
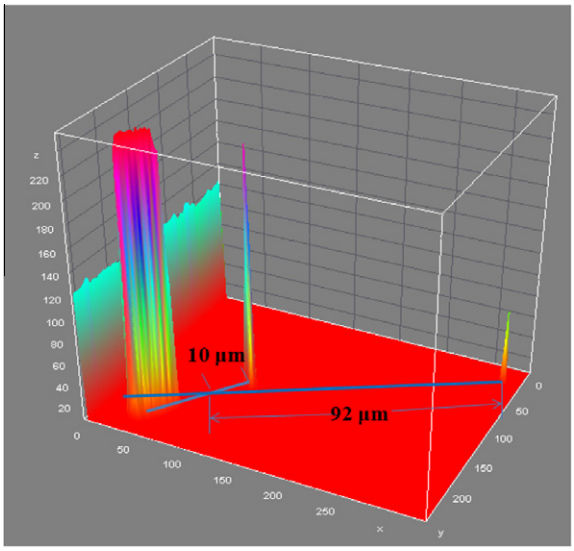

Fig. 8. The calculation of the transfer efficiency in Fig. 7b.

indicates that such chiral structure could also serve as optical waveguide materials. The distance-dependent photoluminescence spectra along a single microtwist were also measured with a SNOM. Fig. 9d shows the logarithmic plot of relative intensities of PL peak of the microtwists with a pitch of 1 μm. The microtwist showed photo waveguide properties similar to that of the microwire. Although its loss coefficient is systematically higher (8.3 dB/100 μm with a pitch of 1 μm according to Eq. (1)), the loss coefficient is still lower than many other organic photo waveguide materials [30]. The comparatively higher performance of the microribbons can be attributed to two factors: first, as demonstrated by SAED experiment [31], the microribbons are single crystalline while the microtwists are relative polycrystalline. Single crystalline materials are known to have superior device performance due to less grain boundaries and scattering. Second, the dramatic curvature change at the groove of the twists might constitute many scattering sites, which further increased the optical loss. The scattered strength should be strongly dependent on the size of the scattering center; further investigation is undergoing focused on these problems. In general, the loss coefficient increased with the decrease of the pitch, which is a result of the lower crystallinity and more scattering sites. Nevertheless, the ability of realizing single twist device with definite chirality allowed us to explore the interesting possibility of chirality-coupled optical devices. We are currently examining this possibility in a single left-handed or right-handed twist.

4. Conclusion

In summary, we have demonstrated a series of 1D microstructure which can be used as optical waveguide materials. 1D microwires and microtwists were prepared from X-shaped conjugated molecules through simple solution process in high yield, which provides us a convenient and low-cost fabrication method for functional organic microstructures. The as-prepared microwires demonstrated excellent properties in low-loss long-distance (4.9 dB/100 μm, >200 μm) photo waveguide in single wire as well as the transfer of light between the wires, showing the potential as building blocks in complex optical devices

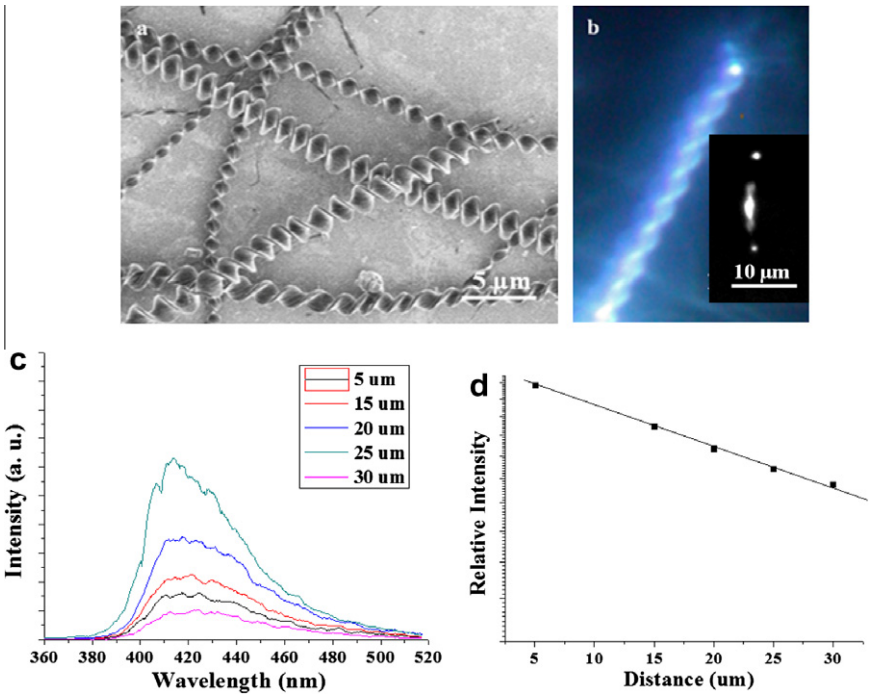

Fig. 9. (a) SEM image of the microtwists prepared at 15 °C. (b) Photoluminescence images of a single microtwist. Inset: the photo waveguiding behavior of the microtwist. (c) The distance-dependent photoluminescence spectra of propagated light through single microtwist measured with an SNOM detection tip. (d) The logarithmic plot of relative intensities of PL peak at 424 nm.

at micrometer scale. On the other hand, we were also able to greatly change the morphology of the microstructure by a slight change in the chemical structure. Our microtwist is the first chiral material that shows waveguiding properties. Despite the medium performance (8.3 dB/100 μm), realization of photo waveguiding in chiral materials suggest many interesting possibilities for novel devices. Further efforts would be made to control the distribution of PL between two wires, and to reveal the relationship between the coupling efficiency and the surface condition of the wires at the contact point. Also, we are further developing microtwists with pitch comparable to the wavelength of guided light in order to check whether the chirality of the materials would influence its interaction with light.

ABSTRACT

We report a comparative study of optical properties, structure and morphology, field-effect transistor (FET) and solar cell performance between poly(4-(3,4′-dihexyl-2,2′-bithiophen-5-yl)-7-(5′-(9,9-dioctyl-9*H*-fluoren-2-yl)-3,4′-dihexyl-2,2′-bithiophen-5-yl)benzo[*c*][1,2,5]-thiadiazole) (F8TTBTT), and its predecessor poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthien-5-yl)-2,1,3-benzothiadiazole]-2′,2″-diyl) (F8TBT). Compared to F8TBT, F8TTBTT has two more thiophene units incorporated in its monomer structure. Such a modification leads to a reduced optical band gap, improved charge injection and significantly enhanced ambipolar field-effect mobilities reaching 5×10^{-2} $cm^2 V^{-1} s^{-1}$ for holes and 4×10^{-3} $cm^2 V^{-1} s^{-1}$ for electrons. The enhanced carrier mobilities are most likely a result of an increased backbone planarization and interchain interaction. As a consequence of ambipolar transport, light-emission was observed from the transistor channel during operation. The reduced band gap and improved charge transport make F8TTBTT an interesting candidate also for solar cell applications. Unoptimized solar cells based on F8TTBTT:PCBM blends were found to exhibit power conversion efficiency under AM 1.5 illumination of ~1.54%.

1. Introduction

Solution-processed semiconducting conjugated polymers have attracted extensive interest in recent years in applications such as organic field-effect transistors (FETs) and organic photovoltaics (OPV) [1–4]. This class of materials combines several appealing characteristics such as low-cost synthesis, tunable optical and transport properties, high absorption coefficients, physical flexibility, and large-scale industrial processing. For FET applications, recent synthetic progress has demonstrated impressive field-effect mobility values in between 0.1 and 0.8 $cm^2 V^{-1} s^{-1}$ in some conjugated polymer systems [5–7]. Yet the charge transport properties of polymers are often extremely sensitive to their morphology and crystallinity [1,8,9]. Many amorphous polymers synthesized to-date, while demanding less processing control over semicrystalline systems, still have field-effect mobilities lower than 0.01 $cm^2 V^{-1} s^{-1}$ [4,10–12]. Much research efforts are currently being addressed to achieve improved transistor performance by understanding material synthesis, microstructure, processing, and device architecture. Furthermore, ambipolar charge transport with balanced electron and hole mobilities has been discovered to be an intrinsic property of many organic semiconductors [4,11]. This has opened up exciting opportunities for application of organic materials in new device architectures. These

architectures include complementary-like voltage inverters with a single semiconducting material [13,14] and light-emitting FETs [15–17], which combine the switching behavior of transistors and the light-emitting behavior of light-emitting diodes (LEDs). In terms of scientific understanding there are still subtle differences between electron and hole mobilities in many polymer families and better understanding of how these depend on the molecular structure of the polymer is needed. This requires classes of materials where ambipolar transport properties can be correlated with targeted modifications of chemical structure.

For solar cell applications new conjugated polymers having efficient charge transport of electrons and holes and good absorption properties are required [2]. In organic bulk heterojunction solar cells, the photocurrent is governed by two main factors: (1) the amount of absorbed photons in the active layer under a fixed total flux of photons; (2) the internal quantum efficiency defined by the fraction of collected carriers per absorbed photon, which contains the efficiencies in both exciton dissociation and carrier transport toward collecting electrodes. Approaches to rationally increase carrier mobilities in conjugated polymers and extend their absorption ranges to cover a larger portion of the solar spectrum, while maintaining efficient charge generation at the donor–acceptor heterojunction, are currently under intensive research [2,18].

Among many conjugated polymer systems reported recently, the poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthien-5-yl)-2,1,3-benzothiadiazole]-2′,2″-diyl) (F8TBT) system and similar derivatives without side chains on the thiophene units (often labeled as APFO-3 or PFDTBT) have received much research attention in LED, solar cell and FET studies [16,19–25]. Compared to other polyfluorene derivatives such as poly(9,9-dioctylfluorene) (F8) and poly(9,9-di-*n*-octylfluorene-*alt*-benzothiadiazole) (F8BT) [11,12], F8TBT has a higher HOMO level and a smaller band gap [19,22]. Due to the electron-withdrawing benzothiadiazole (BT) moiety and the relative small band gap, F8TBT FETs exhibit good ambipolar transport characteristics with gold as injection electrodes [16]. Even though the hole and electron mobilities in such ambipolar F8TBT FETs are imbalanced, red light emission during device operation was observed. On the other hand, because F8TBT shows larger absorption range in the solar spectrum compared to other polyfluorene derivatives, it has also shown potential for use in solar cells [21–23]. Due to its ambipolar nature, efficient solar cells have been demonstrated based on the use of F8TBT as an electron donor (in polymer/small molecule blends) [21–23] and an electron acceptor (in polymer/polymer blends) [2,21–24]. P3HT-F8TBT polymer blend solar cells are currently among the best performing non-fullerene based organic solar cells [26]. Based on the chemical structure of F8TBT, a recent study showed that increasing the number of thiophene rings in the repeating units of this donor–acceptor type of polymers can effectively red-shift the absorption spectra [25]. Even though enhanced solar cell performance was shown, the charge transport properties in these new systems containing more thiophene units have not yet been studied.

In this work, through a systematic comparison between F8TBT and poly(4-(3,4′-dihexyl-2,2′-bithiophen-5-yl)-7-(5′-(9,9-dioctyl-9*H*-fluoren-2-yl)-3,4′-dihexyl-2,2′-bithiophen-5-yl)benzo[*c*][1,2,5]thiadiazole) (F8TTBTT), we present a comprehensive study aiming to understand the effect of these additional thiophene units on electronic structure, optical properties, structure and morphology, charge transport in FETs and solar cell performance. In particular, by comparison to other previously reported polyfluorene derivatives, we find that F8TTBTT demonstrates enhanced field-effect mobility for hole transport, while extending its absorption range due to its reduced band gap. Combined improvements in both carrier mobility and absorption range make this new material an interesting system for its further optimization and application in FETs and solar cells.

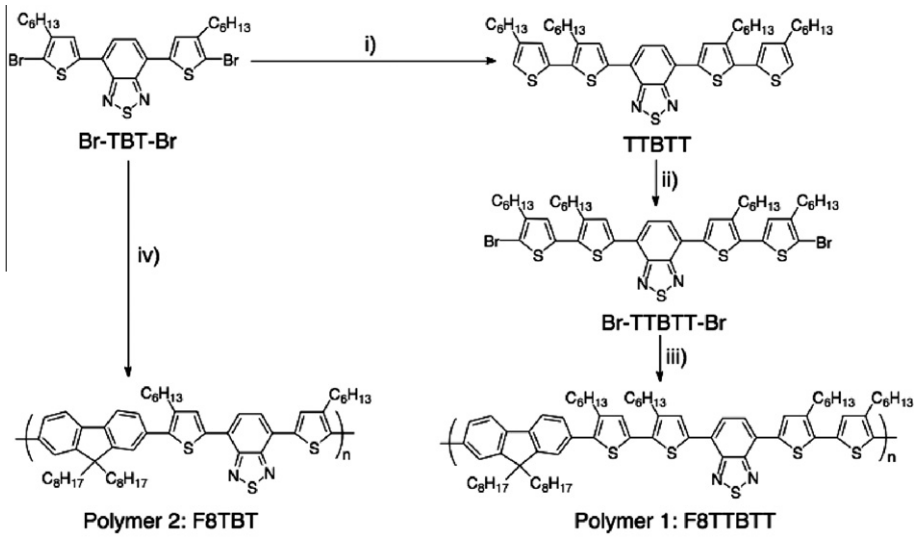
2. Experimental section

2.1. Synthesis

All commercial chemical reagents were obtained from Aldrich and used as received. 4,7-Dibromo-2,1,3-benzothiadiazole, 3-hexylthiophene and fluorene were purchased form Aldrich for precursor synthesis. 2,7-bis(1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene, 4,7-bis(5-bromo-4-hexylthiophen-2-yl)benzo[*c*][1,2,5]thiadiazole (Br–TBT–Br), 4,7-bis(5′-bromo-3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[*c*][1,2,5]thiadiazole (Br–TTBTT–Br) were prepared following the already published procedures [20,27]. Synthetic pathways are described in Scheme 1. For step (i), $PdCl_2(PPh_3)_2$ was added to a solution of tributyl(4-hexylthiophen-2-yl)stannane and Br–TBT–Br in tetrahydrofuran (THF). The mixture was refluxed under a nitrogen atmosphere for 6 h before solvent removal and purification. For step (ii), TTBTT was dissolved in THF under a nitrogen flow and then *N*-bromosuccinimide (NBS) was added. The reaction mixture was stirred at 0 °C for 2 h before product extraction. Details of these steps can be found in previous reports [20,27].

2.1.1. 4,7-Bis(3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[c][1,2,5]thiadiazole (TTBTT)

0.06 mmol $Pd(PPh_3)_4$ was added to a solution of 1 mmol 4,7-bis(5′-bromo-3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[*c*][1,2,5]thiadiazole (TBT) and 2.5 mmol tributyl-(4-hexyl-2-thienyl)stannane in THF under nitrogen. The mixture was refluxed under a nitrogen atmosphere for 12 h. The reaction solution was cooled to room temperature. After the removal of most of the solvent at a reduced pressure, the residue was purified by column chromatography on silica gel (eluent CH_2Cl_2/hexane) to yield pure product (TTBTT) with a yield of 90%. ^{1}H NMR (400 MHz, $CDCl_3$). δ (ppm): 7.90 (s, 2H), 7.75 (s, 2H), 7.00 (s, 2H), 6.87 (s, 2H), 2.79–2.75 (m, 4H), 2.58–2.54 (m, 4H). 1.70–1.56 (m, 8H), 1.37–1.24 (m, 24H), 0.85–0.81 (m, 12H). ^{13}C NMR (100 MHz, $CDCl_3$). δ (ppm): 153.00, 144.15, 140.65, 137.01, 136.06, 133.30, 130.99, 127.82, 125.88, 125.59, 120.69, 32.09, 31.01, 30.92, 30.82, 29.91, 29.71, 29.42, 23.05, 23.03, 14.50.



Scheme 1. Synthetic pathways to precursors and the structures of the two polymers studied in this work: F8TTBTT and F8TBT.

2.1.2. 4,7-Bis(5′-bromo-3,4′-dihexyl-[2,2′-bithiophen]-5-yl)-benzo[c][1,2,5]thiadiazole (Br–TTBTT–Br)

4,7-Bis(3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[*c*][1,2,5]thiadiazole (TTBTT) was dissolved in THF under a nitrogen flow at 0 °C. After complete dissolution of the solid, 2.05 equal *N*-bromosuccinimide (NBS) was added. The reaction mixture was stirred at 0 °C for 5 h and warmed to room temperature for 10 h. The reaction solution was extracted with ether, and the organic layer was washed with brine for three times and dried over anhydrous sodium sulfate. The solvent was removed at a reduced pressure to give the product as a red solid. The crude solid was purified by column chromatography on silica gel (yield: 80%); ^{1}H NMR (400 MHz, $CDCl_3$). δ (ppm): 7.83 (s, 2H), 7.67 (s, 2H), 6.83 (s, 2H), 2.72–2.68 (t, 4H), 2.52–2.48 (t, 4H), 1.65–1.53 (m, 8H), 1.35–1.27 (m, 24H), 0.85–0.81 (m, 12H). ^{13}C NMR (100 MHz, $CDCl_3$). δ (ppm): 152.86, 142.96, 141.05, 135.92, 130.87, 127.19, 125.75, 125.54, 109.37, 32.08, 32.05, 31.00, 30.08, 29.98, 29.91, 29.70, 29.35, 23.06, 23.02, 14.50.

2.1.3. Polymerization of F8TTBTT (step iii of (Scheme 1))

2,7-Bis(1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (0.5 mmol, 265.18 mg), 4,7-bis(5′-bromo-3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[*c*][1,2,5]thiadiazole (Br–TTBTT–Br) (0.5 mmol, 478.08 mg) and $(PPh_3)_4Pd$ (8 mg) were dissolved in a mixture of toluene and aqueous 2 M K_2CO_3 under nitrogen flow. The solution was refluxed under vigorous stirring for 72 h under a nitrogen atmosphere. The mixture was then poured into methanol. The precipitate was recovered by filtration and was extracted by acetone, methanol for 24 h separately to remove oligomers and catalyst residues. The resulting polymer was dried under vacuum to afford the polymer (420 mg, 70%) as a black powder. ^{1}H NMR (400 MHz, $CDCl_3$). δ (ppm): 7.95 (m, 2H), 7.79 (m, 2H), 7.71–7.69 (m, 2H), 7.45–7.40 (m, 4H), 7.11 (m, 2H), 2.84–2.86 (m, 4H), 2.68–2.66 (m, 4H), 2.05–1.95 (m,4H), 1.73–1.64 (m, 8H), 1.48–1.03 (m, 48H), 0.85–0.73 (m,18H). Element Anal. Calcd for $C_{75}H_{100}N_2S_5$: C, 75.70; H, 8.47; N, 2.35. Found: C, 75.26; H, 8.39; N, 2.37.

2.1.4. F8TBT (step iv)

For comparison we also synthesized F8TBT following the already published procedure [20]. The polymerization procedure was the same as described for F8TTBTT except using 4,7-bis(5-bromo-4-hexylthiophen-2-yl)benzo[*c*][1,2,5]thiadiazole as the reactant instead of 4,7-bis(5′-bromo-3,4′-dihexyl-[2,2′-bithiophen]-5-yl)benzo[*c*][1,2,5]thiadiazole.

2.2. Material characterizations

The number-averaged molecular weight (M_n) and molecular weight distribution (M_w/M_n) were measured using a gel permeation chromatography (GPC) instrument. GPC was carried out using THF as the eluent (1.0 mL/min) at 35 °C on two PLGel 5 μm mixed-C columns from Polymer Laboratories (with pore size ranging from 10 to 10^5 Å), connected in series with a SPD M20A prominence diode array detector (Shimadzu) and a differential refractometer/viscometer model 200 (Viscotek) calibrated by polystyrene standard. AFM images were obtained using a Digital Instruments Dimension 3100 AFM in tapping mode. UV–Visible absorption spectra were measured in air using a Hewlett–Packard HP845× Visible–UV spectrometer (using quartz Spectrosil B substrates for polymer films and quartz cuvettes for solutions). The ionization potential (HOMO level) was measured by photoelectron spectroscopy with a Riken AC-2 spectrometer. Photoluminescence (PL) and photoluminescence quantum efficiency (PLQE) measurements were carried out at room temperature with a nitrogen-purged integrating sphere using polymer films on quartz Spectrosil B substrates. The 515 nm line of an argon-ion laser (Coherent Innova305) was used as the excitation source and a cooled CCD camera (Oriel Instaspec IV) was used for photon detection. The PLQE value was calcu-

lated as described by de Mello et al. [28]. For optical experiments (UV–Vis, AC-2 and PL/PLQE), thin films were spin-coated from 1,2,4-trichlorobenzene solutions. The θ–2θ X-ray diffraction data was obtained using a Pan-Analytical diffractometer with the X-ray wavelength to be 1.54 Å (CuKα). A TA Instruments DSC Q1000 was used in the modulated differential scanning calorimetry (MDSC) mode with a heating/cooling rate of 5 °C/min. Film thickness was measured using a Veeco Dektak 6 M stylus profilometer. Raman spectra were obtained using a WITec Raman microscope with a 785 nm excitation (Starbright diode laser system, ~0.6 mW) focused through a ×100 normal microscope objective. For Raman samples, film thickness ranging from 100 nm to 300 nm were investigated for F8TTBTT and F8TBT and no significant thickness dependence was found. For F8TTBTT and F8TBT Raman samples, we used different substrates, including quartz Spectrosil B substrates and glass substrates with 30-nm-thick gold evaporated on top. Besides the polymers synthesized in this work we also include in Fig. 3 a reference Raman spectrum measured on a F8BT thin film (~100 nm thick, on quartz Spectrosil B substrate). F8BT was obtained from Cambridge Display Technology Ltd. and its molecular weight M_n was 62 kg/mol.

