutions were prepared under a N_2 atmosphere as described in our previous paper [12]. Precursor solutions were stored under a N_2 atmosphere following filtration, and were then diluted with 2-propanol, to prepare TiO_x layers by spin-coating onto the ITO electrode at 2000 rpm. The films were then hydrolyzed for 30 min in a controlled atmosphere with a relative humidity about 45%. The films were heated at various temperatures for 1 h on a hot plate, to remove the solvent and complexing agent. Two kinds of TiO_x films prepared from the precursor solutions containing complexing agents AA and DEA were denoted as AA-TiO_x and DEA-TiO_x, respectively. Fig. S1 shows the plots of the thickness of TiO_x film versus the concentration of the DEA-TiO_x precursor solution. The thickness was estimated by cross-sectional AFM imaging. The TiO_x films of 30 and 100 nm in thickness were used for the TiO_x cells containing Glass-ITO and PET-ITO substrates, respectively.

2.3. Fabrication of organic solar cells

ITO-Glass electrodes were cleaned by sonication in 2-propanol, washed in boiling 2-propanol, and then dried in air. PET-ITO electrodes were cleaned only by sonication in 2-propanol to prevent substrate warping. For spin-coating, PET-ITO electrodes were fixed on glass plates using adhesive tape. Cell fabrication was carried out in a N_2 filled glove box with less than 1 ppm moisture and 1 ppm oxygen as follows. The AA-TiO_x or DEA-TiO_x films were prepared by the method described above. A mixed solution of P3HT and PCBM (weight ratio = 5:4) was spin-coated onto the ITO/TiO_x substrate. A PEDOT:PSS dispersion in water containing 0.01 wt.% PTE was heated to 85 °C, and then spin-coated onto the PCBM:P3HT layer. The Au back electrode was vacuum-deposited at 2×10^{-5} torr onto the PEDOT:PSS layer. Finally, the device was heated at various temperatures for 5 min to crystallize the P3HT, and then at 70 °C for 30 min. The effective area of the solar cell was restricted to 1 cm^2, by depositing the Au electrode with a shadow mask.

2.4. Measurements

I–V curves of solar cells were measured by linear sweep voltammetry at a scan rate of 5 V min^{-1}, under AM 1.5G simulated sunlight conditions of 100 mW cm^{-2} intensity. The light source was a SAN-EI Electric XES-502S solar simulator calibrated by an EKO MS-601 pyranometer. All electric measurements were performed using a Hokuto Denko HZ-5000 electrochemical analyzer. UV–vis absorption

spectra were measured using a Hitachi U-3310 spectrophotometer. Atomic force microscopy (AFM) was carried out using a SII SPI3800N AFM apparatus. All measurements were carried out under an ambient atmosphere (15–30 °C, 40–60% relative humidity).

3. Results and discussion

3.1. TiO_x layer prepared by drying at 100 °C

The boiling points of DEA (55 °C) and AA (140 °C) are sufficiently low to allow their use as complexing agents for TiO_x precursor solutions, and to fabricate TiO_x cells at low-temperature. TiO_x films on ITO-glass substrates prepared from the AA-TiO_x and DEA-TiO_x precursor solutions were dried at 100 or 150 °C. Fig. 2 shows *I–V* curves of the polymer solar cells containing TiO_x films, and cell performance is summarized in Table 1. When the TiO_x layer was dried at 150 °C, and TiO_x cells containing PCBM:P3HT were annealed at 150 °C, both AA-TiO_x and DEA-TiO_x cells exhibited PCE values of ~2.2%. These two cells are denoted as AA-150/CB-150/glass and DEA-150/CB-150/glass, respectively. Throughout this manuscript, the first label represents the complexing agent and TiO_x film heating temperature. The second label represents the solvent and PCBM:P3HT film heating temperature. The third label represents the substrate, as glass or PET. For a controlled experiment, a TiO_x cell was fabricated using a TiO_x layer prepared from a precursor solution containing no complexing agent (denoted as Non-150/CB-150/glass). TiO_x layers prepared from precursor solutions containing complexing agents acted as electron collection layers, and were superior to that prepared from a precursor solution without complexing agent. When TiO_x layers were dried at 100 °C, PCE values of the AA-TiO_x and DEA-TiO_x cells decreased to 0.66% and 1.10%, respectively. TiO_x cells containing PCBM:P3HT blend film prepared from the CB solution, were heated at 80 °C for 5 min (denoted as AA-100/CB-80/glass and DEA-100/CB-80/glass). Their PCE values were small compared with those of the cells prepared by treatment at 150 °C, and the performance of DEA-100/CB-80/glass was better than that of AA-100/CB-80/glass. DEA could more easily be removed from the TiO_x film by heat treatment at 100 °C than AA, as the DEA boiling point was lower than the drying-temperature. This may have resulted in a small electrical resistance of the DEA-TiO_x film, and a higher PCE was obtained for DEA-100/CB-80/glass prepared at lower temperatures.

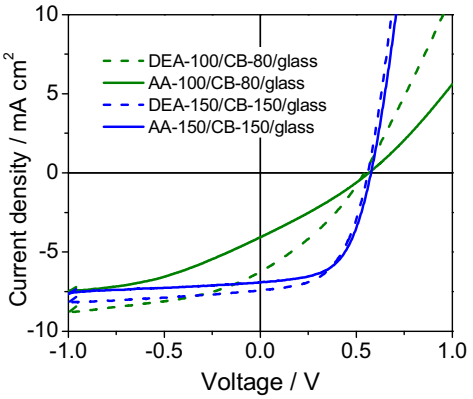

Fig. 2. *I–V* curves of polymer solar cells containing TiO_x on glass substrates, prepared from AA-TiO_x and DEA-TiO_x precursor solutions.

3.2. PCBM:P3HT films prepared by heating at 100 °C

When the DEA-TiO_x layer was dried at 150 °C, DEA-150/CB-80/glass exhibited a low PCE of ~1.1% (Table 1). This was probably because P3HT in the blend film had not crystallized at 80 °C, and suggested that PCBM:P3HT did not act as a sufficient photoactive layer. Solvent annealing is one of the major methods used so far to improve the performance of P3HT:PCBM bulk-heterojunction solar cells [25–27]. The blend film was slowly prepared by using high boiling point solvents such as o-DCB (180.5 °C), and the crystallization of P3HT was achieved without thermal annealing. Thus, DCB was used instead of CB to obtain a more effective photoactive layer. Fig. 3 shows *I–V* curves of cells containing CB and DCB, and their performance is summarized in Table 2. For DEA-100/DCB-80/glass, a PCE of ~2.4% was obtained, because P3HT crystallization had proceeded considerably. This was confirmed from absorption spectra of the PCBM:P3HT film, where crystalline P3HT showed an enhanced shoulder at around 600 nm (Fig. S2).

3.3. Fabrication of flexible TiO_x cells

DEA-TiO_x cells containing PCBM:P3HT prepared using DCB, were fabricated on ITO-glass and PET-ITO substrates at a relatively low temperature of 100 °C. DEA-100/DCB-100/glass showed the short-circuit photocurrent (J_{sc}) of

6.91 mA cm^{-2}, an open-circuit voltage (V_{oc}) of 0.59 V, a fill factor (FF) of 0.60, and a resulting PCE of 2.45% (Table 3). DEA-100/DCB-100/PET exhibited J_{sc} = 6.54 mA cm^{-2}, V_{oc} = 0.58 V, FF = 0.60, and a PCE of 2.27%. The PCE was ~10% lower than that for DEA-100/DCB-100/glass. This originated from a lower transmittance at wavelengths below 600 nm, especially in the UV region (see transmission spectra of glass-ITO and PET-ITO, Fig. S3). None the less, a fabrication method for TiO_x-containing inverted polymer solar cells on thin PET films was successful.

To improve the performance of the flexible cell, we tested Tetralin as a high boiling point solvent, [28] and Tetralin containing a small amount of ODT (denoted as Tetralin:ODT). Tetralin was chosen in attempt to more efficiently generate and separate photo-charge. Fig. S2 shows absorption spectra of PCBM:P3HT films prepared using these solvents. When the blend film was prepared using Tetralin and heated at 100 °C, an enhanced shoulder was observed at ~600 nm, indicating a greater degree of P3HT crystallinity. The addition of ODT into the PCBM:P3HT solution enhanced the PCE because of improvements in nanoscale phase separation [29,30]. Thus, a 2% ODT vol. ratio was added to DCB and Tetralin (denoted as DCB:ODT and Tetralin:ODT, respectively). The performance of DEA-100 solar cells prepared using DCB, Tetralin, DCB:ODT and Tetralin:ODT is summarized in Table 3. For DEA-100/DCB:ODT-100/glass, the PCE was 2.4%. This was the same as for DEA-100/DCB-100/glass, regardless of addition of ODT. DEA-100/Tetralin-100/glass showed a relatively small PCE of 1.48%, although greater crystallinity was observed for P3HT in the blend film (Fig. S2). For PCBM:P3HT prepared using Tetralin:ODT, the absorbance at ~600 nm was lower than that of the blend film prepared without ODT (Fig. S2). The performance of DEA-100/Tetralin:ODT-100/glass exhibited J_{sc} = 7.09 mA cm^{-2}, V_{oc} = 0.59 V, FF = 0.66, and a PCE of 2.76%. The PCE was much larger than that for DEA-100/Tetralin-100/glass. Fig. 4 shows surface AFM images of PCBM:P3HT films prepared using Tetralin containing varying ODT vol.%. Lee et al. reported AFM images of exposed *p*-conjugated polymer PCPDTBT networks after selective removal of C_{71}-PCBM from PCPDTBT:C71-PCBM blend film using alkanedithiol [30]. They distinguished interconnected regions consisting of polymer and porous domains consisting of PCBM by such a method. On the analogy from such an investigation, we

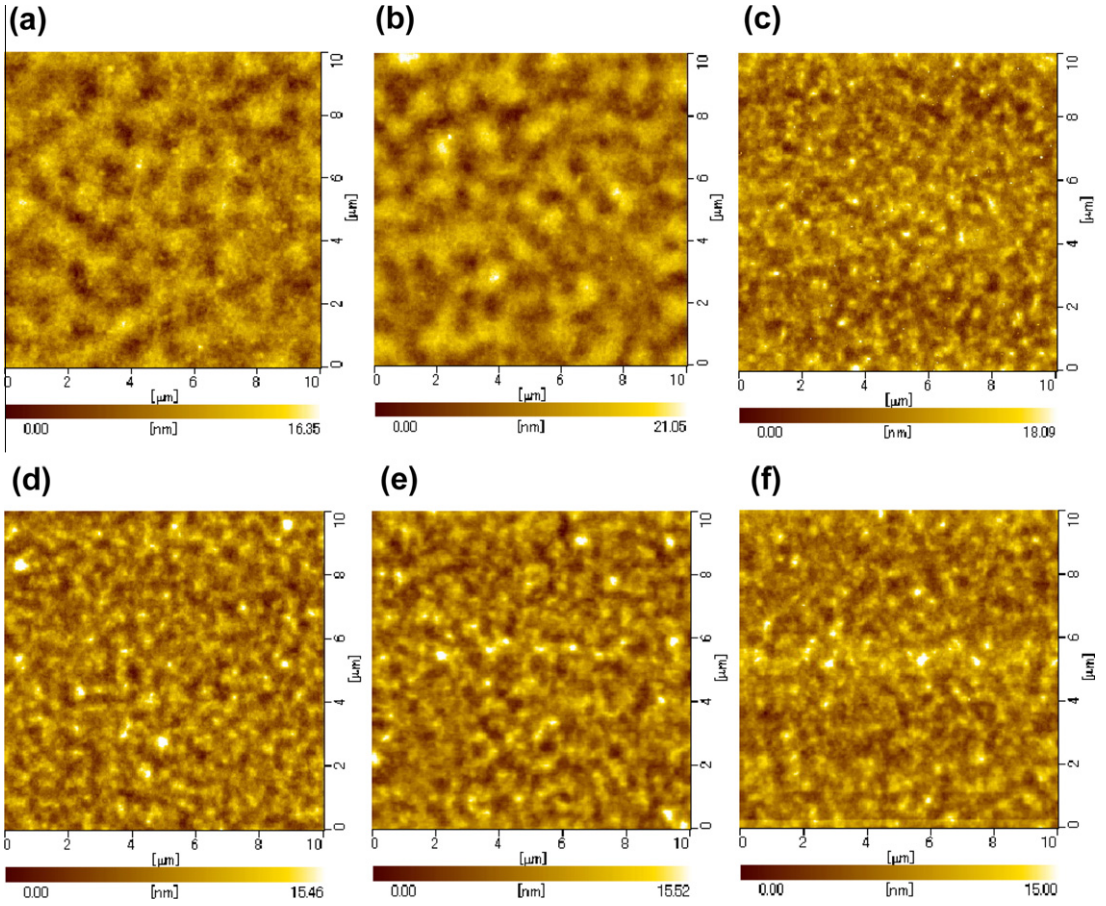

Fig. 4. Surface AFM images of PCBM:P3HT blend films prepared using Tetralin containing varying ODT vol.%. (a) 0, (b) 1, (c) 2, (d) 2.5, (e) 3 and (f) 6 vol.%.

presumed that interconnected regions of lower height were P3HT-rich domains and dotted regions of higher height were PCBM-rich domains from the surface AFM images of PCBM:P3HT films in Fig. 4. For PCBM:P3HT prepared by adding ODT of 2 vol.% or greater, the phase particle size of P3HT-rich and PCBM-rich domains greatly diminished, compared with those in films prepared using Tetralin containing 0 or 1 vol.% ODT. Fig. S4 shows plots of PCE and J_{sc} against vol.% of ODT for DEA-100/Tetralin:ODT-100/glass. When the blend film was prepared using Tetralin containing 2 vol.% ODT, a better performance with J_{sc} = 7.09 mA cm^{-2} and a PCE of 2.76% was observed. When the blend film was prepared using Tetralin containing ODT of 6 vol.%, J_{sc} and PCE values decreased. This was despite AFM images showing little particle size change (compare Fig. 4(c) and (f)). This may have been caused by residual ODT in the PCBM:P3HT film. These results suggest that controlling the morphology of the blend film, in addition to enhancing P3HT crystallinity, is important for overall cell performance. Fig. 5 shows *I–V* curves of DEA-100/Tetralin:ODT-100/glass and DEA-100/Tetralin:ODT-100/PET, where PCBM:P3HT films were prepared using Tetralin containing 2 vol.% ODT, and heated at 100 °C. The flexible DEA-100/Tetralin:ODT-100/PET exhibited better performance, with J_{sc} = 6.89 mA cm^{-2}, V_{oc} = 0.57 V, FF = 0.61,

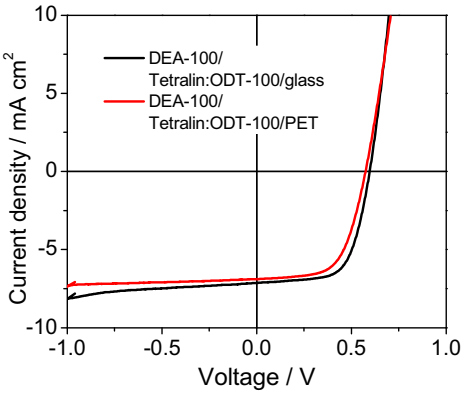

Fig. 5. *I–V* curves of DEA-TiO$_x$ cells prepared on glass and PET substrates, by treatment at 100 °C. PCBM:P3HT films were prepared using Tetralin containing 2 vol.% ODT.

and a PCE of = 2.43%. Its PCE was smaller than that of DEA-100/Tetralin:ODT-100/glass at 2.76%.

It is known that blending bis-PCBM as an acceptor into P3HT as a donor enhances the V_{oc} of polymer solar cells compared to blending PCBM as the acceptor, because bis-PCBM has ca. 100 meV higher LUMO than PCBM [11,31]. Hence, we tried to use the bis-PCBM as the acceptor. A

Tetralin:ODT solution containing 21.8 mg mL^{-1} P3HT and 17.4 mg mL^{-1} bis-PCBM (weight ratio = 5:4) was spin-coated as the organic active layer. The film thickness was ca. 250 nm. As we would expect, the flexible DEA-100/Tetralin:ODT-100/PET containing bis-PCBM acceptor showed higher performance of J_{sc} = 6.22 mA cm^{-2}, V_{oc} = 0.72 V, FF = 0.62, and a PCE of 2.81%.

4. Conclusions

When DEA was used as the complexing agent in the TiO_x precursor solution, the resulting DEA-TiO_x film functioned sufficiently well as an electron collection layer, even when drying at 100 °C was carried out. When using a solvent of high boiling point such as Tetralin containing 2 vol.% ODT, the morphology of the resulting PCBM:P3HT blend film gave higher cell performance. Combining these two techniques, we have fabricated a PET-ITO/TiO_x/PCBM:P3HT/PEDOT:PSS/Au cell without warping of the thin PET film. The resulting PCE was 2.43%, for the unsealed device with a 1 cm^2 working area in air. A PCE value of 2.81% was obtained for the PET-ITO/TiO_x/bis-PCBM:P3HT/PEDOT:PSS/Au cell, when bis-PCBM was instead used as the electron acceptor. We employed a spin-coating method for preparing the TiO_x electron collection and PCBM:P3HT photoactive layers. However, this device could have easily been fabricated by other coating methods such as doctor blading and roller printing.

OTFT reliability

ABSTRACT

(Polytetrafluoroethylene) PTFE-like films, deposited by using CHF_3/Ar gas mixtures in a plasma reactor, have been used as encapsulation layers in pentacene thin film transistors. The PTFE-like encapsulation layers allow to carry out photolithographic processes without damaging pentacene film. However, the PTFE-like encapsulation layers are not effective in reducing hysteresis of electrical characteristics when measured in air. On the contrary, the degradation of the device electrical characteristics, induced by oxygen diffusion into pentacene film after storing the devices in air, is almost completely suppressed by the encapsulation with the PTFE-like films.

1. Introduction

Organic thin film transistors (OTFTs) based on pentacene show, at present, the best OTFT performance [1–3]. Pentacene OTFTs are promising candidates for the large area, printable and flexible electronic applications like sensor arrays, radio frequency identification tags (RFID) and paper-like displays. In this context patterning and stability of organic semiconductors are key factors for OTFTs applications.

Unfortunately, the interaction with the common solvents, during the fabrication processes, can lead to a degradation of the exposed pentacene layer [4]. In addition, it has been shown that organic devices are very sensitive to exposure to air. Pentacene OTFTs exhibit a hysteresis of the transfer characteristics when measured in air and this phenomenon has been related to the diffusion of water molecules into the device active layer [5,6]. Furthermore, permanent variation of transfer characteristics has been observed when the devices are exposed to air for a long time [7,8], with the degradation of the main electrical parameters (field effect mobility, threshold voltage and subthreshold swing). So, it is mandatory to find out a suitable barrier layer that reduces gas diffusion into the OTFT active layer, preventing pentacene damage during lithographic processes and acting as encapsulating layer for further integration. Several encapsulation layers have been proposed based on solution processed materials, as PVA with single [9] or multilayer structures [10,11], or vapour deposited materials, as parylene [12–14], polyimide [15] and evaporated PTFE [16]. While all these materials show good properties as barriers for lithographic processes, they are not equally effective as a barrier for water and oxygen diffusion. In addition, the deposition of the encapsulation layer often induces a degradation of the electrical characteristics of the pentacene OTFTs. In this work, we have investigated the performance, as encapsulation layers, of polytetrafluoroethylene-like (PTFE-like) films deposited by using different CHF_3/Ar gas mixtures in a plasma reactor.

2. Experimental

Bottom contact devices have been fabricated on heavily doped silicon wafers (acting as gate electrode), with thermal silicon dioxide, 90 nm thick, as gate dielectric. Source

and drain gold contacts, 20 nm thick, are defined using optical lithography and wet-etching ($W = 200$ μm, $L =$ 20–100 μm). A thin film of polycrystalline pentacene, 30 nm thick, has been thermally evaporated, at growth rate of 0.01 nm/s, on a PMMA buffer layer used to improve the structural properties of pentacene [17]. Indeed, the atomic force microscopy showed that the pentacene layers have a highly ordered polycrystalline structure with large grain size (>1 μm). PTFE-like films, about 200 nm thick, have been deposited by using different CHF_3/Ar gas mixtures (20%, 50%, 60% and 70% of Ar) in a plasma reactor. All the deposited PTFE-like films result hydrophobic with a contact angle of about 100° for water (Fig. 1). After the PTFE deposition the device active regions have been defined by conventional photolithography and oxygen plasma etching, without damaging the pentacene active layer (Fig. 2).

The device electrical characteristics were measured in a MMR cryostat using a Keythley 236 source/measure unit and a Keythley 2635 source/meter. In order to measure the hysteresis of the transfer characteristics, the measurements have been performed sweeping the gate voltage, sequentially, from off-to-on and from on-to-off (between 20 V and −30 V).

3. Results and discussion

3.1. FTIR measurements

The Ar influence on the deposited PTFE-like films has been studied by FTIR analysis. Independently on the CHF_3/Ar ratio, the FTIR spectra (see Fig. 3) of PFTE-like films show a broad peak, located at 1220 cm^{-1} induced by CF_x [18]. The asymmetry of this absorption peak indicates the existence of strong CF_2 symmetric and asymmetric stretch vibration modes. In particular, it is evident a shoulder located approximately at 1180 cm^{-1}, induced by CF_2 symmetric stretching mode [18], that highlights the "Teflon-like" character of the film. Minor peaks can be observed at 980 cm^{-1}, induced by CF_3 stretch, and at 739 cm^{-1}, which is identified as amorphous PTFE [19]. No absorptions induced by C–C and C–O bonds have been observed in the range 1800–1700 cm^{-1}.

3.2. OTFTs electrical characteristics and numerical simulations

Fig. 4 shows the transfer characteristics of the device measured before and after the PTFE deposition with

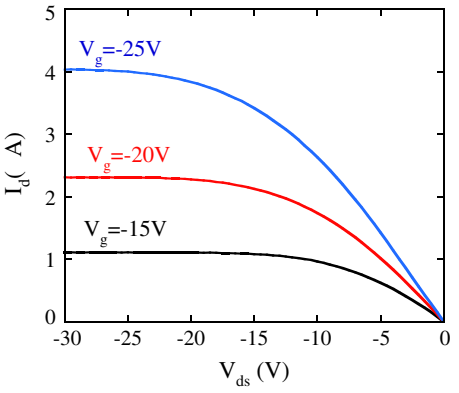

Fig. 5. Output characteristics of a pentacene OTFT before the PTFE encapsulation.

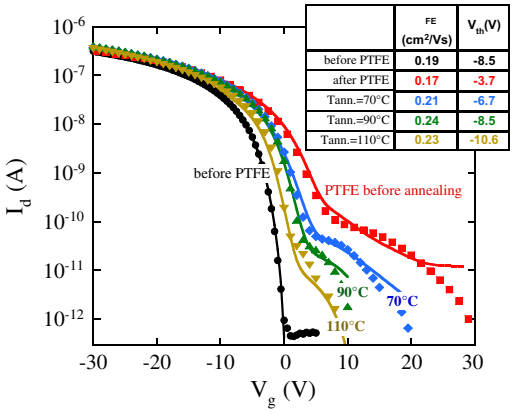

Fig. 6. Experimental (symbols) and simulated (solid lines) transfer characteristics of a pentacene OTFT without and with the PTFE encapsulation layer (deposited with 50% of Ar) after annealing at different temperatures. The field effect mobility and the threshold voltage of each characteristic are shown in the table.

different CHF_3/Ar ratio. Before the PTFE deposition the pentacene OTFTs show a field-effect mobility of about 0.2–0.3 cm^2/V s and no hysteresis of the transfer characteristics is observed, when measured in vacuum. Furthermore, the output characteristics (Fig. 5) show a good linear behaviour at low V_d, suggesting a low contact resistance of the pentacene/PMMA/Au contacts. After the PTFE deposition, the transfer characteristics show a hump in the subthreshold region that decreases with increasing Ar partial pressure in the gas mixture (Fig. 4). The hump disappears for Ar concentration equal or higher than 60%, whereas a degradation of subthreshold slope can be still observed. The encapsulated devices have been thermally annealed (1 h in vacuum) at increasing temperatures, from 70 °C up to 130 °C. The device transfer characteristics improve up to 110°–130 °C (see Fig. 6) and the electrical characteristics in sample annealed at 110 °C, with encapsulation layer deposited at 60% (or higher) Ar dilution, almost completely recover the electrical characteristics before the encapsulation.

In order to gain a physical insight on the effect of the PTFE-like encapsulation layer on the electrical characteristics of pentacene OTFTs, the experimental data have been fitted by using one-dimensional numerical simulations. It has been shown [20,21] that it is possible to perfectly reproduce the pentacene-based OTFT characteristics assuming drift-diffusion transport model and a spatially uniform distribution of localized states, that includes the contributions of the in-grain and grain boundary defects as well as of the dielectric/pentacene interface defects. The density of interface states can be approximated by the sum of two exponential terms (one for the acceptor-like states and one for the donor-like states): $N(E) = N_a e^{-(E_c-E)/E_a} + N_d e^{(E-E_v)/E_d}$, where E is the energy, E_c is the energy of the bottom of the conduction band, E_v is the energy of the top of the valence band, E_a and E_d are the characteristics energies for the acceptor-like and donor-like states distributions, respectively, and N_a and N_d are the acceptor-like and donor-like densities for $E = E_c$ and $E = E_v$, respectively. In the following analysis we are considering a symmetric distribution of interface states, with $N_a = N_d$ and $E_a = E_d$. The transfer characteristics have been computed by evaluating the channel conductance using a one-dimensional approach, by solving numerically the Poisson equation in the direction perpendicular to the channel surface. In order to speed up the computation, the charge trapped in the localized states is evaluated assuming an approximation for the Fermi function: for E ranging in an interval of 3 kT around the Fermi level, a third order polynomial approximation is used, while, for E lying outside this interval, an exponential approximation is employed [22]. Once discretized, the non-linear Poisson's equation is iteratively solved using the Newton's method (or relaxation method) and the resulting carrier distribution, along the depth of the channel, is computed. The density of states (DOS) parameters have been determined by using a least squares approach: the optimization method used is the Levenberg–Marquardt method [23].

The experimental characteristics have been perfectly reproduced by the numerical simulations (see Figs. 4 and 6) considering fixed negative charge and interface traps at the pentacene/PTFE-like interface. Both types of defects can be generated during the early stage of the deposition of PTFE-like films and could be ascribed to the poor quality of the interface between PTFE-like film and pentacene as well as to the plasma damage. The negative fixed charge appearing at the PTFE-like film/pentacene interface produces the formation of a back-channel (see Fig. 7a). Since the pentacene active layer is very thin, the back channel can be modulated by the gate for high positive gate voltages, originating a normally-on back-channel transistor. Due to the different threshold voltage of front and back transistors, the contribution of the back channel to the total current is dominant when the front channel is in either off or subthreshold regime (as schematized in Fig. 7b), producing the hump observed in the experimental characteristics. The fixed charge and interface states densities are related to the deposition conditions and thermal annealing process and by the numerical simulations we have been able to evaluate these quantities as a function of the Ar concentration (Fig. 8) and annealing temperatures (Fig. 9). In the analysis we have considered as parameter the integral of the interface states, $N(E)$, over the lower half of the

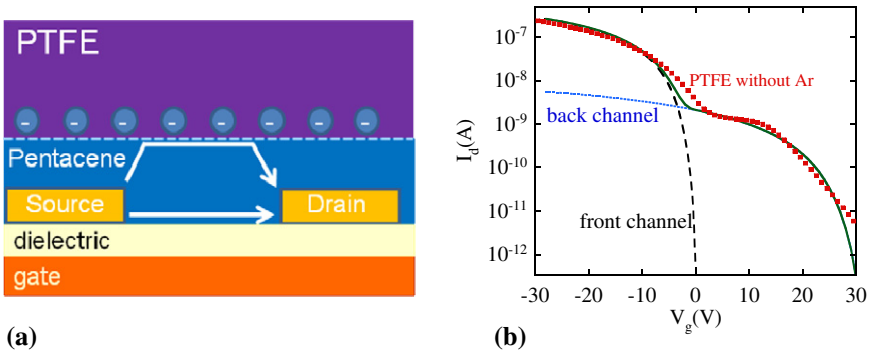

Fig. 7. (a) Schematic of current paths in presence of back-channel conduction. (b) Simulated front (dashed line) and back (dotted line) channel contribution to the device transfer characteristics (solid line) compared to the experimental data (symbols) after PTFE deposition with no argon dilution.

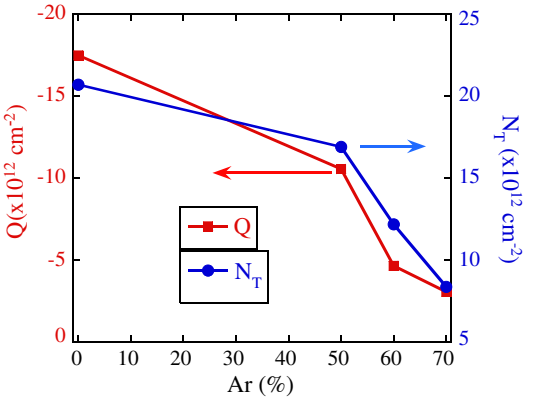

Fig. 8. Negative fixed charge density, Q, and integrated interface state density, N_T, deduced from the analysis of device characteristics after PTFE encapsulation, vs. Ar-dilution used during PTFE-like film deposition.

bandgap, N_T. As can be seen in Fig. 8, the improvement of the characteristics with increasing Ar partial pressure in the gas mixture is related to a decreasing of both fixed charge, Q, and interface state density, N_T. The fixed charge reduction decreases the threshold voltage of the back transistor, reducing its contribution to the total current in the subthreshold region of front transistor. Furthermore, the reduction of the interface states allows a more efficient modulation of the gate on the back transistor with a sharper reduction of the back-channel current for increasing gate voltage, resulting in an improvement of the transistor subthreshold slope. Similarly, the annealing process decreases both the fixed charge and the interface states (Fig. 9), allowing to restore almost completely the electrical characteristics measured prior to the encapsulation.

3.3. Reliability evaluation

We have investigated the stability of the pentacene OTFTs with the PTFE-like encapsulation layer measuring the devices in air and after several days of storing in air. The above analysis showed that the devices with encapsulation layer deposited at higher Ar dilutions have, after annealing, electrical characteristics comparable with those of the OTFTs before the encapsulation. Therefore, in order to compare the performance of the non-encapsulated and encapsulated devices, reliability tests were carried out on devices with the encapsulation layer deposited at 60% Ar dilution. Fig. 10 compares the transfer characteristics, measured in air, of a non-encapsulated pentacene OTFT and a OTFT with PTFE-like encapsulation layer, before and after the thermal annealing at 110 °C. The measurements have been performed sweeping the gate voltage, sequentially, from off-to-on and on-to-off between 20 V and −30 V, in order to point out the hysteresis of the transfer characteristics. As can be seen, the hysteresis observed in the non-encapsulated device is still present in the encapsulated OTFT, whereas it is slightly reduced after the annealing process. The reduction of the hysteresis after annealing is probably a consequence of the improved structural properties of pentacene that reduces water diffusion in the active layer. This result shows that the PTFE-like layer is not an efficient barrier against water diffusion.

In order to evaluate the aging effects, a PTFE-encapsulated and a non-encapsulated OTFTs have been stored in air for several days, and they have been repeatedly measured,

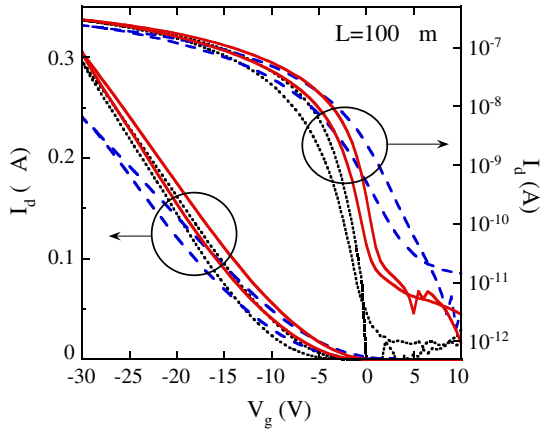

Fig. 10. Transfer characteristics of pentacene OTFTs measured in air without (dotted line) and with encapsulation layer, before (dashed line) and after annealing at 110 °C (solid line). The PTFE-like film was deposited with 60% Ar-dilution.

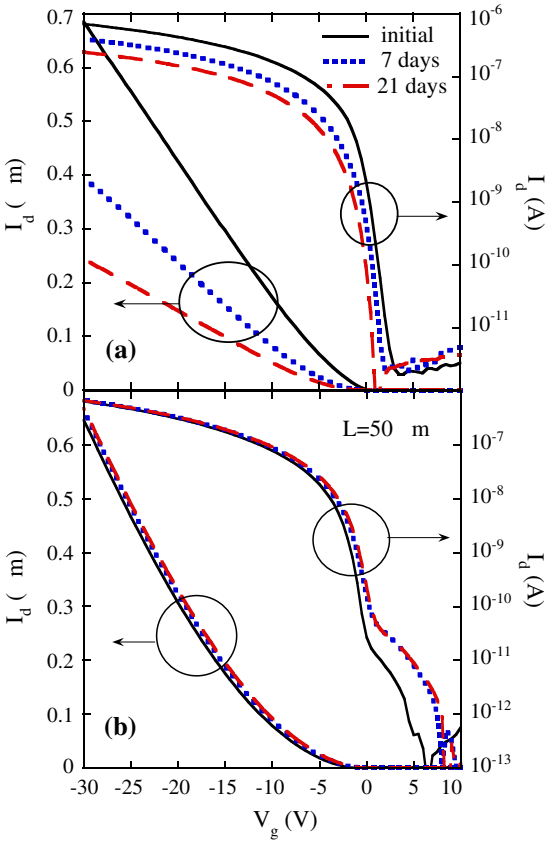

Fig. 11. Transfer characteristics of non-encapsulated (a) and PTFE-encapsulated (b) pentacene OTFTs measured before (solid line) and after storing the device in air for 7 (dotted line) and 21 (dashed line) days. The PTFE-like film was deposited with 60% Ar-dilution.

in vacuum, as a function of the aging time. As can be seen in Fig. 11, after a few days by the starting of aging, the non-encapsulated device (Fig. 11a) shows a large decrease of field effect mobility ($\Delta\mu/\mu_0 = 0.35$) and a small variation of the V_{onset}, $\Delta V_{onset} = -0.9$ V (V_{onset}, can be defined as the gate voltage for which current starts to increase). At the same time, the PTFE-encapsulated device shows an increase of the hump in the subthreshold regime (Fig. 11b), while the field effect mobility remains unchanged. After 3 weeks the degradation of electrical characteristics of the non-encapsulated OTFT continued, with $\Delta\mu/\mu_0 = 0.63$ and a $\Delta V_{onset} = -0.8$ V. On the contrary, no further variation of the electrical characteristics is observed in the PTFE-encapsulated device. In particular, from the linear regime of the transfer characteristics, it is evident that the field effect mobility remains unchanged, relative to the curve before aging, and only a small rigid shift of the curve is observed. From these results we can conclude that the encapsulation with the PTFE-like layer efficiently prevents the diffusion of oxygen into the active layer, which induces degradation of the electrical characteristics in non-passivated pentacene OTFTs.

4. Conclusions

PTFE-like films, deposited by using different CHF_3/Ar gas mixtures in a plasma reactor, have been used for the first time as encapsulating layer for pentacene-OTFTs. They show good structural properties, as demonstrated by FTIR spectra, and allow pentacene channel photolithographic definition and annealing of the passivated OTFTs. After the PTFE-like film deposition, the pentacene OTFT transfer characteristics show, depending on the presence of Argon during the deposition, degraded transfer characteristics in the subthreshold regime, whereas smaller changes are observed in the linear regime. We showed, by numerical simulations, that the subthreshold degradation is related to the formation of a back-channel, at the PTFE-pentacene interface, induced by fixed negative charge and interface traps. These defects, related to the poor quality of the interface between PTFE-like film and pentacene as well as to plasma damage, can be removed by thermal process. Indeed, after the annealing at 110 °C, prior to encapsulation characteristics have restored almost completely.

The reliability of the encapsulated devices has been tested by measuring the electrical characteristics in air and after storing the devices in air for several days. The results show that the PTFE-like encapsulation layer is not effective in reducing the water diffusion, indeed the electrical characteristics show hysteresis when measured in air, with a small reduction of the effect obtained through the annealing process. On the contrary, the degradation of device characteristics after air exposure, due to oxygen interaction with pentacene film, is almost completely suppressed (apart from a minor increase of drain current in subthreshold regime), suggesting that the PTFE-like films act as effective barriers for oxygen.

ABSTRACT

Three triphenylamine-based organic dyes **SD6**, **SD7**, and **SD8** containing the bulky dual-role moieties (fluorene, carbazole, and spirobifluorene) in the molecular frameworks were synthesized, characterized and applied in dye-sensitized solar cells (DSSCs). The effects of dual-role moieties of organic dyes on their photophysical, electrochemical, and photovoltaic properties have been investigated in detail. These dyes exhibit strong charge transfer absorption bands in the visible region. Their redox potential levels were estimated by cyclic voltammetry and found to suit well to the charge flow in DSSCs. Inserting the dual-role moieties as the secondary donor between the triphenylamine and thiophene units increased the electron density of the donor groups, therefore reduced the HOMO–LUMO band gaps. The combination of ultraviolet–visible (UV–vis) region broad absorption bands with fairly high extinction coefficients and appropriate redox properties observed in these triphenylamine-based dyes make them promising dyes for DSSCs. For a typical solar cell device based on dye **SD6**, the maximal monochromatic incident photon-to-current conversion efficiency (IPCE) can reach to ~73%, with a short-circuit photocurrent density (J_{sc}) of 14.25 mA/cm^2, an open-circuit photovoltage (V_{oc}) of 0.70 V, and a fill factor (FF) of 0.705, which corresponds to a power conversion efficiency (PCE) of 7.03%.

1. Introduction

The growing worldwide demand for environment friendly energy sources has led to a great focus on solar energy conversion devices. Dye-sensitized solar cells (DSSCs) have attracted significant attention [1,2] since their report by Regan and Grätzel et al. in 1991 [3]. The relatively high performance and low production costs render DSSCs as competitive alternatives to conventional silicon-based photovoltaic devices [4]. Photosensitizers play a crucial role for highly efficient DSSCs. Ruthenium-based sensitizers (e.g., N719 dye [5]) have achieved power conversion efficiencies (PCEs) over 11% in standard air mass 1.5 sunlight. In the meantime, there are also increasing interests in metal-free organic dyes [6] due to their many advantageous features, such as high molar extinction coefficients, easily modified molecular structure and relatively low cost materials. Power conversion efficiencies up to ~9% have been achieved for DSSCs based on metal-free dyes [7–9]. Moreover, highly impressive PCEs (~10%) and excellent stability were also reported in very recent publications of Wang et al. [10,11].

A common strategy in the design of highly efficient metal-free dyes for DSSCs is the linking of electron donor/acceptor (D–A) systems through π-conjugated bridges (called as D–π–A molecular structure), with TiO_2 surface

anchoring groups (e.g., carboxylate) integrated onto the acceptor moiety. Among the metal-free organic dyes, it has been demonstrated that triphenylamine (TPA) [12,13], thiophene based aromatics [14–17] and cyanoacetic acid [18,19] are the effective electron donating moiety, π-conjugated bridge and electron acceptor (anchoring group), respectively. At the same time, metal-free organic dyes with D–D–π–A structure were also reported by several groups [20–23]. Their results indicated that organic dyes with D–D–π–A structure can achieved better photovoltaic performances than those of dyes with the simple D–π–A molecular configuration due to the increased electron-density of donor and enhanced molar extinction coefficient by introducing a secondary electron donor into the dye molecules [24–26]. On the other hand, some studies [24,27,28] suggested that the extended π-conjugated bridge benefits the improvement of the photovoltaic performances of DSSCs due to the broadened absorption range. Moreover, our group developed some series of triarylamine-based metal-free dyes for DSSCs [29–32]. The results indicated that the hexyl-substituted thiophene moiety was found to be capable of efficient π-conjugated bridge to enhance the performances due to effectively inhibiting dye aggregation and suppressing the charge recombination.

Organic dyes possessing carbazole [28,33–36] and fluorene [13,16,37–39] moieties have achieved good photovoltaic performances in the application of DSSCs. Nevertheless, there are few reports on DSSCs with spirobifluorene [40,41] unit in the framework of dyes. Expanding on the foregoing points and as part of our efforts to investigate the structural modifications of triphenylamine-based dyes, we herein reported three new D–D–π–A structural metal-free dyes (**SD6**, **SD7**, and **SD8**, see Fig. 1) featuring the dual-role carbazole, fluorene and spirobifluorene moieties, apart from the blocks of a triphenylamine electron-donor (D) and a cyanoacrylic acid electron-acceptor (A). Here, carbazole, fluorene and spirobifluorene moieties inserted between D and 3-hexylthiophene not only acted as the secondary donor but also as the extended π-conjugated bridge together with 3-hexylthiophene. On the one hand, TPA unit incorporated with the electron-rich carbazole, fluorene and spirobifluorene moieties would enhance electron-donating ability of donors which facilitates intramolecular charge transfer (ICT) between the donor and the acceptor and leads to a red shift of the absorption; on the other hand, the bulky structural dual-role moieties combined with thiophene spacer could be beneficial to obtaining high molar extinction coefficients of the absorption as well as suppressing dye aggregation due to incorporation of the hydrophobic alkyl chain. In this study, we mainly investigated the photophysical, electrochemical, and photovoltaic properties of the three as-synthesized dyes with dual-role moieties. DSSCs with excellent performance characteristics were successfully fabricated using these organic dyes. In particular, **SD6** exhibited the highest PCE of 7.03% under AM 1.5 irradiation with 100 mW/cm^2 simulated sunlight, indicating its potential application as metal-free organic dyes in DSSCs.

2. Experimental details

2.1. Materials and reagents

All starting materials were purchased from commercial suppliers (Pacific ChemSource and Alfa Aesar) in analytical grade. THF and toluene were dried and distilled over sodium and benzophenone. DMF, $CHCl_3$, and CH_3CN were dried over by accustomed methods and distilled before using. All other solvents and chemicals used in this work were analytical grade and used without further purification. All chromatographic separations were carried out on silica gel (200–300 mesh).

2.2. Analytical instruments

^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance 400 instrument. UV–vis spectra of the dyes were measured on a Perkin–Elmer Lamada 25 spectrometer. The PL spectra were obtained using Perkin–Elmer LS-50 luminescence spectrometer. FT-IR spectra were obtained on Perkin–Elmer Spectra One spectrophotometer. The elemental analysis of all compounds was performed

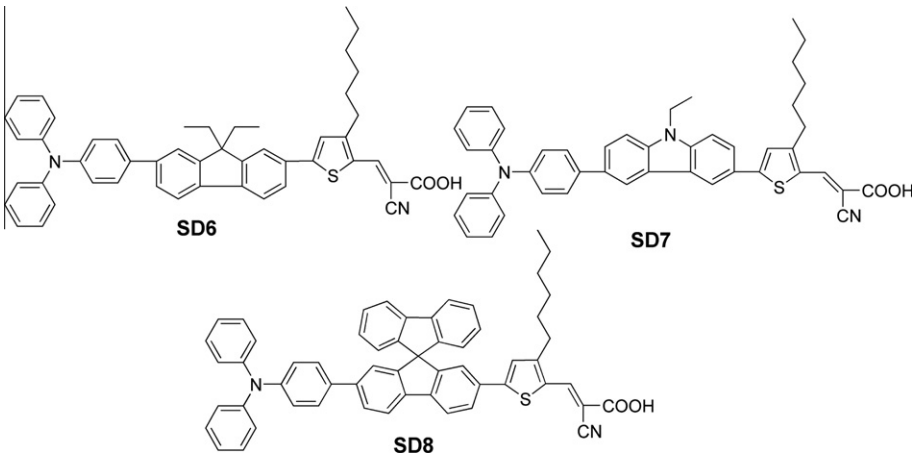

Fig. 1. Molecular structures of the dyes **SD6**–**SD8**.

with an Elementar Vario EL III element analyzer for C, H, N and S determination. Mass spectra were recorded on a Bruker AutoFlex III MALDI-TOF (Germany). Electrochemical redox potentials were obtained by cyclic voltammetry (CV) using a three-electrode cell and an electrochemistry workstation (CHI830B, Chenhua Shanghai). The working electrode was a Pt ring electrode; the auxiliary electrode was a Pt wire, and saturated calomel electrode (SCE) was used as reference electrode. Tetrabutylammonium perchlorate (TBAP) 0.1 M was used as supporting electrolyte in dry acetonitrile. Ferrocene was added to each sample solution at the end of the experiments, and the ferrocenium/ferrocene (Fc^+/Fc) redox couple was used as an internal potential reference. The potentials of dyes vs. NHE were calibrated by addition of 0.63 V to the potentials vs. Fc^+/Fc [14]. The solutions were purged with argon and stirred for 15 min before the measurements.

2.3. General procedure for fabrication and characterization of DSSCs

Fluorine-doped SnO_2 conducting glass (FTO) were cleaned and immersed in aqueous 40 mM $TiCl_4$ solution at 70 °C for 30 min, then washed with water and ethanol, sintered at 450 °C for 30 min. The TiO_2 colloid was prepared from 12 g P25 (Degussa AG, Germany) following a literature procedure [5]. First the 20–30 nm particles sized TiO_2 colloid was coated onto the above FTO glass by sliding glass rod method to obtain a TiO_2 film of 10–15 μm thickness after drying. Subsequently, the 200 nm particles sized TiO_2 colloid was coated on the electrode by same method, resulting in a TiO_2 light-scattering layer of 4–6 μm thickness. The double-layer TiO_2-coated FTO glass were sintered at 450 °C for 30 min, then treated with $TiCl_4$ solution and calcined at 450 °C for 30 min again. After cooling to 100 °C, the TiO_2 electrodes were soaked in a solution with 0.5 mM dyes and kept at room temperature under dark for 24 h.

The dye-adsorbed TiO_2 electrode washed with ethanol and dried. A drop of electrolyte solution was deposited onto the surface of the electrode and a Pt foil counter electrode was clipped onto the top of the TiO_2 electrode to assemble a dye-sensitized solar cells for photovoltaic performance measurements. The electrolyte consisted of 0.5 M LiI, 0.05 M I_2, and 0.5 M 4-*tert*-butylpyridine (TBP) in 3-methoxypropionitrile and the efficient irradiated area of cell was 0.196 cm^2. The photocurrent–voltage (*J–V*) characteristics of solar cells were measured using a Keithley 2602 Source meter under the 100 Mw/cm^2 irradiation of a 500 W Xe lamp with a global AM 1.5 filter for solar spectrum simulation. Meanwhile, the photoelectric conversion efficiency was calculated. The measurement of monochromatic incident photon-to-current conversion efficiencies (IPCE) was performed by a Zolix DCS300PA Data acquisition system and other optical system.

2.4. The detailed experimental procedures and characterization data

2-(4-(*N*,*N*-Diphenylaminephenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (**1**), [42] 3-hexylthiophene-2-carbaldehyde (**2**) [43], 2-(3-hexylthiophen-2-yl)-1,3-dioxolane (**3**) [31], (5-(1,3-dioxolan-2-yl)-4-hexylthiophen-2-yl)tributylstannane (**4**) [31] 2,7-dibromo-9,9-diethylfluorene (**5**) [44], and 3,6-dibromocarbazole (**6**) [45] were synthesized according to the methods reported in the literatures with some modification. The synthetic routes to the three dyes were shown in Scheme 1. The detailed synthetic procedures were as follows.

2.4.1. 3,6-Dibromo-9-ethylcarbazole (**7**)

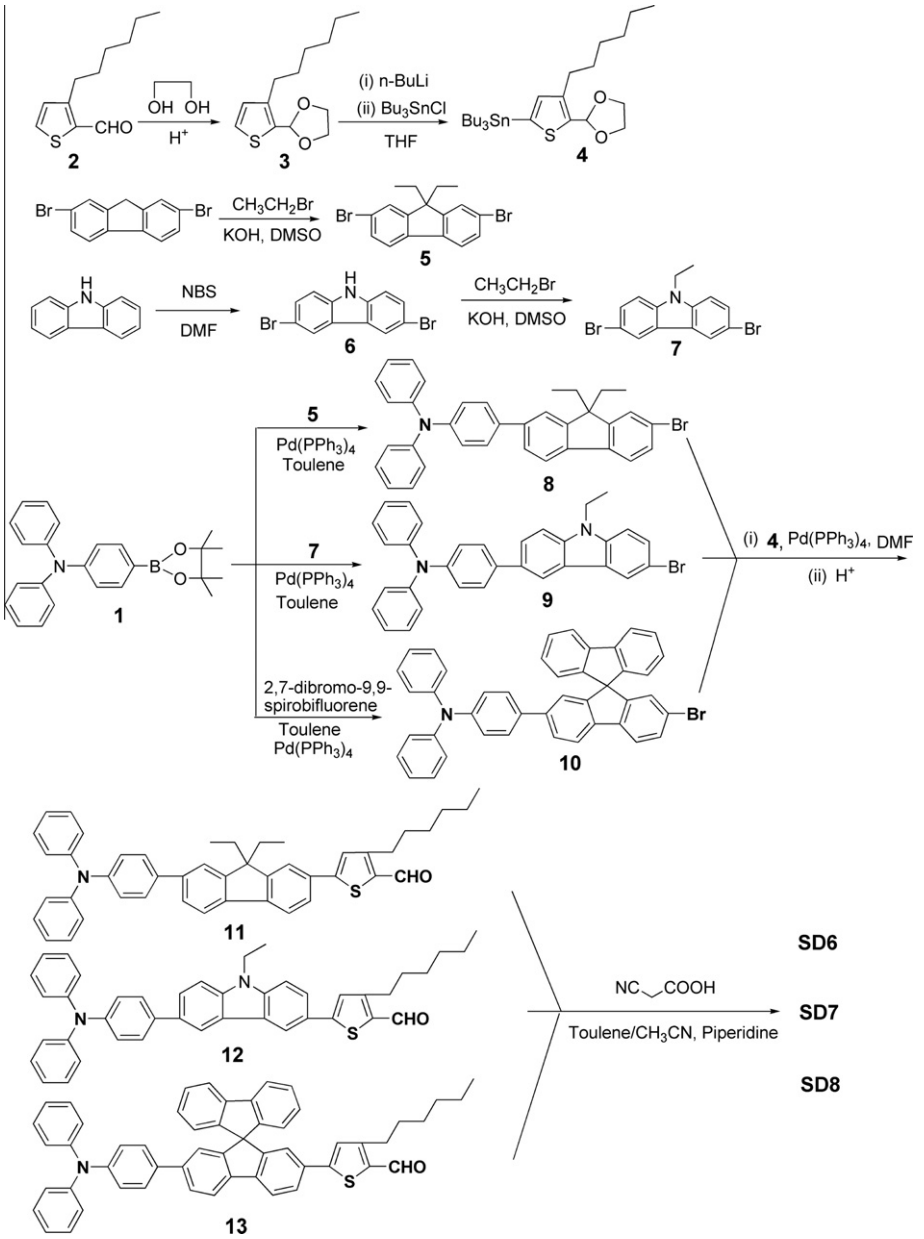
Under nitrogen atmosphere, a mixture of **6** (3.25 g, 10 mmol), bromoethane (1.31 g, 12 mmol), KOH (1.68 g, 30 mmol) and DMSO (30 mL) was stirred at 50 °C for 24 h. After cooling, the reaction mixture was quenched by the addition of water and extracted with dichloromethane. The combined organic layer was washed with dilute HCl and brine several times, dried over anhydrous $MgSO_4$, filtered and evaporated under vacuum. The crude product was purified by recrystallization from anhydrous ethyl alcohol to obtain **7** as a light yellow solid. Yield: 82% (2.88 g). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.15 (s, 1H), 7.56 (d, 2H, J = 8.5 Hz), 7.27 (d, 2H, J = 8.7 Hz), 4.45 (q, 2H, J = 7.1 Hz), 1.53 (t, 3H, J = 7.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 131.5, 121.4, 121.2, 120.1, 117.2, 113.3, 38.3, 13.8. Elem. Anal. Calcd. for $C_{14}H_{11}Br_2N$: C, 47.63; H, 3.14; N, 3.97. Found: C, 47.30; H, 3.17; N, 4.02.

2.4.2. 2-Bromo-7-(4-(diphenylaminephenyl)-9,9-diethylfluorene (**8**)

Under nitrogen atmosphere, a mixture of compound **5** (0.95 g, 2.5 mmol), **1** (0.74 g, 2 mmol), aqueous K_2CO_3 (2 M, 5 mL) and toluene (20 mL) was added in a 50 mL three-necked flask. When the mixture was heated up to 60 °C, $Pd(PPh_3)_4$ (115 mg, 0.1 mmol) was added into the mixture solution quickly, and then the mixture was stirred at 90 °C for 48 h. After cooling to room temperature, the mixture was extracted with dichloromethane. The combined organic layer was washed with dilute HCl and brine several times, dried over anhydrous $MgSO_4$, filtered and evaporated under vacuum. The crude product was purified by silica gel column chromatograph eluted with petroleum ether to obtain **8** as a white solid. Yield: 67% (0.73 g). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.71–7.69 (m, 2H), 7.55–7.51 (m, 8H), 7.46–7.29 (m, 2H), 7.15–7.13 (m, 6H), 7.05–7.02 (m, 2H), 2.04 (q, 4H, J = 7.0 Hz), 0.36 (t, 6H, J = 7.1 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 151.2, 148.4, 147.2, 144.2, 140.6, 139.6, 135.9, 133.4, 130.8, 130.6, 130.4, 129.7, 129.5, 128.9, 128.8, 125.8, 123.2, 123.1, 122.7, 122.5, 50.1, 35.8, 8.8. Elem. Anal. Calcd. for $C_{35}H_{30}BrN$: C, 77.20; H, 5.55; N, 2.57. Found: C, 77.02; H, 5.64; N, 2.60.

2.4.3. 3-Bromo-6-(4-(diphenylaminephenyl)-9-ethylcarbazole (**9**)

Compound **9** was synthesized according the same procedure as that of **8**, except that compound **7** (0.88 g, 2.5 mmol) was used instead of **5**. Yield: 72% (0.75 g). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.25–8.24 (m, 2H), 7.74–7.72 (d, 1H, J = 8.4 Hz), 7.60–7.56 (m, 3H), 7.46 (d, 1H, J = 8.5 Hz), 7.32–7.7.26 (m, 4H), 7.21–7.16 (m, 7H), 7.06–7.03 (m, 2H), 4.38 (q, 2H, J = 7.1 Hz), 1.46 (t, 3H, J = 7.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 147.6,



Scheme 1. Synthetic routes to the three new dyes.

146.4, 144.3, 143.7, 135.7, 134.2, 129.5, 128.8, 125.6, 123.9, 123.2, 122.7, 121.2, 121.1, 119.6, 117.5, 117.1, 113.4, 111.2, 106.3, 37.3, 13.7. Elem. Anal. Calcd. for $C_{32}H_{25}BrN_2$: C, 74.28; H, 4.87; N, 5.41. Found: C, 74.12; H, 4.89; N, 5.46.

*2.4.4. 2-Bromo-7-(4-(diphenylaminephenyl)-9,9-spirobifluorene (**10**)*

Compound **10** was *synthesized* according the same procedure as that of **8**, except that 2,7-dibromo-9,9-spirobifluorene (1.19 g, 2.5 mmol) was used instead of **5**. The crude product was purified by silica gel column chromatograph eluted with petroleum ether/dichloromethane (10/1, v/v) to obtain **10** as a white solid. Yield: 69% (0.88 g). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.86 (d, 2H, J = 7.7 Hz), 7.79–7.77 (m, 1H), 7.60–7.58 (m, 1H), 7.51–7.35 (m, 3H), 7.25–7.21 (m, 8H), 7.16–7.14 (m, 3H), 7.07–7.00 (m, 6H), 6.89 (s, 1H), 6.85 (s, 1H), 6.79–6.77 (d, 2H, J = 7.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 150.1, 148.5, 147.9, 147.7, 147.3, 144.3, 141.2, 140.3, 139.4, 135.8, 133.2, 130.8, 130.5, 130.2, 129.7, 129.6, 128.9, 128.8, 128.7, 128.3, 128.1, 126.9, 125.9, 123.4, 122.7, 122.6, 46.8. Elem. Anal. Calcd. for $C_{43}H_{28}BrN$: C, 80.87; H, 4.42; N, 2.17. Found: C, 80.65; H, 4.48; N, 2.21.

*2.4.5. 5-(2-(4-(Diphenylaminephenyl)-9,9-diethylfluorene-7-yl)-3-hexylthiophene-2-carbaldehyde (**11**)*

Under nitrogen atmosphere, a mixture of compound **8** (0.71 g, 1.3 mmol), **4** (0.86 g, 1.6 mmol), and DMF (30 mL)

was added in a 50 mL three-necked flask. When the mixture was heated up to 60 °C, $Pd(PPh_3)_4$ (115 mg, 0.1 mmol) was added into the mixture solution quickly, and then the mixture was stirred at 100 °C for 48 h. After cooling to 70 °C, the mixture was treated with dilute aqueous HCl (10 mL) solution and stirred for 30 min. Then the resulting mixture was changed into a yellow-green color and extracted with dichloromethane at room temperature. The combined organic layer was washed with brine several times, dried over anhydrous $MgSO_4$, filtered and evaporated under vacuum. The crude product was purified by silica gel column chromatograph eluted with petroleum ether/dichloromethane (5/1, v/v) to obtain **11** as a yellow sticky oil. Yield: 43% (0.37 g). FT-IR (KBr, cm^{-1}): 1667 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 10.04 (s, 1H), 7.76–7.71 (m, 2H), 7.70–7.68 (m, 2H), 7.62–7.56 (m, 6H), 7.31–7.28 (m, 3H), 7.19–7.17 (m, 6H), 7.10–7.05(m, 2H), 2.99 (t, 2H, J = 7.8 Hz), 2.12–2.10 (m, 4H), 1.80–1.76 (m, 2H), 1.56–1.36 (m, 6H), 0.88 (t, 3H, J = 6.5 Hz), 0.40 (t, 6H, J = 7.3 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 182.6, 156.4, 148.6, 148.3, 147.6, 147.3, 144.2, 141.1, 140.8, 139.9, 135.9, 133.3, 130.9, 130.6, 130.1, 129.8, 128.9, 128.7, 127.3, 125.9, 125.5, 123.2, 122.6, 50.1, 35.8, 32.0, 31.9, 29.1, 24.7, 22.8, 14.2, 8.9. Elem. Anal. Calcd. for $C_{46}H_{45}NOS$: C, 83.72; H, 6.87; N, 2.12; S, 4.86. Found: C, 83.86; H, 6.53; N, 2.01; S, 5.02.

2.4.6. 5-(3-(4-(Diphenylaminephenyl)-9-ethylcarbazole-6-yl)-3-hexylthiophene-2-carbaldehyde (**12**)

Compound **12** was synthesized according the same procedure as that of **11**, except that compound **9** (0.67 g, 1.3 mmol) was used instead of **8**. Yield: 42% (0.34 g). FT-IR (KBr, cm^{-1}): 1665 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 10.02 (s, 1H), 8.43 (s, 1H), 8.33 (s, 1H), 7.85 (d, 1H, J = 8.4 Hz), 7.78 (d, 1H, J = 8.4 Hz), 7.60 (d, 2H, J = 8.5 Hz), 7.47 (d, 1H, J = 8.4 Hz), 7.43 (d, 1H, J = 8.5 Hz), 7.31–7.26 (m, 4H), 7.21–7.16 (m, 7H), 7.05–7.04 (m, 2H), 4.41 (q, 2H, J = 7.2 Hz), 2.99 (t, 2H, J = 8.2 Hz), 1.78–1.72 (m, 2H), 1.48 (t, 3H, J = 7.0 Hz), 1.43–1.26 (m, 6H), 0.86 (t, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 182.5, 157.0, 148.9, 147.6, 147.5, 144.3, 143.8, 140.8, 136.6, 132.3, 130.9, 129.8, 129.7, 128.7, 127.2, 125.3, 123.2, 122.8, 119.4, 119.2, 116.7, 111.6, 106.3, 48.5, 32.1, 31.9, 29.1, 24.8, 22.8, 15.8, 14.2. Elem. Anal. Calcd. for $C_{43}H_{40}N_2OS$: C, 81.61; H, 6.37; N, 4.43; S, 5.07. Found: C, 81.76; H, 6.53; N, 4.64; S, 5.61.

2.4.7. 5-(2-(4-(Diphenylaminephenyl)-9,9-spirobifluoren-7-yl)-3-hexylthiophene-2-carbaldehyde (**13**)

Compound **13** was synthesized according the same procedure as that of **11**, except that compound **10** (0.71 g, 1.1 mmol) was used instead of **8**. The crude product was purified by silica gel column chromatograph eluted with petroleum ether/dichloromethane (8/1, v/v) to obtain **12** as a yellow solid. Yield: 33% (0.27 g). FT-IR (KBr, cm^{-1}): 1665 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 10.03 (s, 1H), 7.89–7.88 (m, 4H), 7.72 (d, 1H, J = 7.4 Hz), 7.63 (d, 1H, J = 7.4 Hz), 7.48–7.45 (m, 2H), 7.40–7.20 (m, 10H), 7.14–7.12 (m, 2H), 7.06–6.99 (m, 6H), 6.98 (s, 1H), 6.80 (d, 1H, J = 7.6 Hz), 2.95 (t, 2H, J = 7.7 Hz), 1.67–1.63 (m, 2H), 1.54–1.26 (m, 6H), 0.88 (t, 3H, J = 7.8 Hz). Elem. Anal. Calcd. for $C_{55}H_{47}NOS$: C, 85.79; H, 6.15; N, 1.82; S, 4.16. Found: C, 85.66; H, 6.43; N, 1.80; S, 4.61.

2.4.8. 3-(5-(2-(4-(Diphenylaminephenyl)-9,9-diethylfluorene-7-yl)-3-hexylthiophene-2-yl)-2-cyanoacrylic acid (**SD6**)

Under nitrogen atmosphere, a mixture of compound **11** (0.40 g, 0.61 mmol), cyanoacetic acid (0.1 g, 1.22 mmol), piperidine (0.5 mL), toluene (15 mL) and CH_3CN (5 mL) was refluxed at 80 °C for 12 h. After cooling, the solution was extracted with dichloromethane and 0.1 M aqueous solution of HCl. The organic layer was dried over anhydrous $MgSO_4$, filtered and evaporated under vacuum. The crude product was purified by silica gel column chromatograph eluted with chloroform/methanol (15/1, v/v) to obtain **SD6** as a red solid. Yield: 68% (0.30 g). FT-IR (KBr, cm^{-1}): 2216 ($\nu_{\equiv}$), 1682 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.50 (s, 1H), 7.79–7.76 (m, 3H), 7.65(s, 1H), 7.62–7.57 (m, 4H), 7.38 (s, 1H), 7.32–7.28 (m, 4H), 7.20–7.06 (m, 6H), 7.08–7.04 (m, 2H), 2.86 (t, 2H, J = 8.1 Hz), 2.15–2.14 (m, 4H), 1.72 (br, 2H), 1.43–1.28 (m, 6H), 0.93 (br, 3H), 0.39 (t, 6H, J = 7.2 Hz). MALDI-TOF: m/z 726.169.

2.4.9. 3-(5-(3-(4-(Diphenylaminephenyl)-9-ethylcarbazole-6-yl)-3-hexylthiophene-2-yl)-2-cyanoacrylic acid (**SD7**)

SD7 was synthesized according the same procedure as that of **SD6**, except that compound **12** (0.2 g, 0.32 mmol) was used instead of **11**. The crude product was purified by silica gel column chromatograph eluted with chloroform/methanol (10/1, v/v) to obtain **SD7** as a red solid. Yield: 59% (0.13 g). FT-IR (KBr, cm^{-1}): 2210 ($\nu_{\equiv}$), 1679 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.49 (s, 1H), 8.47 (s, 1H), 8.40 (s, 1H), 7.85 (d, 1H, J = 7.7 Hz), 7.74 (d, 1H, J = 7.9 Hz), 7.64 (d, 2H, J = 8.1 Hz), 7.49–7.45 (m, 3H), 7.38 (s, 1H), 7.17–7.13 (m, 9H), 7.05–7.04 (m, 2H), 4.42 (br, 2H), 2.86 (t, 2H, J = 7.6 Hz), 1.72–1.65 (m, 2H), 1.50 (t, 3H, J = 7.3 Hz), 1.41–1.26 (m, 6H), 0.89 (t, 3H, J = 6.4 Hz). MALDI-TOF: m/z 699.093.

2.4.10. 3-(5-(2-(4-(Diphenylaminephenyl)-9,9-spirobifluoren-7-yl)-3-hexylthiophene-2-yl)-2-cyanoacrylic acid (**SD8**)

SD8 was synthesized according the same procedure as that of **SD6**, except that compound **13** (0.16 g, 0.21 mmol) was used instead of **11**. The crude product was purified by silica gel column chromatograph eluted with chloroform/methanol (20/1, v/v) to obtain **SD8** as a red solid. Yield: 75% (0.13 g). FT-IR (KBr, cm^{-1}): 2214 ($\nu_{\equiv}$), 1689 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.40 (s, 1H), 7.92–7.90 (m, 4H), 7.78 (d, 1H, J = 7.4 Hz), 7.65 (d, 1H, J = 7.4 Hz), 7.45–7.40 (m, 2H), 7.28–7.21 (m, 6H), 7.17–7.14 (m, 2H), 7.09–7.00 (m, 9H), 6.88 (s, 1H), 6.81 (d, 2H, J = 7.6 Hz), 2.73 (t, 2H, J = 7.6 Hz), 1.69–1.55 (m, 2H), 1.34–1.27 (m, 6H), 0.87 (t, 3H, J = 7.9 Hz). MALDI-TOF: m/z 820.267.

3. Results and discussion

3.1. Synthesis and characterization

The molecular structures and synthetic routes of the three organic dyes **SD6**, **SD7**, and **SD8** are shown in Fig. 1 and Scheme 1, respectively. All of the dyes have been synthesized by the stepwise synthetic protocol. Firstly, the dual-role fluorene, carbazole and spirobifluorene moieties were introduced through the Suzuki coupling reaction between triphenylamine-based boric ester (**1**) and dibrominated aryl compounds (**5**, **7**, and 2,7-dibromo-9,9-spirobifluorene). Then, the extension of π-conjugated aryl chain in **8**, **9**, and **10** was accomplished by Stille coupling reactions for adding a 3-hexylthiophenyl-2-carbaldehyde moiety (compound **2**), respectively. Finally, the Knoevenagel condensation reactions of aldehyde derivatives **10**–**13** with cyanoacetic acid afforded the target dyes **SD6**–**SD8** in the presence of piperidine. It is necessary to note that tributylstannyl compound **4** was obtained according to our previous report [31] started from compound **2** which was synthesized from 2-bromo-3-hexylthiophene in the presence of Mg and DMF using the method as described by Demandrille et al. [43] The yields of compounds **8**–**10** via Suzuki coupling reactions were quite satisfactory, i.e., in a range of 67–72%. Whereas, for compounds **11**–**13** by Stille coupling reactions exhibited relatively low yields (33–43%). The structures of all dye molecules were characterized unambiguously with FT-IR, ^{1}H NMR spectroscopy as well as MALDI-TOF. All final products can be crystallized into deep color solids.

3.2. Optical properties

The ultraviolet–visible (UV–vis) absorption spectra of the three dyes in diluted $CHCl_3$ solution (10^{-5} M) are displayed in Fig. 2, and the corresponding data are collated in Table 1. All the dyes exhibit two distinct absorption bands: one absorption band is in the UV region (300–370 nm) corresponding to the π–π^* electron transitions of the conjugated molecules; and the other is in the visible region (400–550 nm) that can be assigned to an intramolecular charge transfer (ICT) between the triphenylamine containing double donating unit and the cyanoacrylic acid anchoring moiety [46]. It can be seen that the maximum absorption (λ_{max}) of the visible region red-shifts from 450 nm to 457 and 469 nm for **SD8**, **SD6**, and **SD7**, respectively. This red-shifted phenomenon may be ascribed to the following two aspects. The first reason is the various ability of electron-denoting of spirobifluorene, fluorene and carbazole moieties. Among the three dual-role moieties, the ability of electron-denoting of carbazole moiety is the strongest, which results in an obviously red shift of **SD7** compared to **SD6** and **SD8**. The other reason may be ascribed to the more planar geometry in **SD7** and **SD6**, because the inserting carbazole and fluorene moieties between phenyl rings and thiophenyl group show longer conjugation relative to spirobifluorene moiety for it's non-coplanar geometry.

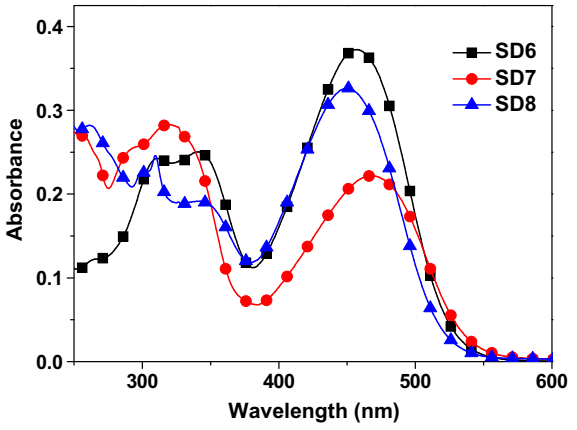


Fig. 2. Absorption spectra of the three dyes in $CHCl_3$ solutions (10^{-5} M) at 25 °C.

As depicted in Table 1, the molar extinction coefficient (ε) of the ICT bands of the three dyes ($2.2–3.7 \times 10^4$ M^{-1} cm^{-1}) are higher than that of SD2 (1.9×10^4 M^{-1} cm^{-1}) [29], indicating a better ability of light harvesting of the D–D–π–A structure than that of the corresponding D–π–A counterpart. Moreover, the ε of the ICT bands increases in the order of **SD8** < **SD7** < **SD6**, which suggests that **SD6** may have the best ability of light harvesting. The higher ε of the organic dyes allows a correspondingly thinner nanocrystalline film so as to avoid the decrease of the film mechanical strength. This also benefits the electrolyte diffusion in the film and reduces the recombination possibility of the light-induced charges during transportation [47,48].

We also measured the emission spectra of dyes **SD6**–**SD8** when they are excited with their λ_{max} of the visible region in $CHCl_3$ solution (10^{-5} M). The corresponding data are also summarized in Table 1. As shown in Fig. 3, the maximum emission (λ_{em}) of **SD7** (556 nm) is very obviously blue-shifted in comparison with **SD6** (667 nm) and **SD8** (666 nm) which indicates that the excited states of **SD7** need more energy for the excited from the ground state. It is unfavorable for light harvesting of the solar spectrum.

The absorption spectra of dyes **SD6**–**SD8** absorbed onto the surface of TiO_2 displayed broader and a slight red shift of 11 nm (**SD7**) and 6 nm (**SD8**) or blue shift of 7 nm (**SD6**) with respect to those in solutions, respectively (Fig. 4). It is presumed that the red and blue shifts of the absorption spectra may be contributed to the formation of aggregates [14,28] on the TiO_2 surface. Such a slight shifts indicates that the aggregates of dyes are not obvious which may be explained that the introduction of the bulk dual-role moieties incorporated with the long alkyl of thiophenyl unit inhibits the aggregates to some extent. Another noteworthy feature in the spectra of dyes adsorbed on TiO_2 surfaces is an apparent tailing toward longer wavelength region (Fig. 4). In solutions the low energy edge of absorption bands does not exceed 600 nm (Fig. 2), yet on TiO_2 the absorption threshold extends to 750 nm. The long wavelength absorption should be result from the formation of a certain degree of aggregates on the surface of TiO_2. The

Table 1
Maximum absorption and emission data of the three dyes.

Dye	λ_{max}[a]/nm (ε/M^{-1} cm^{-1})			λ_{max}[b]/nm	λ_{em}[c]/(nm)
SD6	457(37,000)	342(25,000)	309(24,000)	450	667
SD7	469(22,000)	319(28,000)	–	480	556
SD8	450(33,000)	342(19,000)	309(24,000)	456	666

[a] Maximum absorption in $CHCl_3$ solution (10–5 M).
[b] Maximum absorption on TiO_2 film.
[c] Maximum emission of the dyes in $CHCl_3$ solution (10^{-5} M). ε is the extinction coefficient at λ_{abs} of maximum absorption.

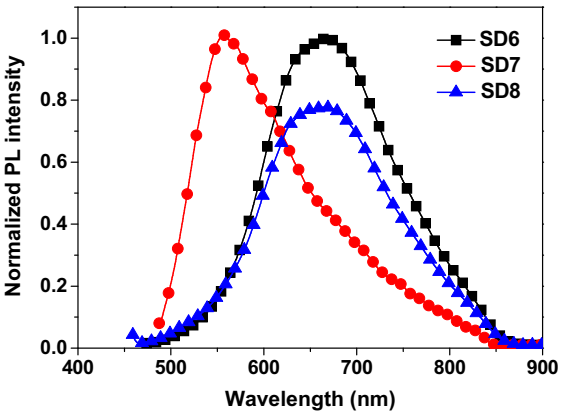

Fig. 3. Emission spectra of the three dyes in $CHCl_3$ solutions (10^{-5} M) at 25 °C.

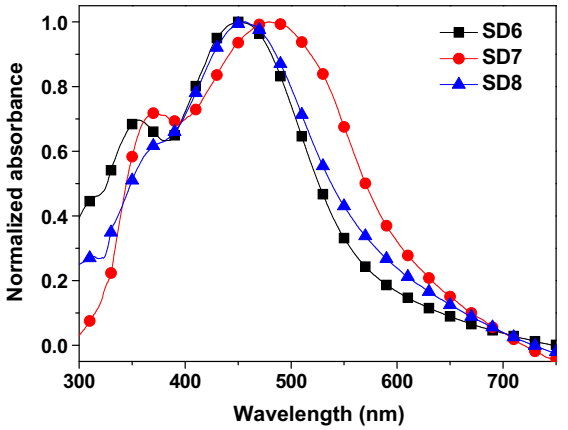

Fig. 4. Absorption spectra of the three dyes adsorbed on TiO_2 surface.

absorption of aggregates is responsible for the induction of photocurrent in the regions of ⩾600 nm (Fig. 6) [49].

3.3. Electrochemical properties

To evaluate the possibility of electron transfer from the excited dye molecule to the conductive band of TiO_2, cyclic voltammetry (CV) was performed in CH_3CN with 0.1 M tetrabutylammonium perchlorate (TBAP) as a supporting electrolyte (Fig. 5). The first oxidation potential vs. NHE (E_{ox}), which corresponds to the highest occupied molecular orbital (HOMO vs. NHE), was calibrated by addition of

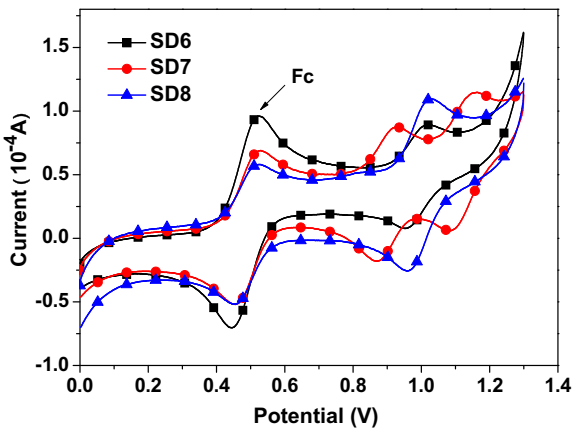

Fig. 5. Cyclic voltammograms of the three dyes: working electrode, Pt ring; auxiliary electrode, Pt wire; reference electrode, Hg/Hg_2Cl_2; scanning rate is 100 mV/s.

Table 2
Electrochemical data of the three dyes.[a]

Dye	λ_{int}/nm	E_{0-0}/eV	E_{ox}/V vs. NHE	E_{red}/V vs. NHE	E_{gap}/V
SD6	531	2.34	1.13	−1.21	0.71
SD7	514	2.41	1.03	−1.38	0.88
SD8	521	2.38	1.13	−1.25	0.55

[a] E_{0-0} values were calculated from intersection of the normalized absorption and the emission spectra (λ_{int}): $E_{0-0} = 1240/\lambda_{int}$. The first oxidation potential (vs. NHE), E_{ox} was measured in acetonitrile and calibrated by addition of 0.63 V to the potential vs. Fc/Fc^+. The reduction potential, E_{red}, was calculated from E_{ox}–E_{0-0}. E_{gap} is the energy gap between the E_{red} of dye and the CB level of TiO_2 (−0.5 V vs. NHE).

0.63 V to the potential (vs. SCE) vs. Fc/Fc^+ by CV. The first oxidation potentials of **SD6** and **SD8** were measured as same as 1.13 V, which shifted in positive direction compared with **SD7** (1.03 V) (Table 2). Moreover, the three dyes show higher E_{ox} than that of SD2 dye (0.93 V) [29], which predicts that a higher open-circuit voltage (V_{oc}) may be obtained for **SD6**–**SD8** due to the comparatively lower-lying HOMO levels [24]. It is can be seen that all the HOMO levels of three dyes are more positive than the iodide/triiodide redox couple (~0.42 V vs. NHE), ensuring that there is enough driving force for efficient regeneration of the dye through the recapture of the injected electrons by the dye cation radical.

By neglecting any entropy change during light absorption, the reduction potential vs. NHE (E_{red}), which corresponds to the lowest unoccupied molecular orbital

(LUMO vs. NHE), can be obtained from the first oxidation potential (E_{ox}) and the E_{0-0} value determined from the intersection of absorption and emission spectra, namely, E_{ox}–E_{0-0}. The calculated LUMO levels of **SD6**, **SD7**, and **SD8** were −1.21, −1.38, and −1.25 V vs. NHE (Table 2), respectively, which all are sufficiently higher than that of the conduction band (CB) level of TiO_2 (−0.5 V vs. NHE). A visible positive shift of the reduction potential (E_{red}) in **SD6** relative to that of **SD7** and **SD8** may be due to more delocalization of the π-conjugation system. The E_{gap} between the CB of TiO_2 and the E_{red} (vs. NHE) ranges from 0.55 (**SD8**) to 0.88 eV (**SD7**) (Table 2). Provided that energy gap of 0.2 eV is necessary for efficient electron injection [7,18], these driving forces are sufficiently large for effective electron injection. Therefore, the three dyes used as sensitizers will have sufficient driving force for electron transfer from the excited dye molecules to the conduction band of TiO_2 electrode. Table 2 summarizes all the electrochemical properties of the three dyes.

3.4. Electronic structure quantum chemical calculations

In order to gain an insight into the molecular structure and electron distribution, density functional theory (DFT) calculations were performed on the dyes **SD6**–**SD8** using the Gaussian 03 program package. In particular we used B3LYP as exchange–correlation functional and 3-21G* as basis set. The electron distribution of the HOMO and LUMO of the dyes is shown in Table 3. It is obvious that the electron density of HOMO is localized mainly on the triphenylamine moiety and is extended along the π-conjugated bridge to the central region of the molecule. On the other hand, the LUMO is localized over the cyanoacrylic unit through thiophene. We notice that the HOMO–LUMO excitation induced by light irradiation could move the electron distribution from the TPA-unit to the cyanoacrylic acid moiety via dual-role moiety-containing π-conjugated bridges and the photo-induced electron transfer from the dyes to the TiO_2 electrode can occur efficiently by the HOMO–LUMO transition.

To gain insight into the excited states giving rise to the optically active absorption bands in the UV–vis region, we performed time dependent DFT (TDDFT) excited states calculations at the B3LYP/6-31G* level in vacuo with the B3LYP/6-21G* optimized ground-state geometries, given the negligible effect of solvation on the electronic structure. The lowest transition of three dyes is calculated at 2.13–2.20 eV (Table 4) and corresponds to the intramolecular charge transfer (ICT) excitation from the triphenylamine-dual moiety-based the HOMO to the LUMO, localized on thiophene–cyanoacrylate moieties. Another transition calculated at 2.75–2.83 eV is a $\pi-\pi^*$ excitation from the HOMO−1 to the LUMO, therefore taking place within the thiophene–cyanoacrylate moiety.

Table 3
Frontier molecular orbitals of the HOMO and LUMO calculated with DFT on a B3LYP/3-21G* level of the dyes **SD6**, **SD7**, and **SD8**.

Dye	HOMO	LUMO
SD6		SD7		SD8		
Table 4
Calculated TDDFT excitation energies for the lowest transition (eV, nm), oscillator strengths (*f*), composition in terms of molecular orbital contributions, and experimental absorption maxima.

Dye	State	Composition	*E* (eV, nm)	*f*	Exp. (eV, nm)
SD6	S1	70%, HOMO → LUMO	2.19(566)	0.32	457
	S2	64%, HOMO−1 → LUMO	2.81(441)	1.11	342
SD7	S1	70%, HOMO → LUMO	2.13(583)	0.04	469
	S2	65%, HOMO−1 → LUMO	2.75(451)	0.52	319
SD8	S1	70%, HOMO → LUMO	2.20(563)	0.31	450
	S2	64%, HOMO−1 → LUMO	2.83(438)	0.90	342

The calculated absorption wavelength increases in the order of **SD8** < **SD6** < **SD7** (Table 4), which is in qualitative agreement with experimental absorption spectra. However, the calculated wavelengths are considerably red-shifted compared to the experimental absorption maximum. This is expected since traditional exchange–correlation functionals, such as B3LYP, underestimate the energies for ICT transitions and the error increases with the distance between the negative and positive charges of the charge-transfer state [50].

3.5. Photovoltaic performance of DSSCs

DSSCs were fabricated using these dyes as the sensitizers, with an effective area of 0.196 cm^2, TiO_2 particles on FTO, and the electrolyte composed of 0.5 M LiI, 0.05 M I_2, and 0.5 M 4-*tert*-butyl-pyridine (TBP) in 3-methoxy-propionitrile. Fig. 6 shows incident photon-to-electron conversion efficiency (IPCE) as a function of the wavelength for the sandwiched DSSCs based on the three dyes as sensitizers. As shown in Fig. 6, the IPCE action spectrum for DSSC based on **SD7** is broader than those of **SD6** and **SD8**, which is consistent with the tendency of UV–vis absorption spectra on TiO_2 surface (Fig. 4). The IPCE spectrum of **SD8** is blue shifted compared to those of **SD6** and **SD7** as a result from distortion of dual-role unit, which is in agreement with bulk steric hindrance of spirobifluorene moiety in **SD8** framework. In comparison with **SD8**, **SD6** and **SD7** give the higher IPCE values with the maximum of ~73% at 427 nm and 68% at 443 nm, respectively, which implies the two sensitizers would show a relatively large photocurrent in DSSCs. The higher IPCE values might attribute to an effective intramolecular cascade energy transfer from the double donor to cyanoacetic acid acceptor via π-bridge.

Fig. 7 shows current density–voltage (*J*–*V*) characteristics of devices based on the three dyes. The detailed photovoltaic performances are listed in Table 5. Compared to **SD7** and **SD8**, the **SD6**-sensitized cell exhibited better photovoltaic performances with a short-circuit photocurrent density (J_{sc}) of 14.25 mA/cm^2, an open-circuit voltage (V_{oc}) of 0.70 V, and a filled factor (FF) of 0.705, corresponding to a power conversion efficiency (PCE) of 7.03% (Table 5). According to Fig. 7, it is clear that the photovoltaic performances of the DSSCs can be evidently affected by the dual-role moieties in the dye molecules. In comparison with **SD8**, the J_{sc} and V_{oc} values of **SD6** and **SD7** are significantly improved by introducing better electron-donating ability of fluorene and carbazole moieties to act as the secondary donor. The remarkably increased J_{sc} values can be reflected in their broad and high maximum IPCEs values of **SD6** and **SD7**. The improved V_{oc} values of **SD6** and **SD7** compared to **SD8** could be attributed to the effective retardation of charge recombination between the electrons at the TiO_2 and the oxidized dyes, which may be resulted from the extra hydrophobic alkyl chains of fluorene and carbazole groups in the dyes **SD6** and **SD7** [28–31]. In addition, the broader absorption band and higher IPCEs in range of 500–650 nm of **SD7** likely results in a higher J_{sc} (14.79 mA/cm^2) value compared with

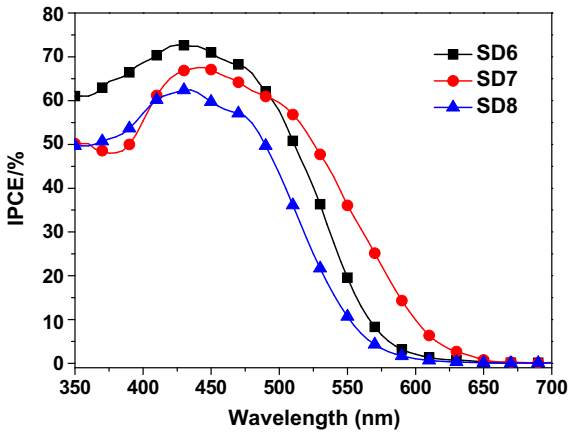

Fig. 6. IPCE plots for the DSSCs based on the three dyes.

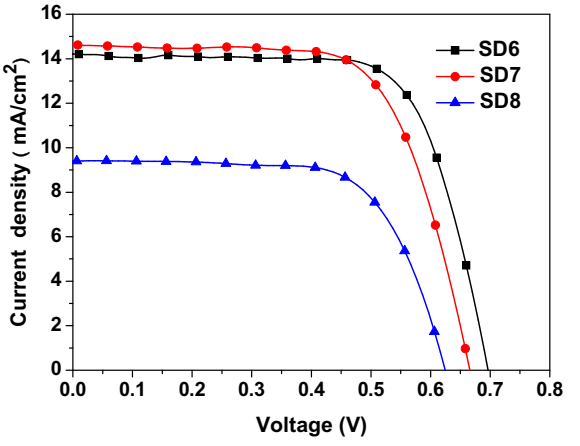

Fig. 7. Current density–voltage characteristics for DSSCs based on the three dyes.

Table 5
Photovoltaic performance of DSSCs based on the three dyes.

Dye	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
SD6	14.25	0.70	0.705	7.03
SD7	14.79	0.66	0.667	6.51
SD8	9.12	0.63	0.717	4.12

that of **SD6** (14.25 mA/cm^2), but the lower V_{oc} (0.66 V) and FF (0. 667) for the device of **SD7** lead to the lower efficiency (6.51%) finally. The higher V_{oc} of **SD6** than that of **SD7** might be due to the comparatively lower-lying HOMO of the former (estimated from the CV), which offers enough larger driving force for the reduction of the oxidized dye. This, in turn, will lead to a slower back electron transfer from TiO_2 to the dye and result in a lager V_{oc} value [24].

3.6. Electrochemical impedance spectroscopy studies

Electrochemical impedance spectroscopy (EIS) is a powerful technique of characterizing the important interfacial charge transfer processes in a DSSC. The EIS was measured in the dark to elucidate correlation of V_{oc} with those dyes. The Nyquist plots of DSSCs with three dyes are shown in Fig. 8. Three semicircles were observed in the Nyquist plots. The small and large semicircles, respectively located in the high- and middle frequency regions, are assigned to the charge transfer at Pt/electrolyte and TiO_2/dye/electrolyte interface, respectively [24,28,51,52]. Another small semicircle, which should have appeared at the low-frequency region, is overlapped by the middle frequency large semicircle. The charge recombination resistance (R_{rec}) on the TiO_2 surface, which is related to the charge recombination rate between injected electron and electron acceptor (I_3^-) in the electrolyte, is estimated by the large semicircle width. A large R_{rec} means the small charge recombination rate and vice versa. The R_{rec} values for **SD6**, **SD7**, and **SD8** were estimated to be 52, 40 and 29 Ω, respectively. The significantly increased R_{rec} values in the cells of **SD6** and **SD7** imply the retardation of the charge recombination between injected electron and electron acceptor (I_3^-) in the electrolyte, with a consequent increase of V_{oc}. The result appears to be consistent with the above-mentioned changing tendencies of V_{oc} values in the cells of three dyes.

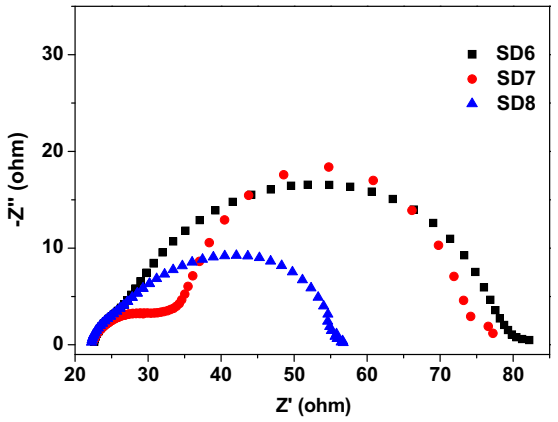

Fig. 8. EIS Nyquist plots for DSSCs based on the three dyes measured in the dark.

4. Conclusions

In summary, we have synthesized and characterized three triphenylamine-based D–D–π–A sensitizers **(SD6–SD8)**, featuring dual-role carbazole, fluorene and spirobifluorene moieties, for the application in DSSCs. There are several advantages preformed by these D–D–π–A structural dyes: (1) enhanced light-harvesting ability as reflected from the improvement of extinction coefficients in the visible region and as a result of high short-circuit photocurrent density (J_{sc}); (2) lower-lying HOMO levels of the dyes, which are favorable for achieving high open-circuit voltage (V_{oc}); (3) reduced dyes aggregates and effective retardation of charge recombination due to the extra hydrophobic alkyl chains of dual-role moieties incorporated with the long alkyl of thiophenyl unit. The DSSCs fabricated by using these dyes display remarkable PCEs, typically in a range of 4–7%. The optimal IPCE value reaches beyond 70%. The best photovoltaic performance among the three dyes exhibits a J_{sc} value of 14.25 mA/cm^2, V_{oc} value of 0.70 V, and FF value of 0.705, all summed up to a PCE of 7.03%. Our results continue to show that the molecular design and modification of organic dyes are a very effective strategy to achieve highly efficient DSSCs.

White organic light-emitting diodes
bis(2-(4-trifluoromethyl-2-hydroxyphenyl)benzothiazolate)zinc [Zn(4-TfmBTZ)$_2$]
Electroplex

ABSTRACT

An efficient white-light emitting diode ITO/NPB/Zn(4-TfmBTZ)$_2$/Alq$_3$/LiF/Al was obtained when a new material bis(2-(4-trifluoromethyl-2-hydroxyphenyl)benzothiazolate)zinc [Zn(4-TfmBTZ)$_2$] was used as an electron-acceptor emitting layer, NPB as an electron-donor emitting and hole-transporting layer, and Alq$_3$ as an emitting and electron-transporting layer. In this device, the exciton emissions of NPB, Zn(4-TfmBTZ)$_2$ and Alq$_3$ in addition to the electroplex emissions of Zn(4-TfmBTZ)$_2$/NPB interface render white light output. Inserting an Alq$_3$ layer with appropriate thickness can increase EL efficiency and improve chromaticity. The most pure white light emission with CIE coordinates of (0.30, 0.34) and CRI of 90.2 can be attained by adjusting Alq$_3$ layer thickness to 20 nm. Moreover, CIE coordinates are very insensitive to the applied voltage. The CIE coordinate region is (0.29–0.30, 0.33–0.34) at various forward bias (8–13 V). This device showed the maximum luminance of 2445 cd/m^2 at 14 V and the maximum current efficiency of 1.39 cd/A, which will be improved further by optimizing the preparation technique of device.

1. Introduction

In recent years, white organic light-emitting diodes (WOLEDs) have attracted a great deal of interest due to their potential applications in full color displays, back lighting of flat-panel display, and lighting purposes [1–3]. Several routes have been typically employed to obtain white light: (i) multilayer structure, (ii) multi-doped system in a single layer, (iii) bimolecular excited species (exciplex/excimer/electroplex/electromer), and so on. Among them the method based on bimolecular species is considered to be a simple, cheap and general technique [4–7]. The bimolecular excited states are a kind of transient complexes formed under energy and/or charge exchange between neighbor molecules and usually lead to an additional redshifted broad band emission, and consequently can be utilized to tune emission color and design white OLED by a simple device structure [8–18]. Unless the dissociation process of the excited states into the separated ion pair is facile, photoexcitation rarely generates free charge carriers. Therefore, the electroplexes are visible mostly in electroluminescence (EL) spectrum but not normally in photoluminescence (PL) spectrum. However, exciplexes are readily observed in EL and PL processes [19].

It is well known that bis(2-(2-hydroxyphenyl)benzothiazolate)zinc (Zn(BTZ)$_2$) can be used as an effective white light emissive and electron transport material in EL device [20,11,21,22]. Hamada et al. [20] reported a greenish white OLED combining the emissions of Zn(BTZ)$_2$ exciton and Zn(BTZ)$_2$/TPD interface exciplex. Recently, Singh et al. [11] demonstrated an improvement white OLED with a broadened EL spectrum and the CIE coordinate of (0.38, 0.40) due to formation of exciplexes and electroplexes at Zn(BTZ)$_2$/TPD interface. But the latest report [21] had

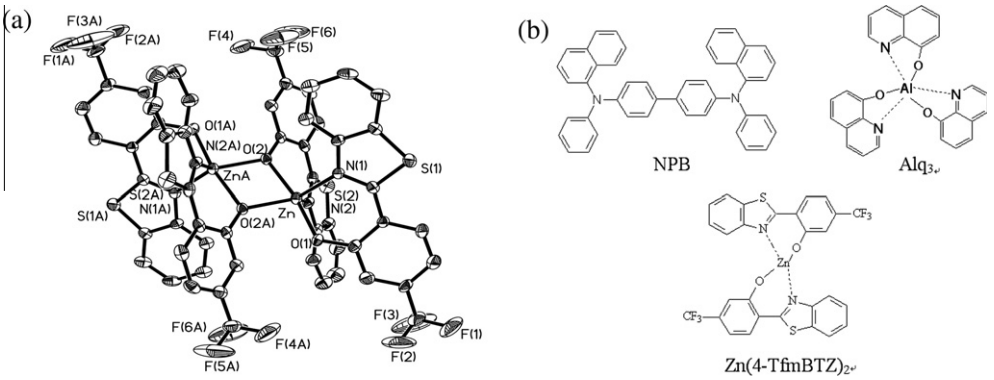

Fig. 1. Crystal structure of $Zn(4\text{-}TfmBTZ)_2$ (a) and chemical structures of materials used in this study (b).

showed that the unusually broad white-light emitting of the device based on $Zn(BTZ)_2$/TPD is due to optical interference effect and light emission originating from fluorescence and phosphorescence.

To date, zinc complexes based on functionalized 2-(2-hydroxyphenyl)benzothiazole derivatives for WOLEDs have not been reported to the best of our knowledge. In this paper, we will demonstrate an excellent WOLED with bis(2-(4-trifluoromethyl-2-hydroxyphenyl)benzothiazolate)-zinc ($Zn(4\text{-}TfmBTZ)_2$) as an electron-acceptor emitting layer, N,N′-diphenyl-N,N'-bis(1-naphthyl)-(1,1′-biphenyl)-4,4′-diamine (NPB) as an electron-donor emitting and hole-transporting layer, and Alq_3 as an emitting and electron-transporting layer. $Zn(4\text{-}TfmBTZ)_2$, which was synthesized in our laboratory [23], is a derivative of $Zn(BTZ)_2$, one additional electron-withdrawing group trifluoromethyl incorporating in 4-position of BTZ. The single crystal structure of $Zn(4\text{-}TfmBTZ)_2$ was determined by single crystal X-ray diffraction (see Fig. 1) [23]. $Zn(4\text{-}TfmBTZ)_2$ forms a monoclinic crystal; $a = 16.866$, $b = 9.8055$, $c = 16.912$ Å; $\alpha = \gamma = 90$, $\beta = 115.771°$, space group P21/n. It can be seen from Fig. 1 that $Zn(4\text{-}TfmBTZ)_2$ exists as an anhydrous dimer structure, where the zinc ions are five-coordinate to 2-(4-trifluoromethyl-2-hydroxyphenyl)benzothiazolate) ligands. $Zn(4\text{-}TfmBTZ)_2$-based WOLED is a typical electroplex light-emitting-device. The best performances for exciplex-type WOLEDs at present had been reported by Kalinowski et al. [6,24]. They combined PtL^2Cl phosphorescence with excimer and exciplex emissions to yield white light with high color rendering index (CRI = 90) and efficiency (EQE = 6.5%, PE = 9.0 lm/W) [6]. Recently, they utilized molecular exciton and excimer phosphorescence from new organic phosphor $PtL^{26}Cl$ to realize white light with high color purity (CIE coordinates $x = 0.34$, $y = 0.35$) and efficiency (EQE = 11.5%, PE = 6.8 lm/W) [24]. Compared with these advanced WOLEDs, $Zn(4\text{-}TfmBTZ)_2$-based WOLED has high CRI (=84.0–90.2), color stability and purity (CIE coordinate region $x = 0.29$–0.30, $y = 0.33$–0.34 at 8–13 V), but its luminous efficiency is required to improve further.

2. Experimental

The chemical structures of organic materials used here are shown in Fig. 1. The devices have structure A: ITO/NPB (35 nm)/$Zn(4\text{-}TfmBTZ)_2$ (30 nm)/Alq_3 (x nm)/LiF (1.8 nm)/Al (150 nm), where x, Alq_3 thickness, was changed from 0 to 40 nm by step of 10 nm. Herein, relatively thin, 30 nm-thick $Zn(4\text{-}TfmBTZ)_2$ layer was chosen with the aim of removing the aforementioned optical interference effect.

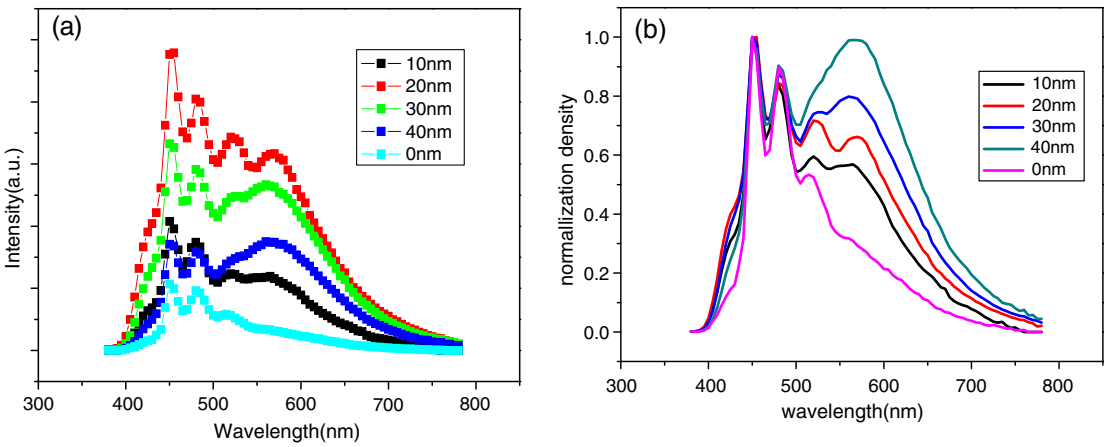

Fig. 2. EL spectra (a) and normalized EL spectra (b) of device A at applied voltage of 12 V.

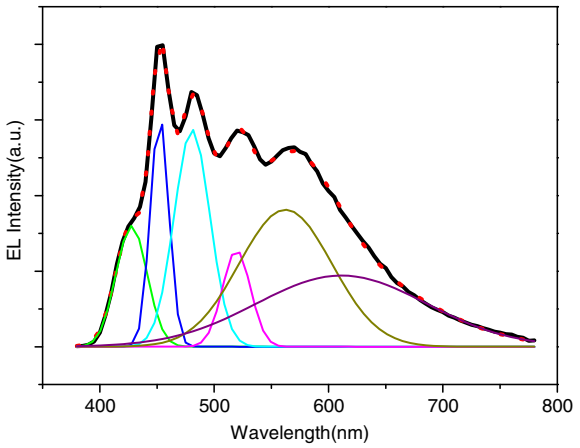

Fig. 3. EL spectra of device A with Alq_3 layer thickness of 20 nm at applied voltage of 12 V: the experiment (black solid) and Gaussian fitting (red dot). (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

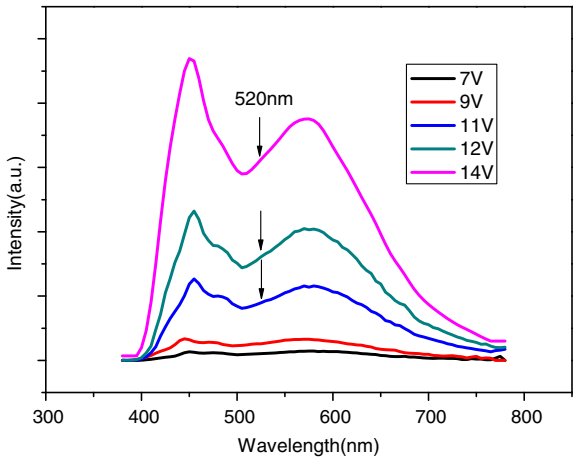

Fig. 4. EL spectra of device B at different driving-voltage.

As comparison, the devices with structure B: ITO/NPB (35 nm)/Zn(4-TfmBTZ)$_2$ (30 nm)/BCP (20 nm)/Alq_3 (20 nm)/LiF (1.8 nm)/Al (150 nm) and C: ITO/NPB (35 nm)/Zn(4-TfmBTZ)$_2$ (x nm)/LiF/Al (x = 20, 30, 40 nm) were designed. The device B was inserted a hole-blocking layer BCP (2,9-dimethy-4,7-diphenyl-1,10-phenanthroline). The device C contain no Alq_3 layer and the thickness of Zn(4-TfmBTZ)$_2$ was changed from 20 to 40 nm by step of 10 nm. All devices were fabricated by successive vacuum deposition of the organic materials onto ITO-coated glass substrates at a deposition rate of 0.1–0.2 nm/s in vacuum of 4.0×10^{-4} Pa and sequential deposition of LiF and aluminum layer without breaking vacuum. The luminance–current–voltage characteristics were measured by a keithley 2400 source meter and ST-900 M photometer. The EL spectra, Commission International De I'Eclairage (CIE) and color rendering index (CRI) were obtained with the SPR-920D spectrofluorometer. The NPB (200 nm) film, Zn(4-TfmBTZ)$_2$ (200 nm) film and layered NPB (100 nm)/Zn(4-TfmBTZ)$_2$ (100 nm) film were prepared on quartz substrates. The PL spectra were measured by Cary Eclipse fluorescence spectrophotometer. The absorption spectra were measured by Cary 300. All measurements were carried out at room temperature under ambient.

3. Results and discussion

As shown in Fig. 2, the EL spectra of device A are composed of multi-emission bands and cover the range from 400 to 700 nm uniformly, approaching an ideal white light. In order to confirm the origins of every emission band, we fit EL spectrum of the device with 20 nm-thick Alq_3 layer at 12 V, as shown in Fig. 3. The EL spectrum is decomposed into six curves by Gaussian fitting. The six emission peaks are located at 425, 454, 481, 519, 561, and 613 nm, respectively. Undoubtedly, the second emission peak is associated with NPB exciton, the third with Zn(4-TfmBTZ)$_2$ exciton. The first peak might be due to optical interference effect because this peak appears only when NPB thickness is 35 nm, but disappears when NPB layer is thicker or

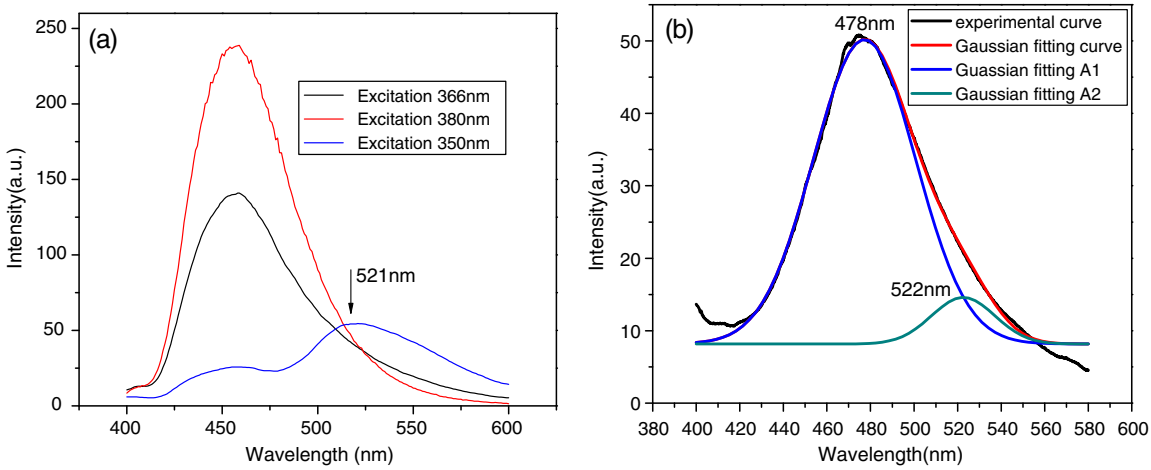

Fig. 5. PL spectra of Zn(4-TfmBTZ)$_2$ in THF solution (a) and film state (b) under excitation of 350 nm including fitting and deconvoluted components.

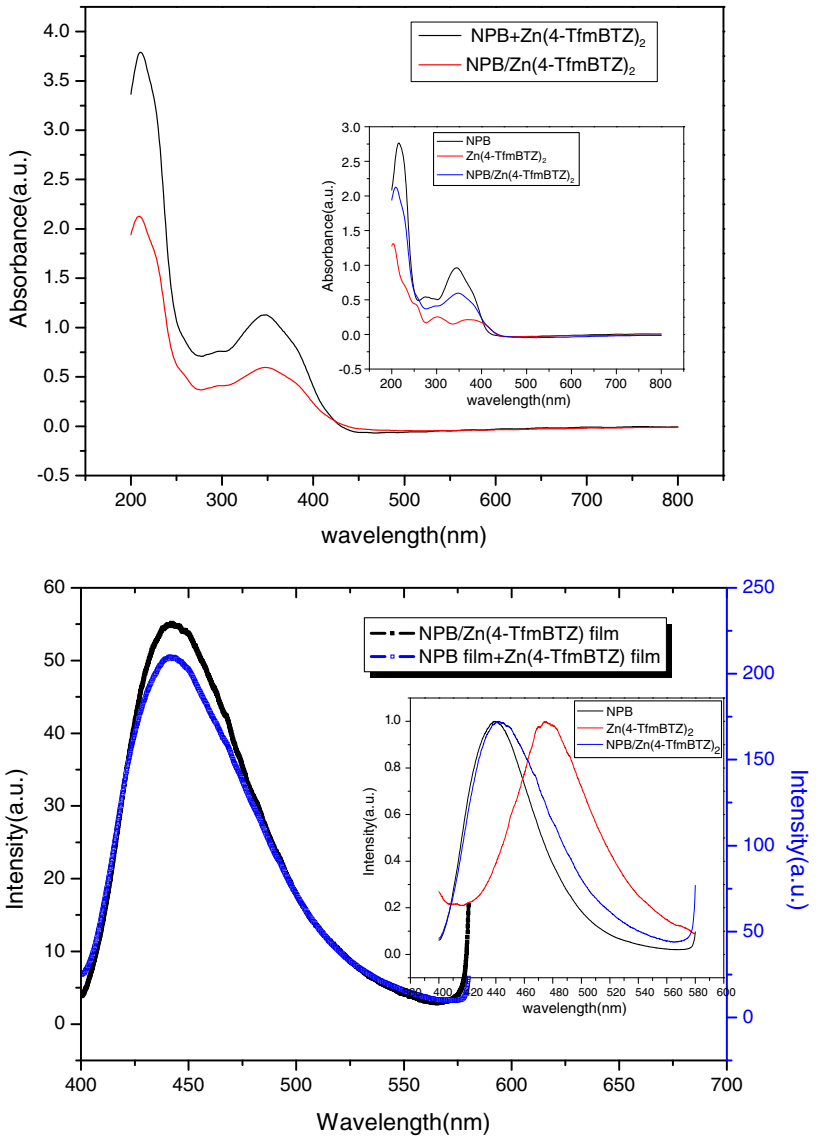

Fig. 6. Absorption (upper) and PL (lower) spectra of NPB film, $Zn(4\text{-TfmBTZ})_2$ film, and layered NPB/$Zn(4\text{-TfmBTZ})_2$ film.

thinner. It seems that the emission band peaked at 519 nm comes from Alq_3 exciton. In order to confirm this point of view, the device B with a hole-blocking layer BCP was designed. Its EL spectra at different voltage were displayed in Fig. 4, where the peak of 519 nm almost disappears. The most likely reason is the eliminating of Alq_3 emission because the holes are blocked not to inject Alq_3 layer resulting from low HOMO level of BCP (−6.4 eV [10]). But this peak also appears in the EL spectra of device C containing no Alq_3 layer (see Fig. 8). This means that $Zn(4\text{-TfmBTZ})_2$ also has contribution on the emission peaked at 519 nm. Though the single crystal structure of $Zn(4\text{-TfmBTZ})_2$ shows a dimer, it is not representative of the entire sample. In order to confirm this point of view, the PL spectra of $Zn(4\text{-TfmBTZ})_2$ in THF solution with the concentration of 10^{-5}M was measured, as shown in Fig. 5, where two emission bands peaked at 456 and 521 nm appear under photoexcitation of 350 nm. These two emission bands are not attributed to ligand 4-TfmBTZ, whose PL peaks at 508 nm in THF solution. Similarly, the PL spectra for $Zn(4\text{-TfmBTZ})_2$ film is decomposed into two curves peaked at 478 and 522 nm by Gaussian fitting, respectively. Thereby, we suggest that $Zn(4\text{-TfmBTZ})_2$ may exist in different oligomeric forms, and tentatively assign the emission of 456 nm to the dimer $[Zn(4\text{-TfmBTZ})_2]_2$ and that of 521 nm to other oligomeric species of $Zn(4\text{-TfmBTZ})_2$. In $Zn(4\text{-TfmBTZ})_2$ film, the dimer is dominant, while other oligomeric species is present in a small amount. Thus, the emission of dimer red-shifts 22 nm in film state compared with that in solution state because of intermolecular interaction while the emission of other oligomeric species is basically unchanged in film and solution state because of similar

molecule space-separation. The emission from dimer is more efficient under photoexcitation so that the emission from other oligomeric species is enshrouded. While the EL emission of other oligomeric species as electron traps becomes obvious by direct charge trap. In a word, the bulk emissions of Zn(4-TfmBTZ)$_2$ and Alq$_3$ are responsible to the emission band peaked at 519 nm. What do the latter two emission peaks stem from? In order to explain this question, we measured the absorption and PL spectra of NPB film, Zn(4-TfmBTZ)$_2$ film, and layered NPB/Zn(4-TfmBTZ)$_2$ film, as shown in Fig. 6. The superposition of absorption spectra of NPB, Zn(4-TfmBTZ)$_2$ film is in accord with that of NPB/Zn(4-TfmBTZ)$_2$ film, where no new absorption is observed. This means that no new components occur in layered NPB/Zn(4-TfmBTZ)$_2$ film. Similarly, the superposition of PL spectra of NPB, Zn(4-TfmBTZ)$_2$ film is in accord with that of NPB/Zn(4-TfmBTZ)$_2$ film. This result confirms that no exciplex appears in NPB/Zn(4-TfmBTZ)$_2$ interface under photoexcitation, that is, the emission of 561, and 613 nm do not belong to exciplex. Thus, we can conclude that these two new emitting components are assigned to the electroplex at NPB/Zn(4-TfmBTZ)$_2$ interface. The abovementioned phenomena can be explained by the energy band diagram of the device A (see Fig. 7), where the HOMO and LUMO of Zn(4-TfmBTZ)$_2$ were measured by Cyclic voltammetry in our experiment. Fig. 7 displays distinctly the exciton distribution and electroplex formation within multilayer device. The electrons can easily inject into Alq$_3$ layer, then partially into Zn(4-TfmBTZ)$_2$ layer and to NPB/Zn(4-TfmBTZ)$_2$ interface region. Further, a fraction of electrons at interface tunnel into NPB layer, the others are limited at NPB/Zn(4-TfmBTZ)$_2$ interface. Similarly, the holes injecting NPB layer partially drift to NPB/Zn(4-TfmBTZ)$_2$ interface region, and then a fraction of holes at interface can leak through Zn(4-TfmBTZ)$_2$ and Alq$_3$ layer, the others are accumulated at NPB/Zn(4-TfmBTZ)$_2$ interface. As a result, not only NPB, Zn(4-TfmBTZ)$_2$ and Alq$_3$ excitons form but also effective cross transition recombination between electrons blocked on LUMOs of Zn(4-TfmBTZ)$_2$ and holes blocked on HOMOs of NPB occurs, that is, electroplex forms. Additionally, other oligomeric species of Zn(4-TfmBTZ)$_2$ as charge traps can capture directly charge to form excitons contributing to EL of 519 nm. The emission band maximum position of electroplex approximated by [10,18].

$$hV_{EX}^{\max} = I_D - A_A - E_c \quad (1)$$

Herein I_D and A_A is the ionization potential of the donor and electron affinity of the acceptor of the electroplex components, respectively. E_c is the coulombic attraction energy between donor and acceptor ion represented by

$$E_c = \frac{e^2}{4\pi\epsilon_0\epsilon r} \quad (2)$$

where r is the donor–acceptor intermolecular distance and $\varepsilon_0\varepsilon$ is the dielectric constant. For most organic semiconductors, ε = 3.5–5.5 [25]. Here ε = 3.8 for Zn(4-TfmBTZ)$_2$ referring to that of Alq$_3$ [26], ε = 2.6 for NPB referring to that of TPD [27], thus, an average dielectric constant ε = 3.2 is obtained to calculate r. The ionization potential of NPB is 5.46 eV and electron affinity of Zn(4-TfmBTZ)$_2$ is 2.99 eV. Thereby, corresponding to 561, and 613 nm emissions give r_{EC1} = 1.67 nm and r_{EC2} = 0.99 nm according to Eqs. (1) and (2), respectively. These values are larger than those reported by Kalinowski et al. [28], where all r fall below 1 nm. Such largely separated ion pairs should originate from the dimeric configuration of Zn(4-TfmBTZ)$_2$. Subsequently, we investigated whether optical interference effect is responsible for the white-light emitting of the device A. For this purpose, we designed a series of devices with structure C. Its EL spectrum profiles are independent on the thickness of Zn(4-TfmBTZ)$_2$, as shown in Fig. 8, therefore the optical interference effect is excluded. Thus, we can conclude that the white light emission of device A results from the overlap of the emissions of NPB, Zn(4-TfmBTZ)$_2$, Alq$_3$ exciton in addition to NPB/Zn(4-TfmBTZ)$_2$ interface electroplex. Because of the amorphous nature of

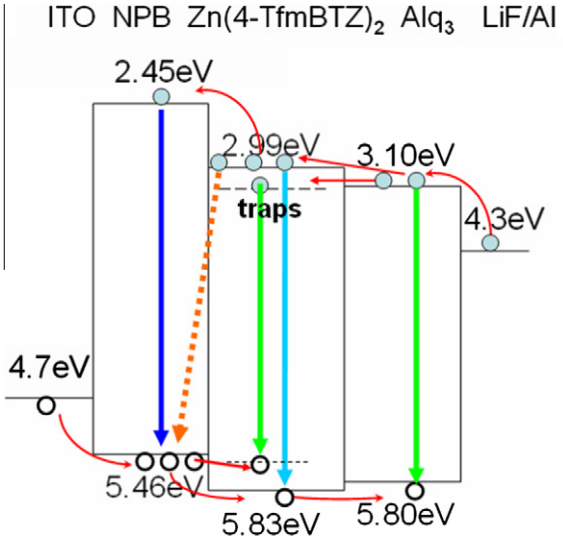

Fig. 7. Energy band diagram of device ITO/NPB/Zn(4-TfmBTZ)$_2$/Alq$_3$/LiF/Al.

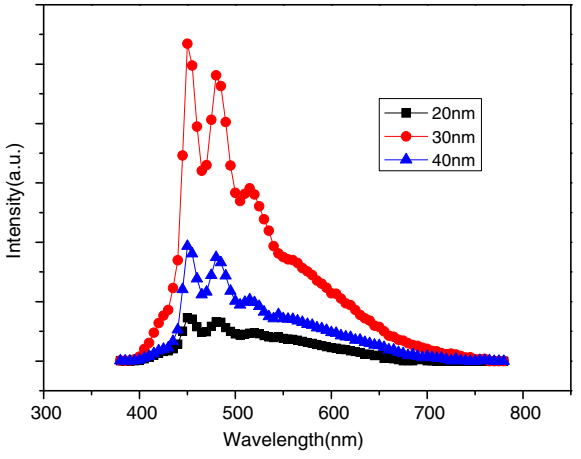

Fig. 8. EL spectra of the devices ITO/NPB (35 nm)/Zn(4-TfmBTZ)$_2$ (x nm)/LiF (1.8 nm)/Al (150 nm) at applied voltage of 8 V, x = 20, 30, 40 nm.

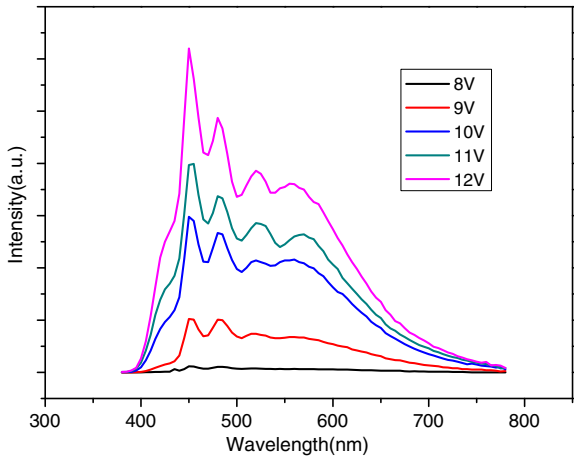

Fig. 9. EL spectra of device A with 20 nm Alq_3 layer at different applied voltage.

organic material film, a wide range of intermolecular distance and relative orientations exist at organic/organic interface, none of donor and accept molecular pairs are necessarily optimum for electroplex formation. This results in a wide range electroplex emission frequencies and efficiencies.

As can be seen from Fig. 2, EL spectra of device A at a certain voltage are dramatically controlled by thickness of Alq_3 layer. A similar phenomenon had been reported [29]. The intensity of all emission bands can be increased with increasing thickness of Alq_3 layer from 0 to 20 nm, and then decreased from 20 to 40 nm. The Alq_3/LiF/Al forms an Ohmic contact [30] so that inserting Alq_3 layer increases injecting of electrons, moreover, Alq_3 as an excellent electron transporting material also improves electron transporting rate. Thus, the charge injection and transport are balanced to lead to high recombination of electron–hole pair in every layer and NPB/Zn(4-TfmBTZ)$_2$ interface. Here, the optimization thickness of Alq_3 is 20 nm, which is just the diffusion length of Alq_3 exciton [31]. An evaporated Alq_3 film appears to be microcrystalline with grain size [31]. So Alq_3 layer is too thin to play well electron transporting role, moreover, Alq_3 excitons diffuse easily to cathode to be quenched in this case. But if Alq_3 becomes thicker than 20 nm, electric-field distributed in every layer at a certain voltage becomes weaker so that charge mobility was deduced, thus, the electron–hole pair ratios are decreased in every bulk and NPB/

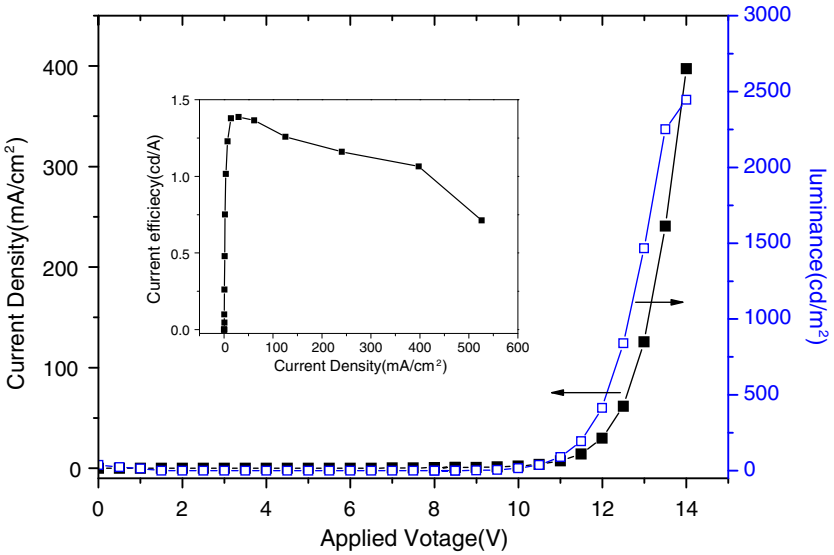

Fig. 10. Current density–luminance–voltage curves of device A with 20 nm Alq_3 layer, the inset shows its current efficiency vs current density curve.

$Zn(4\text{-}TfmBTZ)_2$ interface. When Alq_3 is 20 nm, electron transporting and Alq_3 exciton emission reach optimization simultaneously. It can be seen from the normalized EL spectra that the emission of electroplex increases in relative intensity with increasing thickness of Alq_3 layer. This is the reason that the charge tunneling through NPB/$Zn(4\text{-}TfmBTZ)_2$ interface becomes relatively more difficult because of weaker electric-field for the device with thicker Alq_3. In this case, the electroplex formation is relatively favorable in comparison with excions. Of course, Alq_3 exciton radiations also increase in relative intensity with increasing thickness of Alq_3 layer. The EL spectra of the device A with 20 nm Alq_3 at different applied voltage were shown in Fig. 9. Rising operating voltage will lead to an increased exciton emission at a larger rate than that of electroplex. This further indicates that the electroplex emission at low electric-field is relatively favorable while the exciton emissions are relatively facilitated at high electric-field.

Above mentioned results indicate that pure white light emission can be attained by adjusting Alq_3 layer thickness for device A. The CIE coordinates of device A at 12 V change from (0.29, 0.32) to (0.34, 0.38) when Alq_3 thickness changes from 10 nm to 40 nm. The most pure white-light emitting with CIE coordinate (0.30, 0.34) is obtained when Alq_3 layer thickness is 20 nm. Moreover, CIE coordinate of the devices are very insensitive to the applied voltage. For example, CIE coordinate region of the device A with Alq_3 thickness of 20 nm is (0.29–0.30, 0.33–0.34) at various forward bias (8–13 V). Its maximum CRI is 90.2 at 8 V (see Table 1), and maximum luminance reaches 2445 cd/m^2 at 14 V and maximum current efficiency 1.39 cd/A, as shown in Fig. 10. The brightness and luminous efficiency of the devices here are worse than the advanced WOLEDs at present, but it is believed that these characterizations will be improved further by optimizing the prepared technique of device.

4. Conclusion

In this paper, a new material $Zn(4\text{-}TfmBTZ)_2$ was used for white-light emitting. For the device ITO/NPB/$Zn(4\text{-}TfmBTZ)_2$/Alq_3/LiF/Al, the radiative processes from two different excited states: (i) molecular excited states (NPB, $Zn(4\text{-}TfmBTZ)_2$ and Alq_3 exciton), and (ii) bimolecular excited species (electroplexes at NPB/$Zn(4\text{-}TfmBTZ)_2$ interface) render white light output. Inserting an Alq_3 layer with appropriate thickness can increase intensity of every emission species. The most pure white light emission with CIE coordinates of (0.30, 0.34) can be attained by adjusting the Alq_3 layer thickness to 20 nm. Moreover, CIE coordinate of the devices are very insensitive to the applied voltage. The CIE coordinate region of the device with Alq_3 layer thickness of 20 nm is (0.29–0.30, 0.33–0.34) at various forward bias (8–13 V). For this device, the maximum CRI is 90.2 at 8 V, the maximum luminance reaches 2445 cd/m^2 at 14 V and the maximum current efficiency 1.39 cd/A.

Blend organic semiconductors

ABSTRACT

Organic transistors based on blends of 2,8-difluoro-5,11-bis(triethylsilylethynyl) anthradithiophene (diF-TES ADT) and poly(triarylamine) [PTAA] are strong candidates for application in future large-volume organic electronics because of their record breaking carrier mobility and environmental stability. Here we report on the dependence of hole transport on the composition of diF-TES ADT:PTAA blends. Maximum mobility is obtained only for blends containing $\geqslant$39 wt.% diF-TES ADT. At compositions below this threshold the hole mobility is drastically reduced and is found to be equal to that of the neat polymer matrix, i.e. PTAA ($\sim 10^{-3}$ cm^2/V s). Scanning atomic force and polarised light microscopy, combined with differential scanning calorimetry, show that this threshold corresponds to the appearance of crystalline, acene-rich regions in such blend films, and the formation of high mobility conduction pathways between the source and drain electrodes. The dependence of hole mobility on diF-TES ADT concentration can be modelled using a simple percolation model. The present results provide important insights into the microstructure evolution in this high performance semiconducting blend and could prove valuable for the development of the next generation organic transistors.

1. Introduction

Blends comprising small-molecular and polymeric organic semiconductors have recently shown great promise for organic electronics due to their high charge carrier mobilities, ease of solution processing and device performance uniformity [1–9]. One such system based on 2,8-difluoro-5,11-bis(triethylsilylethynyl) anthradithiophene (diF-TES ADT) blended with amorphous poly(triarylamine)s [PTAA], has demonstrated a hole mobility up to 2.4 cm^2/V s when integrated in organic field-effect transistor architectures (OFETs) [1]. The microstructure of the diF-TES ADT:PTAA blend film is the key factor in achieving this high mobility value. Spin casting of the blend solution onto a suitably treated substrate produces a highly desirable vertical phase separation of the two components, which leads to the formation of large acene crystals at the top surface. A carefully designed top-gate bottom-contact (TG-BC) transistor architecture can then be used to exploit the excellent charge carrier properties at this blend film/air interface. It is important to note, however, that the solid-state microstructure of such blend films is most likely more complex; lateral phase separation may occur and grain boundaries between the high mobility acene-dominated crystalline domains can form [3].

One specific problem associated with the polymer matrix used in the diF-TES ADT:PTAA blend is its low hole mobility, which is typically several orders of magnitude lower ($\sim 10^{-3}$ cm^2/V s) than that of diF-TES ADT (>1 cm^2/V s) [10]. In order to overcome this limitation, efficient

percolation of charge carriers through the diF-TES ADT phase is required to realise good device performance [5,11,12]. A high polymer content yields lower mobility values due to the fact that insufficient amount of the acene phase is formed at the semiconductor–dielectric interface. This has already been previously shown for blends based on triisopropylsilylethynyl (TIPS) pentacene – another promising small-molecular semiconductor – and an amorphous polymer. A minimum TIPS-pentacene concentration in the range 40–50 wt.% was required to achieve efficient vertical phase separation in such binaries, with the acene being expelled towards the dielectric, resulting in a good transistor performance [7]. However, in the case of diF-TES ADT blends, if the semiconductor content is too high, the film starts to become non-uniform, and increased dewetting occurs during solution processing. Therefore, judicious formulation of the blend composition is necessary in order to allow sufficient percolation while maintaining good film forming properties and at the same time minimising the quantity of diF-TES ADT required.

Here we study the microstructural evolution of diF-TES ADT:PTAA blend films as a function of diF-TES ADT concentration and its effect on field-effect hole mobility. The diF-TES ADT:PTAA blend was selected because it is known to exhibit the highest hole mobility ever measured in solution processed blend based OFETs. A connection between the solid-state microstructure, degree of crystallinity and the electronic properties of OFETs using such blends is established based on the percolation model outlined below. The latter could provide valuable information for the development of next generation of high-performance organic semiconducting blends.

2. Percolation theory

Percolation thresholds have been observed previously in other polymer/small-molecule blend OFETs and have been successfully modelled using a percolation analysis based upon high and low mobility materials [4]. In this analysis the overall measured mobility (μ) in the OFET can be fitted by a sigmoidal function of the form,

$$\mu = \mu_{\text{polymer}} + \frac{\mu_{\text{blend-max}}}{1 + \exp(\frac{c_0 - c}{d})} \quad (1)$$

where c is the concentration of high mobility material, c_0 is the percolation threshold and d a fitting parameter. The two carrier mobilities are the mobility of the low mobility material, i.e. the matrix polymer (μ_{polymer}) in this case, and the maximum mobility ($\mu_{\text{blend-max}}$) obtainable in the blend. If we now consider the morphology at the conduction interface (i.e. the top film/dielectric interface in the case of a TG-BC transistor) both small-molecule rich and polymer rich phases will be present, with the former dominating charge transport. It is therefore reasonable to assume that conduction pathways from source to drain (S–D) electrodes will contain certain fractions of each of these two phases. A particular percolation pathway in the film will have a mobility of μ_{path} given by,

$$\mu_{\text{path}}(f) = \frac{\mu_H}{1 + f(\frac{\mu_H}{\mu_L} - 1)} \quad (2)$$

where f is the volume fraction of low mobility material and the subscripts H and L correspond to high and low mobility, respectively. When μ_H becomes considerably larger than μ_L then μ_{path} becomes essentially independent of μ_H. In diF-TES ADT:PTAA blend systems, the low mobility regions will be approximately equal to the mobility of the pure polymer ($\mu_L \approx \mu_{\text{polymer}}$). It is to be noted that the high mobility region must have a mobility value equal to or greater than the maximum possible value in the blend. The latter should, in principle, be equal to the intrinsic mobility of the neat small-molecule material (i.e. the high mobility component) but in practice is not measureable in a thin film OFET due to problems related to processing a small-molecular material from solution without dewetting, the presence of grain boundaries, and/or limited charge carrier injection from the S-D contacts, all of which can negatively affect transport. Hence we can assume that $\mu_H \geqslant \mu_{\text{blend-max}}$. Finally, combining the fit of Eq. (1) to data and Eq. (2), the fraction of high mobility phase ($1-f$) at the conduction interface (i.e. the transistor channel) can be determined as a function of small-molecule concentration, c, from the measured device mobility, μ, of these blend structures.

3. Experimental

Thin films were deposited onto glass substrates that had been cleaned by sonication in detergent solution (DECON 90) from 4 wt.% (total solid content) 1,2,3,4-tetrahydronaphthalene (tetralin) solutions by spin coating at 500 rpm for 10 s followed by 2000 rpm for 20 s. Neat diF-TES ADT was spin coated at 3000 rpm for 30 s from a 1 wt.% solution in chloroform. The PTAA had a weight average molecular weight of 96 kDa. All films were then annealed at 100 °C for 5 min in nitrogen. Light microscopy images were taken in transmission between crossed polarisers using a Nikon LV100. Atomic force microscopy was carried out using a Pacific Nanotechnology Nano-R2 machine in close-contact mode.

Differential scanning calorimetry (DSC) was conducted on drop-cast films (prepared from solutions as described above), which had been dried at 100 °C for > 1 h to ensure that no solvent peaks were measured. Drop-cast films were employed because spin-casting could not provide enough material to perform the DSC measurements. Thermograms were recorded under nitrogen at a scan rate of 10 °Cmin^{-1} with a Mettler Toledo DSC822 instrument. The sample weights were ~5 mg.

Top-gate, bottom-contact transistors were fabricated on glass using the same spin conditions and solutions detailed above. Gold source and drain electrodes (30 nm) were first deposited by thermal evaporation and then treated with a pentafluorobenzene thiol monolayer (see reference [1]). Channel lengths and widths were in the range of 20–100 μm, and 0.5–2 mm, respectively. After semiconductor deposition, a fluoropolymer dielectric (CYTOP) was spin coated at 2000 rpm for 60 s to form a 900 nm layer. The CYTOP was cured at 100 °C for 20 min. Finally, aluminium top-gate electrodes were thermally evaporated. Electrical characterisation of the OFETs was carried out in nitrogen using a Keithley 4200 semiconductor parameter analyser. The field effect mobility in saturation was calculated from,

$$\mu_{sat} = \frac{L}{WC_i}\frac{\partial^2 I_{D,sat}}{\partial V_G^2} \quad (3)$$

where L is the device channel length, W the channel width, C_i the geometric capacitance of the dielectric (2.1 nFcm^{-2} for our films), V_G the gate voltage and $I_{D,sat}$ the drain current in the saturation regime.

4. Results and discussion

Blend films prepared on glass as described above were first characterised using polarised optical microscopy (PLM) and atomic force microscopy (AFM) (Fig. 1). In the PLM images, crystallisation of a diF-TES ADT rich phase is evident for compositions of > 37.5 wt.% diF-TES ADT, with grain sizes of the crystals formed being of the order of 50 μm. Above 75 wt.% the thin-films started to become non-uniform with some regions of the substrates found to be not fully covered. At 95 wt.% diF-TES ADT, the films severely dewetted from the substrates, resulting in only small semiconducting islands. In order to create a thin film of neat diF-TES ADT, it was necessary to spin cast from chloroform rather than tetralin. The lower boiling point of this solvent allowed rapid solvent removal, and thus prevented dewetting from occurring. However, chloroform is not an ideal solvent for the blends since it does not allow time for significant phase separation or the formation of large ordered grains. Indeed, the grain size of diF-TES ADT crystals in such neat films were found to be considerably smaller (~5 μm) compared to the crystalline blend structures.

Crystallisation of the organic semiconductor on the top surface of the blend architecture, especially for higher diF-TES ADT content, is also evident using AFM (Fig. 1, bottom panels). In addition, peak-to-peak surface roughness, R, can be deduced from the AFM data. For blend compositions below 25 wt.% diF-TES ADT the roughness was found to be (2.1 ± 0.7) nm, whereas at 50 wt.% R increased to (10.7 ± 1.3) nm. At an intermediate small-molecule content (37.5 wt.%), partial crystallisation is observed with diF-TES ADT domains on the micron scale forming. At high diF-TES ADT content, extremely non-uniform thin-film structures are again observed. The surface roughness of the neat diF-TES ADT film cast from chloroform was significantly more pronounced (~100 nm) compared to blend films, rendering such structures less suitable for use in top-gate OFETs.

In addition to domain/grain size, the degree of crystallinity of the semiconductor in the diF-TES ADT:PTAA blend was quantified using differential scanning calorimetry (DSC). Melting endotherms were observed for blends of a diF-TES ADT content of ⩾25 wt.% (Fig. 2a). The melting temperature, T_m, was affected by addition of PTAA only at a polymer concentration of >40 wt.% (Fig. 2b), indicating that for blends comprising more than ~70 wt.% small-molecule, the latter can crystallise essentially unhindered. From the melting endotherms we also can deduce the enthalpy of fusion, ΔH_f, which is directly correlated to the degree of crystallinity of the diF-TES ADT structures in such blends. For diF-TES ADT rich blends (75–100 wt.%), ΔH_f first linearly decreases with PTAA content (Fig. 2c), however, then stabilises for blends comprising 32.5–62.5 wt.% at around a value of 30 J/g. Only when decreasing the diF-TES ADT content further, is ΔH_f drastically reduced. This suggests that for the interim blend compositions (37.5–62.5 wt.% diF-TES ADT) the degree of crystallinity of the small-molecule component, while lower than for neat structures, is essentially unaffected by the further addition of PTAA, but below this there is a rapid reduction in crystallinity.

Top-gate, bottom-contact thin film transistors were then fabricated from blends of a range of compositions. Fig. 3 shows the transfer characteristics for devices based on blends with low (Fig. 3a) and high (Fig. 3b) concentrations of diF-TES ADT. It is evident that there is a significant enhancement of the channel current in devices based on blends with high diF-TES ADT concentrations with virtually no change to the threshold voltage, current on/off ratio or hysteresis during transistor operation. All devices exhibit threshold voltages between +5 and −5 V, on/off ratios of $10^{3.5}$–$10^{4.2}$ and generally display well behaved characteristics. The minor degradation of the subthreshold

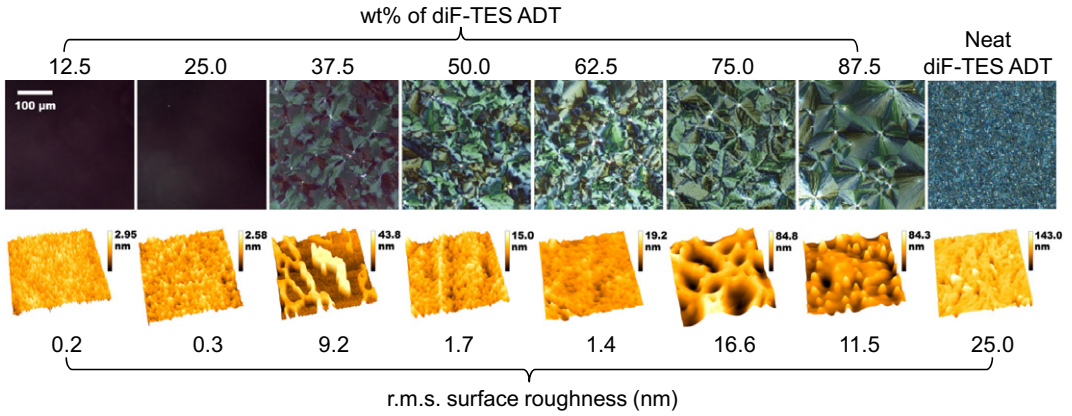

Fig. 1. Polarised optical microscopy and atomic force microscopy images for blend films of diF-TES ADT and PTAA. Numbers indicate the wt.% of diF-TES ADT in the blend. All films were spin cast from tetralin except the neat diF-TES ADT which was spin cast from chloroform. AFM images are of a 5 × 5 μm area and r.m.s. surface roughnesses, as well as peak-to-peak heights, are indicated.

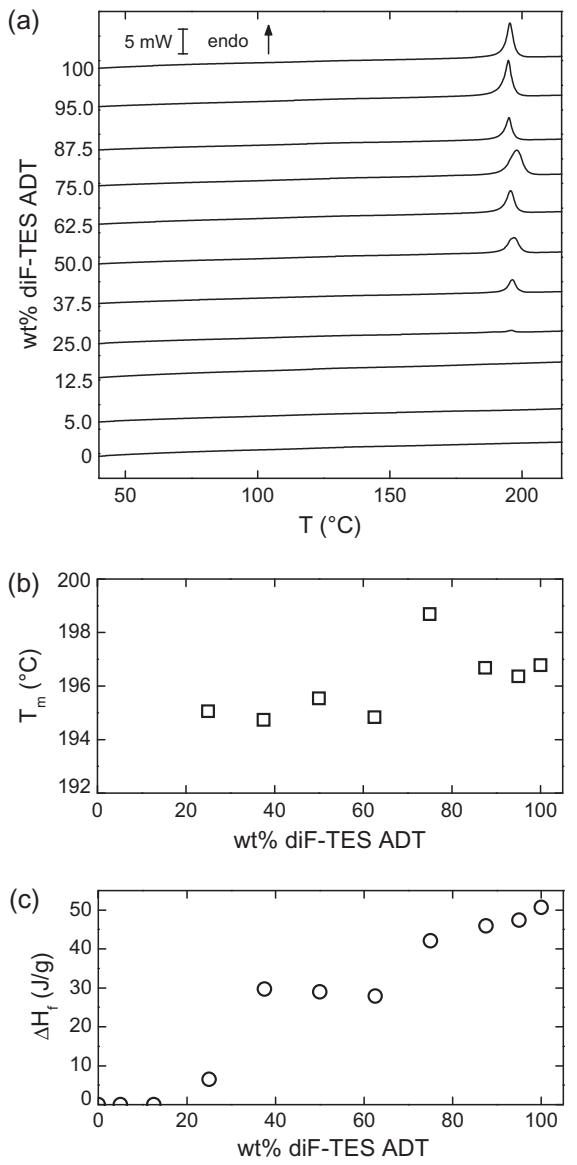

Fig. 2. (a) Differential scanning calorimetry first-heating thermograms obtained for diF-TES ADT:PTAA blends of a range of compositions (heating rate at 10 °C min^{-1}). (b) Melting temperatures of the diF-TES ADT rich phase as function of blend composition. (c) Enthalpies of fusion as deduced from the thermograms presented in (a), which can be directly correlated to the degree of crystallinity of the diF-TES ADT fraction. Crystallisation is evident above ~20 wt.% diF-TES ADT.

slope in OFETs with high diF-TES ADT concentrations may be attributed to the formation of traps at the grain boundaries of the polycrystalline acene phase [13]. There is also a very slight decrease in on/off ratio on the addition of more diF-TES ADT, most likely as a result of the increased bulk conductivity of the small molecule leading to higher off currents. The hole mobility, measured in saturation, is plotted in Fig. 4 as a function of diF-TES ADT content, with averages taken over at least three transistors, and demonstrates a clear threshold concentration. When fitting the OFET data using Eq. (1) for compositions of less than 62.5

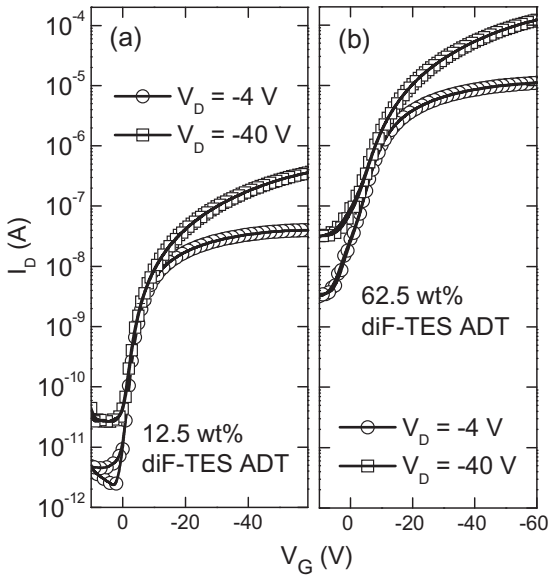

Fig. 3. Transfer characteristics for diF-TES ADT:PTAA OFETs with (a) 12.5 wt.% diF-TES ADT and (b) 62.5 wt.% diF-TES ADT. Devices had a top-gate bottom-contact architecture and were measured at $V_D = -4$ V (linear) and -40 V (saturation). Devices had channel lengths and widths of 50 μm and 1 mm, respectively.

wt.% diF-TES ADT, the following parameters were extracted: $\mu_{polymer} = 0.0048$ $cm^2/V\,s$, $\mu_{blend-max} = 1.79$ $cm^2/V\,s$, $c_0 = 38.9$ wt.% and $d = 2.06$ wt.%. From Eq. (2), f was calculated as a function of diF-TES ADT concentration and the fraction of high mobility phase, $(1-f)$, is also plotted in Fig. 4. The reduction in mobility and increase in mobility variation above 62.5 wt.% can be attributed to the decreased unifor-

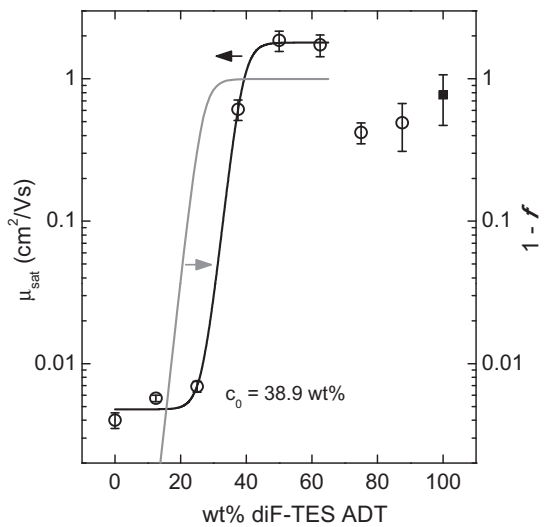

Fig. 4. Hole mobility calculated for OFETs with varying blend composition. The data is fitted with Eq. (1) to extract a percolation threshold, c_0. Right axis shows the fraction of diF-TES ADT $(1-f)$ in the conducting pathways based on the percolation model. (The 100 wt.% diF-TES ADT film was processed from chloroform while all other compositions were processed from tetralin).

mity and increased surface roughness of the blend film as the semiconductor appeared to be able to crystallise essentially unhindered, which is evidenced by the fact that the melting point was not significantly affected by addition of the polymer. Increased grain boundary density may also play a role in the relatively poor device performance found in the case of neat diF-TES ADT. This observation further highlights the benefit of blending small-molecules with polymers since a $\mu_{blend-max}$ can be obtained that is greater than the OFET mobility obtained by simple solution deposition of neat diF-TES ADT.

The percolation threshold for hole mobility corresponds well with the observation of birefringence in the PLM images, and evidence of crystallinity from DSC, which suggests that the diF-TES ADT rich phase forms molecularly ordered regions suitable for high device performance. At very low diF-TES ADT content, the blend films appear to exhibit a single amorphous phase and hence the mobility is low. For diF-TES ADT concentrations between ~20–39 wt.% the fraction of the crystalline phase in the conduction pathways, $(1-f)$, increases sharply but it is only when it becomes significant (i.e.>0.5) that a rapid enhancement of the measured mobility is seen. Above the percolation threshold $(1-f)$ is very close to 1. This highlights the importance of electronic percolation between high mobility regions in the thin film and demonstrates that for the best device performance there must be a very high fraction of diF-TES ADT rich phase at the charge transporting interface. In our case, for the highest mobility blends, only ~0.3 wt.% polymer phase is present in the conduction pathways. This is consistent with the previously observed vertical phase separation effect measured using dynamic secondary ion mass spectrometry and dual-gate transistor architectures [1] whereby the small-molecule moves to the top surface. Such effects are one of the major factors contributing to the high hole mobilities achieved, however, the dependence of crystalline grain microstructure on blend composition also plays a role.

5. Summary and conclusions

In summary, we have demonstrated that for the diF-TES ADT:PTAA blend system there is a critical concentration of small-molecular material required to obtain high performance OFETs. The saturation mobility in these devices can be fitted using a percolation model with the threshold relating to the formation of a crystalline, high mobility, diF-TES ADT rich phase. For diF-TES ADT concentrations greater than ~20 wt.%, the acene-rich phase starts to form but percolation only occurs when a significant fraction of this phase accumulates into conduction pathways. The measured mobility threshold is observed to be ~39 wt.% diF-TES ADT. Above this value uniform, polycrystalline films can be fabricated yielding OFETs with hole mobilities approaching 2 cm^2/V s. However, high concentrations of diF-TES ADT lead to the formation of non-uniform films and a significantly reduced hole mobility. Further improvements to the device performance could therefore be made by increasing the polymer mobility whilst ensuring that phase separation still leads to a high fraction of diF-TES ADT rich phase in the conducting pathways of the OFET. To this end, the understanding of relevant interrelationships between microstructure and charge transport, and in particular knowledge of how to induce efficient percolating pathways in such binaries, is vital to produce blend semiconductor systems that combine excellent mobilities with good film forming characteristics and uniformity. The present work provides an important contribution to OFET design for future high performance applications.

Polymer light-emitting diode

ABSTRACT

The effect of the surface composition of a mixed self-assembled monolayer on the work function and wetting property of silver substrate are investigated with the mixtures of a fluorinated alkanethiol and a carboxyl-terminated alkanethiol of various chain lengths. The work function of silver can be tuned from 4.3 to 5.3 eV by changing the mixing ratio while the wetting property can be modulated by adjust the relative chain length of the fluorinated thiol and the carboxyl-terminated thiol. Thus solution-processed poly(para phenylene vinylene)-based polymer light-emitting diode was made possible with high efficiency of 6.7 cd/A and brightness of 40,000 cd/m^2.

1. Introduction

The operation of most organic semiconductor devices depends on a proper energy alignment of the metal electrodes and the organic layers. For example, low energy barriers for both hole and electron injection are required for the organic light-emitting diode, whereas the organic transistor requires Ohmic contact between the source-drain and the semiconductor [1–3]. For relatively stable and common metals, there are however practically very few choices of work functions: 4.3 eV for silver and aluminum, and 5.0 eV for gold [4–6]. The device design will become much more flexible if the work functions of the metals can be continuously tuned in a wide range. Modification/treatment of a metal surface by the adsorption of a specific species changes the tendency for charge departure from or attraction to the surface due to the local dipole moment introduced by the adsorbates [7–9]. In particular, self-assembled monolayers (SAMs) have been used to systematically modulate the work function of a metal through the various functional groups of the adsorbed molecules. Among these, SAMs of fluorinated hydrocarbon chains have been frequently used to increase the work function of various electrodes due to the strongly electron-withdrawing fluorine atoms [10–12]. It is demonstrated that carrier injection in hole-only devices can be enhanced by such modification. Whereas, SAMs of hydrocarbon were found to decrease the work function and suppress hole charge injection [13]. It is further demonstrated that continuous tuning of the work function can be achieved by the use of mixed SAMs of a fluorocarbon and a hydrocarbon [13,14], so that the amount of hole carriers can be systematically modulated by controlling the composition of the two compounds [13]. However, for devices prepared by solution process such as spin coating, there is a dilemma that the highly electronegative fluorine atoms provide not only the desired dipole moment for work function tuning but also the undesired poor wettability due to the low surface energy of the substrate it creates. In a mixed SAM where fluorinated hydrocarbon is mixed with a non-polar

doi:10.1016/j.orgel.2010.10.013

hydrocarbon component, wettability did not improve because the non-polar nature of hydrocarbon component, but the work function is reduced simultaneously. The poor wettability may cause problem in process such as spin-coating as the semiconducting materials may not adhere to the substrate. It is therefore of interest to control the work function and the wetting property of the metal independently.

Mixed monolayers containing one hydrophobic component and one hydrophilic component offer the opportunity to modulate the wetting property of the surface over a wide range [15]. It has also been demonstrated that the contact angle is highly surface-sensitive since the wetting liquid senses the structural change at the very top 2–3 Å region of the surface [15]. Thus by controlling the relative chain length of the two components, it is possible to "shield" the non-wetting character of one component by the wetting character of the other, or vice versa. In this work, mixtures of a fluorinated alkanethiol and a carboxyl-terminated alkanethiol with different chain lengths are used to form mixed SAMs on silver substrate in order to decouple their effect on the work function and surface wetting. The fluorinated alkanethiol serves to increase the work function, whereas the carboxyl-terminated alkanethiol is used to impart the needed wettability. The effect of the carboxyl group can be further enhanced by adjusting the relative chain length of the two in the mixture. As shown in Fig. 1(b), the carboxyl-terminated thiol is chosen to be longer than the fluorinated thiol such that solution containing the semiconductor is in contact mostly with the hydrophilic carboxyl groups. In the case where the two components are of the same chain length (Fig. 1(a)), the solution is in contact with both the hydrophilic carboxyl groups and the hydrophobic CF_3 groups. By forming mixed SAMs with different lengths, the work function of silver can be increased from 4.3 eV for the bare silver metal to 5.3 eV for modified silver without compromising the wetting/spreading of emissive conjugated polymer for PLED.

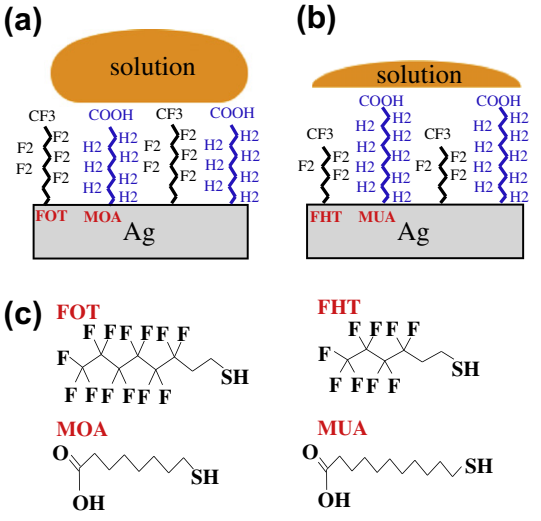

Fig. 1. The schematic plots showing the shapes of the solution drops on the mixed-SAMs with (a) equal molecular lengths and (b) non-equal molecular lengths. (c) Molecular structures of the molecules used for mixed self-assemble monolayer formation.

With proper SAM-modified silver as anode, polymeric light-emitting diodes with high efficiency and brightness close to that with ITO/PEDOT:PSS as anode were achieved for both top and bottom emission devices. This offers the opportunity to replace the commonly used but more resistive and expensive indium-tin-oxide (ITO)/poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) anode with the low resistive and low cost silver metal anode for large area PLED and polymer solar cell application.

2. Experimental

Silver substrates were prepared on chromium-primed glass slides by thermal evaporation. The mixed SAM was prepared by submersing Ag substrate into a 1 mM ethanolic solution containing a fluorinated alkanethiol and a carboxyl-terminated alkanethiol in different ratios. The fluorinated alkanethiol used was either 3,3,4,4,5,5,6,6,6-nonafluoro-1-hexanethiol (FHT) or 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluoro-1-octanethiol (FOT), and the carboxyl-terminated alkanethiol used was either 8-mercaptooctanoic acid (MOA) or 11-mercaptoundecanoic acid (MUA), all obtained from Aldrich and used without purification. The molecular structures of these SAM-forming components are shown in Fig. 1(c). Reflection–absorption IR spectra were taken with a Biorad FTS-60 Infrared spectrometer equipped with a MCT detector. A custom-designed optics unit with 86° incidence angle and p-polarized light were employed. Plasma-cleaned gold wafer was used as reference for all spectra. Contact angle was taken with a GBX DIGIDROP Goniometer, and Teflon-coated needles were used to dispense water and Toluene as the contacting liquid onto the surface of the monolayers. The data reported are the average of 4–5 drops measured on both sides. The structure of the PLED is Cr/Ag/mixed-SAMs/emission layer/cathode. The Cr is used as the adhesive layer for Ag. The thickness of Cr is 100 Å for top-emitting device and 30 Å for bottom-emitting device. The thickness of Ag is 800 Å for top-emitting device and 150 Å for bottom-emitting device. The substrate was immersed for 1 h before rinsing with absolute ethanol, acetone and blown dry with a pure nitrogen flow. Poly(para-phenylene vinylene, 800 Å) (Super Yellow from Merck) was spin-coated from a toluene solution (0.8 wt.%) as emission layer. The sample was annealed at 80 °C for 20 min in a glove box to remove the residual solvent. The cathode was Ca (100 Å)/Ag (150 Å) for top-emitting devices and Ca (350 Å)/Al (1000 Å) for bottom-emitting devices. ITO/PEDOT:PSS is used as anode for standard device. A 40 nm PEDOT:PSS (CLEVIOS™ P VP AI 4083) layer is spin coated on a cleaned and patterned ITO substrate and annealed at 200 °C in nitrogen for 10 min. The active area of the PLED was 1 mm^2. Electrode deposition was done by thermal evaporation under 10^{-6} torr. The work functions of the SAM-modified Ag surfaces were measured with a photoelectron spectrometer (AC-2, Riken Keiki) in ambient air with a UV source. The work function was calculated by plotting the square root of the total electron counts versus photoelectron energy and extrapolating the linear fit of the counts to zero as described in

literature [16]. The current density–voltage (J–V) and luminance–voltage (L–V) characteristics of the devices were measured by Keithly 2400 source meter and spectrophotometer PR650.

3. Results and discussion

Ellipsometry measurement of the mixed monolayer was carried out to confirm the monolayer nature of the co-adsorbed films. For example, in the MUA/FHT system, the measured film thickness varies between 6.5 Å (for single component FHT) and 12.0 Å (for single component MUA), depending on the composition.

Reflection absorption IR spectra were taken for the mixed monolayers as a function of the solution composition. With 8-mercaptooctanoic acid (MOA) mixed with the same chain length fluorinated thiol FOT, the intensity of characteristic absorption for carboxyl group at 1712 cm^{-1} decreases with increasing amount of FOT in the adsorbing solution, whereas that for the characteristic absorptions for C–F stretches between 1350 and 1250 cm^{-1} increase with more FOT in the adsorbing solution (Fig. 2). The surface composition correlates with the solution composition. Similar trends for the IR spectra of mixed monolayers composed of MOA and FHT or MUA and FHT, where the carboxyl-terminated thiol is longer than the fluorinated thiol. Based on the integration of the respective peaks, the surface composition was estimated and plotted versus solution composition, as shown in Fig. 3. The surface composition may deviate from the solution composition. Particularly when the chain lengths are much different. Thus for MUA/FHT system, the longer chain MUA will be more favored on the surface than the shorter chain. For the same chain length mixed system of MOA/FOT, the fluorinated component is more favored, presumably because its lower solubility in the ethanol solvent used [15].

One concern is the possible phase separation of the fluorinated component and the carboxyl-terminated alkyl component. In earlier work for mixed monolayer of fluorinated chain and alkyl chain [13], phase separation is possible but of small scale (tens of nanometers) that it is insignificant in affecting the macroscopic properties such as wetting and work function. In the current case where carboxyl groups are introduced, the potential H-bonding interaction between carboxyl group and fluorinated hydrocarbon [17,18] is expected to alleviate, not aggrevate the problem of phase separation.

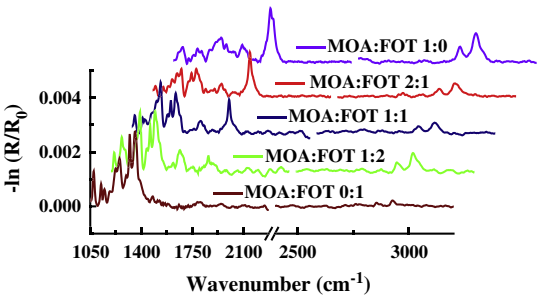

Fig. 2. Reflection–absorption IR spectra of mixed monolayers of MOA (carboxyl-terminated thiol) and FOT (fluorinated thiol) on Ag.

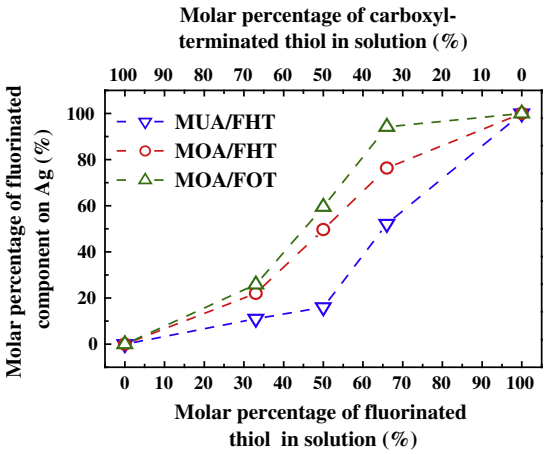

Fig. 3. Plots of surface composition as a function of solution composition, based on the integrated areas under the ν_s (CF-) band (~1350 cm^{-1}) and ν_s (C=O in COOH) band (~1712 cm^{-1}), for the mixed SAMs.

The influences of the molar percentage and chain length of fluorinated and carboxyl-terminated thiols on the wetting property of Ag are shown in Fig. 3(a). On Ag surface covered by a single component MOA or MUA monolayer, the water contact angle is lower than 20°, due to the hydrophilic nature of carboxyl group at the outmost surface. The contact angle increases with increasing amount of fluorinated alkanethiol in the solution. For mixed-SAMs with equal chain length (MOA/FOT), the water contact angle reaches a plateau over 90° as the molar percentage of FOT is higher than 50%.

For Ag surface modified by mixed-SAMs of MOA/FHT, where the carboxyl-terminated thiol is two carbon atoms longer than the fluorinated thiol, the water contact angle increases with increasing ratio of FHT in solution and reaches a plateau as the percentage of FHT is higher than 80%. The wetting property is improved (contact angle decreased) comparing the contact angles at the same mixing ratios. For mixed monolayers prepared from MUA/FHT, where the carboxyl-terminated thiol is six carbon atoms longer than the fluorinated thiol, the contact angle of FHT/MUA-modified Ag surface increases linearly without a plateau and reaches the highest water contact angle around 110° for pure FHT monolayer. This implies the wettability of the MUA/FHT-modified Ag surface is further improved if comparing the contact angles at the same mixing ratios in solution. Longer carboxyl-terminated thiol seems to shield the hydrophobic component down under and rendering the surface relatively more "hydrophilic".

Wettability relates to the sticking property of a polymer by spin-coating. In this work, it was found that formation of polymer film by spin-coating is impossible or very difficult when the substrate surface is highly hydrophobic (for example, the water contact angle is higher than 90°). The polymer solution tends to slip away from the substrate while the substrate spins. It is noted that toluene is used as the solvent for the polymer solution. Similar wetting behavior for toluene on the modified surface was observed (Fig. 4). For the equal length MOA/FOT mixed

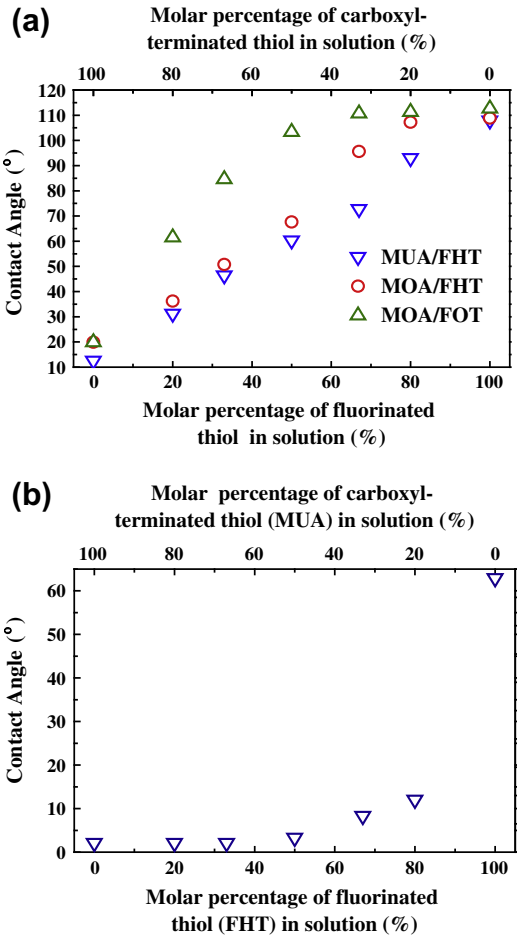

Fig. 4. (a) The water contact angle on mixed SAMs-modified Ag. FHT and FOT are fluorinated alkanethiol with six and eight carbon atoms, respectively. MOA and MUA are carboxyl-terminated alkanethiol with eight and eleven carbon atoms, respectively. (b) The toluene contact angle on mixed SAMs containing MUA and FHT on Ag.

monolayer-modified Ag, the polymer cannot be spun on as the amount of FOT is higher than 50%. For the Ag surface modified by MUA/FHT monolayer, the wetting property of the surface is improved as stated above. Higher percentage of FHT is allowed before the surface becomes too hydrophobic to retain the polymer upon spin coating. The higher amount of FHT serves to increase the work function and reduce the hole injection barrier.

SAM-induced work function change was measured by AC2 in ambient, as shown in Fig. 5. The work function of bare Ag is 4.3 eV (compare to a value of 4.4 eV reported in literature [10]). For Ag modified with carboxyl-terminated SAM (MOA or MUA), the work function increases to about 4.9–5.0 eV which is still not sufficient for hole injection into most luminescent polymers. By increasing the amount of fluorinated component in a mixed monolayer, the work function of the modified Ag now can be tuned. It is noted that for MOA/FHT or MUA/FHT systems, where the carboxyl-terminated chain is longer than the fluorinated chain, the work functions initially remained similar or even decreased until the

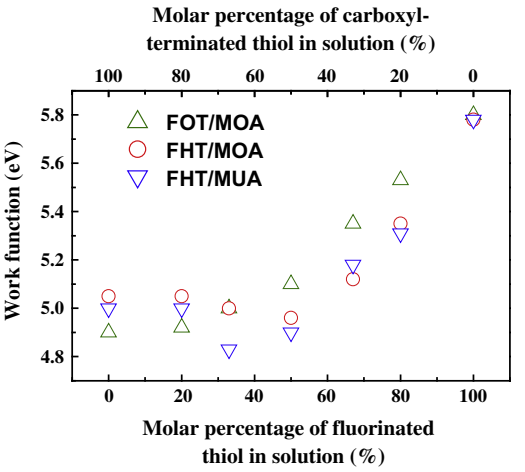

Fig. 5. The work function of mixed SAMs-modified Ag. FHT and FOT are fluorinated alkanethiol with six and eight carbon atoms, respectively. MOA and MUA are carboxyl-terminated alkanethiol with eight and eleven carbon atoms, respectively.

solution percentage for fluorinated component is more than 50%, when the work function increased steadily, up to around 5.8 eV as the amount of fluorinated component is 100%. This value is somewhat higher than the 5.5 eV reported for perfluorinated C10 alkanethiol monolayer on Ag [10]. With equal length MOA/FOT monolayer as modifier, no such dip in work function was observed. The initial decrease of the work function may be due to the re-orientation of the carboxyl groups at the interface. Nevertheless, the amount of FOT is limited to well below 50% to give acceptable wettability for spin-coating to work. This will limit the work function to be below 5.0 eV. With fluorinated component shorter than the carboxyl-terminated component, higher amount of fluorinated component is allowed to give acceptable wettability and the work function can be increased up to 5.3 eV, which is favorable for reducing charge injection barrier.

To further demonstrate the continuous work function change of mixed-SAM-modified Ag surfaces indeed influence the hole injection property of Ag electrode, the current density (J)–voltage (V) relationship of hole-only diodes are compared. J–V curves of the device in the structure Cr/Ag/mixed SAMs (FHT/MUA)/super yellow (SY) or poly(3-hexyl thiophene) (P3HT)/Al are demonstrated in Fig. 6. SY and P3HT layers are fabricated by blade and spin coating technique [19,20]. The blade and spin coating technique can be utilized to deposit a film on all mixed-SAM-modified Ag electrodes no matter the wetting property of the metal. The highest occupied molecular orbital (HOMO) of P3HT and SY are 5.1 and 5.4 eV, respectively. For the P3HT diode, J increases as the FHT ratio increases from 0% to 66%. However, J of devices with 66% and 80% FHT are similar. This is attributed to the work function of FHT modified Ag electrodes with FHT ratio larger than 66% are higher than the HOMO level of P3HT and hence forming an Ohmic contact between electrode and P3HT. As for the diode made by SY with higher HOMO level, J increases as the FHT ratio increases from 0% to 80%. This

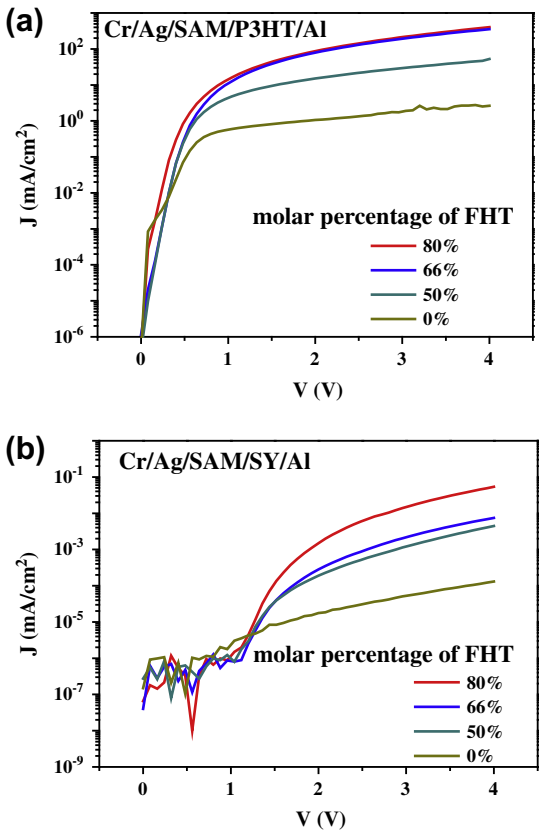

Fig. 6. The current density as a function of voltage of the hole-only devices made by (a) P3HT and (b) super yellow.

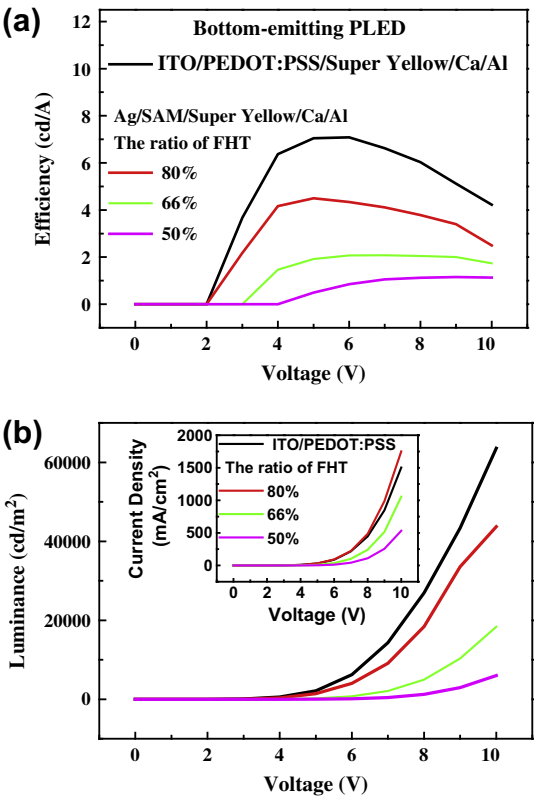

Fig. 7. Characteristics of bottom-emission polymer light-emitting diodes with the structure of anode/super yellow/Ca/Al. FHT/MUA mixed-SAMs-modified Ag and ITO/PEDOT:PSS are utilized as anode. (a) The current efficiency as a function of voltage. (b) The luminance as a function of voltage. The inset shows the current density as a function of voltage.

demonstrates that the mixed-SAM indeed modifies the work function continuously which is suitable serving as an anode.

The effect of mixed SAM-modification on charge injection is demonstrated by a bottom-emitting PLED, as shown in Fig. 7. The current density at same bias increases with increasing amount of FHT in the monolayer, presumably due to the increase in work function of FHT/MUA-modified Ag. The maximum current efficiency of the devices with 80%, 66%, 50% FHT is 4.5 cd/A (at 5 V), 2.1 cd/A (at 7 V), and 1.2 cd/A (at 9 V), respectively. The maximum luminance of the device with 80% FHT is higher than 40,000 cd/m^2 at 10 V. This demonstrates the mixed SAMs-modified Ag can be used as anode to replace ITO. Standard device with ITO/PEDOT:PSS anode is also fabricated for comparison. The standard device achieves a maximum current efficiency of 7.1 cd/A at 6 V. The lower efficiency in the device with 80% FHT results from the reduced transparency of the anode (30 Å Cr/150 Å Ag) as shown in Fig. 8. The top-emitting PLED with FHT/MUA-modified Ag as anode is also fabricated and its characteristics are shown in Fig. 9 (a) and (b). The current density at same bias also increases with increasing amount of FHT. The maximum current efficiency of the devices with 80%, 66%, 50% FHT is 6.7 cd/A (at 6 V), 3.7 cd/A (at 7 V), and 0.8 cd/A (at 8 V), respectively. The maximum luminance of the device with 80% FHT is also

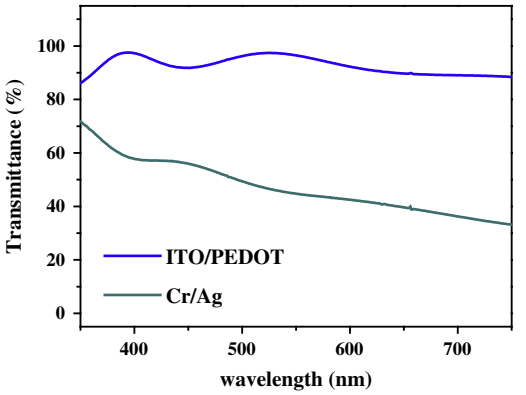

Fig. 8. The optical transmittance of ITO/PEDOT and Cr/Ag electrode.

higher than 40, 000 cd/m^2 at 10 V. Finally, a top-emitting green phosphorescence PLED is also fabricated with FHT/MUA-modified Ag as anode. The emission layer is a blend of tris[2-(p-tolyl)pyridine]iridium(III) (Ir(mppy)$_3$), *N*,*N*′-bis(3-methylphenyl)-*N*,*N*′-bis(phenyl)-benzidine (TPD), 2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (PBD) into poly(vinylcarbazole) (PVK, Mw = 1100,000) in the weight ratio of 6:9:24:61. Some spike can be observed in the current density–voltage curve shown in Fig. 9(c)

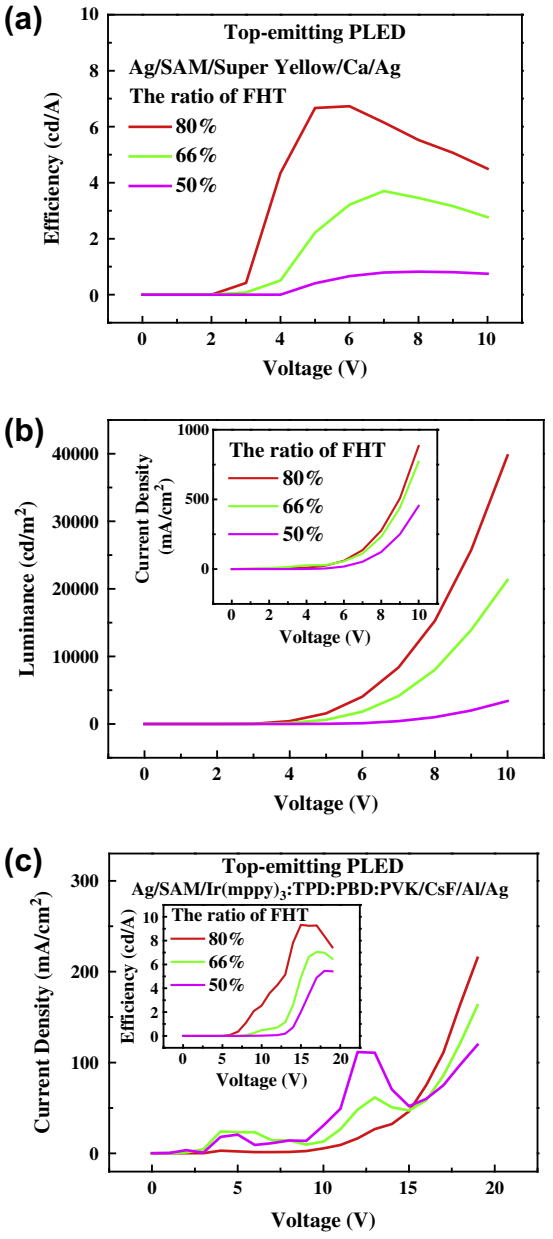

Fig. 9. Characteristics of top-emission polymer light-emitting diode with the structure of Cr/Ag/SAM/super yellow/Ca/Ag. FHT/MUA mixed-SAMs-modified Ag electrodes are utilized as anode. (a) The current efficiency as a function of voltage. (b) The luminance as a function of voltage. The inset shows the current density as a function of voltage. (c) Current density–voltage plot of top-emission polymer light-emitting diode with the structure of Cr/Ag/SAM/Ir(mppy)$_3$:TPD:PBD:PVK/CsF/Al/Ag. The inset shows the current efficiency as a function of voltage.

which may result from current leakage path. The current efficiency is 9.3 cd/A at 15 V. The leakage path may results from the pinhole or aggregation of the component which formed during spin coating. Interaction between SAM-modified Ag surface and polymer solution plays an important role during spin coating process.

4. Conclusion

In conclusion, mixed monolayers of a fluorinated alkanethiol and a carboxyl-terminated alkanethiol of different chain lengths can be used to decouple the effect on the work function and surface wetting for silver. Using a longer carboxyl-terminated component, which may shield or and bury the shorter fluorinated component in the SAM allows higher amount of fluorinated component to be used for increasing the work function of silver, without compromising the wetting property of the substrate needed for spin-coating of emissive conjugated polymer for PLED. PLED with high efficiency and brightness close to the case of ITO/PEDOT:PSS anode are achieved for both top and bottom emission PLED. The tunability in both work function and wettability of silver electrode offers more flexibility in device design.

ABSTRACT

By simply doping Li_2CO_3 in an alcohol soluble neutral conjugated polymer poly[9,9-bis(6′-diethoxylphosphorylhexyl)fluorene] (PF-EP), we demonstrate highly efficient multilayer electrophosphorescence white polymer light-emitting diodes with air-stable Al cathode. From the mechanism studies, we find that the phosphate groups can make Li ions movable in the PF-EP film, resulting in great improvement in the electron injection and transport ability of PF-EP. The hole-blocking ability is also strengthened.

1. Introduction

White polymer light emitting diodes (WPLEDs) have gained much research interest nowadays due to their potential applications in solid-state lighting sources and full-color displays. The low-cost manufacturing technology, the easy fabrication of large-area device and the compatibility with flexible substrate are the major charming merits for WPLEDs [1]. In order to generate the desired white-light emission, the blending of two complementary colors or three primary colors is typically required. Various approaches have been reported to realize this goal, including the synthesis of polymers incorporating different color moieties, blending several color complementary polymers, doping several dyes into a single emitting layer (EML) and usage of excimer or exciplex system [2–7]. However, the performance of WPLEDs is often poor due to imbalanced hole and electron transport and mismatched injection energy barriers, especially for electron injection. The imbalanced charge transport can be adjusted by introducing charge transport materials or dopants, and lots of highly successful works have been reported in this aspect. On the other hand, considerable efforts have also been devoted to the researches on cathode interfacial engineering. The low work function metals (Ca and Ba) [3,4] and inorganic salts (LiF, CsF, Cs_2CO_3 and Li_2CO_3) [2,8–10] were used as an electron injection layer in an attempt to enhance the electron injection in PLEDs. However, the low work function metals Ca and Ba are highly reactive and still not low enough to match the lowest unoccupied molecular orbital (LUMO) levels of most conjugated polymers. Comparatively, the alkaline metal salt can release Li or Cs by the Ca or Al covered on top of it, behaving more effectively

[9,11]. Recently, several water/alcohol soluble conjugated polymers were reported to significantly improve electron injection with high work-function Al cathode [12–22]. It is believed that the metal ions contained in the interlayer or the polar groups on their side chains can form interfacial dipoles between the electron injection layer (EIL) and metal cathode to enhance electron injection [16,20]. More recently, Huang et al. [10] reported a highly efficient WPLEDs with a power efficiency of 23.4 lm W^{-1} by doping a water/alcohol soluble conjugated polymer poly[9,9-bis(2-(2-(2-diethanolaminoethoxy)ethoxy)ethyl)fluorene] (PF-OH) with Li_2CO_3 as electron injection layer. This supplies an effective method to improve electron injection property by introducing effective electron transport layer, thus balancing electrons and holes to fabricate high efficiency multilayer PLEDs.

In this article, we achieved high efficiency WPLEDs by simply doping Li_2CO_3 in an alcohol soluble neutral conjugated polymer poly[9,9-bis(6′-diethoxylphosphorylhexyl)fluorene] (PF-EP) with air-stable Al cathode. It can be seen that the electron injection and transport ability of PF-EP can be dramatically enhanced due to the doping of Li_2CO_3. The WPLEDs show a peak luminous efficiency (LE) of 25.7 cd A^{-1} and a peak power efficiency (PE) of 13.1 lm W^{-1}, which are equivalent to those of incandescent light bulbs. As we see, the WPLED will show significant advantages in practical applications due to the utilization of simple solution-processed active layer and air-stable Al cathode.

2. Experimental

2.1. Materials

The polymer PF-EP was synthesized as follows: 2,7-dibromo-9,9-bis(6′-diethoxylphosphorylhexyl)-fluorene **1** was prepared according to the procedure reported previously, which in turn underwent cross-coupling with the pinacol ester of diboron to give the aryboronic ester **2**. The Suzuki-polycondensation of monomers **1** and **2** with the $Pd(PPh_3)_4$ as catalyst and Na_2CO_3 as base gives the polymer PF-EP. The ^1H NMR is consistent with the PF-EP prepared through Yamomoto polycondensation reaction [15]. $(fbi)_2Ir(acac)$ was synthesized using a method previously described [23]. Poly(styrenesulfonate) (PEDOT:PSS, Baytron P VP CH 8000) was obtained from H.C. Stark. PVK was purchased from Aldrich. Firpic and OXD-7 were purchased from Nichem Fine Technology Co. Ltd. All materials were used as received.

2.2. Device fabrication

First, an 80 nm thick layer of PEDOT/PSS mixture was spin-coated on top of oxygen plasma treated indium tin oxide (ITO). This coated PEDOT on substrate was baked at 80 °C overnight and then at 120 °C for 30 min in a vacuum oven. Afterwards, the PEDOT:PSS-coated substrate was moved into a glovebox under a nitrogen-protected environment to perform the subsequent multilayer process. A 60 nm thick emitting layer was spun-cast from chlorobenzene (PVK:OXD-7(70 w/30 w):10 wt% Firpic:0.2 wt% $(fbi)_2Ir(acac)$). The samples were annealed on a hot plate at 120 °C for 30 min to remove residual solvent. Following that, about 30 nm thick PF-EP films (doped with 0 wt%, 0.75 wt%, 1.25 wt%, 2.5 wt% and 5 wt% Li_2CO_3) as EILs were casted from MeOH:H_2O (3:1). Finally, after annealing on a hot plate at 95 °C for 30 min, a 100 nm thick Al was thermally deposited as a cathode. All the solutions will be filtered using 0.22 μm filter membranes before spin-coating. The vacuum was $<10^{-4}$ Pa. The device area was 16 mm^2.

2.3. Measurements

The EL spectra of WPLEDs were measured with Keithley 2400 source meter and a coupled PR650 spectroscan photometer. *J–V–L* characteristics were measured by a Keithley source measurement unit (Keithley 2400 and Keithley 2000) with a calibrated silicon photodiode. For photovoltaic measurement, the photocurrent–voltage characteristics were recorded using a computer-controlled Keithley 236 source meter under a white light illumination with intensity of 100 mW cm^{-2}. XPS experiments were performed in Thermo ESCALAB250 using monochromatic Al Kα (1486.6 eV). The thickness of the evaporated films were monitored by frequency counter and calibrated by Dektak 6M Profiler (Veeco). The thicknesses of spin-coated films were controlled by Dektak 6M Profiler (Veeco) directly. AFM studies were carried out directly on the devices after EL performance measurement. All the device testing was carried out in ambient atmosphere. Except that the measures in Fig. 5 were carried out in glovebox, all other measurements were performed in ambient atmosphere.

3. Results and discussion

3.1. Device performance

Device structure and energy diagrams used in this study are shown in Fig. 1(a) [24]. The device structure is ITO/PEDOT:PSS(80 nm)/[(PVK:OXD-7)(7:3)]:FIrpic(10 wt%):$(fbi)_2Ir(acac)$(0.2 wt%)(60 nm)/EIL(30 nm)/Al(100 nm), where PEDOT:PSS is used as both the hole injection and transport layer (HITL), a blend containing poly(N-vinylcarbazole) (PVK), 1,3-bis[2-(4-tert-butylphenyl)-1,3,4-oxadiazo-5-yl] benzene (OXD-7), [bis(4,6-difluorophenyl)-pyridinato-N,C^2] picolinate iridium (III) (FIrpic), and bis(2-(9,9-diethyl-9H-fluoren-2-yl)-1-phenyl-1H-benzoimidazol-N,C^3) iridium-(acetylacetonate) ($(fbi)_2Ir(acac)$) [24] as the EML. Alcohol soluble PF-EP doped with 0 wt%, 0.75 wt%, 1.25 wt%, 2.5 wt% and 5 wt% Li_2CO_3 is used as the EIL. The chemical structures of the relevant materials are shown in Fig. 1(b).

Fig. 2(a) and (b) compares the efficiency of the fabricated WPLEDs for different Li_2CO_3 doping concentrations in PF-EP. It can be seen that the Li_2CO_3-doping in PF-EP EIL leads the devices to higher efficiency than that of the Li_2CO_3-undoped device. The performances of the white devices are summarized in Table 1. The maximum current efficiency and power efficiency of the device with pure PF-EP as EIL reach 21.5 cd A^{-1} and 9.0 lm W^{-1}, respectively.

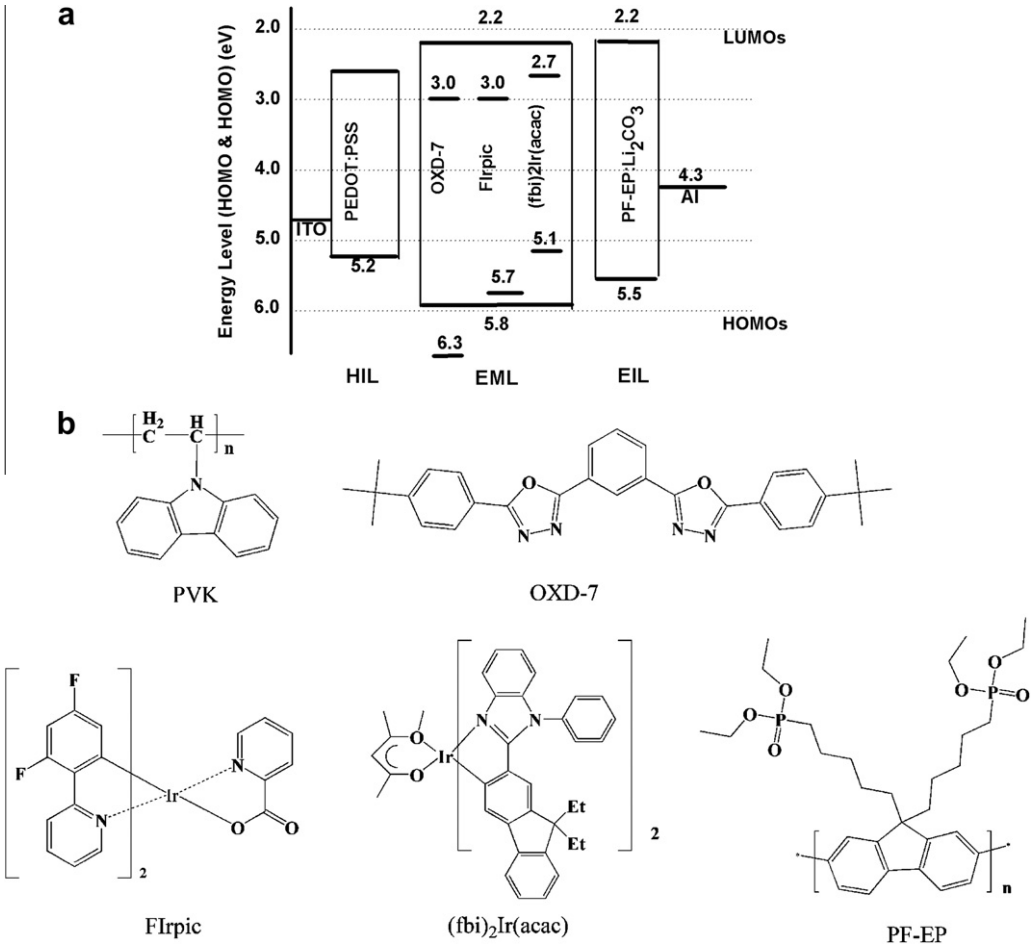

Fig. 1. (a) Device structure and energy diagrams used in this study. (b) Molecular structures of the relevant materials.

Correspondingly, when Li_2CO_3 (0.75 wt%, 1.25 wt%, 2.5 wt% and 5 wt%) is introduced into PF-EP as EILs, the maximum luminance efficiency is 25.6, 25.7, 23.8 and 15.4 cd A^{-1} and the power efficiency is 11.9, 13.1, 11.5, and 6.6 lm W^{-1}, respectively. All devices can realize white-light emission, and the Commission Internationale de l'éclairage (CIE) coordinates of the WPLED device with 1.25 wt% Li_2CO_3 doped EIL are shown in Fig. 2(c), the CIE coordinates variation is negligible and only shifts from (0.41, 0.46) at 8 V to (0.39, 0.45) at 12 V. Fig. 2(d) gives the brightness–voltage (*B*–*V*) curves. It can be found that the devices with Li_2CO_3-doped EILs showed much lower operating voltage than that of the Li_2CO_3-undoped device. The turn-on voltage is decreased from 5.3 V to 4.1 V (Table 1). The inset in Fig. 2(d) gives the current density–voltage (*J*–*V*) curves. Three regions can be identified. For an applied voltage less than 4 V where light output is not observed, called region 1, the current density *J* is sensitive to various factors, such as preparation procedure and diffusion of the cathode [25]. As the applied voltage is increased to 4 V where the devices turn on, the curves go to region 2. The current density is increased with the increase of Li_2CO_3 concentration. After going up to 10 V where the brightness tends to be maximum and the efficiency has fallen (region 3), the high Li_2CO_3 concentration will accelerate the degradation of the devices. The significantly different performances mean that the transport or injection processes of the devices are greatly influenced by Li_2CO_3 doping in EIL.

3.2. Mechanism

In order to get insight into the improvement mechanism of the doped Li_2CO_3 in PF-EP EIL in device performance, we first study electron injection properties by photovoltaic (PV) measurements of the open-circuit voltage (V_{oc}) across the light-emitting devices under steady state forward bias with the scan rate of 0.3 V/s [5,18]. As the anode of each device is identical, the V_{oc} is only dependent on the effective work function of the cathode. As shown in Fig. 3, the V_{oc} increases with the increase of Li_2CO_3 concentration. This indicates that the electron-injection ability of PF-EP EIL is improved upon Li_2CO_3 doping. It is well known that alkali metal salts are a kind of excellent electron injection material and have been successfully used as n-dopants in OLEDs [2,9,10]. Therefore, it is reasonable to infer that the lower barrier is caused

by the enhanced interfacial dipole or the space charge electrical field [18].

To further understand the mechanism of the enhanced electron injection, the pure PF-EP film and 2.5 wt% Li_2CO_3 doped PF-EP film are studied by XPS. Fig. 4(a) shows the spectra corresponding to the P 2p core levels. For the sample of pure PF-EP film, the P 2p peak at 133.15 eV is assigned to P═O/P—O (Fig. 4(a)) [26]. However, for the sample of 2.5 wt% Li_2CO_3 doped PF-EP film, the P 2p spectra are broadened. The higher-energy part is not present in the control sample (Fig. 4(a)). We attribute this extra part to an interaction between P and Li. The O 1s signals from the Li_2CO_3-doped and -undoped PF-EP films are shown in Fig. 4(b). For the sample of pure PF-EP film, the peaks at 531.45 eV and 532.75 eV are assigned to P═O and P—O groups (Fig. 4(b)) [27,28], respectively. After doping with

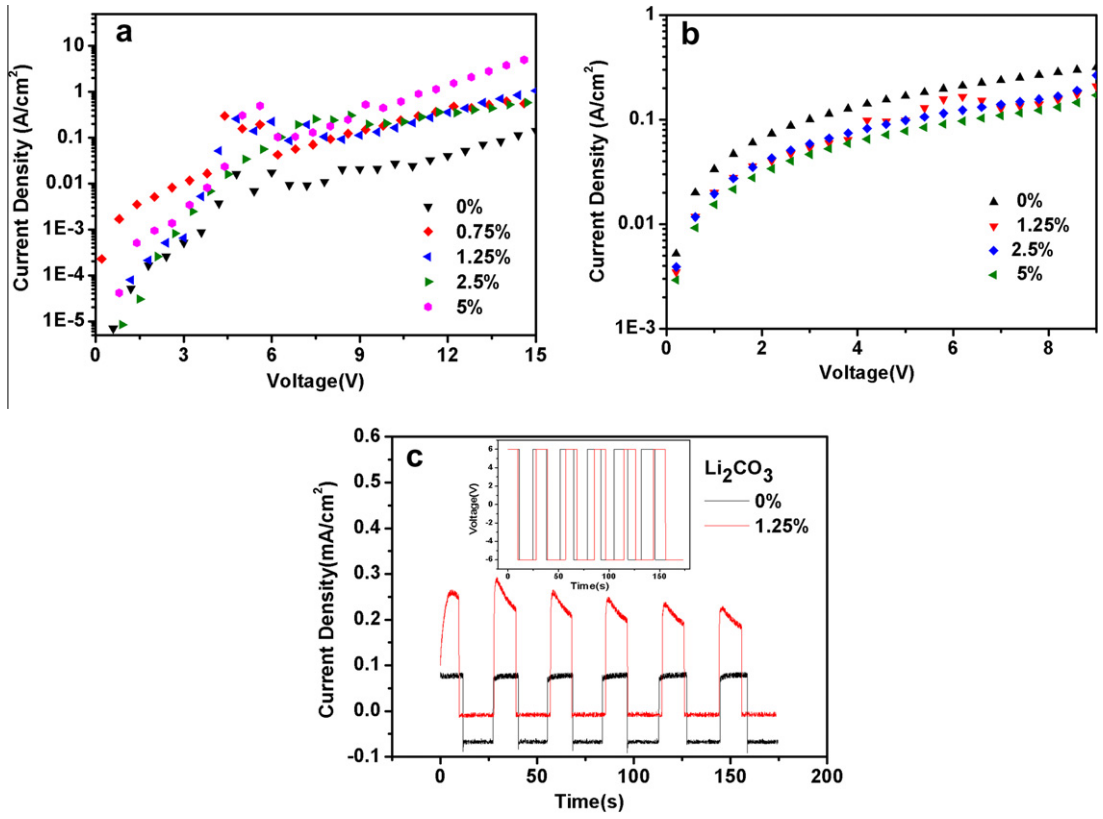

Fig. 5. *J–V* characteristics of the single-carrier devices: (a) electron-dominated device and (b) hole-dominated device. (c) Current density as a function of time for ITO/PEDOT:PSS/EML/PF-EP + Li_2CO_3 (0% or 1.25%)/Al device.

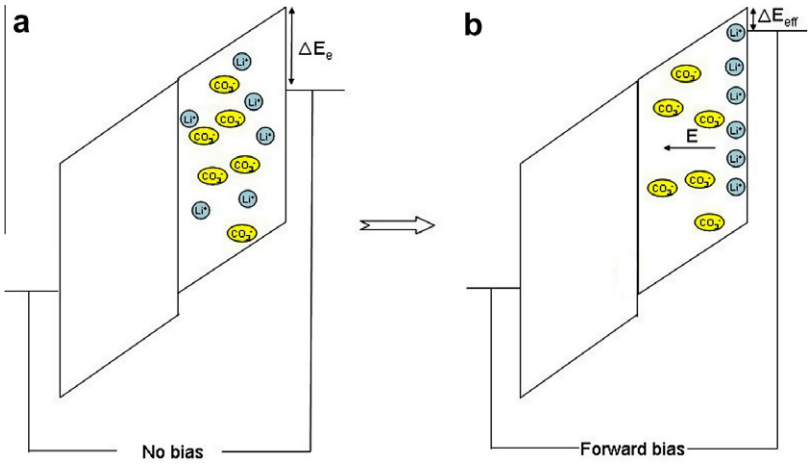

Fig. 6. Schematic of the interface mutative processes: (a) no bias and (b) forward bias across the light emitting device.

Li_2CO_3, the O 1s peak at 531.45 eV becomes strong which is caused by the C═O groups. The O 1s peak at 532.75 eV shows 0.2 eV positive shifts to higher binding energy (532.95 eV). This indicates that the introduction of Li ions also has an effect on O atoms [29,30]. The interaction between P, O and Li makes it possible to transport the Li ions in the EIL, which is similar with the typical polymer electrolytes like PEO and alkali metal salts system [31]. Fig. 4(c) gives the schematic diagram of this transport process [32]. One mechanism of the enhanced electron injection in devices due to Li_2CO_3 doping in EIL can be attributed to the mobile Li ions. Li ions can easily transport into the EIL due to the interaction with the phosphate groups.

Furthermore, two kinds of single-carrier devices are fabricated as follows:

(A) The electron-dominated device: ITO/Ca(20 nm)/[(PVK:OXD-7)(7:3)](60 nm)/EIL(30 nm)/Al(100 nm).
(B) The hole-dominated device: ITO/PEDOT:PSS(80 nm)/[(PVK:OXD-7)(7:3)](70 nm)/EIL(30 nm)/Au(20 nm)/Al(30 nm).

As shown in Fig. 5(a) and (b), the doping of Li_2CO_3 in EIL greatly enhances electron current, but reduces hole current. This indicates that the doping of Li_2CO_3 improves the electron injection and transport of EIL and also plays the role of blocking the hole at the interface of EML/EIL at the same time. Fig. 5(c) shows the *J–V* characteristics of the devices as a function of time with pure PF-EP film and 1.25 wt% Li_2CO_3 doped PF-EP film as EILs. The inset of Fig. 5(c) gives the periodic square wave signal (the amplitude is 6 V and the cycle is about 20 s). It can be found that the rectification ratio of the PLED with 1.25 wt% Li_2CO_3 doped PF-EP EIL is obviously larger than that of the PLED with the pure PF-EP film as EIL. This further verifies that the doped PF-EP film can more effectively enhance the electron injection and transport, and prevent the hole injection into the EILs than the pure PF-EP film does. Furthermore, as we see, the current in device with Li_2CO_3 doped PF-EP EIL shows a long time response. This should indicate that the Li ions are movable in EIL. In this case, the Li ions will gradually move to the interface at the cathode with time at electrical field. As a result, the electron current will gradually increase due to the enhancement of electron injection by formation of interface dipole, leading to the time delay. As reverse bias, the partial ions will leave the interface again, therefore, as again positive bias, the response time becomes short.

On the basis of the above analyses, we draw a scheme to clarify the mechanism on how the movable ions enhance electron injection. As shown in Fig. 6, the ions are freely dispersive in the EIL initially. When the forward bias is applied, the ions redistribute. The Li^+ cations move towards the EIL/cathode interface by interacting with the phosphate groups at electrical field and accumulate at the EIL/cathode interface. These accumulated Li^+ cations can form stronger interfacial dipoles between the EIL and metal cathode than that of pure PF-EP. Thus, the electron injection barrier can be more effectively reduced. For the CO_3^{2-} anions, we infer that the mobility is limited by the big diameter (CO_3^{2-}: 0.402 nm, Li^+: 0.152 nm) [33,34] and shows indistinct interaction with the PF-EP. The CO_3^{2-} anions cannot move to the interface like the Li^+ cations. One of the roles is that the holes are effectively blocked within EML. Therefore, the improved efficiency of PLEDs can be attributed to balance the carriers via enhancing electron injection and blocking hole injection into EIL. As we see, the efficiency is dependent on the doping concentration of Li_2CO_3; higher Li_2CO_3 doping will quench the excitons, leading to the gradual decrease of efficiency. Obviously, it is necessary to optimize the doping concentration of Li_2CO_3 in EIL when fabricating devices.

4. Conclusion

We demonstrate efficient multilayer WPLEDs with air-stable Al cathode by introducing Li_2CO_3-doped PF-EP EIL. The results from the mechanism research reveal that the electron injection and transport ability of PF-EP EIL can be

dramatically improved upon Li_2CO_3 doping. Facilitated migration of Li ions by ion transporting phosphate groups greatly improves the electron injection and transport. What is more, the hole-blocking ability is greatly strengthened. Consequently, the devices with Li_2CO_3-doped EIL exhibit much better performances than the ones without Li_2CO_3 doping. The best efficiencies of 25.7 cd A^{-1} and 13.1 lm W^{-1} are obtained in WPLEDs with air-stable Al cathode.

ABSTRACT

Charge transport is comparatively studied in the bulk and at the interface of disordered fullerene films fabricated using physical vapour deposition. Charge carrier concentration and temperature dependent electron mobilities are comparatively studied using charge extraction by linearly increasing voltage (CELIV) technique and organic field-effect transistors (OFET) measurements. Electron mobility is at least two orders of magnitude higher than hole mobility in the fullerene films. Lower mobility values and stronger concentration dependence in diodes is observed. Carrier concentration dependent activation energy is experimentally measured in both types of devices. Larger activation energy for electron transport is required at lower carrier concentrations. Meyer–Neldel rule (MNR) for electron mobility is observed in both the bulk of the fullerene films and in the transistor channel at the interface. Meyer–Neldel energy (E_{MN} = 35 meV), which is interpreted as disorder parameter, is the same in both device geometries, which suggest that the level of disorder and energetical landscape for charge transport is similar in the bulk of fullerene films and at the interface with the insulator. Disorder formalism is used to qualitatively explain that either carrier concentration or the nature of non-equilibrium charge carrier transport in CELIV compared to steady-state OFET measurements is responsible for observed transport properties.

1. Introduction

The charge carrier transport mechanisms are fundamentally important for understanding the electronic phenomena in organic semiconductor devices. In general, charge carrier transport is dependent on the material structure and nanoscale order in the film [1]. One of the advantages of organic electronic devices is their solution processability, which results in disordered film structures. The absence of translational symmetry with a three-dimensional periodic lattice in disordered films results in a random distribution of potential wells yielding a distribution of localized density of states (DOS). Hopping type of charge transport leads to a lower carrier mobility compared to crystalline inorganic semiconductors. Charge carrier transport studies in disordered organic semiconductors are challenging due to low charge carrier mobility (<1 $cm^2 V^{-1} s^{-1}$) (limits the applicability of Hall effect), a significant amount of thermally generated carriers (limits the applicability of time-of-flight – TOF), pronounced trapping, dispersive transport, non-Ohmic contacts (limits the applicability of space charge limited current – SCLC) makes the standard measurement methods difficult to apply [2–7].

Various physical processes, including charge carrier transport in disordered media, are thermally activated and follow the Arrhenius exponential law of the form [8]:

$$\mu = \mu_0 \exp\left(-\frac{E_A}{kT}\right), \quad (1)$$

where k is the Boltzmann constant, T is the temperature, μ_0 is the prefactor and E_A is the activation energy. Meyer and

doi:10.1016/j.orgel.2010.10.014

Neldel first observed the exponential dependence of the prefactor μ_0 on the activation energy E_A:

$$\mu_0 = \mu_{MN} \exp\left(\frac{E_A}{kT_{MN}}\right), \quad (2)$$

where μ_{MN} is the Meyer–Neldel mobility and $kT_{MN} = E_{MN}$ is the Meyer–Neldel energy. Substituting Eq. (2) into Eq. (1) leads to the consequence that there exist an isokinetic temperature $T = T_{MN}$, where the charge carrier mobility becomes independent on activation energy E_A. In a plot of $\ln(\mu)$ versus the inverse temperature (Arrhenius plot), the lines of different Arrhenius dependencies should show one common intersection at T_{MN}. Charge carrier concentration is a parameter which changes the activation energy in MNR. During the transport, the charge carriers become detrapped by being excited from localized states to extended states (or to the states with higher energies where density of states is higher if delocalized states do not exist) by acquiring thermal energy (Arrhenius type behaviour) [9]. Carrier concentrations determines the occupation of DOS as well as the activation energy required for carriers to acquire in order to be promoted to states with higher mobility. Therefore, higher carrier mobility is expected at high concentrations.

The Meyer–Neldel rule (MNR) was observed in charge carrier mobility of fullerenes [10], porous and amorphous silicon [11], microcrystalline silicon films [12], ionic conductivity [13] glassy materials [14] organic materials [15] in various devices such as charge-coupled devices [16], liquid semiconductors [17] and thin-film transistors [18]. Meyer–Neldel temperature was even attributed as a figure-of-merit for the quality of materials used in field-effect transistors [19]. Even though a number of theoretical models were proposed to explain the origin of MNR, none of them is universally accepted. One common explanation is based on the Fermi level shift with temperature [20]. Others suggest that MNR arises for processes for which the total energy is provided by multiple excitations [21,22]. It was also shown that multiple processes coexisting at the same time also lead to the MNR [23]. Theoretical studies by Fishchuk et al., proposed this Meyer–Neldel energy kT_{MN} to be directly proportional to the width of the DOS in the disordered energy band [24].

Usually electric current, conductivity, diffusion and other physical parameters are used to determine the presence of MNR. In order to clearly understand the mechanisms of MNR it is important to demonstrate the MNR in fundamental quantities such as charge carrier mobility. Other quantities might depend on non-transport parameters, for instance material conductivity or total current are dependent on both charge carrier mobility and density which hinders the interpretation of experimental results.

In order to understand and be able to develop device independent unifying models of charge transport it is important to study transport in various device configurations. A number of studies have comparatively studied the charge transport using TOF and OFETs is the past [25–28]. The charge carrier mobility as a function of carrier concentration and temperature is comparatively studied in the bulk of fullerene (C_{60}) diodes and at the interface with gate insulators in OFETs. Usually a large discrepancy between the bulk and the interface mobility values is observed, which is attributed to the difference in charge carrier concentrations and to the difference of the DOS at the interface and in the volume of the film [29,30].

Due to the possibility to experimentally vary carrier concentration and temperature, charge extraction with linearly increasing voltage (CELIV) technique and organic field effect transistor (OFET) measurements are advantageous for studying the charge carrier transport, whereas carrier concentration cannot be varied in classical time-of-flight technique. However, non-equilibrium transport of photogenerated charge carriers is studied using CELIV, whereas steady-state transport is measured in OFETs. Photogenerated carriers lose their excess energy during thermalization processes (downward jumps in energy scale) and their mobility decreases with time after photogeneration resulting in a time-dependent dispersive transport [31]. Therefore, when comparing photogenerated with steady-state transport this has to be taken into account.

In this work the charge carrier mobility as a function of carrier concentration and temperature is studied in fullerene (C_{60}) diodes and OFETs. Comparative studies of charge transport in the bulk of the film and at the interface of fullerene and dielectric are reported using CELIV as well as OFET techniques. MNR parameters have been used to determine the quality of the films and the degree of disorder [19]. Activation energy of electron transport is experimentally measured as a function of carrier concentration.

2. Experimental

The schematic structures of the devices studied here are shown in Fig. 1. Diodes are made of sandwich type geometry, where the semiconducting film is placed between aluminum and PEDOT covered ITO electrodes. OFETs are planar contacted structures where charge carrier transport proceeds between the source and drain electrodes within the channel at the interface of the semiconductor and insulator.

2.1. Charge carrier mobility measurements by charge extraction by linearly increasing voltage (CELIV)

CELIV allows the charge carrier mobility and concentration to be measured from current transients directly and independently. Moreover, time, density, electric field and temperature dependent charge carrier mobility can be studied in the films with rather dispersive charge transport, where other methods (e.g. time-of-flight) are inapplicable due to required experimental conditions [2]. It was shown in the past that the charge carrier mobility measured from CELIV is in good agreement with values measured by TOF [32]. Schematic time dependence of the applied triangle rising voltage pulse and current transient response is shown in Fig. 2.

A linearly increasing voltage pulse with the slope $A = U_{max}/t_{pulse}$, here U_{max} is the maximum voltage of triangle pulse and t_{pulse} is the pulse duration) is applied to the sample to extract the equilibrium charge carriers. The

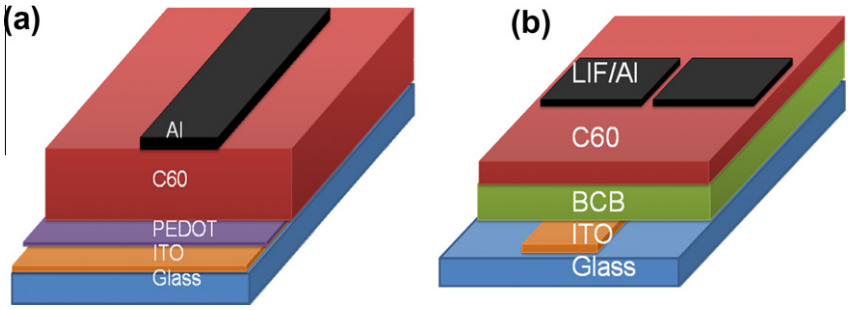

Fig. 1. Schematic illustration of diodes (a) for CELIV and organic field effect transistor (b) for OFET structures used to comparatively study the charge carrier transport in the bulk of the C_{60} film (between Al and ITO/PEDOT contacts) and at the interface of fullerene with the gate insulator (between LiF/Al contacts but at the C_{60}/insulator (BCB) interface).

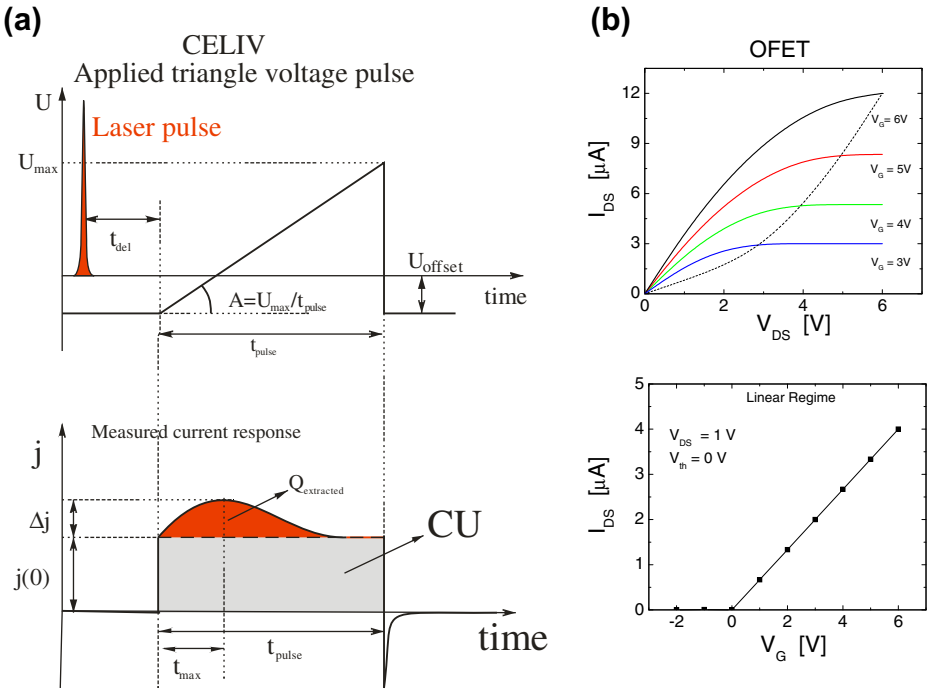

Fig. 2. Schematic charge extraction by linearly increasing voltage (CELIV) current transients (a) and organic field effect transistor (FET) output and transfer curves (b) used to experimentally measure the charge carrier mobility. The charge carrier mobility was studied as a function of the following parameters: temperature, time t_{del} from CELIV, electric field (by changing the rising slope of triangle voltage pulse in CELIV and drain-source voltage V_{DS} in OFET), charge carrier concentration (by changing t_{del} and measuring extracted charge $Q_{extracted}$ in CELIV and changing V_G in OFET).

charge carriers inside the film can also be photogenerated by a light pulse (sometimes called photo-CELIV technique, herein referred also as CELIV). Then, the photogenerated charge carriers are extracted by the linearly increasing voltage pulse after some delay time t_{del}. At the beginning of the CELIV current transient a capacitive current step $j(0)$ is seen (Fig. 2a). The following current increase Δj is related to the extraction current caused by the charge carriers transported in the film. The current continues to increase as the voltage increases until the charge carriers are extracted from the film and the current drops down to the capacitive step level. In practice, if the duration of the applied triangle voltage pulse t_{pulse} is not long enough, then there might be some carriers left in the film and the extraction current will end at a higher level than the capacitive step. The charge carrier mobility is estimated from the extraction maximum [33]:

$$\mu = K\frac{d^2}{At_{max}^2}, \tag{3}$$

where d is the film thickness, $K = 2/3$ for volume ($\alpha d \ll 1$, where α is light absorption coefficient from Beer–Lambert's law) and $K = 2$ for surface photogeneration ($\alpha d \gg 1$).

The charge carrier concentration ($n = Q_{extracted}/e/V$, where $Q_{extracted}$ is the extracted charge, e the elementary charge and V is the volume) is estimated from the integrated extraction photocurrent transient with respect to time. By changing the delay time (t_{del}) between the laser pulse and applied voltage pulse, or by changing the laser

intensity, the charge carrier mobility was measured as a function of time and concentration [34]. Since the electrical field in CELIV experiments is not a constant value but it is ramping with time, the field at which the charge carrier mobility is measured is estimated from At_{max}/d (electric field at maximum extraction point t_{max}), since majority of carriers are extracted at this field.

Thick fullerene films (≈1–10 μm, in order to ensure surface photogeneration) were grown on ITO/glass substrates using physical vapor deposition [35]. Semitransparent, 30 nm thick aluminum electrode was vacuum deposited on top of the fullerene films. CELIV could only be measured down to 240 K in due to a phase transition and a peel off of the studied films. In both, CELIV and OFET experiments, the charge carrier mobility and its temperature dependencies were measured in a cryostat under vacuum (10^{-6} mbar). The measurements were conducted with a temperature step of 10 K, with a time delay of 1 h so that device got thermally stabilized. Studied devices were loaded in the Oxford cryostat under N_2 atmosphere inside the glove box to avoid exposure to ambient condition.

2.2. Charge carrier mobility measurements by organic field effect transistor (OFET)

Fig. 2 shows typical output characteristics of a FET device at different gate voltages and the corresponding transfer characteristics in the linear regime ($V_G \gg V_{DS}$, where V_G and V_{DS} are the gate and drain-source voltages correspondingly). In linear regime, the applied gate field is much larger than the in-plane drift field, which results in an approximately uniform density of charge carriers in the active channel. At these conditions source-drain current I_D increases linearly with V_G and is approximately described by the following equation:

$$I_D|_{V_{DS} \ll V_G} = \frac{W}{L} \mu \, C_i \, V_{DS}(V_G - V_{th}) \quad (4)$$

where L is the channel length, W is the channel width, C_i is the capacitance per unit area of the insulating layer, V_{th} is the threshold voltage.

By plotting I_D versus V_G at low V_{DS} and evaluating the slope of this plot, the carrier mobility μ can be calculated using Eq. (4). Similarly, mobility can also be determined in the saturation regime ($V_{DS} \geqslant V_G$), but due to pinch off in the channel, the mobility calculated in the saturated regime is not an option to study the charge carrier transport in FET devices, because it is deduced form an inhomogeneous distribution of the charge carriers in the conductive channel of the FET.

The charge carrier concentration n is estimated from the charge accumulated at the semiconductor/insulator interface by increasing V_G in metal–insulator-semiconductor (MIS) capacitor:

$$n = C_i \, V_G \frac{1}{ed}, \quad (5)$$

where e is the elementary charge, C_i is the geometric capacitance of the device with a 35 μm channel length and 2 mm channel width and d is the channel height.

Since the charge carrier transport is strongly dependent on the insulator and interface/surface treatment in OFETs [36], OFET devices were fabricated using indert divinyltetramethyldisiloxane-bis(benzocyclobutene) (BCB) as gate dielectric on ITO/glass substrates. Transistor channel length was 35 μm, width 2 mm and for concentration calculations we assumed the channel thickness on the interface of 10 nm (where most of the charge carriers are accumulated) [37]. Details of device fabrication steps were reported previously [38]. The transistor characteristics were recorded by Agilent 2000 SMU. Low V_{DS} (2, 4, 6, 8, 10 V) compared to high V_G (60 V) was used I the experiment in order to stay in the linear regime of OFET operation.

3. Results and discussion

In order to determine the charge transport properties of the studied C_{60} films, both CELIV and OFET measurements were employed. In order to compare the electron and hole mobility by CELIV, thick fullerene films were illuminated either through semitransparent Al or ITO electrode keeping the same applied voltage polarity [39]. Therefore, either electron (ITO illuminated with negative bias) or hole (Al illuminated with positive bias) transport can be measured in the film where the light absorption profile is much smaller than film thickness (surface photogeneration).

Fig. 3a shows CELIV transients for electron and hole transport. The extraction current is seen only for electron transport, whereas for hole transport the CELIV transients is indistinguishable with the dark response concluding that the electron mobility is much higher (>100 times) compared to hole mobility. Laser signal is well seen before the extraction pulse showing that the electrons and holes are photogenerated at the aluminum interface.

The current response for electron transport resembles a typical CELIV transient. The capacitive (displacement) charging current for dark transients is slightly increasing with time due to sum of both effects: increasing dielectric constant and carrier injection from electrode due to non-perfectly blocking contacts. Extraction maximum is seen only for electron transport, when negatively biased ITO electrode is illuminated with a laser.

The OFET transfer curve, shown in Fig. 3b, shows no significant hole injection into the channel when negative voltage is applied to the gate. Strong electron current is observed under positive gate bias. Therefore, both CELIV and OFET experiments confirm that electron mobility is much higher than hole in fullerene films. Further charge carrier transport studies in this work are shown for electron mobility.

Carrier mobility measurements as a function of carrier concentration at various temperatures is shown Fig. 4. In CELIV experiment (a) and (b) the transients were recorded at different t_{del}. The triangle voltage slope A was fixed, but the delay time between the laser and voltage pulse t_{del} was varied which changed carrier concentration. In OFET experiment (c) and (d) the transfer curves at different gate voltages are shown.

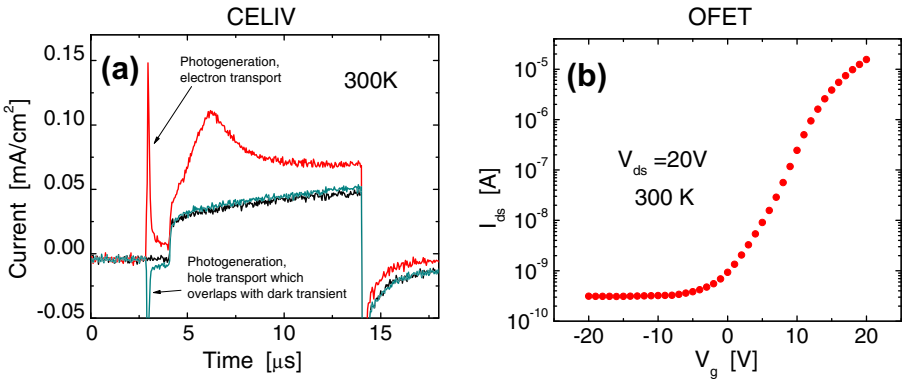

Fig. 3. CELIV transients (a) and OFET transfer curve (b) showing that the electron mobility is at least 100 times larger than hole mobility in C_{60}.

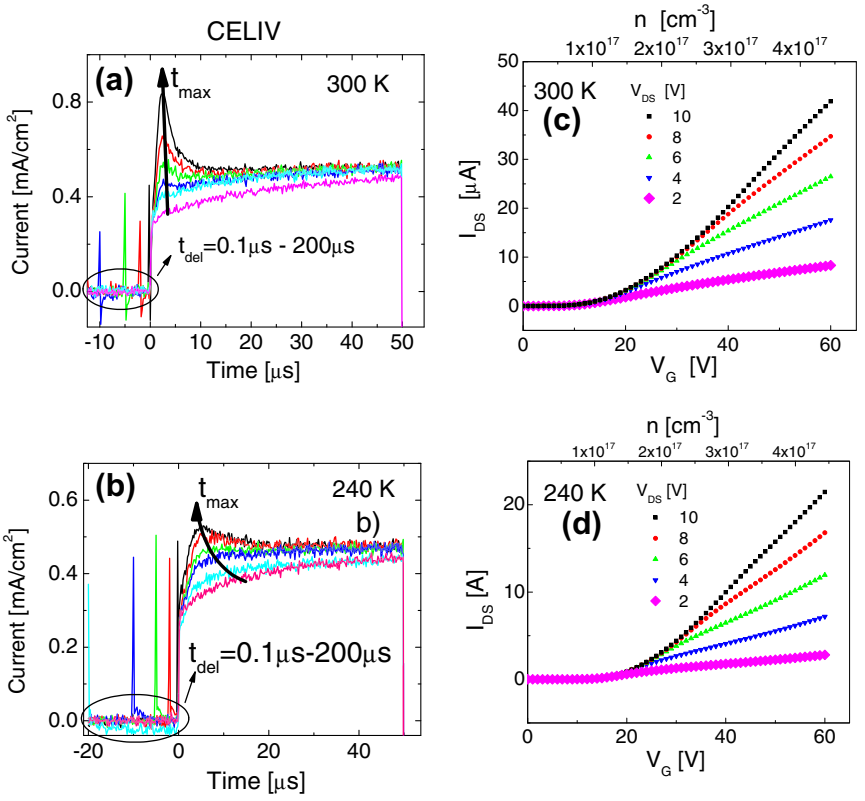

Fig. 4. CELIV current transients at various delay times t_{del} in (a) and (b) shown together with OFET transfer curves in (c) and (d) both at 300 K and 240 K, respectively. From CELIV transient time and concentration dependent carrier mobility as well as carrier density relaxation is measured. OFET curves (shown as thick points) are used to measure carrier concentration dependent electron mobility at different gate voltages.

CELIV transients are similar to the ones observed before only showing more dispersive extraction at lower temperatures. Stronger shift in extraction maximum, which is related to carrier mobility, can be seen at lower temperatures, directly showing that stronger concentration dependent carrier mobility at low temperatures. Charge carrier mobility dependence on time is calculated using Eq. (3) and plotted in Fig. 5a. Because the carrier extraction is not instantaneous and t_{max} is comparable delay time t_{del}, both times have to be taken into account. Therefore, the sum of t_{del} and t_{max} is plotted in Fig. 5 [40].

The charge carrier mobility decreases as a function of time due to the relaxation phenomena of photogenerated charge carriers (thermalization) within the density-of-states to deeper states (time-dependent mobility) as well as due to the charge carrier recombination during the de-

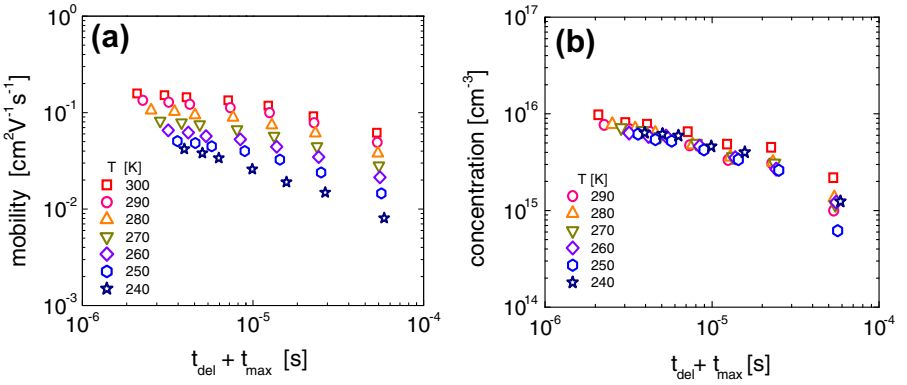

Fig. 5. Non-equilibrium time-dependent electron mobility (a) and density decay (b) in C60 films shown at various temperatures as measured from CELIV.

lay time t_{del} (concentration-dependent mobility) [40]. In the studied films charge transport is weakly dispersive especially at room temperatures, therefore only weak carrier mobility dependence on time is seen. Therefore, measured mobility dependence is attributed to carrier concentration.

By integrating the extraction photocurrent (dark current subtracted) of the CELIV transient over time, we estimate the amount of extracted charge which is proportional to charge carrier concentration in the film. Time-resolved decay of charge carrier concentration is measured and plotted in Fig. 5b. Charge carrier concentration is similar at all temperatures showing that appropriate experimental conditions were chosen to extract all photogenerated charge carriers which allow carrier concentration to be estimated from the photocurrent transients. In order to present the carrier mobility as a function of concentration, Fig. 5a and b are used to eliminate the time scale and plot carrier mobility at different concentrations. Carrier mobility values from OFET are estimated from Fig. 4 using Eq. (4) and plotted together with CELIV values comparatively in Fig. 6. Since the extraction maximum position changes with carrier concentration, so does the electric field at which carrier mobility is estimated. Therefore, non-constant electric field is present during CELIV measurements, but the change is insignificant (from 3000 to 1500 V/cm), whereas in OFET experiment the electric field is constant (500 V/cm).

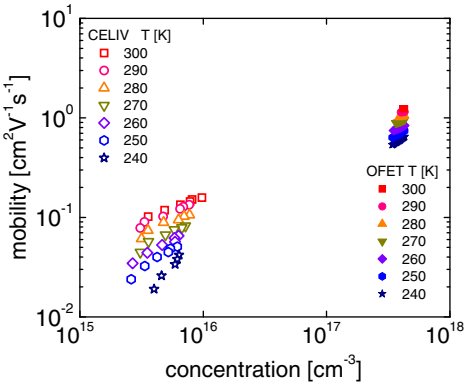

Fig. 6. Concentration dependent electron mobility in C_{60} films measured from CELIV and OFET. Electric field in CELIV experiment changes in the range from 3000 to 1500 V/cm, where in OFETs it is 500 V/cm.

Much lower charge carrier mobility values and stronger concentration dependence is seen in the bulk of the film from CELIV where carrier concentration is significantly lower. Weak dependence of carrier mobility on concentration observed in OFETs is attributed to the trap filling effect at high carrier concentrations which increases the effective transport energy in the DOS to higher values. This allows for carriers to reach higher energies where the mobility is larger and less dependent of concentration due to higher density of available states [41].

Arrhenius plots from both CELIV and OFET experiments are evaluated from the concentration dependent carrier mobility measurements. Fig. 7a and b shows the Arrhenius-type of charge carrier mobility replotted from the Fig. 6 as a function of temperature at different carrier concentrations from both CELIV and OFET experiments, respectively.

In both experiments carrier mobility follows Arrhenius type of dependence in contrast to typically observed non-Arrhenius dependence in π-conjugated polymers and molecularly doped polymer in which Bässler's model is used to describe the charge transport.[32,41] A common intersection point of extrapolated data lines allows the Meyer–Neldel parameters to be estimated. The charge carrier mobility becomes temperature and concentration independent at the isokinetic intersection point. MNR temperature obtained from CELIV is T_{MN} = 406 K and from OFET T_{MN} = 408 K which in both cases corresponds approximately to E_{MN} = 35 meV. Since the MNR energy E_{MN} is directly correlated with the level of disorder in the film quality and properties of DOS in which charge transport occurs [24,42,43], similar MNR energies obtained from CELIV and OFET suggest that charge carriers experience energetically similar landscape for charge transport in the bulk of the film and at the interface in studied devices. The absence of dipoles at the interface of fullerene and BCB forms the interface beneficial for charge transport which allows to reach high carrier mobility values. The MNR mobility

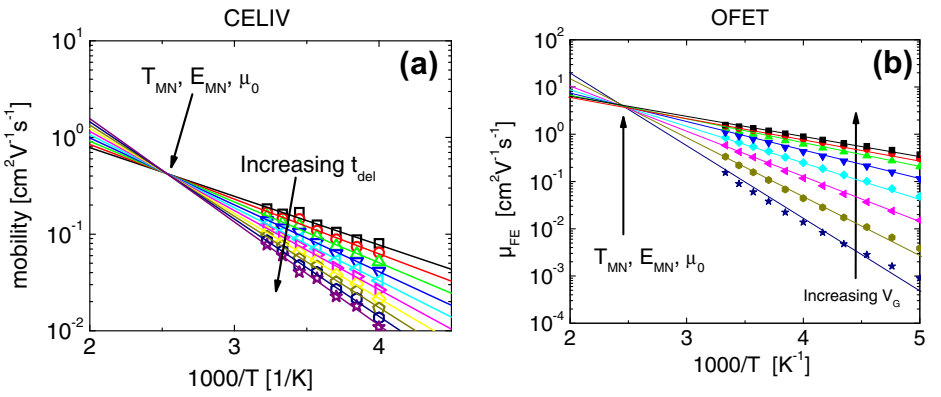

Fig. 7. Arrhenius plots of temperature dependent electron mobility at various concentrations measured from CELIV and OFET. Meyer-Neldel parameters from CELIV: T_{MN} = 406 K, E_{MN} = 35 meV, μ_{MN} = 0.4 $cm^2\,V^{-1}\,s^{-1}$; from OFET: T_{MN} = 408 K, E_{MN} = 35 meV, μ_{MN} = 4 $cm^2\,V^{-1}\,s^{-1}$.

prefactors (Eq. (2)) are μ_{MN} = 0.4 $cm^2\,V^{-1}\,s^{-1}$ from CELIV and μ_{MN} = 4 $cm^2\,V^{-1}\,s^{-1}$ from OFET. Obtained values are in good agreement with the results obtained in similar C_{60} devices in the past [10,24,42,43].

From Arrhenius plots the activation energies for electron transport are estimated from both CELIV and OFET measurements and plotted as a function of carrier concentration in Fig. 8a. Electric field at which concentration dependent carrier mobility was measured is different in both experiments. High voltage was used in CELIV to ensure the lowest error, whereas to satisfy linear regime conditions in OFET measurements, the smallest source-drain voltage was used. Despite a slight mismatch observed in Fig. 8a, the correct trend of activation energy is seen. At lower carrier concentrations larger activation energy is required for transport in disordered media.

We have estimated and plotted in Fig. 8b the mobility prefactor μ_0 as a function of activation energy using Eq. (1). Similar slopes show well matching MNR energies E_{MN} in both the bulk on the film and at the interface. The mobility prefactor μ_0 is order of magnitude higher in the OFET compared to transport in the bulk measured from CELIV, which well agrees with the difference in Meyer–Neldel mobility prefactor μ_{MN} as well as with difference in activation energies E_A.

A mismatch in μ_{MN}, μ_0 and E_A in diodes and OFETs can be caused by the nature of non-equilibrium measurements in CELIV compared to steady-state OFET measurements. Excess amount of energy available for photogenerated charge carriers might reduce the activation energy and be the reason for the observed mismatch. Further studies of concentration dependent activation energy at different electric fields is required in order to see the effect of electric field.

4. Conclusions

Carrier density and temperature dependent mobility is experimentally measured and compared in the bulk of the fullerene films and at the interface with insulator. Non-equilibrium mobility of photogenerated charge carriers measured using charge extraction by linearly increasing voltage (CELIV) technique as well as steady state mobility measured in organic field-effect transistors (OFET) is compared. Much higher electron mobilities (>100 times) as compared to hole mobilities are observed. Carrier concentration dependent electron mobility in both types of devices shows lower mobility values and stronger concentration dependence in diodes. Larger activation energy for electron transport is required at lower carrier

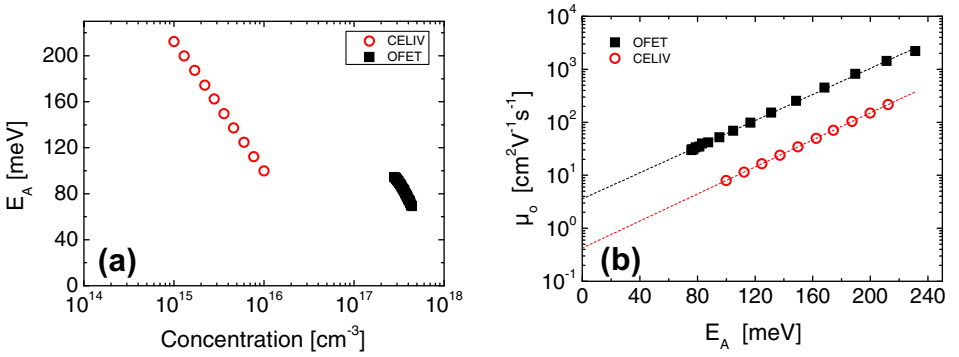

Fig. 8. (a) activation energy dependence on concentration. Electric field changes in the same range as specified in the caption of Fig. 6; (b) mobility prefactor μ_0 dependence on activation energy E_A shown for CELIV and OFET experiments.

concentrations. Arrhenius plots of temperature dependence of mobility at various concentrations demonstrate the presence of Meyer–Neldel rule (MNR). It is shown that MNR energy is the same in the bulk of the semiconductor and at the interface, suggesting similar levels of energetical disorder. Observed differences in charge transport in diodes and OFETs is proposed to be due to either different carrier concentrations or due to the nature of non-equilibrium charge carrier transport in CELIV compared to steady-state OFET measurements.

ABSTRACT

4,4′-*N*,*N*′-Dicarbazolylbiphenyl (CBP) has both the hole- and electron-transport ability, that is, bipolar charge-transport property, and has been widely used for organic light-emitting diodes (OLEDs). In this study, we explain the bipolar charge-transport property of CBP by quantum chemical calculations for the crystal. Both the reorganization energies and the charge transfer integrals were investigated, and charge-transfer rate constants were calculated based on Marcus theory. The hole- and electron-transfer rate constants thus calculated were found to be similar in magnitude. This is in sharp contrast with the case of a structurally similar but a poor electron-transport material, *N*,*N*′-diphenyl-*N*,*N*′-di(*m*-tolyl)benzidine (TPD), for which the hole-transfer rate constants were calculated to be much larger than the electron-transfer rate constants. From the detailed analysis of the charge transfer integrals for CBP, it was found that holes transfer through all the segments of the molecules, using the delocalized HOMO over the whole molecule as in the case of TPD. On the other hand, electrons transfer advantageously through the delocalized LUMO on the carbazole moieties of CBP, which have close intermolecular contacts. The LUMO of TPD localizes on the central biphenylene moiety, resulting in small electron transfer integrals. The results clearly show the difference of the electron-transport property between CBP and TPD.

1. Introduction

Organic light-emitting diodes (OLEDs) are promising devices for flat or flexible displays, and lighting equipments [1,2]. Fig. 1 shows widely known charge-transport materials for OLEDs, 4,4′-*N*,*N*′-dicarbazolylbiphenyl (CBP) [3–10] and *N*,*N*′-diphenyl-*N*,*N*′-di(*m*-tolyl)benzidine (TPD) [2,11–16]. The chemical structures of CBP and TPD are similar to each other, while the charge-transport properties are not. For CBP, both the hole and electron mobilities are on the order of 10^{-3} cm^2/Vs [7,8]. Conforming to the preceding studies [5,7–10], we should like to call CBP as a '*bipolar*' material on the basis of the comparable hole and electron mobilities. The latter, TPD, shows a similar hole-transport property with the mobility of $\sim 10^{-3}$ cm^2/Vs; however, the electron mobility is inferior, $<10^{-7}$ cm^2/Vs [14–16]. Understanding the origins of the different charge-transport properties between CBP and TPD is of importance not only for fundamental science but also for molecular designs with excellent performance.

Charge transports in organic materials have often been discussed based on Marcus theory [17,18], which describes the charge-transfer rate constant, k_{CT}, as Eq. (1).

$$k_{CT} = \frac{4\pi^2}{h} H_{AB}^2 \frac{1}{\sqrt{4\pi\lambda k_B T}} \exp\left(-\frac{\lambda}{4k_B T}\right) \quad (1)$$

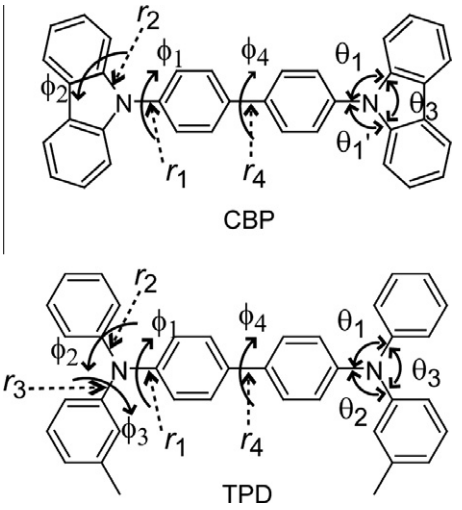

Fig. 1. The chemical structures of CBP and TPD. The θ, ϕ, and r represent bond angles, torsion angles, and bond lengths, respectively.

Here, λ is the reorganization energy, and H_{AB} is the charge transfer integral between the relevant two molecules. The temperature, T, is fixed at 300 K throughout this paper. The h and k_B are the Planck and Boltzmann constants, respectively. In some studies, for example, Refs. [19] and [20], reorganization energies were calculated to account for the charge-transport properties. The charge transfer integrals were assumed to be similar in these studies. The attempts were partly successful for the qualitative description of the charge-transport properties. However, it has been found that some experimental results cannot be explained by the simple consideration. For tris(8-hydroxyquinoline) aluminum(III) (Alq_3), for example, the difference between the hole- and electron-transport properties could not be explained by the consideration only of the reorganization energies. The charge transfer integrals were found to be a key factor [21].

Recently, we found that the hole transfer integrals in TPD crystals are several times larger than the electron transfer integrals [22]. The HOMO of TPD spreads over the molecule. Large intermolecular overlaps can be formed between the phenyl and/or tolyl rings, which have close intermolecular contacts in the crystals. In contrast, the LUMO of TPD is localized on the central biphenylene moiety, which results in small intermolecular overlaps (that is, small electron transfer integrals). Owing to both the small reorganization energies and the large charge transfer integrals for the hole transfers, the hole-transfer rate constants were calculated to be more than two orders of magnitude larger than the electron-transfer rate constants. In addition, there are effective hole-transport paths consisting of consecutive molecular pairs with large hole-transfer rate constants [22]. The results show the favorable hole-transport property of TPD.

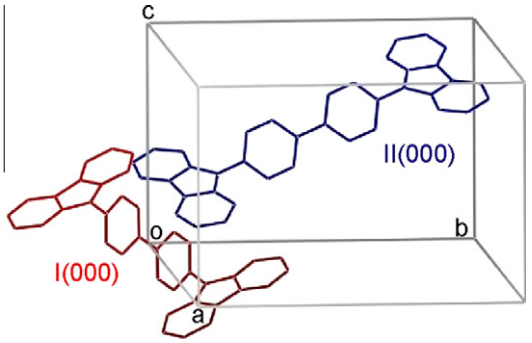

Fig. 2. The unit cell of CBP crystal and representations of molecules I and II. The cell parameters are as follows; a = 8.01 Å, b = 16.01 Å, c = 10.24 Å, $\alpha = \gamma = 90.0°$, and $\beta = 110.2°$.

On the other hand, the origins of the bipolar charge-transport property of CBP have been unclear, despite the practical importance as a host material of emitting layers in OLEDs. In this paper, we analyze the charge-transport property of CBP in the crystal as in the case of TPD. The reorganization energies and the charge transfer integrals are compared with those for TPD. The results explain the difference of charge-transport properties between CBP and TPD.

2. Computation

The structural optimizations were performed for neutral, cationic, and anionic CBP molecules by DFT method using the B3LYP functional [23–25] and the 6-31G(d) basis

Table 1
Structural parameters of a CBP molecule in the crystal, and those optimized by DFT method for the neutral, cationic, and anionic states. The parameters are defined in Fig. 1. As an initial structure for the optimizations, the crystalline structure was adopted. The parameters for the optimized TPD are also shown for comparison.

		Bond angle (°)			Torsion angle (°)				Bond length (Å)

[a] The values are taken from Ref. [26].

set. The molecular structure in Ref. [26] was adopted as an initial structure for the optimizations. Using the DFT-optimized structures, the reorganization energies were calculated, according to Ref. [22]. The packing structure of the CBP crystal was also taken from Ref. [26]. Fig. 2 shows the unit cell. For all the pairs of two molecules in the identical and the neighboring cells, the charge transfer integrals were calculated by extended Hückel method from Eq. (2) [22,27,28].

$$H_{AB} = \frac{\beta - \frac{\alpha_A + \alpha_B}{2} S}{1 - S^2} \tag{2}$$

Here, $\alpha_A = \langle \Phi_A | \mathbf{H} | \Phi_A \rangle$, $\alpha_B = \langle \Phi_B | \mathbf{H} | \Phi_B \rangle$, $\beta = \langle \Phi_A | \mathbf{H} | \Phi_B \rangle = \langle \Phi_B | \mathbf{H} | \Phi_A \rangle$, $S = \langle \Phi_A | \Phi_B \rangle = \langle \Phi_B | \Phi_A \rangle$, and $\mathbf{H}$ is the electronic Hamiltonian. Φ_A and Φ_B are the HOMOs of isolated molecules, A and B, respectively, for the evaluations of hole transfer integrals. Also, for the evaluations of electron transfer integrals, they are the LUMOs of isolated molecules, A and B, respectively. Because the charge-transfer rate constant is a function of H_{AB}^2, the charge-transport property can be discussed by the absolute values of H_{AB} values. Hereafter, the charge transfer integrals are shown by the absolute values for simplicity. All of the quantum chemical calculations were performed by Gaussian 03 program [29] without the constraint of symmetry.

3. Results and discussion

3.1. Molecular structure and reorganization energy

The structural parameters of the crystalline CBP (Fig. 2) are shown in Table 1. Note that the parameters for the two molecules in Fig. 2 are equivalent with each other. The features are as follows. (1) The summation of the three ∠CNC

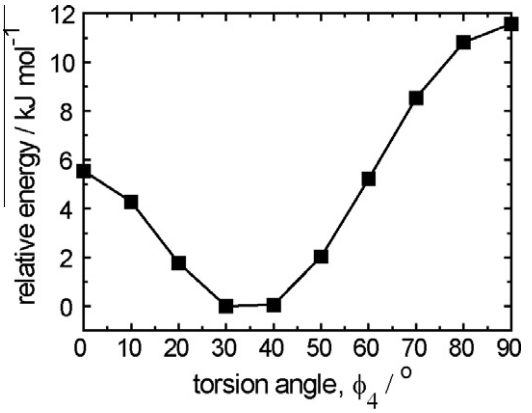

Fig. 3. The torsion angle ϕ_4 dependence of the SCF energy of a CBP molecule. The calculations were carried out with the interval of 10° and the energies are represented as relative values against the minimum energy, -3.93×10^6 kJ mol^{-1} ($\phi_4 = 30°$). The other structural parameters are fixed to the optimized values shown in Table 1. The calculations were performed by B3LYP/6-31G(d) level.

Table 2
The ratio of the maximum hole- and electron-transport rate constants, k_{CT}^+/k_{CT}^-, of CBP and TPD, based on Marcus theory.

	Calculation method for reorganization energy	k_{CT}^+/k_{CT}^{-a}	k_{CT}^+/k_{CT}^{-b}
CBP	Extended Hückel	3.3	1.7
	DFT	1.7×10	9.2
TPD	Extended Hückel	2.0×10	1.4×10^2
	DFT	2.7×10	1.9×10^2

[a] The ratios are obtained under the assumption that the hole and electron transfer integrals are equal.
[b] The ratios are obtained by considering both the reorganization energies and transfer integrals.

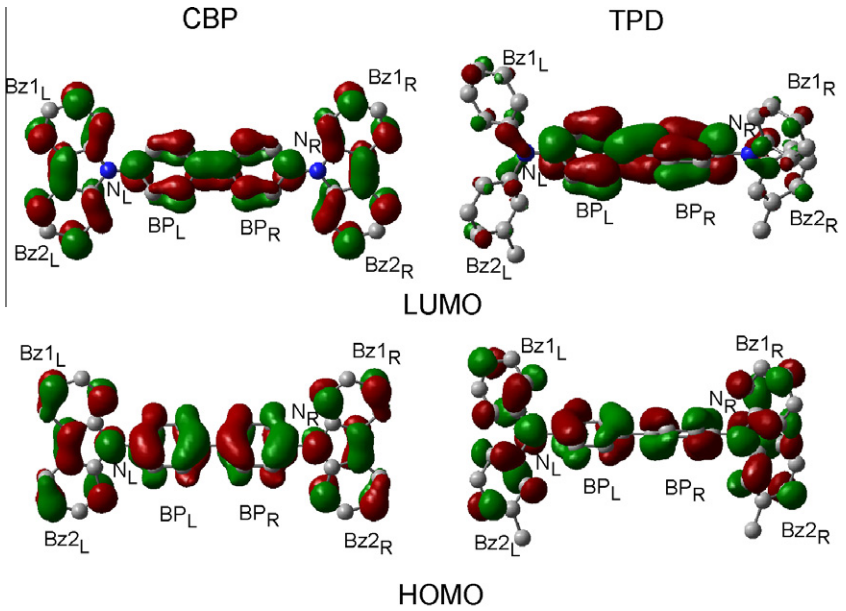

Fig. 4. The HOMO and LUMO of CBP calculated by extended Hückel method for the crystalline conformation. Those of TPD are also shown for comparison. The value for the surfaces is 0.02 a.u.

Table 3
Contributions of the nitrogen (N), biphenylene (BP), and the benzene rings in the carbazole moieties (Bz1, Bz2) of CBP to the HOMO and LUMO. The subscript of "L" or "R" indicates the left or right side of the molecule in Fig. 4. The values for TPD are also shown for comparison.

		N_L	N_R	BP_L	BP_R	$Bz1_L$	$Bz2_L$	$Bz1_R$	$Bz2_R$
CBP	HOMO	11	11	20	20	9	9	9	9
	LUMO	0	0	17	17	17	17	17	17
TPD	HOMO	15	15	18	18	9[a]	9[b]	9[a]	9[b]
	LUMO	1	1	43	43	4[a]	3[b]	4[a]	3[b]

[a] The values are for the phenyl group of TPD.
[b] The values are for the tolyl group of TPD.

bond angles around the nitrogen atom, $2\theta_1 + \theta_3$ (see Fig. 1), is almost 360°, meaning that the nitrogen atom and the three carbon atoms bonded to the nitrogen atom are in the same plane. This is similar to those for other triphenylamine compounds, including TPD. (2) The torsion angle of the central C–C bond in the biphenylene moiety, ϕ_4, is 0°, indicating that the biphenylene moiety has a planar structure in the CBP crystal. This feature is different from that for the TPD crystal, ϕ_4 = 34–37° [30,31]. The difference is considered to originate from a molecular packing effect, as discussed below.

Table 1 also shows the results of the structure optimizations by DFT method for CBP in the neutral, cationic, and anionic states. It must be noted that all of the CBP structures in Table 1 provide imaginary frequencies for a rotational fluctuation around the torsion angle, ϕ_4. Fig. 3 shows the torsion angle ϕ_4 dependence of the self-consistent field (SCF) energy for the optimized structure in the neutral state. The energetic minimum corresponds to ϕ_4 = 30–40°, not 0°. This indicates that the above optimized structure corresponds to a saddle point of the potential. The energetic difference from the potential minimum is about 6 kJ/mol. This result shows that the crystalline structure of CBP is different from the most stable conformation for an isolated molecule, probably due to the intermolecular packing effects in the crystal. In this study, we adopt the optimized structures in Table 1 to estimate the reorganization energies for the crystalline structure.

For the cationic and anionic structures, the torsion angles, ϕ_2 and ϕ_4, are almost comparable with those in the neutral structure. In contrast, the torsion angle ϕ_1 and bond length r_4 are different between the neutral and charged states. Based on these DFT-optimized structures, the reorganization energies were calculated by extended Hückel and DFT methods. The reorganization energies

Table 4
Molecular pairs in the CBP crystal. Pairs between a molecule in the cell (0 0 0) and another molecule in cells (a b c) (a, b, c = −1, 0, 1) are considered. They are classified into 25 types of relative geometries, A–Y. The geometrical types of A, B, and C are shown in boldface.

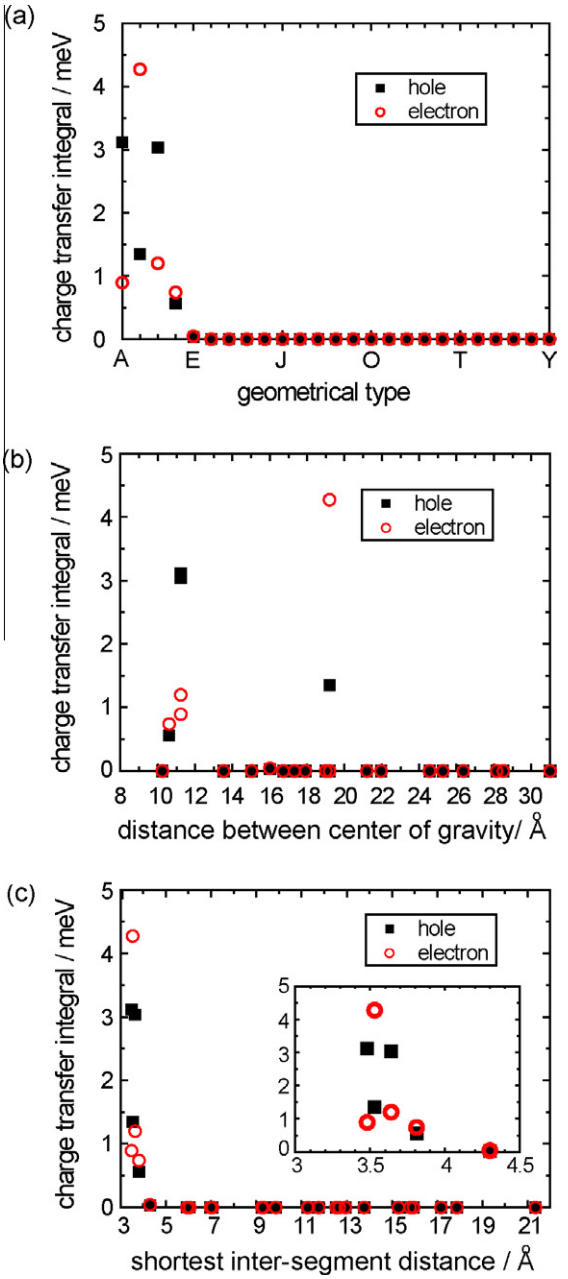

Fig. 5. The hole (filled square) and electron (open circle) transfer integrals for the geometrical types of A–Y in the CBP crystal. The values are shown (a) in order of A–Y, (b) as a function of intermolecular distance between the center of gravity of relevant two molecules, and (c) as a function of shortest inter-segment distance. The inset in (c) shows a expanded figure in the range of 3–4.5 Å.

obtained by extended Hückel method are 0.10 and 0.19 eV for hole and electron transfers, respectively. The value for electron transfer of CBP is found to be small, compared with the values for the electron transfer of TPD (0.15 and 0.40 eV for hole and electron transfers, respectively [22]).

The ratios of hole- and electron-transfer rate constants are summarized in Table 2. Assuming that the hole and electron transfer integrals are equivalent, the ratio of hole- and electron-transfer rate constants for CBP is calculated to be 3.3 from Eq. (1). A better electron-transport property is expected for CBP by comparing the ratio of 20 for TPD [22]. For TPD, the reorganization energies calculated by extended Hückel and DFT methods led the comparable values for the ratio of hole- and electron-transfer rate constants, under the assusmption that hole- and electron transfer integrals are the same (see Table 2 and Ref. [22]). This is not the case for CBP; the ratio of hole- and electron-transfer rate constants calculated by DFT method is larger than that calculated by extended Hückel method. Nevertheless, if both the reorganization energy and charge transfer integral are taken into account, the ratios of hole- and electron-transfer rate constants calculated by extended Hückel and DFT methods are in the same order of magnitude as shown in Table 2. For the following calculations, we use the reorganization energies by extended Hückel method, which has been accepted in Ref. [22].

3.2. Frontier orbital

Fig. 4 illustrates the HOMO and LUMO calculated by extended Hückel method for CBP. The HOMO and LUMO of TPD are also shown for comparison (HOMO−1 and LUMO+1 are shown in Fig. S1 with the orbital energies in the supplementary data). Table 3 summarizes, in percentage, the squares of the MO coefficients of respective segments of CBP, nitrogen (N), biphenylene (BP), and the two benzene rings in the carbazole moiety (Bz1 and Bz2). The subscripts of "L" and "R" mean left and right sides of the molecule, respectively (see Fig. 4). For the HOMO, all the contributions are from 9 to 20%, meaning that the MO is relatively delocalized over the molecule. Among them, the contributions from the biphenylene moieties are the largest (20% each for BP_L and BP_R), as in the case of TPD (see also Table 3). For the LUMO, contributions of the biphenylene moieties of CBP (17% each for BP_L and BP_R) are much smaller than those for TPD (43% each for BP_L and BP_R). Instead, contributions of the carbazole moieties of CBP (17% each for $Bz1_R$, $Bz1_L$, $Bz2_R$, and $Bz2_L$) are large, compared with the LUMO of TPD (3–4% each for $Bz1_R$, $Bz1_L$, $Bz2_R$, and $Bz2_L$). Fig. 4 clearly shows the difference between the LUMO of CBP and that of TPD, which is a critical point for electron transports as discussed later.

3.3. Molecular pair

As shown in Fig. 2, the unit cell of the CBP crystal contains two molecules. We refer to these molecules as I and II, respectively. The center of gravity of I locates on the origin of the cell, and that of II does on the center of the b-c plane. Defining that the cell in Fig. 2 as cell (0 0 0), neighboring cells at the +a, −a, +b, −b, +c, and −c directions are represented as (1 0 0), (−1 0 0), (0 1 0), (0 −1 0), (0 0 1), and (0 0 −1), respectively. Hereafter, a molecule X (X = I or II) in the cell (a b c) (a, b, c = −1, 0, or 1) is referred to as X(abc) as defined in our preceding paper [22]. For example, I(0 0 0) denotes molecule I in the cell (0 0 0).

Charge transfer integrals were investigated for all the molecular pairs between a molecule in the cell (0 0 0)

and that in a cell (a b c) (a, b, c = −1, 0, or 1). The 105 pairs are listed in Table 4. Depending on the relative geometries, the pairs can be classified into 25 independent types, as indicated by geometrical types of A–Y in Table 4. For these 25 types of pairs, the charge transfer integrals were calculated, according to Eq. (2).

3.4. Hole transfer integral

The hole transfer integrals for the geometrical types of A–Y are shown in Fig. 5a. The types of A, B, and C have large values, 3.1, 1.4, 3.0 meV, respectively. The value for the type of D is 0.6 meV, and the values for the other types are less than 0.1 meV. In Fig. 5b, the hole transfer integrals are shown as a function of intermolecular distance between the center of gravity of each molecule. Also, in Fig. 5c, they are presented as a function of the shortest inter-segment distance. Here, we refer to the shortest internuclear distance between the relevant two molecules as the shortest inter-segment distance. Only the distances between carbon and/or nitrogen atoms are considered (hydrogen atoms are neglected), because hydrogen atoms hardly contribute to the frontier orbitals. It is found from these figures that the hole transfer integral strongly depends on the shortest inter-segment distance rather than the distance between the center of gravity.

Since the charge transfer integral in Eq. (2) is found to be almost proportional to β (this relation holds because $1 \gg S^2$ and $\beta \cong 1.75S(\alpha_A + \alpha_B)/2$ [32,33], as shown in Ref. [22]), the contribution of respective segments, N, BP, Bz1, and Bz2, to the charge transport integral can be investigated by separating the β value for the respective segments. The β values separated for the respective segments are called "segmental β values" as defined in Ref. [22]. The segmental β values are useful to understand which segments dominantly contribute to charge transfer integrals. Tables 5–7 show the segmental β values for the representative molecular pairs of the geometrical types of A, B, and C, respectively. The pairs are I(0 0 0)–II(0 0 0) (type A), I(0 0 0)–I(1−11) (type B), and I(0 0 0)–II(1 0 0) (type C) (see Fig. 6). The shortest inter-segment distances are also shown in the tables. Regarding I(0 0 0)–II(0 0 0), the geometrical type of A (Table 5), the following interaction are dominant for the total β value of −6.5 meV; $Bz1_R$–$Bz1_L$ (−7.9 meV), BP_R–N_L (−4.9 meV), and BP_R–$Bz2_L$ (−4.4 meV) (the left and right sides correspond to the segments in I(0 0 0) and II(0 0 0), respectively). All the types of the segments, N, BP, and Bz, contribute to the above interactions. The shortest inter-segment distance is a crucial factor for charge transfers; the distances for the above three segmental pairs are less than 3.8 Å, whereas the segmental β values are 0.0 meV when the distance is longer than 5.1 Å. For I(0 0 0)–I(1 −1 1), the geometrical type of B (Table 6), the segmental interaction between $Bz1_R$–$Bz2_L$ (−1.9 meV) is dominant for the total β value of −3.1 eV. This segmental interaction is smaller than the significant interactions for the types A and C in spite that the shortest inter-segment distance is as short as 3.5 Å. This suggests that the relative orientation of the relevant two molecules also affects the segmental β value as well as the

inter-segment distance. Lastly, the total β value is 7.0 meV for I(0 0 0)–II(1 0 0), the geometrical type of C (Table 7). The most significant interaction is obtained for the segmental pair of BP_R–$Bz1_L$; the segmental β value is 6.4 meV and the shortest inter-segment distance is 3.6 Å. Considering the geometrical types of A–C, holes are favorably transported through any of the segments, N, BP, and Bz.

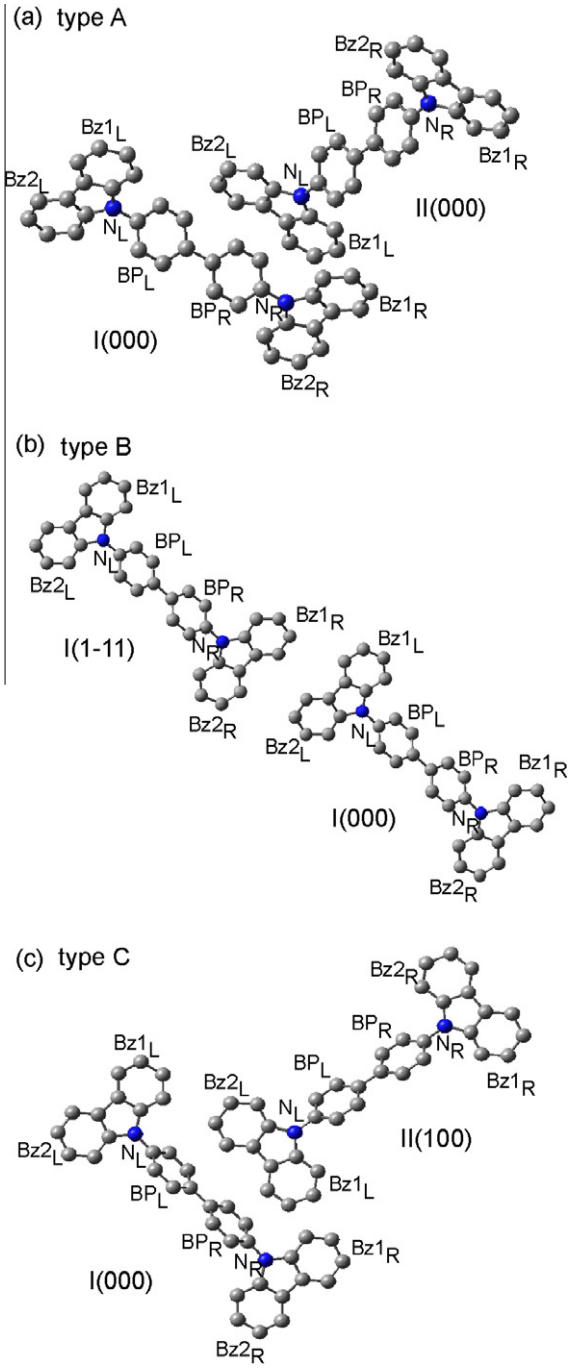

Fig. 6. Representations of the molecular pairs, (a) I(0 0 0)–II(0 0 0), (b) I(0 0 0)–I(1 −1 1), and (c) I(0 0 0)–II(1 0 0). The types of their relative geometries are A, B, and C, respectively.

3.5. Electron transfer integral

Fig. 5a also shows the electron transfer integrals for the geometrical types of A–Y. The geometrical type of B provides the largest value of the electron transfer integral, 4.3 meV. The values for the types of A, C, and D are 0.9, 1.2, and 0.7 meV, respectively. For the others, the values are less than 0.1 meV. In Fig. 5b and c, the electron transfer integrals are also shown as a function of the intermolecular distance between the center of gravity and the shortest inter-segment distance, respectively. As in the case of the hole transfer integral, the electron transfer integral strongly depends on the shortest inter-segment distance rather than the distance between the center of gravity.

The segmental β values of the electron transfer integrals for the geometrical types of A–C are also shown in Tables 5–7, respectively. For the pair of I(0 0 0)–II(0 0 0), the geometrical type of A (Table 5), the β value for $Bz1_R$–$Bz1_L$ with the shortest inter-segment distance of 3.5 Å is dominant, 4.2 meV. This indicates that the LUMO on the carbazole moieties, which have close intermolecular contacts, is advantageous for the large segmental β value. For I(0 0 0)–I(1 −1 1), the geometrical type of B (Table 6), the interaction between $Bz2_L$–$Bz1_R$ is significant, 5.9 meV, also indicating the importance of the carbazole moieties for electron transfers. For I(0 0 0)–II(1 0 0), the geometrical type of C (Table 7), the magnitudes of all the segmental β values are less than 0.8 meV, although the interaction between $Bz2_L$–BP_R is the largest. Considering the geometrical types of A–C, electrons are favorably transported through the carbazole moieties. The LUMO which spreads over the molecule, including the carbazole segments, would be an origin of the different electron-transport property between CBP and TPD. For TPD, the LUMO is localized on the central biphenylene moiety, which is unfavorable for providing large segmental β values.

Fig. 6 shows that only the carbazole moieties are in close intermolecular contact for the geometry of type B. However, this geometry provides the largest electron transfer integral, as shown in Fig. 5a. This result indicates that large transfer integrals can be obtained even if not all the segments are in close intermolecular contacts; only a partial contact is often enough.

3.6. Rate constant and paths for charge transfer

Fig. 7 shows the hole and electron-transfer rate constants for the geometrical types of A–H at 300 K, using the above reorganization energies and charge transfer integrals. For the other geometrical types, I–Y, the values are less than $10^1\ s^{-1}$. The hole-transfer rate constants for the types of A, B, and C are 2.0×10^{11}, 3.7×10^{10}, and $1.9 \times 10^{11}\ s^{-1}$, respectively. The value for the type of D is $6.4 \times 10^9\ s^{-1}$, and those for the rest types are less than $2.1 \times 10^7\ s^{-1}$. On the electron-transfer rate constants, large values are obtained for the types of A, B, and C; 4.8×10^9, 1.1×10^{11}, and $8.6 \times 10^9\ s^{-1}$, respectively. The value for the type D is $3.3 \times 10^8\ s^{-1}$, and those for the rest types are less than $1.2 \times 10^7\ s^{-1}$. The ratio of the maximum hole- and electron-transfer rate constants is 1.7. Compared with the orthorhombic crystal of TPD, for which the ratio is

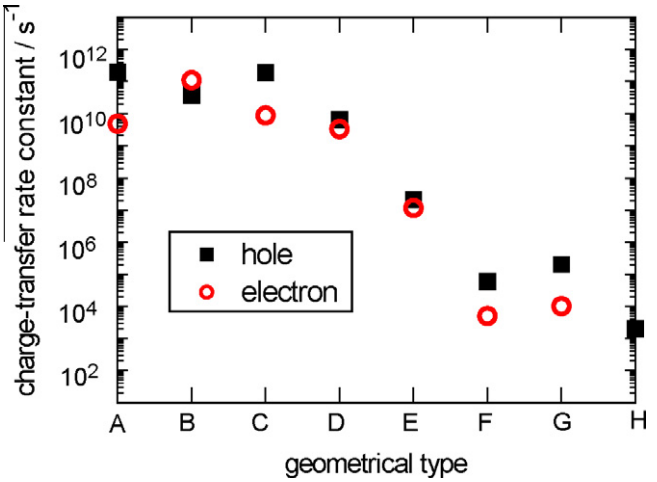

Fig. 7. The hole- (filled square) and electron-(open circle) transfer rate constants, k_{CT}, at 300 K calculated using the transfer integrals in Fig. 5. The rate constants smaller than 10^1 s^{-1} are not shown.

1.4×10^2, the bipolar charge-transport property of CBP is clearly presented.

In the TPD crystals, there are effective paths for the hole transport [22]. The paths consist of successive molecular pairs with large hole-transfer rate constants. Here, we investigate paths for the hole and electron transports in the CBP crystal. The molecular pairs of the geometrical types of A, B, and C, which are the most advantageous for both the hole and electron transports, are considered. As shown in Table 4, there are seven molecular pairs for the geometrical type of A. The pairs are illustrated in Fig. 8a. Through the pairs, both holes and electrons can be effectively transported in the b–c plane. In other words, effective percolation paths for charge transports are formed in the plane. For the geometrical type of B, four molecular pairs exist (see Table 4), which are presented in Fig. 8b. Through the periodic pairs of I(0 0 0)–I(1 −1 1) and I(0 0 0)–I(−1 1 −1), both holes and electrons are favorably transported along the [1 $\bar{1}$ 1] direction of the crystal. Also, they can be transported along the [1 1 1] direction by the periodic pairs of II(0 0 0)–II(1 1 1) and II(0 0 0)–I(−1 −1 −1). For the geometrical type of C, there are eight molecular pairs (see Table 4). The pairs are shown in Fig. 8c and d. The periodic pairs of I(0 0 0)–II(1 0 0)

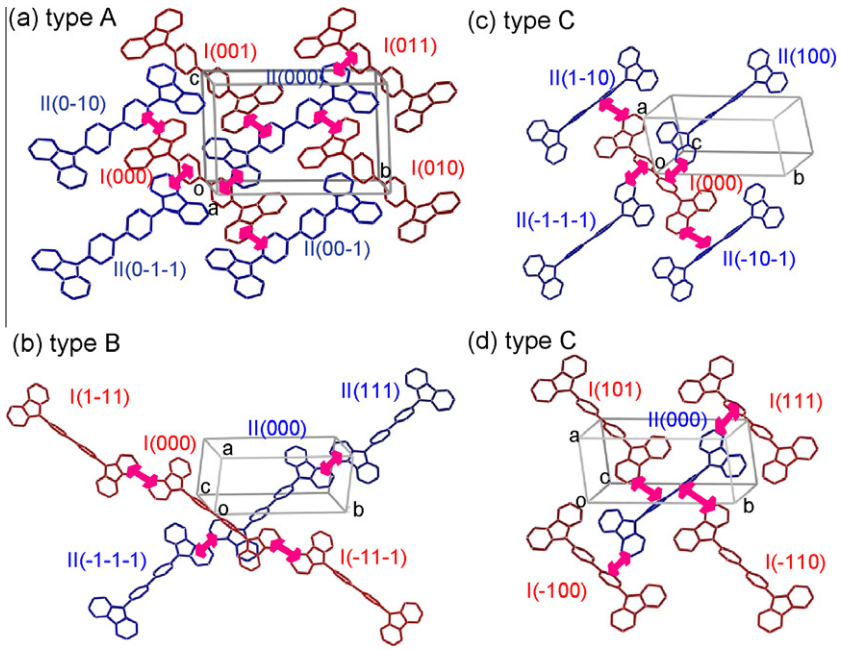

Fig. 8. Representations of percolation paths for both the hole and electron transports. The paths consist of the molecular pairs with large charge-transfer rate constants in the geometrical types of (a) A, (b) B, and (c, d) C.

and I(0 0 0)–II(−1 −1 −1), or II(0 0 0)–I(1 1 1) and II(0 0 0)–I(−1 0 0) can transport both holes and electrons along the [1 2 2] direction of the crystal. In addition, charges can be effectively transported along the [1 $\bar{2}$ 2] direction through the periodic pairs of I(0 0 0)–II(1 −1 0) and I(0 0 0)–II(−1 0 −1), or II(0 0 0)–I(1 0 1) and II(0 0 0)–I(−1 1 0). From the above discussion, effective paths exist for both the hole and electron transports in CBP, confirming the bipolar charge-transport property of CBP.

4. Conclusion

We have investigated the charge-transport property of CBP, based on Marcus theory. By investigating both the reorganization energies and charge transfer integrals, the hole- and electron-transfer rate constants were calculated to be similar in magnitude. In addition, effective paths for both the hole and electron transports exist in the CBP crystal, showing the bipolar charge-transport property of CBP. Through the delocalized HOMO over the CBP molecule, holes are conveyed via all the segments of molecules. In contrast, electrons favorably transfer through the carbazole moieties. This is in sharp contrast with TPD; the LUMO is localized on the central biphenylene moiety, which results in small electron transfer integrals.

ABSTRACT

The air- and encapsulation-induced degradations of poly(3-hexylthiophene) (P3HT) organic thin-film transistors (OTFTs) encapsulated with solution-processed polymer films were systematically analyzed to realize air-stable devices. By studying the potential degradation-inducing factors from air–O_2, moisture, N_2, and light, we determined that device degradations could be eliminated by isolating the devices from two of the factors: moisture and light. In terms of encapsulation-induced degradations, we examined 10 types of encapsulating polymers and found that such degradations could be avoided with polymers containing low-polarity function groups, including poly(vinyl methyl ketone), poly(methyl vinyl ether), poly(methyl methacrylate), and polystyrene. Based upon the identified sources of degradations, we demonstrated an encapsulation approach that involved (1) using a low-polarity encapsulating polymer layer to serve as a moisture barrier and to avoid encapsulation-induced degradation, and (2) applying a light-blocking agent. The resultant OTFTs showed no encapsulation-induced degradation while maintaining stable device characteristics for >5500 h of storage in the ambient air.

1. Introduction

Organic thin-film transistors (OTFT) offer many advantages such as processability and mechanical flexibility over inorganic technologies [1–3] and have been developed for use in a wide range of applications including displays [4,5], sensors [6,7], and radio frequency identification [8,9]. Through the intensive research efforts of recent years, reasonably high device performance as well as manufacture-enabling processing techniques have been demonstrated for OTFTs [10,11]. Among the studied organic semiconductors, poly(3-hexylthiophene) (P3HT) is one of the more promising materials because of its solution processability, high charge carrier mobility, and commercial availability [4]. However, the practical application of P3HT-based OTFTs has been hindered by the susceptibility of P3HT to environment-induced degradations [12,13]. Such problem of poor stability is shared by many other types of organic semiconductors as well [14,15]. Therefore, an effective passivation or encapsulation method is paramount to the development of the OTFT technology. Previous research on the encapsulation of P3HT OTFTs has relied on the use of vapor-deposited films, taking advantages of the good gas-barrier performance of such films and the low contamination level of the vapor-deposition process [16], the latter of which is necessary to minimize encapsulation-induced degradations because of P3HT's high sensitivity to environmental factors. Despite the satisfactory results reported with such approaches, practical application of OTFTs calls for solution-processed encapsulation methods to reduce the cost and complexity of the encapsulation process as well as to improve the compatibility of the encapsulation process with the preceding and subsequent device fabrication processes. Solution-processed encapsulation method that can prevent both encapsulation- and air-induced degradations has not been reported for P3HT OTFTs.

In this work, we develop solution-processed encapsulation for P3HT OTFTs to achieve air-stable devices while avoiding encapsulation-induced degradations. We determine the sources of air-induced degradations by systematically studying the potential degradation-inducing factors including O_2, moisture, N_2, and light. To eliminate encapsulation-induced degradations, we investigate 10 types of encapsulating polymers as well as their solvents. Based on the obtained knowledge about the sources of degradations, we devise and demonstrate a solution-processed encapsulation method for P3HT OTFTs.

2. Materials and methods

P3HT (molecular weight 87K, region-regularity ratio = 98.5%) was purchased from Sigma–Aldrich co., and used as received. The substrates were heavily p-type doped silicon wafers with a 200 nm thermal oxide layer on the surface as the dielectric layer. The devices were of the bottom gate/bottom contact structure with 100 μm/1500 μm channel length/width (L/W). The device fabrication procedure was as follows: (1) a 100 nm gold layer was thermally evaporated onto the substrates as the bottom contact; (2) the gold layer was patterned with photolithography into the source and drain electrodes; (3) the substrate surface was treated with octadecyltrichlorosilane (OTS), which forms a self-assembled monolayer (SAM) on the SiO_2 dielectric layer [17]; (4) a 50 nm P3HT was spin-coated from a 1 wt.% P3HT solution in dichlorobenzene at 800 rpm for 30 s, followed by a 30 min bake at 130 °C. The I–V characteristics of the OTFTs were measured with a Keithley 4200-SCS Semiconductor Characterization System. Air-induced degradations of the OTFTs were studied by exposing the devices to pure N_2, O_2, or moisture at room temperature in a vacuum chamber equipped with a viewport, through which the devices could be illuminated with a 150 W halogen lamp. The device characteristics were measured in situ. The applied pressures were 760 torr for N_2, 760 torr for O_2, and 11 torr for H_2O. For encapsulation tests, an encapsulating polymer film was spin-coated onto the devices from a 15 wt.% polymer solution at 3000 rpm for 3 min, followed by a bake at 130 °C for 30 min. Ten encapsulating polymers were tested, including poly(vinyl methyl ketone) (PVMK) (solvent: methyl ethyl ketone), poly(methyl vinyl ether) (PMVE) (water), poly(methyl methacrylate) (PMMA) (methyl ethyl ketone), polystyrene (PS) (methyl ethyl ketone), poly(vinylidene chloride-co-vinyl chloride) (PVDC-co-PVC) (dimethyl sulfoxide), poly(vinyl chloride) (PVC) (dimethyl sulfoxide), poly(vinylidene fluoride) (PVDF) (dimethyl sulfoxide), polyacrylonitride (PAN) (dimethyl sulfoxide), poly(vinyl alcohol) (PVA) (water), poly(vinyl phenol) (PVP) (propylene glycol monomethyl ether acetate). The thickness of the encapsulating polymer films was 1–3 μm. The optimized encapsulation method used a PS film spin-coated with Sudan black B dye (Sigma–Aldrich co.). All device fabrication and encapsulation steps were performed in nitrogen-filled glove box except for the PVA and PMVE encapsulation steps, which were performed in air.

3. Results and discussion

3.1. Air-induced degradations

The device characteristics of the as-fabricated P3HT OTFTs were as follows: field-effect mobility = 0.008 cm^2/V, threshold voltage (V_{th}) = 20 V, on/off ratio = 4×10^4. Upon exposure to air at room temperature, the devices showed significant degradations (Fig. 1), as was consistent with previously reported results [12,13]. To investigate the sources of the degradations, the potential degradation-inducing factors from air—O_2, moisture, N_2, and light—were separately applied to the devices while the device characteristics were monitored. The findings were as follows: (1) in N_2, the devices did not noticeably degrade irrespective of the presence of light (see Supplementary materials); (2) in moisture, the devices degraded severely and rapidly (within 100 min) irrespective of the presence of light: the on current decreased, the off current increased and the V_{th} shifted to a more positive value (Fig. 2); notably, the degradations were fully recoverable upon thorough removal of moisture by evacuation, where the I–V curve became nearly identical to the pristine curve; (3) In

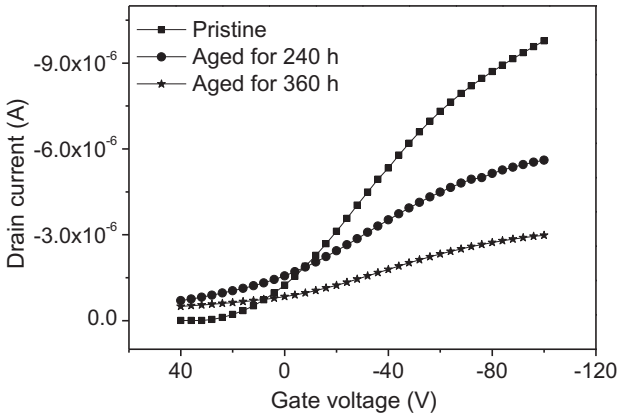

Fig. 1. IV characteristics of OTFTs before and after aging in air at room temperature.

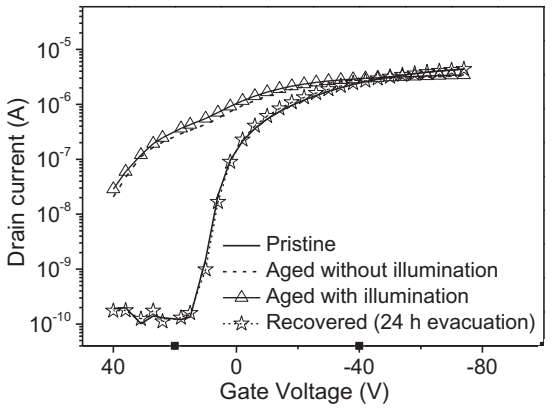

Fig. 2. Transfer characteristics of OTFTs before and after aging in moisture for 100 min with or without illumination. The source-to-drain bias was 60 V.

O_2 with illumination, upon 24 h of aging, the devices showed similar degradations to those caused by moisture (Fig. 3a), of which only the off current and the V_{th} could be recovered upon the removal of O_2 by heating in vacuum; but in the absence of light, the devices did not noticeably degrade for 500 h (Fig. 3b).

The moisture-induced degradations may be attributed to two mechanisms: (1) p-type doping, due to the polar interactions between P3HT and the hydroxyl group of H_2O, which upon the application of an external electric field (from the source/drain electrodes or the gate) induced holes in P3HT, thereby raising the off and on currents and shifting V_{th} to a more positive value [13,18]; (2) charge trapping, by the H_2O molecules absorbed in P3HT or adsorbed on the hydrophilic surface of the gate dielectric, which suppressed the charge mobility and therefore reduced the on current [15,19]. These mechanisms were consistent with the fact that the degradations were fully recoverable upon the removal of the applied moisture, as they involved only intermolecular forces and no chemical bonding. As for the O_2-induced degradations, the increased off current and positively-shifted V_{th} were also attributable to p-type doping, which is known to occur via O_2's complexing with organic semiconductors [20,21]. However, our observation that the degradations required light illumination revealed that such complexing for P3HT involved photo-excited states of P3HT and/or O_2. Importantly, such complexing was found to be reversible when the devices were evacuated for 24 h, upon which the off current and V_{th} returned to the original values (Fig. 3a). The reduced on current and charge mobility with illumination, which was not recoverable, was attributable to photo-oxidation of P3HT [12] (also see analyses in Supplementary materials).

3.2. Encapsulation-induced degradation

The encapsulating polymers, which directly contacted the P3HT layer in the OTFTs, were found to cause varying degrees of device degradation depending upon their functional groups, as shown in Figs. 4 and 5. It should be noted that the effects of the solvents used in casting the encapsulating films were verified to be negligible, provided that the encapsulating films were completely dried (see Supplementary materials). Of the 10 polymers tested, PVMK, PMVE, PMMA, and PS did not cause observable degradation, while the other six polymers—PVA, PVP, PAN, PVC, PVDC-co-PVC, and PVDF—induced strong p-type doping, i.e., increased off current (by 2–4 orders of magnitude), increased on current (by 2–7 folds), and reduced on/off ratio (by ~3 orders of magnitude). In other words, the P3HT layer encapsulated with the six doping-inducing polymers essentially became conductive, with conductivity rising from the pristine value of 1.1×10^{-5} S/cm to up to 1.6 S/cm. The strong p-type doping by the six polymers was attributable to their electron-withdrawing functional groups: –OH for PVA and PVP, –C≡N for PAN, and halogens for PVC, PVDC-co-PVC, and PVDF. The –OH, –C≡N, and halogen groups tend to induce holes in thiophene-based semiconductors through strong polar interaction aided by an external electric field [13,18,22–24]. A few trends were also observable from comparing the different degrees of p-doping effect induced by polymers with similar

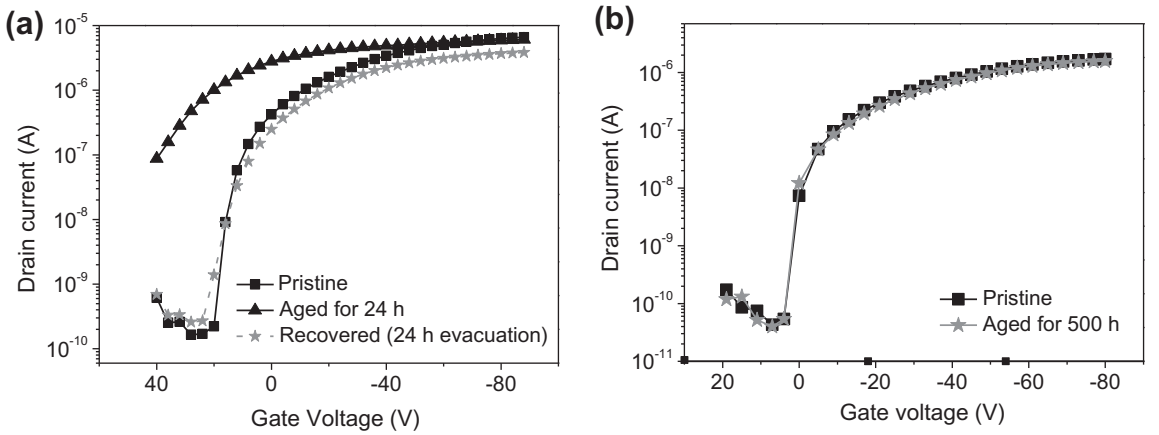

Fig. 3. Transfer characteristics of OTFTs before and after aging in O_2: (a) with illumination, and (b) without illumination. The source-to-drain bias was 60 V.

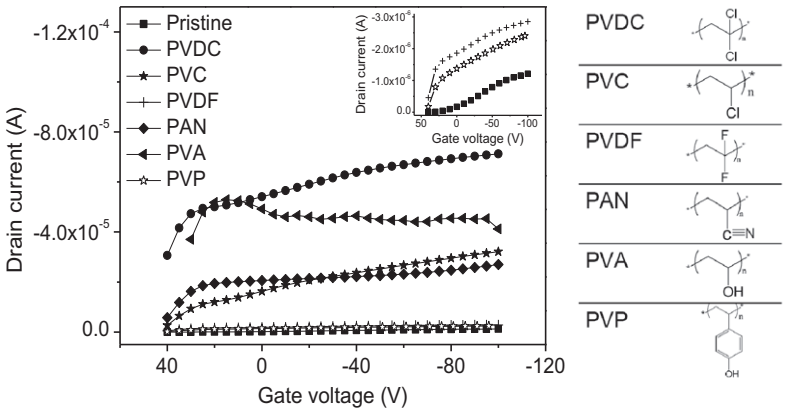

Fig. 4. Transfer characteristics of OTFTs before and after being encapsulated with 6 of the 10 encapsulating polymers tested. Inset shows the device characteristics with PVDF and PVP in smaller drain current range. The chemical structures of the polymers are also provided. The source-to-drain bias was 60 V.

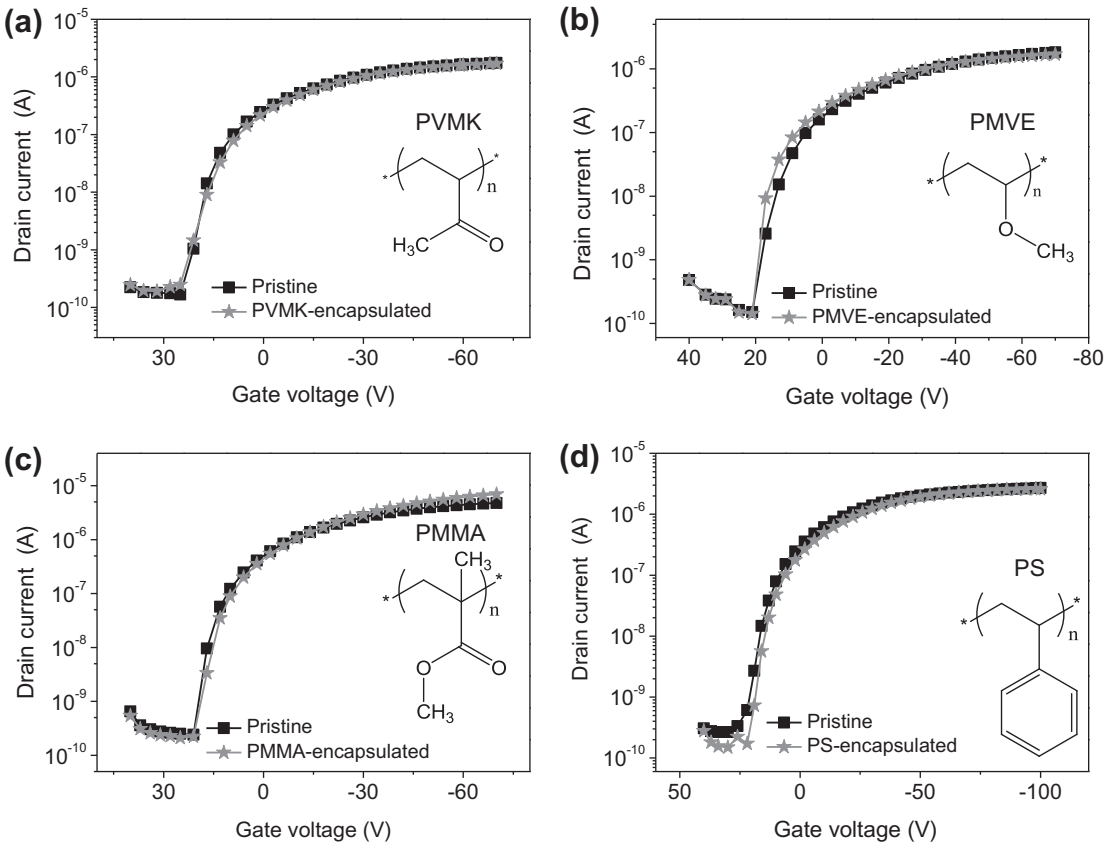

Fig. 5. Transfer characteristics of OTFTs before and after being encapsulated with (a) PVMK, (b) PMVE, (c) PMMA, and (d) PS. Insets show the chemical structures of the polymers. The source-to-drain bias was 60 V.

functional groups: (1) PVDC-co-PVC ≫ PVC, which was attributable to the greater number of Cl atoms on PVDC (two per repeating unit) than on PVC (one per repeating unit); (2) PVDC-co-PVC ≫ PVDF, which was due to the stronger dipole moment of the C–Cl bond than C–F, which would correspond to stronger polar interaction with P3HT [25]; (3) PVA ≫ PVP, which was attributable to PVP's greater steric hindrance (by the phenyl ring) against the –OH/P3HT interactions.

The observation that PVMK, PMVE, PMMA, and PS did not cause device degradation indicated that the functional groups on these polymers were not inducing charge-

displacing interactions with P3HT. This was attributable to the lack of electron-withdrawing group on PS and PMVE. On PVMK and PMMA, although there were the electron-withdrawing carbonyl groups, the absence of degradation suggested that the interactions between P3HT and the carbonyl groups may have been hindered by the alkyl groups adjacent to the carbonyl groups.

One interesting observation about the doping-inducing polymers was that, although the polymers' interactions with the P3HT film were limited to the polymer/P3HT interface with possibly a small intermixing region, their p-doping effects far exceeded those observed with moisture (Section 3.1), which could affect the bulk of the P3HT film upon absorption. The more pronounced effects of the polymers may be accounted for by the following mechanism. In the case of moisture, the high polarity (required for p-doping) of H_2O would limit its uptake in the low-polarity P3HT film, which in turn would limit the extent of doping. In the case the polymers, on the other hand, the connectivity of the polymer chains could bring a large number of the polar side groups into contact with the P3HT layer, thereby forming a heavily doped interfacial/intermixing layer, which could serve as a conduction path between the source and the drain electrodes.

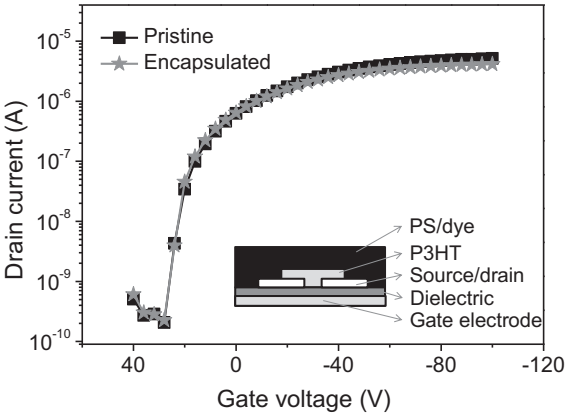

Fig. 6. Transfer characteristics of OTFTs before and after being encapsulated with the PS/dye approach. Inset shows a schematic drawing of the encapsulation approach. The source-to-drain bias was 60 V.

3.3. Device encapsulation

We determined our approach for encapsulating the P3HT OTFTs based on the findings discussed above, i.e. (1) O_2 does not cause degradation unless the devices are illuminated with light; (2) H_2O induces severe p-type doping and charge trapping; (3) encapsulation-induced degradation can be avoided with low-polarity encapsulating polymers, such as PVMK, PMVE, PMMA, and PS. Our approach involved using a combination of a low-polarity encapsulating polymer and a light-blocking agent (see Fig. 6 inset for a schematic illustration). The low polarity of the polymer was to prevent encapsulation-induced degradation and to block the permeation of moisture, while the light-blocking agent was to eliminate the effects of O_2, thereby removing the need for an O_2 barrier. We demonstrated this encapsulation approach with PS as the encapsulating polymer and a black dye as the light-blocking agent, and confirmed that this approach was indeed highly effective. As shown in Figs. 6 and 7, the encapsulated devices showed nearly identical device characteristics before and after encapsulation; moreover, the devices remained relatively stable for >5500 h of storage in air at room temperature. This long-term stability was a significant improvement over previously reported results with thiophene-based OTFTs [16,26–28], many of which used vacuum-deposited encapsulating films. The long lifetime of the encapsulated devices indicated that the water vapor permeability of the PS layer, at 9×10^{12} cm^3 cm/cm^2 s Pa [29], was sufficiently low for protecting the devices from moisture. It should be noted that devices encapsulated with the PS layer without the light-blocking agent showed rapid degradations due to photo-oxidation, as shown in Fig. 8. This was because PS is not a particularly good oxygen barrier owing to its lack of polar side groups [29]; and in the presence of light illumination, it allowed significant photo-oxidation to occur.

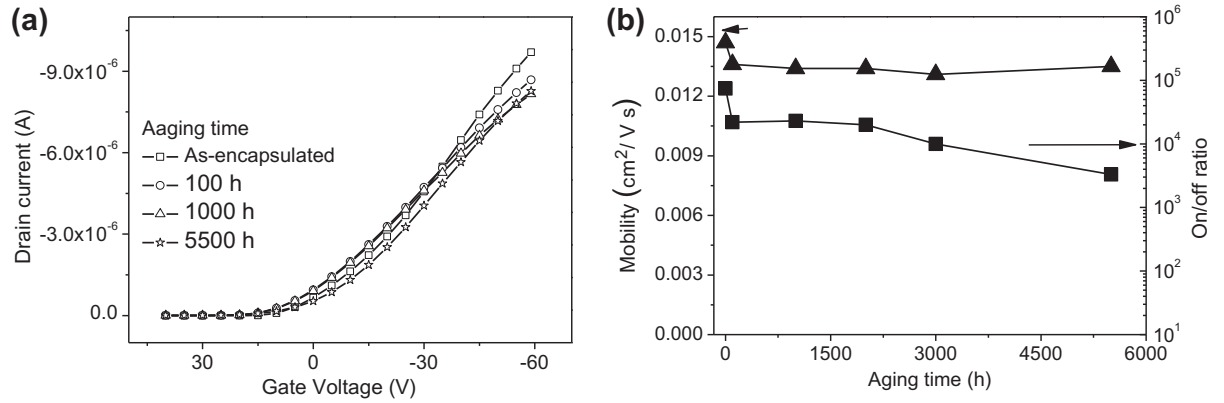

Fig. 7. (a) Transfer characteristics, and (b) field-effect mobility and on/off ratio, of the PS/dye-encapsulated devices as a function of aging time in air at room temperature. The source-to-drain bias in (a) was 60 V.

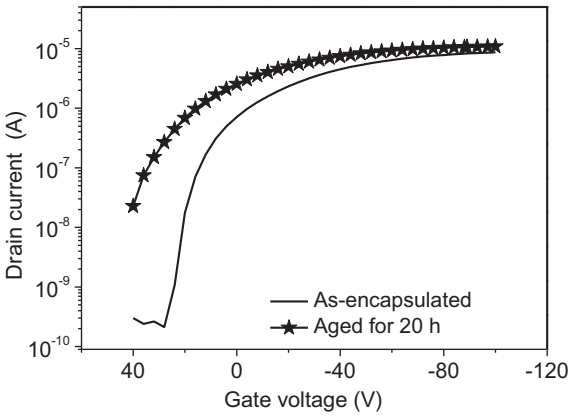

Fig. 8. Transfer characteristics of OTFTs passivated with only a PS layer before and after aging for 20 h in air at room temperature.

4. Conclusion

We demonstrated effective encapsulation of P3HT OTFTs using solution-processed polymer films via systematic analysis and elimination of the air- and encapsulation-induced degradations. In terms of air-induced degradations, moisture caused p-type doping (increased on and off currents with positive shift in V_{th}) and charge trapping (reduced on current) regardless of whether the devices were illuminated with light, and the degradations were fully recoverable upon removal of the applied moisture; on the other hand, oxygen exerted no effect without illumination, but caused pronounced p-type doping and irreversible photo-oxidation with illumination. Encapsulating the devices with a polymer film could result in significant degradations due to contact-doping of the P3HT layer by the encapsulating polymer film. By studying 10 encapsulating polymers, we found that such degradations were dependent upon the polarity of the polymers' functional groups: polymers with strong electron-withdrawing side groups—PVA, PVP, PAN, PVC, PVDC-co-PVC, and PVDF—induced various degrees of p-type doping depending upon the number and steric hindrance of the electron-withdrawing side groups, while those with low-polarity side groups—PVMK, PMVE, PMMA, and PS—caused no degradation. Taking into account the identified sources of degradation, we demonstrated an encapsulation approach that involved (1) using a low-polarity encapsulating polymer (polystyrene) layer to serve as a moisture barrier and to avoid encapsulation-induced degradation, and (2) applying a light-blocking dye to eliminate the effects of oxygen. The resultant OTFTs showed no encapsulation-induced degradation and maintained nearly constant device characteristics for >5500 h of storage in the ambient air.

ABSTRACT

In this paper, an alternative bi-stable resistive switching mechanism for non-volatile organic memory applications is reported. The memory device is formed from a sandwiched structure of Au/polyaniline:poly(4-styrenesulfonic acid) (PANI:PSSH)/ITO and operates via the migration of negatively charged counter-ions (PSS^-) within the polymer composite. The electro-statically bonded PSS^- within the polymer film segregates at the polymer's interface upon electrical biasing, serving to disrupt current conduction pathways through the polymer by influencing the resonance state of the conducting main chain. By relocation of this PSS^- layer at the polymer interface, electrical conductivity was modulated and an electrical bi-stable device was achieved. The resistive ratio between the ON/OFF states of the device is about 2–3 orders of magnitude, both of which can be read out for up to 500 times with negligible degradation.

1. Introduction

Organic electronics have attracted considerable attention in recent years due to their low cost, flexibility and easy-fabrication through solution processing. One aspect of the organic electrical circuit that has received considerable attention in recent years is the organic electronic memory. Resistive memories with two terminal cross-bar device structures are alternatives for up-coming non-volatile memory architectures. There are various organic materials that have shown resistive switching capabilities including polystyrene [1], polyethylene [2], poly(*N*-vinylcarbazole) (PVK) [3], 8-hydroxyquinoline [4], etc. There are also a large number of switching mechanisms responsible for switching behavior ranging from: filamentary switching due to device physical damage resulting in carbon-rich filaments from the local degradation of polymer materials [1]; space charge or traps either at the bulk or interface of the polymer, affecting carrier mobility and charge injection, respectively [3]; charge transfer effects between conjugated polymers and metal nano-particles [4]; tunneling related effects affecting the potential barriers [5]; conformational changes of molecules [6], etc. Till date, the continuous search for a robust and reliable resistive switching behavior has lead to many findings on various material combinations, device configurations and operating mechanisms.

With interest at hand to seek out a consistent memory source, an alternative operating mechanism for resistive switching application was discovered. This work describes the switching characteristics exhibited by a conjugated conductive polymer: polyaniline (PANI) doped with poly-(4-styrenesulfonic acid) (PSSH). PANI is advantageous due to the non-redox doping by protonic acids and easy modification of the oxidation states of its polymer chains. The alternative switching mechanism is based on migration related effects of charged counter-ions functioning to suppress one of the resonance/mesomeric states of the conduction parent chain, and serving as a barrier to charge translation along the polymer chains [7]. In this report, memory devices were fabricated in a simple two terminal

capacitor structure, using ITO coated glass substrates as bottom electrode and evaporated gold as top electrodes for electrical measurements. Compositional analysis of PANI:PSS was studied by X-ray photoelectron spectroscopy (XPS), time of flight-secondary ion mass spectroscopy (TOF-SIMS) and the device electrical characteristics were also measured.

2. Experimental section

2.1. Materials

Materials used for the synthesis of PANI:PSS are aniline, poly(4-styrenesulfonic acid) PSSH (18% water w/w), and ammonium persulfate (APS), purchased from Sigma–Aldrich.

2.2. Sample preparation/experimental procedures

PANI:PSS was synthesized by interfacial polymerization using aniline with ammonium persulfate in the presence of aqueous poly(styrenesulfonic acid) (PSSH) [8]. Aniline was added to PSS^- with a ratio of 1:2 in water followed by stirring at 0 °C for 30 min. Addition of ammonium persulfate was carried out over another 30 min at 10 min intervals, followed by stirring at 0 °C for 2 h and lastly stirring of the mixture at ambient conditions overnight.

ITO coated glass was cleaned prior to polymer deposition by immersing it in acetone, isopropyl alcohol and finally de-ionized water with ultrasonic cleaning for a duration of 10 min each. Deposition of the polymer film was done by two step spin-coating conducted, first at 500 rpm for 5 s, followed by another spin step at 2500 rpm for 20 s. The resultant polymer films were approximately 150 nm thick when measured using a surface step profilometer. For top electrical contact, 100 nm thick circular gold electrodes were deposited using electron-beam evaporator through a shadow mask, with electrode diameters ranging from 0.3 mm, 0.2 mm and 0.1 mm. For bottom electrical contact, the edge of the spin-on PANI:PSS film was removed with acetone to expose the underlying ITO substrate. During electrical characterization, grounding was applied at the ITO surface, and all electrical biasing was applied onto the Au top electrode, with all electrical characterization carried out using the Keithley 4200-SCS. Compositional analysis of the polymer film was studied by X-ray photoelectron spectroscopy (XPS) and time of flight-secondary ion mass spectroscopy (TOF-SIMS).

3. Results and discussion

PANI:PSS polymer films fabricated via the interfacial polymerization route were electrically conductive, as the presence of PSSH induced acid doping in PANI to a conductive emeraldine form [8,9], which resulted in the formation of protonated parent $PANI^+$ chains accompanied with electro-statically bonded PSS^- as counter-ions. Electrical transport occurs along the percolation pathways between $PANI^+$ chains throughout the film via hole conduction involving resonance translation of quinoidal structures [7,10], hence all the memory devices fabricated exhibits high electrical conductivity initially. Fig. 1a and b shows the current density–voltage (*J–V*) characteristics of the 0.3 mm diameter top electrode fabricated samples when swept from 0 to ±10 V.

It can be seen that the device displayed an initial high conductivity state (ON state) which was switched to a low conductive state upon application of a sufficient voltage/current density regardless of polarity. Subsequent sweeps showed stable current flow with three orders of magnitude lower (OFF state) than that of the initial conductive state. Application of opposite bias was unable to switch the devices back to its initial high conductive state, even when bias was applied up to 20 V in the opposite polarity (Fig. S1 in Supplementary data); suggesting

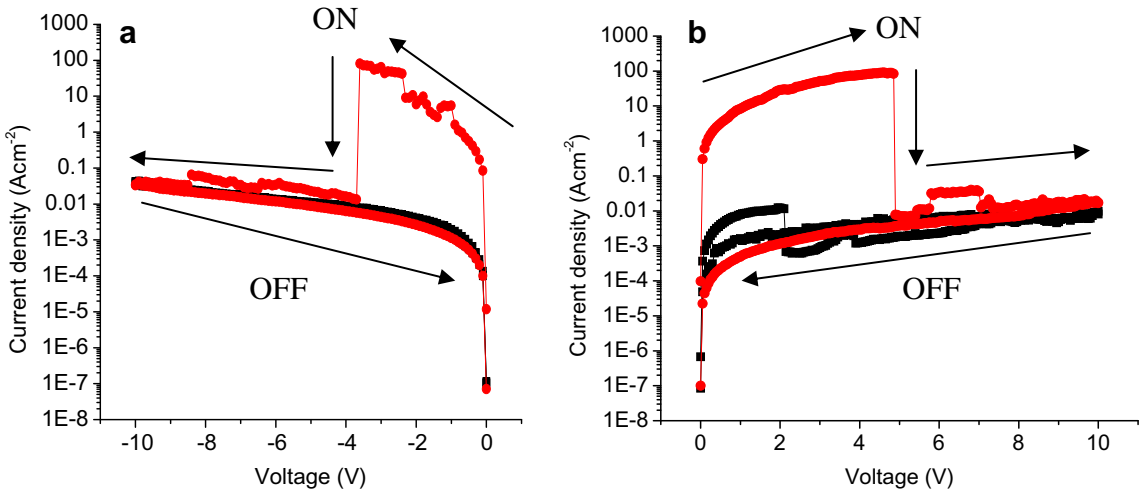

Fig. 1. *J–V* results of device demonstrating WORM memory characteristics in both polarities, when swept with voltages of 10 V magnitudes in both polarities. Red represents first initial sweep, and black represents second sweep. (a) Switching in negative polarity. (b) Switching in positive polarity. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

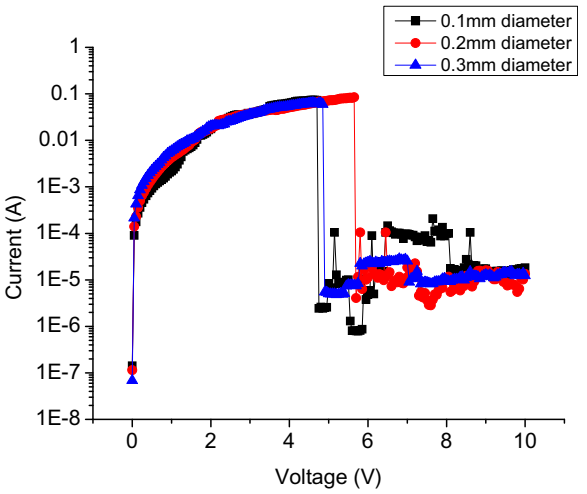

Fig. 2. *I–V* results for devices with 0.1 mm, 0.2 mm and 0.3 mm electrode sizes.

WORM (write once read many) memory characteristic similar to PEDOT:PSS in the literature [11]. Fig. 2 shows the current–voltage (IV) curve of devices with diameters 0.1 mm, 0.2 mm and 0.3 mm top electrodes. Comparison of switching characteristics between these devices suggests that the electrically induced conductivity drop only occurs when sufficient current was applied, with a current flow of approximately 1 A required before conductivity drop occurred. Comparing our results (PANI:PSS) to that exhibited by PEDOT:PSS [11], both the switching current density (10–100 A/cm^2) and voltage required (4 V) were of a similar magnitude, suggesting it to be electrical conditions required for migration of PSS^- to occur.

Though the memory device was unable to switch back to its initial conductive state by application of voltage sweeps alone; when current pulses were applied, conductivity changes were made possible. To demonstrate the conductivity changes achieved through current pulsing, the device was first switched to its low conductive state by a voltage sweep of 0–10 V. With the device in its low conductive state, another voltage sweep from 0 to 1 V was applied, serving as the conductivity baseline for further identification of any conductivity changes. Current pulses were then applied at magnitudes of ±0.1 A, for duration of 10 ms each; with 0.1 A serving to change the device from a low conductive state to a high conductive state, and −0.1 A switching back to a low conductive state. After application of each current pulse, a voltage sweep of 0–1 V was applied for identification of any conductivity changes. Fig. 3 shows the switching results after each current pulse, achieving a resistance ratio of 2–3 orders of magnitude before and after electrical pulsing. The inset in Fig. 3 demonstrates the stability of the two conductive states when undergoing a continuous readout at 0.2 V for 500 times with negligible degradation.

The switching mechanism responsible for the conductivity changes of the device is proposed to be related to the electro-migration of electro-statically bonded PSS^- counter-ions; which occurs upon the application of a voltage sweep. For the verification of migration related effects responsible for conductivity modulation, XPS was conducted on the polymer/gold interface before and after the initial 0–10 V voltage sweep, with nitrogen N_{1S} and sulphur S^{2P} peaks being monitored for the identification of PANI and PSS^-, respectively. This was done by peeling off the gold electrodes from the polymer after application of the voltage sweep. XPS was also conducted on the underside of the extracted gold electrodes which shows negligible nitrogen and sulphur contents (*Fig. S2*), suggesting that the peeling off process did not result in a removal of polymer surface layers. It was also noted that prior to any electrical biasing, the metal electrode could not be cleanly peeled off. This observation is also similar to the reported PEDOT:PSS and provides further evidence that interfacial changes has occurred as a result of the electrical biasing [11]. The result of the XPS analysis is shown in Fig. 4, a 15% increase in PSS^- concentration at the interface after application of voltage sweep was found. The XPS result also indicates a peak shift in the nitrogen N_{1S} peaks. The inset in Fig. 4 shows the deconvoluted N_{1S} contributions of

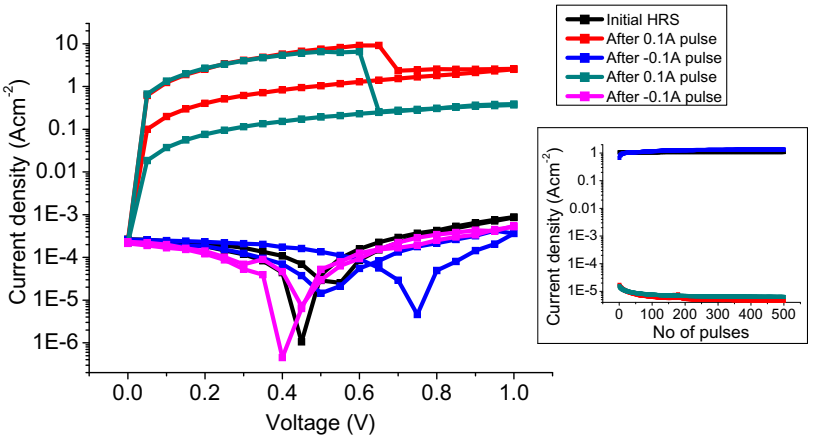

Fig. 3. *J–V* results demonstrating a resistance ratio of 2–3 orders of magnitude before and after current pulsing. Inset shows negligible degradation of conductivity states when undergoing continuous readouts at 0.2 V up to 500 times.

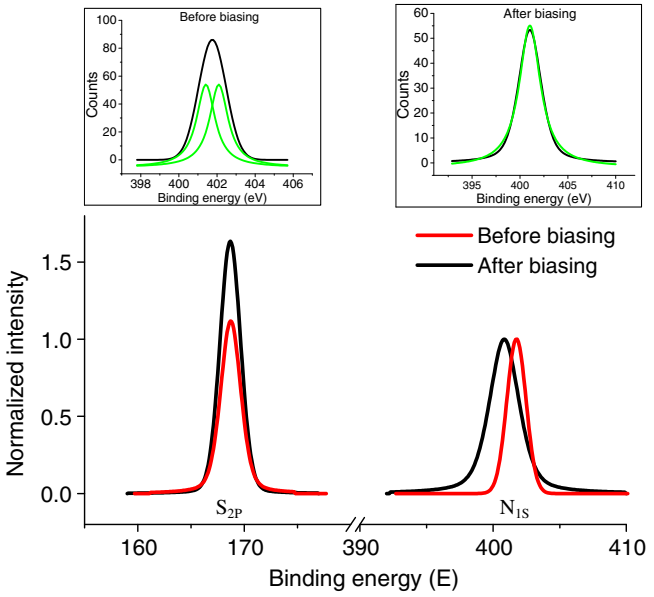

Fig. 4. XPS results on the PANI:PSS before and after electrical stimuli. The presence of PSS is represented by sulphur 2P peaks (168.5 eV) and the presence of PANI is represented by nitrogen 1S peaks (398.1–401.3 eV). Peak intensities of the XPS results were then normalized to the nitrogen peaks to compare the relative intensity difference of sulphur peaks. Black line represents peak intensity of PANI:PSS without electrical biasing applied and red line represents peak intensity of PANI:PSS after electrical biasing was applied. Inset shows the deconvoluted nitrogen 1S. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

401.1 eV and 402.6 eV, ascribing to the positively charged nitrogen: oxidized amine and protonated imine, respectively [12]. It was also noted that no nitrogen contributions attributed to quinoid di-imine and benzenoid diamine at 398.5 eV and 399.6 eV can be identified in the XPS readings, suggesting that all of the nitrogen components present within PANI were protonated.

The XPS result demonstrates that nitrogen contributions were altered as a result of the electrical biasing; from 50% oxidized amine and 50% protonated imine to almost 100% oxidized amine before and after biasing, respectively. This alteration is likely to have occurred due to the presence of excess PSS^- within the vicinity of the PANI main chain; as the ratio of protonated and charged nitrogen atoms has been reported to be related to the nature of counter-ions present [13]. Oxidized amine and protonated imine are representations of resonance/mesomerism demonstrated by acid doped polyaniline, and are believed to be accountable for the high charge carrier mobility demonstrated by the polymer [7,14]. Hence the absence of one of the mesomeric states (protonated imine) after electrical biasing is likely to render the polymer non-conductive.

To further examine the migration related effects of both voltage sweeps and current pulses, TOF-SIMS was conducted on the device before and after electrical biasing was done, with sulphur intensities used to map out the PSS^- content through the polymer film. Spectroscopy was carried out using a Cs source sputtering at 3 keV with a beam current of 15 nA over a $150 \times 150\ \mu m^2$ area, and the analysis were conducted on three electrodes: one without any electrical biasing in its pristine high conductive state; another after application of a voltage sweep, switching it to a low conductive state; and lastly one undergoing a voltage sweep to a low conductive state, followed by a current pulse, switching it back to a high conductive state. Results in Fig. 5 show a random distribution of PSS^- throughout the bulk polymer film before voltage application (curve (i) in Fig. 5), indicating no preferential positioning of the charged counter-ion within the polymer film. Application of a negative voltage sweep results in

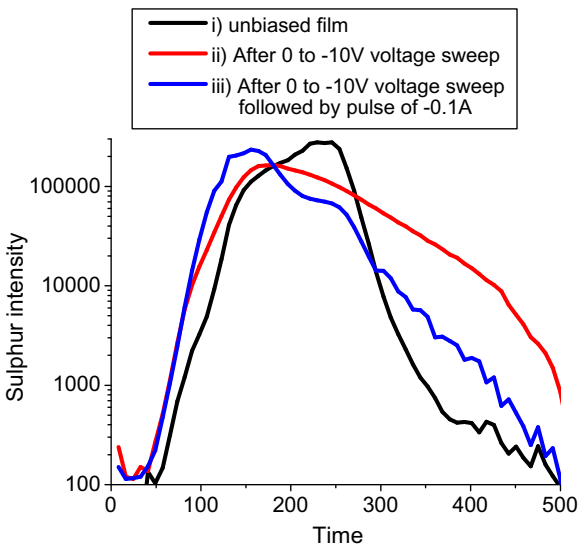

Fig. 5. Three SIMS curves showing the sulphur content in the polymer film (i) no bias applied, (ii) negative voltage sweep from 0 to −10 V, (iii) negative voltage sweep from 0 to +10 V followed by a current pulse at −0.1 A.

increasing the PSS^- content towards the bottom of the film due to the electro-static repulsion of the charged counter-ions with respect to the applied bias (curve (ii) in Fig. 5). This is in agreement with the previous XPS result, indicating that the drop in electrical conductivity is due to the increase in PSS^- at the bottom interface of the polymer. Effect of current pulse application was demonstrated in curve (iii) of Fig. 5, with a reduction in sulphur concentration at the bottom interface of the polymer film (previously high sulphur concentration due to the application of the voltage sweep); indicating reduction in PSS^- content at the polymer interface via back-migration. With this redistribution of negatively charged PSS^- content, the device switches back to a high conductive state; due to restoration of the resonance states of doped nitrogen species. Hence we have evidently demonstrated the modulation of electrical conductivity via migration of PSS^-, serving to alter the ratio of protonated and charged nitrogen atoms within the parent PANI chain; representing an alternative working mechanism for resistive switching application.

4. Conclusion

This is the first report of PANI:PSS displaying resistive switching characteristics. The conductivity of the polymer composite was altered by migration of electro-statically bonded PSS^- counter-ion, which functions to suppress one of the two resonance/mesomeric states of the proton doped polymer necessary for electrical conduction. Restoration of conductivity was achieved by relocation of previously segregated counter-ions. As the bi-stable memory states were brought about by solid state re-arrangement of composite components, this type of memory switching aims to provide a robust memory system not susceptible to memory loss. This work reveals an alternative switching mechanism for the operation of ReRAMs, which serves to supplement the family of switching mechanisms established for resistive switching applications.

Polymer solar cell
Efficiency limit
Photoinduced charge transfer

ABSTRACT

Polymer solar cell operation is based on the photoinduced charge transfer between polymer donor and acceptor. Marcus theory of electron transfer was applied to calculate the upper limit of the polymer solar cell efficiency in no-recombination approximation. Such calculation becomes possible by optimizing the position of the acceptor LUMO for any band gap value, which in turn maximizes the multiplication product of photocurrent, calculated according to Marcus theory and V_{oc}, which is determined by the difference between the acceptor LUMO and the polymer HOMO. Ultimate efficiency of polymer solar cell critically depends on λ -parameter describing reorientation of neighbouring dipoles in Marcus theory. The model provides a method for selection of optimal acceptor molecules for use in the polymer solar cells.

1. Introduction

Polymer solar cells, based on heterojunction between polymers and various acceptors, introduced by team, headed by Alan Heeger [1] are broadly researched now and demonstrate quantum efficiencies better than 90% [2] and photovoltages up to 1,5 V [3]. The molecular engineering of conjugated polymers and acceptor molecules [4] allows to tailor properties like optical absorption and charge transfer; supramolecular assembly [5] helps to optimize device structures allowing to efficiently generate charge carriers, dissociate them into a photocurrent, transport and collect this photocurrent at electrodes. Design rules for efficient collection of energy from the solar spectrum would therefore be very worthwhile. A number of models with the approach to calculate polymer solar cells efficiency appeared during the last 10 years [6–9]. Most of these models [6–8] are devoted to the optimization of donor polymer Band Gap and absolute values of polymer HOMO and polymer LUMO levels in respect to acceptor LUMO position, which can maximize the energy conversion. Other model [9] uses standard Schockley–Queisser (S–Q) theory [10], applying it directly to polymer solar cell.

However, one should be very careful, from our point of view, applying S–Q theory to polymer solar cells based on donor–acceptor photoinduced charge transfer. The S–Q theory implies the radiative recombination of excited electron–hole pairs as a main factor, decreasing the efficiency from the ultimate upper limit. In case of donor/acceptor-based polymer solar cells the ultra-fast photoinduced charge transfer takes place with a time constants $\cong 10^{-14}$ s [1]. This is ~4 orders of magnitude faster, than the characteristic time for spontaneous emission from most of the polymers, used in solar cells. Thus, luminescence from the excited state is completely quenched in the presence of acceptor molecules in the neighbourhood, and the S–Q theory can not be applied directly. Also such photoinduced charge transfer is irreversible in it's nature, for the theoretical description of this irreversibility one should read the very good paper by Tributsch [11], so we will refer to this paper and will not explain, why the photoinduced charge transfer is irreversible.

Since the photoinduced charge transfer plays the key role in the photophysics, utilized in polymer solar cells, the model of solar cell efficiency should therefore include the photoinduced charge transfer. The description of latter is well known due to Rudolf Marcus, who first introduced a model [12] to describe the electron transfer in electrolytes, which was later generalized , covering almost all processes involving electron transfer in chemistry, including photoinduced charge transfer [13] (R.Marcus and S.Sutin). There were a number of successful attempts to describe the photoinduced charge transfer in donor–acceptor systems using Marcus theory of electron transfer, including possibility of multiply hopping in case of Donor-bridge-Acceptor molecules [14]. The main prediction from Marcus theory – existence of inverted region – was experimentally observed for photoinduced electron transfer in Ruthenium(II)–Polypyridine Complexes with Phenolate Ions [15]. The paper of W. Duncan [16] deals with peculiarity of photoinduced charge transfer on the interface between TiO_2 , dye and electrolyte applied in Graetzel cells, where it is found, that in such system Marcus theory also gives adequate description of the experimental photophysical data. Recently appeared review of V. Dyakonov and co-authors [17] provides the treatment of photoinduced charge transfer in Polymer Solar Cells, including intermediate Charge Transfer States (CTS) in terms of Marcus theory, providing some experimental results, supporting Marcus treatment of the photoinduced charge transfer process. Concluding, we would like to stress, that there are many examples of successful description of photoinduced charge transfer using Marcus theory, both theoretical and experimental.

The main equation of Marcus theory [12]:

$$k_{et} = \frac{2\pi}{\hbar}|H_{AB}|^2 \frac{1}{\sqrt{4\pi k_b T}} \exp\left(\frac{(\lambda + \Delta G)^2}{4\lambda k_b T}\right)$$

where $\triangle G$ - driving force of the process, namely the difference in free energy between the initial and the final state, H_{AB} - parameter, describing the intersection of the wave functions of the initial and the final state and λ - a parameter, describing the reorientation of the dipoles in the vicinity of electron final placement.

It is important that Marcus equation describes the rate of electron transfer, which is not a thermodynamic, but a kinetic parameter. The reason to switch to the kinetic approach from thermodynamic is the irreversible character of the photoinduced charge transfer which is followed by further charge separation in respect to light absorbance-luminescence. That is why the act of the photoinduced charge transfer will be described here in kinetic terms, as it was done by Marcus. If we treat the operation of the polymer solar cell as a photochemical reaction, we should use kinetic constants of stages, yields and conversion rates. Actually, the treatment of organic solar cell using Marcus theory was introduced already by S.-S.Sun [18], but from the author's point of view treatment of most of processes, taking place in organic solar cell using Marcus theory seems to be not exactly correct, since exciton decay is a process, having different nature from electron transfer described by Marcus model, as well the CT state recombination (ground state charge transfer) is the two-particle process, involving both electron and the hole, which is also out of limits of Marcus treatment. Also we will not try here, in distinction to S.-S.Sun, to include the kinetics of CT state recombination, since, as it will be described below, it does not correspond to ultimate efficiency case (no-recombination limit), which will be the main object of this paper.

2. Calculation

Writing down the main stages of this reaction, initiated by photon:

- $P + h\nu \leftarrow k_1, k_{-1} \rightarrow P_{exc}(I)$ absorption of photon leads to excited state
- $P_{exc} \leftarrow k_2, k_{-2} \rightarrow P^+F^-(II)$ charge separation occurs from excited state
- $P^+F^- \leftarrow k_3, k_{-3} \rightarrow PF + e + h(III)$ charge dissociation and transport to the electrodes

One can write the kinetic constant of the whole process as [11]:

$$K = \frac{k_1}{1 + [1 + \frac{k_{-2}}{k_3}] * \frac{k_{-1}}{k_2}}$$

Equivalent to: $K = \frac{k_3 k_2 k_1}{k_3 k_2 + k_{-2} k_{-1}}$ which can be rewritten as $\frac{1}{K} = \frac{1}{k_1} + \frac{k_{-2} k_{-1}}{k_3 k_2 k_1}$ where first term can be neglected due to it's incomparability with the second term (K_2>>K_1).

Since $\frac{k_{-1}}{k_1} = 1$, (Einstein), $K = \frac{k_3 k_2}{k_{-2}}$ where k_2/k_{-2} – the rate of Marcus Electron Transfer.

This confirms the fact that the rates of absorbance and luminescence are not influencing the rate of the overall process.

We can rewrite $k_3 = k_4 * k_5$, where $k_4 = k_d(F,T) = \frac{3\beta}{4\pi a^3} \exp(-\frac{E_{ch}}{kT})(1 + b + \frac{b^2}{3} + \frac{b^3}{18} + \frac{b^4}{180} + \ldots)$ Onsager dissociation rate [19] and $k_5 = \mu_e \mu_h / (\mu_e + \mu_h)$ charge transport rate.

The only term depending on the energy levels, shown at the Fig. 1 is the rate of Marcus process of photoinduced electron transfer. Rudolf Marcus in his Nobel lecture [20] has pointed out the fact that the polymer solar cells will

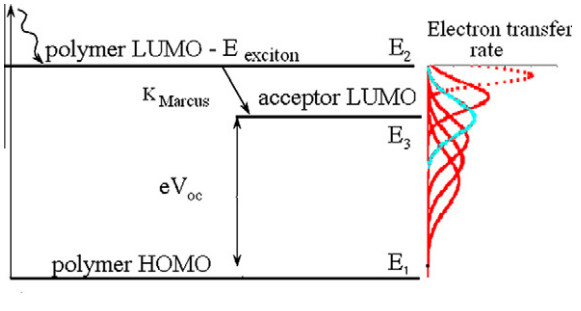

Fig. 1. The three-level diagram for donor–acceptor polymer photovoltaic cells, right side graph - dependence of Marcus rate of electron transfer from Energy level of Acceptor for different λ. Blue curve corresponds to Acceptor LUMO level, depicted at diagram. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

work most optimally if $\Delta G = -\lambda$, since at these values the rate of electron transfer is maximal. The steepness of the dependence of kinetic constant from energy in vicinity of optimum Energy level (Fig. 1) determines the drastic downfall of kinetic rate for non-optimal E_{LUMO} values, to the point where kinetic rate of photoinduced charge transfer equals the luminescence rate, and the yield of the overall reaction (EQE) drops down to 50% and less.

In this paper we would like to determine the optimal position of the Acceptor LUMO level, as depicted at Fig. 1, giving the maximum power output. It should be noted also, that in distinction from S. S. Sun approach [18], where the optimum, maximizing the charge transfer rate is determined, we will determine the Optimum position of Acceptor LUMO, which maximizes the Energy Conversion Efficiency of a Polymer Solar Cell. Since we are calculating the ultimate efficiency of the cell, we can assume the Fill Factor = 1. The maximum power output is than: $P_{max} = V_{max} * I_{max}$.

V_{max} is determined by the difference $V_{max} \sim E_3 - E_1 \sim E_g + E_3 - E_2$ [6].

More accurately speaking, we should substitute E_g with $E_g - E_{\text{exciton binding}}$, which is of the order of 0.1–0.2 eV [3], so let us say that $E_2 - E_1 = E_g - E_{\text{exciton}}$, where $\sim$ means upper limit and then:

$$I_{max} = \frac{2\pi}{h} H^2 \frac{1}{\sqrt{4\pi\lambda kT}} \exp\left(-\frac{((E_3 - E_2) + \lambda)^2}{4\lambda kT}\right) \quad (1)$$

We can write than:

$$P_{max} = \frac{2\pi}{h} H^2 \frac{1}{\sqrt{4\pi\lambda kT}} \exp\left(-\frac{((E_2 - E_3) + \lambda)^2}{4\lambda kT}\right) \times (E_g + (E_3 - E_2)) \quad (2)$$

In order to find the P_{max} we have to take derivative of the expression (2) $P_{max}' = 0$. It gives us:

$$E_{LUMOptimal} = \frac{E_g - \lambda + \sqrt{(E_g - \lambda)^2 + 8\lambda kT}}{2} \quad (3)$$

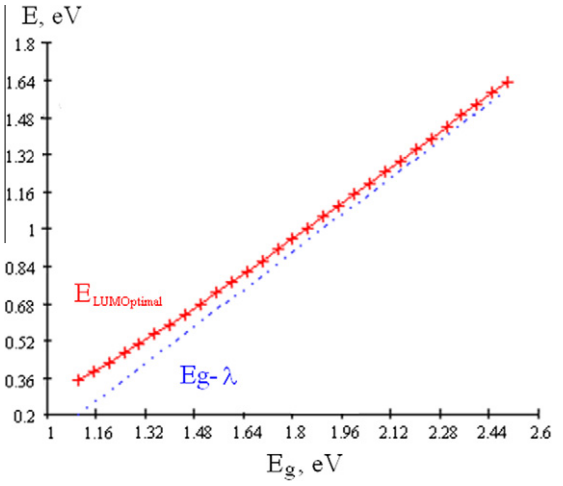

Fig. 2. Dependence of Optimal position of Acceptor LUMO level, maximizing the power output of the PV cell from the Band Gap Value for $\lambda = 0.9$. Solid line – $E_{LUMOptimal}$, dashed line – $E_g - \lambda$.

The position of $E_{LUMOptimal}$ from the E_g value can be seen from Fig. 2.

It can be seen that the optimal position of Acceptor LUMO is close to $E_g - \lambda$ value, but is higher in energy, and for the smaller band gaps this difference can be up to 0.2 eV.

Since we know the position of LUMO level of acceptor, which maximizes the power output, we can derive the expression for the Ultimate Efficiency of the polymer solar cell. Here we treat the Ultimate Efficiency in S–Q model sense, meaning that the cell with no radiative recombination losses lowering the efficiency is described, and also taking the ideal cell with Fill Factor = 1. This approximation describes the so-called no-recombination limit in S–Q model. Thus the expression for the Ultimate efficiency of the Solar Cell will be:

$$v = \frac{[\int_{E_g}^{\infty} N(h\omega)\alpha(h\omega)dh\omega] * eE_{LUMOptimal}}{\int_0^{\infty} N(h\omega)h\omega dh\omega} \quad (4)$$

Where $N(h\omega)$ the number of photons with corresponding energy, $\alpha(h\omega)$ Absorbance coefficient and $eE_{LUMOptimal}$ – ultimate limit of V_{oc}, in case of ideal device architecture, where $E_{LUMOptimal}$ is taken from (3).

It should be defined, which absorbance function we should use in expression (4). It seemed appropriate to model the Absorbance coefficient with the Heaviside step function:

$$H(x) \approx \frac{1}{2} + \frac{1}{2} tahn(E_g k) = \frac{1}{1 + e^{-2kE_g}} \quad (5)$$

Which is 0 for $E < E_g$ and 1 for $E > E_g$ and some transition curve whose steepness depends on the "k" value.

We believe (5) better corresponds to the Ultimate efficiency case, since the polymers which absorb all photons above the Band Gap are available [2] and (5) definitely corresponds to upper limit of efficiency. So we have used mentioned assumptions to calculate the Ultimate Efficiency and numerically calculated the integral (4), optimizing the E_{LUMO} for each taken Band Gap value. We modelled the Sun as black body with $T = 5800$ K, $T_{cell} = 320$ K, incident light perpendicular to the cell surface.

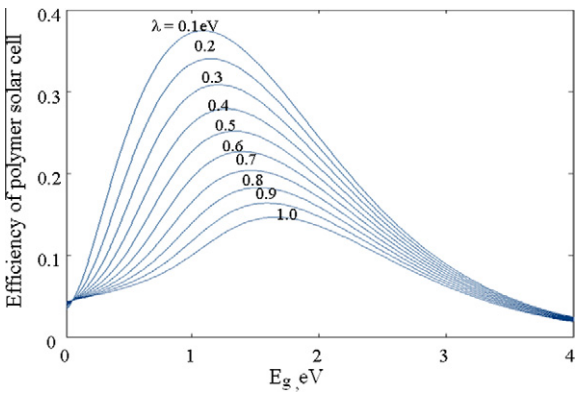

Fig. 3. Efficiency of the *D–A* based plastic solar cell depending on Band Gap energy for different values of λ parameter, obtained using equation (4).

The results of such modelling can be seen from Fig. 3. There are two facts, which result from the modelling: The ultimate efficiency for $\lambda = 0$ is the same, as in S–Q model [10], but as λ becomes higher, the absolute value of efficiency decreases and the maximum efficiency shifts to the higher E_g domain.

This result can be interpreted in Marcus theory terms: the polymer solar cell differs from inorganic one by the fact, that the dipole reorganization or intra-molecular reorganization takes place following the act of electron transfer. This reorganization is the heat dissipating process. Therefore the thermodynamic reversibility is impossible and the heat is evolving, thus lowering the ultimate solar cell efficiency. The larger the λ, the more energy is spent for reorganization, the lower is the upper limit of solar cell efficiency. Also the difference in E_2 and E_3 should be as high as ca. λ to allow the optimal power conversion. Marcus-based approach therefore describes the physics of operation of polymer solar cell, using kinetics, instead of thermodynamics, as in S–Q case.

It should be noted, that according to calculations even for smaller band gap values and even for E_g close to 0 we have non-zero efficiencies of the polymer solar cell. That is due to the fact, that, according to our model, for smaller band gaps the $E_{LUMOptimal}-E_{LUMOAcceptor}$ can be lower than polymer HOMO in energy. Even though it is counter-intuitive case, but in the frame of the given model, even in this case there will be power, generated in the external circuit. As it is assumed, upper limit of $V_{oc} = E_{LUMOAcceptor}-E_{HOMODonor}$ also equals to V_{BI} – built-in electric field in the polymer solar cell (in full accordance with C.Brabec et al. modelling [7]). If acceptor LUMO will be lower in energy than Donor HOMO we will still have the built-in field in the device: $V_{BI=}E_{HOMODonor}-E_{LUMOAcceptor.}$ This field, even though "inverse" in respect to usually met in polymer solar cell, will still be able to produce the energy by means of charge separation for every absorbed photon, equalling to $E = eV_{BI,}$ in the frame of the given model. That is why, even in such counter-intuitive case there will be non-zero efficiencies even for the small polymer band gaps, in limit approaching zero. Of course this should not be true for the point where $E_g = 0$, since at this point we have a metal-like and not a semiconductor-like polymer, therefore value corresponding to $E_g = 0$ should not be considered correct. This trend, appearing for small values of the polymer band gap, reflects the fact, that in polymer solar cells the built-in field, responsible for charge separation and for power output, is determined not by the E_g of the polymer, but by the difference $|E_{LUMOAcceptor}-E_{HOMODonor}|$. Whether this is just a model assumption or there is a deep physical meaning in it, is not clear.

The λ value for the fullerene molecule in different polymer matrices was calculated numerically [21], and was found to be ca. 0.6 eV. One can see the place of optimal band gap for conjugated polymer, blended with fullerene, and the maximum efficiency of PV cell with fullerene acceptor from Fig. 3. One design rule for acceptor moiety can be drawn from Fig. 3: the lower is the λ value, the higher is the efficiency of the solar cell. Author can express his own view, consisting in assumption, that due to rigidity of fullerene buckyball the restructuring of it, following the additional electron uptake, is quite low, comparing to other acceptor molecules, which are not so "rigid". So maybe the success of fullerene-like acceptors for polymer solar cells is due to their unique structure, giving low λ values in comparison with other acceptors.

It should be noted, that to calculate the real Fill Factor and Real V_{oc} values, one should take into consideration the radiative recombination, taking place between levels E_3 and E_1 (Ground state charge transfer). Such calculation was recently done and the results can be found in [22]. It should be stressed, that in our paper we treated the upper limit of efficiency (no-recombination limit) for the polymer solar cell. One can imagine the "ideal" polymer solar cell, where built-in field, caused by difference of two electrodes work functions is so high, that all separated electron–hole pairs are split, and radiative recombination does not take place. This "ideal" situation corresponds to upper limit in our terminology.

Even though our model does not give the exact expressions for V_{oc} and does not include the calculation of Fill Factor, which should be based on detailed treatment of three processes: Onsager dissociation of charge transfer states, caused by external field, competing with the ground state charge transfer, and secondly the recombination and resistive losses taking place during charge transport, it provides some sound clues on ultimate efficiency decrease in polymer solar cells due to the very nature of photoinduced charge transfer in organic media. Also calculating the upper limit, we do not treat the ohmic losses and recombination during charge transfer to electrodes. This detailed treatment is to follow. But even treating the no-recombination limit case we come to the sound results: upper limit is determined by λ of acceptor moiety, optimal band gap shifts with the change of λ and the optimal LUMO position is determined by expression (3). Also the fact that λ of acceptor should be as low as possible to maximize energy conversion efficiency gives a direction in search for new acceptors for polymer solar cells.

To check the validity of the model, one can take "classical" system in polymer solar cells, consisting of P3HT poly-3(hexylthiophene) and PCBM as an acceptor. In this system difference between LUMO of P3HT and LUMO of PCBM equals to 0.9 eV. If we take λ for PCBM similar to λ of fullerene (0.67 eV) and calculate $E_{LUMOptimal}$ according to expression (3), the difference will be 0.65 eV. Since one should take LUMO of P3HT – $E_{exciton}$, which is 0.15–0.2 eV for P3HT [17] it gives us 0.75–0.7 eV as real value versus 0.65 eV, obtained as a result from presented here modelling. It seems that, at least in first approximation, in P3HT-PCMB case the PCBM LUMO is pretty close to the optimal value, maximizing the Energy Conversion Efficiency, according to model presented here.

3. Conclusion

We used Marcus theory to model the ultimate efficiency of polymer solar cells in no-recombination sense. The main assumption, which is presented here, is the deviation of efficiency of polymer or organic solar cells from the standard S–Q theory, caused by absence of thermodynamic

equilibrium between photons, absorbed by solar cell, and photons emitted due to electron–hole pairs recombination. Such deviation is due to very nature of fast and irreversible photoinduced charge transfer from donor to acceptor, which destroys such equilibrium. Thus the main assumption here is, that polymer or organic solar cells operation is similar to photochemical reaction, where reagents are irreversibly converted to products under the action of photon flux. Modeling becomes possible by optimizing the relative position of acceptor molecule LUMO level in respect to polymer LUMO and polymer HOMO levels, which maximizes the power conversion efficiency of the polymer solar cell. The ultimate efficiency, calculated using such optimal acceptor LUMO level position, as it was found, critically depends on λ parameter, describing the reorientation of neighboring dipoles, or change of intra-molecular bonds, caused by photoinduced charge transfer of electron to acceptor molecule in accordance with Marcus theory. The presented model gives useful rules to choose or design the acceptor molecules for use in the polymer solar cells, basing on their LUMO level position and λ parameter, which can be calculated numerically [15] for any given polymer matrix, surrounding the acceptor moiety. It is possible, that the model can be applied not only to polymer, but also to small molecule organic solar cells, based on photoinduced charged transfer between the donor and the acceptor and Dye Type Solar Cells.

Organic thin-film transistor
HOMO-band-edge fluctuation

ABSTRACT

To clarify relationship between crystallographic and electronic structures in pentacene polycrystalline films grown on SiO_2, in-plane crystallite size and random strain of the films were analyzed by grazing incidence X-ray diffraction (GIXD) using synchrotron radiation source. The results indicate that the diffraction peak width is not determined by random strain but by crystallite size. The crystallite size remains constant within the range of 25–50 nm even when the size of polycrystalline domain, or crystal grain, increases more than tenfold by elevating the growth temperature. The crystallite size agrees well with characteristic periods of both HOMO-band-edge fluctuations in pentacene films, which was reported in our previous paper, and surface corrugation of the substrate. These facts strongly suggest that roughness of the SiO_2 surface limits the crystallite size and the interruption of long-range order in pentacene lattice introduces the HOMO-band-edge fluctuation.

1. Introduction

Organic thin-film transistors (OTFTs) are attracting significant research efforts to realize flexible RFID tags and flexible displays due to their ease of processing on polymer substrates and low cost of processing [1–4]. Around the year 2000, field-effect carrier mobility of pentacene, which is the most widely studied small-molecule organic semiconducting material, rapidly increased and became comparable to that of amorphous silicon [5–8]. However, the mobilities reported in literatures have been stagnating at around 1.0 $cm^2/V\,s$ for this decade. On the other hand, a mobility of 15–40 $cm^2/V\,s$ was reported for a field-effect transistor using a pentacene single-crystal active layer [9]. This value agrees well with the mobilities expected from band dispersion obtained by angle-resolved ultraviolet photoemission spectroscopy [10,11] and band calculations for single crystals [12]. Although these results may not indicate the final physical property of an ideal pentacene single crystal, 40 $cm^2/V\,s$ could be a target of the performance of pentacene TFTs at this stage. Accordingly, the disagreement between the real and the target values suggests that the apparent mobility of a practically important polycrystalline thin film is only less than 10% of that of a single crystal, and the material's true ability for carrier transport is not fully utilized.

It is widely believed that the reason for the mobility of polycrystalline films being lower than that of single crystals is the presence of energy barriers at morphological grain boundaries, which is easily observed by atomic force microscopy (AFM) [13]. Besides, we have reported that such energy barriers with a height of around 100 meV exist not only at the morphological grain boundaries but also at "polycrystalline domain" boundaries [14] which originate in the dendritic growth nature and divide the morphological grains typically into four parts [15]. Furthermore, by using AFM potentiometry (AFMP), we found that HOMO-band-edge fluctuations in the range of 10–20 meV_{rms} exist

even within a "polycrystalline domain" formerly regarded as a single crystal [16]. There are two possible origins of these fluctuations. First, the "polycrystalline domain" itself is a single crystal in fact but contains random strains. Second, the "polycrystalline domain" is a mosaic of smaller crystallites and potential fluctuations are generated due to the crystallite boundaries. To determine a major cause of the band-edge fluctuation, the microstructures in pentacene thin films need to be precisely evaluated.

Some groups have reported about the correlation between out-of-plane crystallite sizes of pentacene films on SiO_2 and their mobility [17,18]. However, there have been a limited number of reports that mention the "in-plane" microstructures in pentacene thin films, even though they must be more important for carrier transport in a TFT channel rather than out-of-plane ones. This is mainly because crystallite sizes of organic polycrystalline materials tend to be larger than those of inorganic ones, which obliges us to use narrower-width slits or an analyzer crystal to measure very narrow full-width-at-half-maximum (FWHM) of the diffraction peaks, and also because organic materials are composed manly of light elements. Since both of them significantly weaken the intensity of diffracted X-ray, it is almost impossible to use a laboratory-scale grazing incidence X-ray diffraction (GIXD) instrument for this purpose. Therefore, to use very bright X-ray from a synchrotron radiation source is necessary for the GIXD analyses of in-plane microstructures. Natsume et al. reported a crystallite size in pentacene films grown by their special solution process [19], and Hong et al. reported that in pentacene films on Au electrodes [20]. However, none of these studies considered the random strain in crystals in their analyses, although such random strain also broadens the FWHM of diffraction peaks. Moreover, the in-plane microstructures of the vacuum-evaporated pentacene on SiO_2, which is the most popular OTFT combination of an active material and a gate insulator, has not been reported so far.

In this paper, we demonstrate that the influence of in-plane random strain on the FWHMs of in-plane GIXD peaks is negligible and that the crystallite sizes of pentacene polycrystalline films grown on SiO_2 substrates are in the range of 25–50 nm, which is at least one order of magnitude smaller than the polycrystalline domain size. Crystallite sizes were verified by also high-resolution frictional force microscopy (FFM). Contrary to conventional wisdom in thin-film growth, the crystallite size remains constant even when the apparent grain size increases tenfold by elevating the growth temperature. Our results demonstrate that it is highly probable that the mosaic structure of the polycrystalline domain causes the HOMO-band-edge fluctuation.

2. Experimental

2.1. Thin film growth

Pentacene films were deposited on Si wafers with 300 nm-thick silicon oxide. All samples were fabricated using the same method as in previous studies [15,16,21]. A heavily doped n-type silicon (1 0 0) wafer (Mitsubishi Materials, resistivity is less than 0.02 Ω cm) with thermally grown SiO_2 (300 nm) was used as the substrates. They were cleaned with acetone and UV/O_3 (200 °C, 30 min) to remove surface contamination. Pentacene with a purity of over 99.9% (Tokyo Chemical Industry, sublimation grade) were then deposited onto the substrates by molecular beam deposition in an ultra-high vacuum ($\approx 5 \times 10^{-8}$ Pa) [21]. The film thickness and deposition rate were controlled using a crystal thickness monitor. The growth rate was 0.3 nm/min, and the substrate temperature was varied in the range of 5–100 °C.

2.2. GIXD measurements

All GIXD measurements were performed using monochromated synchrotron radiation at the BL46XU beam line in SPring-8 with a goniometer manufactured by HUBER, which is specially designed for the characterization of thin films. The wavelength and incident angle of X-ray were 1 Å and 0.12°, respectively. All measurements were performed in a helium atmosphere. A lithium fluoride analyzer crystal was used for higher wavenumber resolution in the X-ray detection. GIXD peaks obtained in this work are however broadened to some extent due to the limit of angle resolution (instrumental function). GIXD patterns of the pentacene films were therefore fitted using a Voigt function whose width of the Gaussian component was fixed with that of the instrumental function and the width of the Lorentzian component was varied to analyze the true width of the diffraction from the pentacene film. The FWHM of the Gaussian instrumental function was estimated to be 0.047 nm^{-1} from (0 2 2) diffraction of Si(1 0 0) wafer.

2.3. Frictional force microscopy

FFM measurement was performed using an AFM (JEOL, JSPM-4200) in a nitrogen atmosphere just after the film growth. The AFM was operated in a contact (constant-height) mode by setting the force load as low as possible. Triangular-shaped silicon nitride cantilevers with a stiffness of 0.09 N/m (Olympus, OMCL-TR400 PB) were scanned in the perpendicular direction and torsion of the lever was corrected as the frictional signal. Using the triangular shape lever, all of the tip–sample force components in lateral directions were mixed due to the crosstalk between bending and torsional motion of the lever, which equalizes the sensitivities to parallel and perpendicular components of the frictional force and thereby molecular lattice images become relatively insensitive to the angle between the scanning direction and molecular crystals.

2.4. Atomic force microscope potentiometry

AFMP measurements were performed using an AC-mode AFM (JEOL, JSPM-5200) equipped with a conductive cantilever and a high-input impedance voltage-measurement circuit which is integrated in a cantilever holder. This technique is capable of accurately measuring the potential (voltage) distribution in working thin-film transistors

[16,22–24]. The spatial resolution of AFMP is estimated to be <10 nm and the potential resolution ~100 μV. All AFMP measurements were performed in nitrogen atmosphere with Pt-coated Si cantilevers.

3. Results

3.1. Film morphologies and GIXD patterns

Fig. 1 shows AFM height images of the pentacene films. By changing the growth temperature in the range of 5–100 °C, pentacene films with an average polycrystalline domain size (mean diameter of the area surrounded by 100 meV-order energy barriers, defined as half of the morphological grain size in the case of pentacene [15]) of 400–2.5 μm were prepared. Tall lamellar grains, in which the molecules lie flat [21], are seen in films grown at 5 and 20 °C. Although they strongly decrease the apparent mobility of the film grown at lower temperature [25], they are beyond the scope of the present work, and their volume is so small that they hardly appear in the GIXD pattern.

Fig. 2 shows GIXD patterns measured with the pentacene films. The FWHM of all the peaks are much wider than those of the instrumental function. Among many detectable in-plane diffraction peaks, these three peaks shown in the figure, corresponding to the thin-film phase [26,27], were selected for further analysis because they exhibited clear peak shapes with sufficient signal-to-noise ratios. It should be noted that the (0 2 0) and (1 2 0) peaks have asymmetric shoulders. By fitting two Voigt functions to these peaks, the lattice constant obtained from the major components was equal to that of the thin-film-phase pentacene, and the constant from the minor peaks was in between those of the thin-film and the bulk phases, of which composition ratio increases while increasing the thickness [28]. This suggests that the minor component is an intermediate state wherein the crystal structure of the pentacene changes from a thin-film phase to a bulk phase. In the structural analyses, we only use the major thin-film-phase components because the minor components is judged not to affect carrier transport in the film.

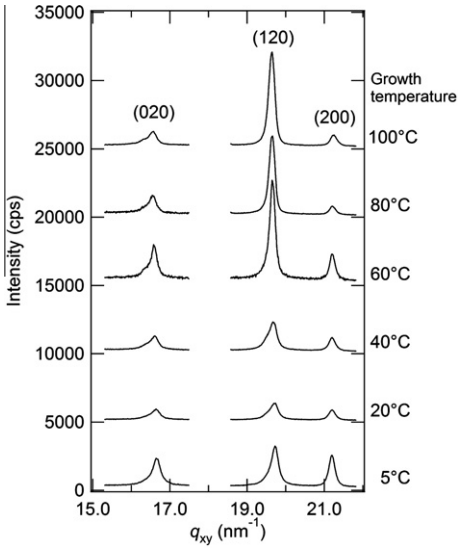

Fig. 2. In-plane GIXD patterns of pentacene thin films grown on SiO_2 substrates at various temperatures. The indexes of a thin-film phase pentacene crystal are labeled.