2.3. Thin film field-effect transistors (FETs) fabrication and measurements

The polymer dielectric and all solvents used in device fabrications were used as purchased without further purification. We used poly(methyl methacrylate) (PMMA) as the gate dielectric (M_w = 319 kg/mol, polydispersity index (PDI) of 1.25, Polymer Source Inc.). The anhydrous solvent used to dissolve the semiconducting polymers was 1,2,4-trichlorobenzene (TCB, from Romil), and the solvent used to dissolve PMMA was *n*-butyl acetate (Aldrich). The top-gate/bottom-contact (TGBC) FET configuration was used for all transistors studied in this work. The gold source and drain bottom electrodes (with Cr as the adhesion layer) were patterned by photolithography and a double-layer lift-off process on low-sodium glass (Corning 7059) substrates. The semiconducting polymers were dissolved in TCB at 10 mg/mL by heating at 100 °C for 30 min. Polymer solutions were then deposited onto substrates by spin-coating with film thicknesses of ~30–50 nm. The as-spun films for FETs were dried at 100 °C for more than five hours to ensure residual solvent removal. For further annealing FET samples were placed on a hotplate (preheated to the annealing temperature) for 30 min before cooling down to room temperature. PMMA solution (45 mg/mL in *n*-butyl acetate) was then spin-coated onto the semiconducting polymer resulting in a dielectric layer of 500–600 nm thickness. After spin-coating the dielectric layer, samples were further dried at 80 °C for 30 min to remove any residual *n*-butyl acetate. A layer of semi-transparent gold (8.5 nm-thick) was then evaporated through a shadow mask onto the dielectric layer as the gate electrode by a thermal evaporator integrated into the glovebox. The transistors were characterized with an Agilent 4155B semiconductor parameter analyzer (SPA). In order to apply higher voltage (>100 V) we used a dual channel Keithley 2636A system sourcemeter. The dielectric capacitance (C_i) was determined with separate capacitor structures using a HP 4192A impedance analyzer. Light emission during FET operation was measured with a silicon photodiode (Hamamatsu, S1133-01) mounted directed above the gold top gate of the FETs. The sensitivity of the silicon photodiode is 0.39 A W^{-1} at λ = 670 nm, and 0.43 A W^{-1} at λ = 714 nm. To record electroluminescence (EL) spectra during FET operations, an Ocean Optics USB 2000 spectrometer was mounted directly on top of the gold top gate. Starting from the step of making the semiconductor polymer solution to the final step of FET measurements, all procedures/measurements were carried out inside a dry nitrogen glovebox.

2.4. Solar cell fabrication and measurements

[6,6]-Phenyl-C_{61}-butyric acid methyl ester (PCBM) was purchased from Nano-C. F8TTBTT:PCBM blend solutions were prepared with a weight ratio of 1:1, 1:2, 1:3, and 1:4 and heated at 100 °C to dissolve in anhydrous chlorobenzene (Romil). Blend solutions were then spin-coated onto PEDOT:PSS-coated indium-tin oxide substrates. Two kinds of active layer (blend film) thickness were experimented by controlling the spin rate (6000 rpm for thickness ~100 nm, and 8000 rpm for ~80 nm). Device were completed by evaporation of 100 nm of aluminum deposited at a vacuum lower than 2×10^{-6} mbar. For annealed solar cells, after the aluminum evaporation, samples were placed onto a hotplate (preheated to 150 °C) for 30 min before cooling down to room temperature. As-spun and annealed solar cell devices were then encapsulated before removal from the glovebox for testing in air. Device external quantum efficiency (EQE) was evaluated as a function of wavelength at intensities $\leqslant$1 mW cm^{-2}, with short-circuit current measured by a Keithley 237 source measure unit (SMU). Current–voltage (*I*–*V*) characteristics were recorded in the dark and under monochromatic light source λ = 550 nm using Keithley 237 SMU. For optimized devices, *I*–*V* characteristics were also recorded under simulated solar conditions (100 mW cm^{-2} air mass AM 1.5 global spectrum) from an Oriel 81160-1000 solar simulator calibrated to a silicon reference cell.

3. Results and discussion

3.1. Material characterization

The chemical structures of the two polymers examined in this study are shown in Scheme 1. UV–Vis absorption experiments on F8TTBTT and F8TBT solutions and spin-coated thin films reveal characteristic "camel-back"-shape [19,29] absorption spectra (Fig. 1a). In the case of F8TBT, using semi-empirical quantum-chemical method, the "camel-back" absorption spectrum was previously attributed to one charge transfer state at lower energy localized on the TBT unit and one delocalized excitonic state at higher energy corresponding to the π-conjugated segment of the polymer backbone [29]. Based on the similarities previously found between F8BT and F8TBT, we speculate that

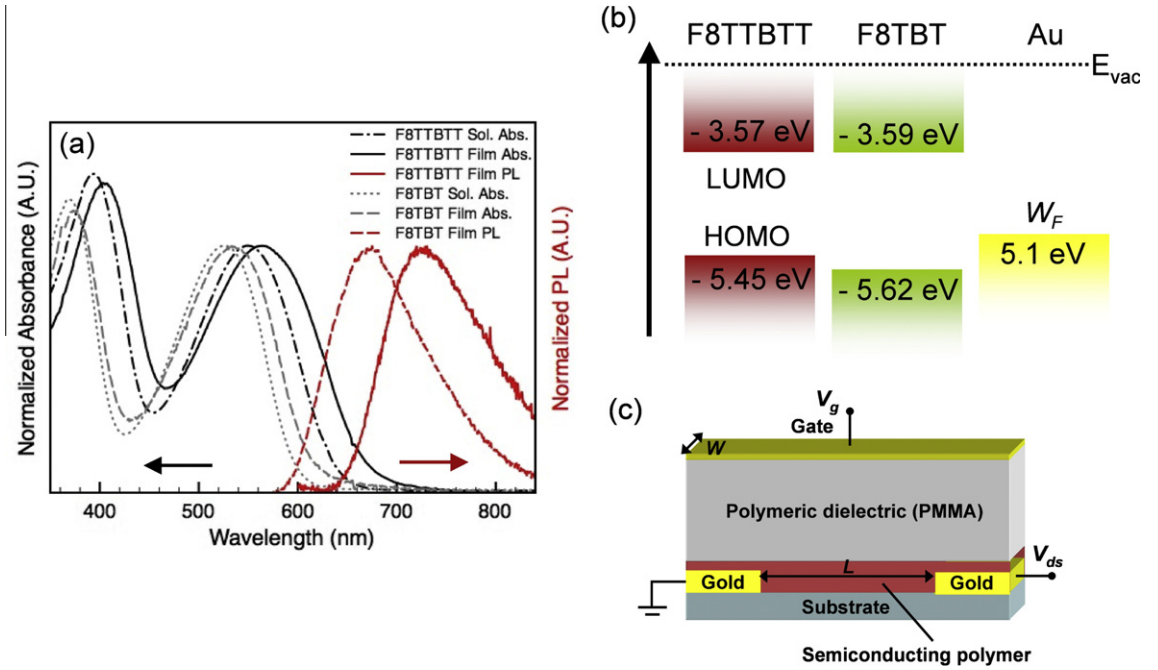


Fig. 1. (a) Room-temperature UV–Visible absorption and photoluminescence of F8TTBTT and F8TBT solutions and as-spun thin films (solvent: TCB). PL excitation was at 515 nm. (b) Schematic energy level diagram of F8TTBTT and F8TBT thin films in relation to Au assuming vacuum level alignment. The HOMO levels were determined by AC-2 photoelectron spectroscopy. The LUMO level of each material was estimated from the HOMO level by adding the optical band gap. The work function (W_f) of gold was taken from the literature [33]. (c) Schematic diagram of the top-gate/bottom-contact organic field-effect transistor structure.

the nature of electronic states in the F8TTBTT is qualitatively the same as in F8TBT. In thin films, the onset of absorption in F8TTBTT is ~660 nm (1.88 eV), while F8TBT thin films start to absorb at higher energy ~610 nm (2.03 eV). This reflects the reduced optical band gap in F8TTBTT compared to F8TBT as a result of the incorporation of additional thiophene units. For both systems, a notable red shift can be observed comparing solution and thin film absorptions. This indicates that as the polymer goes into the solid state a certain extent of either interchain delocalization or chain planarization occurs [30]. This effect is stronger in the case of F8TTBTT compared to F8TBT, i.e., the solution-to-film absorption red shift is larger in F8TTBTT (Fig. 1a). Room-temperature PL and PLQE measurements reveal red emission in both F8TTBTT and F8TBT thin films, centered at ~730 nm and 675 nm respectively. We observed a lower PLQE (~11%) in F8TTBTT films compared to F8TBT films (~22%). The reduced PLQE observed in F8TTBTT may be attributed to the existence of impurities, defects, different molecular packing, and/or the increased conjugation length (and reduced localization of excited states) associated to the addition of thiophene units in the polymer main chain. Using photoelectron spectroscopy (with a Riken AC-2 spectrometer) we determined the ionization potential (IP) of F8TTBTT and F8TBT to be about 5.45 eV and 5.62 eV, respectively (AC-2 measurement spectra see Supplementary Data Fig. S1). Using the measured IP and optical band gap values, we estimated the HOMO and LUMO levels in these two systems (Fig. 1b). These energy level values for the F8TBT system are in excellent agreement with those previously reported [24]. The reduced band gap in F8TTBTT mainly originates from the destabilization of the HOMO levels while the LUMO levels stay similar as F8TBT. For FET applications with gold source and drain electrodes (Fig. 1c), we therefore expect improved hole injections in F8TTBTT.

θ–2θ X-ray diffraction (XRD) experiments on both as-spun F8TTBTT and F8TBT thin films reveal no observable diffraction peak, indicating an amorphous microstructure in these polymer films. Absence of any crystalline order in either pristine or annealed F8TBT has been previously reported [31]. In order to identify any possible phase transitions, we performed modulated differential scanning calorimetry (MDSC) experiments on polymer powders, which can characterize not only the total heat flow but also the heat capacity and non-reversing (kinetic) components. For both F8TTBTT and F8TBT, no melting or any clear phase transition was observed upon heating to 300 °C. Upon cooling we identified the glass transition temperature (T_g) of F8TTBTT and F8TBT to be located at approximately 110 °C (see Supplementary Data Fig. S2). In both polymers similar morphology displaying nodule-like structures was observed using atomic force microscopy (AFM) on films of either as-spun or annealed (above T_g) conditions (Fig. S3). Summary of the material characteristics of F8TTBTT and F8TBT in terms of molecular weight, optical properties, thermal behavior and microstructure is tabulated in Table 1.

Table 1
Summary of molecular weight and polydispersity index, thin film optical characteristics from AC-2, UV–Vis, PLQE measurements, thermal characteristics from modulated differential scanning calorimetry (MDSC), and thin film structural characteristics from θ–2θ X-ray diffraction.

Material	M_n (g/mol)	M_w/M_n	HOMO (eV)	$E_{g,\ optical}$ (nm)	PLQE (%)	T_{glass} (°C)	θ–2θ XRD
F8TTBTT	33,000	1.93	−5.45	660	11	113	Amorphous
F8TBT	167,000	1.2	−5.62	610	22	111	Amorphous

3.2. Thin film field-effect transistor characterization

We employed a top-gate/bottom-contact (TGBC) device configuration with lithographically patterned gold source/drain electrodes for all FETs studied in this work (Fig. 1c). Such a device structure has been shown to lower contact resistance and allows greater flexibility to use different dielectric to reduce charge trapping [14,32]. The unipolar parts of the transfer characteristics were used to extract threshold voltages V_{th} and saturation field-effect mobilities μ [16,33], by applying

$$I_d^{sat} = \frac{WC_i}{2L}\mu_h(V_g - V_{th,h})^2 \text{ for holes} \quad (1)$$

$$I_d^{sat} = \frac{WC_i}{2L}\mu_e((V_g - V_{ds}) - V_{th,e})^2 \text{ for electrons} \quad (2)$$

Here, W is the channel width, L the channel length, I_d^{sat} the source–drain current in saturation, V_g the gate voltage, and C_i the capacitance per unit area of the gate dielectric. PMMA ($\varepsilon = 3.6$) was used as the dielectric for all FETs studied in this work since it contains very few electron-trapping groups thus allowing ambipolar charge transport [14,16,33].

FETs fabricated from as-spun F8TTBTT showed clear ambipolar characteristics exhibiting saturation hole mobility $\mu_h \sim 2 \times 10^{-2}$ cm^2 V^{-1} s^{-1} and electron mobility μ_e in the range of 1×10^{-3}–4×10^{-3} cm^2 V^{-1} s^{-1} for devices of channel length $L = 20$ or 40 μm (Fig. 2a and b). The highest μ_h was observed to be 5×10^{-2} cm^2 V^{-1} s^{-1} on a $L = 10$ μm as-spun F8TTBTT-based FET (device characteristics see Fig. S4). In comparison, as-spun F8TBT FETs (Fig. 2b) studied in this work showed much lower field-effect mobilities (μ_h up to 1.5×10^{-3} cm^2 V^{-1} s^{-1}, and μ_e up to 4×10^{-5} cm^2 V^{-1} s^{-1}), in good agreement with those previously reported for F8TBT FETs [16]. This is in spite of the higher molecular weight and lower PDI of the F8TBT polymer, which should have a tendency to increase the electron and holes mobilities [34]. Previous studies on as-spun and annealed F8BT FETs suggested that annealing polymer films close to or above their melting temperature in the range of 250–290 °C can significantly improve the ambipolar transistor performance and reduce threshold voltages [33]. In this work we also studied FETs fabricated from polymer films annealed at 260 °C. As shown in Fig. 2b, FET performances based on annealed F8TTBTT films are qualitatively the same as FETs fabricated by as-spun films. On the other hand, annealing F8TBT films at 260 °C did significantly improve the electron mobility and electron threshold voltage compared to the as-spun case. The mobility and threshold voltage values of as-spun/annealed F8TTBTT and F8TBT FETs are summarized in Table 2.

From Table 2 it is evident that the polymer F8TTBTT shows much enhanced ambipolar field-effect mobilities compared to F8TBT (in either as-spun or annealed condition). In fact, compared to various reported polyfluorene derivatives [4], F8TTBTT FETs exhibit a remarkably high hole mobility, even without undertaking additional efforts to induce chain alignment. This mobility improvement compared to F8TBT can be understood considering the following factors:

(1) For *p*-channel operation, improvement of hole injection is apparent when comparing the output characteristics of FETs from these two material systems (Fig. 2c and e). Besides the overall increased output current levels, the drain current of F8TTBTT FETs is less suppressed at low source–drain voltages in the output characteristics, indicating reduced contact resistance. This improvement can be understood as a result of the reduced difference between the HOMO level and the work function of gold in F8TTBTT compared to F8TBT (Fig. 1b). In addition, as previously discussed in the cases of F8BT and F8TBT [12,16,29], holes are expected to delocalize along the polymer backbone whereas electrons are largely localized on the BT unit. Besides charge injection, by adding thiophene units on the polymer backbone in F8TTBTT, the conjugation length for hole transport is further increased and this is likely to contribute to the observed, more efficient hole transport.

(2) For *n*-channel operation, a priori, we had expected less efficient electron transport in F8TTBTT compared to F8TBT due to the increased distance between BT units, on which the electron wavefunction is likely to be localized, but the opposite situation was observed. One potential reason for this is suggested by comparing the output characteristics (Fig. 2d and f). The electron contact resistance in F8TTBTT FETs seems to be slightly better than in F8TBT FETs. As the LUMO levels between these two materials are approximately the same, the slight improvement in electron injection in F8TTBTT may be due to a different polymer microstructure at the polymer–metal interface [35] or a slightly different extent of LUMO localization between the two materials. A second factor for the improved electron mobility could be an increased backbone planarity, leading to somewhat lower degree of electron localization on the BT unit, and enhanced interchain interactions and more compact packing of the polymer chains in F8TTBTT. These aspects are further studied below using Raman spectroscopy. We note that the enhanced mobility is observed in spite of a larger electron threshold voltage of F8TTBTT, which is most likely due to more electron trapping by impurity and/or chain-end defects, as suggested by the molecular weight of F8TTBTT studied in this work, which is at present still lower than that achieved by the more optimized synthesis of F8TBT.

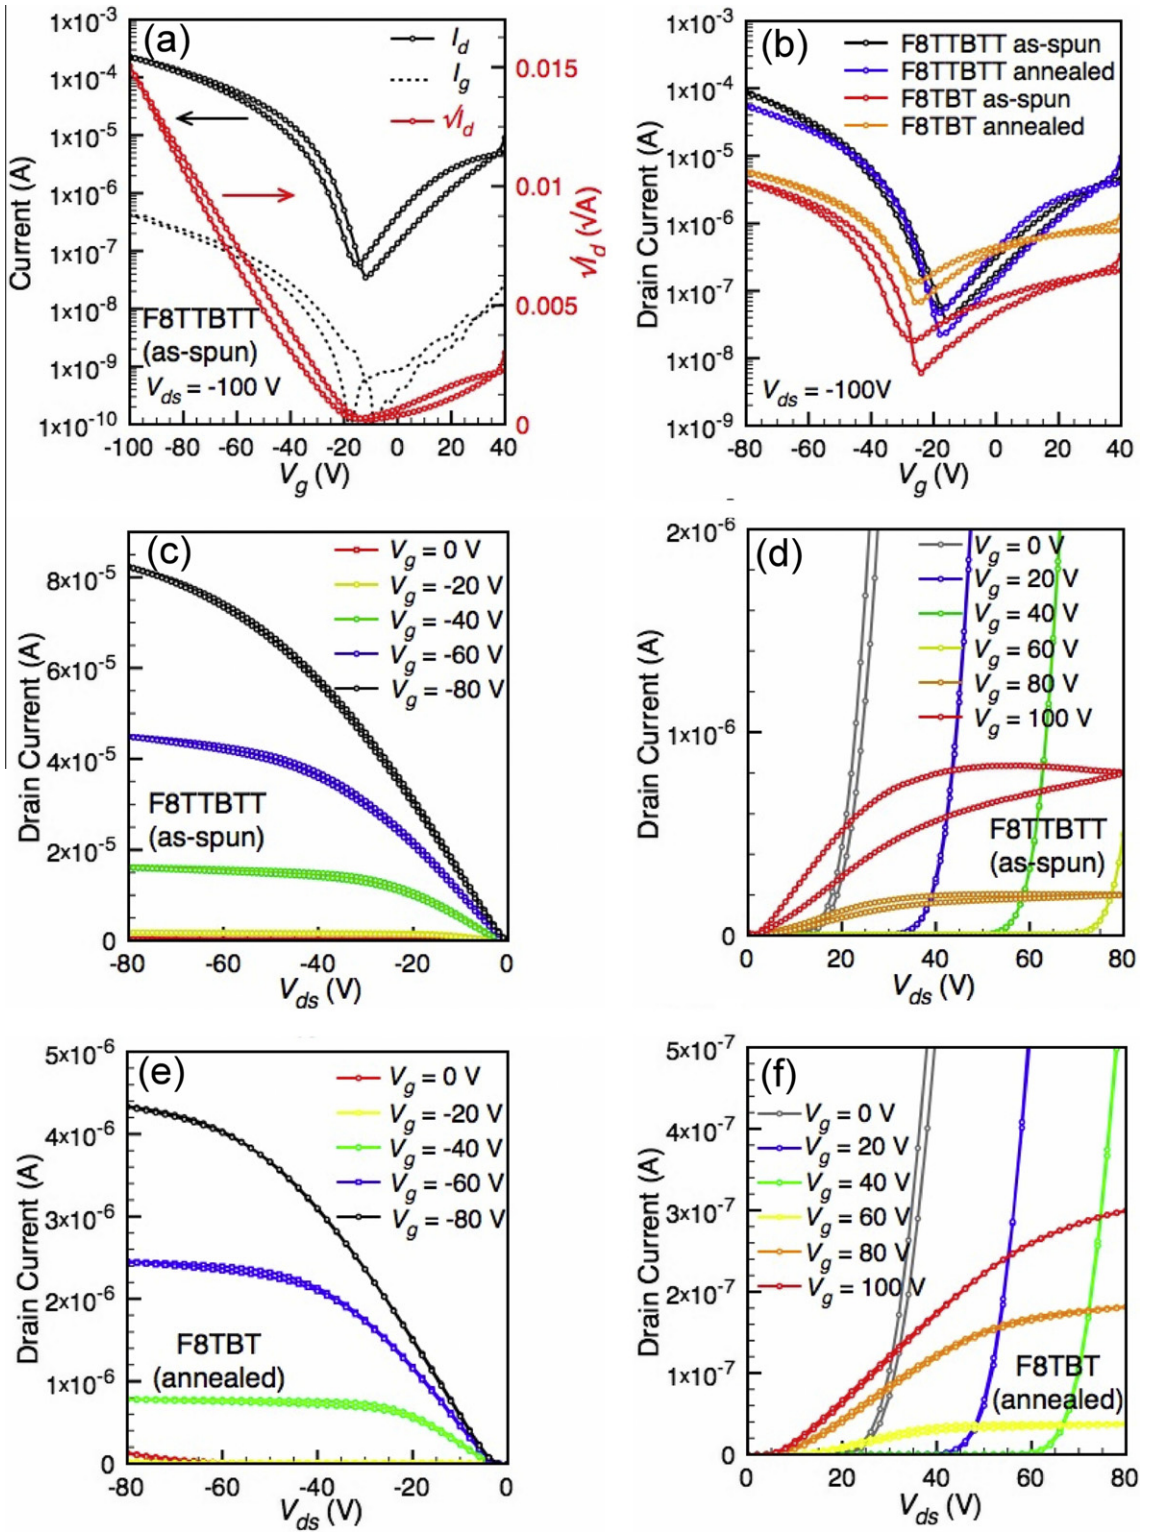

Fig. 2. (a) Transfer characteristics of an as-spun F8TTBTT FET (drain current: I_d, leakage current: I_g, and the square root of drain current: $\sqrt{I_d}$, W/L = 500, L = 20 μm). (b) Comparison of the transfer characteristics of as-spun and annealed (at 260 °C) F8TTBTT and F8TBT FETs (W/L = 500, L = 40 μm). (c, d) Output characteristics of an as-spun F8TTBTT FET (the same FET as shown in (b)). (e, f) Output characteristics of an annealed F8TBT FET (the same device as shown in (b)). All FETs in this figure were fabricated with ~550 nm-thick PMMA as the gate dielectric (capacitance C_i = 6.2 nF cm^{-2}).