3.2. Analysis of GIXD peaks

As mentioned previously, the peak widths of XRD patterns are broadened not only by the size of crystallite but also by the random strain in the crystal structure. The Williamson–Hall (W–H) method can separate these two factors from the widths of the XRD peaks [29]. In this

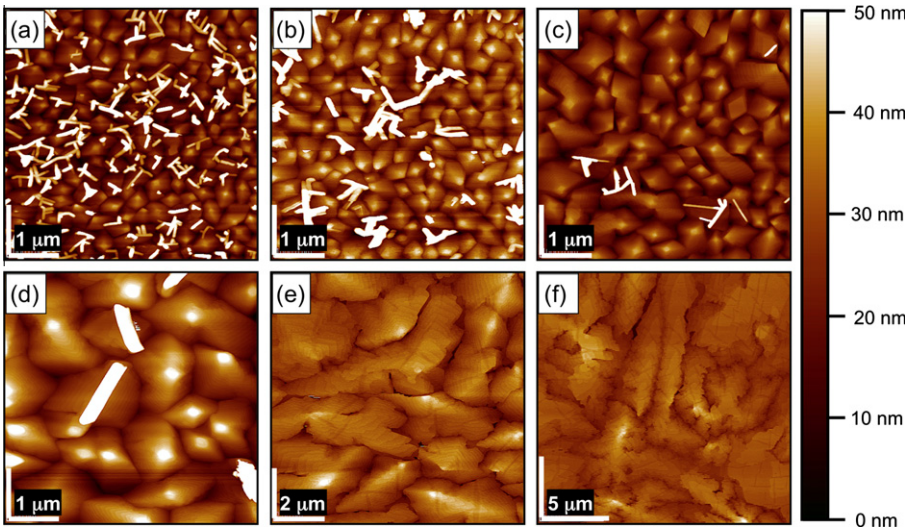

Fig. 1. AFM height images of pentacene thin films grown on SiO_2 substrates at (a) 5 °C, (b) 20 °C, (c) 40 °C, (d) 60 °C, (e) 80 °C, and (f) 100 °C. The displayed height range is evenly set to 50 nm.

method, the relationship between these structural parameters and peak width is described as follows:

$$\beta_q = \frac{2\pi K_s}{\langle D \rangle} + \varepsilon_{rms} q_{xy} \quad (1)$$

where β_q is the FWHM of a peak, K_S is the Scherrer constant, $\langle D \rangle$ is the average crystallite size, ε_{rms} is root mean square of the random strain, and q_{xy} is the scattering vector. The Scherrer constant is determined depending upon the composition and type of crystal. For organic crystals, values of 0.87–1.05 are frequently used [30–33]. In this work, we adopt $K_S = 0.95$ which is in middle of the range used for organic crystals. The error in crystallite size due to uncertainty in the Scherrer constant is less than 10% and does not influence the discussion in the present study. By fitting a straight line to the β_q versus q_{xy} plot, the random strain and crystallite size can be estimated from the positive slope and the positive intercept of the fitted line, respectively. In the case of the pentacene films studied in this work, there is no large anisotropy in the in-plane crystallite size as explained later. Therefore, we apply the W–H method to the three peaks from different diffraction planes, although it should be used for a series of higher-order diffraction peaks from the same diffraction plane as a general rule.

Fig. 3a shows W–H plots of all major peaks in Fig. 2. It is to be noted that no sample has a clear positive slope in its W–H plot. This result indicates that the FWHMs of the X-ray diffraction peaks from the pentacene films are determined by their finite crystallite sizes and the contribution of random strain is negligible. Therefore, hereafter, we only discuss the crystallite size estimated for each peak by the Scherrer equation

$$\langle D \rangle = \frac{2\pi K_s}{\beta_q}. \quad (2)$$

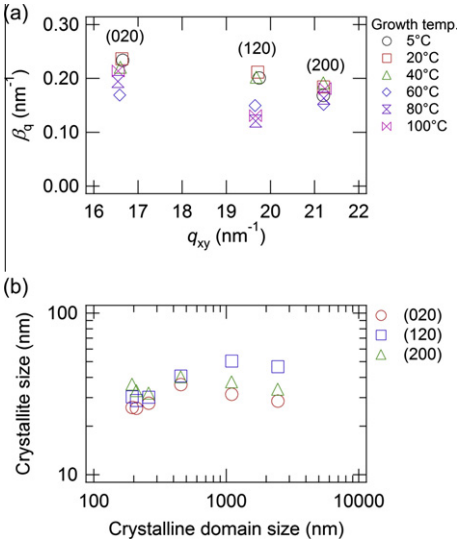

Fig. 3. (a) Williamson–Hall plot of the major GIXD peaks in Fig. 2. (b) Relationship between crystallite size estimated using the Scherrer equation and the polycrystalline domain size of the pentacene film. A Scherrer constant value of 0.95 was used to calculate the crystallite sizes.

In Fig. 3b, the crystallite size calculated from each peak is plotted against the polycrystalline domain size of the film. Although polycrystalline domain sizes are varied more than 10 times by changing the growth temperature, surprisingly, the crystallite sizes are unchanged. The estimated crystallite size is within the range of 25–50 nm and one- to two-orders-of-magnitude smaller than the domain size.

3.3. Comparison with molecular lattice image

To verify the small crystallite size estimated from GIXD, scanning probe microscopy is a good complementary technique. We observed molecular lattice images on flat terraces of a 5 nm-thick (three to four molecular layers) pentacene film using high-resolution frictional force microscopy (FFM), which is suitable for observations of lattice images of organic crystals [34,35]. Fig. 4 shows a 50×50 nm^2 FFM image along with a magnified one which indicates the unit cell structure of thin-film-phase pentacene. White rectangles denote directions of unit cells in each area. Shorter and longer sides correspond to a and b of the unit cell, respectively, and its direction was determined by period of the molecular rows. Judging from the direction of molecular lows, there exist at least three differently oriented crystallites within this area. Similar images were observed for many different terraces in different grains. In most of the same-sized images, at least one boundary between differently oriented crystallites was observed. No strongly anisotropic crystallite shape was seen. The FFM results strongly support the small (25–50 nm) crystallite size estimated by GIXD. Accordingly, a polycrystalline domain of pentacene considered to be a single crystal by many researchers is undoubtedly a mosaic crystal of several tens of nm-sized crystallites.

4. Discussion

4.1. Temperature independent crystallite size

As shown in Fig. 1, the size of a polycrystalline domain generally increases by elevating the growth temperature. This is explained by the decrease in the nucleation density due to the increased desorption rate of the molecules that form the nuclei. Since film growth of pentacene is strongly two-dimensional in this thickness range, the nucleation density at the initial stage of the growth, during the growth of the first or the second molecular layer, determines the polycrystalline domain size. On the other hand, the size of the crystallite is determined by the generation probability of stacking faults during horizontal crystal growth, which interrupts the coherency of the molecular lattice. The generation of stacking faults must be strongly influenced by the roughness of the substrate surface. Fig. 5a shows a fast-Fourier-transform (FFT) spectrum of the surface topography of the SiO_2 substrate used in this work. To improve the signal-to-noise ratio, the FFT spectrum is obtained by averaging eight FFT spectra calculated from line profiles at different positions. A dashed line shows a smoothing result of the FFT spectrum using the 5-point

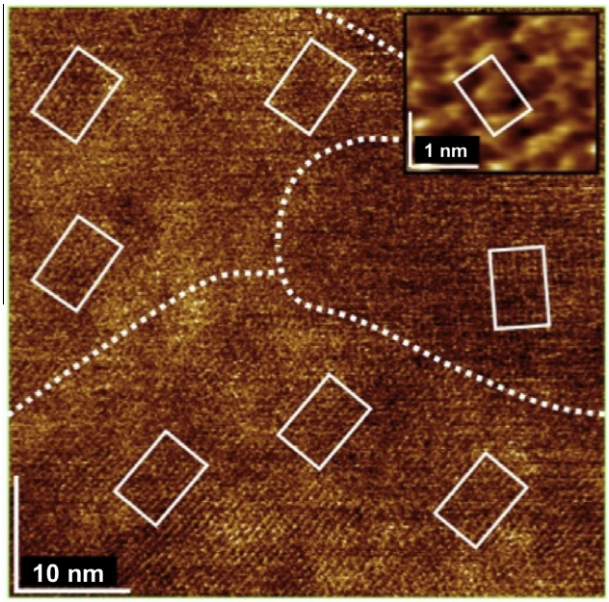

Fig. 4. A 50 × 50 nm^2 molecular lattice image obtained with an FFM on a flat molecular terrace of a pentacene film. The inset shows a magnified image to show a unit cell. Rectangles in the wide image show directions of unit cells in each area and the broken lines show boundaries between differently oriented domains.

Savitzky–Golay method [36]. A clear peak is seen within the range of the crystallite size (25–50 nm), while totally three peaks are prominent in the spectrum. Two peaks seen in the lower frequency side are components with double and quadruple period of the highest frequency one. Minor features in the higher frequency side also indicate the surface topography unless the period does not become smaller than the tip radius, less than 10 nm. Their amplitudes are, however, much smaller than those of the major peaks. Consequently, the highest spatial frequency of the characteristic surface corrugation of the substrate is at around 0.03 nm^{-1} (30 nm in period), which agrees well with the crystallite size. Based on the above discussion, it is highly probable that the crystallite size is regulated by the corrugation of the substrate surface, which induces stacking faults during the growth of the first or second layer [37]. Once these stacking faults are introduced, successive growth of the upper layers will follow the underlying crystallographic structure. Thus, crystallite size cannot be increased even by elevating the growth temperature.

4.2. Origin of HOMO-band-edge fluctuation

Single crystal pentacene exhibits band dispersion of HOMO with a bandwidth of a few hundred meV, and its carrier mobility reaches 40 cm^2/V s [9–12]. These characteristics are produced by high coherency of the molecular lattice and a relatively large transfer integral of the π orbitals. Under this condition, both random strain in the molecular lattice and disruption of lattice coherency lead to modulation of the band structure. According to the GIXD results in this work, the lattice coherency of the pentacene thin-film on SiO_2 is mainly disturbed by the small crystallite size rather than the random strain. Therefore, the mosaic structure of the polycrystalline domain with small crystallites would be the most probable cause of the band-edge fluctuation. To confirm the validity of this assumption, characteristic period of the band-edge fluctuation was also compared to the crystallite size. Inset of Fig. 5b shows a typical line profile of the band-edge fluctuation obtained with AFMP on a polycrystalline domain in a pentacene film grown at 60 °C [16] and Fig. 5b shows its corresponding FFT spectrum together with its smoothing result using the 5-point Savitzky–Golay method. Although AFMP measures a completely different physical property from the topography of the substrate, the FFT spectrum has similar prominent peaks as in Fig. 5a. Based on the same discussion as for Fig. 5a above, the highest spatial frequency of the characteristic band-edge fluctuation is concluded to be around 0.03 nm^{-1} (30 nm in period), which again agrees well with the crystallite size. The characteristic periods of the band-edge fluctuation were nearly constant among many pentacene films grown at different temperatures as in this work. Accordingly, it is highly probable that the mosaic structure with small crystallites causes the band-edge fluctuation. Detailed mechanism of the band-edge modulation is however still an open question. Further investigation using theoretical and computational studies is strongly desired to completely elucidate this issue.

4.3. Overview of HOMO-band-edge and crystallographic structures in pentacene thin films

Fig. 6 schematically summarizes the energy diagram and film structure of a pentacene polycrystalline film based on the results in this work and some previous stud-

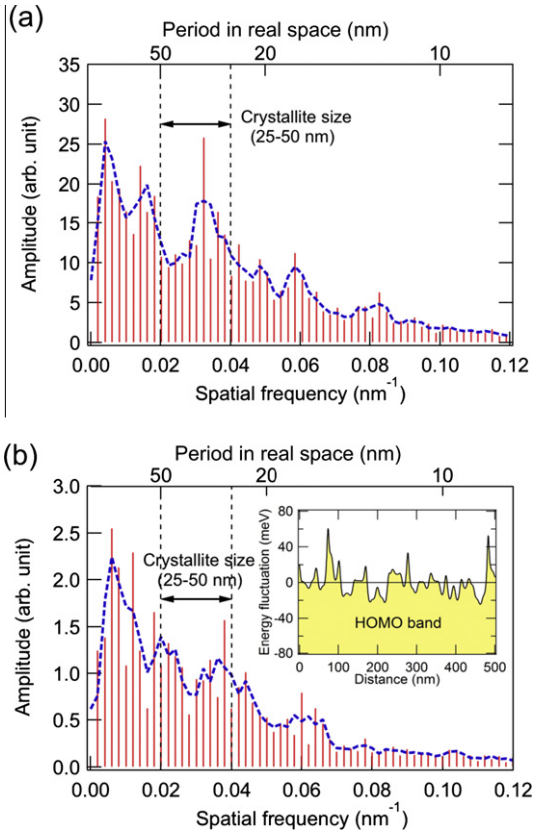

Fig. 5. FFT spectrums of (a) the surface topography of the SiO_2 substrate (average of eight spectra) and (b) the HOMO-band edge profile of the sample grown at 60 °C. Two pairs of dashed vertical lines show the range of crystallite size estimated in this work. Thick dashed lines are smoothing results of the FFT spectra using the 5-point Savitzky–Golay method. The inset in (b) is a typical HOMO-band-edge profile of the same sample taken on a flat terrace of pentacene.

ies [15,16,25]. A pentacene polycrystalline film consists of hierarchical structures, including (i) the micrometer-scale morphological grain, (ii) the polycrystalline domain surrounded by large energy barriers for carrier transport, (iii) the ten-nanometer-scale crystallite, (iv) the unit cell of the crystal, and (v) the molecule. A morphological grain of pentacene on SiO_2 has its nucleus at around the center and four branches grow from the nucleus toward four directions. Each branch finally becomes the polycrystalline domain (ii). During the film growth, they coalesce so as to form, in most cases, a smooth pyramid-shaped morphological grain (i) and the boundary of (ii) is invisible in an AFM image. The boundaries of (i) and (ii) are however almost equivalent and crucial limiting factors for carrier transport because their barrier height is more than 100 meV. Moreover, (ii) is still not a single crystal and the boundary of (iii) introduces 10 meV-scale fluctuations of the band edge. The barrier height at the boundary of (ii) is much higher than that of (iii) because crystal orientations are more different between two neighboring domains than between connected crystallites due to the different orientation of triclinic crystals. Overall apparent carrier mobility of the film is also reduced by the band-edge fluctuation by (iii) because it is proportional to the mobility in (ii) [15].

5. Conclusions

Crystallographic order in the most popular active layer material for OTFT, pentacene polycrystalline thin films grown on SiO_2, was analyzed using in-plane GIXD and FFM. The coherency of the molecular lattice was disturbed not by the random strain but by the size of the crystallites. The crystallite size was estimated to be 25–50 nm and remained almost constant even though the size of the polycrystalline domain was enlarged from 200 nm to 2.5 μm by elevating the growth temperature. A FFM molecular lattice image also indicated the presence of the small crystallite even within a flat molecular terrace. The crystallite size

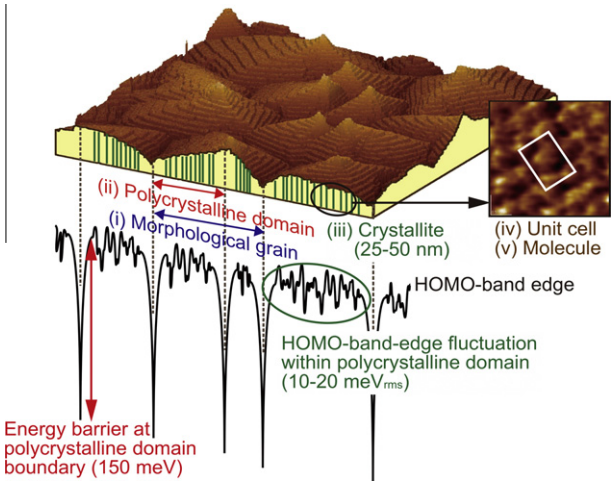

Fig. 6. Schematic illustration showing (top) crystallographic and (bottom) HOMO-band-edge structure in a pentacene polycrystalline film. A pentacene polycrystalline film consists of hierarchical structures, including (i) the micrometer-scale morphological grain, (ii) the polycrystalline domain surrounded by large energy barriers for carrier transport, (iii) the ten-nanometer-scale crystallite, (iv) the unit cell of the crystal, and (v) the molecule.

agreed well with the characteristic periods of both the corrugation of the substrate surface and the HOMO-band-edge fluctuation in a pentacene film. These facts suggest that the surface roughness of the substrate limits the crystallite size and thus band-edge fluctuation is introduced in the HOMO band of pentacene.

Acknowledgment

This work is supported in part by the Chiba University Global COE Program "Advanced School for Organic Electronics" and Grant-in-Aid for Scientific Research (No. 21350099). Synchrotron radiation experiments were performed in the SPring-8 with the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (Proposal No. 2008A1813).

Conjugated copolymers
Donor–acceptor

ABSTRACT

2-Dodecyl benzotriazole and 9,9-dioctylfluorene containing alternating copolymers poly((9,9-dioctylfluorene)-2,7-diyl-(2-dodecyl-benzo[1,2,3]triazole)) (**P1**), poly((9,9-dioctylfluorene)-2,7-diyl-(4,7-bis(thien-2-yl) 2-dodecyl-benzo[1,2,3]triazole)) (**P2**), poly((9,9-dioctylfluorene)-2,7-diyl-(4,7-bis(3-hexylthien-5-yl) 2-dodecyl-benzo[1,2,3]triazole)) (**P3**) were synthesized via Suzuki polycondensation. Electronic and optical properties of resulting polymers showed that all polymers are both p and n dopable and have multicolored electrochromic states. HOMO and LUMO values, band gaps and spectral response of polymers upon externally applied potential and trifluoro acetic acid (TFA) addition were given in detail.

1. Introduction

Conjugated polymers (CPs) have been extensively studied for their potentials as active materials in numerous industrial applications namely, electrochromics (ECDs) [1], light emitting diodes (OLEDs) [2], photovoltaic devices (OPVs) [3], and thin film transistors (OFETs) [4]. They combine the physical properties of polymers with those of semiconductors to obtain unique and novel materials. Since the small structural modifications on polymer backbone allow tuning of band gap and hence their optical and electronic properties, there have been several methods to obtain polymers with desired properties [5]. However, for optoelectronic applications, recent research interest have mainly focused on donor–acceptor (DA) type materials in which alternating electron rich and electron deficient groups are both present on the backbone [6]. Electronic and optical properties of these types of polymers are tuned efficiently by intramolecular charge transfer (ICT) [7]. In terms of electrochromic devices, the use of DA type CPs as active layers became more popular over the time due to their variation of optical properties via structural alternations [8]. Possibility for applications of CPs to large and flexible display devices makes their development significant for future display technologies [9].

Poly-9,9-dialkylfluorenes (**PFOs**) and their copolymers with different groups are considered as some of the most promising materials to be used in organic electronics and have been examined quite extensively up to date [10]. Combination of **PFOs** with an acceptor or a donor–acceptor–donor (DAD) group ensures that the band gap of the polymer can be modified according to device applications [8]. Alkylation of fluorene provides high solubility and stabilizes the carbon atom on 9-position; however, unsubstituted fluorenes form fluorenones which disturb effective conjugation on polymer backbone. These **PFO** copolymers, particularly benzothiadiazole (BTd) derivatives, were used in optoelectronic applications and inserting BTd units in **PFO** chains resulted in highly efficient OPVs, OLEDs and OFETs [11]. On the other hand, benzotriazole (BTz) was introduced to the **PFOs** in few studies where it was used as internal molecular additive [12].

doi:10.1016/j.orgel.2010.11.001

However, properties of alternating copolymers with BTz groups with fluorene are yet lack of scientific inventory. We expect that the use of BTz may bring an improvement on the several properties of such devices.

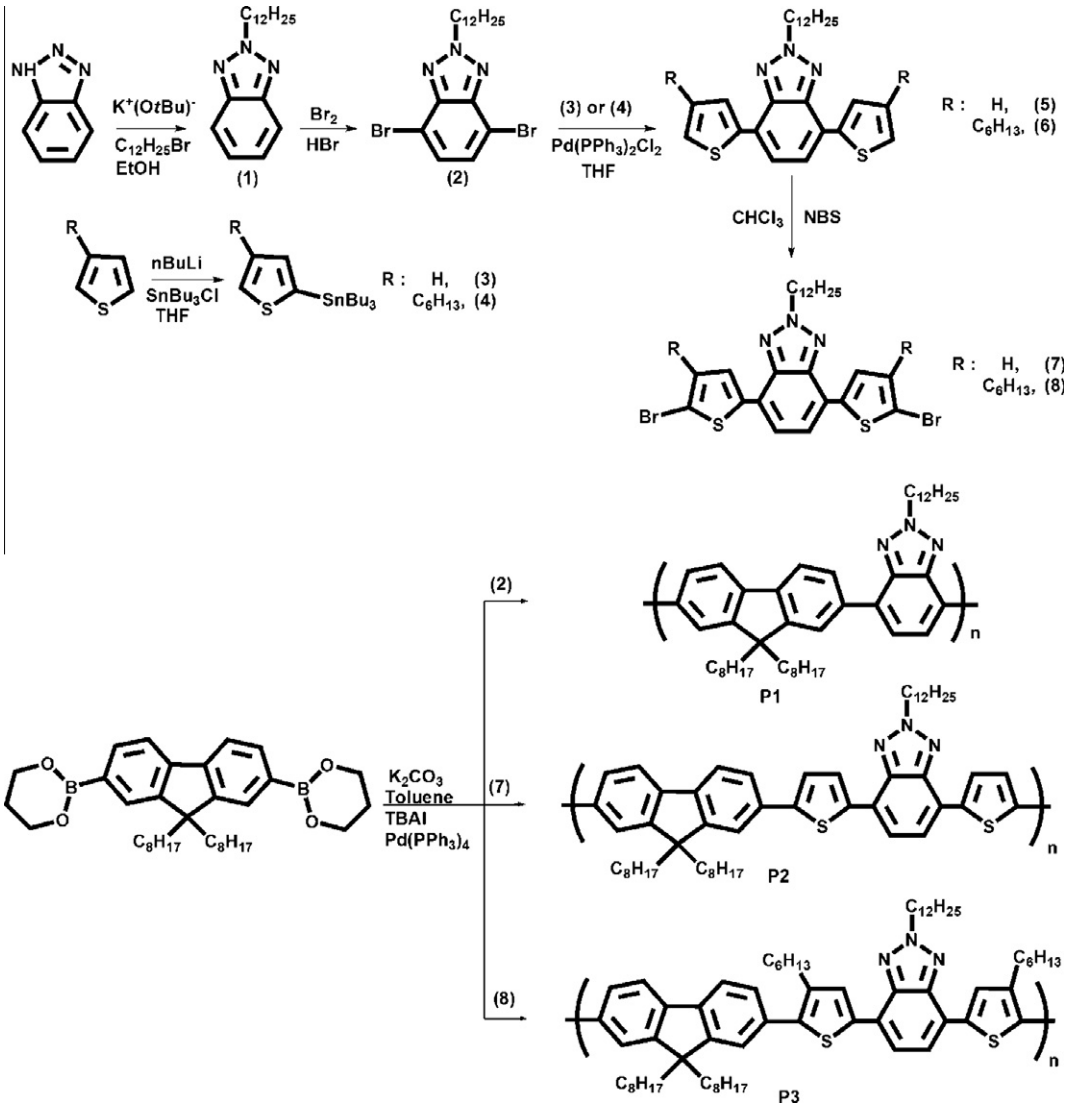
Recently, BTz containing DAD type polymers has been received a great deal of attention in optoelectronic research due to their ease of synthesis and tremendous optical and electronic properties [13]. DAD type polymers of BTz with different donor units were shown to be multipurpose materials for device applications such as ECDs and OPVs with promising results [14].

Here, we report the synthesis and characterizations of benzotriazole and **PFO** containing alternating copolymers **P1**, **P2**, and **P3**. Electronic doping in thin film formed by externally applied potential revealed that polymers **P2** and **P3** are great candidates for multicolored electrochromic device applications. Furthermore, oxidative doping of polymers in toluene resulted in multi-colored solution phases due to varied oxidation states. Electronic and optical properties of new alternating fluorene–BTz copolymers and comparison of results with those of parent polymers (**PFO**, **PTBT**, and **PHTBT**) were given in detail.

2. Results and discussion

2.1. Synthesis

Synthetic pathway for polymers; poly((9,9-dioctylfluorene)-2,7-diyl-(2-dodecyl-benzo[1,2,3]triazole)) (**P1**), poly((9,9-dioctylfluorene)-2,7-diyl-(4,7-bis(thien-2-yl) 2-dodecyl-benzo[1,2,3]triazole)) (**P2**), poly((9,9-dioctylfluorene)-2,7-diyl-(4,7-bis(3-hexylthien-5-yl) 2-dodecyl-benzo [1,2,3] triazole)) (**P3**) is outlined in Scheme 1. The synthesis of 4,7-bis(thien-2-yl) 2-dodecyl-benzo[1,2,3]triazole (**TBT**) [13a] and 4,7-bis(3-hexylthien-5-yl) 2-dodecyl-benzo[1,2, 3]triazole (**HTBT**) [13b] was reported previously by our group.



Scheme 1. Synthetic pathway for **P1**, **P2**, and **P3**.

TBT and **HTBT** were brominated by *N*-bromosuccinimide (NBS) in chloroform ($CHCl_3$). All polymers (**P1**, **P2**, and **P3**) were synthesized by Suzuki cross-coupling reactions [15]. Obtained polymers were purified by Soxhlet extraction using acetone and structurally characterized by ^1H NMR. All polymers are highly soluble in common organic solvents such as chloroform, dichloromethane, THF, and toluene. The average molecular weight (Mn) of **P1**, P2, and **P3** determined by gel permeation chromatography (GPC) using polystyrene as the standards is 5900, 6900, and45,000 g/mol, respectively, with relatively low polydispersity indexes. All the polymers showed excellent thermal stability with decomposition temperature (measured by TGA, 10 °C/min) of more than 350 °C. There was no transition observed up to 300 °C.

2.2. Cyclic voltammetry

For electrochemical characterization, polymers were dissolved in chloroform to a concentration of 5 mg/mL and spray coated on indium tin oxide (ITO) coated glass slides. The polymer films on ITO were subjected to cyclic voltammetry (CV) in ambient conditions to determine the redox potentials in 0.1 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$)/acetonitrile (ACN) solutions at a scan rate of 50 mV/s. The potentials were swept between 1.5 and −2.4 V for **P1**, 1.4 and −2.3 for **P2** and 1.4 V and −2.1 V for **P3** versus Ag wire pseudo-reference electrode (50 mV versus Fc/Fc^+). Initially, polymer films were subjected to a repeated cycling to obtain electrochemically stable and reproducible doping–dedoping (Fig. 1).

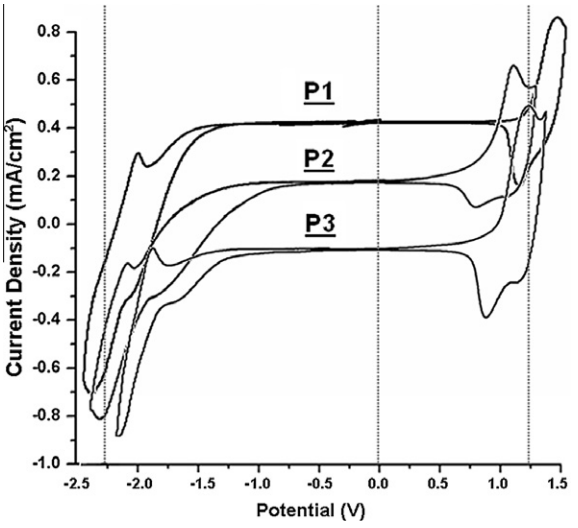


Fig. 1. Cyclic voltammograms for spray coated polymer films of **P1**, **P2**, and **P3** in ACN/$TBAPF_6$ solution at a scan rate of 50 mV/s.

P1 film revealed reversible redox couple at positive potentials pointed at 1.43 and 1.19 V versus Ag wire pseudo-reference electrode. Due to incorporation of electron donating thiophene rings in **P2** chains, polymer film showed lower redox potentials at (1.16 and 0.96 V) compared to those of **P1** versus the same reference electrode (Fig. 1). The highest oxidation potential was observed for **P1** among all as expected since it possesses electron poor structure relative to **P2** and **P3**.

True n-type doping properties of the polymers were investigated by CV which also enabled the determination of HOMO and LUMO levels for polymers electrochemically. Reversible doping/dedoping peaks confirmed that all polymers were both n-type dopable at negative potentials. Reduction of **P2** film was achieved at −2.17 V and the corresponding de-doping peak at −1.96 V which were −2.07/−1.8 V for **P3** and −2.35/−1.96 V for **P1**.

Due to their dual properties, HOMO/LUMO energy levels were calculated precisely from the onset potentials of p and n doping peaks from CV. The onset values were estimated by taking the intersection between the baseline and the tangent line drawn to the increasing part of the current. The reference electrode and all the results were subsequently calibrated to Fc/Fc^+ and the band energies were calculated relative to the vacuum level considering that the value of NHE is −4.75 eV versus vacuum. Table 1 summarizes the electrochemical data for polymers **P1**, **P2**, and **P3**. As seen from table, higher onset potentials for **P3** due to sharper p and n doping peaks than those of **P2** resulted in slightly higher HOMO energy and a wider electronic band gap. The electrochemical band gap values were calculated from the onset potentials as 2.56 and 2.68 eV for **P2** and **P3**, respectively. Calculated electrochemical band gaps were comparatively higher than the ones estimated from π–π^* transition due to the creation of free ions by means of applied potential [16].

In order to have a better understanding on structure–electronic properties relationship for **PFO** copolymers, they were compared with previously reported parent polymers **PFO**, **PTBT**, and **PHTBT** in terms of their HOMO/LUMO energy levels (Chart 1). π–π interaction between donor and acceptor determines the match between these units and plays a crucial role on the electronic properties of the resulting polymers since it influences the intramolecular charge transfer in these types of polymers [7a]. Fig. 2 shows that the addition of fluorene unit in **PTBT** did not

Table 1
Oxidation potentials and onset values for both p- and n-type doping, estimated HOMO–LUMO energies and band gaps of synthesized polymers **P1**, **P2**, and **P3**.

	Oxidation potential (V)		Reduction potential (V)		Band gap (eV)		Energy levels[a] (eV)	
	E_{ox}	E_{ox}^{onset}	E_{red}	E_{red}^{onset}	E_g^{ec}	E_g^{op}	HOMO	LUMO
P1	1.43	1.19	−2.35	−1.78	2.97	2.55	−5.94	−2.97
P2	1.16	0.96	−2.16	−1.60	2.56	2.16	−5.71	−3.15
P3	1.25	0.98	−2.10	−1.70	2.68	2.24	−5.73	−3.05

[a] Calculated from CV.

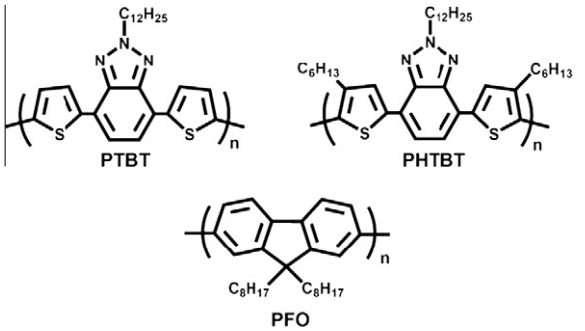

Chart 1. Chemical structures of related polymers.

significantly alter the electronic band gap of the resulting polymer **P2** (2.56 eV), but only lowered the HOMO–LUMO levels ca. 0.1 eV. Considering the energy levels of **P3**, LUMO level was intact upon addition of **PFO**, however; HOMO of the polymer was lowered due to the contribution of valence band (VB) of **PFO** and resulted in a higher electrochemical band gap (Fig. 2).

Although **PHTBT** has slightly lower band gap than **PTBT**, thiophene containing polymer **P2** revealed narrower band gap than that of its hexyl thiophene included analogue **P3**. This may be due to the steric interactions between the hexyl groups and the adjacent fluorene units. The same trend also is the case for benzothiadiazole bearing copolymers [18]. According to donor–acceptor approach, increasing donor strength should have raised the HOMO level while having less effect on LUMO energy. However, here both HOMO and LUMO levels were affected by incorporation of electron rich thiophene and hexyl thiophene units to **P1**.

2.3. Spectral properties

Neutral **P1**, **P2**, and **P3** films were spray coated on ITO coated glass slides from a solution of 3 mg/mL in chloroform. UV–vis–NIR spectra were recorded for corresponding polymer films in 0.1 M $TBAPF_6$/ACN solution upon gradually increased external bias. Coated films were subjected to subsequent redox cycling by CV to obtain electrochemical stability prior to spectroelectrochemical analysis. Fig. 4 exhibits that λ_{max} values for the π–π^* transitions for **P2** and **P3** were centered at 503 and 460 nm, respectively. Substitution of 9,9′-dioctyl fluorene units resulted in blue shifted absorption for polymers **P2** and **P3** compared to their previously studied parent polymers **PTBT** and **PHTBT**. Stepwise oxidation of the polymer films by applied external potentials resulted in a decrease in the π–π^* transitions and their lower energy transitions intensified at 715 and 1560 nm for both **P2** and **P3**. These absorbance bands in near-IR (NIR) region indicate the formation of lower energy charge carriers such as polarons and bipolarons. Visible polaronic absorbance for **P2** and **P3** allowed detection of different colored states upon stepwise oxidations. However, their electron poor homologue **P1** revealed blue shifted dominant wavelengths both in visible and in NIR regions (Fig. 3) which were consistent with electrochemical data. Electron deficient structure of **P1** complicated the formation of positive charge carriers on the polymer backbone upon oxidative doping. Thus, the neutral state absorption in the visible region (430 nm) did not reveal a significant depletion as **P2** and **P3** but hypsochromically shifted to 380 nm. Although the oxidation potential for **P1** was determined as 1.43 V, spectroelectrochemical data were recorded up to 1.3 V since at higher potentials no spectral change was observed. This indicates the limited formation of polaronic and bipolaronic bands for **P1** (Fig. 3).

Since neutral state absorptions for **P2** and **P3** are at around 400 nm and lower energy transition emerged at 700 nm, partially oxidized polymer films revealed green color for which these two absorption maxima are crucial. Further oxidation of polymer films resulted in blue color due to diminished π–π^* transition intensity.

Highly soluble polymers **P2** and **P3** were dissolved in toluene (8×10^{-3} mg/mL) and oxidatively doped by the stepwise addition of trifluoroacetic acid (TFA). TFA addition to solutions was continued until no spectral change was observed. As seen from the spectra (Figs. 4 and 5), initially neutral **P2** and **P3** have absorption maxima at 475 and 446 nm, respectively, in solution. Upon addition of

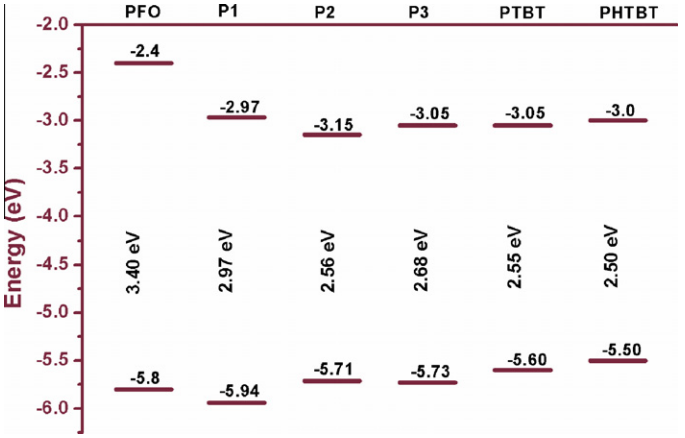

Fig. 2. HOMO/LUMO levels and band gaps of related polymers. Values for **PFO** [17], **PTBT** [13a], and **PHTBT** [13b] were taken from previous reports.

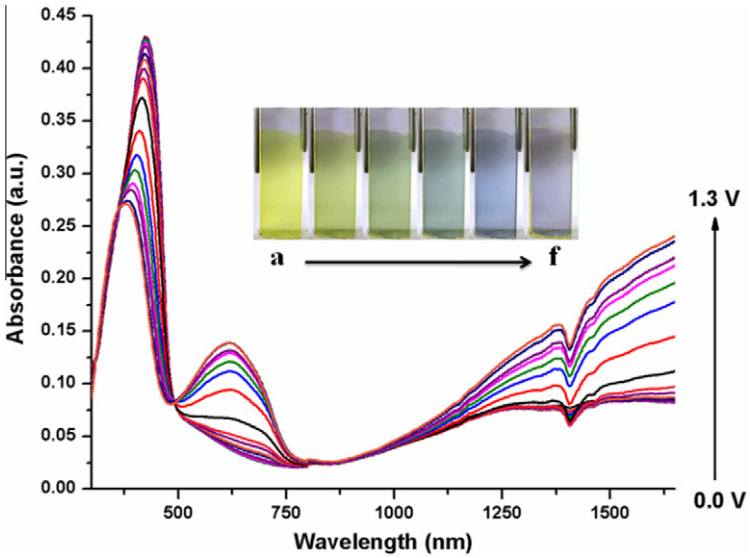

Fig. 3. Electrochemical p-type doping electronic absorption spectra of **P1** between 0.0 and 1.3 V with 0.1 V potential intervals.

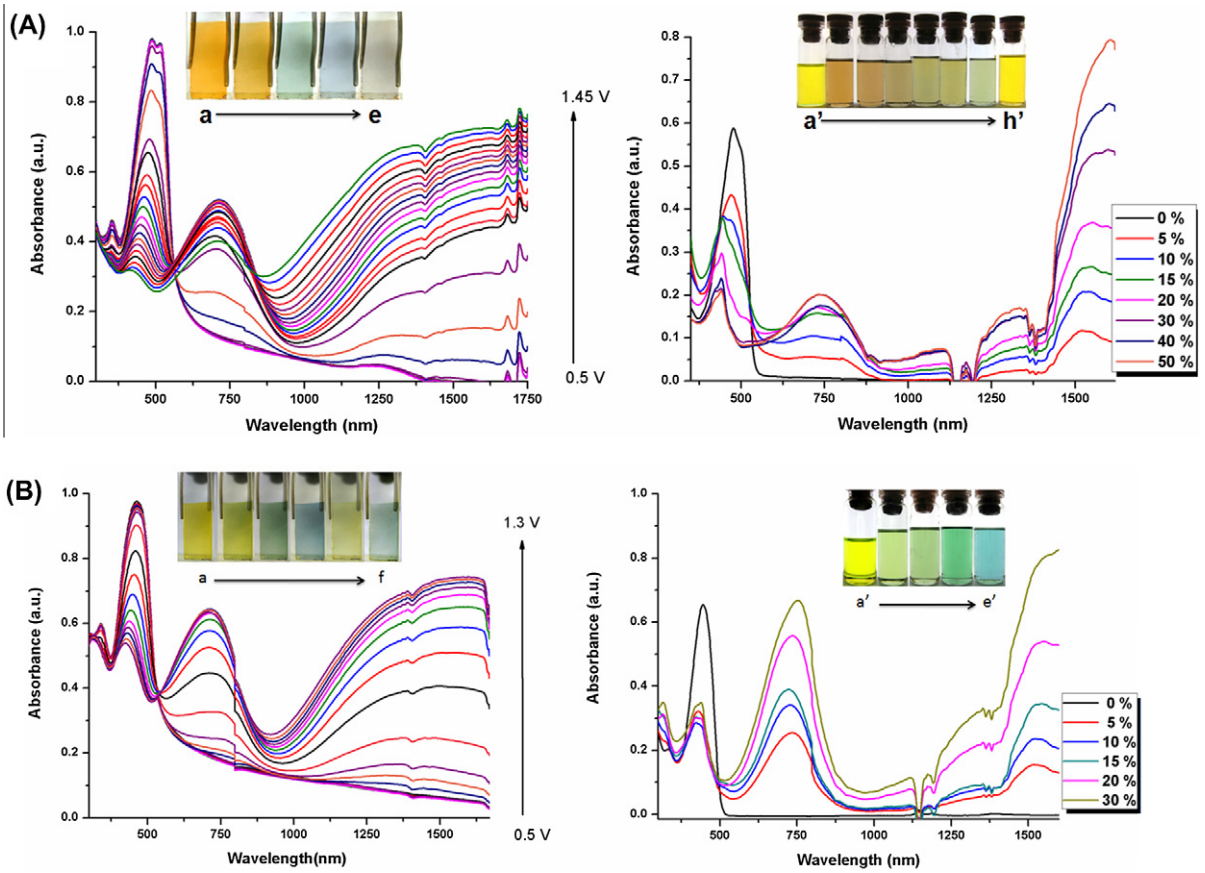

Fig. 4. (A) UV–vis–NIR spectra of **P2** in film form (left) and in toluene (right). (a) 0.5, (b) 0.8, (c)1.0, (d) 1.2, and (e) −2.16 V and (a′) 0%, (b′) 5%, (c′) 10%, (d′) 20%, (e′) 30%, (f′) 40% (g′) 50% TFA (v:v) and (h′) dedoped form with 1 mL TEA. (B) UV–vis–NIR spectra of **P3** in film form (left) and in toluene (right). (a) 0.5, (b) 0.8, (c) 1.0, (d) 1.2, (e) −2.0, and (f) −2.10 V and (a′) 0%, (b′) 5%, (c′) 10%, (d′) 20%, and (e′) 30% TFA (v:v).

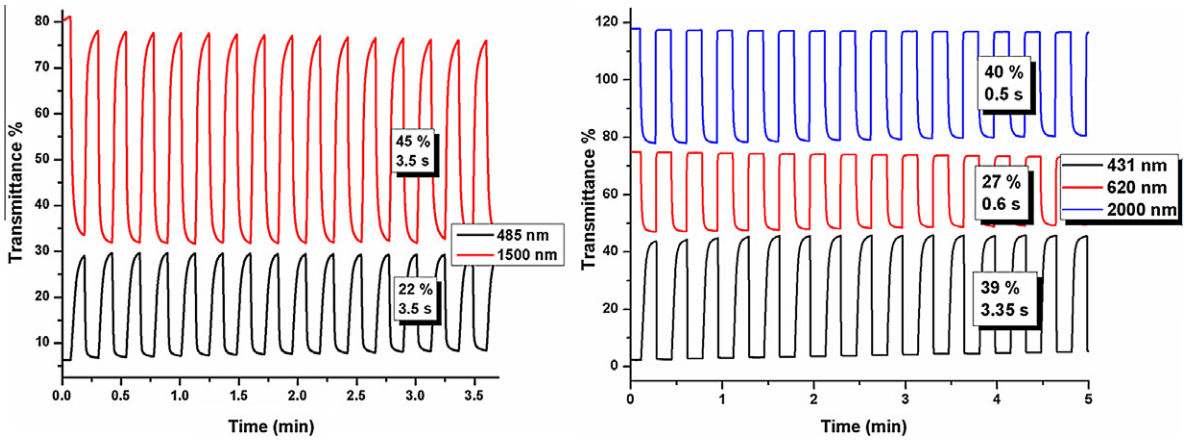

Fig. 5. Kinetic switching results in both visible and NIR regions for **P1** (right) and **P2** (left).

5% TFA (v:v) new absorption bands emerged at 750 and 1550 nm which are accompanied by a decrease in neutral state absorptions. The sharp peaks for the π–π^* transitions resulted in wider band gaps for polymers in solution than in film due to trapped dopant ions and the more dense polymer morphology in film form. The oxidative doping also resulted in color change in solutions. Neutral solutions of both polymers were yellow however upon the addition of TFA, the solution turned into green and blue as is shown as inset picture in Fig. 4[1] for **P2** and **P3**, respectively.

After doping, 1 mL of triethyl amine (TEA) was added to solutions which resulted in immediate appearance of the initial colors for both polymer solutions. This indicates the reversibility of solution doping process by adding TFA and pH responsive characters of polymers. It is worth noting that spectral responses of the polymers to stepwise oxidation were identical in both solution and thin film forms regardless of the doping or dopant type. Any color or spectral change was not observed by TFA addition to **P1** although reversible doping (both p and n) and de-doping were possible in thin film form electrochemically. This obviously indicates the effect of the presence of thiophene unit on solution doping process. Oxidation starts on electron rich thiophene heterocycle prior to charge transport along the conjugated polymer backbone (Fig. 4B).

Absorption spectra for **P2** revealed isosbestic point in thin film form which confirms the coexistence of discrete chromophores which is not taking place in solution. However, **P3** showed isosbestic point both in film and in solution indicating well-separated chromophores. That also eased the detection of different colors for **P3** solutions upon TFA addition in toluene.

The electrochemical stability as well as percent transmittance changes can be monitored by successive potential cycling of the polymer films in monomer-free solutions. Optical studies were carried out for polymers **P1** and **P2** in ACN/$TBAPF_6$ solution in order to observe the changes between their neutral and fully oxidized states upon applied external bias within 5 s time intervals. Percent transmittance changes were recorded for **P2** at its dominant wavelengths at 485 and 1500 nm. The polymer film revealed 22% optical contrast with a switching time of 3.5 s in visible region and 45% transmittance change (3.5 s) was recorded between doped and de-doped states in NIR region (Fig. 5). Although the switching times were relatively slow, the polymer film was stable upon repetitive cycles. Due to the high rigidity in **P3** films which stems from the long alkyl chains on both fluorene, thiophene and benzotriazole units, reasonable kinetic values could not be acquired. Since **P1** revealed a blue shift for high energy transition upon oxidation, it showed relatively high optical contrast for the one observed at 431 nm (Fig. 5).

3. Conclusion

Multicolored electrochromic alternating **PFO** and BTz copolymers **P1**, **P2** and **P3** were synthesized and investigated in terms of their electronic and optical properties. Convenient HOMO and LUMO levels, band gaps, and strong absorptions in the visible region suggest that they should be tested for various optoelectronic applications. Solution doping of **P2** and **P3** revealed multicolored solutions which make them pH responsive chromophores that may be used in different applications in due course. Reported properties prove that fluorene and BTz-based copolymers are multipurpose materials which will be subject of further research interest in near future.

4. Experimental

4.1. General

All chemicals were used without further purification as they were purchased from commercial sources. All reactions were carried out under argon atmosphere unless otherwise mentioned. Electrochemical studies were performed in a three-electrode cell consisting of an indium tin oxide doped glass slide (ITO) as the working electrode,

[1] For interpretation of color in Fig. 4, the reader is referred to the web version of this article.

platinum wire as the counter electrode, and Ag wire as the reference electrode under ambient conditions using a Voltalab 50 potentiostat. The value of normal hydrogen electrode (NHE) was taken as −4.75 eV [19]. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on Bruker Spectrospin Avance DPX-400 Spectrometer. Chemical shifts were given in ppm downfield from tetramethylsilane. Varian Cary 5000 UV–vis spectrophotometer was used to perform the spectroelectrochemical studies of the polymer. Average molecular weight was determined by gel permeation chromatography (GPC) using a Polymer Laboratories GPC 220. Differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA) were performed on Perkin Elmer Diamond DSC and Perkin Elmer Pyris 1 TGA. Trifluoroacetic acid (TFA) used for solution doping was 99%. 2-Dodecylbenzotriazole [13], 4,7-dibromo-2-dodecyl benzotriazole [13], tributyl(thiophen-2-yl) stannane [20], tributyl(4-hexylthiophen-2-yl)stannane [21], 4,7-bis(thien-2-yl) 2-dodecyl-benzo[1,2,3]triazole (TBT) [13a], 4,7-bis(3-hexylthien-5-yl) 2-dodecyl-benzo[1,2,3]triazole (**HTBT**) [13b] were synthesized according to previously published procedures.

4.2. Synthesis of 4,7-bis(5-bromothien-2-yl)-2-dodecylbenzo[1,2,3]triazole (7)

Two hundred milligrams of TBT (0.44 mmol) and 190 mg of *N*-bromosuccinimide (1.07 mmol) were stirred in 100 mL of $CHCl_3$ at room temperature by preventing the mixture from light exposure. After 12 h, solvent was removed under reduced pressure and crude product was filtered over silica by $CHCl_3$ to obtain 250 mg (93%) 7 as yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$, δ): 7.72 (d, J = 5.6 Hz, 2H), 7.44 (s, 2H), 7.04 (d, J = 6.0 Hz, 2H), 4.72 (t, J = 7.0 Hz, 2H), 2.10 (m, 2H), 1.32–1.17 (m,18H), 0.80 (t, J = 6.9 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$-d_6, δ): 144.4, 142.2, 140.4, 127.3, 125.8, 123.9, 123.0, 57.1, 32.2, 30.3, 29.9, 29.8, 29.7, 29.6, 29.5, 29.3, 26.9, 22.9, 14.4. MS (m/z): 608 [M+].

4.3. Synthesis of 4,7-bis(5-bromo-4-hexylthien-2-yl)-2-dodecylbenzo[1,2,3]triazole (8)

Bromination of **HTBT** was performed with the same procedure explained for TBT above. Two hundred milligrams of **HTBT** (0.32 mmol) and 138 mg of *N*-bromosuccinimide (0.77 mmol) were used to obtain 235 mg (94.4%) 8 as yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$, δ): 7.69 (s, 2H), 7.41 (s, 2H), 4.77 (t, J = 8.0 Hz, 2H), 2.61(t, J = 8.0 Hz, 4H) 2.16 (m, 2H), 1.65 (m, 4H), 1.41–1.24 (m, 26H), 0.91–0.85 (m, 9H); ^{13}C NMR (100 MHz, $CDCl_3$, δ): 143.1, 141.7, 139.2, 127.5, 123.0, 122.0, 110.1, 56.8, 32.0, 31.7, 30.0, 29.8, 29.7, 29.6, 29.5, 29.4, 29.1, 29.0, 26.7, 22.7 14.1. MS (m/z): 778 [M+].

4.4. General route for synthesis of *P1*, *P2,* and *P3*

Dibromo compound (1 mol equivalent), 2,2′-(9,9-dioctyl-9H-fluorene-2,7-diyl)bis(1,3,2-dioxaborinane) (1 mol equivalent), $Pd(PPh_3)_4$ (5 mol%), and tetrabutylammonium iodide ($N(Bu)_4I$, 1 mol%) were added into a degassed mixture of potassium carbonate (K_2CO_3, 2 M in H_2O), toluene (3:2 toluene:water). The mixture was refluxed at 115–120 °C for 48 h under argon. Solvent was removed and extracted with $CHCl_3$:H_2O twice to remove alkali solution. Combined organic layers were dried over anhydrous $MgSO_4$ and evaporated under reduced pressure. The crude product was washed with methanol and Soxhlet extracted by acetone to obtain corresponding polymer. **P1**: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 8.20 (benzotriazole), 8.1 (fluorene), 7.9 (fluorene), 7.7 (fluorene), 4.8 (N–CH_2), 2.2 (C–CH_2), 1.6–0.7 (pendant alkyl chains). GPC: Mn: 5900, Mw: 10,600, PDI: 1.8, **P2**: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 8.1 (benzotriazole), 8.8–8.5 (fluorene, thiophene), 7.4 (thiophene), 4.8 (N–CH_2), 2.2 (C–CH_2), 1.6–0.7 (pendant alkyl chains). GPC: Mn: 6900, Mw: 17,500, PDI: 2.5, **P3**: 1H NMR (400 MHz, $CDCl_3$, δ): 8.00 (benzotriazole), 7.8 (fluorene), 7.6 (fluorene), 7.4 (fluorene, thiophene), 4.9 (N–CH_2), 2.8 (CH_2), 2.2 (C–CH_2), 1.8–0.7 (pendant alkyl chains). GPC: Mn: 45,000, Mw: 183,000 PDI: 4.1.

ABSTRACT

Two new copolymers were synthesized by electrochemical polymerization of 2-[3-thienylmethylene]aminophenol (2,3-TMAP) and poly-2-[3-thienylmethylene]aminophenol (P-2,3-TMAP) with thiophene (Th) and the obtained thiophene copolymers were examined as electrochromic materials. Electro copolymerization reactions of the compounds were performed in acetonitrile (AN)/boron trifluoride ethyl etherate (BF_3EtE) solvent mixture (9:1, v/v) where $LiClO_4$ utilized as the supporting electrolyte. After electro copolymerization reaction, obtained electrochromic films deposited on ITO glass plates, 2,3-TMAP-co-Th and P-2,3-TMAP-co-Th, were investigated as spectroelectrochemically. The new electrochromic materials derived from Schiff base substituted-phenol/oligophenols are red colored at low potentials and blue colored at high potentials. Electro copolymerization mechanism was identified. Spectroelectrochemical monitoring showed good absorption recovery for P-2,3-TMAP-co-Th, while absorbance decrease was observed for 2,3-TMAP-co-Th during the repeated potential scans. Suitable potential range for operating the device from red to blue was found to be between 0 and +1.4 V. P-2,3-TMAP-co-Th showed 12–13% transmittance changes at applied potentials and the response times were 3.1 and 4.1 s for 476 and 800 nm, respectively. As a result P-2,3-TMAP-co-Th may be good candidate for electrochromic devices and can be thought as a feasible nominee for anodically coloring electrochromic layers in ECDs.

1. Introduction

Electrochromism is defined as reversible change in optical properties of a material like absorbance, transmittance, color, etc. [1]. Several kinds of electrochromic materials have been synthesized and characterized, so far [2]. A few SNS (thiophene–pyrrole–thiophene) derived electrochemical devices were also synthesized and improved as color-switching materials with different colors in oxidized and reduced states. Several color changes of SNS derivatives were observed like dark purple-blue [3], yellow-green-violet [4], and yellow-blue [5], etc. Polythiophene derivatives and its copolymer kinds have been widely chosen in improving such electrochromic devices. Polythiophenes are an important representative class of conducting polymers that can be used as electrical conductors [6]. Synthesis of new polythiophene derivatives with improved conductivity and processing properties is an important part of conducting polymer research [7]. Polythiophenes, a versatile class of conjugated polymers, are still of growing interest due to their potential applications in the development of new materials such as photovoltaics [8,9], electrochromic devices [10,11] and energy storage [12,13]. Processability and easy modification of monomer that alters properties of the conducting polymers (CP) have, therefore, attracted the attention of both academia

and industries. Conducting polymers generally reveal an optical absorption band in the visible region due to their extended delocalization of the p electrons along the polymer backbone. Upon doping, charge carriers are formed in the conjugated backbone, namely polaron and bipolarons, which results in a change in the optical spectra [14]. One of the most important characteristics exhibited by the polymers of polythiophene family is their enhanced electrochromism upon application of a small voltage. A variety of conjugated polymers have colors both in the oxidized and reduced states since the band gap is in the visible region. After oxidation, the intensity of the π–π^* transition decreases, and two low energy transitions emerge to produce a second color. Therefore, there are many absorption changes in the visible region of the spectrum making them useful in the construction of electrochromic devices [15]. Polymers with imine (HC═N) linkages are isoelectronic with the HC═CH linked derivatives and result in significant difference in the electronic and opto electronic properties. Tsai et al. found that thiophene based poly(azomethine)s had lower band gaps than the phenylene based similar kinds [16]. Also, variation of the backbone ring and donor/acceptor side group on the phenylene ring significantly affected the electronic properties (like band gap) of the poly(azomethine)s. Schiff base substituted carbazole derivatives combined with thiophene moieties have been copolymerized electrochemically in the presence of thiophene and a clearly color change from yellow to green was observed when the potential increased from 0 up to 1.6 V [17]. Some kinds of imine coupled pyrrole monomers have been also employed as the comonomer agents to obtain new electrochromic materials via electrochemical copolymerization with pyrrole [18]. Ali et al. have investigated optical radio-chromic properties of polyaniline and found that imine (HC═N) linkages between the aniline units at the emeraldine form are responsible for the green color [19]. Other polyazomethine derivatives are still needed to examine as electrochromic materials. In all mentioned studies imine linkages were placed in polymer backbones. However, at the present study we synthesized new polythiophene derivatives with conjugated side phenylene/polyphenylene units bound with imine linkages. These conjugated side groups were expected to increase the conjugation length of polythiophene resulting in new electrochromic properties.

Oligophenol derivatives of Schiff bases have been previously synthesized and investigated as semi-conductive polymers by Kaya and co-workers [20–23]. Obtained Schiff base-substituted oligophenols were also found to be electroactive materials [24]. Also, obtained polymers have been studied with their optical and thermal properties as well as anti microbial activity [25]. However, their processibility as electrochromic devices are still interest. For this need we investigated the electrochromic application of newly synthesized imine-bounded phenol and oligophenol (2,3-TMAP and P-2,3-TMAP) containing electropolymerisable thiophene moiety as the side group. Electro copolymerization was carried out in the presence of thiophene. Potential range used in the experiments was 0–1.4 V. According to the obtained results the synthesized 2,3-TMAP and P-2,3-TMAP copolymers are red colored at 0 V and blue colored at 1.4 V. Resultantly, we demonstrated that Schiff base substituted oligophenol derivatives could also be used in construction of new electrochromic devices (ECDs).

2. Experimental

2.1. Chemicals

2-aminophenol, methanol, DMSO, KOH, acetonitrile (AN) and hydrochloric acid (HCl, 37%) were supplied from Merck Chemical Co. Thiophene-3-carboxyaldehyde and thiophene (Th) were supplied from Aldrich. Boron trifluoride ethyl etherate (BF_3EtE) and sodium hypo chloride (NaOCl) (30% aqueous solution) were supplied from Fluka and Paksoy Chemical Co. (Turkey), respectively.

2.2. Synthesis of 2-[3-thienylmethylene]aminophenol (2,3-TMAP)

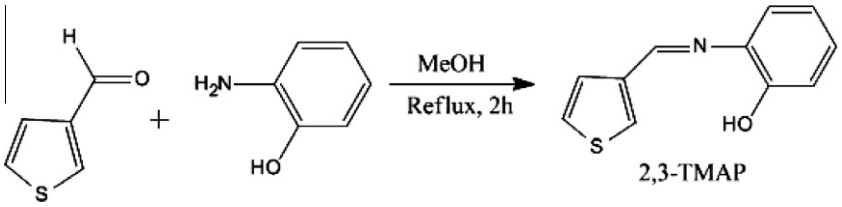
2-[3-Thienylmethylene]aminophenol (2,3-TMAP) was prepared by the condensation of thiophene-3-carboxyaldehyde (1.22 g, 0.01 mol) with 2-aminophenol (1.37 g, 0.01 mol) in methanol (30 ml) achieved by boiling the mixture under reflux for 2 h (Scheme 1). The precipitated Schiff base was filtered, recrystallized from methanol and dried in a vacuum desiccator at 80 °C [20].

UV–vis (λ_{max}) (DMSO): 254, 268 and 343 nm. FT-IR (cm^{-1}): (OH aromatic) 3297; (C–H aromatic) 3083, 3035; (–CH═N–) 1615, (C═C phenyl) 1595, 1580, 1480; (C–S) 785. ^{1}H NMR (DMSO-d_6): δ ppm, 9.93 (s, 1H, –OH), 8.68 (s, 1H, –CH═N–), 7.81 (s, 1H, Ar–Ha), 7.69 (d, 1H, Ar–Hb), 7.02 (d, 1H, Ar–Hc), 7.25 (d, 1H, Ar–Hd), 7.19 (t, 1H, Ar–He), 6.90 (t, 1H, Ar–Hf), 7.39 (d, 1H, Ar–Hg).

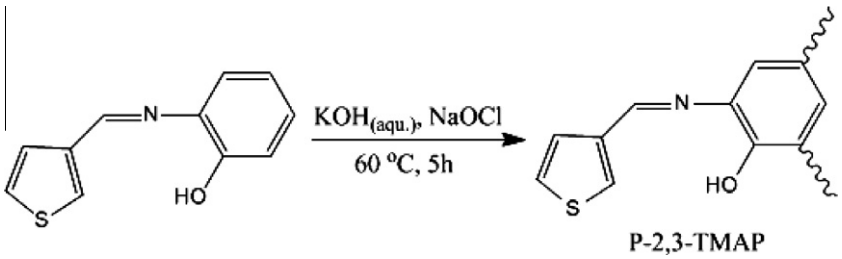
2.3. Oxidative polymerization of 2,3-TMAP

P-2,3-TMAP was synthesized through oxidative polycondensation of 2-[3-thienylmethylene]aminophenol using NaOCl as the oxidant [23–25]. 2,3-TMAP (0.203 g, 0.001 mol) was dissolved in an aqueous solution of KOH (10%, 0.001 mol) and placed into a 50 ml three-necked round-bottom flask which was fitted with a condenser, thermometer, stirrer and an addition funnel containing 2 ml of NaOCl aqueous solution (30% by weight). After heating up to 60 °C, NaOCl was added drop by drop over about 20 min. Reaction was maintained for 5 h. Then, the reaction mixture was cooled at the room temperature, 0.001 mol HCl (37%) added for neutralization, and kept for 24 h at the room temperature for precipitation of the polymer. The mixture was filtered, washed with hot water (3×25 ml) and methanol (2×20 ml) to separate the mineral salts and unreacted monomers, respectively. The obtained polymer dried in a vacuum oven at 60 °C for 24 h. The reaction design is given in Scheme 2.

UV–vis (λ_{max}) (DMSO): 260, and 438 nm. FT-IR (cm^{-1}): (OH aromatic) 3228; (C–H aromatic) 3100; (–CH═N–) 1605, (C═C phenyl) 1566, 1516, 1497; (C–S) 747. ^{1}H NMR (DMSO-d_6): δ ppm, 10.02 (s, 1H, –OH), 9.20 (s, 1H,



Scheme 1. Synthesis of 2-[3-thienylmethylene]aminophenol (2,3-TMAP).

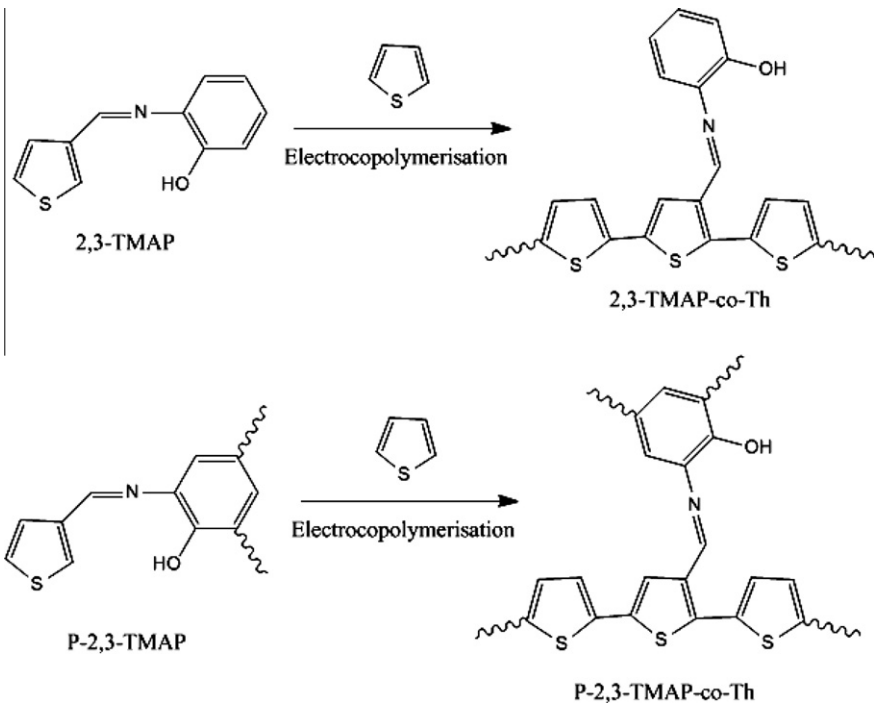


Scheme 2. Synthesis of poly-2-[3-thienylmethylene]aminophenol (P-2,3-TMAP).

–CH=N–), 8.79 (s, 1H, Ar–Ha), 8.61 (d, 1H, Ar–Hb), 7.62 (d, 1H, Ar–He), 7.33 (d, 1H, Ar–Hc), 6.88 (d, 1H, Ar–Hd).

2.4. Electrochemical copolymerization of 2,3-TMAP and P-2,3-TMAP with thiophene

Cyclic voltammetry (CV) measurements were carried out with a CHI 660 C Electrochemical Analyzer (CH Instruments, Texas, USA) at a potential scan rate of 200 mV/s. CV was employed in order to assay the electroactivity of the compounds and to determine the oxidation–reduction peak potentials. Electro polymerizations were carried out in the presence of thiophene. The system consists of a CV cell containing indium tin oxide (ITO)-coated glass plate as the working electrode, platinum wire as the counter electrode, and Ag wire as the reference electrode. The measurements were carried out in $LiClO_4$ (0.1 M)/acetonitrile (AN:BF_3EtE) (9:1, v/v) solvent mixture at the room temperature under argon atmosphere [5]. Electrocopolymerizations were carried out as follows: 2,3-TMAP or



Scheme 3. Electro polymerization reaction of 2,3-TMAP and P-2,3-TMAP in the presence of thiophene (Th).

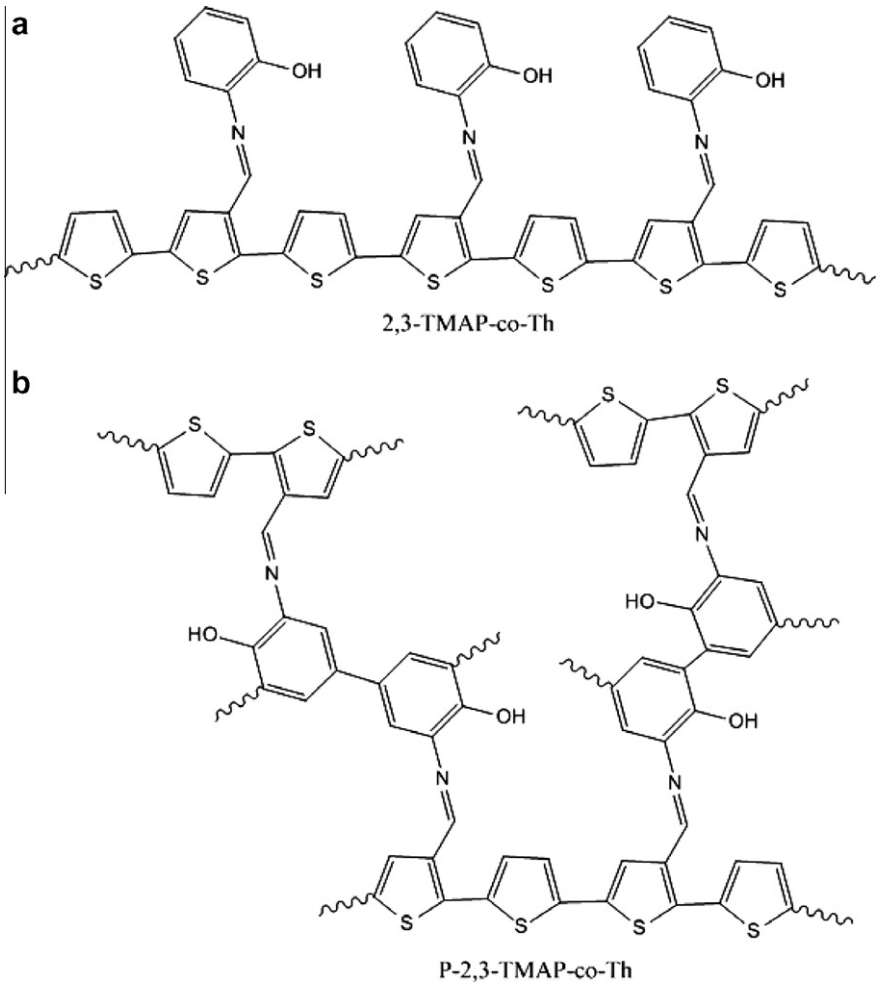
P-2,3-TMAP (1 g/L) was dissolved in 10 ml 0.1 M AN/$LiClO_4$:BF_3EtE (9:1, v/v) and placed into a CV cell. Four milligrams of thiophene was added into the cell. Electro polymerizations were run by repeated electrochemical scanning of the solutions between 0 and 1400 mV (scan rate: 200 mV/s; cycle number: 24 and 50 for 2,3-TMAP and P-2,3-TMAP, respectively). Resulting copolymer films were washed with AN to remove $LiClO_4$ and BF_3EtE. Polythiophene film was also deposited on ITO glass plate for comparison by similar method (cycle number: 9, scan rate: 200 mV/s) [26]. Electro polymerization reactions of 2, 3-TMAP and P-2,3-TMAP and their possible structures are given in Schemes 3 and 4, respectively.

2.5. Spectroelectrochemistry

In order to carry out the spectroelectrochemical experiments, the copolymer films were used which were electrochemically deposited on ITO-coated glasses. Spectroelectrochemical and electrochromic measurements were made in AN/$LiClO_4$ using Ag wire as the reference and a Pt wire as the auxiliary electrodes. The data obtained from the cyclic voltammetry measurements were used for spectroelectrochemical measurements of the copolymer films [27]. These measurements were carried out to consider absorption spectra of these copolymer films under applied voltages. The spectroelectrochemical cell includes a quartz cuvette, a Ag wire (RE), Pt wire counter electrode (CE) and polymer film coated ITO/glass as transparent working electrode (WE). These measurements were carried out in the 0.1 M $LiClO_4$ as supporting electrolyte in AN.

2.6. Solubility and characterization techniques

The solubility tests of 2,3-TMAP and P-2,3-TMAP were done in different solvents by using 1 mg sample and 1 ml solvent at 25 °C. 2,3-TMAP is completely soluble in organic solvents such as methanol, acetone, acetonitrile, THF, ethyl acetate, chloroform, DMSO, and H_2SO_4 but it was partly soluble in toluene. 2,3-TMAP was insoluble in heptane. P-2,3-TMAP was dark brown in powder form and was completely soluble in strong polar solvents like DMSO and H_2SO_4. However, P-2,3-TMAP was partly soluble in methanol, acetonitrile, toluene, acetone, ethyl acetate, chloroform, THF whereas insoluble in heptane.



Scheme 4. Possible structure of 2,3-TMAP-co-Th (a) and P-2,3-TMAP-co-Th (b) including iminophenol as the side groups.

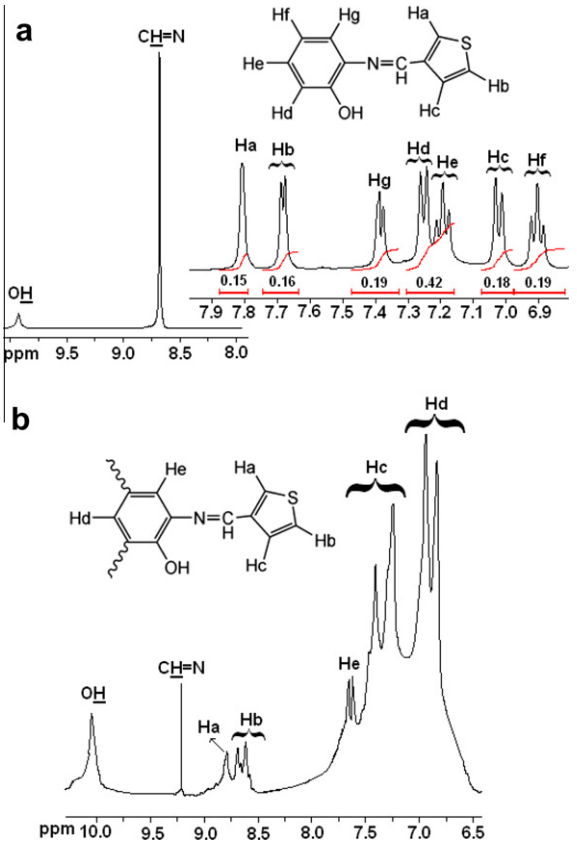


Fig. 1. ^{1}H NMR spectra of 2,3-TMAP (a) and P-2,3-TMAP (b).

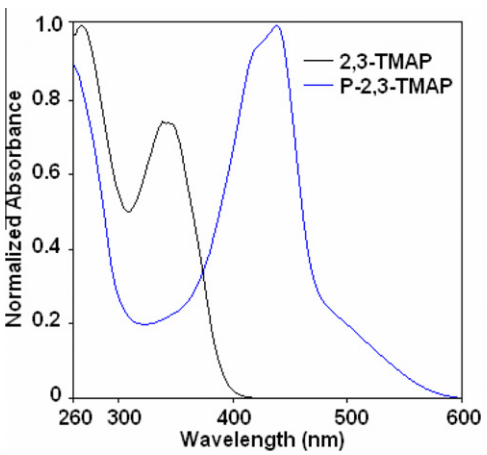

Fig. 2. Normalized absorption spectra of 2,3-TMAP and P-2,3-TMAP.

The infrared spectra were measured by Perkin Elmer FT-IR Spectrum one. The FT-IR spectra were recorded using universal ATR sampling accessory (4000–550 cm^{-1}). ^{1}H NMR spectra (Bruker AC FT-NMR spectrometer operating at 400 and 100.6 MHz, respectively) were also recorded by using deuterated DMSO-d_6 as a solvent at 25 °C. The tetramethylsilane was used as internal standard. The number-average molecular weight (M_n), weight-average molecular weight (M_w) and polydispersity index (PDI) were determined by size exclusion chromatography (SEC) techniques of Shimadzu Co. For SEC investigations a SGX (100 Å and 7 nm diameter loading material) 3.3 mm i.d. × 300 mm column was used; eluent: DMF (0.4 ml/min), polystyrene standards. A refractive index detector (RID) and UV detector were used to analyze the products at 25 °C.

3. Results and discussion

3.1. Structures of the synthesized compounds

The structures of the synthesized compounds are confirmed by FT-IR, UV–vis, and ^{1}H NMR analyses. According to the FT-IR spectra of 2,3-TMAP and P-2,3-TMAP imine bonds appear at 1615 and 1605 cm^{-1}, respectively. Also, phenolic O–H stretch and C–S stretch vibrations of thiophene rings are observed at 3297 and 785; and 3228 and 747 cm^{-1}, respectively. After the polycondensation reaction the peaks broaden and shift to lower wave number values. ^{1}H NMR spectra are given in Fig. 1. As seen in Fig. 1, at the NMR spectrum of P-2,3-TMAP the peaks indicating the aromatic protons broaden due to the polyconjugated structure [24]. At the ^{1}H NMR spectrum of 2,3-TMAP –OH and CH=N protons are observed at 9.93 and 8.68 ppm, respectively. These values shift up to 10.02 and 9.20 ppm at the ^{1}H NMR spectrum of P-2,3-TMAP, respectively. As compared of the both spectra, 2,3-TMAP polymerizes mainly by C–C coupling mechanism. Kaya et al. have been previously studied the coupling selectivity of the oligophenol derivatives. According to the mentioned studies phenol derivatives could be polymerized by C–O–C and/or C–C coupling mechanisms. Kaya et al. were determined the C–C/C–O–C coupling ratio using the integration area of imine and OH protons at the ^{1}H NMR spectra. The ^{1}H NMR results show that the polymerization of 2,3-TMAP mainly proceeds from *ortho* and *para* positions of phenolic –OH group by C–C coupling [24].

Normalized absorption spectra of the chemically synthesized compounds are shown in Fig. 2. R band of the absorption spectrum of 2,3-TMAP shifts from 342 to 439 nm, after the oxidative polymerization. Optical band

Table 1
The number-average molecular weight (M_n), weight-average molecular weight (M_w), polydispersity index (PDI), and % values of P-2,3-TMAP.

Detector	Molecular weight distribution parameters										
	Total			Fraction I				Fraction II			
	M_n	M_w	PDI	M_n	M_w	PDI	%	M_n	M_w	PDI	%
RI	17,460	18,810	1.077	59,790	60,390	1.010	18	8170	9680	1.185	82
UV	34,330	36,660	1.068	59,170	59,800	1.011	46	13,170	16,950	1.287	54

gap values are determined from the absorption edges as in the literature [28]. Optical band gaps of 2,3-TMAP and P-2,3-TMAP are calculated as 3.13 and 2.17 eV, respectively. These results clearly indicate that the polyphenol derivative of 2,3-TMAP has lower band gap than its monomer due to its polyconjugated structure.

According to the SEC chromatograms P-2,3-TMAP has two separate fractions and the results are given in Table 1. Total values of number-average molecular weight (M_n), weight-average molecular weight (M_w), and polydispersity index (PDI) of P-2,3-TMAP are calculated to be 17,460, 18,810 g mol^{-1}, and 1.077; and 34,300, 36,660 g mol^{-1}, and 1.068, using RI and UV detectors, respectively. According to the obtained results from RID P-2,3-TMAP has nearly 86–92 repeated units, whereas 168–180 repeated units according to the results obtained from UV detector. These values also confirm the polymer structure of P-2,3-TMAP.

3.2. Cyclic voltammetry

Thiophene derivatives readily undergo one-electron oxidation to form a radical cation (polaron) if the α-positions are unsubstituted. Continuous oxidation subsequently affords higher ordered oligomers by a radical coupling mechanism that ultimately results in polymer formation [29]. Cyclic voltammogram of P-2,3-TMAP in the presence of thiophene in AN/$LiClO_4$ solvent/electrolyte couple indicates two consecutive reversible oxidation peaks at 0.45 and 0.99 V which reverse at 0.26 V when the potential range between 0 and +1.3 V is scanned (Fig. 3c). Also, at the same potential scan range of 2,3-TMAP only one reversible oxidation peak at 0.95 V is observed that reverses at 0.56 V (Fig. 3b) [30]. Since the reduction potential values are sensitive to intramolecular and intermolecular electron transfer. Because of the same effect in the anodic area, reduction peak were also influenced by thiophene [17]. The formation of an electroactive film on the electrode is observed with the oxidation peaks combination at the potential of 0.61 V (see Fig. 3c). Upon consecutive cycle formation, a new oxidation peak appeared at 0.61 V due to the oxidation of the polymer. As the number of cycle increases, there is an increase in the intensity of the current. This is due to increase in the active area of the working electrode owing to electroactive polymer coating on the electrode [31].

Electrochemical homopolymerisations of 2,3-TMAP and P-2,3-TMAP without any active comonomer agent (like thiophene) in AN/$LiClO_4$ solvent/electrolyte mixture were also tried in various scan rates and concentrations. But the polymerizations failed. This means an electrochemically active comonomer agent is certainly needed. In order to investigate the CV behavior of the copolymer, we performed CV studies in the presence of thiophene. There is a drastic changes between the voltammograms of thiophene, 2,3-TMAP, and P-2,3-TMAP. As seen in Fig. 3, at the voltammogram of the polythiophene an increasing oxidation peak at the potential of 0.74 V is observed (Fig. 3a). However, at the voltammograms of 2,3-TMAP and P-2,3-TMAP new increasing oxidation peaks are at 0.95 and 0.61 V, respectively. Fig. 3 clearly presents the change in the anodic peak currents as a function of the potential [5]. The peak current increases are recorded during the

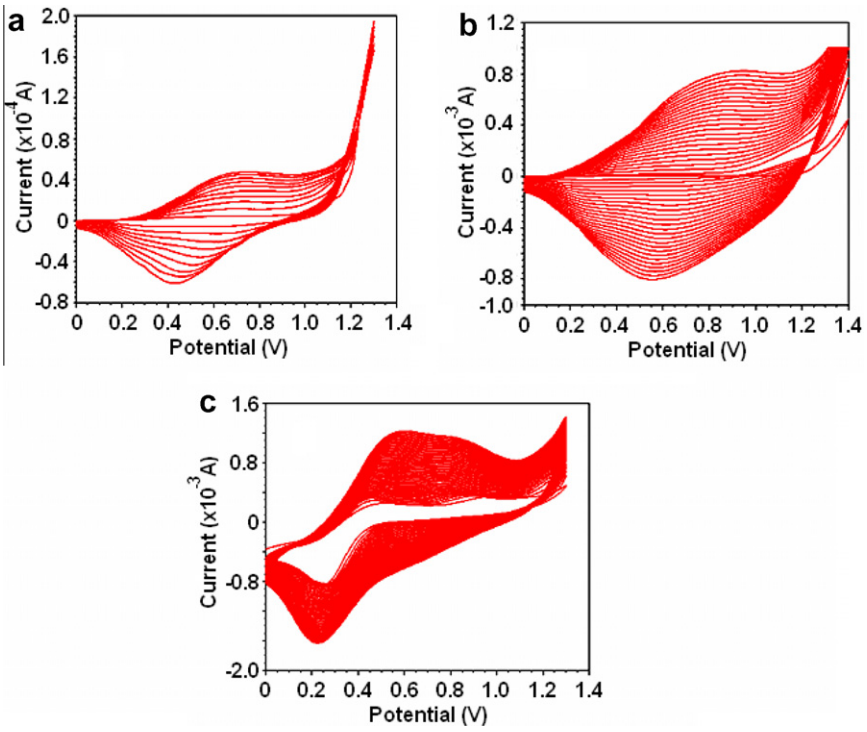

Fig. 3. Cyclic voltammograms of repeated potential scan of polythiophene (a), 2,3-TMAP (b), and P-2,3-TMAP (c) in the presence of thiophene (scan rate: 200 mV/s, cycle numbers: 9, 24, and 50, respectively).

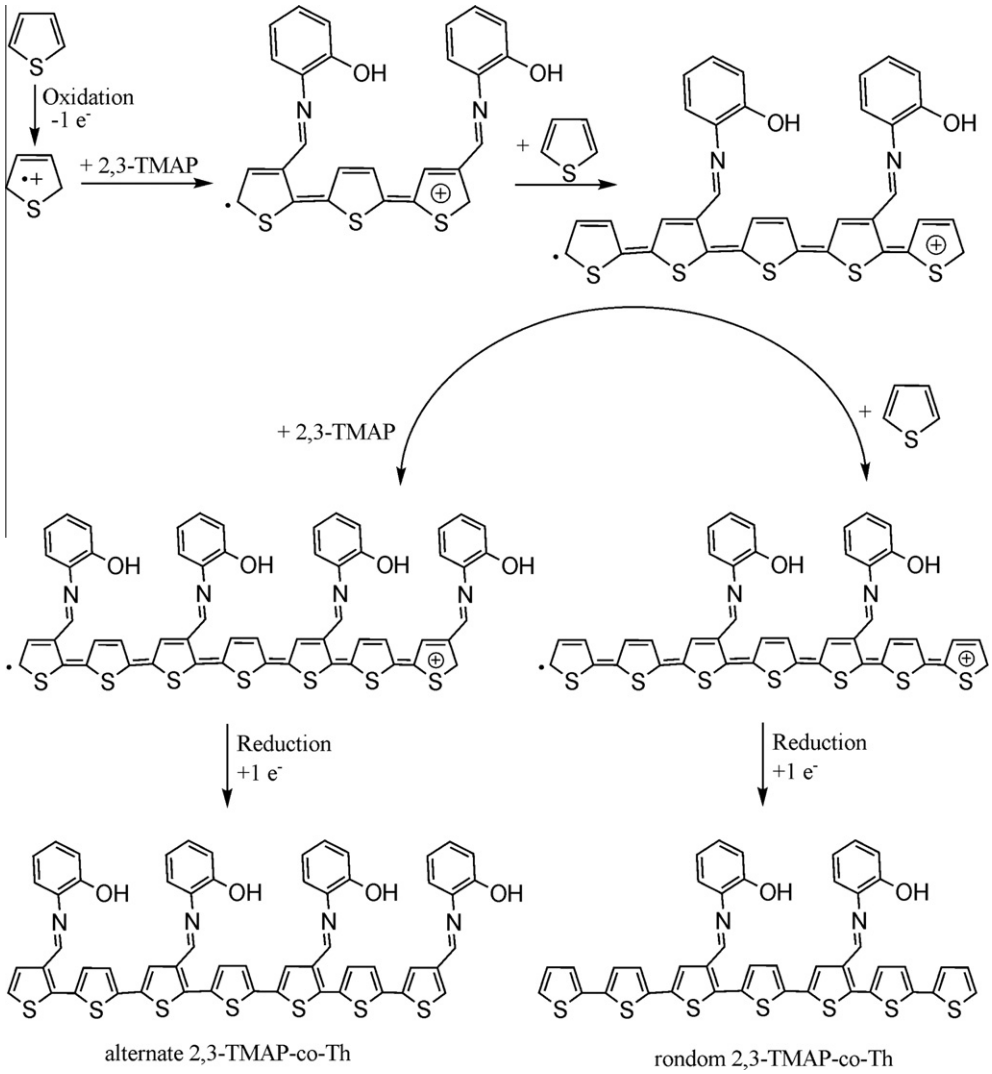
formation of homo-polythiophene and the copolymers at the different potentials. This confirms the copolymer structures. The reaction mechanism of electro copolymerization of 2,3-TMAP with thiophene can be proposed as shown in Scheme 5 [32,33]. There are two different kinds containing electropolymerisable thiophene units in the electro



Scheme 5. Possible electro copolymerization mechanism of 2,3-TMAP in the presence of Th.

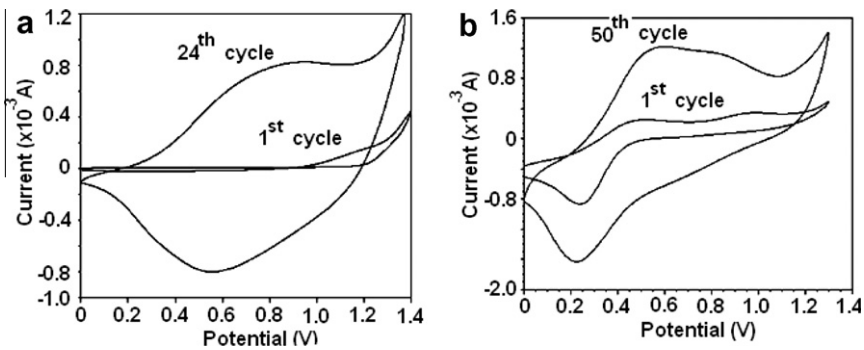


Fig. 4. The first and the last cycles of 2,3-TMAP (a) and P-2,3-TMAP (b) in the presence of thiophene.

polymerization cell: pure thiophene and thiophene substituted iminophenol/imino(polyphenol) (2,3-TMAP and P-2,3-TMAP). As examined the structures of 2,3-TMAP and P-2,3-TMAP the electronic attractive effect of azomethine on the thiophene ring increases the oxidation potential compared with that of thiophene. As a result, thiophene is expected to be firstly oxidized species and the polymerization starts by forming the polaron structure (radical cation) of thiophene. Moreover, the obtained polymer could have random or alternate copolymer structure (see Scheme 5). The first and the last cycles of 2,3-TMAP and P-2,3-TMAP are also given in Fig. 4a and b which is obtained by the electro copolymerization in the presence of thiophene.

3.3. Electro-optical properties

Spectroelectrochemistry is the best way of examining the changes in optical properties of a polymer on ITO upon applied potentials. It also provides information on the properties of conjugated polymers, such as band gap (E_g) and the intergap states that appear upon doping. Spectroelectrochemical measurements were carried out between the potential range of 0 V and +1.4 V in AN/$LiClO_4$ (0.1 M) solution. The λ_{max} for the π–π^* transitions in neutral states of 2,3-TMAP-co-Th and P-2,3-TMAP-co-Th at 0 V are found to be 437 and 476 nm, respectively. These λ_{max} values are higher than those of 2,3-TMAP and P-2,3-TMAP which indicate the higher conjugated-copolymer structures. Figs. 5a and 6a indicate the changes of the absorption spectra of 2,3-TMAP-co-Th and P-2,3-TMAP-co-Th at various applied potentials. The 3D optoelectrochemical spectrum of P-2,3-TMAP-co-Th between 0 and 1.4 V is also shown as insert figure of Fig. 6. As the copolymer devices get oxidized, the intensities of the π–π^* transitions decrease while the charge carrier bands at about 800–900 nm increase in intensities due to polaron formation [34].

3.4. Electrochromic switching and the stabilities

In order to carry out the spectrelectrochemical measurements a repeated scan mode of cyclic voltammetry coupled with optical spectroscopy method is used for 10 cycles scan. Potential scan range is 0–1.4 V which the colors clearly differ. Scan rate was chosen as 280 mV/s and the results were in cycle completions in a 10 s-time periods. The graphs are given in Figs. 5 and 6b. Measurements are carried out using two wavelengths in which the absorption intensities clearly change. For this purpose λ_{max} values of the copolymers and 800 nm are chosen. During the

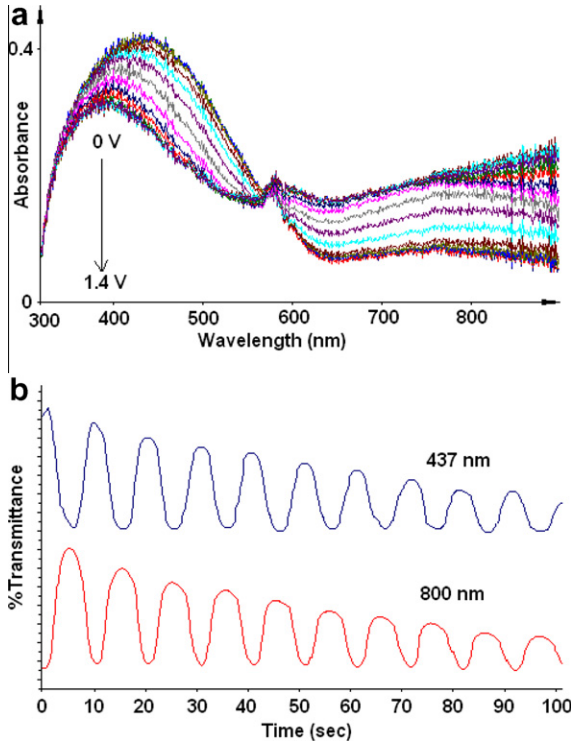

Fig. 5. (a) Optoelectrochemical spectrum of 2,3-TMAP-co-Th in the presence of 0.1 M $LiClO_4$ in AN and (b) electrochromic switching, optical absorbance monitored for 2,3-TMAP at 437 and 800 nm in the presence of 0.1 M $LiClO_4$ in AN.

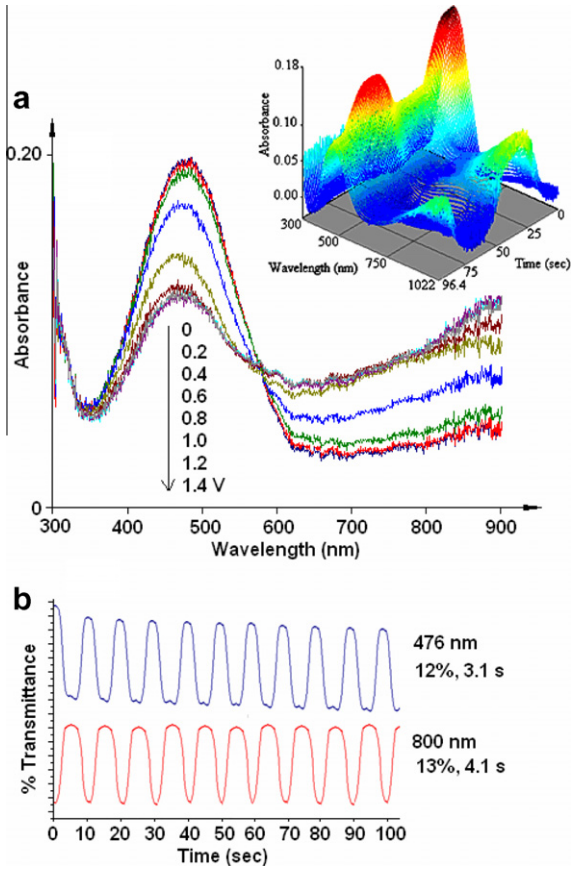

Fig. 6. (a) Optoelectrochemical spectrum of P-2,3-TMAP-co-Th in the presence of 0.1 M $LiClO_4$ in AN (insert: 3D optoelectrochemical spectrum of P-2,3-TMAP-co-Th at applied potentials between 0 and 1.4 V, scan rate: 100 mV/s) and (b) electrochromic switching, optical absorbance monitored for P-2,3-TMAP at 476 and 800 nm in the presence of 0.1 M $LiClO_4$ in AN.

switching experiment, the λ_{max} values are measured as 437 and 476 nm for the 2,3-TMAP-co-Th and P-2,3-TMAP-co-Th, respectively. The polymer film was deposited on ITO-coated glass slides under constant potential conditions, as mentioned above. The absorbances are then monitored at λ_{max} while the polymer and monomer are switched between 0 V and +1.4 V. As seen in Fig. 5b, during the repeated potential scan absorption intensities of 2,3-TMAP slowly decrease indicating the low absorption recovery at applied potentials. On the other hand, as seen in Fig. 6b P-2,3-TMAP-co-Th has good absorption recovery at applied potentials which indicates the percentage transmittance changes ($\Delta T\%$) of 12% and 13% for 476 and 800 nm, respectively. The stability between the redox states during the several scans is the most important property for an electroactive polymer to be useful in construction of new electrochromic devices [34]. Response time of P-2,3-TMAP-co-Th from the neutral (0.0 V) to oxidized (1.4 V) states are found to be 3.1 and 4.1 s for two wavelengths, respectively. For electrochromic applications, the ability of the material to exhibit a noteworthy color change is important. The synthesized electrochemical copolymers coated on ITO-glass exhibit red colors at the neutral states and blue colors at the oxidized states.

4. Conclusion

A new Schiff base and its oligophenol derivatives which contain electropolymerisable thiophene side groups were synthesized and characterized via FT-IR, ^{1}H NMR, UV–vis, and SEC analyses. Optical band gaps of 2,3-TMAP and P-2,3-TMAP were found as 3.13 and 2.17 eV. The copolymers of the synthesized materials were prepared in the presence of thiophene potentiostatically in AN:BF_3EtE (9:1, v/v) using $LiClO_4$ (0.1 M) as electrolyte. Electrocopolymerisation reactions were maintained by repeating potential scans between 0 and 1.4 V. Obtained electrochromic films deposited on ITO glass plates, 2,3-TMAP-co-Th and P-2,3-TMAP-co-Th, were investigated as spectroelectrochemically and monitored at two wavelengths in which the absorption intensities clearly change. For this purpose λ_{max} values of the copolymers (437 and 476 nm) and 800 nm were chosen. Obtained results showed that the new electrochromic materials derived from thiophene substituted-iminophenol/oligophenols were red colored at low potentials and blue colored at high potentials. However, on the contrary of P-2,3-TMAP-co-Th, spectroelectrochemical monitoring of 2,3-TMAP-co-Th showed an absorbance decrease during the repeated potential scans which may recover by changing the experimental conditions like copolymerization ratio. Suitable potential range for operating the device from red to blue was found to be between 0 and +1.4 V. Stable absorption recovery of P-2,3-TMAP-co-Th could make the new material appropriate for construction of novel electrochromic devices. P-2,3-TMAP-co-Th show 12–13% transmittance changes at applied potentials and the response times were 3.1 and 4.1 s for 476 and 800 nm, respectively.

Fermi level pinning

ABSTRACT

Threshold voltage and turn-on voltage of organic field effect transistors are very sensitive to the fabrication process. Their knowledge and control are required for design and fabrication of OFET based circuits. A simple gradual channel OFET model is not appropriate close to threshold, and even fails to describe turn-on voltage. Therefore a distributed model has been developed, based on a numerical calculation of the accumulated charge along the channel, allowing the calculation of the transistor output characteristics both below and above threshold. Also, uneven source contact carrier injection can be modelled, based on physical parameters. In the present work, in-depth analysis of contact influence is carried-out, both below and above threshold, and impact on threshold voltage and turn-on voltage is outlined. Besides, surface Fermi level pinning effects and influence of the semiconductor layer thickness is also discussed.

1. Introduction

Knowledge and control of threshold voltage (U_T) and turn-on voltage ($U_{TURN\text{-}ON}$) are mandatory for design and fabrication of organic field effect transistor (OFET) based circuits [1]. These two parameters are very sensitive to the device process, and their behaviour may appear difficult to understand. In a previous study, we outlined the influence of poor source contact on the OFET threshold voltage [2,3], using a self-consistent implementation of carrier injection phenomena. If the threshold voltage was proved to be very sensitive to uneven source contact, no such quantitative conclusion could be drawn on the turn-on voltage. Indeed, the model is based on the gradual channel approximation, except close to the source, using the usual $Q = C_i(U_{GC}\text{-}U_T)$ approximation [4,5]. This approach is convenient to describe the OFET behaviour above threshold (i.e. for gate voltage higher than U_T). However this equation is not valid below threshold, and the turn-on voltage remains out of reach. A numerical calculation of the accumulated charge along the channel appeared necessary, leading to a distributed model described in this work. Detailed discussion of threshold voltage and turn-on voltage behaviour is given.

2. Band diagram and accumulated mobile charge

A schematic transistor view is given in Fig. 1. In this work, the gate structure is a Au/SiO_2/organic semiconductor (OSC) stack. Material parameters and transistor dimensions are given in Table 1. The OSC is considered intrinsic, and single carrier transport is considered: here a p-type transistor is described. Although the electron concentration is calculated during the Poisson equation resolution, electrons are not considered to contribute to the channel conductivity: the accumulated mobile charge is restricted to the accumulated holes. This assumption leads to a floor in the accumulated mobile charge when a positive gate bias is applied (visible Fig. 3). This is likely to occur close to the drain contact, where the gate-to-channel bias can be highly positive, in particular in saturation regime.

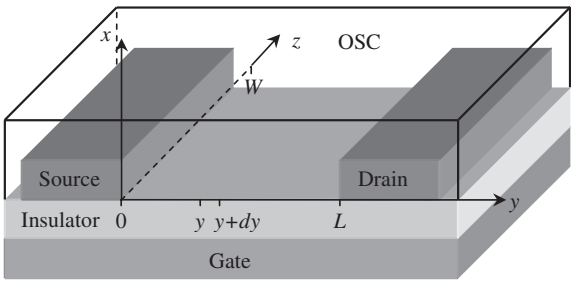

Fig. 1. Schematic view of the simulated OFET structure.

Neglecting any transverse field gradient, Poisson equation across the gate stack is simply given by:

$$\frac{\partial^2 V_y(x)}{\partial x^2} = \frac{(p(x) - n(x))}{\varepsilon_0 \varepsilon_r(x)} \tag{1}$$

Where $V_y(x)$ is the potential profile across the gate structure at a given channel position (y), $\varepsilon_0\varepsilon_r(x)$ the permittivity of a given layer, and $n(x)$ and $p(x)$ the free carrier concentration in this layer. This equation can be solved numerically using a 3D DOS and Fermi–Dirac statistics [4], as for example in [6]. A typical band diagram is given in Fig. 2 in reverse gate bias, together with free carrier concentrations across the structure. For comparison, a usual MOS-like band diagram is also shown in the figure, where the semiconductor bulk is intentionally n-type doped to allow inversion in the p-type channel. Resulting bands bending in both structures are quite different, due to the bulk semiconductor doping. In the intrinsic organic case, the Fermi level position at the semiconductor surface $(x = d)$ was arbitrarily fixed at its equilibrium position. However, both the semiconductor thickness and the surface Fermi level position will impact band bending and accumulated carrier concentrations. In the transistor structure considered here, a quantitative shift of the threshold voltage

and onset voltage with Fermi level position will occur for semiconductor thicknesses below 100 nm, as illustrated in the following sections. Such influence of the semiconductor interface opposite to the channel has been recently reported [7].

Traps in real organic field effect transistors play a major role [8,9]: significant shift of threshold voltage, turn-on voltage, or below threshold current slope can be observed. Traps may be located within the organic semiconductor, in the insulator, or at the various structure interfaces. Their concentration, energetic distribution, or location, are strongly dependent on material and technology. Although strongly impacting real devices, due to the numerous issues to be considered, and in order to clarify the impact of many contributions to the transistor behaviour, this work will not consider traps in order to focus on other phenomenon, such as indirect contact contributions, also very detrimental and so often observed. This is a first and necessary step to further analysis of more complex structures. The following results will give a figure of what one could expect from a trap free device with emphasis on contact contribution.

In order to carry on with the transistor current calculation, the accumulated hole concentration is integrated along the semiconductor thickness and stored for a range of positive to negative gate bias. An example is given in Fig. 3, where the surface charge density is plotted in linear and logarithmic scale. Despite not contributing to the transistor drain current, the electron surface density is also shown in order to locate the flat-band voltage.

3. Distributed OFET model

Considering only drift carrier motion with constant mobility, the transistor drain current I_{DS} can be written all along the channel as [4]:

$$I_{DS} = Q(U_{GC}(y))\mu\frac{\partial U_{GC}(y)}{\partial y} = \mu\frac{\partial U_{GC}(y)}{\partial y} q\int_0^d p(x,y)dx \qquad (2)$$

Where $U_{GC}(y)$ is the gate-to-channel voltage at a given channel position (y), $Q(U_{GC}(y))$ is the accumulated charge concentration (limited to the mobile holes), and μ is the hole drift mobility.

As shown in Fig. 1, in the distributed approach, the channel is divided along (y) into a number (N) of slices (y_i). Both $U_{GC}(y_0) = U_{GS}$ and $U_{GC}(y_N) = U_{GS} - U_{DS}$ are known. Starting from an initial drain current guess, the gate-to-channel voltage at position $(y_1 = y_0 + dy)$ can be obtained from Eq. (2). Then, in an iterative way the potential profile can be propagated through the N slices towards the drain contact. The drain bias $U_{GC}(y_N)$ can be compared to the applied bias, and the guess drain current is modified accordingly. Finally a simple algorithm allows calculating the drain current corresponding to a given bias point. The drain current can be obtained both below and above threshold, since the accumulated charge in the channel can be evaluated at any bias point.

The threshold voltage is usually extracted from the $\sqrt{I_{DS}} = f(U_{GS})$ characteristic in saturated regime. Unfortunately, uneven source contact behaviour, in particular non-linear injection, was demonstrated to shift the extracted value [2]. This complicates interpretation of threshold voltage variations with technological parameters since both the source contact and the gate structure determine the drain current near threshold. In order to study the source contact influence on below threshold OFET characteristics, source contact non-linear injection has been implemented in the distributed model as in [2], the physics of the injection model being discussed in [3]. In this model, an energetic barrier ϕ_B between the source contact and the organic semiconductor is responsible for a depleted region at the contact edge. All injection parameters at the source contact edge are evaluated within the drain current algorithm, in a self-consistent approach. These parameters are: the injecting field E_{inj} at the source edge, the potential drop U_{inj} across the depleted region, and the depleted region extension Y_{inj}.

An example of drain current characteristic is shown in Fig. 4, with a significant injection barrier $\Phi_B = 0.5$eV. Non-linear behaviour is clear, as frequently observed in

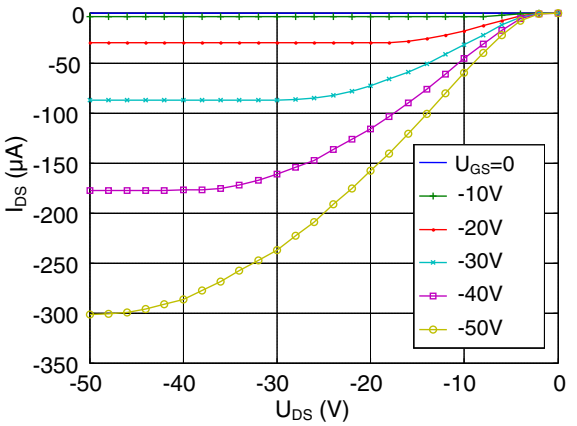

Fig. 4. Simulated I_{DS} characteristics: non-linearities observed at low drain bias are due to the carrier injection barrier at the source contact.

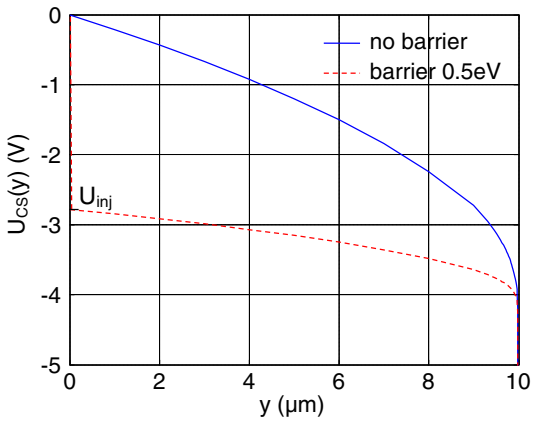

Fig. 5. Simulated potential profile along the channel without or with an injection barrier ($U_{DS} = -5$ V and $U_{GS} = -10$ V). The potential drop U_{inj} at the source ($y = 0$) is due to the injection barrier.

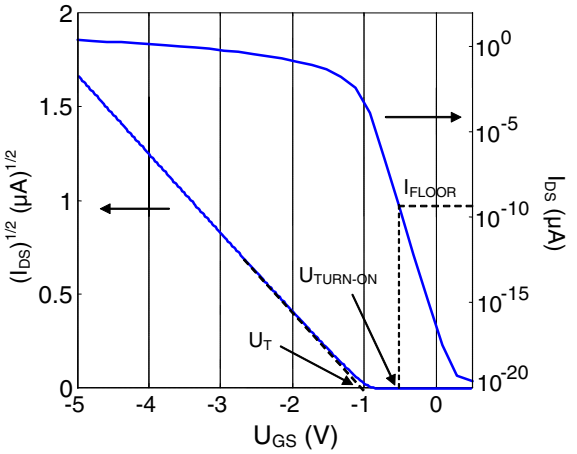

Fig. 6. Simulated $\sqrt{I_{DS}} = f(U_{GS})$ and $\log((I_{DS}) = f(U_{GS})$ characteristics, with extracted threshold voltage U_T and turn-on voltage $U_{TURN\text{-}ON}$.

published experimental results [10,11]. In Fig. 5, the potential profile along the channel is shown with or without injection barrier. At this bias point ($U_{GS} = -10$V and $U_{DS} = -5$V), due to the 0.5eV barrier height, the potential drop at the source contact edge is significant (as observed experimentally, see for example [12]), and represents more than half of the applied drain-source bias. The depleted zone extension (about 15 nm) is negligible compared to the channel length, and the potential drop at the source contact appears abrupt.

4. Threshold voltage and turn-on voltage

The threshold voltage U_T is usually obtained from the $\sqrt{I_{DS}} = f(U_{GS})$ characteristic, while the turn-on voltage $U_{TURN\text{-}ON}$ is extracted from the $\log(I_{DS}) = f(U_{GS})$ plot. Fig. 6 shows both plots, as obtained from the distributed model. Unfortunately, the threshold voltage cannot be calculated analytically in intrinsic organic FETs, as for their silicon MOSFET counterpart, since only accumulation occurs. For real device characterization, several extraction methods have been proposed for the threshold voltage, often derived from silicon devices [13]. For simulated device characteristics, we will consider here the previous straightforward method. To give a figure, one may consider the band diagram shown in Fig. 2 for organic FETs. For limited insulator thickness, one can see that the gate bias U_T required for accumulation to become significant should be about:

$$U_T \approx U_{FB} - qE_G/2 \tag{3}$$

Where U_{FB} is the flat-band voltage and E_G the OSC band gap.

Concerning the turn-on voltage $U_{TURN\text{-}ON}$, we will consider the intercept of the theoretical $\log(I_{DS}) = f(U_{GS})$ characteristic with a given floor current I_{FLOOR}, representing contributions such as gate leakage or surface leakage, not taken into account in the present model. Again to give a figure, a 10fA floor current is plotted (Fig. 6). This floor current is by far higher than the theoretical turn-on current (almost ten decades). Consequently, practical $U_{TURN\text{-}ON}$ will differ from the theoretical value, here by about a volt, depending on the actual transistor materials and gate structure. This shift is sensitive to the floor current, to the threshold slope, and in particular to traps. Note also that the theoretical $U_{TURN\text{-}ON}$ value will slightly differ from U_{FB}, as can be understood considering the hole surface density in Fig. 3. The floor charge is obtained for a gate bias above U_{FB}.

5. Surface Fermi level pinning

As mentioned, the surface Fermi level position, opposite to the accumulated charge interface, is usually unknown. To evaluate its influence, simulations have been performed for various semiconductor thicknesses and Fermi level positions, ±0.5 eV away from the intrinsic Fermi level. Free moving surface Fermi level cannot be simulated using the present model since this would prevent biasing the gate

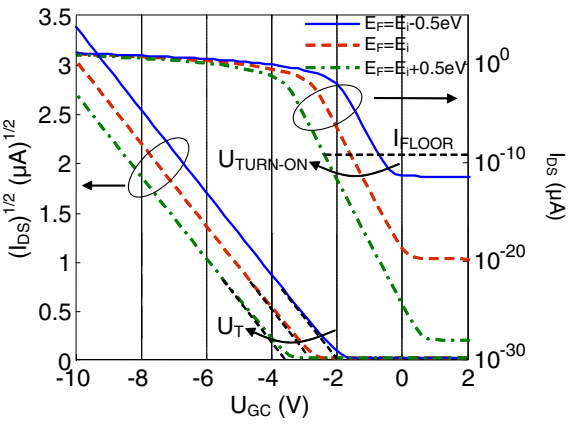

Fig. 7. Surface Fermi level pinning effect on threshold voltage and turn-on voltage.

structure. Results are shown in Fig. 7 for a 50 nm semiconductor thickness. No change in the threshold slope can be seen, but a significant shift of both the threshold voltage and the practical onset voltage is observed due to the Fermi level pinning, as well as a significant increase of the theoretical floor current. The surface Fermi level pinning may prevent the decrease of the hole concentration at positive gate bias, increasing the floor current. Above about 100 nm, the threshold voltage and the turn-on voltage are hardly affected by the surface Fermi level position. Only the theoretical floor current is shifted by almost the same amount. In the following, the Fermi level position is fixed to its intrinsic level.

6. Contact influence below and above threshold

To study indirect contact influence on threshold voltage and turn-on voltage, it appears necessary to distinguish between ohmic contributions (i.e. linear) and non-linear contributions. In Fig. 8, impact of linear contributions is shown. Ohmic series resistances have been varied from limited values to huge values (10 kΩ to 10 MΩ): reasonably no impact on threshold voltage nor onset voltage can be observed. In Fig. 9, non-linear effects due to an injection barrier have been illustrated. Obviously, the threshold voltage is significantly shifted towards higher values (more negative) when non-linear injection occurs, although the gate structure remains unchanged. Indeed, the gate-source voltage can be expressed as the sum of two contributions:

$$U_{GS} = U_{GC} + U_{CS} \tag{4}$$

where U_{GC} is the gate-channel voltage, depending on the gate structure, and U_{CS} is the source-channel voltage, depending on the source contact. The source contact and gate structure influences are additive. We get an intricate situation: practical analysis of its behaviour against technological parameters appears difficult, if not misleading.

In contrast, the transistor characteristic below threshold appears almost unaffected by the source contact. For reasonable contact barriers, within 0–0.7 eV, practical turn-on voltages are not be affected by the source contact: $U_{TURN\text{-}ON}$ remains a good indicator of the gate structure behaviour.

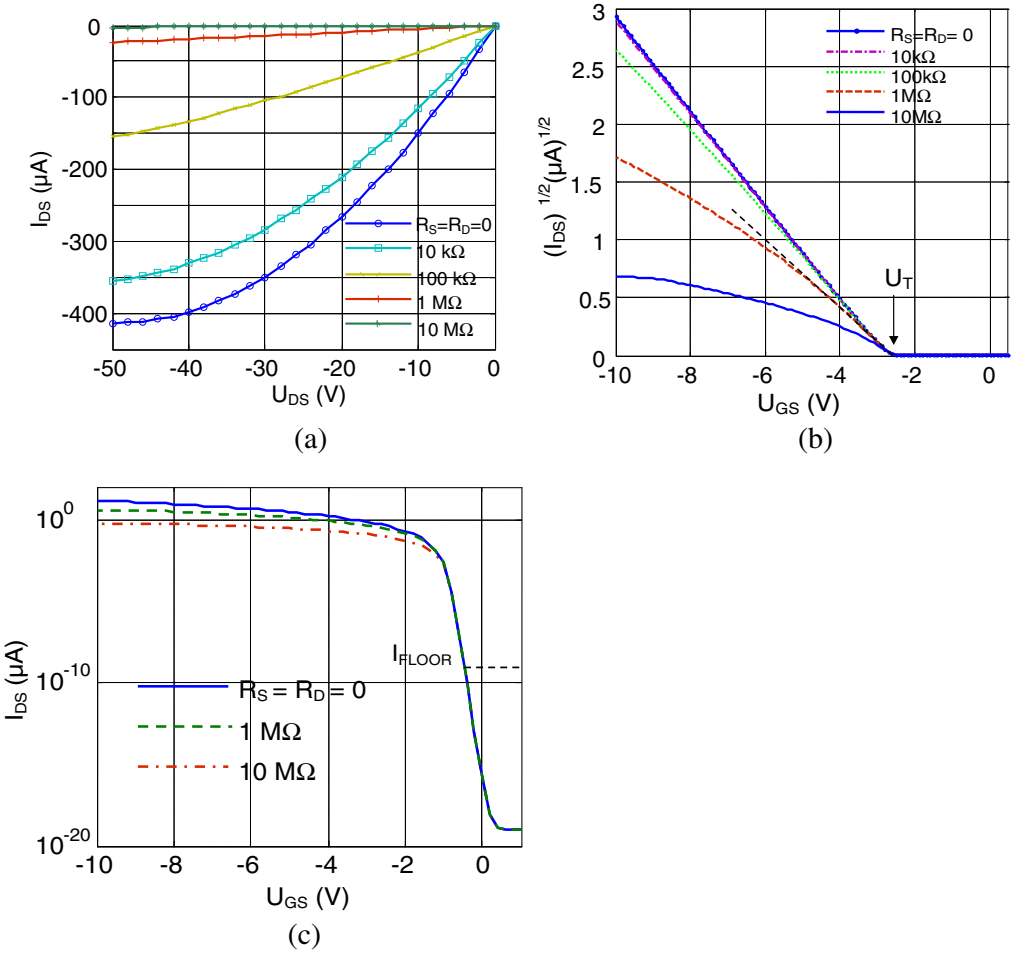

Fig. 8. Linear contact contribution: Ohmic contact impact on drain current (a), threshold voltage (b) and turn-on voltage (c).

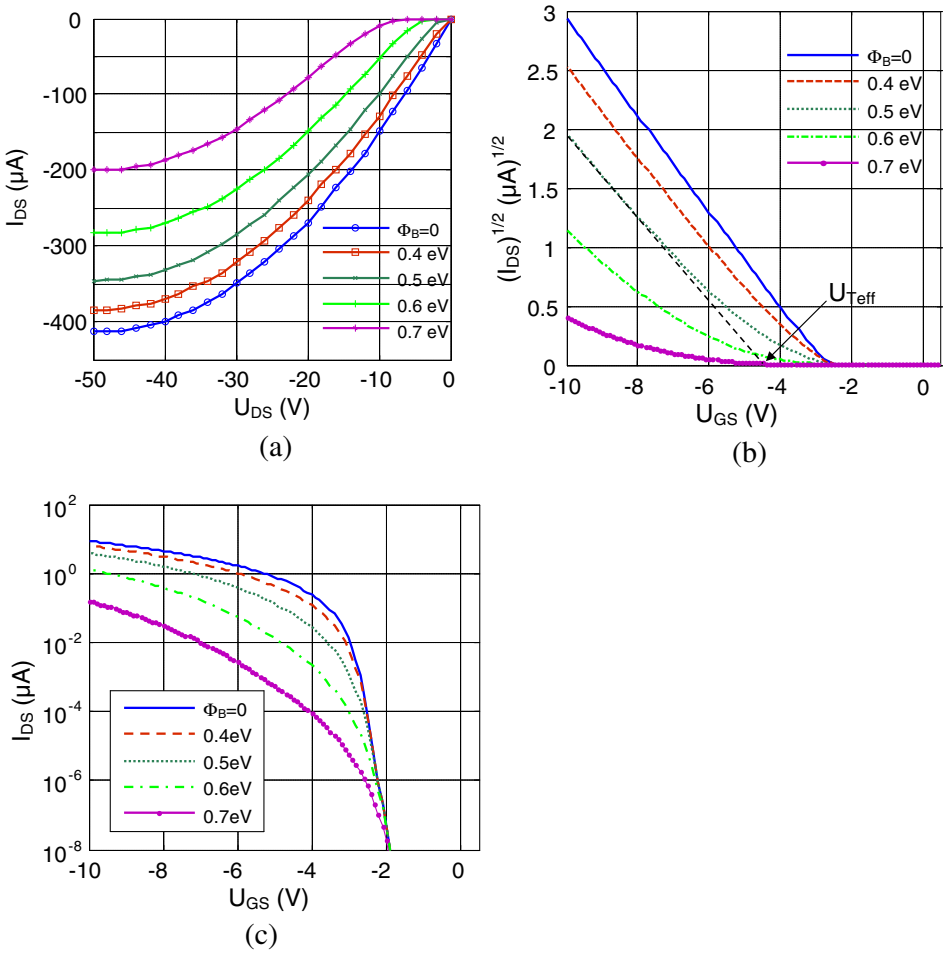

Fig. 9. Non linear contact contribution: Injection barrier impact on drain current (a), threshold voltage (b) and turn-on voltage (c).

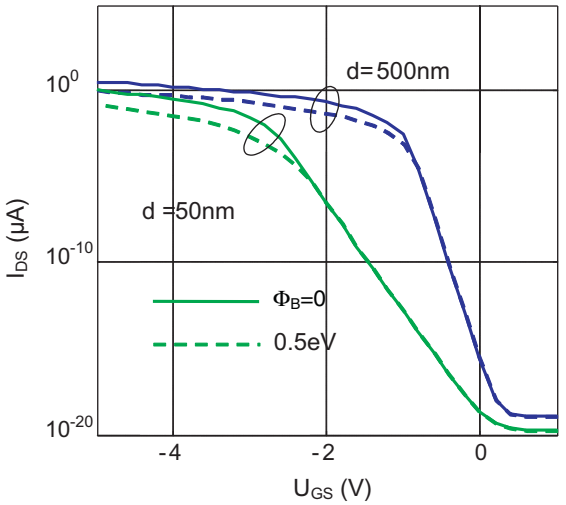

Fig. 10. Influence of the semiconductor layer thickness on below threshold $\log(I_{DS}) = f(U_{GS})$ characteristic, with or without a 0.5 eV injection barrier.

7. Semiconductor thickness

Following the above discussion, the below threshold part of the $I_{DS} = f(U_{GS})$ characteristic is a reliable indicator of the gate structure behaviour. In order to check the influence of the semiconductor thickness, simulations have been performed for 50 and 500 nm layers, with or without a significant injection barrier. The results, shown in Fig. 10, are in agreement with the previous statements: a reduction of the semiconductor thickness will impact the threshold slope, and will shift the turn-on voltage, which is consistent with a modification of the gate structure band diagram. However the source contact barrier will not impact the sub-threshold part of the characteristic.

8. Conclusions

A distributed model has been developed to study above and below threshold OFET drain current characteristics. Dependence of threshold voltage and turn-on

voltage on source contact misbehaviour has been studied, also considering surface Fermi level pinning and semiconductor thickness influence. Following a detailed discussion, it appears that the threshold voltage is unreliable to study the gate structure behaviour with technological parameters, since the source contact also strongly influence its value. On the other hand, the turn-on voltage and the threshold slope are not modified when uneven contacts are considered, and appear as much better indicators of the gate structure stack behaviour. Besides, pinning of the Fermi level is shown to shift both the threshold voltage and the turn-on voltage when thin organic semiconductor layers are considered, while the threshold slope appears sensitive mainly to the semiconductor thickness.

Heat transfer

ABSTRACT

We investigate the heat transfer property of thin-film encapsulation (TFE) for organic light-emitting diodes (OLEDs). It is demonstrated that the TFE combined with a flexible heat sink shows better thermal performance, compared with the epoxy-filled glass encapsulation and the conventional glass encapsulation. By way of experiments and simulations, we verify that the multi-heterojunction configuration and the low thermal conductivity of the polymer layer in the TFE film have no impact on the thermal performance. Furthermore, we find through simulations that a significant temperature gradient appears inside the TFE layers only when the thermal conductivity of the polymer is lower than 1×10^{-3} W/m K. This enables us to perform design optimization of the TFE configuration with relaxed heat dissipation.

1. Introduction

Organic light-emitting diodes (OLEDs) have attracted much attention for their potential applications in flat panel lightings and backlight units of flat panel displays [1,2]. One of the key issues of OLEDs is to protect them from oxygen and moisture. To this end, various encapsulation techniques have been studied. The most commonly used method utilizes UV-cured epoxy along with a desiccant inside the glass-capped OLED device (hereinafter referred to as a glass encapsulation) [3]. Recently, many studies have been made on a thin-film encapsulation (TFE) [4–9]. It is required to have a water vapor transmission rate (WVTR) of below 10^{-6} g m^{-2} day^{-1} to achieve the lifetime of OLEDs above 10,000 h. Of many TFE methods, TFE based on vacuum based organic/inorganic multi-layers is very promising as a gas diffusion barrier [4,10,11].

Meanwhile, heat dissipation is another key issue for flat panel OLED lighting applications. In analogy to the conventional lighting sources such as bulbs, fluorescent lamps, and inorganic LEDs, flat panel OLED lightings generate a great deal of heat. Unlike inorganic LEDs that have a long heat transfer pathway due to the packaging issue, however, OLEDs have a very short one between the internal heat source (i.e., light-emitting active area) and the outer device surface; namely, the heat difference between them is very small. This facilitates heat dissipation of OLEDs without using a bulk heat sink. Even so, the Joule heating problem is always parasitic on the devices. Due to Joule heating induced by high current injection during operation, there arise a reduction of luminance, short lifetime, and large spectral shift of OLEDs. To suppress the thermal degradation of organic molecules, the use of a heat sink is inevitable. Such a heat sink is desirable to be slim in such a way as to show up the salient feature of ultra-thin OLEDs.

For bottom-emitting OLED lighting panels, heat transfers through the encapsulation layers to the heat sink. As such, encapsulation need allow high gas diffusion barrier while simultaneously meeting heat transfer requirements. The epoxy seal of the glass encapsulation may not be good moisture barrier. Besides, the glass encapsulation may show poor thermal performance as nitrogen gas resides inside the device, separating a heat sink from the OLED device without any contact involved between them. One may come up with an advanced glass encapsulation where a glass cover is filled with a thermally conductive epoxy through which a heat sink is in contact with the OLED device (hereinafter referred to as an epoxy-filled glass encapsulation). In this case, a significant temperature

Fig. 1. Schematic view of the layer structure of a thin-film encapsulated OLED.

gradient may appear if the thermal conductivity of epoxy is low [12]. In this respect, the TFE structure shown in Fig. 1 would be in good combination with a heat sink provided that its barrier property is satisfactory since the TFE layer is extremely thin (several μm). However, it still concerns us in respect that the TFE layer is composed of alternating organic/inorganic materials (namely, a multi-heterojunction is entailed) and furthermore organic (polymer) materials have relatively low thermal conductivity, which may degrade the heat transfer property. Though many researches on the encapsulation technologies are available in the open literature, yet not much has been reported on their thermal property.

This paper is written with the following objectives. We make a comparative analysis of those encapsulation methods in terms of the heat transfer property. In the presence of a flexible heat sink, it is addressed that the TFE shows the best thermal performance, followed by the epoxy-filled glass encapsulation and then the conventional glass encapsulation. We have also implemented a 1D numerical model and performed numerical simulations of OLEDs to study more systematically the thermal property of the TFE configuration. It is found that the multi-heterojunction of the TFE structure and the low thermal conductivity of a polymer material therein have no impact on the thermal performance.

2. Model

In this study, the OLED structure (Fig. 1) consists of a 150-nm-thick indium-tin-oxide (ITO) pre-coated on a glass substrate, 70-nm-thick N,N′-diphenyl-N,N′-bis(1-naphthyl)-1-1′biphenyl-4,4″diamine (α-NPD) for a hole transport layer (HTL), 45-nm-thick tris-(8-hydroxyquinoline) aluminum (Alq_3) for an electron transport layer (ETL), 1-nm-thick lithium fluoride (LiF) for an electron injection layer (EIL), and 150-nm-thick aluminum (Al) for cathode. The TFE layer is composed of alternating inorganic (50-nm-thick Al_2O_3)/organic (500-nm-thick polymer) multilayers. With attempt to capture the heat generation and transfer inside the OLED device, we have implemented a comprehensive 1D numerical model [13–16] in which Poisson's equation, drift–diffusion equation, and heat flow equation are coupled to one another.

2.1. Poisson's equation

$$\frac{\partial E(x,t)}{\partial x} = \frac{q}{\varepsilon_0 \varepsilon_r}\left(p(x,t) - n(x,t) + N_D - N_A\right) \tag{1}$$

where the variable E denotes the electric field, n and p the electron and hole densities, respectively, and N_D and N_A the donor and acceptor impurity concentrations, respectively.

2.2. Drift–diffusion equation

$$\begin{aligned}\frac{\partial n(x,t)}{\partial t} &= \frac{1}{q}\frac{\partial J_n(x,t)}{\partial x} - r(x,t)n(x,t)p(x,t)\\ \frac{\partial p(x,t)}{\partial t} &= -\frac{1}{q}\frac{\partial J_p(x,t)}{\partial x} - r(x,t)n(x,t)p(x,t)\end{aligned} \tag{2}$$

where

$$\begin{aligned}J_n(x,t) &= q\mu_n(x,t)n(x,t)E(x,t)\\ J_p(x,t) &= q\mu_p(x,t)p(x,t)E(x,t)\end{aligned} \tag{3}$$

with the variable μ_n defined as the electron mobility, and μ_p the hole mobility. The degree of disorder of the organic molecules is reflected in the field- and temperature-dependent carrier mobility expressed as [17,18]

$$\mu(E(x,t),T) = \mu_0(T)\exp\left(\sqrt{\frac{E(x,t)}{E_0(T)}}\right) \tag{4a}$$

where

$$\mu_0(T) = \mu_A \exp\left(-\frac{\Delta}{kT}\right) \tag{4b}$$

$$E_0^{-1/2}(T) = D_m\left(\frac{1}{kT} - \frac{1}{kT_0}\right) \tag{4c}$$

with $\mu_0(T)$ defined as the zero-field temperature-dependent mobility, μ_A a constant, Δ the activation energy, $E_0(T)$ the temperature-dependent characteristic field, and D_m and T_0 material-related constants. The recombination rate r is expressed in the Langevin form [19]

$$r(x,t) = q(\mu_n(x,t) + \mu_p(x,t))/\varepsilon_0\varepsilon_r. \tag{5}$$

2.3. Heat flow equation

$$C\frac{\partial T(x,t)}{\partial t} = \frac{\partial}{\partial x}\left(k(x,t)\frac{\partial T(x,t)}{\partial x}\right) + \left[\frac{J_n(x,t)^2}{q\mu_n(x,t)n(x,t)} + \frac{J_p(x,t)^2}{q\mu_p(x,t)p(x,t)}\right] \tag{6}$$

where C is the volumetric heat capacitance and k is the thermal conductivity. The second term in the right-hand side of Eq. (6) represents the Joule heating. The thermal conductivity is assumed to be independent of temperature. Dirichlet boundary condition has been applied at the air/heat sink interface. In the simulation, the ambient temperature was assumed to be 300 K. For simplicity, the thermoelectric effects such as the Seebeck effect and the Peltier effect are not considered in the model. The model is capable of capturing the temperature-dependent OLED behaviors by solving the equation governing the electrical behaviors and the heat flow equation, which are coupled to each other through the temperature-dependent carrier mobility (Eq. (4)). The solutions to the governing equations are obtained in a self-consistent manner. Table 1 lists the

Table 1
Material parameter values.

Layer	$\mu_{0,n}$ (cm^2/V s)	$\mu_{0,p}$ (cm^2/V s)	$E_{0,n}$ (V/cm)	$E_{0,p}$ (V/cm)
HTL (α-NPD)	1×10^{-8}	4.3×10^{-4}	1×10^{5}	1×10^{6}
ETL (Alq_3)	1.2×10^{-6}	0.12×10^{-6}	1959×10^{3}	1959×10^{3}

parameter values related to carrier mobilities [14], which are typical for such a device with the material system chosen.

3. Results and discussion

For experiments, we have employed a Polynetwork flexible heat sink (PN-FHB050N) [20] in the form of bonding sheet. It consists of a 50-μm-thick copper sheet and 35-μm-thick thermal radiation layer. The bonding sheet has the thermal conductivity of 0.86 W/m K. After depositing organic and cathode layers, we have formed alternating Al_2O_3/monomer layers using Barix™ thin-film encapsulation equipment. Alumina layers are deposited by reactive sputtering of an alumina target. Polymer layers are deposited by organic acrylate evaporation and condensation, followed by a UV cure. The alumina layers form the basis of the moisture and oxygen barrier. Alternating polymer layers provide a smooth surface to facilitate defect free alumina deposition. Shown in Fig. 2 is the scanning electron microscope (SEM) image where 5.5 dyads TFE layers are deposited. The Al_2O_3 and polymer layer thicknesses are measured to be about 44 and 590 nm, respectively.

To evaluate the barrier property of the TFE films, we have conducted a Ca test and estimated the WVTR. The Ca test has been done in the same manner presented in [6]. It is based on the corrosion of thin calcium films. We have carried out the Ca test at temperature of 20 °C and a common relative humidity of 50%. As presented in Table 2, we have achieved the WVTR as low as 2.7×10^{-6} g/m^2 day, which is acceptable for lighting applications.

We have then investigated the heat transfer property of the TFE film. To this end, we have fabricated three bilayers

(HTL/ETL) OLEDs with different encapsulation structures (i.e., the conventional glass encapsulation, epoxy-filled glass encapsulation, and thin-film encapsulation) and made a comparative analysis of them in terms of the thermal performance. The emission area of the devices is 4.0 mm^2. Fig. 3 shows the measured *J–V* curve of the bilayer OLED, exhibiting the driving voltage of 4.7 V at 1000 cd/m^2 (21 mA/cm^2) and the luminance of 14,120 cd/m^2 at 7.5 V (378 mA/cm^2). For a comparison, we have measured the surface temperature of OLEDs without and with the flexible heat sink at a fixed voltage of 7.5 V using a thermal imager.

From Fig. 4, it is visible to the naked eye that there is no big difference in the surface temperature distribution between the glass encapsulated OLEDs with and without the heat sink. To quantify it, we have measured the transient variation of the maximum surface temperature. It is observed that the maximum surface temperature has been reduced by only 6 °C (from 55.5 °C to 49.6 °C) with the aid of the heat sink. Such a small reduction is due to the fact that there exists air (nitrogen gas) between the OLED device and the heat sink. Nitrogen gas has the thermal conductivity of 0.024 W/m K [12], which is much lower than that of glass. It hence results in poor heat transfer performance of the conventional glass encapsulation.

To eliminate nitrogen gas from the device, we have filled a thermally conductive epoxy resin (XNR 5570-B1, Nagase ChemteX Corp.) in the glass cover and then UV-cured it. Except for the epoxy-sealed area, the 0.7-mm-

thick glass cover is hollowed out such that its thickness becomes 0.35 mm and thus the epoxy resin can be filled therein. Just in case that epoxy causes any damage on the organic and cathode layers, we have inserted a buffer layer that consists of a 40-nm-thick NPB and 50-nm-thick LiF. For OLEDs with the epoxy-filled glass encapsulation, the maximum surface temperature is observed to be only 49 °C (Fig. 5) when the heat sink is not even involved, which is almost the same as that of the glass encapsulated OLED with the heat sink. It seems that heat transfers through the thermally conductive epoxy resin to the glass

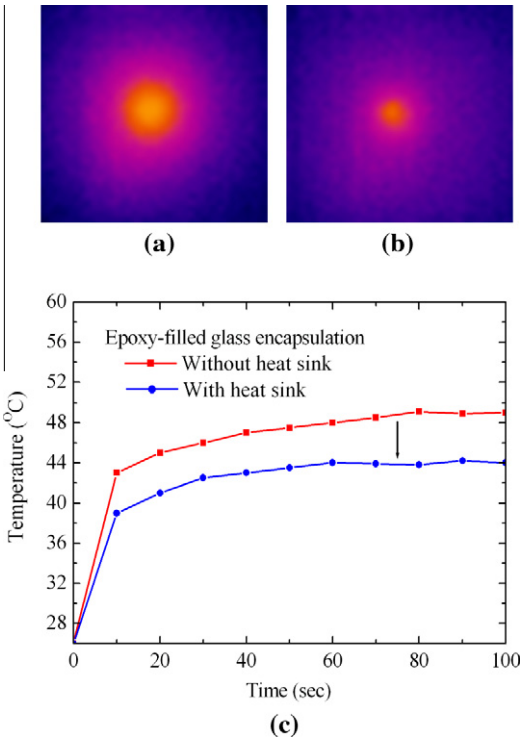

Fig. 5. Surface temperature distribution over the epoxy-filled glass encapsulated OLED (a) without and (b) with heat sink, and (c) transient variation of the maximum surface temperature measured at 7.5 V.

cover and then air. In fact, it is attributed that the thermal conductivity of epoxy is about 0.35 W/m K [12], which is much higher than that (0.024 W/m K) of nitrogen gas. Therefore, heat can be transferred to the surroundings even without the heat sink. However, the effect of the heat sink attached is likely to be little as the temperature reduction by the heat sink is only 5 °C (from 49 °C to 44 °C). It may be because the heat transfer pathway is very long and thus there appears a significant temperature gradient inside the thick (0.35 mm) epoxy layer, resulting from the fact that the thermal conductivity of epoxy is still low. There's plenty of room for improving its thermal performance. For instance, one may blend higher thermal conductivity materials (e.g., carbon nanotubes, Ag paste, etc.) with the epoxy. Meanwhile, the outgassing problem of this encapsulation scheme may be resolved by replacing the epoxy resin with a getter dryer such as a calcium oxide (CaO) powder.

We have then evaluated the thermal property of the thin-film encapsulated OLED. From Fig. 6, one can clearly see that the surface temperature is reduced to a great extent by the heat sink. It is observed to fall from 58 °C to 33 °C. Such a large reduction in temperature (25 °C) results from a short heat transfer pathway of the TFE structure. The total thickness of the TFE layer is only 3.2 μm. As such, heat generated in the emitting layer can be well transferred to the heat sink and dissipated by it. From this, one may jump into conclusion that the TFE structure combined with a heat sink shows the best heat transfer prop-

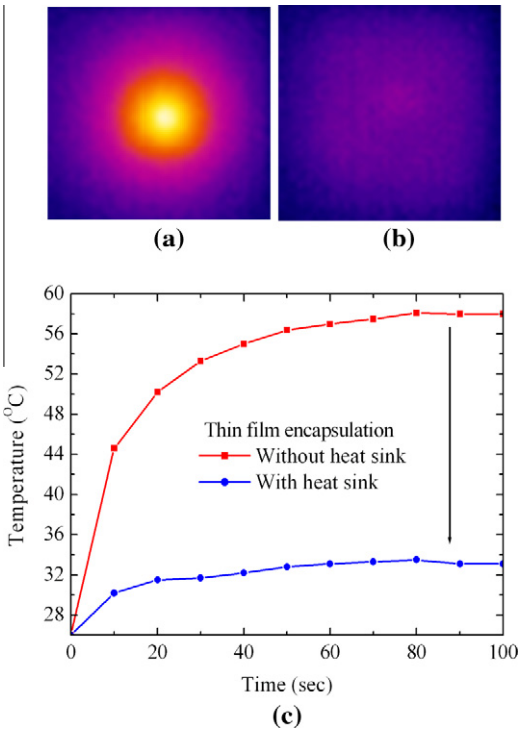

Fig. 6. Surface temperature distribution over the thin-film encapsulated (3.5 dyads) OLED (a) without and (b) with heat sink, and (c) transient variation of the maximum surface temperature measured at 7.5 V.

erty. Therefore, it is highly preferred for OLEDs provided that its oxygen barrier requirement is well met.

We have further investigated the positive effect of heat dissipation by the heat sink on the device performance of the thin-film encapsulated OLEDs. Shown in Fig. 7 are the power efficiency and luminance of thin-film encapsulated (3.5 dyads) OLEDs with and without heat sink as a function of bias voltage measured after 50 min of aging at 7.5 V (~10,000 nit). It is found that both devices exhibit a reduction of luminance and power efficiency because they were

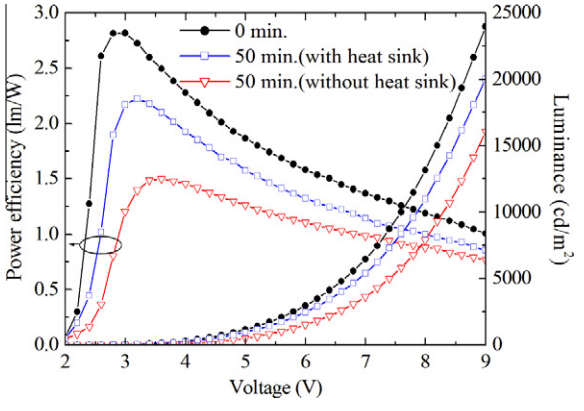

Fig. 7. Power efficiency and luminance of thin-film encapsulated (3.5 dyads) OLEDs with and without heat sink as a function of bias voltage measured after 50 min of aging at 7.5 V (~10,000 nit).

operated at high luminous intensity. However, less performance degradation appears in the device with heat sink due most likely to effective heat dissipation (Fig. 6). As such, it is desirable to employ a heat sink when OLEDs are operated at high luminance in order to reduce the unwanted Joule heating effect.

It is known that the heat transfer performance could be degraded if a multi-heterojunction is involved (namely, various different types of materials are interfaced) in the TFE structure and/or a polymer material used in the TFE film has low thermal conductivity. To verify it, we have simulated the heat transfer property of the TFE structure (Fig. 1) using the model introduced in Section 2. Summarized in Table 3 are the parameter values of thermal conductivity of those layer materials, which are required for simulations. The thermal conductivity of the polymer in the TFE film is assumed to be the same as that of the organic materials. For simplicity, we also make an assumption that the thermal conductivity of α-NPD is the same as that of Alq_3. By way of simulations, one can visualize where severe heat generation occurs inside the device. From Eqs. (3) and (6), the induced high carrier concentration along with the electric field is known to generate severe heat in the organic films. As presented in Fig. 8 showing the simulation results of the electric field and carrier density distributions inside the device, steep carrier accumulation takes place at the organic/organic interface and high electric field is induced near the interface inside the ETL layer, where severe heat is generated.

With attempt to investigate the effect of the thermal conductivity of the polymer layer on the heat transfer property, we have intentionally reduced its thermal conductivity from 0.107 W/m K to 0.107×10^{-3} W/m K and performed simulations of the spatial heat distribution without and with the heat sink. As shown in Figs. 9 and 10, when the thermal conductivity of the polymer is equal to 0.107 W/m K (i.e., it is close to the real value of the polymer conductivity), the simulation results of the surface temperature (61.7 °C without heat sink and 27.03 °C with heat sink) are very close to the measured ones (58 °C without heat sink and 33 °C with heat sink), validating our numerical calculations. It is observed that the temperature rises up with reduced thermal conductivity of the polymer. Consequently, there appears a significant temperature gradient inside the TFE layers. However, there will not arise a steep temperature gradient inside the TFE layers once the thermal conductivity of a polymer material is higher than 0.107×10^{-2} W/m K, which offers a wide choice of a polymer material. Since not many materials have such a low

thermal conductivity in reality, it can be concluded that the effect of a low thermal conductivity polymer material on the thermal performance of the TFE structure is negligible.

To find whether or not the multi-heterojunction configuration affects the thermal performance of the TFE film, we have further measured the maximum surface temperature

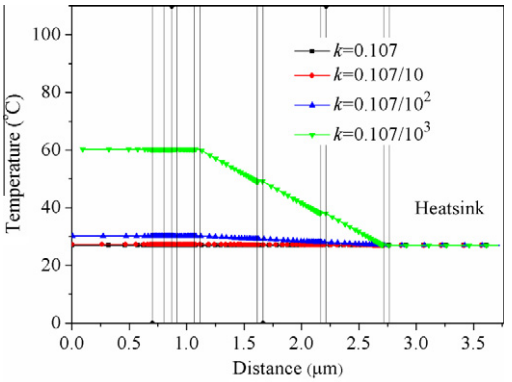

Fig. 10. Simulation results of temperature distribution over the thin-film encapsulated OLED with heat sink at 7.5 V.

by varying the TFE structure. Namely, we have reduced the number of TFE dyads to 1.5 or increased it up to 5.5. As presented in Table 4, there is no big difference in the temperature. It means that though the TFE structure is based on the multi-heterojunction configuration, yet no significant degradation in the heat transfer performance is brought in since the overall thickness of the TFE film is very small, which is also supported by the simulation results in Table 4.

4. Conclusion

We have made a comparative analysis of the thermal performance of three different encapsulation schemes; namely, the conventional glass encapsulation, epoxy-filled glass encapsulation, and thin-film encapsulation. It has been found that, in the presence of a slim and flexible heat sink, the thin-film encapsulation shows the best thermal performance, followed by the epoxy-filled glass encapsulation and then the conventional glass encapsulation. By way of experiments and simulations, we have verified that the multi-heterojunction configuration and/or the low thermal conductivity of a polymer material in the TFE film have no impact on the thermal performance due to its extremely short heat transfer pathway.

Polaron dynamics

ABSTRACT

We simulate the processes of electron extraction from 1D conjugated polymers to metal electrodes in the presence of electric fields based on the Su–Schrieffer–Heeger (SSH) model extended to a polymer/electrode contact structure. From the simulation, we can obtain the lifetime of the process that a charged carrier known as polaron at the polymer chain end starts to dissociate and the released electron tunnels to the electrode immediately. An effective carrier mobility named interface mobility can be defined for this process and calculated from the lifetime. It is found that the interface mobility is independent on the external electric fields. However, this mobility increases with decreasing the work function of the electrode. By enhancing the coupling between the polymer and the electrode, the interface mobility is shown to increase. Kinetic energy of the electrons is also shown to favor the improvement of the mobility.

1. Introduction

In the past decades, organic moleculars and conjugated polymers have shown important applications in light-emitting diodes [1], field effect transistors [2] and photovoltaic devices [3,4]. In light-emitting diodes, charge injection process greatly affects the efficiency of electroluminescence. In photovoltaic devices, however, charge extraction from organic layers to electrodes is more important. The processes of charge injection and ejection in polymer/electrode structures is asymmetric because additional electron or hole in conjugated polymers results in discrete levels in the energy gap [5]. This asymmetry has been experimentally confirmed by the hysteretic current characteristic [6]. Despite many advances, further understandings of charge injection and extraction to and from organic materials are still necessary to improve the performance of organic-based electronic devices.

Carrier transport in organic layers has notorious effect on the efficiency of organic-based electronic devices [1–14]. Charge carrier mobility has been extensively studied and shown in close relevance with the performance of the devices [15–35]. Most of the studies show charge carrier mobility in organic materials depends closely on electric field and carrier density. It is well-known that in conjugated polymers, due to strong electron and lattice interactions, additional electrons or holes will induce self-localized excitations such as solitons [36], polarons [37] and bipolarons [38]. Many studies have been performed on polaron dynamics in 1D conjugated polymer chains [39–42]. The carrier mobility is shown relatively small and dependent on the strength of the applied electric fields [40]. In most devices, the organic layers as channels for charge carriers are usually connected with electrodes. Charge migration behavior is quite different within the polymer chain far from the interface from that near the interface due to the interface scattering effect [29]. Thus carrier mobility within the chain is also expected to differ from that near the interface. Experimentally obtained carrier mobility is essentially an incorporated result. Extensive researches have been carried on polaron dynamics and carrier mobility within polymer chains far from the chain ends [29,39,40]. However, polaron dynamics at the polymer/electrode joint has been

less considered, which is an important aspect of functioning photovoltaic devices.

In the present work, we will focus on the electron extraction process at polymer/electrode joints and investigate the effects of electric field, kinetic energy of the electron, the work function of the electrode and the coupling strength between the electrode and the polymer on the electron extraction process. The model and the method employed in this work are described in the following section. The results are presented and discussed in Section 3. A summary of our findings is presented in Section 4.

2. Model and method

We consider a one dimensional polymer/metal structure. The conjugated polymer chain is described with SSH model [36–38] in which electron–phonon (e–p) interaction plays an important roll. The metal electrode is also described by SSH model, wherein however the e–p coupling is neglected [5,42,43]. Thus the Hamiltonian can be written as,

$$H = H_e + H_{latt} + H_F. \tag{1}$$

The electronic part is

$$H_e = -\sum_{n,s} t_n \left(c^\dagger_{n,s} c_{n+1,s} + c^\dagger_{n+1,s} c_{n,s} \right) + \mu \sum_{n,s} c^\dagger_{n,s} c_{n,s}, \tag{2}$$

where $c_{n,s}(c^\dagger_{n,s})$ denotes the electron annihilation (creation) operator at site n with spin $s(\uparrow,\downarrow)$. t_n is the hopping integral between sites n and $n+1$. For electrodes $t_n = t_0$, and for polymers $t_n = t_0 - \alpha(u_{n+1} - u_n) + (-1)^{n+1} t_e$, where u_n is the monomer displacement of site n and α the coefficient of electron–lattice coupling. t_e is introduced to lift the ground-state degeneracy for nondegenerate polymers [37]. $t_n = t_c$ represents the coupling between the sites connecting the organic molecule and the electrode. μ is the chemical potential. The lattice of the organic part is described by

$$H_{latt} = \frac{K}{2} \sum_n (u_{n+1} - u_n)^2 + \frac{M}{2} \sum_n \dot{u}_n^2, \tag{3}$$

where K is the elastic constant and M the mass of the repeat monomer. The first term on the righthand side of Eq. (3) describes the potential energy of the σ-bond, and the second term is the kinetic energy for the monomers. H_F describes the contribution from the external electric field,

$$H_F = \sum_{n,s} V_n \left(c^\dagger_{n,s} c_{n,s} - \frac{1}{2} \right), \tag{4}$$

V_n being site energies due to the applied field, $V_n = -|e|E[(n - n_0)a + u_n]$, with e being the electron charge, n_0 the first site of the polymer chain, a the lattice constant and E the uniform electric field.

For convenience, polymers are always assumed to be undoped. Thus the chemical potential μ of polymers is zero provided the virtual central level (VCL) of the gap is assigned to zero. For electrodes, if $\mu = 0$ the Fermi level and the VCL align. The electrode work function can be reduced by increasing the electrode chemical potential μ. The parameters in this model are those generally used in the SSH model without loss of universality [38]: $\alpha = 4.1$ eV/Å, $K = 21$ eV/Å^2, $M = 1349.14$ eV·fs^2/Å^2, $t_0 = 2.5$ eV, $t_e = 0.06$ eV and $a = 1.22$ Å. The interface coupling coefficient t_c is usually much smaller than t_0 indicating a relatively weak interchain charge transfer as compared to the intrachain transfer.

A nonadiabatic dynamics method has been used to study charge transfer across polymer/electrode contacts. The electronic wave functions evolve according to the Schrödinger equation,

$$i\hbar\dot{\psi}_i(n,t) = -t_{n-1}\psi_i(n-1,t) + V_n\psi_i(n,t) - t_n\psi_i(n+1,t), \tag{5}$$

where i is the index for the π-electrons. The lattice displacements of polymers are determined classically by the Newtonian equations,

$$M\ddot{u}_n = -K(2u_n - u_{n+1} - u_{n-1}) + 2\alpha[\rho_{n,n+1}(t) - \rho_{n,n-1}(t)] - |e|E[\rho_{n,n}(t) - 1] - \lambda M\dot{u}_n, \tag{6}$$

where the density matrix ρ is defined as $\rho_{n,m}(t) = \sum_i f_i \langle n|\psi_i(t)\rangle\langle\psi_i(t)|m\rangle$. $f_i(= 0, 1, 2)$ is the time independent distribution function determined by initial occupation number. λ is the damping coefficient introduced to give a realistic behavior of the system as a function of time [40]. $\lambda = 0.08$ fs^{-1} throughout the work. The coupled differential Eqs. (5) and (6) can be numerically solved by use of the same technique as in Refs. [40] and [42]. In our numerical simulations, fixed-end boundary condition [44] was employed because of the finite chain length character of the model. To avoid the numerical errors, we take the time step as small as 0.1 fs. In order to describe the configuration of the polymer lattice we define

$$y_n \equiv \frac{1}{2}(-1)^n(u_n - u_{n-1}). \tag{7}$$

3. Results

Due to strong electron and lattice interaction, an extra electron in conjugated polymer chain cannot stay steadily in the bottom of the conduction band. Instead, it induces surrounding lattice to deform. As a result, the deformed lattice constructs a new potential well and shallowly binds the electron. Under an external electric field, this electron can be pushed ahead towards the reverse direction of the field. The previously deformed lattice zone recovers to its normal state and the zone where the electron passes by is involved in a new distortion. Thus the carrier mobility in conducting polymers is usually small especially for cases of low electric field strength. However, if a relatively high electric field is applied the time the electron is injected into the polymer chain, the lattice deformation actually occurs near the chain end. In consequence, carrier mobility has a nonlinear enhancement in the strong field regime [29].

In order to simulate the process of electron transfer across the polymer/electrode interface, we consider 100 monomers in the polymer on the left side and 100 monomers in the electrode connected on the right side. Initially we have an electron appear at the polymer chain end near

the interface. Due to the strong electron and lattice interaction, a polaron is induced to form near the interface. An electric field, $\boldsymbol{E}$, of sufficient strength is then applied so that the electron can overcome the interface barrier and hop to the electrode. The lifetime T of the process of electron transfer from the polymer to the electrode can be numerically obtained. Although it is very difficult to define the thickness of the interface, the electron velocity v across the interface is proportional to the inverse of T,

$$v \sim \frac{1}{T}. \tag{8}$$

Thus we can define an effective carrier mobility for this charge transfer process as

$$v \equiv \frac{1}{T|\boldsymbol{E}|}. \tag{9}$$

We name this mobility as interface mobility (IM) in the following. By IM, the correlation of charge carrier transfer velocity particularly across the interface with electric field strength can be described.

Depicted in Fig. 1 is the evolution of the total charge on the polymer chain(line) and the metal electrode(dot) in the presence of an electric field of 3×10^4 V/cm with the electrode chemical potential $\mu = 0$. It can be seen the total charge on the polymer chain reduces with time, while the total charge on the metal electrode increases correspondingly. This indicates that the electron is being transferred from the polymer to the electrode. We can also find from the figure that the electron transfer process can be largely separated into two phases by the time of about 4800 fs. Before 4800 fs, although the total charge on the polymer reduces, it is more than 0.5. Thus in this period, the electron is actually still at the polymer chain end. The reduction in the quantity of the total charge suggests that the electron is breaking away from the binding of the lattice and preparing for the immediate charge tunneling process. After 4800 fs, the total charge on the electrode exceeds 0.5, which suggests that this is the charge extraction process. At about 9500 fs, the total charge of the polymer as well as of the electrode keeps almost invariant. The total charge of the electrode is very close to unit 1, which suggests that the electron has tunneled to the electrode. Thus the lifetime of the charge transfer process is T = 9500 fs. This process can also be recognized from Fig. 2 in which the dots describe a polaron initially rests at the right end of the polymer chain and the line describes the lattice configuration at 9500 fs. It is clear that at 9500 fs, the electron has hopped to the electrode and thus can the lattice recover to the dimerized state.

To discover the field effect on IM, we perform three other charge transfer simulations with field strengths of 2×10^4 V/cm, 4×10^4 V/cm and 5×10^4 V/cm, respectively, and with the chemical potential of the metal electrode being fixed to zero for all the cases. The result for effective charge tunneling velocity versus electric field is shown by the blocks in Fig. 3. The connecting lines are only the guides for eyes. We can see the four blocks are nearly lying in one line. If we extrapolate the line, it can be found that the line almost passes by the origin. Thus the slope of the curve actually describes the IM of the process. Interestingly the block-curve suggests that the IM is independent on electric field strength because the slope at each point is almost identical. This result is quite different from the field dependent carrier mobility within the polymer chain

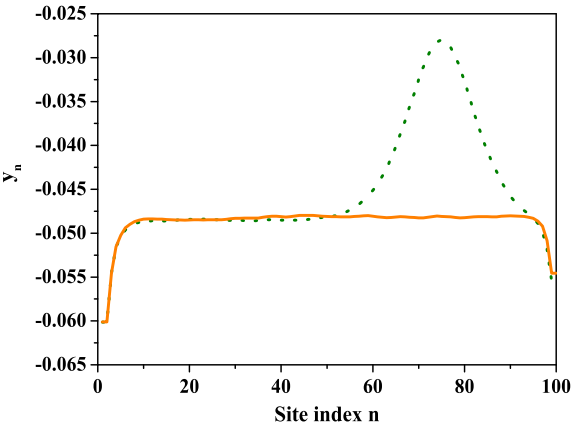

Fig. 2. Polymer lattice configuration at $t = 0$ (dot) and $t = 9500$ fs (line).

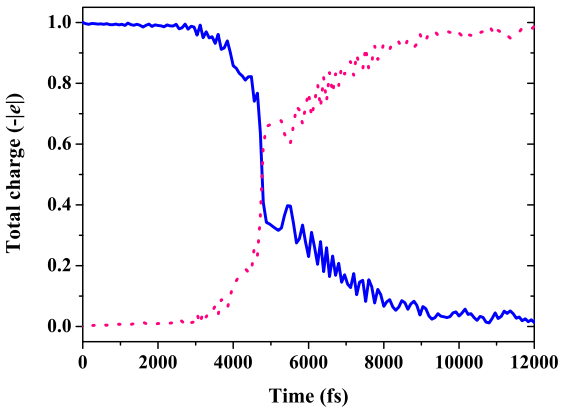

Fig. 1. Total charge evolution on the polymer chain(line) and the metal electrode(dot). Applied electric field is 3×10^4 V/cm.

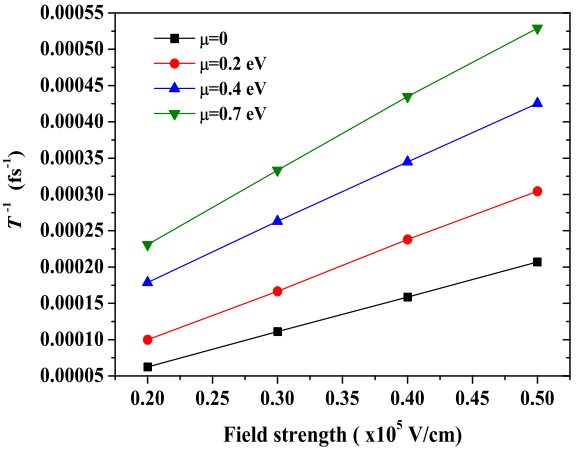

Fig. 3. Effective charge tunneling velocity with respect to electric field for various chemical potentials of the electrode $t_c = 1.0$ eV.

[40]. Thus we can conclude that the dependence of carrier mobility on electric fields is dominated by the intra-body behavior of charge carrier motion in polymers.

As is known, electrode work function has great impact on charge transfer between electrodes and organic layers. So it is necessary to investigate the influence of electrode work function on IM. In our model, the electrode work function is manipulated by changing the chemical potential μ of the metal electrodes. By increasing the electrode μ, the electrode work function is equivalently adjusted to a lower value. In order to readily observe the electron tunneling processes from the polymer to the electrode, we have the Fermi level of the electrodes always lower than the lowest unoccupied molecular orbital (LUMO) of the polymers. In Fig. 3 we show electronic velocity across the interface with respect to electric fields for four kinds of metal electrodes with various work functions. We can find that the triangles and the dots almost lie in a same line respectively like blocks. Moreover, the lines almost pass by the origin if extrapolated. Thus the slope of the lines represents the IM of the electron extraction processes. It is clear that the IM has no dependence on the applied electric fields in all the four cases. However, the IM increases with the chemical potential of the electrodes as indicated by the increasing slope of the curves. As the work function of the electrode decreases, the occupied level of the polymer has more and more correlation with the unoccupied levels of the electrode near the Fermi level because they gradually get access to each other in energy. Thus the correlation between the levels of electronic donor and acceptor stresses great effect on IM.

Typically, in electronic devices the property of polymer/electrode contacts can be markedly affected by chemisorptions or physisorptions in the preparation processes. In the present model, we have taken the polymer/electrode joint as a simple contact by introducing a coupling constant t_c to reflect the correlation between the electrodes and the polymers. In order to find out the influences of the joint character on IM, we carried out three groups of simulations for polaron transfer with three different interface coupling strengths. All the simulations are based on the same chemical potential of the electrode $\mu = 0.4$ eV. The results are shown in Fig. 4. One can find that the blocks, dots and triangles are almost lying in a same line respectively and the lines nearly pass by the origin if extrapolated. Thus it is clear that the correlation between the members of the contact has obvious effect on the electronic tunneling process. By increasing the correlation, both the IM and the electron tunneling velocity increase.

In real cases, migratory electrons do not have to be in the lowest energy state in polymers especially when thermal effect has to be taken into account. To this point, numerically we initially have the extra electron lying in an excited state (LUMO + 5 in the present work) in the polymer. It is different from the previous discussions where the extra electron is initially in the ground state (LUMO) and thus the charged carrier is polaron in the polymer that the extra electron in the excited state results in a delocalized charge carrier. The whole lattice is involved in vibrations due to the strong *e–p* coupling in the polymer. In order to compare with the previous results, we have the

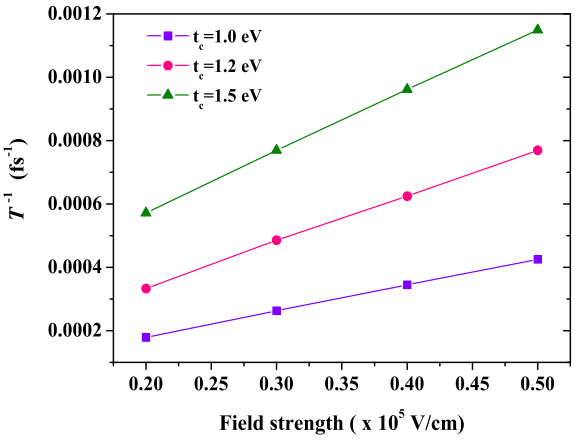

Fig. 4. Effective charge tunneling velocity with respect to electric field for various coupling strengths between the polymer and the metal electrode.

chemical potential of the electrode be zero and the charge tunneling simulation is performed under an electric field of the strength 3×10^4 V/cm. Fig. 5 gives the curves of total charge evolution of both the polymer(line) and the electrode(dot). It can be clearly seen that the lifetime of the charge transfer process is obviously reduced as compared to that shown in Fig. 1 where the charged carrier is localized polaron. This suggests that electrons of higher kinetic energy should have larger tunneling velocities. This point is more clearly shown in Fig. 6. The dots in this figure describe effective charge tunneling velocity versus electric field. The blocks of this figure are essentially the copies of the blocks in Fig. 3, only the scale of the ordinate is changed. Fig. 6 clearly shows that the electronic tunneling velocity is greatly increased for electrons with higher kinetic energy. By the comparison of the dots and the blocks of Fig. 6, it is also clear that the slope (or dv/dE) of these two cases are almost identical. However, since the dotted line does not pass by the origin, the IM of the dots are greater than that of the blocks. Thus we come to the conclusion that dv/dE is not impacted by the kinetic energy of the electrons although the electronic tunneling velocity as well as the IM is greatly enhanced.

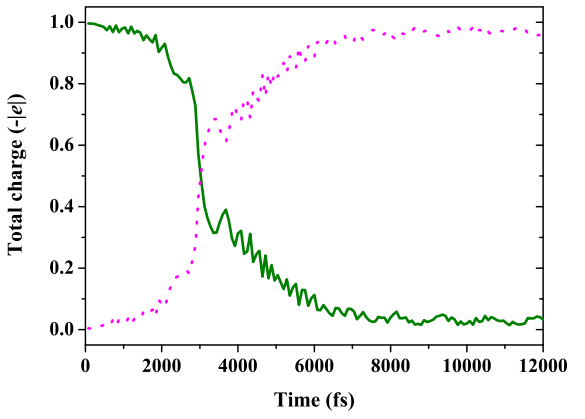

Fig. 5. Total charge evolution on the polymer chain(line) and the metal electrode(dot). Applied electric field is 3×10^4 V/cm.

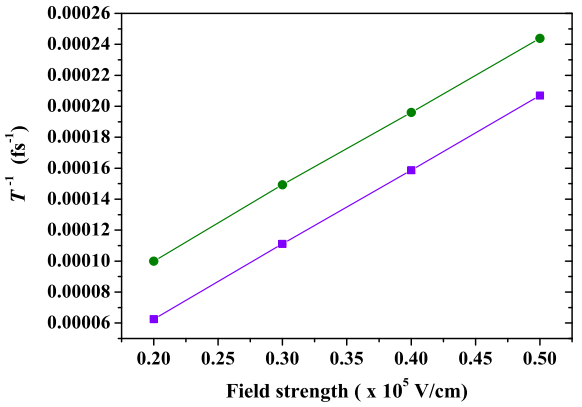

Fig. 6. Effective charge tunneling velocity with respect to electric field, with blocks for electrons initially lying in the ground state (LUMO) and dots for electrons initially lying in the excited state (LUMO + 5). For both cases the chemical potential of the metal electrode is 0.4 eV t_c = 1.0 eV.

From the previous discussions, we can find that the IM is essentially same as dv/dE if the charged carrier is polaron. As the electron is in an excited state and the charged carrier gets delocalized, the IM turns to be much large compared with dv/dE.

In the present work, the joint of the polymer and the electrode has been taken to be a simple contact. In real cases, however, the joint can be more complicated in both spacial organization and chemical ingredient. All the factors are important for practical device design task and will be studied in future work.

4. Summary

In conclusion, we have investigated electron transfer processes from polymers to metal electrodes through a dynamics method combined with an extended SSH model. We find that the IM is independent on the applied electric fields given the charged carriers being mainly composed of polarons. This suggests that the dependence of carrier mobility on electric fields is dominated by the intra-body behavior of the charged carrier in conducting polymers. In addition, we find that the IM closely depends on the work function of the electrode and the coupling of the polymer and the electrode. The IM can be obviously increased by decreasing the work function of the electrode or by increasing the correlation between the polymer and the electrode. We also find that the kinetic energy of the electrons in polymers does not affect dv/dE although it stresses great impact on electronic tunneling velocity as well as the IM.

ABSTRACT

Photoconductivity and field effect transistor (FET) performance of thin films of a thiadiazole-annulated porphyrazine compound, tetrakis(thiadiazole)porphyrazine (abbreviated as H_2TTDPz) were examined. The photocurrent-action spectra for ITO/H_2TTDPz/Au photocell exhibited symbatic and antibatic responses, depending on the bias polarity. This characteristic difference in photocurrent responses was interpreted as a filter effect in Schottky-type photocells; the dissociation of the excitons generated near the negative electrode can effectively produce photocurrent in n-type semiconductors. We also found n-type semiconductor behavior of H_2TTDPz in the thin-film FETs operated by the gates of an ionic liquid and SiO_2, and obtained a field effect mobility of 7.2×10^{-4} $cm^2 V^{-1} s^{-1}$ and an on/off ratio of 10^4.

1. Introduction

Organic semiconductors have attracted much attention due to their potential applications in organic electronics to field effect transistors (FETs), photovoltaic cells, light-emitting diodes, etc. Among organic semiconductors, porphyrazine compounds such as phthalocyanines (Pcs) have been extensively studied due to their excellent electrical and optical properties and to their chemical stability [1–3]. While most Pcs are p-type semiconductors, a very limited number of Pc analogs are known to exhibit n-type behavior [4,5]. Since, in general, n-type organic semiconductors are more unstable than p-type ones against oxygen and moisture, it is important to develop stable n-type semiconductors. The stable Pc family includes a halogen-substituted derivative, F_{16}CuPc, which exhibits n-type conduction in its FETs with a carrier mobility of 0.2 $cm^2 V^{-1} s^{-1}$ [6]. Introduction of such an electron-withdrawing group reduces the orbital energy of the lowest unoccupied molecular orbital of Pc and makes it close to the work functions of metal electrodes, providing an efficient electron injection from the electrodes to the LUMO [7].

Thiadiazole rings possess electron-withdrawing properties due to their electronegativity [8]. This chemical moiety was introduced to the molecular skeleton of Pc by the groups of Ercolani and Stuzhin through synthesis of the thiadiazole-ring annulated Pc, tetrakis(thiadiazole)porphyrazine (abbreviated as H_2TTDPz, see Fig. 1a) [9–12]. In our previous work, we have fabricated highly oriented thin films of H_2TTDPz and found a graphite-like structure: H_2TTDPz forms a 2D layer with an electrostatic side-by-side contact between the thiadiazole rings and the 2D layers stack perpendicular to substrates (see Fig. 1b) [13–15]. Furthermore, we have revealed the robustness of the thin films in electrochemical processes; the cyclic voltammogram of the H_2TTDPz thin film exhibited a repeatable reduction

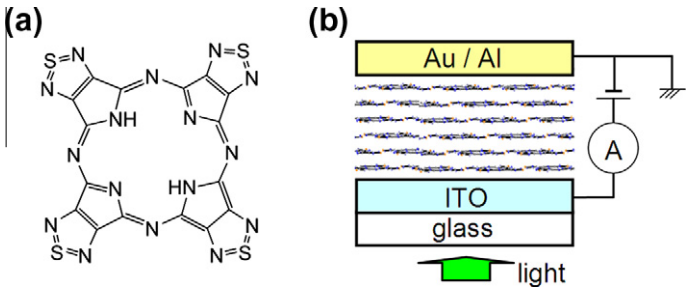

Fig. 1. H_2TTDPz molecule (a) and a schematic diagram for photoconductivity measurements (b).

peak at ca. −0.1 V *vs.* Ag/AgCl. This small negative value indicates a good electron-accepting ability of H_2TTDPz and its potential n-type semiconductor behavior. In the present report, we describe the photocurrent and the FET performance of the H_2TTDPz thin films, and present firm evidence for n-type transport.

2. Experimental

H_2TTDPz was prepared by the literature method [9]. We adopted sandwich cells (Fig. 1b) for the photocurrent measurements, and fabricated them as follows [16]. First, a thin film of H_2TTDPz was evaporated onto a glass substrate on which a 2 mm-width ITO electrode of thickness 100 nm was formed. Then a 2 mm-width Au or Al electrode with a thickness of 50 nm was evaporated onto the film perpendicular to the ITO electrode. The effective sample area was 0.04 cm^2. In order to avoid short circuiting, the thickness of H_2TTDPz was set to 200 nm, which was longer than the light penetration depth of 80 nm at the top of the Q-band.

The dc and ac photocurrent measurements were carried out with a 500-W halogen lamp [16]. The light intensity was calibrated with a Si photodiode. The monochromated light was allowed to illuminate the transparent ITO electrode, and the photocurrent was recorded under vacuum. To obtain the photocurrent-action spectra, the light was chopped with a frequency of 17–18 Hz, and the signals were detected by a two-phase lock-in amplifier [16]. The ac voltage appearing on a series resistance (1 MΩ) was measured under applied dc bias between two electrodes. The photocurrent-action spectra were then normalized in such a way that the incident photon number was constant ($10^{15}/cm^2$).

The FET performance of the H_2TTDPz thin films was examined using two kinds of gate materials, an ionic liquid, *N*,*N*-diethyl-*N*-methyl(2-methoxyethyl)ammonium bis(trifluoromethylsulfonyl)imide (abbreviated as DEME-TFSI), and SiO_2. Thin films of H_2TTDPz with a thickness of 100 nm were evaporated on interdigitated array electrodes (source and drain) with a channel width of W = 20 cm and a channel length of L = 10 μm, which are prepared by photolithography on surface-oxidized n-doped Si substrates (SiO_2: 300 nm). The ionic-liquid gate was prepared by putting a droplet of a commercial ionic liquid, DEME-TFSI, on the H_2TTDPz surface and inserting a Pt wire in it (see the inset of Fig. 6), while the surface-oxidized Si layer was used as gate in the SiO_2-gate FETs. The source and drain electrode materials were Pt and Au for ionic-liquid-gate and SiO_2-gate FETs, respectively. The performance of these FETs was examined under vacuum.

3. Results and discussion

3.1. Photocurrent

Fig. 2 shows the I–V characteristics of an (+)ITO/H_2TTDPz (200 nm)/Au(−) cell, shown in Fig. 1b. In the dark state, a clear rectifying behavior was observed (black curve), indicating the presence of a Schottky barrier, while, under illumination of white light, photocurrent was observed for both bias directions (red curve). The photocurrent quantum yield was calculated as approximately 0.1% under light illumination of 532 nm. Fig. 3 shows the photocurrent-action spectra with bias voltages of −2 (red), −1 (orange), 1 (green), and 2 V (blue), applied to the ITO electrode. This figure also shows the optical absorption spectrum of a 100-nm film of H_2TTDPz as a broken curve. When the ITO was negatively biased (red and orange), the photocurrent appeared in the range of photon energy above 1.4 eV, with a maximum of 1.8 eV. After passing through a minimum at 2.5 eV, the photocurrent increased again. These action spectra are nearly 'in phase' with the optical absorption, representing 'symbatic' behavior. When the ITO was positively biased (green and blue curves), however, the action spectra reached three maximums at

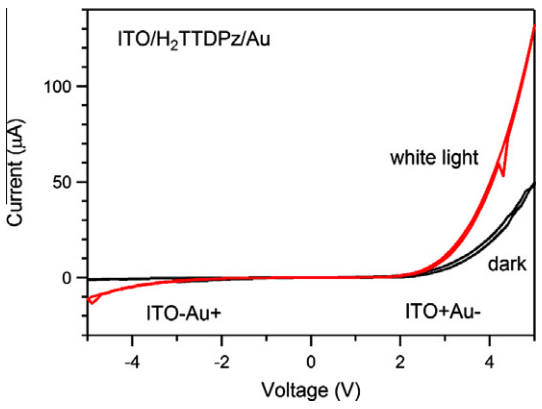

Fig. 2. I–V characteristics of the ITO/H_2TTDPz/Au photocell under dark and white light illumination.

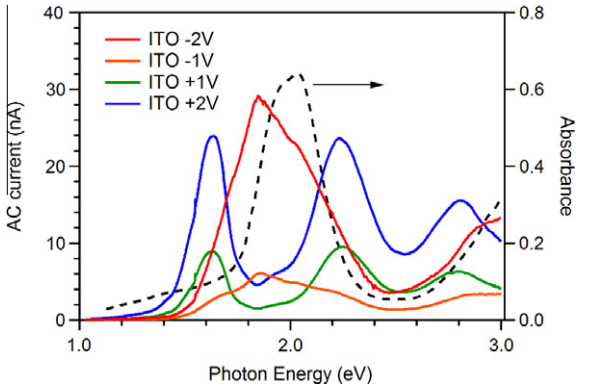

Fig. 3. Photocurrent-action spectra of the ITO/H_2TTDPz/Au photocell illuminated from ITO side under applied bias of −2 to +2 V. A broken line represents the optical absorption spectra.

1.6, 2.2, and 2.8 eV, being 'out of phase' with the photoabsorption ('antibatic' behavior).

Fig. 4 shows the photocurrent-action spectra of an (+)ITO/H_2TTDPz (200 nm)/Al(−) photocell under biases of −2 (red), −1 (orange), 1 (green), and 2 V (blue). When the Au anode was replaced with Al, the photocurrent became much smaller. In addition, the photocurrent always exhibited symbatic behavior under biases between 2 and −2 V.

The observed symbatic and antibatic behavior and the significant dependence on the anode metal can be explained as follows. Schottky-type photocells are known to exhibit a so-called filter effect in photocurrent-action spectra, in case in which the film thickness is larger than the light penetration depth [16–18]. More specifically, it is the light absorption near the Schottky contact that results in effective dissociation of excitons into free carriers because the electric field is concentrated on the barrier region [18]. The excitons far from the blocking contact cannot reach the barrier region, so they would recombine geminately without producing photocarriers.