3.3. Raman spectroscopy

In order to gain further insight into the understanding of the enhanced mobilities in F8TTBTT compared to F8TBT, we used Raman spectroscopy to probe the vibrational modes in these materials and study their conformations. For this purpose, Raman spectroscopy is a powerful technique and has been widely used in many conjugated polymer systems [12,36–39]. In particular, combined with density functional theory (DFT) calculations, increased conformational planarization in F8BT (induced by pressure effects) has been shown to result in an increased I_{1545}/I_{1608} Raman intensity ratio [38], where the 1545 cm^{-1} peak corresponds to the BT ring-stretching mode and 1608 cm^{-1} to the ring-stretching mode for the F8 units [12,36,38].

Fig. 3 shows the Raman spectra obtained from approximately 100 nm-thick films of as-spun F8TTBTT and F8TBT on gold-coated glass substrates (gold layer thickness ~30 nm). Experiments on quartz spectrosil substrates revealed identical spectra (Fig. S5) but the use of gold-coated substrates provides a better signal-to-noise ratio due to signal enhancement. For a better comparison, we also include a Raman spectrum obtained from an approximately 100 nm-thick film of F8BT (Fig. 3). The F8BT spectrum is in very good agreement with previously reported Raman spectra for this material [12,36,38,39]. In all three spectra shown in Fig. 3 we can assign the 1545 cm^{-1} peak to the BT ring-stretching mode and the 1608 cm^{-1} peak to the ring-stretching mode of the F8 units. The peak around 1450 cm^{-1}, clearly present in F8TTBTT and F8TBT but not in F8BT, is due to the C=C stretching of the thiophene [37,40]. In the wave number region between 1250 and 1400 cm^{-1}, in F8BT there should be four peaks around 1280, 1315, 1342, and 1358 cm^{-1} as previously reported [12,39]. The peak around 1280 cm^{-1} may be due to the C–C stretch between phenylene rings [41]. The 1315 and 1342 cm^{-1} peaks have been previously assigned to C–C and C–H stretches within the F8 unit, whereas the 1358 cm^{-1} peak can be attributed to the C–C stretch involving the two carbon atoms common to the benzene ring and the thiadiazole unit in the BT. However, we were not able to resolve these four peaks clearly in our F8BT reference film. For F8TTBTT and F8TBT there are two more easily resolved peaks in this spectral range, centered around 1280 cm^{-1} and 1353 cm^{-1}, respectively.

As shown in Fig. 3, a notable increased intensity ratio of I_{1545}/I_{1608} was observed in F8TTBTT compared to F8TBT and F8BT. Similar increased intensity ratio of the BT ring-stretching mode (at 1545 cm^{-1}) over the ring-stretching mode for the F8 units (1608 cm^{-1}) was previously experimentally observed in F8BT thin films upon application of pressure [38]. A decreased F8-BT torsional angle and the resultant increased coupling of the BT ring-stretching mode to the electronic HOMO–LUMO transition in the planar structure were identified as the origin for this on the basis of theoretical calculations. In analogy to this study on F8BT, our Raman results suggest that the incorporation of more thiophene units on the polymer backbone of F8TBT also leads to increased planarization of the polymer backbone.

Furthermore, the peak corresponding to the C=C stretching of the thiophene at around 1450 cm^{-1} is slightly shifted to higher frequency ($\Delta \sim 5$ cm^{-1}) in F8TTBTT compared to F8TBT. Previous Raman studies in oligothiophene reported two mechanisms to explain the frequency shift of this mode [37]. On one hand, conformational ordering and longer conjugation length will cause a red-shift in this C=C stretching mode. On the other hand, increased intermolecular interactions (e.g. due to smaller intermolecular distance) will result a blue-shift in this mode. When both situations are simultaneously present, the effect from intermolecular interactions was found to be dominating [37]. Similar blue-shift in this Raman mode due to increased intermolecular interactions was observed in sexithiophene single crystals with applied pressure [42]. An analogous dependence was also observed in polyacetylene with increasing pressure [43,44]. Studies of *in situ* heated oligothiophene thin films reported a red-shift in this Raman mode due to *decreased* intermolecular interactions (upon lattice expansion) compared to room-temperature samples [37]. Therefore, our Raman results also suggest stronger intermolecular interactions and more compact chain-packing in F8TTBTT compared to F8TBT.

The Raman results are overall consistent with our optical and field-effect mobility measurements in F8TTBTT and

Table 2
Summary of saturation field-effect mobilities μ and threshold voltages of F8TTBTT and F8TBT FETs studied in this work.

Materials	μ_h (cm^2 V^{-1} s^{-1})	μ_e (cm^2 V^{-1} s^{-s})	$V_{th,h}$ (V)	$V_{th,e}$ (V)
F8TTBTT[a]	2×10^{-2}–5×10^{-2}	1×10^{-3}–4×10^{-3}	~−20	~65
F8TBT (as-spun)	1×10^{-3}–1.5×10^{-3}	3×10^{-5}–4×10^{-5}	~−22	~55
F8TBT (annealed)	1.5×10^{-3}–2×10^{-3}	1×10^{-4}–2×10^{-4}	~−20	~30

[a] No clear difference in terms of mobilities and threshold voltages was observed between F8TTBTT FETs fabricated from as-spun films and annealed films at 260 °C (see Fig. 2b). Thus their characteristics are not tabulated separately.

F8TBT. The increased conformational planarization in F8TTBTT leads to more extended conjugation length for holes transport. Since electron transport in both systems is likely to rely mainly on interchain hopping, the increased intermolecular interactions in F8TTBTT will result in more efficient electron transport as well. Note that a previous study in semi-crystalline F8BT speculated that worse electron transport might result if backbone planarization is associated with a change in packing geometry, i.e., in the relative positions of BT units between adjacent chains [12]. However, our current systems of F8TTBTT and F8TBT are both amorphous, and it appears unlikely that backbone planarization could result in a specific packing geometry unfavorable for electron transport. Instead, we believe that the dominant effects is that more compact chain-packing in F8TTBTT facilitates interchain hopping and enhances both electron and hole transport.

3.4. Light-emission during the F8TTBTT FET operation

As a consequence of efficient ambipolar charge transport, F8TBT has been shown to emit red light during transistor operation [16,23]. Similarly, we also expect light emission from F8TTBTT FETs due to its ambipolar characteristics. Employing a very thin semi-transparent gold gate in the same FET structure shown in Fig. 1c, we were able to observe a deep-red light emission during the operation of F8TTBTT FETs (Fig. 4a and b). Due to the imbalanced hole and electron mobility and the relatively large electron threshold voltage, the light-emission zone is very close to the electron-injecting electrode for a wide range of bias conditions. By placing an optical fiber connected to a spectrometer directly on top of the metal top gate, we recorded the electroluminescence from F8TTBTT, which is slightly blue-shifted from its PL (Fig. 4c). This mismatch may be due to interference effects, and/or polaron absorption below the band gap. By placing a silicon photodiode directly on top of the FET metal gate, we measured the photocurrents I_{ph} simultaneously with the transfer I–V curve (Fig. 4d). From the ratio between the photocurrent and the drain current, taking into account the photodiode sensitivity [45], we estimated the EQE of F8TTBTT light-emitting transistors to be up to ~0.2% (Fig. 4d). The EQE values from the F8TTBTT FETs are within the same order of magnitude but slightly lower than those reported in F8TBT (up to ~0.4%) [16], which can be understood as the combined consequence from the relatively lower PLQE, imbalanced ambipolar mobilities, and larger electron threshold voltage found in F8TTBTT.

3.5. F8TTBTT:PCBM blend bulk heterojunction (BHJ) solar cells

Since F8TTBTT shows much higher field-effect mobility for hole transport compared to F8TBT and an absorption range further extended to lower energy, it can be potentially interesting for photovoltaic applications. We fabricated BHJ solar cells by blending F8TTBTT (as the hole transporting phase) with PCBM (as the electron transporting phase). In this work the best solar cell performance was obtained from a F8TTBTT:PCBM blend of 1:4 weight ratio and a ~80 nm-thick active layer. Fig. 5 shows the EQE (recorded at low light intensity) and current–density–voltage (J–V) characteristics (under 100 mW/cm^2 simulated AM 1.5 global illumination) of as-spun and annealed F8TTBTT:PCBM devices. As-spun solar cells exhibit decent photovoltaic operation, demonstrating ~25% in EQE (at 550 nm) and 1.54% in power conversion efficiency (PCE). Our current result is comparable to the solar cell performance recently reported on polymers of similar structure but different side-chains [25]. Detailed summary of the F8TTBTT:PCBM solar cell J–V characteristics is shown in Table 3.

Previous solar cell reports on other material systems often reported improved performance by post-annealing (annealing after electrode evaporation) [2,23]. Such improvements may be due to either improving the transport properties of the active material by annealing or inducing more favorable blend morphology, for example, by inducing more efficient percolation pathways. Attempts to anneal our solar cells led to significantly worse performance (Fig. 5). As presented above, as-spun F8TTBTT already showed relatively high field-effect mobilities which

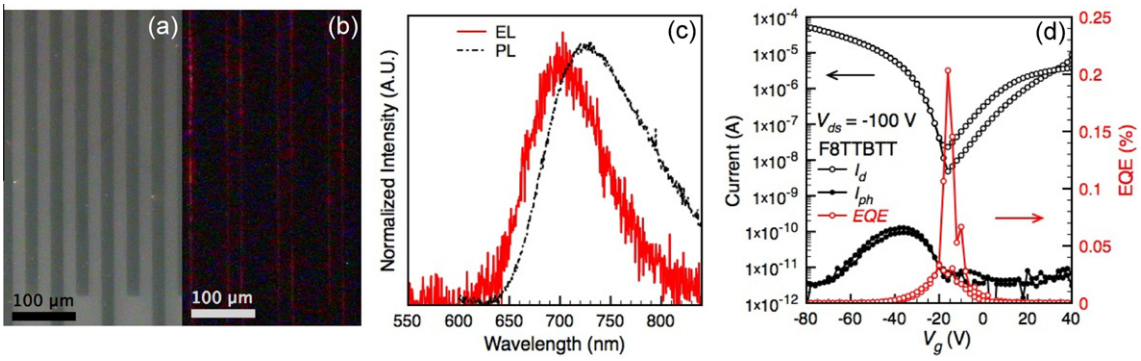

Fig. 4. (a) Digital camera image of an F8TTBTT FET under illumination showing source and drain electrodes (W/L = 500, L = 20 μm). (b) The digital camera image of the same FET at the same position as (a) recorded in the dark and under the bias condition of V_{gs} = −200 V, V_{ds} = −300 V. (c) Electroluminescence (EL) spectra of a light-emitting F8TTBTT FET recorded under the bias condition of V_{gs} = −100 V, V_{ds} = −200 V. Fig. 5. (a) External quantum efficiency (EQE) and (b) current–voltage characteristics (under 100 mW/cm^2 simulated AM1.5G illumination) of F8TTBTT:PCBM-based solar cells for as-spun and annealed (150 °C) conditions.

Table 3
Summary of the current–voltage characteristics of the F8TTBTT:PCBM solar cells under illumination from solar simulator (AM 1.5 global, 100 mW/cm^2).

Conditions	J_{sc} (mA/cm^2)	V_{oc} (V)	Fill factor	PCE (%)
As-spun	4.7	0.93	0.35	1.54
Annealed[a]	1.1	0.87	0.34	0.32

[a] Annealing was performed after aluminum electrode evaporation and annealing temperature was 150 °C.

did not further increase with annealing. As annealing will not lead to more efficient charge transport, even a slight grain coarsening upon annealing would lead to reduced performance because fewer interfaces are available for exciton dissociation.

Reports on F8TBT:PCBM solar cells presented power conversion efficiency (under AM 1.5 illumination) ranging from 1.25% to 2.8% [22,23,46,47]. Even though not yet fully optimized, the overall performance of our as-spun F8TTBTT:PCBM solar cells are comparable to that reported for F8TBT:PCBM solar cells. Further performance optimization is likely to be achievable through the use of different solvents to optimize blend morphology, other electrodes for more efficient charge collections and F8TTBTT polymers with higher molecular weight and reduced PDI. Moreover, since F8TTBTT exhibits good ambipolar charge transport characteristics with enhanced electron mobilities over F8TBT, it also appears as a promising acceptor phase in polymer:polymer blend solar cells.

4. Conclusion

We have studied the comparison between two donor–acceptor polymers F8TTBTT and F8TBT in terms of optical properties, structure and morphology and ambipolar field-effect transistor performance. The incorporation of more thiophene units on the polymer backbone leads to smaller optical band gap (by destabilization of HOMO levels) and a more planar backbone conformation. Compared to F8TBT, F8TTBTT exhibits more efficient charge injection due to the reduced ionization potential and improved ambipolar mobilities, most likely as a result of the more planar backbone configuration and more compact chain-packing. Ambipolar F8TTBTT FETs exhibit deep-red light emission from within the transistor channel. Even though not fully optimized, F8TTBTT:PCBM solar cells were demonstrated to show comparable performance to F8TBT:PCBM devices.

Organic light-emitting diode
Light extraction efficiency

ABSTRACT

Close-packed hemispherical microlens arrays have been fabricated using a soft lithography method and used to enhance the light extraction efficiency in organic light-emitting devices (OLEDs). A close-packed monolayer of polystyrene microspheres was used to produce a soft template of polydimethylsiloxane for fabricating microlens arrays from a photopolymerizable optical adhesive. The microlens contact angle and array fill-factor increase with the polystyrene microsphere size, reaching (85° ± 5°) and (85 ± 3)% for 100 μm size microspheres, respectively. Attaching such a large-area (2 cm in diameter) microlens array on the glass substrate of an OLED leads to up to 70% efficiency enhancement, which also shows dependencies on the area and detailed structure of the OLED.

1. Introduction

Organic light-emitting devices (OLEDs) have important application in flat-panel displays and as solid-state lighting sources [1]. Many advances in material development and device structure innovations have led to the demonstration of high efficiency and long-lived monochromatic or white OLEDs [2–5]. A significant issue limiting the further improvement in device efficiency lies in the relatively low light extraction or outcoupling efficiency, η_{out}, which is typically ~20% due to the total internal reflection (TIR) losses at multiple interfaces of planar OLEDs [6]. Several different methods have been reported in order to improve η_{out}, such as using a photonic crystal [7], embedded low-index grids [8], or a resonant cavity [9]. However, these methods typically require complicated and expensive fabrication processes, modification of active layer structure, and/or insertion of additional layers between the substrate and the transparent indium-tin oxide (ITO) anode. Microlens arrays directly deposited on the light-emitting surface of the glass substrate can be more easily integrated with the OLED fabrication, offering a potentially effective, yet low cost light extraction enhancing mechanism. There have been several previous reports on microlens array fabrication, such as using photolithography and wet-etching of silicon substrate for microlens mold [10], melting self-assembled polystyrene (PS) spheres on a pre-patterned substrate [11], liquid crystal droplet microlens [12], three-dimensional diffuser lithography for microlens mold [13], and ink-jet printed microlens [14]. Although Sun et al. recently improved the imprint lithography method obtaining η_{out} enhancement of (1.68 ± 0.09) [8,15], high-cost and complicated photolithography and wet-etching processes are considered as the inefficient fabrication steps for making a reproducible microlens mold.

Here, we demonstrate the fabrication of large-area (several square inches), close-packed hemispherical polymer microlens arrays using a soft lithography method, and the application of such microlens arrays for enhancing the light extraction efficiency in OLEDs. A close-packed monolayer of polystyrene (PS) microspheres was formed using a convective and capillary assembly [16], which was employed to generate a polydimethylsiloxane (PDMS) concave template for the fabrication of transparent microlens arrays based on a Norland optical adhesive (NOA). Similar templating methods have been previously used to produce microlens arrays from monolayer of sub-micron

or a few micron size PS spheres prepared by spin-coating, leading to microlenses with contact angles (θ_c) < 45° [17–18]. Here, we found that θ_c increases with the PS microsphere size (ϕ_{PS}), approaching hemispherical shape ($\theta_c \sim 85° \pm 5°$) for ϕ_{PS} = 100 μm. While close-packed monolayer of PS microspheres with such large sizes cannot be achieved over a large-area by spin-coating due to the strong centrifugal force, we have achieved that using the convective and capillary assembly method we employed here [16].

2. Experimental

Fig. 1 illustrates the fabrication procedures for the microlens arrays. PS microspheres in an aqueous solution were dispersed on a pre-cleaned [19] UV-ozone treated glass or SiO_2 substrate. Three different sizes of PS microspheres (ϕ_{PS} = 5, 20, and 100 μm, from Thermo Scientific) were used. A PS monolayer covering several square inches could be easily formed for 20 and 100 μm size PS microspheres, whereas it was much more challenging to generate a uniform, large-area monolayer using 5 μm size PS microspheres due to the increased domination of the capillary force. For a reproducible soft template of microlens arrays, PDMS (Sylgard 184, Dow Corning) was prepared with a 10:1 mixing ratio (base polymer:curing agent) and poured above the PS monolayer. Following thermal curing of PDMS for 2 h at 60 °C in a vacuum oven, the substrate was separated from the cured PDMS, and the PS microspheres embedded in PDMS was subsequently removed using scotch tapes leading to a concave PDMS mold. We used a NOA 61 (refractive index ~1.56 for the cured polymer) as the microlens material. With a few drops of NOA 61 on the concave surface of PDMS mold, the glass substrate of an OLED was placed on top without any additional pressure. After curing for 3 min under UV-light (365 nm, 200 mW/cm^2), the PDMS mold was then released leaving behind convex microlens arrays on the glass substrate of the OLED. The PDMS mold could be reused for many times without any breakage. Optical microscopy and scanning electron microscopy (SEM, JOEL 6335F) were used to characterize the geometry and surface topology of the PS microsphere array, the PDMS stamp, and the microlens array.

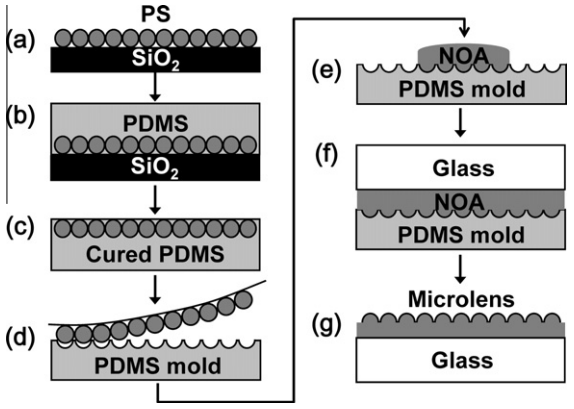

Fig. 1. Schematic illustration of fabrication procedures for hemispherical microlens arrays. See text for details.