Since the major carrier in n-type semiconductors is electrons, their photocurrent should be dominated by photocarriers generated near the negatively biased electrode, forming a Schottky contact with the n-type materials [19–22]. After charge separation near the negative electrode, the positive carriers or holes are easily absorbed into this electrode and electrons as negative carriers travel to the opposite positive electrode, producing photocurrent. Therefore, when the negative electrode is illuminated, the photocarrier yield is proportional to the light intensity and the photocurrent action spectrum coincides with the optical absorption spectrum of the semiconductor, resulting in 'symbatic' behavior. If the positive electrode is illuminated, however, the light intensity might attenuate before reaching the negative electrode at which the photocarriers are generated, due to a strong absorption in the organic semiconductors. Therefore, a larger photocurrent is expected at the absorption edges than at the absorption center, because such weakly absorbed light can reach the negative electrode and can induce charge separation there. The photocurrent action spectrum becomes out of phase with the optical absorption spectrum, resulting in 'antibatic' behavior.

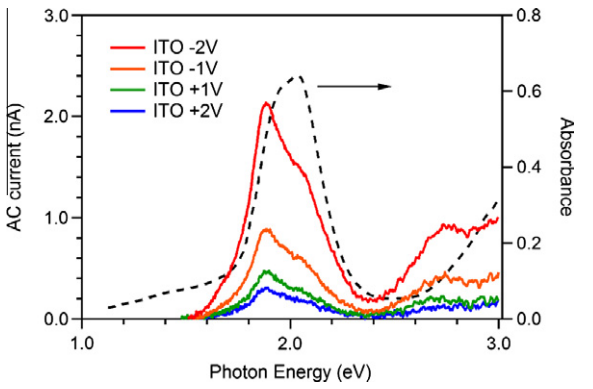

Fig. 4. Photocurrent-action spectra of the ITO/H_2TTDPz/Al photocell illuminated from ITO side under applied bias of −2 to +2 V. A broken line represents the optical absorption spectra.

Fig. 5a schematically shows the workfunctions of the ITO and Au electrodes as well as the HOMO and LUMO levels of H_2TTDPz. The expected charge separation region in the ITO/H_2TTDPz/Au photocell is indicated as a yellow oval. Photoelectron spectroscopy and photoabsorption spectroscopy on H_2TTDPz suggest that the LUMO and HOMO levels of H_2TTDPz are 4.6 and 6.6 eV, respectively, from the vacuum level [23]. Because these levels are far from the workfunctions of ITO (4.8–5.1 eV) and Au (5.1 eV), either ITO/H_2TTDPz or Au/H_2TTDPz contact would act as a blocking contact with a Schottky-type barrier when negatively biased. In contrast, the workfunction of Al (4.2 eV) is close to the LUMO level so that the Al contact probably forms an ohmic contact with H_2TTDPz. The symbatic and antibatic behavior and the strong electrode dependence of the ITO/H_2TTDPz/Au and ITO/H_2TTDPz/Al photocells are consistent with H_2TTDPz acting as an n-type semiconductor.

3.2. FET characteristics

In our previous work, we examined the solid-state electrochemical reduction of the H_2TTDPz thin films in an electrolyte solution, taking advantage of their robustness. In situ conductivity measurements for the thin films in NH_4Cl electrolyte revealed a conductivity enhancement on the order of 10^3, associated with penetration of the counter cations into the thin films. In the present work, we fabricated thin-film FETs of H_2TTDPz with an ionic liquid, DEME-TFSI, as a gate electrolyte (see the inset of Fig. 6). By using such an ionic liquid, high-density carrier accumulations were expected through an electric double layer (EDLs) formed on the H_2TTDPz surface in the gate electrolyte solution [24,25].

Fig. 6 shows the output characteristic, namely the source-drain current I_D *vs.* voltage V_D plots, measured in the dark under vacuum with the gate voltages V_G = 0.0, 0.2, 0.4 and 0.6 V. There is little deviation from zero current with an increase in V_G, indicating that current leakage through the dielectric is negligibly small.

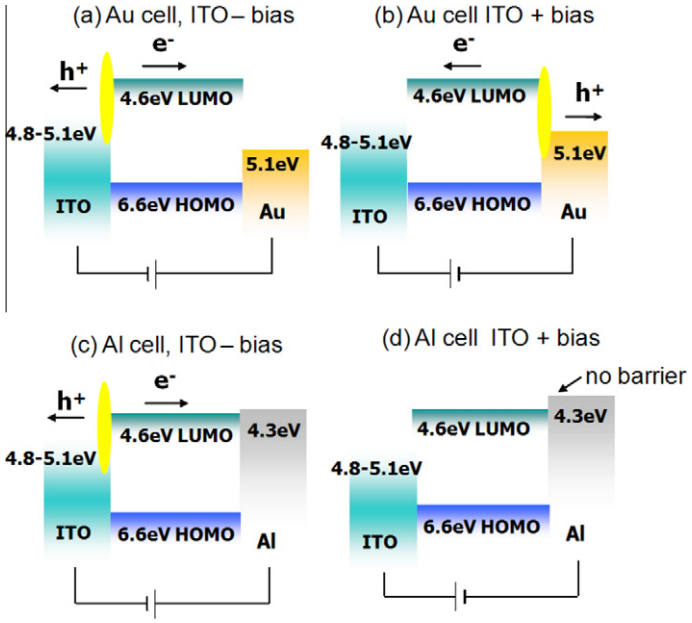

Fig. 5. Schematic energy diagram for ITO/H_2TTDPz/Au (a) and (b) and ITO/H_2TTDPz/Al (c) and (d) cells under negative (a) and (c) or positive (b) and (d) bias applied to the ITO electrode.

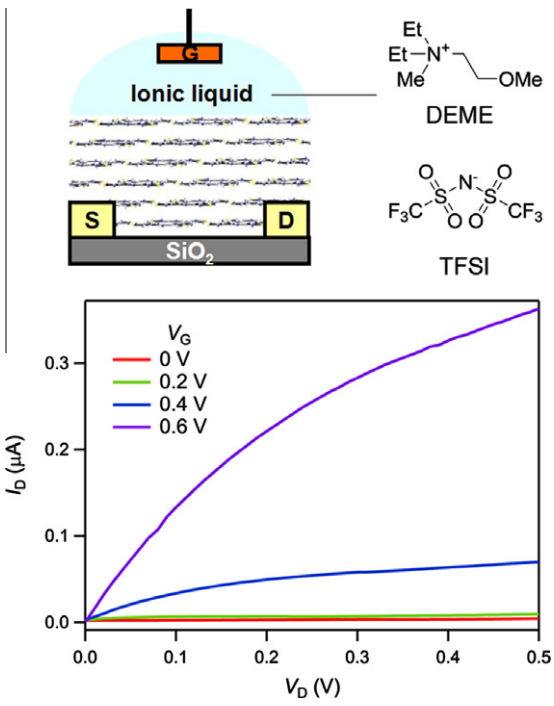

Fig. 6. Output characteristics of the ionic liquid-gate FET of H_2TTDPz. The inset shows a schematic illustration of the device configuration.

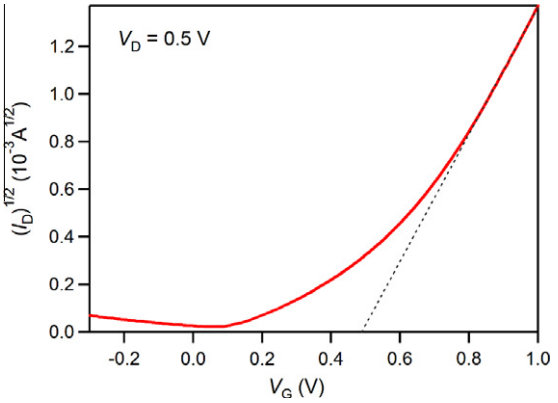

Fig. 7. Transfer characteristics of the ionic liquid-gate FET of H_2TTDPz.

Fig. 7 shows the transfer characteristic, namely the source-drain current $I_D^{1/2}$ *vs.* gate voltage V_G plots, measured in the dark under vacuum with a source-drain voltage of $V_D = 0.5$ V. The I_D value at $V_G = 0$ V is less than 1 nA, indicating that the present transistors are in normally off states. With an increase in V_G towards a positive value, I_D shows a quick increase above $V_G = 0.2$ V with an on/off ratio of ca. 10^4. This value is higher than the conductivity enhancement factor (10^3) obtained in solid-state electrochemistry [15]. In addition, the I_D *vs.* V_G curves showed a good reversibility, so that there should be no penetration of the counter cations in the present EDL-FET system.

This FET behavior clearly indicates that H_2TTDPz operates as an n-type semiconductor. The extrapolation of the $I_D^{1/2}$ *vs.* V_G curve from the large V_G range indicates a very low threshold voltage of $V_G^{th} = 0.5$ V. This type of low power operation is an advantage of ionic-liquid gate dielectrics transistors. The field effect mobility in the saturation regime is calculated as $\mu = 7.2 \times 10^{-4}$ cm^2 V^{-1} s^{-1}, using the equation $\mu = 2L/WC \cdot (\partial\sqrt{I_D}/\partial V_G)^2$, where L, W, and C are the channel length, the channel width, and the capacitance of the dielectric layer, respectively. The value of C for DEME-TFSI was obtained as 1 μF cm^{-2} in a separate measurement using a parallel plate capacitor of this

material. The μ value of H_2TTDPz is nearly comparable to that of F_{16}MPc [6]. We have also examined the performance of the SiO_2-gate thin-film FETs of H_2TTDPz. The results are shown in Supplementary Fig. S1, indicating $V_G^{th} = 10$ V, the on/off ratio = $\sim 10^2$, and $\mu = 1.3 \times 10^{-5}$ $cm^2\,V^{-1}\,s^{-1}$.

Although we found a slight improvement in μ by using wider gap electrodes, the obtained μ values for H_2TTDPz were not very high. This is perhaps because of a mismatch between the conduction pathway and the π stacking direction, as indicated in the inset of Fig. 6. Namely, the molecular planes of H_2TTDPz are parallel to substrates, so that the π stacking does not bridge the distance between the source and drain electrodes [15]. However, the n-type semiconductor behavior of H_2TTDPz indicates that p–n junctions between the series of Pc and H_2TTDPz would be highly possible, which are applicable to bulk heterojunction photovoltaic cells. Since porphyrazine has a good chemical stability and is useful in organic electronics, all porphyrazine-based organic devices would be promising.

4. Conclusion

We have performed photocurrent and FET performance measurements on the thin films of H_2TTDPz and have found firm evidence of n-type semiconductor behavior. The ITO/H_2TTDPz/Au cells exhibited symbatic and antibatic behavior, according to bias voltage direction, which was well-interpreted as a filter effect for the semiconductors. The thin film FET of H_2TTDPz also showed a typical feature of n-type semiconductors. The electron mobility was evaluated from the transfer characteristics as $\mu = 7.2 \times 10^{-4}\,cm^2\,V^{-1}\,s^{-1}$. Although this value is not very high, the chemical stability of H_2TTDPz as a porphyrazine derivative suggests the potential application of the M-TTDPz series in organic electronics as an n-type semiconductor.

ABSTRACT

The series resistance of a bulk heterojunction solar cell diode affects the measurement of the voltage dependence of the diode photocurrent, $P(V)$. An empirical model for the effect is described and shows that $P(V)$ can be significantly modified, particularly at high bias voltages. Experimental measurements on PCDTBT:PCBM solar cells with added series resistance demonstrate the effect and confirm the model. The model provides a method to correct the photoconductivity data using measured quantities.

1. Introduction

Organic solar cells are formed from a nanostructured composite of electron donor and acceptor domains with a bulk heterojunction (BHJ) diode structure [1]. Excitons which are optically excited in one or other domain are split by the band offset at the BHJ interface so that the electrons move in the acceptor and holes in the donor. The charge is collected by the internal voltage of the diode. The cell structure comprises metal contacts which are usually an indium tin oxide (ITO) anode and a suitable metal cathode, a hole contact layer which is typically poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and is principally in electrical contact with the donor, the BHJ diode and sometimes an additional optical spacer layer of TiO_x in electrical contact with the acceptor [2]. The diode built-in potential arises from the difference in the effective Fermi energy on either side of the diode.

The recombination of the electrons and holes is of great interest because it has a detrimental effect on the solar cells efficiency and because it is fundamentally interesting to understand the role of the nanostructure on the opto-electronic properties. There are several possible recombination mechanisms and considerable disagreement over which mechanism dominates in any particular cells [3–7]. A useful measure of the recombination is the voltage dependence of the cell photocurrent [7–9]. Barring contact injection or avalanche gain, both of which are negligible at low electric fields [10], the diode is limited to unity gain in reverse bias. Hence, the photocurrent normalized to the effective generation rate, $P(V)$, measures the fraction of carriers that reach the contacts, and $1 - P(V)$ is the fraction that recombine.

A knowledge of $P(V)$ therefore allows different recombination models for the BHJ diode to be tested. Since the recombination occurs at the interface in the BHJ structure, it is important that $P(V)$ correctly reflects the internal photocurrent of the diode and the electronic properties of the junction. The purpose of this paper is to point out that this is not necessarily the case. Generally it is expected that $P(V)$ will drop monotonically to zero when the applied voltage equals the built-in potential, V_{BI}, because at this voltage the internal field changes sign.

It is well known that a series resistance influences the current in a solar cell and reduces the fill factor as shown in BHJ cells by recent work [11]. The physical origin of the series resistance in any particular cell is not obvious

doi:10.1016/j.orgel.2010.11.012

because there are several possibilities. Most cells use an ITO transparent conductor and its resistance between the cell stack and the contact leads can be significant. Within the cell stack the PEDOT:PSS layer and the TiO_x (if used) have higher resistivity than the metal contacts, and could be the origin. Any of the junctions between the layers could also add resistance. For example, ITO and PEDOT:PSS have different work functions, and the alignment of the Fermi energy across the junction occurs by charge transfer at the interface. The resulting dipole layer at this or other junctions may introduce a series resistance. The internal resistance of carriers in the BHJ diode itself may also be the origin of the series resistance.

This paper describes how the resistance specifically affects the cell photocurrent. An empirical model is described that does not presuppose any specific physical origin of the series resistance. Indeed we show that some measured forms of $P(V)$ are a consequence of a series resistance that could be of any origin. Analytical expressions relating the experimentally measured and internal $P(V)$ are developed in Section 2 and compared to experimental data in Section 3.

2. Series resistance model

The photocurrent is the difference between the current measured under illumination, J_L, and the dark current, J_D,

$$J_L(V) = J_D(V) - e \cdot G \cdot P(V), \tag{1}$$

where G is the effective carrier generation rate (the concentration of optically excited excitons that are split at the BHJ interface), and the sign of the photocurrent is chosen so the $P(V)$ is positive under solar cell operating conditions. The diode dark current is described by [12,13],

$$J_D(V) = J_0 \exp\left(\frac{e(V - J_D(V)R_S)}{nkT}\right) = J_0 \exp\left(\frac{eV_{IDJ}}{nkT}\right), \tag{2}$$

where n is the diode ideality factor, R_S is the ohmic series resistance (in units of $\Omega\,cm^2$) and the shunt resistance is not included. $V_{IDJ} = V - J_D R_S$ is the internal diode junction voltage with the voltage drop across the resistance subtracted, and is the voltage that defines the diode junction. This conventional form of the dark current applies well to many BHJ solar cells at the voltages of interest [7,13]. Inserting Eq. (2) into Eq. (1) gives the experimentally measured $P_{EXP}(V)$,

$$eGP_{EXP}(V) = J_0 \exp\left(\frac{e(V - J_D(V)R_S)}{nkT}\right) - J_L(V) \tag{3}$$

$P_{EXP}(V)$ is the difference between the experimentally measured dark current and the experimentally measured current under illumination. However, inspection of Eq. (3) indicates that it cannot be the correct expression for the photocurrent, since the right side of the equation has the current J_L in one term and J_D in the other. The problem is that the voltage drop across the series resistance must reflect the current under illumination rather than the current in the dark. Consequently the photoconductivity derived experimentally from Eqs. (1) and (2) is not the correct internal photoconductivity when there is significant series resistance. The voltage drop across R_S has a different magnitude in the dark and under illumination and also changes sign with the current, and is therefore of opposite sign for the dark current and the photocurrent for $V < V_{OC}$.

There is a second related problem with the use of Eq. (3) to extract the internal $P(V)$. The term $(V - J(V)R_S)$ in the diode equation (Eq. (2)) arises because the internal voltage across the diode differs from the external applied voltage. The physically interesting $P(V)$ also reflects the internal diode voltage V_{IDJ}, rather than the external voltage. The internal diode photocurrent, $P_{INT}(V)$, is therefore described by Eqs. (1) and (2), in which V is replaced by V_{IDJ} in the expression for $P(V)$, which gives

$$eGP_{INT}(V_{IDJ}) = J_0 \exp(eV_{IDJ}/nkT) - J_L(V) \tag{4}$$

Inserting the value of V_{IDJ} gives,

$$eGP_{INT}(V - J_L(V)R_S) = J_0 \exp\left(\frac{e(V - J_L(V)R_S)}{nkT}\right) - J_L(V) \tag{5}$$

Combining Eqs. (3) and (5), relates the experimental and internal $P(V)$,

$$eGP_{INT}(V - J_L R_S) = eGP_{EXP}(V) - J_0 \times \exp\left(\frac{eV}{nkT}\right)\left[\exp - \frac{J_D(V)R_S}{nkT} - \exp - \frac{J_L(V)R_S}{nkT}\right] \tag{6}$$

or alternatively,

$$eGP_{INT}(V - J_L R_S) = J_D(V) \exp\left(\frac{eGP_{EXP}(V)R_S}{nkT}\right) - J_L(V) \tag{7}$$

The internal and experimental values of $P(V)$ are the same only when $J_L(V)R_S \ll V$ over the whole voltage range, otherwise they are different. The experimentally measured quantities are $J_L(V)$ and $J_D(V)$ from which $P_{EXP}(V)$ is obtained from Eq. (1). With the additional knowledge of R_S, which can be obtained from $J_D(V)$ using Eq. (2), $P_{INT}(V)$ can be deduced from these equations.

Calculations of $P_{EXP}(V)$ for a given $P_{INT}(V)$ with different series resistance and different illumination intensities were made to illustrate the effect. The parameters of the dark diode current calculation are chosen to correspond to the data for a PCDTBT/PCBM solar cell and we set $J_0 = 3 \times 10^{-12}$ A/cm^2, $n = 1.7$ and $V_{BI} = 0.86$ V. The internal $P_{INT}(V)$ in Eq. (7) is modeled by the charge collection equation used in Ref. [7], since it gives a good fit to the photoconductivity data but any suitable form could be used. The procedure for modeling the effect of series resistance to obtain $P_{EXP}(V)$ is to calculate the dark diode current from Eq. (2), the illuminated diode current, $J_L(V)$, from Eq. (5), and use these to calculate $P_{EXP}(V)$ from Eq. (3). The dark current is shown in the inset to Fig. 1, for a series resistance of 12 $\Omega\,cm^2$ and is a good fit to the data from Ref. [7].

Fig. 1 shows the calculated $P_{EXP}(V)$ for different series resistance at fixed generation rate and Fig. 2 shows the same as a function of the generation rate at fixed R_S. When the series resistance is zero, the internal and experimental $P(V)$ are identical. At low illumination levels, $P_{EXP}(V)$ differs from $P_{INT}(V)$ primarily at high forward voltages when $J_D(V)$ is large and $J_D(V)R_S$ is significant compared to V. At high

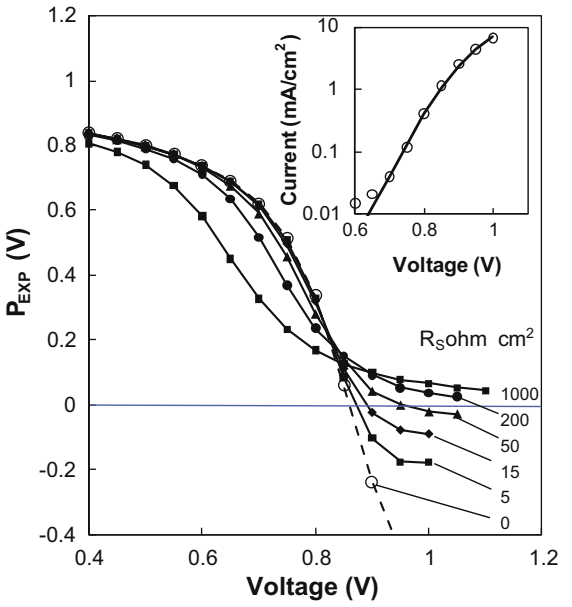

Fig. 1. Calculated $P_{EXP}(V)$ for fixed illumination and various series resistances as shown. The parameters of the calculation reflect data obtained for PCDTBT:PCBM cells, with V_{BI} = 0.86 V. $P_{INT}(V)$ is the dashed line. The illumination corresponds to a reverse saturation current of ~0.1 mA/cm^2. The inset shows the measured dark current for a PCBTBT:PCBM cell (data points), and the corresponding model (solid line) with R_S = 12 Ω cm^2, $J_0 = 3 \times 10^{-12}$ A/cm^2 and n = 1.7.

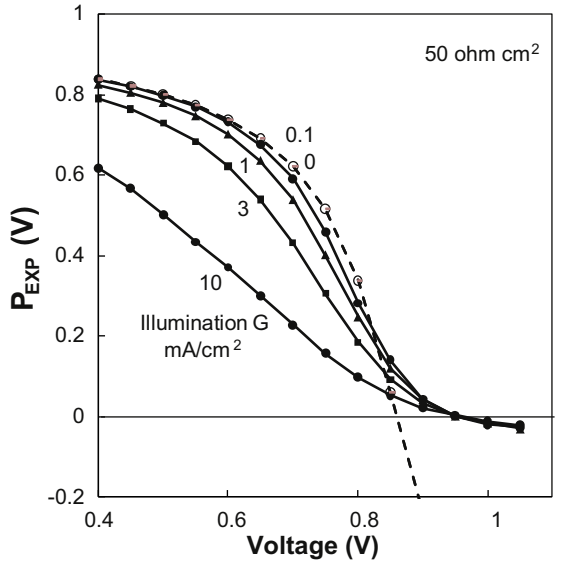

Fig. 2. Calculated $P_{EXP}(V)$ for a fixed series resistance and various illumination intensities as shown, with the same parameters as for Fig. 1.

light intensity $P_{EXP}(V)$ differs from $P_{INT}(V)$ over a wider range of voltages because $J_L(V)R_S$ is also large. Focusing on the high voltage behavior, there is an extended tail of $P_{EXP}(V)$ to high voltage, so that the zero crossing (the value of $V = V_X$ when $P_{EXP}(V_X) = 0$) moves to higher voltage with increasing R_S. Inspection of Eq. (6) shows that when $P_{EXP}(V_X)$ is zero, which occurs by definition, when $J_L = J_D$, then the right side of Eq. (6) is zero, so that $P_{INT}(V_X - J_L R_S)$ is also zero. This occurs when the internal voltage is the built-in potential, V_{BI}, so that,

$$V_X = V_{BI} + J_D(V_X)R_S \tag{8}$$

The voltage at which $P_{EXP}(V_X)$ crosses zero is therefore larger than V_{BI} and according to Eq. (8), should be independent of illumination, since none of the terms in the equation depend on the illumination intensity.

Further into forward bias than V_X, the increasing forward current results in a larger voltage drop across R_S, and the internal voltage is an increasingly small fraction of the applied voltage. $P_{EXP}(V > V_X)$ will therefore tend to a constant with absolute value <1 determined by the small residual internal voltage. Its value can be calculated from Eq. (3) and should decrease as R_S increases. If the series resistance is large enough to completely dominate the diode current, then $J_D \sim V_X/R_S$ and Eq. (8) has no solution. In this case $P_{EXP}(V_X)$ tends to zero asymptotically and never crosses zero, as is seen in the high resistance model calculations in Fig. 1.

The open circuit voltage V_{OC} occurs when $J_L(V_{OC}) = 0$, when from Eqs. (3) and (5),

$$eGP_{EXP}(V_{OC}) = J_0 \exp\left(\frac{e(V_{OC} - J_D(V)R_S)}{nkT}\right) \tag{9}$$

$$eGP_{INT}(V_{OC}) = J_0 \exp\left(\frac{eV_{OC}}{nkT}\right) \tag{10}$$

so that,

$$\frac{P_{INT}(V_{OC})}{P_{EXT}(V_{OC})} = \exp\left[-J_D(V_{OC})R_S/nkT\right] \tag{11}$$

Eq. (11) shows that $P_{INT}(V)$ is smaller than $P_{EXP}(V)$at V_{OC}, because the exponent is negative. However, at low illumination intensity and small V_{OC}, the right side of Eq. (11) becomes very close to unity.

3. Experimental measurements

To further illustrate the effects, we have measured $P_{EXP}(V)$ for BHJ solar cells in which an additional external series resistance is included. The cells are fabricated from a PCDTBT/$PC_{70}BM$ blend [14], and are similar to those used in the previous recombination studies [7]. Details of cell fabrication are given elsewhere [2]. The measurements are made using illumination chopped at 230 Hz, and a lock-in amplifier to record the photocurrent with the dark current automatically subtracted. The input to the lock-in amplifier is the voltage developed across a resistor, which was varied from R = 5 Ω–10 kΩ, and this resistor also acts as the added series resistance of the cell. The use of chopped illumination prevents possible effects of a temperature difference between measurements in the dark and under illumination.[15] The cell has an area of about A = 0.04 cm^2, and $R_S = R{\cdot}A$ for comparison with the model.

Fig. 3a shows the measurements of $P_{EXP}(V)$ for different added series resistance, and Fig. 3b shows measurements for different illumination intensities. The data also shows

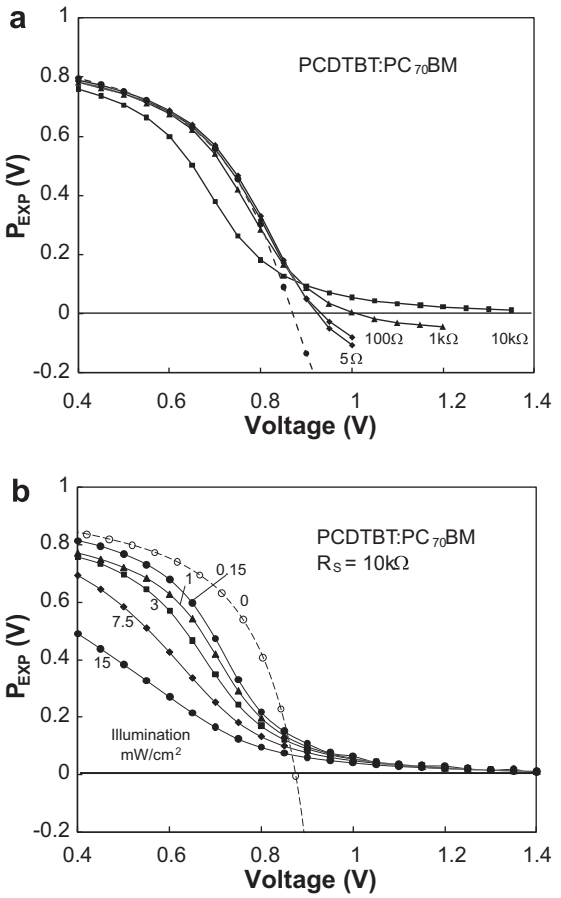

Fig. 3. (a) Measurements of $P_{EXP}(V)$ for a PCDTBT:PCBM solar cell with (a) added series resistance as shown and a constant light intensity, and (b) a fixed added series resistance of 10 kΩ, and for different light intensity, as shown. The measurements use a lock-in amplifier which automatically subtracts the dark current. The area of the cell is ~0.04 cm^2.

the charge collection model as used in the simulations of Figs. 1 and 2, with parameters chosen to fit the particular data set. Comparison of the data with the models in Figs. 1 and 2 shows qualitative and quantitative agreement. The change in shape of $P_{EXP}(V)$ for different resistance and light intensity is evident. The data shows no change in the $P_{EXP}(V)$ until R exceeds about 100 Ω ($R_S \sim 4\ \Omega\ cm^2$). The zero crossing voltage increases with series resistance, and at sufficiently large R, $P_{EXP}(V)$ remains positive and approaches zero asymptotically, as expected from the model. The data in Fig. 3a have a zero crossing at 0.92 V for the 5 Ω resistance and is almost the same for 100 Ω. The data in this voltage range deviate from the charge collection equation and have a higher zero crossing than we found previously (0.92 V versus 0.86 V). The curvature near the zero crossing indicates that there is a significant series resistance in this device even in the absence of the added resistance.

The variation with illumination intensity shown in Fig. 3b similarly agrees with the model, and demonstrates the expected decrease in $P_{EXP}(V)$ at lower voltages when G is sufficiently large. A large resistance was used for this experiment to accentuate the effects. The results illustrate that $P_{EXP}(V)$ can differ greatly from $P_{INT}(V)$.

The built-in potential and the corrected $P_{INT}(V)$ can be extracted from the measurement of $P_{EXP}(V_X)$ using set of equations given above. Fig. 4 shows measured $P_{EXP}(V_X)$ data for the PCDTBT/PCBM cell and the calculated $P_{INT}(V)$. The dark current, which is measured separately, provides a value of R_S, J_0 and n, and these parameters are shown in Fig. 4. The built-in potential can be obtained from the measured crossing point using Eq. (8). For the data in Fig. 4, the zero crossing voltage is 0.9 V and decreases to 0.87 V after the correction. The calculated $P_{INT}(V)$ in Fig. 4 differs from $P_{EXP}(V)$ mostly near the crossing point, and to a lesser extent at lower voltages, as expected. Cells with a much larger internal series resistance prove to be difficult to correct accurately, probably because R_S has a small voltage dependence rather than being constant, and the correction relies on an increasingly accurate model for J_D.

Previous data on similar PCDTBT cells had a zero crossing at 0.86 V and did not show significant curvature near the zero crossing [7]. The inset of Fig. 1 shows that the dark current data from Ref. [7] has a series resistance of 12 Ω cm^2 and the current at 0.86 V is about 1 mA/cm^2. The zero crossing voltage V_X is shifted by $J(V_X)R_S \sim 0.01$ V, which shows for that particular sample, that the measured P(V) is minimally affected by the series resistance. The cell in Fig. 4 has a larger internal resistance and hence a slightly different shape and crossing point. However the corrected values of the built-in potential for the two devices agree well.

The analysis of Fig. 4 shows that the series resistance measured in the dark leads to a function $P_{INT}(V)$ which is consistent with theoretical expectations and with measurements of $P_{EXP}(V)$ in similar devices with a lower resistance [7]. It is possible that the series resistance varies with light intensity in some solar cells [16]. In such cases the resistance can be treated as a free parameter and obtained from a best fit to any known property of $P_{INT}(V)$.

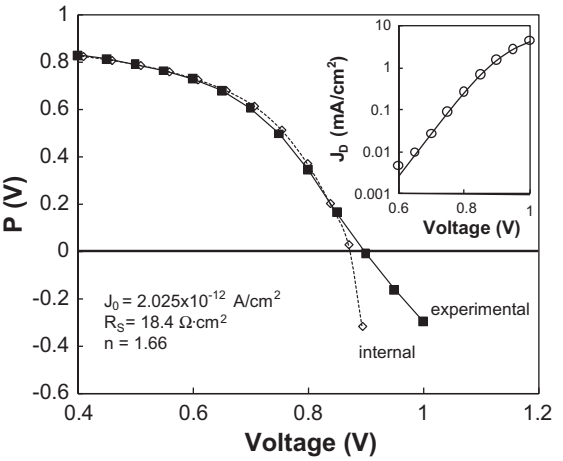

Fig. 4. Measurements of $P_{EXP}(V)$ for the same PCDTBT:PCBM cell as in Fig. 3, using dc illumination, and the calculation of $P_{INT}(V)$ as derived from Eq. (4). The series resistance and other diode parameters are obtained from the dark forward bias current, as shown in the inset (points are data and the line is the model). The reverse bias photocurrent is 0.7 mA/cm^2.

4. Discussion

The model and experiments show that $P(V)$ can be significantly modified by a series resistance. The data can be corrected to give the internal $P(V)$, provided that the series resistance can be determined and is not too large. The best test of whether there is a significant series resistance effect is to measure the dark forward bias characteristics, $J_D(V)$. If the exponential region of $J_D(V)$ continues up to at least the built-in potential, then the measured $P(V)$ is not influenced by series resistance at low illumination intensity, but otherwise will be increasingly distorted at high voltages. At high illumination intensity there is a series resistance effect whenever $J_L R_S$ is significant.

Other publications discuss the cell photoconductivity, $P(V)$, and exhibit a form of $P(V)$ that is similar to those that we demonstrate are influenced by series resistance. For example, Ooi et al. described P3HT/PCBM cells with a symmetric photocurrent response that is similar to the calculations in Fig. 1 and the data of Fig. 3 [16]. Ooi et al. correct for the possible change in temperature when the cell is illuminated which has a different effect on J_D and therefore on the experimental $P_{EXP}(V)$. The data by Ooi et al. show the same general shape as given by Fig. 1, as well as a zero crossing of $P_{EXP}(V)$ which is independent of illumination, and the saturation of $P_{EXP}(V)$ in forward bias at a value much lower than in reverse bias. Their data therefore closely follow the predictions expected for a cell with significant series resistance. Indeed the paper shows a forward current that is almost ohmic above $\sim$0.7 V, and a zero crossing at $\sim$0.9 V, which is much higher than other P3HT cells. Ooi et al. explain their results in terms of different extraction barriers at the two contacts, but a significant series resistance effect may be a more likely explanation.

Since our analysis of the series resistance is empirical, the effects described are independent of the physical mechanism that provides the series resistance. The shape of $P_{EXP}(V)$ can demonstrate that a series resistance effect is present, and the corrected value of $P_{INT}(V)$ provides insight into the photoconductivity of the cell diode, but neither measurement can give direct evidence for the origin of the series resistance, which requires additional experimental information.

5. Conclusions

The series resistance has a significant effect on the voltage dependence of the photocurrent, such that the measured result is different from the internal photocurrent of the diode. When the photocurrent is used to deduce the properties of the solar cell, it is important that the internal $P_{INT}(V)$ is determined. The presence of a significant series resistance effect can often be deduced from the form of $P_{EXP}(V)$ and the magnitude of the R_S can be obtained from the dark diode characteristics. It is possible to extract V_{BI} and $P_{INT}(V)$ from the experimental measurements, although the accuracy decreases with increasingly large values of the series resistance.

Acknowledgements

The authors are grateful to A. Heeger for enabling the collaboration to study BHJ solar cells. Research at UCSB was supported as part of the Center for Energy Efficient Materials, an Energy Frontier Research Center funded by the US Department of Energy, Office of Science, Office of Basic Energy Sciences under award Number DE-SC0001009. The materials used for the fabrication of the solar cells were provided by Dr. D. Waller of Konarka Technologies.

ABSTRACT

Layer-to-layer registration is a significant problem in printed electronics since parasitic overlap capacitances resulting from the poor registration of conventional printers substantially degrade device operating speeds. To overcome this, a novel inkjet printing process was utilized to demonstrate an all inkjet-printed and fully self-aligned transistor, as well as fully self-aligned inverters for the first time. Self-alignment of transistor source/drain electrodes to gates was achieved by a printed wetting-based roll-off process, resulting in an improved overlap capacitance as small as 0.14–0.23 pF mm^{-1}. Circuit building blocks including transistor arrays and inverters were demonstrated using a novel self-split source/drain and a self-aligned interconnect printing technique. Due to the substantial reduction in overlap capacitance, demonstrated inverters showed a propagation delay as low as 0.488 ms at a fan-out of 1, despite using materials with mobility of 0.01 cm^2 V^{-1} s^{-1}, thus showing a performance that is suitable for use in a range of low-cost electronics applications, realized using a simple, scalable process.

1. Introduction

Printing techniques have been industrialized and become an essential part of publishing and transaction printing for a century. In recent years, printed electronics has emerged as a candidate for the realization of low-cost and large area electronic systems. Unlike its conventional silicon counterpart, printed electronics reduces the major cost points of semiconductor manufacturing, including subtractive lithography and vacuum processing. Moreover, printing is compatible with flexible substrates and roll-to-roll processing, making it promising for use in such applications as low-cost printed radio frequency identification (RFID) tags and large-area flexible electronics and displays [1–3].

All printed passive devices [4,5] and active transistors [6] are maturing as printable materials have become widely available in recent years. Unfortunately, printed transistors typically suffer from degraded performance due to poor material quality, large channel length and very high overlap capacitance [7–9], limited by the coarse resolution of state-of-the-art printing techniques such as inkjet [10], rotogravure [11] and offset printing [12]. The material quality has been improved recently [13,14], resulting in devices with higher mobilities. Furthermore, printed transistors have been successfully downscaled to the range of 100 nm channel length by using self-aligned printing techniques to realize feature separation and definition in individual layers [15–17]. However, the poor layer-to-layer registration of printing techniques remains a tremendous bottleneck in printed devices. While some efforts have been made to realize self-aligned registration, these have necessitated the use of lithographic techniques [17–19], which are undesirable from a cost perspective, and could potentially damage the organic materials during back side exposure and photoresist developing processes.

Given this need, in this work, we demonstrated the self-alignment of the source and drain (*S*/*D*) to the gate

of fully-printed organic transistors using wetting-based roll-off techniques [20]. Using such techniques, we demonstrated fully self-aligned transistors and circuit elements in an all inkjet-printed process, without the need for any lithography or vacuum processing. We achieved a minimum overlap of 0.47 μm between the gate and *S*/*D*, contrasted to the >10 μm typically required in conventional printed transistors [19], resulting in an overlap capacitance as low as 0.14–0.23 pF mm^{-1}. As a result, the speed of the printed transistor is significantly enhanced since the overlap capacitances are minimized. We further extend this technique to demonstrate the self-alignment across circuits consisting of multiple devices, including the formation of transistors, interconnects, and vias to thus realize an extremely simple, high-performance fully-printed integrated circuit technology.

2. Results and discussion

In this work, printed transistors with a bottom gate and bottom contact structure were fabricated by four layers of inkjet printing (Fig. 1a; see Section 4). While the peak-process temperature used here was 200 °C, primarily because of the high-temperature anneal needed for the dielectric used in this work, the process will be applicable to sub-150 °C processing as well, as required for polyethylene terephthalate (PET) substrates, by using lower temperature sintering particles and dielectrics, which have been developed recently [21]. The general concept of wetting-based self-alignment was first introduced by Sirringhaus et al. [10,22] and applied to the formation of narrow-gap source–drain structures. In this work, the authors started with a lithographically patterned spacer as a hydrophobic mesa structure. Then, a conducting polymer poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonic acid (PEDOT/PSS) was inkjet printed onto the mesa structure. The hydrophilic PEDOT/PSS then dewetted the mesa structure and self-aligned the spacer to form *S*/*D* electrodes. The transistor was then completed by spin-coating of dielectric, semiconductor and inkjet-printed top gate. Herein, we apply the concept of wetting-based self-alignment to solve the critical issue of layer-to-layer alignment. We inkjet-printed silver as a bottom gate, followed by a PVP insulator, thus forming a mesa suitable for use in subsequent self-alignment. Fig. 1b illustrates the interfacial tension components of a source or drain drop on the side slope or the mesa-like structure of a printed transistor. Excluding the hydrostatic pressure, which is justified by the small drop volume of 10 pL [23], by Young's relation, the equilibrium of the drop is maintained by balancing the silver ink surface tension γ, poly(4-vinylphenol) (PVP)

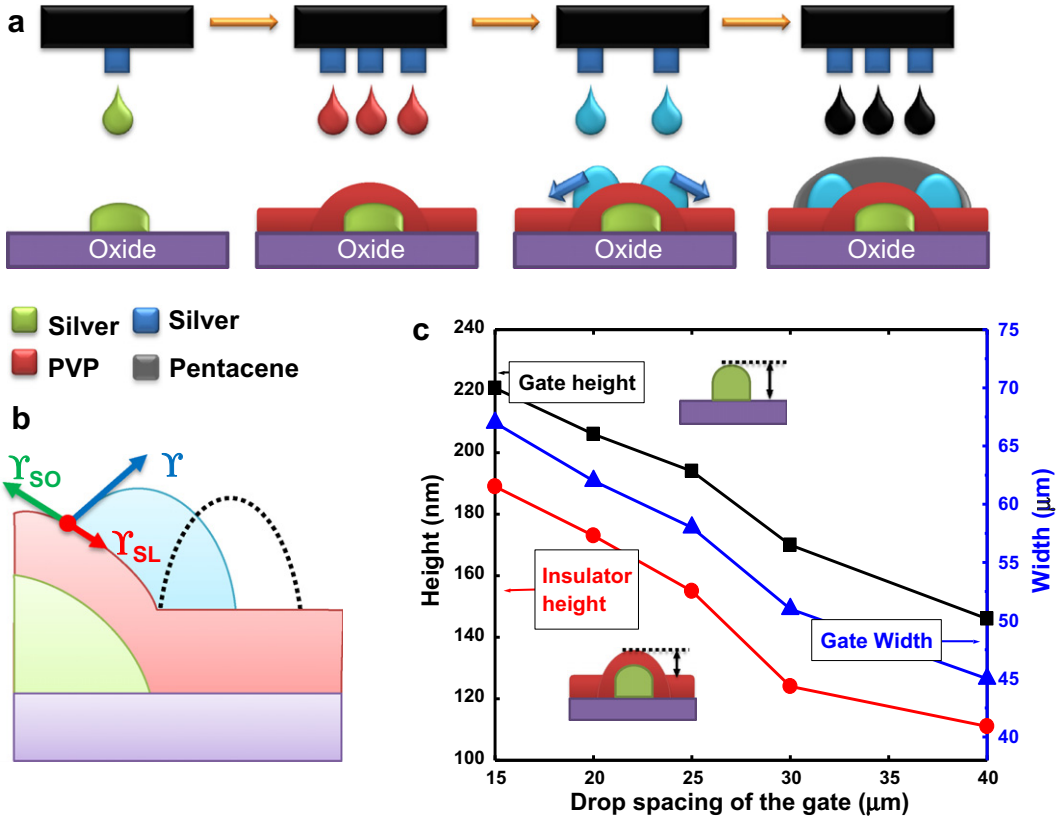

Fig. 1. Inkjet transistor process with self-aligned *S*/*D*. (a) Inkjet transistor process, consisting of four layers of printing. (b) Diagram showing the interfacial tension of a printed source or drain on the mesa structure. (c) Gate height, insulator height or mesa thickness and gate linewidth as a function of printed drop spacing of the gate.

surface energy γ_{SO} and a liquid–solid interaction γ_{SL}. To maximize the roll-off, it is, therefore, desirable to decrease γ_{SO}; unfortunately, the printed silver line integrity is often degraded by this decrease, causing the line to break into separate droplets. Therefore, to facilitate the roll-off of the printed *S*/*D*, we have optimized the inkjet process to achieve a roll-off without degrading the line morphology by (i) increasing the silver ink surface tension (ii) optimizing the PVP thickness, and (iii) increasing the step height. The silver ink, with a surface tension of 30 dyn cm^{-1}, consists of silver nanoparticles with an average size of 80 nm in an alcohol-based solvent (Supplementary information, Fig. S1a). This water miscible ink was diluted with water, with a surface tension of 70 dyn cm^{-1}, to increase the overall surface tension. Note that adding water reduces the ink viscosity, resulting in degraded jetting stability. Therefore, an upper bound of 15 vol.% water was added while maintaining the optimum viscosity of 10 cP in this work (Supplementary information, Fig. S1b). The step height of the mesa structure was naturally created by printing PVP atop the bottom gate. An outward convection flow driven by the coffee stain effect [24] occurred while the PVP solvent evaporated, resulting in a conformal coverage of the bottom gate and a mesa-like structure. As indicated by previous work [22], a thicker mesa structure promotes dewetting. On the other hand, thicker dielectrics degrade device performance due to poorer gate capacitive coupling. Therefore, PVP was kept as thin as possible to preserve the mesa geometry while maintaining good dielectric properties and device electrostatic integrity. Herein, 110 nm of PVP was printed. The mesa structure was thickened by increasing the gate height, achieved by reducing the printing drop spacing of the gate. Reducing drop spacing increases the deposited drop volume, resulting in a thicker gate profile. Fig. 1c shows the mesa structure thickening monotonically with increasing gate height due to the conformality of PVP. However, as indicated in Fig. 1c, line width increases simultaneously with step height, resulting in a slightly larger channel length. In order to obtain repeatable dewetting without compromising on the device speed through increased channel length, the gate line was printed with a 30 μm drop spacing throughout this work.

With the optimization, the printed *S*/*D* overlaps the gate initially, but starts to dewet gradually with time. Interestingly, dewetting mostly initiates at the head of the printed gate line as shown in the Supplementary information (Fig. S2a). This can be rationalized by the thicker mesa structure at the line head, which originated from the slightly more deposited drop volume (Supplementary information, Fig. S2b). Similar results showing a larger line head have been reported and modeled in detail in a previous work [25]. As a result, it is energetically favorable for the *S*/*D* to dewet starting at the head. Fig. 2a shows the optical micrographs of three post-*S*/*D*-sinter transistors, with different waiting times between printing and sintering. If sintered immediately after printing, the *S*/*D* remains overlapped over the gate; if 9 min of waiting are followed by sintering, the *S*/*D* partially dewets the gate. After 15 min, the *S*/*D* completely dewets and self-aligns to the gate. The overlap between the *S*/*D* and the gate was characterized using profilometry (Supplementary information, Fig. S2c and d). A minimum overlap of 0.47 μm was achieved, in contrast to a typical overlap of >10 μm in devices fabricated by printing. To demonstrate the overall improvement by self-alignment, overlap capacitance was measured (see Section 4). As shown in Fig. 2b, the overlap capacitance reduced with increasing waiting time and saturated after 15 min, matching the observation from Fig. 2a. An average overlap capacitance as low as 0.185 pF mm^{-1} with a standard deviation of 0.031 pF mm^{-1} was achieved purely by printing, substantially surpassing the results obtained by a previously reported lithography-reliant, semi-printing process [17]. As described above, the general mechanism of self-alignment is related to the roll-off from the gate, followed by pinning at the gate corner. There are several possible physical phenomena that govern the rolling-off behavior (1) the force gravity of the drop causes the *S*/*D* to minimize the potential energy by moving down the mesa structure. However, a calculation of the gravitational force from the volume and density of the ink indicates that the force is merely 5.9×10^{-7} dyn cm^{-1}, which is negligible when comparing to the ink surface tension and PVP surface energy. (2) The surface energy of PVP could be locally reduced due to the interactions with the underlying gate line, causing the *S*/*D* drop to minimize the energy by migrating to a much higher energy surface. However, we have found no specific evidence showing that the underlying gate alters the chemical structure of the PVP atop yet. (3) The geometry of the corner of the mesa structure could induce a capillary force to locally break the *S*/*D* drop into two parts. Subsequently, the ink located on the channel surface contracts upon evaporation, while the ink at the side of the mesa structure remained pinned. While this appears likely, and is consistent with the time-resolved optical micrographs of the self-alignment process, it is possible that the actual self-alignment is in fact a combination of these effects. A further study is required in the future to thoroughly understand the underlying physics. Overall, however, the self-aligned process is repeatable and has been used on a regular basis over more than 6 months of daily device and circuit printing, and has been found to be robust for printing transistors and circuits.

Fig. 2c and d shows the transfer and output characteristics of a printed self-aligned transistor with the channel width and length of 600 μm and 50 μm, respectively. The transistor shows an output characteristic without a contact barrier, implying that an ohmic contact is formed between the pentacene precursor-based channel and the silver electrodes, with the latter's work function adjusted through an interfacial dipole [26]. The average value of mobility, on/off ratio, threshold voltage and sub-threshold swing are 0.01 $cm^2 V^{-1} s^{-1}$, 1440, −1.5 V and 4.28 V $decade^{-1}$, respectively (see Supplementary information Fig. S3 for more statistical data). The degraded mobility, on/off ratio and the sub-threshold swing are likely caused by the annealing temperature of the pentacene precursor (150 °C), approaching the glass transition temperature of PVP (170 °C), resulting in degraded dielectric interfacial quality [27]. This can be improved in the future by using state-of-the-art inkjet printable organic semiconductor materials requiring low annealing temperatures, such as 6,13-bis(triisopropyl-silylethynyl)

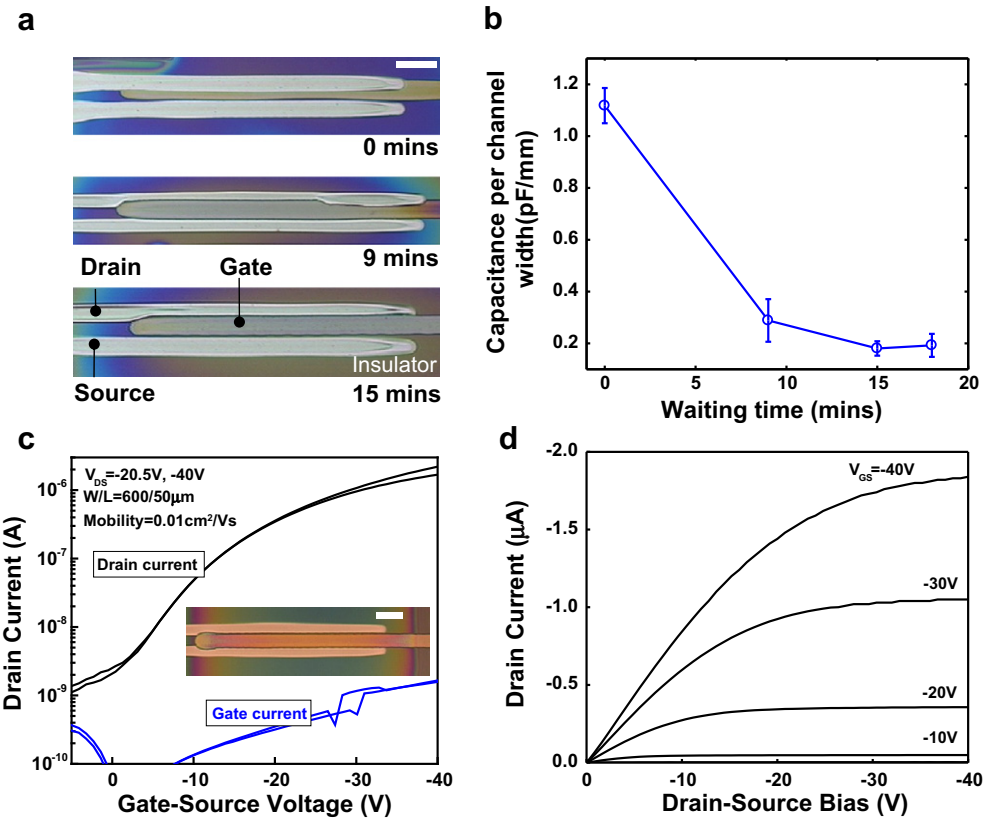

Fig. 2. Self-aligned *S*/*D* and electrical characteristics. (a) Optical micrographs of three post-*S*/*D*-sinter transistors, with three different waiting time between printing and sintering. (b) Measured overlap capacitance per channel width as a function of waiting time between printing and sintering. (c) Transfer characteristics of the printed self-aligned transistor. (d) Output characteristics of the printed self-aligned transistor. All scale bars represent 100 μm.

(TIPS) pentacene, which has been demonstrated to offer a high mobility and a low sub-threshold swing on PVP dielectrics [9,28,29]. Nevertheless, the printed transistors are reliable enough for the following circuit printing work.

The principle of dewetting the source and drain was extended beyond the single transistor level to entire circuit blocks, through a novel printing process – a self-split *S*/*D* device. The printing flow is illustrated in Fig. 3a, starting with the printing of gate, followed by the printing of PVP.

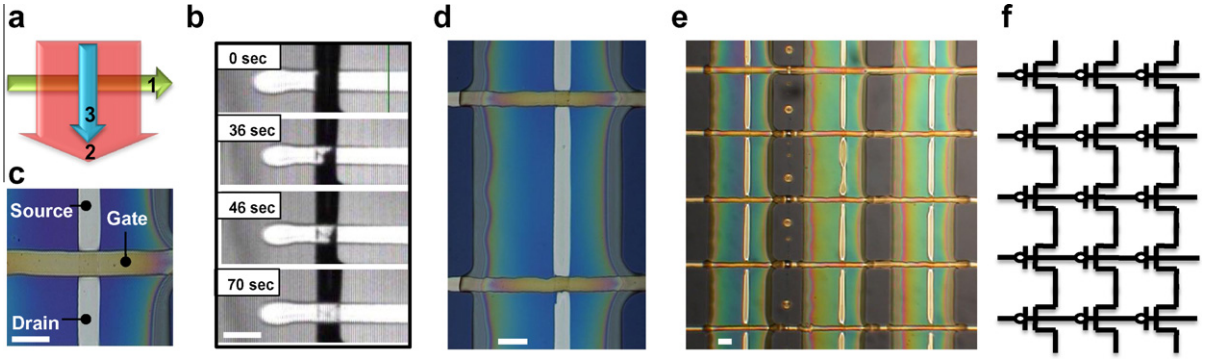

Fig. 3. Self-split *S*/*D* and transistor array. (a) Printing flow of a self-split transistor. (b) Time-lapse optical micrographs captured by the Dimatix printer showing the process of *S*/*D* self-splitting with time. (c) Optical micrograph of a printed self-split transistor. (d) Optical micrograph of an inverter structure printed using self-split *S*/*D*. (e) Optical micrograph of the printed self-split transistor array. (f) The equivalent circuit of the transistor array. All scale bars represent 100 μm.

The same optimization was performed on the gate, PVP and *S*/*D*. A perpendicular silver line was then printed across the gate line. The silver line self-split into *S*/*D* while simultaneously self-aligning the gate as shown in Fig. 3b. After sintering the *S*/*D*, as shown in Fig. 3c, a self-split transistor was then completed by printing the pentacene precursor on top. Similar electrical characteristics to our typical printed transistors are obtained (Supplementary information, Fig. S4a–c). The self-split technique is highly compatible with integrated circuit fabrication as illustrated in Fig. 3d. The line printed perpendicular to the gate self-splits into the *S*/*D* electrodes of the two transistors and provides the interconnect simultaneously in a single-printing pass. This is very promising for realizing a fully printed self-aligned Complementary Metal-Oxide-Semiconductor (CMOS) inverter in the near future, where pull-up and pull-down transistors have similar driving currents. Herein, however, we will demonstrate a fully printed inverter with more flexible sizing capability below. The self-split process was extended into the printing of a transistor array as shown in Fig. 3e, and the equivalent circuit in Fig. 3f. The array is completed in three passes of printing. An array printed by such a simple process is promising for realizing low-cost circuitry, such as disposable sensor arrays or tree-decoder applications.

To demonstrate more sophisticated printed circuits, the self-splitting technique has further been utilized for printing of an interconnection. Without a self-aligned interconnect, connecting discrete printed transistors becomes challenging. Short/open circuits caused by poor printing registration dramatically deteriorate fabrication yields. Herein, a self-split/self-align interconnect using the principal of selective wetting was demonstrated. Fig. 4a shows the time-lapse optical micrographs captured by the fiducial camera on Dimatix printer. A perpendicular interconnect was printed, intending to connect three adjacent printed post-*S*/*D*-sinter transistors. Instead of manually patterning the line into segments to align to the *S*/*D* pad of each transistor, a straight line was printed across all the three transistors. Similarly to the aforementioned self-split *S*/*D*, the silver dewets the channel of each transistor and spontaneously flows perpendicularly into the *S*/*D* electrodes, forming good contacts with no needed pad area. The resulting *S*/*D* electrodes completely split while three transistors are connected in a cascade scheme, resulting in borderless contacts with excellent alignment. A complete process module for interconnection requires a printable via technique to allow for interconnection between layers separated by a dielectric. The first printed via-hole was demonstrated by Sirringhaus et al., using a good solvent of isopropanol to dissolve PVP and form a crater-like via-hole [30]. Here, we demonstrated a novel semi-additive via process combining the printing of a via-hole with the printing of an interconnect line. Fig. 4b shows the optical micrograph of a printed contact chain demonstrating the connection of two metal layers through a sandwiched PVP insulator. The printing flow is illustrated in Fig. 4c, starting with the printing of two vertical silver lines, followed by sintering and the printing of a PVP insulator. Then, a horizontal silver line was printed prior

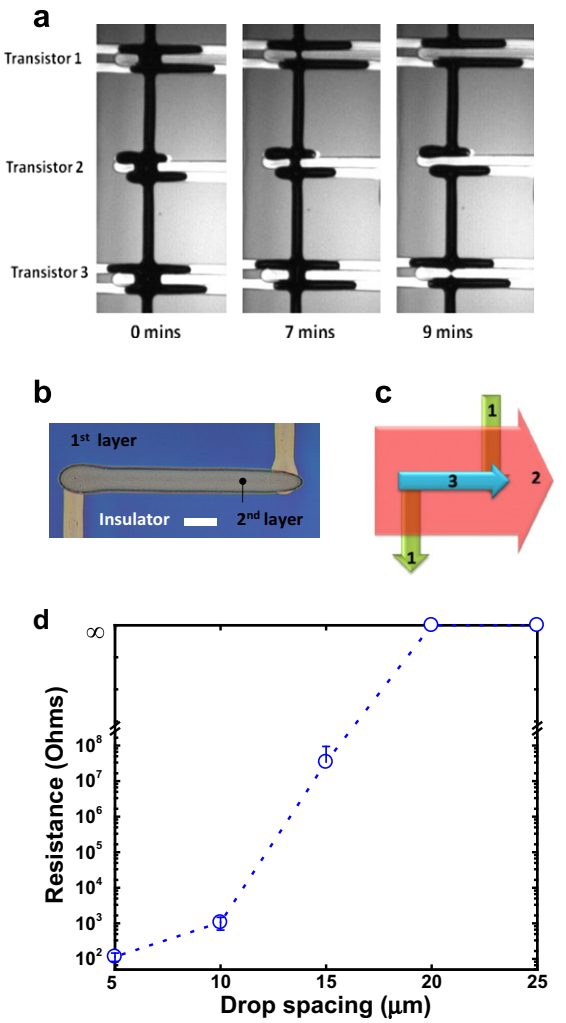

Fig. 4. Novel printed interconnect. (a) Time-lapse optical micrographs captured by the Dimatix printer, showing the process of self-split/self-aligned interconnect. (b) Optical micrograph of a printed contact chain. (c) Printing flow of the contact chain. (d) Resistance of the contact chain versus the drop spacing of the horizontal line. All scale bars represent 100 μm.

to cross-linking the PVP to dissolve the same and deposit silver nanoparticles simultaneously, followed by a single heating step to cross-link the PVP and sinter the silver. The horizontal line was printed with various drop spacing and the corresponding resistances of the contact chain are shown in Fig. 4d. Smaller drop spacing results in larger deposited solvent volume and silver concentration, and, therefore, the contact chain becomes conducting below drop spacing of 15 μm. The minimum resistance of 100 Ω, which is negligible comparing to the transistor resistance, is obtained at 5 μm drop spacing. The resistance of the contact chain is limited by the horizontal line, rather than the contact resistance between two metal layers.

Finally, a printed logic element–inverter was demonstrated using the self-aligned *S*/*D* and the interconnect introduced previously. Fig. 5a shows the circuit schematic

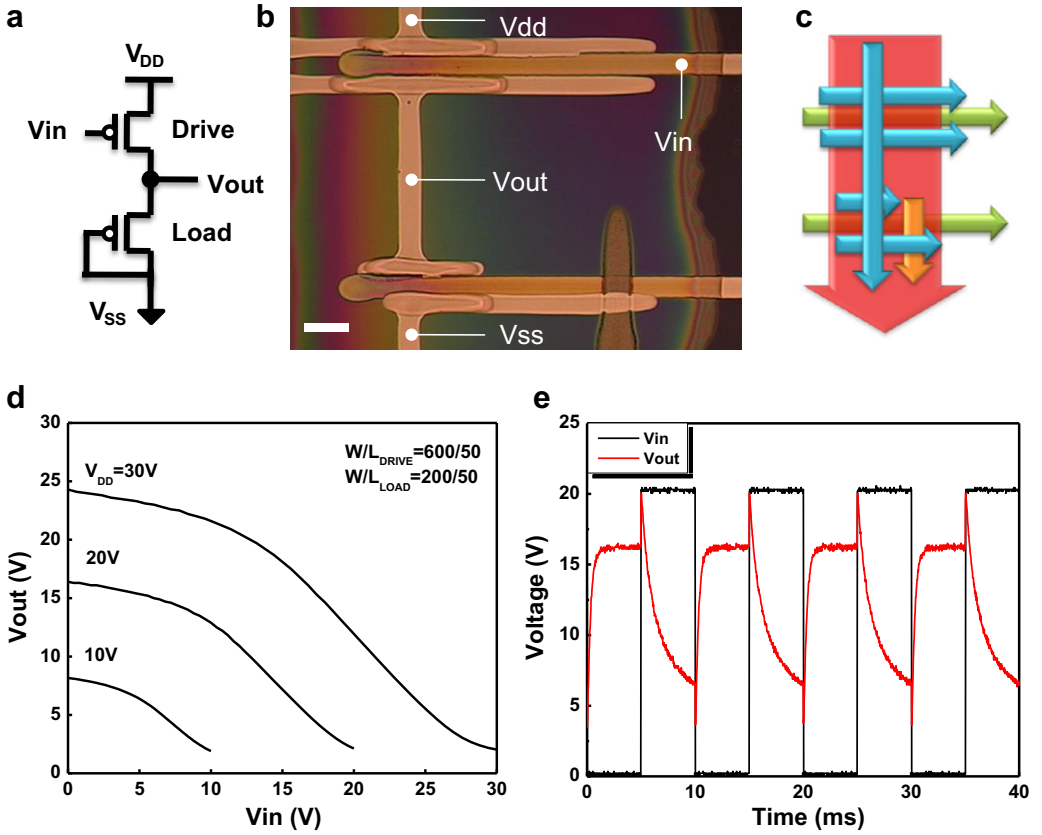

Fig. 5. Printed inverter. (a) The circuit schematic of the printed inverter. (b) Optical micrograph of the inverter. (c) Printing flow of the inverter. of the inverter using a diode connected transistor as a load device. The β ratio (the channel width ratio of the drive transistor to the load transistor) of 3 is chosen to enlarge the voltage gain and the output swing. The optical micrograph of the inverter shown in Fig. 5b was fabricated by the printing flow shown in Fig. 5c (see Section 4). The voltage transfer characteristic (VTC) of the printed inverter measured with various V_{DD} is shown in Fig. 5d. Maximum voltage gain of −1.46 was achieved under V_{DD} of 50 V (see Fig. 5a–c for detail inverter characteristics). The performance of the inverter was then determined by measuring the propagation delay time between an input square wave and the output waveform (see Section 4). As shown in Fig. 5e, a low-to-high delay of 0.3 ms and a high-to-low delay of 1.65 ms are measured at 10 V, resulting in an average propagation delay of 0.975 ms. Due to the extra loading caused by the parasitic capacitance between the output electrode and the bottom silicon wafer, the output load was equivalent to a fan-out of 2 ($C_{load}/C_{in} = 2$). Since propagation delay is proportional to the product of the equivalent resistance and the load capacitance ($T_p \sim R_{eq}C_{load}$), the inverter is expected to have a smaller propagation delay of 0.488 ms at a fan-out of 1 ($C_{load} = C_{in}$). While this performance level is suitable for many low-cost electronic applications, and is already competitive with the best fully printed circuits reported to date [31,32], the inverter gain can be further improved by enhancing the transistor performance and optimizing circuit design to maximize the product of gm (transconductance) and Rout (output resistance). The noise margin can also be improved by reducing the subthreshold leakage of the transistor. Furthermore, the gate delay is expected to be improved by downscaling of the channel length, improved mobility and the use of CMOS circuits in the future. Despite this, however, the benefits of self-alignment in terms of parasitic capacitance reduction are clear; the low parasitic capacitance achieved in this work will facilitate the realization of high-performance, high-yield fully printed circuits with simple printing processes.

3. Conclusions

We have demonstrated various novel printing techniques including self-aligned *S*/*D* to gate, self-split *S*/*D* and self-aligned interconnection for the first time. Using these, we demonstrate overlap capacitances as low as 0.14–0.23 pF mm^{-1} achieved by a purely printing process. We also demonstrated a fully printed inverter with a low propagation delay of 0.488 ms, despite the use of relatively low performance materials. Using such a simple process

formed entirely by printing with complete self-alignment, we are able to realize a robust integrated process suitable for use in a range of low-cost electronics applications.

4. Experimental

4.1. All inkjet-printed transistor process

An N-type silicon wafer with a thermally grown oxide of 100 nm was used as an underlying mechanical substrate. Silver nanoparticle ink (Suntronic U5603) was printed as a gate electrode with a drop spacing of 30 μm, and subsequently sintered at 200 °C for 10 min. Poly(4-vinylphenol) (PVP) (7.6 wt.%) dissolved in hexanol with 0.6 vol.% of cross linker poly(melamine-co-formaldehyde) was printed atop the gate and cross-linked at 200 °C for 10 min. Five nozzles were used simultaneously to print the PVP layer with a drop spacing of 30 μm, resulting in a dielectric thickness of 110 nm. Silver ink was then printed to form source and drain electrodes with a drop spacing of 20 μm. This was followed by a sintering step identical to that used for the gate electrode. The PVP surface was then treated with hexamethyldisilazane (HMDS) vapor to obtain a low energy channel-surface with a water contact angle in the range of 66°. Finally, 1.5 wt.% of pentacene precursor (Sigma–Aldrich) dissolved in anisole (Sigma–Aldrich, anhydrous, 99.7%) was printed as a p-type semiconductor. The precursor was annealed at 150 °C in a nitrogen ambient atmosphere with a 10 ppm oxygen level. All inkjetting was performed using a Dimatix DMP-2800 printer and a jetting frequency of 2 kHz was used at all times.

4.2. Measurement of overlap capacitance

An Agilent 4285A was used to measure capacitance. A small signal of 100 mV and 75 kHz was used as the input. Two co-axial probes that were connected to the 4285A were connected to the gate and drain electrodes, respectively. Before the measurement, calibration was performed to cancel out the parasitic components resulting from the cable and oxide substrate. The measurement was then performed on five to ten different devices and statistically consistent results were obtained.

4.3. Printing of an inverter

As shown in Fig. 5c, the process starts with the printing of silver as gate electrodes, followed by sintering at 200 °C for 10 min. PVP was then printed atop the gate as a gate insulator. Before cross-linking the PVP, a printed via and interconnect (step 3) was used to connect the gate and source of the load transistor to form a diode-connect configuration. A heating step of 200 °C was performed for 10 min to cross-link PVP and sinter the silver. *S*/*D* electrodes of both the drive and load transistors were then printed, self-aligning the gate, followed by sintering at 200 °C for 10 min. An interconnect was then printed to self-split and self-align the two transistors. Finally, a pentacene precursor was printed on the transistor channel, followed by an annealing step.

4.4. Electrical characterization of the transistor and the inverter

An Agilent 4156C semiconductor parameter analyzer was used to measure the transfer and output characteristics of the printed transistor and the voltage transfer characteristics of the printed inverter. The mobility was extracted from the slope of the extrapolated square-rooted drain current at a drain voltage of 40 V, and the threshold voltage was extracted from the *x*-intercept of the same fitting line. For the transient output measurement of the inverter, the 4156C was used to bias the circuit. The input square wave of 200 Hz was provided by an Interstate Electronics Corporation F34 function generator. The output was buffered by an operational amplifier Burr Brown OPA602BP and the waveform was measured using an Acute DS-1202 Oscilloscope.

Power conversion efficiency

ABSTRACT

Improved power conversion efficiency (PCE), by up to ~27%, of organic solar cells based on poly(3,4-ethylenedioxy-thiophene):poly(styrenesulfonate) (PEDOT:PSS)/poly(3-hexylthiophene):[6,6]-phenyl-C_{60}-butyric acid methyl ester (P3HT:PCBM) were obtained via simple modifications, widely applicable, in the fabrication of the spin-coated PEDOT:PSS layer. These included (i) further diluting the original PEDOT:PSS solution with deionized water, (ii) mixing the original PEDOT:PSS solution with ethylene glycol (EG), and (iii) spin coating EG over a PEDOT:PSS layer fabricated using the original solution. The optimal dilutions, spin coating rates, and durations were determined. Approach (iii) resulted in the best cell with a PCE of 4.7% as compared to 3.7% for the untreated PEDOT:PSS. To evaluate the origin of the improvements we monitored the PEDOT:PSS conductivity, external quantum efficiency of the devices, and their I–V curves that indicated an increase of ~16% in the short-circuit current I_{SC}. Other characteristics included the PEDOT:PSS layer thickness, its transmittance, P3HT:PCBM absorption spectra, its morphology, and surface chemical composition. The results indicate that in addition to the enhanced PEDOT:PSS conductivity (following some of the treatments) that improves charge extraction, enhanced PEDOT:PSS transmission and especially, enhanced P3HT:PCBM absorption contribute to improved solar cell performance, the latter by increasing I_{SC}. While the various treatments in the optimized devices had a minor effect on the PEDOT:PSS thickness, its morphology, and consequently that of the active layer, were affected. The surface roughness of the active layer increased significantly and, importantly, in devices with PEDOT:PSS/EG/P3HT:PCBM, PCBM aggregates were observed near the cathode. Such aggregates may also result in increased absorption and improved charge extraction.

Introduction

The development of organic solar cells is a fast-growing field as such devices have the advantage of being flexible, simple to fabricate, and potentially low cost [1–4]. Solar cells with a poly(3-hexylthiophene):[6,6]-phenyl-C_{60}-butyric acid methyl ester (P3HT:PCBM) active layer have been studied extensively with reports of typical power conversion efficiency (PCE) of ~3% to ~5% and fill factors (FF) of ~50% to 70% [4–11]. The PCE and FF depend on the starting materials, fabrication conditions and treatments at various stages of device fabrication. As an example, a PCE of 4.4% was obtained by varying the annealing conditions of the active layer [7,8]. The PCE was improved to 5.3% by replacing the PEDOT:PSS layer with NiO_2 [9]. A PCE of 5% was obtained for a single cell with TiO_x as an

doi:10.1016/j.orgel.2010.11.008

optical spacer, and a two-unit tandem structure with 6.5% PCE was obtained by applying the TiO_x layer as an electron transport and collecting layer for the first unit and as a stable foundation to fabricate the second unit [10–12]. To obtain a good short-circuit current (I_{SC}), the active layer needs to have strong absorption of the solar spectrum, efficient exciton diffusion, good charge transfer, and sufficient charge extraction at the electrodes [13]. To achieve a high open-circuit voltage (V_{OC}), the offset between the highest occupied molecular orbital (HOMO) of the donor material and the lowest unoccupied molecular orbital (LUMO) of the acceptor material should be high, and ohmic contacts between the electrodes and the organics are required [13–16]. To get a high FF, the series resistance of the device should be low and the shunt resistance should be high. The polymer/electrode interfaces and the active layer properties play an important role in determining these parameters [17–19].

It is well known that the conductivity of PEDOT:PSS films is enhanced by over 100-fold by addition of organic materials, such as dimethyl sulfoxide (DMSO), *N*,*N*-dimethylformamide, tetrahydrofuran, sorbitol (with baking), glycerol, or ethylene glycol (EG) to the aqueous PEDOT:PSS solution [20–30]. Depending on the additive, the enhancement was related to the dielectric constant of the additive and to retention of some of the solvents used in the film [26], to reorientation of PEDOT chains with heat treatment [29], and to washing away of PSS [27]. For diethylene glycol addition, it was suggested that the particle size of the PEDOT:PSS reduces as the insulating, inter-particle excess PSS layer becomes very thin [28]. It was also shown that not only dilution of the PEDOT:PSS solution with EG enhances the conductivity, but also immersing the untreated PEDOT:PSS in EG solution for a few minutes [21]. It was reported that EG affects the solubility of the PEDOT:PSS film in water, suggesting, together with other measurements, that EG affects the conformation of the polymer chains with the surface becoming more hydrophobic. The conformational change of the PEDOT chains was attributed to the interaction between the dipole of one of the polar groups (only additives with two or more polar groups were found to enhance conductivity) of the organic additive and the dipoles or positive charges on the PEDOT [21]. It was also reported that the size of the PEDOT:PSS particles was increased by adding DMSO [23]. The increased conductivity was linked to the increased particles' size, due to reduced particle boundaries. Hence, there are still different fundamental explanations for the enhanced PEDOT:PSS conductivity upon addition of polar solvents.

Additives to PEDOT:PSS that enhance performance of solar cells were also evaluated. In addition to the effect of DMSO [23], for example, the substitution of ITO by PEDOT:PSS and PEDOT:PSS doped with glycerol or sorbitol was studied [22]. Glycerol and the surfactant ethylene glycol butyl ether at specific concentrations were also mixed with PEDOT:PSS for improved ink-printed solar cells [24]. The authors suggested that these additives may also affect the morphology of the ink-jet printed PEDOT:PSS, with a strong ionic interaction between the glycerol and the PEDOT, including with the addition of low-levels of the surfactant to enhance the conductivity. Improved device performance was attributed to surface morphology and enhanced conductivity that increase charge collection [24].

As every step in the fabrication of the solar cells affects device performance, this paper describes a systematic study of the effect of treatments of the PEDOT:PSS layer on the performance of the common P3HT:PCBM-based solar cells. Morphology variations of P3HT:PCBM were observed, with increased roughness, when PEDOT:PSS was treated in different ways. The treatments included (i) dilution of the as-received PEDOT:PSS solution with deionized (DI) water or (ii) with EG, and (iii) spin coating EG over the PEDOT:PSS layer. Among the various treatments that included optimization of the dilution and spin coating rate and duration, treatment (iii), namely the EG-treated PEDOT:PSS layer (following the fabrication of the latter from the original aqueous solution) exhibited the largest change in the P3HT:PCBM morphology, which is probably responsible for the observed largest improvement in the, I_{SC}, FF, and PCE. Importantly, small aggregates of PCBM, whose size depended on the anneal period of the EG-treated PEDOT:PSS layer, were observed at the surface of the active layer. These aggregates at the active layer/cathode interface may improve charge extraction and light absorption, and hence I_{SC}, FF, and PCE. Importantly, the conductivity of PEDOT:PSS exhibited a relatively minor contribution to the enhanced performance.

Experimental procedure

Materials

P3HT (P#200) was obtained from Rieke Metals and PCBM from nano-C; both materials were used without further purification. A solution of a 1:1 weight ratio of P3HT:PCBM in 1,2-dichlorobenzene, with a concentration of 30 mg/mL was used. The P3HT solution was filtered using a 0.22 μm Millex PTFE Filter before it was mixed with PCBM. The mixture was then stirred for 24 h before spin-coating. PEDOT:PSS was a Clevios™ P VP AI 4083 obtained from H.C. Starck. The PEDOT:PSS ratio was 1:6 by weight and the solid content 1.3–1.7%. EG was obtained from Fisher Scientific.

Procedures

The PEDOT:PSS layers (~40 nm thick) were baked for ~1 h at 120 °C under ambient conditions; they were then transferred into an argon-filled dual-sided MBraun glovebox. The oxygen level in the glovebox was ~30 ppm and that of water <0.1 ppm. Three different treatments of the PEDOT:PSS were evaluated in an attempt to improve the device performance. These treatments were: (i), diluting PEDOT:PSS with DI water (ii) mixing PEDOT:PSS with EG, and (iii) spin-coating EG following fabrication of the PEDOT:PSS layer. Each treatment was optimized by varying the spin-coating speed and duration as well as the dilution ratio as detailed above. The P3HT:PCBM solution was spin-coated on top of the PEDOT:PSS layer at the optimized 600 rpm rate for 60 s, and immediately placed under a petri dish for 2 h before baking at 110 °C for 12 min. The Ca

(25 nm)/Al (100 nm) were deposited on the P3HT:PCBM layer by low vacuum ($\sim 10^{-6}$ mbar) thermal evaporation. The active layers in all devices were fabricated under the same experimental conditions.

Measurements

The thickness of PEDOT:PSS layers was estimated with an AFM by using a sharp blade to generate ~9 μm wide cuts in the layer. In all cases a thickness of ~40 nm resulted in devices with the best performance, regardless of the treatment. I–V curves were obtained using a 100 mW/cm^2 ELH bulb. The EQE was measured at 0 V. AFM measurements were performed using a Digital Instruments system. SEM and Auger were measured with JEOL JAMP 7830F.

Results and discussion

Devices with an untreated PEDOT:PSS layer were optimized by varying the spin-coating rate, in the range of 1000–4000 rpm, and the spin duration, in the range of 60–120 s. The optimized condition for the untreated (prepared from the original solution) PEDOT:PSS was 3000 rpm for 60 s. Devices in which the PEDOT:PSS solution was further diluted with DI water (treatment (i)) were optimized by varying the volume ratio of PEDOT:PSS to water from 1:5 to 4:1, in combination with varying the spin-coating speed from 500 to 3000 rpm for each dilution. Optimized layers, as evaluated by the performance of the solar cells, were obtained for a volume ratio of 3:7 that was used to fabricate the PEDOT:PSS layers at 600 rpm for 60 s. Similarly to the dilution of the PEDOT:PSS with DI water, the volume ratio of the PEDOT:PSS to EG (treatment (ii)) varied from 10:3 to 3:7, and the spin-coating speed from 500 to 3000 rpm. The optimized condition for the EG-mixed PEDOT:PSS was obtained by using a 1:1 volume ratio and spin coating at 1000 rpm for 60 s. The performance of solar cells with the latter was similar to those based on the DI water dilution.

EG-treated devices were prepared also by spin-coating EG on top of the PEDOT:PSS layer (treatment (iii)). Different spin-coating speeds for both, the PEDOT:PSS layer and the EG, ranging from 500 to 3000 rpm, were tested. The best device was obtained by spin-coating the EG at 2000 rpm for 60 s on top of an untreated PEDOT:PSS layer prepared by spin-coating at 2000 rpm for 60 s.

All PEDOT:PSS layers were annealed at 120 °C for ~1 h. Following the application of the P3HT:PCBM, the samples were annealed at 110 °C for 12 min.

Fig. 1 shows the I–V curves of different, optimized P3HT:PCBM-based devices with PEDOT:PSS layers that underwent the different treatments, and Table 1 summarizes the values of V_{OC}, I_{SC}, FF and PCE for each device, including for devices prepared by spin coating EG at different rates for 60 s. As clearly seen, the treatments improved the cells' performance, in particular I_{SC} increased by up to 16% from 9.94 to 11.5 mA/cm^2 and PCE by up to ~27% from 3.7% to 4.7% for the device with the EG-treated PEDOT:PSS

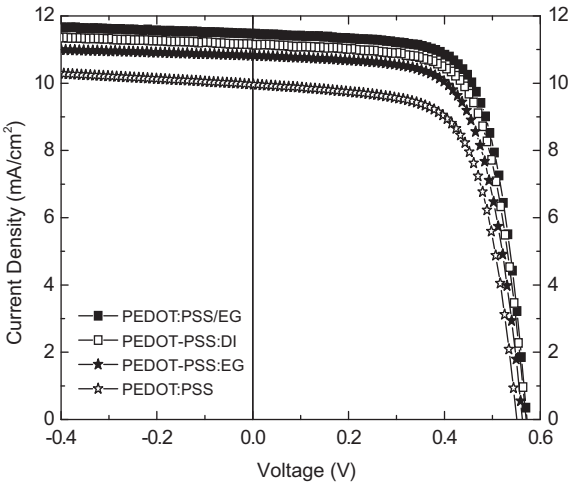

Fig. 1. I–V curves of optimized (see text) P3HT:PCBM-based solar cells, with the PEDOT:PSS layer generated by spin coating the original solution (open stars), the original solution diluted with EG (solid stars) or with DI water (open squares), and by spin coating EG on the untreated PEDOT:PSS layer (solid squares).

Table 1
Device characteristics of solar cells prepared with different treatments of the PEDOT:PSS layer. The data in the top three rows indicate EG solution spin coated over the PEDOT:PSS layer at various rates for 60 s.

Treatment	V_{OC} (V)	I_{SC} (mA/cm^2)	FF (%)	PCE (%)
EG 1000 rpm	0.571	10.7	71.8	4.39
EG 2000 rpm	0.573	11.5	71.3	4.70
EG 3000 rpm	0.566	11.2	70.3	4.46
PEDOT–PSS:DI (3:7 volume ratio)	0.571	11.2	69.5	4.44
PEDOT–PSS:EG (1:1 volume ratio)	0.563	10.8	69.3	4.21
Untreated PEDOT–PSS	0.551	9.94	67.6	3.70

in comparison to the untreated one. V_{OC} was unchanged at 0.55–0.57 V.

To elucidate the origin of the observed improvement in the device performance, various parameters described next were measured. The thickness of the PEDOT:PSS films, which may affect absorption, was measured by making fine cuts (~9 μm wide) on them with a sharp blade, and using scanning atomic force microscopy (AFM) with a scan size of 20 μm across the cuts to measure the films' thickness. The AFM results showed that the typical thickness of the optimized PEDOT:PSS layers of both treated and untreated samples is ~40 nm. This situation excludes a change in the PEDOT:PSS layer thickness as a major contributor to the observed enhancement.

The conductivity of the different PEDOT:PSS layers, which affects charge extraction and therefore, I_{SC} and FF, was also measured. The conductivity of the layer in the best performing devices, i.e., where EG was spin-coated on top of the PEDOT:PSS, was ~0.1 S/cm. It was ~10-fold larger than that of the untreated PEDOT:PSS film, but ~10-fold smaller than that of the PEDOT:PSS layer

prepared from the mixed solution of PEDOT:PSS and EG. The conductivity of the layer prepared from the solution diluted with DI water was comparable to that of the untreated film. Hence, the improved performance of the devices is not directly related to the enhanced conductivity. That is, the I_{SC} of the cell with the PEDOT:PSS layer with the highest conductivity (prepared from a mixture of PEDOT:PSS with EG) was inferior to that of the other devices with the treated PEDOT:PSS layer. And, the I_{SC} of the cell with the PEDOT:PSS layer prepared from further diluting the original solution with DI water was larger that of the device with the untreated layer, though their conductivities were comparable. Hence, and as shown below, other factors besides the conductivity play an important role in improving the performance of the solar cells.

Fig. 2 shows the external quantum efficiency (EQE) spectra of the four devices of Fig. 1. As seen, the EQE increased with PEDOT:PSS treatments, with a trend comparable to that shown in Fig. 1, as expected. The highest EQE, peaking at ~540 nm, was ~62%; it was observed for the device in which EG was spin coated at 2000 rpm for 60 s on top of the PEDOT:PSS prepared from the original solution at 2000 rpm for 60 s. The corresponding EQE for the optimized untreated device was ~50%.

In view of the above results, specifically the significant, reproducible increase in I_{SC} and EQE following modification of the PEDOT:PSS, the transmission of the different PEDOT:PSS layers and the absorption spectra of the different PEDOT:PSS/P3HT:PCBM structures were measured (Fig. 3). As seen in Fig. 3, the transmission of the DI water- and EG-treated PEDOT:PSS in the range 500–700 nm (which covers the main absorption region of the P3HT:PCBM) is slightly larger than that of the untreated layer. Similarly, the absorption spectra of PEDOT:PSS/P3HT:PCBM in the 400–700 nm range show that the absorption increases with the PEDOT:PSS treatments, with the largest absorption observed for the PEDOT:PSS over which EG was spin-coated.

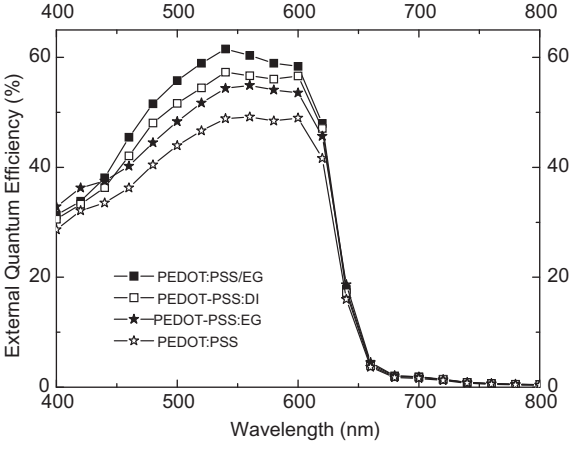

Fig. 2. External quantum efficiency vs wavelength for optimized devices with differently treated PEDOT:PSS layers, i.e., untreated – prepared using the original PEDOT:PSS solution (open stars), prepared by EG dilution of the original PEDOT:PSS solution (solid stars), prepared by DI water dilution (open squares), and EG-treated following PEDOT:PSS fabrication (solid squares). See text for details.

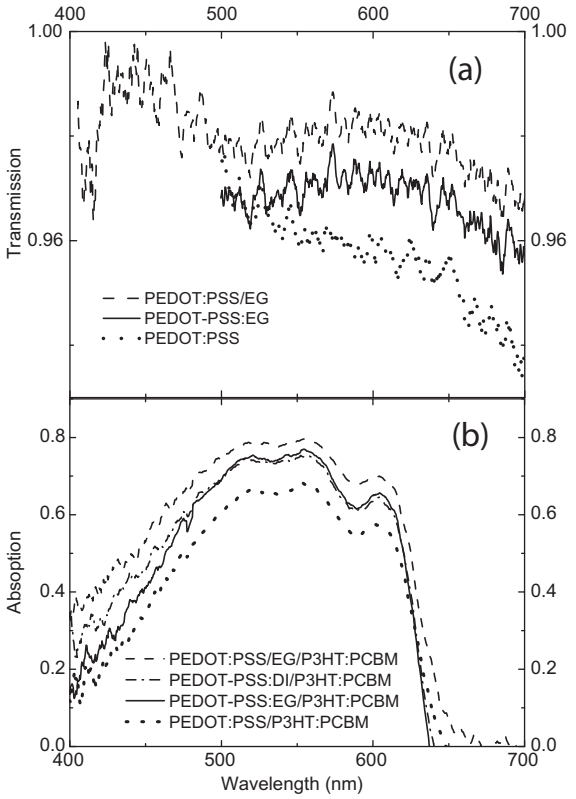

Fig. 3. (a) The transmission spectra of the PEDOT:PSS layer following different treatments. The PEDOT:PSS transmission at wavelengths <500 nm is comparable for all films and for clarity is shown only for one case. (b) The corresponding absorption spectra of the PEDOT:PSS/P3HT:PCBM structures: an untreated PEDOT:PSS film (dotted line), PEDOT:PSS film prepared from a volume dilution ratio of 3:7 PEDOT-PSS:DI water (solid line), PEDOT:PSS film prepared from a 1:1 PEDOT-PSS:EG volume ratio dilution (dashed-dotted line), and PEDOT:PSS film with post-fabrication EG spin coating (dashed line). In all spectra the transmission/absorption of the ITO/glass were subtracted.

To identify potential device characteristics that are responsible for the enhanced absorption and hence increased I_{SC} and EQE, the surface morphology of the PEDOT:PSS and P3HT:PCBM layers as well as the surface chemical composition of the P3HT:PCBM were monitored using AFM, SEM, and Auger electron spectroscopy.

The roughness of the PEDOT:PSS layer, as measured by AFM (Fig. 4) increased slightly from 2.8 nm RMS in the untreated layer and 2.7 nm RMS in the DI water-diluted solution to 3.4 nm in the PEDOT:PSS/EG film. Also, as seen, following the treatments, a more condensed packing of particles was observed. Specifically, the particles appeared smaller for the DI water- and EG-treated samples, in particular for the latter. The smaller particle size is in accordance to previous reports suggesting that the reduced size is due to removal of excess inter-particle PSS [21]. The slightly increased roughness of the PEDOT:PSS layer, and most importantly, the significantly increased "graininess" from untreated to DI water-diluted to EG-coated PEDOT:PSS likely increase the contact area between the PEDOT:PSS and the active layer, improving hole extraction to the anode.

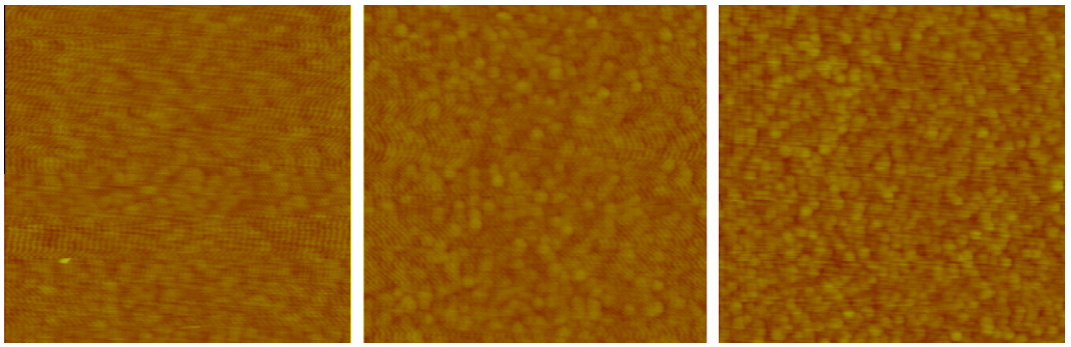

Fig. 4. AFM images of the morphology of PEDOT:PSS films differently treated: left-untreated, original PEDOT:PSS; center-additional dilution of 3:7 PEDOT-PSS:DI water volume ratio; right-EG-treated PEDOT:PSS following the fabrication of the latter. The full scale in each image is 5 μm.

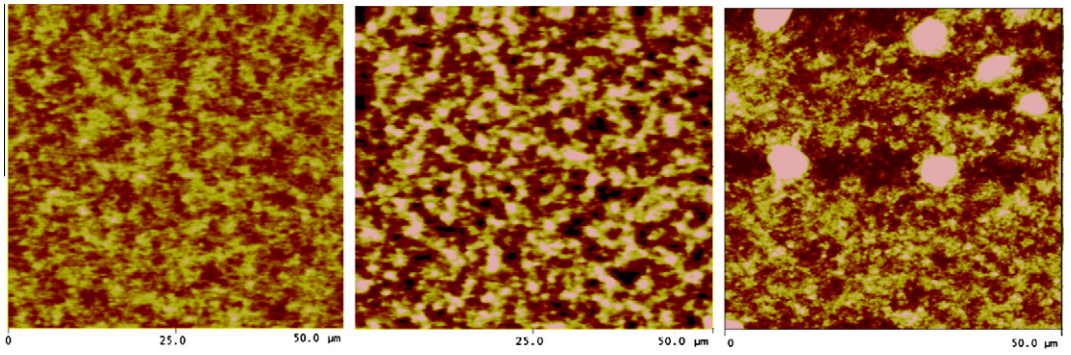

Fig. 5. Morphology AFM images of the P3HT:PCBM layers on top of the different PEDOT:PSS layers (full scale 50 μm). Left: untreated PEDOT:PSS; center: DI water diluted PEDOT:PSS; right: PEDOT:PSS layer with EG spun on top.

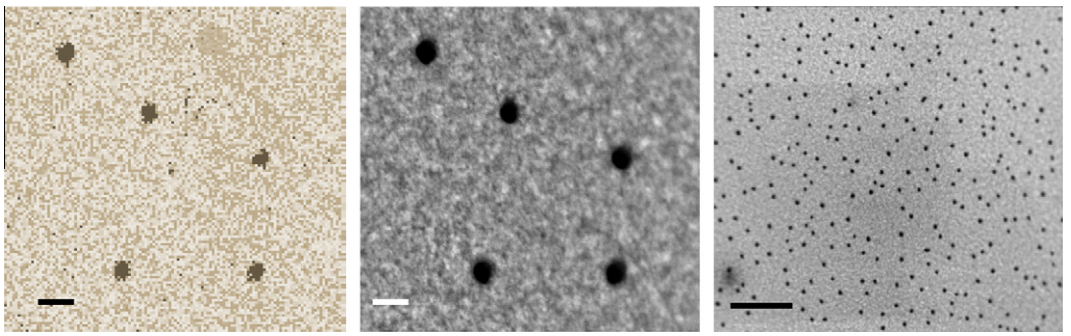

Fig. 6. Left: Auger carbon mapping of the surface of P3HT:PCBM spin-coated on top of the EG-treated PEDOT:PSS post-fabrication of the latter; the darker color indicates a higher concentration, center: the corresponding SEM image with 10 μm scale bar, and right: SEM image with 100 μm scale bar showing the distribution of the aggregates.

Significant morphology variations were observed in the P3HT:PCBM layers spin-coated on the differently-treated PEDOT:PSS layers, as seen in the AFM and SEM images of Figs. 5 and 6. The RMS surface roughness of P3HT:PCBM with the untreated PEDOT:PSS layer was 13.3 nm, that of the active layer with the PEDOT:PSS layer spun from DI water-diluted PEDOT:PSS (treatment (i)) was 28.5 nm, and the RMS of the active layer with the PEDOT:PSS layer on top of which EG was spin-coated (treatment (iii)) was 34.5 nm. Since all the P3HT:PCBM layers were prepared under the same experimental conditions, these changes in the surface roughness are obviously due to the various treatments and resulting graininess of the PEDOT:PSS layers. Rough surfaces may increase scattering of the incident light back into the active layer and hence lead to increased absorption. In addition, the larger roughness also enlarges the contact area between the active layer and the cathode, which may lead to better electron extraction.

As seen in Figs. 5 and 6, small aggregates, ~3 μm wide, were distributed across the surface of the P3HT:PCBM layer spin-coated on the EG-treated PEDOT:PSS layer. The dimensions of these aggregates, which are largely at the active layer/cathode interface, increased with anneal duration; this behavior is currently being investigated. We note that these features were not present if PEDOT:PSS annealing was performed for less than 30 min.

Auger surface mapping (Fig. 6) revealed a higher carbon (but no sulfur) concentration in those aggregates, which indicates that the aggregates were predominantly of PCBM. Increased PCBM level near the cathode following annealing of PEDOT:PSS/P3HT:PCBM is a known phenomenon, which facilitates electron extraction, improving the efficiency of the solar cells [31–33]. Similarly, the PCBM aggregates may result in an improved FF, since more of the acceptor molecules contact the metal cathode, resulting in more efficient charge collection. Moreover, the aggregates may also lead to light scattering into the active layer, and thus increased path of the light and consequently, its absorption.

Conclusions

Various treatments of the PEDOT:PSS layer in ITO/PEDOT:PSS/P3HT:PCBM/Ca/Al solar cells resulted in improved overall device performance. In particular, the use of a PEDOT:PSS film with spin coated EG on it post-fabrication resulted in an increase in the P3HT:PCBM absorption, and hence, an increase of ~16% in I_{SC} and a 27% increase in PCE, from 3.7% in the cell with the untreated PEDOT:PSS to 4.7% in the former. The FF increased to 71–72% (from ~68% in the untreated cell). Dilution of PEDOT:PSS with DI water, and not only with organic solvents, also improved device performance. Based on the above results, it appears that the improved devices result mostly from an increased surface roughness of the P3HT:PCBM associated with the treatment and consequently graininess of the PEDOT:PSS layers. The increased roughness generates a better contact with the metal electrode, which, possibly, together with the observed PCBM aggregates near the cathode improves charge extraction. The improved PEDOT:PSS transmission and PEDOT:PSS/P3HT:PCBM absorption, together with the improved PEDOT:PSS conductivity in some of the cases, improved the I_{SC} and the overall cell performance. This improvement is possibly also due to improved light scattering by the rougher surfaces that results in enhanced absorption in the active layer. The results do not indicate that a change in the thickness of the PEDOT:PSS films is a major contributor to the observed improvements, as optimized spin-coating conditions were employed in each case (untreated and treated PEDOT:PSS) and the optimized thicknesses of the different layers were comparable. Similarly, changes in the PEDOT:PSS conductivity did not correlate with the improved performance.

The simple routes that led to the significantly increased PCE are expected to be applicable to other organic-based solar cells.

ABSTRACT

A near-field scanning microwave microprobe (NSMM) is employed to visualize the carrier distribution in the active layer of an organic field-effect transistor (OFET). Experiments using this technique with a pentacene OFET reveal changes of the conductivity profiles in the channel which arise from the development and exhaustion of an accumulated charge region. Electric field profiles that are visualized by using the electric field induced optical second harmonic generation (EFISHG) method, verify the results. NSMM is a powerful tool, and in combination with EFISHG will provide a way to directly probe carrier transport.

1. Introduction

Understanding carrier behaviors in materials is one of the most fundamental subjects in physics, material science, electronics, and electrical engineering. The study of carrier mobility and conductivity is important not only for device application [1], but also for understanding carrier transport, accumulation, charging, and trapping [2]. Interest in the dynamic behavior of carriers in organic material remains high due to possible application of organic devices, e.g., organic thin film transistors (OTFTs) [3], and organic electro-luminescent devices [4]. The recent research efforts to clarify the mechanism of OTFTs have been made to utilize efficiently organic materials [5], where probing the charge carrier is a key issue and many electrical measurements are being used [6,7]. Carrier trapping phenomena in OTFTs is generally observed by using electrical measurement [1,2,7], such as capacitance–voltage (C–V) and thermally simulated current measurements. Here the basic experimental concept is indirect characterization of charge storage using the C–V behaviors. The dynamical carrier motion has been explored using a variety of electrical techniques, e.g., the time-of flight (TOF) measurement [8]. The idea of these techniques is the indirect probing of the carrier motion and its related electrical phenomena through the current–voltage (I–V) characteristics. A Maxwell-displacement current pulse is recorded by electrical instruments and is analyzed in terms of the carrier motion [2,9]. Nevertheless, these techniques have drawbacks in discriminating carrier species, carrier-injection and carrier-transport processes. Direct probing and visualization of the carrier distribution can overcome these difficulties, and hence opens a new and fundamental way to discuss device operation [10].

In this paper, we demonstrate a direct probing of conductivity distribution in an organic thin film in terms of I–V characteristics, which relies on a near-field scanning microwave microprobe (NSMM) [11–14]. This is a direct

observation method that allows visualizing conductivity profiles caused by injected carriers in a channel of OTFT. The near-field microwave reflection coefficient (S parameter) image from the organic thin film directly visualizes the conductivity dependence on bias voltages. This NSMM approach is based on nondestructive probing of a local electromagnetic near-field interaction between the probe tip and the organic materials, and can be used in exploring carrier behaviors in devices such as OTFTs. The results obtained with NSMM are confirmed by the complementally visualized profile of the electric-field distribution which is obtained by using an electric field induced optical second harmonic generation (EFISHG) method [15,16].

2. Experimental

In our design of NSMM experiments, the probe is simply a sharpened metal wire tip in which voltage oscillations are present at microwave frequencies. The tip is brought to a distance of 10 nm from the sample surface. Because tip-sample interactions take place over a distance of nanometers, much less than the microwave wavelength (~1 cm), these interactions occur under near-field conditions. If the sample is translated under the tip, changes in tip-sample coupling can be used to obtain images of the sample with submicron resolution. The resolution is governed by tip geometry rather than the diffraction limit. At its other end, the probe is inserted into a microwave resonance cavity, or "resonator", populated by standing microwaves. The resonator microwave fields drive the electronic oscillations in the probe and the microwaves are continually excited through an input wire line connected to an external source.

We designed a NSMM with a tuning fork distance control system to keep a constant distance between the sample and the tip [12,13]. The probe tip was made of tungsten wire with a diameter of 50 μm with tapered end size of 1 μm. The probe tip was oriented perpendicular to the sample surface and the other end of the tip was directly connected to a coupling loop in the resonator cavity. The resonance frequency of a given TE_{011} mode (4.1 GHz) was measured with a network analyzer (Agilent 8753ES). To drive the tuning fork, an AC voltage was applied to one contact on the tuning fork at its resonance frequency using the oscillator of a lock-in amplifier (Signal Recovery 7265). The output from the lock-in amplifier was fed into the feedback system to control the tip-sample distance (10 nm) using a piezo electric tube (PZT) that supports the sample stage. The general idea is that the tip-sample distance is modulated with the vibration amplitude of the quartz tuning-fork oscillator at the resonant frequency, and the modulated signal is used to control the separation of a few nanometers. As the probe tip is brought into close proximity of the sample surface, the amplitude and resonant frequency of the oscillation are changed by interactions between the probe tip and the sample. As result, the amplitude of the oscillation is a function of the distance at which this control can be performed: for smaller amplitude, a smaller control distance can be maintained. All NSMM measurements were done at the same tip-sample

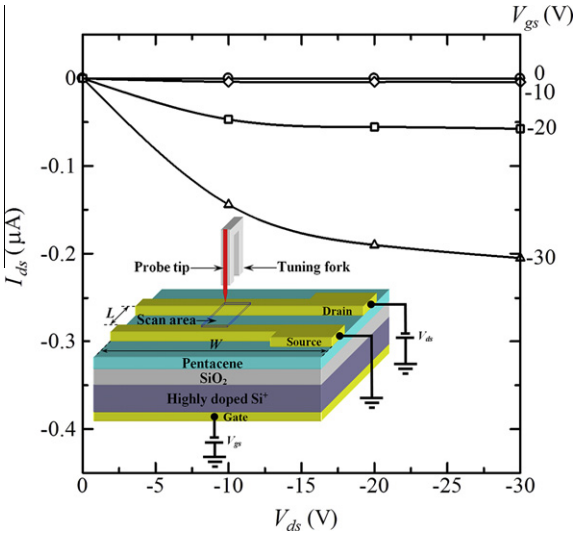

Fig. 1. I–V characteristics of the source–drain channel at the various negative gate biases obtained from the pentacene OFET. The inset shows the schematic diagram of the pentacene OFET with electrical connections and tuning fork attached probe tip for microwave scanning.

distance. The sample was mounted onto an x–y–z-translation stage for coarse adjustment which was driven by a computer-controlled microstepping motor with a resolution of 100 nm, whereas fine movement of the sample was controlled by a PZT tube with 10 nm resolution. The resulting spatial and lateral resolutions of mapping were about 2 μm and 5 μm, respectively, however, the NSMM incorporating with a commercial AFM probe-tip and 2D PZT scanner is able to map with an effective resolution of up to 50 nm [17].

The sample used in the experiments was a top-contact pentacene organic field-effect transistor (OFET) as schematically shown in the inset of Fig. 1. Before deposition of the pentacene, highly doped Si substrates were covered with a 500 nm thick SiO_2 insulating layer. The process pressure during deposition of the pentacene was kept at less than 10^{-4} Pa and the deposition rate were controlled at approximately 3 nm/min. After deposition of the pentacene, the top Au electrodes (source and drain electrodes) were deposited on the pentacene surface with a thickness of 100 nm. The channel length L and width W were 50 μm and 3 mm, respectively. For the field-effect transistor structure, a highly doped Si substrate was used as a gate electrode.

3. Results and discussion

The microwave reflection coefficient S_{11} measurements for a pentacene OFET reveal the changes of conductivity distribution in the OFET channel. That is, the electric conductivity distribution probed by NSMM depends on applied positive and negative drain–source (V_{ds}) and gate–source (V_{gs}) voltages. The electric conductivity distribution probed by NSMM during the off state obeys the Laplacian field. Here, this Laplacian field is the electric field caused

by the applied potentials on electrodes in the absence of any charge between the electrodes, and is formed when the pentacene shows the intrinsic nature of dielectric materials, e.g., low carrier density and lower conductivity [7,9]. On the other hand, electric-field distribution during the *on*-state deviates from this Laplacian field formed at the *off*-state, because excessive carriers injected from the source electrode makes a dominant contribution to the electric field formation, and regulates the carrier transport across the OFET channel, depending on the gate bias. By selecting an appropriate wavelength, the S_{11} signal could be localized in the various layers of the OFET due to the dependence of the penetration depth (so called skin depth: $\delta_s = (\pi\nu\mu\sigma/\lambda)^{-1/2}$, here ν is the speed of light, μ and σ are the permeability and the conductivity of the material) on the scanning wavelength, λ and material parameters, μ and σ [18].

NSMM is capable of imaging at submicron resolutions, is noncontact and nondestructive. This affordability stems in part from the use of microwave frequencies which do not require lens-based optics since the electromagnetic signals propagate along metal wire transmission lines. NSMM functions by sensing changes in electrostatic coupling between a near-field microwave probe and a sample [18,19]. An important feature of the present design, responsible for its high sensitivity, is that at the start of measurement the impedance of the cavity is equalized with that of the input line [20]. This tuning process consists of minimizing the complex reflection coefficient Γ given by assuming impedance matching between the probe and the microwave source [18].

$$\Gamma = \left|\frac{Z_{in} - Z_0}{Z_{in} + Z_0}\right|, \tag{1a}$$

where Z_0 is the characteristic impedance of the probe and Z_{in} is the modulus of the complex impedance of the OFET system. Analyzing the system as a four-layer model on the basis of transmission theory, we obtain [18,19]

$$Z_{in} = Z_a k_a t_{s^+}(1 - Z_g^R \sigma_p t_p) \tag{1b}$$

with Z_a and k_a (the impedance and wave number of free-space, respectively), t_{s^+} (the thickness of the n^+ doped silicon), Z_g^R (the real part of the complex impedance of the Au gate) and σ_p and t_p (the conductivity and thickness of the pentacene thin film, respectively). For a perfectly tuned system, $Z_{in} = Z_0$ and $\Gamma = 0$; in practice, we typically achieve $\Gamma \sim 10^{-3}$. Importantly, Z_{in} includes contributions from probe-sample interactions; therefore, tuning by necessity requires selection of a "reference state" for the sample. This is conveniently accomplished by using a surface region of known composition, for example one with zero coverage of molecules [20]. Minimization of Γ for the reference surface is analogous to subtraction of background in a fluorescence measurement.

The electrical property changes of active layer in pentacene OFET due to injected carriers, i.e., space charge generation, were investigated by measuring the changes of the reflection coefficient S_{11} ($S_{11} = 20\log|\Gamma|$). The S_{11} behavior depends on the V_{ds} and V_{gs} conditions. The behavior is due to injected charges into the OFET channel, hole injection is suppressed with $V_{gs} > 0$, whereas it is assisted with $V_{gs} < 0$. The changes of impedance of the pentacene films due to the accumulation of space charge are discussed based on how the changes in reflection coefficient depend on impedance changes.

The drain–source current, I_{ds} vs. V_{ds} characteristics at various negative gate voltages is shown in Fig. 1. The inset of Fig. 1 shows the sample structure and electrical connections for negative biases. The OFET shows typical *p*-type semiconductor characteristics. Let us briefly review the expected physics focusing on the operation of the *on*-state OFET. In OFETs, carrier transport is realized by charge accumulation and transport at the semiconductor/metal interface. A negative gate voltage, at zero drain bias, induces a uniform positive charge density, at the interface between the SiO_2 insulator and pentacene channel. This accumulated charge stems from the carriers injected from the source and drain electrodes, and its distribution is dependent on the V_{ds} and V_{gs}.

The situation is described by using a model that accounts for charge accumulation caused by the difference of dielectric relaxation times between the adjacent two materials (Maxwell–Wagner effect) [21], and carrier transport is described using macroscopic physical parameters, such as conductivity and electric field. In a *steady*-state, current flowing along the interface is always given by

$$j(x) = \sigma(x)E(x) = \text{const}, \tag{2}$$

where $\sigma(x)$, and $E(x)$ are the conductivity and electric field as a function of channel position x. In a three-electrode pentacene OFET system, charge transport is basically due to interface charging propagation by the accumulated charge on the semiconductor/insulator/gate interface. Injected carriers are excess charges and form a space charge field. The electric field profile $E(x)$ in the *on*-state is calculated by a transmission line model using an equivalent circuit consisting of infinitesimally small resistors and capacitors connected in series along the channel [22–24].

Transient analysis of the transmission line model gives a solution of the *steady*-state in the limit $t \to \infty$. In the *steady*-state, the potential distribution $V(x)$ ($V(0) = V_{gs} \cong V_g - V_s < 0$: source and $V(L) = V_{gs} - V_{ds}$: drain electrode) and electric-field distribution $E(x) = -\partial V(x)/\partial x$ are derived to be

$$V(x) = V_{ds}\sqrt{\frac{L-x}{L}} + V_{gs} - V_{ds}, \quad E(x) = \frac{V_{ds}}{2\sqrt{L(L-x)}}. \tag{3}$$

Note that $V(x)$ is a square root function of x, but it gives a linear potential profile in the region $x < L$, in the region of the source electrode side. In that region a gradual channel approximation is valid. Hole accumulation is created at the position x when the potential on the surface is attractive for holes, that is, $V(x) < 0$ while hole accumulation is not allowed when $V(x) > 0$ owing to the repulsive potential. Hence for $V_{ds} > V_{gs}$, charge accumulation is allowed over the entire region along the channel, whereas for $V_{ds} < V_{gs}$, the accumulated charge layer is established only in the region $0 \leqslant x \leqslant x_p$, and further charging is not allowed in the region $x_p \leqslant x$. Here $V(x_p) = 0$ and x_p is given by

$x_p = (1 - (1 - V_{gs}/V_{ds})^2)L$. In other words, x_p represents the maximum position where holes injected from the source are allowed to accumulate [21,22]. Note that the position x_p corresponds to the so-called "pinch-off" position [1], but it is different from the common use in semiconductor physics in that the position is determined by the potential caused by accumulation and propagation of injected holes. The potential $V(x)$ in Eq. (3) suggests that the carrier density profile is changing in proportion to $-C_g V(x)$, where C_g is the gate capacitance per unit area. Based on the above discussion, we find that when a negative bias ($V_{gs} < 0$) is applied to the gate under the condition $V_{ds} = 0$ (see Eq. (3)), firstly a uniform charge distribution is formed along the entire interface (channel formation), while when a negative drain bias V_{ds} is applied, a non-uniform charge distribution is created with lower density near the drain. When a more negative bias (more negative than the gate bias) is applied to the drain, an accumulated charge exhaustion layer is formed in the vicinity of the drain, i.e., an x_p position is created. Owing to the formation of this layer, the conductivity value is decreased and approaches the intrinsic one though the electric field is enhanced.

The NSMM probes the conductivity $\sigma(x)$ directly in the microwave frequency region, as follow from the relation in Eq. (1b). On the other hand, the EFISHG probes the static electric field $E(x)$ directly [21]. There is a reciprocal relationship between the conductivity $\sigma(x)$ and the static electric field $E(x)$ (see Eq. (2)). Hence the conductivity distribution mapped by the NSMM can be confirmed with the EFISHG profile.

Fig. 2 shows the 3D NSMM images from the channel of a pentacene OFET at various negative source–drain and gate bias voltages. Voltages are applied to the drain and gate electrodes with the source electrode grounded. As clearly shown in the images, the microwave reflection images correspond to the *I–V* characteristics. The change of microwave reflection coefficient traces the channel conductivity distribution. The conductivity along the pentacene channel is caused by accumulated charge and intrinsic carriers, and is given in the transmission line model by the expression

$$\sigma = \sigma_0 + \mu_p C_g \left[V_{ds} \left(1 - \sqrt{\frac{L - x}{L}} \right) - V_{gs} \right] \tag{4}$$

in the region $0 \leqslant x \leqslant x_p$, whereas in the region $x_p \leqslant x$, $\sigma = \sigma_0$. Here μ is the mobility of the carriers and σ_0 is the intrinsic conductivity of pentacene ($\mu_p = 5 \times 10^{-4}$ cm^2/Vs [25] and $\sigma_0 = 0.38 \times 10^{-6}$ S/cm [26]).

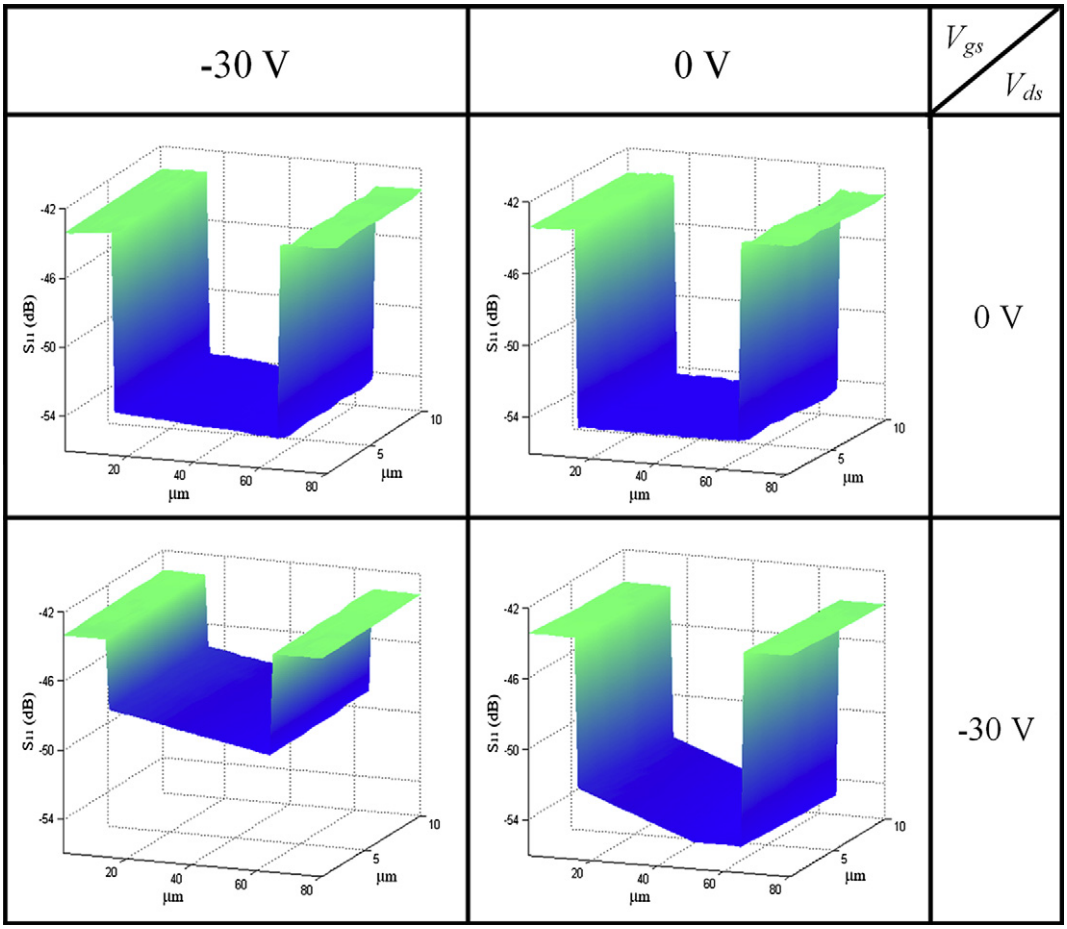

Fig. 2. 3D NSMM image of the pentacene OFET source–drain channel at the various negative gate biases.

Fig. 3 shows the relative change of estimated conductivity distribution in the pentacene OFET source–drain channel at $V_{ds} = -10$ V. The conductivity was estimated from measured microwave reflection coefficient S_{11} by using Eqs. (1a) and (1b) with empirical correlation of the experiment and the model [19]. As the magnitude of the negative gate bias increased the conductivity of the channel increased and a non-uniform conductivity distribution, with low density near the drain, was obtained. The inset of Fig. 3 shows the measured relative change of conductivity (from NSMM) vs. Eq. (4). Based on this good agreement, we conclude that the injection charges dominate in the conductivity. On the other hand, at $V_{gs} = 0$ V, a convex point x_p, corresponding to the boundary between charge accumulated and exhausted region, is seen. Eq. (4) accounts well for this result taking into account a threshold voltage $V_{th} = -10$ V, that is by replacing V_{gs} with $V_{gs} - V_{th}$. By increasing positively the biasing voltage V_{gs} ($V_{gs} > 0$), the conductivity decreased caused by hole depletion near the drain. In this situation, the role of the source and drain are converted into each other. Hence for analyzing the conductivity profiles using Eq. (4), we replace V_{ds} with $V_{sd} = -V_{ds}$, V_{gs} with $V_{gd} = V_{gs} - V_{sd} = V_{gs} + V_{ds}$, and x with $L - x$. Then the charge accumulation region is $L - x_p \leqslant x \leqslant L$. The convex point x_p shifts to the drain with increase of V_{gs} with $x_p = (V_{gs}/V_{ds})^2 L$, though we need to consider the contribution of V_{th} by replacing V_{gs} with $V_{gs} + V_{th}$.

To confirm our experiments with the NSMM, we probed the electric-field distribution along the OFET channel by using the reciprocal relationship between the NSMM and EFISHG. The system used for the EFISHG measurement was the same as in Ref. [10]. The EFISHG experiments were carried out in a manner as described in Ref. [27] at $V_{gs} = -100$ V, focusing on the electric field enhancement in the region where the conductivity is extremely low.

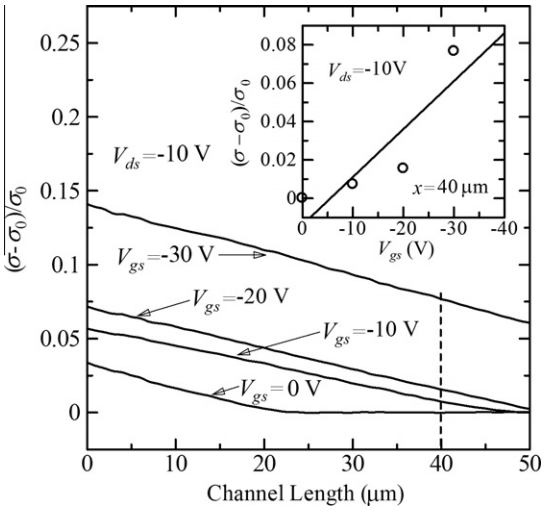

Fig. 3. The relative change of estimated conductivity distribution of the pentacene OFET source–drain channel at the various negative gate biases ($V_{gs} = 0$, -10, -20, -30 V). The inset shows the relative change of estimated conductivity (measured by NSMM), $(\sigma - \sigma_0)/\sigma_0$ vs. applied gate bias at a channel position of $x = 40$ μm and $V_{ds} = -10$ V. The solid line is a fit to Eq. (4) with $C_g = 7 \times 10^{-9}$ F/cm^2 and $\mu_p = 5 \times 10^{-4}$ cm^2/vs.

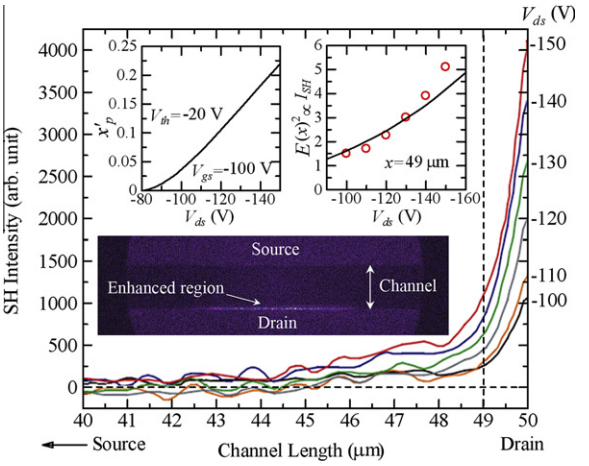

Fig. 4. SH intensity graph generated at various negative V_{ds} voltages. The gate bias was fixed at $V_{gs} = -100$ V. The upper left inset shows that $x_p' = 1 - x_p/L$ increases V_{ds} becomes more negative. The upper right inset shows that the calculated SH signal (see Eq. (3)) agrees well with the experimental data ($x = 49$ μm). The lower inset shows the EFISHG image of the pentacene OFET source–drain channel.

EFISHG is generated in proportion to square of electric field, $E^2(x)$. Fig. 4 shows a typical example of the experiments, in which we could see the second harmonic (SH) enhancement in the region where conductivity is low (lower inset of Fig. 4). That is, as the electric field is high in this region (see Eq. (2)), we could observe the enhanced EFISHG in proportion to $V_{ds}{}^2$ (see Eq. (3) and upper insets of Fig. 4). Note that EFISHG is a spectroscopic measurement, and the signal was selectively generated at a wavelength of 560 nm from the pentacene layer by the use of a incident laser with a wavelength of 1120 nm [10,26]. This supports the fact that EFISHG is probing carrier motion in the pentacene layer while the NSMM is probing the carrier distribution along the channel in the OFET. It is significant that the two experimental probes test the model in two different spatial regions of the interface; EFISHG works best where the electric field is high while NSMM works well in the high conductivity region (along the interface $j = E$ and so the regions are complementary). When we were carrying on the NSMM experiments shown in Fig. 2, we discovered the conductivity increased around the source with increase of V_{ds} ($V_{ds} < 0$) under the constant V_{gs} ($V_{gs} < 0$), though the fixed constant value $\sigma = \sigma_0 - \mu C_g V_{gs}$ (at $x = 0$) was suggested from Eq. (4). These results indicate the presence of hole injection from the source and transport via interfacial and bulk trapping states [12] caused by defects in the pentacene (otherwise the conductivity would not increase) [28–30].

4. Conclusions

The NSMM image clearly distinguishes the conductivity profiles caused by charge motion from source to drain. This is an advantage of direct observation by a NSMM. We anticipate that the use of this microwave method will be of great help for the understanding of carrier transport in organic materials, including bio-materials and molecules.

Further we should note that NSMM experiments in combination with EFISHG measurements could be an effective method for directly characterizing the *I–V* and *C–V* characteristics of materials on a microscopic scale. This study is a preliminary one and to clarify the details of the NSMM including the spatial and lateral resolution, dynamic range, etc., is our next work, but we may conclude from this study that NSMM provides a novel way to probe carrier behaviors in OFET.

ABSTRACT

Polymer solar cells (PSCs) are often fabricated using a well-known 4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene and 4,7-di(thiophen-2-yl)benzo[c][1,2,5]thiadiazole-based polymer as a low-bandgap polymer. Further, PSCs are also fabricated by mixing methanofullerene [6,6]-phenyl C61-butyric acid methyl ester ($PC_{61}BM$) with the polymer. We prepared poly[4,4-bis(2-ethylhexyl)-4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene-2,6-diyl-alt-4,7-bis(2-thienyl)-2,1,3-benzothiadiazole-5′,5″-diyl] after anchoring the penta-1,4-diene in the side chain of the cyclopentadithiophene and investigated the long-term performance stability of a photocrosslinked bulk heterojunction (BHJ) photovoltaic (PV) cell based on the polymer. The photocrosslinking reaction was monitored via infrared spectroscopy without the use of a photoinitiator, by carrying out a spontaneous radical coupling reaction. The polymer film has a broad absorption band extending from 300 to 850 nm with an optical bandgap as low as 1.52 eV. The polymer was employed to fabricate a PSC with $PC_{61}BM$. The resultant PSC device, which was treated by UV irradiation (λ = 254 nm, I = 40 mW/cm^2, 5 min), had good preliminary results with an open-circuit voltage of 0.62 V, a short-circuit current density of −5.37 mA/cm^2, a fill factor of 0.41, and an overall power conversion efficiency of 1.37%. All parameters of the UV-cured PSC device were more stable over the course of 300 h than those of P3HT-$PC_{61}BM$ devices, indicating the long-term stability of the polymer.

1. Introduction

Substantial progress has been made in the exploration of organic semiconductors as active elements in electronic devices such as light-emitting diodes, thin-film transistors (TFTs), and solar cells [1–7]. With regard to the application of organic semiconductors in electronic and optoelectronic devices, the organic photovoltaic (OPV) cell is expected to play an important role in developing devices to meet future energy requirements [8–15].

Bulk heterojunction (BHJ) PSCs have been shown to be the most promising devices for OPV cells. PSCs made of regioregular poly(3-hexylthiophene), poly[p-phenylene vinylene] and polyfluorene derivatives have been demonstrated with [6,6]-phenyl C (61 or 71) butyric acid methyl ester (PCBM) and exhibited quite promising power conversion efficiency (PCE) [16–22]. Since the photon flux of the solar emission has a maximum at 680 nm, many promising low-bandgap polymers have been designed and reported in the literatures [23–26].

The PCE value is often considered to evaluate device functionality and material properties in the PSC devices. The durability of PCEs, however, has not been much discussed. In fact, the lifetime of PSC is relatively short compared to silicon-based solar cells. In order to achieve good performance stability of PSC devices, the blend morphology of donor and acceptor materials should be sufficiently stable. Kim et al. emphasized the importance of the stability of the blend morphology in enabling the practical application of well-known BHJ PV devices, because any heat generated by solar emission can be detrimental to the performance of the devices. This damage is a result of the relatively low glass transition temperature (T_g) of the polymer blend and the miscibility of donor and acceptor materials in the photoactive layer [27]. Several useful methods for improving the performance stability of PSCs have been suggested in the literature, including the use of a proper compatibilizer and a fixation process involving two materials that stabilizes the two phases after nanophase separation [28]. Thermal crosslinking reactions have also been adopted to improve the stability of the blend morphology. However, thermal treatments used to induce crosslinking may be detrimental in that they prevent the annealing processes from being properly carried out [29–31]. Consequently, one of the major goals of this research is to control such "trade-off" problems.

In order to achieve this goal, we employed a photocrosslinking reaction to activate the thermal annealing process, followed by a separate photocrosslinking reaction. Considering all of the requirements for a photocrosslinkable BHJ, we designed a new copolymer based on a known low-bandgap polymer employing penta-1,4-diene, which undergoes a spontaneous photoreaction without the need for a photoinitiator. We hypothesized that the blend morphology would be tightly confined in three-dimensions following photocrosslinking as a result of volume shrinkage. The acceptor materials inside the polymer were expected to be more tightly caged by reducing the free volume through a lattice hardening mechanism. We also sought to control the stability of the interfacial contact between the materials by maintaining the semiconducting molecular nature and intrinsic electronic properties of the polymer.

The structures of the low-bandgap host polymers were designed such that the donor and acceptor moieties could be combined in the repeating unit in an alternating fashion. The electronic molecular energy levels (e.g., HOMO and LUMO levels) can be controlled through the intramolecular charge transfer (ICT) in D–A alternating copolymers.

In this study, we report the synthesis of the 4,7-di(thiophen-2-yl)benzo[c][1,2,5]thiadiazole (or 4,7-bis(thien-2-yl)-2,1,3-benzothiazole) and 4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene-based copolymer using an alternating heteroarene-fused π-conjugated system containing bis(heptyl penta-1,4-dien-3-yl succinate) in the repeating unit. The feasibility of the polymer for fabricating PSC devices was investigated. In addition, the polymer was mixed with $PC_{61}BM$ to fabricate BHJ PSC devices. For comparative purposes, we also fabricated a control device, i.e., P3HT/$PC_{61}BM$ (1:2 w/w, η = 3.7–4.0%). The thermally annealed and UV-cured samples had an average PCE of 1.37% in OPV devices. The photocured BHJ PSC device fabricated using the new photoreactive polymer showed a significant improvement in stability relative to that of the BHJ fabricated with P3HT/$PC_{61}BM$ over a duration of 300 h.

2. Experimental

2.1. Materials

All commercially available starting materials and solvents were purchased from Aldrich, TCI, and ACROS Co. and used without further purification unless otherwise stated. HPLC grade toluene, methylene chloride (MC), Dimethylsulfoxide (DMSO) and tetrahydrofuran (THF) were purchased from J.T. Baker and distilled from CaH_2 immediately before use.

We synthesized 4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene, **1** [32], 4,7-bis(2-bromo-5-thienyl)-2,1,3-benzothiazole, **5** [33] by following the literature method. Poly(3-hexylthiophene) and $PC_{61}BM$ was purchased from Rieke Metals and Nano-C, respectively.

2.2. Synthesis

2.2.1. (6-Bromohexyloxy)(tert-butyl)dimethylsilane (2)

6-Bromo-1-hexanol (11 g, 61 mmol), imidazole (12 g, 182 mmol), and 4-dimethylaminopyridine (DMAP, 0.74 g, 6.1 mmol) were mixed in 100 mL of MC under argon gas purging in a 250 mL three necked flask. *tert*-Butylchlorodimethylsilane (TBDMSCl, 18 g, 121 mmol) was added into the mother solution and the solution was allowed to stand for 3 h. Next, 10 mL of deionized water was added to quench the reaction. The mixture was extracted with MC (100 mL) and water (300 mL). The organic layer was collected and dried with sodium sulfate (Na_2SO_4). After concentrating the solution, the crude product was purified by silica gel column chromatography (eluent; ethyl acetate: *n*-hexane = 1:3). The reaction produced 14 g of product (**2**) (yield: 78%).

^{1}H NMR (300 MHz, CDC13): δ(ppm) 3.60 (t, J = 6.3, 2H), 3.40 (t, J = 6.9, 2H), 1.86 (q, J = 5.1, 2H), 1.54–1.35 (m, 6H), 0.89 (s, 9H), 0.04 (s, 6H) ^{13}C NMR (CDC13): δ(ppm) 63.0, 33.8, 32.8, 32.6, 27.9, 25.9, 25.0, 18.3, 5.3.

2.2.2. 4,4′-Bis(((tert-butyl)dimethylsilyloxy)hexyl)dicyclopenta[2,1-b:3,4-b′]dithiophene (3)

Compound (**1**) (1.5 g, 8.4 mmol) was dissolved in 70 mL dimethylsulfoxide (DMSO) at 0 °C and the solution was allowed to stir for 10 min under an argon atmosphere after the addition of KOH (1.5 g, 27 mmol) and KI (35 mg, 0.21 mmol). Compound (**2**) (6.2 g, 21 mmol) was added into the mother solution and the reaction was kept at 25 °C for 24 h. The reaction mixture was extracted with MC (100 mL) and water (300 mL). The organic layer was collected and dried with Na_2SO_4. The concentrated solution was purified by silica gel column chromatography (eluent; ethyl acetate: *n*-hexane = 1:3), yielding product **3**, 3.4 g (yield: 66%).

^{1}H NMR (300 MHz, CDC13): δ(ppm) 7.14 (d, J = 4.68 Hz, 2H), 6.91 (d, J = 4.68 Hz, 2H), 3.51 (t, J = 6.6, 4H), 1.81 (m, J = 5.1, 4H), 1.41–1.13 (m, 16H), 0.87 (s, 18H), 0.01 (s, 12H) ^{13}C NMR (CDC13): δ(ppm) 157.9, 136.4, 124.4, 121.5, 67.9, 63.2, 53.1, 37.6, 32.7, 29.7, 25.9, 24.4, 25.5, 18.3, 5.3.

*2.2.3. 2,6-Di(tributyltin)-4,4′-bis((tert-butyl)dimethylsilyl)hexyl)dicyclopenta[2,1-b:3,4-b′]dithiophene (**4**)*

Compound (**3**) (3 g, 5 mmol) was dissolved in 70 mL of THF at 25 °C in a 250 mL round bottom flask and the solution was kept under an argon atmosphere. Next, *n*-butyllithium (2.5 M) in *n*-hexane (50 mL, 20 mmol) was added using a microsyringe. After the addition was completed, the reaction mixture was allowed to stir for 1 h, and then tributyltin chloride (6.4 g, 20 mmol) was added. After 6 h, the mixture was extracted with MC (200 mL) and water (400 mL). The organic layer was dried with Na_2SO_4 and the solution was concentrated. The crude product was purified by silica gel column chromatography treated with triethylamine (eluent; chloroform: *n*-hexane = 1:1) to produce 4.57 g of compound **4** (yield: 78%).

^{1}H NMR (300 MHz, CDC13): δ(ppm) 6.87 (s, 2H), 3.52 (t, J = 6.6, 4H), 1.72 (m, 4H), 1.10–1.50 (m, 24H), 0.80–1.00 (m, 30H), 0.87 (s, 9H), 0.01 (s, 6H) ^{13}C NMR (CDC13): δ(ppm) 160.1, 142.2, 135.8, 129.6, 63.2, 51.9, 37.7, 32.8, 29.8, 29.2, 28.9, 27.1, 25.9, 25.6, 24.6, 18.36, 13.6, 10.8, 8.7.

*2.2.4. Polymer (**6**)*

Compound (**4**) (2.3 g, 1.9 mmol) and compound (**5**) (0.87 g, 1.9 mmol) were dissolved in 70 mL of toluene under an argon atmosphere. After adding $Pd(PPh_3)_4$ (0.11 g, 0.09 mmol), the reaction mixture was heated to 90 °C and stirred for 48 h. An End-capping reaction was performed by adding a toluene solution (5 mL) of tributyl tin thiophene (400 mg, 1.1 mmol). 2-Bromothiophene (800 mg, 4.9 mmol) in 5 mL of toluene was added dropwise into the mother solution. The reaction mixture was cooled to room temperature and was added dropwise into 60 mL of methanol to precipitate the crude solid product. The crude product was purified by Soxhlet extraction with methanol and acetone. The solid product was dissolved in 20 mL of chloroform and precipitation was performed in 300 mL of methanol again. The product was filtered and dried under vacuum for 48 h. Finally, 0.95 g of a dark blue solid powder (**6**) was obtained (yield: 53%).

^{1}H NMR (300 MHz, CDC13): δ(ppm) 7.89–6.98 (8H), 3.56 (s, br, 4H), 1.85 (s, br, 4H), 1.45–1.24 (m, 16H), 0.89 (s, 18H), 0.04 (s, 12H) GPC (THF): M_n = 3886 g/mol, M_w = 10,705 g/mol, PDI = 2.75 EA analysis calcd. for C47H64N2S5Si2: C, 62.34; H, 7.12; N, 3.09; S, 17.71; found: C, 62.88; H, 7.31; N, 3.55; S, 17.31.

*2.2.5. Polymer (**7**)*

Polymer **6** (0.4 g, 0.43 mmol) was dissolved in THF (70 mL) containing HCl (0.86 g, 8.6 mmol). The reaction was kept at room temperature for 48 h. After checking the progress of the reaction by thin layer chromatography, the reaction was neutralized with triethylamine. After concentrating the solution, the solution was dissolved into 300 mL methanol for precipitation. The crude product was filtered and dried under vacuum for 48 h. After drying, 0.25 g of a dark brown solid, compound (**7**), was obtained (yield: 83%).

EA analysis calcd. for C35H36N2O2S5: C, 62.09; H, 5.36; N, 4.14; S, 23.68; found: C, 62.92; H, 5.67; N, 3.80; S, 22.27.

2.2.6. Photoreactive polymer 8

Polymer **7** (0.2 g, 0.28 mmol) was dissolved in 80 mL of THF and 30 mL of MC. Dicyclohexyl carbodiimide (DCC, 0.15 g, 0.71 mmol) and DMAP (35 mg, 0.28 mmol) were added successively. 4-Oxo-4-(penta-1,4-dien-3-yloxy)butanoic acid (0.30 g, 1.4 mmol) was introduced into the mother solution and the solution was allowed to stand for 24 h. The residual hydroxyl group was protected with acetyl chloride. After the reaction was complete, the solid was purified by Soxhlet extraction with methanol and acetone successively. The solid was dissolved in chloroform again and precipitation was performed in methanol. The solid was filtered and dried under vacuum for 48 h. A dark blue solid polymer, compound **8**, was obtained (0.21 g, yield: 72%).

^{1}H NMR (300 MHz, CDC13): δ(ppm) 7.89–6.93 (8H), 5.79 (m, 4H), 5.70 (t, 2H), 5.23 (m, 8H), 4.02 (s, br, 4H), 2.63 (s, br, 8H), 1.92 (s, br, 4H), 1.27 (m, br, 16H) GPC (THF): M_n = 5991 g/mol, M_w = 20,431 g/mol, PDI = 3.41.

EA analysis calcd. for C53H56N2O8S5: C, 63.07; H, 5.59; N, 2.78; S, 15.88; found: C, 63.43; H, 5.33; N, 2.95; S, 15.06.

2.2.7. Instrumentation

^{1}H NMR spectra were recorded on a Varian Mercury NMR 300 MHz spectrometers using $CDCl_3$ purchased from Cambridge Isotope Laboratories, Inc. Elemental analyses were performed by the Center for Organic Reactions using an EA1112 (Thermo Electron Corp.) elemental analyzer. Thermal properties were studied under a nitrogen atmosphere on a Mettler DSC 821^e Instrument. Thermal gravimetric analysis (TGA) was conducted on a Mettler TGA50 (temperature rate 10 °C/min under N_2). The redox properties of synthesized polymers were examined by using cyclic voltammetry (Model: EA161 eDAQ). Thin films were coated on a platinum plate using methylene chloride as a solvent. The electrolyte solution employed was 0.10 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in a freshly dried methylene chloride (MC). The Ag/AgCl and Pt wire (0.5 mm in diameter) electrodes were utilized as reference and counter electrodes, respectively. The scan rate was at 50 mV/s. Fourier transformed-Infrared (FT-IR) spectra were recorded using a Nicolet 380 infrared spectrophotometer.

2.2.8. Absorption and PL spectroscopy

In order to study absorption behavior, the polymer film was fabricated on quartz substrates as follows. The solution (2.5 wt%) of polymer in monochlorobenzene was filtered through an acrodisc syringe filter (Millipore 0.2 μm) and subsequently spin-cast on the quartz glass.

The film was dried overnight at 80 °C for 12 h under vacuum. Absorption spectra of film samples were obtained using a UV–vis spectrometer (HP 8453, photodiode array type) in the wavelength range of 190–1100 nm.

When we investigate the PL spectral behavior, two emission spectra were recorded using the 488 nm line of a Ar^+ laser as the excitation light source. For PL measurements, the film specimen was mounted on the cold finger in the vacuum chamber (pressure < 10^{-5} Torr) of a closed cycle refrigerator. Emitted light was collected by a lens and analyzed using a single monochromator with 1 m focal length and a GaAs cathode photomultiplier. Standard lock-in detection techniques were used to maximize the signal-to-noise ratio. The diameter of incident laser beam was about 0.3 mm.

2.2.9. OTFT fabrication

Bottom-gate top-contact device geometry was employed for characterization of TFT performance. Spin-coated films (thickness ~40–50 nm) of polymer **8** were prepared on a heavily n-doped Si/SiO_2 substrate with monochlorobenzene (MCB) as solvent. Surface modification was carried out with octyltrichlorosilane (OTS) to give hydrophobic dielectric surfaces. The OTFTs were fabricated by directly spin-coating the polymer solution onto the dielectric substrate at 1200 rpm. The fabricated thin films were heated in air at 120 °C to remove the solvent and to anneal them thermally at 150 °C for 20 min. Then, the film was exposed to UV light for 5 min at 25 °C for inducing photocrosslink.

Source and drain electrodes were then thermally evaporated (t = 100 nm) through a shadow mask with a channel width and length of 1500 μm, and 100 μm, respectively. All the field effect mobilities were extracted in the saturation regime using the relationship $\mu_{sat} = (2I_{DS}L)/(WC(V_g - V_{th})^2)$, where I_{DS} is the a saturation drain current, C is the capacitance of the silicon oxide dielectric, V_g is the gate bias, and V_{th} is the threshold voltage. The device performance was evaluated in air using Keithley 4200-SCS semiconductor characterization system under ambient conditions.

2.2.10. PSC device fabrication

The hole collecting electrode was 300–400 nm thick indium tin oxide (ITO) coated glass with resistance of 19.5 Ω/cm. ITO glass was cleaned by boiling in chloroform, isopropyl alcohol, and acetone for 30 min in each solvent, sonification for 15 min in 50:50 isopropyl alcohol and acetone solution, and finally rinsed with de-ionized water. The cleaned ITO coated glass was treated with O_2 plasma and flattening ITO with a microwave-generated plasma reactor (Plasmatic Systems Inc., PLASMATIC-PREENII, 24 GHz) for 15 min. 30 nm thick PEDOT:PSS layer (Baytron P, 1 S cm^{-1}) was coated by spin coating stock solution at 2500 rpm for 30 s. PEDOT:PSS coating was heat treated in the glove box at 200 °C for 5 min.

The polymer and $PC_{61}BM$ were dissolved in anhydrous monochlorobenzene. The thickness of a resulting photoactive layer was ~80 nm. For inducing photocrosslinking, the film was exposed to UV light for 1 and 5 min. LiF (0.8 nm thick) which served as a buffer layer, was vacuum deposited on top of active layer and 150 nm thick aluminum was evaporated. Thickness of the photoactive film was measured with surface profiler (TENCOR®, P-10 α-step). Current–voltage characteristics were measures with Keithley 2400 source-measure unit. Xe lamp (300 W) was used as a light source to produce intensity of 100 mW/cm^2. To mimic sun light, AM 1.5 filter (Oriel) was used neutral density filter was used to reduce intensity as necessary. Intensity of incoming light power was measured with calibrated broadband optical power meter (Spectra Physics model 404).

3. Results and discussion

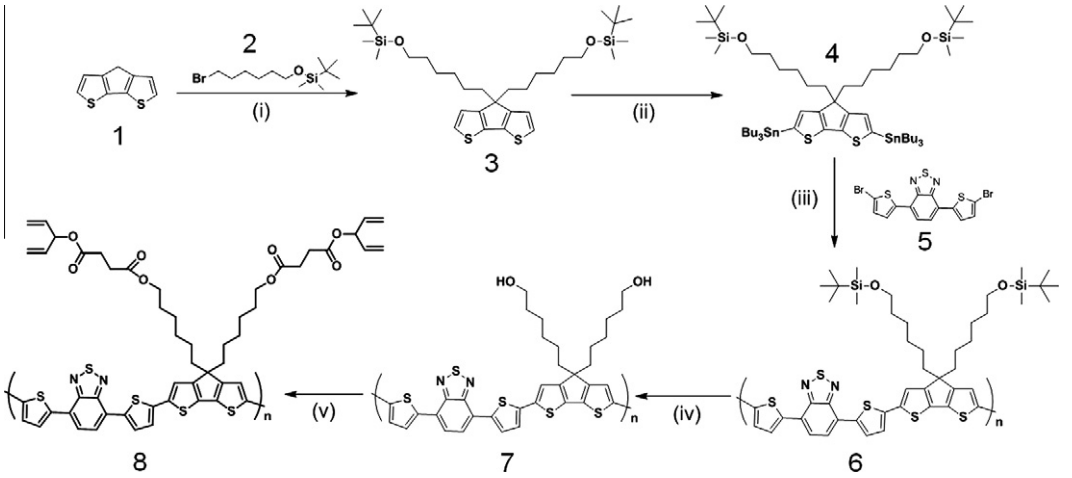
3.1. Synthesis and characterization

Scheme 1 illustrates the synthetic routes for the monomers and a π-conjugated D–A alternating copolymer having heteroaromatic-ring moieties as a repeating group. TBDMS-protected hexyl bromide was reacted with 4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene to yield compound **3**. Compound **3** was then lithiated using *n*-butyllithium, with a reaction yield of 78%. Following lithiation, the tributyl tin groups were reacted with 4*H*-cyclopenta[2,1-b:3,4-b′]dithiophene in order to conduct Stille coupling polymerization. The 4,7-di(thiophen-2-yl)benzo[c][1,2,5]thiadiazole was synthesized following the method given in literature [33]. Bromination of 4,7-di(thiophen-2-yl)benzo[c][1,2,5]thiadiazole with *N*-bromosuccimide (NBS) yielded the dibromide monomer **5**. Eventually, the Stille coupling polymerization of monomer **5** was conducted with monomer **4** bearing tributylstannyl groups in the presence of a catalytic amount of $Pd(PPh_3)_4$ to afford polymer **6**. The TBDMS unit was then removed in the presence of hydrochloric acid at 25 °C. After removing the TBDMS groups from polymer **6**, the DCC esterification of polymer **7** and 4-oxo-4-(penta-1,4-dien-3-yloxy)butanoic acid produced polymer **8** in good yield (72%).

The identity and purity of the synthetic materials were confirmed by ^1H NMR, ^{13}C NMR, and elemental analysis. As solubilizing groups, tert-butyl(heptyloxy)dimethylsilane side chains were substituted in the dicyclopenta[2,1-b:3,4-b′]dithiophene groups in the polymer structures. The weight-average molecular weight (M_w) of **8** was determined by gel permeation chromatography (GPC) using a polystyrene standard and was found to be 20,431 (M_w/M_n = 3.41). The polymers **6**–**8** are soluble in various organic solvents including chloroform, xylene, MC, chlorobenzene, and THF, and they can be fabricated into smooth films by a spin-coating method.

The thermogravimetric analysis (TGA) measurements were conducted at a heating rate of 10 °C/min under nitrogen. The measurements revealed that the polymers were thermally stable having a decomposition temperature, T_d, of 325 °C (see Fig. 1A). The thermally induced phase transition behavior of polymer **8** was investigated with differential scanning calorimetry (DSC) under a nitrogen atmosphere. The glass transition temperature of the polymer was not detected but the melting temperature was determined to be 75 °C, indicating the semi-crystalline nature of the polymer.

FT-IR spectroscopy: An FT-IR investigation was carried out to confirm that photocrosslinking had occurred



Scheme 1. Synthetic procedure for a photoreactive low-bandgap D–A alternating copolymer. (i) KOH, KI, DMSO, rt; (ii) Bu_3SnCl, *n*-BuLi, −78 °C; (iii) $Pd(pph_3)_4$, toluene, 90 °C; (iv) HCl, THF, rt; (v) 4-oxo-4-(penta-1,4-dien-3-yloxy)butanoic acid, DCC, DMAP, rt.

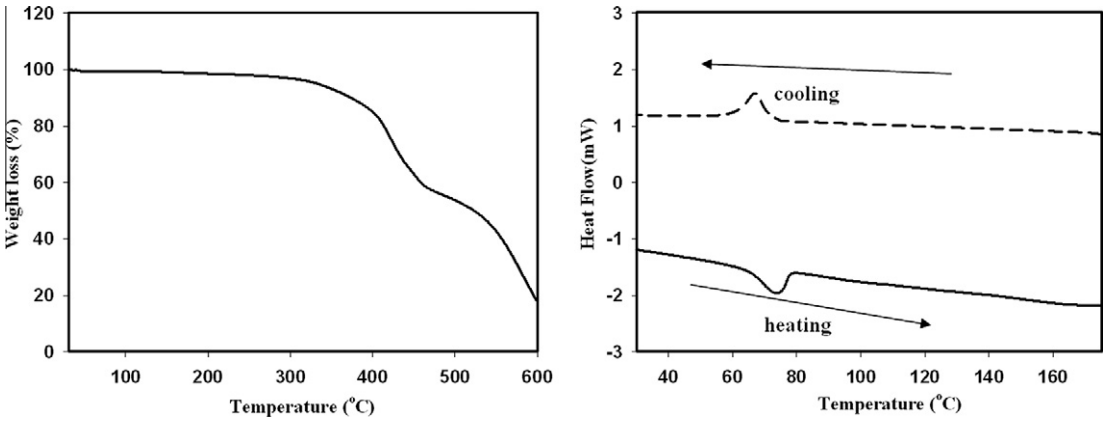


Fig. 1. TGA and DSC thermal analysis of the polymer. (A) TGA and (B) DSC.

between the pentadiene units. The film sample was prepared on a KBR window using the spin-coating method. Fig. 2 shows the FT-IR spectra of the polymer films before and after UV exposure (λ = 254 nm, I = 40.5 mW/cm^2). The characteristic absorption bands at 931, 985, and 1446 cm^{-1}, which can be unambiguously assigned to the pentadiene photoreactive groups, are labeled in the figure. The observed decrease in the intensity of the CH out-of-plane deformation in –CH=CH_2 at 985 and 931 cm^{-1} was clear evidence of the polymerization. Further verification of crosslinking was found from the slight decrease in the intensity of the in-plane deformation band of =CH at 1446 cm^{-1}.

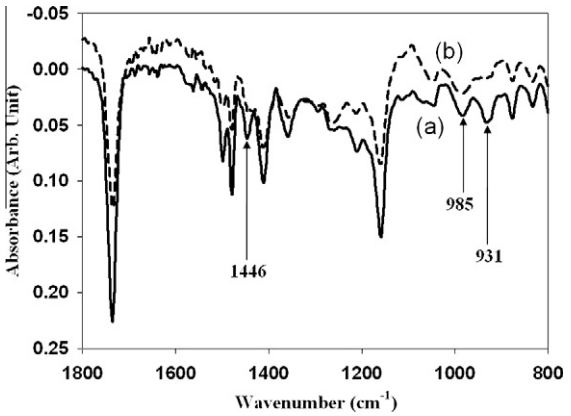

Fig. 2. FT-IR spectra of polymer **8** film before (a) and after (b) UV exposure.

3.2. Absorption and photoluminescence (PL) spectroscopy of polymer 8

The absorption spectra of polymer **8** in both dilute chloroform solution (conc. = 1 × 10^{-6} M) and thin solid films spin coated on a quartz substrate are illustrated in Fig. 3. The absorption maxima of polymer **8** and the other measured data are summarized in Table 1. In the solution state, polymer **8** exhibited absorption maxima at 657 and 446 nm and an absorption edge at 790 nm, indicating an optical

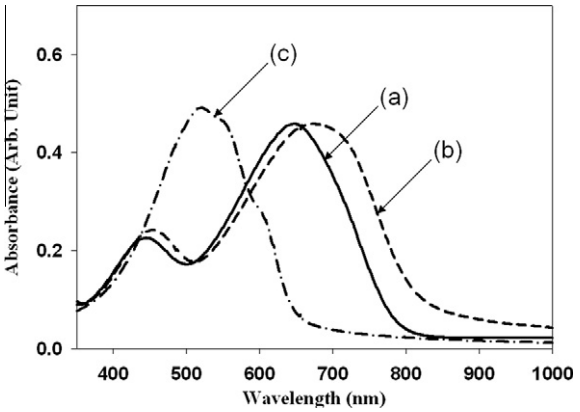

Fig. 3. Absorption spectra of polymer **8** in (a) solution and (b) film states. Spectrum (c) was obtained from P3HT film for comparison.

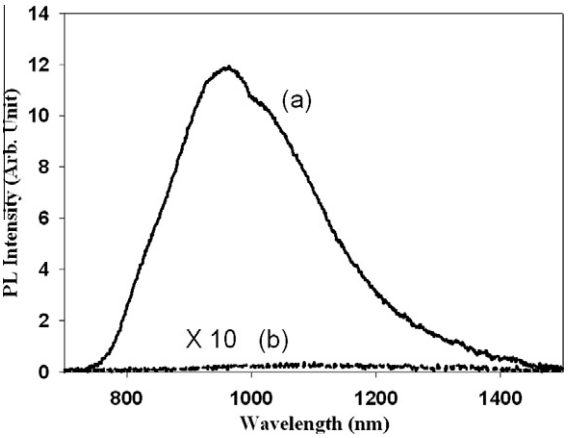

Fig. 4. PL spectra of the copolymer (a) and the blend sample with $PC_{61}BM$ (1:2 w/w) The PL intensity scale in spectrum (b) has been enlarged by 10 times.

bandgap energy of 1.52 eV. The low energy band is due to ICT between the donor and acceptor.

The absorption spectrum of the film of polymer **8** exhibits slight broadening and is red shifted by 10–12 nm compared to that of the solution state. This bathochromic shift results from strong intermolecular interactions in the solid state. The absorption maximum is hard to determine accurately, and the spectrum of the film floated over the base line, indicating the existence of scattering loss as a result of solid-state crystallization. Polymer **8** exhibits significant absorption throughout the visible region, extending into the NIR wavelength range. The optical spectrum of the film ranges from 300 to 850 nm, which can be fitted to the solar spectrum. The optical bandgap energy ($E_g^{opt.}$) in the film state was determined to be 1.52 eV, which is much smaller than that of the widely used regioregular poly(3-hexylthiophene) (P3HT) ($E_{HOMO} = -5.07$ eV, $E_{LUMO} = -3.24$ eV, $E_g^{opt.} = 1.83$ eV).

The photoluminescence (PL) spectra of the pristine film and blend film with $PC_{61}BM$ (1:2 w/w) were also acquired and are presented in Fig. 4. Because these polymers were expected to have an emission band in the near-IR region, a customized optical set-up was built to measure the emission spectrum generated by excitation at 488 nm with an Ar^+ laser. The wavelength of maximum emission is approximately 964 nm and the emission edge occurs in the region of 1500 nm, which is a typical emission spectrum for low-bandgap polymers, and corresponds to the long wavelength range of the absorption maximum.

As a representative example, the absorption spectrum of the blend sample with the copolymer and $PC_{61}BM$ (1:2 w/w) in the film state is illustrated. No emission was observed in the blended sample film (curve b) under 488 nm excitation. This PL quenching behavior can be explained by the aggregation-induced self-quenching of the excited polymer states and $PC_{61}BM$ units. The lack of emission might also be a result of intermolecular electron transfer from the photoexcited polymers to the $PC_{61}BM$ sensitizer. The photoinduced charge transfer in other conjugated molecular composites by PL quenching can be found in the literature, and is a prerequisite for efficient solar cells [34–36].

3.3. Electrochemical analysis

The electrochemical properties of the polymer were investigated by cyclic voltammetry and the scanned cyclic voltammogram is shown in Fig. 5. The HOMO and LUMO energies of the polymer are quite important for determining how to facilitate the photoinduced electron transfer in the BHJ OPV device after blending with $PC_{61}BM$. The voltammogram of a film sample was recorded and the potentials were obtained relative to an internal ferrocene reference (Fc/Fc^+).

The HOMO and LUMO levels of the polymer were estimated using the onset potentials of the oxidation and reduction waves. Polymer **8** showed one quasi-reversible oxidation peak and one quasi-reversible reduction peak. The HOMO and LUMO energy levels and electrochemical bandgap energy (E_g^{ec}) of the copolymer calculated from E_{ox}^{onset} and E_{red}^{onset} are listed in Table 1. The voltammogram

Table 1
Physical properties of polymer **8**.

	T_m (°C)	T_c (°C)	T_d (°C)	Solution		Film		E_{ox}^{onset} (V)/HOMO (eV)	E_{red}^{onset} (V)/LUMO (eV)	E_g^{ec} (eV)	E_g^{opt} (eV)
				λ_{max}^{abs} (nm)	$\lambda_{cut\text{-}off}$ (nm)	λ_{max}^{abs} (nm)	$\lambda_{cut\text{-}off}$ (nm)				
Polymer	74	67	325	446,657	785	453,669	815	0.51/−4.91	−0.85/−3.55	1.36	1.52

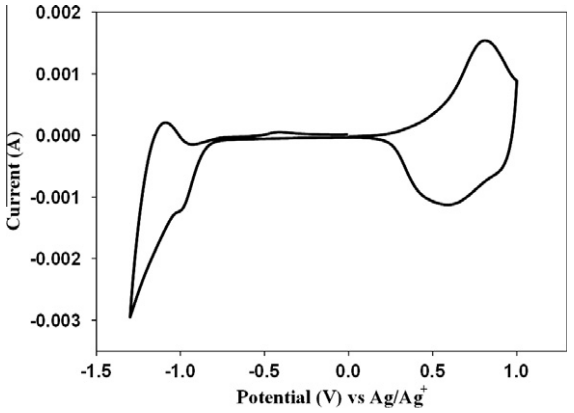

Fig. 5. Cyclic voltammogram of the polymer **8** film.

of the polymer in the film state showed that its lowest oxidative wave was at +0.51 eV. As shown in Table 1, polymer **8** has a HOMO level of −4.91 eV.

In addition, polymer **8** has a LUMO energy level of −3.55 eV. The electrochemical bandgap energy of the film sample was determined to be 1.36 eV, which is 0.06 eV less than the optical bandgap energy ($E_g^{opt.}$ = 1.52 eV). For comparison, the HOMO and LUMO levels of regioregular P3HT were also measured under identical conditions, and were found to have energies of −5.07 and −3.24 eV, respectively.

Although the HOMO level is too low to show low open-circuit voltage (V_{oc}), in the energy diagram (see Fig. 7) of the BHJ OPV devices, efficient photoinduced electron transfer between the host polymers and acceptor is expected on the basis of the PL quenching behavior.

3.4. Properties of OTFT made of polymer 8

A 40-nm-thin film of polymer **8** was deposited on OTS-SiO_2 by spin coating a 1 wt% solution of the polymer in monochlorobenzene. After spin coating the polymer solution onto the surface of the insulator, the thin-film layer (t = 70 nm) was annealed at 150 °C for 10 min and exposed to UV light (λ = 254 nm, I = 40 mW/cm^2). The gold electrodes were then deposited via thermal evaporation for the fabrication of thin-film transistors.

Fig. 6 shows the typical drain current (I_{DC}) versus source–drain voltage (V_{DS}) plots for various gate voltages

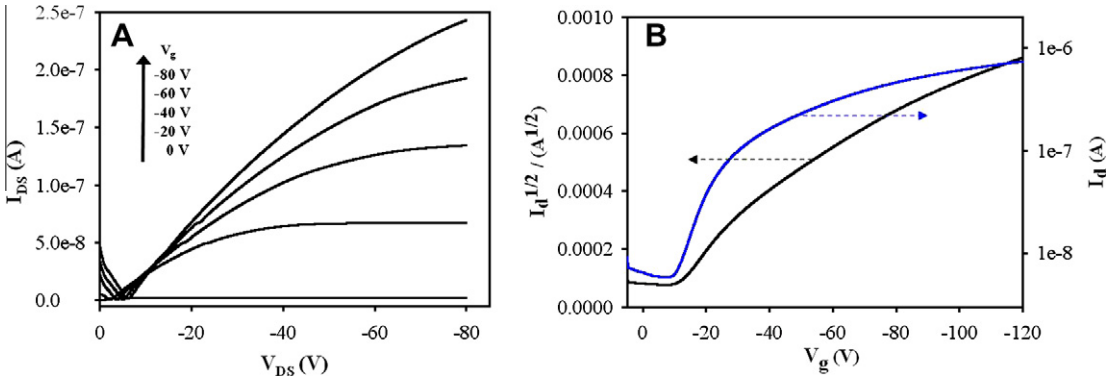

Fig. 6. Current–voltage characteristics (I_{DS} versus V_{DS}) at different gate voltages (V_g) (left) and I_{DS} and $(-I_{DS})^{1/2}$ versus V_g plots at V_{DS} of −100 V (right) for a top contact device (annealing at 150 °C, W = 1.5 mm, L = 100 μm). Insulator: OTS treated SiO_2.

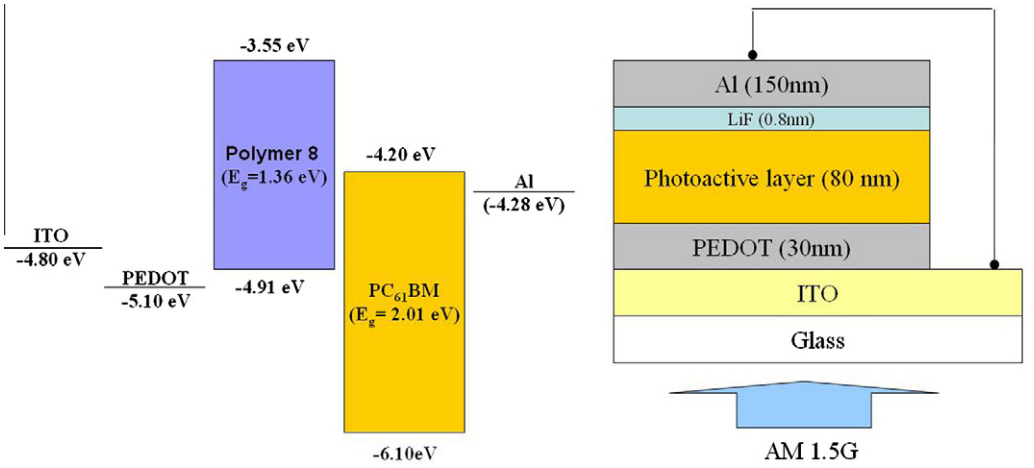

Fig. 7. Energy diagram of polymer photovoltaic cell (left). Device configuration of polymer solar cell (right).

in the accumulation mode of the polymer **8**-based TFTs. The output characteristics showed good saturation behaviors at low gate voltages, and clear saturation currents that were quadratic to the gate bias. The saturated field-effect mobilities, μ_{FET}, can be calculated from the amplification characteristics using the classical equations that describe field-effect transistors. The average mobility value obtained from five different devices equaled $(2.5 \pm 0.5) \times 10^{-3}$ cm^2/Vs with a current on/off ratio of approximately (1×10^2)–(3×10^2) and a threshold voltage, V_{th}, less than −15 V, under ambient conditions. The mobility value of the device fabricated using polymer **8** is comparable to those of D–A polymers for PSC, as reported in the literature [24].

The UV-induced photocrosslinking reaction is known to be detrimental to the semiconducting properties of the cell due to disruption of crystallization and molecular orderness [37]. It is noteworthy that a UV-induced crosslinked film of polymer **8** is very homogeneous and exhibits self-organization for uniform domains, which in turn enhances the ordered structure and charge transport in the thin film. Therefore, the mobility of the device made with the UV-cured film is comparable to that ($\mu = 3 \times 10^{-3}$ cm^2/Vs) of the device with unexposed film.

3.5. PSC device performances

PSC devices were fabricated by spin coating a solution of polymer **8**/$PC_{61}BM$ onto the PEDOT:PSS layer. After drying the blend film, the photocrosslinking reaction was induced using UV irradiation. The samples were exposed to UV light ($\lambda = 254$ nm, $I = 40$ mW/cm^2) for 20 min in order to cure the BHJ. The device configurations are as follows: ITO/PEDOT:PSS/polymer **8**:$PC_{61}BM$/LiF/Al (see Fig. 7).

Fig. 7 clearly illustrates the molecular energy levels and device configuration. First, PSC devices were fabricated using three polymer mixtures with $PC_{61}BM$ (1:1, 1:2, and 1:4 w/w). The characteristics of the device performances were determined under identical ambient conditions. The current density (J) versus voltage (V) curves of the PSCs are shown in Fig. 8. The devices **I**, **II**, and **III** contain photoactive layers with compositions of 1:1, 1:2, and 1:4 (polymer **8**:PCBM, w/w), respectively. The open-circuit voltage (V_{oc}), short-circuit current density (J_{sc}), fill factor (FF), and the PCE of the devices are summarized in Table 2. No significant change of the PCE was observed for the three different compositions, with all three samples displaying a PCE of almost unity ($\eta \approx 0.91$–1.08%). The effect of the annealing process on the device performances after annealing the samples at 80 °C followed by UV irradiation was also investigated. However, no significant annealing effects on the device performance accompanying the slight decrease of PCEs were observed. It appears that the photocuring effect is dominant over the thermal annealing effect, and manipulates the polymer structure toward the formation of ordered molecular structures in the PSCs. These preliminary experiments led us to select the blend ratio of 1:4 for further experiments to investigate the long-term stability of the PSCs.

In this experiment, the thermal annealing processes were excluded and the UV irradiation time was varied.

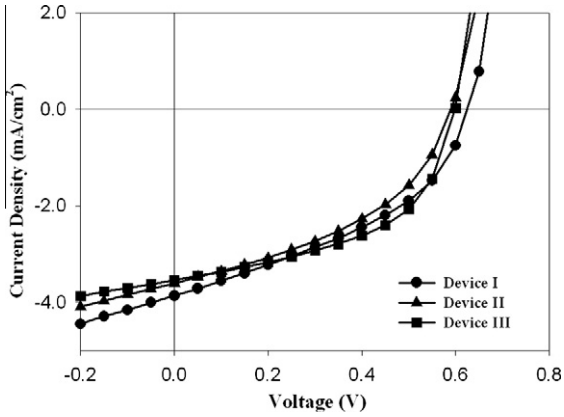

Fig. 8. Current density versus voltage curves of polymer **8**: $PC_{60}BM$ solar cells under AM 1.5G illumination. Circle: device **I**, triangle: device **II**, square: device **III**.

Table 2
Summary of polymer **8**-based PSC device performance.

Polymer **8**:PCBM (w/w)	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
1:1	−3.86	0.62	0.41	0.99
1:2	−3.61	0.59	0.43	0.91
1:4	−3.55	0.60	0.51	1.08

Fig. 9 shows the current density–voltage characteristics of the three devices under AM 1.5G illumination. The UV irradiation times were selected to be 0, 1, and 5 min at room temperature (see Table 3). Device **IV**, which was not UV irradiated ($t = 0$ min) demonstrated V_{oc}, J_{sc}, FF, and PCE values of 0.52 V, −3.35 mA/cm^2, 0.42, and 0.72%, respectively. The V_{oc} value (0.52 V) of device **IV** is smaller than the value shown in Fig. 8. For device **V**, in which the sample was exposed to UV light for 1 min, there was an increase in the J_{sc} value accompanied by an incremental increase in V_{oc}. The resultant PCE rose to 0.97% under these conditions. Finally, the sample that was irradiated for 5 min (device **VI**) had a PCE value of 1.37%, with increased J_{sc} and V_{oc} values relative to device **IV**. From the data, we concluded that a longer UV irradiation time leads to better device performance. In particular, the V_{oc} values varied with the irradiation time from 0.52 V for $t = 0$ min to 0.62 V for $t = 5$ min. In effect, the energy difference between the HOMO of the host polymer and the LUMO of the acceptor was found to most closely correlate with the V_{oc} value.

Theoretically, if the HOMO levels are identical, different devices having the same components should exhibit the same V_{oc} values regardless of the device conditions. These three samples exhibited inconsistent V_{oc} values, which could be attributed to the different surface morphological and interfacial properties between polymer **8** and $PC_{61}BM$, which could control the build-up potential.

In order to investigate the reason that device **III** showed the highest PCE value, the surface topographies of the blended films were observed using AFM microscopy. The AFM micrographs of the three samples are displayed in Fig. 10 along with the UV exposure time.

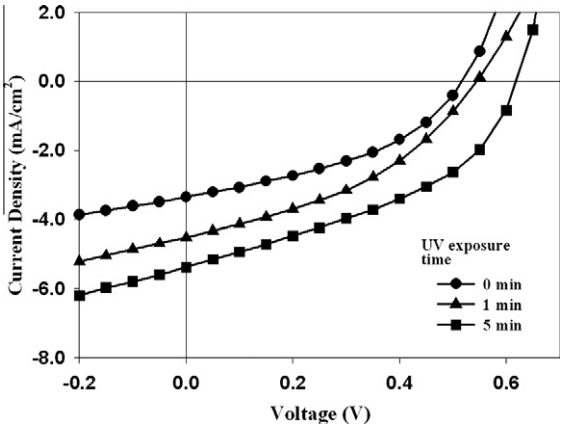

Fig. 9. Current density versus voltage curves of CP:$PC_{60}BM$ solar cells under AM 1.5G illumination. Device **IV**: pristine sample (circle); device **V**: UV exposure for 1 min (triangle); device **VI**: UV exposure for 5 min (square).

Table 3
Summary of polymer **8**-based PSC device performance with the UV exposure time.

Device	UV exposure time (min)	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
Device **IV**	0	−3.35	0.52	0.42	0.72
Device **V**	1	−4.52	0.54	0.39	0.97
Device **VI**	5	−5.37	0.62	0.41	1.37

From the three AFM images, it is easily noticeable that the surface topography changes with the UV exposure time. The pristine samples showed a surface roughness of 1.8–2.0 nm and contained a lot of large pinholes and dark areas. For longer irradiation times, the size of the pinholes significantly reduced and the surface became coarse. The sample exposed to UV light for 5 min has 8–10 nm surface roughness and the size of its pinholes is drastically reduced compared to the pristine sample. In principle, photopolymerization and the photocrosslinking reaction gave rise to the reduced volume of the polymer. It can be conjectured that under these conditions, the $PC_{61}BM$ domains were more tightly encompassed by polymer domains so that the interfacial contact could be highly improved. Therefore, more tightly bound polymer chains increase the short-circuit current (J_{sc}), resulting in increased PCE values. The reason for the increase in V_{oc} remains unclear in this study. A dense binary matrix has better interfacial contact that can reduce the build-up potential in the gap between the polymer and $PC_{61}BM$ domains.

Finally, we fabricated two devices; the first is the BHJ PSC cell made of P3HT and $PC_{61}BM$ (1:2 w/w), whereas the other is composed of polymer **8** and $PC_{61}BM$ (1:4 w/w). The latter was photocured by UV irradiation for 5 min under ambient conditions. The effect of photocrosslinking on the long-term stability of the devices was explored at 25 °C over a prolonged time period (t = 200 h). The decay behaviors of the PCEs are depicted in Fig. 11.

A P3HT:$PC_{61}BM$ (1:2 w/w) blended device was also prepared; it was not exposed to UV light and served as a control sample. The V_{oc}, J_{sc}, FF, and PCE values of the control sample were 0.60 V, 10.18 mA/cm^2, 0.60, and 3.79%, respectively. The photocured sample initially had V_{oc}, J_{sc}, FF, and PCE values of 0.65 V, 3.07 mA/cm^2, 0.47, and 0.97%, respectively. However, the photocured samples were quite different in terms of their long-term stability at ambient temperatures. The performance of the polymer **8**-based PSC devices treated with UV irradiation for 5 min were more stable in terms of device performance. In particular, the inset of Fig. 11 clearly showed slow decaying behavior of PCE of photocured sample in 40 h. Even after 200 h, the photocured devices retained more than 78% of the initial PCE. It was clearly observed in the inset of Fig. 11. In contrast, the device performance of the pristine-P3HT:$PC_{61}BM$ blend decreased rapidly to 25% of its initial efficiency value after 200 h. This result clearly shows that the photocrosslinking concept holds promise for thermally stable high-performance devices. All other evidence supports the efficacy of this synthetic strategy for improving the long-term stability of PSC device performance. Although we still observe a decreasing behavior for PSC device performance, the precise optimization of curing conditions and alternative methods for device fabrication may enhance the long-term stability of this polymer for fu-

ture use in practical applications. Our work unambiguously demonstrates that a photocrosslinkable and low-bandgap D–A alternating copolymer can be utilized for fabricating better PSC devices.

4. Conclusions

A soluble, photoreactive, low-bandgap D–A alternating copolymer based on cyclopentadithiophene and di(thiophen-2-yl)benzothiadiazole repeating units was synthesized by a palladium(0)-catalyzed Stille coupling reaction. The polymer contains pentadiene units in the side chain, which are reactive under UV exposure. A clear advantage of using the $PC_{61}BM$-containing polymer **8** in BHJ PSCs is that photocrosslinking can freeze the optimum internal morphology and long-term stability performance of the device can be achieved. Under optimized curing conditions, UV-cured polymer **8**-based PSC devices had a PCE of up to 1.37% under AM 1.5G illumination and the stability of PCE of photocured sample is better than the sample before UV exposure. BHJ solar cells based on the mixture of a D–A copolymer and $PC_{61}BM$ showed much improved long-term stability over long measuring periods as compared to conventional devices made of P3HT:$PC_{61}BM$.

These results can contribute to the design of photoreactive semiconducting π-conjugated polymers for practical applications in electronic and optoelectronic devices.

ABSTRACT

We reveal the effect of UV–ozone treatment on the electrical properties of poly (styrenesulfonate) doped poly (3,4-ethylenedioxythiophene) (PEDOT:PSS) film by clarifying the respective roles of UV light irradiation and exposure to ozone gas. The UV–ozone treatment induced increases in both work function and resistivity. Furthermore, the film thickness was reduced at a rate of 0.13 nm/min. The ozone-exposed films also exhibited a marked increase in the work function. However, such variations were not observed in the resistivity and film etching. Angle resolved X-ray photoelectron spectroscopy revealed that the main role of the UV light was to decompose the chemical bonds in the PEDOT:PSS film, resulting in a resistivity increase and film etching. In contrast, the ozone and atomic oxygen were absorbed and oxidized the surface, which was responsible for the increase in the work function. Due to these different functions, UV–ozone treatment is capable of controlling the work function and resistivity of PEDOT:PSS film thus allowing them be adjusted to the device application.