Microlens arrays (fabricated from 20 or 100 μm PS spheres) covering a circle of approximately 2 cm in diameter were attached to the glass surface of OLEDs to examine light extraction efficiency enhancement. Both fluorescent and phosphorescent OLEDs (FOLEDs and PHOLEDs, respectively) have been fabricated on glass substrates commercially precoated with an indium-tin oxide (ITO) transparent anode (sheet resistance ~20 Ω/square). The FOLED structure was glass/ITO/N, *N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)-benzidine (NPB, 60 nm)/tris(8-hydroxy-quinolinato) aluminum (Alq_3, 60 nm)/Cs_2CO_3(1 nm)/Al(100 nm), and the PHOLED structure was glass/ITO/NPB (40 nm)/8.0 wt.% *fac*-tris-(phenylpyridine) iridium [$Ir(ppy)_3$] doped 4,4′-*N*,*N*′-dicarbazole-biphenyl (CBP) (20 nm)/bathocuproine (BCP, 20 nm)/Alq_3 (40 nm)/Cs_2CO_3(1 nm)/Al(100 nm). The organic and cathode layers were sequentially evaporated in a custom-made vacuum thermal evaporator with a base pressure ~3×10^{-7} Torr. Two different sizes of OLEDs (small-area = 2×2 mm^2, large-area = 12×12 mm^2) in cross-bar electrode geometry were fabricated following procedures published elsewhere [3,19].

The η_{out} enhancement factor, *f*, was obtained using two different measurement methods. First, OLEDs (with and without microlens arrays) are aligned and attached to the entrance port of a Newport integrating sphere (819D 3-Port) and an Ocean Optics Jaz spectrometer is connected to the outlet port to measure the total luminous flux in the forward direction from the OLEDs, excluding the emission from the glass substrate edge. Only the light-emitting device area is opened toward the inside of an integrating sphere, while all the other non-emitting areas are completely blocked. The second method involves the direct measurement of the near-field emission intensity at the normal direction. An optical fiber (diameter = 400 μm) was positioned vertically within 1 mm of the light-emitting surface of the glass substrate, and the near-field optical intensity was recorded by the Ocean Optics Jaz spectrometer. The angular distribution of the luminous intensity for the OLEDs was also measured using a small-area Si spot photodetector at 10 cm away from the device (corresponding to a half angle of ~0.5°).

3. Results and discussion

Using 20 and 100 μm size PS microspheres, close-packed domains with size ranging from a few mm to over 1 cm can be observed and the total area could easily cover a few square inches. As shown in Fig. 2(a), there are imperfections at the domain boundaries and occasionally inside individual domains. A top-view of the concave PDMS mold (with ϕ_{PS} = 100 μm) near the edge of the array under the SEM is shown in Fig. 2(b), whereas the cross-sectional image in the inset of Fig. 2(b) clearly shows the hemispherical concave shape of the PDMS mold.

Fig. 3(a) shows an optical image of a hexagonally close-packed microlens array of ϕ_{PS} = 100 μm, and the smooth microlens surface is also revealed by the SEM image shown

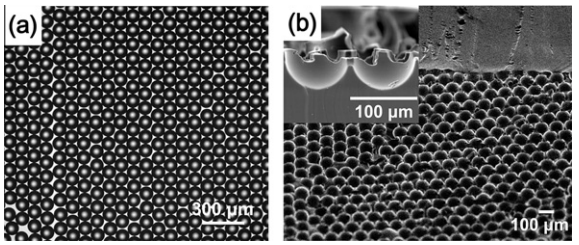

Fig. 2. (a) Optical microscope image of a part of a large-area polystyrene (PS) monolayer fabricated using 100 μm PS spheres. (b) Tilted scanning electron microscope (SEM) image of a concave PDMS template for 100 μm microlens arrays. PS spheres were completely removed by a scotch-tape. Inset: cross-sectional SEM image of the concave PDMS mold.

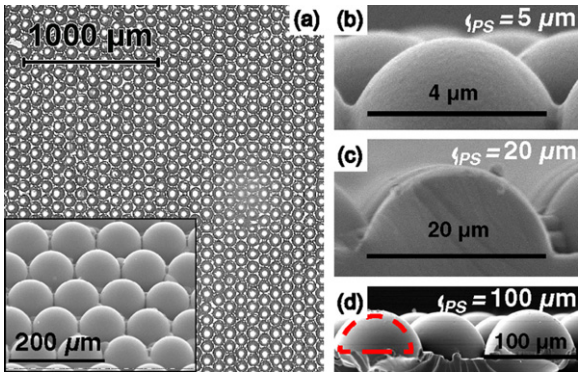

Fig. 3. (a) Optical microscope image of a part of a large-area microlens array fabricated using 100 μm PS spheres. Inset: tilted-view of the microlens array using a scanning electron microscope (SEM). Cross-sectional SEM images of microlenses with varying size of polystyrene spheres (ϕ_{PS}) are shown in (b–d). In (d), a semi-circle (dashed line) is drawn just inside the microlens contour for comparison.

in the inset of Fig. 3(a) (sample tilted). The measured fill factor (*FF*) of the microlens array is (85 ± 3)%, which is very close to the ideal *FF* of two-dimensional hexagonally close-packed spheres (91%). The same microlens fabrication method could be applied to different sizes of PS microspheres, however, θ_c of the microlenses is dependent on ϕ_{PS} as shown in the cross-sectional SEM images of Fig. 3(b)–(d). Here, θ_c was averaged over more than 10 microlenses, and summarized in Table 1 along with the average base size of the microlenses and the array fill factor. We obtained $\theta_c = (45° \pm 5°)$ with ϕ_{PS} = 5 μm, which is similar to previous reports [17–18]. As the ϕ_{PS} was increased to 20 and 100 μm, θ_c was increased to (65° ± 5°) and (85° ± 5°), respectively. From the cross-sectional SEM images shown in the Fig. 3(d) in which a semi-circle is drawn just inside the microlens contour, clearly hemispherical microlenses were achieved with ϕ_{PS} = 100 μm. We believe that this size dependence for θ_c is related to the mechanical robustness of the PDMS mold. When PDMS was poured onto the PS microspheres in order to make a concave template, it could completely cover the PS microspheres, penetrating all the way down to the SiO_2 surface through the interstitials among the microspheres, which after curing form columns connecting PDMS below and above the PS microspheres. For ϕ_{PS} = 100 μm, these columns are mechanically robust, and are broken at the narrowest neck area (corresponding to the horizontal plane through the center of the PS microspheres, see Fig. 1(d)) when the PS microspheres were removed from the thermally-cured PDMS using scotch tapes, resulting in hemispherical concave shapes on the PDMS mold. However, for smaller PS microspheres, the narrower PDMS columns were more easily torn off away from the narrowest neck area, resulting in concave shapes on the PDMS mold with height less than the PS microsphere radius, and in turn less than 90° contact angles for the microlenses. The smaller microlens base size (see Table 1) than the corresponding ϕ_{PS} also corroborates the above explanation.

Attaching microlens arrays to the glass substrates of OLEDs does not change the current density–voltage (*J–V*) characteristics, however, it does increase the total luminous flux (or luminance) at a given voltage. For small-area FOLEDs, for example, the peak external quantum efficiency η_{EQE} at J = 100 mA/cm^2 is increased from 0.75% for a bare device (without a microlens array attached) to 0.94% or 1.01% when 20 or 100 μm microlens array is attached to the OLED, respectively. This corresponds to a light extraction enhancement factor (*f*) of (1.25 ± 0.04) and (1.35 ± 0.04), respectively. It should be noted that *f* is virtually independent of the OLED operating condition (*J–V* characteristics), suggesting that the light extraction enhancement mechanism is purely attributed to the optical effect.

Table 1 also summarizes the different light extraction enhancements when microlens arrays were attached to the OLEDs in various situations, as obtained from the integrating sphere measurement method. Comparing microlens arrays for ϕ_{PS} = 20 and 100 μm, we have found that the larger PS microspheres lead to a higher *f* for the corresponding OLEDs in all cases. This is most likely attributed to the higher lens contact angle for ϕ_{PS} = 100 μm as the fill

Table 1
Comparison of the light extraction efficiency enhancement factor (*f*) for small-area (2 × 2 mm2) and large-area (12 × 12 mm^2) fluorescent and phosphorescent OLEDs (FLOEDs and PHOLEDs, respectively) using microlens arrays fabricated from different sizes of polystyrene microspheres (ϕ_{PS}). The actual microlens base diameter (ϕ_{lens}), contact angle (θ_C), and array fill-factor (*FF*) are also listed.

ϕ_{PS} (μm)	ϕ_{lens} (μm)	θ_C (°)	*FF* (%)	*f*		
				FOLEDs		PHOLEDs
				Small-area	Large-area	Large-area
5	4.6 ± 0.1	45 ± 5	–	–	–	–
20	18.4 ± 0.4	65 ± 5	77 ± 3	1.25 ± 0.04	1.45 ± 0.05	1.44 ± 0.05
100	98 ± 2	85 ± 5	85 ± 3	1.35 ± 0.04	1.70 ± 0.07	1.56 ± 0.06

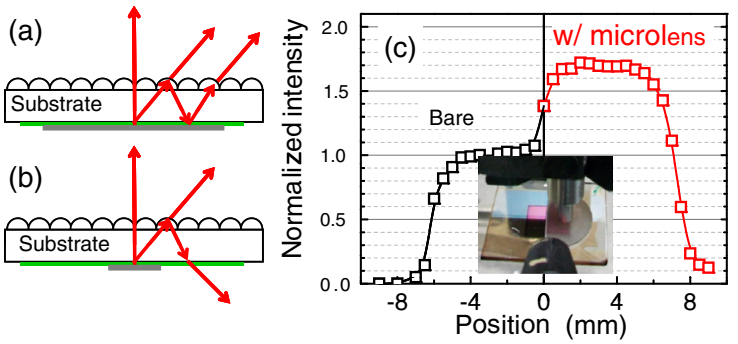

Fig. 4. Schematic illustrations for light extraction in a large-area (a) and a small-area (b) OLED with a microlens array attached to the glass substrate. (c) The normalized near-field optical intensity profile across a large-area fluorescent OLED, half of which was covered with a microlens array while the other half was bare (a picture of the device is shown in the inset). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

factors for the two microlens arrays are relatively close, although optical simulation may be needed to identify the relative contribution of these two factors.

Moreover, we have also observed greater outcoupling enhancement in larger size devices. For small-area FOLEDs with microlens arrays based on 20 and 100 μm PS spheres, we obtained $f = (1.25 \pm 0.04)$ and (1.35 ± 0.04), respectively. However, for large-area FOLEDs, f is significantly improved to (1.45 ± 0.05) and (1.70 ± 0.07), respectively, resulting in peak $\eta_{EQE} = 1.28\%$ at $J = 100\ \mathrm{mA/cm^2}$ when 100 μm microlens array is attached to the glass surface of the large-area FOLED. Such a device size dependence is attributed to the larger Al cathode size allowing for more effective re-direction of light into the forward-viewing direction, as illustrated in Fig. 4(a). For a small-area device, as shown in Fig. 4(b), light that is reflected back towards the cathode from the microlens/air interface may travel to outside the cathode area due to the ~1 mm thick glass substrate, and not be re-directed to forward-viewing directions.

The light extraction enhancement factor due to microlens arrays attached to FOLEDs was also confirmed from the near-field optical intensity measurement with an optical fiber. As shown in the inset of Fig. 4(c), a large-area FOLED was partially covered with a microlens array ($\phi_{PS} = 100$ μm). As the optical fiber was scanned perpendicularly to the boundary between the bare side and the side covered with the microlens array, the near-field optical intensity was recorded in the spectrometer attached to the optical fiber. Fig. 4(c) shows that the intensity on the microlens covered side is $(69 \pm 4)\%$ higher than the bare side, in excellent agreement with the integrating sphere measurement for large-area FOLEDs.

For the large-area PHOLED, the enhancement factor is somewhat lower, $f = (1.56 \pm 0.06)$ (see Table 1), compared with that for the FOLED based on the near-field optical intensity measurement. We attribute this difference to the multi-layered structure of PHOLEDs which can generate more significant confinement of the optical modes in the emissive layer, particularly considering that the CBP emissive layer in the PHOLED has a higher index of refraction at the OLED emission wavelength than the Alq_3 emissive layer in the FOLED, 1.83 vs. 1.75 as measured by ellipsometry.

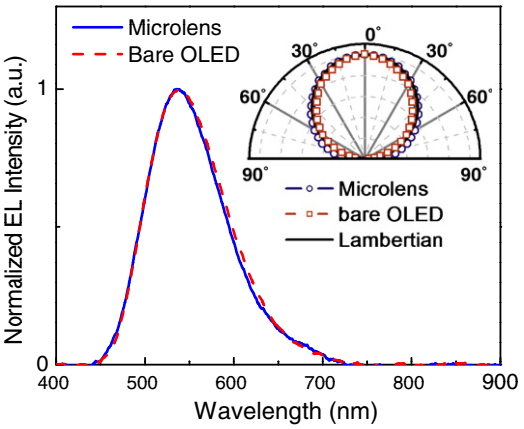

Fig. 5. Normalized electroluminescence (EL) spectra of the fluorescent OLED with and without a microlens array attached to the glass substrate. Inset shows the normalized luminous intensity as a function of the viewing angle from the substrate normal for a bare fluorescent OLED (red open squares) and the same OLED with a hemispherical microlens attached (blue open circles), as well as that for a Lambertian source (solid line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 5 shows the normalized electroluminescence (EL) spectra of the FOLED with or without a microlens array attached. Negligible changes in the emission spectrum, with a 4 nm blue shift in the peak wavelength and a 3 nm reduction in the full width at half maximum, were observed after the microlens array was attached. The inset of Fig. 5 compares the angular emission pattern of the FOLED with or without a microlens array along with that for a Lambertian source. The attachment of the microlens array only slightly modified the angular emission profile, slightly enhancing luminous intensities at larger angles. Note that Sun et al. demonstrated enhanced luminous intensities at larger angles (especially at >50°) using 7 μm microlens arrays [15], which is consistent with what we observed with our microlens array. This could be attributed to the broadened

light-emission area with microlens arrays, creating a blurred pixel image.

4. Conclusions

In conclusion, we have demonstrated large-area, close-packed hemispherical microlens arrays using a simple and low-cost fabrication method. Different contact angles of the microlens are achieved by varying the size of PS microspheres, reaching (85° ± 5°) with 100 μm PS microspheres. The measured fill factor of lens array is as high as (85 ± 3)%. The attachment of such microlens arrays to OLEDs can improve the light outcoupling efficiency by up to 70%, which only slightly modifies the angular emission pattern. The light extraction efficiency depends on the lens contact angle, device area, and the detailed layered device structure of the OLED. The technique described here could have important applications to OLED-based device systems, especially for lighting applications where large-area devices instead of small pixels are sought after.

ABSTRACT

Controlling threshold voltage (V_{TH}) and field-effect mobility (μ_{FET}) in organic thin-film transistors (OTFTs) is of primary importance to attain reliable devices that can be harnessed in more complicated circuits and eventually commercialized. In particular hysteresis in OTFT transfer curves is an issue that has to be better understood and analyzed. In this regard, even if the interface between organic dielectric and organic semiconductor seems to play an important role, our study shows that a further and relevant factor is played by the transport of charges across the bulk of the dielectric layer. Here, an analytical approach is applied to identify and understand the different components that give rise to the hysteresis in the transfer curves of pentacene-based OTFTs using poly(vinyl alcohol) (PVA) and poly(-vinyl alcohol) cross-linked with ammonium dichromate (PVAad) as the (polymeric) gate dielectric. Transfer curves simulations which include charge transport in the PVA show a hysteretic behavior in good agreement with the experimental data. Moreover, the hysteresis measured in OTFTs can be reduced by the insertion of an underlying dielectric layer of SiO_2 that blocks the above-mentioned effect. The residual contribution to the hysteresis is then analyzed by investigating the chemistry nature of both PVA and PVAad, which show different electron trapping efficiency at the interface with the pentacene layer. Therefore, a consistent explanation of how the polymeric dielectric is able to impact the transfer curves requires considering all mentioned factors.

1. Introduction

Organic thin-film transistors (OTFTs) have been attracting an increasing interest for 20 years as promising technology candidates for large area, low-cost applications which can be eventually implemented on cheap, low-temperature, flexible and unconventional substrates [1–3]. Recent advances in organic semiconductor performances pave the way towards commercialization of OTFTs [4,5]. In addition these devices are widely used as tools for studying material properties on the device scale [6]. In particular, drain current vs. gate voltage (I_d–V_g) curves, also called *transfer characteristics*, are a very powerful means for analyzing the behavior of a field-effect device since threshold voltage (V_{TH}), field-effect mobility (μ_{FET}), I_{on}/I_{off} can be extracted from these curves [7,8]. Transfer curves are traced at a fixed value of the drain voltage, which can be set in the linear range ($V_d < V_g - V_{TH}$) of the transistor current, i.e. with mobile charges

accumulated along the whole distance between source and drain or, alternatively, in the so-called saturation regime ($V_d > V_g - V_{TH}$), i.e. with mobile charges accumulated only between the source electrode and the pinch-off point (whose potential difference referred to the gate is equal to the threshold voltage, V_{TH}). In the latter case the drain current curve exhibits not a linear but rather a quadratic dependence from the gate voltage. Consequently, Sqrt(I_d) vs. V_g rather than I_d vs. V_g has to be plotted and fitted linearly in order to extract both threshold voltage and field-effect mobility values in the saturation regime [9]. Transfer characteristics hold the potential to reveal charge trapping effects. In particular, trap states may give rise to hysteresis when the gate voltage is swept forward and backward in the working range of the device. Information on trapping mechanisms can be therefore derived from the magnitude and sign of the threshold voltage shifts [10]. As mentioned, hysteresis appears when the input voltage V_g is swept forward and backward; hence, two different values of the threshold voltage are derived whenever the forward and the backward branch of the drain current curve differ. In addition, transfer curves affected by hysteresis usually have different slopes which consequently result in significantly different values of the extracted mobility. Unpredictable threshold voltage shifts represent a major problem for the applicability of these devices as they introduce uncertainty about the capability of the device switching between two different values of the input voltage. Furthermore, they degrade the amplification ability of the device when used in an amplifying configuration as they modify its transconductance. In addition to that, the threshold voltage values usually shift further with aging. So, ideally, for being successfully harnessed in a circuit, a field-effect device should not show any unpredictable hysteresis. A marked, stable and repeatable threshold voltage shift could be in fact exploited for using the device as a memory, in which a voltage step could be used to permanently "write" information on the device. For these reasons it would be extremely interesting to understand the mechanisms that cause the hysteresis effect to appear, in order to finely control it and achieve an ideal transistor behavior or, alternatively, obtain a permanent memory effect.

This picture becomes even more complicated when polymeric gate dielectrics are used for the fabrication of field-effect transistors. They feature optical transparency, flexibility and a wide range of dielectric constants. Despite the fact that some ultrathin polymeric gate dielectrics featuring low leakage values have been put forward [11–13], organic dielectrics generally suffer from not always having good insulating properties i.e. they usually require thick film thicknesses to minimize the gate current (I_g).

In this paper we investigate how hysteresis is related to the properties of the gate insulating layer in devices using polymeric dielectrics. In particular, we used poly(vinyl alcohol) (PVA) and poly(vinyl alcohol) cross-linked with ammonium dichromate (PVAad). The former is commonly believed to give rise to a large hysteresis and it is therefore used in non-volatile memory applications [14,15].

Up to now, hysteresis in transistors using polymeric gate dielectrics has been largely attributed to different mechanisms such as semiconductor–dielectric interface effects, residual dipole-induced effects and moisture [16,17]. In the following, we will show a number of experimental observations that aim to clarify a key factor that heavily affects the hysteretic device behavior i.e. the current flowing through the bulk of the gate dielectric layer as well as the role of the semiconductor–insulator interface. It has been previously observed that the hysteresis in OTFTs is influenced by the current flowing through the bulk of polymeric dielectrics but this current contribution has been never measured or analyzed quantitatively [18]. In our study the hysteresis was found to be much larger in devices having only a polymeric film as the insulating layer rather than a double one, formed by an organic dielectric on a Si/SiO_2 substrate which shields any possible transport occurring between polymeric dielectric and gate electrode.

Our results show that: (i) the current flowing through the dielectric in metal–insulator–metal (MIM) capacitors at typical OTFTs' operation voltages follows a Space–Charge Limited Current (SCLC) trend [19]; (ii) modeling of the charge transport across the polymeric dielectric as well as numerical simulations of transfer curves were found to be in good agreement with the experimental data; (iii) the transport and the trapping mechanisms at the interface between the semiconductor and the dielectric layer, also affecting the I_d–V_g curve, must be interpreted only after considering and possibly removing the contribution of the leakage current through the dielectric.

2. Experimental

Organic thin-film transistors and metal–insulator–metal (MIM) structures were assembled on the same glass substrate, or, alternatively on heavily doped silicon substrates with a 500 nm thick layer of silicon dioxide (Fig. 1). PVA (Mowiol® 40-88) with an average molecular weight of 120,000 (Sigma–Aldrich) was used as received. PVA solution (10% weight in bi-distilled water) was spun at 600 rpm for 60 s and successively baked in an oven at 100 °C for 24 h. Cross-linked PVA solution was composed of PVA (10% in water), ammonium dichromate (Sigma–Aldrich) (1.4% weight) as a cross-linking agent and bi-distilled water as a solvent. PVAad solutions were spun at the same conditions as PVA (600 rpm for 60 s). Spin-coated PVAad films were cross-linked by UV irradiation (5′) and then baked at 100 °C for 24 h. Glass and silicon substrates (oxide nominal thickness 500 nm) were both cleaned through ultrasonic baths first in acetone (15 min) and successively in isopropanol (15 min).