1. Introduction

Poly (3,4-ethylenedioxythiophene) (PEDOT) is an electrochemically stable conjugated polymer that provides electrical conductivity with optical transparency. Polystyrenesulfonic acid (PSS) works as a charge balancing dopant giving PEDOT water solubility and high electrical conductivity. Thus, PEDOT:PSS has found a number of applications including as hole transport layers in polymer-based light-emitting diodes (LEDs) and in backlights for liquid crystal displays [1–5]. PEDOT:PSS has a high work function (~5.2 eV [2,6–8]), which is advantageous for opto-electronics applications such as a Schottky photo detector. Nakano et al. demonstrated a high quality Schottky contact on a zinc oxide (ZnO) single crystal [9]. The work function is critical to device performance, and so simple ways of tuning the work function to match the organic energy levels are technologically important. Some groups have increased the work function of PEDOT:PSS by employing UV-ozone treatment [10–12]. Benor et al. improved and controlled the device efficiency in phosphorescent organic light-emitting diodes with ultraviolet-ozone treatment, in which PEDOT:PSS was utilized as a hole injection layer [13–15]. They suggested that the changes in the PEDOT:PSS work function improved the external quantum efficiency of the phosphorescent organic light-emitting diodes. In these reports, two mechanisms of the work function increase have been proposed. Tengstedit et al. reported that UV–ozone treatment formed a surface dipole induced by surface oxidization [11]. In contrast, Helander et al. reported that the surface accumulation of residual Na^+ decomposed by UV–ozone treatment increased the work function [12]. However, the mechanism of the UV–ozone treatment of PEDOT:PSS has yet to be elucidated in detail. Understanding and controlling the UV–ozone treatment effect are both essential for practical device applications.

In this paper, the effects of UV–ozone treatment on the electrical properties of PEDOT:PSS film are examined using electrical measurements, surface observations, and angle resolved X-ray photoelectron spectroscopy (AR-XPS). All the measurements were carried out with and without UV light irradiation to distinguish the effect of ozone gas exposure from that of UV light.

2. Experimental procedures

Glass substrates were employed to eliminate additional factors responsible for electrical properties. The substrates were cleaned at room temperature in organic solvents and a deionized water rinse, and this was followed by conventional UV–ozone cleaning (Filgen, UV253). The substrate surface was spin coated with a PEDOT:PSS aqueous solution (Sigma–Aldrich, 483095) and dried on a hot plate at 100 °C for 30 min in an ambient atmosphere. The rotation speed for the spin coating was set at 5000 rpm. The thickness of the PEDOT:PSS film was about 75 nm. The UV–ozone treatment was performed with a UV–ozone cleaner at UV wavelengths of 184.9 and 253.7 nm and an energy density of 33.3 mW/cm^3. For the ozone exposure, the samples were partly covered with a piece of aluminum foil to eliminate direct UV irradiation on the sample surface. The resistivity was measured with the four-point contact probe method (Napson, Model RG-80N), where the distance between each probe was 0.5 mm. The distance is much greater than the film thickness, and the obtained values can be regarded as bulk region resistivity. The work function was measured in air by employing photoelectron yield spectroscopy (Riken Keiki, AC-3) with a scan energy range of 4.0–7.0 eV and with an energy of 50 nW. The chemical bonding states were evaluated with XPS (Thermo, Theta Probe) using a monochromated Al Kα X-ray at an energy of 1486.6 eV. The samples were connected to the electrical ground of the system by using conductive copper tapes. The work function of the system was calibrated with reference to the Au $4f_{7/2}$ and Ag $3d_{5/2}$ peak positions. The total energy resolution was set at 700 meV. The depth profiles of the observed electronic states were examined with AR-XPS. The take off angles (TOA) of 0° and 76°, which are bulk-sensitive and surface-sensitive angles, respectively, correspond to average detection depths of 5.8 and 1.5 nm as calculated by the Tanuma–Powell–Penn (TPP-2M) equation (Ref. [16]). The film thickness was determined by X-ray reflection (XRR). The XRR measurement system had a 5-kW rotating anode Cu target (Bruker AXS, D8 Discover Super Speed with GADDS). For the XRR measurements, the glass substrates were replaced with c-plane sapphire substrates. This is because, to achieve reproducible high resolution measurements, the surface should be strictly aligned parallel to the traveling direction of the X-ray. The sapphire substrates were coated with PEDOT:PSS using the same procedure as that employed with the glass substrate, which had the same surface morphology and film thickness to the PEDOT:PSS film on glass substrate. The surface morphology was observed using atomic force microscopy (AFM; SII NanoTechnology, Inc., SPI4000 & E-sweep).

3. Results

3.1. Electrical properties

Fig. 1(a) shows the photoelectron yield spectra of the PEDOT:PSS films on glass substrates. The ionization energy of the polymer film is defined as the energy difference between the vacuum level and the extrapolated edge of the highest occupied molecular orbital (HOMO) [17]. Therefore the work function can be estimated by linearly extrapolating the edge of the square-root photoelectron yield to the baseline. The work function of the as-coated PEDOT:PSS film (denoted as as-PEDOT) was 5.16 eV, which is comparable to previously reported values (4.9–5.2 eV) [2,6–8]. Both the UV–ozone treatment and ozone exposure for 30 min caused shifts in the edge of the photoemission to a higher energy. The work functions were determined as 5.41 and 5.68 eV, respectively. These results suggest that both treatments affected the chemical states of the PEDOT:PSS film surface.

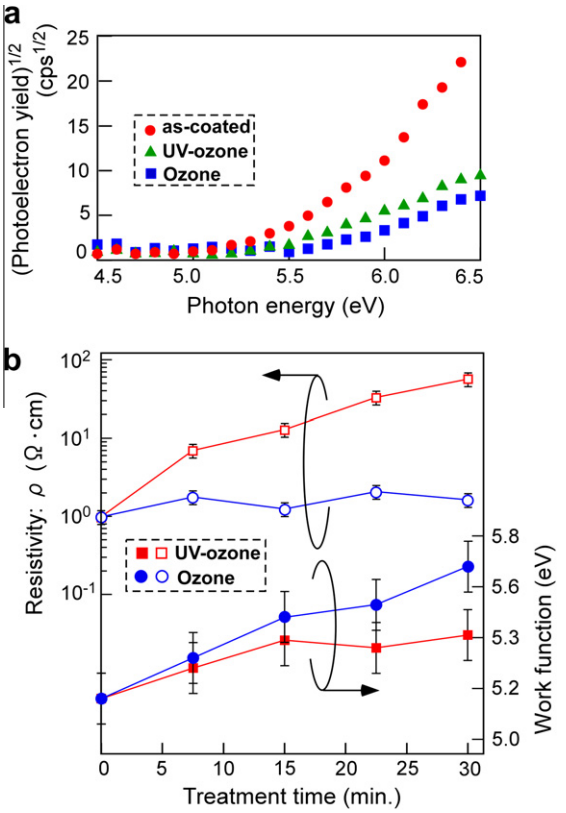

Fig. 1. (a) Photoelectron yield spectrum of as coated (circles), UV–ozone treated (triangles), and ozone exposed (squares) PEDOT:PSS films on glass substrates. (b) Treatment time dependence of resistivity (open symbols) and work function (solid symbols) of the PEDOT:PSS films with UV–ozone treatment (squares) and ozone exposure (circles).

The treatment time dependence of the resistivity and work function of the PEDOT:PSS films are summarized in Fig. 1(b). The variations in the resistivity differed noticeably with the respective treatments. The UV–ozone treated PEDOT:PSS film (denoted as UV–O_3–PEDOT) exhibited an almost two-order increase in resistivity. In contrast, the ozone exposed PEDOT:PSS film (denoted as O_3-PEDOT) exhibited a constant resistivity (~1.5 Ω cm). The work function increased with each treatment in a similar manner. However, a clear difference was observed after a treatment time of 15 min. The work function of the UV–O_3–PEDOT saturated around 5.4 eV, which is consistent with

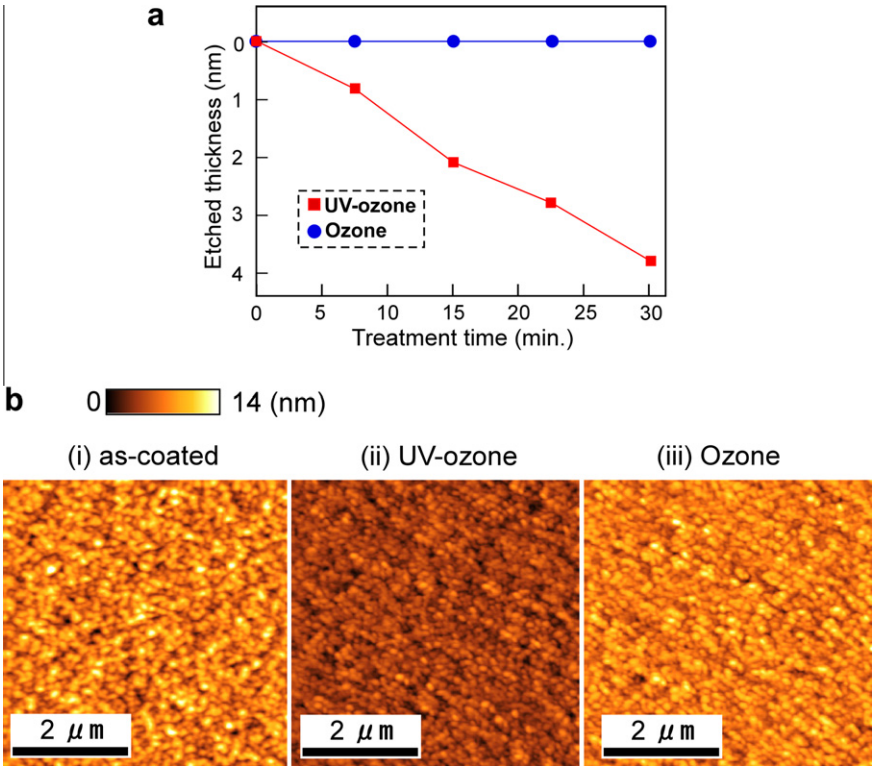

Fig. 2. (a) Relative etched film thickness of the UV–O_3–PEDOT (squares) and the O_3–PEDOT (circles) against the treatment time. (b) AFM images of (i) as-PEDOT, (ii) UV–O_3–PEDOT, and (iii) O_3–PEDOT.

a previous report [11]; the O_3–PEDOT exhibited a monotonic increase in the work function against exposure time.

3.2. Surface etching

The surface etching caused by the UV–ozone treatment was examined with XRR measurements and AFM observation. The O_3–PEDOT film thickness exhibited no significant change against the treatment time as shown in Fig. 2(a). In contrast, the UV–O_3–PEDOT film thickness decreased with an etching rate of approximately 0.13 nm/min. The etching effect on the UV–O_3–PEDOT was observed in the surface roughness as shown in Fig. 2(b). Although all the samples had similar small-grained surfaces, the surface roughness of the UV–O_3–PEDOT decreased. The root mean square roughness values of the as-PEDOT, UV–O_3–PEDOT, and O_3–PEDOT were 1.4 ± 0.1, 0.7 ± 0.1, and 1.3 ± 0.1 nm, respectively.

3.3. Chemical states

Representative S 2*p* core level spectra for the PEDOT:PSS films at the bulk sensitive TOA of 0° are shown in Fig. 3. To analyze the XPS spectra, we fitted all the spectra by the convolution of a Gaussian and a Lorentzian [18]. The background was subtracted by the Shirley method [19]. The S 2*p* core level consists of a spin-split component of S $2p_{1/2}$ and $2p_{3/2}$, whose reported energy difference and relative intensity are 1.18 eV and 1:2, respectively [13]. The peaks in the low binding energy peak around 164 eV correspond to the sulfur atoms in the thiophene rings of the PEDOT [13,20,21]. The higher binding energy peak around 169 eV corresponds to the sulfur atoms in the PSS. The contribution of PSS to the S *2p* peak is due to the doping ions PSS:H^+ (168.4 and 169.6 eV) and to the PSS:Na^+ salt (168.0 and 169.2 eV) [13,20,21]. Na^+ residues originate from the $Na_2S_2O_8$ oxidizing agent used for the polymerization of the PEDOT:PSS [22].

After the UV–ozone treatment, there was a pronounced binding energy peak at 168.7 eV, which corresponded to the sulfur atoms bonding with oxygen (PSS:O), as seen in Fig. 3(b), suggesting that the main effect of the UV–ozone treatment is to decompose and oxidize the PSS–Na^+ and –H^+ bonds. Although such bonding decomposition was not detected, a broadening of the PEDOT binding energies was observed in the O_3–PEDOT (Fig. 3(c)). This is because the positive charges are delocalized over the PEDOT chains, leading to a spread in the binding energies [23]. This charge distribution was affected by the oxidization of the PEDOT chain, resulting in the broad binding energy distribution of the sulfur atoms.

Fig. 4 summarizes the TOA dependence of the intensity ratio of PSS:O/PSS(–Na^+ and –H^+). The ratio for the UV–O_3–PEDOT exhibited a constant value of 0.3 through the TOAs, i.e., the decomposition and oxidization of PSS spread over the bulk region. The slight increase around the high TOAs (surface-sensitive angles) can be attributed to the native

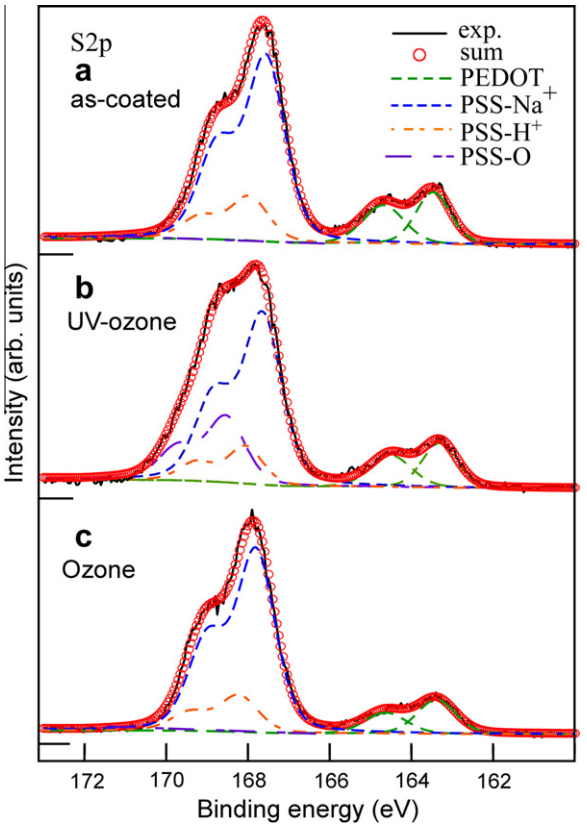

Fig. 3. S 2*p* core spectra of (a) as-PEDOT, (b) UV–O_3–PEDOT, and (c) O_3–PEDOT. The treatment time was 30 min. Solid lines and open circles show measured spectra and sum-fitted curves, respectively. Dashed lines are fitted curves for each bond: PEDOT, PSS–Na^+, PSS–H^+, and PSS–O.

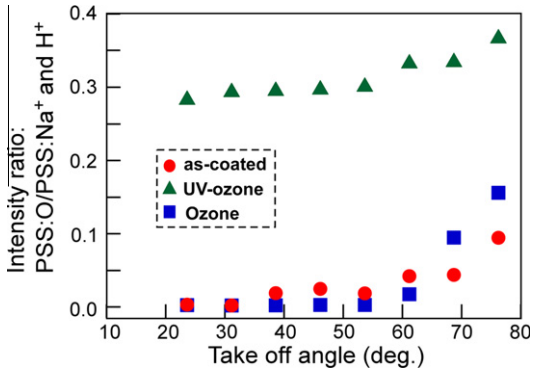

Fig. 4. TOA dependence of the intensity ratio between PSS–O and PSS–(Na^+ and H^+) for as-PEDOT (circles), UV–O_3–PEDOT (triangles), and O_3–PEDOT (squares).

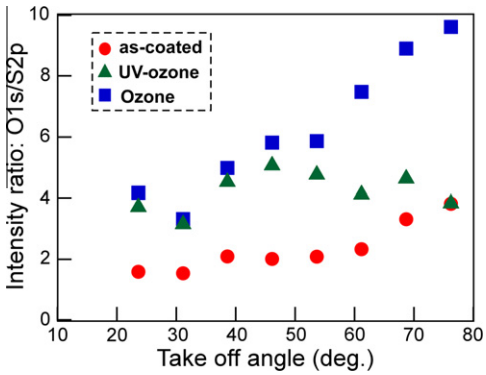

Fig. 6. TOA dependence of the intensity ratio between O 1*s* and S 2*p* for as-PEDOT (circles), UV–O_3–PEDOT (triangles), and O_3–PEDOT (squares).

oxidation as observed in the as-PEDOT. In contrast, no signals from PSS:O were detected with the shallow TOAs (bulk-sensitive angles) for the O_3–PEDOT as with the as-PEDOT. The distinction of the O_3–PEDOT can be ascribed to the steep increase in the ratio at high TOAs. These results indicate that ozone exposure induced a high concentration of absorbed oxygen only at the surface region.

The O 1*s* core spectra shown in Fig. 5 can be assigned as the convolution of four different components, namely 533.7 eV from PEDOT [13,20,21], 531.5 eV from PSS:Na^+, 532.1 and 532.85 eV from PSS:H^+ [23], and 532.1 eV from the adsorbed oxygen that overlaps with the PSS:H^+ signal.

The intensity ratios of O 1*s*/S 2*p* were plotted as a function of TOA in Fig. 6 to discuss the amount and distribution

of oxygen. After the UV–ozone treatment and the ozone exposure, the ratios at a TOA of 20° were double that of the as-PEDOT indicating that the total amounts of increased oxygen were the same for both UV–O_3–PEDOT and O_3–PEDOT. With respect to the TOA dependence, the O_3–PEDOT increased monotonically at a higher rate than the UV–O_3–PEDOT, indicating that the oxygen diffused into the PEDOT:PSS film on the UV–O_3–PEDOT. In contrast, the O_3–PEDOT surface had a higher concentration of oxygen than the bulk region and other PEDOT films. These results are consistent with the TOA dependence of the intensity ratio of PSS:O/PSS(–Na^+ and –H^+).

4. Discussion

The UV light from the low-pressure mercury lamp in the UV–ozone cleaner comprises two major wavelengths of 184.9 and 253.7 nm (denoted as 184.9-UV and 253.7-UV) [24,25]. The intensities of 184.9-UV and 253.7-UV are approximately 5% and 90%, respectively [26,27]. During the UV–ozone cleaning process, the 184.9-UV decomposes and activates oxygen molecules to form ozone gas. Furthermore the 253.7-UV decomposes the ozone and generates atomic oxygen that has strong oxidizability. The 253.7-UV also decomposes chemical bonds such as C–C, C–H, and C–OH bonds. The UV–ozone treatment cleans the sample surface by combining the oxidization and the decomposition of the chemical bonds. The energy (E) of UV light is given as [27]:

$$E = Nhc/\lambda \times 105(\mathrm{kJ/mol}), \quad (1)$$

where N, h, c and λ are Avogadro's number, Planck's constant, light speed and wavelength, respectively. The energy of 253.7-UV is 472 kJ/mol, which is higher than the bonding energy of single chemical bonds: C–C (347.7 kJ/mol), C–H (413.4 kJ/mol), C–O (351.5 kJ/mol), and C–S (370 kJ/mol) [28].

PEDOT has a two-ring structure as illustrated in Fig. 7(a) that consists of a π-conjugated thiophene ring and an ethylenedioxyl ring including C–O single bonds. The π-conjugated part, which is responsible for the conductivity of PEDOT, has a higher bonding energy than a single bond. Although PSS also has C=C double bonds (Fig. 7(b)), it does not form π-conjugated polymer chains. That is, the main role of the PSS is to provide carriers to the PEDOT, and it only contributes slightly to the conductivity. The 253.7-UV mainly decomposed the single bonds of PSS such as the C–C, S–H, and S–Na bonds, resulting in the functional inhibition of PSS as a dopant. Note that the energy of 184.9-UV is 647 kJ/mol, which is sufficiently high to decompose C=C double bonds [28]. However, the PEDOT decomposition is negligible because of the very low intensity of 184.9-UV.

According to the electrical measurements, surface observations, and AR-XPS results, the effects of ozone exposure and UV–ozone treatment on PEDOT:PSS films can be explained as follows.

(A) Ozone exposure (Fig. 7(c)): with ozone exposure, the atomic oxygen oxidized the film surface and was adsorbed thus forming oxygen molecules. The amount of adsorbed

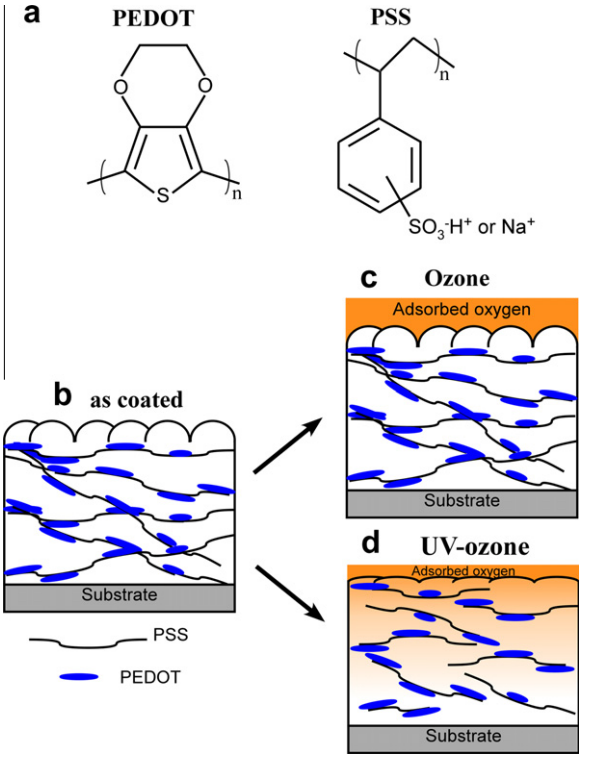

Fig. 7. (a) Chemical structure of PEDOT:PSS. Schematic structural illustrations of (b) as-PEDOT, (c) O_3–PEDOT, which has thick adsorbed oxygen on the surface, and (d) UV–O_3–PEDOT, which consists of decomposed PSS chains. The PEDOT structure maintains its initial state after both treatments.

oxygen increases with the treatment time. The absorbed oxygen molecules withdraw electrons from the PEDOT:PSS surface, because the electron affinity of oxygen is larger than that of PEDOT:PSS. Further oxygen adsorption makes the surface more negatively charged and forms a positive space–charge layer beneath the surface. As a result, dipoles are generated at the surface region lifting the HOMO level towards the high-binding energy. This is the main reason for the increase in the work function. In this process, the resistivity remains constant against the treatment time because the UV light was shadowed and decomposition of the chemical bonds was prevented.

(B) UV–ozone treatment (Fig. 7(d)): the decomposition of chemical bonds by UV light irradiation, resulting in the functional inhibition of PSS as a dopant, is promoted simultaneously with the oxidization and oxygen adsorption at the surface. The decomposed bonds are sufficiently reactive for further oxidization. Some of oxidized carbons were removed from the surface, resulting in the surface etching, which is conventional UV–ozone cleaning process. These are the reasons for the uniform distribution of oxygen across the entire film, and the increase in resistivity as well as the film etching. Furthermore, we assumed that the adsorbed oxygen could be re-activated by the UV light and be desorbed from the surface, leading the saturation of amount of adsorbed oxygen at the surface. As a result, the work function of UV–O_3 PEDOT increased at a slower rate than that of O_3 PEDOT and finally saturated.

5. Conclusion

We clarified the effect of UV–ozone treatment on the electrical properties of PEDOT:PSS films by distinguishing between the roles of UV light irradiation and ozone gas exposure. UV light was found to be responsible mainly for the decomposition of chemical bonds. On the other hand, ozone exposure caused dipoles to form on the film surface as a result of oxidization. This is the reason for the increase in the work function. In fact, the experimental data for the UV–O_3–PEDOT film showed the results of the overlap of both effects, namely a resistivity increase and surface etching, as well as an increase in the work function. Meanwhile, the O_3–PEDOT exhibited a variation only in the work function. In conclusion, a detailed understanding of these functions makes it possible to fine tune the electrical properties of PEDOT:PSS and improve device performance. Using UV–ozone treatment provide us to tune the electrical property of organic light-emitting diodes. In contrast, when we use PEDOT:PSS as a conductive electrode such as a Schottky electrode, ozone treatment should be better than UV–ozone treatment to eliminate the damage of PEDOT:PSS layer and to keep its conductivity.

ABSTRACT

This study examined the mechanism of performance degradation induced by the plasma sputtering process for the formation of the ITO top anode in inverted top-emitting organic light-emitting diodes (ITOLEDs) with WO_3 thin film as the hole injection layer (HIL) and the buffer layer. The degradation is mainly caused by the changes in the physical properties of the WO_3 thin film as well as the damages of organic layers, which are caused by the bombardment of energetic particles induced by the plasma sputtering process. The number of oxygen vacancies in the WO_3 thin film is increased with the increase of the bombardment energy of energetic particles such as Ar ions, resulting in the decrease in the work function and optical band gap and the dramatic increase in conductivity. Above all, the increase in the energy potential difference between WO_3 HIL and NPB HTL, which was attributed to the reduced work function of the WO_3 HIL, reduces the efficiency of carrier injection and dominantly affects the device performance. These results show that the plasma damage effect, induced by the sputtering process for ITO deposition, could not be effectively removed, even when the metal oxide thin film is used as the buffer layer in ITOLEDs.

1. Introduction

Top-emitting organic light-emitting diodes (TOLEDs) are quite attractive for their large aperture ratio and high pixel resolution [1–3]. In particular, TOLEDs with the inverted staggered structures, called as inverted TOLEDs (ITOLEDs), have been investigated actively because they are expected to be more suitable for n-type thin film transistors (TFTs) than the conventional TOLEDs [4,5].

To fabricate high performance ITOLEDs, the top anode of transparent conducting oxides (TCO), such as indium tin oxide (ITO) and indium zinc oxide (IZO), needs to be deposited on the hole injection layer by using the plasma sputtering process [6]. However, during the sputtering process, the underlying organic layers can be attacked easily by the bombardment of energetic particles (ions, electrons and neutralized particles), heating, and ultra violet (UV) radiation [7,8]. In particular, the energy of the charged particle bombardment is sufficiently high to break most of the carbon-based bonds in the organic layers [8]. If such breakage occurs because of the sputtering process, ITOLEDs will display degraded performance.

Over the past few years, many research groups have examined new sputtering technologies for depositing the TCO top anode, which would induce less damage to the underlying layers by reducing the energy of the particle bombardment [2,9,10]. Other groups have used a metal oxide hole injection layer (HIL) as a buffer layer to protect the organic layers from the energetic particle bombardment during the sputtering process. Recently, several transition metal oxides, such as tungsten oxide (WO_3),

molybdenum oxide (MoO_3), vanadium oxide (V_2O_5), rhenium oxide (ReO_3), and nickel oxide (NiO), have been evaluated as superior buffer layers with excellent HIL function [10–13]. Although these methods – new sputtering technologies and buffer layer – can somewhat reduce the plasma process-induced damage to the underlying layers, they still gave degraded device performance compared to the device not adopting sputtering deposition.

This study examined the changes in the physical properties of WO_3 thin films after Ar plasma irradiation to clarify the cause of the performance degradation in ITOLEDs with ITO top electrode formed by plasma sputtering. The correlation between the changes in the physical properties of the WO_3 thin film and device degradation was investigated by measuring various properties of the WO_3 thin films and the electro-optical characteristics of hole-only devices and OLED test devices. Moreover, the results suggested that under appropriate conditions, Ar plasma treatment can be used to obtain suitable physical properties of the WO_3 HIL for applications to high performance.

2. Experimental

Initially, to evaluate the plasma process-induced effect on ITOLEDs, we fabricated inverted bottom-emitting OLEDs (IBOLEDs) adopted with a 10 nm-thick top ITO electrode, which was deposited by the conventional DC magnetron sputtering process. The structure of the IBOLEDs in this study was the same as that in our previous work [2,4]; ITO (143 nm)/thin Al (3 nm)/8-hydroxyquinolatolithium (Liq) (0.9 nm)/tris (8-hydroxyquinoline) aluminum (Alq_3) (60 nm)/(*N*,*N*′-di-(naphthalene-1-yl)-*N*,*N*′-diphenyl-benzidine (NPB) (60 nm)/WO_3 (*x* nm)/ITO (10 nm)/Al (100 nm). The thickness of WO_3 was varied from 5 nm to 60 nm to investigate the buffering effect on the organic layers against the energetic particle bombardment generated by the DC magnetron sputter. The thin Al cathode layer was evaporated on a 143 nm-thick ITO coated glass (Shin–An SNP Co. Ltd.) with a sheet resistance of 11 Ω/square after cleaning the ITO coated glass in acetone and ethanol. All organic layers and the Al electrode layer were evaporated thermally in a high vacuum (under 1×10^{-6} Torr) chamber. The deposition rates of WO_3 and Liq were 0.01 nm/s and the evaporation rates of NPB, Alq_3 and Al ranged from 0.1 nm/s to 0.15 nm/s. All deposition rates were monitored by the in situ quartz oscillation thickness sensor. The DC magnetron sputtering deposition for top ITO was carried out with pure Ar gas at 3 mTorr for a 2×8 inch square ITO target. The distance between the substrate and target was 80 mm and the DC sputtering power was 40 W, which yielded a deposition rate of about 0.21 nm/s.

The changes in the physical properties of WO_3 thin films after Ar plasma irradiation were examined to determine the plasma bombardment effects on only the WO_3 HIL and not the organic layers. The WO_3 thin film was evaporated thermally with a WO_3 powder (99.99%) onto a bare glass after cleaning the glass by ultrasonification in acetone and ethanol. The sample was transferred to the reactive ion etching (RIE) chamber for Ar plasma treatment after vacuum break, and irradiated with Ar plasma at various power conditions of the radio frequency (RF) source, 40, 120, and 200 W, where the measured self bias (V_{self}) were −124, −267, and −348 V, respectively.

UV–Vis spectroscopy (Shimadzu, UV-3101PC) was used to measure the optical band gap. Atomic force microscopy (AFM) and electrostatic force microscopy (EFM) (Park system, XEP-100) were employed to determine the surface morphology and the work function in air environment. A source measure unit (HP, 4156C) and X-ray photoelectron spectroscopy (XPS) (Kratos, AXIS-NOVA) were used to examine the conductivity and binding energy, respectively. The electrical conductivity was calculated from the current–voltage data. For the XPS measurements, a monochromated Al Kα (150 W) X-ray source was used at 5.0×10^{-9} Torr and a charge neutralizer was turned onto exclude the charging effect. The XPS spectra were fitted with a combination of Gaussian and Lorentzian distributions after a Shirley background subtraction.

Hole-only devices and conventional bottom-emitting OLED test devices were fabricated to investigate the Ar plasma effect on the devices having WO_3 HIL. The structure of the hole-only device was ITO (143 nm)/WO_3 (5 nm)/NPB (60 nm)/Al (100 nm). The configuration of the conventional bottom emission OLED was ITO (143 nm)/WO_3 (5 nm)/NPB (60 nm)/Alq_3 (60 nm)/Liq (0.9 nm)/Al (100 nm). In the fabrication of both devices, after depositing the WO_3 HIL, the Ar plasma was irradiated under RF power conditions of 40, 120, and 200 W in the RIE chamber.

3. Results and discussion

In order to investigate the effect of the sputtering process for the deposition of ITO top electrode on the degradation of OLED performance, a 10 nm-thick ITO thin film was deposited by the DC plasma sputtering process and 100 nm-thick Al was deposited by thermal evaporation to produce the top anode in the IBOLED. To reduce the damage of the organic materials by the bombardment of energetic particles, induced by the sputtering process, WO_3 thin film was used as a buffer layer. The protection of the organic materials by the WO_3 thin film of various thicknesses, such as 5, 10, 20, and 60 nm was evaluated.

In the case of the IBOLED which did not undergo the sputtering process for ITO deposition, as shown in Fig. 1a, there were no serious differences in the *J*–*V*–*L* characteristics for various thicknesses of WO_3 thin film between 5 and 60 nm. In Fig. 1b, however, the *JV* characteristics of all of IBOLEDs that underwent the sputtering process indicated high leakage current from 10^{-2} mA/cm^2 to 10^{-1} mA/cm^2 in −8 V (Region I: reverse bias region). As reported by many researchers [9,14,15], the causes for the high leakage current are the damages in the underlying organic layers, which are generated by plasma sputtering process of ITO deposition. When energetic particles with high kinetic energy, such as Ar^+ ion, bombard the WO_3 HIL, the kinetic energy is transferred to organic layers. As a result, micro-current paths are induced by the local damages in the organic layers as well as the interface damages between the metal or metal oxide layer and organic layers [9,14].

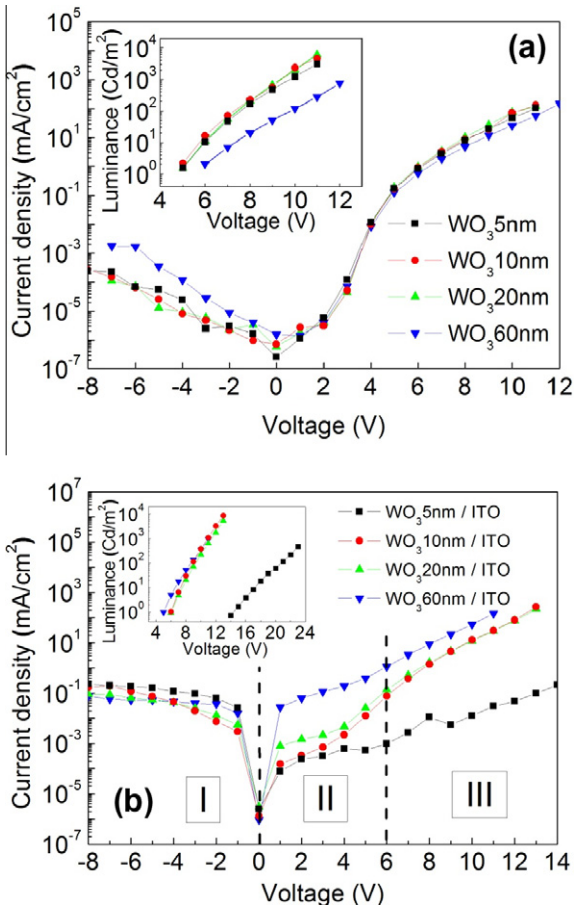

Fig. 1. Current density–voltage–luminance characteristics of (a) IBOLED without ITO sputtering deposition and (b) IBOLED with 5–60 nm-thick WO_3 buffer layer following deposition of top ITO by plasma sputtering process.

Unlike the results of Meyer et al. [15], however, the device with 60 nm WO_3 HIL shows high leakage current similar to other devices with much thinner WO_3 HIL.

In the forward bias region over 6 V (III region: typical space charge limited current (SCLC) region), the current density of the device with the 60 nm WO_3 HIL was increased to 4.75×10^1 mA/cm^2 at 10 V, which was 3700 times the current density of 1.3×10^{-2} mA/cm^2 in case of the device with a 5 nm WO_3 HIL. Moreover, while the IBOLEDs with a 5 nm-thick WO_3 HIL had a turn-on voltage of 14 V, the IBOLEDs with a thicker WO_3 HIL showed an improved turn-on voltage under 6 V. As reported by Meyer et al., the WO_3 buffer layer with the critical thickness could restrictively protect the organic layers from the bombardment of energetic particles [15].

In the forward bias region under 6 V (II region: strongly related with carrier injection properties), however, the devices with a thicker WO_3 HIL indicated higher current density. While the current density of the device with 5 nm-thick WO_3 was 3.12×10^{-4} mA/cm^2 in 3 V, the device with 60 nm-thick WO_3 indicated higher current density of 1.16×10^{-1} mA/cm^2. Unlike the analysis for "Region I", the higher current density of device with thicker WO_3 HIL could not be explained only by the mechanism of micro-current path induced by the local damages and be interpreted by a new mechanism, related with carrier injection properties.

In an actual DC magnetron sputtering process for ITO deposition, higher power density is needed than the power conditions of preceding studies [9,14,15]. As well as higher power density, energetic particles such as Ar^+, Ar, O_2, O, and In bombard the organic layers at much higher energy. Therefore, plasma sputtering process effects should be studied at high power density conditions, similar to actual sputtering process conditions.

To examine the degradation mechanism for the devices by ITO sputtering process, the physical properties of the WO_3 thin film subjected to energetic particles bombardment were analyzed, and the *J–V–L* characteristics of hole-only devices and conventional bottom OLEDs, which include the WO_3 HIL altered by plasma treatment under various conditions, were examined.

Initially, in order to investigate the Ar plasma-induced effect on the physical properties of WO_3 thin film, 50 nm-thick WO_3 thin films were thermally evaporated on glass substrates and were irradiated with the Ar plasma in the RIE chamber under RF powers of 40, 120, and 200 W. (The Ar ion bombardment energies corresponding to these powers were 124, 257, and 348 eV.)

Table 1 shows measured physical values, such as the work functions (Φ), optical band gaps (E_g) and conductivities (σ) of the as-deposited WO_3 thin film and WO_3 thin films with Ar plasma treatment. And some significant values were calculated, which are energy level difference between WO_3 and NPB ($\Delta\Phi$ (NPB–WO_3)) and between WO_3 and ITO ($\Delta\Phi$ (WO_3–ITO)). These values are directly related to the hole injection from anode to organic material. Detailed explanations about energy barrier are given in later part analyzing devices (Figs. 3 and 5). And atomic ratios of the W 6+ and 5+ states in the WO_3 thin films with various plasma treatments are calculated, also. We explain this value in depth with Fig. 2.

At RF power of 40, 120, and 200 W, the work function of the as-deposited WO_3 thin film decreased gradually from 5.2 to 4.8, 4.6, and 4.4 eV, respectively. In addition, the optical band gap slightly decreased from 4.08 to 4.02 eV after the plasma treatment. On the other hand, the conductivity drastically increased from 2.13×10^{-8} to 8.85 S/cm with increasing RF power.

However, from the AFM data, there were no remarkable changes in the surface roughness and grain size of the WO_3 thin films (0.02–0.1 nm), suggesting that Ar ion bombardment does not affect the surface and the generation of the crystallization of a WO_3 thin film.

XPS was used to determine the stoichiometry of WO_3 thin films before and after the Ar plasma treatment in order to investigate the theoretical mechanism for the changes in the physical properties of WO_3 thin films by Ar plasma treatment. As shown in Fig. 1a and b, the W4f core level of the as-deposited WO_3 thin film contained a well-resolved doublet of two symmetric peaks for W4f5/2 at 37.24 eV and W4f7/2 at 35.11 eV, with spin–orbit splitting (S.O.S.) of 2.14 eV and a peak ratio of 3:4. This is in good agreement with the data reported in the literature

Table 1
Physical values for the as-deposited WO_3 thin film and the WO_3 thin films after Ar plasma irradiation under various RF power conditions; the work functions (Φ) of the WO_3 thin films, energy level differences between WO_3 and NPB ($\Delta\Phi$ (NPB–WO_3)) and between WO_3 and ITO ($\Delta\Phi$ (WO_3–ITO)), optical band gaps (E_g), conductivities (σ), and atomic ratios of the W 6+ and 5+ states.

RF power (W)	Φ (eV)	$\Delta\Phi$ (NPB–WO_3) (eV)	$\Delta\Phi$ (WO_3–ITO) (eV)	E_g (eV)	σ (S/cm)	W 5+/W 6+ ratio
W O plasma treatment	5.2	0.2	0.4	4.08	2.13×10^{-8}	0.08
40	4.8	−0.6	0	4.07	4.18×10^{-4}	0.10
120	4.6	−0.8	−0.2	4.05	2.4×10^{-1}	0.14
200	4.4	−1.0	−0.4	4.02	8.85	0.13

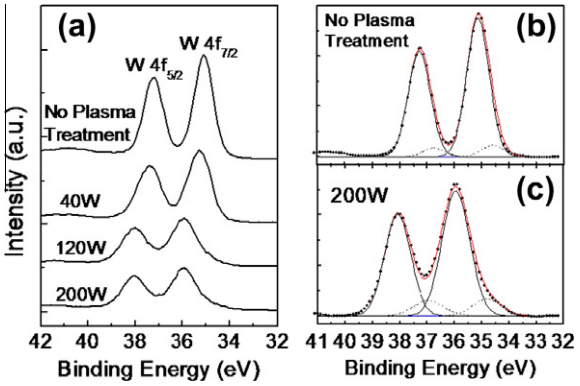

Fig. 2. (a) XPS spectra of W4f in WO_3 thin film surfaces after Ar plasma treatment at various RF power conditions. Peak fitting results of W4f core levels on WO_3 thin films (b) without and (c) with Ar plasma treatment (200 W RF power).

[12,13]. However, in the WO_3 thin films after Ar plasma treatment, the W4f doublet spectra decreased in intensity with increasing RF power and became broader due to the emergence of a shoulder peak at the lower binding energy region (Fig. 2a).

These results could be explained by the generation of oxygen vacancies in WO_3 thin film by Ar ion bombardment. The electronic structure of tungsten is [Xe]4f145d46s2 with empty 5d and 6s orbitals in its 6+ oxidation state close to the Fermi level [13]. Therefore, the XPS spectrum of the as-deposited WO_3 thin film showed a well-separated and sharp W4f doublet related mainly to the 6+ oxidation state, as shown in Fig. 2b.

However, energetic ion bombardment, which occurs on the surface of the WO_3 thin film during Ar plasma treatment, releases oxygen, creating a 5+ oxidation state of tungsten. Consequently, the spectra with the superposition of 6+ and 5+ oxidation states were observed. Fig. 2c shows the peak fitting result of the WO_3 thin film after the Ar plasma treatment at RF power 200 W (V_{self} = −348 V), indicating that the doublet of the 5+ oxidation state consists of W4f7/2 and W4f5/2 components positioned at the lower binding energies of 37 and 34.8 eV, respectively. In Table 1, the increasing atomic concentration ratio calculated with a spectrum area of 5+ and 6+ oxidation states confirms our hypothesis that Ar plasma treatment induces oxygen vacancies in WO_3 thin film. The creation of oxygen vacancies caused by Ar plasma treatment are similar to those caused by a range of different treatments for electrochromism reported by other, such as annealing at high temperature, UV radiation or X-ray exposure [12,16–22].

The changes in the work function, optical band gap and conductivity, as mentioned above (Table 1), can be explained by the more creation of oxygen vacancies. In the WO_3 thin film, which is a n-type semiconductor, the 5+ oxidation state was formed at a lower energy level than the 6+ oxidation state. Consequently, it moved the Fermi level upwards, as shown in Fig. 3. As a result, the work function and optical band gap decreased slightly. Furthermore, the conductivity increased dramatically because the upward shift in the Fermi level induced an increase in free electrons due to the electrons released from the 5d and 6s states.

Hole-only devices were fabricated and JV characteristics were examined to determine how the WO_3 HIL with altered properties affect the hole injection in the OLEDs (Fig. 4). The Ar plasma treatments at RF power 40, 120, and 200 W were carried out on WO_3 HIL prior to the deposition of NPB. While the current density of the hole-only device without the Ar plasma treatment was 108 mA/cm^2 at the operating voltage of 5.5 V, it decreased by 98% to 2.3 mA/cm^2 at 5.5 V in the case of the device subjected to 120 W Ar plasma treatment.

This result can be explained by the combination of the increased conductivity of the WO_3 thin films and the increased energy barrier between WO_3 HIL and NPB HTL. In other words, as shown in Table 1, the conductivity of WO_3 thin film that underwent Ar plasma treatment of 200 W was dramatically increased from 2.13×10^{-8} to 8.85 S/cm, which means improved conductance of the holes. However, the energy barrier between WO_3 HIL and

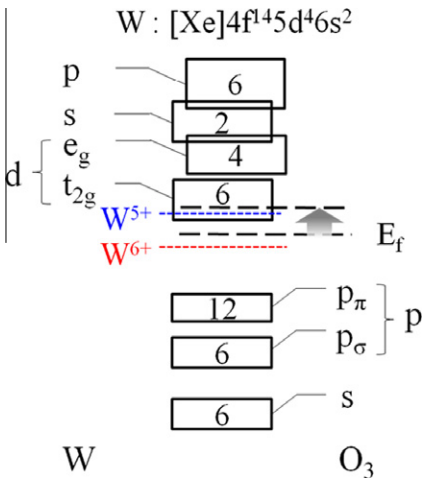

Fig. 3. Schematic band structure of WO_3. The numbers in the different bands define electron capacities.

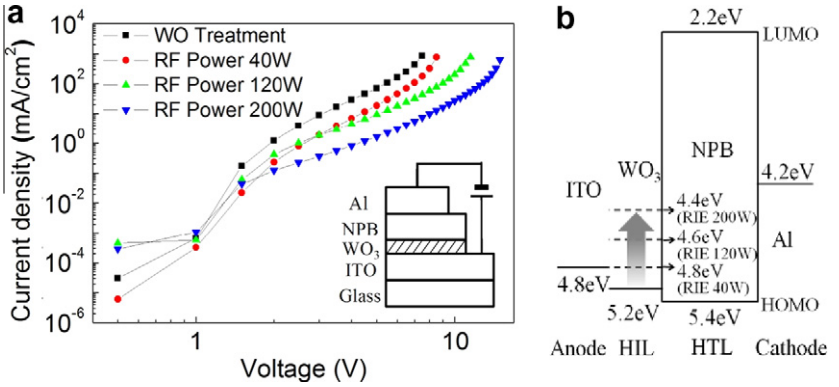

Fig. 4. (a) Current density–voltage characteristics (inset indicates the schematic structure of device) and (b) schematic energy level diagrams of hole-only devices without or with Ar plasma treatment.

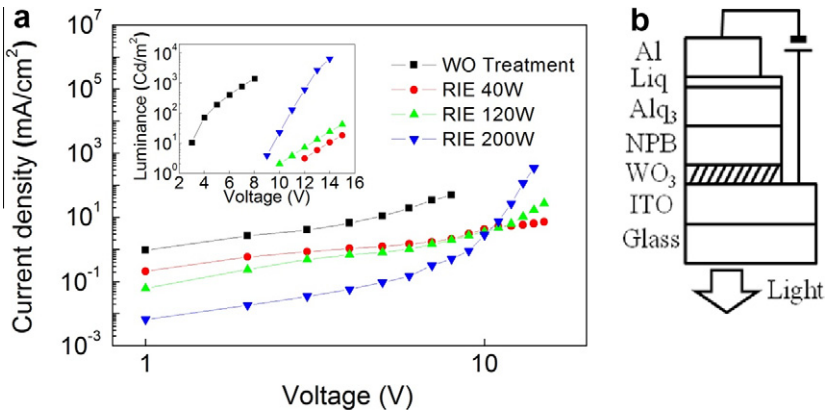

Fig. 5. Current density–voltage–luminance characteristics of (a) conventional OLEDs with plasma treatments for various conditions of WO_3 HIL and (b) schematic structures of devices.

NPB HTL was increased from 0.2 to 1.0 eV, degradation of hole injection can be expected (Fig. 4b).

From the decrease of the hole current in Fig. 4, we can know that the increase of the energy barrier between WO_3 HIL and NPB HTL more dominantly affected the *JV* characteristic than the increase of conductivity in WO_3 thin film did.

To investigate the effect of the altered physical properties of WO_3 thin film on the hole–electron recombination efficiency in OLEDs, the conventional bottom emission OLEDs with WO_3 HIL treated by Ar plasma at the same conditions as the hole-only devices were fabricated (Fig. 5).

The current density of the OLEDs in Fig. 5a decreased with increasing RF power because of the increased potential energy barrier between the WO_3 HIL and NPB HTL, similar to the case of the hole-only devices. The reduced hole-transfer from the HIL to HTL causes a decrease in hole–electron recombination in EML, which results in degradations of the luminance, current density and device efficiency.

At voltages over 10 V, however, current density was drastically increased and turn-on voltage was shifted to lower voltages with increasing RF power. This result can be explained as follows. High RF power reduces the work function of the WO_3 thin film. When a high bias is applied, band banding increases and more hole carriers are injected from ITO to NPB by the Poole–Frenkel effect. Therefore, the current density and hole–electron recombination increase and the turn-on voltage decreases.

Different from the report of Meyer et al. [15], when ITO thin film is deposited on WO_3 thin film by plasma sputtering process, the degradation of the *J–V–L* characteristics of OLEDs is affected by the changes of the physical properties on WO_3 thin film as well as by the damages of the organic layers.

On the other hand, the degradation effect on OLEDs by the bombardment of energetic particles could not be effectively removed even with the use of a metal oxide such as WO_3 as a buffer layer. Therefore, to adopt the plasma sputtering process in ITOLEDs fabrication, it is necessary to adopt the plasma damage free sputtering process, which can effectively control the energy of particle bombardment and deposit a TCO thin film of good quality. For this reason, we are also studying a novel method for ITO deposition that uses the hyper-thermal neutral beam (HNB) technology [2,23].

4. Conclusion

In summary, this paper reported a theoretical mechanism that relates the degradation of ITOLEDs subjected to

the sputtering process, which is used for the deposition of top ITO anode, to the changes in the physical properties of the WO_3 HIL as well as the damages on the organic layers. The number of oxygen vacancies in the WO_3 thin film increased with increasing bombardment energy of energetic particles, resulting in a decrease in work function and optical band gap and a dramatic increase in conductivity.

Above all, the increase in the potential energy difference between WO_3 HIL and NPB HTL, which was attributed to the reduced work function of WO_3, dominantly affected the device performance. In other words, although the metal oxide inorganic materials such as WO_3 was used as the buffer layer, the effect of the energetic particles bombardment induced by the plasma sputtering process on device performance could not be eliminated. In conclusion, it is necessary to study a new TCO deposition process which can control the bombardment energy of energetic particles effectively.

ABSTRACT

Solution processed multilayer white phosphorescent organic light-emitting diodes with a double layer emitting structure were developed using an alcohol soluble phosphorescent host and dopant materials. An alcohol soluble blue phosphorescent emitting layer was spin coated on a toluene soluble red/green emitting layer. A high current efficiency of 17.8 cd/A with a color coordinate of (0.31, 0.46) was obtained from the solution processed double emitting layer white phosphorescent organic light-emitting diodes. In addition, all solution processed multilayer white phosphorescent organic light-emitting diodes were also developed by using the two layer emitting structure.

1. Introduction

White organic light-emitting diodes (WOLEDs) hold great potential in display and lighting applications given their high efficiency and design versatility. In particular, solution processed WOLEDs are attractive because of lower material consumption and simple fabrication processes [1–5].

However, it is very difficult to improve the efficiency of soluble WOLEDs because the device structure cannot be diversified. While it is important to fabricate a multilayer stack structure to optimize WOLED device performance, realization of multilayer stack structures within WOLEDs is difficult [6–10]. An orthogonal film with no interlayer mixing between stacked organic layers has to first be formed to fabricate a multilayer structure in a soluble WOLED; however, most organic materials used in WOLEDs are soluble in similar solvents. Therefore, orthogonal film formation is difficult, although a double layer stack structure was reported using alcohol soluble polymer emitting material [6]. No WOLEDs with a double layer phosphorescent emitting layer structure have been reported. Our group has reported that an alcohol soluble blue phosphorescent emitting layer could be fabricated using a phosphine oxide-based host material and a fluorinated blue phosphorescent dopant [11].

In this work, WOLEDs with a double layer phosphorescent emitting layer were developed for the first time and the device performance of the WOLEDs were investigated. An alcohol soluble blue phosphorescent emitting layer was stacked onto a toluene soluble red/green phosphorescent emitting layer and the double layer phosphorescent emitting structure realized. All solution processed two emitting layer phosphorescent WOLEDs were demonstrated and a high efficiency of 17.8 cd/A was reported from the white phosphorescent organic light-emitting diodes (WPHOLEDs).

2. Experimental

A device configuration of indium tin oxide (ITO, 150 nm)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate(PEDOT:PSS, 60 nm)/poly(*N*-vinylcarbazole)(PVK): iridium(III) tris(2-phenylpyridine)(Ir(ppy)$_3$):iridium(III) bis(2-phenylquinoline) acetylacetonate(Ir(pq)$_2$acac) (15 nm, *x*%, 1%)/2,7-bis(diphenylphosphoryl)-9,9′-spirobi[fluorene] (SPPO13): iridium(III) bis(2-(4,6-difluorophenyl)-pyridinato-*N*,C^2)picolinate (FIrpic) (40 nm, 10%)/SPPO13

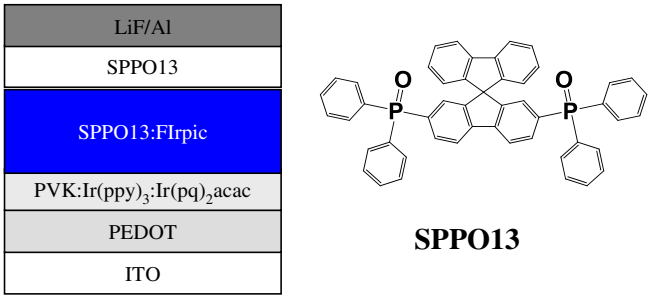

Fig. 1. Chemical structures of SPPO13 and device structure of WPHOLEDs fabricated in this work.

(30 nm)/LiF (1 nm)/Al (200 nm) was used to fabricate all phosphorescent soluble WPHOLEDs. The doping concentration of $Ir(ppy)_3$ was changed from 5% to 15%, while the doping concentration of the $Ir(pq)_2acac$ was fixed at 1.0%. Devices I, II, and III had $Ir(ppy)_3$ doping concentrations of 5%, 10%, and 15%, respectively. A representative device structure of the WPHOLEDs, and chemical structure of the SPPO13 are shown in Fig. 1. In addition, a device without the SPPO13 electron transport layer (device IV) was also fabricated. The device structure of the device IV was the same as that of device III except that SPPO13 was not deposited on the emitting layer. Red–green device and blue device were also fabricated for comparison. The device structure of the red–green device was ITO/PEDOT:PSS (60 nm)/PVK:$Ir(ppy)_3$:$Ir(pq)_2acac$ (40 nm, 5%:1%)/SPPO13 (30 nm)/LiF/Al and blue device had a device structure of ITO/PEDOT:PSS (60 nm)/PVK (10 nm)/SPPO13:FIrpic (40 nm, 10%)/SPPO13 (30 nm)/LiF/Al. The concentration of the PVK:$Ir(ppy)_3$:$Ir(pq)_2acac$ solution was 0.5 wt%, while the concentration of the SPPO13:FIrpic solution was 1.0 wt%. The PVK emitting layer was spin coated from toluene, while the SPPO13 emitting layer was deposited from a 2-propanol solution. Each emitting layer was baked at 80 °C for 10 min after spin coating. The SPPO13 electron transport layer was deposited by vacuum evaporation, followed by LiF/Al deposition. All devices were encapsulated with a glass lid and a getter after device fabrication. Device performances of the soluble WPHOLEDs were measured with a Keithley 2400 source measurement unit and CS 1000 spectroradiometer.

3. Results and discussion

Development of a multilayer emitting structure is paramount as various device structures can subsequently be fabricated and device performances improved [12–14]. In the case of vacuum evaporation-based small molecule WOLEDs, device performances were tuned by managing the stack structure of the emitting layers [12–15]. However, the stacked device structure was difficult to prepare in soluble WOLEDs because most emitting materials are soluble only in aromatic solvents, not polar. In particular, phosphorescent emitting materials are soluble only in aromatic solvents. However, our group reported alcohol soluble phosphorescent host and dopant materials that could be applied to fabricate multilayer emitting structures in soluble WPHOLEDs [11].

Fig. 2 shows the current density–voltage-luminance curves of the soluble WPHOLEDs with a two layer emitting structure. Red and green dopants were dispersed into the toluene soluble PVK layer and the blue dopant dispersed into the 2-propanol soluble SPPO13 layer. The doping concentration of the $Ir(ppy)_3$ was controlled from 5% to 15%. The current density of the WPHOLEDs was increased according to the doping concentration of the $Ir(ppy)_3$. It is well known that current density depends on the charge trapping and charge hopping effect of the dopant in the emitting layer [16]. In general, dopant is a trap site in the emitting layer and the use of the dopant reduces the current density at low doping concentration because of charge trapping by the dopant. However, the charge transport can be increased at high doping concentration due to the charge hopping effect. The trapped charges can be transported through hopping at high doping concentration. Therefore, the increase in the current density, according to the doping concentration, was due to the decreased hopping distance between dopant materials. Charge hopping between dopant materials was the main mechanism for the charge transport that was enhanced at high doping concentrations. The current density was even higher in the device IV without SPPO13 electron transport layer. The SPPO13 in the blue emitting layer played a role of an electron transport layer and the current density was not decreased. The high current density of the device IV is due to low thickness of the total organic layer. The luminance of the WPHOLEDs followed the same trend as the current density because the luminance depended on the current density and recombination efficiency.

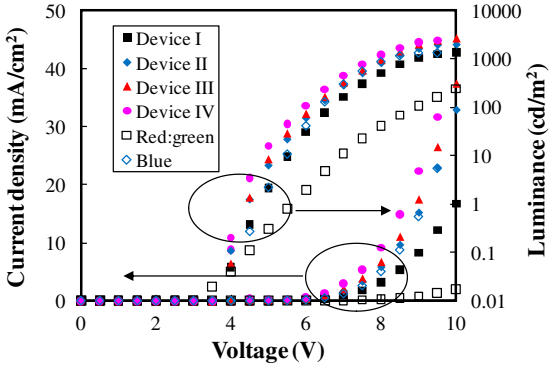

Fig. 2. Current density–voltage–luminance curves of WPHOLEDs.

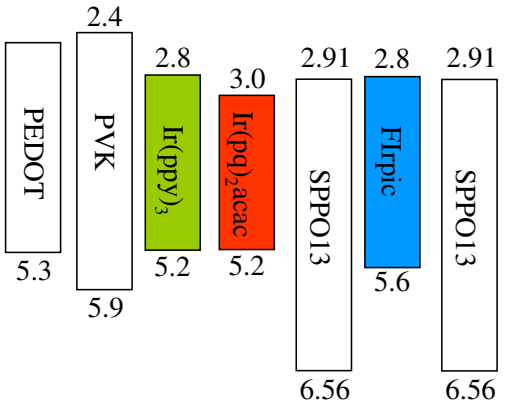

Fig. 3. Energy level diagram of the WPHOLED.

The current density–voltage and luminance–voltage curves of the red:green[1] and blue single layer devices are also shown in Fig. 2. The current density of the red:green device was much lower than that of the blue device. The charge trapping by the red and green dopants was significant in the red:green device due to the large energy level difference between the PVK host and red/green dopants (Fig. 3), leading to a low current density in the red:green single layer device.

The quantum efficiency–luminance and current efficiency–luminance curves of the WPHOLEDs are shown in Fig. 4. The quantum efficiency of the WPHOLEDs at 100 cd/m^2 was maximized at a Ir(ppy)$_3$ doping concentration of 5% and decreased according to the doping concentration. The quantum efficiency of device I at 100 cd/m^2 was 7.9%, compared with 7.2% and 6.9% for devices II and III. The high quantum efficiency of device I was due to the strong blue emission, compared with red and green emissions. As shown in the electroluminescence (EL) spectra in Fig. 5, device I showed stronger blue emissions than devices II and III. The quantum efficiency of the blue device was much higher than that of the red:green device, as shown in Fig. 4. Therefore, device I, with greater blue emission, showed a higher quantum efficiency than devices II and III with weak blue emissions.

Although the quantum efficiency at 100 cd/m^2 was high in device I, with a low doping concentration, the quantum efficiency at 1000 cd/m^2 was high in device III, with a 15% doping concentration. The high efficiency of device III at high luminance can be explained by the reduced triplet exciton quenching. The quantum efficiency of the blue single layer device sharply dropped at high luminance due to the triplet exciton quenching that originated from the narrow recombination zone. The contribution of the blue emission decreased in device III, resulting in less efficiency and a decrease at high luminance. Therefore, the efficiency at 1000 cd/m^2 was high in device III and low in device I. The device IV without any electron transport layer showed similar quantum efficiency to that of the device III. Although no electron transport layer was used in the device IV, the quantum efficiency was not degraded in the device IV. This is due to strong electron transport properties of the SPPO13. The emission is formed close to the interface between the red:green and blue emitting layers due to electron transport properties of the SPPO13 host, minimizing the triplet exciton quenching by the cathode. Therefore, the quantum efficiency was not degraded at all in the device IV. The device IV was fabricated by all solution process without any vacuum deposition process, indicating that all solution processed WPHOLEDs can show similar device performances to solution WPHOLEDs with vacuum deposited organic layers. The current efficiency of the WPHOLEDs is also shown in Fig. 4. The current efficiency of device I at 100 cd/m^2 was 17.8 cd/A, while devices II and III showed a current efficiency of 16.2 cd/A. Device IV without any electron transport layer showed as high current efficiency of 16.9 cd/A.

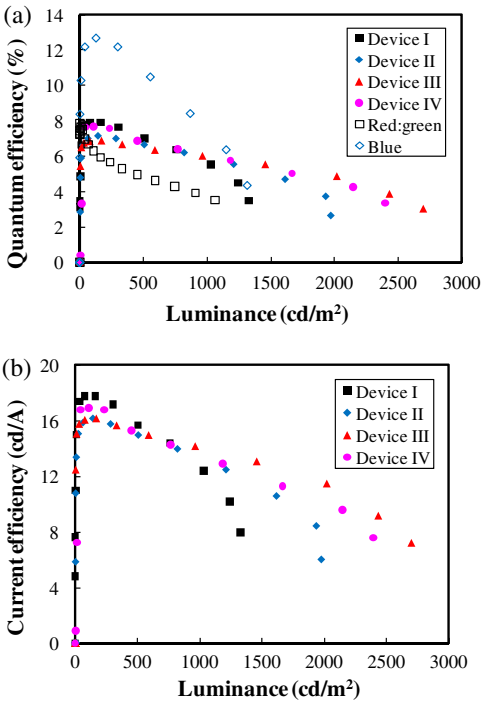

Fig. 4. Quantum efficiency and current efficiency of WPHOLEDs.

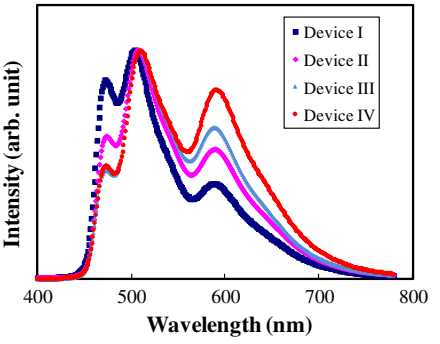

Fig. 5. Electroluminescence spectra of WPHOLEDs.

[1] For interpretation of colour in Figs. 2–5, the reader is referred to the web version of this article.

The EL spectra of the WPHOLEDs are shown in Fig. 5. All WPHOLEDs showed red, green, and blue emissions, and the relative emission intensity depended on the doping concentration. The blue intensity was strong in device I and decreased according to doping concentration. The decrease of the blue intensity at high doping concentration can be explained by the improved electron injection from the SPPO13:FIrpic layer into the PVK:$Ir(ppy)_3$:$Ir(pq)_2$acac layer. As explained in the current density–voltage curves, the charge transport was improved at high doping concentrations. In particular, the PVK is a hole transport type host material and the electron transport is limited by the host material. Electron transport was mainly determined by electron hopping through dopant materials and was improved by the $Ir(ppy)_3$ at high doping concentration due to a reduced electron hopping distance. Therefore, more electrons are injected from the blue emitting layer to the red:green-emitting layer, leading to the less blue emission intensity in device III. In addition, the blue emission was absorbed by the green emitting material and little blue emission was observed at high green doping concentrations. The red and green emission was even stronger in device IV due to more exciton generation in the red and green emitting layer.

The color coordinates of devices I, II, and III were (0.31, 0.46), (0.35, 0.47), and (0.39, 0.50). The coordinate was red-shifted according to the doping concentration because of increased green and red emissions. Therefore, the color coordinate of the soluble WPHOLEDs could be controlled by managing the doping concentration of the $Ir(ppy)_3$ in the red:green emitting layer. In general, the doping concentration of the green emitting material, in common soluble three color WPHOLEDs, was less than 1%, making color control difficult due to too low doping concentrations [17]. Slight changes of the doping concentration can result in large shifts in the color coordinate; the process margin for the white emission is too narrow. The process window for the doping concentration could be widened by using the double layer emitting structure developed in this work. There was only a 0.04 shift of the color coordinate by changing the doping concentration of the $Ir(ppy)_3$ from 10% to 15%, compared with the 0.04 shift of the color coordinate by changing the doping concentration by 1% in a single layer device. Therefore, control of the color in the stacked device structure proved simple as the blue and red:green layer gave separate emissions. The color coordinate of the device IV was (0.39, 0.47).

4. Conclusions

In conclusion, soluble WPHOLEDs with a double layer emitting structure were developed using an alcohol soluble blue phosphorescent emitting layer and a red:green phosphorescent emitting layer dissolved in an aromatic solvent. The color coordinate could be simply managed by changing the $Ir(ppy)_3$ doping concentration, with other parameters fixed, and a high current efficiency of 17.8 cd/A was achieved in the soluble WPHOLEDs. In particular, all solution processed two emitting layer WPHOLEDs could be fabricated for the first time. This double layer emitting structure can be useful in fabricating high efficiency soluble WPHOLEDs in display and lighting applications.

ABSTRACT

Density-functional theory with a semi-empirical dispersion correction was used to systematically examine how the number of fluorine (F) atoms affects atomic and electronic structures of fluorinated pentacene ($C_{22}F_nH_{14-n}$) adsorbed on Cu(1 1 1) surfaces. The fluorination effect on the carrier injection efficiency at organic/metal interfaces was investigated. We found that as the number of F atoms decreases, the electron affinity of isolated molecules decreases, suggesting that the molecule becomes less reactive. However, for adsorbed systems, as the number of F atoms decreases, molecular orbitals of $C_{22}F_nH_{14-n}$ strongly hybridize with the substrate states while retaining the n-type energy level alignment, resulting in lowering the barrier height of the carrier injection. Based on the calculation results, we propose using $C_{22}F_nH_{14-n}$ ($n \leqslant 8$) with Cu electrodes for efficient electron injection.

1. Introduction

Understanding the electronic structure at organic/metal interfaces is of great importance in developing organic devices [1,2]. The interface dipole at organic/metal interfaces induces vacuum level shift that modifies the barrier height of the carrier injection, which plays a decisive role in organic devices [1,2]. Therefore, accurate prediction and control of the interface dipole is crucial to designing the electrodes of organic devices.

Pentacene ($C_{22}H_{14}$, Pen) and perfluoropentacene ($C_{22}F_{14}$, PFP) are prototypical p-type [3] and n-type [4] organic semiconductors, respectively. Accordingly, the interactions of Pen and PFP with metal substrate have been studied extensively both experimentally and theoretically [5–20]. In particular, elucidation of the electronic properties of PFP on metal is crucial, because n-type organic/metal interfaces are not as well understood as p-type organic/metal interfaces [21,22]. Efficient n-type interfaces must be designed to fabricate complementary integrated circuits.

PFP is expected to lower the electron injection barrier height, because larger electron affinity makes the lowest unoccupied molecular orbital (LUMO) level closer to the Fermi energy of the electrode than that of Pen [23]. However, experimental reports have shown that the highest occupied molecular orbital (HOMO) state relative to the Fermi energy for PFP/Cu(1 1 1) is almost the same as that for Pen/Cu(1 1 1) [11], and moreover, that the PFP–substrate distance is larger than that for Pen/Cu(1 1 1) [16]. These indicate that the electron injection for PFP/Cu(1 1 1) is less efficient than that for Pen/Cu(1 1 1), because the overlap between the molecular orbitals and the substrate for PFP/Cu(1 1 1) becomes smaller than that for Pen/Cu(1 1 1). Our previous paper pointed out that the large PFP–Cu(1 1 1) distance originates from repulsion of F atoms by the substrate [10]. Therefore, it might be possible to modify the adsorption distance and electron injection barrier, by changing the number of F atoms in PFP.

In this work, we have examined systematically how the number of F atoms affects the atomic and electronic structures of fluorinated pentacene ($C_{22}H_nF_{14-n}$) adsorbed on Cu(1 1 1) using density-functional theory (DFT) within the generalized gradient approximation (GGA) with a semi-empirical dispersion correction. We show that adsorption distance and hybridization of molecular orbitals of $C_{22}H_nF_{14-n}$ on Cu(1 1 1) are tunable by changing the number of F atoms, and we propose an optimal organic/metal interface for efficient electron injection.

2. Calculation method

Calculations were carried out using STATE [24], which implements a plane wave basis set and pseudopotentials [25,26]. The plane-wave kinetic-energy cutoff for the wave functions and augmented charge density were set to 25 and 225 Ry, respectively. The Perdew–Burke–Ernzerhof (PBE)-GGA [27] was adopted to describe the exchange–correlation functional. Because a semilocal GGA functional cannot correctly describe van der Waals (vdW) forces, which dominate the interaction between π conjugated molecules and metal surfaces [5,7–10,18,19,28–31], we used a semi-empirical dispersion correction proposed by Grimme [32] (DFT-D) for adsorption systems. DFT-D was shown to yield accurate adsorption distances of organic molecules on metal surfaces as well as the work-function changes [7,9,10].

In this work, we examined the following three $C_{22}F_nH_{14-n}$ molecules as shown in Fig. 1: 1, 2, 3, 4, 5, 7, 8, 9, 10, 11, 12, 14-dodecanefluoropentacene (F12), 1, 2, 3, 4, 8, 9, 10, 11-octafluoropentacene (F8), and 2, 3, 9, 10-tetrafluoropentance (F4). The numbers of F atoms in F12, F8, and F4 were 12, 8, and 4, respectively.

Isolated molecules were calculated in a $2 \times 1 \times 1$ nm^3 rectangular unit cell using the Γ point.

The Cu(1 1 1) surface was represented by a repeated slab model, in which one slab consisted of four Cu atomic layers. A vacuum region of ~2 nm was inserted in between slabs. A $C_{22}F_nH_{14-n}$ molecule was adsorbed on only one surface of the slab with its molecular plane parallel to the surface in a $\sqrt{43} \times 2\sqrt{3}$ surface unit cell, which is the same as that used in our previous calculation of PFP/metal systems [10]. A 2×4 **k**-point mesh was used to sample the surface Brillouin zone. The center of $C_{22}F_nH_{14-n}$ was assumed to be located at an hcp-hollow site on the Cu(1 1 1) surface with the long molecular axis aligned with close-packed metal atom rows as shown in Fig. 2. In the geometry optimization, we fixed the bottom layer of the substrate slabs at their respective bulk positions. The remaining degrees of freedom were optimized with the DFT-D method until the maximum force dropped below a threshold value of 0.2 nN. The work-function difference between the two surfaces of a slab was compensated for by using a dipole correction [33]. Work-functions were calculated from the difference between the Fermi energy of the system and the average electrostatic potential at the center of the vacuum region, and the vacuum level shifts were calculated from the work-function changes induced by the adsorption of $C_{22}F_nH_{14-n}$.

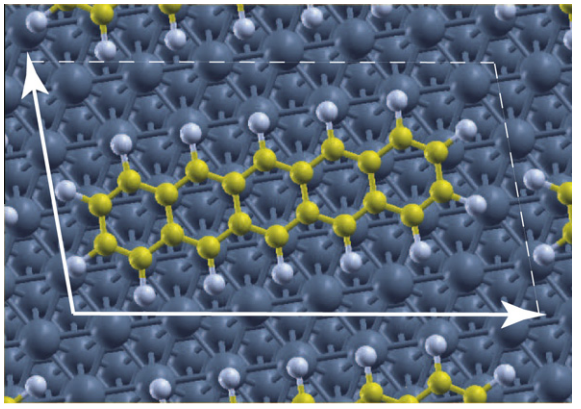

Fig. 2. Plan view of a $C_{22}F_nH_{14-n}$ molecule on Cu(1 1 1).

3. Results and discussion

3.1. Isolated molecules

First, we calculated the atomic and the electronic structures of isolated PFP, F12, F8, F4, and Pen molecules. The optimized molecular structures of F12, F8, and F4 are planar, similar to Pen and PFP. The ionization potential (IP) and electron affinity (EA) of PFP, F12, F8, F4, and Pen are summarized in Table 1. The IP and EA were estimated from

Table 1
IP and EA of PFP, F12, F8, F4, and Pen.

	PFP	F12	F8	F4	Pen
IP/eV	5.25	5.27	5.17	4.90	4.50
EA/eV	4.28	4.30	4.04	3.72	3.36

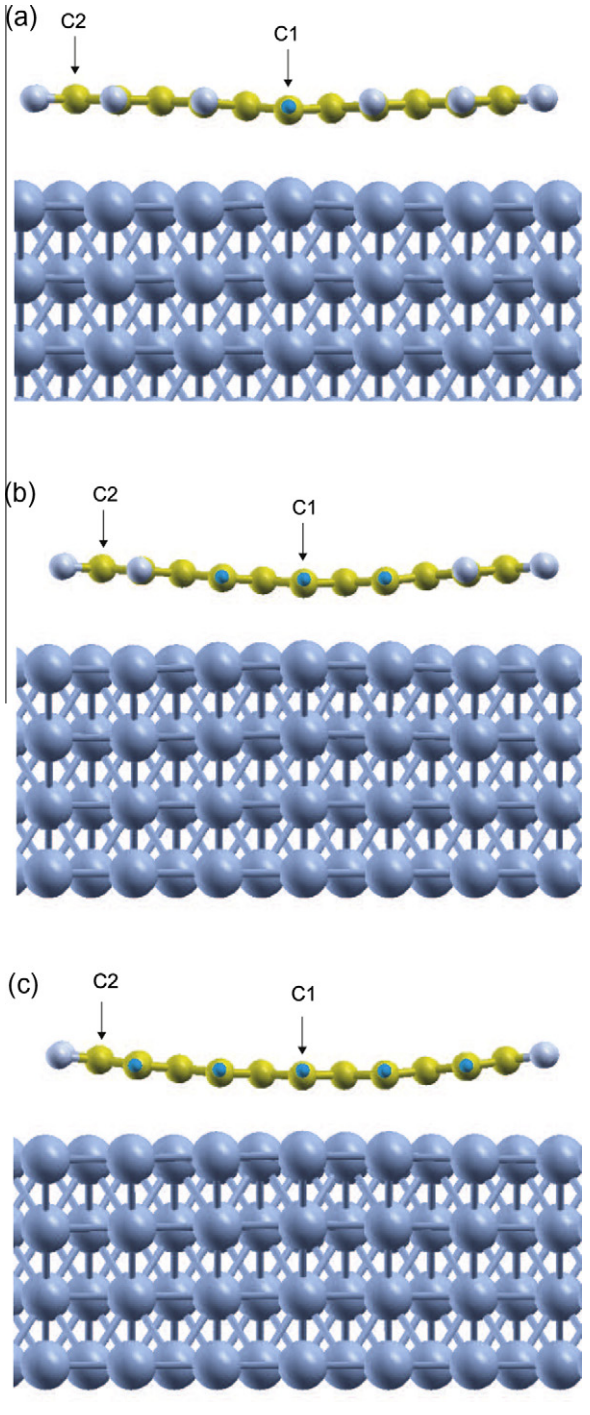

Fig. 3. Cross-sectional view of F12 (a), F8 (b), and F4 (c) on Cu(1 1 1).

the Kohn–Sham energy levels of the HOMO and LUMO relative to the vacuum level, respectively. We found that as the number of F atoms in $C_{22}F_nH_{14-n}$ decreases, the IP and EA of each molecule become small, suggesting that the molecule becomes less reactive. We also found that the IP and EA of F12 are almost the same as those of PFP.

3.2. Adsorbed systems

Next, we calculated the atomic geometries and the vacuum level shifts of PFP, F12, F8, F4, and Pen adsorbed on Cu(1 1 1) and then inspected the electronic structures of the adsorption systems.

3.2.1. Atomic geometries and vacuum level shifts

Fig. 3(a)–(c) depict a cross-sectional view of the atomic geometries of F12, F8, and F4 adsorbed on Cu(1 1 1). Table 2 summarizes the adsorption distances of C atoms depicted in Fig. 3 relative to the surface and the work-function change ($\Delta\phi$) for PFP, F12, F8, F4, and Pen adsorbed on Cu(1 1 1).

It turns out that as the number of F atoms decreases, the average adsorption distance of the C atoms becomes smaller (Fig. 3 and Table 2), even though decreasing the number of F atoms makes EA smaller, i.e., chemically less reactive. The results suggest that the adsorption distance is mainly determined by the number of F atoms rather than the reactivity of the molecule, because of the repulsion between F 2p and substrate states [10].

As seen in Fig. 3(a)–(c), the $C_{22}F_nH_{n-14}$ molecule is distorted when adsorbed on the surface, and the adsorption distance of an end C atom bonded to F (C1) is larger than that of the center C atom bonded to H (C2) (Table 2). The differences in adsorption distances of C1 and C2 for F12, F8, and F4 are almost the same (0.03–0.04 nm). The molecular distortion is attributed to (i) repulsion between F 2p and Cu substrate states and (ii) hybridization of the molecular orbitals with the substrate states [7]. When the number of F atoms is large (i.e., large distance), repulsion dominates and accordingly hybridization is small. On the other hand, when the number of F atoms is small, the adsorption distance becomes small (hence strong hybridization) because of the reduction of repulsion by F 2p. These effects compensate for each other depending on the distance, resulting in similar molecular distortion. Note that distortion caused by electron transfer is not significant [5,7].

Table 2
The average C adsorption distance (Z_C^{ave}), the adsorption distance of C1 and C2 in Fig. 3 (Z_{C1} and Z_{C2}, respectively), and the work-function change ($\Delta\phi$) for PFP, F12, F8, F4, and Pen adsorbed on Cu(1 1 1). Adsorption distances of C atoms are measured from the Cu surface.

	PFP	F12	F8	F4	Pen
Z_C^{ave}/nm	0.29[a]	0.29	0.27	0.26	0.24[b]
Z_{C1}/nm	–	0.27	0.25	0.24	–
Z_{C2}/nm	–	0.30	0.29	0.27	–
$\Delta\phi$/eV	−0.30[a]	−0.29	−0.41	−0.62	−0.97[b]

[b] Ref. [7].

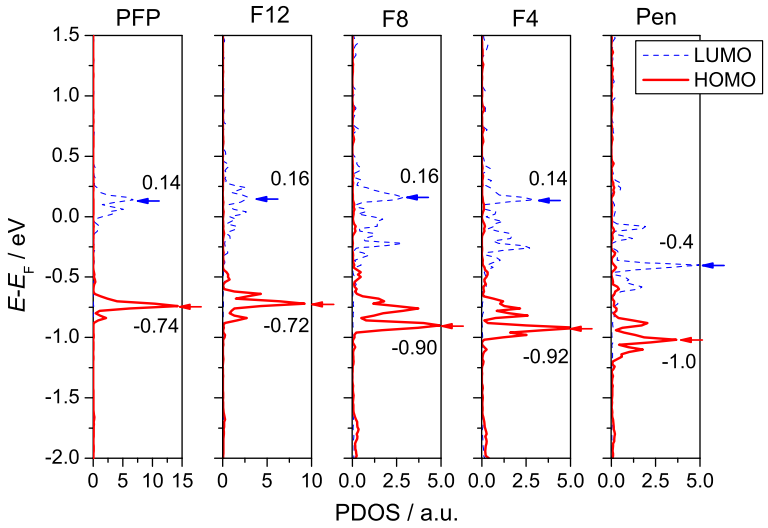

Fig. 4. The density of states projected (PDOS) onto molecular LUMO and HOMO for PFP, F12, F8, F4, and Pen on Cu(1 1 1). The arrows represent the peak positions of LUMO and HOMO states.

$\Delta\phi$ becomes smaller (i.e., larger $|\Delta\phi|$) as the number of F atoms decreases. Because the work-function changes caused by the molecular distortion are small (-0.04, -0.01, and 0.1 eV for F12, F8, and F4, respectively), we ascribe the change in $\Delta\phi$ mainly to the change in the adsorption distance.

3.2.2. Electronic structures

Fig. 4 shows the density of states projected (PDOS) onto molecular LUMO and HOMO for PFP, F12, F8, F4, and Pen on Cu(1 1 1). As shown in Fig. 4, the broadening of the molecular states (LUMO and HOMO) becomes larger as the number of F atoms decreases, as a result of stronger hybridization at a short distance. On the other hand, the PDOS for the molecular states of PFP and F12 are sharp, indicating weaker interaction of the adsorbate with the substrate. Although hybridization of the HOMO and LUMO states with the substrate depends significantly on the number of F atoms, their peak positions are almost unchanged, suggesting that n-type operation would be retained regardless of the number of F atoms. This is because the larger absolute value of $\Delta\phi$ cancels out the smaller EA of the isolated molecule as the number of F atoms decreases.

Our results indicate that the energy level alignment of $C_{22}F_nH_{14-n}$ ($n \geqslant 0$) adsorbed on Cu(1 1 1) is n-type, because a part of the LUMO state is below the Fermi energy. It should be noted that PBE-GGA has the well-known underestimation of the band gap [34–37] but can describe the LUMO and HOMO levels of an organic molecule adsorbed on a metal surface qualitatively [5,7,10].[1] Our results suggest that reducing the number of F atoms makes it possible to fabricate an optimal interface for carrier injection because of the strong hybridization. On the basis of our systematic study, we propose using $C_{22}F_nH_{14-n}$ ($0 \leqslant n \leqslant 8$) for efficient electron injection.

4. Conclusions

We have studied the fluorination effect on $C_{22}F_nH_{14-n}$/Cu(1 1 1) interfaces using density-functional calculations with the semi-empirical van der Waals (vdW) correction.

We found that although reducing the number of F atoms decreases the ionization potential and the electron affinity of the $C_{22}F_nH_{14-n}$ molecule (i.e., the molecule became less reactive), the adsorption distance of the molecule on the Cu(1 1 1) surface becomes smaller due to the reduction of repulsion between F 2p and the substrate states.

Calculated electronic structures show that the hybridization of the molecular orbitals with the substrate states becomes stronger, whereas the peak positions of the molecular states remains almost unchanged, retaining n-type interface as obtained with PFP, as the number of F atoms decreases. This suggests that electron injection is made efficient, and we therefore propose using $C_{22}H_nF_{14-n}$ ($n \leqslant 8$) to achieve efficient electron injection.

Our results indicate that controlling only the ionization potential and the electron affinity of isolated molecules is insufficient for designing an optimal organic/metal interface. We conclude that the energy level alignment at organic/metal interfaces is crucially governed by adsorption geometries which are quite flexible and are affected by a subtle balance between repulsive interaction due to Pauli repulsion and attractive interaction due to hybridization and vdW interactions.

Acknowledgments

The work was partly supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Science, Sports, and Technology, Japan (Grant Nos.

[1] The gap underestimation tends to be compensated for by the error in the present GGA to describe the polarization of the metal surface, which reduces the band gap [38].

19054013 and 22241026). Numerical calculations were carried out at computer centers of Osaka University, the Institute for Solid State Physics of the University of Tokyo, and Tohoku University.

ABSTRACT

Mobility versus temperature measurements on two different polymer:fullerene blends intended for solar cell applications have been evaluated in terms of the energetic disorder and how this varies with stoichiometry. The charge transport is shown to be confined to the intended phases in both cases, but with fundamentally different interaction properties. In one case the energetic disorder is a function of stoichiometry for the hole transport, while it is constant and equal to that of the pure fullerene for electrons, and in the other case it is the hole transport that has a stoichiometry independent energetic disorder. Transport site dilution is argued to be present in the fixed energetic disorder system and this is offered as a partial explanation to molecular weight dependent currents in solar cells. Determination of the glass transition temperature through the use of field effect transistors is also demonstrated.

1. Introduction

One of the more severe performance limitations in bulk heterojunction (BHJ) solar cells is their inability to both absorb light efficiently and transport the generated charge to the electrodes in the same device. Charge transport is typically not a big problem in devices less than 100 nm thick, but although the absorption in such a device is quite strong, it is far from sufficient [1]. Due to charge transport limitations there are many materials [1–3] that give optimum performance for thicknesses around the first optical interference maximum, which is device and material dependent, but usually in the 75–100 nm range. Despite very high incident photon to free charge efficiencies [4], peak external quantum efficiencies for good devices are usually only around 50%, but with values around 70% reported in thicker high band gap materials [5] with high extinction coefficients and favorable charge transport conditions.

Understanding charge transport thus goes a long way towards finding ways to improve BHJ solar cell efficiencies. Two promising, in the sense that they make good use of the available energy in terms of delivered voltage, materials are poly(2,7-(9,9-dioctyl-fluorene)-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)) (APFO-3) [2] and poly(2,3-bis-(3-octyloxyphenyl)quinoxaline-5,8-diyl-*alt*-thiophene-2,5-diyl (TQ-1) [3]. Both materials are capable of efficient charge generation and high fill factors in solar cells with active layer thicknesses at the respective first interference induced absorption maximum.

Some polymers interact favorably with fullerenes of the [6,6]-phenyl-C_x-butyric acid methyl ester (PCBM) (where $x = 61$ for the C60 based [60]PCBM and $x = 71$ for the C70 based [70]PCBM) type in terms of mobility. Blend hole mobilities can be significantly higher than the corresponding pure polymer phase values [2,6] even at very high PCBM loading levels. The reason for this can actually be different for different systems. It will be shown here that the blend hole mobility in TQ-1:[70]PCBM is stoichiometry dependent and with variations due to changes in the energetic disorder induced by PCBM; and that the blend hole mobility in APFO-3:[60]PCBM is increased by a different type of interaction with a stoichiometry independent energetic disorder for hole transport.

Furthermore it will be shown that the hole transport is confined to the polymer phase and electron transport to the fullerene phase in both cases, and that molecular

doi:10.1016/j.orgel.2010.11.007

weight becomes much more important in blends than in the pure phase, at least in APFO-3 type systems, due to charge transport site dilution. Site dilution is also offered as a partial explanation to why low molecular weight polymers tend to underperform in solar cells.

2. Experimental

Mobility evaluations have been done with field effect transistors (FET) from transfer characteristics and are maximum saturation values. Different gold electrode geometries with channel lengths in the 10–50 μm range and widths in the 2–20 mm range patterned by photolithography on top of 100 nm thick SiO_2 has been used as bottom contact transistor substrates in all measurements. The active layers were spin coated from a dichlorobenzene solution in air. Electrical characterization was done under high vacuum and illumination [7] using a parameter analyzer. Each measurement was cycled 10 times to allow the devices to settle in a quasi stable state, and the last acquisition was used to generate the presented data. A varying, but at least 15 min long, waiting time after changes in temperature was employed to ensure the correct temperature and to make sure that there was no influence from transient phenomena [2,7,8].

The energetic disorder is here taken to be in the context of the Gaussian disorder model (GDM) [9] with the characteristic energetic disorder parameter σ denoting the standard deviation of a Gaussian density of states through which the charge transport occurs.

Fundamentally the GDM assumes an activation energy that is proportional to $1/T$ based on the relaxation of carriers in the density of states. At high carrier concentrations, such as with FET, this is no longer true due to state filling effects [10] and the mobility temperature dependence will be reduced from its basic $1/T^2$ dependence. In addition to this, the hydrophilic nature of the SiO_2 means that there will be water present at the polymer-insulator interface during the measurements even under high vacuum conditions, which will be reflected in extracted energetic disorder parameters [8]. Supercooled water can also result in mobility-temperature hysteresis and prevent meaningful evaluation of low temperature data [11]. For measurements where extrinsic effects can be avoided and a wide temperature range used, such as in the absence of a hydrophilic interface or under ultra high vacuum conditions, it is possible to account for the carrier concentration effects and obtain accurate σ-values [12] provided, of course, that the charge transport is dominated by disorder and not polaronic effects. This is not possible here, but by using a narrow high temperature range, relative errors can be minimized since no water freezing will occur and carrier concentration effects are dependent on σ/kT [12]. A first order approach to data fitting will thus result in systematic errors in the absolute mobility and σ-values, but will, however, not influence the fundamental behavior as is evidenced by the very systematic data. Although a $1/T$ representation is possible due to the abovementioned effects, the mobility data is still plotted against $1/T^2$ to emphasize the disordered nature of the charge transport.

3. Results and discussion

Mobility versus temperature data for different stoichiometries and two different synthesis batches of TQ-1 are shown in Fig. 1. Each data set, i.e. temperature scan for a specific batch and stoichiometry, is done on a single transistor chosen at random and it may thus deviate from the statistical averages. There is sometimes a scatter in mobility between different devices and there are some uncertainties in stoichiometry due to blending of very small amounts of material, but the stoichiometry induced variations become clear as the number of characterized devices increase. Series resistance and current–voltage hysteresis [7] can have some small effect as the temperature and currents increase (seen as a slight downward bend in the temperature data). The data are nevertheless systematic overall, and any present errors are not significant with

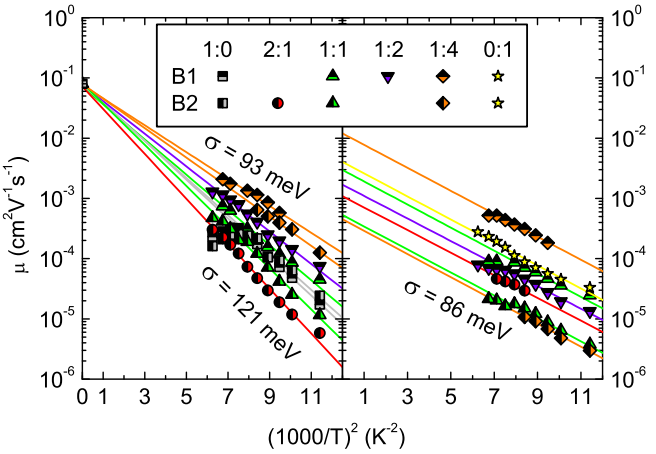

Fig. 1. Hole (left) and electron (right) mobility of TQ1:[70]PCBM blends from two different polymer synthesis batches (B1, B2) as a function of $1/T^2$ according to the GDM. The energetic disorder parameters (σ) do not accurately reflect the materials due to the extrinsic effects of water but is included for comparative purposes. The real σ-values are likely considerably smaller.

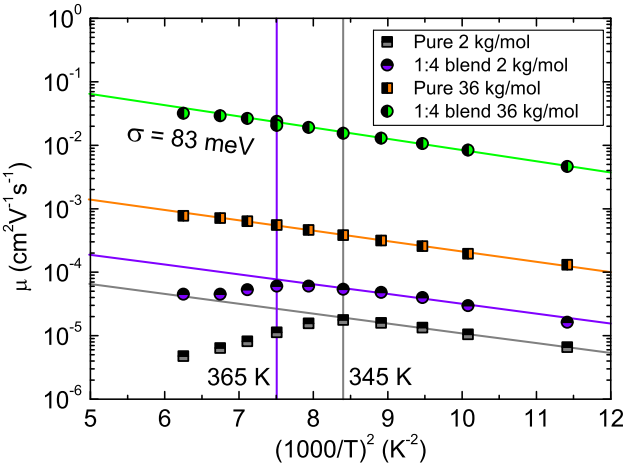

Fig. 2. Hole and electron mobility for two different molecular weights of pure APFO-3 and in 1:4 blends with [60]PCBM as a function of $1/T^2$ according to the GDM. The energetic disorder parameter (σ) is influenced by extrinsic effects of water and is in reality about 70 meV [20], but is included for comparative purposes. Also included in the figure are the glass transition temperatures of the low molecular weight APFO-3 and its [60]PCBM blend. The glass transition temperatures pertaining to the higher molecular weight are considerably higher and not clearly visible.

respect to the fundamental behavior. Occasionally devices break down during a temperature scan or there is too much contact-related noise in a particular measurement to prevent meaningful data evaluation and thus some data points are missing from Fig. 1. More data on these and several other batches have been collected and are considered in the discussion but not included in the figures to avoid heavy cluttering. Adding [70]PCBM to TQ-1 at fist increases the energetic disorder and concomitantly decreases the room temperature hole mobility. At roughly 30% [70]PCBM the energetic disorder starts to decrease and for loading levels above 50% the energetic disorder is less, and hole mobility higher, than in pure TQ-1. All in all the room temperature hole mobility varies on an order of magnitude scale.

Two striking things are immediately obvious from Fig. 1; that all of the hole mobility data seems to converge to a single point for infinite temperature, and that electron mobilities vary while pure [70]PCBM and all the blends share the same energetic disorder. From this it is possible to conclude that the charge transport is confined to the respective phase and that the stoichiometry induced hole mobility variations are due to changes in energetic disorder. The reasoning for this is as follows: pure TQ-1 and the blends share the same infinite temperature hole mobility. This would be extremely unlikely should the PCBM phase be involved actively in the hole transport. Furthermore, there is no trace of changing energetic disorder in the electron mobility data which, should the electron and hole charge transport occur in the same phase, would require vastly different behavior of the two involved energy bands. Considering the similarities in both energetic disorder and absolute mobility values between electrons and holes this is also extremely unlikely.

APFO-3 on the other hand, while still having a strongly stoichiometry dependent hole mobility, has a stoichiometry independent energetic disorder for the hole transport. The mechanism by which the hole mobility is influenced by the fullerene is thus different in APFO-3:[60]PCBM and TQ-1:[70]PCBM. Fig. 2 shows mobility as a function of temperature for pure APFO-3 and 1:4 [60]PCBM blends of two different APFO-3 molecular weights. The energetic disorder is always the same, as reflected in the temperature dependence. One important observation that can be made is that the mobility enhancement is considerably smaller, both relatively and absolutely, for the low molecular weight material. This appears to be a general trend; the hole mobility enhancement at high fullerene loading has a linear correlation to the molecular weight (at least for low to intermediate molecular weights). Interestingly enough, the enhancement is much more predictable than the absolute mobility values, which scatter strongly (order of magnitude) [13] for the available APFO-3 batches. Looking at mobility as a function of stoichiometry for the different molecular weights (Fig. 3) reveals that the hole mobility enhancement is universally about one order of magnitude independent of molecular weight, but that the mobility decreases with increasing fullerene content much faster for lower molecular weights. As has been pointed out elsewhere [2] and is further discussed below it is difficult to measure electron mobilites in APFO-3:[60]PCBM blends in a reliable way using FETs, but it can be shown that it increases monotonically with about one order of magnitude per 20 percentage points of [60]PCBM fraction [2]. Since the stoichiometry dependence of the electron and hole mobilities are opposite for a considerable stoichiometry range, and the energetic disorder is identical in pure APFO-3 and APFO-3:[60]PCBM blends it is possible to conclude that the hole transport in the APFO-3 blends is also confined to the polymer phase.

That the energetic disorder for hole transport is identical in the low and high molecular weight APFO-3 is quite remarkable. The low molecular weight APFO-3 has a degree of polymerization of 3 [13], which means that there are no effects on the transport site energetic distribution from delocalization beyond three or less repeat units.

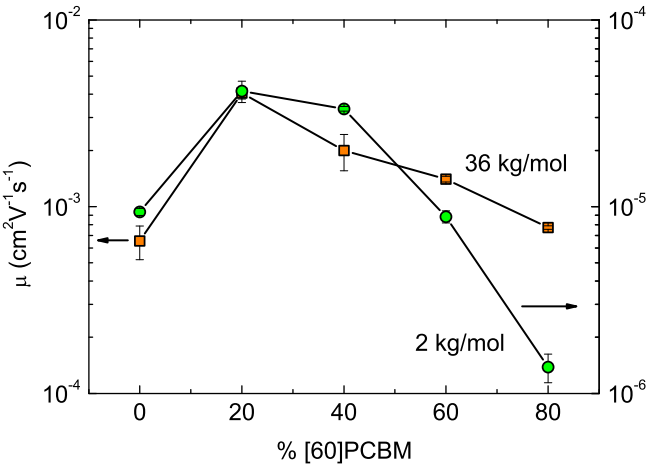

Fig. 3. Hole mobility as a function of stoichiometry for two different molecular weights of APFO-3 blended with [60]PCBM.

Depending on the particular theoretical framework used, different interpretations of the mobility enhancement and stoichiometry independent energetic disorder are possible, but in the context of a Miller–Abrahams type jump rate [9,14] the only explanation for the increased hole mobility in the APFO-3:[60]PCBM blends is an increased site density or an increase in the electronic wave function overlap. The decrease in blend hole mobility seen in Fig. 3 is likely due to site dilution which is quite plausible considering the high solubility of [60]PCBM in APFO-3 [15], and the initial increase in hole mobility should then be due to enhanced electronic coupling between sites.

There is a kink followed by a negative temperature dependence for some of the materials in Figs. 1 and 2. For hole mobilities in pure polymers, and presumably also for the APFO-3 based blends, this corresponds to the glass transition temperature. The glass transition temperature of the high molecular weight APFO-3 is too high to be observed in these measurements, but the low molecular weight values are included in Fig. 2. Interestingly enough, there is no trace of the glass transition temperature in the TQ-1:[70]PCBM blends. The pure TQ-1 glass transition temperature for the molecular weight range and layer thickness used in Fig. 1 is about 363 K, which is almost exactly at the kink in the hole mobility; while for instance a 1:1 blend has its transition close to 346 K where there is absolutely no trace of it in the electrical measurements.

Both TQ-1 and APFO-3 thus have the hole transport in PCBM blends confined to the polymer phase and show hole mobility enhancement upon the addition of PCBM for a relatively wide stoichiometry range. Physically, however, the nature of the enhancements are fundamentally different as it is due to induced ordering in the TQ-1 case, while it is due to some other form of interaction, quite possibly an increased inter-site coupling, in the APFO-3 case. One proposed mechanism for energetic disorder reductions in MDMO-PPV:[60]PCBM blends is through intercalation of PCBM in the polymer phase [16]. TQ-1, like MDMO–PPV, has a straight backbone and an asymmetric monomer unit, and the initially decreasing and then increasing energetic disorder upon the addition of increasing amounts of [70]PCBM to the system is consistent with a similar mechanism.

Although not necessarily obvious from Fig. 1, there seems to be systematic behavior beyond the energetic disorder also in the electron mobilities of TQ-1:[70]PCBM blends. The electron mobility has a maximum in the 50–60% PCBM range and the relative magnitude of this is always about one order of magnitude. On an absolute scale there are more than two orders of magnitude in electron mobility difference between blends based on different TQ-1 batches. That the electron mobilities in blends are dependent on the TQ-1 batch is surprising considering that the electron transport is confined to the [70]PCBM phase. Fundamentally however, there are many similarities between the hole transport in the APFO-3:[60]PCBM blends and the electron transport in the TQ-1:[70]PCBM blends since in both cases there is a predictable variation in mobility, pure material and blends share the same energetic disorder, and blends can exhibit higher mobilities than the pure materials. Even the stoichiometries of the mobility maxima are very similar for the two systems at about 40% [2] of the non transport participating phase.

Whether the absolute variations in electron mobilities of the TQ-1:[70]PCBM blends are real or some sort of measurement related artifact is an open question. There are no differences in the usually mobility sensitive fill factor between solar cells based on the different batches of TQ-1 and there are known issues with FETs that could be responsible for the observed behavior. Like other materials [17], these blends display active layer thickness dependent FET mobilities. For APFO-3 the typical blend behavior is shown in Fig. 4. It can be shown through the use of different solvents that this is unrelated to the spinodal decomposition that can occur in the APFO-3:[60]PCBM system [15]. The generally good correlation between FET hole mobility measurements on thick films and hole mobility measurements through other techniques indicate that, at least for the holes, reproducible results that accurately reflects properties like stoichiometry can be obtained. Electron mobilities are more difficult since there is no convergence to a specific number; the electron currents

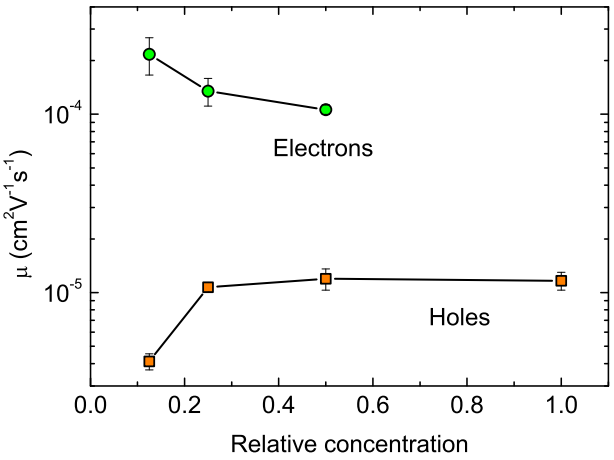

Fig. 4. Mobility versus spin-coating solution concentration for a 4:6 APFO-3:[60]PCBM blend. Higher concentrations give thicker films. The thickest films are close to 80 nm. The molecular weight, and thus hole mobility, is very low for this particular batch of APFO-3. For most molecular weights the hole mobility is higher than the electron mobility in this type of blend.

simply vanish as the thickness increases. This is the reason for the absence of APFO-3:[60]PCBM temperature dependence data and it might, but this is unlikely, explain the batch related variations in the TQ-1:[70]PCBM blends. Compared to APFO-3 there appears to be only very minor effects from the active layer thickness in TQ-1 based devices and electron currents are always visible. A more probable explanation is that there are some impurities present in TQ-1 that mainly influences electron conduction in the FET structure. All devices investigated here are intended to have a thick enough active layer to be in the regime where the thickness dependence is very weak. Different explanations for the active layer thickness dependence in FETs based on crystallization and morphology has been proposed [17], but so far fails to explain the behavior in Fig. 4.

Although it is difficult to measure electron mobilities with FETs in APFO-3:PCBM blends it can still be done in thin films. Such measurements are thickness sensitive and are hard to reproduce. Nevertheless, the available data agree well with an increase in electron mobility with increasing PCBM fraction just as observed with other techniques [2], and there is nothing that indicate that the electron mobility in APFO-3:[60]PCBM blends should depend on the particular batch of polymer. Again, just as for the hole transport, there is a pronounced difference between APFO-3 and TQ-1 based blends.

4. Conclusions

It has been shown that the electron and hole charge transport in the two investigated polymer:fullerene blends is confined to the respective expected and intended phases, and that several different mobility stoichiometry dependencies are possible; ordering induced variations, interaction with enhancement and site dilution, and a monotonous increase with increasing phase fraction. It has also been shown in the literature that simple site dilution without enhancement is possible [18].

These measurements represent a macroscopic average of the microscopic charge transport. Since the site dilution is macroscopically visible and influenced by molecular weight it is quite plausible that percolation problems might arise locally. For applications such as solar cells where charges are introduced everywhere throughout the active layer this might be a problem. A charge generated on a low mobility site will have a much higher probability of recombining without reaching the electrodes. The amount of low mobility sites is higher for low molecular weight materials and probably also for low molecular weight fractions in distributions. This might be one contribution to the decrease in performance with decreasing molecular weight that has been reported but not fully explained through absorption or charge separation [13,19]. Based on this it is possible that materials like TQ-1 in its [70]PCBM blend might be better suited for photovoltaic applications since there is no evidence of transport site dilution.

Piezoresistance

ABSTRACT

We studied the responses of the electrical and optical characteristics of organic light-emitting diodes (OLEDs) with green fluorescent and phosphorescent dyes doped in a polymer matrix to compressive stresses. The phosphorescent OLED converted stresses into measurable and reversible changes in both current density and electroluminescence (EL) intensity. The current showed a nearly linear characteristic response with sensitivity up to 205 μA kPa^{-1}, whereas EL decreased by over three orders of magnitude at 107 kPa. In contrast, the fluorescent OLED exhibited much smaller stress-induced modulations in current and light intensity, and the responses were saturated at stresses above 26 kPa. The discrepancy has been attributed to stress-enhanced back exciton energy transfer between guest and host molecules, which quenches the EL of the phosphorescent OLED, but has a much smaller impact on the performance of the fluorescent OLED.

1. Introduction

Tactile sensors have gained renewed interest as the level of sophistication in the applications of humanoid robotics and minimal invasive surgery increases [1–7]. Most robotic systems incorporate binary touch sensors that can distinguish between touch and no touch. To improve the manipulative capabilities of robotic hands, more sophisticated tactile sensors that can replicate the sensation of touch are needed [1]. That would require the development of a device that can be mounted on a curved surface and sense a distribution of contact stress as low as 10 kPa at a high spatial resolution of about 40 μm over a contact area of ~1 cm^2 [2]. Many technologies have been explored for tactile sensing, including conducting elastomers [3], piezoresistive materials [4,5], and micro-electro-mechanical systems [6]. However, their use in dexterous hands are hampered due to two limitations: (i) poor spatial resolution lagging by one order of magnitude compared to a human finger; and (ii) strain-induced nonuniform background signals in devices built on large curved surfaces due to the lack of flexibility. Recently, Maheshwari et al. [7] reported a new multilayer device structure consisting of metal and semiconducting nanoparticles. The device was capable of imaging stress distributions with a spatial resolution of ~40 μm, and showed significant promise for tactile sensing.

Organic materials are flexible and sensitive to external stresses. Upon compression, their resistivity may change dramatically due to reduced intermolecular distance and increased orbital overlap which lead to higher rates of electron transfer between neighboring molecules [8,9]. This sensitive piezoresistive response to deformation makes them a promising type of materials for pressure sensing applications [10]. In addition, many small-molecule organic materials have superior fluorescent or phosphorescent properties, and have been used to develop high-efficiency organic light-emitting diodes (OLEDs) [11–16]. The quantum efficiency of OLEDs is largely dependent upon carrier tunneling and energy transfer processes, whose rates are strong functions of the intermolecular distance [11–15]. Therefore, organic thin film structures may response to applied forces with changes in current density as well as

luminescent emission. Given these unique behaviors, along with easy fabrication and compatibility with flexible substrates, it is possible to use organic thin films to build a new type of tactile sensors capable of high-resolution imaging of stress distributions. In this work, we explore the applicability of fluorescent and phosphorescent OLED structures as tactile sensing devices by demonstrating their sensitive and repeatable responses to compressive stresses with changes in current density as well as electroluminescence (EL) intensity.

2. Experimental

The OLED structures were fabricated on glass substrates with pre-patterned indium-tin-oxide (ITO) (sheet resistance ~15 Ω/□). The substrates were first cleaned in sequence in acetone, ethanol, and de-ionized water, and then exposed to oxygen plasma for 5 min. The light-emitting layers (EML) were prepared by spin coating a mixture of phosphorescent fac-tris(2-phenylpyridinato-*N*, C2′) iridium(III) [Ir(ppy)$_3$] or fluorescent Tris(8-hydroxyquinolinato)aluminium (Alq$_3$), 4,4′-*N*, *N*′-dicarbazole-biphenyl (CBP), and polycarbonate (PC) dissolved in chloroform (10 mg mL^{-1}) at 3000 rpm for 1 min. Here CBP acts as a host material and PC is used as a polymer matrix to enhance the device robustness. The wt% ratio of the mixtures was 20:50:30. The thickness of the coated films was about 60 nm. The samples were then transferred to a high-vacuum thermal evaporation system with a base pressure of ~10^{-8}τ, and a 20 nm-thick 2,9-dimethyl-4,7-diphenylphenanthroline (BCP) hole blocking layer and 15 nm-thick Alq$_3$ electron transport layer were sequentially deposited at rates of ~0.1 nm s^{-1}. Finally, a 0.5 nm-thick LiF and 120 nm-thick Al cathode were deposited on the organic films through a shadow mask, which defined the active area of the OLEDs to be 3 × 3 mm^2. Under forward injection, the OLEDs exhibited green EL from Ir(ppy)$_3$ or Alq$_3$ with a brightness at 5 mA cm^{-2} of 184 and 169 cd m^{-2}, respectively. To characterize device responses to compression, forces were applied uniformly to the OLEDs through a 3 × 3 mm^2 Si sample placed atop the Al cathode using a probe tip attached to a micropositioner, and were measured by an electronic precision balance with 0.1 g readability. The current–voltage (I–V) characteristics of the OLEDs under different stresses were measured using an Agilent 4156C semiconductor parameter analyzer. The EL behaviors at different fixed currents or voltages were recorded in air from the glass side using an Ocean Optics spectrometer. The schematic diagram of the experimental apparatus is shown in Fig. 1. The maximum stress was limited to ~700 kPa, under which the deformation of the Si piece can be neglected.

3. Results and discussion

Fig. 2 shows the forward I–V characteristics of the Ir(ppy)$_3$-based phosphorescent OLED under different stresses. As seen, the current density increases with a remarkably high sensitivity as the stress is raised. A small stress of 16 kPa leads to an increase in the low-bias current by

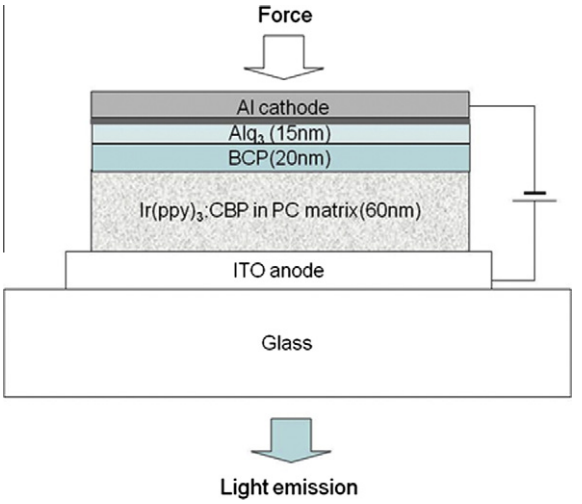

Fig. 1. Schematic diagram of the experimental apparatus for stress-sensing measurements.

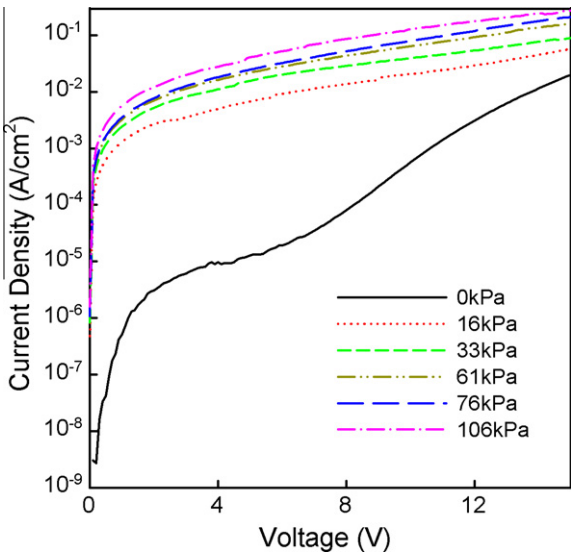

Fig. 2. Forward *I–V* characteristics of a green phosphorescent OLED under different compressive stresses.

more than two orders of magnitude. The influence of stress on the current density measured at three different fixed voltages is displayed in Fig. 3(a). At all voltages, the current shows a rapid and nearly linear increase with increasing stress over the entire range from 0 to 107 kPa. The current sensitivity varies from 94 to 205 μA kPa^{-1} as the voltage is changed from 10 to 14 V. The current response of the Alq$_3$-based fluorescent OLED is quite different, as seen in Fig. 3(b). At a constant bias, the current initially increases rapidly with increasing stress, but tends to saturate above 26 kPa. The current sensitivities in the low stress region are ~38–78 μA kPa^{-1}, which are still several times lower than that of the phosphorescent OLED. On the basis of the fact that two OLEDs with the same matrix/host materials

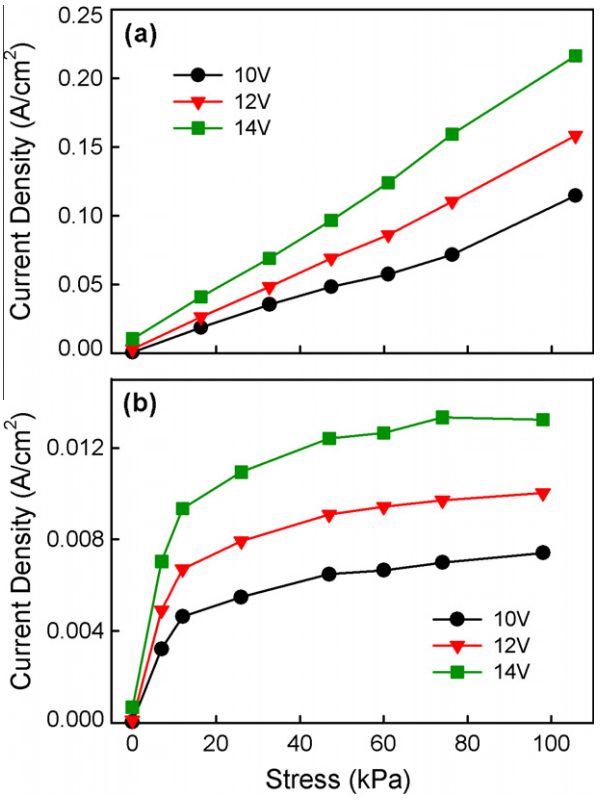

Fig. 3. Stress-dependent currents in (a) a green phosphorescent OLED and (b) a green fluorescent OLED measured at different fixed biases.

showed very different yet repeatable current responses to compression, we may rule out that localized shunt leakage paths are responsible for the current changes.

Since the applied stresses are relatively small, they can reduce the intermolecular spacing, but may not change the molecular geometry. Therefore, the stress-induced changes in the electronic states and energy levels should be minimal. This is supported by that fact that luminescence spectra of the OLEDs remained unchanged under compression. The observed current responses thus reflect changes in the electrical conductivity of the organic films rather than reduced barriers for charge injection. When a uniaxial stress is applied and the current flows along the same direction, the longitudinal piezoresistance coefficient π_l^σ can be defined as the relative change in electrical conductivity per unit stress:

$$\pi_l^\sigma = \frac{1}{X}\frac{\Delta\sigma}{\sigma_0} = \frac{1}{X}\frac{\Delta J}{J_0}$$

where σ_0 and J_0 are the conductivity and current density under zero stress, respectively, and X is the stress. π_l^σ for the phosphorescent OLED structure is found to be nearly independent of the stress and has a value of $\sim 2 \times 10^{-3}$ Pa^{-1} at 10 V. This value is more than two orders of magnitude greater than that of typical conjugated polymers [5] and five orders of magnitude greater than that of Si nanostructures [17]. We attribute the sensitive piezoresistive response to increased charge mobilities resulted from stronger intermolecular interaction in the compressed films. Young's moduli of PC and small molecular materials are on the order of GPa. Therefore, our results suggest that even a small percent of deformation may lead to a significant change in the rates of charge transfer between neighboring molecules through hopping. The stress of a human finger applies to sense texture and shape is typically on the order of 10–40 kPa. In our devices, an applied stress as low as 6 kPa can produce a noticeable current change, suggesting that the devices are capable of sensing touch on a par with a human finger. Compared to the fluorescent OLED, the phosphorescent OLED is clearly better suited for this application due to its high sensitivity over a wider stress range.

The EL of the phosphorescent OLED exhibited even more sensitive but opposite response to the applied forces. Fig. 4(a) illustrates the EL spectra measured at a fixed current of 6 mA from the OLED under various stresses. While the peak position and spectrum shape stay constant, the light intensity decreases sharply with increasing stress. A similar trend of EL evolution has been observed for the fluorescent OLED (Fig. 4(b)), though the magnitude of stress-induced quenching is much smaller. Fig. 5 plots the dependences of light intensity of the two OLEDs on stress at different currents. As with the current response, the EL of the phosphorescent OLED exhibits a much higher sensitivity upon compression. At 6 mA, the light intensity shows a monotonic decrease by over three orders of magnitude as the stress varies from 0 to 107 kPa. In contrast,

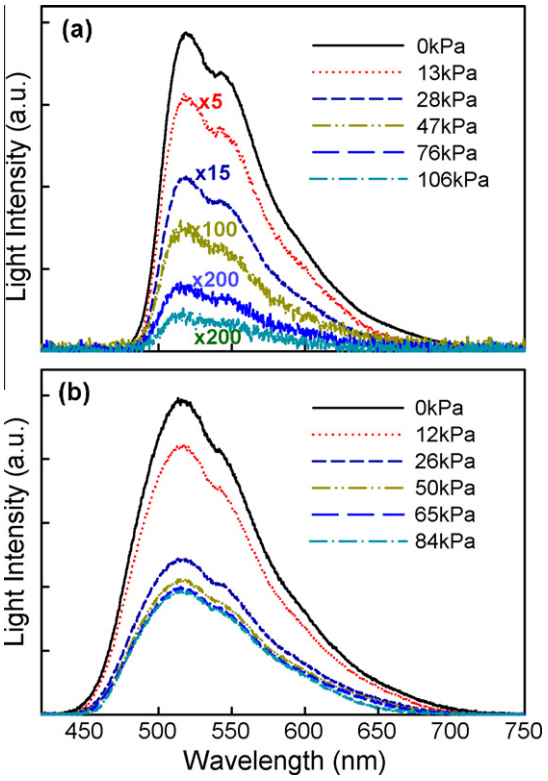

Fig. 4. EL spectra of (a) a green phosphorescent OLED and (b) a green fluorescent OLED recorded at 6 mA under different compressive stresses.

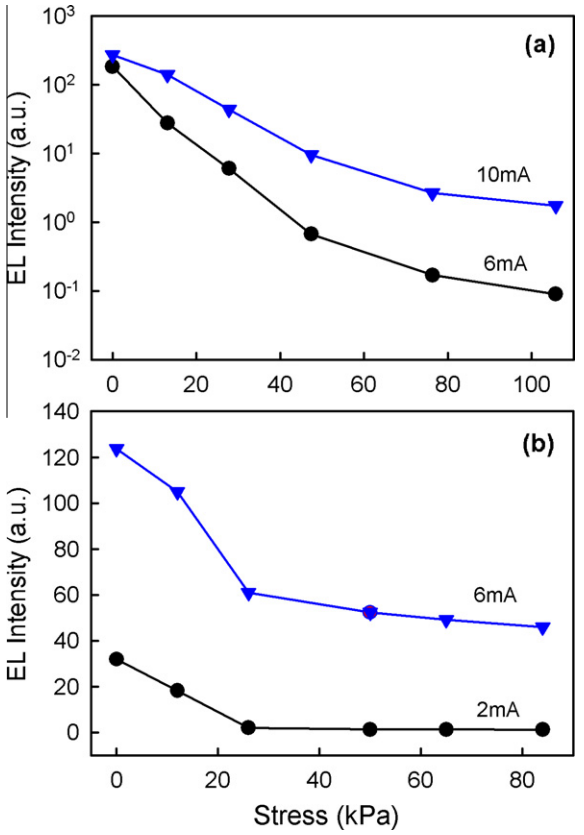

Fig. 5. Stress-dependent EL intensity of (a) a green phosphorescent OLED and (b) a green fluorescent OLED recorded at different fixed currents.

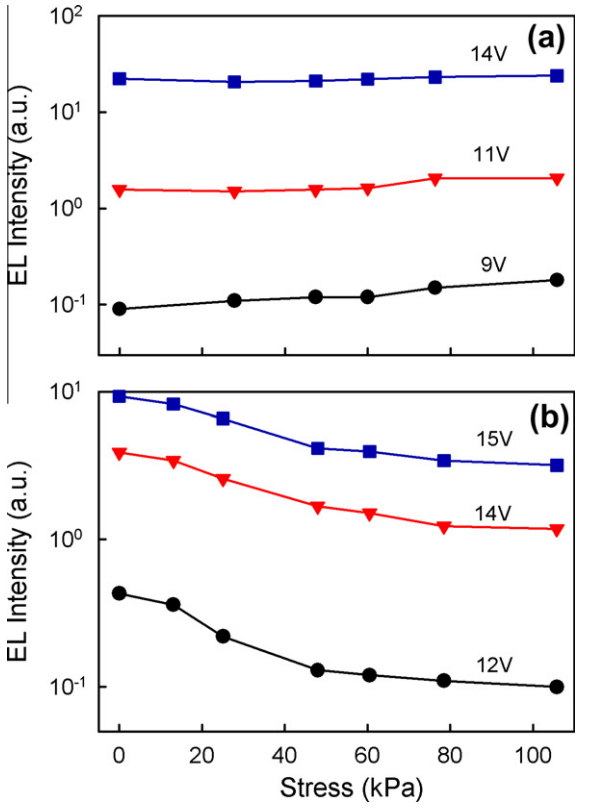

Fig. 6. Stress-dependent EL intensity of (a) a green phosphorescent OLED and (b) a green fluorescent OLED recorded at different fixed voltages.

the optical power of the fluorescent OLED drops by only 50% at 26 kPa and essentially stabilizes at higher stresses. These results suggest that the phosphorescent OLED may convert local stresses into both measurable electrical and optical signals with a high sensitivity, and is thus capable of direct imaging of contact stress distributions.

The stress-induced modulations in the EL intensity while fixing the voltage have also been measured. Interestingly, at a constant voltage, compression only causes small changes in the light intensity of the phosphorescent OLED, as seen in Fig. 6(a). Apparently, the EL quenching of the OLED under stress is largely offset by stress-induced increase of injection current at a constant bias. The light intensity of the fluorescent OLED under a constant bias decreases slightly with increasing stress, as seen in Fig. 6(b). In this device, EL quenching is a more dominant response to stress compared to the piezoresistance effect.

The vastly different optical responses of the two OLEDs to stress are believed to be associated with their different luminescent mechanisms. In the phosphorescent OLED, the excited singlet state of the $Ir(ppy)_3$ molecules is quickly and efficiently transferred to the triplet state via intersystem crossing. The EL originates from triplet excitons relaxing radiatively to the singlet ground state, whereas the radiative decay of singlets is negligible [11–16]. In contrast, despite that injection leads to the formation of both singlet and triplet states on Alq_3 molecules, the EL of the fluorescent OLED is limited to the radiative decay of singlet excitons that conserves spin symmetry [11,12]. Since the lifetime of the emitting triplet state of Ir(III) complexes is much longer than that of singlet excitons on fluorescent molecules, the EL of the phosphorescent OLED is expected to be much more sensitive to back energy transfer from triplets on the guest to triplets on the host molecules via a Dexter process. Dexter transfer is a short range process where excitons diffuse from donor to acceptor sites via intermolecular electron exchange [18]. The transfer rate is exponentially dependent on the donor–acceptor separation R_{DA}, and is proportional to the expression below [16]:

$$K_{ET} \propto \exp(-2R_{DA}/L),$$

where L is the sum of the van-der Waals radii of the donor and acceptor. Under normal conditions, the back energy transfer from $Ir(ppy)_3$ to CBP is insignificant due to relatively large R_{DA} as well as the fact that the process is endothermic given the higher energy of the host triplet ($E_{T,CBP}$ = 2.56 eV) compared to that of the guest triplet state ($E_{T,Ir(ppy)3}$ = 2.42 eV) [19]. However, as the intermolecular spacing is squeezed, its rate may increase substantially, leading to weaker confinement of excitons on the guest. When the film is further compressed, the back energy transfer followed by nonradiative decay at defects may become the major energy dissipation process. On the other hand, increased triplet–triplet back energy transfer has

no impact on the efficiency of the Alq_3 emission. Although Dexter transfer also permits singlet–singlet transfer, it only has a limited influence on the EL of the Alq_3 OLED due to the fast decay (~1 ns) of fluorescent dyes. To validate our hypothesis that back energy transfer is the physical origin of the dramatic EL quenching in the $Ir(ppy)_3$-based OLED, we characterized the performance of a phosphorescent OLED with 20 wt% Bis(1-(phenyl)isoquinolinato-*N*, C^2) iridium acetylacetonate [$Ir(piq)_2(acac)$], a red phosphorescent dye, doped in CBP. Its EL spectrum peaks at 632 nm with a brightness of 189 cd m^{-2} at 5 mA cm^{-2}. The triplet state energy of $Ir(piq)_2(acac)$ is 2.0 eV. It is therefore expected that the back energy transfer rate is much lower than that in the green phosphorescent OLED, leading to much weak responses to compression. Indeed, for stresses below 100 kPa, we observed little changes in current and EL intensity. The red OLED only exhibited noticeable yet moderate optical responses to stresses greater than 160 kPa at a constant current, as seen in Fig. 7.

Another factor which may contribute to the unexpected EL quenching in the phosphorescent OLED is the compression-enhanced concentration quenching effect. It is known that phosphorescent OLEDs suffer from self-quenching when the concentration of the phosphorescent molecules is high [12–15]. The efficiency of OLEDs with $Ir(ppy)_3$ doped in CBP peaks at ~6 wt% of $Ir(ppy)_3$ and decreases rapidly as the doping level is increased [12]. In OLEDs with a neat $Ir(ppy)_3$ EML, the maximum EL quenching magnitude is found to be ~90% [15]. Previous studies have suggested that the quenching effect originates from long-range Förster energy transfer between $Ir(ppy)_3$ molecules [13–15], whose rate is proportional to $(R_0/R)^6$, where R_0 is the Forster radius (on the order of several nanometers) and R is the intermolecular distance. Therefore, compressing the organic film could lead to increased concentration quenching of EL. If concentration quenching is indeed one of the underlying mechanisms of stress-induced EL quenching in the phosphorescent OLED, it would play a larger role as the $Ir(ppy)_3$ concentration is reduced to 6%, where EL is the most sensitive to changes in the dopant concentration resulted from compression. To test this assumption, we compared the responses of OLEDs with $Ir(ppy)_3$ doping of 6 and 20 wt% under the same applied stresses. As a result of reduced concentration quenching, the OLED with 6 wt% $Ir(ppy)_3$ is 5× brighter. Fig. 8 shows the current density at a fixed bias of 12 V and EL intensity at a constant current of 7 mA of the two OLEDs, as a function of stress. The OLED doped with 6 wt% $Ir(ppy)_3$ displays a similar linear current response with slightly lower sensitivity. Another finding is that the magnitudes of stress-induced EL quenching in the two OLEDs are comparable, indicating that concentration quenching may play a minimal role.

Since the device fabrication consists of simple spin casting and evaporation deposition, the phosphorescent OLED structure may be made on large curved surfaces of flexible substrates to replicate sensation of touch. The excellent flexibility of organic and polymer materials ensures a high spatial resolution of the OLEDs required for tactile sensing [7]. To test the robustness of this type of devices, we studied the stability of the OLED with 6 wt% $Ir(ppy)_3$ under fixed stresses and biases. Fig. 9(a) and (b) illustrates its current responses recorded at a fixed bias of 12 V over short testing periods under different constant stresses and a step-modulated stress of 55 kPa, respectively. Even though the measurements were carried out in air without device encapsulation, the current density in the deformed device at a fix bias was nearly constant. During the cycle testing, as the stress was alternatively applied and released, reversible changes in current were observed, suggesting that the deformation of the organic film is reversible with minimal hysteresis. The abrupt changes in current reflect rapid responses of the device to applied forces. These results demonstrate very good repeatability and stability of the phosphorescent OLED required for stress sensing applications.

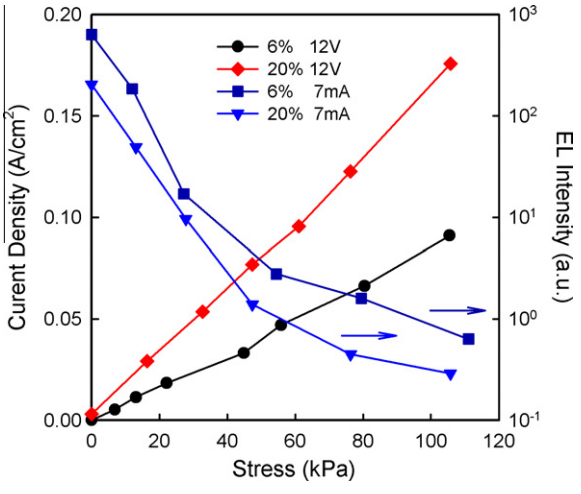

Fig. 8. Stress-dependent current density and light output power of green phosphorescent OLEDs doped with 6 and 20 wt% $Ir(ppy)_3$ measured at different fixed voltages or currents.

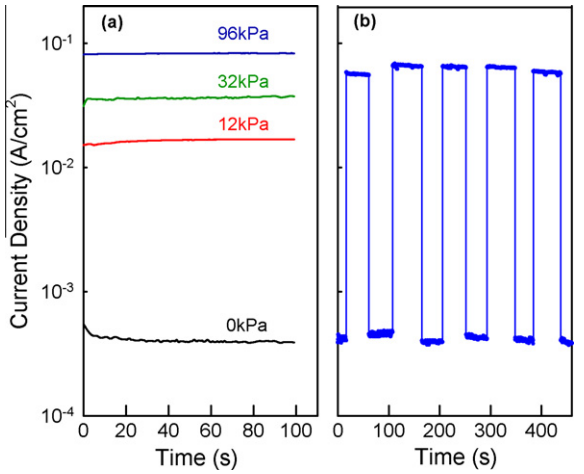

Fig. 9. Current responses of a green phosphorescent OLED recorded at a fixed bias of 12 V under (a) different constant stresses and (b) a step-modulated stress of 55 kPa.

4. Conclusion

In summary, we compared the responses of the electrical and optical characteristics of fluorescent and phosphorescent OLEDs with luminous dyes doped in a polymer matrix to compressive stresses. The phosphorescent OLED converted a stress as low as 6 kPa into measurable and reversible changes in both current density and EL intensity. The current showed a nearly linear characteristic response with sensitivity up to 205 μA kPa^{-1}, whereas EL decreased by over three orders of magnitude. In contrast, the stress-induced modulations in current and light intensity in the fluorescent OLED were much smaller and saturated at stresses above 26 kPa. The discrepancy has been explained by that stress-enhanced nonradiative back energy transfer between guest and host molecules severely quenches the EL of the phosphorescent OLED, but has a minimal impact on the performance of the fluorescent OLED. It is expected that similar phosphorescent OLEDs built on large curved surfaces may directly image stress distributions and sense touch on a par with a human finger.

ABSTRACT

Vertical diodes made of chromium/gold/poly(3-hexylthiophene) (P3HT)/aluminum are used to implement AC–DC charge pump circuits. A single stage polymer charge pump with 470 nF capacitors is able to supply 7.2 V DC to a load of 1 MΩ || 20 pF when an AC signal with a peak value of 10 V is applied. The circuit can be used up to 10 kHz. High turn-on voltages and internal resistances and capacitances of the diodes limit the DC output voltages. The ramp-up time of the circuit built with 10 nF capacitors is 9.4 ms for a 1 kHz, 10 V peak AC signal. Diodes are modeled and simulated in SPICE using space charge limited conduction model. The simulated charge pump circuit produces consistent results with measurements. Performances of air exposed vertical diodes deteriorate under vacuum, prolonged operation at atmospheric conditions and electrical bias stress resulting in blistering, emphasizing the importance of packaging the devices under inert atmosphere. The DC output voltage and the input impedance of the circuit can be adjusted by using multiple stages.

1. Introduction

Current electronic circuits made of polymer semiconductors may require very high supply voltages in the range of tens of volts [1]. Similarly, micromachined capacitive actuators require voltages in the same high levels [2]. Without a scheme to step up the supply voltages available from a commercial battery, portable applications of polymer semiconductor devices would be impractical. Furthermore, the potential for low cost and high volume fabrication makes polymer semiconductors attractive in a particular area, the polymer RFID tag. In this application, the power necessary for device operation needs to be transmitted wirelessly, in order not to include a battery that would drastically increase the cost of the device. Several approaches for the extraction of DC power from an RF signal are present, and a previous work shows a possible solution with two half-wave rectifiers to constitute the ground and supply rails of the RFID circuitry using diodes made out of pentacene [3]. This design confines the tag supply voltage to the peak-to-peak voltage of the RF signal picked up by the tag antenna, minus twice the turn-on voltage of the diodes, which tend to be high in current polymer electronics. The charge pump method has been evaluated favorably to the half-wave rectifier scheme in RFID applications [4], for the charge pump approach gives more flexibility to designer in many ways. Cascading multiple stages of charge pumps allows the designer to adjust the supply voltage levels as desired and compensate for the large voltage drops across diodes. In addition, the input impedance of a charge pump depends on the number of stages and the loading of the charge pump [5], which allows the designer to perform impedance matching to the antenna that feeds the charge pump, maximizing the extracted power [4]. This leads to the reasoning that charge pump circuits built with polymer semiconductors are worthwhile to explore.

Polymer and organic diode half-wave rectifiers were built in previous literature using P3HT [6,7], as well as other organic/polymer semiconductor materials such as PTAA [8], pentacene [3,9–11], and hybrid p–n junction organic diodes using n-ZnO/(PQT-12) [12], and their AC characteristics were demonstrated. For high performance

doi:10.1016/j.orgel.2010.11.006

organic semiconductors such as pentacene, 3-dB cut-off frequencies of 15 MHz [9] to 50 MHz [10] were reported for half-wave rectifier topologies, the latter publication demonstrating that organic diodes can be operated at the 13.56 MHz RFID frequency with acceptable performance levels [10]. Half-wave rectifiers fabricated using P3HT, which can be solution-processed at relatively low cost, exhibit lower AC performance on the other hand. Cut-off frequencies between 1–1.8 MHz [7] and 2 MHz [6] were reported for half-wave rectifiers fabricated using this material.

In this work, a charge pump circuit built using regioregular poly(3-hexylthiophene) (rr-P3HT) is investigated, the aim being to meet the demand for high supply voltages in electronic devices fabricated from polymer semiconductors, as well as the possible application of wireless power transmission to polymer electronic devices. The charge pump topology that is featured in this work is shown in Fig. 1. This is a more useful method in generating supply voltages from RF signals, since the design is scalable as opposed to supplying power from a single half-wave rectifier. The number of charge pump stages determines both the DC levels of the output voltage and the input impedance of the charge pump itself.

In the design of the charge pump circuits, an electrical model for fabricated vertical diodes has been used. After the diodes are fabricated, their electrical model parameters are extracted and used in a computer aided design tool, simulation program with integrated circuit emphasis (HSPICE), to investigate the operation of the charge pump circuit. In the models, the environmental effects on the characteristics of polymer diodes are also studied. Since in polymer semiconductor the performances of devices are deteriorated by environmental variables such as oxygen, humidity, ambient temperature [13–15] and electrical bias stress, the parameters of the model are also changed accordingly. Parameter fittings for the model have been done to the vertical diodes using the results of experiments that expose them to the mentioned environmental variables.

This paper is organized in five sections. Section 2 describes the fabrication of lateral and vertical polymer diodes and presents their current–voltage characteristics under various environmental conditions. Section 3 presents the theory and a model for the fabricated vertical diodes to be used in the charge pump circuits. Section 4 explains the operation of the charge pump circuit and gives experimental results for various conditions and compares them to the simulation results. Discussions and conclusion are given in Sections 5 and 6, respectively.

2. Polymer diodes

Polymer diodes are the main components of this work. They are fabricated, characterized and modeled before they are used in a charge pump circuit. Since polymer diodes are not stable under ambient conditions and they degrade, they are also tested for their changing performances under ambient conditions to check whether degradations can be modeled and predicted or tolerated in certain circuit applications. For this purpose, two types of diodes have been fabricated and tested; lateral and vertical diodes. The main purpose of the fabrication of the lateral diodes were to study the environmental effects on semiconductor polymers more easily since its active polymer is directly in contact with the environment. Its surface is not covered with a metal film.

2.1. Lateral diodes

2.1.1. Fabrication of lateral diodes

In fabricating lateral diodes, two electrodes of the diodes are fabricated in plane in an interdigitated manner. The aluminum cathode and the silver-epoxy anode are deposited on top of the glass substrate such that the diode, from the top view, resembles a system of interlocking fingers as drawn in Fig. 2. 90 nm thick aluminum is thermally evaporated on a glass substrate and patterned using lithography. Silver electrodes are formed by drop-casting a silver epoxy liquid and then cured on a hotplate at 110 °C. A sharp metal tip with a reservoir filled with silver epoxy is attached to a micromanipulator and is moved to make the silver electrodes between aluminum ones. This limited the gap size between electrodes to 300 μm. The total length of the diode formed by the interdigitated layout is measured to be 10.5 mm and the gap between the electrodes 300 μm. After the deposition of the electrodes, rr-P3HT (from Sigma–Aldrich) solution is deposited by drop-casting and annealed for one hour at 110 °C to evap-

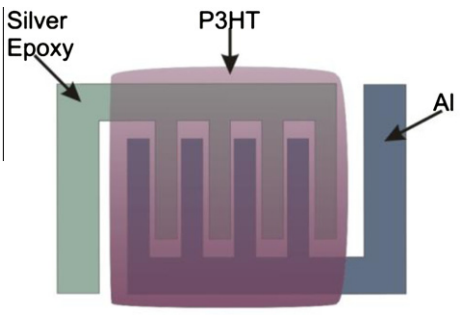

Fig. 2. Top view of the interdigitated lateral diode.

orate solvent. The polymer is dissolved in 1,2,4-trichlorobenzene with a weight concentration of 2.5 mg/ml and filtered through a 0.2 μm pore sized PTFE membrane syringe filter.

2.1.2. Experimental results of lateral diodes

Following fabrication, the lateral diodes stayed at ambient conditions for a day. Then, they are placed into a vacuum chamber and 30 mTorr vacuum is achieved inside the chamber before the characterization of the devices are initiated. DC voltage sweeps are conducted with Keithley semiconductor parameter analyzer (SCS4200) and the current through the diodes are measured at varying time intervals after the start of the vacuuming to investigate the effects of time under sustained vacuum on device performance. Results are summarized in Fig. 3. Vacuum treatment of the lateral diodes resulted in the decrease of both forward and reverse currents, indicating a drop in the parasitic conductivity. This is expected since the vacuum dedopes the semiconductor polymer by removing the atmospheric oxygen inside, which has been absorbed during the fabrication steps done at room conditions. Atmospheric oxygen is known to dope semiconductor polymer, thus create parasitic conductivity [1]. As the vacuum is maintained, reverse current diminishes more rapidly than the forward current, increasing the rectification ratio of the diode. The ratio of the diode's currents at a forward bias of 7 V and a reverse bias of 7 V is around 2 just before the vacuum started. This ratio increases to 240 after 4 h of vacuuming.

After vacuum tests, the chamber pressure is brought to 1 atm by releasing argon gas into the chamber. Being a noble gas, argon is used to eliminate the possibility of P3HT to react with doping agents such as oxygen and water vapor that would have been present had the experiment been conducted at atmospheric conditions. After the desired pressure is obtained, the diodes are heated to varying temperatures and current–voltage measurements are acquired after 5 min of maintaining the desired temperature. This waiting period is needed for the front surface of the glass wafer, where the diodes are, to reach the desired temperature. The results are shown in Fig. 4. Elevated temperatures resulted in a dramatic increase in forward current as well as the rectification ratio in lateral diodes. As theory suggests, the P3HT thin film, when formed, is an amorphous

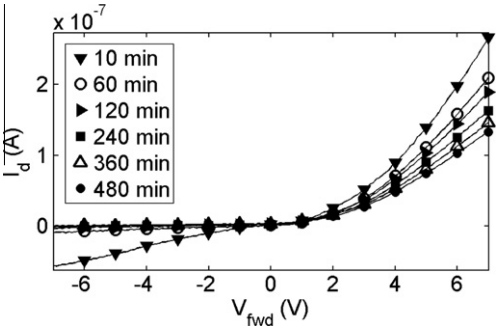

Fig. 3. Change in current–voltage characteristics for lateral diode under vacuum with elapsing time.

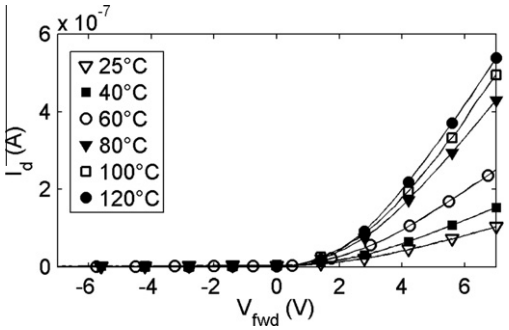

Fig. 4. Lateral diode current–voltage characteristics recorded at various temperatures.

composition of grains of polymer. The charges cannot hop between two neighboring grains unless the energy barrier constituted by the intergrain boundary, called a trap state, is overcome [15,16]. Elevated temperatures causes the excitation of a greater number of these trap states, which enables charges to move across the trap states. The end result is an increase in current density for a given voltage, increasing the performance of the diode. The improvement is not sustained after the temperature is reduced back to room temperature [17]. Therefore, it is determined that annealing of the thin film P3HT does not occur in lateral diodes in the applied temperature range of this work [18]. As a result of heating from 25 °C to 120 °C, the forward current increases from around 100 nA to 540 nA at 7 V forward bias. Similarly, rectification ratio of around 80 at 25 °C increases to 900 at 120 °C.

As observed in the vacuum tests, the rectification ratio of the lateral diode is improved by vacuum treatment, which can be preserved by an adequate packaging of the device following the vacuum treatment. The rectification ratio, which can also be referred to as the on–off ratio, is of vital importance in a charge pump application since a diode that leaks current when it is supposed to behave like an open circuit detracts from the efficiency of the charge pump. Despite the potential performance improvement, the lateral diode can provide small amounts of forward current (around 100 nA) since in this work electrode space is large, around 300 μm, forming a high parasitic resistance in series with the diode. This makes it ineligible for a charge pump application in which the charge pump acts as a current source for resistive current loads in need of about 10 μA. However, this electrode gap can be easily made to around 1 μm if another metal thin film such as Chromium (Cr)/Gold (Au) is evaporated and lithographically patterned. In that case it could conduct more current for the same voltage applied. Nevertheless, vertical diodes whose electrode gap between anode and cathode is the thickness of the polymer, would have less resistive parasitic and can supply more current than lateral diodes. However, one advantage of lateral diode may be that its semiconductor polymer is exposed to the environment directly. Since the semiconducting polymer is not capped with another thin film metal, it can be treated thermally or with vacuum much easily than the packaged one.

2.2. Vertical diodes

2.2.1. Fabrication of vertical diodes

The fabrication of the vertical diodes involves sandwiching the drop casted P3HT layer between two metal layers. While the bottom electrode is deposited by a high vacuum evaporator and patterned by lithography, the top electrode is formed by means of shadow mask evaporation. Alignment errors and the spread of the deposited metal in shadow masking cause deviations from designed device sizing.

The process sequence of the fabrication, as shown in Fig. 5, starts by lithographically patterning the thermally evaporated Cr/Au thin films to form bottom electrodes. Similar to the lateral diode fabrication, P3HT is dissolved in trichlorobenzene with a ratio of 2.5 mg/ml. This solution is drop-casted and is left to dry on the substrate at room conditions for 2 h, resulting in a film thickness of approximately 750 nm. For the deposition of the aluminum electrodes, a shadow mask is prepared from a 50 μm thick stainless steel (SS301) sheet. A photoresist mask is patterned on steel surface using lithography and then steel is isotropically etched using electrochemical etching in 1:7 HCl:DI water solution [19]. A vacuum chamber with a base pressure of 10^{-6} Torr is used to evaporate a 90 nm thick aluminum layer. The shadow mask is aligned perpendicular to the patterned Cr/Au electrodes and evaporation forms orthogonal aluminum electrodes resulting in diodes with active area of 2 mm × 0.5 mm.

2.2.2. Experimental results of vertical diodes

Similar to the lateral diode tests, vertical diodes are subjected to vacuum and elevated temperatures to determine the effects of atmospheric doping and thermal activation on them. Additionally, a set of diodes are operated under atmospheric exposure to observe the degradation of performance that is expected to happen as the P3HT thin film deteriorates.

Diodes tested under atmospheric conditions are kept at these conditions for a week before they are electrically tested. During tests, they continued to get exposed to atmospheric conditions. The results are presented in Fig. 6. The diodes continue to operate without much degradation in forward current up to 60 min after the start of the tests. Forward current is recorded to be around 1.2 mA at 8 V forward bias during this interval of time. The decline in forward current is discernible at 180 min, and after 420 min the forward current suffers drastically. This part of the experiment reveals that operation under atmospheric exposure causes the deterioration of device performance.

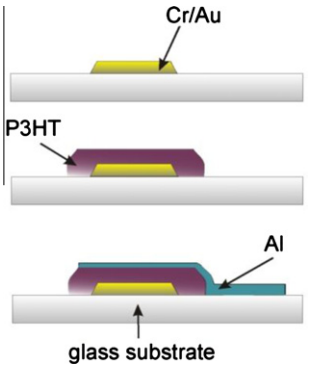

Fig. 5. Fabrication steps for polymer charge pump circuits, from top to bottom: evaporation of Cr/Au contacts, deposition of P3HT, followed by the evaporation of aluminum through a shadow mask.

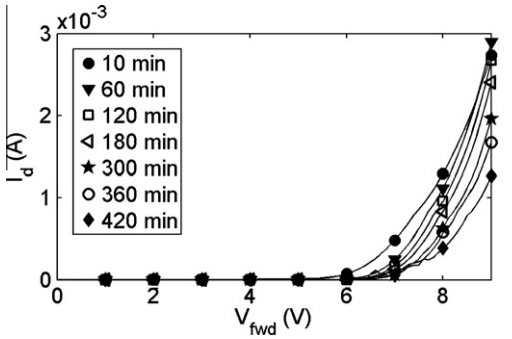

Fig. 6. Current–voltage characteristics of the vertical diode under atmospheric exposure with elapsing time.

Deterioration of the behavior of the diodes is correlated to changes in their physical appearance. The vertical diodes exhibited blistering under the top aluminum cathode of the diode as shown in Fig. 7. The existing bubbles and blisters are inflated with device operation, and new blisters emerge as tests are performed. Similar blistering was reported in P3HT-PEDOT systems [13] and in inkjet printed P3HT devices [14]. The explanation for this phenomenon was identified as the electrolysis of the atmospheric impurities such as water vapor that has dissolved inside the P3HT thin film with electrical bias stress. The resulting gases would try and escape the thin-film, but they would encounter the top electrode, where they form the observed blisters. Blistering mechanism might be a contributing factor in the decrease in diode forward current with time; since the bubbles break the integrity of the P3HT-Al interface where they form, thereby reducing device efficiency.

Vacuum treatment of the vertical diodes with the conditions mentioned at the lateral diode section reveals worse degradation than the atmospheric results. Current–voltage characteristics of the vertical diode just after vacuuming started are shown in Fig. 8. Diodes have been at atmospheric conditions for a day after their successful fab-

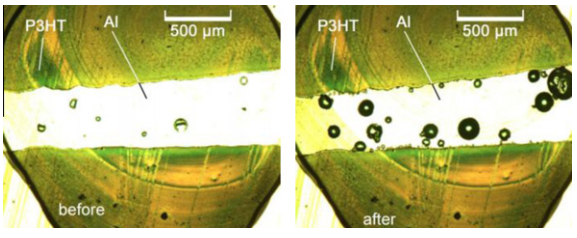

Fig. 7. Before (left) and after (right), operation of vertical diodes under atmospheric conditions.

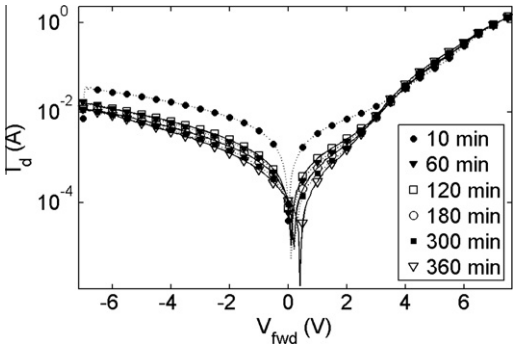

Fig. 8. Semilog plots for the current–voltage characteristics showing the effects of vacuum treatment on vertical diodes with elapsing time.

rication. At the beginning of the tests certain improvement in diode performance occur since the vacuum starts to extract the dopants inside the polymer, thus decreases the leakage currents in the reverse bias. However, the measured current–voltage curves deteriorate after some time. These deviations could be the result of an increasing number of blisters as the device is subjected to electrical bias stress. Severe deterioration on the aluminum surface due to vacuum and operation can be seen in Fig. 9. The blistering observed under vacuum treatment is extensive, resulting in comparatively smaller but far more numerous blisters beneath the top electrode, in contrast with devices tested under atmospheric conditions. A possible explanation for this is that the applied vacuum sucks out the dissolved impurities from the thin-film, collecting a portion of them under the top electrode through which they cannot diffuse away. The applied bias stress causes the electrolysis of these impurities, resulting in the blisters. Since vacuum drives a larger amount of impurities in comparison to the air exposed diodes, the blisters are numerous and cover the layer beneath the top electrode almost entirely. This also explains why these deteriorations are not observed on lateral diodes. Since the top of the lateral diode is not blocked by a thin metal film, vacuum treatment improves the diode performance with time steadily.

This situation for the vertical diodes may be avoided if a slower and gradual increase of vacuum is applied with thermal annealing to give a chance to dissolved impurities to leave the device surface without causing any deformation. Starting vacuum treatment at a lower vacuum value such as 150 Torr and then gradually and slowly increasing the vacuum while keeping the samples at elevated temperatures such as 90–110 °C may avoid blisters on the surface. During this time, the devices should not be operated. After this postfabrication treatment, the devices can be packaged under these conditions [20].

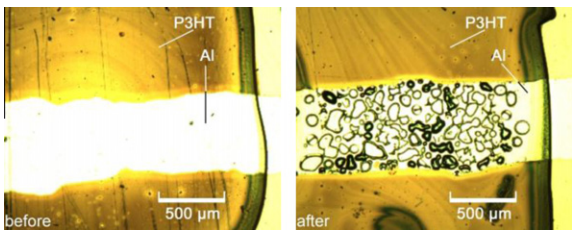

Fig. 9. Before (left) and after (right) operation of vertical diodes under vacuum.

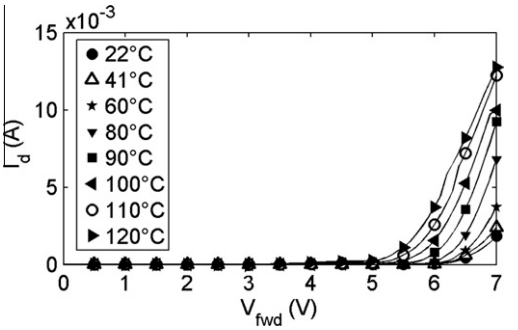

Fig. 10. Current–voltage characteristic of vertical diode at elevated temperatures.

A separate vertical diode is subjected to elevated temperatures under argon gas environment with the pressure maintained at around 1 atm. Before this test, the diode stayed at atmospheric conditions for a week. Similar to the performance improvement of lateral diodes at elevated temperatures, the vertical diodes are also observed to conduct more current at the same voltage values as the temperature is increased, as shown in Fig. 10. The thermal activation of the intergrain boundaries results in more carriers with enough energy to cross the trap states. As a result of heating, the forward current increases from around 2 mA to 12 mA at 7 V forward bias as the temperature increased from 22 °C to 120 °C. Lowering the temperature back to the initial temperature values does not sustain the improvement, leading to the conclusion that annealing of the thin-film did not occur in the process.

3. Polymer diode model

Simulation models for organic and polymer diodes have been reported, modeling the properties of various organic and polymer semiconductors with a voltage dependent mobility factor [21,22]. A more straightforward approach in modeling both organic [9] and organic–inorganic hybrid [12] diodes features two diodes connected in parallel but in reverse directions, one diode modeling the forward current component while the other modeling reverse current component. Both approaches produce good results in modeling the DC behavior of the measured characteristics; however it is found that the approach that makes use of voltage varying mobility produces a more accurate model of the charge pump operating at higher frequency ranges and for different values of peak amplitudes of input voltage.

Under high electric fields, (reported to be in the order of 10^5 V/cm for P3HT [22]) space charge limited conduction (SCLC) is dominant in polymer semiconductors such as P3HT [22]. In SCLC regime, current conduction is dominated by Mott–Gurney equation:

$$J = \frac{9}{8} \cdot \frac{\epsilon_0 \epsilon_r}{d^3} \cdot \mu \cdot V^2 \quad (1)$$

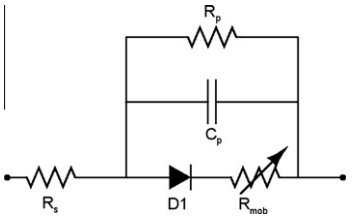

Fig. 11. Circuit model for the P3HT vertical diode.

where μ is the voltage dependent mobility, ϵ_0 is the electrical permittivity of air, ϵ_r is the dielectric constant of the polymer. V represents the voltage across the diode and d the thickness of the polymer film, estimated to be around 750 nm for this work. The voltage dependent mobility is expressed as follows:

$$\mu = \mu_0 \cdot e^{0.89\cdot\gamma\sqrt{V/d}} \tag{2}$$

where μ_0 is the zero-field mobility and γ is the electric field prefactor [22]. Including the voltage dependent mobility within the Mott–Gurney equation integrates the Frenkel effect into the model, emulating the effects of trap states within the polymer film. This yields a more accurate model since the rapid departures from the original Mott–Gurney equations, resulting from high electric field ranges, are now taken into account [23]. In low field regimes, current voltage characteristics of our device model, shown in Fig. 11, are dominated by the diode element, modeling the effects of Schottky contact. As the device enters SCLC regime, the current through the device is dominated by the modified Mott–Gurney equation that includes the Frenkel effect. This latter current regime is modeled by the voltage varying resistor R_{mob} in an approach similar to the work in [21].

The procedure for fitting the model to the measured data starts with fitting the model to the DC sweep measurements of the diode, which gives the reverse saturation current, *IS*, and the ideality factor, *N*, in the SPICE model of the diode element and series and parallel resistances, as well as field-dependent mobility parameters. Junction capacitance, *CJO*, in the SPICE model of the diode element is due to the depletion region caused by the Schottky contact between P3HT and aluminum. Junction capacitance value is estimated to be in the proximity of 100 pF based on the area of the diode and data reported in previous work on rr-P3HT/aluminum Schottky contact, which estimates the depletion width to about 170 nm for zero voltage bias [24]. The parasitic capacitance, C_p, is simply a parallel plate capacitor formed by the two metal electrodes and the polymer film in-between. It is set to 36 pF, based on the approximated polymer thickness of 750 nm, the relative permittivity of 3.0 [13], and an active device area of 1 mm^2. Transit time parameter, *TT*, in SPICE diode model, was also set to 150 μs to fit the model to the measurements. The model was simulated in HSPICE.

4. Charge pump circuits

Charge pump circuit is built using two of the fabricated vertical polymer diodes and two external capacitors. Its operation principle and the experimental results are given in the sections below.

4.1. Operation of the charge pump circuit

Assuming an alternating signal is applied as the input voltage to the charge pump circuit shown in Fig. 1, the negative cycle of the input switches diode D1 on while D2 remains turned off, allowing the capacitance C1 to charge up to the peak voltage of the applied signal. In this situation, D1 and C1 work as a clamper. The following positive cycle of the signal reverse biases D1 and forward biases D2. As a result, C2 is charged up to a positive peak voltage that is the sum of the peak voltage of the applied signal and the voltage stored in C1 from the previous cycle. In this situation, D2 and C2 form a half-wave rectifier. The two terminals of C2 can be used as a DC voltage source, yielding a DC level with some small ripple voltage superposed that is twice the peak voltage of the applied signal under ideal circumstances such as very small stray capacitances along with negligible diode turn on voltages. If a second stage is appended to the first stage, D3 would have its cathode connected to the DC output voltage of the prior stage, and the output voltage that is observed over C4 would be four times that of the peak amplitude of the applied signal.

A typical charge pump circuit given in Fig. 1 can have K stages. Each stage can have identical diodes with turn-on voltage of V_{on} and identical capacitors with capacitance of C. The output of this circuit, V_{out}, can be made to supply a current of I_{out} at the output when an AC signal with a frequency of f and a peak voltage of V_{peak} is applied to the input. Since there would also be stray capacitances, C_s, at the nodes that diodes are connected, a simple output equation for this charge pump circuit can be expressed as [5]:

$$V_{out} = 2\cdot K\cdot\left[\frac{C}{C+C_S}\cdot V_{peak} - V_{on} - \frac{I_{out}}{(C+C_S)\cdot f}\right] \tag{3}$$

It can be observed from this equation that the stray capacitances diminish the peak voltage on the output by sharing the stored charge within the charge pump capacitors, C. Eq. (3) fails to include the diminishing effects of the parasitic parallel plate capacitance, C_p, and the junction capacitance, *CJO*, of the diodes on the peak voltage. These parasitic capacitors must also be lumped to C_s to get a more accurate analytical result. Numerical results acquired from the simulations of HSPICE take the effects of these capacitors into account.

As a minimal requirement, the single stage polymer charge pump is designed to deliver 10 V DC when an oscilloscope probe is connected to its output node. The oscilloscope probe presents a 1 MΩ || 20 pF load to the charge pump. This load is similar to a load that is formed by multiple polymer transistors that we fabricate. Our typical polymer transistor passes a drain current of around 1 μA when a source-drain voltage of −40 V is applied to turn it on. The continuous, resistive current load provided by the oscilloscope brings down the DC output levels according to Eq. (3). The continuous resistive loading is a realistic model for a charge pump circuit driving multiple polymer transis-

tors, where current leakage is significant even if the devices are turned off.

4.2. Experimental results of charge pump circuits

Fabricated charge pumps are tested with external capacitors of 470 nF added on, soon after the completion of the fabrication of vertical diodes. Tests are conducted under argon environment after diodes have been exposed to atmosphere for about a week. These results are shown in Fig. 12. The frequency response of a single stage charge pump for different peak voltages of the input AC signal reveals that the device operates at reasonable output levels up to 1 kHz and it could possibly operate acceptably at around 10 kHz.

Simulation results for the charge pump circuit using the models developed for the vertical polymer diodes are also plotted in Fig. 12. In order to do this, first, the DC current–voltage characteristics of the vertical diodes are measured. Then, the DC parameters for the model described in Section 3 are extracted from these DC measurements. The measured DC current–voltage characteristics and the simulation results done with the extracted parameters are shown in Fig. 13. This figure shows a good match between them. Using these DC parameters, the AC characteristics of the model are also fit to the measurements, shown in Fig. 12.

The experimental and simulation results of the charge pump circuit in Fig. 12 are mostly in agreement. The observable mismatch between the experimental measurements and the simulation results, visible in the 7 V, 6 V and 5 V curves in Fig. 12, can be explained by the fact that the diodes are not under high enough electric fields at these voltage values to meet the SCLC condition that is assumed in this model [22]. For a peak voltage of 7.5 V and an estimated polymer thickness of 750 nm, the electric field becomes 10^5 V/cm, residing in the reported regime where SCLC becomes dominant for P3HT [22]. Above this voltage, i.e. for 8 V, 9 V and 10 V curves in Fig. 12, the featured SCLC model is highly accurate.

Following these tests, charge pump circuits using various capacitor sizes are built and tested. For different charge

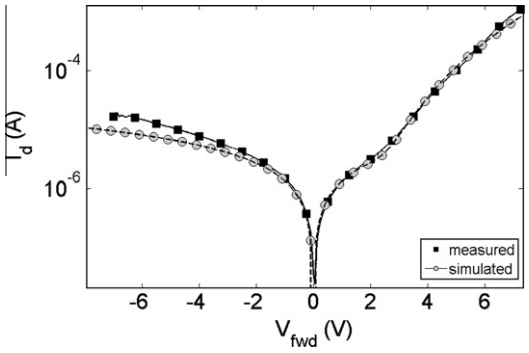

Fig. 13. Simulated and measured DC current–voltage characteristic of the fabricated vertical diodes.

pump capacitors, output voltages are measured as the frequency of the applied AC signal with a peak voltage of 10 V is changed. The results are summarized in Fig. 14. A drastic reduction in output voltage is observed as the pump capacitors are lowered from 68 nF to 10 nF, implying that the stray capacitance is relatively close to, but smaller than 10 nF, since the circuit can still operate with 10 nF capacitors. Simulation results using the diode model are also plotted on this figure.

It is observed that the model parameters fitted for diodes of the charge pump circuit with a fixed capacitor of 470 nF given in Fig. 12 do not fit accurately to the results of the output voltage measurements done using lower pump capacitors such as 68 nF and 10 nF shown in Fig. 14. Variances between the model parameters that are used to fit the former and latter measurements, the 470 nF and 10–68 nF cases, respectively, are reported in Table 1. *CJO*, *N* and *IS* are SPICE parameters defining the diode, and parameters *B* and u_0 belong to voltage dependent mobility element, electric field prefactor and zero-field mobility, respectively. This inaccuracy can be attributed to the degradation of the aluminum-P3HT interface with prolonged usage. The blisters that are induced due to electrical bias stress cause imperfections within the metal–semiconductor interface, where Schottky contact occurs. Since the initial measurements are made using

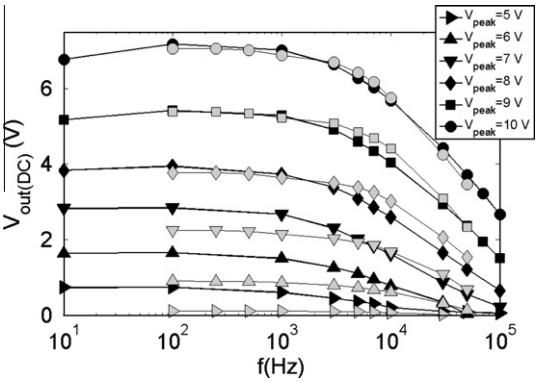

Fig. 12. V_{out} vs. frequency plots for various V_{peak} values of the AC input, C_{pump} = 470 nF. Simulation results are in grey and measurement data in black.

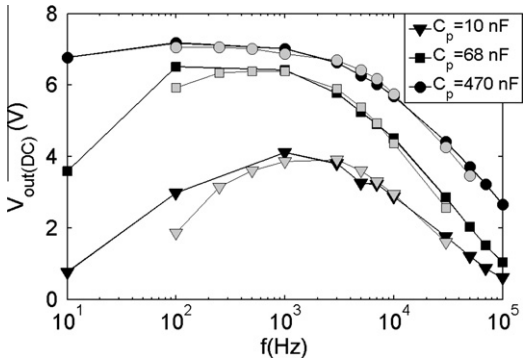

Fig. 14. V_{out} vs. frequency plots for various pump capacitors using AC signals with peak voltages of 10 V. Simulation results are in grey and measurement data in black.

Table 1
Varying model parameters used to fit two separate measurement runs; 470 nF and 68–10 nF cases.

Parameters	470 nF	10 nF & 68 nF
CJO	0.1n	0.5n
N	10.5	11.5
IS	2.5e−14	25e−14
B	1.25e−2	1.8e−2
u_0	1.75e−6	0.2e−6

470 nF capacitors, the model parameters that are required to fit the simulation results to the measurements are closer to the ideal than the latter charge pumps tested with 68 nF and 10 nF capacitors, using degraded diodes from previous use.

The expected effects from the increased number of defects due to the deterioration of the aluminum-P3HT interface include charge trapping within the defects and increased dependence of mobility on electric field. Charge trapping effects observed in similar vertical structures of aluminum-P3HT diodes have been modeled as capacitors parallel to depletion capacitor in the literature [25]. Trapping action due to the increased number of defect sites is incorporated into the junction capacitance in our model as an approximation, the reason being that the defects are occurring at the aluminum- P3HT interface where depletion capacitance also forms, increasing the overall junction capacitance in the deteriorated diode samples.

In addition to the measurements showing how the output voltage of the charge pump circuit changes with the frequency and the peak voltage value of the AC input, ramp-up times of charge pump circuits with various capacitor sizes are investigated. The operation of the charge pump may require a rapid rise time to the final output voltage value. For example in an RFID scenario, the reception of the RF signal must result in the power-up of an RFID tag as soon as possible or data might be lost during the process. Measured ramp-up times are shown in Fig. 15 for an input AC signal with a peak voltage of 10 V at 1 kHz frequency. The final output voltage is reached within 9.4 ms in charge pumps that used 10 nF, 32.5 ms for 68 nF and 205 ms for 470 nF designs. The ramp-up time for 470 nF case is much greater than 68 nF and 10 nF cases, and might be slow even for polymer electronics applications. The final DC levels reached in this figure are close to each other for the charge pump circuit with 470 and 68 nF capacitors, similar to the results in Fig. 14. However, charge pump circuit with 470 nF capacitors has smaller ripple voltages than the one with 68 nF.

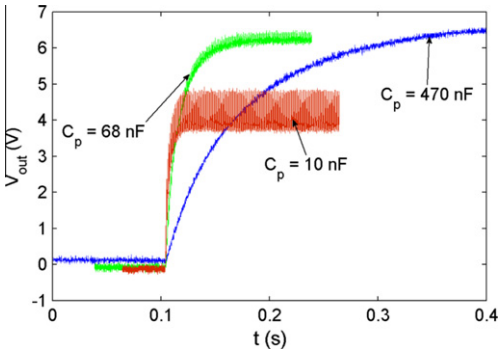

Fig. 15. Ramp-up waveforms for charge pumps built with various pump capacitors, with oscilloscope data for 470 nF, 68 nF and 10 nF cases superposed for comparison purposes. AC input signals are applied with a peak voltage of 10 V at frequency of 1 kHz.

5. Results and discussion

Experimental results from the lateral and vertical diodes reveal that the deterioration in their performance when operated under atmospheric conditions is drastic. This emphasizes the importance of packaging the devices under inert atmosphere, thus preserving the diodes in their best states. Considering that current–voltage characteristics that approximate an ideal switch is pivotal in the operation of the charge pump circuit, packaging process becomes as important as the design of the charge pump.

The thermal experiments reveal that both lateral and vertical diodes benefit from increased temperatures within a certain range. It is determined that the on/off ratios of the diodes improve invariably when the ambient temperature is raised from room temperature to 120 °C. This improvement in performance has been explained by the thermal activation of trap states formed by the boundaries between grains of polymer. Improvement in on-current is not sustained when the diodes are brought back to room temperature, therefore it is reasoned that thermal annealing does not take place within the temperature range that is used during the experiments.

The charge pump built using vertical polymer diodes in this work is considered to be the building block of larger charge pumps. The best case output voltage expected from the charge pump is, according to Eq. (3), twice the difference between AC input peak voltage and the turn-on voltage of the diodes. The output voltage can be improved by a peak voltage much larger than the turn-on voltage of the diode, which is roughly around 5 V in this work, and charge pump capacitors much greater than the stray capacitances, including the junction capacitances of the diodes. To ensure the best case condition in terms of capacitances, 470 nF capacitors are used, diminishing the effect of stray capacitances. For a peak voltage of 10 V, expecting an output load current of around 10 μA, the best case output voltage would be 9.6 V from this single stage charge pump. In meeting the above conditions, we have observed output voltages of 7.2 V between 100 Hz and 1 kHz frequency range, 75% of the calculated best case output voltage of the single stage charge pump under these conditions. The probable source of error is the parasitic internal resistances and capacitances of the diodes formed as a result of deterioration, which is caused by impurities inside under electrical bias stress. This causes the diodes to further deviate from the desired ideal switch behavior.

Another consideration is that the vertical diode with dimensions of 2 mm × 0.5 mm is able to adequately supply currents within milliampere range but only tens of microamperes is required by the following electronic circuit composed of polymer transistors. Excessive diode area does not help if the extra current is not used by the circuit

at the load. In fact an excessively wide device area introduces larger stray capacitances to the charge pump, shares the charge that would otherwise be stored entirely on the pump capacitors and reduces the high frequency performance of the design, as reported in the literature for P3HT rectifiers [7]. Therefore, a minimal diode area that satisfies the design objectives must be sought for, without neglecting some additional device area to safely meet any possible fabrication error.

Even though the output voltage of this circuit is lower than expected due to the high turn-on voltage of the diodes, internal diode resistances and capacitances that are the result of the deterioration of the exposed P3HT and high stray diode capacitances, cascading a number of stages of such cells would recover the loss in voltage in the expense of efficiency and frequency response. The cascading of multiple cells of charge pump is not preferable, but might be necessary for matching purposes [4]. The number of stages in a charge pump, as well as its loading and its operation frequency, controls its input impedance [4,5], and by adjusting the input impedance of the charge pump, impedance matching to the antenna that drives the charge pump can be achieved in an RFID application.

Simulation models based on SCLC theory are shown to be accurate under high electric field conditions, given that necessary adjustments to the model are made to adapt the models for the physical deterioration that can be observed after prolonged electrical bias stress. It is determined that by increasing the diode capacitance and the ideality factor of the diode, along with increasing the electrical prefactor (to make the diode current more dependent on the applied voltage) and decreasing the zero-field mobility, as expected when physical defects are introduced to the aluminum-P3HT interface, the degradation effects can be expressed within the SCLC model. DC current–voltage characteristics of P3HT diodes are modeled using a similar approach [22], and we demonstrate that the SCLC model featured in this work is also accurate and practical for the transient simulation of P3HT diodes at varying frequencies.

Along with their potential use in future polymer RFID tags, the charge pump is also attractive for other battery-powered, portable polymer electronics applications where very high voltages would be needed for device operation but supplying such amplitudes from conventional batteries would be impractical. In such devices, such as flexible polymer displays and micromachined capacitive actuators, polymer charge pumps could be implemented on plastic substrate without using additional, dedicated integrated charge pump chips or charge pumps built from discrete elements, which would cause the cost of such a system to rise noticeably. The frequency limitations of the multi-stage charge pump would become less of a problem in such systems since a steady DC voltage would be all that is needed, in contrast with the RFID data transmission problem.

6. Conclusion

Lateral and vertical polymer diodes have been fabricated using P3HT. Evaluations of the performances of the diodes were done under elevated temperature and vacuum/atmospheric exposure. Performances of air exposed lateral diodes improved continuously under vacuum since there was no metal film covering the polymer film. However, air exposed vertical diodes under vacuum and prolonged operation at atmospheric conditions showed deteriorated performances. Blistering of the vertical diodes was observed with electrical bias stress; and although the blistering was observed to be extensive under vacuum and air exposure, the performance of the devices operated under argon did not seem to suffer too much. Performances of both the lateral and vertical diodes under argon environment improved steadily when the ambient temperature was raised from room temperature to 120 °C. This was due to the thermal activation of trap states formed by the boundaries between grains of polymer. Improvement was not sustained when the diodes were brought back to room temperature indicating that thermal annealing did not take place. It was determined that protecting the device from atmospheric elements was necessary to preserve their current–voltage characteristics.

Circuit models have been developed for the vertical diodes. Transient simulations of P3HT diodes using SCLC model were demonstrated. Fabricated charge pumps using vertical diodes and various capacitors revealed similar results as the models predicted. Charge pump circuits were able to generate DC voltages from AC voltages in the frequency range from 100 Hz to 10 kHz. Generated DC voltage level was lower than ideal because of the high turn-on voltages of the diodes and their internal parasitic resistances and capacitances.

The simulation model was implemented in HSPICE and was practical to use. However, some modifications might be required to cover the smaller voltage amplitudes. Degradation effects that were observed under prolonged use of polymer diodes were incorporated into the model by modifying certain model parameters, which produced results consistent with experimental measurements.

ABSTRACT

Blue top-emitting organic light-emitting devices (TEOLEDs) based on blue phosphor iridium (III) bis[(4,6-difluorophenyl)-pyridinato-N,$C^{2\prime}$] picolinate (FIrpic) are demonstrated. Instead of using microcavity effects to obtain the blue top emission in conventional reports, the blue emission with a good chromaticity is achieved in this paper through the suppression of the multiple-beam interference by introducing a 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline light outcoupling layer onto the semitransparent Sm/Ag cathode. The electroluminescent performances of the blue emission is further improved based on the effective carrier transport and the consideration of the wide-angle interference at the emission peak of FIrpic with a maximum luminance of 8029 cd/m^2 and a luminous efficiency of 4.02 cd/A achieved at 14 V and 10 V, respectively. With a polarizer on the top cathode, a high pixel contrast ratio of 113:1 is realized under an ambient illumination of 140 lx and a pixel brightness of 1000 cd/m^2.