Pentacene (Sigma–Aldrich, 98%) films with a nominal thickness of 30 nm were grown by thermal evaporation at a nominal deposition rate of about 0.5–1 Å s^{-1}. Gold source and drain contacts ($W/L = 100$) were thermally evaporated onto the semiconducting layer (top-contact configuration) through a shadow mask. Employed polymeric gate layers were 3 μm thick in all of the tested devices as estimated from capacitance–frequency measurements performed on the corresponding MIM structures.

Drain current (I_d) measurements were carried out at room temperature, in dark, in an inert nitrogen environ-

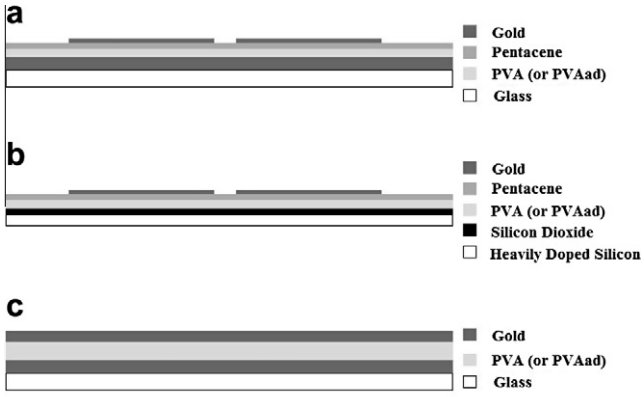

Fig. 1. Schematic illustration of the tested devices: (a) transistor in bottom-gate top-contact configuration assembled on a glass substrate (single dielectric layer); (b) transistor in bottom-gate top-contact configuration assembled on silicon/silicon dioxide (double dielectric layer); (c) Metal–Insulator–Metal (MIM) capacitor (thermally evaporated gold plates) with a single polymeric dielectric layer, assembled on glass.

ment (glove box). Agilent HP 4155 Semiconductor Parameter Analyzer, provided with gold tips for contacting the electrodes, was used to supply both the gate voltage (V_g) and the drain voltage (V_d) (the source being the common ground) and to measure the gate (I_g) and the drain (I_d) currents. All transfer curves reported in the main manuscript were acquired at a gate sweep rate of 13.3 V/s. Measurements with varying the gate sweep rate are reported in the Supplementary Data.

Space–Charge Limited Current (SCLC) measurements were carried out with a Keithley 6517 Electrometer, at room temperature, in vacuum. Capacitance–frequency as well as quasi-static capacitance–voltage measurements were acquired in inert environment (glove box) by using a 4284A precision LCR meter.

FT-IR spectra were recorded with a Nicolet Nexus 470 spectrometer, configured with a Nicolet Continuum microscope and a MCT/B liquid-nitrogen-cooled detector. Spectra were collected in ATR (Attenuated Total Reflectance) mode through a Cassegrain objective (14×), reaching a spatial resolution of ~100 μm^2 on PVA and PVA ad films deposited on glasses slides from 10% water solutions. The spectra were recorded (as sum of 256 scans with a resolution of 4 cm^{-1}) in the spectral region of the medium infrared (800–4000 cm^{-1}). Sixteen spectra (recorded with a nominal resolution of 4 cm^{-1}) were averaged to improve the signal-to-noise ratio.

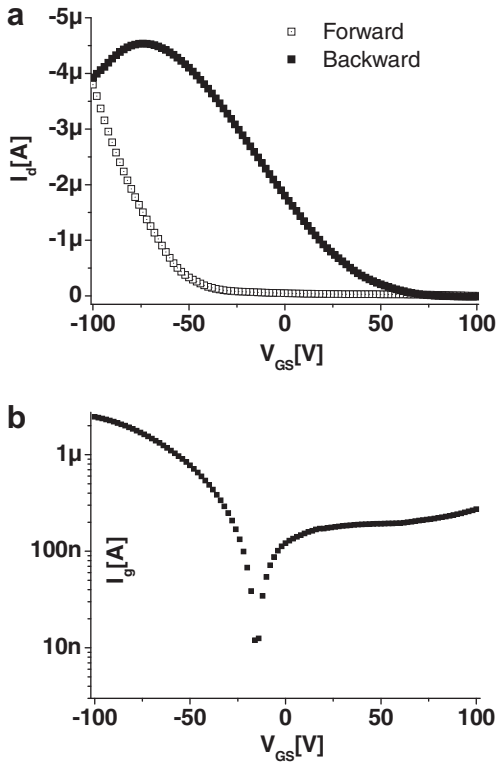

Fig. 2. (a) Transfer curve (I_d vs. V_g) recorded on a transistor in top-contact bottom-gate configuration having PVA as the dielectric layer (C_i = 2.95 nF cm^{-2}, L = 50 μm, W/L = 100) during a double sweep of V_g swept from +100 V to −100 V, V_d = −100 V (saturation regime); (b) I_g vs. V_g curve measured on the same device (V_g swept from +100 V to −100 V, V_d = −100 V, saturation regime).

3. Results and discussions

The following sections will show the results of a systematic study performed on pentacene-based OTFTs with thermally evaporated gold source and drain electrodes in top-contact bottom-gate configuration, having either glass (Fig. 1a) or silicon/silicon dioxide (Fig. 1b) as the substrate, and PVA or alternatively PVAad as a gate dielectric. In addition MIM capacitors (Fig. 1c) were fabricated and tested in order to investigate the conduction mechanisms through the dielectric layer.

3.1. Analysis of the hysteresis in transistors employing PVA as the gate dielectric

In Fig. 2a and b, we report a couple of typical curves taken on a pentacene-based transistor assembled on glass with PVA as the gate dielectric. These graphs show respectively (a) the I_d vs. V_g recorded during a double sweep of V_g

between +100 and −100 V, being the drain voltage (V_d) set to −100 V (saturation regime) and (b) the gate current (I_g) collected at the electrode. In Fig. 2a is shown a large hysteresis (with a clockwise direction) which appears on the drain current curve, leading to a big shift in the threshold voltage values extracted from the I_d–V_g curve. According to the well-known equation

$$I_d = \frac{1}{2}\mu_{SAT} C_i \frac{W}{L}(V_{GS} - V_{TH})^2 \quad (1)$$

which adequately models the drain current in the saturation regime [7], threshold voltage values were calculated by plotting the Sqrt|I_d| vs. V_g curve and then extracting the intercept with the voltage axis of the line which fits the linear part of the curve.

Consistently with this method, two remarkably different values were extracted, respectively $V_{TH,forward} = -30$ V and $V_{TH,backward} = +75$ V which produce a huge overall voltage threshold shift (ΔV_{TH}) of 105 V. Gate sweep rate was found not to sensibly affect the hysteresis or induce threshold voltage shifts as reported in Figs. S1 and S2.

In agreement with Eq. (1) field-effect mobility can be calculated as

$$\mu_{SAT,p} = 2\frac{\left(\frac{\partial\sqrt{I_d}}{\partial V_{GS}}\right)^2}{C_i \frac{W}{L}} \quad (2)$$

Being $\mu_{SAT,p}$ the saturation mobility value for a transistor working in accumulation mode, where holes are the majority carriers, and $C_i = 2.95$ nF cm^{-2} the capacitance of the PVA layer measured through capacitance–frequency measurements on MIM capacitors. The width-to-length ratio was 100. The dielectric permittivity of PVA was set to 8, as reported in literature [15]. The forward and backward curve (Fig. 2a) differ in slope and this leads to a slope difference also on the Sqrt|I_d| vs. V_g curves. In view of that, two different field-effect mobility values are extracted, respectively $\mu_{forward} = 5.4 \times 10^{-3}$ cm^2 V^{-1} s^{-1} and $\mu_{backward} = 1.8 \times 10^{-3}$ cm^2 V^{-1} s^{-1}. The same mobility and threshold voltage values were found by measuring tens of devices made using the same technological steps and device parameter (W/L, C_i) and biased with the same gate, source and drain voltages.

Though threshold voltage and field-effect mobility values could be easily extracted, the straight interpretation as well as the physical meaning of the discrepancy among them is still an issue that needs to be addressed. A correlation between hysteresis and charge trapping is commonly invoked to explain this data inconsistency [20]. Although it has been previously reported that leakage current may affect OTFTs performance and it has therefore to be minimized [21,22], the relationship between the current flowing through the bulk of polymeric gate dielectrics and the hysteresis appearing on the transistor curves has not yet been directly addressed and is not actually being taken into account when evaluating the FET device performances.

As a matter of fact, Fig. 2b reveals that a large current flows through the PVA layer and is collected at the gate electrode. In particular, the I_g follows the same trend as the transfer curves, thus indicating a dependance from I_d,

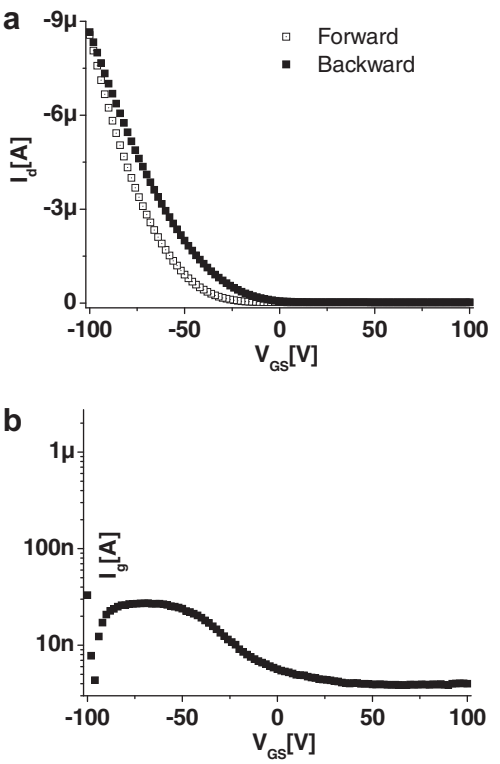

Fig. 3. (a) Transfer curve (I_d vs. V_g) recorded on a transistor in top-contact bottom-gate configuration having PVA/SiO_2 as the dielectric layer ($C_{TOT} = 2.1$ nF cm^{-2}, $L = 50$ μm, $W/L = 100$) during a double sweep of V_g swept from +100 V to −100 V, $V_d = -100$ V (saturation regime); (b) I_g vs. V_g curve measured on the same device (V_g sweeping from +100 V to −100 V, $V_d = -100$ V, saturation regime).

reaching larger current values at negative gate voltages. It is therefore necessary to get rid of this relevant current contribution before commenting on possible source of drain current hysteresis due to other mechanisms.

Interestingly, to completely remove this undesired contribution (and discard possible interferences of the leakage current with different phenomena as trapping) one should use PVA (or any other "leaky" dielectric) only as a surface layer deposited on another not leaky dielectric, as for instance SiO_2.

This is clearly shown in Fig. 3a, showing I_d vs. V_g current recorded on device having a double PVA/SiO_2 dielectric layer, where a remarkable reduction on the hysteresis in the transfer curves due to the insertion of a silicon dioxide layer (see Fig. 1b) is highlighted. The polymeric gate dielectric in these devices was around 3 μm thick, as the one in the devices assembled on glass (see Fig. 1a), which only used PVA as the dielectric layer.

The same equations as above were used to extract threshold voltage and field-effect mobility, except for the capacitance value. When a double dielectric is employed the resulting capacitive contribute to the device is equivalent to the series of two capacitors, C_{PVA} and C_{SiO2} in this case.

Consequently the total capacitance of the double dielectric layer will be given by Eq. (3)

$$C_{TOT} = \frac{C_{PVA} C_{SiO_2}}{C_{PVA} + C_{SiO_2}} \quad (3)$$

where C_{PVA} and C_{SiO2} are respectively 2.95 nF cm^{-2} and 6.9 nF cm^{-2} (as measured from several capacitance–frequency measurements on MIM structures) and the total capacitive contribute is therefore C_{TOT} = 2.1 nF cm^{-2}. After replacing C_{TOT} with C_i in Eq. (2) the field-effect mobility can be properly calculated.

The threshold voltage values extracted from Sqrt$|I_d|$ vs. V_g curve are $V_{TH,forward}$ = −25 V and $V_{TH,backward}$ = −5 V (both of them having the same sign) which gives place to an associated overall threshold voltage shift (ΔV_{TH}) far lower than in the case of Fig. 2a. The extracted mobility values, $\mu_{forward} = 1.4 \times 10^{-2}$ cm^2 V^{-1} s^{-1} and $\mu_{backward} = 0.9 \times 10^{-2}$ cm^2 V^{-1} s^{-1}, are higher and their values match better than in the case of devices using only PVA as the gate insulator; this is also clearly evidenced by the I_d–V_g curve slope change as a consequence of the insertion of a further shielding dielectric layer (Fig. 3a). These results point out that (1) the hysteresis phenomenon is largely reduced due to the strong reduction in leakage current (now only being 0.1% of I_d) through the dielectric (compare Fig. 3b with Fig. 2b), (2) the extracted mobility values relative to the hole transport in pentacene-based transistor with PVA as the gate dielectric can now be considered reliable for studying the charge transport.

3.2. Modeling and simulation of transfer curves in OTFTs having PVA as the polymeric gate dielectric

To assess the possible influence of transport mechanisms across the dielectric in the transistor curves, we performed a numerical simulation in which a transistor with charge transport occurring in the bulk of the dielectric is considered. The simulated device is a pentacene-based thin-film transistor in top-contact bottom-gate configuration. Pentacene and dielectric thickness was set to 30 nm and 3 μm, respectively. The width-to-length ratio was set to 100.

We used the Sentaurus program by Synopsys, which is a well-known tool for semiconductor device modeling, to simulate the hysteresis of the device [23]. The Poisson equation coupled with the current continuity equations was solved:

$$\begin{cases} \nabla^2 V = \frac{q}{\varepsilon}(n - p - N + n_t - N_t) \\ \nabla \cdot \boldsymbol{J}_n = -qR + \frac{\partial n}{\partial t} \\ -\nabla \cdot \boldsymbol{J}_p = -qR + \frac{\partial p}{\partial t} \end{cases} \quad (4)$$

where q is the elemental charge, V is the electrostatic potential, ε is the dielectric permittivity, n is the density of electrons, p is the density of holes, N is the doping profile, N_t is the density of trap states, if present, n_t the density of occupied traps; R is the recombination factor. We model the current with the drift diffusion equations, therefore

$$\begin{cases} \boldsymbol{J}_n = q\mu_n n\mathbf{E} + qD_n \nabla n \\ \boldsymbol{J}_p = q\mu_p p\mathbf{E} - qD_p \nabla p \end{cases} \quad (5)$$

for the current of electrons and holes, respectively. μ_n and μ_p are the carrier mobilities, $D_n = \mu_n kT/q$ and $D_p = \mu_p kT/q$ are the diffusivities.

For the pentacene, the following properties were set up: band gap $E_g = 2.5$ eV, electron affinity $q\chi = 2.6$ eV, density of states $N_C = N_V = 2 \times 2.9 \times 10^{21}$ cm^{-3} [24]. The hole mobility in agreement with the experimental data was set to $\mu_p = 1.7 \times 10^{-3}$ cm^2 V^{-1} s^{-1}, whereas the mobility for electrons was supposed to be negligible $\mu_n = 10^{-11}$ cm^2 V^{-1} s^{-1}. Source and drain contacts, realized in gold, had a metal work-function $q\phi_m = 5.1$ eV.

On the other hand, PVA cannot be modeled as an ideal insulator, because current flows through it. A fully detailed description of the current physics is still under investigation [25]; however, we will assume that carriers follow Eqs. (4) and (5). This hypothesis has already been used to simulate ion channels with drift–diffusion simulators [26]. We will also suppose that the boundary conditions for the gate electrode define charge neutrality at the interface, therefore Dirichlet boundary conditions hold [27].

The intrinsic carrier density in the PVA was set to an arbitrary small value. We assumed a density of donor traps $N_t = 10^{17}$ cm^{-3}, with an energy, estimated by fitting the transfer curves of the transistors, $E_{tr} = E_V + 0.3$ eV. The mobility of the carriers were determined as fitting parameters: $\mu_n = 10^{-11}$ cm^2 V^{-1} s^{-1}, $\mu_p = 10^{-10}$ cm^2 V^{-1} s^{-1}. The order of magnitude of the carrier mobility used in the simulation of the PVA is in agreement with the value extracted from the SCLC measurements on MIM capacitors using PVA as the insulator.

Using the same sweep times of the experimental measurements, we obtained the curve reported in Fig. 4, which shows a very good qualitative agreement with the experimental data, for both magnitude and sign of the hysteresis. The large hysteresis is determined by the carriers in the PVA, whose slow motion in the dielectric, due to the electric field, affects the threshold voltage of the device; the traps in the dielectric further contribute to the change in threshold voltage and, therefore, to the hysteresis.

To increase the agreement with the experimental data, a more in-depth description of the pentacene/PVA interface should be achieved, including details about the band-gap of the dielectric and the energy distribution of possible trap states at the interface. The carrier transport in the PVA itself could be better described, if the physical nature of the current across the dielectric layer could be described in detail. These points are currently under investigation, and will be addressed in future publications.

3.3. SCLC characterization of PVA and PVAad/analysis of trapping at the semiconductor-polymeric dielectric interface

Following the previous considerations, the current through the polymeric dielectric layer seems to play a major role on both performance and characteristic parameters of the device. To further investigate the transport mechanisms across the dielectric layer, current vs. voltage measurements were performed on MIM structures as shown in Fig. 5a and b. This electrical behavior can be described in the framework of the Lampert and Mark model for trap-controlled electrical transport in semi-insulating materials [19]. Three different regimes can be resolved in the I–V curves: a linear (ohmic) regime at low voltages, a quadratic regime named "space–charge limited current"

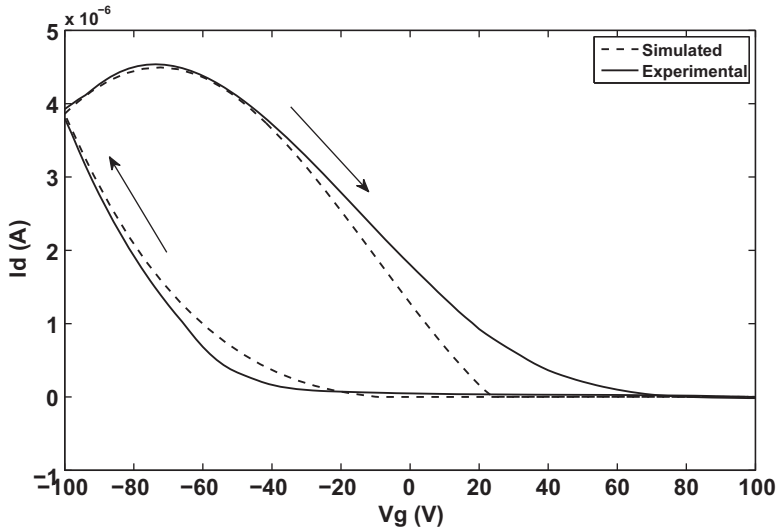

Fig. 4. Simulation and fitting of the I_d–V_g curve reported in Fig. 2a. The simulated device is a pentacene-based thin-film transistor in top-contact bottom-gate configuration with a single polymeric gate dielectric layer. Here only the charge transport occurring in the bulk of the polymeric gate dielectric is considered. The simulation is in good agreement with the experimental data, revealing that charge transport across the dielectric layer represents the major contribution to the hysteretic behavior.

(SCLC) at higher voltages and the so-called "trap filled limited" (TFL) region characterized by the steep increase of the current. The charge carrier mobility μ can be estimated from the equation describing the SCLC curve in a trap-free semi-insulator (Mott–Gurney law) $\mu = \frac{8JL^3}{9\varepsilon V^2}$ for $V = V_{TFL}$, where J is the current density at the beginning of the trap-free region, ε the dielectric constant and L is the separation between the contacts (the dielectric thickness). We can also estimate the density of traps from the voltage V_{TFL}, where the trap-free region starts, using the relation $N_t = \frac{\varepsilon V_{TFL}}{eL^2}$, where e is the electron charge. In particular, significant current flows through the dielectric layer (Fig. 5a) at voltage values that are typical of transistor operation. Only after the V_{TFL} (Trap Filled Limit Voltage) is reached, the material behaves as a trap free insulator following the Mott–Gurney quadratic law. From the V_{TFL} value, majority carrier mobility (10^{-10} cm^2 V^{-1} s^{-1}) and trap density (10^{17} cm^{-3}) can be estimated [19].

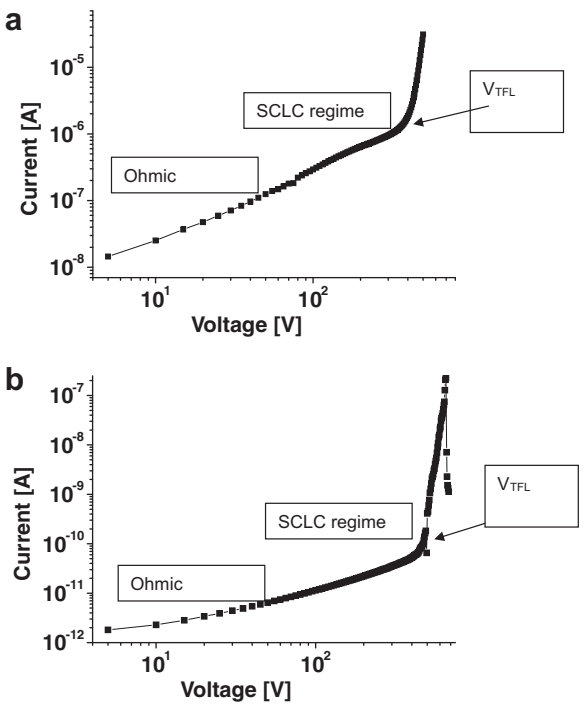

Fig. 5. I vs. V (logarithmic scale) curves of (a) a PVA-based MIM capacitor and (b) a PVAad-based MIM capacitor (in vacuum).