1. Introduction

Full-color organic light-emitting devices (OLEDs) can be constructed in different ways, e.g., patterning pixels with the three principle colors (blue, green, and red) or with the blue and orange–yellow complementary colors, white OLEDs with color filters [1,2], etc. It is obvious that blue light emission plays a key role in the manufacture of full-color displays [3]. Compared with the conventional bottom-emitting OLEDs (BEOLEDs), top-emitting OLEDs (TEOLEDs) are much more suitable for active matrix OLEDs applications, since the thin film transistors (TFTs) are buried below the bottom reflective anode and the light is extracted from the top semitransparent cathode. Besides, the TFTs can be largely increased without reducing the aperture ratio (AR) in TEOLEDs. However, due to the commonly used highly reflective metal as both cathode and anode, microcavity effects exit inevitably in TEOLEDs. The resonant wavelength corresponding to the major peak wavelength of blue emission is much thinner or thicker than that of red or green emission, which means it is easily broken down under a high bias or needs a high operating voltage. A common solution to this problem is fabricating blue TEOLEDs by introducing a thickness-adjustable ITO on the bottom reflective layer to fit the optical length of blue emission [4–7]. In our work, the blue TEOLEDs are obtained by using a suitable thickness of a 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) layer as a light outcoupling layer onto the semitransparent top metal cathode, with which a low reflectivity of the top cathode is achieved with desirable suppression of multiple-beam interference in devices [8,9]. In addition, it is worth mentioning that the blue light electroluminescent (EL) performance can be further improved by optimizing the

doi:10.1016/j.orgel.2010.11.018

thickness of the organic multilayer sandwiched between the emissive layer and the bottom reflective anode to satisfy wide-angle interference at the emission peak of iridium (III) bis[(4,6-difluorophenyl)-pyridinato-N,$C^{2\prime}$] picolinate (FIrpic). Furthermore, it is known that the high reflection of the metal cathode also leads to a strong reflection of ambient light with a result of a low pixel contrast ratio (PCR) in TEOLEDs [10,11]. In this paper, the PCR is obviously improved by using the BCP light outcoupling layer together with a polarizer.

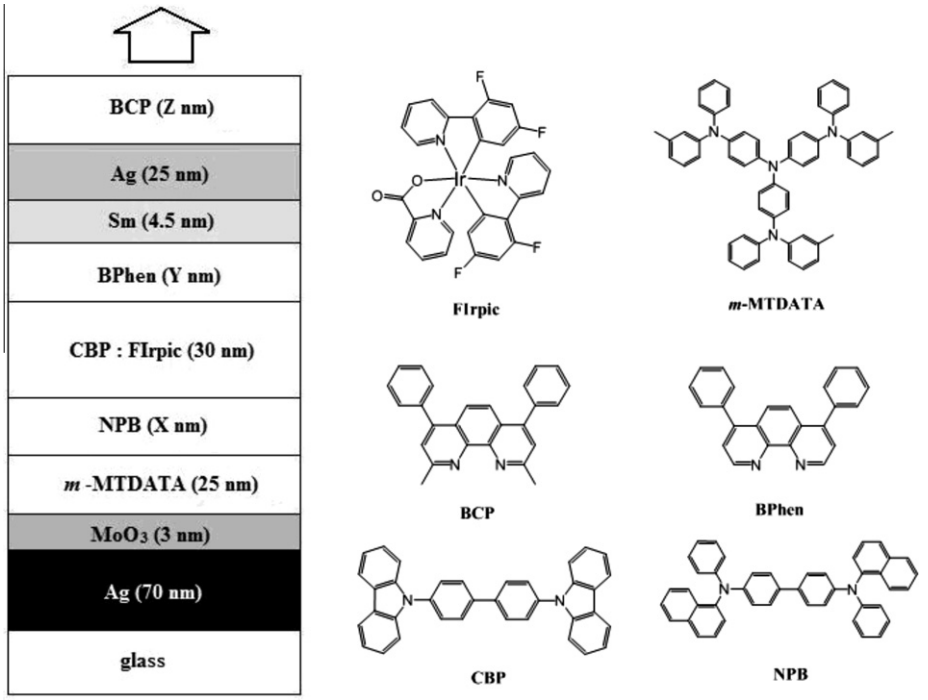

Fig. 1. Schematic configuration of TEOLEDs and chemical structures of materials used in this paper.

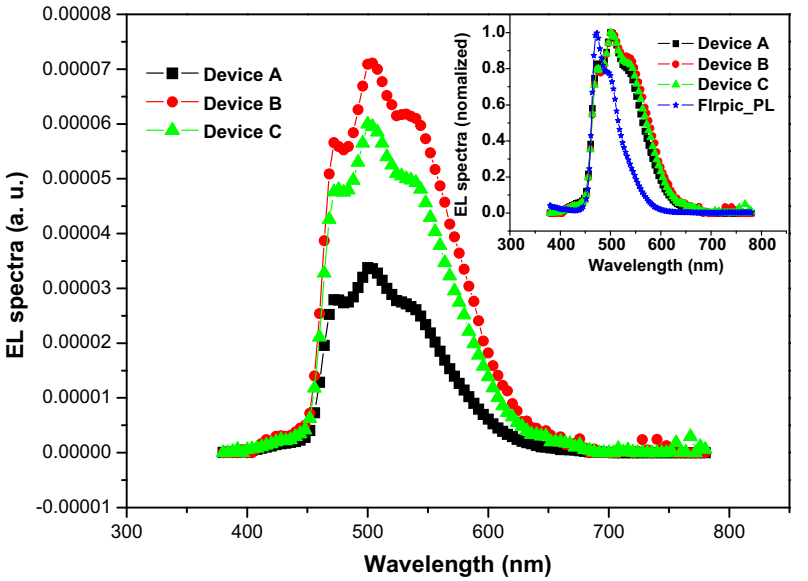

Fig. 2. The EL spectra of devices A, B, and C under the current density of 1 mA/cm^2. Inset: normalized EL spectra of devices A, B, and C at the same current density of 1 mA/cm^2, and the measured PL spectra of the blue phosphor FIrpic in a solid film state.

2. Theory calculation

The resonant wavelength that corresponds to multiple-beam interference satisfies Eq. (1) [12,13]:

$$\frac{2\pi}{\lambda}\sum 2n_m d_m \cos\theta - \Phi_1(\lambda) - \Phi_2(\lambda) = k2\pi. \quad (1)$$

Here, λ is the resonant wavelength, n_m and d_m are the refractive index and the thickness of the mth organic layer between the two electrodes, respectively, θ is an angle in the spacer layer (here, 0° is perpendicular to the electrode plane), $\Phi_1(\lambda)$ and $\Phi_2(\lambda)$ are the phase changes on reflection corresponding to the opaque anode/organic material and the organic material/semitransparent cathode, and k is the mode number.

In a TEOLED, when only the wide-angle interference is taken into account, Eq. (1) can be simplified by ignoring $\Phi_2(\lambda)$ and only the organic layers between the emission area and the reflective anode are under consideration.

The PCR of a device is calculated with Eqs. (2) and (3) [10,14]:

$$PCR = \frac{L_{on} + LR_L}{L_{off} + LR_L}, \quad (2)$$

and

$$R_L = \frac{\int_{\lambda_1}^{\lambda_2} V(\lambda)S(\lambda)R(\lambda)d\lambda}{\int_{\lambda_1}^{\lambda_2} V(\lambda)S(\lambda)d\lambda}. \quad (3)$$

Here L_{on} and L_{off} are the brightness of a pixel at on- and off-state, respectively, L is the ambient illumination, R_L is the luminous reflectance, $V(\lambda)$ is the standard photometric curve, $R(\lambda)$ is the optical reflection of the device, and $S(\lambda)$ is the D65 light source.

3. Experimental

Our blue TEOLEDs were grown on glass substrates. Prior to the device deposition, the substrates were cleaned with acetone and ethanol by using an ultrasonic bath, rinsed with deionized water, and then dried in an oven. The TEOLED structure was glass/Ag (70 nm)/MoO_x (3 nm)/4,4′,4″-tris(3-methylphenylphenylamino)triphenylamine (*m*-MTDATA, 25 nm)/N,N′-bis(naphthalen-1-yl)-N,N′-bi (phenyl)-benzidine (NPB, X nm)/4,4′-bis(carbazol-9-yl)-biphenyl (CBP): FIrpic (7 wt.%, 30 nm)/4,7-diphenyl-1, 10-phenanthroline (Bphen, Y nm)/Sm (4.5 nm)/Ag (25 nm)/BCP (Z nm), as shown in Fig. 1. Here, *m*-MTDATA, NPB, CBP, FIrpic, BPhen, and BCP were utilized as a hole injection layer, a hole transport layer, a blue host, a blue phosphorescent guest, an electron injection and transport layer, and a light outcoupling layer, respectively, whose molecule structures were demonstrated in Fig. 1. Ag and MoO_x were utilized as the anode and the hole injection layer, respectively. The Sm/Ag bilayer was utilized as an effective cathode due to Sm's low work function of ~2.7 eV and relatively high transparence in the visible range and Ag's environmental stability. All depositions were finished in a high vacuum about 10^{-6} Torr with a rate of 0.1–0.3 nm/s. Current density–voltage–luminance characteristics of the devices were measured with a Keithley 2400 source measurement unit and a Photo-Research PR-655 SpectraScan Colorimeter in room-temperature air. The reflectivity characteristics of devices were measured with a Shimadzu UV3600 spectrometer at 25 °C. The photoluminescence (PL) spectra of the blue phosphor FIrpic were measured with a Shimadzu RF-5301PC.

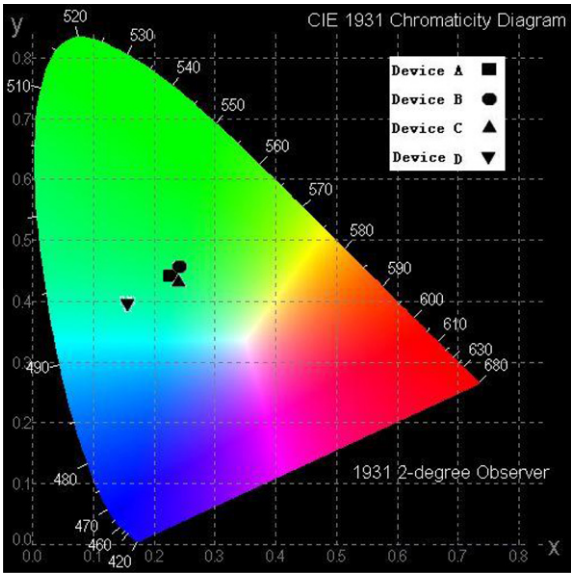

Fig. 5. CIE coordinates of devices A–D.

To realize wide-angle interference at the emission wavelength of FIrpic with a main peak wavelength of 472 nm, the total thickness of *m*-MTDATA and NPB is calculated with Eq. (1), where the exciton recombination zone is supposed at the NPB/CBP interface and the NPB thickness is adjustable. The total thickness of the organic multilayer keeps invariable and is fixed at 105 nm, so the BPhen layer thickness changes simultaneously accompanying with that of the NPB layer.

4. Results and discussion

In a cavity device, both wide-angle and multiple-beam interference have effects on the EL performances, especially for those devices when one electrode has a high reflectivity and the other has a low reflectivity. From Eq. (1), the calculated NPB thickness that satisfies the wide-angle interference at the blue emissive peak wavelength of FIrpic is 10 nm (Suppose that the excitons are generated at the NPB/CBP interface and the recombination area is just at the interface). Considering of the exciton diffusion, several devices are fabricated with different NPB thicknesses of 5 (Device A), 10 (Device B), and 15 nm (Device C). Fig. 2 demonstrates the EL spectra of devices A, B and C under the current density of 1 mA/cm^2, from which one can observe the EL intensity mainly caused by the wide-angle interference and balance of exciton formation. In the Fig. 2, which have a main peak of 502 nm with two shoulders of ~472 and ~540 nm is observed. The shoulder peak at 472 nm originates from native emission of FIrpic, while the other shoulder peak at 540 nm can be attributed to the multiple-beam interference, which is well matched with the calculated result of 542 nm. The main peak of 502 nm is resulted from the overlap of peak values of 472 and 540 nm together with the intrinsic minor shoulder of FIrpic at 500 nm (The PL spectra of FIrpic are in the inset of Fig. 2). The normalized EL spectra of device A, B, and C are shown in the inset of Fig. 2, from which we find device A exhibits the highest intensity at the peak value of 472 nm among all devices. Compared the experimental data with the theoretical one, we deduce the major exciton recombination area is not at the NPB/CBP interface, but in the CBP host and the site is 5 nm away from the interface (considering NPB and CBP have similar refractive indexes). In other words, it satisfies the wide-angle interference at the blue emissive peak wavelength of FIrpic in device A, which can be further proved by a better chromaticity (0.22, 0.45) in device A in the blue emission area, while the corresponding Commission International de L'Eclairage (CIE) coordinates (Fig. 5) for devices B and C are (0.24, 0.47) and (0.24, 0.46) at 10 V. Here, we conclude the exciton diffusion length in our blue emission devices is about 5 nm and we also find the wide-angle interference is weak although to some extent it affects the chromaticity coordinates. Moreover, from Fig. 2, we find the fact that the intensity of the EL spectra from device B is larger than those from devices A and C in the whole emission range, which indicates the thickness changes of NPB and BPhen influence the carrier transport. It exhibits a better transport ability in the structure of device B than those in devices A and C. As a result, both the carrier transport ability and the wide-angle interference affect the EL performances, where the former plays a more important role. The current density–luminance–voltage (J–L–V) and luminous efficiency–external quantum efficiency–current density (η–EQE–J) characteristics of devices A, B, and C shown in Fig. 3a and b also prove the result. Devices A, B, and C achieve their maximum luminance of 3420, 4687, and 3946 cd/m^2 at 14 V, and their maximum luminous efficiency are 1.45 (at 28.2 mA/cm^2), 2.69 (at 20.7 mA/cm^2), and 2.44 cd/A (at 23.8 mA/cm^2), respectively. Devices A, B, and C achieve their maximum EQE of 0.51% (at 29 mA/cm^2), 1.18% (at 21 mA/cm^2), and 0.905% (at 25 mA/cm^2), respectively. Device B demonstrates a best η–EQE–L performance among all the devices, mainly due to the effective transport of holes and electrons by adjusting the NPB and BPhen thickness and more excitons generation in device B.

The multiple-beam interference exists inevitably in devices A–C due to a relatively high reflectivity of the Sm/Ag cathode, as shown in Fig. 4, which results in the CIE coordinates apart from the blue light emission, as shown in Fig. 5. For further improvement of light outcoupling and reduction of the reflectivity of the Sm/Ag cathode, a BCP layer is introduced in the devices, aiming for suppressing

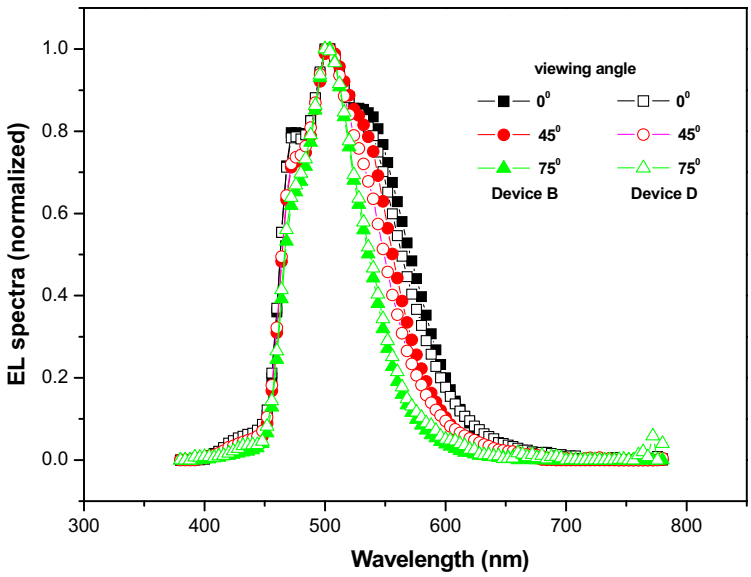

Fig. 6. EL spectra for devices B and D with viewing angles of 0°, 45° and 75°.

the multiple-beam interference in the devices. The optimization of the BCP layer thickness is based on device B with the NPB and BPhen thickness of 10 and 40 nm, respectively, since its EL performance is the best among all the devices. Since the exciton recombination and light generation takes place predominantly in the blue dopant layer and about 5 nm away from the NPB/CBP interface, light passes through the multilayer system of CBP (25 nm)/BPhen (40 nm)/Sm (4.5 nm)/Ag (25 nm)/BCP (if with) and then escapes from the Sm/Ag cathode of TEOLEDs, where the effect of the FIrpic dopant on refractive index of the CBP host is neglected. The transmittivity (T) and reflectivity (R) of the multilayer system with different thicknesses of the BCP layer are calculated with transfer matrix theory [15] and the transmittivity and reflectivity curves are shown in Fig. 4. Without a BCP layer, the *R* value is 49.3% at 472 nm (the emissive peak wavelength of FIrpic), while *T* value is 30%. The *R* value of the blue TEOLED gradually decreases and *T* increases with the increasing thickness of the BCP layer. Balancing the aspiration of achieving higher *T* and lower *R* simultaneously round 472 nm, the BCP thickness that we employ is chosen to be 35 nm.

Device D corresponding to device B is covered with another 35 nm-thick BCP light outcoupling layer, with which a low reflectivity of the cathode at the blue emission region can be achieved. As can be seen in Fig. 5, the CIE coordinates of device D show better chromaticity than those of device B without a BCP layer. The effective suppression of multiple-beam interference in device D, as shown in Fig. 5, leads to the blue shift of the CIE coordinates changing from (0.24, 0.47) to (0.17, 0.40), which is comparative to those of the blue BEOLEDs [16]. The EL spectra of devices

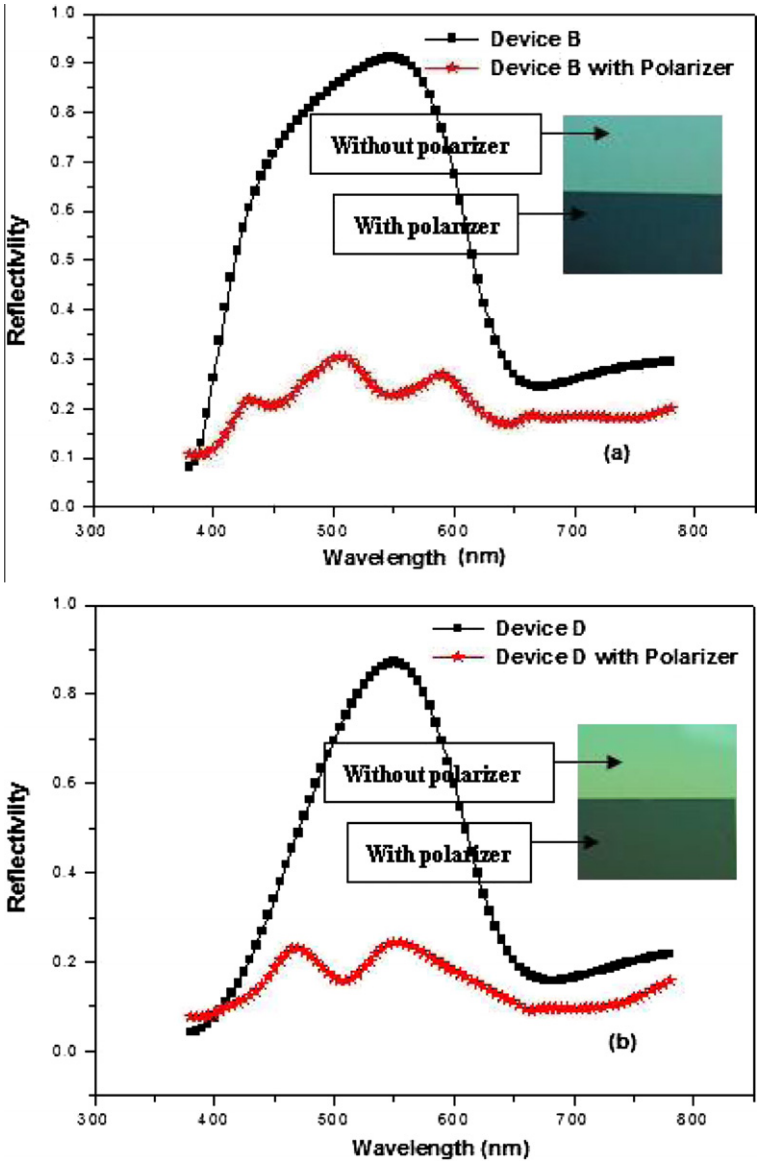

Fig. 7. Luminous reflectance of devices B (a) and D (b) with and without a polarizer. Inset: photographs of devices B and D with and without a polarizer under environmental lighting.

B and D with different viewing angles of 0°, 45°, and 75° are also compared in Fig. 6. From the figure we observe an obvious suppression of multiple-beam interference in device D until 75°. In addition, the utilization of an additional BCP layer results in 1.7 and 1.5 times improvement for L (Fig. 3a) and η (Fig. 3b) in device D, reaching 8029 cd/m^2 at 14 V and 4.02 cd/A at 25 mA/cm^2, respectively.

As an important parameter in full-color display applications, PCR is also explored in this paper. Fig. 7a and b gives the $R(\lambda)$ curves of devices B and D with or without a polarizer on the top cathode. With the on-state brightness and ambient illumination are 1000 cd/m^2 and 140 lx, respectively, the PCR of device D with the 35 nm-thick BCP layer is 32:1, which is almost the same with that of device B without a BCP layer (29:1). To enhance the PCR of the devices, we add a polarizer on the top cathode of the blue TEOLEDs. The PCRs increase to 92:1 and 113:1 for devices B and D, respectively, about 4 times of the corresponding devices without a polarizer layer. Such high-contrast TEOLEDs incorporated into active matrix OLED displays would possess a good readability under a strong ambient illumination.

5. Conclusion

In summary, we fabricate blue TEOLEDs based on the blue phosphor FIrpic. Through suppressing the multiple-beam interference with the utilization of a BCP light outcoupling layer and considering the wide-angle interference, an improved blue emission with a maximum luminance of 8029 cd/m^2 and a luminous efficiency of 4.02 cd/A is obtained. The better chromaticity of the blue emission in the TEOLED with the CIE coordinates (0.17, 0.40) is also achieved, which is comparative to those of the blue BEOLEDs. In addition, the device with a BCP light outcoupling layer shows a high PCR of 113:1 by adding a polarizer on the top of the device under an ambient illumination of 140 lx and a pixel brightness of 1000 cd/m^2. Such high-contrast TEOLEDs incorporated into active matrix OLED displays would possess a good readability under a strong ambient illumination.

ABSTRACT

We have measured the charge transfer processes on near IR small molecule solution processes solar cells under working conditions. The results show that there are two different behavior, for the device under working conditions, controlled by the intrinsic properties of the organic bulk-heterojunction phase to store charges at the different organic materials. Furthermore, our recombination kinetic studies show the origin of the photovoltage on these thin organic devices (80 nm thick) and the reason for the difference between the observed open circuit cell potential and the theoretical expected value based on the LUM-OPCBM–HOMO phthalocyanine difference.

1. Introduction

Solar cells based on organic molecular materials are currently undergoing intense research due to their expected low cost for the production of electrical energy [1–10]. Amongst the different molecular photovoltaic devices, small molecule organic solar cells (sMOSC) offers the possibility to be fabricated either by sublimation under high vacuum or by solution processing both techniques already implemented in commercially available optoelectronic devices [11–15]. However, solution processing allows the preparation by ink-jet printing or roll-to-roll coating, with the advantage of cover large area, and fine tuning of the morphology by changes on the solvent for example.

The best efficiencies of sMOSC reported to date contain a fullerene derivative as acceptor, the well known PCBM ([6,6]-phenyl-C61-butyric acid methyl ester). However PCBM contribution to the device light harvesting efficiency is rather small and hence a broad and intense absorption is a must from the donor material. Based on semi-empirical calculations organic photovoltaic devices based on PCBM as acceptor are predicted to have an efficiency of 10% [16]. Although attempts to increase the device photocurrent have been made by using C_{70} based PCBM as electron acceptor material the photocurrent generated is limited by the low molecular absorption extinction coefficient of the material [17]. Thus, the use of electron donor organic molecules with small band-gaps and high molecular absorption extinction coefficient are desirable for efficient photon harvesting in the near IR region of the solar spectrum with the subsequent increase in photocurrent

[18,19]. There are few studies using molecules with a strong absorption on the near IR and great efforts are currently being made to obtain low bandgap polymers with absorption spectra shifted towards the IR [20–22]. For example, Inganäs et al. published devices with light-to-energy conversion efficiencies of 0.3% using a polymer as electron donor material with light absorption close to 800 nm [20,23,24]. Cao and co-workers increased the efficiency to 0.7% in similar conditions [25], but the record was achieved by Heeger et al. with a 5.5% efficiency [26]. However, less attention have been focused on the use of phthalocyanines as electron donor materials in sMOSC [27,28]. Nevertheless, the use of Zinc phthalocyanines (ZnPc) in organic small molecular solar cells using high vacuum sublimation techniques has paved the way towards light-to-energy conversion efficiencies as high as 7.7% [29,30].

A recent result, using functionalized dendritic oligothiophene Ruthenium phthalocyanines with PCBM in bulk heterojunction devices [31], showed the potential of Ruthenium phthalocyanines as efficient electron donor for near IR sMOSC and fuelled our interest to investigate the possibility to obtain similar efficiencies with less synthetically demanding phthalocyanine based sensitizers. Thus, in this manuscript we aim to evaluate the use of a symmetrical Zinc phthalocyanine (Zinc 2,9,16,23-tetra-tert-butyl-29H,31H-phthalocyanine, (Scheme 1a) which have several advantages for sMOSC such as: (i) easy to synthesize and purify, (ii) possible to obtain in multi-kilogram scale and (iii) soluble in organic solvents with an intense absorption in the near IR [32]. Moreover, ZnPc molecules have a series of structural properties that favor their use as electron donor materials in sMOSC such as: (a) the formation of π–π stacking units which could lead to the formation of nanoscopic

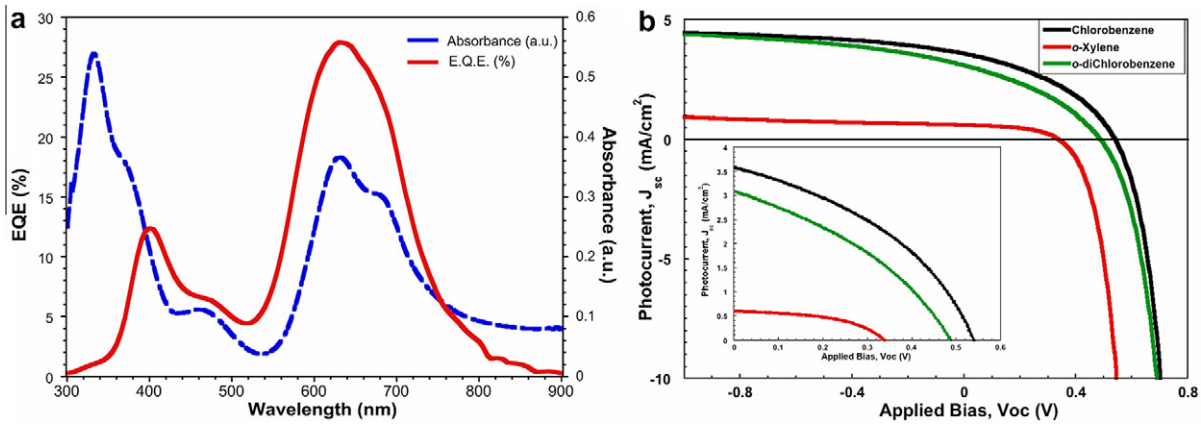

Fig. 1. (a) Absorption of ZnTBPc:PCBM blend film (dashed blue line) on top of PEDOT:PSS covered ITO substrate, prepared as for efficient devices and the external quantum efficiency, EQE, measurement (red line) of a complete device. (b) Characteristic photocurrent–voltage curves for our ZnTBPc/PCBM sMOSC when cast from different solvent solutions. The inset is a magnification of the first quadrant of the IV characteristics. routes for the transport of polarons to the device metal contact, (b) the molecular symmetry, which promotes charge delocalization, thereby minimizing Coulombic repulsions, and (c) its ability to undergo oxidation at mild potentials to give a long lived radical cation. Furthermore, we measured and analyzed the interfacial charge transfer reactions in complete devices under working conditions to obtain additional information, which could be used for further device improvement. The ZnTBPc:PCBM film absorption spectrum, Fig. 1a, extends from the visible (λ = 400 nm) to the near IR region of the solar spectrum (λ = 800 nm) with a prominent maximum at a wavelength of λ_{max} = 630 with a molar extinction coefficient ε = 50,000 L mol^{-1} cm^{-1} [32]. For comparison purposes absorption spectrum is plotted with the measured external quantum efficiency (EQE), which refers to the efficiency of the device to convert absorbed light into free carriers and collect them at the device electrodes. It is clear that the EQE follows the same trend as the absorption spectrum and no ground state additional charge transfer bands are observed. We want to stress the fact that the sensitivity of our system might not be high enough to observe subgap charge transfer bands, which are typically low level signals [33–35]. The higher absorption in the 300–350 nm region of the spectrum is assigned to the transparent conducting glass based on Indium-doped Tin Oxide (ITO).

It is worthy to notice that, despite the thin film thickness of 60 nm, an EQE of ca. 30% is obtained, which corresponds to a theoretical photocurrent of 3.6 mA cm^{-2} when integrated using the 1.5 AM G solar spectrum as a reference for the device made using chlorobenzene as solvent. This thickness was found to be the optimum during the thickness optimization process, and is in agreement with the results found in ZnPc/C60 evaporated devices [36].

Fig. 1b illustrates the current density versus voltage (J–V) curve for the ZnTBPc/PCBM sMOSC upon illumination at 100 mW/cm^2 using sun-simulated light with the standard 1.5 AM G spectrum. The use of the correct organic solvent was critical to achieve the efficiency reported above. Table 1 shows the power conversion efficiencies for the devices made using different organic solvents. As can be observed, the use of chlorobenzene (CB) gives the best efficiency while *o*-Xylene (OX) shows very poor device performances. Table 1 shows the most relevant parameters for the different devices. The origin of this differences were evaluated by morphology measurements using Atomic Force Microscopy (AFM) Fig. 2. An apparent formation of homogeneously distributed holes in the film appear as a main feature when tapping mode was used to measure the surface morphology. The origin of this holes is intrinsic to the film formation, as they are also present in not thermally treated films. The poorer performance of devices prepared using *o*-dichloro benzene (ODCB) when compared to CB can be ascribed to a bigger hole formation, as better performance was obtained using CB. In the case of CB and OX the holes were significantly smaller than with ODCB. Also between the last two it can be seen that OX has a higher hole density, which might partially explain the poorer device performance when compared to CB. The solvents investigated herein were chosen because allow good solubility for both donor and acceptor molecules. As AFM only shows surface features, Differential Scanning Calorimetry (DSC) and Bright-field TEM were also used to investigate differences in crystallization of the films prepared with different solvents, respectively. For the DSC analysis, solutions of ZnTBPc/PCBM in different solvents were dried on the crucible where DSC was measured. The DSC results can be found at the Supporting information document Fig. S1. The results did not show significant differences at the crystallization temperature, with peaks at 110 °C. However the crystallization peak for the OX film was half intense than what it was obtained for the chlorinated solvents, which means a hindered crystallization after the annealing process. Therefore crystallization temperature in the film remains constant after the annealing step independently on the solvent used, but [37] not the final morphology which is indeed induced by the solvent selection and determines the output energy of the device. In-deep details of the crystallinity were also investigated using Bright-field TEM. The selected-area electron diffraction (SAED) patterns are consistent with our AFM and DSC results, and support our hypothesis that OX is less crystalline than CB and ODCB as it can be seen in the Supporting information Fig. S2, where less defined rings were obtained for the OX with respect to the CB and ODCB. The BF-TEM images show no segregation on the OX film, whereas for the chlorinated solvent prepared films an homogeneously distribution of aggregates are present, specially on the CB film where bigger domains were observed and from the IV-results such aggregates seems to be key for the overall device efficiency.

Once the characteristics of the blend and the device were analyzed we turned into the study of the interfacial charge recombination dynamics that limit the overall device efficiency. We focused only in the most efficiency device, which turns out to be the blend obtained by suing CB as solvent. The Fig. 3a illustrates the measured L-TAS spectrum of the film prepared using the same procedure as for complete devices. The spectrum taken 4 μs after the laser pulse excitation (λ_{ex} = 630 nm) exhibits an absorption peak at λ = 500 nm, which is assigned to the ZnTBPc radical cation species. The excitation at λ = 630 nm prevent direct excitation of the PCBM molecules [38].

Table 1
List of sMOSC J_{sc}–V_{oc} characteristics under 100 mW cm^{-2} 1.5 AM G simulated light.

Solvent	J_{sc} (mA cm^{-2})	V_{oc} (V)	Fill factor (%)	Efficiency (%)
Chlorobenzene	3.577 ± 0.005	0.539 ± 0.005	39.71 ± 0.05	0.765 ± 0.005
o-Xylene	0.602 ± 0.005	0.338 ± 0.005	48.68 ± 0.05	0.100 ± 0.005
o-Dichloro benzene	3.078 ± 0.005	0.489 ± 0.005	36.14 ± 0.05	0.543 ± 0.005

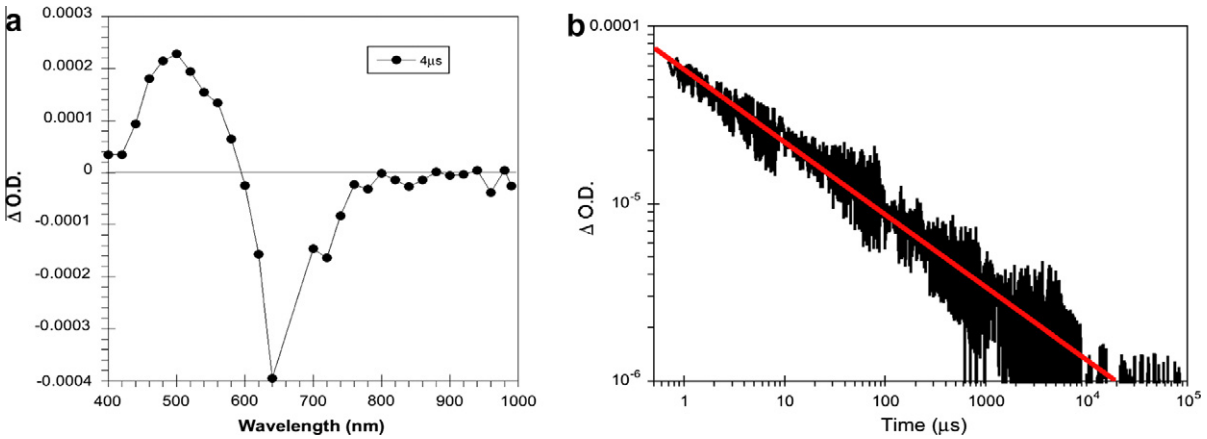

Fig. 3. (a) L-TAS spectrum upon excitation at 630 nm of a ZnTBPc/PCBM sMOSC after 4 μs. (b) Transient absorption decay obtained for a ZnTBPc/PCBM film (1:0.5 w.w. spin coated from chlorobenzene). The measured thickness was 50 nm after annealing at $T = 110\ ^{\circ}C$ for 10 min. Excitation wavelength was $\lambda = 630$ nm and the decay was monitored at $\lambda = 500$ nm. The solid line is the result of the fitting of the experimental data to a power-law exponential equation.

The time evolution of the transient signal optical density (ΔOD) at 500 nm was successfully fitted to a power equation of the form $\Delta OD = At^{-\alpha}$. The power-law decay Fig. 3b is characteristic of the bi-molecular charge recombination of long-lived, dissociated charged species in organic photovoltaic devices [39,40]. The exponent in the power equation was $\alpha = 0.5$ and the proportionality constant $A = 3.3 \times 10^{-8}$. The sub-unity value for α (α would be expected to equal 1 for ideal bimolecular recombination) has been discussed previously in terms of polaron trapping in a distribution of energetic traps at the tail of the Density of States (DOS) of the electron donor material and indicates the presence of bi-molecular charge recombination kinetics [39,41]. Yet, the presence of geminative recombination processes, that may also limit the device efficiency, cannot be discarded. The instrument response of our system did not allow us to measure kinetics faster than 500 ns.

To further verify a bimolecular recombination process, transient photovoltage measurements were carried out on complete devices. Both techniques allow the determination of charge densities and carrier lifetimes in working devices under standard operating conditions [42–44].

The total charge in the cell at V_{oc} was measured by "charge extraction" technique. In this method, a 1 sun white LED illumination source is turned off in <1 μs, while simultaneously, the cell is switched from open to short circuit. The resulting current, as the cell returns to $V = 0$ and $J = 0$, is integrated to give a direct measurement of the excess charge in the film. The number of charges measured is always smaller than real, given that some charges may recombine internally instead of traveling through the external circuit. This loss of charge will affect the magnitude of the curves, however the shape that is directly related with the DOS, will be the same, also previous studies showed an error lower than 10% when employing this technique on similar device structure [45,46]. Strikingly, the electron density rise linearly up to light biases of 500 mV Fig. 4a and from 500 mV to higher open circuit voltages (V_{oc}) an exponential increase is observed. Capacitance can also be measured by using $C = \Delta Q/\Delta V$. As observed in Fig. 4a, below 500 mV the capacitance is in

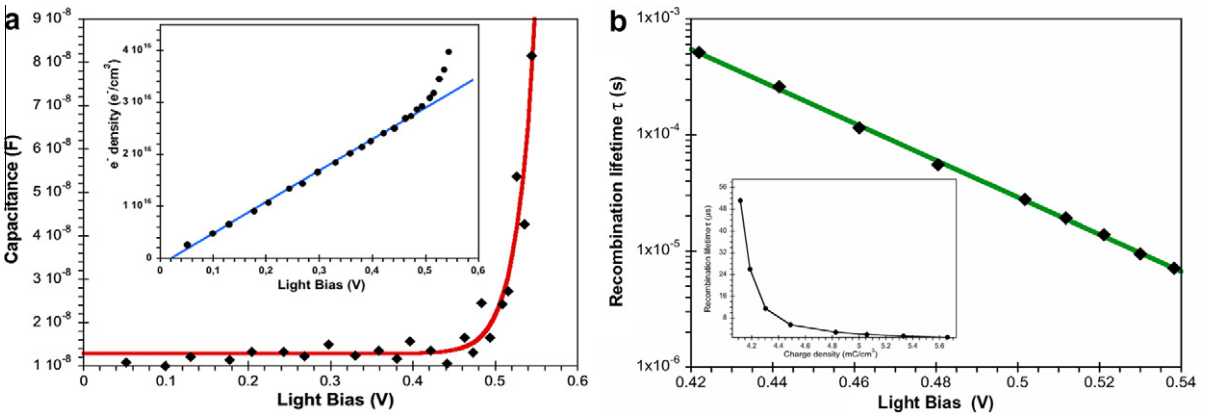

Fig. 4. (a) Capacitance of complete devices measured under standard operating conditions. The inset shows the electron density, measured with the charge extraction technique versus light bias induced open circuit voltage (V_{oc}). (b) Recombination lifetime at open circuit conditions extracted from fitting the transient photovoltage to a single exponential equation, the line corresponds to an exponential fit. The inset corresponds to small perturbation carrier lifetime as a function of charge density for V_{oc} from 570 to 420 mV, the solid line is a guide to eye.

the same range as the geometrical capacitance which is $\sim$15 nF cm^{-2}, calculated using $C = \varepsilon_r \varepsilon_0 A/d$ where $\varepsilon_r \approx 4.8$ is a suitable value for the relative static permittivity [47–50], $\varepsilon_0 \approx 8.854 \times 10^{-12}$ F m^{-1} is the dielectric permittivity of vacuum, A is the area of the device, and d is the active layer thickness. The capacitance curve suggests that below 500 mV there is no excess of charge accumulated in the device active layer and the capacitance obtained corresponds to the electrode capacitance. However, at light bias higher than 500 mV the capacitance is found to increase exponentially with increasing V_{oc} and it is assigned to a measure of charge carriers within the bulk of the device. Since the charge accumulation starts at potentials close to the V_{oc} observed in the I–V curve, the recombination lifetimes were measured at these potentials, in order to extract the limiting factors of the device under working conditions.

The recombination in complete devices was measured by transient photovoltage (TPV). For the TPV measurements, the devices were connected to the 1 MΩ input terminal of an oscilloscope, and illuminated with white light to set the light bias. A small optical perturbation was applied using a nitrogen pumped dye LASER as an excitation source with wavelength of 630 nm (frequency 1 Hz, pulse duration <1 ns), which resulted in a voltage transient with an amplitude of 2 mV. The intensity of the LASER pulse was attenuated as necessary using a circular neutral density filter. In open circuit conditions under white light an equilibrium is reached between charge formation and charge recombination, the pulsed small perturbation creates an excess of charges that will eventually recombine to reach the equilibrium set by the white light at the same rate determined by the equilibrium position.

The transients measured at different light bias were well fitted to a single exponential equation. In Fig. 4b is shown the recombination mean lifetime (τ) extracted from the fitting versus light induced open circuit voltage.

The charge carrier (τ) was found to be exponentially dependent on light bias,

$$\tau = \tau_0 e^{(-\beta V_{oc})}$$

where τ_0 corresponds to the lifetime at zero light bias and is $\sim 2.7 \times 10^5$ μs, β is the decay constant and it relates to the rate of decay, it was found to be $\sim$37. As the light intensity is increased, the lifetime decreases exponentially, reaching $\sim$10 μs at an approximate intensity of 1 sun.

The recombination lifetimes were plotted versus charge density to stress the relationship between charges stored in the device under working conditions and the charge recombination rate. In Fig. 4b is shown that as the charge density increases, the recombination lifetime decreases exponentially. This behavior implicates that the bimolecular recombination process, within the bulk, limits the device photocurrent in a way that at potentials close to the V_{oc}, the recombination is fast enough to directly compete with the charge extraction process at the electrodes. Therefore, according to this observation, we believe that the device open circuit voltage (V_{oc}) is limited by the bimolecular recombination process. The observed fast recombination kinetics under operating conditions (100 mW cm^{-2} sun-simulated light irradiation) has a direct influence over the materials Fermi level splitting hindering the charge occupancy of upper energetic levels that will lead to higher V_{oc} [51].

We have demonstrated that efficient near IR small molecule based solution processed bulk-heterojunction solar cells that incorporate a soluble Zinc phthalocyanine can be used as light harvester. When mixed with PCBM and sandwiched between selective electrodes, efficiencies at 100 mW cm^{-2} sun-simulated light reached 0.77%. The limiting factors in the device under working conditions were studied using time-resolved spectroscopic techniques, and we found a strong increase of the bimolecular recombination process at light-bias close to the device V_{oc} and above. The enlarged recombination kinetics can be directly correlated with the number of charges accumulated at the bulk and, moreover, we demonstrated that the faster recombination dynamics are one of the main factors limiting the device open circuit voltage. Therefore, strategies affecting such recombination kinetics must be applied in the synthesis of new phthalocyanines in order to improve the light-to-energy conversion efficiency of this type of solar cells.

2. Experimental

2.1. Photophysical characterization

Microsecond to millisecond LASER Transient Absorbance Spectra (L-TAS) employed 630 nm (1.97 eV) excitation pulses (frequency 1.5 Hz, duration <1 ns). The change in the sample transmission was monitored using a tungsten lamp with monochromators before and after the sample set at 540 nm. Data resulted from averaging 100–1000 laser shots. UV/visible spectra recorded before and after transient absorbance experiments did not indicate any sample degradation.

2.2. Device fabrication and characterization

Indium Tin Oxide (ITO) 4 Ω^2 covered glass substrates were first cleaned with acetone for the removal of the photo-protective layer with 5 min sonication. The glasses were then placed in an ultrasonic bath twice in 2-propanol (IPA) for 5 min. The ITO substrates were then treated in a UV ozone cleaner for 20 min followed by spin coating of poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS, Baytron P) (5000 rpm 30 s followed by 3500 rpm 10 s). The PEDOT:PSS film was dried at 100 °C inside a glove box for 10 min which yielded a film of 30 nm thick. A 15 (mg ml^{-1}) ZnTBPc and 7.5 (mg ml^{-1}) PCBM (Nano-C USA) solution in chlorobenzene was prepared inside a glove box and stirred for 12 h.

The spin coating of the photoactive layer was made inside a glove box and the conditions used were 1500 rpm during 20 s followed by 2000 rpm 30 s. These conditions gave thicknesses in the range of 60 nm.

Subsequently the devices were placed in a UHV chamber (1×10^{-6} mbar), and 10 nm of Calcium followed by 150 nm of Silver were deposited on top of the active layer through a shadow mask that leads 9 mm^2 devices.

Thermal annealing was carried out by directly placing the completed devices on a digitally controlled hotplate at 110 °C for 10 min inside the glove box.

The thickness of the films was measured with a stylus profilometer Ambios Tech. XP-1, from a scratch applied in the middle of the film to have accurate measurements.

Following fabrication, the films were maintained under a nitrogen atmosphere and stored in the dark until used.

The J_{sc}–V_{oc} characteristics measurement was carried out with a ABET 150 W Xenon light source equipped with the correct set of filters to achieve the solar spectrum 1.5 AM G. The light intensity was adjusted to 100 mW cm^{-2} using a calibrated Si photodiode. The applied potential and cell current were measured with Keithley model 2600 digital source meter. The current to voltage (I–V curve) was measured automatically with a home-built Labview© software.

Atomic Force Microscopy (AFM) of the samples was performed on tapping mode on a Molecular Imaging model Pico SPM II (pico +). Images were collected in air using silicon probes with a typical spring constant of 1–5 nN/m and a resonant frequency of 75 kHz.

TEM was performed on a JEOL JEM-1011 transmission electron microscope operated at an acceleration voltage of 100 kV. To quantitatively relate the diffraction intensity in SAED patterns to the crystallinity of the specimen investigated, all these SAED patterns were performed using a standard recording mode, i.e. fixed magnification, field-limiting apertura of 100 mm, current density of 0.6 pA cm^2 and exposure time of 11.0 s for SAED acquisition. Identical time and conditions were used for film development. All the negatives were digitalized using the same settings.

Organic thin-film transistor
Contact resistance
Pentacene film morphology

ABSTRACT

With the use of the stencil lithography, we fabricated pentacene thin-film transistors prepared directly on thermally oxidized silicon gates with channel lengths ranging from 2 to 600 μm. By performing 4-probe measurements or by using the transfer line method on these field-effect transistors, we were able to separate the respective contributions of the channel and the contacts to the transistor performance. The contact resistance depends strongly on the gate voltage and on the grain size and morphology; this behavior has been attributed to screening effects at the contact barriers. The low-field mobility in the channel is 0.5–0.6 cm^2/Vs in long-channel transistors and reaches mobility in the order of 10 cm^2/Vs in short-channel transistors consisting essentially of a single grain.

1. Introduction

The performance of an organic field-effect transistor is related to the microstructure and purity of the organic semiconductor [1,2], the degree of order at the interface [3], and the quality of the contacts. The need to miniaturize the organic electronic circuit and the use of standard lithographic methods has led to smaller and smaller channel lengths [4–7]. Several authors have observed that in such cases, the contact resistance dominates the device characteristics [8–11]. For very short channels ($L < 5$ μm), the Schottky barrier at the source and drain contacts dominates device performance [9]. For long channels ($L > 100$ μm), the contact resistance is not determined by the barrier at the metal–organic semiconductor interface, but rather by drift/diffusion of carriers close to this interface [12,13]. It has also been observed that the presence of a small concentration of residual carriers produced by doping the channel can decrease the contact resistance [3,14].

In the present work, we fabricated a series of pentacene thin-film transistors with channel lengths ranging from 2 to 600 μm. We have employed stencil technology, which is a one-step technique with high resolution down to the sub-100 nm range thus eliminating solvent-based processing steps [15]. In this large range of channel lengths, the transistor performance changes from contact limited to channel dominated. We investigated the influence of the pentacene film morphology on the contact and channel performance by separating their contributions; this was made possible using both 4-probes and transfer line methods.

2. Methods

The organic thin-film transistors (OTFTs) are based on pentacene as organic semiconductor and fabricated by high-vacuum deposition in top-contact configuration. Heavily *boron* doped *Si* wafers (resistivity of 0.1–0.5 Ω cm) were used as substrates and served also as gate contacts. The wafer was coated with a thermal SiO_2 layer (200 nm in thickness).

Pentacene was deposited by thermal evaporation in a high-vacuum chamber at a rate of about 1 nm/min ($p <$

10^{-7} mbar). The film thickness was 40 nm. The substrate temperature is either 20 °C (room temperature) or 55 °C. The growth processes lead to different grain sizes (small grains at RT, larger grains at 55 °C). The film morphology was imaged by AFM in semi-contact mode (*NT-MDT* with a *SMENA* scanner). Pentacene was purchased at *Fluka* and twice purified in a furnace with a temperature gradient.

The gold top contacts were deposited by thermal evaporation under high vacuum ($p < 10^{-7}$ mbar) and have a thickness of 25 nm. The substrate was cooled to the temperature of liquid nitrogen (−185 °C) during evaporation to avoid gold diffusion into pentacene.

OTFTs with different contact geometry were fabricated. Contacts for long-channel transistors were patterned by a metallic shadow mask. The channel has a length of 100, 200 and 600 μm, respectively, and a width of 6 mm. A stencil was used to define the contacts for short-channel transistors. The stencils are made of a low-stress *SiN* membrane supported by bulk silicon. The channel aspect ratio is 10 and includes the channel lengths of 2, 5, 10 and 20 μm, respectively.

The OTFTs were characterized by measuring output and transfer curves (*Keithley 4200 SCS*) under Argon atmosphere (after at least 4 h under vacuum). Drain and gate voltages were swept between +10 and −40 V while the drain and gate currents were measured. The apparent field effect mobility is calculated in the linear regime, from the slope of the conductance $g_D(V_G) = dI_D/dV_D|_{VD=0}$ as a function of the gate voltage V_G. The threshold voltage is the intercept between the gate voltage axis and the linear fit of the transfer curve for high negative gate voltages [3,16]. The results are shown in Table 1.

One of the main goals of the present work is to separate the resistance of the channel from the resistance of the contacts. This was achieved by using two different methods: the 4-probe measurements and the transfer line method.

By means of 4-probe measurements (*Keithley 236 source measure unit*), the channel resistance was determined independent of the contact resistance [17]. The contact resistance was then determined as the difference between the values obtained by the 2-probe and the 4-probe measurements.

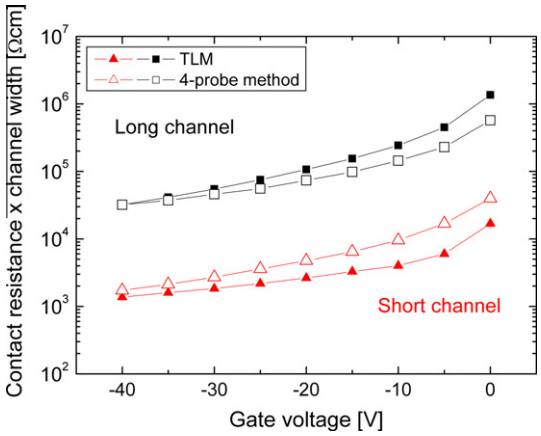

Fig. 1. Contact resistance (normalized to the channel width) measured by the 4-probe method (one transistor) and extrapolated by the transfer line method (5–6 transistors of the same batch). The long-channel transistors have a channel length of 100–600 μm and a channel width of 6 mm; the 4-probe measurements were done for a distance between the contacts of 600 μm. The short-channel transistors have a channel length of 2–20 μm and a channel width 10 times larger; the 4-probe measurements were done for a distance between the contacts of 10 μm. The pentacene film consists of large grains. The film thickness is 40 and 20 nm for long-channel and short-channel transistors, respectively.

The transfer line method uses transistors of the same batch but of different channel lengths. The contact resistance is obtained by extrapolating the resistance at zero channel length [18,19].

In Fig. 1, we compare the results of the 4-probe and the transfer line method for two different batches of transistors. The two measurements coincide within a factor of two at low gate fields and within 20% at large gate fields; the discrepancy is in large part due to the transfer line

Table 1
Characteristic values for OTFT with different channel lengths. The apparent mobility refers to the entire device and contains hidden contributions due to the contacts (see Table 2). The conductivity results from 4-probes measurements with a floating gate; they reflect the presence of a density of residual carriers in the channel.

	Apparent mobility (cm^2/Vs)	Conductivity (10^{-8} S □)	Threshold voltage (V)	Total resistance (MΩ)
Long channels, small grains (0.2–0.5 μm)				
600 μm	0.45	7.2	8.3	1.39
200 μm	1.04	14.3	1.0	0.23
100 μm	1.21	14.6	−1.1	0.12
Short channels, small grains (0.2–0.5 μm)				
20 μm	1.51	17.1	−1.4	0.58
10 μm	1.39	14.9	−4.3	0.67
5 μm	1.27	5.0	−6.3	2.0
2 μm	1.08	1.3	−5.1	8.0
Long channels, large grains (2–3 μm)				
600 μm	0.58	3.4	−2.7	2.92
200 μm	0.68	0.88	−12	3.78
100 μm	0.28	0.31	−12	5.36
Short channels, large grains (2–3 μm)				
20 μm	1.31	5.79	−4.8	1.73
10 μm	1.57	3.17	−10.8	3.15
5 μm	0.69	3.61	−3.3	2.77
2 μm	0.82	7.31	2.9	1.38

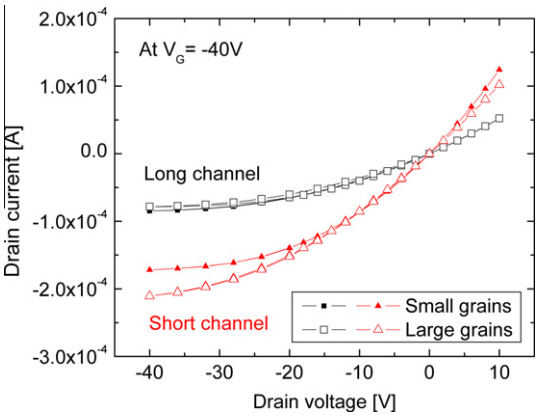

Fig. 2. Output curves of OTFTs with long and short channels (600 and 10 μm, respectively) and different film morphologies (small and large grains). The gate was polarized at a voltage of −40 V.

method which assumes a perfect homogeneity in the batch what is difficult to achieve in practice. As observed by other groups [12,13], the 4-probe method is also questionable when the potential of the inner electrodes is perturbed by the current flowing between the outer electrodes, especially for thick film when the electrodes do not penetrate enough in the channel region. But in the present work where large effects are observed and thin films are used (20 and 40 nm), the errors on the absolute value of the contact resistance are well below the measured variations.

3. Results

On the top of SiO_2, the morphology of the 40 nm thick pentacene film depends on the substrate temperature during pentacene deposition. At room temperature, the film has grown in submicron grains with a dendritic shape [20]. If the substrate temperature is 55 °C, the grains increase in size (2–3 μm in diameter) and become more compact.

The output curves in Fig. 2 show that all transistors have a linear regime around zero drain voltage and reach saturation. At a gate voltage of −40 V, the drain current through a transistor with a short channel (10 μm in length) is about twice as high as through a long-channel transistor (600 μm in length).

The transfer characteristics in Fig. 3 show that the short- and long-channel transistors behave differently.

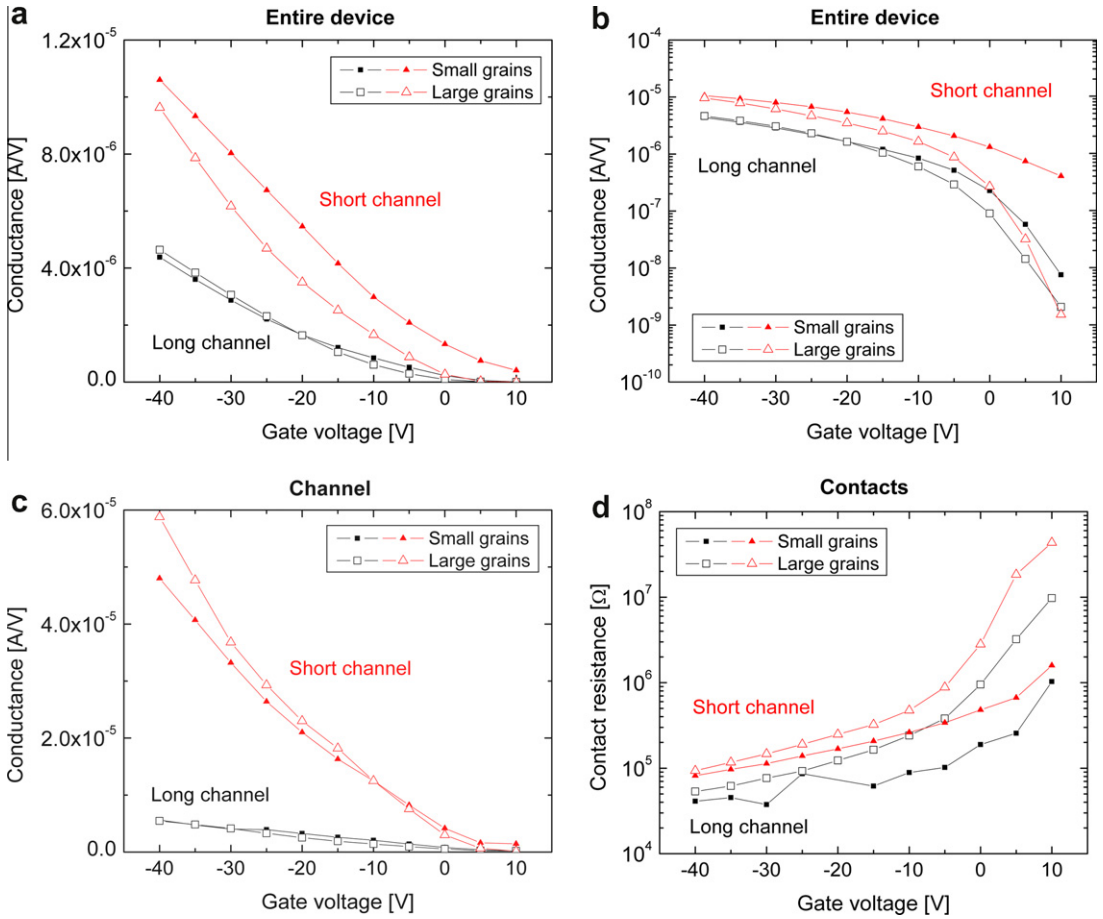

Fig. 3. Transfer curves (a) and (b) of the entire device and (c) of the channel, (d) contact resistance depending on the applied gate voltage for OTFTs with long and short channels (600 and 10 μm, respectively) and different film morphologies (small and large grains, respectively). The samples are the 4-probe devices of Table 2.

Table 2
Characteristic values for the entire device and the channel only. The density of residual carriers, P_{res}, can be derived from the following equation: $P_{res} = \sigma/(e\,\mu_{app})$, where σ is the conductivity, e the elementary charge, and μ_{app} the apparent mobility in the linear regime [17].

	Channel		Entire device		At floating gate			Residual carriers (cm^{-2})
	Apparent mobility (cm^2/Vs)	Threshold voltage (V)	Apparent mobility (cm^2/Vs)	Threshold voltage (V)	Total resistance (MΩ)	Channel resistance (MΩ)	Contact resistance (MΩ)	
Long channel (600 μm), small grains (0.2–0.5 μm)	0.59	7.3	0.45	8.3	1.39	1.26	0.14	1.0×10^{12}
Long channel (600 μm), large grains (2–3 μm)	0.74	−1.8	0.58	−2.7	2.92	2.11	0.81	3.7×10^{11}
Short channel (10 μm), small grains (0.2–0.5 μm)	7.42	−6.9	1.39	−4.3	0.67	0.23	0.44	6.7×10^{11}
Short channel (10 μm), large grains (2–3 μm)	10.2	−10.8	1.57	−10.8	3.15	0.33	2.82	1.3×10^{11}

The performance of long-channel transistors is dominated by the channel; this is shown in the small difference between the transfer curves of the entire device and the curve of the channel alone (see Fig. 3a–c). Consequently, the apparent and channel mobility do not differ significantly (from 0.45 to 0.74 cm^2/Vs, see Table 2).

In contrast, the transistors with a short channel (2–20 μm) are limited by the contacts. The channel conductance is approximately five times higher than the conductance of the entire device (see Fig. 3a–c). As expected, this behavior is reflected in the mobility values. While the apparent mobility of the entire device is in the range of 1.0–1.5 cm^2/Vs, the channel mobility is more than five times higher, and reaches 10 cm^2/Vs (see Table 2).

4. Discussion

The most important results of this work are those summarized in Fig. 3 and Table 2. Let us consider first the behavior of the pentacene channel resistance in a floating gate configuration. Table 2 shows that pentacene films made of small grains are always more conductive than films of the same length made of large grains; this fact demonstrates that grain boundaries do not act as simple barriers but also modify the trap distribution. In fact, some of the defects at the oxide surface act as traps (≡Si–H for instance) while others are recombination centers (the radical ≡Si–O· for example) inducing charge transfers by capturing electrons of the pentacene and leaving additional holes as residual carriers in the organic semiconductor film [3].

Apparently, small dendritic grains which lead to a higher density of grain boundaries in the film induce more charge transfers at the interface of the oxide than large grains. These charge transfer reactions explain why the devices do not show a clear off regime in the transfer curves. Fig. 3d shows that the contact resistance depends significantly on the gate voltage and also on the grain size and morphology. We attributed these effects to the concentration of charge carriers in the channel; the higher the charge carrier concentration is, the stronger are the screening effects at the contact barrier, and thus the contact resistance is smaller [14].

Gold films evaporated on small dendritic grains always give smaller contact resistances than the same films evaporated on large grains. To understand this result, the contact resistance has been plotted as a function of the residual carrier concentration in the channel (Fig. 4a). A clear correlation appears between these two quantities;

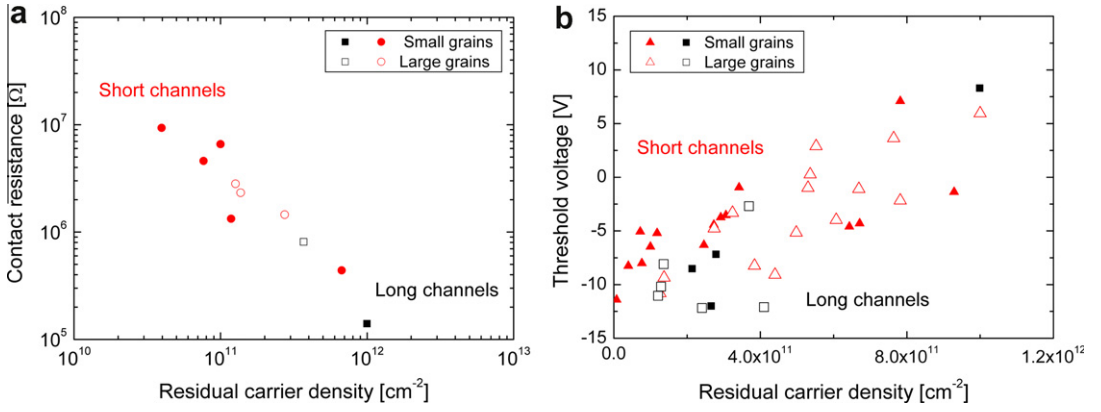

Fig. 4. (a) Contact resistance measured at floating gate (by the 4-probe method) versus residual carrier density for OTFTs with long and short channels (600, 10 and 20 μm, respectively) and (b) threshold voltage versus residual carrier density for OTFTs with long and short channels and different film morphologies (small and large grains, respectively).

residual carriers have a clear screening effect on the contact barriers [14]. The fact that small grains give smaller contact resistance than large ones is once again due to charge transfer reactions mainly occur at grain boundaries. For the same reason, a short-channel transistor with only a few grains in the channel exhibits larger contact resistance because of lower residual carrier concentration.

The threshold voltage of the transistors presented here varies from −10 to +10 V. The voltage also correlates with the residual carrier concentration (see Fig. 4b). The negative values reflect the distribution of dipolar traps at the oxide surface, while residual carriers in the channel push the voltage threshold towards positive values [17].

The transistors which were compared in this work have been fabricated with pentacene layers of 40 nm thickness. For the sake of clarity, the results obtained for 20 and 80 nm-thick pentacene layers are not presented here; however, we observed essentially the same behavior for all thicknesses. It is worth mentioning that the thickness of 40 nm represents a sort of optimum; the channel mobilities in both 20 and 80 nm transistors are 20% lower.

Some transistors have also been fabricated on aluminum oxide gate insulators. We have observed that the behavior of aluminum oxide is similar to that of silicon oxide; in particular, from the point of view of charge transfer reactions and residual carriers [3].

5. Conclusion

Pentacene thin-film transistors have given rise to a very large number of studies in the literature, which are not always consistent with each other. The use of the stencil technology together with 4-probe measurements has helped to clarify the surprising behavior of the apparent mobility with the pentacene grain size and the channel length. In fact, the contact resistance and the channel resistance are both gate voltage dependent and can vary in an opposite way with grain size and morphology. In pentacene transistors prepared directly on an oxide gate insulator, the interface traps and charge transfer centers dominate the transport. Although they belong essentially to the oxide, their activity is very often related to the presence of the grain boundaries of the pentacene dendritic grains. It is worth mentioning that a self-assembled monolayer (SAM) reduces the morphology and defect dependence by separating the interface traps and charge transfer centers from the pentacene film (surface passivation) [18,21]. When the passivation of the oxide by the SAM is efficient (number of residual carriers lower than 10^{11} per cm^2), then the mobility slowly increases with the grain size [22].

Intrinsic degradation
Blue phosphorescent OLEDs

ABSTRACT

We present an investigation of the intrinsic chemical degradation mechanisms of phosphorescent OLEDs based on the common sky blue emitter bis(2-(4,6-difluorophenyl)-pyridyl-*N*,C2′)iridium(III)picolinate (FIrpic). The OLEDs are investigated using the laser-desorption/ionization time-of-flight mass spectrometry. The comparison between the collected spectra for electrically aged and unaged OLEDs allows the identification of different reaction products, like fragments which are mainly related to the chemical dissociation of FIrpic molecules during the OLED operation. We present different reaction pathways of the blue emitter FIrpic. One proposed reaction indicates that the short lifetimes of the OLEDs may be related to the irreversible dissociation of the FIrpic molecule by the loss of carbon dioxide (CO_2) from the picolinate ligand. Additionally, the formation of chemical complexes between different fragments of the FIrpic molecules with their neighbour materials is visible. The cesium adducts of FIrpic formation indicate a possible contribution of the dopant to the OLED degradation process. Finally, we show rearrangement effects in the Cs doped electron transporting layer. This rearrangement is indicated by the presence of m/z signals of the BPhen dimer and adducts of the dimer with Cs.

1. Introduction

Organic Light Emitting diodes (OLEDs) have attracted much interest in the past years due to their potential application in next generation light sources and display technologies. OLEDs allow a thinner, lighter, and more flexible design, and are also quite efficient [1]. Unfortunately, apart from its current high manufacturing costs, lifetime is one of the major drawbacks of this technology. Although a remarkable improvement in efficiency and lifetime of *p-i-n* phosphorescent OLEDs have been reported recently [2–7], the short lifetime of blue emitting devices is still the major limitation for a broad application of this promising technology. For blue OLEDs, two different types of emitters can be used, phosphorescent [7] and fluorescent [8] molecules. These two types of emitters differ significantly in terms of light emission efficiency. In comparison to devices using fluorescent emitters, devices employing phosphorescent emitters can achieve higher external quantum efficiencies because they allow simultaneous harvesting of both singlet and triplet excitons [9]. Therefore, phosphorescent materials are ideal for use in both lightning and display devices.

Despite the importance of a detailed understanding of the intrinsic degradation mechanisms involved in the aging processes of blue phosphorescent OLEDs, only little information about the nature of the chemical reactions associated to the low stability of the blue emitters are known. For investigations of the degradation behavior of

blue phosphorescent OLEDs, special attention has been paid to the phosphorescent emitter bis(2-(4,6-difluorophenyl)pyridyl-*N*,C2′)iridium(III)picolinate (FIrpic), unfortunately known to be relative unstable. The degradation processes of FIrpic based OLEDs have been previously analyzed by High Performance Liquid Chromatography coupled with a mass spectrometry (HPLC–MS) [10–12], and Laser-Desorption/Ionization Time-of-Flight Mass Spectrometry (LDI-TOF-MS) [13]. Within these investigations the degradation processes of the OLEDs has been attributed to different reaction mechanisms such as: (i) FIrpic molecule isomerization, as well as (ii) chemical dissociation of the FIrpic emitter by the cleavage of the picolinate ligand from the FIrpic molecule [10], (iii) chemical degradation of the materials used in the HTL and a further coupling reaction between its fragments and neighbouring molecules resulting in the formation of new products [11,12]. In previous work, we used the LDI-TOF-MS to discover the laser induced photochemical reaction mechanism of single FIrpic layers as well to investigate the possible reaction products in fully processed and aged OLEDs [13]. The excitation of the FIrpic molecule via laser light induces the formation of sodium and potassium adducts with FIrpic as well as the dissociation of the emitter molecule. This general reaction of dissociation may occur via two different chemical pathways. One of them is the reversible dissociation of the FIrpic molecule, where the picolinate ligand is removed and the second one is the irreversible loss of the carbon dioxide (CO_2) unit from the picolinate ligand with a further dissociation step to form a $Ir(F_2ppy)_2^+$ species, which may undergo further reactions. Although the reversible dissociation pathway could be observed in electrically driven OLEDs, the first hint of the irreversible pathway was obtained by creating a differential spectrum of an aged and an unaged OLED. In this differential spectra the m/z signal, which is related to the $[FIrpic\text{-}CO_2]^+$ fragment, was only poorly visible [13].

In this work we will present evidence that the FIrpic molecule may dissociate by two different reaction pathways, which occur during the OLED operation. Additionally, new degradation products, which may be associated to the short lifetime of the FIrpic based OLEDs, such as formation of chemical complexes between different fragments of the FIrpic molecules with their neighbour material like TPBi used as host and hole blocking layer, 4,7-diphenyl-1,10-phenanthroline (BPhen) dimerization, and adducts of the BPhen dimer with Cs will be presented as well.

2. Experimental

The OLEDs, as shown in the inset of Fig. 1(d), consist of a six-layer *p-i-n* organic structure, sandwiched between a 90 nm thick indium tin oxide (ITO) anode and a 100 nm thick aluminium top electrode. The devices are prepared by vacuum sublimation under a base pressure of 10^{-8} mbar (vacuum sublimation tool from the Kurt Lesker Co.). Immediately after preparation, the devices are encapsulated under a nitrogen atmosphere using epoxy glue and glass lids. The devices consist of a 20 nm thick

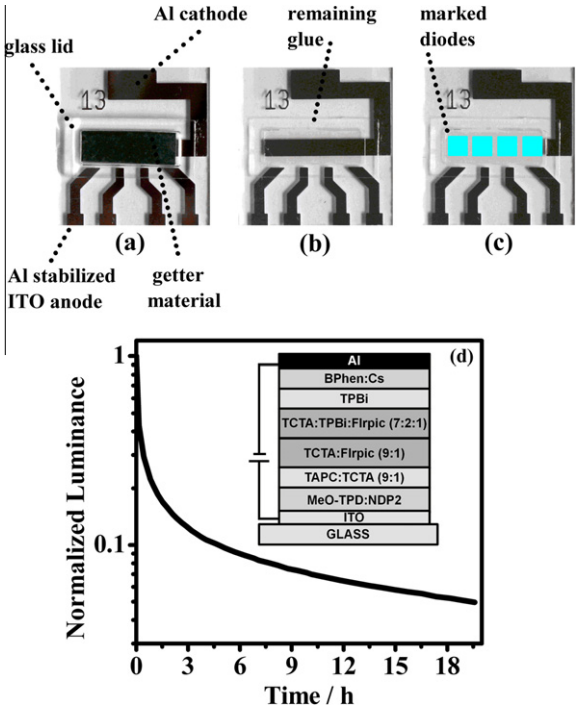

Fig. 1. OLED samples before (a), after removing the encapsulation (b), and after removing the Al cathodes from the samples (c). Typical lifetime characteristics of the FIrpic phosphorescent OLED aged under a constant current density of 30 $mAcm^{-2}$ corresponding to an initial luminance of $L_0 = 3623$ cdm^{-2} (d). The inset figure shows the structure of the blue sky phosphorescent OLED used in LDI-TOF-MS investigations.

hole injection and transport layer (HTL) from *N*,*N*,*N*′,*N*′-tetrakis 4-methoxyphenylbenzidine (MeO-TPD) doped with 4 mol% NDP-2 (Novaled AG) [14], a 10 nm thick electron blocking layer (EBL) composed by a mixture of 90 wt.% 1,1-bis(4-di-*p*-tolylaminophenyl)cyclohexane (TAPC) and 10 wt.% 4,4′,4″-tris(carbazol-9-yl)triphenylamine (TCTA), a double emission layer (D-EML) consisting of one 10 nm

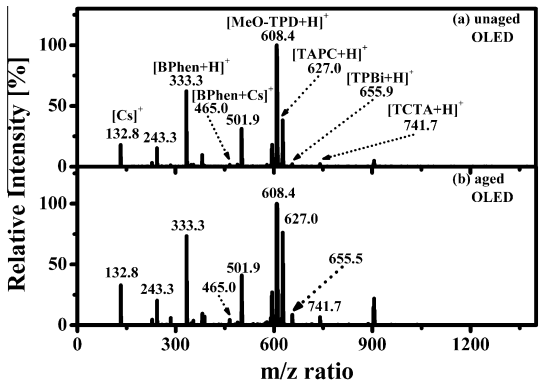

Fig. 2. LDI-TOF MS spectra collected in the positive mode of an unaged (a) and an aged (b) OLED sample. Both spectra show the signals of the materials $[Cs]^+$ at 132.8 amu, $[BPhen + H]^+$ at 333.3 amu, $[MeO\text{-}TPD+H]^+$ at 608.4 amu, $[TAPC + H]^+$ at 627.0 amu, $[TPBi + H]^+$ at 655 amu, and $[TCTA + H]^+$ at 741.7 amu used in the OLED stack. Additionally, some degradation products with very low signal intensities could also be detected and will be presented in the following enlarged figures.

thick layer of TCTA doped with 10 wt.% FIrpic and a layer of 10 nm of 70 wt.% TCTA, and 20 wt.% 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBi) doped with 10 wt.% FIrpic, a 10 nm thick hole blocking layer (HBL) TPBi, and finally an electron transport layer (ETL) of Cs doped BPhen (30 nm). The devices are aged under a constant current density of 30 $mAcm^{-2}$ corresponding to an initial luminance (L_0) of 3623 cdm^{-2}, until the emission decreased to about 5% of the initial luminance. Fig. 1(d) shows the normalized luminance decay, recorded during OLED operation. This aged sample is used for the LDI-TOF-MS investigation. Under the mentioned conditions, a half-lifetime ($t_{0.5}$) of only 13 min was observed. Although, a longer half-lifetime ($t_{0.5}$ = 13 h) was obtained for OLEDs driven at L_0 = 100 cdm^{-2}, this value is still far below the values required for most OLED applications. The aged and unaged OLEDs were analysed upon LDI in positive and negative detection mode, using the method of LDI-TOF-MS (Bruker Daltonics Autoflex TOF/TOF tandem mass spectrometer). Before mounting the OLEDs on a MALDI sample holder the encapsulation glasses (Fig. 1(a and b)), and the Al cathode (Fig. 1(b and c)) are removed from the samples under protective nitrogen. Removing the Al cathodes allows the analysis of the OLEDs at a very low laser intensity of about 120 μJ/pulse. The use of a low laser intensity during the spectra acquisition is important to avoid the formation of additional photochemical reactions during the analyzing process [15]. Transferring the samples into the LDI-TOF-MS set-up required less than 2 min in air. The samples are excited at a wavelength of 337 nm, where the maximum pulsed laser beam intensity can be set to 300 μJ/pulse (at 25 Hz). In total 180 single mass spectra from three different points of each sample are taken.

3. Results and discussion

Fig. 2(a), and (b) show the full scale LDI-TOF-MS spectra collected between 0 and 1400 amu for the unaged and aged

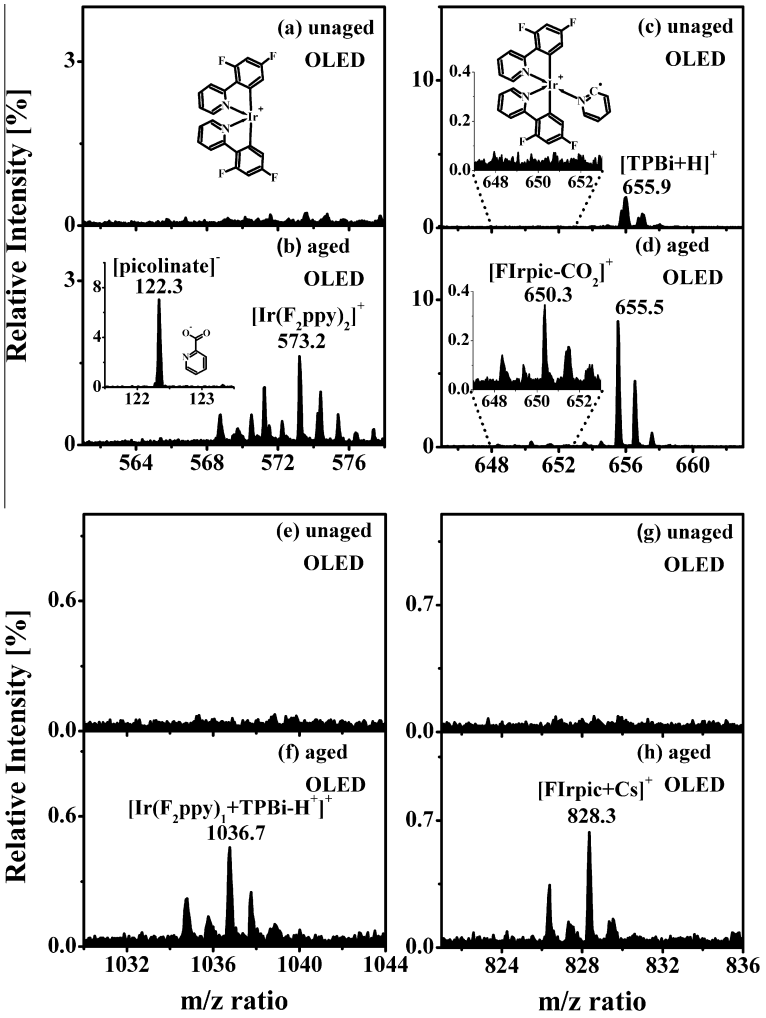

Fig. 3. Enlarged LDI-TOF-MS spectra of degradation products formed during the OLED aging process (b, d, f and h) in comparison to the spectra collected for unaged sample in the same m/z ratio range (a, c, e and g). The generated degradation products are related to $[Ir(F_2ppy)_2]^+$ at 573.2 amu, $[FIrpic–CO_2]^+$ at 650.3 amu, $[Ir(F_2ppy)_1 + TPBi\text{-}H^+]^+$ at 1036.7 amu, and $[FIrpic + Cs]^+$ at 828.3 amu. Inset Fig. 3(b) shows the spectrum of the negatively charged FIrpic fragment related to the $[picolinate]^-$ at 122.3 amu.

OLEDs, respectively. Both spectra show the expected mass/charge (m/z) signals of the materials $[Cs]^+$ at 132.8 amu, $[BPhen + H]^+$ at 333.3 amu, $[MeO\text{-}TPD]^+$ at 608.4 amu, $[TAPC + H]^+$ at 627.0 amu, $[TPBi + H]^+$ at 655 amu, and $[TCTA + H]^+$ at 741.7 amu. The presence of $[Cs]^+$ and $[BPhen + H]^+$ signals indicate that the ETL on top of the investigated samples has not been effected by the Al cathode removing procedure. The other signals at 243.3 and 501.9 amu correspond to the fragments of TCTA and MeO-TPD molecules, respectively. Additionally, a signal at 465 amu related to the laser induced degradation product $[BPhen + Cs]^+$ is observed in both samples analyzed. The signal present different relative intensities for the unaged (1.4%) and aged (4.5%) samples. One should be aware that the spectra are normalized using the $[MeO\text{-}TPD + H]^+$ signal, which is set to 100%. MeO-TPD itself undergoes some photochemical degradation reactions during the measurements as well. This may led to an influence on the relative intensities of the other signals, as observed in the case of the signal of $[BPhen + Cs]^+$. The comparison between LDI-TOF-MS spectra, collected for aged and unaged OLED samples, allows the identification of very low concentrations of reaction products and fragments which are mainly related to the chemical dissociation of FIrpic molecules during the OLED operation. Due to the low concentration of the degradation products formed during the OLED operation, the spectral analysis will be focused on the comparison of m/z signals at low signal intensities between the aged and unaged spectra.

3.1. Chemical degradation processes of FIrpic molecules

The spectrum in Fig. 3(b) shows the signal at 573.2 amu, which corresponds to the FIrpic molecule fragment $[Ir(F_2ppy)_2]^+$. The formation of such a fragment is an indication of the chemical dissociation of FIrpic by the loss of the picolinate ligand. To verify the dissociation reaction pathway of the FIrpic molecule during the OLED operation, a spectrum in negative mode was taken, which is displayed as inset in Fig. 3(b). In this spectrum a signal at 122.3 amu can be observed, which relates to the negatively charged picolinate ion. The enlarged spectrum inset Fig. 3(d) shows a second feature at 650.3 amu with a very low value of relative intensity, close to the more intense signal of $[TPBi + H]^+$ at 655.5 amu. This compound is the result of the dissociation of the FIrpic molecule by the loss of a carbon dioxide unit (CO_2). Although the signal $[FIrpic\text{-}CO_2]^+$ presents a very low intensity, it is difficult to correlate the signal intensity with the corresponding concentration as the LDI-TOF-MS is not a quantitative technique. This specie may exhibit lower ionization due to its instability. Even at higher concentrations of the fragment within the OLED, the fast fragmentation within the LDI experiment does not allow a quantitative characterization of the material at the LDI-detector. To interpret these results, we assume a dissociation reaction mechanism for FIrpic molecules as proposed in Fig. 4. According to this reaction mechanism, the FIrpic molecule is excited during the OLED operation and it is converted into an ionized form. The ionized FIrpic molecule may not be stable and can suffer further dissociation processes according to two different reaction pathways: a reversible (pathway 1) and/or an irreversible (pathway 2). In pathway 1 the FIrpic is reversibly dissociated by the scission of picolinate ligand from the FIrpic molecule with the formation of a [FIrpic–picolinate]$^+$ ion. A irreversible dissociation of FIrpic molecule is proposed in the pathway 2 by the loss of a neutral CO_2 molecule from the picolinate ligand accompanied by the

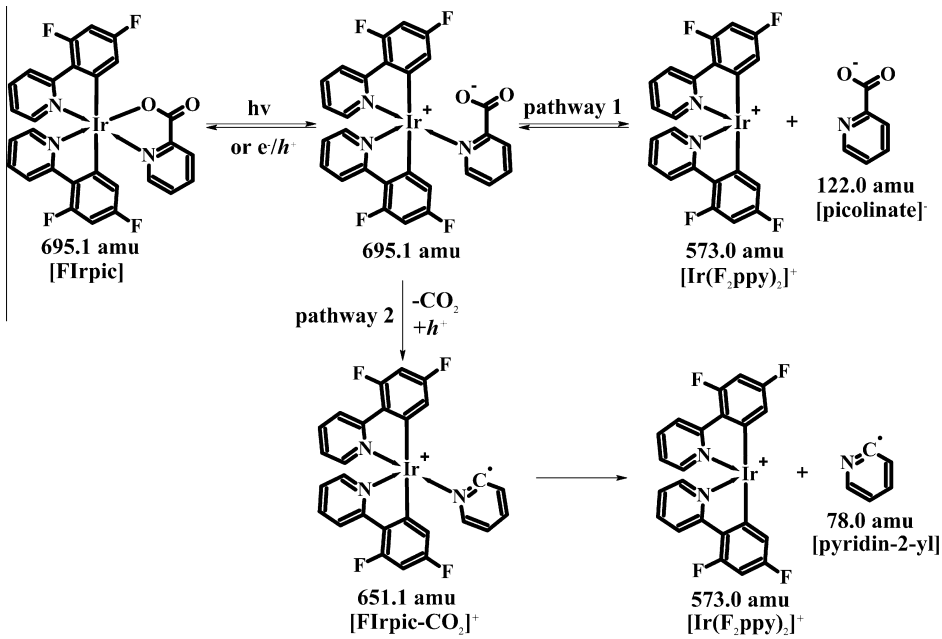

Fig. 4. Proposed dissociation reaction of the FIrpic molecule during the OLED operation according to two different dissociation pathways: a reversible (pathway 1), and/or an irreversible (pathway 2).

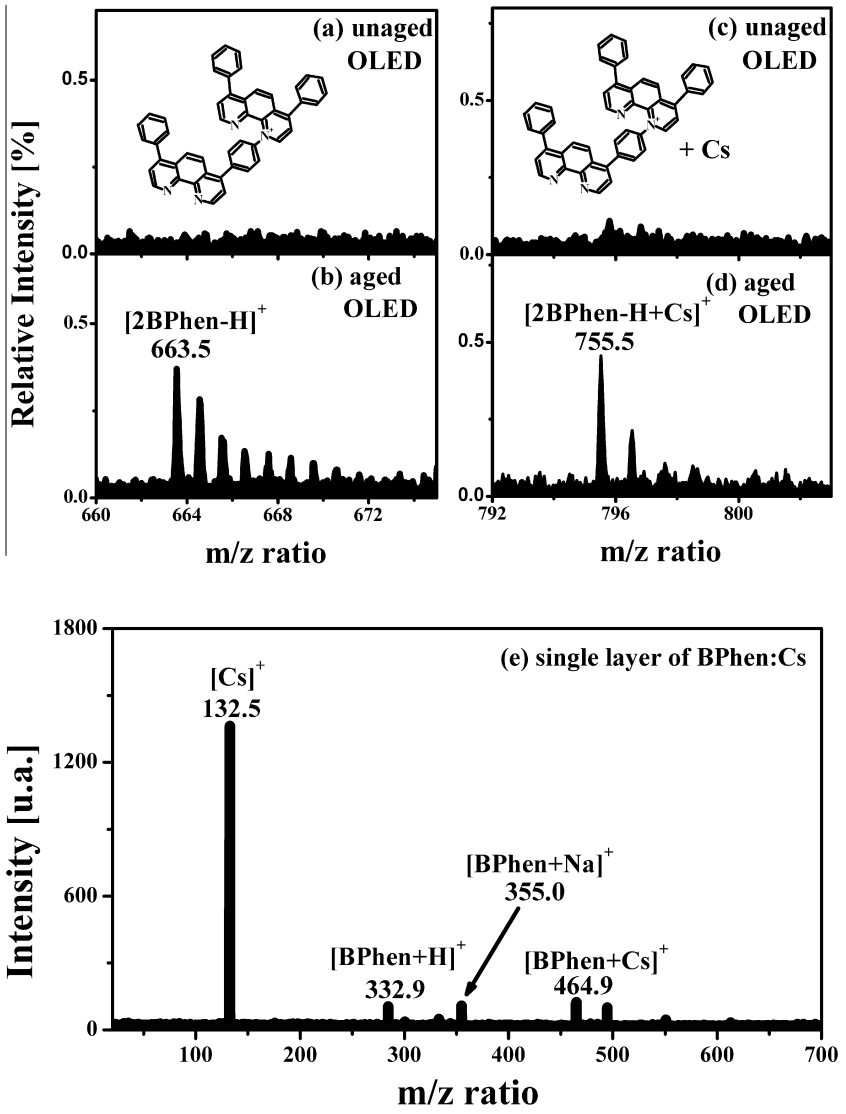

Fig. 5. LDI-TOF-MS spectra of single layers of BPhen doped with 10% cesium (10 nm) at 120 μJ/pulse. The spectrum shows that the doping of BPhen with Cs suppresses the formation of photo induced BPhen dimers and only the m/z signals related to $[Cs]^+$ at 132.5 amu, $[BPhen + H]^+$ at 332.9 amu, $[BPhen + Na]^+$ at 354.9 amu, $[BPhen + Cs]^+$ at 464.8 amu are observed.

formation of the $[FIrpic–CO_2]^+$ ion. The positively charged fragment $[FIrpic–CO_2]^+$ can suffer a further dissociation process with the formation of the positively charged fragment $[Ir(F_2ppy)_2]^+$ and pyridin-2-yl neutral radical. These findings are in agreement with the results of the photoinduced degradation process of a pure FIrpic layer in an LDI-TOF-MS investigation published by Scholz et al. [13]. We believe that the irreversible oxidation of the picolinate ligand may lead to a degradation of the FIrpic molecules and act as an exciton quencher during the OLED operation. To the best of our knowledge, this is the first time that a direct evidence of an irreversible dissociation process of the FIrpic occurring during OLED operation has been shown.

Fig. 3(f) and (h) show the spectra of two other degradation products presenting the characteristic iridium-complex isotopic pattern. Fig. 3(f) exhibits the signal at 1036.7 amu, which can be attributed to two possible reaction products; either to the interaction of the iridium fragment with surrounding TPBi, material used as host and HBL, or the interaction with the charged complex $[BPhen + Cs]^+$. Therefore the structure of degradation product can be described as $[Ir(F_2ppy)_1TPBi\text{-}H^+]^+$ or $[Ir(F_2ppy)_2BPhen\text{-}H + Cs]$ with a good agreement with the experimental value of the m/z signal. Although the formation of neither degradation products can be discarded we believe that the formation of $[Ir(F_2ppy)_1TPBi\text{-}H^+]^+$ seems more probable. The formation of the complex between TPBi and $[Ir(F_2ppy)]^{2+}$ may occur by the release of one proton from the $[Ir(F_2ppy)_1TPBi\text{-}H^+]^+$ complex like the mechanism proposed for the complexation of red triplet emitter iridium(III)bis(2-methyldibenzo-[f,h]quinoxaline)(acetylacetonate) $[Ir(MDQ)_2(acac)]$ frag-

ment with the TPBi molecule [15]. The formation of such iridium complexes, which are believed to act as non-radiative exciton quenchers, would cause a decreased photon emission during the OLED operation and therefore decrease the device lifetime. As already shown for highly stable red phosphorescent OLEDs containing [Ir(MDQ)$_2$(acac)], the dissociation behavior of the Ir-complex and the ability of its fragments to form chemically stable complexes with the neighbour materials such as TPBi have been directly correlated with the decrease of the devices lifetime [15–16]. However, the chemical structure of the [Ir(F$_2$ppy)$_1$TPBi-H$^+$]$^+$ is still unknown. Finally, the signal at 828.3 amu of [FIrpic + Cs]$^+$, shown in Fig. 3(h) indicates a possible contribution of the dopant to the OLED degradation process. The diffusion of the cesium into the emission layer with the formation of cesium adducts of FIrpic may act as non-radiative recombination centers as well.

3.2. Chemical reaction involving the BPhen molecule

In Fig. 5(b), and (d) the signals at 663.5 amu, and 795.5 amu are attributed to [2(BPhen)-H]$^+$ and [2(BPhen)-H + Cs]$^+$, respectively. The formation of chemically stable dimers of BPhen is well described in previous studies [17], where it has been suggested that the BPhen dimers form lower HOMO–LUMO gaps as compared to the unreacted BPhen and therefore they may act as trap states for charges and as quencher for excitons. Such a contribution to exciton quenching may be enhanced for wide band gap emitters compared to red emitting systems. The formation of BPhen dimers [15,16,18] as well as their cesium adducts [19] has been already observed, but only during the aging process of stable phosphorescent OLEDs with BPhen used as HBL. Our results show that the BPhen dimerization can occur even when a 10 nm layer of TPBi was used as HBL. The formation of such species may be induced by the unbalance of charge promoted by the dissociation process of the FIrpic molecules in the emitting layer and/or by the high current density applied during the OLED aging process.

To further investigate the reaction mechanism of the cesium BPhen dimer adduct, we performed a photo-induced experiment on a single BPhen layer doped with cesium by the LDI-TOF-MS method. The spectrum collected at 120 μJ/pulse for a 10 nm layer of BPhen doped with 10% of cesium is presented in Fig. 5(e), which shows the signals assigned to [Cs]$^+$ at 132.5 amu, [BPhen + H]$^+$ at 332.9 amu, [BPhen + Na]$^+$ at 354.9, and [BPhen + Cs]$^+$ 464.8 amu. The sodium adduct formation was forced by wetting the MALDI target with the solvent isopropanol without drying under a nitrogen stream in order to remain the alkaline impurities on the target. These results show clearly that the doping process of BPhen with cesium suppresses the BPhen dimerization. Therefore, we conclude that during the OLED degradation process, the BPhen dimer is the first species which is formed. Afterwards, in a further step it reacts with cesium. The role of the adducts between the BPhen dimer and the cesium on the performance and lifetime of OLED devices is still unclear and more investigations are needed in order to clarify these questions. The mechanism of the FIrpic degradation reveals a serious problem regarding the stability of the picoline containing emitters. In order to improve the stability of a blue phosphorescent dopant molecule it would be more appropriate to develop a molecule with three equivalent ligands, where an excitation (and therefore a metal–ligand-bond-opening) is statistically shared on all three ligands, which may promote an increase of the molecule lifetime. We are aware that due to the symmetry, such emitter molecules may show a decreased efficiency compared to other asymmetric species. Nevertheless the higher triplet gap has a major effect on the degradation effect due to the relative near to the dissociation state of any kind of molecules (even on the matrix [20]). Therefore the C–N binding energy is a critical parameter, e.g. for corresponding matrix materials as well.

4. Conclusion

In this contribution, we present an investigation of the intrinsic chemical degradation mechanisms of phosphorescent OLEDs based on the common sky blue emitter FIrpic by the use of the LDI-TOF-MS. The results show that LDI-TOF-MS is a powerful analytical technique to investigate fully processed OLEDs without the need to dissolve the OLED samples. The comparison between LDI-TOF-MS spectra collected for aged and unaged OLED samples allows the detection of different degradation products which may be associated to shorten the lifetime of the OLEDs. The analysis of the m/z signals and the shape of the isotopic pattern of individual spectra enabled us to identify some reaction products which are mainly related to the chemical dissociation of the FIrpic molecules used as phosphorescent emitter. Based on the FIrpic fragments observed only in the LDI-MS spectrum collected for the aged OLED sample a dissociation reaction pathway is proposed, which involve two different pathways: a reversible (pathway 1), involving the scission of the picolinate ligand from the FIrpic, and a second one related to the irreversible dissociation (pathway 2) of the FIrpic molecule by the loss of carbon dioxide (CO_2). Beside the chemical dissociation process of FIrpic, the formation of iridium complexes between different FIrpic fragments and surrounding materials as well as the formation of an adduct of FIrpic with cesium may also contribute to the degradation process of the OLED. Finally, the presence of m/z signals of BPhen dimers and adducts of BPhen dimers with cesium show a rearrangement of the ETL during the OLED operation.

Acknowledgments

This work has been funded by the BMBF under contract No. 13N 9872, project acronym "OPA". Additionally the authors wish to thank the Chemistry Department of the TU Dresden for providing access to their MALDI-TOF-MS device and NOVALED AG, Dresden for providing the HTL-dopant NDP-2.

ABSTRACT

We report a high-performance and air-stable flexible and invisible semiconductor which can be substitute for the n-type organic semiconductors. N-type organic–inorganic nanohybrid superlattices were developed for active semiconducting channel layers of thin film transistors at low temperature of 150 °C by using molecular layer deposition with atomic layer deposition. In these nanohybrid superlattices, self-assembled organic layers (SAOLs) offer structural flexibility, whereas ZnO inorganic layers provide the potential for semiconducting properties, and thermal and mechanical stability. The prepared SAOLs–ZnO nanohybrid thin films exhibited good thermal and mechanical stability, good flexibility, transparent in the visible range, and excellent field effect mobility (>7cm^2/V s) under low voltage operation (from −1 to 3 V). The nanohybrid semiconductor is also compatible with pentacene in p–n junction diodes.

1. Introduction

Flexible thin film transistors (TFTs) have been extensively studied over the past few decades because they have potential applications in low-cost displays, wearable devices, paper displays, and flexible electronics [1–6]. In particular, flexible semiconducting materials are considered essential elements for development of flexible TFTs. Organic semiconductors such as small organic molecules, conjugated oligomers, and conducting polymers are promising materials in electrical performance comparable to amorphous silicon (ca. 1 cm^2/V s) [7–10]. Most high-performance organic semiconductors are more likely to transport holes as charge carriers rather than electrons, leading to p-type semiconductors. In contrast, development of n-type organic semiconductors falls far behind p-type materials [11–15]. Compared to the field effect mobility (15 cm^2/V s) of p-type organic semiconductors such as single crystal rubrene, the highest reported electron mobility of n-type organic semiconductors is 1.83 cm^2/V s, which was obtained by employing thiazole derivatives [16,17]. This inferior electrical performance is caused by the inherent instability of organic anions (i.e. carbanions) which are known to react with oxygen and water in ambient conditions. Those factors also cause degradation of electrical performance in organic semiconductor devices [18–22]. Tuning electron affinity or modifying hydrophobic functionalities of n-type organic semiconductors can prevent the carbanions from reacting with oxygen and water under the normal operating conditions of devices. Despite the efforts of many research groups for over a decade, however, it is still difficult to enhance the field effect mobility of n-type organic semiconductor FETs to levels as high as p-type ones [23–27].

Organic–inorganic nanohybrid thin films provide both the stable and elegant optical, electrical, and magnetic properties of inorganic components and the structural flexibility of organic components [28–30]. Organic–inorganic hybrid superlattices are particularly attractive as flexible

doi:10.1016/j.orgel.2010.11.026

semiconducting materials because they allow the combination of the excellent electrical and flexible properties of inorganic and organic components, respectively. Recently, we developed a new vapor phase deposition method of high quality self-assembled organic layers (SAOLs), called molecular layer deposition (MLD), in order to realize precisely controlled organic–inorganic nanohybrid superlattices [31–33]. MLD is a gas phase process analogous to atomic layer deposition (ALD), which is a potentially powerful method for preparing high quality multicomponent superlattices under vacuum conditions. Using the MLD method, high quality organic thin films can be quickly formed with monolayer precision under ALD conditions (temperature, pressure, etc.) [34–37]. The MLD method can be combined with ALD to take advantages of the possibility of obtaining organic–inorganic nanohybrid thin films [38–40].

Herein, we report a high-performance and air-stable flexible semiconductor which can be substituted for n-type organic semiconductors. We combined crystalline inorganic nanolayers with organic layers, leading to organic–inorganic nanohybrid semiconductors. The inorganic layer constitutes an extended framework bonded by powerful covalent or ionic interactions to furnish high carrier mobility and good thermal and mechanical stability. The organic layer adds mechanical flexibility to the inorganic framework. MLD combined with ALD (MLD–ALD) was applied to fabricate a new n-type organic (SAOLs)–inorganic (ZnO) nanohybrid semiconductor on flexible plastic substrates with accurate control of film thickness, large-scale uniformity, excellent conformality, good reproducibility, multilayer processing capability, sharp interfaces, and excellent film qualities at low temperature. The prepared SAOLs–ZnO nanohybrid thin films exhibited good thermal and mechanical stability, good flexibility, and excellent field effect mobility (>7 $cm^2/V{\cdot}s$) under low voltage operation (from −1 to 3 V). Furthermore, we also demonstrate the performance of p–n junction diodes prepared with the SAOLs–ZnO nanohybrid superlattices and pentacene.

2. Experimental section

2.1. Preparation of Si substrates

The flexible substrates employed in this study were cut from Glastic® polyethersulfone films (i-components Inc.). The polyethersulfone (PES) substrates were cleaned with methanol and de-ionized water, and blow-dried with nitrogen to remove contaminants. The Si substrates were cut from n-type (1 0 0) wafers (LG Siltron) with resistivity in the range of 1–5 Ω cm. The Si substrates were initially treated with a chemical cleaning process that involved degreasing, HNO_3 boiling, NH_4OH boiling (alkali treatment), HCl boiling (acid treatment), rinsing in deionized water, and blow-drying with nitrogen to remove contaminants and to grow a thin protective oxide layer on the surface [41]. The ITO-coated glass substrates were cleaned with acetone, methanol, de-ionized water, and blow-dried with nitrogen to remove contaminants.

2.2. Molecular layer deposition with atomic layer deposition (MLD–ALD)

The ZnO thin films were deposited onto the substrates at 150 °C using diethylzinc (Zn 52.0 wt.%, Aldrich) and H_2O as ALD precursors. Ar served as a carrier and purging gas at a rate of 50 sccm. The diethylzinc (DEZ) and water were evaporated at 20 °C. The cycle consisted of a 0.5 s exposure to DEZ, a 5 s Ar purge, a 1 s exposure to water, and a 5 s Ar purge. The vapor pressure of the Ar in the reactor was maintained at 300 mTorr. Alkene-terminated self-assembled organic layers (SAOLs) were formed by exposing the substrates to $[CH_2{=}CH(CH_2)_6SiCl_3]$ (Aldrich; 96%) with H_2O vapor at 150 °C in the ALD chamber. 7-Octenyltrichlorosilane (7-OTS) and water were evaporated at 100 and 20 °C, respectively. Exposure times in this process were 5 s for 7-OTS with water vapor and 10 s for the Ar purge. The reactor pressure during the process was about 300 mTorr. The terminal C=C groups of the SAOLs were converted to carboxylic acid groups with ozone treatment in the ALD chamber [31]. The ozone was generated by an ozone-generator and dosed to the 7-OTS coated samples for 30 s at 150 °C. The C=C groups of the SAOLs reacted with ozone to convert to carboxylic acid groups, which provided highly active adsorption sites for the anchoring of the next monolayer. The SAOLs–ZnO nanohybrid superlattices were grown using the cyclic MLD–ALD process.

2.3. Device fabrication

The 100 nm-thick Cr gate electrode of the TFT was formed on the PES substrates by radio frequency sputter through shadow masks (pressure: $\sim 10^{-8}$ Torr, temperature: room temperature, radio frequency power: 300 W). The 30 nm-thick SAOLs–Al_2O_3 dielectric layer was grown by MLD–ALD at 150 °C. The SAOLs–ZnO nanohybrid thin films as active channel layers were deposited by MLD–ALD through shadow masks in intimated contact with the substrates. The channel dimension was 50 μm(L) × 100 μm(W). The 100 nm-thick Al source and drain electrodes were deposited by thermal evaporation through shadow masks under a pressure of $\sim 1 \times 10^{-6}$ Torr. An inverted staggered structure was employed in TFT device fabrication. The 55 nm-thick SAOLs–ZnO nanohybrid n-type semiconducting layer was deposited on the ITO-coated glass by MLD–ALD. The pentacene (Aldrich; 99%) p-type semiconducting layer was fabricated on the SAOLs–ZnO layer through a shadow mask at room temperature by thermal evaporation. The deposition rate was fixed to 1 Å/s using an effusion cell (ALPHAPLUS Co., LTE-500S) in a vacuum chamber under a pressure of $\sim 1 \times 10^{-7}$ Torr. The thickness of the pentacene films was 50 nm as monitored by a quartz crystal oscillator and confirmed by ellipsometry. The 100 nm-thick Au dot electrodes (300 μm in diameter) were deposited by thermal evaporation in a vacuum chamber under a pressure of $\sim 1 \times 10^{-6}$ Torr.

2.4. Sample characterization

The samples were analyzed by JEOL-2100F transmission electron microscopy. Specimens for cross-sectional TEM

studies were prepared by mechanical grinding and polishing (~10 μm thick) followed by Ar-ion milling using a Gatan Precision Ion Polishing System (PIPSTM, Model 691). All current–voltage (I–V) properties of the TFTs and test structures were measured with a semiconductor parameter analyzer (HP 4155C, Agilent Technologies), and C–V measurements were made with a capacitance meter (HP 4284 LCR meter, Agilent Technologies, 1 MHz) in the dark and in an air ambient (relative humidity ~45%) at 20 °C.

3. Results and discussion

We fabricated an inverted staggered thin-film transistor (TFT) using an n-type organic–inorganic nanohybrid semiconducting superlattice on a polymer substrate. The inverted staggered TFT consists of an n-type organic–inorganic nanohybrid semiconducting channel and an organic–inorganic nanohybrid dielectric between the Cr bottom gate and Al source/drain electrodes on a polyethersulfone (PES) substrate, as shown in the device schematics of Fig. 1a. The n-type organic–inorganic nanohybrid semiconductor thin films were deposited on Cr gate-patterned PES substrates by molecular layer deposition combined with atomic layer deposition (MLD–ALD). The alkylsiloxane self-assembled organic layers (SAOLs) were grown by MLD, which is self-controlled and proceeds via layer-by-layer growth. ZnO inorganic nanolayers were grown by ALD using self-terminating surface reactions at 150 °C, followed by deposition of the SAOLs films using MLD at 150 °C: we named those organic–inorganic hybrid layers as SAOLs–ZnO (Fig. 1b). In these nanohybrid superlattices, SAOLs offer structural flexibility, whereas the ZnO inorganic layers provide the potential for semiconducting properties, as well as thermal and mechanical stability.

The SAOLs–ZnO nanolaminate films were grown on Si(1 0 0) substrates at 150 °C by repeating a cyclic MLD–ALD in the same deposition chamber, as shown in Fig. 2a. The Si substrates were first coated with a 10 nm-thick ZnO nanolayer by ALD and the top layer of each nanolaminate film was ZnO. The thicknesses of SAOLs and ZnO nanolayers in each sample were controlled by adjusting the number of MLD and ALD cycles with SAOLs and ZnO growth rates of about 11 and 1.5 Å/cycle, respectively. Fig. 2b shows a TEM image of SAOLs–ZnO active channel thin films with SAOLs–Al_2O_3 gate dielectric layers on the Si(1 0 0) substrates. The root mean square (RMS) roughnesses of the SAOLs–ZnO and the SAOLs–Al_2O_3 surfaces were about 6.0 and 3.0 Å, respectively, as measured by AFM. In comparison, the surface roughness of the initial cleaned Si substrate was about 2.1 Å. The SAOLs–ZnO layers appear to be relatively uniform despite polycrystallinity of the ZnO nanolayers. Fig. 2b suggests that flat and sharp interfaces enhance electrical performance of the TFTs which include organic–inorganic nanohybrid thin films grown by using MLD–ALD.

The unit TFT was fabricated on a PES substrate using the organic–inorganic hybrid superlattices. The SAOLs–ZnO hybrid films were approximately 32.2 nm-thick and consisted of three [SAOLs (1.1 nm)/ZnO (10 nm)] bilayer subunits. As shown in Fig. 3a, typical output (drain current–drain voltage: I_D–V_D) curves were obtained from our SAOLs–ZnO TFTs with SAOLs–Al_2O_3 dielectrics at low operating biases (−1 to 3 V). The maximum I_D level was around 8 μA under 3 V gate bias. According to the transfer characteristics (I_D–V_G) of Fig. 3b, a high field effect mobility of >7 $cm^2/V\,s$ was achieved in the saturation regime of V_D = 3 V along with an on/off ratio of $>10^6$ and a threshold voltage of 0.6 V. Gate leakage current (I_G) was below 10^{-11} A. Our device mobility is the highest among other n-type OTFTs with low threshold voltage. These SAOLs–ZnO TFTs could increase operating speed and decrease power consumption for flexible electronic devices operated under low operating biases. For comparison, a TFT was also fabricated on the PES substrate using a pure ZnO thin film grown by ALD at 150 °C. The mobility of the ZnO TFT (14 $cm^2/V\,s$) is higher than that of the SAOLs–ZnO while our operating voltage (3 V), on/off current ratio (10^6), and threshold voltage (0.6 V) are quite comparable.

The transfer characteristics of the SAOLs–ZnO TFTs before and after bending (bending direction across the channel) are presented in Fig. 3b. No significant loss in performance was observed when the devices were bent to a radius as small as 6 mm, as found in bending experiments performed on five randomly chosen devices that all exhibited similar behavior. The SAOLs–ZnO TFTs are also transparent in the visible range, as shown in Fig. 3c. These data demonstrate that our nanohybrid TFTs are potentially useful for flexible and invisible electronics.

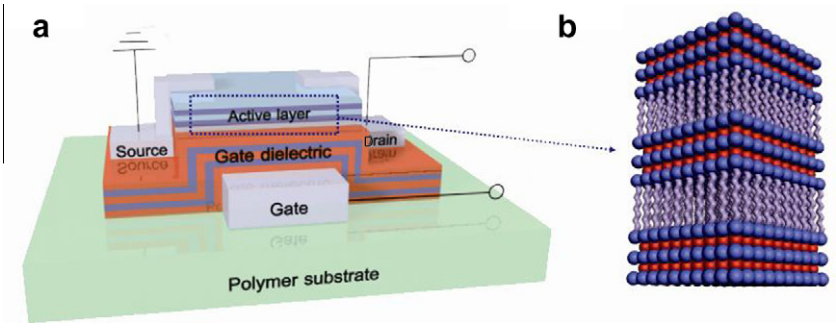

Fig. 1. (a) Schematic diagram of the TFTs with organic–inorganic nanohybrid active channel layers and gate dielectrics on flexible substrates. (b) Molecular structure of the SAOLs–ZnO organic–inorganic nanohybrid semiconducting thin films made by MLD–ALD.

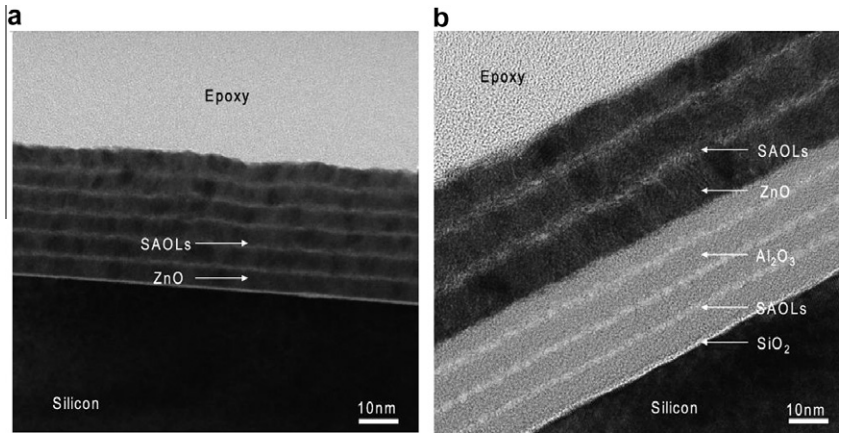

Fig. 2. (a) TEM image of SAOLs–ZnO nanohybrid superlattices made by MLD–ALD. (b) TEM image of SAOLs–ZnO nanohybrid superlattices on SAOLs–Al_2O_3 nanohybrid superlattices made by MLD–ALD.

We also estimated the stability and lifetime of the SAOLs–ZnO TFTs in air under controlled relative humidity and temperature. Our experiments were carried out in an environmental chamber, where relative humidity (±2%) and temperature (±1 °C) can be controlled simultaneously. Relative humidity and temperature were kept fixed in all experiments at 50% and 20 °C, respectively. After 6 months, this device still operated with constant field effect mobility and on-current, and slightly increased off-current, presumably due to light-generated oxygen vacancies and electrons.

To verify that our organic–inorganic superlattice is compatible with organic pentacene semiconductors, vertical p–n junction diodes were fabricated on ITO-coated glass. Pentacene was chosen as a p-type organic semiconductor because it is considered the benchmark material for maximum mobility in organic layers. A 55 nm-thick SAOLs–ZnO superlattice was grown on ITO-coated glass as the n-type semiconductor layer using MLD–ALD. A 50 nm-thick pentacene thin film was deposited on the SAOLs–ZnO layer by using a vacuum as the p-type semiconductor layer. In this diode, ITO and Au metals were used

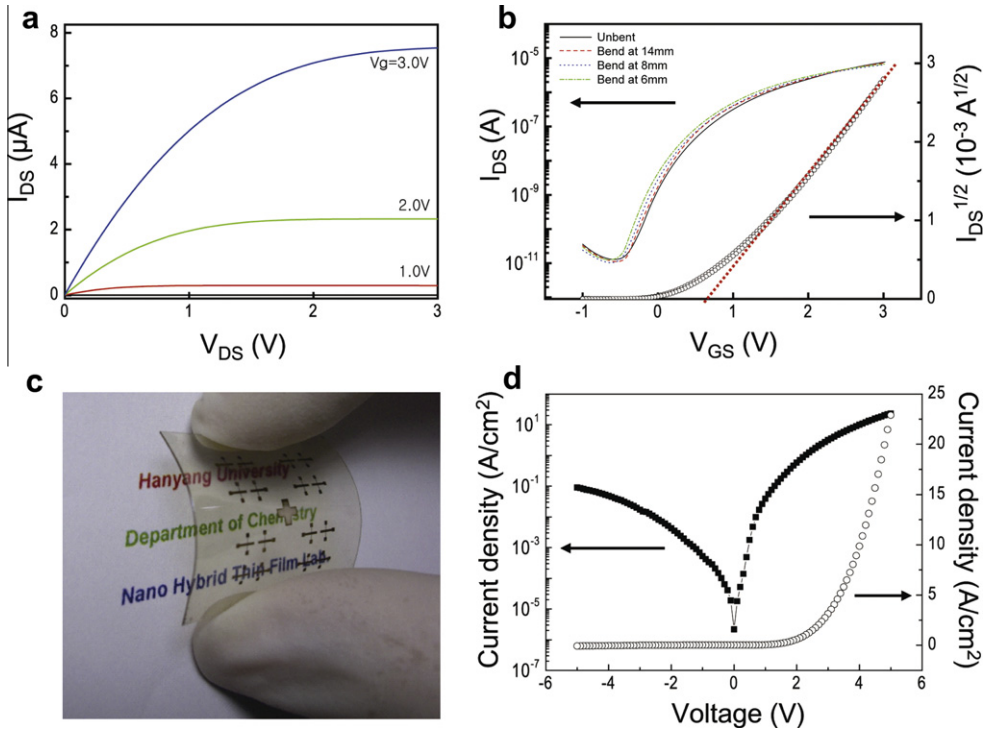

Fig. 3. (a) Drain current–drain voltage (I_{DS}–V_{DS}) output curves for our TFTs with the SAOLs–ZnO active channel layers. (b) Drain current–gate voltage (I_{DS}–V_{GS}) transfer curves of the TFTs unbent and bent at 14 mm, 8 mm, and 6 mm bending radius. (c) Photograph of our flexible TFT. (d) Current density–voltage characteristics (I–V) for the vertical p–n junction diodes with the SAOLs–ZnO nanohybrid and pentacene thin films.

as bottom and top electrodes, respectively. Fig. 3d shows *I–V* characteristics of the vertical p–n junction diodes. The current density at 5 V of the operating bias is 23 A/cm^2, which is comparable to that of other organic vertical diodes. The DC rectification ratio at ±5 V is more than 100. The forward turn-on voltage of the diode is approximately 2 V. The reverse breakdown voltage of the diodes is −17 V, eight times higher than the threshold voltage.

4. Conclusion

In conclusion, n-type organic–inorganic nanohybrid superlattices were developed for active semiconducting channel layers of TFTs at a low temperature of 150 °C by using MLD–ALD. SAOLs–ZnO TFTs on a flexible plastic substrate show a high field effect mobility of 7 cm^2/V·s, operating at 3 V with an on/off current ratio of 10^6 and also with a threshold voltage of 0.6 V. The ZnO inorganic component is a high-mobility n-type semiconductor and the SAOLs organic component provides structural flexibility. The stability and lifetime of the SAOLs–ZnO TFTs with good flexibility and excellent transparence in the visible range were tested under controlled relative humidity and temperature for 6 months. Field effect mobility of these TFTs was constant within measurement error range. Vertical p–n junction diodes were fabricated using the SAOLs–ZnO as the n-type semiconductor layer and pentacene as the p-type semiconductor layer, to verify that the organic–inorganic nanohybrid semiconductors can work with organic semiconductors.

ABSTRACT

We have studied the fabrication of an inverted P3HT:$PC_{71}BM$ bulk hetero-junction (IBHJ) solar cell using ultrathin cesium carbonate (Cs_2CO_3) and molybdenum trioxide (MoO_3) as the cathodic and anodic buffer layers, respectively. The influence of MoO_3 thickness on the performance of the IBHJ solar cells was investigated for thicknesses ranging from 0.75 to 3 nm and the optimum thickness was found to be 2 nm, which showed the highest power conversion efficiency of 4.01%. We also found that the power conversion efficiency of the IBHJ solar cells is relatively retained even in low temperature while that of BHJ solar cell rapidly decreased with decreasing temperature and the stability in air is also much better.

1. Introduction

Organic solar cells are of increasing interest because of their potential low cost manufacturing via simple processes [1,2]. Of particular interest are bulk hetero-junction (BHJ) solar cells, which have so far been regarded as having the promising structure for obtaining high internal quantum efficiency (IQE). Moreover, solution process-based BHJ solar cells with a blend of polymer and fullerene derivatives have emerged as promising candidates for flexible photovoltaic devices and a variety of large area applications [1–3]. Owing to the interpenetrating network between donor and acceptor materials, the BHJ structure, compared to the bi-layer structure of single junction solar cells, has a wider interface region that enhances the dissociation of excitons into mobile electrons and holes [4,5]. Using regio-regular poly(3-hexylthiophene) (rr-P3HT) and [6,6]-phenyl C71 butyric acid methyl ester ($PC_{71}BM$), conventional BHJ solar cells with high PCE above 3–5% have been reported.

Although the efficiency of BHJ solar cells is increasing steadily, stability remains as an obstacle to its commercialization. Since the conventional organic BHJ solar cell is composed of an *ITO/PEDOT:PSS/active layer/low work function metal cathode* structure, problems associated with the electrodes are common; a low work function metal is easily oxidized and PEDOT:PSS can degrade the ITO electrode due to its strong acidity [6]. To overcome these problems, PEDOT:PSS is often replaced by metal oxides such as MoO_3 [7], WoO_3 [8], NiO [9], as the anodic buffer layer in the conventional structure. It is also known that n-type metal oxides such as TiO_2 [10], ZnO [11], and low work function alkali metal compounds such as LiF [12], Cs_2CO_3 [13] can be used to improve electron extraction and device stability. The inverted structure, in which polarities of electrodes are converted using anodic/cathodic buffer layers such as metal oxides or alkali metal compounds have thus received more attention as a new device structure for high efficiency as well as good stability. Recently, the Y. Yang group demonstrated an efficient inverted solar cell with Cs_2CO_3 and V_2O_5 buffer layers [14] and introduced the concept of vertical phase separation [15]. According to this concept, an inverted structure would be an advantage for higher efficiency as well as stability.

In this study, we demonstrate a stable inverted P3HT:$PC_{71}BM$ BHJ (IBHJ) solar cell with Cs_2CO_3 and MoO_3 buffer layers. IBHJ solar cells showed better stability and efficiency as compared with the conventional BHJ solar cells. We also investigated the influence of MoO_3 thickness to obtain an optimum layer thickness and studied the temperature dependency of the solar cell properties.

2. Experiment

The device structure of the solar cell studied in this work is an ITO (150 nm)/Cs_2CO_3 (0.5 nm)/Active layer (70 nm)/MoO_3 (*x* nm)/Al (100 nm). Fig. 1a shows the cross sectional view of the solar cell. The IBHJ solar cells were prepared according to the following procedure: A 0.1wt.% Cs_2CO_3 resolved in 2-ethoxy ethanol was spin coated at 4000 rpm on the patterned ITO glass substrate to form an ultra-thin layer. The Cs_2CO_3 layer was annealed at 150 °C for 20 min. The active solution was formed by a 1 wt.% of P3HT (Aldrich) and 1 wt.% of $PC_{71}BM$ (Aldrich), which were separately dissolved in 1, 2 dicholorobenzene and blended together in ratios of 1:0.6. The active solution was spin-casted at 700 rpm on the top of the ultra-thin Cs_2CO_3 layer. The fabricated active layer was then annealed at 130 °C for 30 min.

The thickness of active layer was ~70 nm, measured by a surface profiler (ET-3000 Kosaka. Lab. Ltd.). Following this, a MoO_3 layer was evaporated on the active layer and then a 100 nm Al layer was deposited without breaking the vacuum (~10^{-7} Torr, deposition rates (MoO_3: 0.01 nm/s; Al: 0.2–0.4 nm/s)). Without the post annealing, the cells were encapsulated with a glass cap and UV-resin. We used a current meter (Keithley 2400 LV) and a xenon lamp based solar simulator (MAX-302) to measure the solar cell properties under AM 1.5 (100mWcm^{-2}). External quantum efficiency (EQE) was measured by using a 300 W xenon light source with a monochromator (Oriel Cornerstone 130). The temperature dependence measurements were carried out in a cryostat system (JANIS CCS-450) having 10^{-3} mbar of vacuum.

3. Results and discussion

Fig. 1b shows the energy level diagram of an IBHJ solar cell. The deposition of an ultra-thin Cs_2CO_3 layer on ITO increases the contact angle and reduces its effective work function [14]. We changed the annealing temperature between 130 °C and 190 °C and the spin coating speed from 4000 rpm to 700 rpm. The optimum annealing temperature and spin speed were found to be 150 °C and 4000 rpm, respectively. The optimized fabrication condition of Cs_2CO_3 layer is similar to that of Liao's result [14]. At the optimum Cs_2CO_3 deposition condition, the MoO_3 thickness was varied from 0.75 to 3 nm.

Fig. 2 shows the *J*–*V* characteristics of the solar cells with different MoO_3 thickness under illumination. The optimized IBHJ (with MoO_3 of 2.0 nm) shows the highest J_{SC} of 10.1 mA/cm^2 and PCE of 4.01%. Note that the conventional BHJ solar cell having the structure ITO/PEDOT:PSS/Active layer (70 nm)/LiF/Al (100 nm) exhibited a J_{SC} of 8.8 mA/cm^2 and PCE of 3.63%. The device with MoO_3 of 0.75 nm shows unstable solar cell properties with high sheet resistance (R_S), poor fill factor (FF) and open circuit voltage (V_{OC}). The reason for this lies in the small MoO_3 intermolecular distance (~0.7 nm) and thus 0.75 nm is not enough to have full-coverage on the Al electrode; making the formation of islands more favorable compared to a thin layer [16]. With increasing MoO_3 thickness, the V_{OC}, FF

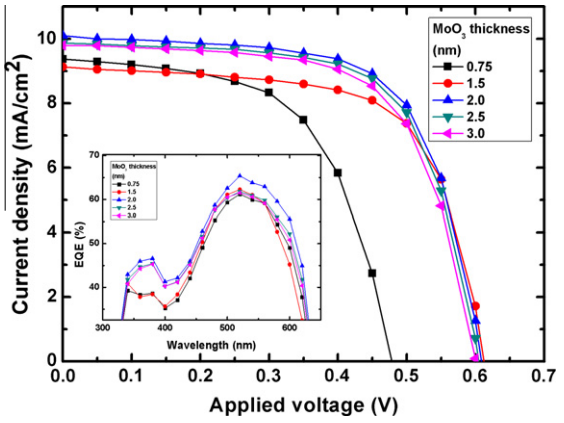

Fig. 2. The *J–V* characteristics of the inverted BHJ solar cells with different MoO_3 thicknesses under AM 1.5 illumination. The inset shows the EQE of the inverted BHJ solar cells with different MoO_3 thicknesses.

and R_S are thus improved, and in our case, up until 2 nm, after which the R_S increases due to the increased MoO_3 resistance.

A thin MoO_3 layer, with 1–3 atom layers, is able to convert the electrode polarity because MoO_3 has very deep LUMO (Lowest Unoccupied Molecule Orbital) and HOMO (Highest Occupied Molecule Orbital) levels of −5.8 and −9.0 eV [17], respectively. Such deep HOMO and LUMO levels results in easy formation of a strong dipole effect. Moreover, it was previously reported that a thin MoO_3 layer increases the work function of Al and thus reduces the hole injection barrier between Al and the p-type organic material by Fermi level pinning [18]. A MoO_3 thin layer would also modify the electronic structure of the P3HT/Al interface. The work function of the 2 nm MoO_3 on Al in our experiment was found to be 5.12 eV by ultraviolet photoelectron spectroscopy (UPS) measurement, and this value is very close to the HOMO of P3HT (5.2 eV). Therefore, hole extraction can be improved by inserting a MoO_3 layer on Al.

Table 1 summarizes the solar cell properties as a function of MoO_3 thickness. With increasing the MoO_3 thickness, the FF increased to the maximum and R_S decreased to the minimum at 2 nm. With further increase in the MoO_3 thickness (above 2.0 nm), the R_s increases slightly due to the resistance of MoO_3. A 2 nm MoO_3 anodic buffer layer induces a good ohmic contact to extract holes, resulting in high FF and low R_S.

The inset of Fig. 2 shows the external quantum efficiency (EQE) of the IBHJ solar cells with different MoO_3 thicknesses. The PCE accords with the enhancement of EQE. Even in the most dominant absorption range of conventional P3HT:$PC_{71}BM$ cells, which ranges from 480 to 550 nm, the EQE of IBHJ solar cell is ~18% higher. T. Ameri et al. previously reported this phenomena where an IBHJ solar cell with a TiO_x layer had a higher EQE than the conventional structure [19]. In our result, the main peak in EQE shifted slightly to the short wavelength region compared to that one of the conventional device. No wavelength shift was found in UV–Vis absorption measurement for the PEDOT/active and Cs_2CO_3/active layers. The shift of EQE indicates the modification of the optical field distribution due to total thickness variation of the device and may be related to the absence of the PEDOT:PSS layer. In our measurements, conventional PEDOT:PSS layers of several tens of nanometer thicknesses show around 95% transmittance and several hundreds of Ohm-centimeter resistivity values. This will lead to reduced efficiency due to optical absorption and inefficient carrier transport processes. On the other hand, since the Cs_2CO_3 layer is ultrathin, there is nearly 100% transmittance and thus no loss in efficiency.

Table 1
The solar cell performances of IBHJ devices with different MoO_3 thickness.

MoO_3 thickness (nm)	0.75	1.5	2.0	2.5	3.0
V_{OC} (V)	0.478	0.605	0.609	0.605	0.601
J_{SC} (mA/cm^2)	9.37	9.14	10.1	9.87	9.82
FF (%)	58.36	64.72	65.37	65.07	64.12
PCE (%)	2.62	3.58	4.01	3.89	3.79
R_S (Ω cm^2)	4.17	3.27	3.07	3.24	3.38

We also calculated the spatial distribution of the optical field in the IBHJ solar cells using the transfer matrix method [20]. Fig. 3 shows the comparison of the optical field distributions between inverted cells with a thin MoO_3 layer and PEDOT:PSS layer. The intensity is almost the same, but the optical field distribution in the active layer is better for the inverted structure with a thin MoO_3 layer compared to that with a PEDOT:PSS layer, because, in this structure, the field distribution is pushed towards the active layer.

In our result, the highest J_{SC} is also obtained for a MoO_3 thickness of 2 nm. To confirm the optical spacer effect as the MoO_3 layer thickness is varied from 0.75 to 3 nm, we calculated the spatial distribution of the optical field in IBHJ solar cells for each thickness. Considering the refractive index of ~2.4, there is a little effect on the absorption of the BHJ when the MoO_3 thickness is less than 3 nm. By increasing the MoO_3 thickness to 3 nm, the optical field distribution shifts slightly to the anodic buffer layer.

Fig. 4 shows the stability of an IBHJ solar cell in air. The IBHJ shows better stability than the conventional BHJ solar cell in ambient air at 295 K for 40 days. The PCE of the IBHJ solar cell drops to about 93.5% of the initial value, while that of BHJ solar cell decreases to 87.7%. This may be due to less damage to the ITO in the IBHJ because there is no PEDOT:PSS process and the improvement of carrier extraction due to the existence of a thin MoO_3. Therefore, IBHJ solar cell shows better stability and efficiency compared to conventional BHJ solar cells.

Fig. 5 shows the *J–V* characteristics of an IBHJ solar cell with a 2 nm MoO_3 layer at various temperatures. While the J_{SC} increases with increasing temperature up to 340 K and starts to decrease at temperatures $\geqslant$360 K, the V_{OC} decreases gradually with increasing temperature. The same tendency was previously reported for silicon-based inorganic solar cells [21,22]. As a result, the cells exhibited their maximum efficiency at ~300 K. Prolonged heating of the devices would induce irreversible reactions such as thermal oxidation, P3HT rearrangement and PCBM aggregation [23,6]. The degradation in efficiency observed at

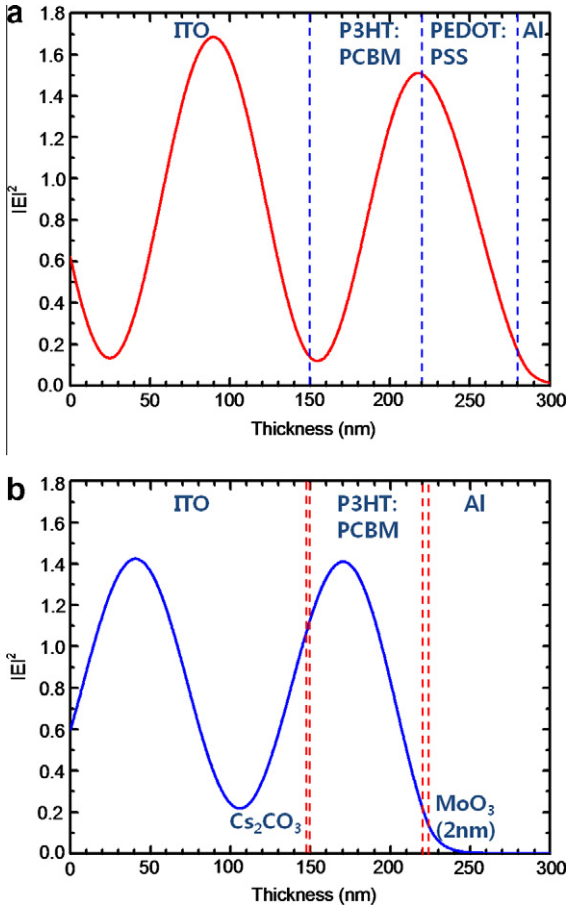

Fig. 3. The spatial distributions of optical field in inverted BHJ solar cells with (a) PEDOT:PSS layer and (b) Cs_2CO_3 and MoO_3 layer.

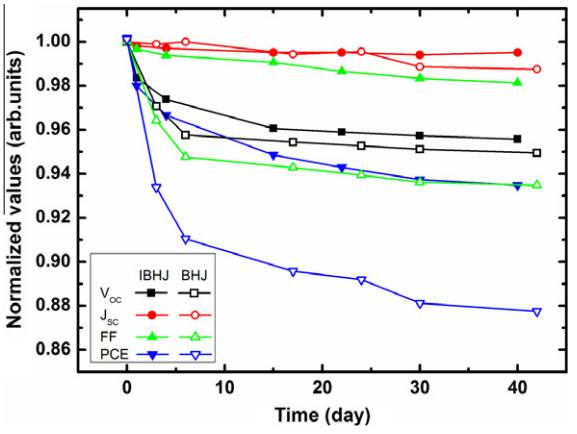

Fig. 4. Plot of solar cell parameters as a function of time in ambient air. The parameters are normalized to initial values. Solid symbols represent the parameters of inverted BHJ solar cell and open symbols represent that of conventional BHJ solar cell.

temperatures $\geqslant$360 K in both structures is due to this thermal effect. Fig. 6 shows the J–V characteristics of our conventional BHJ solar cell under AM 1.5 illumination at low

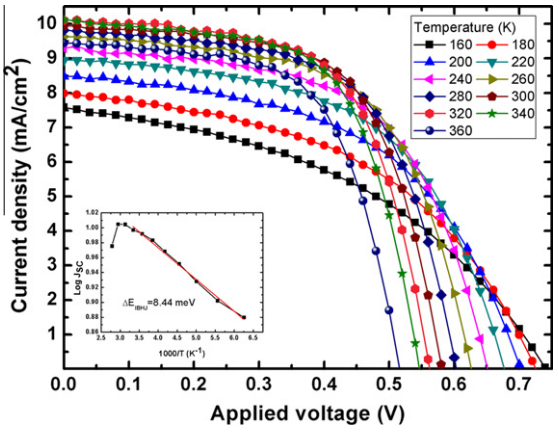

Fig. 5. The J–V characteristics of the inverted BHJ solar cells under AM 1.5 illumination with a 2.0 nm of MoO_3 layer at low temperatures. The inset shows the extraction of activation energy ΔE and J_0 under illumination.

temperatures. The insets of Figs. 5 and 6 show the extraction of activation energy ΔE and J_0 of both solar cells under illumination in the temperature range showing linearity between log J_{SC} and the inverse of absolute temperature.

J_{SC} has the temperature dependence behavior due to the thermally assisted hopping conduction in the disordered organic material. The activation energies of both structures are shown in the insets of Fig. 5 and 6. For the IBHJ solar cell with a 2.0 nm thick MoO_3 layer, an activation energy of 8.44 meV and J_0 of 13.63 mA/cm^2 are extracted using the following equation [21];

$$J_{SC}(T) = J_0 \exp(-\Delta E/kT), \tag{1}$$

where J_0 is a pre-exponential factor, ΔE is the activation energy, k is the Boltzmann constant, and T is an absolute temperature.

The IBHJ solar cells are more stable in ambient air and the reduction of efficiency at low temperature is much less as compared to conventional BHJ solar cell. The

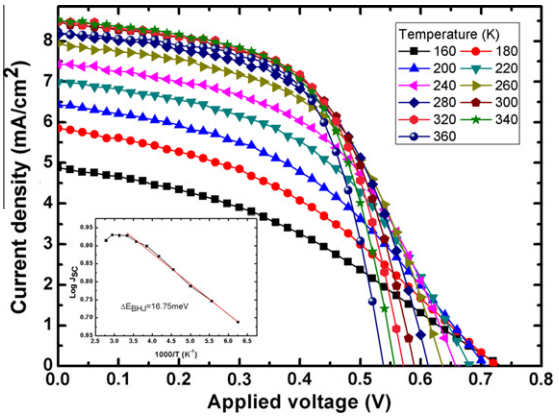

Fig. 6. The J–V characteristics of the conventional BHJ solar cells under AM 1.5 illumination at low temperatures. The inset shows the extraction of activation energy ΔE and J_0 under illumination.

variation in solar cell properties such as J_{SC}, FF, and PCE are relatively small with decreasing temperature. As the measurement temperature changes from 300 to 240 K, the PCE of the IBHJ solar cell decreases to 98% of the value at 300 K.

The activation energy of J_{SC} for the IBHJ solar cell is 8.44 meV which is much smaller than that (16.75 meV) of conventional BHJ solar cell, indicating that the efficiency lowering is much less for the IBHJ solar cell as compared to that of the conventional BHJ. The difference appears to be due to the different carrier extraction mechanisms for the same active layer in the two structures.

4. Conclusion

We have studied the fabrication of the inverted BHJ solar cells with Cs_2CO_3 and MoO_3 buffer layers. IBHJ solar cells show better performance due to the absence of the PEDOT:PSS layer and the existence of an efficient hole extraction mechanism through the MoO_3 layer. The cell using both the Cs_2CO_3 and MoO_3 layers has improved lifetime and conversion efficiency. The reduction in efficiency of the proposed IBHJ solar cell with decreasing temperature is also much lower than that of the conventional BHJ solar cell.

ABSTRACT

A new multifunctional compound, 4,4′-di-(1-pyrenyl)-4″-[2-(9,9′-dimethylfluorene)]-triphenylamine (DPFA) has been designed, synthesized and applied respectively as host-emitter, electron- and hole-transporters in organic light-emitting devices (OLEDs). The compound exhibits good thermal stability with a glass transition temperature (T_g) of 161 °C and shows blue emissions in both solution and films. OLEDs with DPFA playing various roles have been fabricated and characterized. The results show that DPFA has efficient bipolar charge transport properties for both hole and electron. By using DPFA as a blue emitter in a typical three layer device with a configuration of ITO/NPB(50 nm)/DPFA(20 nm)/TPBI(30 nm)/LiF(0.5 nm)/MgAg, highly efficient blue emission with a maximum luminescence efficiency of 5.1 cd/A (5.3 lm/W) is obtained.

1. Introduction

White organic light-emitting devices (OLEDs) have drawn much attention due to their applications as backlights for liquid–crystal displays and for solid-state lightings [1–4]. For these applications, high efficiency and long life-time are important. Phosphorescent OLEDs have been shown to harvest 100% of the excitons generated by electrical injection, corresponding to a four times increase in efficiency compared to that achievable in singlet-harvesting fluorescent OLEDs [5]. For this reason, white OLED using phosphorescent emitters has been a focus of intense research. Meanwhile, one bottleneck for further enhancing the efficiency of white OLEDs is the performance of blue phosphorescent emitters, which is far behind those of green and yellow phosphorescent emitters. Although many blue phosphorescent emitters have been reported, Iridium(III)bis[(4,6-difluorophenyl)-pyridinato-N,$C^{2'}$]picolinate (FIrPic) is still the best and most widely used blue phosphorescent emitter [6–10]. However, FIrPic is in fact a blue–green emitter, with two peaks at 472 and 500 nm, respectively [11,12]. The color purity of the OLEDs based on FIrPic is thus compromised. Moreover, it is known that lifetime of FIrPic-based devices are often inadequate [2]. Till now, efficient blue phosphorescent emitters with a long lifetime have been scarce. Thus, more and more researchers have put efforts on white OLEDs which take advantages of red or yellow phosphorescent and blue fluorescence emitters. Therefore, high performance blue fluorescent emitters are expected to play an important role in white OLEDs.

On the other hand, keeping a good balance of electron and hole currents in OLEDs is known to be important for achieving a high efficiency [13]. One possible way to

doi:10.1016/j.orgel.2010.12.001

improve the charge balance in OLEDs is to use emitters with bipolar charge transporting properties. Till now, reported bipolar emitters are mostly emitting in longer wavelength and there are few bipolar blue emitters [14–19].

In this paper, we report the synthesis and characterization of a new compound, 4,4′-di-(1-pyrenyl)-4″-[2-(9,9'-dimethylfluorene)]-triphenylamine (DPFA). The compound exhibits good thermal stability with a glass transition temperature (T_g) of 161 °C and shows blue emission in both solution and films. It was found that in addition to giving a strong blue emission, DPFA can also efficiently transport both electrons and holes. A device with the configuration of ITO/NPB(50 nm)/DPFA(20 nm)/TPBI(30 nm)/LiF(0.5 nm)/MgAg shows a low turn-on voltage of 2.8 V and highly efficient blue emission with a maximum luminescence efficiency of 5.1 cd/A (5.3 lm/W).

2. Experimental

2.1. Material synthesis

All solvents were purified by routine procedures. Other reagents were used as received from commercial sources, unless otherwise stated.

4-[2-(9,9′-dimethylfluorene)]-triphenylamine (compound 1): 2-bromo-9,9′-dimethylfluorene (2.72 g), and triphenyl boronic acid (2.41 g), Pd $(PPh_3)_4$ (0.07 g), aqueous Na_2CO_3 (2.0 M, 15 mL), ethanol (10 mL), toluene (30 mL) were mixed in a flask. The mixture was degassed for several times and then the mixture was refluxed at 100 °C for 24 h under a nitrogen atmosphere. After cooling to room temperature, the solvent was evaporated under vacuum and the product was extracted with dichloromethane (CH_2Cl_2). The CH_2Cl_2 solution was washed with water and dried with $MgSO_4$. Evaporation of the solvent, followed by column chromatography on silica gel gives a white solid. Yield: 83%; MS (m/z): 437 (M^+); ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 1.53 (*s*, 6H), δ: 7.01–7.06 (*t*, 2H), 7.13–7.18 (*m*, 6H), 7.24–7.26 (*d*, 2H), 7.27–7.38 (*m*, 4H), 7.43–7.46 (*d*, 1H), 7.52–7.56 (*m*, 3H), 7.57–7.63 (*d*, 1H), 7.72–7.78 (*t*, 2H).

4,4′-Dibromo-4″-[2-(9,9′-dimethylfluorene)]-triphenylamine (compound 2): compound 1 (2.18 g) was dissolved in 50 mL of DMF and then the solution was cooled by ice water. A solution of N-bromosuccinimide (NBS) in 30 mL of DMF was added drop-wise into the solution of compound 1. The reaction mixture was stirring for 3 h while kept cooled by ice water. Two hundred and fifty milliliters of cooled water was then added into the mixture to obtain a white precipitate. The precipitate was washed by plenty of water and further purified by column chromatography on silica gel to give a white solid. Yield: 86%; MS (m/z): 595 (M^+); ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 1.53 (*s*, 6H), δ: 6.98–7.03 (*t*, 4H), 7.12–7.15 (*d*, 2H), 7.30–7.40 (*t*, 6H), 7.44–7.47 (*m*, 1H), 7.53–7.58 (*m*, 3H), 7.61–7.62 (*d*, 1H), 7.73–7.79 (*t*, 2H).

4,4′-Di-(1-pyrenyl)-4″-[2-(9,9′-dimethylfluorene)]-triphenylamine (DPFA): compound 2 (1.78 g), and pyrene boronic acid (2.46 g), Pd $(PPh_3)_4$ (0.05 g), aqueous Na_2CO_3 (2.0 M, 10 mL), ethanol (7 mL), toluene (20 mL) were mixed in a flask. The mixture was degassed several times and the mixture was then refluxed at 100 °C for 24 h under a nitrogen atmosphere. After cooling to room temperature, the solvent was evaporated under vacuum and the product was extracted with dichloromethane (CH_2Cl_2). The CH_2Cl_2 solution was washed with water and dried with $MgSO_4$. Evaporation of the solvent, followed by column chromatography on silica gel gives a white green solid. Yield: 62%; MS (m/z): 835 (M^+); ^{1}H NMR ($CDCl_3$, 300 MHz): δ: 1.56 (*s*, 6H), δ: 7.33–7.39 (*m*, 2H), 7.46–7.50 (*m*, 7H), 7.62–7.65 (*d*, 5H), 7.70–7.82 (*m*, 5H), 8.00–8.08 (*m*, 5H), 8.11 (*s*, 5H), 8.18–8.27 (*m*, 6H), 8.35–8.38 (*d*, 2H). Anal. Calcd. For $C_{65}H_{43}N$: C, 93.41; H, 5.15%; N, 1.44%. Found: C, 95.20; H, 5.14%; N, 1.49%.

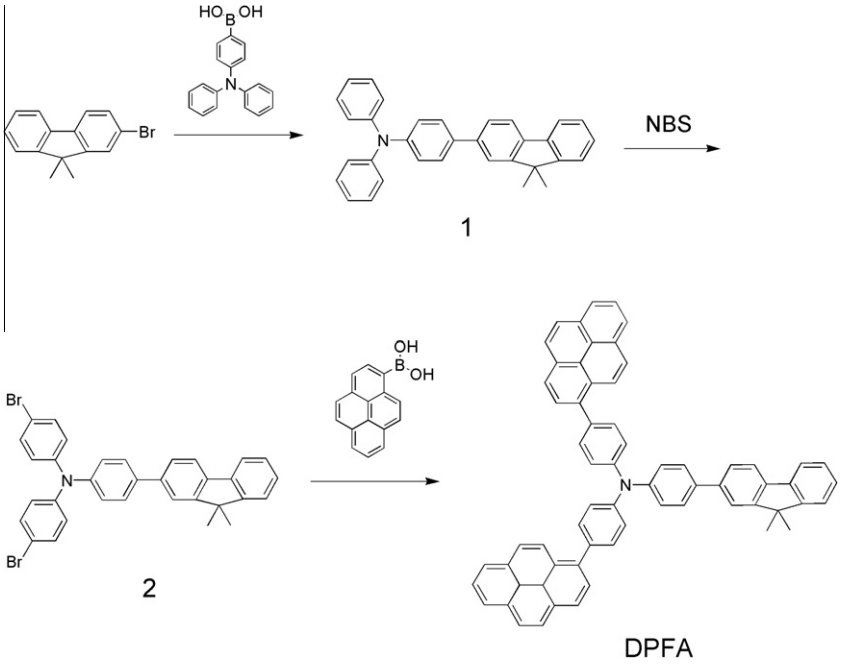
Absorption and fluorescence spectra were recorded using a Perkin Elmer Lambda 2S UV–Vis spectrophotometer and a Perkin Elmer LS50B Luminescence spectrophotometer, respectively. Glass transition temperatures (T_g) were determined with a differential scanning calorimeter (DSC, TA instruments 2910MDSC) at a heating rate of 5 °C/min. Decomposition temperature (T_d) was obtained from TGA measurements using a TA instruments Q50 TGA with a heating rate of 20 °C/min. Highest occupied molecular orbital (HOMO) levels of the new compound were measured directly by using ultraviolet photoelectron spectroscopy (UPS), while the lowest unoccupied molecular orbital (LUMO) values were determined from the HOMO and the lowest energy absorption edge of the UV absorption spectra.

Device fabrication and measurement: OLEDs were fabricated by vacuum deposition on ITO glass substrates with a sheet resistance of 30 Ω/□. The emission area of each device was 10 mm^2. Before deposition, the ITO substrate was carefully cleaned, rinsed with deionized water several times, dried in an oven at 120 °C for an hour, and finally treated with UV–ozone. The ITO substrate was then loaded into a deposition chamber with a base pressure better than 3×10^{-6} mbar. The devices were fabricated by evaporating organic layers onto the ITO substrate sequentially at an evaporation rate of 2–4 Å/s. The Mg:Ag alloy cathode was prepared by co-evaporation of Mg and Ag at a volume ratio of 10:1. EL spectra and CIE color coordinates of unpackaged devices were measured with a Spectrascan PR650 photometer and the current–voltage–luminescence characteristics were measured with a computer-controlled Keithley 236 source meter under ambient condition.

3. Results and discussion

4,4′-Di-(1-pyrenyl)-4″-[2-(9,9′-dimethylfluorene)]-triphenylamine (DPFA) was synthesized according to the synthetic route in Scheme 1. The molecular structure of DPFA was confirmed by ^{1}H nuclear magnetic resonance, mass spectrometry and element analysis.

Thermal properties of DPFA were characterized by TGA and DSC measurements. DPFA is thermally stable up to 450 °C as shown by its high decomposition temperatures (T_d) in the TGA measurements. DPFA sample melted at 268 °C in the first run of the DSC measurement. As the melted sample was reheated on the second run, a glass transition was observed at 161 °C.



Scheme 1. The synthetic route of DPFA.

Fig. 1 shows absorption and photoluminescence (PL) spectra of DPFA in a dichloromethane solution and in a solid film. The PL spectrum of DPFA in solution shows a deep blue emission peak centered at 425 nm. The PL spectra in solution and in film are similar except for a red shift of 45 nm in the solid film. The fluorescence quantum yield of DPFA in a dichloromethane solution was measured to be 0.63. HOMO and LUMO energy levels of DPFA were determined to be 5.5 and 2.8 eV, respectively, by UPS and optical absorption.

To investigate the electroluminescence and charge transporting properties of DPFA, five devices were fabricated with active layers of,

I: DPFA(100 nm);
II: NPB(50 nm)/Alq_3(20 nm)/DPFA(30 nm);
III: DPFA(50 nm)/Alq_3(50 nm);
IV: DPFA(60 nm)/TPBI(30 nm) and
V: NPB(50 nm)/DPFA(20 nm)/TPBI(30 nm).

All the devices were sandwiched between an ITO anode and a composite cathode of LiF(0.5 nm)/Mg:Ag.

Device I is single layer device in which DPFA plays the role of emitter, hole- and electron-transporters. As shown in Fig. 2, the turn-on voltage (defined as the driving voltage required to give a brightness of 1 cd/m^2) of Device I is only 2.7 V, which is unexpectedly low for an OLED employ only one organic material. At 5 V the device can give a blue emission (peaked at 476 nm) of more than 100 cd/m^2 with CIE coordinates of $x = 0.17$ and $y = 0.29$. Similarity of the PL

and the EL spectra suggests that the EL can be attributed to the emission from the singlet excited state of DPFA. Table 1 lists key performance data of the device. While, the efficiency of device I is low, these results clear shown that DPFA can transport hole and electron and can be used as a host emitter.

To further explore the bipolar carrier transport properties of DPFA, devices II and III have been fabricated to use DPFA as electron and hole-transporter, respectively. In device II (NPB/Alq_3/DPFA) DPFA is used as the electron-transporter. The device turns on at 3.1 V (Fig. 3 and Table 1) and gives green Alq_3 emission peaked at 524 nm. It delivers a brightness of 11,490 cd/m^2 at 13 V and has a

Table 2
Electroluminescence data of state-of-the-art OLEDs based on bipolar blue emitters.

Compound	Turn-on voltage (V)	Maximum current efficiency (cd/A)	Maximum power efficiency (lm/W)	Maximum luminous peak (nm)	CIE coordinates (at 20 mA/cm^2)	References
PhSPDPV	3	5.4	5.7	478	0.14, 0.22	[20]
TP-EPY	4.4	1.7	0.7	453	0.15, 0.07	[21]
CzThB	5.5	–	4.9	473	0.13, 0.21	[22]
DPF	3.3	6.0	3.6	470	0.15, 0.19	[14]
DPFA	2.8	5.1	5.3	472	0.14, 0.24	This work

maximum efficiency of 3.0 cd/A. As performance of this device is similar to that of a standard bilayer NPB/Alq_3 device, it can be reasonably expected the electron-transporting ability of DPFA is comparable with that of Alq_3.

Device III has a typically double layer structure (DPFA/Alq_3) in which DPFA functions as the hole-transporter; whereas Alq_3 is used as the emitter and electron-transporter. The device shows green Alq_3 emission peaked at 518 nm. As shown in Fig. 4, the turn on voltage of device III is just 2.5 V and the brightness is higher than 12,000 cd/m^2 at a voltage of 8 V. Device III has a maximum efficiency of 3.9 cd/A (3.2 lm/W), which is better than the performance of the standard NPB/Alq_3 device. The results suggest that DPFA is likely to have a better performance than NPB in terms of hole-transporting ability.

Device IV has a bilayer structure of DPFA/TPBI. Due to the low-lying HOMO of TPBI, it is commonly used a hole-blocker. Thus, in device IV, electrons and holes are expected to recombine in the DPFA layer. Therefore, DPFA functions as a hole-transporting emitter here. As shown in Fig. 5, the device shows a blue EL peak at 472 nm which can be attributed to the singlet emission of DPFA. A high maximum efficiency of 4.3 cd/A (4.5 lm/W) and CIE coordinates of $x = 0.14$ and $y = 0.22$ were observed. These results can firm that DPFA has good hole transporting properties and efficient blue emission.

While results from devices I–IV do show that DPFA has good electron and hole transporting properties, charge balance of electron and hole currents were not optimized due to mismatching of the energy levels between the organic layers and the electrodes in these devices. Thus, a typical three layers device with a configuration of NPB/DPFA/TPBI (device V) has been fabricated with DPFA as an emitter to improve device performance. *I–V–L* characteristics of device V are shown in Fig. 6. The turn-on voltage of the device is only 2.8 V and the device delivers bright blue emission with a maximum brightness of 8072 cd/m^2 at a voltage of 7.6 V and a current density of 230 mA/cm^2.

Fig. 7 shows an EL spectrum of device V. The EL spectrum centers at 472 nm and the CIE coordinates are $x = 0.14$, $y = 0.24$. Current and power efficiencies of the device are shown in the inset of Fig. 7. Device V has a maximum efficiency of 5.1 cd/A (5.3 lm/W).

For accessing the performance of DPFA, operation parameters of several state-of-the-art OLEDs based on bipolar blue-emitters are tabulated in Table 2. It can be seen that the efficiency of the device based on DPFA is among the best. With its highly efficient blue emission and bipolar charge transporting properties, DPFA can be a promising material for applications in both blue and white OLEDs.

In summary, a new multifunctional compound, 4,4′-di-(1-pyrenyl)-4″-[2-(9,9'-dimethylfluorene)]-triphenylamine (DPFA) has been synthesized and used respectively as a high efficiency blue emitter, a hole- and an electron-transporters in OLEDs. The compound exhibits good thermal stability with a glass transition temperature (T_g) of 161 °C. The results show that DPFA has efficient bipolar charge transporting properties for both hole and electron. A typical three layer device with a configuration of ITO/NPB(50 nm)/DPFA(20 nm)/TPBI(30 nm)/LiF(0.5 nm)/MgAg gives blue emission of high efficiency (5.1 cd/A or 5.3 lm/W) comparable or better than current state-of-art bipolar blue-emitters.

Inverted structure

ABSTRACT

Tandem solar cells with normal and inverted device geometries were prepared by a solution process. Both device types were based on the use of zinc(II)oxide as the electron transporting layer (ETL). The hole transporting layer (HTL) was either PEDOT:PSS for normal geometry tandem solar cells or vanadium(V)oxide in the case of inverted tandem cells. It was found that the inverted tandem solar cells performed comparable or better than the normal geometry devices, showing that the connection structure of vanadium(V)oxide, Ag nanoparticles and zinc(II)oxide functions both as a good recombination layer, ensuring serial connection, and as a solvent barrier, protecting the first photoactive layer from processing of the second layer. This successfully demonstrates a tandem solar cell fabrication process fully compatible with state-of-the-art solution based automated production procedures.

1. Introduction

Since the first reports of the polymer solar cell that presented power conversion efficiencies (PCEs) of less than 1% [1,2] the PCE has increased to above 8% that today represents the state-of-the-art [3]. To convincingly qualify as a photovoltaic technology with a potential to provide clean renewable energy polymer solar cells should have PCEs exceeding 10% in addition to low materials costs, ease of processing [4] and long-term stability under photovoltaic operation [5]. In terms of efficiency, several schemes of improving polymer solar cells have been proposed, the most successful ones being the use of low-band gap photo-active materials [6,7] and multi-junctions, i.e. tandem solar cell structures [8,9]. Efficiencies of 6.5% have been reported for tandem solar cells employing a combination of high- and low-band gap photo-active materials [10–17]. In the latter case the processing of the solar cell was an all-solution based process up to the point of depositing the Al back electrode, which was done by thermal evaporation. So far no viable route for printing an Al electrode has been found, and therefore normal geometry (Fig. 1A) solar cells requiring a cathode with a low work function (such as Al) are so far not realizable by all-solution and fully printable processes. To achieve an all printable solar cell one may reverse the polarity of the system (an inverted structure as shown in Fig. 1B) and employ a printable paste of Ag, now acting as the anode. Such inverted single junction solar cells have been shown to have similar photovoltaic characteristics compared to normal geometry devices employing an evaporated Al electrode [18].

Hence at this point it is clear that both the low-band gap and tandem polymer solar cell concepts have proven viable and that these most likely will be found in future incarnations of polymer solar cells, provided that the appropriate metal electrode can be deposited by printing. In the present study we describe a method for preparing inverted tandem solar cells which are compatible with an all printable process.

There are several challenges in the development of efficient tandem polymer solar cells which go beyond processing of a single junction cell. Firstly, the fabrication of a multi-layer stack involving more than one photo-active polymer layer is challenging since these polymers typically are processed from rather similar organic solvents. Hence, to protect the preceding photo-active layer from re-dissolving during the solution processing of a subsequent

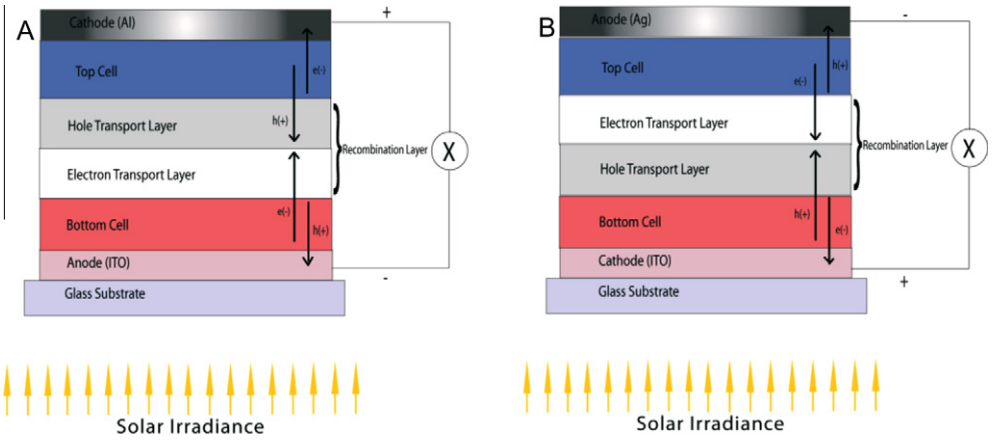

Fig. 1. Diagram of the two different tandem device geometries; (A) normal geometry, and (B) inverted geometry.

photo-active layer, the interlayer, the so called recombination layer, must be processed from an orthogonal solvent, typically some aqueous solution or suspension. Secondly, for two-terminal monolithic tandem solar cells the sub-cells are serially connected through the recombination layer which makes this part of the device critical to the operation of the tandem cell, since the layer must enable electron–hole recombination with as little potential drop as possible (otherwise the open circuit voltage is adversely affected) while also being optically transparent. Thirdly, for series connected tandem solar cells, the two (or more) sub-cells must be current matched, i.e. produce approximately the same current when subject to the respective and appropriate spectral ranges of the sun spectrum. The lack of current matching in the best case limits the current of the tandem solar cell to that of the sub-cell with the lowest current but may well limit it even further due to space charge build up at various interfaces. Finally, optical matching is important to ensure that complementary parts of the sun spectrum are harvested by the sub-cells, which in case of monolithic tandem solar cells with non-opaque layers may require optical simulations.

In this study we have a particular focus on finding a suitable solution processable recombination layer that will work for inverted tandem structures as depicted in Fig. 1B. Fully solution processable recombination layers for tandem solar cells have previously been realized by a sequence of either TiO_x [10] or ZnO [11] as electron transport layers (ETLs) and PEDOT:PSS or pH-neural PEDOT:PSS as hole transport layer (HTL). The pH neutrality is required to enable processing of aqueous PEDOT:PSS on top of previously deposited ZnO nanoparticles. In particular, the success of the ZnO/PEDOT:PSS recombination layer is derived from the fact that nanoparticles become insoluble after drying in both organic solvents and aqueous solutions. However, the polarity of these recombination layers suits only normal geometry tandem solar cell structures as shown in Fig. 1A.

Reversing the layer sequence of the recombination layer to match the polarity of an inverted tandem solar cell (Fig. 1B) has been attempted previously [12,29]. In the case of Hagemann et al. PEDOT:PSS/ZnO was interfacing an insoluble high-band gap polymer (P3CT) obtained by thermal cleaving of P3MHOCT and a low-band gap polymer (P3CTTP) obtained by thermal cleaving of P3TMDCTTP. Both sub cells employed zinc(II)oxide nanoparticles as electron acceptor and a printed back electrode. It presented a relatively low performance while showing stable operation in ambient air.

However, any efficient inverted tandem solar cell design should enable the use of high efficiency polymer materials, and in an all solution process this demands that a HTL is coated on top of the low surface energy polymer:fullerene photo-active layer. Aqueous PEDOT:PSS dispersions that present large surface tensions makes this challenging or very difficult.

A series of transition metal oxides have previously been demonstrated as suitable substitutes for PEDOT:PSS. In a recent paper, Chou et al. [29] realize PEDOT:PSS free, high efficiency inverted tandem cells, using evaporated MoO_3 as HTL and ZnO as ETL. Another interesting candidate is vanadium(V)oxide (V_2O_5) [19,20], and recently it was shown that V_2O_5 may also be solution processed as an efficient and nearly optically transparent HTL in inverted polymer solar cells [21] due to a high work function similar to that of PEDOT:PSS. Chou et al. [29] attempted the use of V_2O_5 as HTL, however the material was found incompatible with the subsequent processing of the ZnO layer. From this we expected that V_2O_5 could still function well as a HTL in a recombination layer, given an orthogonal ZnO formulation, and we present a work utilizing a V_2O_5 formulation based on isopropanol, and an orthogonal ZnO formulation based on methanol.

2. Materials and methods

Films were fabricated under ambient conditions only using a spin-coater and a digitally controlled oven, apart from the final electrode evaporated under vacuum. ITO patterned glass substrates, were cleaned by sonication for 10 min in both isopropanol and demineralized water, and blown dry with air.

First layer: For 'inverted' devices, the glass/ITO substrate was spin-coated with $Zn(OAc)_2{\cdot}2H_2O$, dissolved in methanol, at 3000 rpm for 30 s, followed by annealing for

10 min at 140 °C, giving a layer thickness of 50 nm. For 'normal' devices the first layer was made by spin-coating of PEDOT:PSS (Aldrich) at 3000 rpm for 1 min followed by annealing for 5 min at 140 °C, leading to a layer thickness of 90 nm.

Second layer: This layer was processed under similar conditions for both device types, the active polymer blend for the bottom cell; P3HT(17 mg/ml):PCBM(15 mg/ml) dissolved in chlorobenzene, was spin-coated at 1500 rpm for 30 s leading to an approximate layer thickness of 75 nm, followed by annealing for 30 s at 140 °C and drying/cooling under ambient conditions for 5 min.

Third layer: For the 'inverted device' a solution of vanadium(V)-oxiisopropoxide diluted with isopropanol to a concentration of 50 mg/ml were prepared, and applied by spin-coating at 3000 rpm for 10 s, followed by annealing for 2 min at 140 °C, leading to a clear and slightly yellowish film, with a thickness of approximately 45 nm as determined by ellipsometry. For normal devices the layer was made by spin-coating the $Zn(OAc)_2{\cdot}2H_2O$/methanol solution at 3000 rpm for 30 s, followed by annealing for 6 min at 140 °C, giving an approximate layer thickness of 50 nm.

Intermediate silver layer: For some cells an intermediate silver layer was made; either by spin coating (3000 rpm, 1 min) a silver nanoparticle (100 ± 15 nm) solution prepared as described earlier [22] and further diluted in isopropanol to a final concentration of 10 mg/ml followed by annealing for 2 min at 140 °C, or by evaporating a thin Ag layer using the same procedure as for the final back electrode.

Fourth layer: For the 'inverted' device this was made by spin-coating the $Zn(OAc)_2{\cdot}H_2O$/methanol solution at 1000 rpm for 30 s, followed by annealing for 6 min at 140 °C, after which the procedure was performed for a second time. The two depositions are found necessary to best protect the cell against the second active layer deposition. This leads to a ZnO layer thickness of 160 nm, determined with AFM. For normal devices the layer was made by spin-coating of PEDOT:PSS (Aldrich) at 5000 rpm for 1 min, followed by annealing for 2 min at 140 °C.

Fifth layer: The active layer of the back cell for all device types was prepared from a blend of 15 mg/ml of PDTTDABT or P3HT mixed with 15 mg/ml of PCBM and dissolved in chlorobenzene, which was then spin-coated at 800 rpm for 1 min leading to an approximate layer thickness of 140 nm.

Sixth layer: For the inverted device this layer was made from PEDOT:PSS (Orgacon EL-P 5010 diluted with isopropanol 2:1 w/w) spin-coated at 3000 rpm for 1 min, followed by annealing for 2 min at 140 °C.

The final metal back electrode was applied with evaporation through a shadow mask in a vacuum chamber under a pressure of less than 3×10^{-6} mbar, the metal being Ag for inverted or Al for normal devices. The back electrode defines the active area of the cells to be 0.5 cm^2.

IV-characterization of the solar cells was carried out immediately after evaporation, under simulated sunlight at 1000 W m^{-2}, AM1.5G conditions, using a Keithley multiplexer setup.

3. Results and discussion

For the purpose of this study we constructed four different types of tandem solar cells, and descriptions of the different multilayer stacks can be found in Table 1 alongside the photovoltaic parameters from electrical characterization. Each of the tandem cells consists of two serially connected sub cells; a high band gap front cell and a low band gap back cell, utilizing P3HT:PCBM and PDTTDABT:PCBM, respectively, as photoactive layer (see Fig. 2).

In order to estimate the performance of the tandem cells, each of the constituent sub cells were also constructed as single junction reference cells (see Table 1). During this work several additional approaches were pursued based on the choice of zinc oxide (ZnO) as the ETL material, while various PEDOT:PSS types were employed as HTL material, but it was only when using vanadium oxide (V_2O_5) as HTL material that reliable tandem devices were realized.

3.1. The best performing tandem design

The most successful tandem cell design, retaining the all solution processing compatibility, is depicted in Fig. 3. The cell presents a novel recombination layer employing three sub layers; a HTL of V_2O_5, followed by a thin

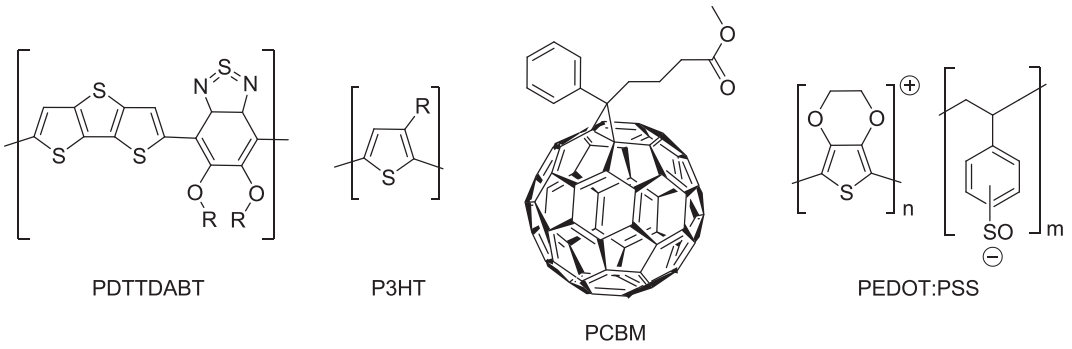

Fig. 2. Structure of PDTTDABT, P3HT, PCBM and PEDOT:PSS. $R_1 = C_{14}H_{29}$, $R_2 = C_6H_{13}$.

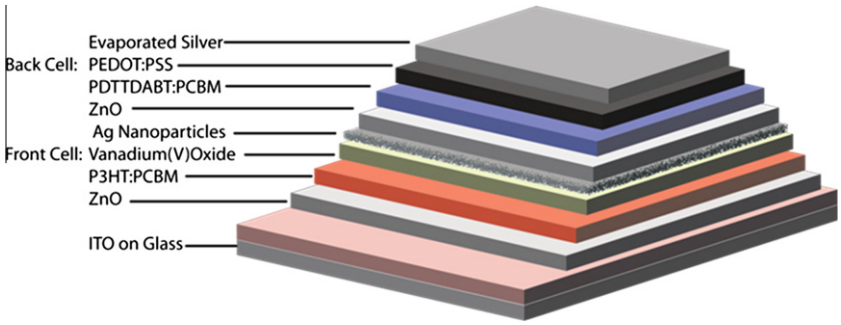

Fig. 3. The layer stack of the best performing inverted tandem solar cell.

transparent layer of Ag nanoparticles (Ag-NP) dispensed in isopropanol, and an ETL of ZnO. The *J–V* curves of the best device and corresponding reference sub cells are shown in Fig. 4.

The tandem cell yields a PCE of 1%. The open-circuit voltage (V_{oc}) is 0.81 V, corresponding to a voltage drop of 0.25 V with respect to the estimated ideal sum of the two reference sub cell voltages while the short circuit current density of 3.6 mA cm^{-2} is significantly lower than that the corresponding value of −5.8 mA cm^{-2} for the supposedly current limiting back cell reference. However significant, most of the loss in both current and voltage is probably explainable by losses due to the imperfect nature of the recombination layer, and poor current matching of the sub cells.

The issue of current matching is evident already from the difference between the currents produced in the reference sub cells (Table 1), and due to overlap of the absorption bands of P3HT and PDTTDABT (Fig. 5) and optical transmission losses across the recombination layer; it is likely that this current imbalance is further augmented in the actual tandem cell. This is investigated in the following section.

3.2. Estimating sub cell performance

To correctly quantify the problem of current matching in a tandem cell it is necessary to know the actual performance of the individual sub cells. And because the sub cells are in an environment hardly mimicked by a single junction reference cell, it would demand a three- or four terminal tandem architecture in order to do a proper *J–V* characterization. While such designs have been realized [13,14] this is not the goal of this study. Instead we utilize optical simulations based on the transfer matrix formalism [23,24] which can predict the number of photons absorbed in the active layers per unit time.

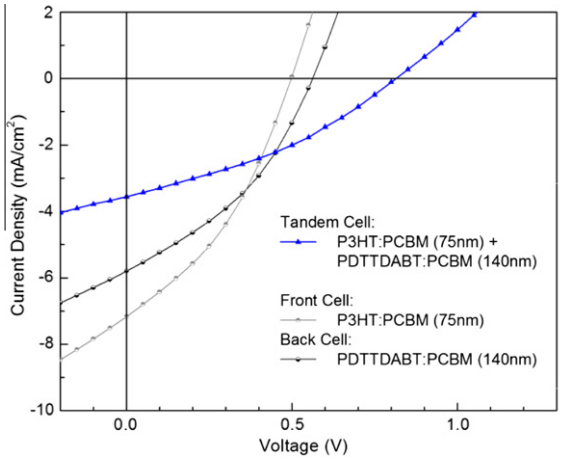

Fig. 4. *J–V* curve of the best performing tandem cell using a larger band gap polymer in the front cell (P3HT), and a lower band gap in the back cell (PDTTDABT).

The model takes as input the optical constants *n* and *k* for each layer, which are measured by ellipsometry, as well

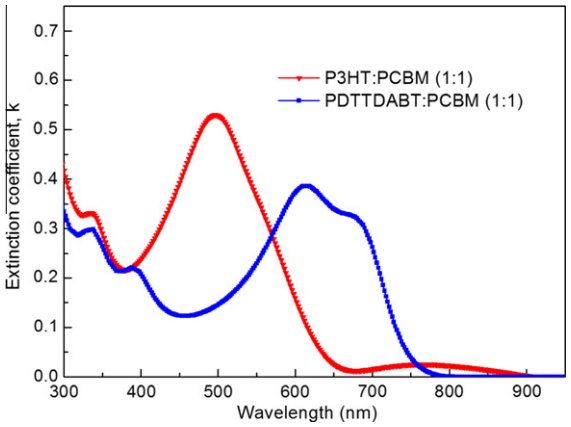

Fig. 5. The *k*-values for the P3HT:PCBM and PDTTDABT:PCBM blends, depicting their complementarily in terms of absorption.

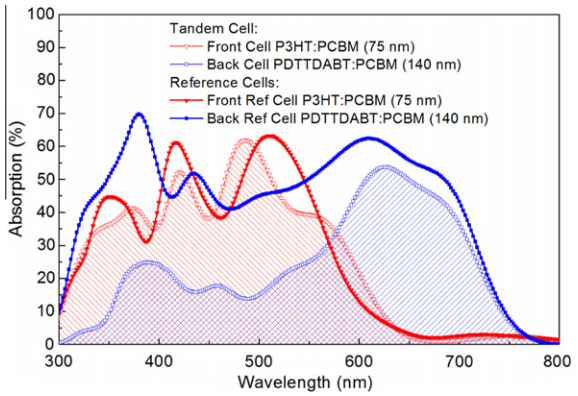

Fig. 6. The simulated absorption profiles for the sub cells of the tandem cell compared to the simulated absorption profiles of corresponding reference cells.

as the AM1.5G solar irradiance spectrum. In Fig. 6 we show the calculated absorption profiles for the sub cell photoactive layers and corresponding reference cells, illustrating the effect of the overlapping absorption bands. Key simulation parameters are summarized in Table 2, where $J_{\text{max-sim}}$ is the maximum available photocurrent density, supposing an internal quantum efficiency (IQE) of 100%, and

$$J^{\text{sub}}_{\text{sc-sim}} = \frac{J^{\text{reference}}_{\text{sc}}}{J^{\text{reference}}_{\text{max-sim}}} J^{\text{sub}}_{\text{max-sim}} = \text{IQE}_{\text{flat}} J^{\text{sub}}_{\text{max-sim}}$$

where IQE_{flat} infers an assumed constant IQE within the relevant spectrum of wavelengths. From the simulations we gather that the actual back cell probably delivers a J_{sc} closer to 4.2 mA cm^{-2} than the 5.8 mA cm^{-2} of the back cell reference, while the actual front cell is estimated to deliver equal to the reference current. According to these current estimates, only about 4 out of 7 holes from the front cell will be able to recombine with electrons from the back cell. We suspect that this significant current mismatch and resulting charge build-up at the recombination layer will compensate the build-in potentials across the sub cells, ideally leading to an equilibration of the tandem current density close to the limiting sub current density [25], which in this case would mean the estimated ~4.2 mA cm^{-2}. Moreover it should be noted that a complete understanding of the quantitative effect of current mismatch in a two terminal polymer tandem device is limited, and it is possible that charge pile-up at the less-than-perfect ohmic contact of the recombination layer will lead to further degrading effects of the photovoltaic performance such as lowering the effective V_{oc} [16] or fill-factor, in turn explaining the deviation from ideality that we observe. This will be further investigated in the following section.