With the purpose of investigating the relationship between transport and leakage current into a polymeric gate dielectric, current vs. voltage measurements were performed also on PVAad. Surprisingly, I–V curves (Fig. 5b) show that SCLC regime occurs later in voltage than for PVA, which means that PVAad has a much lower ability than PVA to transport injected charges (in the operational voltage range of transistor). Thanks to the consequent low leakage currents through the dielectric (the leakage current being respectively three orders of magnitude lower than I_d, Fig. 6b, and four orders of magnitude lower than I_d, Fig. 6d), hysteresis is almost negligible on PVAad-based FET devices when they are assembled both on glass (Fig. 6a) and silicon dioxide (Fig. 6c). These results partially differ from what Park et al. highlighted in their work where residual hysteresis still appears when using PVAad together with silicon dioxide (100 nm thick) as the gate dielectric layer [18]. This is probably due to the fact that a thicker both silicon dioxide layer (500 nm) and polymeric insulating layer (3 μm) was used in our study thus shielding more efficiently this parasitic contribute to the hysteresis.

At this point, the residual and not negligible hysteresis on PVA-based devices assembled on silicon/silicon dioxide

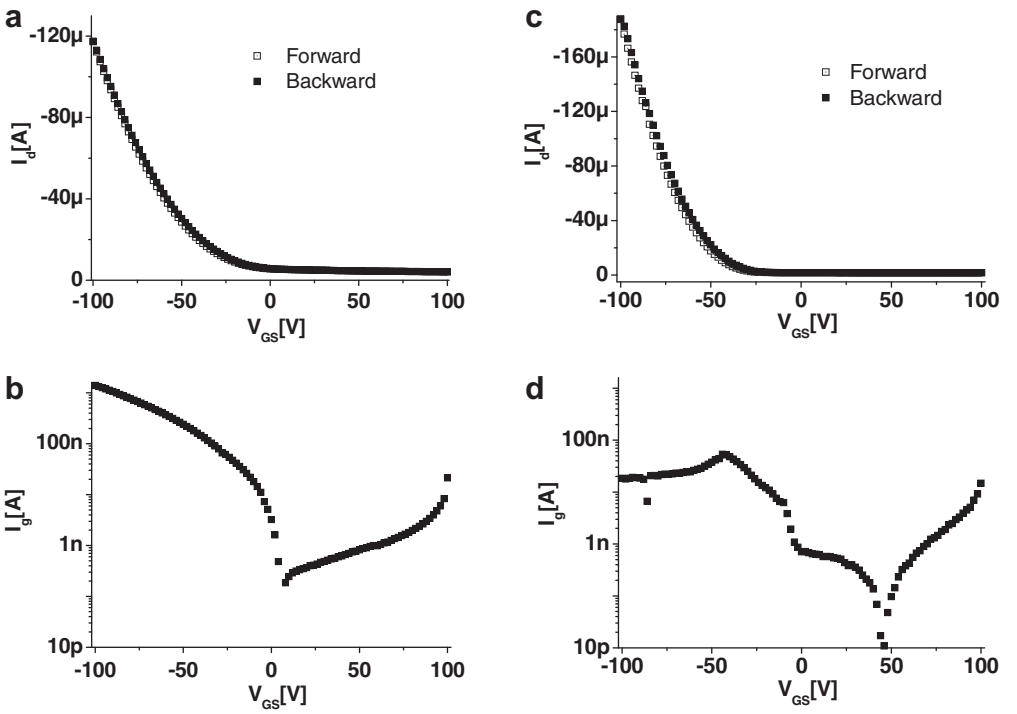

Fig. 6. (a) Transfer curve (I_d vs. V_g) recorded on a transistor in top-contact bottom-gate configuration having PVAad as the dielectric layer (C_{TOT} = 2.1 nF cm^{-2}, L = 50 μm, W/L = 100) during a double sweep of V_g swept from +100 V to −100 V, V_d = −100 V (saturation regime); (b) I_g vs. V_g curve measured on the same device in Fig. 6a (V_g sweeping from +100 V to −100 V, V_d = −100 V, saturation regime); (c) transfer curve (I_d vs. V_g) recorded on a transistor in top-contact bottom-gate configuration having PVAad/SiO_2 as the dielectric layer during a double sweep of V_g swept from +100 V to −100 V, V_d = −100 V (saturation regime); (d) I_g vs. V_g curve measured on the same device in Fig. 6c (V_g sweeping from +100 V to −100 V, V_d = −100 V, saturation regime).

(Fig. 3a) has to be further investigated. Residual hysteresis can be attributed to (a) dipole-induced effect due to slow polarization of dipole groups (inside the dielectric bulk) that can be slowly reoriented by an applied electric field or (b) trapping at the semiconductor/dielectric interface due to the chemical nature of the gate dielectric.

Slow polarization mechanism has been widely proved on organic transistors with poly (vinyl 4-phenol) (PVP) as a gate dielectric [28–30]. In particular, OH groups inside the dielectric are considered possible source of hysteresis on transfer curves. Hysteresis was reduced by exposing PVP to cross linking reaction with polymelamine-co-formaldehyde. This condensation reaction led to a dielectric layer having minimal density of hydroxyl groups and internal impurities, but does not actually affect the surface groups of the dielectric and consequently not changing the semiconductor/insulator interface [29]. In order to minimize the possible presence of residual dipoles (water molecules) into the dielectric film, our dielectric layers were baked for 24 h at 100 °C (as described in the experimental session) before pentacene and source and drain electrodes deposition. Capacitance–frequency measurements recorded at different bias voltages were performed on MIM structures having double dielectric (PVA and silicon dioxide) to verify the existence of slow polarization coming from slow dipoles. PVA layers were as thick as the ones used as the gate dielectrics in the transistor device. Results are shown in Fig. 7 where a comparison between two different measurements (using different bias voltage) is shown; no significant effect due to a bias voltage application was observed over all the used range of frequencies. This means that a slow polarization effect due to residual immobile dipoles in the insulating PVA layer can be considered negligible and cannot actually represent the major contribute to hysteresis on transfer curves.

Even by using different experimental conditions than ours, other authors have observed hysteresis in organic

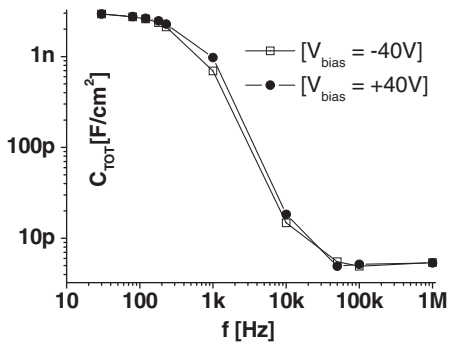

Fig. 7. Capacitance vs. frequency curves at V_{bias} = −40 V and V_{bias} = +40 V recorded on a MIM capacitor having PVA and silicon dioxide as a double dielectric layer. The curve shows that there is no evidence (at any frequency) for a slow polarization effect due to residual immobile dipoles in the insulating PVA layer.

thin-film transistors employing only a PVA layer as the gate insulator [25]. This phenomenon was ascribed to ionic impurities which moved in the dielectric bulk of the transistor. Such evidence is in accordance with the outcome of our study where the presence of charge motion in the polymeric dielectric layer was attributed to low mobility charges as consistently modeled in the simulations.

Examining the organic/dielectric interface is therefore crucial to draw conclusions on hysteresis. The chemical nature of polymeric gate dielectric/semiconductor interface has been found to play a key role for deeply understanding transport behavior and electrical performances in OTFTs [31–33]. In particular, a different electron trapping efficiency depending on the terminal side chains of the polymeric dielectrics has been suggested by Yoon et al. [34].

To assess the chemical end-groups on the both PVA and PVAad, FT-IR analyses were performed (Fig. 8). The reaction of PVA with ammonium dichromate results in the oxidation of hydroxyl groups. We can notice a considerable increase of the two bands at 1702 and 1560 cm^{-1} which, in agreement with the literature, can be attributed to C=O stretching vibrations of ketones and carboxylate groups respectively. Furthermore we observe the decrease of the OH stretching vibration band and two new absorption bands at 1658 and 1620 cm^{-1} which are quite characteristic of amide groups. The formation of these two bands might be due to some interaction between the starting NH_4 and chromium(VI), that would react with residual ester groups, leading to amide functions [35]. PVA is thus a hydroxyl-terminated dielectric, while PVAad contains a higher amount of ketone functionalities as already reported [36]. Ketone groups are known to be more effective electron traps than hydroxyls [34]. Therefore, the interface chemistry indicates that in both cases electron traps could play a major role and that, possibly, charge (electron) trapping should be even more efficient in PVAad based devices. The fact that PVAad does only show negligible hysteresis can be ascribed to either the presence of a few trap states or to the ability of these trap sites to trap and retain charge for times that are much longer than the measurement time. The possibility of strong electrostatic interaction with charge carriers due to polar carbonyl groups has been also recently pointed out [37].

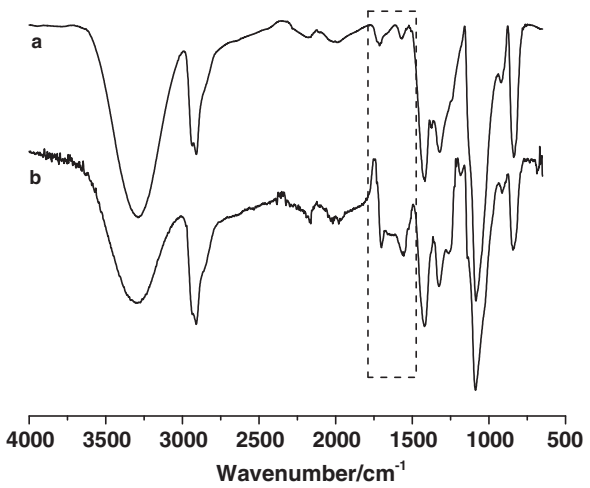

Fig. 8. FTIR Spectrum of (a) PVA and (b) PVA cross-linked with ammonium dichromate.

In the case of PVA (Fig. 3a), electron traps act by subtracting electrons while gate voltage is swept from positive to negative values (forward) but also, passing from positive to negative voltages, re-emit electrons which recombine with holes, thus lowering the drain current value. Analogously, when the gate voltage is swept backward since all of the electrons are likely to having been re-emitted, the hole population will be no longer (or much less) influenced by the presence of electrons so that the net amount of measured current will be higher. This explains the clockwise hysteresis loop observed on the I_d–V_g curves in devices using PVA and silicon dioxide as the insulating layer. On the other hand, if we assume that in devices using PVAad electron traps are much more effective than in PVA, as suggested by the chemistry of ketone and hydroxyl groups, it can be inferred that electron re-emission does not happen in the timeframe of the measurement. The forward curve does not therefore differ significantly from the backward curve. As further evidence, I_d–V_g curves were acquired on PVAad transistors at various gate sweep rate to explore the possible charge carriers re-emission, but negligible dependance on this parameter was observed (see Supplementary Data, Fig. S3).

In addition, these observations shed light on why n-type behavior has been never observed onto devices using PVAad as the gate dielectric whilst n-type transport has been widely reported on PVA-based transistors [32,38,39].

4. Conclusions

We have found that the charge transport across the bulk of a polymeric dielectric layer exerts a strong influence on the performances of the organic field-effect transistors. In particular it gives place to a large hysteresis on the transfer curves which impacts the extraction and the straight interpretation of major device parameters such as the field-effect mobility and the threshold voltage. This charge contribution was highlighted through space-charge limited current measurements carried out on MIM capacitors having a polymeric dielectric as the insulating layer. The extracted parameters were employed first to model and then to simulate the transfer curves of a pentacene-based thin-film transistor using PVA as the gate dielectric. The simulations confirmed the experimental data showing that the charge transport in the dielectric is the main responsible for the hysteresis that arises in the electrical measurements. The undesired contribution was blocked by the insertion of a silicon dioxide layer underlying the polymeric dielectric. The residual hysteretic behavior was analyzed and ascribed to the trapping effects occurring at the interface between the organic semiconductor and the polymeric dielectric. In this regard, the impact of the trapping efficiency due to the different chemical nature between PVA and PVAad was assessed: the increase of carbonyl groups in PVAad supports the idea of a stronger trapping

effect that could in fact lead to longer carrier emission times and reduced hysteresis in the I_d–V_g curves. From a practical perspective our work clearly shows that organic thin-film transistors should use organic dielectric layers in which this undesired charge contribution is blocked. In addition, this work points out the importance of the transistor device as a tool for investigating material properties and, on the other hand, it underlines that the extracted charge carrier mobility and threshold voltage values might not only depend on the chemical nature of the semiconductor/dielectric interface as widely shown in the past.

ABSTRACT

We studied the triplet decay dynamics in the fluorescent polymer–polymer host/guest system F8BT/MEH-PPV and in the small molecule host/guest system Alq_3/DCM. The triplet lifetime was determined by a highly sensitive time-resolved measurement of the triplet state absorption via a pump and probe experiment in a waveguide structure. We were able to identify triplet–triplet annihilation as a major decay mechanism of triplet states in the pristine amorphous organic materials at room temperature (rate constant: $k_{TT} \approx 10^{-12}\,cm^3\,s^{-1}$). On the contrary, the host/guest systems showed a significantly increased triplet lifetime caused by a reduced triplet–triplet annihilation rate which we attribute to a substantially lowered mobility of the localized triplet excitons. Our results are expected to be of paramount importance for organic light emitting devices based on fluorescent emitters (e.g. organic lasers and organic light emitting diodes).

1. Introduction

Fluorescent organic materials are widely used in organic light emitting diodes (OLEDs) and organic lasers. Systems consisting of an emitter doped into a wider energy band gap host material generally increase the device performance compared to neat materials. Organic devices like OLEDs or lasers using these host/guest systems show higher efficiencies [1], a lower lasing threshold, or a wider tuning range [2]. In OLEDs, singlet and triplet excitons are generated by charge carrier recombination at a ratio of 1:3. In fluorescent materials, the emission from triplet states is very weak because the triplet energy is efficiently converted to heat. This limits the internal efficiency in fluorescent OLEDs to less than 25%. Nevertheless, triplet–triplet annihilation (TTA) can be used in fluorescent OLEDs to generate additional singlet states from otherwise useless triplet excitons [3–6], which leads to very high efficiencies, even exceeding the classical theoretical limit [7,8]. This is particularly important for lighting applications, where elevated luminance levels are required. Today, highly efficient OLEDs commonly use triplet emitters which suffer from a strong decrease in efficiency at high current densities (''roll off'') [9]. Here, fluorescent OLEDs using the TTA to generate additional singlet excitons may be promising alternatives especially for the blue spectral region. On the other hand, triplet excitons can also reduce the device performance by singlet–triplet annihilation [10] or by the triplet state absorption. These effects are especially relevant for organic lasers [11,12], where the triplet absorption is predicted to be a major obstacle preventing electrically driven lasing [11,13].

In view of the importance of triplet related processes in both OLEDs and organic lasers, information about the TTA rate at room temperature and the lifetime of triplet excitons is a key to the understanding and the design of efficient devices. Based on the approach presented in this paper, we are able to assess these quantities and study the triplet dynamics in organic host/guest systems.

The TTA rate is related to the triplet diffusion coefficient since the triplet mobility directly relates to the probability that two triplet excitons meet. Giebink et al. demonstrated

a reduced triplet diffusion in 4,4′-bis(*N*-carbazolyl)biphenyl (CBP) by blending with *p*-bis(triphenylsilyl)benzene (UGH2) [14]. They attributed this observation to the higher triplet energy of UGH2 which forms an energy barrier for CBP triplets. In commonly used fluorescent host/guest systems, the wide-band-gap host might support the localization of triplets on the guest molecules in a similar way and thereby hinder their diffusion. In this case, one has to be careful by simply using the often reported TTA rates for pristine materials for fluorescent host/guest devices without change. To our knowledge, this important effect has not been studied for fluorescent systems so far, mainly due to the difficulties in the observation of the predominantly non-radiative nature of triplet states at room temperature.

In this paper we study the triplet lifetime in the polymer–polymer host/guest system *poly*[(9,9-di-*n*-octylfluorenyl-2,7-diyl)-alt-(benzo[2,1,3]thiadiazol-4,8-diyl)] (F8BT) and *poly*[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylene-vinylene (MEH-PPV) and the small molecule host/guest system tris(8-hydroxyquinoline)aluminium(III) (Alq_3) and 4-(dicyanomethethylene)-2-methyl-6-[*p*-(di-methyl-amino)styryl]-4H-pyran (DCM). The triplet lifetime is determined by measuring the time resolved triplet absorption at room temperature in amorphous thin films. A waveguide structure is used to achieve a highly sensitive measurement [15]. We determined the triplet decay in the host/guest systems as well as in the corresponding pristine materials. As a result, we found a significantly longer triplet lifetime in the host/guest systems due to a reduced TTA rate, which we attribute to a decreased diffusion constant for triplet excitons, whereas in pristine materials the TTA is dominating the decay mechanism at triplet densities relevant for OLEDs.

2. Experimental

The triplet lifetime measurement was carried out as shown in Fig. 1. The organic layers form a waveguide structure for the light generated by the pump and the probe pulse. Both pulses were separated spatially and temporally to exclusively measure the triplet absorption. Specifically, the edge emission of the waveguide is detected with spectral and temporal resolution. For the determination of the triplet lifetime, the wave guided emission generated by excitation with the probe pulse has to pass the region, where the previous excitation by the pump pulse has led to the creation of triplet excitons. Therefore, the intensity of the edge emission, detected for different delay times between pump and probe pulse, will be directly related to the absorption due to triplets in this region of the waveguide. All measurements are carried out at room temperature.

The organic layers were deposited on silicon wafers covered with 2 μm silicon dioxide. The 180 nm thick polymer layers were spincast from chlorobenzene solution and dried at 60 °C for ten minutes on a hotplate. The 200 nm thick small molecule thin films were prepared by thermal evaporation in ultra high vacuum (base pressure 10^{-8} mbar). The organic layer thicknesses were chosen to build up a waveguide structure on top of the silicon

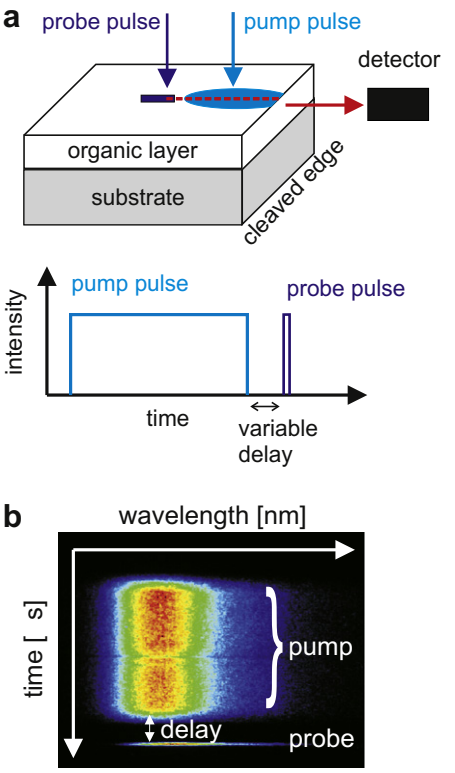

Fig. 1. (a) Measurement setup for triplet lifetime determination. (b) Streak camera image of the detection signal.

dioxide which enables only the propagation of the first transverse electrical mode (TE_0). To simulate the optical mode a transfer matrix algorithm [17] was used taking the dispersion of the refractive index into account. As a pump source for triplet generation via ISC we used two InGaN based laser diodes ($\lambda = 445$ nm and $\lambda = 405$ nm) provided by Nichia Chemical (NBD7112, NDHV220APAE1). If not mentioned explicitly the laser diode emitting at $\lambda = 445$ nm was used in the experiments. The laser diodes were driven with a pulse width of 10 μs and a repetition rate of 2 kHz. The multimode output of the diode is focussed on a spot of around 0.77×0.18 mm^2 with a pump pulse energy density of 600–900 μJ/cm^2.