Apart from estimating the sub cell current imbalance, the simulations shown in Fig. 6 also illustrates the potential of the tandem principle, where the complementary absorption bands of the two junctions provide ample amounts of current, meaning that the rather low efficiency of this tandem device is due to the low IQE of the PDTTTDABT:PCBM cell.

3.3. Current matching

To study the effect of current imbalance on the photovoltaic performance of the presented tandem device design, a tandem device having two P3HT:PCBM junctions was constructed. The front and back cell thicknesses were found with the aid of optical simulations, so as to deliver closer to the same amounts of photo current. The thickness of the front cell was kept at 75 nm while the back cell was given a thickness of approximately 100 nm. The *J*–*V* curves for the best P3HT-P3HT tandem device can be seen in

Table 2
Summary of simulation data.

Cell Description	Experimental	Simulation		
	J_{sc} (mA/cm^2)	$J_{\text{max-sim}}$ (mA/cm^2)	$J_{\text{sc-sim}}$ (mA/cm^2)	IQE_{flat} (%)
P3HT-PDTTDABT Tandem device:				
Front Cell Reference: P3HT:PCBM (75 nm)	−7.2	−9.4	–	75
Back Cell Reference: PDTTDABT:PCBM(140 nm)	−5.8	−15.8	–	37
Front Cell: P3HT:PCBM(75 nm)	–	−9.4	−7.2	75
Back Cell: PDTTDABT:PCBM(140 nm)	–	−11.5	−4.2	37
P3HT-P3HT Tandem device:				
Front Cell Reference: P3HT:PCBM (75 nm)	−7.2	−9.5	–	76
Back Cell Reference: P3HT:PCBM (100 nm)	−8.8	−11.3	–	78
Front Cell: P3HT:PCBM(75 nm)	–	−9.5	−7.2	76
Back Cell: P3HT:PCBM(100 nm)	–	−7.2	−5.6	78

Fig. 1, where it is compared to the tandem device having a PDTTDABT back cell. The photovoltaic parameters are summarized in Table 1, and as can be seen the efficiency has increased to 1.4%, most likely due to higher current of the P3HT back cell compared to the PDTTDABT back cell.

To investigate we performed the analysis based on optical simulations as described and done for the P3HT-PDTTDABT tandem, in Section 3.2. The results are summarized in Table 2. The simulations suggest that it is in fact a higher current from the P3HT back cell which drives the increased PCE. However the back cell is still the current limiting tandem device, having an estimated short circuit current density of $-5.6\ mA\ cm^{-2}$ against the estimated value of $-7.2\ mA\ cm^{-2}$ for the front cell, while the actually measured J_{sc} of the P3HT–P3HT tandem cell is $-5.2\ mA\ cm^{-2}$. The V_{oc} is 0.8 V which corresponds to a voltage drop of 0.21 V compared to the estimated ideal sum of the reference sub cells. These overall lower deviations from the ideal performance as compared to the P3HT–PDTTDABT tandem cell can be interpreted as an effect of the expected smaller current mismatch of the sub cells in the P3HT–P3HT tandem cell as shown in Fig. 7. However, these modest improvements do not suggest that a completely current matched tandem cell will exhibit ideal performance, thus it seems likely that losses associated with this particular recombination layer is expected. This is investigated in the following section.

3.4. Recombination layer

In this study we compared four different recombination layers; V_2O_5/ZnO, V_2O_5/Ag-NP/ZnO and V_2O_5/Ag(evap)/ZnO employed in the inverted geometry tandem cell (see Fig. 1), and ZnO/PEDOT:PSS used in the normal geometry cell.

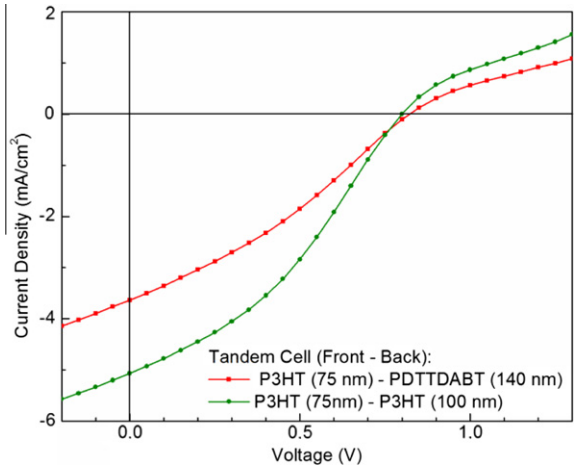

Fig. 7. Comparison of two inverted geometry tandem devices, having a different back cell, both without the silver interlayer added to the recombination layer. The P3HT back cell delivers more current than the PDTTDABT back cell, and thus increases the total current of the tandem device.

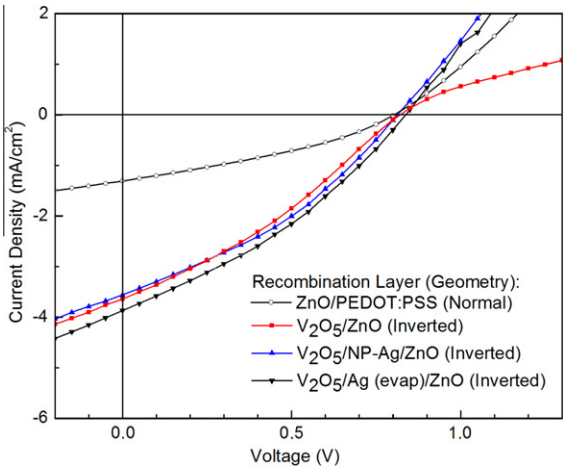

Fig. 8. Comparison of different recombination layers. For the inverted geometry tandem devices, applying a thin layer of Ag nano-particles (NP-Ag) or evaporated Ag to the recombination layer, seemingly has the effect of removing the inflection point.

First, we consider the cells having two-layered recombination structures, and representative *J–V* curves for these two types of tandem cells are presented in Fig. 8. As can be seen, the inverted type shows a significant inflection point in the *J–V* curve above short circuit, this phenomenon has been ascribed to low (majority) charge carrier concentrations in the recombination layer [11,17] leading to recombination inefficiency close to open circuit conditions. In the case of Gilot et al. [11] it was found that the inflection point was due to low charge carrier concentration in the ZnO ETL part of the recombination layer, a common problem in ZnO containing solar cells [22], resolved by exposure to UV-light triggering a photodoping process described elsewhere [26]. It can be seen that in our case no inflection point is observed in the *J–V* characteristics of the normal geometry tandem cell, having a recombination structure of ZnO/PEDOT:PSS, nor did the photovoltaic parameters improve under UV exposure. This leaves the V_2O_5 as potential bottle neck, and ways to improve the p-doping level of this material should be investigated further.

In order to certainly isolate the source of the inflection point to the recombination layer we pursued a method reported earlier [16,27] showing that such counter diodes can be counteracted by evaporating a thin metal interlayer, and in Fig. 8 the *J–V* curves for comparable tandem cell with and without an added Ag interlayer are presented. From this it is obvious that the addition of evaporated silver effectively removes the counter diode. In an attempt to avoid a vacuum demanding step, such as the evaporation of a thin Ag layer, and to keep the design compatible with solution based production-methods, the Ag nanoparticles were pursued as a remedy displaying a similar effect on the *J–V* characteristics. It is suggested that in both cases the silver forms an incomplete layer, where clusters act as recombination sites that due to their limited size will be aided by a coulomb charging effect [28]. However one

would suspect that the morphology of the two types of silver layers is quite different as the nano-particles are on the order of 100 nm while the evaporated layer is suspected to be less than 10 nm thick, nevertheless they induce a similar effect on the *J–V* characteristics, and further investigations of intermediate silver layers are warranted.

In summary, the addition of an intermediate silver layer between the HTL and ETL effectively removes the inflection point as seen in Fig. 8, but surprisingly the removal of the counter diode only seems to improve the photovoltaic performance minutely (Table 1), suggesting that the losses are not due to improper recombinatory properties of the recombination layer, rather we suspect that the significant sub cell current imbalance and possibly the low p-conductivity of V_2O_5, are causing the voltage drop and current losses, as compared to the ideal.

3.5. Future perspectives

A major perspective of this work lies in processing, and having described a process for inverted polymer tandem solar cells compatible with solution processing of all layers including the final electrode, the natural next step will be to transfer the method onto a roll-to-roll platform. In terms of optimizing the efficiency it is evident that the inefficient current generation of the low band-gap back cell is a limiting factor that should be resolved, whereby insights into the effect of current mismatch could be obtained. Also the materials of the recombination layer should be investigated and optimized, focusing on routes to improve the HTL. In this respect it would be interesting to improve the conductivity of V_2O_5 by possibly p-doping, or to investigate the usefulness of other metal oxides. It is believed that optimization of only a few of the mentioned parameters will lead to a tandem cell efficiency larger than the corresponding single junction cells, and in conjunction with the high throughput fabrication prospects this would conclusively demonstrate the importance and rigidness of the inverted tandem approach which do have significant processing requirements when compared to single junction cells.

4. Conclusion

We have presented a process for the fabrication of inverted tandem solar cells compatible with all solution processing of all layers, and demonstrated its usefulness by fabricating and characterizing inverted tandem solar cells utilizing a larger band gap P3HT:PCBM front cell serially connected with a lower band gap PDTTDABT:PCBM back cell, by means of a three layered solution processed recombination structure consisting of vanadium(V)oxide, Ag nanoparticles and zinc(II)oxide. The tandem cells yielded a PCE of 1%, mainly limited by a low IQE of the PDTTDABT:PCBM back cell, leading to poor current matching with the front cell, and a resultant low J_{sc} of the tandem cell. When preparing a similar tandem cell, having a P3HT:PCBM back cell, expected to deliver more current, the PCE increases to 1.4%, led by relative increases in J_{sc} and V_{oc} as compared to the expected ideal values, sustaining the idea of performance degrading effects from sub cell current mismatch. Normal geometry solar cells were also demonstrated, using the same photo active materials but with a two-layered recombination structure of zinc(II) oxide and PEDOT:PSS. The normal geometry cells exhibited a lower J_{sc}, while all tandem cells showed a V_{oc} just around 0.8 V which was about 0.2 V lower than the ideal. The findings suggest that although none of the trialed recombination layers are able to deliver perfect serial connection, vanadium(V)oxide is indeed a compatible substitute for PEDOT:PSS for the use as hole transporting material in cases where aqueous solutions cannot be used easily, such as the case for inverted polymer tandem solar cells.

ABSTRACT

The electronic properties of potassium doped cobalt phthalocyanine (CoPc) films have been investigated using near-edge X-ray absorption fine structure measurements. Our results demonstrate that charge transfer to the CoPc molecules changes both the valence of the phthalocyanine ring as well as that of the central Co ion. The first electron transferred to the molecule occupies a Co 3d state, which is connected to a change of the magnetic moment of the molecule.

1. Introduction

Charge transfer, i.e. the addition or removal of charges to or from molecules in organic solids is one route to modify and control their electronic properties. There are prominent examples, where charge transfer is an essential ingredient in the control of the electronic properties of the respective material class. For instance, the formation of charge transfer compounds is accompanied by fascinating, and sometimes unexpected physical properties. Well-known examples are the so-called charge transfer salts (e.g. TTF-TCNQ) with low dimensional electronic behavior and very rich phase diagrams [1], or alkali doped fullerenes [2–6] and picene [7,8], which support superconductivity, or Mott insulating phases depending on the doping level. In addition, charge transfer induced by doping has been successfully applied to tune the electronic properties of organic semiconductor devices [9–13] or to tailor the spin functionality of hybrid metal–organic interfaces [14].

Recently, it has been demonstrated that selective charge transfer can be achieved by the formation of some well ordered phthalocyanine or porphyrine monolayers on noble metal surfaces (Au, Ag). Thereby, the charge is transferred from the metal substrate to a particular part of those molecules, the central transition metal ion. In other words, the formation of the corresponding monolayer is connected to valence changes of these transition metal centers [15–23], and in many investigated molecules, the transition metal center is Co. Moreover, this valence change is directly related to a change of the magnetic moment of the corresponding molecule, which represents an important aspect in view of the application of magnetic molecules in molecular or organic spintronic devices or the appearance of the Kondo effect in adsorbed molecules on surfaces [15].

The question now arises whether such valence and spin changes of the cobalt center in e.g. cobalt phthalocyanine (CoPc) upon charging are a consequence of the interface formation, or in a more general sense driven by charge

doi:10.1016/j.orgel.2010.12.003

transfer independent of the presence of an interface and respective local interactions. In order to test this, we report here charge transfer to CoPc molecules in thin solid films that has been achieved by the addition of potassium. We demonstrate that selective charge transfer to the central Co ion not only occurs on metal surfaces but can also be realized by our doping procedure. Thereby, the first electron added to a CoPc molecule fills a metal 3d state, and in this way changes the orbital and magnetic ground state of the molecule.

2. Experimental

Our experiments using near-edge X-ray absorption fine structure (NEXAFS) were performed at the Berliner Speicherring für Synchrotronstrahlung (BESSY) using soft X-ray light emitted by the Russian–German high energy resolution dipole beam line. This type of beam line provides moderate-intensity radiation with a continuous distribution over a wide photon energy range (30–1500 eV). Therefore this beam line is well suited for the NEXAFS measurements and for organic materials, which are relatively fragile and potentially could be damaged under irradiation. The soft X-ray absorption spectra were recorded in the total electron yield mode and normalized to the incident photon flux. The resolution of the NEXAFS measurements is determined exclusively by the performance of the beam line and was about 80 meV full width at half maximum at the C 1s (283 eV) threshold, while it was about 100 meV for the Co 2p threshold (770 eV). In the NEXAFS experiments the photon incidence angle was selected to be 35 degrees relative to the sample surface normal. We have chosen this angle to explore simultaneously both excitations into π and σ derived states of the highly oriented molecules [24–26]. The pressure in the experimental system during data acquisition was always better than 2×10^{-10} Torr .

As substrate for CoPc film deposition we used the (100) surface of a gold single crystal. The surface was prepared by repeated sputtering and annealing cycles, after which a 5×20 surface reconstruction was observed using low energy electron diffraction, while no remaining contamination was detected in core level photoemission spectra. The CoPc film was deposited in a sample preparation chamber (base pressure of 2.5×10^{-10} Torr) directly connected to analyzer chamber. The CoPc deposition rate, monitored by a quartz microbalance, was 1–2 Å/min. The CoPc films used for our studies were about 70 Å thick. From previous studies it is known that CoPc films grown in this manner result in CoPc molecules that are arranged parallel to the substrate surface [24].

Potassium was evaporated onto the CoPc film at rates of 1–10 Å/min from a properly outgassed SAES alkali metal dispenser, without detectable pressure increase during deposition. The K concentration in the CoPc films was deduced from a comparison of the relative intensities of the K 2p and C 1s NEXAFS spectra. These relative intensities have been compared to previous core level excitation data at these edges from potassium doped molecular films of known stoichiometry ($K_6C_{60}, K_4C_{60}, K_4CuPc$) [6,27]. For more details about this procedure see Refs. [27,28].

3. Results and discussion

In Fig. 1 we show the evolution of the C 1s NEXAFS data upon potassium doping. The inset shows the data of the highest doped sample in a larger energy range including the excitations at the K 2p absorption edge. The C 1s excitation spectrum of undoped CoPc is characterized by a double peak feature at lowest excitation energy, labelled A′ and A, which is caused by excitations into the lowest unoccupied molecular orbital (LUMO) at either the benzene carbon atoms (A′) or those belonging to the pyrrole rings (A). The energy difference thereby is given by the different binding energies of the C 1s core levels due to different chemical environments (chemical shift). This shift can be directly seen in corresponding core level photoemission experiments [22,29]. The data for CoPc as presented here are very similar to the corresponding results for the related copper phthalocyanine material [30,31].

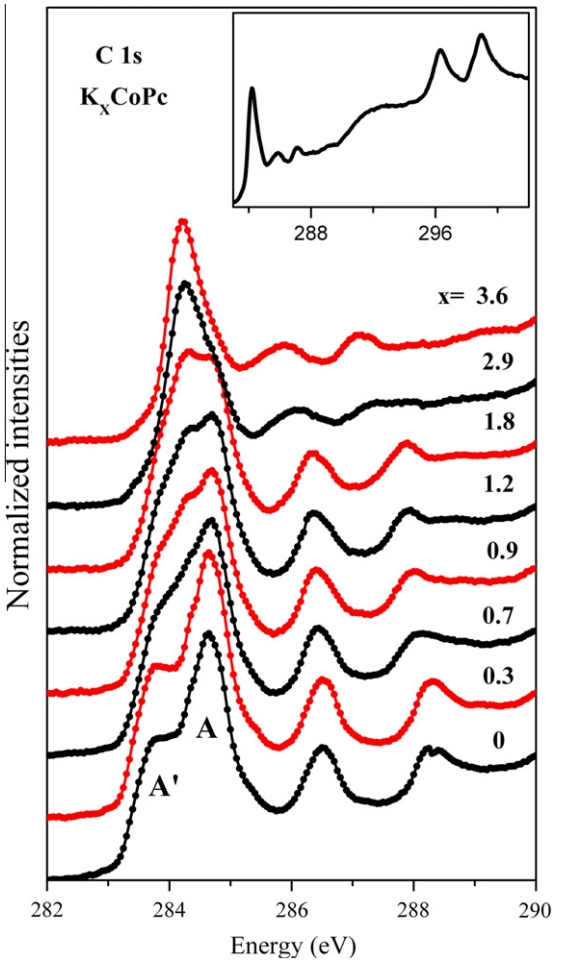

Fig. 1. C 1s X-ray absorption data of potassium doped CoPc films (K_xCoPc). The inset shows the data for the highest doping level including the K 2p absorption edge with maxima at 296.3 and 299 eV.

Upon increasing K content, one can see that the intensity of the peaks following the absorption threshold decreases. In analogy to K doped CuPc [32], we attribute this decrease to a filling of the LUMO of CoPc as a consequence of charge transfer of the outer s electron of potassium to the CoPc molecules. Furthermore, the fine structure of the C 1s spectra is smeared out upon potassium addition, which results in a broad excitation feature in the intermediate doping range before it narrows again at highest doping. The broadening and loss of fine structure has also been observed for K doped copper [32] and iron phthalocyanine [33] (CuPc and FePc) films, and there it has been ascribed to the appearance of a further, chemically shifted C 1s core level binding energy caused by the doping and the potential of the adjacent K^+ ions (see Refs. [32,33] for details). At highest doping the lowest excitation structure becomes narrower again, which most likely arises from a further filling of the LUMO level, and which indicates that the doping procedure renders the carbon atoms in the phthalocyanine molecule more similar in the sense of the chemical environment. An exact analysis of this behavior can only be achieved with the help of sophisticated calculations and detailed structural knowledge and is beyond the scope of this short contribution. However, from Fig. 1 it becomes clear that even at the highest doping level excitations into the LUMO are still possible, i.e. the LUMO level of the phthalocyanine ligand is not completely filled. Further, the remaining intensity implies that not all electrons donated by the introduced potassium are going to this ligand orbital, since in this case we would expect a lowest excitation feature with much lower spectral weight. We note that this is not due to the presence of unreacted (undoped) CoPc molecules in our sample. This will become clear in the discussion of the Co 2p absorption edge below, which clearly shows a complete change of these spectra upon doping with no indication for undoped CoPc. Finally, the absorption features at higher energies as depicted in Fig. 1 shift to lower energies with increasing potassium doping. This shift is caused by a relaxation of the molecular and electronic structure of CoPc while filling an antibonding molecular orbital, similar to what has been observed in other doped molecular films such as K_xC_{60}, K_xCuPc, or K_xFePc [6,27,32,33].

We are thus left with the question which further molecular state other than the LUMO arising from the phthalocyanine ligand is filled via the doping process? In order to clarify this question, we show in Fig. 2 the evolution at the Co 2p absorption edge induced by the potassium doping. We concentrate on the energy region of the Co $2p_{3/2}$ excitation edge as it reveals much more details on the different unoccupied Co 3d states [25]. For undoped CoPc the Co $2p_{3/2}$ excitation edge has been recently analyzed in detail as a function of polarization using NEXAFS and atomic multiplet calculations [25]. It is important for the discussion here that the lowest excitation feature at about 774.8 eV is due to excitations into unoccupied Co $3d_{3z^2-r^2}$ (in the following called $3d_{z^2}$) orbitals. The following excitations with maxima at 776.8 and 778 eV arise from a multiplet split feature related to excitations into the Co $3d_{x^2-y^2}$ orbital. Upon doping, Fig. 2 demonstrates clearly that the lowest excitation feature decreases in intensity until it

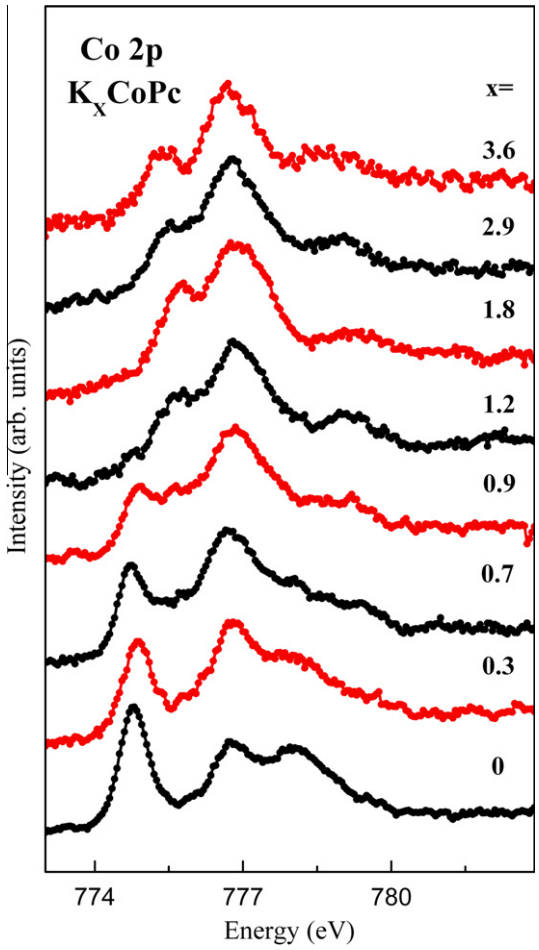

Fig. 2. Co $2p_{3/2}$ X-ray absorption edges of K_xCoPc films.

has vanished at a doping level of about $x = 1$ (K_xCoPc). This now indicates a predominant filling of the $3d_{z^2}$ orbital upon doping before ligand π derived states are charged. Increasing the doping level induces an energy shift of the remaining structures at the Co 2p excitation edge to lower energies but no further change in spectral shape can be observed. We again attribute this change to the relaxation of the molecule and thus also the molecular orbitals upon charging/filling state with antibonding character.

At this point it is important to notice that in the case of CuPc the Cu 2p absorption edge does not change at all upon doping with potassium [32]. In other words, while for CuPc a negative charging of the molecules does not affect the valence and spin of the central transition metal ion, this clearly is the case for CoPc studied here. At first glance, this looks surprising since many physical properties of CuPc and CoPc, such as their growth/orientation on metal surfaces [16,24,34,35], the energy position of the highest occupied ligand orbital [29] or the optical absorption spectra [29] are very similar. However, going from CuPc to CoPc the relative energy of the metal 3d levels and the π ligand orbitals changes mainly due to the different nucleus potentials of the transition metal

[36]. As a consequence, Co 3d levels are closer to the chemical potential in CoPc and can play a role in the low energy electronic behavior. Moreover, the metal 3d orbital filling is also different, $3d^9$ in CuPc and $3d^7$ in CoPc, which provides more orbitals for electron addition. From electrochemistry studies [37] it has been concluded that the first reduction state of CuPc is of pure ligand π character, while in CoPc there is evidence for a Co reduction to Co(I), similar to our observations.

In addition, the observed filling of the Co $3d_{z^2}$ orbital upon potassium addition demonstrates the formation of Co(I) centers, which is accompanied by a loss of the magnetic moment (spin zero). This now opens a way to deliberately change the magnetic properties of such molecules via charge transfer in thin films. It additionally has consequences for the charge transport behavior of CoPc films, since electrons injected into a film will occupy metal 3d rather than ligand π orbitals with a rather different wave function and hopping probabilities. The associated variation of the spin state of CoPc will also affect the spin scattering mechanisms in spin-dependent transport through CoPc films.

4. Summary

In conclusion, our studies show that a reduction of cobalt phthalocyanine via doping with potassium results in the formation of non-magnetic, charged Co(I)Pc molecules. The situation thus parallels that on noble metal surfaces where an equivalent Co reduction has been reported. This points to a general behavior of CoPc upon charge addition and might be of relevance for the use of this molecule in organic devices with spin functionalities.

ABSTRACT

Over the past years, organic light-emitting diodes (OLEDs) have attracted increasing interest because of their great potential for use in high-quality flat-panel displays and solid-state lighting. One of the basic requirements in any emissive device is to provide adequate stability to ensure a sufficiently long lifetime. Recently, it was observed that small molecules migrate toward the ITO anode under a direct driving voltage while retaining their original structures. To prevent this bias-driven migration of small molecules, a chemical structure with a higher steric hindrance could be introduced as a blockade, thus molecular migration could be suppressed and the device half-life increased. In this work, OLED devices with different hosts, including CBP, mCP, SimCP2, and SimCP, with increasing steric hindrances are fabricated. The spatial distribution of the tracking molecules after operation for different lengths of time is examined by using X-ray photoelectron spectroscopy (XPS) with *in situ* high-energy C_{60}^{+} and low-energy Ar^{+} co-sputtering for depth profiling. It is found that the bias-driven molecular migration is suppressed and the device half-life prolonged as the steric hindrance of the host increases.

1. Introduction

Over the past decades, semiconductor development has proceeded at a rapid pace [1,2]. Inorganic semiconductors, such as Si and Ge, have several important applications. For example, silicon-based devices, like high performance chips [3–5], photodetectors [6], light-emitting diodes (LEDs) [7,8], have been widely used around the world. On the other hand, organic semiconductors, like organic light-emitting diodes (OLEDs), are also increasingly attracting interest because of their great potential as high-quality flat-panel displays and solid-state lighting [9–12]. For both inorganic and organic semiconductors, device reliability and lifetime are critical issues [13,14].

In silicon-based devices, the electro-migration of atoms [15] is known to degrade the device performance. Electrons flowing through the device can collide with atoms causing them to migrate from their original sites during operation [15]. As a result, the device structure changes, in turn leading to failure. Fortunately, the problem can be solved using heavier atoms like Cu, Pd, and Sc [15].

For organic semiconductors, there are many issues that may cause device degradation [16]. In terms of intrinsic degradation mechanisms, Franky So and Denis Kondakov found that the device degradation is because of the chemical transformations in the region nearby the recombination zone [17]. In addition, Karl Leo's group investigated the possible degradation products and dissociation of

doi:10.1016/j.orgel.2010.12.005

molecules in an OLED aged by electrical driving [18,19]. In particular, it is proposed the FIrpic may dissociate irreversibly through the loss of CO_2 from the picolinate ligand. Furthermore, the migration of inorganic electron injection layers like Cs:BPhen [19], Li [20], and LiF [21] and migration of inorganic ITO anode [22] are also observed.

Recently, it was observed that in thin-film organic devices, like OLEDs, small molecules may also migrate from their original positions to other layers under direct DC bias operation [21]. Consequently, the distribution of molecules (namely electron-transporting materials) is significantly changed, while the chemical structure is retained. This phenomenon is very similar to the electro-migration of atoms reported before. However, the mechanism differs in that there are no quasi-free electrons in organic semiconductors that drive the molecules directly. Instead, the electrons hop between molecules and the molecules gain negative charge temporally. These charged molecules are then driven by the bias. Furthermore, small dopants tend to penetrate into other layers and thus change the composition and electrical properties [23]. Because the device structures that control the device performance are well designed at the beginning of the fabrication process, any change in the device structure, or the distribution, may affect the carrier-injection balance and lifetime significantly. To date, while the problem of electro-migration in inorganic semiconductor industry is well known and already solved, the similar phenomenon of bias-driven molecular migration in organic electronics is under-studied and there is no accepted method that solves the problem.

Because of the amorphous nature of OLED devices, the direct observation of the molecular distribution is known to be difficult [24]. X-ray photoelectron spectroscopy (XPS) is one of the most common techniques for studying the surface of materials due to its high surface sensitivity and the wealth of elemental and molecule information [21]. When combined with *in situ* cluster-ion (C_{60}^+) and Ar^+ ion co-sputtering, the depth distribution of materials close to the surface has been profiled successfully with nanometer resolution [25–27]. Because this technique provides a direct method for analyzing the distribution of materials in organic electronics with high depth-resolution, we use it to study bias-driven molecular migration in OLED devices.

2. Experimental

2.1. Fabrication of OLED devices

The details of the OLED fabrication processes and the properties are illustrated elsewhere [28]. In short, a 35-nm-thick hole-transporting layer (HTL) consisting of Baytron® Clevios P VP AI 4083, a composition of poly(ethylenedioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS) in a molar ratio of 1:4.5, was spin-coated on a 125-nm-thick layer of indium tin oxide (ITO) on glass. An emissive layer (EL, 40 nm thick) comprised of a host material, 4,4′-bis(carbazol-9-yl)biphenyl (CBP), doped with 14 wt.% bis(3,5-difluoro-2-(2-pyridyl)-phenyl)-(2-carboxypyridyl) iridium (III) (FIrpic) was spin-coated on the HTL. Other host materials, including 1,3-di(9*H*-carbazol-9-yl)benzene (mCP), bis(3,5-di(9*H*-carbazol-9-yl)phenyl) diphenylsilane (SimCP2), and 9,9′-(5-(triphenylsilyl)-1,3-phenylene)bis(9*H*-carbazole-9-yl) (SimCP), were also used and doped with 14 wt.% FIrpic as the guest material. An electron-transporting layer (ETL, 32 nm) consisting of 2,2′,2″-(1,3,5-benzenetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi) was then thermally evaporated on the EL. An electron injection layer (EIL, 0.7 nm) of LiF and an Al cathode (150 nm) were also thermally evaporated on the top of the ETL. Beside of the use of different host materials, all other parameters are fixed so that the degradation mechanisms other than the effect of host materials make the same contribution to the device lifetime hence can be ignored. The luminescence area of each device was 2×2 mm, and each chip contained 4 OLED devices, which were separated by 2 mm.

2.2. XPS measurements

The experiments were performed on a PHI 5000 VersaProbe (Chigasaki, Japan) XPS system with a C_{60}^+ ion source (IOG C60-10, Ionoptika, UK). A micro-focused Al Kα X-ray (25 W, 100 μm) was used as the source, and the take-off angle of the photoelectron was 45°. The acceptance lens of the analyzer and the X-ray was rastered over an area of 500×500 μm and centered at the center of luminescence area of the OLED device. A dual-beam charge neutralizer, containing a 7 V Ar^+ beam and 30 V flooding electron beam, was used to compensate charge on the device surface during data acquisition. The Ar^+ sputter source was operated at 0.2 kV, 300 nA with an incident angle of 45°, and the C_{60}^+ ion-cluster source was operated at 10 kV, 10 nA with an incident angle of 70°. Both the Ar^+ and C_{60}^+ ion beams were rastered at the same time over an area of 2×2 mm. The beam currents were measured with the target current on an Au foil and were stable for at least 2 weeks of continuous operation. In addition, reference devices on the same chip were profiled to ensure steady sputtering conditions and to eliminate chip-to-chip variations between each profile. The as-fabricated devices were operated in a nitrogen atmosphere without encapsulation for the aging experiment. A power supply was used to provide a stable 5 V forward bias for 12, 24, 36, 72, and 120 h. Then the devices were measured and the depth in the profile was normalized to the relative thickness of the ETL and EL inside the device, which was defined by a vanishing Al cathode (relative thickness: 0) and the appearance of S in the PEDOT:PSS layer (relative thickness: 1).

2.3. Molecular structure

The molecular dipole moment was calculated with Gaussian 03 revision D.02 using the B3LYP density functional theory (DFT). The 6-31G basis set was employed for all atoms.

2.4. Device lifetime measurement (accelerated experiment)

For device reliability measurements, all of the studied devices with encapsulation were operated in a nitrogen atmosphere for accelerated experiments. In order to

examine the proposed field-driven migration of molecules, fixed driving force is desired. Therefore, a power supply was used to provide a constant forward bias (8.5 V) to the device to generate a constant electric field hence fixed driving force. The luminances of the resultant devices were measured with a Minolta CS-100 luminance meter and all the devices presented here has a similar luminance around $3–4 \times 10^3$ cd/m^2 and the current density is around 20–40 mA/cm^2 [28]. The time for the device to reach 50% initial luminance was reported. The emission area of all the resultant devices was 2×2 mm, and only the luminance in the forward direction was measured.

3. Results and discussion

Previously, we reported the direct observation of the OLED degradation process using XPS depth profiles. Fig. 1a shows the XPS depth profile of the CBP containing device before and after operating the device with a forward DC bias for different lengths of time in a nitrogen atmosphere. Initially, the difference in N intensity clearly delineated the TPBi (ETL, 11 at.% N and 89 at.% C) and CBP (EL, 5 at.% N, 95 at.% C) thin-film stack although it is noted that the observed atomic concentration is lower than expected owing to the implantation of C associated with C_{60}^+ sputtering [21,29]. Since TPBi has more N atoms, the intensity of N observed in XPS is higher than that in CBP layer. After 12 h of operation, the N distribution changed significantly. In short, the N intensity in the original ETL decreased and that in the EL increased. Such an obvious change in the N distribution can be attributed to the molecular migration of small TPBi molecules all the way into the PEDOT:PSS layer under DC bias [21]. We propose the following mechanism for the migration of the TPBi molecules (Fig. 1d). (1) The injected electrons hop on and between the disk-shaped TPBi molecules (Fig. 1c), and the molecules become temporarily charged (TPBi$^-$) and higher current density may lead to more charged molecules; (2) The negatively charged TPBi molecules migrate towards the anode in the electric field caused by the DC bias. In other words, the TPBi molecules are exposed to a driving force to push them from the cathode (Al) to the anode (ITO), and this force causes the TPBi molecules to migrate to the EL and HTL. It is noted that the joule heat generated during device operation may increase the mobility of molecules and assist the molecular migration.

The ease of TPBi (Fig. 1c) migration in CBP (Fig. 1b) may be related to the relative planarity of the host structure. This process significantly changes the device structure, leading to the failure of the device. To prolong the device lifetime, it is preferred to suppress the migration of the TPBi. One possible method is to replace the CBP host with other molecules that have stronger inter-molecular interactions or higher molecular weights. This change in

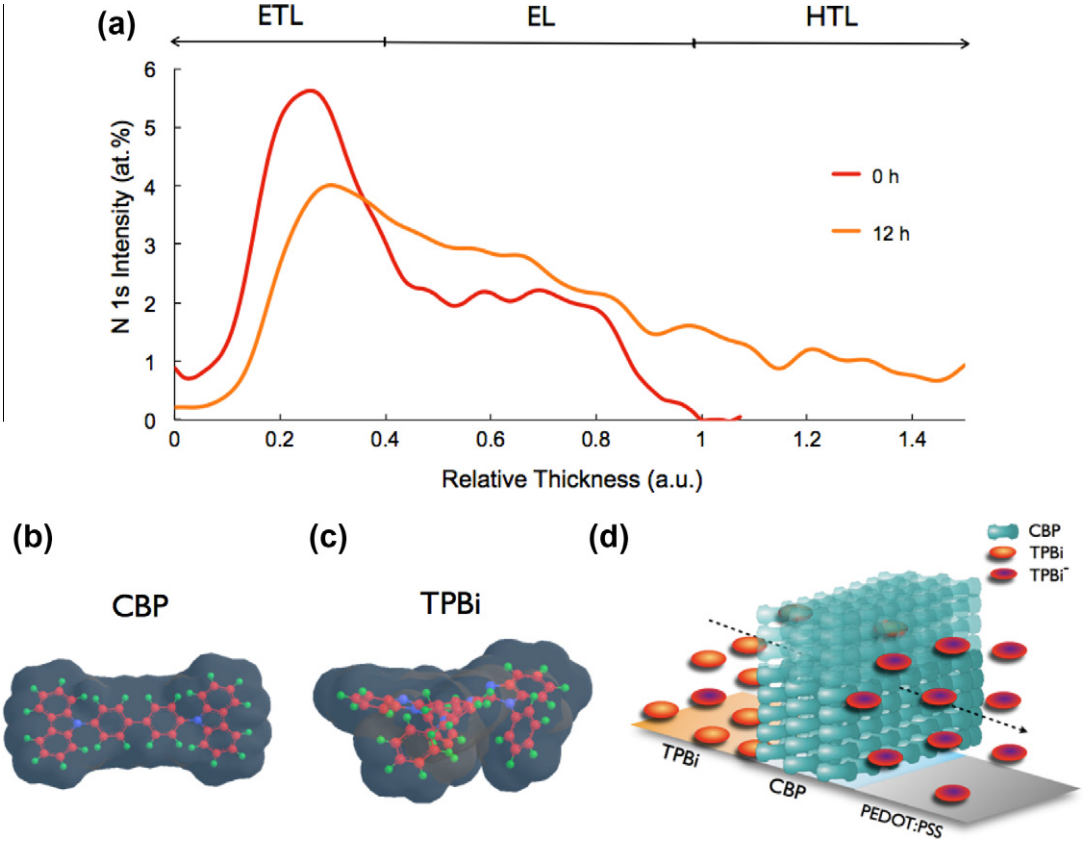

Fig. 1. (a) XPS N 1s depth profiles of the organic layers in the CBP devices operated at a 5 V forward bias for different lengths of time. (b) and (c) Molecular structure of CBP and TPBi (ETL), respectively. (d) A schematic illustration of the molecular migration through the CBP layer toward the anode.

materials can increase the energy barrier for the TPBi to move between the host molecules, and thus suppress the molecular migration inside the device. To examine this hypothesis, devices with mCP, SimCP2, and SimCP were fabricated using the same parameters as for those made with CBP and exposed to a constant 5 V bias (fixed driving force) for different lengths of time. The molecular distribution in these devices was then examined and compared with device half-life determined using an accelerated experiment at a constant 8.5 V operation.

The N distribution of the mCP-containing device after different operation times is shown in Fig. 2a. The mCP device could retain its stacking structure longer than the CBP device, as can be seen by comparing Figs. 1a and 2a. Because mCP molecules have a less symmetric molecular structure (Fig. 2b), the dipole moment of mCP is higher than that of CBP (Table 1). This higher dipole moment yields stronger van der Waals forces between molecules. Figs. 1d and 2c show schematic illustrations of the migration of TPBi through the EL. Although the mCP molecules are smaller than CBP molecules, the stronger inter-molecular interaction between them makes them harder to separate and hinders the migration of TPBi through the mCP layer. Hence, the energy barrier for TPBi to migrate through mCP is higher than that required to migrate through CBP. As a result, the TPBi molecules cannot migrate through mCP layer as easily as they can migrate through the CBP layer; therefore, the change in N distribution after 12 h operation is suppressed using mCP. Although mCP shows a better ability for suppressing the molecular migration of TPBi molecules than CBP, due to the stronger inter-molecular interactions, the molecular migration phenomenon is still apparent after prolonged operation. This limitation may be attributed to the small size of the mCP molecules and their low steric hindrances, which are not sufficient to block the TPBi for prolonged operation. To further improve the device lifetime by suppressing the migration of TPBi molecules, SimCP2, which has larger molecular weight and higher dipole moment, was selected as a host and blocking material.

Fig. 3a shows the XPS depth profiles of the SimCP2-containing device after operating device for different lengths of time. Comparing the SimCP2 with the mCP devices, SimCP2 devices show further retardation in the change of the N distribution during the first 24 h of forward bias. Due to the higher molecular weight, its bulky structure provides stronger steric hindrance that could be more efficient in preventing the TPBi molecules to migrate through (Fig. 3c). Furthermore, the asymmetrical structure (Fig. 3b) of SimCP2 yields higher dipole moment than mCP (Table 1) thus the van der Waals forces between molecules

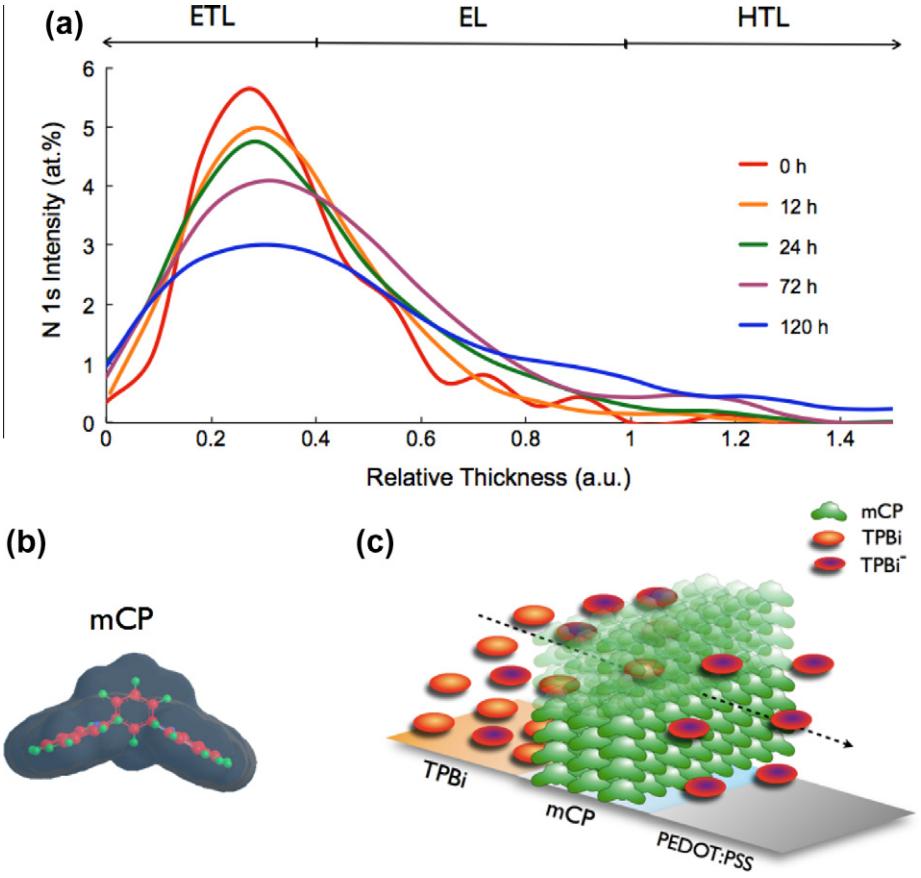

Fig. 2. (a) XPS N 1s depth profiles of the organic layers in the mCP devices operated at 5 V forward bias for different lengths of time. (b) Molecular structure of the mCP host. (c) A schematic illustration of the molecular migration through the mCP layer toward the anode.

Table 1
Physical properties of the four host materials.

	Density (g/cm^3)[a]	Molecular weight (g/mol)	Dipole moment (D)	Device half-life (min)[b]
CBP	1.28	484	0.00	4
mCP	1.25	408	1.34	6
SimCP2	0.80	997	2.40	9
SimCP	1.09	666	2.29	13

[a] The density was measured by using materials with a given weight and its displacement volume of hexane where materials does not dissolve.
[b] The device half-life were measured under 8.5 V forward bias (accelerated aging).

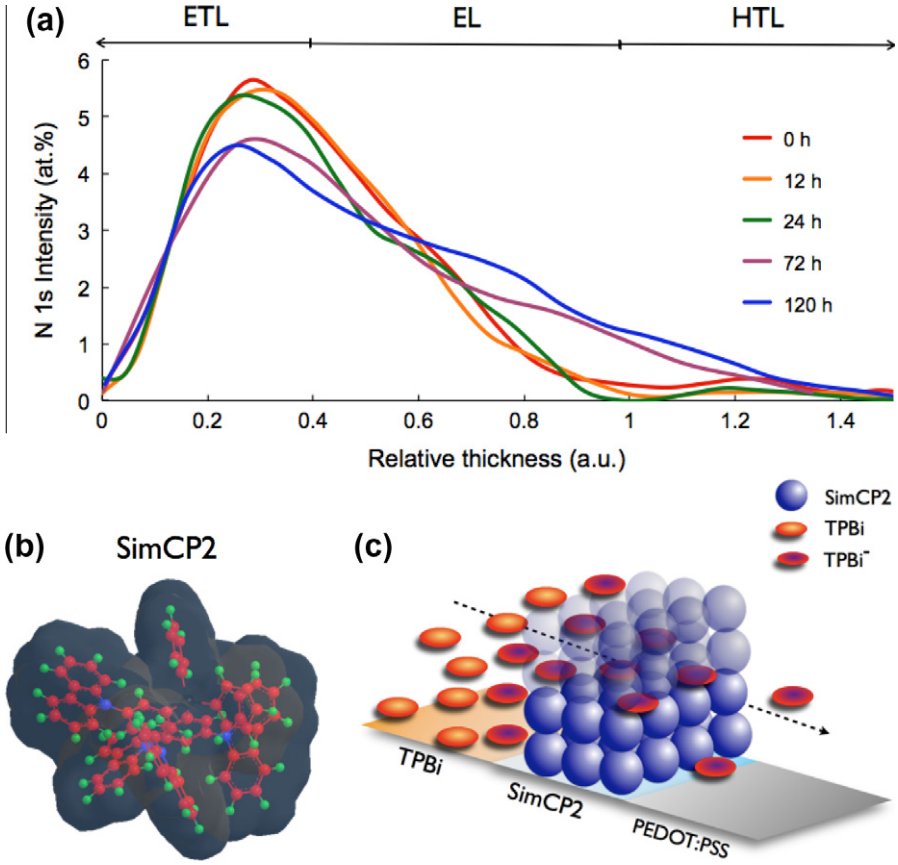

Fig. 3. (a) XPS N 1s depth profiles of the organic layers in the SimCP2 devices, operated at 5 V forward bias for different times. (b) Molecular structure of the SimCP2 host. (c) A schematic illustration of the molecular migration through SimCP2 layer toward the anode.

is stronger. As a result, the energy barrier for TPBi molecules to migrate through the SimCP2 is increased, and the bias-driven molecular-migration phenomenon is not clearly observed during the first 24 h of operation. However, after 72 h operation, the change in device structure due to the migration of TPBi toward the EL and HTL is still evident as the N distribution is broader than the original distribution.

It is found that the density of SimCP2 is significantly lower than other materials (Table 1). Such a low density suggests that the SimCP2 is not densely packed and there may be significant micro-pores in the solid due to its bulky structure. Although the high molecular weight serves as a blockade to TPBi migration and the stronger inter-molecular interaction increases the energy barrier for TPBi to migrate between SimCP2 molecules, these micro-pores provides a low-energy route for TPBi to pass through. In other words, there may be a compromise between the use of a bulky molecular structure and the existence of micro-pores. Therefore, SimCP, which has a similar dipole moment and higher density than SimCP2 (Table 1), was investigated as an alternative host material. Fig. 4a shows the XPS depth profile of the SimCP-containing device after operating for different lengths of time. It is clear that even after 120 h of device operation, the distribution of N-containing species did not change significantly from the initial distribution. This result indicated that the migration of TPBi molecules through the SimCP-containing EL is prevented. Although the molecular structure of SimCP (Fig. 4b) is smaller and

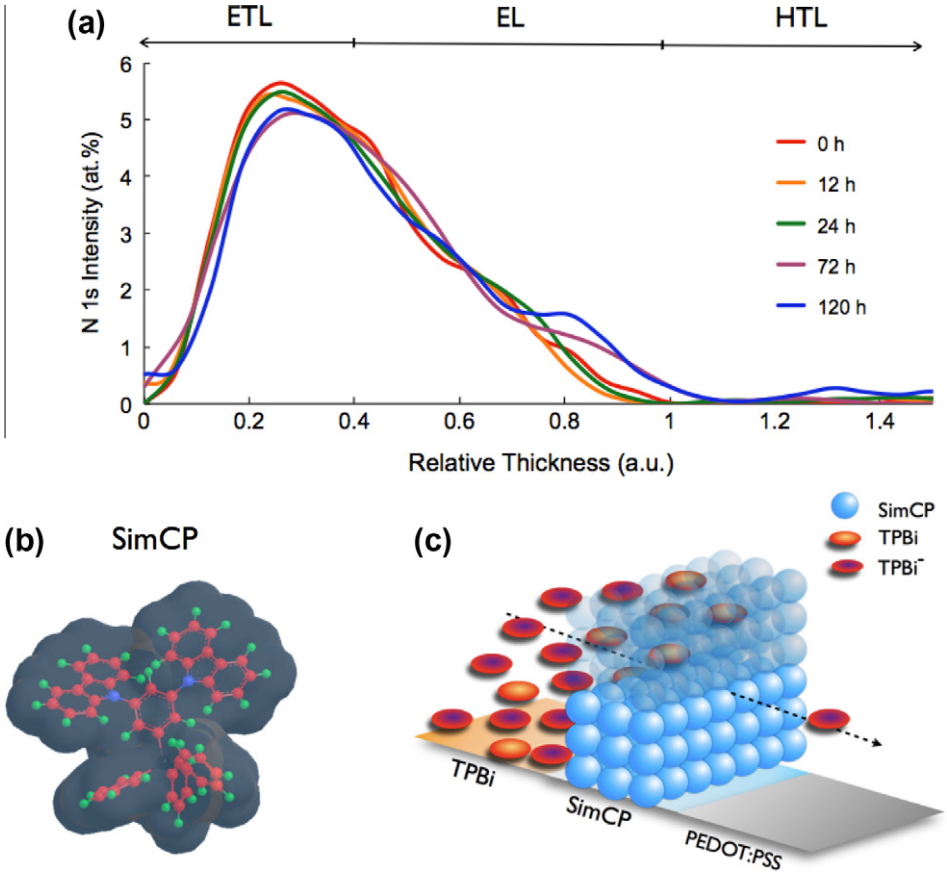

Fig. 4. (a) XPS N 1s depth profiles of the organic layers in the SimCP devices, operated at 5 V forward bias for different lengths of time. (b) Molecular structure of SimCP. (c) A schematic illustration of the molecular migration through the SimCP layer toward the anode.

more symmetrical than that of SimCP2 (Fig. 3b), the higher density of SimCP indicated that the molecules are packed closer than those in SimCP2, and hence it is more difficult for TPBi to pass through the SimCP layer (Fig. 4c).

To correlate the observed bias-driven molecular migration through different host materials and the device reliability, an accelerated experiment on the device lifetime was carried out. Table 1 shows the device half-life of different host materials. Although even under the nitrogen atmosphere, the device half-life is rather short due to the high bias, it was found that the half-life increased sequentially in CBP, mCP, SimCP2, and SimCP. This trend in device half-life is the same as the trend for the suppression of TPBi migration. In other words, by carefully designing a host material that can block the migration of electron-transporting materials toward the anode, the device lifetime can be enhanced.

4. Conclusion

Using *in situ* co-sputtering of high-energy C_{60}^{+} and low-energy Ar^{+} with XPS analysis, OLED devices (Al/LiF/TPBi/Hosts:FIrpic/PEDOT:PSS/ITO) with different hosts materials (CBP, mCP, SimCP2, and SimCP) were profiled to examine the distribution of molecules as a function of operation time. Under a forward bias, the TPBi molecules tend to migrate toward the ITO anode due to the electric field. This bias-driven molecular migration would affect device performance and lifetime reliability. To suppress the migration, organic materials with higher molecular weights, higher dipole moments, and thus stronger inter-molecular forces would increase the energy barrier for the change in device structure. Furthermore, organic materials with high thin-film packing densities can also efficiently suppress the migration. As a result, bias-driven molecular migration could be effectively suppressed by the design of host materials, thus enhancing device reliability.

ABSTRACT

Planar and textured heterojunction solar cells (OPVs) are reported for vacuum deposited chloroindium phthalocyanine (ClInPc)/C_{60} heterojunctions, and their response compared to previously explored OPVs based on titanyl phthalocyanine (TiOPc)/C_{60} heterojunctions. As for TiOPc/C_{60} OPVs, the photoelectrical activity of ClInPc/C_{60} OPVs extends well into the near infrared, with good activity out to ca. 900 nm. As-deposited ClInPc films (Phase I) produce open-circuit photopotentials, V_{OC} as high as ca. 0.8 V (Phase I form of ClInPc), ca. 0.15 V larger than previously observed for Phase I TiOPc/C_{60} OPVs. The offsets in frontier orbital energies (E^{Pc}_{HOMO}–$E^{C_{60}}_{LUMO}$) revealed by UV-photoemission studies (UPS) are slightly smaller for ClInPc/C_{60} versus TiOPc/C_{60} heterojunctions, and the interface dipole contribution (shift in local vacuum level) to these offsets is in the opposite direction for ClInPc/C_{60} versus TiOPc/C_{60} heterojunctions, or missing altogether, suggesting differences in molecular interaction at the Pc/C_{60} interface. Higher V_{OC} values are correlated with lower reverse saturation currents, J_o, for ClInPc/C_{60}, versus other Pc or pentacene/C_{60} heterojunctions, suggesting weak intermolecular interactions at the ClInPc/C_{60} interface and large barriers to dark charge injection. Solvent annealing of the ClInPc films enhances the near-IR response, and textures the Pc film, enhancing the Pc/C_{60} interfacial contact area and the short-circuit photocurrent, J_{SC}. J_{SC} under AM 1.5 illumination conditions was estimated by integration of the incident photon current efficiency (IPCE) response, to compare relative power conversion efficiencies for the two different device types. The estimated efficiency of Phase I ClInPc/C_{60} OPVs is ca. 2.6%. The estimated AM 1.5 efficiency of ClInPc/C_{60} OPVs with solvent annealed Pc layers is estimated to be ca. 3.3%, arising from the extensive texturing achieved of the Pc layer, which nearly doubles J_{SC} for the Phase II versus Phase I Pc films.

1. Introduction

Organic photovoltaics (OPVs) based on "Type II" donor (D)/acceptor (A) heterojunctions [1], have been under investigation for over two decades, in either planar heterojunction (PHJ) or bulk heterojunction (BHJ) formats [2–20]. OPVs have recently achieved AM 1.5 efficiencies higher than 7% in both polymer BHJ formats [2,21], and in PHJ tandem OPVs [22–24]. Improving the efficiency of OPVs requires enhancing the short-circuit current (J_{SC}), utilizing materials with enhanced near-IR absorption, and nanotexturing of the donor/acceptor (D/A) interface, facilitating efficient exciton dissociation [15,18,20,25]. Such enhancements need to occur without sacrificing open-circuit voltage, V_{OC}, which is controlled by offsets in transport frontier orbital energies, E^{D}_{HOMO}–E^{A}_{LUMO} [1,26–30], and by the strength of intermolecular interactions at the D/A interface, and ultimately the magnitude of the reverse saturation current, J_o [8,12,31].

We show here that OPVs based on heterojunctions of C_{60} with planar and textured layers of the trivalent metal phthalocyanine chloroindium phthalocyanine (ClInPc) meet several of the criteria for good near-IR spectral overlap, high V_{OC} brought about by higher ionization potentials (IP) versus most other small molecule donors, and low values of J_o in the Pc/C_{60} heterojunction. Efficiencies of these ClInPc/C_{60} OPVs are higher than those we recently reported on using titanyl phthalocyanine (TiOPc) as the donor layer [14,15].

The tetravalent and trivalent metal phthalocyanines (titanyl and vanadyl phthalocyanines, TiOPc and VOPc, and the halo-aluminum, -gallium and -indium phthalocyanines, e.g. ClAlPc, ClGaPc, ClInPc) have been explored as xerographic photoreceptors and as photoelectrochemical energy conversion platforms, in both their as-deposited Phase I polymorph, or as Phase II or related polymorphs [11,14,32–41]. The ionization potentials (IP) of the tetravalent and trivalent metal Pcs are generally higher than seen in other Pc donors (e.g. CuPc, ZnPc), or pentacene and related polycyclic aromatic hydrocarbons [9,11,14,15,42–47]. For OPVs based on as-deposited (Phase I polymorph) TiOPc/C_{60} heterojunctions V_{OC} as high as 0.65 V has been observed [14]. Upon solvent annealing of these Pc films significant nano-texturing occurs during the formation of the Phase II polymorph along with a significant broadening of the *Q*-band absorbance out to ca. 900 nm. The increase in interfacial area between the Pc and C_{60} layers, along with the added near-IR absorbance, leads to a near doubling of power conversion efficiency as a result of these polymorphic transitions [15].

In this paper, we discuss planar and textured heterojunction OPVs based on ClInPc/C_{60} (Fig. 1), showing enhanced near-IR responses as for TiOPc OPVs, but with a larger V_{OC}. ClInPc demonstrates close to the same near-IR absorptivity (α, cm^{-1}) in its Phase I and Phase II polymorphs as seen in TiOPc polymorphs. As for TiOPc, ClInPc ohms per square is believed to have a high probability for triplet state formation [48], as has been hypothesized for OPVs based on thin films of other heavy metal phthalocyanines (e.g. SnPc) [49]. The trivalent and tetravalent Pcs, especially ClInPc films, can also be formed as well-ordered, epitaxial thin films, demonstrating layer-by-layer growth on ordered substrates, lending themselves to the formation of well-ordered organic/organic′ heterojunctions [50,51], amenable to characterization of their ionization potentials and interface dipole effects using UV-photoemission spectroscopies (UPS) [6].

We demonstrate here that OPVs based on Phase I ClInPc/C_{60} heterojunctions show values of V_{OC} nearly 0.2 V higher than their Phase I TiOPc/C_{60} counterparts. Estimated AM 1.5 efficiencies for the Phase I polymorph of ClInPc based OPVs are twice as those seen previously for Phase I TiOPc/C_{60} heterojunctions. Solvent annealing of the Phase I ClInPc films provides texturing of the Pc/C_{60} interface on ca. 100 nm length scales that enhances the short-circuit photocurrent, J_{SC}, with only small declines in V_{OC}, leading to estimated AM 1.5 efficiencies for heterojunctions based on the Phase II polymorph of ca. 3.3%. Improved efficiencies for OPVs based on textured Phase II and Phase III TiOPc films are reported elsewhere, but have also shown significant enhancements in efficiencies relative to our earlier reports [52].

The larger values of V_{OC} for OPVs based on ClInPc do not arise from larger $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ offsets, estimated from UPS studies of ClInPc/C_{60} versus TiOPc/C_{60} heterojunctions, since these energy offsets are comparable for both donor layers. We show here that $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ and the magnitude and sign of the interface dipole at the ClInPc/C_{60} heterojunction are dependent on the deposition rate of the Pc film, which likely controls the micro-crystallinity of these layers. Previous studies of organic heterojunctions of ClInPc with perylene-based acceptors have shown that interface dipoles seen at the O/O′ heterojunction are strongly dependent upon molecular architecture at this interface [6,18], as predicted by several other investigations [53–56]. We also observed much lower values of J_o for ClInPc/C_{60} heterojunctions, suggesting that apparently weaker intermolecular interactions at this interface are primarily responsible for enhanced values of V_{OC}.

2. Experimental methods

Commercial ITO was obtained from Colorado Concept Coating, LLC, with a sheet resistance of ca. 15 ohms per square. ITO substrates were cleaned with a micro-fiber cloth using 10% Triton-X100, followed by successive sonications in 10% Triton-X100 for 15 min, nanopure water for 5 min, and pure ethanol for 15 min. Prior to the deposition of organic thin films, substrates were dried under a

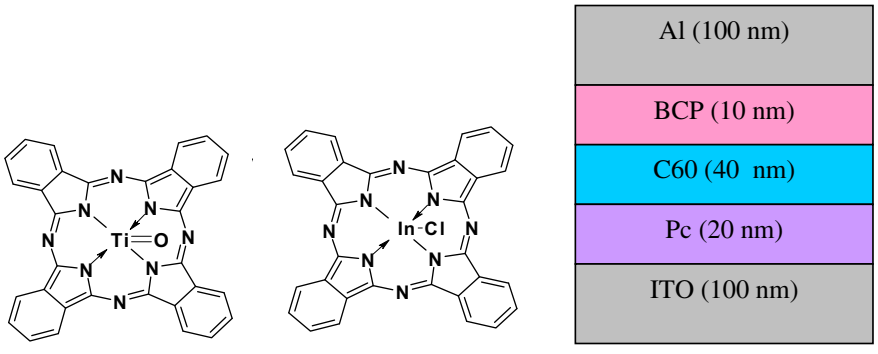

Fig. 1. Molecular structure of TiOPc and ClInPc, and OPV device structure, respectively.

stream of nitrogen and then etched via oxygen plasma cleaning (Harrick PDC-32G) for 15 min.

Titanyl phthalocyanine (TiOPc), chloroindium phthalocyanine (ClInPc), and bathocuproine (BCP) were purchased from Sigma–Aldrich. Fullerene (C_{60}) was obtained from MER. All chemicals were purified by multiple entrainer sublimation prior to use [57,58].

Organic thin-films were deposited via vacuum deposition (ca. 1 Å/s) at base pressures of ca. 10^{-7} Torr via Knudsen-type sublimation cells, monitored with a 10 MHz quartz crystal microbalance (QCM-Newark), and an Agilent Technologies frequency monitor (Model 53131A). Solvent-annealed TiOPc and ClInPc films were created by depositing the desired Pc film thickness, transfer of the film under nitrogen to an adjacent glovebox where it was placed in a sealed vessel adjacent to a reservoir of liquid chloroform for up to 5 h [15]. The Pc film was then returned to vacuum and the Pc/C_{60} OPV device completed. Aluminum top contacts were deposited at pressures no greater than 10^{-6} Torr at a deposition rate of 1–3 Å/s, monitored via a 6 MHz QCM (Tangidyne) and Inficon deposition monitor (Model 758-500-G1). These aluminum top contacts defined the device area, and we typically made from 9 to 26 devices for each deposition sequence, on ITO/glass substrates with dimensions approximately 2.5 × 2.5 cm. The region at the center of some of these substrates was left open to allow for absorbance spectra to be measured on the same films for which IPCE data was obtained.

Current–voltage (J/V) data was obtained for several OPVs for each ClInPc films composition, with areas of 0.019 cm^2. The J/V data presented here are representative of at least nine devices. IPCE data was obtained for devices with an area of 0.125 cm^2, apertured so as to minimize "edge effects" in the photocurrent response [15,59]. OPV testing was carried out in a N_2-filled double-glovebox (MBrawn Labmaster), with water and oxygen levels at less than 0.1 ppm. Current–voltage measurements were made with a Keithley 2400 source meter, while the data was acquired with in-house software created with *Labview* ver.8.2 (National Instruments). Scans ranged from −1.00 to 1.50 V using a 20 mV step starting from negative bias. A CUDA products light source with a 250 W quartz-halogen lamp (Model I-250) was used as the illumination source. The light was filtered with a 750 nm cutoff filter, along with a sand-blasted light diffuser (the spectral distribution for this filter set is shown in Supporting information). We adjusted the distance to the OPV device arrays to achieve an output of approximately 100 mW/cm^2 as measured with an Apogee PYR-S pyranometer.

Incident photon current efficiency (IPCE) measurements were carried out in atmosphere immediately after device fabrication. IPCE data were acquired after characterizing dark/light J/V behavior in the glovebox environment. IPCE measurements were made with a 500 W quartz-halogen lamp with a Mercron power stabilizer (Model TXC-500 120/120). The modulated light (250 Hz) was passed through a Jobin Yvon (Model H10/1200) monochromator. Spectra were acquired at 4 nm steps. Incident power through the monochromator was measured with a calibrated Hamamatsu photodiode acquired from Newport Optics (Model 818-SL). The bias for the OPV was maintained so as to obtain short-circuit current at each excitation wavelength. The current-to-voltage output was input to a EG&G (Model 5209) lock-in amplifier, and output into in-house software created with *Labview* ver.8.2 (National Instruments).

XPS/UPS measurements of Pc/C_{60} heterojunctions were carried out in a Kratos Axis-Ultra X-ray photoelectron spectrometer using an Al Kα source at 1486.6 eV for XPS measurements and a He(I) excitation source (21.2 eV) for UPS measurements. A −9.00 V bias was applied to the sample to further enhance the collection of lowest kinetic energy electrons [14,50,60]. For XPS data, the spot size was 300 × 700 μm, while for UPS, spot size ranged between 1 and 3 mm. A UHV organic deposition system attached to the Kratos spectrometer allowed for depositions of organic thin-films under conditions like those used to create OPVs. Thin-films were deposited (about 1 Å/s) on gold substrates (Alfa-Aesar) that were polished and etched with pirahna solution prior to the UPS studies [14,60]. Gold substrates were sputtered clean in vacuum to ensure that their effective work functions were 5.1 eV and to provide for measurement of the Fermi energy [60]. For the data shown in Fig. 6, photoemission from the Au Fermi level occurred at 32.0 eV for sputter-cleaned gold substrates and we made sure that this energy did not change during organic film deposition, which would have indicated charging effects [60]. For exploration of solvent-annealed ClInPc films, after the initial deposition and UPS characterization, the films were removed from vacuum into a nitrogen-filled glovebag and annealed as described above. Samples were then returned to vacuum, followed by subsequent UPS characterization.

Absorbance measurements were carried out with an Agilent Technologies UV/visible spectrophotometer (Model 8453) at 1 nm intervals with an integration time of 10 s and a range of 400–1100 nm. The morphology and root-mean-square (rms) roughness of ClInPc films were obtained from images collected using a Digital Instruments atomic force microscope (Dimension 3100). The images were collected in tapping mode with Mikromasch silicon cantilevers (Model TESP-7). Images were obtained in ambient air at a scan rate of 0.5 Hz with image sizes of 2.5 × 2.5 μm. SEM images were taken on a Hitachi 4800 FE-SEM (15 kV accelerating voltage) on as-prepared samples (i.e. no metallic over coating).

3. Results and discussion

3.1. Characterization of microstructure and thin film absorbance spectra and absorptivities

Figs. 1 and 2 show the schematics of the Pc donors, the OPV device configurations, and the field-emission (FE-SEM) images for ClInPc and TiOPc films of ca. 20 nm thickness, in as-deposited (Phase I) and solvent annealed (Phase II) form, on ITO. Fig. 3 (upper panel) shows the absorbance spectra of device-thickness TiOPc and ClInPc films (Phase I ClInPc films (20 nm), Phase I TiOPc films (18 nm), Phase II ClInPc films (22 nm) and Phase II TiOPc films (20 nm)). SEM and AFM images suggest that the Phase I TiOPc film is conformal, and reflects the structure of the underlying

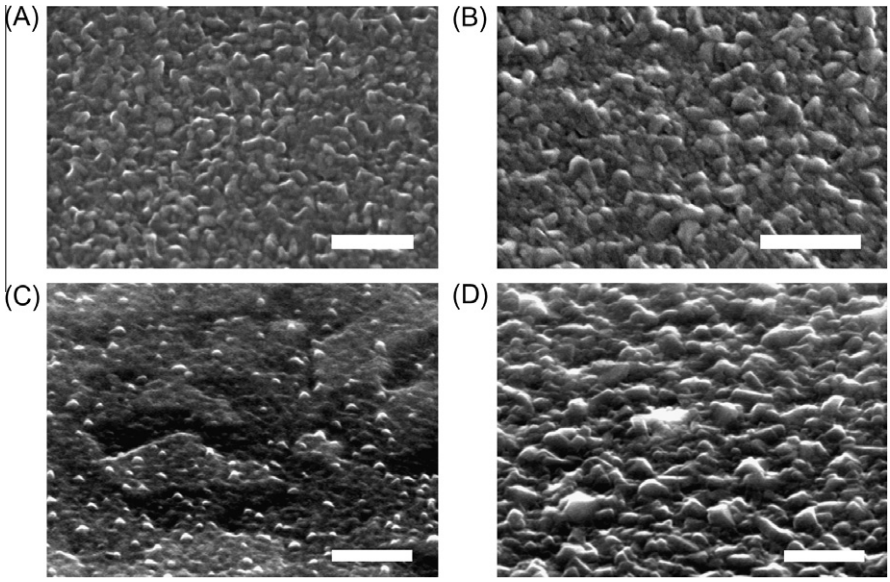

Fig. 2. SEM of ClInPc (A and B) and TiOPc (C and D) on ITO, in as-deposited, Phase I polymorph (A and C) and solvent annealed, Phase II polymorph (B and D) for 20 nm film thickness. Scale bar = 200 nm.

ITO [15]. The Phase I ClInPc film shows more texturing and surface roughness (rms roughness = 2.9 ± 0.6 nm) versus the Phase I TiOPc film (rms roughness = 0. 9 ± 0.03 nm, i.e. these Phase I TiOPc films were nearly conformal with the ITO substrate) (see AFM data in Supporting information).

After solvent annealing, which causes a change in Pc crystal structure from monoclinic (Phase I) to triclinic (Phase II) [34,38], both Phase II ClInPc and Phase II TiOPc films show greatly increased surface roughness (rms roughness = 5.0 nm for Phase II ClInPc and 6.6 for Phase II TiOPc), which subsequently leads to enhanced interfacial contact area between the Pc donor and C_{60} acceptor, coupled with greatly enhanced absorptivities in the near-IR, out to wavelengths of ca. 900 nm (we estimate that $\alpha \approx 1.5 \times 10^5\,cm^{-1}$ at the peak absorbance – Fig. 3). It has been proposed that this shift in the TiOPc *Q*-band absorbance is due to the formation of a charge-transfer-like state, owing to the much closer proximity of the opposed oxo-metal dipoles in these dyes, accompanying the shift in their crystal structures from monoclinic (Phase I) to triclinic (Phase II) [34,35,43–45,61–63]. We assume a similar situation may occur for the ClInPc system, although the internal dipole moment along the metal-halogen bond is not as large as along the metal-oxo bond in TiOPc [64–66]. We also note the similarity in structure of the polymorphic forms of this pigment, relative to those observed for TiOPc and VOPc [67,68]. Although there is substantial roughening of the Pc film, it should be noted that each asperity still has dimensions which exceed the presumed exciton diffusion length ($3 \times L_D$ in Pc films $\approx$ 18–22 nm) [20,69], so the kind of texturing needed to increase external quantum efficiencies (IPCE, see below) to greater than 0.85 (seen in polymer bulk heterojunction devices) [3,21], has not yet been achieved.

3.2. UPS studies of frontier orbital energy offsets for ClInPc/C_{60} versus TiOPc/C_{60} heterojunctions

Fig. 4 shows the UPS data used to characterize the frontier orbital energy offsets that set the upper limit for open-circuit photopotentials, V_{OC}, for Phase I ClInPc/C_{60} heterojunctions (upper panel) and Phase II ClInPc/C_{60} heterojunctions (lower panel). Figs. 5 and 6 show the energy level offsets inferred from these UPS data, and from estimates of LUMO levels from either optical absorbance data, or from inverse photoemission spectroscopic data for related Pcs and C_{60} [70,71]. The data shown in Fig. 4 were obtained by first depositing ClInPc thin films on clean Au substrates (work function $\approx$ 5.1 eV), followed by the deposition of C_{60} layers in small thickness increments. Using those UPS data in Fig. 5 and previously described analysis protocols [14,50,72–75], we determined the ionization potential (IP) for both Phase I ClInPc and Phase II ClInPc to be ca. 5.4 eV. A shift of ca. −0.3 eV in the local vacuum level (interface dipole effect) was observed as C_{60} was deposited onto Phase I ClInPc, while a vacuum level shift of −0.2 eV was observed for Phase II ClInPc/C_{60} heterojunctions. No difference in the photoemission features for C_{60} were observed for the last two incremental depositions of C_{60}, indicating that it had reached its bulk electronic properties. The IP of C_{60} in these heterojunctions was estimated to be ca. 6.4 eV.

Those IP values and vacuum level shift derived from the UPS data are used to estimate the frontier orbital energy offsets for the ClInPc/C_{60} junctions. The band diagrams are then compared with those for the TiOPc/C_{60} heterojunction in Fig. 5 (Phase I Pc/C_{60} junctions) and Fig. 6 (Phase II Pc/C_{60} junctions) [14,15,18]. The LUMO energies were estimated from combinations of absorbance spectroscopy, inverse photoemission spectroscopy (IPES), solution electrochemistry,

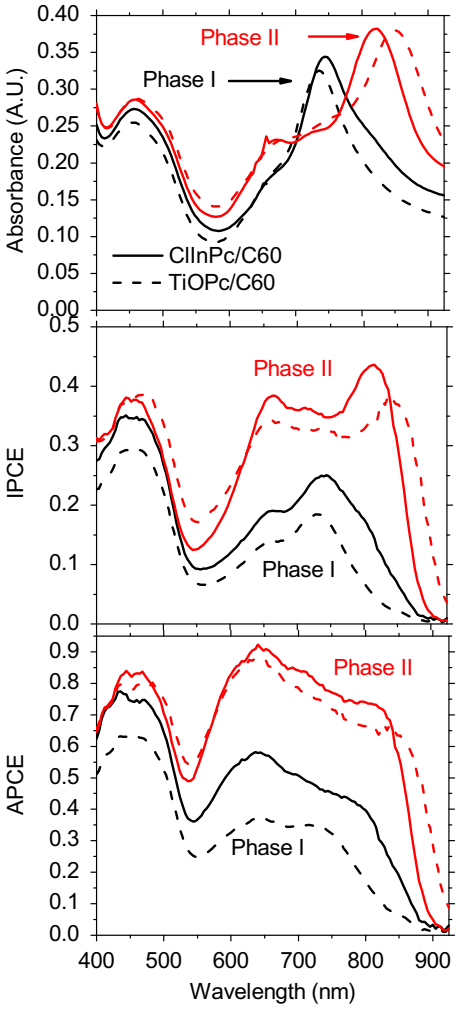

Fig. 3. (Upper panel) Absorbance spectra, (middle panel) incident photon to current conversion efficiency (IPCE) and (bottom panel) absorbed photon to current conversion efficiency (APCE) plots for Phase I TiOPc (18 nm)/C_{60} (40 nm)/BCP (10 nm) (dark dashed line), Phase I ClInPc (20 nm)/C_{60} (40 nm)/BCP (10 nm) (dark solid line), Phase II TiOPc (20 nm)/C_{60} (40 nm)/BCP (10 nm) (red dashed line), Phase II ClInPc (22 nm)/C_{60} (40 nm)/BCP (10 nm) (red solid line). Fig. 4. He (I) UPS spectra for C_{60} deposited, in small thickness increments, on Phase I ClInPc at low kinetic energy cutoff edge (A) and at high kinetic energy cutoff region (B); and for C_{60} deposited, in small thickness increments, on Phase II ClInPc at low kinetic energy cutoff edge (C) and at high kinetic energy cutoff region (D).

and scanning tunneling spectroscopic (STS) data for other Pc systems and for other studies of C_{60} [9,15,50,70,76–78]. We note that LUMO energies and electron affinities estimated from IPES data can be much smaller than those estimated from absorbance data in the Pc films, owing to the significant exciton binding energy for donor layers like the Pcs, and there is additional uncertainty in determining the LUMO energy to less than ±0.2 eV in IPES experiments, owing to the resolution of that data [70]. For comparison of otherwise quite similar Pc/C_{60} heterojunctions the uncertainties in these estimates of LUMO energy, which can be ±0.3 eV, are not of concern.

We note that $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO} \approx 1.0$ eV for Phase I ClInPc/C_{60} junction versus Phase I TiOPc/C_{60} where $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO} \approx 1.3$ eV (the absolute values of these offsets are larger if we use transport LUMO levels estimated from other IPES data) [70], suggesting that V_{OC} should be larger for Phase I TiOPc/C_{60} heterojunctions. As shown below, we actually see larger values of V_{OC} in ClInPc/C_{60} OPVs. In addition to these difference in $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ the shift in local vacuum level for ClInPc/C_{60} heterojunction (−0.33 eV) is opposite in sign to that observed at the TiOPc/C_{60} heterojunctions (0.2 eV). Interface dipoles observed for previously explored Pc/C_{60} heterojunctions have been greater than zero, including Phase I TiOPc/C_{60} (0.2 eV), CuPc/C_{60} (0.3 eV) and SubPc/C_{60} (0.5 eV) [14,15,79].

We have recently observed, however, interface dipoles of −0.3 eV for both ClInPc and ClAlPc films in heterojunctions with electron acceptors such as perylenetetracarboxylicdianhydride (PTCDA), which has a slightly higher electron affinity than C_{60}. These different interactions may be attributable to variations in packing structures and the local density of these trivalent metal Pcs, which impacts on the density of local dipoles from the metal-halogen bond, which in turn is dependent upon deposition rate, and the molecular nature of the donor/acceptor

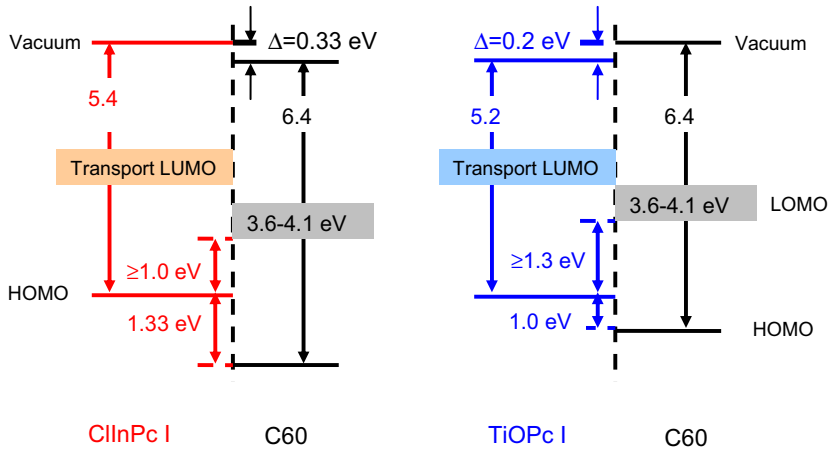

Fig. 5. Frontier orbital offset energies for ClInPc/C_{60} and TiOPc/C_{60} heterojunctions. The UPS data used to obtain these energies for ClInPc/C_{60} junction is summarized in Fig. 4. The UPS data used to obtain the energies for TiOPc/C_{60} junction is from previously published work [14,15]. For Phase I ClInPc/C_{60} heterojunction, an inverse interface dipole (−0.33 eV) was observed, suggesting a different kind of structure and polarizability the ClInPc I/C_{60} interface, comparing with Phase I TiOPc/C_{60} heterojunction with a positive interface dipole of 0.2 eV. After correction for vacuum level shifts for each heterojunction, we conclude that the critical energy differences which form the upper limit for V_{OC} in OPVs, $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$, is lower for Phase I ClInPc/C_{60} than for Phase I TiOPc/C_{60} heterojunctions. The energetic driving force for exciton dissociation, however, is higher for Phase I ClInPc/C_{60} heterojunctions, versus Phase I TiOPc/C_{60} heterojunctions, consistent with the higher photocurrent from the Phase I ClInPc/C_{60} heterojunctions.

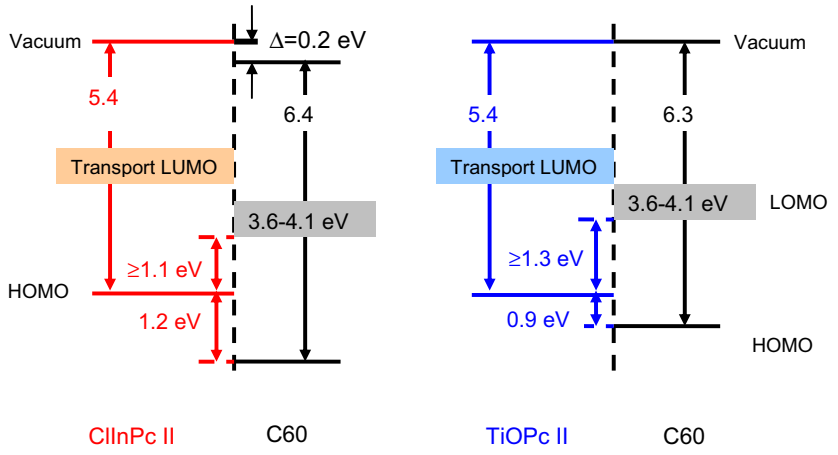

Fig. 6. Frontier orbital offset energies for Phase II ClInPc/C_{60} and Phase II TiOPc/C_{60} heterojunctions. The UPS data used to obtain these energies is summarized in Fig. 4. The UPS data used to obtain the energies for TiOPc/C_{60} junction is from previously published studies [15]. For Phase II ClInPc/C_{60} heterojunction, an inverse interface dipole (−0.2 eV) was observed, suggesting a different kind of reaction at the ClInPc II/C_{60} interface, comparing with Phase II TiOPc/C_{60} heterojunction with no interface dipole. After correction for vacuum level shifts for each heterojunction, we conclude that the critical energy differences which form the upper limit for V_{OC} in OPVs, $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$, are slightly lower for Phase II ClInPc/C_{60}, versus Phase II TiOPc/C_{60} heterojunctions. The energetic driving force for exciton dissociation, however, is higher for Phase I ClInPc/C_{60} heterojunctions, versus Phase I TiOPc/C_{60} heterojunctions, consistent with the higher photocurrent from the Phase I ClInPc/C_{60} heterojunctions.

interface formed. Jones and coworkers [80], have recently shown that the interface dipole at ClAlPc/C_{60} heterojunction is −0.1 eV at low deposition rates of ClAlPc films, and that as the deposition rate of ClAlPc increases, and the molecular density decreases, the interface dipole at the ClAlPc/C_{60} heterojunction changes from −0.1 to 0.2 eV. We have observed similar differences in UPS-derived interface dipoles, dependent upon ClInPc deposition rate. For ClInPc films deposited at 2–3 Å/s (a factor of 3× larger than used for OPV heterojunction formation) we saw no interface dipole upon formation of the Pc/C_{60} heterojunction, and larger $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ offsets (see Fig. SI-1, Supporting information).

We also explored Phase II ClInPc/C_{60} heterojunctions (Fig. 6). Similar to Phase I Pc/C_{60} heterojunction in Fig. 5, we observed lower value of $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ ($\geqslant$1.1 eV) for the Phase II ClInPc/C_{60} junction than for Phase II TiOPc/C_{60} junction ($\geqslant$1.3 eV). An inverse interface dipole (−0.2 eV) is again observed at the ClInPc/C60 heterojunction, while no interface dipole is observed at the TiOPc/C_{60} heterojunction. Despite these uncertainties in energy levels, it does appear that for both Phase I and Phase II

Table 1
Device parameters for OPVs based on ClInPc/C_{60} and TiOPc/C_{60} heterojunctions.

Type of Pc/C_{60} heterojunction (and Pc film thickness); C_{60} thickness in all cells = 40 nm	V_{OC} (V)[a]	J_{SC} (mA/cm^2)[b]	Fill factor	n_o[c]	η (%)[d]	J_o (mA/cm^2)[e]	$E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ (eV)
Phase I – ClInPc (20 nm)	0.79	−11.1	0.58	2.3	2.6	1.0×10^{-5}	1.0
Phase I – TiOPc (18 nm)	0.61	−8.1	0.53	2.3	1.3	1.7×10^{-4}	1.3
Phase II – ClInPc (22 nm)	0.68	−15.9	0.50	2.3	3.3	4.8×10^{-5}	1.1
Phase II – TiOPc (20 nm)	0.57	−15.1	0.53	2.5	3.0	7.1×10^{-4}	1.3

[a] Open-circuit photovoltage.
[b] Short-circuit photocurrent.
[c] Ideality factor calculated from fitting the dark *J–V*.
[d] AM 1.5 power conversion efficiency [(V_{OC}·J_{SC}·*FF*)/P_{IN}].
[e] Reverse saturation current – estimated from lowest dark current (log plots).

ClInPc polymorphs the estimated $E^{Pc}_{LUMO}-E^{C_{60}}_{LUMO}$ energy offsets, which control the exciton dissociation efficiency [8,9], are larger for ClInPc/C_{60} versus TiOPc/C_{60} heterojunctions. The expectation is that for equivalent thickness and textured Pc films, the short circuit photocurrent for ClInPc OPVs will be larger, which is born out in the *J*/*V* data for equivalent devices described below.

3.3. ClInPc/C_{60} photovoltaic device performance

ClInPc/C_{60} OPVs based on optimized thicknesses of Phase I ClInPc film and Phase II ClInPc donor films are compared to Phase I and Phase II TiOPc/C_{60} OPVs, created as described previously (device configuration in Fig. 1 and data in Figs. 2 and 3) [15]. Table 1 summarizes the device parameters for these OPVs.

We first compare Phase I TiOPc/C_{60} and ClInPc/C_{60} OPVs. Fig. 7 shows the dark and illuminated *J–V* characteristics for ITO/Phase I TiOPc (18 nm)/C_{60} (40 nm)/BCP (10 nm)/Al and ITO/Phase I ClInPc (20 nm)/C_{60} (40 nm)/BCP (10 nm)/Al. Optimum OPV performance was obtained for Pc film thicknesses of ca. 18 nm (TiOPc) and ca. 20 nm (ClInPc). For Phase I TiOPc OPVs $J_{SC}=-8.1$ mA/cm^2; $V_{OC}=0.6$ V; $FF=0.53$, while for Phase I ClInPc OPVs $J_{SC}=-11.1$ mA/cm^2, $V_{OC}=0.8$ V, $FF=0.58$. There was a significant increase (almost 0.2 V) in V_{OC} as the donor layer was changed from TiOPc to ClInPc. J_{SC} was also improved for the ClInPc OPVs (Fig. 3 – upper panel), correlating with the enhanced light absorption for these films in the near-IR. We found that we could produce optimum response in ClInPc OPVs with 22 nm Pc layers (versus 20 nm thickness for TiOPc devices – see Table 1). For both Pcs the estimated absorptivity, $\alpha=1.5\times10^5$ cm^{-1} at the *Q*-band absorbance maximum, suggesting that other factors lead to improved performance of the ClInPc OPVs, such as enhanced exciton diffusion lengths, and/or enhanced charge mobilities [81,82]. The estimated AM 1.5 power conversion efficiency, η, was doubled for Phase I ClInPc versus TiOPc OPVs. Comparable values of V_{OC} have recently been reported for "Phase I" ClAlPc/C_{60} OPVs, where thin molecular interlayers (PTCDA) were used at the ITO interface to "template" the growth of ordered ClAlPc layers, and/or add a hole-selectivity to this interface [83,84]. Li and Forrest have also recently reported OPVs based on textured Phase I ClAlPc layers with a V_{OC} of ca. 0.8 V [16,25].

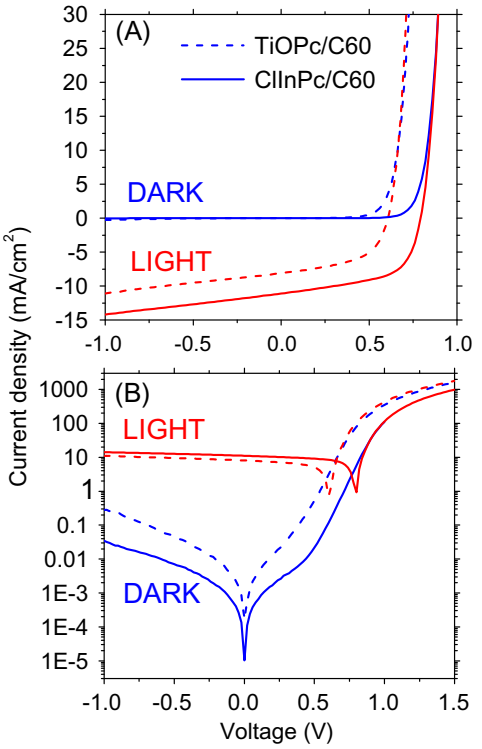

Fig. 7. The *J–V* characteristics for Phase I TiOPc (18 nm)/C_{60} (40 nm)/BCP (10 nm) (dashed lines) and for Phase I ClInPc (20 nm)/C_{60} (40 nm)/BCP (10 nm) (solid lines) in the dark (blue lines) and under illumination (red lines). (A) Linear *J–V*; (B) semi-log *J–V*. At 140 mW/cm^2 for the TiOPc/C_{60} solar cell, $J_{SC}=8.12$ mA/cm^2; $V_{OC}=0.61$ V; $FF=0.53$; for the ClInPc/C_{60} solar cell, $J_{SC}=11.11$ mA/cm^2; $V_{OC}=0.79$ V; $FF=0.58$. Device area = 0.019 cm^2. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 8 shows the *J–V* characteristics for Phase II ClInPc (22 nm)/C_{60} (40 nm)/BCP (10 nm) and Phase II TiOPc (20 nm)/C_{60} (40 nm)/BCP (10 nm), in the dark and under illumination. For the Phase II TiOPc OPVs $J_{SC}=15.10$ mA/cm^2; $V_{OC}=0.57$ V; $FF=0.53$, while for Phase II ClInPc OPVs, $J_{SC}=15.86$ mA/cm^2; $V_{OC}=0.68$ V; $FF=0.50$. Both devices have comparable J_{SC} and *FF*, but V_{OC} for Phase II ClInPc solar cell is higher than for Phase II TiOPc solar cell, although lower than seen in the Phase I OPV, still leading, however, to substantially higher efficiency for Phase II ClInPc OPVs.

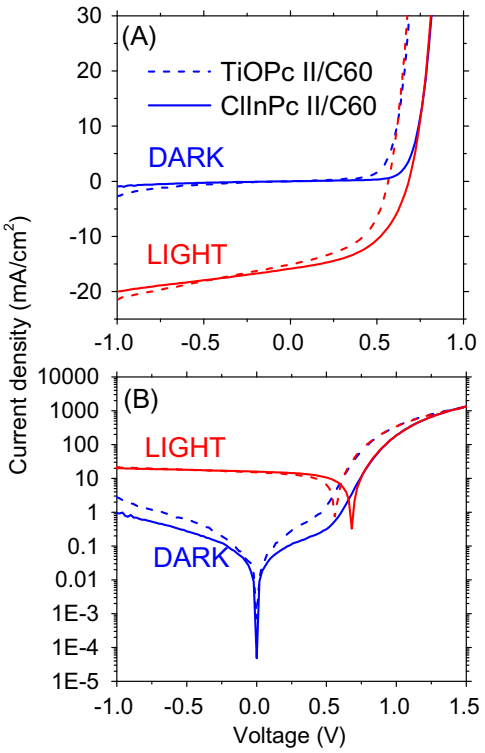

Fig. 8. The *J–V* characteristics for Phase II TiOPc (20 nm)/C_{60} (40 nm)/BCP (10 nm) (dashed lines) and for Phase II ClInPc (22 nm)/C_{60} (40 nm)/BCP (10 nm) (solid lines) in the dark (blue lines) and under illumination (red lines). (A) Linear *J–V*; (B): semi-log *J–V*. At 140 mW/cm^2 for the TiOPc/C_{60} solar cell, J_{SC} = 15.10 mA/cm^2; V_{OC} = 0.57 V; *FF* = 0.53; for the ClInPc/C_{60} solar cell, J_{SC} = 15.86 mA/cm^2; V_{OC} = 0.68 V; *FF* = 0.50. Device area = 0.019 cm^2. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.4. Incident photon and absorbed photon current efficiencies (IPCE and APCE)

Incident photon current efficiency (IPCE) and absorbed photon current efficiency (APCE) data for OPVs based on Phase I ClInPc films (20 nm), Phase I TiOPc films (18 nm), Phase II ClInPc films (22 nm) and Phase II TiOPc films (20 nm) are shown in Fig. 3 (middle and lower panels, respectively). As described elsewhere [15], IPCE data were obtained for OPVs with a device area of 0.125 cm^2, with a metal aperture used to eliminate "edge effects" in the photocurrent response [59]. APCE data was calculated using the IPCE data and the absorbance (transmittance) spectra for the solar cell under test, in a region near the OPV, but away from the opaque contacts.

For both the Phase I and Phase II Pc/C_{60} OPVs ClInPc-based devices outperform the TiOPc-based OPVs throughout the entire *Q*-band spectral region. The spectral shift in the *Q*-band is not as large for the Phase I → Phase II transition for ClInPc versus TiOPc (the absorption peak for Phase II ClInPc is at 820 nm, while the maximum absorbance seen for Phase II TiOPc is at 850 nm), however, the shapes of the IPCE curves are comparable for both Phase II Pc/C_{60} heterojunctions. For both device types some of the enhanced OPV response can be attributed to this enhanced *Q*-band spectral response and the corresponding integrated increase in IPCE at wavelengths above 750 nm, however, the texturing of the Pc/C_{60} heterojunction via the solvent-annealing process also accounts for a significant enhancement in J_{SC} and IPCE [15]. Normalizing IPCE by the actual absorbance (transmittance) for these Pc/C_{60} heterojunctions gives the APCE which reaches its maximum at ca. 620 nm, gradually decreases out to ca. 850–900 nm for both Phase I and Phase II heterojunctions, and then sharply declines in spectral regions where there is still appreciable optical density. APCE is a reflection of the efficiency of photocurrent production per absorbed photon, and might be expected to be constant at all wavelengths in the *Q*-band region for either the Phase I or Phase II Pc films.

The integration of the IPCE data in Fig. 3 over the spectral irradiance of the filtered light source provides estimates of J_{SC} close to the observed J_{SC} values seen in Figs. 7 and 8. Subsequently integrating the IPCE responses in Fig. 3 over the standard AM 1.5G spectrum, we predict a $J_{SC} = -5.7$ mA/cm^2 for OPVs based on Phase I (20 nm) ClInPc films, while we predict a $J_{SC} = -9.7$ mA/cm^2 for OPVs based on Phase II (22 nm) ClInPc films under such illumination conditions. Using the fill-factors and V_{OC} values obtained from Figs. 7 and 8 and Table 1, we predict an AM 1.5G power conversion efficiency for devices based on Phase I ClInPc films $\eta = 2.6\%$ (comparing with Phase I devices based on TiOPc films, $\eta = 1.3\%$), while for Phase II ClInPc films $\eta = 3.3\%$ (comparing with Phase I devices based on TiOPc films, $\eta = 3.0\%$). Examining the IPCE plots of Fig. 3 we conclude that a significant fraction of the increased efficiency of ClInPc/C_{60} versus TiOPc/C_{60} OPVs is due to enhanced V_{OC}, not predicted from the estimated values of E^{Pc}_{HOMO}–$E^{C_{60}}_{LUMO}$.

As seen in Table 1 V_{OC} in these OPVs has an inverse correlation with the observed reverse saturation current J_o. The Phase I ClInPc/C_{60} solar cell with the highest V_{OC} (0.8 V) has the lowest J_o (1.0×10^{-5} mA/cm^2), consistent with expectations from the Shockley equation [12]:

$$V_{OC} = \frac{n_o k_B T}{e} \ln\left(\frac{J_{ph}}{J_o} + 1\right)$$

where J_{ph} is the photocurrent, n_o is the ideality (quality) factor, k_B is the Boltzmann constant, T is the absolute temperature, and e is the charge of an electron. Several different studies have recently suggested that the strength of intermolecular interaction at the D/A interface plays a key role in determining the magnitude of J_o, and thus the maximum obtainable V_{OC} [8,12,31,85]. Kippelen and coworkers, exploring the temperature dependence of J_o, have proposed that J_o is controlled by the energy barrier to dark charge injection, which favors donor layers with high IPs, such as TiOPc, over donor layers such as pentacene or CuPc [12]. Ingannas and coworkers have suggested that, for polymer bulk heterojunction OPVs, the spectral position of a charge-transfer band, which depends mainly on E^{D}_{HOMO}–E^{A}_{LUMO}, can cause exponential changes in J_o, and thus changes in V_{OC}. The theoretical maximum V_{OC} can be obtained by eliminating all non-radiative pathways, resulting in maximum charge-carrier lifetime [31]. In the case of

ClInPc OPVs we see one of the largest values for V_{OC} seen for small molecule systems, and a value that is ca. 0.2 V below the maximum predicted built-in potential, limited by the size of $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$, because of these low values for J_o (see Table 1 for summary). Using these values of J_o, ideality factor n, J_{SC} (see Table 1), and the Shockley equation, the difference in V_{OC} between ClInPc/C_{60} and TiOPc/C_{60} solar cell are predicted to be 0.19 V for Phase I and 0.11 V for Phase II cells, respectively, consistent with the observed increase in values of V_{OC} for those solar cells.

4. Conclusions

ClInPc/C_{60} heterojunctions are an attractive materials combination as a small molecule OPV. With proper film processing to form the Phase II polymorph, the photoelectrical activity extends well into the near infrared, retaining a reasonably large V_{OC}. As a result of the large $E^{Pc}_{HOMO}-E^{C_{60}}_{LUMO}$ offsets, and the low J_o values for ClInPc/C_{60} heterojunctions, V_{OC} is larger, and the AM 1.5 efficiency of Phase I ClInPc/C_{60} OPVs is twice as that of Phase I TiOPc/C_{60} solar cell (2.6% versus 1.3%). For textured Phase II ClInPc/C_{60} heterojunctions improved efficiencies arise from both improved absorptivities in the near IR, and the increased Pc/C_{60} interfacial area. It is encouraging that IPCE values for our best ClInPc/C_{60} heterojunctions investigated to date maximize at ca. 0.45, suggesting that much greater improvements in efficiency will be achievable as texturing of the Pc/C_{60} interface allows feature sizes to approach $3 \times L_D$, providing that J_o can simultaneously be kept low (and V_{OC} high), by minimizing intermolecular interactions at the Pc/C_{60} interface leading to dark charge injection processes [13,86]. It is clear that if IPCE could be doubled to 0.9, through texturing of the Pc/C_{60} interface to create features comparable in size to $3 \times L_D$, keeping V_{OC} and FF constant, power conversion efficiencies near 6% might be achievable for single heterojunction ClInPc/C_{60} OPVs. Studies are underway to explore texturing approaches which would produce those kinds of efficiencies, and to create side chain modified forms of these tetravalent and trivalent metal Pcs which provide the advantages of near-IR absorbing phases, coupled with solution processability.

Density functional theory
Polarizable continuum model
Ionisation energy
Electron affinity
Cancellation of errors

ABSTRACT

Energy level engineering has become one of the central ideas in organic optoelectronics; particularly in the field of organic photovoltaics. However, this paradigm has led to significant ambiguities and errors in the literature. To investigate and address these issues we calculate solid state ionisation energies and electron affinities of a range of organic molecular semiconductors from density functional theory and the polarizable continuum model. We show that the differences between these results and measurements from (inverse) photoemission are on the same scale as the differences between the measured values reported by different groups. We compare our results with *in vacuo* calculations and estimates of the ionisation energies and electron affinities from the eigenvalues of the Kohn–Sham equations. *In vacuo* calculations overestimate the ionisation energies measured in the solid state, but underestimate solid state electron affinities. However, the Kohn–Sham eigenvalues predict the measured ionisation energies nearly as well as the full calculation. However, we show that the apparent accuracy of the Kohn–Sham eigenvalues is fortuitous and arises from the cancellation of the errors due to the use of Kohn–Sham molecular orbital energies as predictions of ionisation energies and electron affinities and the neglect of the polarizable solid state environment. These results stress the importance of descriptions based on molecular states rather than molecular orbitals when designing and characterising materials for organic electronic and optoelectronic devices.

1. Introduction

Devices based on the optoelectronic and electronic properties of organic molecules are rapidly coming to market. Yet despite the maturity of the experimental and technological aspects of the field [1] the theoretical understanding of the electronic and optoelectronic properties of organic molecular semiconductors is far from complete. The lack of predictive power in current models of such materials is a major hurdle in the goal of rationally designing new compounds for organic electronic and photonic applications. Thus, most improvements in organic electronic materials have been brought about by a combination of empirical rules and trial and error. This should be contrasted with the state-of-play in inorganic electronics, where the deep theoretical underpinnings of Fermi liquid theory and band structure [2] have lead to important design criteria from the very beginning of the field [3–5].

Empirical design rules in organic electronics are often based on the concept of engineering the energy levels of the frontier molecular orbitals, particularly the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) [6]. Establishing a firm theoretical basis for these empirical rules is somewhat problematic as molecular orbitals are an abstraction from molecular orbital theories [7]. Molecular orbitals are not well defined once electronic correlations are included, and it is well known that electronic correlations are

doi:10.1016/j.orgel.2010.11.025

extremely important in organic molecules [7]. In particular, it is important to stress that one cannot measure molecular orbital energies, even in principle. Rather, one can for example measure the oxidation or reduction potential, ionisation energy (IE), electron affinity (EA), optical absorption or emission spectra of molecules. Outside of the very simplest molecular orbital theories one does not expect any of these properties to equal any other; with the differences resulting from electronic correlations [7].

It is easy to understand, on a purely physical basis, why electronic correlations mean that the electron affinity is not the same as molecular orbital energies. When an electron is added to the system, one does not only have to account for the energy of that electron; that electron now interacts with all of the other electrons in the molecule. Further, this changes the details of the correlations between the other electrons. Similarly, when an electron is removed one must also account for all the interactions that are no longer there. These effects can be very large in organic molecules that form electronically active materials [8,9]. Further, the geometry of a molecule will typically relax once an electron is added/removed, further changing the energy [10].

In practice, further complications arise because the quantities of interest, such as the IE and EA, depend strongly on the environment surrounding the molecule [11]. This means that the electrochemical measurements of the oxidation or reduction potential in solution will typically differ from measurements of the solid state IE by, say, ultraviolet photoemission spectroscopy (UPS) and the solid state EA using inverse photoemission spectroscopy (IPES). Furthermore, these differences are typically on the scale of changes one wants to control to optimise material design [12], for example, the offset in the energy between a donor–acceptor pair required for so-called 'exciton dissociation' in bulk heterojunction solar cells. Therefore, any theoretical approach should include a description of the environment sufficient to capture these effects.

There have been a number of recent studies where density functional theory (DFT) was used to predict the IE or EA for broad ranges of the molecules used in organic electronics [13–16]. The choice of DFT is motivated because it is computationally much cheaper than more accurate methods, yet still provides reasonable accuracy. The cost of the computational method is important if we are to eventually screen large numbers of molecules for an application. We have therefore limited our approach below to low cost computational methods. Both Djurovich et al. [13] and Nayak et al. [14,15] treated density functional theory as a semi-quantitative approach and, by studying a large selection of molecules, demonstrated correlations between their calculations and experimental measurements. In principle such correlations, once established, could be used to rescale calculated data to make quantitative predictions, although this would be rather unsatisfactory unless one has a clear understanding of when such a rescaling is likely to work and when it should be expected to fail. Alternatively, one could also ask how well the absolute values predicted by DFT compare with experiment. This has clear advantages, but the inherent limitations of the approximations in currently available functionals may mean that accurate predictions are not possible.

The accurate calculation of IEs and EAs from molecular orbital energies is a particular problem for DFT. This long-standing problem is closely related to the 'band gap problem' in solid state physics [17]. To understand the root of this problem a brief discussion of the foundations of DFT [18] is required. The twin foundations of DFT are the Hohenberg–Kohn theorem, which proves that the ground state energy of a molecule or solid can be expressed as a functional of the electron density, and the Kohn–Sham scheme, which provides a practical framework to calculate the electron density and hence the total energy. To do this Kohn and Sham introduced a set of differential equations, know as the Kohn–Sham equations, that have a strong mathematical resemblance to the approximate form of the Schrödinger equation obtained from the Hartree–Fock (molecular orbital) approximation [18].

It is therefore tempting to treat the solutions of the Kohn–Sham equations as molecular orbitals (in molecular systems) or bands (in periodic structures). However, there is no theoretical justification for this interpretation of the Kohn–Sham equations [19]. Nevertheless, this interpretation is frequently employed and has been used to, at least semi-quantitatively, describe materials in a broad range of contexts [16,18]. However, this additional approximation (on top of those already inherent in approximating the exchange-correlation functional) significantly reduces the accuracy of DFT. A classic example is the band structure of Si. The eigenvalues of the Kohn–Sham equations do reproduce, qualitatively, what is known experimentally about the band structure of Si, such as the indirect gap and the locations of the valence band maxima and conduction band minima; but, the band gap calculated is $\sim$50% larger than that measured experimentally [17]. Similar problems are found in calculating the IEs and EAs and optical gaps in molecular systems [18,20].

An important result about the density functional formalism is Janak's theorem [21], which proves that the exact functional could be used to calculate the Lagrange multiplier associated with conservation of particle number. In a solid this corresponds to the chemical potential and in a molecule it is the IE, [22,23]. This suggests that the Kohn–Sham HOMO energy should predict the IE, although this is, of course, approximate for approximate functionals. However, there is no theoretical basis for this for other orbitals, and in particular the Kohn–Sham LUMO is not required to correspond to the EA even for the exact functional. It is well known that, in practice, electron affinities estimated from Kohn–Sham LUMO eigenvalues are less accurate than the corresponding ionisation energies estimated from the Kohn–Sham HOMO energies [16,17,24]. Nevertheless, this approach has found widespread application in the organic electronics literature [13,16].

In this paper we consider eleven molecules with application in organic electronics (shown in Fig. 1). We calculate their IE and EA by three different DFT-based methods: (i) from the Kohn–Sham eigenvalues; (ii) directly from the ground state energies of the relevant charge states and (iii) by method (ii), but including the polarizable

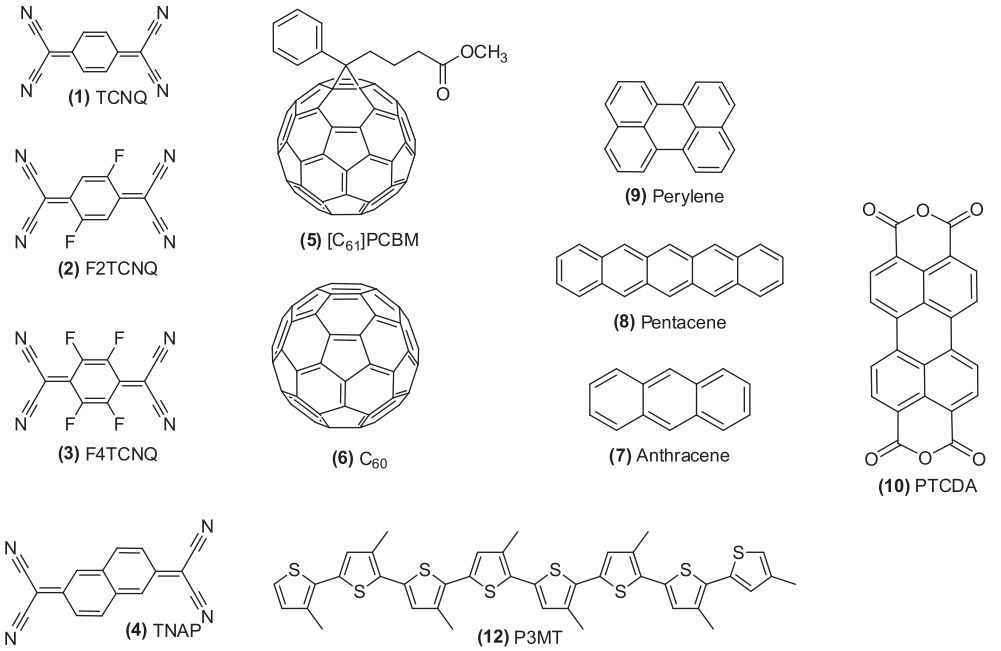

Fig. 1. The molecules studied in this paper: (1) tetracyanoquinodimethane (TCNQ); (2) difluoro-tetracyanoquinodimethane (F2TNCQ); (3) tetrafluoro-tetracyanoquinodimethane (F4TCNQ); (4) tetracyanonaphthoquinodimethane (TNAP); (5) [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM); (6) Buckminsterfullerene (C_{60}); (7) anthracene; (8) pentacene; (9) perylene (or dibenzanthracene); (10) perylenetetracarboxylic acid dianhydride (PTCDA); (11) poly-(3-methylthiophene) (P3MT), which is a model compound for poly(3-n-hexylthiophene) (P3HT).

environment of the solid state via the polarizable continuum model (PCM). Method (iii) reproduces both the trends and absolute values found in experiments accurately. However, surprisingly, method (i) performs almost as well as method (iii) and significantly outperforms method (ii). We show that this is because of a cancellation of errors, specifically those due to the approximation that molecular orbital energies approximate ionisation energies and electron affinities and the neglect of the environment.

2. Methods

All density functional calculations were performed in the GAMESS-US software package [25] with the B3LYP hybrid functional [26,27] in the 6−31+G basis set. This, relatively small, basis set was chosen for compatibility with future studies of larger numbers of molecules and larger molecules. Diffuse functions were used to better represent the loosely held extra charges in anions [28,29]. Extensive benchmarking on C_{60} showed that, despite its small size, this basis set gave good agreement with larger basis sets and with literature calculated and measured values of the IE and EA [30–34]. The geometries of the molecules were optimised in DFT so as to keep the procedure independent of experimental data.

The PCM [35] assumes that a cavity made of a continuous solvent surrounds each 'solute' molecule. In the case of a single component amorphous molecular solid, which we consider here, the 'solute' and 'solvent' molecules are the same species. However, this does not increase the complexity of the problem as the solvent is simply described by its dielectric constant, ε, and radius, R. The charges on the solute molecule inside the cavity interact with this dielectric medium, causing it to polarize. This induced polarization in the solvent medium then interacts back on the wavefunction of the solute. The energy of the resultant interaction is minimized self consistently.

The geometry of the molecule and ion were optimised at the B3LYP/6−31+G level *in vacuo*. ChemDraw 3D Ultra version 12.0 was used to calculated the Connolly molecular area (CMA) of the neutral molecule. The CMA is determined by the contact surface created when a spherical probe (with a standard radius of 1.4 Å) representing the solvent molecule is rolled over the molecular model [36]. This area defines a sphere of the same surface area. The radius of this sphere, $R = \sqrt{A/4\pi}$, was used to define the 'radius' of the solvent molecule.

The Clausius–Mossotti equation [2] can be solved for ε, which yields

$$\varepsilon = \left(1 + \frac{8\pi\bar{\alpha}}{3v}\right)\left(1 - \frac{4\pi\bar{\alpha}}{3v}\right)^{-1}, \quad (1)$$

where v is volume occupied by a single molecule, which we take as the Connolly molecular volume (CMV), the volume of a sphere with an area equal to the CMA, $\bar{\alpha}$ is the isotropic component of the molecular polarizability, $\bar{\alpha} = \frac{1}{3}\sum_i \alpha_{ii}$, and the α_{ii} are the diagonal matrix elements of the first order polarizability tensor. The polarizability was calculated for each molecule from DFT. A sequence of fields were applied to the molecule and the polarizabilities extracted [37]. The step size for the applied field strength was 0.001 in atomic units. Four layers of points

were chosen on successive fused van der Waals spheres. The sum of fitted atomic charges were constrained to reproduce the total molecular charge.

3. Results and discussion

3.1. Kohn–Sham eigenvalues

The Kohn–Sham HOMO energies ($HOMO_{KS}$) and the ionisation energies measured by ultraviolet photoemission spectroscopy (I_{UPS}) are listed in Table 1 and compared in Fig. 2. A linear regression analysis (to the form $I_{UPS} = c - m \times HOMO_{KS}$) resulted in a slope $m = 0.91 \pm 0.10$ and intercept $c = 0.5 \pm 0.7$ with a linear least squares correlation co-efficient $r^2 = 0.89$, which show that this approach correctly predicts the trends observed across this series of molecules. Note that in Fig. 2 (and, indeed, Figs. 3–7) we do not show the line of best fit, rather the line indicates perfect agreement between the prediction and experiment. The root mean squared deviation (RMSD) of $HOMO_{KS}$ from the I_{UPS} was 0.4 eV or equivalently the mean absolute deviation (MAD) was 4.1%. Considering the extremely low computational cost of these calculations this is rather encouraging accuracy, which has been noted previously on the basis of similar calculations [13,16].

In Fig. 3 a similar comparison is made for the energies of the lowest unoccupied Kohn–Sham molecular orbital ($LUMO_{KS}$) and the electron affinity measured by inverse photoemission spectroscopy (A_{IPES}). The data are listed in Table 2. A linear regression results in a slope $m = 0.80 \pm 0.09$, intercept $c = 0.6 \pm 0.4$ and $r^2 = 0.89$. The correlation is clearly not as strong as that between the $HOMO_{KS}$ and I_{UPS}. Further, the slope is further from unity, the intercept is further from the origin, and the RMSD (0.50 eV) and the MAD (13%) are both significantly larger than for the data shown in Fig. 2. Thus, it is clear that the calculations of the $LUMO_{KS}$ predict A_{IPES} less accurately than calculations of $HOMO_{KS}$ predict the I_{UPS}. While the qualitative trends are reasonable, the quantitative accuracy is not sufficient to describe the subtle changes needed to design molecules for organic electronic applications. This is, of course, consistent with what one expects from the foundations of DFT [17,21] and several decades of DFT literature [16,17,20]. The level of accuracy of prediction of electron affinities provided by the Kohn–Sham energies may be sufficient for some purposes, but a more accurate method would be a significant advantage. In particular, the RMSD, 0.50 eV, is rather large considering the scale on which one would like to tune interactions to design better materials for organic electronic and optoelectronic applications.

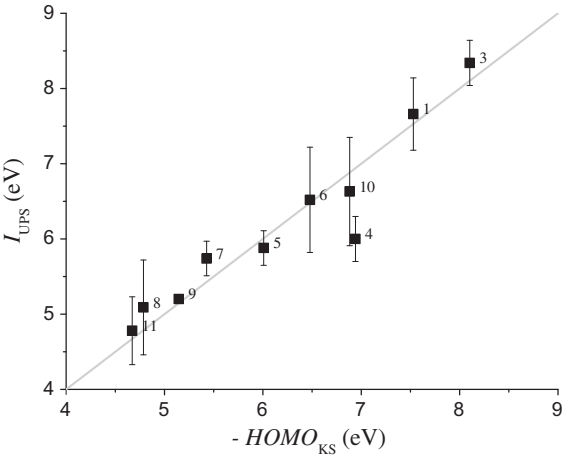

Fig. 2. Comparison of the ionisation energy measured by UPS, I_{UPS}, (see Section 3.5 and Table 1 for references and error analysis) with the Kohn–Sham HOMO, $HOMO_{KS}$, for the compounds shown in Fig. 1 where the experimental data exists in the literature. Surprisingly good agreement is found between theory and experiment. The line is $-HOMO_{KS} = I_{UPS}$.

Table 1
Comparison of the literature values of ionisation energies measured by ultraviolet photoemission spectroscopy (UPS) to the calculated energies of the Kohn–Sham HOMOs ($HOMO_{KS}$), gas phase and solid state vertical (I_g^v, I_s^v) and adiabatic (I_g^a, I_s^a) ionisation energies. All values in eV. Quoted errors on the experimental data indicate two standard deviations in the range of the literature values. The absence of errors indicates that we were only able to identify one reported experimental value. We were unable to identify any reports of the ionization energy for F2TCNQ.

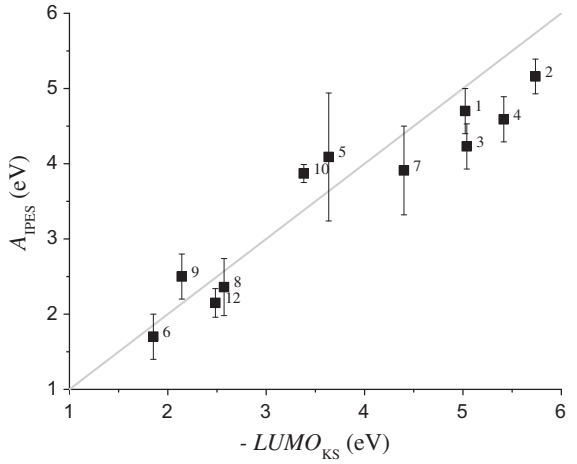

Fig. 3. Comparison of electron affinity measured by IPES, A_{IPES}, (see Section 3.5 and Table 2 for references and error analysis) with Kohn–Sham LUMO ($LUMO_{KS}$) for the compounds shown in Fig. 1 where the experimental data exists in the literature. The agreement with experiment is not as strong as that seen in Fig. 2, but qualitative trends are reproduced, as is indicated by a linear regression analysis, $r^2 = 0.89$ (not shown). The line is $-LUMO_{KS} = A_{IPES}$.

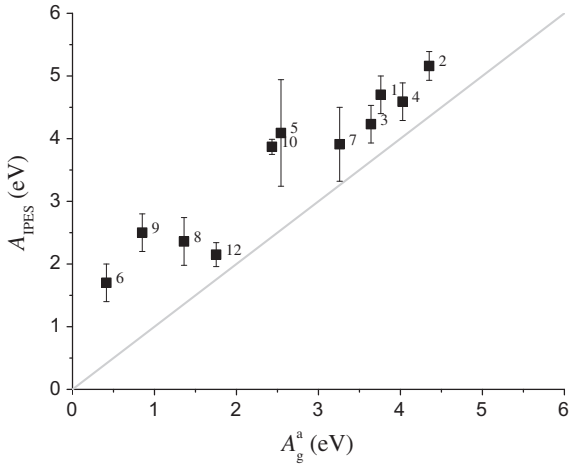

Fig. 5. Comparison of experimental electron affinities measured by IPES, A_{IPES}, (see Section 3.5 and Table 2 for references and error analysis) and calculated *in vacuo* electron affinities, A^a_g. A^a_g consistently underestimates A_{IPES}, as one would expect from Eq. 2b, as the polarizable solid state environment, which stabilises the anion, is not accounted for in the calculation. The line is $A^a_g = A_{IPES}$.

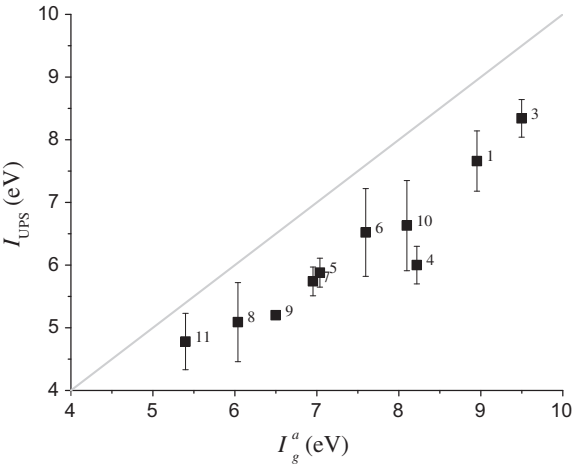

Fig. 4. Comparison of experimental ionisation energies measured by UPS, I_{UPS}, (see Section 3.5 and Table 1 for references and error analysis) and calculated *in vacuo* ionisation energies, I^a_g. I^a_g consistently overestimates I_{UPS}, as one would expect from Eq. 2a, as the polarizable solid state environment, which stabilises the cation, is not accounted for in the calculation. The line is $I^a_g = I_{UPS}$.

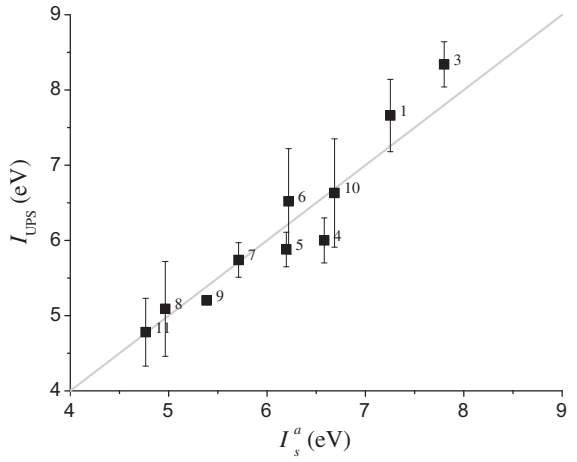

Fig. 6. Comparison of experimental ionisation energies measured by UPS, I_{UPS}, (see Section 3.5 and Table 1 for references and error analysis) and calculated solid state ionisation energies, I^a_s. I^a_s provides a consistently accurate prediction of I_{UPS}. The line is $I^a_s = I_{UPS}$.

3.2. Direct calculation of the ionisation energy and electron affinity

Although, density functional formalism does not imply any correspondence between the Kohn–Sham eigenvalues and, say, the electron affinity, the ionisation energy, I, and the electron affinity, A, are defined in terms of the differences between the *ground state* energies of different charge states, specifically,

$$I \equiv E_0(+1) - E_0(0) \tag{2a}$$

$$A \equiv E_0(0) - E_0(-1), \tag{2b}$$

where $E_0(q)$ is the ground state energy of the molecule with charge q. Ground state energies are what we do have general expectations of calculating in DFT and what DFT gives most accurate answers for. Therefore, a natural way to improve the accuracy of the DFT calculation is to directly calculate $E_0(q)$ for the relevant charge states. This approach has recently been applied to organic molecules that form strongly correlated molecular metals, Mott insulators and superconductors [8,9]. One subtlety in this calculation is whether one considers the vertical ionisation energy, I^v_g (where the molecular geometry is kept fixed in the neutral ground state geometry irrespective of the charge on the molecule) or the adiabatic ionisation energy, I^a_g (where the geometry is relaxed in the ionic state). Similarly, one

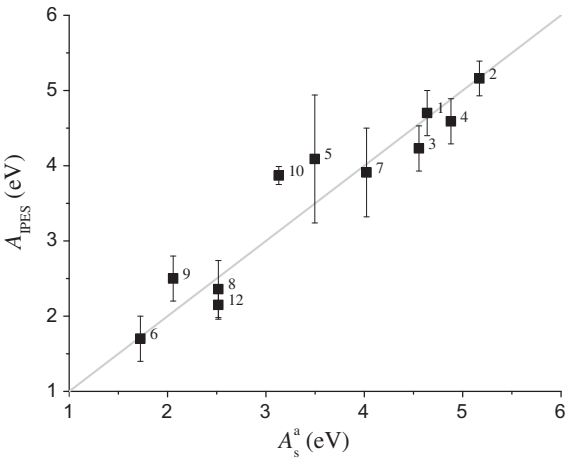

Fig. 7. Comparison of experimental electron affinities measured by IPES, A_{IPES}, (see Section 3.5 and Table 2 for references and error analysis) and calculated solid state electron affinities, A_s^a. For the most part A_s^a provides an accurate prediction of A_{IPES}: outliers are discussed in Section 3.3. The line is $A_s^a = A_{IPES}$.

can calculate either the vertical electron affinity, A_g^v, or the adiabatic electron affinity, A_g^a. However, as can be seen in Tables 1 and 2, the differences between the vertical and adiabatic energies are relatively small compared to the other uncertainties in the problem. Therefore we will focus primarily of the adiabatic energies.

We carried out direct calculations of the IE and EA for the molecules shown in Fig. 1. The calculated ionisation energies and electron affinities are listed in Tables 1 and 2, respectively. Comparisons with the experimentally measured ionisation energies and electron affinities are presented Figs. 4 and 5, respectively. What is immediately evident from these figures is that the calculated EA and IE give significantly worse predictions of experimental results than a naive interpretation of the Kohn–Sham eigenvalues. For the IE there is a MAD ≈20% while for the EA this increases to >30%. These correspond to RMSDs in excess of 1 eV, meaning the direct comparison of the calculated IE/EA is too inaccurate to be of any real value. However, it is interesting to note that the correlation between the calculated and measured IEs/EAs is significant: a linear regression gives $r^2 > 0.89$ ($m = 0.84 \pm 0.10$, $c = 0.0 \pm 0.7$) for the IE and $r^2 > 0.89$ ($m = 0.83 \pm 0.09$), $c = 1.4 \pm 0.3$) for the EA, showing that this method also captures the overall trends seen experimentally.

It is important to stress that the direct calculation of the IE/EA is known from the foundations of density functional theory to be an improvement over the values taken from the Kohn–Sham eigenvalues. Therefore, the finding that the Kohn–Sham eigenvalues are much closer to the experimentally measured values than the direct calculation suggests that this agreement is fortuitous and presumably results from some uncontrolled cancellation of errors.

The direct calculations overestimate the IE and underestimate EA. Note that all of the calculations reported above are for molecules *in vacuo*. However, the measurements were performed in the solid state. The solid provides a polarizable environment for the molecule, which will stabilise the ionic species, lowering the IE and increasing the EA (cf. Eq. (2)). Thus, one expects the *in vacuo* IE to overestimate the solid state IE and the *in vacuo* EA to underestimate the solid state EA. Thus, at least qualitatively, the direct calculation of the IE and EA is consistent with expectations, whereas the values from the Kohn–Sham eigenvalues are not! In order to address the complication of the solid state environment we repeated the calculations above with the environment included via the PCM.

3.3. Solvation effects in the solid state

The PCM requires the knowledge of the dielectric constant, ε, and the effective radius of the molecule. In order to keep our methodology viable as an approach to screen large numbers of candidate molecules we have calculated ε from first principles even where experimental values are available. In Table 3 we report the calculated molecular polarizabilites, the CMA, the CMV, the permittivities calculated from Eq. 1 and, where available, the measured permittivities, ε_{exp}, for each of the molecules in Fig. 1. For all

Table 2
Comparison of the literature values of electron affinities experimentally measured by inverse photoemission spectroscopy (IPES) to the calculated Kohn–Sham energies ($LUMO_{KS}$), gas phase and solid state vertical (A_g^v, A_s^v) and adiabatic (A_g^a, A_s^a) electron affinities. All values in eV. Quoted errors on the experimental data indicate two standard deviations in the range of the literature values. The absence of errors indicates that we were only able to identify one reported experimental value.

bar one of the molecules for which there are measurements of the permittivity we find that the calculation gives excellent agreement with experiment. The exception is PCBM, where the calculated permittivity is only about 70% the literature experimental value. It is interesting to note that the calculation predicts rather different values of ε for PCBM and C_{60}, whereas experimentally the two molecules have similar permittivities. This may indicate that the 'tail' of the molecule leads to an overestimation of CMV – recall that the CMV is defined by a sphere with surface area defined by CMA.

It is natural to extend the notation of IEs and EAs to the solid state. Thus, we define the solid state ionisation energy as

$$I_s \equiv E_0^{(s)}(+1) - E_0^{(s)}(0) \tag{3a}$$

and the solid state electron affinity as

$$A_s \equiv E_0^{(s)}(0) - E_0^{(s)}(-1), \tag{3b}$$

where $E_0^{(s)}(q)$ is the ground state energy of the molecule with charge q *in the solid state environment*. We report the vertical and adiabatic IEs and EAs calculated from Eq. 3 in the PCM in Tables 1 and 2. In Fig. 6 we compare the calculated solid-state adiabatic IE, I_s^a, to I_{UPS} and in Fig. 7 we compare the calculated solid-state adiabatic EA, A_s^a, to A_{IPES}. Both data sets show excellent agreement between theory and experiment. The PCM solid state correction to the IE produces a RMSD between the calculated solid state value and that from the UPS measurements of only 0.32 eV, corresponding to a 3.9% MAD. This result is a significant improvement over the gas phase calculations and yields predictions that are of a similar accuracy to the $HOMO_{KS}$ approximation. However, whereas the $LUMO_{KS}$ does not provide a good estimate of A_{IPES}, cf. Fig. 3, A_s^a does. The PCM reduces the RMSD between A_{IPES} and A_s^a to 0.36 eV, which corresponds to a MAD of 8.6%.

Thus we see that by calculating the IE/EA directly from DFT with the solid state environment included via the PCM one is able to give a qualitatively accurate account of the experiments. The errors in this method are now approximately the same as the experiment uncertainty, therefore it is not possible to use comparison with experiments to judge the efficacy of further refinements (cf. Section 3.5).

3.4. Charge transport

The type of calculation reported above can straightforwardly be extended to determine a number of additional properties that are important for the design of organic photovoltaic devices.

The so-called 'transport gap', E_t, is defined as the difference between the ionisation energy and electron affinity in the solid state and represents the minimum energy needed to completely separate an electron and hole in the solid,

$$E_t = I_s - A_s. \tag{4}$$

Physically, the transport gap represents the energy difference between the ground state of the system and the state where two charges have been taken to infinity. Thus, this number can give some insights into the energetics of charge transfer in monocomponent systems.

Table 4 lists the experimental transport gap E_t^{exp} derived from the difference between I_{UPS} and A_{IPES} energies (Eq. 4). The transport gap was also calculated from the Kohn–Sham orbital energies, $E_t^{KS} \equiv LUMO_{KS} - HOMO_{KS}$, the gas phase ionic energies, $E_t^g \equiv I_g^a - A_g^a$, and the solid state IE and EA, $E_t^s \equiv I_s^a - A_s^a$. Error analyses of the transport gaps follow as one would expect given the discussion above and provide no new information.

In a donor–acceptor system an important quantity is

$$V = I_s^D - A_s^A, \tag{5}$$

where I_s^D is the solid state ionisation energy of the donor and A_s^A is the solid state electron affinity of the acceptor. V is the energy require to take two charges too infinity and is therefore strongly correlated with the maximum open circuit voltage achievable in this type of organic solar cell [88].

Understanding the energetics of charge transport is a key first step to understand the performance of organic photovoltaic devices. However, kinetics are probably at least as important [89]. Thus, it is also important to understand the reorganisation energy, which includes an internal part, λ_i – the difference between adiabatic and vertical IE/EA, and terms arising from the polarizability of the crystalline environment. In Marcus–Hush theory [90] the greatest charge transfer rate is achieved when the total reorganisation energy is equal and opposite to the energy difference between the initial and final states.

In molecular solids ionic states are characterized by strong coupling of the localized charge to the polarizable environment. The energetics of this coupling are characterized by the polarization energies,

$$P_+ = I_g^a - I_s^a \tag{6a}$$

$$P_- = A_s^a - A_g^a. \tag{6b}$$

Therefore, understanding the trends in the polarisation energies across large ranges of molecules is a key step towards the ability to design new materials.

The polarization energies calculated from Eq. (6) and the internal reorganisation energies are also reported in Table 4. Experimental data for negative polarization energies are lacking and the reported values for the positive polarization energies can vary widely. Therefore, P_+ and P_- are usually assumed equal, however the results in Table 4 show that this assumption is not generally valid. A similar conclusion has previously been argued for on experimental grounds [91].

In order to fully examine the charge transfer rates one also needs to consider the relaxation rates and energetics of the relevant transition states. These will be discussed in a forthcoming publication. Nevertheless, Marcus–Hush theory gives a clear design principle for organic photovoltaics: matching the reorganisation energy to energy difference between ionic and neutral configurations will allow one to optimise for the desired reaction pathways, leading to more efficient photovoltaic devices. The calculations above, when extended to all of the additional transition states, will provide a computationally cheap method to explore these effects.

3.5. Experimental uncertainties

Given that the RMSD deviations between experiment and the IEs/EAs calculated from the PCM + DFT approach the of order of the uncertainty in experiments, a brief discussion of those uncertainties is required.

Photoemission spectroscopy is very sensitive to surface conditions. In the analysis of photoemission spectra, the threshold energy is believed to provide a better characterisation of the ionisation energy than the peak [38,92]. This difference adds uncertainty to the reported values found in the literature which can vary by as much as 1 eV [38] – three times the RMSD between our calculations and the experimental values!

There are also great difficulties in making IPES measurements on organic materials [92,93]. Again the onset is believed to represent the solid state electron affinities [92]. But this poorly defined IPES threshold value further adds to the variation between different reported experimental EAs.

Finally, note that experimental issues, such as sample thickness, sample charging and substrate workfunction, have profound effects on the measured polarization energy, and can vary the experimental value by nearly 1 eV [94–96]. Therefore, to guard against the temptation to cherry pick the literature, we carried out a systematic literature search using ISI Web of Science. In Tables 1 and 2 we report the mean values of the standard deviations in this literature data. Where only one measurement has been reported in the literature we have estimated an error of ±0.3 eV in Figs. 2–7, which is typical of the errors found in the literature data. Similar or larger errors have been estimated by previous authors [12,13]. Note that, for the solvated calculations the RMSD from experiment compares favourably with the deviation between different experiments.

Table 4
Calculated and experimental transport gaps and polarization energies. Vertical values were calculated using the geometry of the neutral molecule whereas the adiabatic values were derived from optimised geometry for the ionic species. E_t^{exp} are the experimental values from the literature. E_t^{KS}, E_t^g and E_t^s represent the transport gaps calculated from the $HOMO_{KS} - LUMO_{KS}$ gap, gas phase energies and PCM, respectively. P_+ and P_- correspond to the polarization energies calculated for the relevant ionic species. Here, $\lambda_i^{s,I} \equiv I_s^v - I_s^a$ is the internal reorganisation in the solid state following ionisation. Similarly, $\lambda_i^{s,A} \equiv A_s^v - A_s^a$.

4. Conclusions

We have seen that the Kohn–Sham orbitals provide a qualitative and even semi-quantitative prediction of the IE and EA in organic molecular semiconductors. However, the Kohn–Sham HOMO predicts the IE far more accurately than the Kohn–Sham LUMO predicts the EA.

The calculated *in vacuo* IE and EA do not accurately predict the solid state IE and EA. Qualitative trends *are* reproduced, but the IE is consistently overestimated and the EA is consistently underestimated with respect to their measured values. As the polarizable solid state environment will stabilise the ionic species and the measurements are made in the solid state, this difference is expected (cf. Eqs. 3 and 6).

Including the effects of the solid state environment via the PCM gives an accuracy comparable to experiment: the RMSD between the calculated and measured IEs and EAs is comparable to or smaller than the deviation between different measurements in the literature. Importantly, this agreement is found for both the IEs and the EAs. The agreement between theory and experiment for the EAs is significantly better for the PCM approach than for simply considering Kohn–Sham LUMOs.

We are now in a position to understand why the Kohn–Sham eigenvalues gave fortuitously good agreement with experiment. Beyond the approximations in the B3LYP functional and the finite basis set used, there are two sources of error in the Kohn–Sham calculation: (i) the approximation that the Kohn–Sham eigenvalues represent the IE and EA and (ii) the neglect of the polarizable solid state environment. When the former approximation is not made, the agreement with experiment is worsened, but in the direction we would expect from a simple analysis of the energetics of ions. Therefore, we conclude that these two errors approximately cancel and that this leads to the apparent success of the Kohn–Sham approach. We stress the common maxim that one cannot rely on approaches that give the right answer for the wrong reason, as one does not know when these approaches might fail dramatically. Therefore, a proper calculation of the ionic energet-

ics, including the polarizable medium, is required to understand charge transfer processes in organic electronics.

The relatively small variation in $P_+ + P_-$ explains the correlation between calculated *in vacuo* IE and EA and the measured solid state IE and EA. However, the variation in $P_+ + P_-$ is large enough to significantly reduce the correlation between *in vacuo* results and experiment relative to the correlation between the PCM calculations and experiment.

Nevertheless excellent accuracy was achieved at the relatively cheap $6-31+G/B3LYP$ level of theory. The accuracy is comparable to that which can be achieved experimentally by UPS or IPES and the theoretical values can be obtained far more cheaply. This suggests that this method will have an important role to play in screening target molecules in the design of new materials for organic electronic and photonic applications.

Most importantly, these results stress the importance of descriptions based on molecular states rather than molecular orbitals when designing and characterising materials of organic electronic and optoelectronic devices.

Inkjet
Cyanine dye
Open-circuit voltage

ABSTRACT

In this study, a kind of disposable and miniaturized organic photodiodes in the visible has been developed based on the J-type aggregated cyanine dyes films by the drop-on-demand inkjet method. Wavelength sensitivity has been found by measuring the open-circuit voltage (Voc) of the organic photodiodes under the excitation of laser pulses at various wavelengths and high spectral resolution around the absorption peak of each cyanine dye J-aggregates can be obtained, where a sharp decrease on the Voc and a Voc in reverse direction are observed. The mechanism responsible for the sharp decrease and reverse Voc are discussed and the feasibility of using the laser output from a solid-state dye laser waveguide as the excitation source for the organic photodiodes which may be possibly integrated together onto the flow-cytometry chips in the future are also demonstrated.

1. Introduction

During the past several years, inkjet printing has generated extensive research interests as a direct patterning technique for the cost-effective fabrication of organic optoelectronic devices such as organic light-emitting diodes (OLEDs) [1–4], organic field-effect transistors (OFETs) [5–7], and organic solar cells (OSCs) [8–10], and so on [11,12]. As compared with other film deposition techniques of organic chemicals, inkjet method is highly preferable due to the concerns on versatility, miniaturization, and high precision patterning. And also, inkjet printing such as the drop-on-demand has the advantages such as being fast and simple with high throughput. The consumption of materials can be reduced to an extremely low level of picoliter of each droplet in volume, providing a low cost, mask free, and non-contact printing approach [1]. Based on this knowledge, it is suggested that the drop-on-demand inkjet printing may be one of the most suitable technical pathway for the fabrication of some optical electrical elements on the disposable integrated flow-cytometry chips, which has been proposed in our previous studies [13–15]. So, as one of the latest application of inkjet method in our group, in this work, organic photodiodes in the visible region have been developed by the inkjet printing technique, which we suggest, may monitor the laser output from the tunable solid-state dye laser waveguides or the laser induced fluorescence from the micro fluid channel on the integrated cytometry chips [15,16]. And it should also be noted that for the fabrication of this kind of disposable and miniaturized organic photodiodes on the flow-cytometry chips, other techniques such as spin-coating is not applicable because of the complicated structures of the flow-cytometry chips, risk of contamination, and the infeasibility to integrate photodiodes in various spectral region on one single chip.

As considering the suitable materials for the photodiodes printed by inkjet method, cyanine dyes dissolved in aqueous solutions are suggested to be the best candidates

because of their self-aggregation tendency due to the hydrophobic nature of the molecular structures, which have been investigated widely in recent years as wideband semiconductors, information recording materials, nonlinear optical materials, and fluorescence indicator in biological researches [17–20]. Depending on the angle between the transition dipoles and molecular axis of the aggregate, the aggregates of cyanine dyes can be classified into J- or H-type aggregates, with an intense red-shifted or broad hypsochemically shifted absorption spectrum, respectively, as compared with their monomer counterparts [21,22]. Recently, J-aggregate cyanine dye films have been fabricated by inkjet method and the influence on J-aggregate formation by inkjet parameters has been investigated [23]. Herein we report, as a new attempt to the best of our knowledge, the disposable and miniaturized organic photodiodes based on the J-type aggregation of cyanine dye films printed by inkjet method, which are wavelength sensitive because of the J-aggregate formation of each cyanine dye.

2. Experimental details

To make photodiodes in the visible region, three kinds of cyanine dyes NK-3989, NK-1952, and NK-2203, which correspond to the blue, green and red spectral regions, respectively, are dissolved into the solution of a conductive polymer, poly(3,4-ethylenedioxythiophene) poly(styrene sulfonate) (PEDOT:PSS, Sigma–Aldrich, 2.8 wt% in H_2O solution) respectively, and applied to the drop-on-demand piezoelectric inkjet system as the ink for printing. Details on the inkjet printing process of J-aggregated cyanine dye/PEDOT:PSS films can be found elsewhere [23]. The cyanine dyes, NK-3989, NK-1952, and NK-2203 (Hayashibara Biochemical Laboratories) and PEDOT:PSS are used as received without further purification. First, 17.5 mg of cyanine dye is mixed with 0.175 wt% of PEDOT:PSS and DI water and the dye/polymer ratio is kept at 10:1 by weight. After ultrasonic treatment to prompt the totally dissolution of the cyanine dye, the viscous cyanine dye/PEDOT:PSS solutions are filtered (Whatman filter GF/B 1.0 μm).

A piezoelectric inkjet system (Microjet IJK-200s) is adopted in this work. The indium tin oxide (ITO) coated polyethylene terephthalate (PET) film is used as the substrate for printing, which has been etched by 10% of aqua regia (120 s) with masks to obtain designed patterns. UV exposure (172 nm, 10 mW/cm^2, Ushio UER20-172) on the ITO substrate before the inkjet printing is applied to make it hydrophilic and reduce the contact angle of cyanine dye/PEDOT:PSS solutions on ITO substrates. The nozzle size of the piezoelectric inkjet is 70 μm and the pulse voltage and pulse duration is 75 V and 67 μs, respectively. Large area patterned films can be made by delicately overlapping neighboring spots. In order to avoid the environmental turbulence interference on the droplet, the distance between the jet nozzle and the ITO substrate is kept to less than 1 mm. The absorption spectra of the printed films are measured with a UV–vis-NIR absorption spectrometer (Shimadzu UV-160A).

A thin Al layer is vapor deposited on the top of cyanine dye films after the inkjet printing (ULAC, 6×10^{-3} Pa). The resistance between the cathode and anode is typically ~1.6 MΩ. A tunable pico-second laser with the pulse duration of 36 ps and maximum output energy of 130 μJ is used as the excitation source and the output wavelength is monitored by a multi-channel spectroscope (Ocean Optics HR4000). The Voc between the cathode and anode of inkjet printed photodiodes is measured by oscilloscope (Tetronix, TDS 3032) with 10^3 times of amplification on the signal. To verify the feasibility of using the organic photodiodes as the detectors for the solid-state dye laser media, which have been investigated widespread in recent years [24–26], the laser output from a Rhodamine 6G (R6G) doped Poly(methyl methacrylate) (PMMA) film is also used as the excitation source for the organic photodiodes and the pump source for the solid-state dye laser film is a passively-Q-switched and frequency-doubled Nd:YAG laser (0.5 ns, 532 nm) with a beam expander and cylindrical lens to focus the pump beam onto the sample surface with the size of 15 × 0.3 mm. The pump energy and repetition rate was 30 μJ/pulse and 500 Hz, respectively. Details on the fabrication process of the R6G doped PMMA film can be found elsewhere [24,27,28].

3. Results and discussion

The typical size of the inkjet printed cyanine/PEDOT:PSS spots on the ITO substrates is ~300 μm in diameter and 20 nm in average thickness, as shown in Fig. 1(a). Large area films with desired patterns are made by delicately overlapping neighboring spots, although just one single spot is also suggested to have sufficient absorption as localized monitoring in the practical applications. The architecture of the photodiodes is shown in Fig. 1(b), with NK-1952 as an example. With the ITO as the anode, while the thin Al layer deposited on the top of NK-1952/PEDOT:PSS films as the cathode, the photodiode behaves as a bulk heterojunction [29]. The lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) energy levels of each chemical and workfunctions of the electrodes are summarized in Fig. 1(c) [30–32].

The absorption spectra of the three kinds cyanine dye/PEDOT:PSS films printed by inkjet method are shown in Fig. 2, in which the red-shifted, sharp and narrow absorption peaks at ~466, 542 and 594 nm can be observed from NK-3989, NK-1952 and NK-2203, respectively, indicating the J-aggregate formation of each dye, as compared with the broad absorption bands of their monomers, for instance, the 502 nm absorption band of NK-1952. So, wavelength resolution can be expected around the peak wavelengths.

With the photodiodes made through above process, the Voc between anode and cathode under various pumping wavelength is measured. As shown in Fig. 3, with the 0.04 ns pulse duration and from 430 to 670 nm tunable range of incident probe beam, the Voc from the photodiode base on NK-1952 doped PEDOT:PSS film increases significantly with the increase of the probe wavelength from 470 to 532 nm, which corresponds well with the

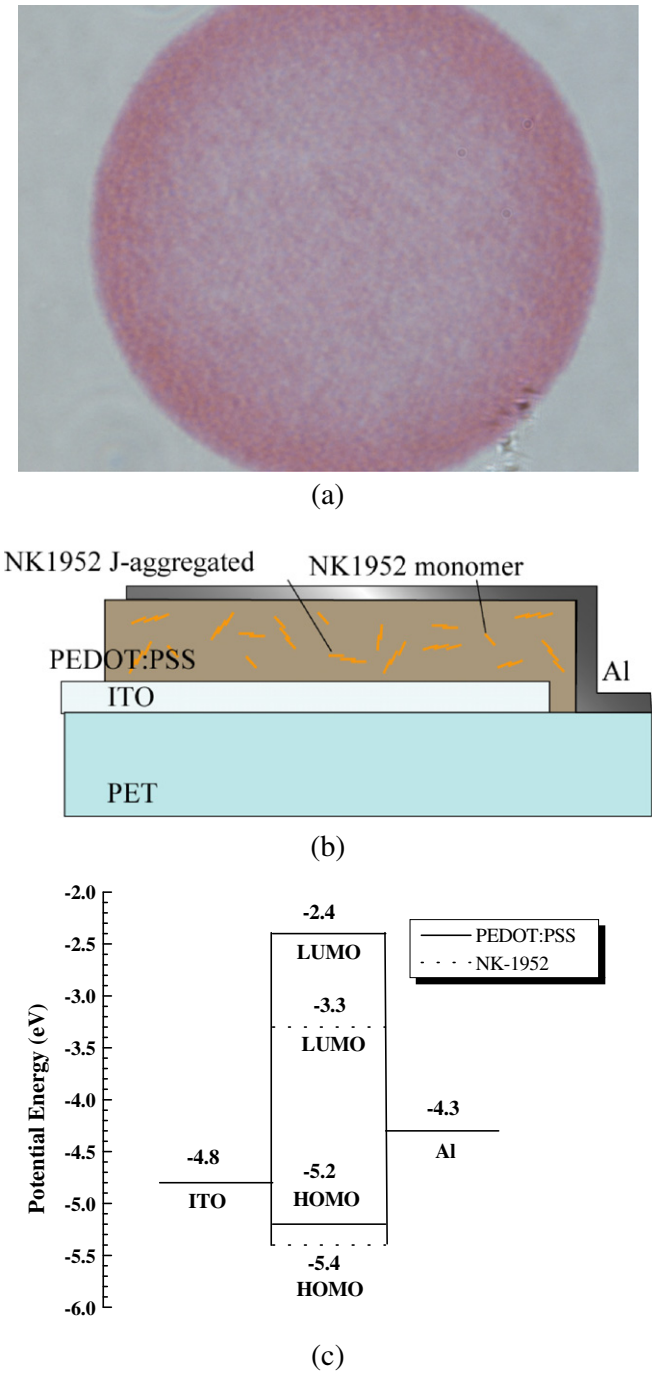

Fig. 1. (a) Image of inkjet printed NK-2203/PEDOT:PSS spot, (b) Architecture of the inkjet printed photo-diodes, (c) the HOMO and LUMO energy levels, and the workfunctions of electrodes.

absorption spectrum of the film. The pulse duration of Voc is ~2 μs, as shown in Fig. 4. However, increasing the probe wavelength around the absorption peak results in a sharp decrease on the voltage, and it can provide relatively high wavelength resolution. In addition, further increase in wavelength makes negative Voc around 550 nm, indicating the possibility of employing this photodiode as the wavelength sensitive detector at this spectral region. To explain the inversed slope and the negative voltage, the vertical inhomogeneous distribution of NK-1952 dye molecules in different J-aggregation degree in the inkjet printed spots is assumed to be responsible. As has be revealed by other cyanine dye based photovoltaic devices, excitons are induced after the absorption of photons by the cyanine dyes

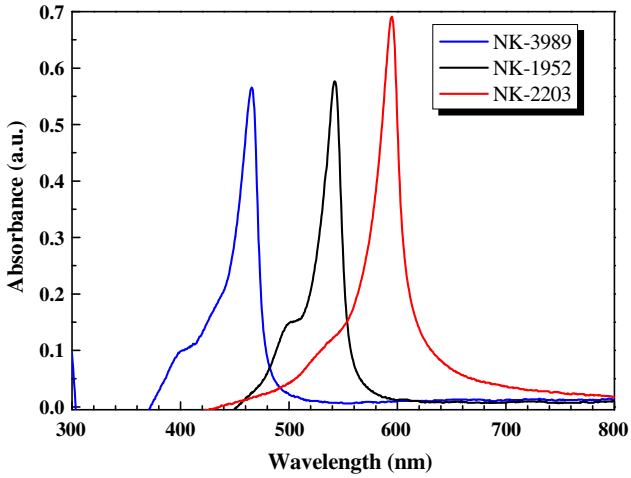

Fig. 2. Absorption spectra of cyanine dye NK3989, NK-1952 and NK-2203 doped into PEDOT:PSS films by inkjet method.

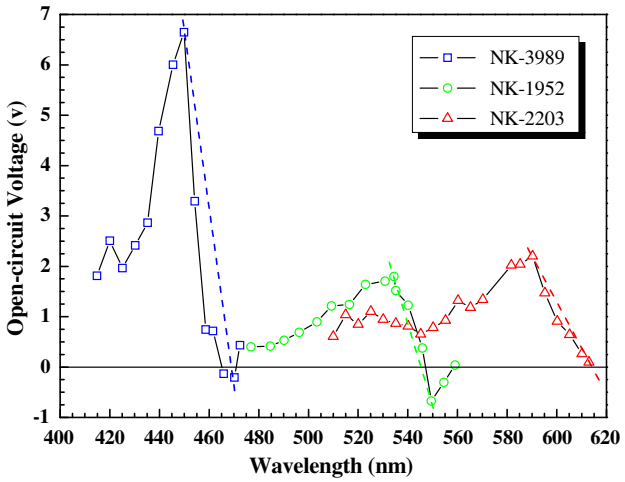

Fig. 3. The open-circuit voltage of photodiodes based on NK-3989, NK-1952 and NK-2203 under various excitation wavelength.

molecules and then separated into electron–hole pairs at the interface between NK-1952 and PEDOT:PSS, which acts as the hole transporting materials [30–32]. So, the Voc increases with the increase of extinction coefficient of NK-1952 J-aggregate from 470 to 532 nm. However, a concentration gradient of the J-aggregated cyanine dye in the inkjet printed spots is assumed during the evaporation of solvent in droplets and J-aggregate formation process. So, further increase the probe wavelength, only NK-1952 dye molecules with the largest J-aggregation degree can absorb the photons. However, as considering the average thickness of ~20 nm, which corresponds to the stack of ~40 molecules [30], the migration distance of electrons from the bottom of spots to the Al cathode is relatively long and an aggregation of electrons at the ITO surface may occur, resulting in the recombination with holes from the ITO anode and thus the reverse Voc can be observed. It is suggested that other mechanisms may also be responsible for the reverse Voc at 550 nm, for instance, the photocurrent in a schottky junction at an interface between ITO/PEDOT:PSS:NK-1952 arised from a space charge [33]. For detailed explanation, this research is now underway.

Similar results are obtained from the photodiodes based on NK-3989, as shown in Fig. 3. With the increase of probe wavelength from 410 to 450 nm, the Voc also increases. The inversed slope of 0.34 V/nm is observed around 465 nm and a small negative Voc is also confirmed. The quantum yield of the NK-3989 based photodiode at 450 nm is estimated to be $\sim 10^{-6}$, which is low as a photovoltaic device [29–32]. It is suggested that the sensitivity of this kind of photodiode can be improved by optimizing the photodiode architecture and materials composition [31,32], for instance, introducing the hole-transport and electron-transport layers between the active cyanine layer and electrodes respectively, or increasing the difference in workfunctions between the anode and cathode. And this is work is now underway. However, as a wavelength sensitive photodiodes, the spectral resolution, which is a much

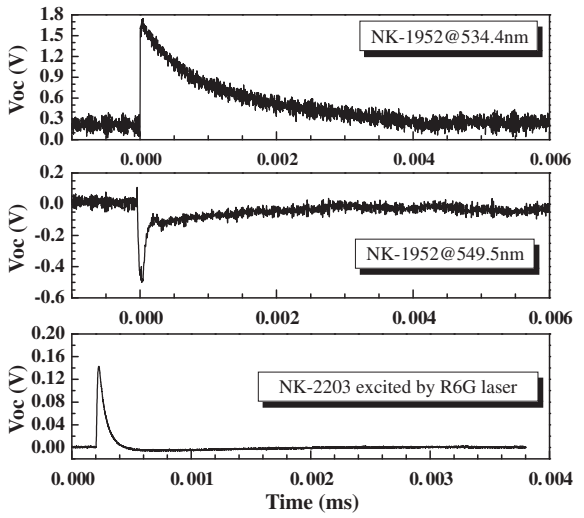

Fig. 4. The waveform of open-circuit voltage of the NK-1952 based photodiode under various excitation wavelength and that of NK-2203 based photodiode under the excitation of laser output from a R6G doped polymeric waveguide laser.

more important performance parameter, can be expected to reach the level of 0.1 nm due to the inversed slope of 0.34 V/nm in the Voc at around 465 nm, with the photodiodes based on NK-3989, indicating the nm-resolved laser spectrum monitor device, for such as integrated waveguide solid state dye lasers, can be realized.

To monitor wavelength around 600 nm, which is a typical wavelength of the waveguide dye lasers [24–28], the Voc of photodiodes based on NK-2203 is also investigated, as shown in Fig. 3. The peak Voc is obtained at the wavelength of ~590 nm, and inversed slope of 0.08 V/nm is confirmed, which is in correspondence with the absorption spectrum of the J-aggregated NK-2203 dye. Based on this result, ~2 μJ of amplified spontaneous emission (ASE) from a R6G doped PMMA film at ~580 nm is coupled into the photodiode based on NK-2203, and ~150 mV of Voc has been obtained, as shown in Fig. 4, indicating the enough sensitivity of this kind of photodiodes for the application on the integrated cytometry chips.

At last, it should also be noted that in this work, overlapped films in the size of $9 * 9$ mm are made, which normally consist of ~900 spots. In our other experiment, smaller films in the size of $1 * 1$ mm can also be made and used as organic photodiodes, which consist of ~16 spots. It is suggested that the advantages of the organic photodiodes made by inkjet printing may be better demonstrated by the smaller size of photodiodes, or in the extreme case, single spot photodiodes, which cost less spots and area size. However, there exist two main problems for this kind of single spot photodiodes. First, the capacity of the photodiodes is decided by the size of the films. Thus, by decreasing the size of the films and numbers of spots needed, a shorter and fast response Voc pulse may be expected while the photodiodes are more easily to be saturated. Second, to make the single spot photodiodes, the precise printing of the ink jet and a new ITO pattern are needed to avoid any contact between the electrodes which causes shortcut. In this work, because of the concerns on the saturation and relatively shorter lifetime of the single spot photodiodes, the large area films are made and used as the first characterisation for the organic photodiodes made by ink jet printing. However, single spot photodiodes can also be fabricate by using a thin polymer film printed by the same ink jet nozzle onto the ITO patterned substrates as the blocking layer to avoid the possible shortcut between the electrodes. Under the excitation of a 532 nm laser beam, ~0.43 V of Voc and much shorter pulse duration have been observed. After overcoming the problems of easy saturation and relatively shorter lifetime, for instance, utilizing several inkjet printed spots which are isolated to each other, it is suggested that this kind of organic photodiodes can be integrated to the flow-cytometry chips. This work is now underway.

4. Conclusion

In conclusion, in this work, disposable and miniaturized photodiodes in the visible based on the J-aggregated cyanine dye films printed by inkjet method have been realized. Wavelength sensitivity of these organic photodiodes has been observed with a sharp decrease and reverse Voc around the absorption peak of each J-aggregated dye and mechanism involved have been suggested. The detection of output from a solid-state dye laser film by the inkjet printed photodiode has been demonstrated, indicating the promise of applying this kind of photodiodes on the integrated cytometry chips.

ABSTRACT

We have fabricated high performance ambipolar thin-film transistors (TFTs) and an inverter based on organic–inorganic bilayer structures composed of an upper pentacene layer and a lower atomic-layer-deposited zinc oxide (ZnO) layer. The insertion of a dodecanoic acid (DA) self-assembled monolayer (SAM) into the interface between pentacene and ZnO results in an improvement in the morphology of the pentacene layer and in well-balanced ambipolarity with hole and electron mobilities of 0.34 and 0.38 $cm^2V^{-1}s^{-1}$, respectively. The ambipolar TFTs with DA-treated ZnO exhibit a hole to electron mobility ratio of approximately 0.90, which is higher by a factor of ~2.8 than that of ambipolar TFTs with untreated ZnO. We also tested the introduction of a perfluorooctyltriethoxysilane (PFOTES) SAM; the effects of the permanent dipole fields of the SAMs on the electrical and ambipolar characteristics of the hybrid TFTs were investigated.

1. Introduction

Thin-film transistors (TFTs) based on organic semiconductors [1] or metal oxide semiconductors [2–6] have been intensively studied as potential alternatives to transistors based on conventional silicon technologies for electronic applications requiring low cost, flexibility, large area, and transparency. The charge carrier mobilities of TFTs based on these two classes of semiconductors have been shown to be superior to those of *a*-Si:H-based TFTs. TFTs based on organic semiconductors are generally used as unipolar devices, and exhibit mostly *p*-type semiconducting behavior. Although high-performance unipolar devices have been achieved with TFTs based on *p*-type organic semiconductors, the use of TFTs based on *n*-type organic semiconductors in complementary logic circuits has been limited by their instability in the presence of atmospheric water and oxygen. TFTs based on metal oxide semiconductors, such as zinc oxide (ZnO), indium zinc oxide, zinc tin oxide and indium gallium zinc oxide, exhibit mostly *n*-type semiconducting behavior, and have the advantages of high charge mobility, excellent environmental stability and high transparency [2–6].

Ambipolar TFTs have also been intensively studied because of their applications in complementary logic circuits, which can be used to overcome the limitations of integrated circuits that use only unipolar logic [5–13]. In addition, the fabrication of complementary circuits based on ambipolar TFTs requires reduced process complexity and manufacturing cost [7]. Ambipolar TFTs based on organic semiconductors with various types of layer structures such as bilayer [8,13], blend [10], and single-component type

[9–12] have been reported by many groups. In particular, ambipolar TFTs with an organic–inorganic bilayer structure composed of a *p*-type organic semiconductor and an *n*-type metal oxide semiconductor have been reported; these TFTs make use of both classes of semiconductors [5,6]. Nakanotani et al. reported high-performance ambipolar TFTs based on an organic–inorganic hybrid structure containing an indium zinc oxide and pentacene bilayer, which was found to exhibit ambipolar TFT characteristics with hole and electron mobilities of 0.14 and 13.8 $cm^2V^{-1}s^{-1}$, respectively [5]. Pal et al. reported pentacene/ZnO bilayer TFTs that exhibit well-balanced hole and electron mobilities of 6.3×10^{-3} and 7.6×10^{-3} $cm^2V^{-1}s^{-1}$, respectively [6]. However, these hybrid bilayer ambipolar TFTs do not exhibit well-balanced hole and electron mobilities and a high charge carrier mobility at the same time due to poor compatibility between pentacene and the oxide semiconductor at their interface. In this paper, we report high-performance ambipolar TFTs and an inverter with well-balanced hole and electron mobilities; this balance is obtained by inserting a self-assembled monolayer (SAM) between pentacene and the ZnO active layer to enhance their compatibility at the interface. We also varied the dipole moment of the interface between the pentacene and ZnO layers by testing various SAMs, and investigated the effects of the permanent dipoles on the ZnO surface on the ambipolar characteristics of these pentacene/ZnO hybrid TFTs.

2. Experiments

Heavily doped *n*-type silicon wafers (n++ Si) with 300 nm thick thermally grown silicon dioxide (SiO_2) layers were used as gate substrates. Each ZnO thin film used as an *n*-type channel material was deposited on a cleaned gate substrate by using atomic layer deposition (ALD) at a temperature of 150 °C. Diethylzinc was used as the source of zinc. Oxygen plasma was used as the oxygen source for ZnO fabrication. The reactor pressure was maintained at 0.7 Torr with argon gas purging at 100 sccm. During the reaction, diethylzinc and the oxygen plasma were sequentially injected into the reactor chamber to produce a ZnO monolayer on the substrate. The thickness of the ZnO layer was 20 nm, which was patterned by using photolithography. A schematic diagram of the device structure of an *n*-type unipolar TFT with a ZnO active layer is shown in the inset in Fig. 1a. The source-drain electrodes of each unipolar TFT were defined on the ZnO active layer by thermally evaporating gold (Au) through a shadow mask. The channel length (L) and width (W) were 150 and 1500 μm, respectively. A schematic diagram of an ambipolar TFT based on a bilayer hybrid structure composed of an upper pentacene layer and a lower SAM-modified ZnO layer is shown in Fig. 2. After the ZnO layer was ultraviolet–ozone-treated for 15 min, the SAMs were then deposited on the ZnO surface by using spin-coating or a dipping process. Two different SAMs, dodecanoic acid (DA) and perfluorooctyltriethoxysilane (PFOTES) were chosen based on their dipole and terminal groups, as shown in Fig. 2. 1 mM of DA in ethanol was spin-coated onto the ZnO film, resulting in the formation of a monolayer of DA through the chemical bonding between carboxylic acid and ZnO [14–17]. The DA-treated ZnO was spin-coated again using pure ethanol to remove physically absorbed DA molecules. In the preparation of the PFOTES SAM, the ZnO sample was dipped into a 1 mM toluene solution of PFOTES with 0.01 vol.% *n*-butylamine as a catalyst. After treating the sample at 45 °C for 90 min, the PFOTES-treated ZnO sample was removed from solution and rinsed with toluene in order to remove excess PFOTES molecules. After drying, 50 nm thick pentacene films were deposited onto the SAM-treated ZnO samples held at room temperature, under a

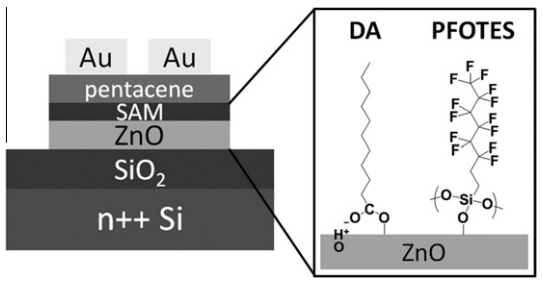

Fig. 2. Device architecture of the ambipolar TFT based on a pentacene/ZnO hybrid structure, and the modification of the interface between pentacene and ZnO by the insertion of a DA or PFOTES SAM, and their chemical structures on the ZnO active layer.

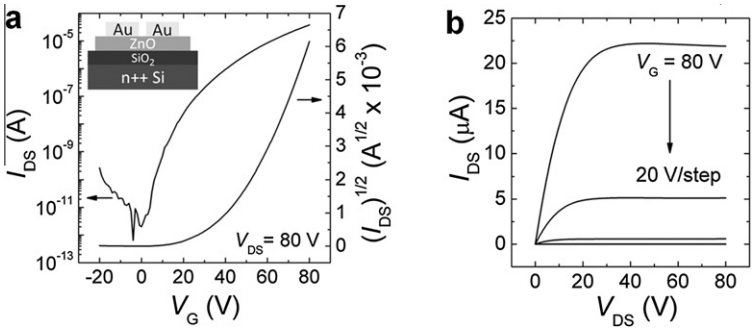

Fig. 1. (a) Saturated (V_{DS} = 80 V) transfer and (b) output characteristics of a unipolar TFT based on an atomic-layer-deposited 20 nm thick ZnO film as the *n*-type active layer. The inset shows a schematic diagram of the TFT structure.

vacuum pressure of $\sim 10^{-6}$ Torr with a deposition rate of 0.2 Ås^{-1}. In the case of the bare sample, the pentacene film was deposited onto the ZnO film without SAM treatment. Finally, 80 nm thick Au source-drain electrodes were deposited though a shadow mask. The channel length L and width W were 100 and 1500 μm, respectively. In particular, Al source-drain electrodes were deposited onto the SAM-treated ZnO without a pentacene layer by using the same shadow mask to fabricate the n-type unipolar TFT shown in the inset in Fig. 5b. We measured the electrical characteristics of the TFTs in air at room temperature by using Keithley 2400 and 236 source/measurement units. The capacitance was measured with an HP 4284A Precision *LCR* meter. The secondary electron emission (SEE) spectra of the bare surface and the DA-treated and PFOTES-treated ZnO on n++ Si substrates were obtained with ultraviolet photoemission spectroscopy (UPS) (Escalab 220IXL) by using the He I emission at 21.2 eV. During the UPS measurements, a −5.0 eV bias was applied to improve the transmission of low kinetic energy electrons and ensure the determination of the low kinetic energy edge.

3. Results and discussion

First, we measured the unipolar TFT characteristics by using a 20 nm thick ZnO film as an n-type channel material with top Au contact source-drain electrodes. Fig. 1 shows the transfer and output characteristics of the unipolar ZnO TFT, which are those of typical n-type TFT operation. The charge carrier mobility (μ) was extracted from the slope of a plot of the square root of the drain-source current (I_{DS}) versus gate voltage (V_G) in the saturation regime by using the following equation:

$$I_{DS} = \mu C_i \frac{W}{2L}(V_G - V_T)^2, \quad (1)$$

where V_T is the threshold voltage. The measured capacitance, C_i, was 10 nFcm^{-2} at 1 kHz. V_G was scanned from −20 to 80 V at a constant V_{DS} of 80 V. The transfer characteristics are those of a good TFT device: a μ value of 0.56 cm^{2}V^{-1}s^{-1}, a current on–off ratio (I_{on}/I_{off}) of $\sim 10^7$, and a V_T value of 44.8 V. These values are comparable to those of previously reported ALD-processed ZnO TFTs [4].

Fig. 2 shows a schematic diagram of an ambipolar TFT based on an organic–inorganic hybrid structure composed of pentacene as the upper p-type layer and ZnO as the lower n-type layer. Balanced hole and electron mobilities are preferred in ambipolar TFT applications. In order to fabricate a high-performance ambipolar TFT based on a pentacene/ZnO bilayer structure with balanced hole and electron mobilities and a high hole mobility (μ_h), the crystallinity of the pentacene layer must be well ordered, but usually only inferior growth of pentacene crystals can be obtained on inorganic oxide films with rough surfaces and high surface energies [17–21]. Therefore, we chose an ALD-processed ZnO film as the underlying n-type active layer because it has a very smooth surface ($R_q \sim 0.59$ nm, Fig. 3a) when compared to those obtained with other methods [3,6]. To improve μ_h further, we introduced DA as an alkyl SAM at the interface between the pentacene and ZnO layers, as shown in Fig. 2. The preparation of alkyl SAMs such as octadecyltrichlorosilane on SiO_2 gate dielectrics is a very effective method for improving the μ_h values of organic TFTs because the crystallinity and the morphology of organic semiconducting films on gate dielectrics are enhanced by the presence of alkyl SAMs [22–24]. In addition, a ZnO layer was modified with a PFOTES SAM, which

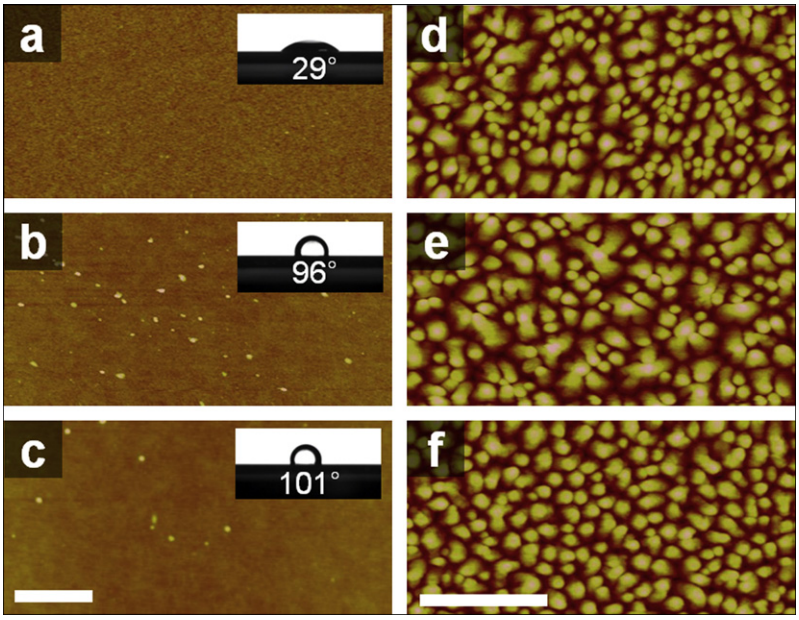

Fig. 3. AFM topographic images of (a) bare ZnO, (b) DA-treated ZnO, and (c) PFOTES-treated ZnO surfaces. The R_q values of the ZnO surfaces are (a) 0.59 nm, (b) 0.90 nm, and (c) 0.68 nm. The AFM images in (d–f) show the morphologies of 50 nm thick pentacene films on surfaces (a), (b), and (c), respectively. The insets show images of droplets on the ZnO surfaces and the corresponding water contact angles (θ_{water}). The scale bars are 1 μm.

contains an electron-withdrawing group, to investigate the effects of permanent dipoles on the electrical characteristics of ambipolar TFTs.

To examine the effects of the SAM treatment on the surface properties of the ZnO layer, we investigated the surface roughness of each sample by using tapping-mode atomic force microscopy (AFM) and measured its water contact angle (θ_{water}). The spin coating of DA onto the ZnO layer was found to result in a hydrophobic surface ($\theta_{water} \sim 98°$) with an rms roughness (R_q) of approx. 0.90 nm, as shown in Fig. 3b, which is higher than the surface roughness of the bare ZnO layer. When ZnO is treated with PFOTES, R_q increases slightly to 0.68 nm, resulting in the most hydrophobic surface ($\theta_{water} \sim 101°$) of the samples, as shown in Fig. 3c. Fig. 3d–f show AFM topographic images of pentacene films on bare, DA-treated, and PFOTES-treated ZnO, respectively. The grain size of the pentacene film on DA-treated ZnO is higher than that on bare ZnO even though R_q increases from 0.59 to 0.90 nm. This increase in grain size despite the increased ZnO surface roughness is due to the hydrophobic surface obtained through the formation of a DA monolayer; variations of the hydrophobic surface roughness within ~1.5 nm have little effect on the grain size, the degree of crystallinity, and the carrier mobility of pentacene [25]. In contrast, the pentacene film on PFOTES-treated ZnO, which has a very low surface energy, formed in the three-dimensional (3D) island growth mode and thus contains small grains (~100 nm) and has a high grain-boundary density, as shown in Fig. 3f.

Fig. 4a shows the current–voltage transfer behaviors (linear regime, V_{DS} = ±10 V) of the ambipolar TFTs containing pentacene on bare, DA-treated, and PFOTES-treated ZnO surfaces; their electrical characteristics are summarized in Table 1. The electron and hole mobilities and V_T values were obtained from the slopes of plots of I_{DS} versus V_G in the linear regime by using the following equation:

$$I_{DS} = \mu \frac{C_i W}{L}(V_G - V_T)V_{DS}. \quad (2)$$

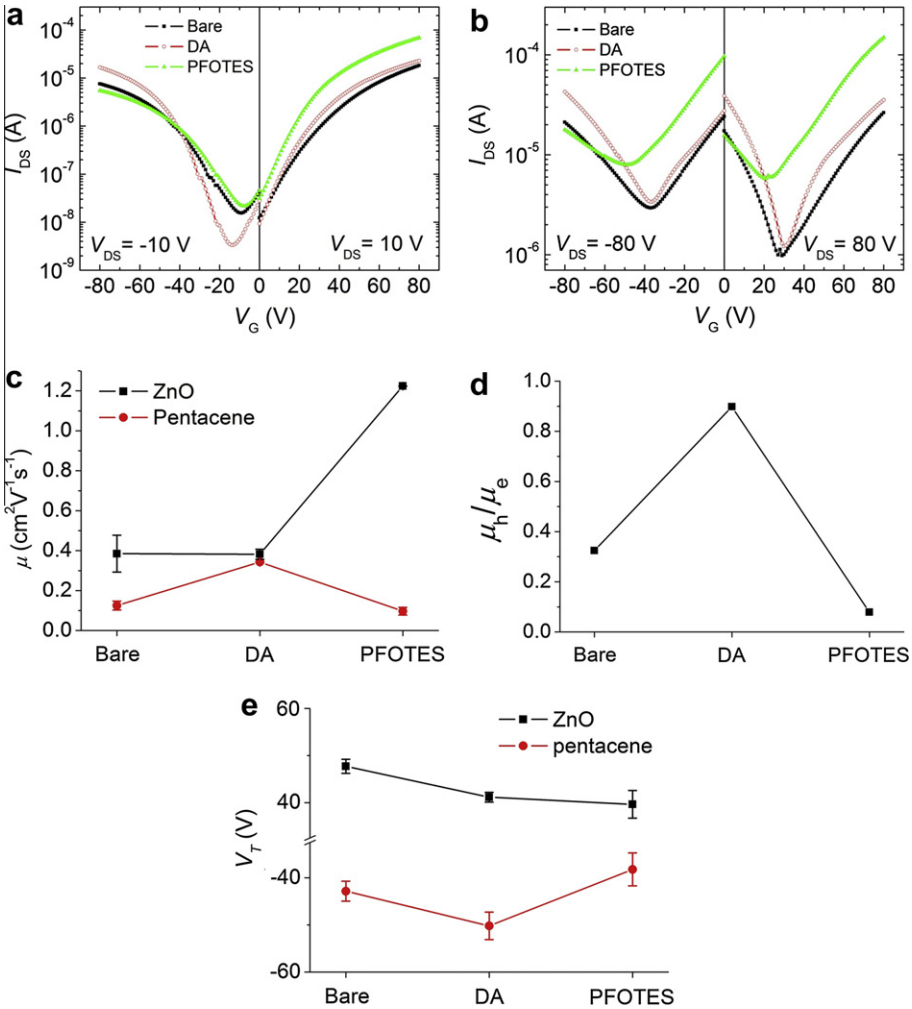

Fig. 4. Transfer characteristics of ambipolar TFTs containing pentacene on bare, DA-treated, and PFOTES-treated ZnO surfaces in (a) the linear regime (V_{DS} = ± 10 V) and (b) the saturation regime (V_{DS} = ± 80 V). The variations in the linear regime of the ambipolar TFTs in (c) the hole and electron mobilities, (d) the hole to electron mobility ratio (μ_h/μ_e), and (e) the threshold voltage.

The electron mobility (μ_e) of the ambipolar TFT containing bare ZnO as the *n*-type layer is 0.385 ± 0.092 cm^{2}V^{-1}s^{-1}, I_{on}/I_{off} is approx. 10^3, and V_T is 47.7 ± 1.5 V. In DA-treated ZnO, the bonding between DA and ZnO arises when carboxylic acid (–COOH) groups react with hydroxyl groups on ZnO to form carboxylate anions (–COO$^-$), which are electron donors and can provide electrons to ZnO [15,26]; as a result, in the *n*-type operation of the ambipolar TFT based on DA-treated ZnO I_{DS} increases and V_T is shifted negatively, even though the direction of the dipole field from the electron-donating alkyl groups in the DA molecules disturbs the injection of electrons at the source (S) electrode. The ambipolar TFTs based on PFOTES-treated ZnO exhibit an average μ_e of 1.224 cm^{2}V^{-1}s^{-1}, which is higher by a factor of ~3.2 than that of the ambipolar TFT based on bare ZnO, and a negative shift in V_T, as shown in Figs. 4a, 4c, and 4e. These changes in μ_e and V_T in the *n*-type operation of the PFOTES device result from the easy electron injection from the source electrode that arises because of the electron-withdrawing PFOTES SAM, which also induces the increase of the charge density due to a charge transfer at the interface between the ZnO and the PFOTES molecules [27].

The μ_h value of the ambipolar TFTs based on bare ZnO is 0.125 ± 0.022 cm^{2}V^{-1}s^{-1}, I_{on}/I_{off} is approx. 10^2, V_T is −42.8 ± 2.11 V, and the subthreshold slope (S) is 11.1 V/decade. In the *p*-type operation of the ambipolar TFT based on DA-treated ZnO, μ_h is 0.343 cm^{2}V^{-1}s^{-1}, V_T is shifted negatively with respect to that of the bare device, and S is 7.50 V/decade. The low grain-boundary density that results from the increase in the grain size of pentacene on DA-treated ZnO reduces the number of interface-trap states, and thus leads to improvements in the μ_h and the S values, as indicated in Table 1. The improvement in μ_h leads to better balance between the hole and electron mobilities with a hole and electron mobility ratio (μ_h/μ_e) of approx. 0.90, which is much better than that of the bare device ($\mu_h/\mu_e \sim 0.32$), as shown in Fig. 4d. In contrast, in the case of the PFOTES device, the low value of μ_h (0.097 cm^{2}V^{-1}s^{-1}), which is due to the formation of an inferior pentacene film on PFOTES-treated ZnO, and the high electron mobility result in poorly balanced hole and electron mobilities; μ_h/μ_e is approx. 0.08. Kwak et al. reported that the μ_h value of a pentacene film on a fluorinated surface with a very low surface energy ($\theta_{water} \sim 103°$) was degraded by the large number of grain boundaries [28]. The reduction in the grain size, i.e. the high grain-boundary density, of the pentacene film on PFOTES-treated ZnO induces an increase in the number of interface-trap states, as shown in the value of S, which can be used as an indicator for estimating the maximum trap density (N_{trap}) at the interface between the semiconductor and the dielectric according to the following equation [24]:

$$N_{trap} \approx \left[\frac{qS\log(e)}{kT} - 1\right]\frac{C_i}{q}, \quad (3)$$

where q is the electronic charge, k is Boltzmann's constant, and T is the temperature. With this equation, we estimated the interface-trap densities of the devices containing bare ZnO, DA-treated ZnO, and PFOTES-treated ZnO to be 1.2×10^{13}, 7.9×10^{12}, and 1.3×10^{13} cm^{-2}, respectively. These results indicate that the electrical characteristics of *p*-type operation of the ambipolar TFTs are in agreement with the results for the morphologies of the pentacene films.

Fig. 4b shows the transfer characteristics for positive and negative gate biases in the saturation regime (V_{DS} = ± 80 V) of the ambipolar TFTs containing pentacene on bare, DA-treated, and PFOTES-treated ZnO. The dependences in the saturation regime of the electrical parameters μ, V_T, and S on the treatment of ZnO are similar to those in the linear regime. When $|V_G - V_T| < |V_{DS}|$, both the source and drain electrodes inject their respective charge carriers and thus both holes and electrons are present in the channel, so this is the ambipolar regime [7–9]. At a V_G of 0 V, I_{DS} increases markedly in contrast with the linear regime, which is explained for *p*-type operation by the injection of opposite carriers at the drain (D) electrode induced by the positive V_G in the ZnO active channel layer, and for *n*-type operation by the negative V_G in the pentacene active channel layer. In particular, a high I_{DS} value (~0.1 mA) was obtained at a V_G of 0 V in the *p*-type operation of the PFOTES device because of the permanent dipole of the PFOTES-treated ZnO surface.

The formation of a permanent dipole in the SAM layer is induced by the charge distribution within the functional groups of the SAM molecule [29]. The permanent dipole in the SAM layer on ZnO influences the secondary electron emission (SEE) onset for the active layers. The changes in the SEE onset on the SAM-treated ZnO surfaces thus indicate the relative strength of the SAM's electron-donating or electron-withdrawing character, and can be determined from the SEE spectra [30]. We determined the relative strengths of the permanent dipoles of the bare and SAM-treated ZnO layers from the changes in SEE onset obtained from their SEE spectra. Fig. 5a shows the SEE spectra of the bare, DA-treated, and PFOTES-treated ZnO. The SEE onset was determined by extrapolating two solid lines from the

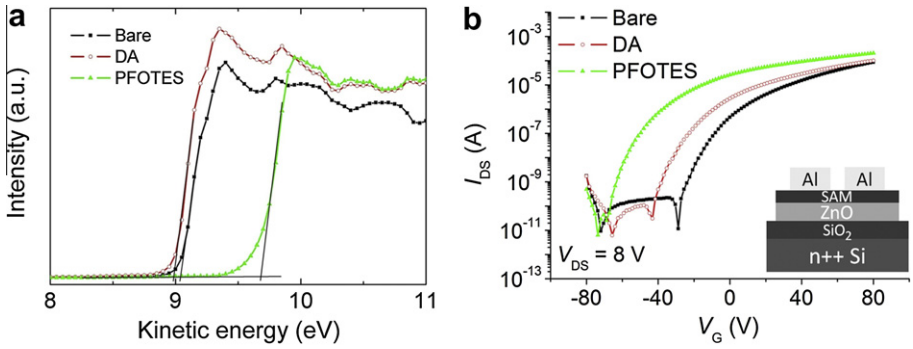

Fig. 5. (a) Secondary electron emissions (SEEs) of the three samples: bare ZnO (closed black rectangles), DA-treated ZnO (open red circles), and PFOTES-treated ZnO (closed green triangles). (b) Transfer characteristics in the linear regime (V_{DS} = 8 V) of *n*-type unipolar TFTs without pentacene based on bare ZnO, DA-treated ZnO, and PFOTES-treated ZnO. Inset: a schematic diagram of a unipolar TFT.

background and the straight onset in each spectrum. The SEE onset for DA-treated ZnO was found to be at a kinetic energy (8.99 eV) that is a little lower (by 0.05 eV) than that of bare ZnO. In contrast, the onset for PFOTES-treated ZnO is higher by 0.64 eV than that of the bare ZnO. The large shift of the SEE onset for PFOTES-treated ZnO originates from the presence of the fluorine-induced strongly negative surface dipole moments of the PFOTES SAM, which is strongly electron withdrawing. The electron-donating alkyl groups of the DA SAM with weakly positive surface dipole moments mean that the DA-treated ZnO has a slightly shifted the SEE onset. These differences influence the density of hole carriers in *p*-type operation, the injection of charge carriers at the S/D electrodes, and the ambipolar characteristics.

For the pentacene films on SAM-treated ZnO, the permanent dipole field demonstrated by the change in the SEE onset (Fig. 5a) modifies the surface potential and the electronic structure of the interface between the pentacene and ZnO layers, and thus results in a change in the carrier density and a shift in V_T [31,32]. In the *p*-type operation of the PFOTES device, the electron-withdrawing properties of the PFOTES SAM on ZnO leads to the formation of a permanent dipole field under the pentacene film. As a result, electrons from the pentacene film are attracted by the PFOTES SAM leaving the more mobile holes in the channel and therefore V_T is shifted more positively, as shown in Fig. 4e [31]. In the case of the DA device, on the other hand, a negative shift in V_T is observed since the dipole field and negative interface charges that originate from the electron-donating DA SAM modify the surface potential, which has the same effect as applying a positive gate bias.

The V_G–I_{DS} transfer characteristics of *n*-type unipolar TFTs without a pentacene layer based on bare, DA-treated, and PFOTES-treated ZnO and a schematic diagram of the device structure are shown in Fig. 5b; the transfer characteristics can be used to investigate the effects of the permanent dipole field of the SAMs on the injection behavior at the source electrode. Inserting the PFOTES SAM between the Al electrodes and the ZnO active layer means that the turn-on voltage (V_{on}) is dramatically shifted from −28.8 to −68.8 V and that I_{DS} increases markedly over that of the TFT without SAM treatment. These differences can be attributed to the easy charge (electrons in this case) injection from the Al electrode to the ZnO active layer that arises because the direction of the permanent dipole field of the PFOTES SAM enhances electron injection at the source electrode [33,34]. Furthermore, the PFOTES SAM with a strong electron-withdrawing ability on the ZnO layer can produce the mobile charges in the channel due to charge transfer at the interface between the ZnO and the PFOTES molecules [27]. For the DA-treated ZnO device, V_{on} is also shifted negatively to −43.2 V despite the disturbance of the electron injection at the source electrode that results from the direction of the permanent dipole field of the DA SAM. This result means that the effects on the TFT transfer characteristics of the electron donation of the carboxylate anions (–COO^-) in the DA SAM to ZnO are greater than those of the weak permanent dipole field of the DA SAM. These effects of the SAMs on the transfer characteristics of the *n*-type unipolar TFTs without a pentacene layer also contributed equally to the *n*-type operation of the ambipolar TFTs shown in Fig. 4.

Fig. 6 shows the output and ambipolar characteristics of the hybrid TFTs based on the pentacene/ZnO bilayer structures illustrated in the insets. The bare device without SAM treatment exhibits typical ambipolar output characteristics (Fig. 6a) similar to those of previously reported ambipolar TFTs [5–10,13]. When $|V_G| \leqslant 40$ V and $|V_{DS}|$ is increased, divergent I_{DS}–V_{DS} behavior is observed, indicating abrupt electron injection (in the case of *p*-type operation) or hole injection (in the case of *n*-type operation) from the drain electrode, which is typical of ambipolar operation in TFTs [5–10,13].

For the ambipolar TFT based on DA-treated ZnO and a positive gate bias, typical *n*-channel characteristics were observed for positive drain-source voltages with $|V_{DS}| \leqslant |V_G - V_T| = |V_{G,eff}|$, where $V_{G,eff}$ is the effective gate voltage. When $|V_{DS}|$ is increased, the additional hole current that originates from the abrupt hole injection at the drain electrode increases when compared with that of the bare device, as shown in Fig. 6b. The negative interface charge produced by the permanent dipole field of the DA SAM attracts additional holes in the channel from the drain electrode and thus results in an increase in the additional hole current [8]. For the DA device with a negative gate

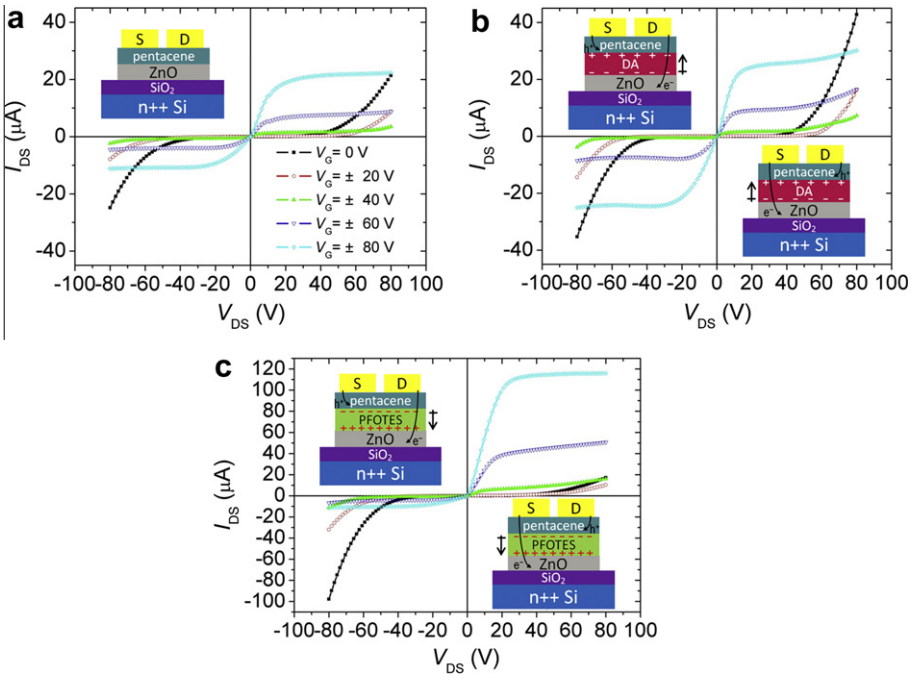

Fig. 6. Output characteristics of ambipolar TFTs containing *p*-/*n*-type layers based on (a) pentacene/bare ZnO, (b) pentacene/DA-treated ZnO, and (c) pentacene/PFOTES-treated ZnO. The *p*- and *n*-type operations were carried out under negative and positive V_G biases, respectively. Insets: schematic cross-sections of the ambipolar TFTs, schematic diagrams of the injection behaviors of electrons (e^-) and holes (h^+) at the source (S) and drain (D) electrodes, and the directions of the permanent dipole fields of the SAMs.

bias, i.e. *p*-type operation, an increase in the drain-injected additional electron current is also observed even though the direction of the permanent dipole field of the DA SAM interrupts the electron injection from the drain electrode to the ZnO, as shown in the schematic diagram in the inset in Fig. 6b. This result means that the weak surface dipole moment of the DA SAM does not affect electron injection from the drain electrode significantly. When in the *p*-type operation of the DA device $|V_{G,eff}|$ decreases due to the negative shift in V_T, a shift of the onset of the drain-injected electron current to lower $|V_{DS}|$ can result in an increase in the additional electron current [8]. The output characteristics of the DA device show that the drain-source current levels of the *p*- and *n*-type operations are almost symmetric due to the well-balanced hole and electron mobilities, as shown in Fig. 6b.

In the output characteristics of the device with pentacene/PFOTES-treated ZnO (Fig. 6c), typical *n*-type operation is observed for positive V_G with a dramatically increased drain-source current (e.g. $I_{DS} \sim 120$ μA at a V_G of 80 V), which results from the improvement in μ_e ($1.224\ cm^2V^{-1}s^{-1}$) that results from treatment with the PFOTES SAM. When the V_G was 0 or 20 V and the V_{DS} was greater than ~40 V, a decrease in the drain-injected hole current with respect to that of the bare device was observed; this decrease can be explained as follows: the positive interface charge produced by the permanent dipole field of the PFOTES SAM repels additional holes in the channel from the drain electrode [8]. In the *p*-type operation of the PFOTES device, on the other hand, a decrease in the saturation current and an increase in the drain-injected additional electron current were observed, as shown in Fig. 6c. The decrease in the saturation current arises because of the low value of μ_h ($0.095\ cm^2V^{-1}s^{-1}$), which is due to the increase in the number of interface-trap states that results from the high grain-boundary density of the pentacene film on PFOTES-treated ZnO, and thus an unbalanced hole and electron saturation current is observed. The increase in the drain-injected electron current results from the direction of the fluorine-induced strongly negative surface dipole field of the PFOTES SAM, which induces easy electron injection from the drain electrode to the ZnO active layer. Thus a high I_{DS} (~0.1 mA) at a V_G of 0 V in the transfer characteristics (saturation regime) was also observed, as shown in Fig. 4b. These unbalanced ambipolar behaviors of the PFOTES device in the *p*- and *n*-type operations produce asymmetric output characteristics.

In addition, we fabricated a complementary-like inverter through the integration of two identical pentacene/ZnO ambipolar TFTs employing DA SAMs. As mentioned above, the presence of the DA SAM between the pentacene and ZnO layers means that μ_h and μ_e of the ambipolar TFT are better balanced than is the case for the other surface treatment layer investigated here, and thus results in the optimization of ambipolar charge transport. Fig. 7 shows the typical voltage transfer characteristics of the resulting inverter; the inset shows a schematic diagram of the inverter structure. The supply voltage (V_{DD}) of 40 V was biased to the inverter, so the output voltage (V_{out}) varied from high to low in response to the swing of the input voltage (V_{in}) from low to high, and a sharp inversion of V_{in} is found near 15.5 V. The voltage gain (defined as the absolute value

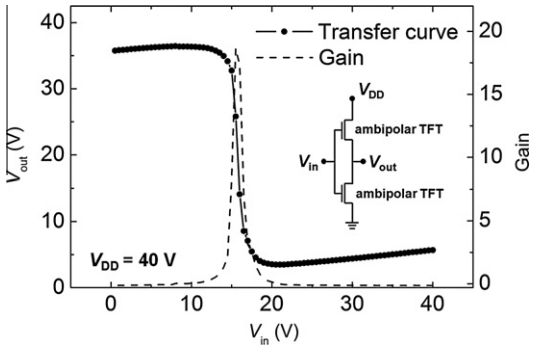

Fig. 7. Voltage-transfer characteristics of a complementary-like inverter comprised of two identical pentacene/ZnO ambipolar TFTs (L = 100 μm, W = 1500 μm) employing a DA SAM. The inset shows a schematic circuit diagram of the inverter.

of dV_{out}/dV_{in}), the noise margin, and the output voltage swing (defined as $V_{out}^{max} - V_{out}^{min}$) were calculated from the voltage transfer curves. The maximum voltage gain reaches a maximum value of 18.6, and the values of the noise margin and the output voltage swing are approx. 4.5 V and 33 V, respectively. The voltage gain of our inverter surpasses recently reported values for complementary-like inverters with ambipolar transistors [10–13], and those of unipolar inverters, in particular those employing pentacene transistors [35,36].

4. Conclusions

We have demonstrated high performance ambipolar TFTs and a complementary-like inverter based on an organic–inorganic hybrid structure composed of pentacene and ZnO as the semiconducting *p*-type and *n*-type layers, respectively. A simple method was developed to modify the interface of the *p*-type and *n*-type layers by the introduction of a SAM between the pentacene and ZnO layers. We achieved well-balanced hole and electron mobilities in the pentacene/DA-treated ZnO ambipolar TFT with a μ_h value of $\sim$0.34 $cm^2V^{-1}s^{-1}$ and a μ_e value of $\sim$0.38 $cm^2V^{-1}s^{-1}$. This modification of the interface between the pentacene and ZnO layers was found to enable the control of the surface energy and the permanent dipole field at the interface, which influences the electrical and ambipolar characteristics such as the hole and electron mobilities, the threshold voltage, and the injection behavior of charge carriers at the S/D electrodes. The optimized interface between the *p*- and *n*-type active layers that is obtained through treatment with a DA SAM produces well balanced ambipolar behavior and thus enables the realization of a high performance complementary-like inverter.

Multilayer interconnects

ABSTRACT

A fully printed ring oscillator circuit is reported, which has not only horizontally arranged parts, but inverter stages stacked vertically on top of each other in four through-connected substrate layers. For the preparation of the inverters exclusively gravure and flexographic printing were used. Characteristics of the stacked ring oscillator are similar to planar circuits. A very interesting path of development for printed electronics is opened with this approach, because three-dimensional circuits become possible.

1. Introduction

Stacking and vertical interconnecting of several circuit layers has been studied in the past within the framework of conventional microelectronics in order to overcome technological barriers that arise with the ongoing increase of integration density [1]. Most importantly, global length of interconnects and thereby signal delay as well as power consumption are expected to be reduced [2]. Although several approaches for the realization of three-dimensional circuits exist, a breakthrough has so far been hindered by technological difficulties limiting three-dimensional integration to a few layers [3]. However, truly three-dimensional arrangement of electronic components, as it is realized for example in the biological brain, would allow for an extremely enhanced complexity of interconnects and thus enable a new way of improving the functionality of integrated circuits [4]. It should be noted that multilayers are state of the art in printed circuit board technology, where dozens of layers can be interconnected [5]. An approach for three-dimensional integration was combining organic and inorganic materials in order to stack numerous circuit layers directly on top of each other, whereby definition of patterns and preparation of interconnects was done by means of mask-based processes such as photolithography [6].

Beside classical silicon electronics, printed electronics is seen as a complementary technology for the manufacture of integrated circuits. Printable inks can be prepared from electronically functional polymers or nanoparticles, which can be used to print electronic devices, e.g. transistors, as well as complete circuits on flexible substrates such as PET-foil [7]. Although nowadays inkjet printing is very often used in printed electronics (for reviews see [8,9]), especially high-volume rotary printing methods, namely offset, gravure and flexographic printing, have an interesting economic potential due to their high productivity [10]. Transistors [11] and ring oscillator circuits [12] realized in unipolar (PMOS-equivalent) logic by means of these methods have been demonstrated already some time ago. Meanwhile, printable n-type semiconductors have become available [13,14], allowing for CMOS-equivalent circuitry [15–17], while at the same time alternative approaches emerge like ambipolar transistors [18] and charged dielectrics [19].

Nevertheless, for further development of printed digital circuits principal challenges exist. Especially the limited homogeneity and topology of printed films limits the

doi:10.1016/j.orgel.2010.12.010

possibilities for straight-forward reduction of feature sizes as well as for enhancement of lateral integration density; hence new paths of development are to be explored. The idea presented here is to use established post-press methods like folding and cutting in order to enable three-dimensional circuitry. Flexible substrate layers printed with electronic devices are supposed to be accurately stacked on top of each other and individual devices to be interconnected in vertical direction throughout the layers. In order to validate this approach, a stacked ring oscillator circuit consisting of five inverter stages was realized (see Fig. 1h for circuitry). Two of the inverter stages were located in the first substrate layer, while the other three were located in separate layers. With the transistors thereby arranged in a truly three-dimensional pattern, a three-dimensional integrated circuit was created.

2. Experimental

A ring oscillator was chosen for the demonstration of a three-dimensional circuit because possible performance variations due to the stacked arrangement in comparison with the planar setup can be easily detected using this kind of circuit. All necessary components were prepared using exclusively gravure and flexographic printing in an identical way for the planar and for the three-dimensional device. Details of printing processes used for manufacturing of integrated circuits have been reported several times [11,12,20]. Here, a 100 μm thick PET-foil (Melinex 400 of DuPont Teijin Films) was used as substrate for printing of transistors in top-gate configuration. Source/drain structures were firstly printed from an adapted formulation of the conductive polymer poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, Clevios P of H.C. Starck) by means of a recently developed technique, called "Cyflex" [21]. The semiconductor used was the p-type liquid crystalline polymer poly(9,9-dioctylfluorene-co-bithiophene) (F8T2 of Evonik), which was gravure printed on top of the source/drain structures from a 0.5 wt.% solution in a 1:1 mixture of toluene and tetrahydrofurane. Subsequently, a dual film dielectric was gravure printed as well, where a thin film of a proprietary butylene copolymer (P105 of Merck) forms the interface with the semiconductor and a poly(methyl methacrylate) film (PMMA of Aldrich, molecular weight = 996,000 g/mol) from a 7.5% solution in ethyllactate/butylacetate serves as gate insulator. In order to ensure good insulation, three successive printing runs of PMMA were conducted. The printing steps described so far were performed on a laboratory roll-to-roll printing machine with a web width of 35 mm and with process speeds between 0.5 and 1 m/s. Finally gate electrodes and contact pads for the source/drain

electrodes were printed from an adapted formulation of Clevios P on a flexographic test printing device (Flexiproof 100 of RK Print).

The experiment reported here was not aimed at the preparation of structures with particular high resolution. In contrast, safely printable and reproducible results were targeted in order to compare the three-dimensional arrangement with the conventional setup. Printed transistors had a channel length (i.e. the distance between source and drain electrodes) of 45 μm, the width of single electrode fingers being 105 μm. Each inverter stage consisted of two transistors, one so-called drive transistor with a channel-width-to-length-ratio of 666 and one so-called load transistor with a ratio of 120. Complete planar ring oscillators (Fig. 1a) were printed together with separated inverter stages with the input contact situated on one of two adjacent sides (Fig. 1b). The latter ones were used for the preparation of the stacked ring oscillator, which thus could be compared with a planar one prepared under identical experimental conditions. The first substrate layer of the stacked ring oscillator consisted of two interconnected inverter stages in order to allow for later contacting, while three more inverter stages were situated in layers two, three and four, respectively. Due to the alternating position of the output contact each of them was positioned so that it could be connected with the input contact of the following one by a vertical interconnect (Fig. 1c).

Vertical interconnects were prepared manually for maximum process control in this basic experiment. Fig. 1d–g illustrates the method. It has been shown, however, that through-connections in printed circuits on foil can be mechanically realized by preparing holes using perforation devices or lasers, which are subsequently overprinted with conductive inks [22]. This process was simulated by cutting into the substrate of the inverter stages three, four and five on a length of approx. one milimeter at the positions of the input and supply voltage contacts. By applying a drop of the gate material (PEDOT:PSS) on the cut from each side of the substrate, a through connection was established. Subsequently these layers were stacked on top of inverter stage two using an anisotropic conductive two-sided adhesive tape (acrylate with embedded silver-coated nickel particles, 9703 of 3 M) for mechanical and electrical connection between adjacent layers. The adhesive tape covered the whole area of the layers so that the mechanical connection was very stable, while for a safe electrical connection with a contact resistance <1Ω an overlap of the adjacent contacts larger than 3 mm^2 is necessary according to the technical data sheet. Fig. 2 shows a photographic image of the stacked ring oscillator.

3. Results and discussion

The contact resistance of the vertical interconnects was determined on a series of samples of two interconnected layers to be 5–6 kΩ, which can be attributed to the through-connection using PEDOT:PSS. This value is in accordance with the total resistance over three interconnects, measured at the conducting path of the supply voltage of the stacked ring oscillator from the first to the fifth inverter stage, which was approx. 21 kΩ. The same conducting path without vertical interconnects in the planar circuit had a resistance of approx. 10 kΩ. In spite of shorter interconnection length, the resistance of interconnects turns out to be larger in the case of the stacked circuit compared to the planar one due to the resistance of through-connections. However, the resistance values of through-connections can be largely reduced when more suitable materials are used. In preliminary experiments with mechanical perforation and a silver ink, resistances of a few Ω have been realized.

The electrical properties were characterized using a two-channel source measure unit (Keithley 2612) controlled by a computer. Fig. 3a shows the static characteristics of the inverter stages of the planar as well as of the stacked circuit, which are typical for unipolar printed

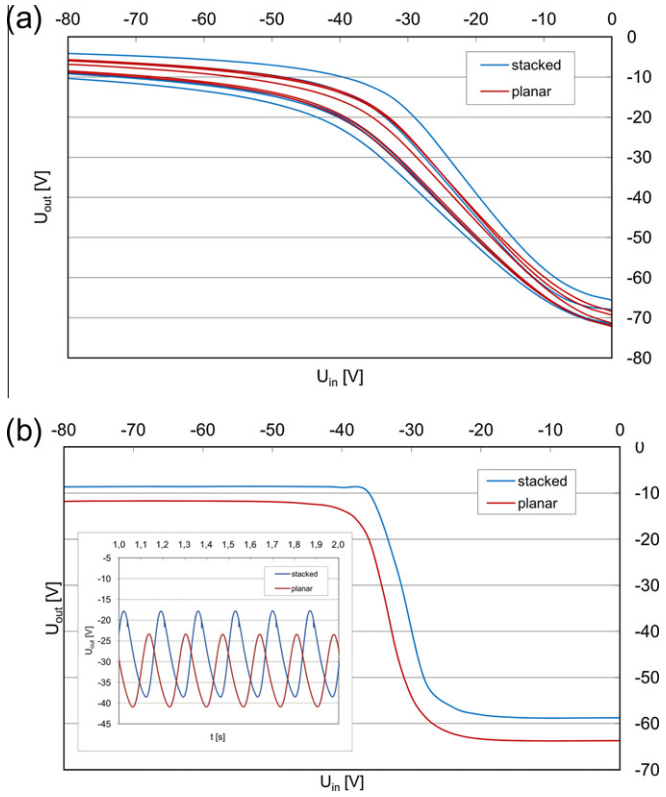

Fig. 3. (a) Static output characteristic of single inverter stages (for stacked and planar ring oscillator) at $V_{DD} = -80$ V. (b) Static output characteristic of 5-stage ring oscillators (stacked and planar) at $V_{DD} = -80$ V. Inset: oscillation of stacked and planar ring oscillator.

inverters. Within the variation of the individual characteristics there is no difference between the two circuits apart from a slightly larger variation in the case of the stacked ring oscillator, which is accidental. The static characteristics of five inverter stages connected in series of the planar and the stacked circuit, respectively, are plotted in Fig. 3b. The voltage swings are 52 V for the planar and 50 V for the stacked circuit, which is an insignificant difference. There is, however, a small shift of a few volts in both directions in between the curves, which can be attributed to the variations among the inverter stages. When the output signal of the last inverter stage is fed back into the input of the first stage, the ring oscillator delivers an oscillating signal. This is the case for both of the configurations; the frequencies of the oscillations, 6.0 Hz for the planar circuit and 5.9 Hz for the stacked circuit at a supply voltage of −80 V, are nearly identical. From these results we conclude that the characteristics of the ring oscillator circuit are not significantly affected by the vertical configuration. Generally alternate stacking of even and odd inverter stages is expected to have a positive effect on parasitic capacitances because of identical charge polarity of adjacent electrode layers (gate of even stage vs. source/drain of odd stage and vice versa) during operation. This "bootstrapping" effect probably compensates for parasitics introduced by vertical interconnects and is thereby responsible for the similar performance of stacked circuits as compared to planar ones.

4. Conclusions

Despite of the poor performance of printed transistors, the improvement of which is subject to investigations not considered here, the reported approach opens a new path for the enhancement of the lateral integration density and the complexity of interconnections in the field of printed electronics. In conventional printing technology it is state of the art to accurately stack and join hundreds of layers. Although technical requirements are different for the case of electronic circuits, there is no basic reason why an integrated printing and post-press processing of electronics should not be possible as well. Thereby the limitations of printed electronics in terms of minimum feature size and lateral integration density could be overcompensated: (a) lateral integration density is growing proportional to the number of layers; (b) interconnect lengths become shorter; (c) qualitatively new degrees of freedom in terms of circuitry emerge, because a significantly larger number of interconnects can be connected to a single contact point.

The path of future development of printed electronics might not be the quest for smaller devices and higher integration density in-plane, but printing of electronic structures on large areas which are converted to a batch of hundreds of layers, using post-press methods like folding and cutting. An interesting model for this kind of circuits is the biological brain. Individual neurons are poorly per-

forming in comparison with silicon transistors in terms of size, switching frequency etc. Instead, the superior performance of the system results from three-dimensional integration and neuronal circuitry. A similar type of circuitry might turn out to be suitable for printed electronics as well.

Bulk heterojunction

ABSTRACT

Hybrid films of ZnO nanoparticles and poly[2-methoxy-5-(3′,7′-dimethyloctyloxyl)-1,4-phenylene vinylene] (MDMO-PPV) were investigated as a model hybrid bulk heterojunction (HBHJ) photovoltaic cell which combines the simple processability and excellent electrical characteristics of inorganic nanoparticle acceptors and conjugated polymer donors. Improved photovoltaic performance was observed when the ZnO nanoparticles were stabilized with a new semiconducting surfactant, 2-(2-ethylhexyl)-1,3-dioxo-2,3-dihydro-1H-benzo[de]isoquinoline-6,7-dicarboxylic acid (BQ). We found that using the BQ surfactant increased the power conversion efficiency (1.23%) while a typical insulating surfactant, oleic acid (OA), decreased the efficiency (0.65%) despite the improvement of the ZnO dispersion, as compared to the HBHJ films prepared without a surfactant (0.75%). The underlying mechanism was delineated by hybrid-morphology study, photoluminescence spectroscopy, and photo-induced absorption spectroscopy.

1. Introduction

In recent years, polymer-based bulk heterojunction (BHJ) solar cells exhibiting promising power conversion efficiencies (PCE) up to 8% have been reported with fullerene derivatives, [6,6]-phenyl C61 butyric acid methyl ester ($PC_{61}BM$) or [6,6]-phenyl C71 butyric acid methyl ester ($PC_{71}BM$), as the electron acceptor [1–3]. Alternatively, inorganic semiconducting nanoparticles, such as TiO_2 [4,5], ZnO [6–10], and CdSe [11,12], have also been investigated as electron acceptors due to their higher electron mobility and lower cost as compared with PCBM. However, despite the high electron mobility, the photovoltaic performance of hybrid bulk heterojunction (HBHJ) photovoltaic cells prepared with inorganic semiconducting nanoparticles and p-type conjugated polymers is significantly lower than the BHJ photovoltaic cells prepared with PCBM. A maximum PCE of 3% was demonstrated for CdSe based HBHJ solar cells [13] and 2% was achieved for metal-oxide based HBHJ solar cells [4,9,12]. The severe aggregation of n-type inorganic nanoparticles in p-type organic polymers is considered to be the main reason for the poor efficiency because the hybrid morphology critically affects the charge separation, charge transport, and recombination in the HBHJ solar cells.

Many groups have been trying to improve the hybrid morphology of inorganic nanoparticles dispersed in polymer matrix by employing various methods such as surfactant addition or in situ HBHJ preparation from the deposited film containing a reactive precursor of inorganic nanoparticles [4–9,11,14]. Although the application of surfactants has become critical to suppressing the severe aggregation of inorganic nanoparticles, previous works mostly employed traditional surfactants such as oleic acid (OA), that are electrical insulators and thus block charge

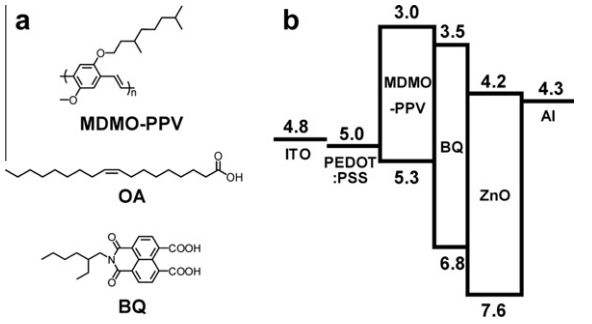

Fig. 1. A schematic diagram shows (a) the structure of MDMO-PPV, OA surfactant, and BQ surfactant, and (b) the energy level diagram of the materials comprising the HBHJ solar cell.

transport. Therefore, the advantage of using surfactants to improve the hybrid morphology was offset by the resultant decrease in charge mobility in the nanoparticle–polymer and nanoparticle–nanoparticle interfaces that are critical to the charge separation and transport in HBHJ solar cells. Although the surfactants could partly be removed from the HBHJ devices, this process also causes poor interfacial contact, and hence degrades the charge separation and transport. Therefore, in order to improve the efficiency of HBHJ cells, it is very desirable to employ non-removable surfactants with semiconducting characteristics of electron mobility and an appropriate energy level of the lowest unoccupied molecular orbital (LUMO). They will help not only with achieving a desired hybrid morphology of nanoparticles dispersed in polymer matrix, but also with intimate electronic contact and transport at the nanoparticle–polymer and nanoparticle–nanoparticle interfaces.

In this study, we investigated how the performance characteristics of HBHJ solar cells are affected by the application of different surfactants. For the n-type inorganic acceptor, we chose zinc oxide (ZnO) nanoparticles due to their easy synthesis and high electron mobility [15–18]. Among the many promising p-type semiconducting polymers, we selected poly[2-methoxy-5-(3′,7′-dimethyloctyloxyl)-1,4-phenylene vinylene] (MDMO-PPV) (Fig. 1a) that was shown to readily form HBHJ films with ZnO nanoparticles [10]. Two kinds of surfactants were investigated: insulating oleic acid (OA) and semiconducting 2-(2-ethylhexyl)-1,3-dioxo-2,3-dihydro-1H-benzo[de]isoquinoline-6,7-dicarboxylic acid (BQ) (Fig. 1a). The hybrid film morphology was studied by transmission electron microscopy (TEM) and atomic force microscopy (AFM), and the device performance was determined from J–V curve analysis. The effects of surfactants on the photoexcited states of ZnO/MDMO-PPV hybrid films were investigated using steady-state photoluminescence (PL) and quasi steady-state photo-induced absorption (PIA) spectroscopy.

2. Experimental details

2.1. Materials

MDMO-PPV which is known to have its glass transition temperature around 25–50 °C [19] was purchased from COVION (now Merck KGaA), with molecular weights of M_n 150,000, polydispersity index of 4.7. Poly(3,4-ethylene-dioxythiophene):poly(styrenesulfonate) (PEDOT:PSS, CLEVIOS™ P VP AI 4083) was purchased from CLEVIOS. Zinc acetate dihydrate ($Zn(Ac)_2{\cdot}2H_2O$, >98% purity) and potassium bromide (KBr, 99+%, FTIR grade) were obtained from Sigma–Aldrich. Potassium hydroxide (KOH, GR reagent) was obtained from Duksan Pharmaceutical Co. Ltd. All solvents used in this work are of analytical grade or purer. All chemicals mentioned above were used without further purification.

2.2. Synthesis of ZnO nanoparticles

The synthesis of ZnO nanoparticles was accomplished using minor modification of the procedure previously described in the literature [15]. The synthesis is carried out under N_2 atmosphere. At first, 1.23 g of $Zn(Ac)_2{\cdot}2H_2O$ was dissolved in 55 mL of methanol at room temperature. Then, 25 mL of a methanol solution containing 0.48 g of KOH is added dropwise over a 20 min time interval at 60 °C with magnetic stirring. After the KOH solution is added, the solution is stirred at 60 °C for 2 h. The product appears as a white precipitate. After collecting by centrifugation, this white precipitate is washed three times with methanol until it transforms to a gel-like precipitate. Each washing process includes dispersion into methanol by sonication and subsequent centrifugation. Finally, the gel-like precipitate is redispersed in chlorobenzene and 10 vol.% of propanol is added for stabilization. The resulting ZnO surface was stabilized with each surfactant and stored as a colloidal solution because of its inability to be redispersed after the complete removal of the solvent.

2.3. Photovoltaic cell fabrication and measurements

Photovoltaic devices were fabricated on cleaned indium tin oxide (ITO) patterned glass substrates. First a 40 nm layer of PEDOT:PSS was deposited on top of the ITO by spin coating and annealing at 120 °C for 30 min. Then the active layer was spun from a ZnO nanoparticle/MDMO-PPV (2:1 ratio by mass) solution using chlorobenzene:propanol (10 vol.%) as the solvent. The thickness of the resulting hybrid film is around 110 (±10) nm, as determined by AFM. After spin coating, 0.5 nm of LiF and 100 nm of Al are deposited onto the active layer by thermal evaporation. All the current density–voltage (J–V) characteristics of the photovoltaic devices were measured in ambient conditions using a computer-controlled Keithley 237 source measure unit; the measurements in vacuum showed practically the same results. The active device area was 0.20 cm^2 and the device performance was measured with 100 mW cm^{-2} AM 1.5G illumination using a commercial solar simulator (Newport91160A). To avoid direct optical excitation of ZnO nanoparticles, a 435 nm long pass UV filter was inserted between light source and device, which slightly decreased the final illumination power to 95 mW cm^{-2}. The EQE measurements were performed using chopped monochromatic light and lock-in detection. A homebuilt setup, utilizing a 300 W Xenon lamp (Müller Elektronik–Optik) and a monochromator (SpectraPro-150, Acton Research Corp.), was used for the light source. The

incident light was chopped at 113 Hz with an optical chopper (model 651, EG&G Instruments). The sample photocurrent was acquired at 0 V bias with DSP lock-in amplifier (model 7265, Signal Recovery). The monochromatic light was focused on the sample using optical lens with 3 mm diameter. The light power versus wavelength was measured with a calibrated silicon photodiode (Hamamatsu Corp.). These measurements were performed without bias illumination.

To obtain UV–Vis, PL, PIA spectra, and AFM images, the same conditions for photovoltaic cell fabrication were used with the exception of thermal evaporation of electrodes. For TEM measurements, thinner film thickness (40 nm) was prepared by controlling the concentration with the same weight ratio of MDMO-PPV and ZnO nanoparticles and then the prepared film was floated onto the surface of deionized water and picked up by a copper grid. The images were acquired with a Hitachi H-7600 transmission electron microscope operated at an acceleration voltage of 100 kV. The AFM images were obtained with PSIA XE-100 atomic force microscope at non-contact tapping mode. UV–Vis spectra were recorded using a JASCO V-530 UV–Vis spectrophotometer. Photoluminescence (PL) spectra were measured using a JASCO FP-6500 spectrofluorometer. PIA spectra were measured at 80 K with excitation at 530 nm wavelength by a LED light source, ca. 100 mW cm^{-2} intensity and a modulation frequency of 317 Hz. The resulting change in transmission was monitored at each wavelength with a dispersed tungsten-halogen light source as a probe and using Si and Ge detectors and with lock-in detection. Cyclic voltammetry was performed using Pt electrodes as the working and counter electrodes, and Ag/Ag^+ as the reference electrodes on a CHI 700C electrochemical instrument at a scan rate of 100 mV s^{-1}. Tetrabutylammonium hexafluorophosphate (0.1 M) in tetrahydrofuran was the electrolyte. The redox potentials (E_{ox} and E_{red}) were calibrated by using ferrocene (Fc) as the standard, whose HOMO energy level is −4.8 eV.

3. Results and discussion

The solvent-stabilized ZnO nanoparticles employed in this work were synthesized by hydrolysis and condensation method [15] with some minor modifications (see Section 2 for details). The estimate of ZnO nanoparticle size from $\lambda_{1/2}$ of the UV–Vis absorption spectrum of the nanoparticles in solution yielded an average particle diameter of 3.2 nm [20], in agreement with the size estimated by TEM image. (Figure S1).

We employed two different surfactants in our study, namely, oleic acid (OA) which is a conventional insulating surfactant and a newly synthesized semiconducting surfactant with a reasonable electron mobility, 2-(2-ethylhexyl)-1,3-dioxo-2,3-dihydro-1H-benzo[de]isoquinoline-6,7-dicarboxylic acid (BQ) (Fig. 1a). The details of the synthetic procedure are shown in the Supplementary Material [21]. OA is a typical surfactant adopted for improving the dispersion properties of inorganic nanoparticles in polymers [11]. BQ has two carboxylic acid groups that can attach to the surface of ZnO nanoparticles and the benzoisoquinoline aromatic group with 2-ethylhexyl side chain, which should be miscible with conjugated polymers. The energy levels of BQ were determined from the cyclic voltammetry and UV–Vis spectra and appear to be appropriate for electron transfer from MDMO-PPV to ZnO nanoparticles when compared with other materials of the HBHJ solar cells (Fig. 1b). Furthermore, the electron mobility of BQ was estimated by the time-of-flight technique to be approximately 10^{-7} cm^2/Vs. (See Supplementary Material for the detailed characteristics of BQ).

The absorbance and the PL spectra of ZnO/MDMO-PPV hybrid films, shown in Fig. 2, were measured on quartz substrates coated with poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) hole transport layer. The UV–Vis spectrum of MDMO-PPV had the maximum absorption peak at 495 nm. It remained unchanged upon addition of ZnO nanoparticles, regardless of the type of added surfactant. The PL emission of the MDMO-PPV was significantly quenched by the addition of ZnO nanoparticles. Moreover, the quenching efficiency of PL spectra of the hybrid films showed a large difference depending upon the added surfactant. The highest PL quenching was achieved in samples prepared with BQ as the stabilizing surfactant of ZnO nanoparticles, while the hybrid films prepared with OA-stabilized ZnO nanoparticles exhibited a reduced quenching efficiency as compared to the hybrid films prepared without a surfactant. Therefore, these PL results show that the semiconducting surfactant BQ resulted in increasing the electron transfer from the excitons of MDMO-PPV to ZnO while the insulating surfactant OA resulted in decreased electron transfer, compared to the hybrid films prepared without any surfactant.

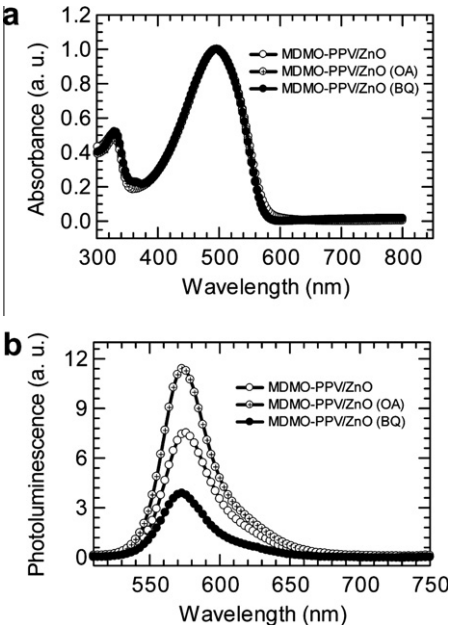

Fig. 2. Normalized (a) UV–Vis, and (b) photoluminescence (excited at 500 nm wavelength) spectra of the ZnO/MDMO-PPV hybrid films spin-coated from ZnO nanoparticles, without a surfactant (open circle), stabilized with OA (open circle with cross), and stabilized with BQ (closed circle).

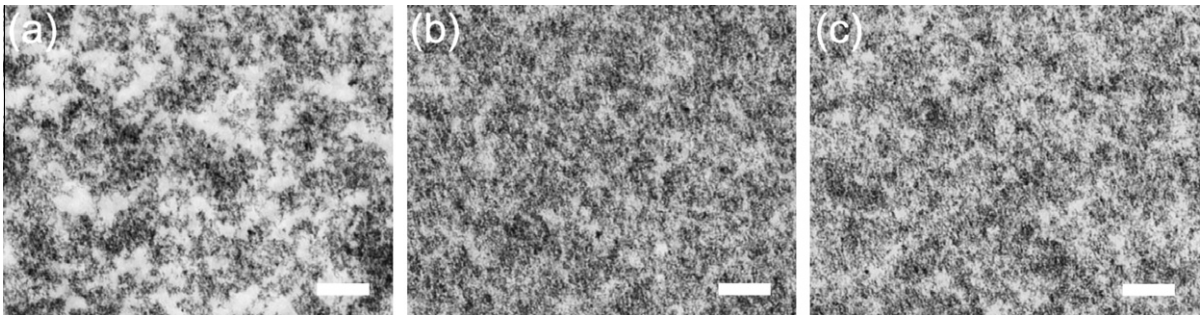

Fig. 3. TEM images of the ZnO/MDMO-PPV hybrid films prepared without a surfactant (a), with OA (b), and with BQ (c). The scale bar indicates 100 nm.

Morphological investigation of the ZnO/MDMO-PPV hybrid films was performed by TEM and AFM. ZnO/MDMO-PPV hybrid films prepared without any surfactant showed a root mean square (RMS) roughness of 4.3 nm by AFM. Applying surfactants to stabilize the nanoparticles in solutions improved the hybrid morphology due to better dispersion of ZnO nanoparticles in the polymer matrix, resulting in an RMS roughness of 2.8 nm for OA and 3.2 nm for BQ. Corresponding changes in the internal microstructure investigated by TEM are shown in Fig. 3. The TEM results clearly showed that both surfactants significantly suppressed the aggregation of ZnO nanoparticles in the MDMO-PPV matrix.

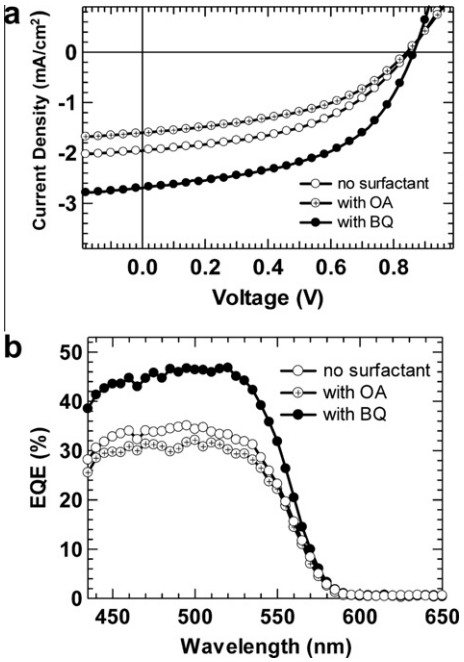

Fig. 4. (a) J–V characteristics, and (b) external quantum efficiency (EQE) of ZnO/MDMO-PPV HBHJ solar cells, prepared without a surfactant (open circle), with OA (open circle with cross), and with BQ (closed circle).

The J–V curves of the ZnO/MDMO-PPV (2:1 ratio by mass) HBHJ devices were measured to investigate the photovoltaic performance. A high open circuit voltage (V_{oc}) of 0.88 V was achieved as expected due to the low HOMO energy level of MDMO-PPV. Together with a short circuit current (J_{sc}) of 1.83 mA cm^{-2} and a fill factor (FF) of 0.44, the power conversion efficiency (PCE) reached 0.75% without any thermal/solvent processing treatment (Fig. 4a and Table 1). This result is somewhat lower than the value reported by Beek et al. [10], but this may be a result of slightly different device preparation and measurement conditions. An increased PCE of 1.23% was observed when approximately 3% (relative to ZnO by mass) BQ surfactant was used for the stabilization of ZnO nanoparticles, with V_{oc} = 0.86 V, J_{sc} = 2.86 mA cm^{-2}, and FF = 0.48. The main reason for the improved efficiency derives from an enhanced J_{sc} when BQ is used as a surfactant. The external quantum efficiency (EQE) was measured and found to reflect the trend in J_{sc} with a maximum EQE over 45% with BQ surfactant (Fig. 4b). On the other hand, applying the same amount of OA surfactant to stabilize the ZnO nanoparticles reduced the J_{sc} and resulted in a decreased PCE of 0.65%, although the OA surfactant significantly improved the dispersion of ZnO nanoparticles, as shown in Fig. 3. The values of the series resistance R_s, also shown in the table, clearly show that the short circuit current is limited by the charge transport at the interface.

To further investigate the surfactant effects on PCE, quasi steady-state photo-induced absorption (PIA) spectra of various ZnO/MDMO-PPV hybrid films were measured

Table 1
Summary of photovoltaic properties of the ZnO/MDMO-PPV HBHJ solar cells prepared with different surfactants[†].

	J_{sc} (mA cm^{-2})	V_{oc} (V)	FF	PCE_{avg} (%)	R_s (Ω cm^2)
Without surfactant	1.83	0.88 (±0.03)	0.44 (±0.04)	0.75 (±0.18)	90.5
With OA	1.56	0.88 (±0.06)	0.45 (±0.02)	0.65 (±0.23)	112
With BQ	2.86	0.86 (±0.07)	0.48 (±0.03)	1.23 (±0.23)	35.7

[†] Uncertainty in the typical device characteristics is estimated by one standard deviation from the mean obtained from over 15 devices and five batches of ZnO preparations. The standard deviation in PCE mainly results from the batch to batch variation of ZnO nanoparticle preparation/handling conditions, while it is much smaller within each batch. The standard deviations in J_{sc} and R_s track the trend in PCE.

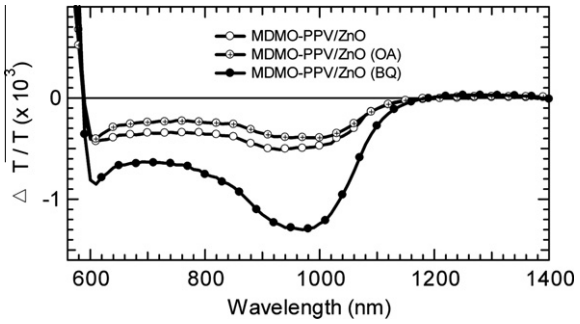

Fig. 5. Normalized photo-induced absorption spectra of ZnO/MDMO-PPV hybrid films, prepared without a surfactant (open circle), with OA (open circle with cross), and with BQ (closed circle), recorded at 80 K with excitation at 530 nm wavelength, ca. 100 mW cm^{-2} intensity and modulation frequency of 317 Hz.

(Fig. 5). The spectra were measured from 600 to 1400 nm at 80 K with excitation from a 530 nm LED light source (see Section 2), and the signal intensity was corrected for the absorption of the films. The PIA of the MDMO-PPV cations is clearly observed at 970 nm. The highest steady-state concentration of MDMO-PPV cations, i.e., the most intense PIA signal, was observed for the hybrid film prepared with BQ stabilized ZnO nanoparticles, while films prepared with OA stabilized ZnO nanoparticles showed a lower concentration of MDMO-PPV cations as compared to the films prepared without a surfactant. Clearly, the PIA results are in line with the trend in PCE observed for the various HBHJ devices. These results are also consistent with the observed PL quenching efficiency and demonstrate that improved electron transfer from MDMO-PPV to the ZnO nanoparticles is the main reason for the enhanced PCE as a consequence of the improved hybrid morphology. Although the OA surfactant also improved the morphology, the electron transfer from MDMO-PPV to the ZnO nanoparticles was partly blocked by the insulating nature of OA surfactant.

4. Conclusions

In conclusion, the dispersion morphology of hybrid bulk heterojunction films from ZnO nanoparticles and MDMO-PPV was significantly improved upon applying two different surfactants, insulating OA and semiconducting BQ. However, the larger interfacial area obtained by the better dispersion of ZnO nanoparticles led to an improved PCE of HBHJ solar cells only when the semiconducting BQ surfactant was used due to its appropriate energy level and electron mobility (10^{-7} cm^2/Vs) which facilitates efficient electron transfer. Devices using the newly synthesized BQ surfactant showed an enhanced photovoltaic efficiency up to 1.23%, nearly 60% increase over the surfactant-free device, as a consequence of an enhanced short circuit current resulting from more efficient charge separation and transport. Therefore, developing novel n-type semiconducting surfactants with appropriate energy levels and electron mobility could open a very promising avenue for significantly improving the efficiency of hybrid bulk heterojunction photovoltaic cells.

ABSTRACT

Organic field-effect transistors (OFETs) based on the pentacene semiconductor with an embedded thin layer of copper oxide (CuO) were investigated. The drain current of OFETs with a thin CuO layer embedded in pentacene increases more than three times compared to that of traditional OFETs without the CuO layer, and the threshold voltage shifts from −17.5 V to −7.9 V. A possible mechanism for OFETs with the CuO layer was discussed via analysis of electron transfer near the contact between CuO and pentacene. OFETs with the CuO layer exhibit an interesting result of a systematic tuning of threshold voltage by controlling the initial voltage of gate-to-source upon scanning transfer curves.

1. Introduction

Organic field-effect transistors (OFETs), as the critical component of organic integrated circuits (ICs), have attracted considerable attention due to their low cost, easy processability, flexibility, and applicability in large-area devices [1,2]. Nowadays, great efforts have been devoted to design and synthesize organic semiconductors as well as to fabricate OFETs with high performance, high stability and low cost [3–5]. However, there are still many challenges of restricting their practical applications in organic ICs, such as wide range tuning of the threshold voltage (V_{TH}). So far, the works on tuning of V_{TH} to control OFETs at low-power modes have made a progress [6–11]. For example, the V_{TH} of OFETs can be tuned by using polar self-assembled monolayers [6], depositing an additional layer of organic acceptor on the top of channel [7], and using ferroelectric gate dielectrics [8] or ion-dispersed gate dielectrics [9,10]. In addition, the shift of threshold voltage could be observed in a single OFET with molybdenum trioxide (MoO_3) covered on the surface of p-bis [(p-styry1) styry1] benzene single crystal [11]. However, these methods are slightly complicated to systematically control V_{TH} in a wide range. In inorganic FETs, doping in the active channel was used to accurately control the V_{TH} of the devices [12]. For organic semiconductors, we found an efficient way to systematically tune V_{TH} in OFETs by embedding a copper oxide acceptor layer in the semiconductor layer.

Copper oxide was normally used for hole injection layer in the OFETs [13] or organic light-emitting diodes (OLEDs) [14,15]. In this paper, we significantly improved both V_{TH} and mobility of the OFETs by embedding a thin CuO layer inside the pentacene semiconductor. Furthermore, a systematic tuning of threshold voltage of the OFETs can be realized by controlling the initial scanning voltage upon measurement of transfer curves. A possible mechanism for the results is discussed.

2. Experimental

The OFETs were fabricated with a top contact configuration (Fig. 1) by using a heavily-doped n-type silicon wafer

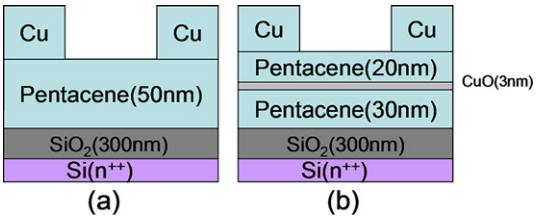

Fig. 1. Cross section of the OFETs, (a) pentacene-based OFET (b) CuO-embedded OFET.

with a 300 nm thick layer of thermally oxided SiO_2 (C_i = 10nF), serving as the gate electrode and gate insulator, respectively. The wafers were cleaned with deionized water, acetone and isopropanol for 10 min in sequence. Pentacene and CuO were thermally deposited at rate of 0.5 Å/s and 0.3 Å/s, respectively, in a vacuum chamber under a pressure of 3×10^{-4} Pa. The 3 nm thick CuO is sandwiched in the pentacene layer with a distance of 30 nm apart from the interface of SiO_2 and pentacene. The total thickness of the pentacene is 50 nm. The Cu source and drain electrodes (40 nm-thick) were then thermally evaporated through a shadow mask. The length (L) and width (W) of the channel were 100 μm and 10,000 μm, respectively. Fig. 1a and b shows the schematic structures of pure pentacene OFET (pentacene-based OFET) and CuO layer embedded pentacene OFET (CuO-embedded OFET). The electrical characteristics of OFETs were measured by using a semiconductor parameter analyzer (Agilent 4155C) at room temperature. The absorption spectra were recorded by using a UV–Vis spectrophotometer (HP 8453). The XPS spectra were measured by using Mutil-photoelectron spectroscopy (Kratos AXis Ultra (DLD)).

3. Results and discussion

Output and transfer characteristics of pentacene-based OFET and CuO-embedded OFET, are shown in Fig. 2 and in Fig. 3, respectively. Obviously, a great increase in saturation current (I_D) of CuO-embeded OFET was observed. The field-effect mobility of OFET in the saturation region can be calculated from the following equation [16].

$$I_D = \frac{W\mu C_i}{2L}(V_{GS} - V_{TH})^2 \quad (1)$$

where C_i is the capacitance of per unit area of the gate insulator, V_{GS} is the gate-to-source voltage, and V_{TH} is the threshold voltage. The mobility, V_{TH} , and current on/off ratio of the pentacene-based OFET are obtained from Eq. (1) to be 0.06 $cm^2 V^{-1} S^{-1}$, −17.5 V, and 4.5×10^4, respectively, while the corresponding parameters of CuO-embedded OFET are 0.18 $cm^2 V^{-1} S^{-1}$, −7.9 V, and 1.4×10^4, respectively. The results show that both hole mobility and V_{TH} are much improved in the CuO-embedded OFET.

3.1. Function of CuO embedded layer

The V_{TH} shift of OFET was usually originated from the following two reasons: (1) slow polarization of the gate dielectric [17]; (2) charge trapping at the interface between dielectric and semiconductor [18] or in the organic semiconductor [19]. Since the polarization of SiO_2 dielectric was hardly occurred in this case, we prefer to the second reason as stated below. In order to clarify the V_{TH} shift mechanism, time domain measurement was carried out in ambient air. This method was often used to determine the type of charge trapping in OFETs [20]. At the beginning, a gate-to-source voltage (denoted as V_{GS0}) was constantly applied for 100 s (for gaining clear signal), and then abruptly stepped to a constant gate-to-source voltage of V_{GS1} (−20 V) for another 100 s. The source-drain current (I_D) was measured under source-to-drain voltage (V_{DS}) at −10 V. Fig. 4a and b shows $-I_D$ versus time (t) curves of applied voltages for both CuO-embedded and pentacene-based OFETs under different V_{GS0}, respectively.

For the p-type CuO-embedded OFET, when the V_{GS} switched from V_{GS0} with negative values (−30 V or −50 V) to V_{GS1} (−20 V), the current ($-I_D$) was slightly decreased and then fixed in the value of about 2.0×10^{-5} A. However, when the V_{GS} switched from V_{GS0} with positive values (30 V or 50 V) to V_{GS1} (−20 V), the current ($-I_D$) was remarkably enhanced. The results of CuO-embedded OFETs suggest that positive V_{GS0} could induce extra hole accumulation in the OFET channel, resulting in current increase under polar change of V_{GS} from positive V_{GS0} to negative V_{GS1}. The production of extra holes was considered to be due to electron trapping in the active layer at a positive V_{GS0} [21]. However, the negative V_{GS0} could not induce any extra charged carriers in p-type OFET. So the $-I_D$ was fixed to a constant value after V_{GS} switched from negative V_{GS0} to

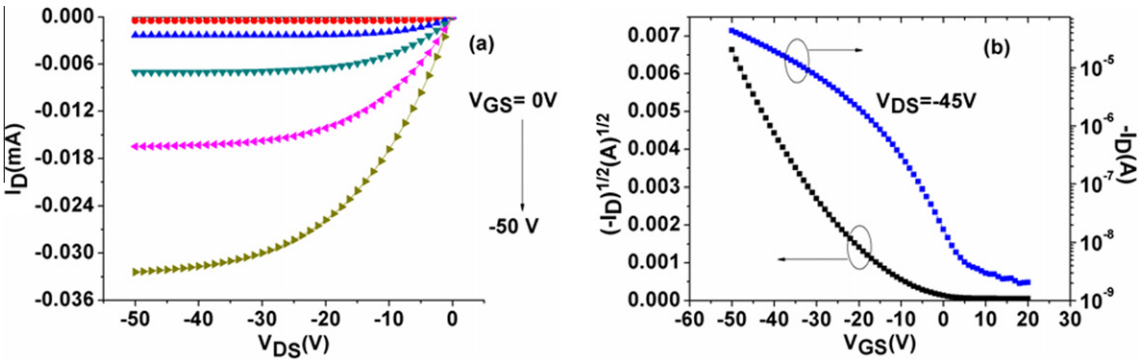

Fig. 2. Output characteristics (a) and transfer characteristics (b) of pentacene-based OFET.

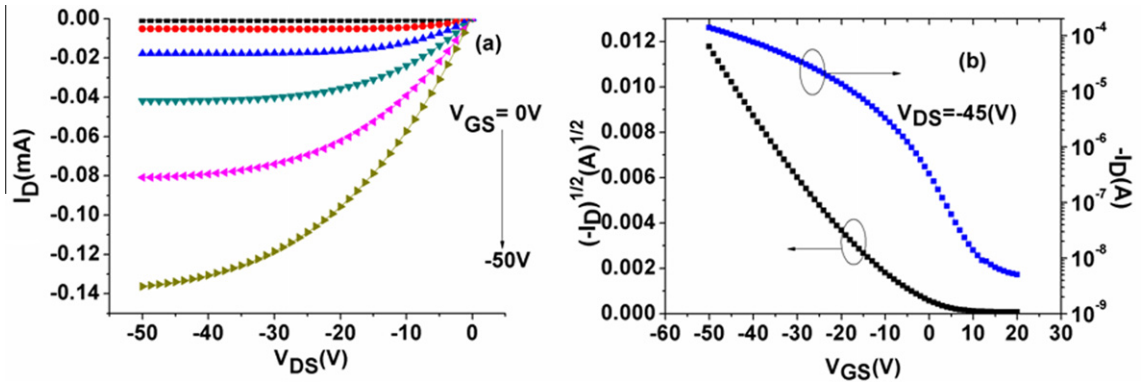

Fig. 3. Output characteristics (a) and transfer characteristics (b) of CuO-embedded OFET.

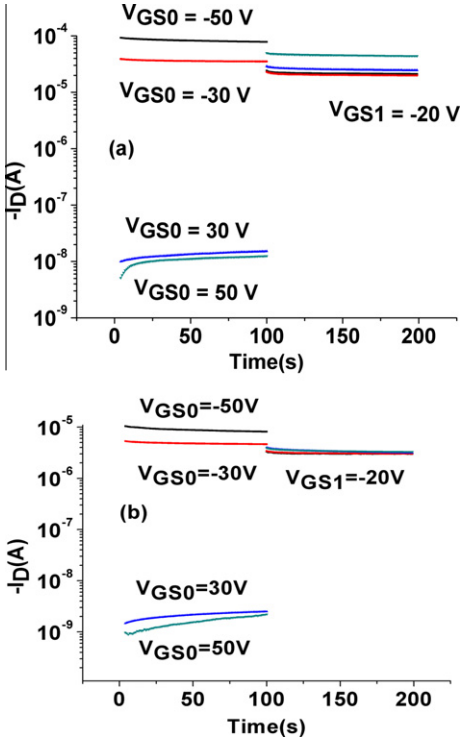

Fig. 4. Time domain measurements of the OFETs (a) CuO-embedded OFET, (b) pentacene-based OFET, in ambient air at different V_{GS0} (V_{GS0} = −50,−30,30,50 V), and V_{GS1} = −20 V, V_{DS} = −10 V.

V_{GS1} (−20 V). In addition, when V_{GS0} was applied at positive value, the larger the V_{GS0} value, the higher the value of $-I_D$ was obtained after switching V_{GS} from positive V_{GS0} to V_{GS1} (−20 V). For example, $-I_D = 2.5\text{x}10^{-5}$ A for V_{GS0} = 30 V, while $-I_D = 4.5 \times 10^{-5}$ A for V_{GS0} = 50 V (see Fig. 4a). The data suggests that electron trapping population could increase with increasing the positive value of V_{GS0}. No such phenomenon was observed from pentacene-based OFETs (see Fig. 4b), hence it was further confirmed that the CuO layer could trap electrons and induce holes in pentacene. The detailed discussion for the roles of the embedded CuO layer is given below.

The capability of CuO accepting electrons could result in electron transfer from pentacene to CuO and formation of charge transfer (CT) complexes between CuO and pentacene, as confirmed by the absorption spectra [22] (see Fig. 5a). The absorption spectrum of the CuO-doped pentacene film shows the additional absorption peaks at around 423 nm and 1000 nm, indicating the electron transfer from pentacene to high work-function CuO (5.3 eV [23]). In addition, X-ray photoelectron spectra (XPS) can also confirm electron transfer at the interface between pentacene and CuO layers, as shown in Fig. 5b. The Cu $2p_{3/2}$ peak shifts to higher energies as shown in the XPS spectra of sample (E). Since a negatively charged atom has a higher binding energy of electrons [24], the peak shift further verifies electron transfer from pentacene to CuO and formation of CT complexes at their interface. The CT complexes could push the Fermi level of pentacene toward its highest occupied molecular orbital (HOMO), because it is p-type doping system [25,26]. The shift of Fermi level can reduce bulk hole trap density in pentacene [26,27] and enhance the bulk hole injection [27]. Therefore, the improvement of field-effect mobility of CuO-embedded OFETs could be attributed to the formation of CT complexes at the CuO/pentacene interfaces. The holes supplied from the CT complexes enhance the drain current and result in the threshold voltage shift from −17.5 V to −7.9 V (see Figs. 2 and 3). Additionally, the field-effect mobility of the CuO-embedded OFET does not vary with V_{GS0} after time domain measurements, as shown from the almost unchangeable slopes of the $(-I_D)^{1/2}$ versus V_{GS} curves in Fig. 6. In this case, similar to the V_2O_5 [28] and MoO_3 layers [29], the embedded CuO layer could act as a charge-generation layer when a positive V_{GS0} was applied. In CuO layer, electrons and holes were dissociated under positive V_{GS0}, and the generated electrons were trapped at the interface between pentacene and CuO due to the poor electron-transporting ability of pentacene and electron traps of CuO surface. The trapped electrons can induce holes in pentacene semiconductor. The larger the V_{GS0} value, the more electron–hole pairs were generated in CuO layer, leading to the higher source-drain current ($-I_D$) (see Fig. 4a). Therefore, the trapped electron population in CuO could be controlled by adjusting of positive V_{GS0}.

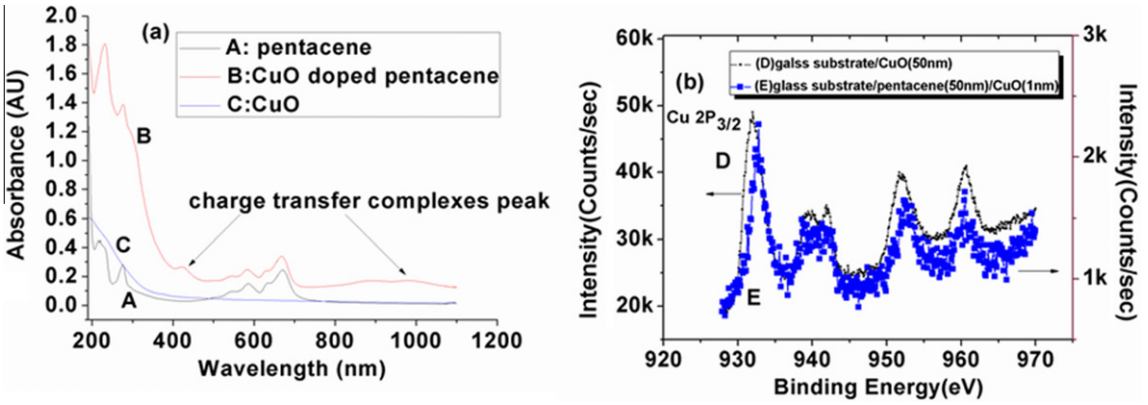

Fig. 5. (a) UV–Vis absorption spectra of samples of (A) pentacene, (B) CuO-doped pentacene and (C) pure CuO films on quartz substrate. (b) XPS spectra: Cu $2p_{3/2}$ peak observed in the samples of (D): glass substrate/CuO (50 nm), and (E): glass substrate/pentacene (50 nm)/CuO (1 nm).

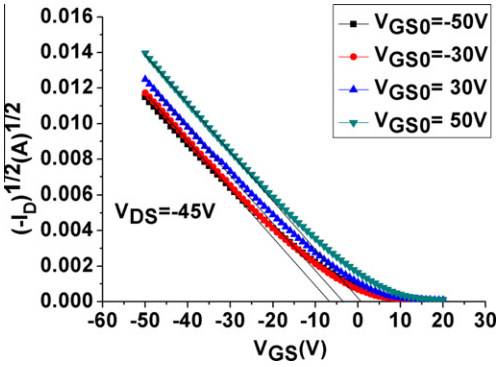

Fig. 6. $(-I_D)^{1/2}$ versus V_{GS} transfer curves for the CuO-embedded OFET after the time domain measurements at different V_{GS0} (V_{GS0} = −50, −30,30,50 V), respectively.

3.2. Tuning of V_{TH}

The shift of V_{TH} is related to trapped charges in OFETs according to the following equation [30].

$$Q_{trap} = -\Delta V_{TH} C_i \quad (2)$$

where Q_{trap} is the amount of trapped charge, ΔV_{TH} the shift of V_{TH}, and C_i the capacitance of per unit area of the gate insulator. If the trapped electrons can be controlled, the V_{TH} of OFETs can be strictly tuned. So the V_{TH} of CuO-embedded OFET depended on the trapped electron population in CuO, and could be changeable with the positive V_{GS0}. The induced holes could act as a floating gate voltage that can influence the threshold voltages. When adjusting

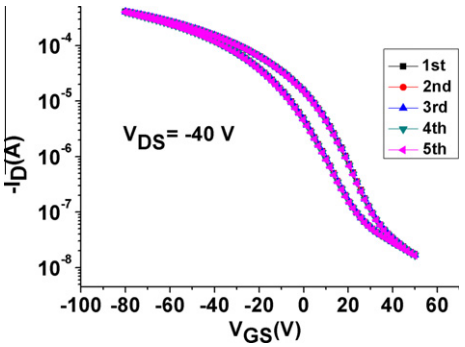

Fig. 8. I_D–V_{GS} transfer curves at V_{DS} = −40 V measured for five times. Each transfer curve is double-swept, V_{GS} scans from 50 V to −80 V then back to 50 V.

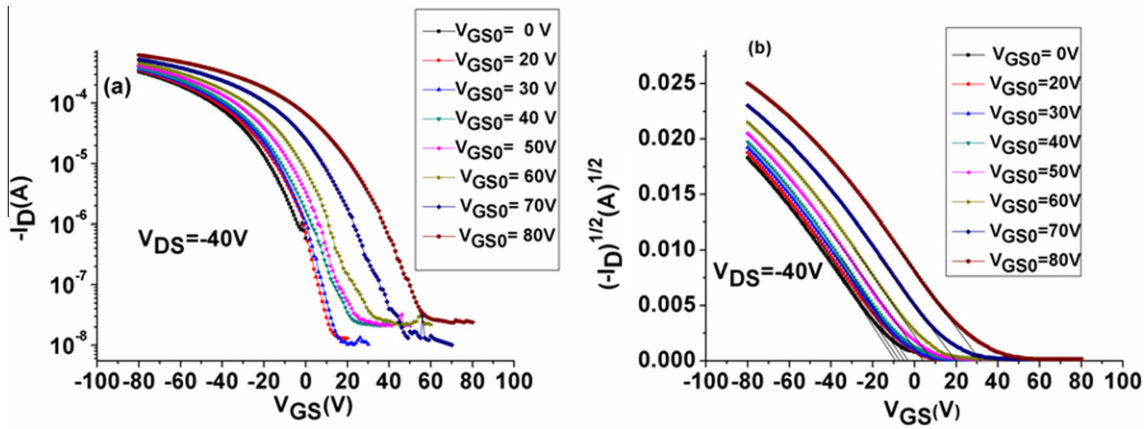

Fig. 7. (a) Log plots of $-I_D$ versus V_{GS} and (b) $(-I_D)^{1/2}$ versus V_{GS} transfer curves for CuO-embedded OFET with different V_{GS0}: 80, 70, 60, 50, 40, 20 and 0 V.

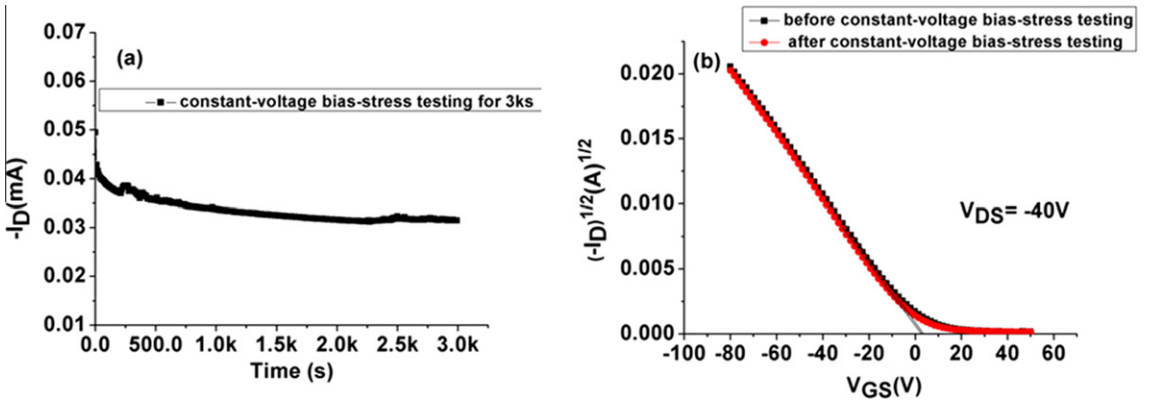

Fig. 9. (a) Drain current as a function of stress time over a period of 3×10^3 s for a constant voltage-bias stress testing, the time interval is 10 s, and the drain current was measured at $V_{GS} = -30$ V and $V_{DS} = -30$ V. (b) $(-I_D)^{1/2}$–V_{GS} transfer curves with $V_{DS} = -40$ V before and after constant-voltage bias-stress testing over a period of 3×10^3 s, respectively.

positive V_{GS0}, trapped electrons in CuO could be changed as discussed (see Fig. 4a). In the transfer curves, when changing the starting gate-to-source voltages (V_{GS0}) in positive range, systematic tuning of the V_{TH} of the CuO-embedded OFET can be realized. For example, when V_{GS0} varies from 0 V to 80 V, the transfer curves regularly shift from negative voltage to positive voltage, and the V_{TH} shifts from −9.5 V to 32.5 V (as shown in Fig. 7a and b). The shift of threshold voltage was not observed in pentacene-based OFET (data is not shown here). Therefore, the systematic tunable V_{TH} in our device can be ascribed to the fact that V_{GS0} influenced the trapped electron population at the interface between CuO and pentacene layers.

3.3. Stability of V_{TH}

To investigate the stability of the tuned V_{TH}, the transfer curves with V_{GS0} at 50 V were repeatedly measured in five times, and exhibited a good repeatability (see Fig. 8). On the other hand, the drain current was measured with $V_{GS} = -30$ V and $V_{DS} = -30$ V at the mode of constant-voltage bias-stress testing for 3×10^3 s (as shown in Fig. 9a), exhibiting a very small decrease of the drain current. The $(-I_D)^{1/2}$ versus V_{GS} transfer curves were then measured at V_{GS0} of 50 V, exhibiting almost unchangeable V_{TH} after constant-voltage bias-stress testing over a period of 3×10^3 s, as shown in Fig. 9b. The results suggest that the trapped electrons at the interface between CuO and pentacene layers are not easily released and the tuned V_{TH} is stable.

4. Conclusion

An organic field-effect transistor based on pentacene with an embedded CuO layer was investigated. With the thin CuO layer embedded in the pentacene semiconductor, the drain current was increased and the threshold voltage shifted from −17.5 V to −7.9 V. The interesting results are attributed to the formation of CT complexes at the interface of CuO and pentacene. Electrons trapped in CuO can induce holes in pentacene. The induced holes act as a floating gate voltage that influences the threshold voltages. The regular tuning on threshold voltages of CuO-embedded OFET is achieved by scanning the transfer curves with different starting positive gate-to-source voltage (V_{GS0}) because the population of trapped electrons can be changed by setting the V_{GS0}. The threshold voltages are stable under stress of source-to-drain and gate-to-source voltages.

Morphology

ABSTRACT

The change of morphology in mixed layers due to different substrate temperature T_{sub} of organic solar cells containing C_{60} and zinc phthalocyanine (ZnPc) is studied. Heating the substrate during deposition of the bulk heterojunction C_{60}:ZnPc leads to a significant improvement of solar cell performance, mainly due to an increase in photocurrent and fill factor (*FF*). This is attributed to improved charge carrier percolation pathways within the C_{60}:ZnPc blend. Using atomic force microscopy, scanning electron microscopy, transmission electron microscopy, organic field effect transistor, X-ray diffraction, and absorption measurements, we observe aggregation, cluster-like, and polycrystalline growth of the heated bulk layer. This provides better transport percolation paths by inducing a phase separation of the molecules. Heated blend layer with thickness of 60 nm shows high performance without loss in *FF*. When heating the substrate to the optimum temperature of 110 °C, a power conversion efficiency of 3.0% is achieved, compared to 1.4% for an identical device prepared on a substrate held at room temperature.

1. Introduction

Since the first copper phthalocyanine/perylene derivative-based flat heterojunction organic solar cell (OSC) by Tang [1], OSCs have attracted considerable interest as a potential cost-efficient alternative to current inorganic solar cells. However, a drawback of flat heterojunction OSC is that the photoactive layer thickness is usually limited by the exciton diffusion length L_D, i.e. the average distance that the excitons diffuse before recombination. Typical values of L_D are in the range of 5–30 nm [2]. This limitation can partially be overcome by the concept of bulk heterojunctions (BHJ) [3–6], consisting of a mixture of donor and acceptor molecules, e.g. fullerene C_{60}:zinc phthalocyanine (ZnPc). Thicker BHJ layers can lead to increased photon harvesting due to higher absorbance and efficient dissociation of photogenerated excitons at the distributed donor–acceptor interface throughout the bulk. A challenge associated with BHJ is that during film deposition, isolated clusters of donor or acceptor molecules can form which have no direct charge carrier percolation path towards an electrode. These clusters or dead ends act as recombination sites, reducing photocurrent and fill factor *FF*. Furthermore, the charge carrier mobilities are also limited due to higher molecular disorder in an amorphous BHJ compared to a pristine crystalline layer [27]. In order to achieve higher photocurrent, it is necessary to control morphology and properties of the BHJ, e.g. by heating, as shown by Suemori et al. [7]. It is desirable to improve the percolation network to reduce isolated clusters and trap sites.

In this contribution, we show improved morphology of a C_{60}:ZnPc BHJ and the formation of percolation paths due to controlled substrate heating, leading to efficient OSC with blend layers of 60 nm.

Despite thicker layers than a standard C_{60}:ZnPc cell with a 30 nm thick BHJ [8], reasonable *FF* of over 55% are achieved. Combined with a photocurrent increase by over 40%, the power conversion efficiency (η) is increased from 1.4% to 3.0%.

The correlation between substrate temperature T_{sub} and OSC performance for 150 nm thick C_{60}:ZnPc blend layers has recently been studied by us [12]. There, the temperature was varied in-situ during evaporation of the organic C_{60} and ZnPc layers between room temperature (RT) and 130 °C. An optimum substrate temperature for this absorber system was found at 110 °C.

In this work we investigate in more detail the mechanism that determine the correlation of substrate temperature and device characteristics. Different characterization tools, e.g. atomic force microscopy (AFM), scanning electron microscopy, transmission electron microscopy (TEM), and organic field effect transistors are applied to gather, information for our studies.

2. Experimental

The solar cells are fabricated in a custom-made multichamber ultrahigh vacuum (UHV) evaporation system (BESTEC, Germany) at a base pressure of 10^{-8} mbar. As substrate, pre-structured tin-doped indium oxide (ITO)-coated glass (Thin Film Devices, USA) is used. The substrates are cleaned in ultrasonic baths with detergent, acetone, ethanol, and iso-propanol prior to processing.

For sample heating during deposition, an additional fully ITO-coated glass substrate is put beneath the sample. The substrate temperature (T_{sub}) is controlled by resistive heating of the ITO layer and is monitored by a thermocouple as depicted in Fig. 1.

The OSC stack consists of ITO, followed by 5 nm of C_{60} and a blend layer of 60 nm co-evaporated C_{60} and ZnPc (volume ratio 1:1). The subsequent layer system consists of 5 nm *N*,*N*′-di(4-(2,2-diphenyl-ethen-1-yl)-phenyl)–*N*,*N*′-di(4-methylphenylphenyl)benzidine (PV-TPD, Sensient), 20 nm of PV-TPD [9] doped with 3.2 wt% of a p-type dopant NDP2 (Novaled AG, Dresden, Germany) [10], and 10 nm of 4.4 wt% p-doped ZnPc. These layers are used as hole transport layers and as electron and exciton blocker, to place the maximum of the optical field within the photoactive layer, and to ensure low energy barriers for good hole extraction to the Au electrode [11]. Finally, a 40 nm reflective Au back contact is deposited.

All organic materials except for the p-dopant had been purified at least twice by vacuum gradient sublimation to remove contaminations. The typical solar cell area is nominal ≈6.4 mm^2, defined by the overlap of ITO and Au.

J(*V*)-characteristics are recorded using a source measurement unit 236 SMU (Keithley) and an AM 1.5G sun simulator (Hoenle AG). All short-circuit current densities (J_{SC}) shown in this work are normalized to 100 mW/cm^2 with respect to a calibrated Si reference diode; the data are not corrected for spectral mismatch. The intensity loss due to the additional ITO glass substrate is taken into account with an average transmission of 85% in the spectral range 350–900 nm [12]. The morphology is analyzed using atomic force microscopy (AFM Nanoscope 3, Digital Instruments), scanning electron microscopy (SEM, Zeiss DSM 982 Gemini), transmission electron microscopy (TEM, Tecnai), and wide-angle X-ray diffraction (WAXRD, URD-6 X-ray powder diffractometer, Seifert FPM GmbH; designed in Bragg–Brentano geometry; monochromatized Cu-Kα radiation). To identify lattice planes by WAXRD reflection positions the Cambridge Structural Database (CSD) [21] is used. For the TEM measurements a 10–15 nm carbon-coated nickel grid and an accelerating voltage of 200 kV are used. Absorption measurements are made using a spectrometer (Perkin-Elmer) Lamda 900 UV/VIS/NIR. Mobilities are determined using organic field effect transistors (OFETs). The OFETs consist of a silicon gate and silicon oxide. The OFET substrates with pre-structured source and drain Au contacts and a channel length in the range of 2.5–20 µm are purchased from the Fraunhofer IPMS (Dresden). C_{60}, ZnPc, and C_{60}:ZnPc (unheated and heated at 110 °C) layers of 30 nm are deposited on the OFET substrates. For the substrate heating during evaporation a heatable copper block is used and the temperature is monitored by a thermal couple glued onto the substrate with silver paste. OFET-characteristics are recorded using source measurement units 236 SMU (Keithley).

3. Results and discussion

3.1. J(V)-characteristics of heated bulk heterojunction solar cells

Here, we use 60 nm instead of 150 nm C_{60}:ZnPc blend layer due to a more distinct heating effect and better processability. This can be attributed to less recombination losses due to shorter transport paths in the bulk to the adjacent charge transport layers. The probability to form then percolation paths without dead ends is higher for thinner blend layers. Furthermore, series resistance and charge carrier mobilities also have to be considered as limiting parameters. This means that for thicker blend layers, the probability for charge carrier recombination is increased even if perfect percolation paths are formed.

Therefore, the solar cell performance is further improved with respect to *FF* and saturation $S = (J(-1V)/J_{SC})$. *J*(*V*) curves under simulated sunlight, see Fig. 2, and in the dark (Fig. 2, inset) are shown for samples processed at RT and T_{sub} = 110 °C. The characteristics of the complete devices are summarized in Table 1.

Generally, a low *FF* hints at charge carrier recombination within the solar cell, in particular for samples with injection or extraction barriers [13], unbalanced charge carrier mobilities, disturbed transport paths, and trap states in the blend layer [14]. It is observed that heating leads to improved, lower saturation *S* and series resistance. The saturation changes from 1.3 at room temperature to 1.1 for 110 °C substrate temperature. The better saturation suggests a better charge carrier separation and transport in the blend layer to the respective electrode. For the heated blend layer the charge carriers can more easily be extracted out of the blend layer before they recombine. In case of the unheated blend layer a higher electric field in backward direction is required to extract the photogenerated charge carriers due to poor transport paths. While at 0 V the difference of J_{SC} between heated and unheated solar cell is 41%, at −1.5 V the photo current differs only by 15%. Since only the blend layer is deposited during substrate heating, no influence of heating on other layers, or changes in energy level alignment are expected. Thus, the improved series resistance of 7.8 Ω cm^2 compared to 28.9 Ω cm^2 is an additional hint at better charge transport through the blend layer in forward bias. V_{OC} is comparable for both devices. Saturation factors are positively influenced by heating, while the most decisive improvements which ultimately lead to the increased η are *FF* and J_{SC}.

Table 1
Solar cell parameters (J_{SC}, V_{OC}, *FF*, $(J(-1V)/J_{SC})$, and η) for substrate temperatures T_{sub} = RT and 110 °C. J_{SC} is normalized to 100 mW/cm^2 with respect to calibrated Si reference.

T_{sub} (°C)	J_{SC} (mA/cm^2)	V_{OC} (V)	*FF* (%)	$J(-1V)/J_{SC}$	η (%)
RT	7.2	0.53	36	1.39	1.4
110	10.3	0.52	57	1.09	3.0

Values of *FF* = 36.4% and J_{SC} = 7.2 mA/cm^2 for the device processed at RT are achieved, whereas *FF* of 56.6% and J_{SC} of 10.3 mA/cm^2 are measured for T_{sub} = 110 °C. Absorption measurements are performed of C_{60} (5 nm)/C_{60}:ZnPc (20 nm, 1:1) samples deposited on quartz glass at RT and 110 °C. No significant enhancement in absorption (Fig. 4b) of the heated layer is observed, which might have explained the increased J_{SC} in the OSC. The slight change in absorption in particular for the ZnPc peak around 625 nm is discussed in Section 3.1.1. Both improvements in *FF* of over 55% and J_{SC} of over 43% lead to an increase of η by a factor of two. Due to an additional thermal energy supply to the molecules evaporated onto the substrate by substrate heating, the molecules can diffuse over a larger area before adsorption. We attribute the solar cell improvement

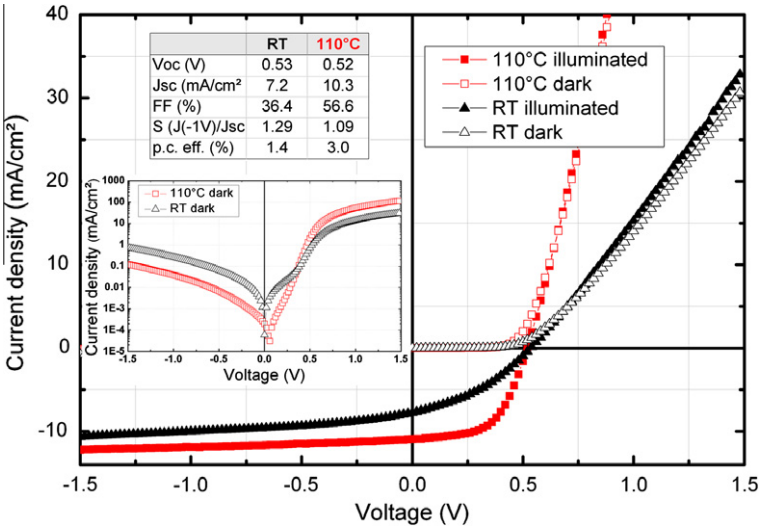

Fig. 2. *J*(*V*)-characteristics of (ITO/C_{60} (5 nm)/C_{60}:ZnPc (60 nm, 1:1)/PV-TPD (5 nm)/p-PV-TPD (40 nm, 4.4 wt%)/p-ZnPc (10 nm, 3.2 wt%)/Au) samples processed at RT and T_{sub} = 110 °C. Short current density J_{SC}, open circuit voltage V_{OC}, fill factor *FF*, saturation $(J(-1V)/J_{SC})$, and power conversion efficiency η are given. J_{SC} is normalized to 100 mW/cm^2 with respect to the Si reference.

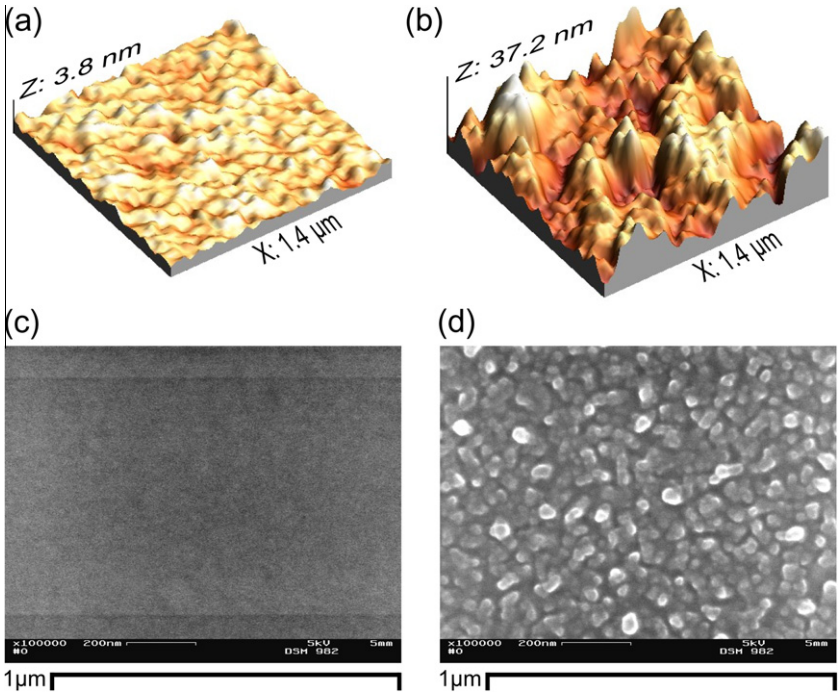

Fig. 3. AFM (a and b) and SEM (c and d) measurements of ITO/C_{60} (5 nm)/C_{60}:ZnPc (30 nm, 1:1) the first two layers of the solar cell stack: (a) unheated blend layer with RMS roughness of 0.5 nm; (b) blend layer deposited at T_{sub} = 110 °C with RMS roughness of 6.4 nm; (c) unheated blend layer; (d) blend layer deposited at T_{sub} = 110 °C.

to a change in BHJ layer morphology. It is estimated that the interaction energies between nearest neighbors are 0.87 eV (CuPc–CuPc) [15], 1.5 eV (C_{60}–C_{60}) [16,17], and 0.44 eV (CuPc–C_{60}) [18], respectively. Similar values for ZnPc are assumed, because CuPc and ZnPc have similarities concerning molecular structure, optical properties, and energy levels. These high interaction energies suggest a preferential aggregation of like molecules. If sufficient thermal energy for diffusion is supplied, formation of interconnected ZnPc and C_{60} networks occurs, which results in an improved percolation network and thus increased charge carrier mobility. To check the preferential aggregation due to heating, the morphology of the bulk layers is investigated by AFM, SEM, TEM, WAXRD, absorption, and photoluminescence measurements.

3.1.1. AFM and SEM measurements

For AFM and SEM investigations, the first two layers of the solar cell C_{60} (5 nm)/C_{60}:ZnPc (30 nm; volume ratio 1:1) are deposited at ambient conditions and T_{sub} = 110 °C, on ITO, respectively. While the unheated device forms a smooth amorphous surface with peak heights of 4 nm and a root mean square (RMS) roughness of 0.5 nm, the heated device shows a rough surface with peak heights of 37 nm and RMS roughness of 6.4 nm, as shown in Fig. 3a and b, respectively. Island and cluster-like growth can also clearly be seen in the SEM picture (Fig. 3d) for the heated structure, while for the unheated structure no such features are observed (Fig. 3c). Clusters on the heated sample have diameters in the range of 20 nm. Bright spots correspond to high peaks on the surface.

3.1.2. Absorption measurements

Maennig et al. [19] have shown absorption measurements (Fig. 4a) of ZnPc prepared at different substrate temperatures: the RT sample was prepared while the substrate was held at 25 °C. The low temperature (LT) sample was prepared while the substrate was cooled to −150 °C. They obtained for the RT sample discrete diffraction spots using transmission electron microscopy due to the polycrystalline morphology of the phthalocyanine, while for the LT sample no such features were observed, which hints at a stable amorphous phase. From the absorption measurements (Fig. 4a) it is concluded that in the solid state, the electronic excitation of ZnPc splits up in to two parts because of the molecular interactions [20]. The positions of the peaks are at 625 and 710 nm for the RT sample and at 635 and 688 nm for the LT sample, respectively. The peak separation is smaller for the amorphous than for the polycrystalline sample. This is a strong hint at a lower interaction of the molecules of the LT sample, which fits well with the lower degree of order.

To check whether polycrystalline domains of ZnPc in the heated blend layers are present, absorption measurements are carried out for C_{60} (5 nm)/C_{60}:ZnPc (20 nm) made at RT and T_{sub} = 110 °C, see Fig. 4b. The peak positions of the RT sample are at 631 and 688 nm and hint at amorphous growth, as reported by Maennig et al. [19]. We conclude that the polycrystalline growth of ZnPc is suppressed in the unheated C_{60}:ZnPc blend layer. A peak shift which might have indicated polycrystalline domains in the heated blend layer is not observed. Anyway, another feature is the peak ratio dependency of ZnPc for amor-

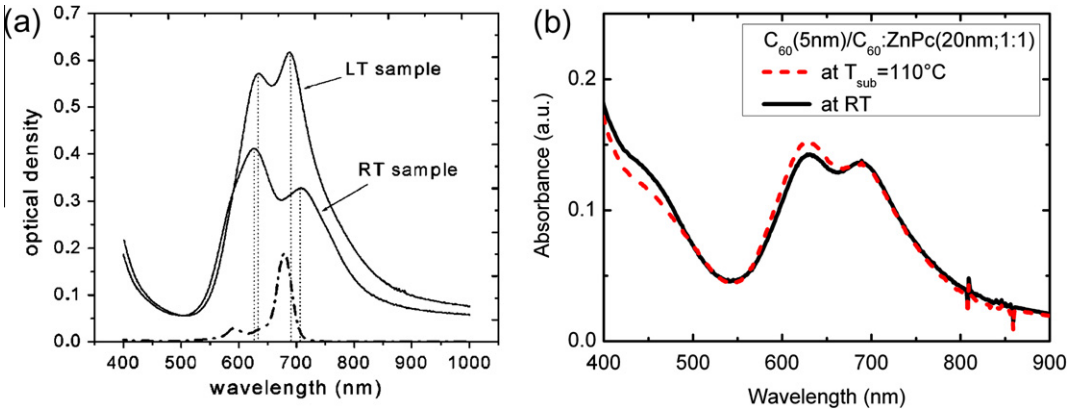

Fig. 4. Absorption spectra of (a) ZnPc layers (50 nm thick) with permission taken from Ref. [19]: the RT sample was prepared at 25 °C substrate temperature and the low temperature (LT) sample at −150 °C substrate temperature. The dotted line shows schematically the absorption of ZnPc dissolved in 1-chloronaphthalene; (b) C_{60} (5 nm)/C_{60}:ZnPc (20 nm; volume ratio 1:1) made at RT (black solid line) and T_{sub} = 110 °C (red dashed line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

phous and polycrystalline layer. In Fig. 4a it can be seen that for the amorphous layer (LT sample) the first peak is smaller than the second one and vice versa for the polycrystalline layer (RT sample) [19]. Such a peak ratio shift is also observed for the blend layer, see Fig. 4b. For the sample at RT, both peaks have almost the same height, while for the heated samples, the first peak is increased compared to the second one. This suggests at least a certain amount of polycrystalline domains of ZnPc in the heated blend layer.

3.1.3. WAXRD measurements

For the WAXRD measurements, a layer sequence of C_{60} (5 nm)/C_{60}:ZnPc (50 nm) volume ratio 1:1 is deposited on silicon at ambient conditions and T_{sub} = 100 °C, respectively. To check whether the cluster formation is also present when using a silicon substrate instead of ITO, additional SEM measurements of these samples are carried out and show similar aggregation and cluster assembly. Measuring over diffraction angle diapazon of 2θ (2–28 °), no characteristic WAXRD reflections indicating at nanocrystalline growth for ZnPc and C_{60} are observed in the blend layer, see Fig. 5. Additionally, pristine 25 nm thick C_{60} and ZnPc layers deposited on heated silicon substrate (T_{sub} = 90 °C) are investigated by WAXRD. In contrast to the heated C_{60}:ZnPc blend layer, nanocrystalline growth is observed, in heated pristine ZnPc indicated by a set of WAXRD reflections. For C_{60} only a very weak reflection is seen in Fig. 5. Probably, the nanocrystalline growth of ZnPc in the blend is reduced resulting in a material that is at least X-ray amorphous. According to Crystal Structure Database (CSD) [21], the reflections detected for the thin ZnPc film can be attributed to modifications, which are isomorphous with triclinic (space group $P\bar{1}$) [22] and monoclinic (space group $C2/n$) [23] α-polymorphs of CuPc. They are characterized by similar molecular structure, molecular weight, and atomic radii of metal elements, Zn and Cu. The observed reflection positions of heated ZnPc, 2θ = 6.89°, 13.76°, and 27.66° correspond, respectively, to the reflections 100 (theoretical 2θ = 6.86°), 200 (13.73°), and 400 (27.67°) of the triclinic modification, or to the reflections 200 (6.73°), 400 (13.45°), and 800 (27.15°) of the monoclinic phase. Note that in both cases, the ZnPc film exhibits a preferred orientation along the [100] crystallographic direction of the corresponding crystalline lattice.

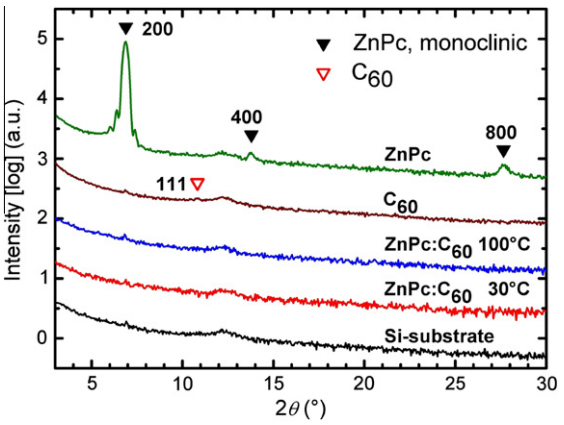

Fig. 5. WAXRD patterns of silicon/C_{60} (5 nm)/C_{60}:ZnPc (50 nm, 1:1) samples of unheated (T_{sub} = 30 °C), heated (T_{sub} = 100 °C) blend layer, heated (T_{sub} = 90 °C) 25 nm thick pristine C_{60}, and ZnPc layers deposited at silicon substrate. For comparison WAXRD pattern of Si substrate is shown at bottom of Fig. 5. The thickness fringes for ZnPc (200) reflection at Bragg angles 2θ = 6.02°, 6.38°, 6.89°, and 7.42° appear due to diffraction at thin layer, and are resolved in the reflection profile. The Miller indices of observed ZnPc reflections are indicated according to possible monoclinic α-polymorphs. The Miller indices of the C_{60} phase are indicated for cubic (space group $Fm\bar{3}m$) structure model [24]. For better visualization the WAXRD patterns are shifted vertically.

3.1.4. TEM measurements

The methods used before show a tendency of molecular phase separation and polycrystalline growth of ZnPc, but could not confirmed yet. To further investigate the blend layer morphology, TEM measurements are performed. The 5 nm of C_{60} of the stack C_{60} (5 nm)/C_{60}:ZnPc (30 nm, 1:1) are deposited at RT while the mixed layers are depos-

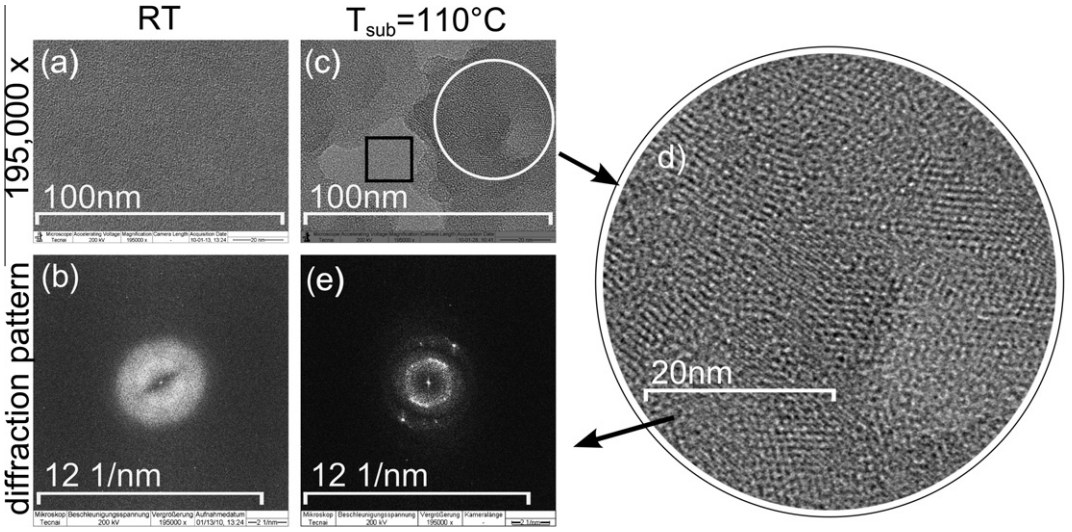

Fig. 6. TEM images at a magnification of 195,000 of C_{60} (5 nm)/C_{60}:ZnPc (30 nm, 1:1) stacks deposited on carbon-coated nickel grids are shown. (a) Blend layer processed at RT; (b) diffraction pattern (a); (c) processed at T_{sub} = 110 °C; (d) region marked by the white circle is enlarged for a better view; (e) diffraction pattern of (d).

ited at RT and T_{sub} = 110°C, respectively. The TEM results are shown in Fig. 6 for a magnification of 195,000. For the sample made at RT (Fig. 6a) only a homogeneous gray area is observed. It indicates amorphous layer growth. This is confirmed by the Fourier transformation as shown in image b, where a pattern with a halo ring typical for amorphous growth can be seen.

In the TEM images of the 110 °C heated sample (Fig. 6c and d), bright and dark regions are observed. The dark regions can be related to thicker layers or molecules with a higher scattering factor, caused by, e.g. Zn with a higher atomic number of Z = 30 compared to Z = 6 for C. It means that phase separation occurs due to heating, and a rougher surface is formed, which was already observed in the AFM measurements.

The dark regions are framed by a white circle and the bright regions by a black rectangle. Polycrystalline structures (white circle) in Fig. 6c are observed, which is not the case for the bright regions (black rectangle). The region of the white circle in Fig. 6c is enlarged and is shown in Fig. 6d. Large polycrystalline domains with lateral diameters of 50 nm are obtained, while the lateral crystal sizes are in the range of 10 nm. A Fourier transformation (Fig. 6e) of this region exhibits a mixture of polycrystalline (diffraction spots) and amorphous (halo ring) domains. Fifteen of such images are taken at different sample positions and evaluated using Fourier transformation to investigate the polycrystalline structure with respect to its composition, either to ZnPc or C_{60}. The same data from the CSD [21], which had already been utilized for the WAXRD measurements are taken. The correlation between theoretical lattice plane spacing d_{hkl} from CSD and the theoretical lattice planes of ZnPc and C_{60} are summarized in Table 2. Only very few crystals can be attributed to C_{60} (1 1 1) atomic planes. Some of the observed lattice plane spacings d_{hkl} are around 8.0 Å and cannot clearly be referred to C_{60} (d_{hkl} = 8.175 Å) or ZnPc (7.882 Å). However, the majority of assigned reflections is attributed to monoclinic ZnPc [23] and consist of 003, 403, and 005 reflections. Usually they are forbidden for space group $C2/n$ due to extinction laws. Evidently, the appearance of the forbidden reflections is related to strong dynamic interaction of the electron beam and crystalline lattice [25,26] of the monoclinic ZnPc in the thin blend layers. Aside from weak intensities of the forbidden reflections, the small scattering volume of the crystalline ZnPc prevents the observation of the ZnPc reflections in the WAXRD measurements.

Table 2
Correlation between the theoretical lattice spacing (d_{hkl}) from CSD and lattice planes (h k l) for monoclinic ZnPc [23] and C_{60} [24]. Measured d_{hkl} are sorted and related to the theoretical lattice planes.

T_{sub} = 110 °C	Lattice plane spacing (d_{hkl}) (Å)	Lattice plane (h k l)
ZnPc monoclinic, space group $C2/n$	7.88	(0 0 3)[a]
	4.87	(4 0 3)[a]
	4.73	(0 0 5)[a]
C_{60}, space group $Fm\bar{3}m$	8.19	(1 1 1)

[a] Forbidden reflections (lattice planes) according to extinction law.

3.1.5. Mobility measurements

To check whether the mobilities are positively influenced by the formation of polycrystals due to substrate heating, OFET measurements in the saturation regime of unheated and heated blend layers are carried out. Using the OFET method, where the silicon oxide sublayer is the same for all devices, a reliable comparison of the mobilities of different samples is possible. Similar aggregation of heated C_{60}:ZnPc on silicon oxide compared to C_{60} is observed by SEM. The hole mobility μ_h of neat ZnPc of 6.5×10^{-4} cm^2/Vs is decreased in a blend layer with C_{60} (volume ratio 1:1) to 5.1×10^{-5} cm^2/Vs. This might be attributed to a smaller overlap of the π-orbitals of ZnPc due to a higher disorder in the blend [27] and to the reduction of the effective channel width by a factor of two. Sim-

ilar observations are made for the electron mobility μ_e of C_{60}. For the neat layer, $\mu_e = 9.2 \times 10^{-3}$ cm^2/Vs and for the blend layer, $\mu_e = 5.2 \times 10^{-3}$ cm^2/Vs is measured. The heated sample shows a clear tendency to higher μ_h of ZnPc. Values of 2.2×10^{-4} cm^2/Vs are achieved due to polycrystalline growth of ZnPc. In case of C_{60}, no improvement of μ_e is determined for the heated sample compared to the unheated, both are on the order of 5.0×10^{-3} cm^2/Vs. This fits to the observations in TEM that no or only very few C_{60} crystals are formed, which would lead to an improvement of the mobility. Furthermore, the increase of μ_h for ZnPc closer to the mobility of C_{60} positively influences the charge carrier balance within the blend layer and leads to less charge carrier recombination and therefore to a higher *FF* [14]. Not only the formation of percolation paths caused by molecular phase separation, but also the increased mobility lead to the improved performance of heated solar cells.

4. Conclusion

In summary, we have shown that controlled in-situ substrate heating during evaporation of a blend consisting of 60 nm C_{60}:ZnPc with volume ratio 1:1 can positively influence the OSC efficiency by a factor of two. The main reasons are that J_{SC} rises by over 40%, and *FF* by over 55%. The observed effects are investigated by AFM, SEM, TEM, and OFET measurements. While X-ray diffraction measurements show no polycrystalline growth in the heated blend layer both for C_{60} and ZnPc, probably due to at least X-ray amorphous material, in the TEM measurements polycrystalline domains of 50 nm are observed and are mainly attributed to ZnPc. The hole mobility of ZnPc is improved by one order of magnitude, probably caused by the formation of percolation paths, while the mobility of C_{60} remains unchanged. Well established percolation networks within the BHJ due to molecular phase separation and polycrystalline growth leads to improved charge carrier extraction and solar cell performance.

Ag(110)

ABSTRACT

Photoelectron-emission microscopy (PEEM) is a very versatile tool for studying dynamic processes like growth and phase transitions on surfaces. But besides the real time characterization of the morphology it can provide local spectroscopic information on a sub-μm scale. To this end we have combined a conventional PEEM setup with a He-discharge lamp delivering high energy photons for electron excitation. The setup thus allows probing the electronic structure of individual crystallites of α-sexithiophene on Ag(110). Upon growth of this organic semiconductor on the surface held at 370 K, needles consisting of flat lying molecules and platelets containing near upright standing molecules are formed. Both types of crystallites can not only be distinguished by their shape but also by their photoelectron emission spectra. We also identify a wetting layer consisting of flat lying molecules which have essentially the same spectroscopic signature as the molecules in the needles.

1. Introduction

The deposition of thick films of organic molecules on surfaces leads often to a variety of crystalline structures because of the polymorphism of the organic material. By tuning the lattice constant and/or the chemical composition of the surface it is possible to favour a particular structure and crystalline orientation with a well defined epitaxial relationship. For instance, on a well prepared TiO_2 substrate α-sexithiophene molecules (α-6T, see Fig. 1) lie flat on the surface with their long molecular axis parallel to the [001] direction. However, if the surface is "disordered", e.g., after sputtering and insufficient annealing, the molecules adsorb in a near upright fashion [1]. Similar results were reported for α-6T on Ag(111) and on Ag(111) pre-covered by α,ω-dihexyl-sexithiophene (DH6T) [2]. In both cases, the different orientation of the molecules leads to characteristic changes in the electronic and optical properties. Besides these changes due to the molecular alignment, the authors also argue that the different facets of a given crystallographic structure will have different ionization potentials due to different molecular states determining the electronic structure of the facets. For inorganic materials like silver this is well known [3,4].

For ultrathin films of other organic materials like phthalocyanines [5,6] ionization potentials (*IP*s) depending on the molecular orientation are observed, but it is not clear to what extend these *IP*s and the associated shift of the molecular electronic levels are merely due to the modified substrate surface or intrinsic to the different phases of the molecular film. To further explore these issues, photoelectron-emission microscopy (PEEM) in combination with imaging photoelectron spectroscopy, which allows to study the properties of different types of crystallites on the very same surface, was applied to the system α-6T on Ag(110). As a result, this method does not only provide information on the local morphology and polymorphism, but also on the associated characteristic electronic structure.

The fundamentals of the PEEM technique were described in the literature already in the early 1930's [7,8].

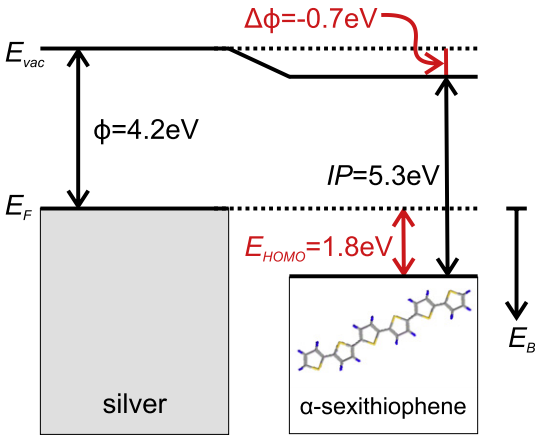

Fig. 1. Schematic of the energy level alignment between the silver surface and the α-6T layer. Substrate and molecules have a common Fermi-level E_F and an interface dipole $\Delta\phi$ is formed. The indicated values are taken from Grobosch and Knupfer for a polycrystalline silver surface [10]. The work function of a Ag(110) surface is slightly higher, namely $\phi = 4.25$ eV [4].

A bright light source, usually a mercury arc discharge lamp (Hg lamp), excites photoelectrons from the sample surface. By means of an electrostatic lens system the emitted electrons are imaged by a combination of a multichannel plate and a fluorescence screen. For most metal surfaces, the excitation energy of 4.9 eV provided by an Hg lamp is sufficient to emit enough electrons for imaging. For instance, the work function of the bare Ag(110) surface is 4.25 eV [4]. Besides the lateral variation of the work function, field enhancement due to the topography of the sample also contributes to the contrast in PEEM [9].

In the case of semiconducting materials, not the work function – defined as the difference between the vacuum level E_{vac} and the Fermi energy E_F – but the ionization potential determines whether electrons can be excited over the vacuum barrier via the photoelectric effect. Since for semiconductors the Fermi-level lies within the band gap, the ionization potential for semiconducting molecular films is larger than their respective work function. Fig. 1 shows qualitatively the alignment of the different energy levels involved in the experiments of α-sexithiophene on Ag(110) [10]. Due to the formation of an interface dipole $\Delta\phi$, the vacuum level of α-6T is lower than that of the substrate. Yet, the ionization potential of α-6T is 5.3 eV which is larger than the energy of the photons from the Hg lamp. Therefore, one expects that no photons are emitted from the α-6T layer under illumination with an Hg lamp. Nevertheless, the PEEM image shown in Fig. 2a reveals a clear contrast between the wetting layer (bright) and the thick α-6T crystallites (dark). Moreover, the wetting layer appears brighter in PEEM than the clean Ag(110) surface. This can be explained by the interface dipole $\Delta\phi = -0.7$ eV formed within the first layer of α-6T on Ag(110) as depicted in Fig. 1. This effectively lowers the energy barrier for the electron emission from the underlying Ag(110) substrate. Although the emission intensity from the substrate is attenuated by the α-6T wetting layer, the overall effect is an increased emission intensity for the α-6T wetting layer as compared to the bare Ag(110) surface. In addition, Grobosch and Knupfer suggest the formation of an interface state for α-6T on silver which would further increase the emission probability. A detailed discussion of similar intensity variations during growth is found in Ref. [11] for para-sexiphenylene on Cu(110)–(2×1)O and in Ref. [12] for pentacene on Si(001). In this work we do not want to discuss the contrast of different layers but different polymorphes of the same organic material, namely α-sexithiophene grown on Ag(110).

2. Experimental setup

The experiments were carried out in an ultra high vacuum system housing a Focus IS-PEEM with a retarding field energy analyzer [13]. The PEEM is equipped with an integrated sample stage with a high mechanical stability allowing a lateral resolution of about 50 nm. The vacuum system has a base pressure of less than 5×10^{-10} mbar.

Besides the standard Hg lamp (Focus GmbH) for the excitation of the photoelectrons the same port can be used to mount a D_2 lamp (Hamamatsu Photonics). Due to the optical parts of the vacuum system the spectrum of the deuterium lamp is limited to a photon energy of 6.4 eV. Another port is used to mount a He lamp (Focus HIS 13, 21.2 eV). For all excitation sources, the angle of incidence of the light beam with respect to the surface normal is about 65°. The angle between excitation source and detector in the PEEM experiment is comparable to that in a usual UPS setup. In contrast to an angular resolved UPS experiment the PEEM detector, however, collects electrons over a larger angular range around the surface normal.

The emitted photoelectrons are imaged by an electrostatic lens system onto a fluorescence screen. The images are acquired with a 12 bit CCD camera (PCO AG, Pixelfly). For spectroscopic measurements the dynamic range of the camera is not sufficient. Therefore, we either use a customized ImageJ software [14] plug-in which automatically adjusts the exposure time or we manually increase the voltage of the multichannel plate with increasing retarding voltage. To maintain a constant energy resolution of the retarding field analyzer we apply a variable voltage to the sample while the retarding field analyzer before the imaging unit remains at a constant potential. As a result, there is a little defocusing of the images while ramping the sample voltage.

The energy scale was calibrated using a Ag(110) sample as shown in the bottom panel of Fig. 3. The half height of the Fermi edge was used to define $E_B = 0$. From this we derive a work function of the Ag(110) surface of $\phi = 4.25 \pm 0.1$ eV, which is in good agreement with Ref. [4].

3. Sample preparation

The substrate used is a Ag(110) single crystal (Mateck GmbH) with a nominal surface miscut of less than 0.1°. The surface was cleaned by repeated cycles of Ar^+ ion sputtering (0.9 kV, 3.6 μA/cm^2, 60 min) and subsequent annealing at 600 K until no impurities could be detected by Auger electron spectroscopy.

The commercially available α-sexithiophene was prepurified by gradient sublimation before inserting it into a Ta-crucible. The α-6T films were prepared within the PEEM while monitoring the intensity integrated over the whole image (using the Hg lamp for photoelectron excitation). The maximum of the intensity was identified with the completion of the monolayer – similar to the case of p-6P on Cu(1 1 0)–(2 × 1)O [11]. The sample temperature during α-6T deposition was 370 K.

4. Results and discussion

In Fig. 2a several dark structures with different shapes can be distinguished which match different types of α-6T crystallites. Most of the crystallites appear as elongated, thin needles which are typically observed for α-6T grown on well ordered substrates [15]. Within these needles, the molecules are orientated parallel to the surface [16]. In addition, more compact islands (platelets) can be observed. The crystallites appear darker than the wetting layer because the electrons emitted from the silver/α-6T interface have to pass through a much thicker organic layer. According to [17] and [18], the inelastic mean free path of the electrons excited by the Hg light from the silver substrate into the organic layer can be estimated to be about 1.5 nm. Therefore, the probability for electrons to pass through more than 5 layers of flat lying α-6T molecules should be negligible. Later on, we will show that the average height of the needles might even exceed 300 monolayers. The electrons are also efficiently attenuated by the more compact two-dimensional α-6T islands (platelets) found on the right side of Fig. 2a. As will be shown later, these platelets have a lower height than the needles and consist of upright standing molecules.

The very same spot on the sample was also imaged by using a D_2 and a He lamp which provide photons of higher energies. If photons with an energy of $h\nu = 21.2$ eV (He I) are used (see Fig. 2c), needles and platelets are both imaged brighter than the wetting layer. As the photon energy is much higher than the ionization potential of the molecules, electrons can easily be emitted from the α-6T molecules. The fact that the wetting layer has now a lower intensity than the crystallites illustrates that α-6T is a dye and acts as an efficient optical absorber for light above a certain threshold energy. In fact, the photoelectron emission from the needles is slightly lower than that from the platelets. The difference in intensity between the needles and the platelets is even more pronounced if the D_2 lamp with a photon energy $h\nu = 6.4$ eV is used (Fig. 2b). In this case, some side facets of the needles appear darker than the top face of the needles. Nevertheless, not all facets show this behaviour and the brightness strongly depends on the direction of the illumination: As the needles are very high compared to their width, there is a strong shadowing effect. Indeed, the facets, which are not facing the light impinging from the top of the image in Fig. 2b, appear darker. The width of the needles ranges between 1 and 3 μm and is definitely large enough to absorb most of the incoming light. The height of the needles can not be measured directly by means of PEEM but it can be estimated from the average film thickness (about 33 monolayers) and the area in the image which is covered by needles and platelets (roughly 10%). This results in an average height of the crystals (needles and platelets) of 320 monolayers. Assuming flat lying molecules this corresponds to a mean height larger than 100 nm.

Taking a closer look at Fig. 2b and the platelets in the lower right of the image, one finds that there is no pronounced shadowing effect. We thus conclude that the platelets have a much lower height as compared to the needles. This is in agreement with our experience of bringing the needles and the platelets into the focus of the PEEM: For the needles – as they are quite high – it is hard to determine an exact focus point, whereas the range for which the platelets are sharply imaged is much smaller.

The top panel of Fig. 3 depicts energy filtered images for three selected values of the retarding field. Note that by using a retarding field analyzer the images are high pass filtered with respect to the kinetic energy E_{kin}, such that only those electrons with a binding energy E_B below a given threshold can be detected:

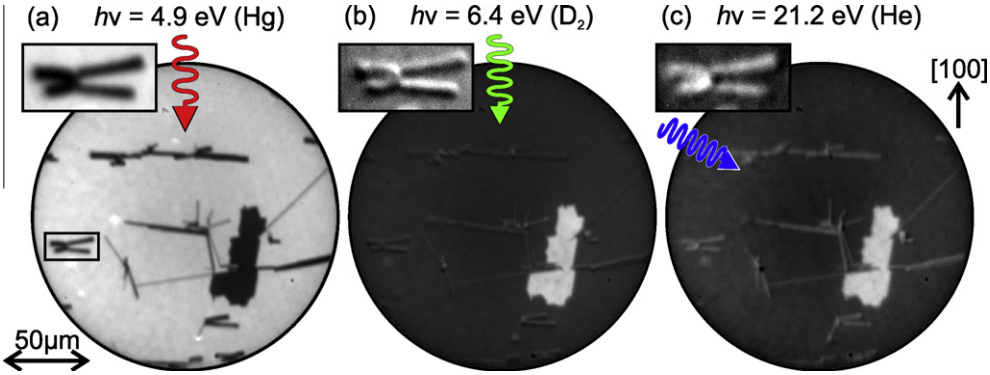

Fig. 2. PEEM images of a 33 monolayer thick film of α-6T grown at 370 K on Ag(1 1 0) using different light sources for electron excitation. The field of view is about 180 μm. The direction and the wavelength of the incoming light are indicated by the coloured arrows. The insets show an enlarged crystallite which consists of several needles arranged into a cross-like structure. The crystallite appears homogenous if the Hg lamp is used for excitation, whereas, under the illumination with the D_2 or the He lamp the contrast of the structure is not uniform. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

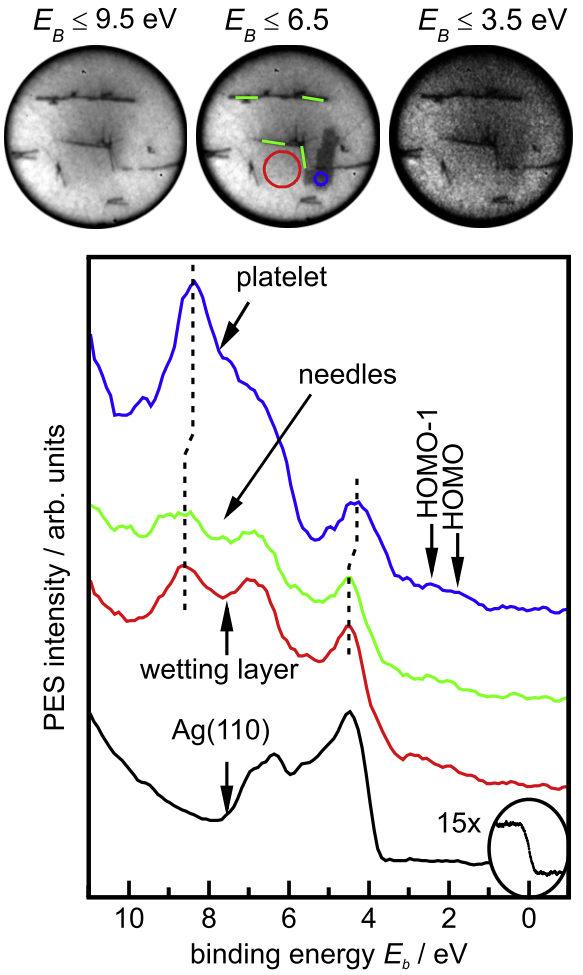

Fig. 3. The top shows three energy filtered PEEM images with different retarding fields applied. The energy ranges indicated correspond to the binding energies which contribute to the image. The contrast of the images was adapted to optimize the visibility; the area imaged is the same as in Fig. 2. The bottom panel shows the photoelectron spectra derived from the energy filtered images for selected regions indicated in the top panel. The arrows indicate two weak features which can be attributed to the lowest occupied states of the organic thin film. For comparison also the spectrum of the clean Ag(1 1 0) surface is shown. The inset in the circle shows a high resolution scan of the Fermi edge. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

$$E_{kin} = h\nu - \phi - E_B - E_{ret} \geqslant 0 \qquad (1)$$

In this equation and in the following, $E_B = 0$ refers to the Fermi level of the silver substrate. The energy indicated above the images corresponds to the allowed binding energy range of the emitted electrons. The images in Fig. 3 are taken from exactly the same spot of the α-6T covered Ag(1 1 0) sample as the unfiltered ones ($E_{ret} = 0$) displayed in Fig. 2. In Fig. 2c, all electrons with $E_B < (21.1\ \text{eV} - IP)$ contribute to the image. For this range of binding energies both the platelets and the needles have a higher intensity than the thinner wetting layer. In Fig. 3, the range of the binding energy contributing to the images is smaller. As a result, the contrast for the images in Fig. 3 is inverted so that the needles now appear darker than the wetting layer. On the other hand, for binding energies $E_B < 9.5$ eV and $E_B < 3.5$ eV, the platelets have the same intensity as the wetting layer, whereas for $E_B < 6.5$ eV the platelets appear darker.

From a series of images recorded with different E_{ret}, the local spectroscopic information can now be obtained from the (numerical) derivative of the intensity curves $I(E_{ret})$ at any given location, in particular those areas covered by the wetting layer (red), needles (green) and the platelet (blue) as indicated in the central image of Fig. 3. The so derived local photoelectron spectra are shown in the lower panel of Fig. 3 in corresponding colours. For comparison and calibration also the spectrum of the bare Ag(1 1 0) surface is presented. As far as the spectroscopic information is concerned, the spectra in Fig. 3 can be compared to traditional UV photoelectron spectra (UPS) data. However, in contrast to conventional UPS, which averages over a large surface area, the spectra obtained by PEEM based imaging spectroscopy are spatially resolved with a lateral resolution of less than 100 nm. The spectra recorded from different molecular structures with the main features at 4.4, 7.0, and 8.5 eV are quite similar to the UPS data shown, e.g., in Fig. 4 of Ref. [1] recorded at normal emission from α-6T layers on "ordered" and "disordered" TiO_2, respectively. The highest occupied molecular orbital (HOMO) are expected at binding energies E_{HOMO} of 1.8 and 2.4 eV (see Fig. 1 and Ref. [10]). Indeed, in Fig. 3 there are two very weak features marked by arrows at the expected positions. The stronger signatures at higher binding energies mainly stem from anti-bonding and nonbonding-orbitals [1,19].

Note that the red and the green curve in Fig. 3, representing the spectra of the wetting layer and the needles, respectively, are essentially the same. This confirms that (i) the area between the crystallites is covered by a wetting layer of α-6T molecules and that (ii) the electronic structure of the molecules in the wetting layer and in the needles is very similar. Since the latter are known to consist of flat lying molecules, we infer that the orientation of the molecules in the wetting layer should also be nearly parallel to the surface. This result is in agreement with previous studies by X-ray absorption (NEXAFS) and scanning tunnelling microscopy [16,20,21].

The correspondence of the two spectra also indicates that local charging does not play an important role. As the wetting layer consists of only two layers of α-6T and the first layer, at least, is strongly coupled to the substrate, we assume that there is no charging effect for the wetting layer. As discussed before, the needles have a height of several hundred layers of flat lying α-6T molecules. The low conductivity may give rise to a charging of the needles. In this case, the local potential of the needles would deviate from that of the wetting layer and, therefore, the spectrum of the needles shown in Fig. 3 should be shifted with respect to the one of the wetting layer. This is obviously not the case and we thus conclude that there is no charging effect for the needles.

The spectrum recorded from a platelet (blue curve) again reveals three main contributions (at 4.3, 6.9, and 8.4 eV), but their relative intensity is considerably different

from that of the needles and the wetting layer. In particular, the feature around 8.4 eV is now most pronounced. In addition, a systematic shift to the lower binding energy of the order of 0.1–0.2 eV for all three major peaks can be noticed.

As mentioned before, a very similar spectrum as the blue curve displayed in Fig. 3 has been obtained by conventional UPS for the growth of α-6T on "disordered" TiO_2 where α-6T forms crystallites in which the molecules align in a near upright standing fashion [1]. We thus ascribe the platelets to α-6T crystallites of near upright standing molecules. This assignment is also consistent with the more compact shape of the platelets [22]. Duhm et al. [2] have used a spacing layer of α,ω-dihexyl-sexithiophene (DH6T) between a thick layer of α-6T and Ag(111) to switch between the growth of flat lying and near upright standing molecules. They also support their experimental data by DFT calculations. In both cases a shift of 0.6 eV for the *IP* was found between flat lying and standing molecules. While we cannot reliably determine the shift of the HOMO level from Fig. 3 but only that of the energetically lower orbitals, our value for the peak shift might actually be lower. This could be due to he fact that we – in contrast to the previous studies – have characterized platelets and needles coexisting on the very same substrate surface, i.e., without modification of the surface. In any case, the *IP* of the standing molecules is definitely lower than that of the flat lying ones. The direction of the shift is opposite to what would be expected if the platelets were positively charged upon photoelectron emission.

Koller et al. [23] have pointed out that the orientation of the π-stacked molecules with respect to the electrodes of a device has an important effect on its performance in organic field effect transistors (OFETs) or organic light emitting diodes (OLEDs). Whereas for the first kind of device a film consisting of upright standing molecules should be preferred for optimum electron transport, flat lying molecules should give the higher photon emission in the direction perpendicular to the film as desired in OLEDs. Therefore, the control of the orientation of the molecular stacking is crucial. In addition, this study shows that besides the macroscopic conductivity along certain crystallographic axes, also the local electronic interface to the vacuum or the electrodes depends on the orientation of the molecules. This has to be taken into account when designing a device.

5. Summary

In summary, our results show that there are two kinds of α-6T crystallites present on the Ag(110) surface – elongated needles of flat lying α-6T molecules and two-dimensional platelets consisting of near upright standing molecules. Both kinds of crystallites grow on a uniform wetting layer. By applying imaging photoelectron emission spectroscopy the differences of the electronic structure can be resolved down to the scale of the individual crystallites. Between needles consisting of flat lying molecules and platelets formed by near upright standing α-6T grown on the very same substrate a distinct shift of the binding energies and different relative emission intensities are evidenced.

Acknowledgements

We gratefully acknowledge the fruitful discussion with Michael Schicketanz and Matthias Escher from Focus GmbH. We also thank Alexander "Sandy" Fleming and Mike Ramsey from the TU Graz for sharing their experience on PEEM.

ABSTRACT

We studied environmental stability of top contact pentacene TFTs with active layer evaporated at different growth rates. We measured the transfer characteristics in vacuum and in air and after storing the devices in oxygen for several days. Different pentacene growth rates result in different grain size of active layer. This morphology difference influences the hysteresis of transfer characteristics induced by water absorption. On the contrary, aging effects on the transfer characteristics of pentacene O-TFTs, induced by oxygen diffusion into the active layer, are not related to structural characteristics of pentacene film.

1. Introduction

The environmental stability of electrical characteristics of devices is a fundamental requirement for organic thin film transistor (O-TFTs) applications. On the other hand, it has been shown that the exposure of these devices to air is in general detrimental for their performance [1–15]. Two main effects of environment have been identified in pentacene TFTs: hysteresis of transfer characteristics [1–7], when the devices are measured in air, and variation of transfer characteristics after exposure to air for a long time [8–15]. These phenomena are attributed to the diffusion of water molecules and/or oxygen into pentacene active layer.

The hysteresis of transfer characteristics is usually related to the effect of water and it has been explained in terms of different microscopic mechanisms. A possible explanation of the hysteresis effect is that the diffusion of water molecules into pentacene induces slow trapping of carriers in the device active layer [1,2] or at the semiconductor/insulator interface [7], with a consequent shift of threshold voltage during measurement. Charge injection into the gate insulator has been also considered as origin of hysteresis [6,16]. In particular, the mechanism proposed by Sharma et al. [16], that explains the bias-stress effect in terms of exchange of holes with protons in the presence of water at the semiconductor/insulator interface and the subsequent migration of protons into the oxide, could also explain the hysteresis phenomenon. Water diffusion has been also considered responsible of a variation of energy barrier at pentacene/metal interface [4] and a reduction of field-effect mobility [4,5]. It has been generally observed that the hysteresis is reversible and disappears almost completely when the devices are stored in vacuum or dry atmosphere. This seems related to a weak interaction between adsorbed H_2O and pentacene molecules [3,8], allowing an easy removal of the water molecules from the active layer.

A permanent variation of transfer characteristics has been observed when the device are exposed to air for a long time [8–15]. In this case all the main electrical parameters (field-effect mobility, threshold voltage and subthreshold swing) are degraded, while the hysteresis remains unaffected [9,12]. Although some studies [4,5] have shown that also moisture can play a role in the aging of pentacene O-TFTs, this effect has been mainly attributed

doi:10.1016/j.orgel.2010.12.013

to the diffusion of oxygen into pentacene layer that induces new gap states located at about 0.2–0.3 and 0.6 eV above the valence band [12–14]. Experimental results are in good agreement with theoretical calculations that consider defects in pentacene molecules induced by oxygen [15].

It has been shown that it is possible to reduce environmental sensitivity of pentacene TFTs by using opportune gate dielectrics [7] or by device passivation through barrier layers in order to reduce the molecule diffusion [11]. On the other hand, also the structure of the pentacene active layer seems to play a role on the environmental stability of pentacene O-TFTs [4,10]. Growth rate, substrate characteristics and deposition temperature have been shown to be key parameters in controlling the nucleation density [17–19] and, therefore, the pentacene film characteristics (grain size and grain boundary density). In this work we have investigated the influence of the morphology of pentacene film, deposited at different growth rates, on the stability of electrical characteristics of O-TFTs, measuring the transfer characteristics in vacuum and in air and after storing the devices in oxygen.

2. Material and methods

Top-contact (TC) bottom gate devices were fabricated using a highly doped-Si substrate as a large area gate with a 90 nm thermal oxide as gate dielectric. Before pentacene deposition a buffer layer of PMMA (5 nm thick) was spin coated and annealed at 70 °C for 15 min. It has been shown that a thin PMMA buffer layer improves the performance of pentacene O-TFTs both in bottom contact (BC) and TC configurations [20], improving the interface quality between pentacene and both Au contacts (in BC-TFTs) and SiO_2 gate dielectric (in BC and TC-TFTs). Pentacene active layers (30 nm thick) were evaporated, with the substrate at room temperature (RT), by using a Radak evaporation source, with growth rates r = 0.01, 0.03 and 0.07 nm/s.

Atomic force microscopy analysis, performed by a PSIA XE100 system in non-contact mode, of the pentacene layers deposited at different growth rates are shown in Fig. 1. As can be seen the film exhibits the typical morphology of highly ordered polycrystalline pentacene, with a characteristic "terrace" structure with 1.6 nm steps, corresponding to the height of one molecular layer. The analysis shows that, as already reported in literature [17,18,21], the deposition conditions influence the morphology of pentacene film. Indeed, whereas pentacene films grown at low rate show grain size up to 2 μm and a very compact structure, pentacene films grown at a faster rate have smaller grain size (less than 1 μm for sample deposited at a growth rate of 0.07 nm/s) and more pronounced grain boundaries. This results in a higher density of grain boundaries for samples deposited at higher growth rates.

Source and drain contacts were formed by evaporating gold (30 nm thick) after pentacene deposition and defined through a shadow mask. Device electrical characteristics were measured in a MMR cryostat using a Keythley 236 source/measure unit and a Keythley 2635 source-meter. In order to evaluate the hysteresis of transfer characteristics, measurements have been performed sweeping the gate voltage, sequentially, from off-to-on and from on-to-off (between 5 and −30 V). Field-effect mobility has been calculated considering the maximum of the transconductance relative to off-to-on curve.

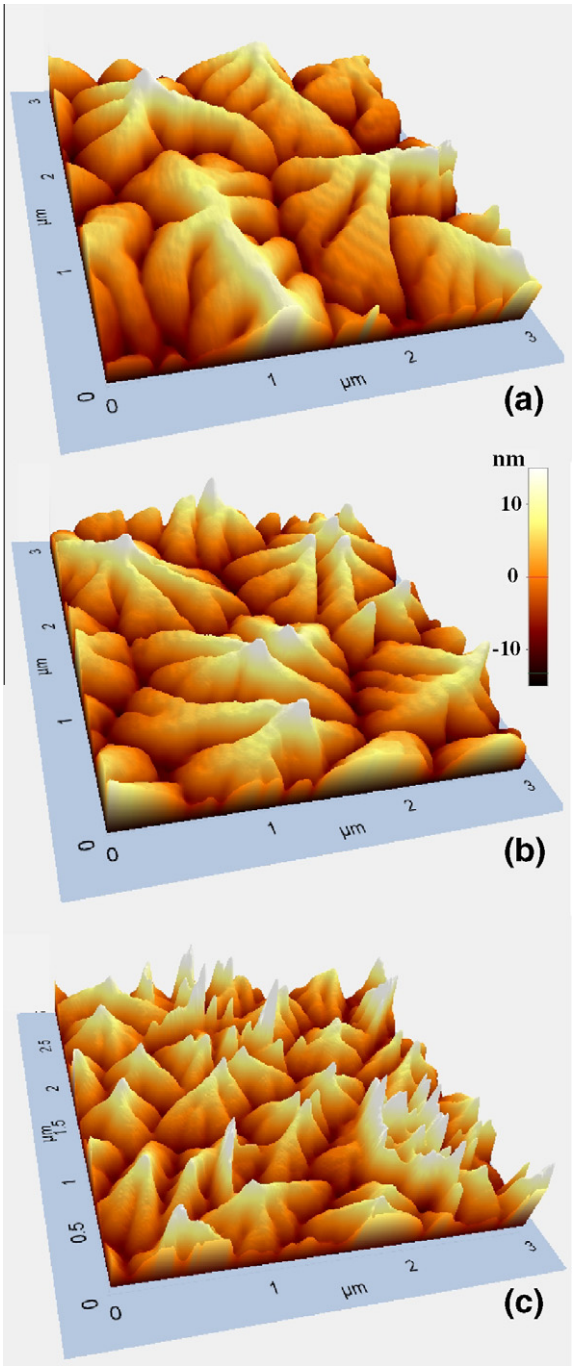

Fig. 1. AFM images of pentacene films deposited at different evaporation rates, (a) 0.01 nm/s (b) 0.03 nm/s and (c) 0.07 nm/s.

Aging effects have been investigated by storing in dark the pentacene O-TFTs in air and in pure oxygen

atmosphere and performing at selected aging time intervals measurements of transfer characteristics in vacuum.

3. Results and discussion

3.1. Water related instability

Fig. 2 shows typical transfer characteristics, measured in vacuum, of TC pentacene O-TFTs fabricated with active layers deposited at different growth rates. As can be seen, the differences of pentacene morphology observed by AFM analysis do not result in major differences in the electrical transfer characteristics. Indeed, transfer characteristics appear quite similar for all devices, with field-effect mobility, μ_{FE}, ranging between 0.3 and 0.4 cm^2/Vs and subthreshold slope of about 0.6 V/dec. It can be also noted that hysteresis of transfer characteristics, measured in vacuum, is very small for all samples. On the contrary, when the measurements are carried out in air (with a relative humidity of 50%) (see Fig. 3) the transfer characteristics measured from off-to-on and from on-to-off are different, resulting in a counter-clockwise hysteresis. As evident in Fig. 3, the differences in the pentacene morphology influence the device electrical characteristics measured in air: whereas only a small increase of hysteresis observed in the low growth-rate devices, high growth-rate O-TFTs exhibit an evident sensitivity to environmental conditions. Also shown in Fig. 3 are the transfer characteristics of a TC pentacene O-TFT fabricated without PMMA buffer layer and with pentacene active layer deposited at a growth rate of 0.07 nm/s. Lower field-effect mobility is observed in such devices, probably related to the different interface quality between pentacene and gate oxide and confirming the beneficial role of the PMMA. On the other hand, the hysteresis remains comparable with the devices with

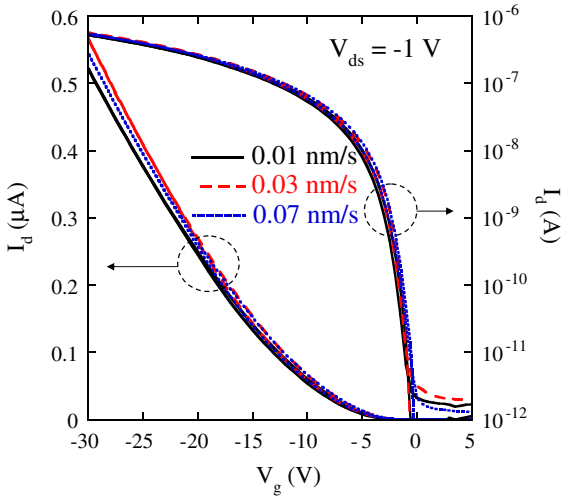

Fig. 2. Transfer characteristics, measured in vacuum, of TC pentacene O-TFTs with active layers deposited at different growth rates (as shown in the legend). The O-TFTs have channel length $L = 100$ μm and channel width $W = 200$ μm. The transfer characteristics are measured sweeping the gate voltage, sequentially, from off-to-on and from on-to-off. Only a small counter-clockwise hysteresis can be observed for all devices.

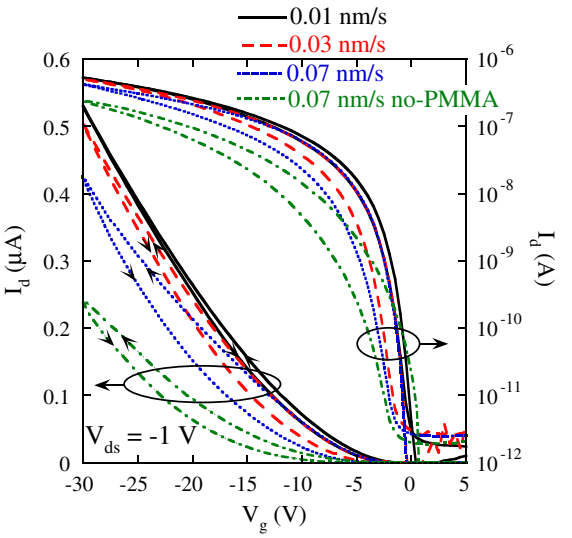

Fig. 3. Transfer characteristics, measured in air, of TC pentacene O-TFTs with active layers deposited at different growth rates. Also shown are the transfer characteristics of a device fabricated without PMMA buffer layer (dot-dashed curve). As in Fig. 2, off-to-on and on-to-off sweeps are sequentially measured and a counter-clockwise hysteresis is observed, dependent on pentacene growth-rate.

PMMA buffer layer and active layer deposited at the same growth rate. This implies that the PMMA layer does not increase the sensitivity of pentacene O-TFTs to moisture and suggests that the hysteresis is unlikely related to the pentacene/gate dielectric interface or to trapping into the gate dielectric.

By analyzing in more detail the experimental data shown in Figs. 2 and 3, we can observe that the off-to-on sweep of characteristics measured in air coincides with the curves measured in vacuum in the subthreshold regime, whereas in the on-regime (above threshold voltages) a current reduction is observed, both in the off-to-on and on-to-off sweeps. This reduction is induced by the progressive shift of threshold voltage and can be related to charge trapping occurring during the off-to-on sweep above threshold voltage [2]. It can be also noted that the on-to-off curve measured in air is almost parallel to the characteristics measured in vacuum, showing that in our devices the field-effect mobility is not influenced by the water diffusion into pentacene active layer, as sometimes observed in literature [4,5].

In order to quantitatively evaluate the hysteresis of the transfer characteristics we can consider, for a given current level, the voltage difference between the transfer characteristics measured in vacuum and in air, as shown in the inset of Fig. 4 for the device with the active layer grown at $r = 0.07$ nm/s. The average voltage shifts, evaluated considering as reference current the drain currents measured in air at $V_g = -30$ V and averaged over more than 12 devices, are reported in Fig. 4. As can be seen, whereas devices with pentacene active layer deposited at low growth rate (0.01 nm/s) show a very small hysteresis, a voltage shift as high as 4 V is observed in devices fabricated at higher growth rate and the hysteresis monotonically

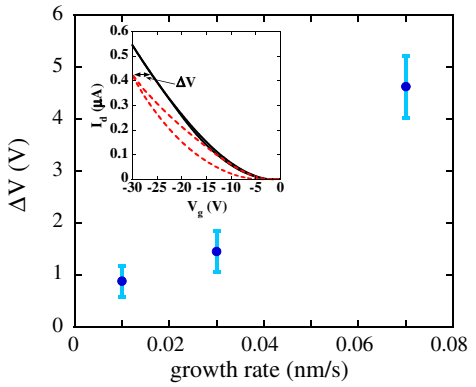

Fig. 4. Average voltage shifts (evaluated according to the method illustrated in the inset) of TC pentacene O-TFT transfer characteristics induced by water absorption in pentacene layers deposited at different growth rates. Average values and standard deviation were obtained from a set of >12 device measurements.

increases with increasing the growth rate. Considering that the hysteresis of transfer characteristics measured in air is related to the diffusion of H_2O into pentacene active layer [1,2], our results suggest that the diffusion takes place mainly at the grain boundaries, being enhanced by a higher density of grain boundaries and a less compact structure of pentacene layer.

3.2. Aging effects

In order to clarify the main cause of degradation of transfer characteristics when pentacene TFTs are exposed to air for a long time, we stored two BC TFTs, fabricated in the same run, in air and in pure oxygen, measuring their electrical characteristics during several days. As can be seen in Fig. 5, both devices show a current degradation mainly related to field-effect mobility reduction. However, as shown in Fig. 6, while the reduction of field-effect mobility of O-TFTs stored in air after 3 weeks is about 45%, a larger degradation (more than 90%) was observed in the devices stored in pure oxygen. These results clearly point out that the main cause of aging in pentacene TFTs is related to the diffusion of oxygen into pentacene film.

We then evaluated the aging effects for devices fabricated with different pentacene growth rates storing the devices in pure oxygen for 10 days and measuring the transfer characteristics of O-TFTs at different aging times. Fig. 7 shows typical transfer characteristics, measured in vacuum, of TC pentacene TFTs fabricated with active layers deposited at different growth rates before and after 10 days in oxygen. Control devices, stored in vacuum for the same aging period, did not show any variation of the transfer characteristics. As for BC TFTs shown in Fig. 5, the transfer characteristics of TC pentacene TFTs show

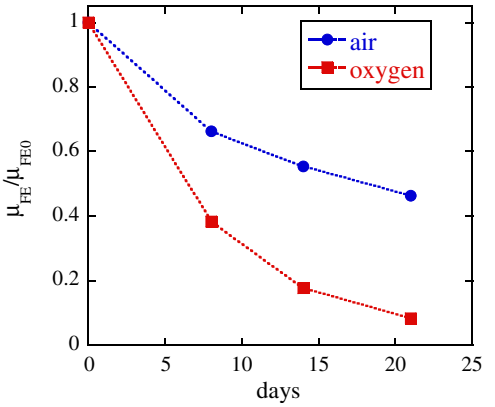

Fig. 6. Relative field-effect mobility variations, calculated from the transfer characteristics shown in Fig. 5, vs aging time for devices stored in air (dot) and oxygen atmosphere (square).

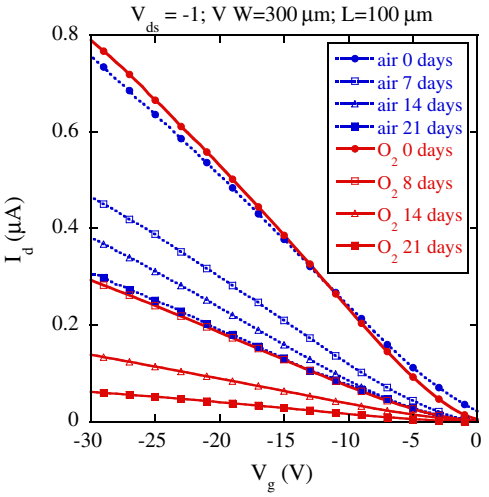

Fig. 5. Transfer characteristics of BC pentacene O-TFTs before and after storing the devices in air (dot lines) and oxygen atmosphere (solid lines) for several days (as shown in the legend).

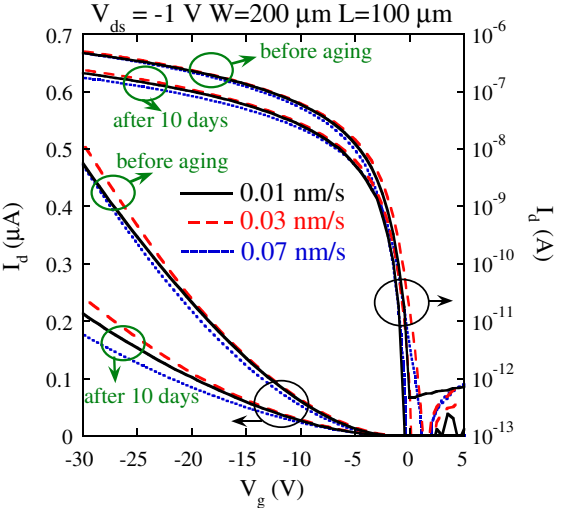

Fig. 7. Transfer characteristics of TC pentacene O-TFTs, with active layers deposited at different growth rates, before and after storing the devices in oxygen atmosphere for 10 days. The measurements are carried out in vacuum.

during the aging period a reduction of the on-current, mainly related to the reduction of field-effect mobility, confirming previous results. The relative variations of the field-effect mobility, averaged over more than 12 O-TFTs, during the aging time are reported in Fig. 8. As can be seen, the field-effect mobility reduction is similar, within the parameter variations observed for different O-TFTs, for devices fabricated at different growth rates, with a reduction of about 50% of the initial field-effect mobility values after 10 days. The average threshold voltage, V_{th}, variation (Fig. 9) during aging time seems not to be correlated to the structure of pentacene active layer. However, the large variation of the V_{th} values prevents to define a clear trend with aging time. It can be noted that the electrical characteristics variation induced by oxygen is not recovered after storing the sample in vacuum at room temperature for several days.

These results suggest that the aging induced by the oxygen is not correlated to the morphology of pentacene film. As a consequence the diffusion of oxygen into the film does not seem to occur at the grain boundaries but it appears to take place through the entire film. In addition, the decrease of field-effect mobility and the stability of subthreshold slope suggest that the effect of the oxygen can be attributed to the creation of defect states near the valence band, according to what observed in Ref. [9,12], while deep states seem to play a minor role.

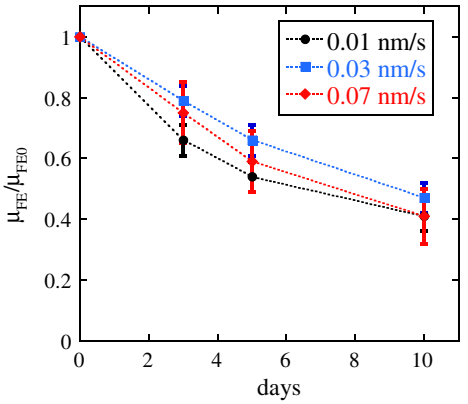

Fig. 8. Relative field-effect mobility variations (average values and standard deviation were obtained from a set of >12 device measurements) vs aging time in oxygen atmosphere for pentacene O-TFTs with active layers deposited at different growth rates.

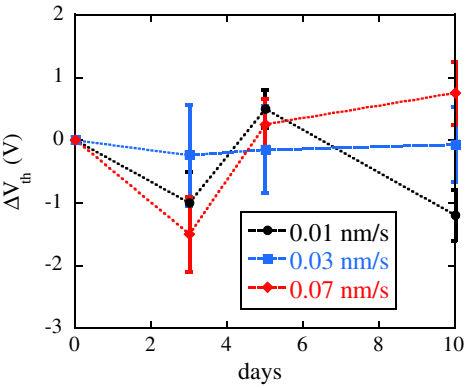

Fig. 9. Threshold voltage variations (average values and standard deviation were obtained from a set of >12 device measurements) vs aging time in oxygen atmosphere for pentacene O-TFTs with active layers deposited at different growth rates.

4. Conclusions

The environmental stability of pentacene TFTs with different active layer structure has been investigated. Higher hysteresis of transfer characteristics has been observed in devices with small grain pentacene films, deposited at high growth rate. This is evidence that a higher density of grain boundaries contributes to a higher sensitivity to moisture, probably due to an enhanced diffusion of water molecules in the pentacene film through the grain boundaries. The water molecules can be trapped at the grain boundaries or incorporated in the film affecting the transport properties of pentacene O-TFTs, probably inducing lattice distortion and polarization that generate slow traps for holes [2].

We showed that long term stability of transfer characteristics of pentacene TFTs is related to interaction with oxygen that induces appreciable degradation of field-effect mobility. The long term stability appears not to be influenced by the pentacene structure and, therefore, by the number of grain boundaries present in the channel, indicating that the diffusion of oxygen takes place through the entire pentacene active layer.

The present results indicate that an improvement of pentacene layer structural properties can reduce the sensitivity of devices to water, reducing the need of a water barrier layer, whereas an oxygen barrier layer is required in order to avoid aging effects of pentacene O-TFTs.

Solution process

ABSTRACT

Single crystalline microwires and polycrystalline microtwists were self-assembled from X-shaped conjugated molecules through solution process in high yield. The excellent long-range optical waveguide ability and efficient light transfer between wires made the as-prepared microwires potential building blocks for complex optical devices at micrometer scale. By slight structural change, well-dispersed polycrystalline microtwists were also successfully obtained. We further demonstrated that such chiral structures could also be used as optical waveguiding materials. The investigation of photo waveguide property in the well-dispersed single microtwist is the first demonstration of chiral microstructures in the application of optical waveguide, which opens the possibility of coupling the chirality of material to that of light.

1. Introduction

Due to the quantum effects of electrons, traditional integrated circuits are facing serious challenges when the device size goes down to tens of nanometers. Therefore, it is important to exploit novel optical materials and technologies for information transmission and processing in the next generation information and communication systems. Most recently, considerable attention has been paid to the preparation and fabrication of semiconducting nanomaterials due to their potential applications as active materials in miniaturized optoelectronic devices [1–8]. Among all kinds of functional optoelectronic materials, submicrometer photo waveguide materials play an important role in integrated light-based devices [9–11]. They can be used to control the efficient delivery of light at nano or micrometer scale, indicating the possibility of high-speed and low-loss integrated circuit. One dimensional single crystal inorganic nanowires for active photo waveguide materials have been obtained through chemical vapor deposition (CVD) or physical vapor deposition (PVD) method, and their photo waveguide properties, including the optical cavity effect and lasing, have been extensively studied [12–16]. Very recently, nano- or micro- architectures (mostly 1D structures) self-assembled from conjugated organic molecules through solution process have been attracting increased interest in this field [3–8]. They might serve as better media to generate or propagate light in a predefined way, due to their flexibility, easy optical tunability, strong luminescence efficiency [17–30]. However, waveguiding behavior has been observed only in few organic materials. Hence, the challenge of fabricating organic nanowires, which could provide photo waveguide devices with enhanced performance and more functionality, is a subject of significant scientific interest and technological importance.

Herein, we report the photo waveguiding behaviors of single crystalline microwires and polycrystalline microtwists fabricated by solution process from a new kind of X-shaped π-conjugated molecules synthesized by us recently [31]. These ultralong microstructures provide us

doi:10.1016/j.orgel.2010.12.016

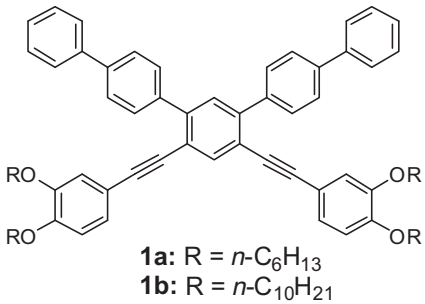
much convenience in the fabrication of optical and electronic devices. Fluorescence microscope and scanning near-field optical microscope (SNOM) show that our 1D microstructures can serve as long-distance active optical waveguides, which allow locally excited photoluminescence to propagate along the 1D structure and out-couple at the tip. We further observed excellent coupling between the as-synthesized organic wires, which is an important element in the construction of complex optical circuits. The ability to change the direction of light would be of great interest for real application in miniaturized complex photonic devices [9–11]. By slight change in chemical structure, we have obtained well-dispersed single microtwist and further demonstrated that such chiral structures could also be used as optical waveguiding materials. Our microtwist is the first chiral structure for waveguide research and opens the possibility of coupling the chirality of material to that of light.

2. Materials and methods

X-shaped molecules were synthesized in our recently published paper [31]. Absorption spectra were recorded on PerkinElmer Lambda 35 UV–vis Spectrometer. Photoluminescent (PL) spectra were carried out on PerkinElmer LS55 Luminescence Spectrometer. Thermal gravity analyses (TGA) were carried out on a TA Instrument Q600 analyzer and differential scanning calorimetry (DSC) analyses were performed on a METTLER TOLEDO Instrument DSC822e calorimeter. Scanning electron microscopy (SEM) was performed on a Philips XL30W/TMP operating at 1 kV. Transmission electron micrographs (TEM) were recorded on a Philips model Tecnai F20 electron microscope operating at 120 kV. Powder X-ray diffraction was recorded on a D/max-RA High Power Rotating Anode 12KW X-ray Diffractometer. Refractive index was measured on a HORIBA JOBIN YVON spectroscopic ellipsometer. The fluorescence images were taken on a DMLS fluorescence microscope (Leica, Germany). The optical waveguide properties were measured with a scanning near-field optical microscope composed of a NSOM-100 near field scanning tip (Nanonics Co.), SPM-100 (RHK Co.) controller and SPEX 0.34 fluorescence optical spectrometer.

3. Results and discussion

Scheme 1 illustrates the chemical structure of our X-shaped molecules. Fig. 1 shows the absorption and photoluminescence (PL) spectra of **1a** in CH_2Cl_2 solution and in the crystalline state. The monomer exhibits two resolved absorption peaks at 300 and 327 nm, and a relative weak shoulder peak at about 350 nm. All absorption peaks slightly red-shifted after the molecules self-assembled into microwires, and the intensity of the shoulder peak increases considerably. In the dissolved state, **1a** exhibits a single emission peak at about 414 nm. In the solid state, a small red-shift of the photoluminescence peak was observed. The small red-shifts in absorption and fluorescence spectra on going from solution to solid state indicated that the π–π stacking interactions among the molecules are not very strong in the microwires. The photophysical properties of **1b** are almost the same as that of **1a** due to the same skeleton.



Scheme 1. Chemical structure of X-shaped molecule **1a** and **1b**.

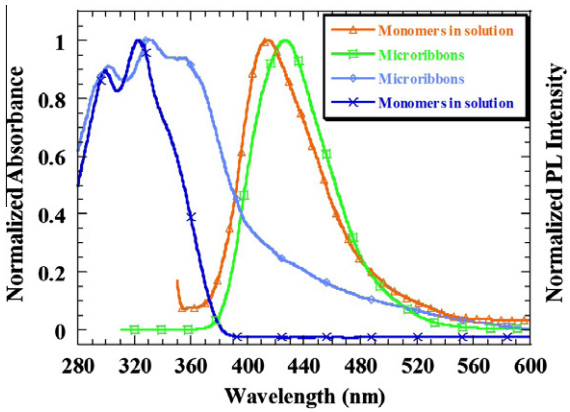


Fig. 1. Normalized absorption and emission spectrum of **1a** in dilute CH_2Cl_2 solution (1×10^{-6} M) and in single-crystalline microribbons.

A facile method that combines reprecipitation and self-assembly techniques [5] was developed to fabricate the single-crystalline microribbons. Experimentally, the microstructures were prepared by dissolving the molecule **1a** in mixed solvents of CH_2Cl_2 and EtOH (1:1.5, V/V) at a concentration of 1 mg/mL and stay with slow evaporation of the solvents. The slow crystallization process results in the formation of ribbon-shaped aggregates from the self-assembly of the molecules. Fig. 2 shows typical scanning electron microscopy (SEM) and fluorescence microscope images of the microribbons. Large-area SEM images of an EtOH suspension of self-assembled **1a** through slow crystallization process on silica substrate showed a uniform fibrous structure (Fig. 2a). Most of the microribbons are hundreds of micrometers long and 1–4 μm wide. Small area SEM image (Fig. 2b) demonstrated that each single ribbon has a fixed size along its entire length. The cross-sections of the microribbons are rectangular (see Fig. 2c), which is a propitious condition to realize the fluorescence out-coupling at the end of the ribbons compared with the microstructures with irregular tips. Some thinner nanowires with length of tens of micrometers and width of 200–400 nm were also found. The selected area electron diffraction (SAED) pattern indicated that the

ribbon-shaped 1D morphology was single crystalline [31]. Fig. 2d shows a PL microscopy image of the microribbons on glass substrate. The microribbons were transferred onto the substrate by spin casting and were directly observed by using a PL microscope. The PL image shown in Fig. 2d indicates that the microribbons exhibit blue emission, with very bright luminescence spots at both tips and relatively weaker emission from the bodies of the ribbons. This is a typical characteristic of an optical waveguide material.

Photoluminescence images of the microribbons on a glass substrate reveal that they are suitable for long-range optical waveguide materials. To study the detailed wave-guiding properties of the microribbons, we employed a continuous laser focused down to the diffraction limit (~5 μm) with a wavelength of 325 nm according to the absorption spectrum of the microribbon. The local emission of light from each single microribbon under laser excitation was so strong that it could be imaged clearly with a color CCD. Fig. 3a shows the micro area fluorescence microscopy image of a single microribbon obtained from scanning near-field optical microscopy (SNOM) in bright field, indicating that the ribbons are suitable single wire long range photo waveguide materials. Guided PL was emitted from both ends of the microribbons irrespective of the excited position. No emission was detected other than the tips and the excited area. It can be supposed that due to a large enough diameter of the crystallite (larger than excitation and fluorescence wavelength), luminescence excited on the ribbon surface spreads out inside the ribbon by means of total internal reflection [22].

A SNOM collection tip was placed stationary at one of the ribbon ends to detect the out-coupled fluorescence. As shown in Fig. 3b, the PL spectra collected at different transmitted distance are very similar, with only a slight red-shift due to self-absorption at low wavelength. The process of light traveling along the wire can be investigated by moving the laser along the ribbon, as shown in Fig. 4. The distance-dependent photoluminescence spectra, showing propagation of light through single microribbons, were also measured with a SNOM. The PL intensity at 424 nm decreases with increasing the guided distance, without any change in outcoupled position (Fig. 3c). The optical loss mainly comes from the reabsorption during propagation of light and coupling between the ribbons and the substrates. Another possible source for the optical loss is the Rayleigh scattering arising from defects and roughness, which will result in the local variation in the refractive index along the length of the ribbons.

$$\alpha = -10 \times \log(I_{out}/I_{in}) \times L^{-1} \quad (1)$$

The optical loss coefficient of guided fluorescence in the microribbons can be calculated by the following Eq. (1). I_{out} and I_{in} are the intensities of incidence and out-coupled light, and L is the propagation distance [30]. The loss coefficients at 424 nm in the microribbons is determined to be 4.9 dB/100 μm, which is much lower than those of many 1D organic nanomaterials reported before [28–30]. This indicated that the microribbons are excellent candidate for low-loss, long-distance optical waveguide material. The PL of the microribbons at 424 nm displays linear losses (Fig. 3d) with increasing propagation length. Hence, by using the loss coefficient and the value of I_{in} from the spectrum of L = 40 μm in Fig. 3d, one could calculate the theoretical intensity of PL at different wavelengths guided through different distance (L) along the microribbons.

The transition from spontaneous PL to stimulated emission is significantly influenced by the size and length of the

microribbons. For example, for thinner ribbons with a width of 300–400 nm, no emission was detected at the tip of the ribbon (Fig. 5). It has been demonstrated that light can only propagate within the transverse magnetic (TM) modes of microribbon waveguides [24], whereby the number of possible modes, m, is restricted by

$$m < \frac{2a}{\lambda} \cdot \frac{n_{\perp}}{n_{\parallel}} \cdot \sqrt{n_{\parallel}^2 - n_s^2} \qquad (2)$$

with a being the width of the ribbon; $\lambda \approx 424$ nm, the wavelength of the propagated light, $n_{\parallel}$ and $n_{\perp}$, the refractive indices along and perpendicular to the microribbon, respectively, and $n_S = 1.46$, the refractive index of the quartz substrate. Here, we assume that both $n_{\parallel}$ and $n_{\perp}$ are close to the value of the bulk material (≈1.62), which was measured using a spectroscopic ellipsometer (as shown in Fig. 6). According to the Eq. (2), the minimum width required for light propagation at 424 nm is approximately 302 nm as given by $m = 1$. This is consistent with the experimental observations that thinner ribbons with a width of 300 nm exhibit no long-range optical waveguide properties. The maximum mode (m) that a microwire with width of 2 μm could propagate is 6.

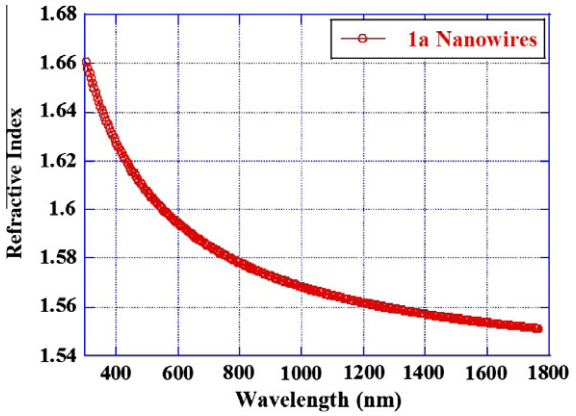

Fig. 6. The wavelength-dependent refractive index of the microwires measured with an HORIBA JOBIN YVON spectroscopic ellipsometer.

The cutoff wavelength above which no propagating mode can exist can be given as follows:

$$\lambda_{\text{cutoff}} = 2a\sqrt{n_{\parallel}^2 - n_s^2} \tag{3}$$

By using the above values of $n_{\parallel}$, $n_{\perp}$ and $n_{S,}$ the λ_{cutoff} is calculated to be 421 and 1402 nm when $a = 300$ and 1000 nm, respectively. This mode analysis implies that due to the cutoff effect, the ribbons with a width of about 300 nm may exhibit an significant increase in the optical loss for $\lambda >$ 421 nm. The cutoff effect can be observed only for ribbons with a relatively narrow width because λ_{cutoff} is out of the wavelength range of the emission band for fibers wider than 650 nm. In our case, most of the ribbons were 1–4 μm along the 1D direction, so the cutoff effect has negligible influence on the out-coupling fluorescence at 424 nm.

Excellent coupling effect (Fig. 7) was found in the system of two or more ribbons from molecule **1a**, which was unusual in organic micrometer scale photo waveguide materials. In Fig. 7a and b, both the right ends of ribbons A and B emitted luminescence as long as any one of the left ends was excited by the laser. This observation suggested that part of the light is transferred from one ribbon to another, and the residual light propagated along the same ribbon. Similar coupling behavior could also be observed for 3 or more microwires, as shown in Fig. 7c and d. The left end of ribbon C emitted intrinsic luminescence of the microribbon if the right end of ribbon A was excited, showing the transfer of light among three ribbons, which was never reported before. This phenomenon is common in our material. We tentatively proposed that the transfer of the light took place at the contact point of the two fibers where the difference of the refractive index disappeared. The surface condition of the fibers at the contact point is an important factor for the transfer of the light. As an example, in Fig. 7b, 46% of the light intensity transfer into ribbon A from ribbon B at the contacting point according to the known loss constant (Fig. 8). The unique feature of the microfibers provides us a convenient way to control the direction and distribution of the fluorescence, indicating the potential in building complex optical system in micrometer or submicrometer scale.

Usually, waveguiding materials have simple geometric shapes such as wire and ribbon. We wondered whether complex microstructure could also used to transport light and whether such materials would give new physical phenomena. As we reported recently, by simply changing the length of peripheral alkoxy groups, well-dispersed, regular microtwists were easily obtained [31]. Such a large change in morphology was remarkable. We ascribed such change to different crystal growth kinetics of **1a** and **1b**. In short, the imbalance in the growth rate between the center and the edge part of a growing front provided the driving force for twist growth in **1b** [31]. In the preparation of the manuscript, Luis Sánchez and coworkers also reported a similar system for the growing of chiral one-dimensional microstructures. However, in our system, the chirality of the microwires was not induced by the chirality of the side alkyl chains but by the intrinsic crystal packing [32]. Fig. 9a shows a SEM image of the microtwists prepared at 15 °C through solution process. The fluorescence microscope image of the microtwist on glass substrate (Fig. 9b and inset)