As a source for the probe pulse we used a Q-switched, frequency-tripled, diode pumped solid-state (DPSS) laser emitting at $\lambda = 355$ nm. The pulse width and repetition rate were 700 ps and 2 kHz, respectively. The probe pulse is focussed on a stripe of 27 μm width and an adjustable length of approximately 0.5 mm. During the optical measurements, the samples were mounted in a nitrogen purged chamber. The probe pulse is positioned 0.1 mm behind the pump pulse with respect to the sample edge, as shown in Fig. 1. This spatial separation excludes singlet–triplet annihilation [12]. The probe pulse follows the pump pulse with a variable time delay of 200 ns to 488 μs. A minimum delay of 200 ns assures that all singlets generated by the pump pulse are decayed. The edge emission is detected by a streak camera (Hamamatsu C4334) to allow spectral and temporal resolution (Fig. 1b)). The light generated by

the probe pulse is monitored against the delay between pump and probe pulse. By using waveguide simulations the triplet induced material absorption is calculated with the optical confinement factor Γ in a spectral region where the principal waveguide loss (without triplet absorption) is sufficiently low [16]. The following spectral regions are used for the calculation of the average material absorption shown in the following: F8BT 557–687 nm; MEH-PPV: 627–657 nm; F8BT/MEH-PPV: 642–727 nm; Alq_3: 517–642 nm; Alq_3/DCM: 632–657 nm.

3. Results

3.1. Triplet generation via intersystem crossing

In this study we use a laser diode pump pulse to generate triplet states. The incident light of the pump pulse is absorbed in the organic material and produces excited singlet states. Triplet states can be formed via intersystem crossing (ISC) from the singlets [18]. The process is described below:

$$S_0 + h\nu \rightarrow S_1 \overset{k_{ISC}}{\rightarrow} T_1 \quad (1)$$

S_0 denotes a molecule in the ground state, S_1 the lowest excited singlet state and T_1 the lowest excited triplet state. The efficiency of this process is determined by the intersystem crossing rate k_{ISC} or by the quantum yield $\Phi = k_{ISC}\tau_S$ (τ_S = singlet lifetime). For F8BT quantum yields of $\Phi = 0.02$ [19,20] and for MEH-PPV $\Phi = 0.0125$–0.025 [21,22] have been published, respectively. Alq_3 showed quantum yields of $\Phi = 0.12$–0.24 [23,24]. During the pump pulse triplets accumulate, whereas the singlets decay relatively fast [20,23]. As we will show later, we achieve triplet densities in the order of 10^{17} cm^{-3}, which is close to typical triplet densities in OLEDs [25] where the triplet states are generated efficiently by charge recombination. In our case high triplet densities are achieved in spite of the less efficient ISC process by using long excitation pulses and a high excitation density.

Beside their intrinsic decay, triplets can decay via TTA determined by the rate constant k_{TT} as described below in detail

$$T_1 + T_1 \overset{k_{TT}}{\rightarrow} S_0 + T_n \rightarrow T_1 + S_0 \quad (2)$$
$$S_n + S_0 \rightarrow S_1 + S_0$$

After the annihilation of two triplet excitons, a highly excited triplet state T_n is populated. Some fraction converts to the S_n state and then, after relaxation, the fluorescence from S_1 can be detected (delayed fluorescence) [26]. In the case of Alq_3 we observed delayed fluorescence at 12 K after excitation with the pump pulse (not shown here), which indicates the occurrence of the discussed triplet–triplet interaction [27]. Note that our subsequent measurements are not influenced by the delayed fluorescence because of its very low intensity at room temperature. To calculate the generated triplet density we will use the triplet absorption cross section σ_T taken from literature data to derive the triplet density.

3.2. Triplet lifetime in F8BT/MEH-PPV

Initially, we studied the pristine material F8BT. In Fig. 2a the absorption spectrum is shown for varied delay times between pump and probe pulse. For the smallest delay time triplet related absorption causes an almost 50% decay of the signal. For longer delay times the triplet density becomes smaller and the signal is less attenuated. The spectral characteristics are in good agreement with previous publications of the triplet absorption spectra [28]. For wavelengths shorter than 540 nm the ground state absorption of F8BT limits the short wavelength site of the measurement. At long wavelengths the measurement is limited by the photoluminescence spectrum of F8BT. Further details concerning the spectral characteristics of triplet absorption and the generation of triplet states via laser diode excitation have been published before for F8BT, MEH-PPV and F8BT/MEH-PPV [12]. From our measurements (Fig. 2a) the triplet induced material absorption is calculated by a simulation of the light propagating in the waveguide. The results are displayed in Fig. 2b (to minimize the impact of noise the average absorption for a reasonable spectral region is taken). The fit is calculated according to the model described below.

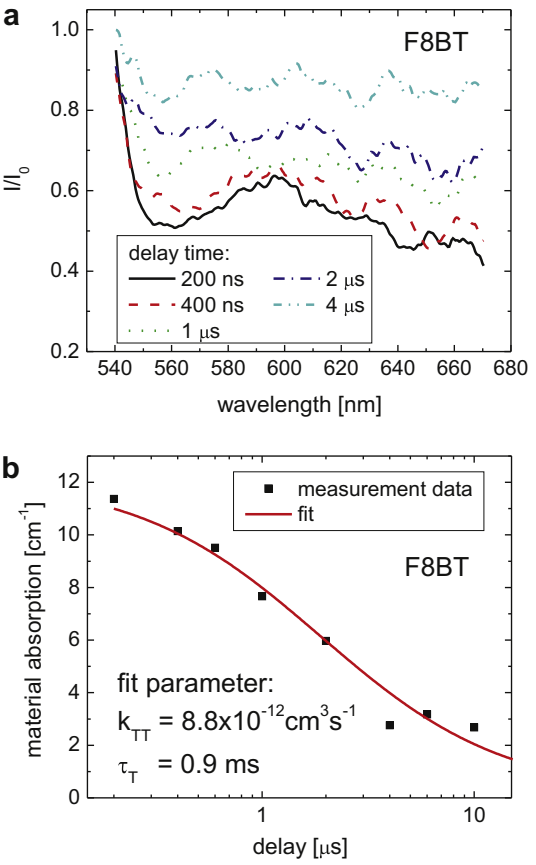

Fig. 2. (a) Spectrally resolved intensity of light generated by the probe pulse (I) for different delays to the pump pulse in comparison to the signal without a pump pulse (I_0). The spectra are shown for the material F8BT. (b): Average material absorption calculated for (a) and fit according to formula (3).

Hale et al. showed that TTA is a major de-excitation mechanism for photo excited triplet excitons in MEH-PPV [29]. In order to express the triplet decay dynamics we used the following model [30]:

$$\frac{dn_T}{dt} = n_0 - \frac{n_T}{\tau_T} - \frac{1}{2}k_{TT} \times n_T^2 \quad (3)$$

Here, aside from the intrinsic decay (intrinsic lifetime τ_T) the TTA rate k_{TT} is included as a further decay mechanism. The triplet density is described by n_T. The initial triplet density n_0 is generated by the pump pulse.

Fig. 3 shows that in the host/guest system F8BT/MEH-PPV (16 wt.%) a significantly slower decay is measured than for pristine MEH-PPV.

It should be noted that a simple mono exponential model which disregards the TTA does not sufficiently describe our observations.

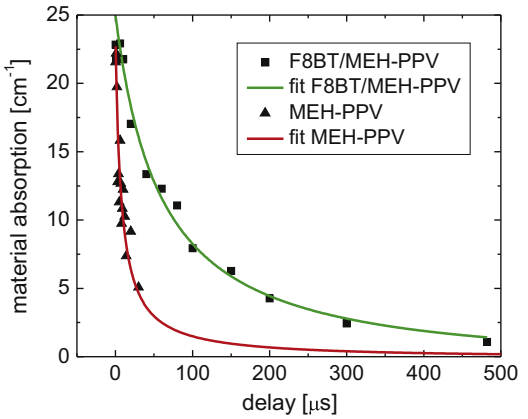
As mentioned above n_0 is calculated straight forward by using the triplet absorption cross section σ_T. For F8BT a cross section of $\sigma_T = 1 \times 10^{-16}$ cm^2 in the spectral region around 600 nm is assumed according to previous reports [19,28,31,32]. For MEH-PPV a cross section of $\sigma_T = 5 \times 10^{-16}$ cm^2 in the spectral region around $\lambda = 680$ nm is taken for the calculation [33]. A higher absorption cross section for PPV in comparison to F8BT has been theoretically predicted by Ford et al. [19]. In case of the host/guest system the same σ_T is assumed as that used for MEH-PPV [12]. The measurement data are fitted with k_{TT} and τ_T as fitting parameters.

For F8BT an annihilation rate of $k_{TT} = 8.8 \times 10^{-12}$ cm^3 s^{-1} and for MEH-PPV of $k_{TT} = 5.4 \times 10^{-12}$ cm^3 s^{-1} is obtained. According to the results of our experiment, TTA is the major decay mechanism in the pristine materials under our experimental conditions. The triplet lifetime τ_T is fitted best with a value of 0.4 ms for MEH-PPV and 0.9 ms for F8BT, respectively. Due to the dominating influence of TTA on the decay, the fitted lifetime τ_T is subject to a relatively large uncertainty. Nevertheless, the determined values of 0.9 ms for F8BT and 0.4 ms for MEH-PPV are in good agreement with earlier reports. For F8BT a triplet lifetime of 0.98 ms has been reported at low temperatures of 10 K where TTA is insignificant [19]. For MEH-PPV in solution triplet lifetimes in the order of 0.1 ms have been reported [22,33].

In case of the host/guest system, the measurement data are favorably simulated with $k_{TT} = 6.2 \times 10^{-13}$ cm^3 s^{-1}, which is nearly one order of magnitude lower than in the pristine materials. Interestingly the intrinsic lifetime τ_T is determined to be 0.4 ms, which is similar to that of pristine MEH-PPV. Disregarding the TTA a mono exponential fit leads to a time constant of $\tau_{mono.exp.} = 138$ µs.

3.3. Triplet lifetime in Alq_3/DCM

In the second experiment, we studied the triplet decay in the archetype small molecule based host/guest system Alq_3/DCM (2 vol.%). The spectrally resolved triplet related absorption for pristine Alq_3 and for the doped system is shown in Fig. 4. As mentioned in the experimental, the observable spectral region is limited by the edge emission spectrum of the sample. For Alq_3 we found an triplet



Fit parameter:

Material	k_{TT}[cm^{3}s^{-1}]	τ_T[ms]
F8BT	8.8x10^{-12}	0.9
MEH-PPV	5.4x10^{-12}	0.4
F8BT:MEH-PPV	6.2x10^{-13}	0.4

Fig. 3. Material absorption of the MEH-PPV and F8BT/MEH-PPV vs. the delay time between pump and probe pulse. Fits are according to (3).

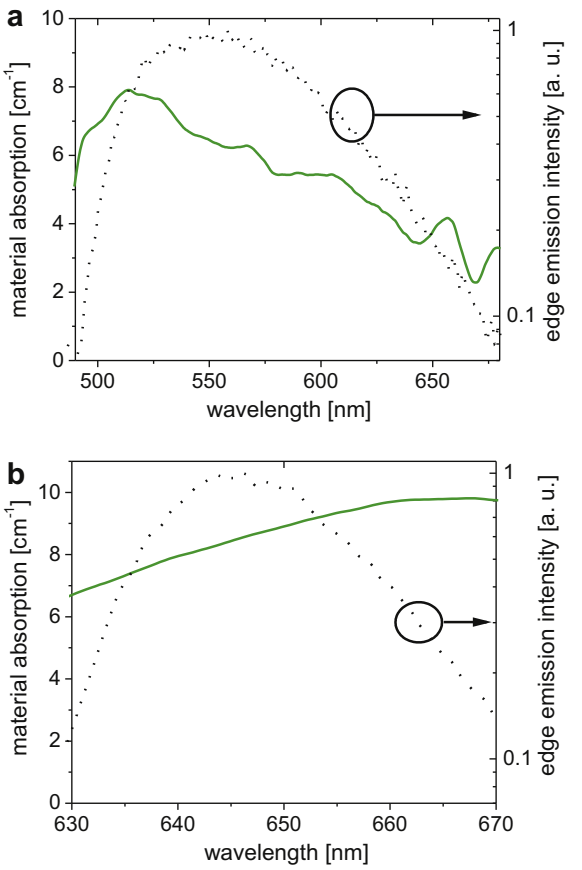


Fig. 4. Triplet absorption spectra and edge emission spectra for Alq_3 (a) and Alq_3/DCM (b).

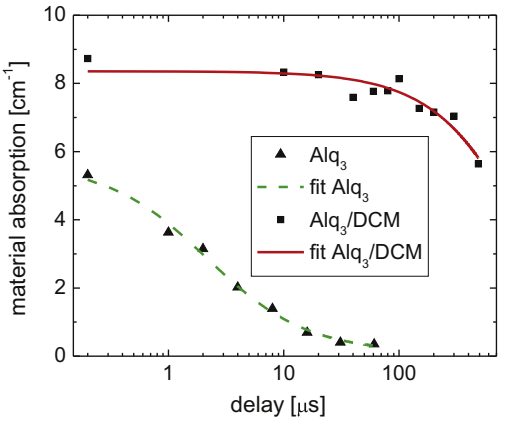
absorption maximum around 515 nm which is in good agreement with former publications [23,24]. In the doped system we measured increasing triplet absorption from 630 nm to 670 nm which has also been observed for pristine DCM [34].

The triplet dynamics are fitted by the model described above. For Alq_3 a triplet absorption cross section of $\sigma_T = 1.27 \times 10^{-17}$ cm^2 is used for the calculation [24]. The host/guest system is fitted with $\sigma_T = 3.4 \times 10^{-17}$ cm^2 as reported for DCM [34]. The results are displayed in Fig. 5. We observed dramatically slower triplet decay in the host/guest system compared to that in pristine Alq_3. Referring to our model the TTA is dominating the decay in pristine Alq_3 with a rate constant of $k_{TT} = 2.2 \times 10^{-12}$ cm^3 s^{-1}. In contrast to this TTA is insignificant in Alq_3/DCM corresponding to very low annihilation rate of $k_{TT} \approx 1 \times 10^{-15}$ cm^2. Zhang et al. proposed a similar rate of $k_{TT} = 2.2 \times 10^{-15}$ cm^{-3} s^{-1} for Alq_3/DCM in OLEDs [10]. In our experiments the decay in the host/guest system is favorably fitted with a triplet lifetime of $\tau_T = 1.55$ ms, which is significantly longer than published for pristine DCM [34,35].

For pristine DCM we observed no triplet induced absorption for a minimal delay time between pump and probe pulse of 100 ns and excitation densities below 1 mJ/cm^2. Also no photoluminescence quenching due to singlet–triplet annihilation was observed in our experiments (details about the used measurement technique have been reported elsewhere [12]). Assuming a triplet absorption cross section of $\sigma_T = 3.4 \times 10^{-17}$ cm^2 (630–670 nm) the triplet density must be lower than 1×10^{16} cm^{-3}, to fall below the detection limit of our technique. A possible cause for these observations is an inefficient generation of triplet excitons by the pump pulse or a very fast triplet decay. Both effects lead to low densities of triplet excitons. For DCM a low quantum yield for triplet generation via ISC has been published ($\Phi \leqslant 3 \times 10^{-3}$) [34,36]. Furthermore, it has been shown that pristine DCM films suffer from strong concentration quenching which obviously influences triplet excitons as well [37].



Fit parameter:

Material	k_{TT}[cm^{3}s^{-1}]	τ_T[ms]
Alq_3	2.2×10^{-12}	0.17
Alq_3/DCM	1×10^{-15}	1.55

Fig. 5. Triplet absorption decay in Alq_3 ($\lambda_{pump} = 405$ nm) and Alq_3 doped with 2 vol.% DCM. Fit parameters are shown in the table.

4. Discussion

Our experimental results have shown a high TTA rate in the pristine materials in the order of 10^{-12} cm^3 s^{-1} at room temperature. In comparison to our results for the pristine F8BT and Alq_3 former publications carried out at low temperatures showed 2–3 orders of magnitude lower TTA rates for pristine fluorescent materials [19,39]. The obvious discrepancy in the TTA rates can be explained by blocked triplet diffusion at extremely low temperatures [26,38].

In contrast to the pristine materials, we observed strongly reduced (by 1–3 orders of magnitude) TTA in both the polymer host/guest system and the small molecule host/guest system. This effect can be explained by assuming a deep trap for the triplet excitons on the guest site. This leads to a strong stabilization of triplet excitons, yielding in low TTA rates similar to TTA rates obtained by low temperature measurements as mentioned above. It has been shown that the diffusion of triplets depends exponentially on the energy difference between the interacting (neighboring) molecules [40–42]. However, Staroske et al. showed that TTA can take place even for low mobility triplet excitons and attributed this to a long range Förster-type energy transfer between the guest molecules [9] yielding in a lower limit for the TTA rate.

Due to the spectral characteristics of the triplet absorption and the efficient energy transfer from the host to the guest molecules we can assume that the majority of triplets are located on the guest. To understand the triplet diffusion in host/guest systems, the triplet energies of the host and the guest as well as the position to each other must be considered. For MEH-PPV a triplet energy of 1.27 eV and a S_1–T_1 splitting of 1.1 eV have been published [22]. Köhler et al. reported on an almost constant S_1–T_1 splitting of 0.7 eV in a large number of conjugated polymers [18]. Assuming a similar S_1–T_1 splitting for F8BT, the triplet excitons on the guest (MEH-PPV) have a significantly lower energy than the triplet states of the host. This energy difference forms a barrier which reduces the triplet diffusion and therefore explains our observation of a strikingly lowered TTA rate. For Alq_3 a triplet energy around 2.1 eV [24,43] and a S_1–T_1 splitting of 0.64 eV [43] was measured. Chang et al. reported on the triplet level of DCM and found a lower T_1 level than S_1 like it is the case in the materials discussed above [44]. As above, the different triplet energies of guest and host form an energy barrier which might hinder the triplet diffusion from the dopant. The non-dispersive triplet diffusion coefficient D_T is proportional to the TTA rate. In case of our polymer–polymer system the reduced TTA rate corresponds to a triplet mobility one order of magnitude lower than of the pristine guest. The extremely low annihilation rate in Alq_3/DCM correlates with a very low diffusion of DCM triplet excitons. As mentioned before we could not study triplets in pristine DCM thin films due to severe concentration quenching of excitons.

In the polymer host/guest system F8BT/MEHPPV we observed a much weaker stabilization of the triplets (corresponding to a weaker decrease of the TTA rate) than in the small molecule host/guest system Alq_3/DCM. In case of the polymer system efficient triplet transfer along the polymer chain can take place [41,42], which is not frustrated by the blending into the host.

5. Conclusion

In summary we measured the triplet decay in the fluorescent host/guest systems F8BT/MEH-PPV and Alq_3/DCM. The measurements were performed using a highly sensitive pump and probe experiment in a waveguide structure. This technique allows studying triplets in amorphous thin films of fluorescent organic materials at room temperature; under conditions relevant for organic devices. For the pristine materials the following TTA rates were calculated: F8BT: $k_{TT} = 8.8 \times 10^{-12}$ cm^3 s^{-1}, MEH-PPV: $k_{TT} = 5.4 \times 10^{-12}$ cm^3 s^{-1} and Alq_3: $k_{TT} = 2.2 \times 10^{-12}$ cm^3 s^{-1}. On the contrary, the host/guest systems showed a triplet lifetime orders of magnitude larger. Based on our model, we attribute this phenomenon to a strongly reduced TTA rate. We determined TTA rates for F8BT/MEH-PPV of $k_{TT} = 6.2 \times 10^{-13}$ cm^3 s^{-1} and for Alq_3/DCM of $k_{TT} = 1 \times 10^{-15}$ cm^3 s^{-1}, respectively. We believe that our findings for these model systems are of a general character and will be of substantial importance for the understanding, the design and optimization of fluorescent organic opto-electronic devices.

Bis-oxadiozole polymer

ABSTRACT

High-efficiency organic light-emitting devices (OLEDs) were fabricated in which solution-processed ambipolar blends of hole- and electron-transport polymer hosts doped with a green-emitting iridium complex are sandwiched between a photocrosslinked hole-transporting layer and a vacuum-deposited electron-transporting layer. The ambipolar host blends consist of blends of bis-oxadiazole-functionalized poly(norbornene) electron-transport materials and poly(*N*-vinylcarbazole). For the best device examined, an external quantum efficiency of 13.6% and a maximum luminous efficiency of 44.6 cd/A at 1000 cd/m^2 with a turn-on voltage of 5.9 V were obtained.

Considerable research has been directed toward the synthesis of organic light-emitting diodes (OLEDs) with respect to their illumination applications and potential to be used to cover surfaces, or to be placed on objects of various shapes [1–5]. Current OLEDs have achieved significant luminous efficiencies at brightness levels that are compatible with portable flat-panel display technologies [6–8]. In particular, efficient OLEDs based on phosphorescent emitters have been demonstrated by either co-evaporation of guest and host molecules from the vapor phase [2,3], or by doping a semiconducting polymer with transport molecules and phosphor emitters [1]. However, a concern with these guest/host approaches is the stability of the resulting material. Another approach of interest is the blending of semiconducting polymers together, where one possesses good hole-transport properties and another possesses good electron-transport properties and provide for a blended ambipolar host for the emissive layer. The polymer blend may be a more challenging approach than the doping of a polymer with small molecules because it can result in materials phenomena, such as vertical phase segregation [9,10], that can decrease device efficiency and lifetime. While blends of conjugated polymers in OLEDs have been widely studied [11] with external quantum efficiencies as high as 6% [12], reports on blends of side-chain polymers are scarce [13] with external quantum efficiencies below 0.1%.

The literature on oxadiazole-type small molecules used for OLEDs demonstrates their use for improvement of electron transporting properties in polymer OLEDs based on polyfluorenes [14–16]. They have also been shown to have effective electron injection and transport functionality [17,18], in addition to hole-blocking properties [19], and their use as hosts for phosphorescent polymeric OLEDs has also been explored [20]. We have therefore, synthesized poly(norbornene)s functionalized with bis-oxadiazole side chain groups for electron-transport application. In order to balance hole and electron transport in the host based on bis-oxadiazole polymers, an additional material with hole transport properties is desirable. This can be achieved by adding a molecular compound or a hole transporting polymer.

Here, we report on some surprising results on green phosphorescent devices based on an emitting layer that is formed by blending an electron transporting polymer and hole transporting polymer together and by doping the blend with the phosphor $Ir(ppy)_3$ [21,22] or $Ir(pppy)_3$ [23]. In this work, the polymer blends are comprised of PVK and one of two bis-oxadiazole polymers. PVK was used as a hole transporting functional moiety and bis-oxadiazole side chain polymers based on a poly(norbornene) backbone were used as a electron-transport component.

Fig. 1 shows the molecular structures of the materials used for this study. The photo-crosslinkable hole-transporting polymer (P-TPD-F) was obtained from corresponding methacrylate monomers via radical initiation polymerization and insolubilized by photocrosslinking as previously described [24]. The poly(norbornene)-based electron-transport polymers with bis-oxadiazole side chains were synthesized by ROMP polymerization using Grubbs ruthenium initiators [25]. These polymers are soluble in common organic solvents and form uniform films when cast from solution. Fig. 2 shows an energy level diagram based on the estimated solid-state ionization energy (IE) and electron affinity (EA) of each of the compounds used [26]; the values for both the PVK and both oxadiazole polymers (OP**1** and OP**2**) relative to those of $Ir(ppy)_3$ should allow for efficient hole and electron trapping on the green phosphorescent dopant.

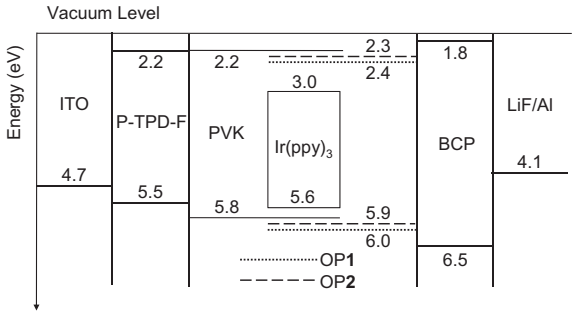

Fig. 2. Energy level diagram showing the estimated IE and EA levels for materials investigated in this work [26].

All of the devices were fabricated on glass substrates coated with indium tin oxide (ITO). The substrates were first cleaned in sequential ultrasonic baths of detergent, deionized water, acetone, and isopropanol. A section of the ITO with a sheet resistance of 20 Ω/□ (Colorado Concept Coatings, L.L.C.) was covered with SiO_x to define the anode and substrates were treated by oxygen-plasma (Plasma-preen II-862, Plasmatic Systems) for 3 min. The holes transport material P-TPD-F was spin-coated from toluene onto the oxygen plasma treated ITO-coated glass substrates and yielded 35 nm-thick films. These films were crosslinked using a standard broad-band UV light with a

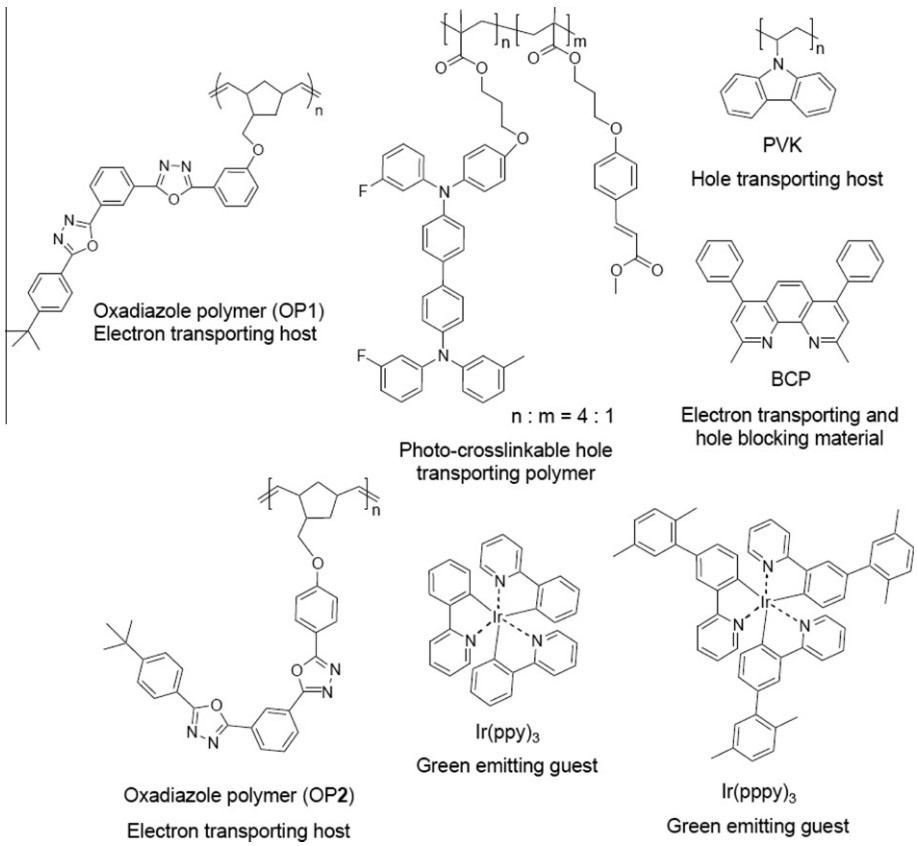

Fig. 1. Chemical structures of the employed materials.

0.7 mW cm^{-2} power density for 1 min. Subsequently, 1% concentration solutions were prepared by dissolving 10 mg of oxadiazole polymer – either OP**1** (device **A**) or OP**2** (devices **B** and **C**), 8.8 mg of PVK, and 1.2 mg of Ir(ppy)$_3$ (devices **A**, **B**) or Ir(pppy)$_3$ (device **C**) in 2 ml of chlorobenzene. All solutions were prepared under inert atmosphere and were stirred overnight. For the hole-blocking and electron-transport layer, a 40 nm-thick 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) was vacuum deposited. Finally, 2.5 nm of lithium fluoride as an electron-injection layer and a 200 nm-thick aluminum cathode were vacuum deposited at a pressure below 1×10^{-6} Torr and at rates of 0.1 Å/s and 2 Å/s, respectively. A shadow mask was used for the evaporation of the metal to form five devices with an area of 0.1 cm^2 per substrate. Luminance–current density–voltage (*L*–*J*–*V*) characteristics of the devices were measured using a Keithley 2400 source meter for current voltage measurements. The devices were tested inside a nitrogen-filled glovebox with O_2 and H_2O levels <20 and <1 ppm, respectively.

Fig. 3 shows the current density (*J*–*V*) and luminance–voltage (*L*–*V*) characteristics of devices **A** and **B**, which differ in the oxadiazole polymer used. Both devices possess a rather high luminance of ca. 7550 cd/m^2 and ca. 7340 cd/m^2 (Fig. 2b, d), respectively.

Device **A** compared to device **B** exhibits lower leakage current as illustrated by the lower current density (<10^{-5} A/cm^2) observed at low voltage (<3 V) before the diode turns on. This lower leakage current directly affects the external quantum efficiency of the devices, especially at applied voltages below 10 V. The leakage current is generally associated with the quality of the films that are formed during device fabrication. The better quality of devices fabricated with OP**1** is tentatively attributed to a better wetting of the photo-crosslinked hole-transport layer by the polymer blend layer. The turn-on voltage (defined as the voltage required to obtain a brightness of 10 cd/m^2) of device **B** (6.1 V) is slightly lower than that of device **A** (6.8 V). At a luminance of 1000 cd/m^2, device **A** shows a maximum external quantum efficiency (EQE) of 9.6% and a current efficiency of 31.6 cd/A, while device **B** shows efficiencies of 10.1% and 32.7 cd/A, respectively.

Devices with emissive layers based on a composite blend of bis-oxadiazole polymer (OP**2**) and PVK with another iridium(III) complex, the more soluble Ir(pppy)$_3$ [23] with the same device geometry were also demonstrated (device **C**). The devices exhibit high current density and an EQE of 13.6% at a luminance of 1000 cd/m^2 and efficiencies of 44.6 cd/A, as shown in Fig. 3. Furthermore, the turn-on voltage of 5.9 V is significantly lower than those of other polymeric electrophosphorescent OLEDs [27]. Electroluminescence spectra of OLEDs based on blended ambipolar host are shown in inset of Fig. 4. The spectra show maxima at 516 and 540 nm, which correspond to the triplet emission of Ir(pppy)$_3$ [23]. The higher EQE observed for device **C** vs. device **B** may be due to decreased aggregation and self-quenching of the more soluble and bulkier phosphors in the former device.

In summary, we have demonstrated efficient green phosphorescent devices based on an emitter layer that is formed by blending two polymers together and by doping the blends with the phosphors Ir(ppy)$_3$ and Ir(pppy)$_3$. The

polymer blends are comprised of two side-chain polymers, namely PVK and a poly(norbornene) with a bis-oxadiazole electron-transporting side chain. Devices show highly efficient light output and low turn-on voltage. Our work suggests that highly efficient solution processed phosphorescence OLEDs can be achieved by finding a combination of polymers with hole and electron transport properties and by doping the blend with a phosphorescent emitter. With an external quantum efficiency of 13.6% and a maximum luminous efficiency of 44.6 cd/A at 1000 cd/m^2 these devices exhibit a performance level that exceeds by several orders of magnitude the performance of previously reported OLEDs based on mixtures of side-chain polymers with a non-conjugated polymer backbone [13]. To the best of our knowledge, the efficiency of these devices (13.4%) also exceeds that of the best OLEDs based on mixtures of fluorescent conjugated polymers (6%) [12] and that of OLEDs based on a mixture of PVK with a fluorene-type conjugated polymer and a phosphorescent emitter (8.4%) [28] .

ABSTRACT

Water soluble poly(1-vinyl-1,2,4-triazole) (PVT) as a novel dielectric layer for organic field effect transistor is studied. Dielectric spectroscopy characterization reveals it has low leakage current and rather high breakdown voltage. Both n-channel and p-channel organic field effect transistors are fabricated using pentacene and fullerene as active layers. Both devices show device performances with lack of hysteresis, very low threshold voltages and high on/off ratios. Excellent film formation property is utilized to make AlO_x and thin PVT bilayer in order to decrease the operating voltage of the devices. All solution processed ambipolar device is fabricated with simple spin coating steps using poly(2-methoxy-5-(2-ethyl-hexyloxy)-1,4-phenylenevinylene) (MEH–PPV) end capped with polyhedral oligomeric silsesquioxanes (POSS) as active layer. Our investigations show that PVT can be a very promising dielectric for organic field effect transistors.

1. Introduction

Organic optoelectronic devices fabricated using organic, polymeric materials possess huge application potential in consumable electronics due to their easy processability and low cost. Moreover, realizing future all plastic electronics relies on the development of efficient organic electronic components. Organic field effect transistors (OFETs) are being extensively studied as basic constituents of such devices [1]. In OFETs, the dielectric insulating layer greatly affects device characteristics. Low hysteresis of the transfer characteristics (source-drain current I_{DS} versus the gate voltage V_{GS}) and a trap free dielectric/semiconductor interface are required for stable working OFETs with comparable performance as those of inorganic ones such as amorphous silicon. One of the major problems in OFETs is their high voltage operation because organic semiconductors, as active layers, generally have relatively low charge carrier mobilities. However, dielectric layer can be optimized to achieve lower operation voltage. One of the approaches is using high dielectric constant metal oxides to obtain high capacitance [2]. Passivation of the metal oxide surface is necessary in order to decrease intrinsic traps at the oxide/semiconductor interface. This can be done by self-assembled monolayers (SAMs) onto the oxide surface [3]. Another approach is to cast an organic insulator thin film on top of the gate. To obtain similar capacitance as of the oxide layer, this passivation layer has to be fairly thin (in submicrometer regime). Therefore, good film formation property is prerequisite for such bi-layer dielectric structures. Most of the polymeric semiconductors are soluble in nonpolar organic solvents. In solution processed devices, to avoid the dissolution of the underlayer, we need organic dielectrics which are well soluble in polar solvents, such as water, with bad solubility in the nonpolar organic solvents.

Poly(vinyl alcohol) (PVA) is one of the most extensively studied water soluble polymers with high dielectric constant and excellent film formation properties [4–8]. Hysteresis had been an issue quite for a while in PVA based OFETs [5,7,8]. Although non-volatile hysteresis behaviour can be implemented for memory elements [5], OFETs should have hysteresis free characteristic in logic circuit applications. Hysteresis mechanism has been investigated in detail and charge trapping as well as mobile ions are ascribed to be the factors [7,8]. Dialysis process can minimize the hysteresis effects in PVA based OFETs and result in good device characteristics for n-channel OFET devices [8]. However, intrinsic OH groups in PVA induce potential electron traps at the dielectric semiconductor interface hindering n-channel electron mobility and ambipolar behaviour of the devices [9]. Therefore, new water soluble polymeric dielectrics need to be explored.

Poly(1-vinyl-1,2,4-triazole) (PVT) was reported to be a non-toxic, biocompatible, thermally stable and easily soluble in water or polar organic solvents [10,11]. Monomers of PVT were first obtained by vinylation of 1,2,4-triazole with acetylene [12]. Later, radical polymerization was realized [13]. Since then, PVT or copolymers have found a wide range of applications in medicine and agriculture such as preparation of soft contact lenses, biosynthetic activation of connective tissue cells, clarification or stabilization of juices and wines [14–16]. Application for nanotechnology was proposed by incorporation of nanoparticles in the polymer matrix [17,18]. PVT based salts are shown to be reliable binders in propellant and explosives as energetic polymers [19]. Recently, acid doped PVTs were studied as promising proton conducting polymer electrolytes in proton exchange membrane fuel cells [20,21].

In his work we investigated the dielectric property of PVT for OFETs. Dielectric spectroscopy measurements show low leakage current and very high breakdown voltage (around 4 MV cm^{-1}). Excellent film formation and smooth surfaces of the PVT films are observed by using atomic force microscopy. We used pentacene as p-channel and C_{60} as n-channel semiconductor layers. Both types of devices based on PVT revealed hysteresis free transfer characteristics with relatively high on/off ratios (>1000) and low threshold voltages. Solution processed ambipolar OFET device was realized using simple spin coating steps. All these technical properties suggest PVT as an excellent polymer dielectric for OFETs.

2. Experimental

2.1. Materials

Vinyl-triazole monomer was bought from Sigma–Aldrich and polymerized using Free radical polymerization technique. Azobisisobutyronitrile was used as radical initiator, benzene as solvent and CCl_4 as chain transfer agent. Pentacene (normal grade, carbon $\geqslant$93.5%) and C_{60} (sublimation grade, 99.9%) were purchased from Sigma–Aldrich and MER corporation, respectively. They were used as received. MEH–PPV–POSS was purchased from American Dye Source Inc. It was purified by repeated precipitation. Device preparation: PVT was dissolved in high resistant ultra-pure water in a weight ratio of 7%. The solution was filtered and spin-coated on glass substrate with evaporated Al gate contact. The films were dried in vacuum oven overnight at a temperature of 50 °C. For AlO_x/PVT bi-layer dielectric, Al gate contacts were partially anodized as described in references [24,25]. In ultra-pure water and citric acid solution (0.01 M), constant current density of 6 mA cm^{-2} was applied between Al contact and stainless steel counter electrode. Final anodization voltage was set to 50 V with anodization ratio around 1.3 nm V^{-1}, which

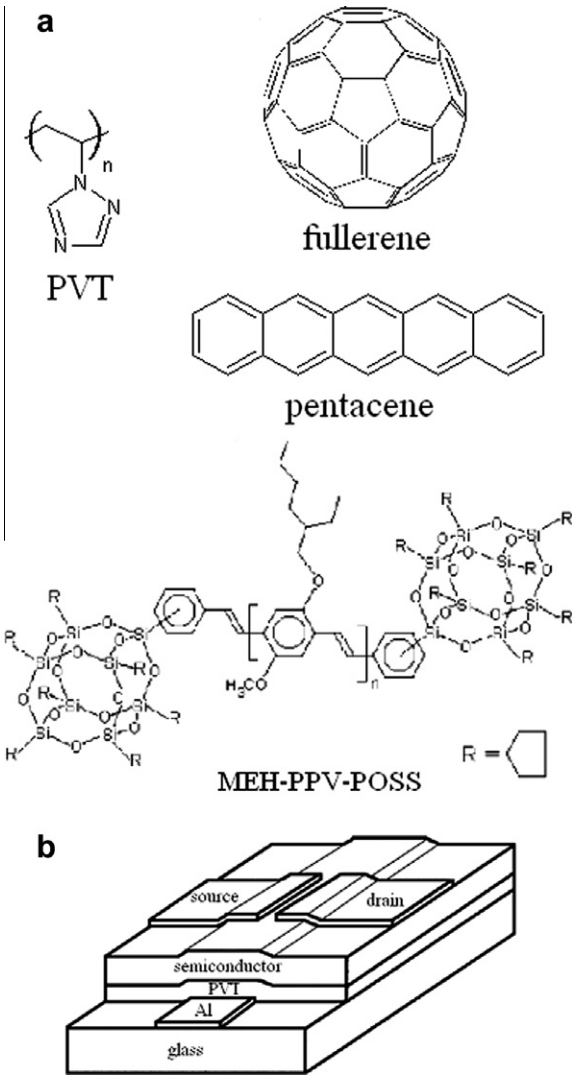

Fig. 1. (a) Molecular structure of poly(1-vinyl-1,2,4-triazole) (PVT), fullerene (C_{60}), pentacene and MEH–PPV–POSS; (b) Device structure of the bottom gate, top contact OFETs structure used. Al gate contact was partially anodized to make AlO_x layer for low voltage operation devices. Pentacene as p-channel semi-conducting layer has Au source/drain contacts, whereas C_{60} as n-channel semi-conducting layer has LiF/Al source/drain contacts. Channel length is 0.06 mm, and channel width is 2 mm. For ambipolar OFET with MEH–PPV–POSS as active layer, Ca/Au asymmetric contacts were angle evaporated. Channel length is 0.05 mm and channel width is 3 mm.

gives around 65 nm thickness of AlO_x layers. They were dried in vacuum oven at 120 °C overnight. On top of it, low concentration PVT solution (1.5% weight ratio) was spin-coated (1500 rpm for 40 s). The films were dried in vacuum oven overnight at a temperature of 50 °C. For dielectric characterization, Al contact was evaporated through shadow mask to make MIM structure. Electrode contact area is 4.84 mm^2. Two different thickness films were spin coated using 2000 rpm and 3000 rpm for 30 s, and thicknesses were measured using AFM. For OFETs, 7% weight ratio PVT solution was spin coated (1500 rpm for 40 s and 2000 rpm for 20 s) on glass substrate with evaporated Al gate contact. Pentance (100 nm) and C_{60} (100 nm) films were thermally evaporated in UNIVEX system. Substrate was kept at room temperature. Evaporation rate is around 0.5 nm s^{-1}. Au (100 nm) for pentance films and LiF(0.6 nm)/Al(100 nm) for C_{60} films as sources/drain contacts were evaporated thermally through shadow mask to complete the bottom gate, top contact OFET devices. Channel length is 0.06 mm and channel width is 2.0 mm. MEH–PPV–POSS was dissolved in Cholorobenzene (15 mg/ml) and spin coated (1500 rpm for 40 s and 2000 rpm for 20 s) directly on top of PVT. Ca (50 nm) and Au (50 nm) asymmetric contacts were angle evaporated using thick shadow mask. Channel length is 0.05 mm and channel width is 3.0 mm. Characterization: PVT film morphology and thickness are investigated with Atomic Force Microscopy (Digital Instruments Dimension 3100) in tapping mode. Images are analysed using WSxM software [26]. For MIM structures, dielectric spectroscopy was obtained with a Novocontrol Alpha Analyzer. Leakage DC current was measured using Keithley 230 unit. I–V characterizations were performed using Agilent E5273A. All the characterizations were carried out in nitrogen glove box or sealed box with nitrogen gas.

3. Results and discussions

Chemical structure of PVT is given in Fig. 1a). Electron rich nitrogen atoms in triazole ring can form hydrogen bonds with water molecules, which is an exothermic dissolution process.

Spin coating of PVT films results in very homogeneous film. AFM images of the films with 720 nm and 960 nm thicknesses are shown in Fig. 2a and b. Both give very low root-mean-square roughness of about 0.2 nm. We have made metal–insulator–metal (MIM) structure of PVT films sandwiched between evaporated Al electrodes for dielectric characterization, results of which are shown in Fig. 3. The contact area is 4.84 mm^2, and film thicknesses are 720 nm and 960 nm as measured by AFM. Frequency dependence of the capacitance is given in Fig. 3a. From

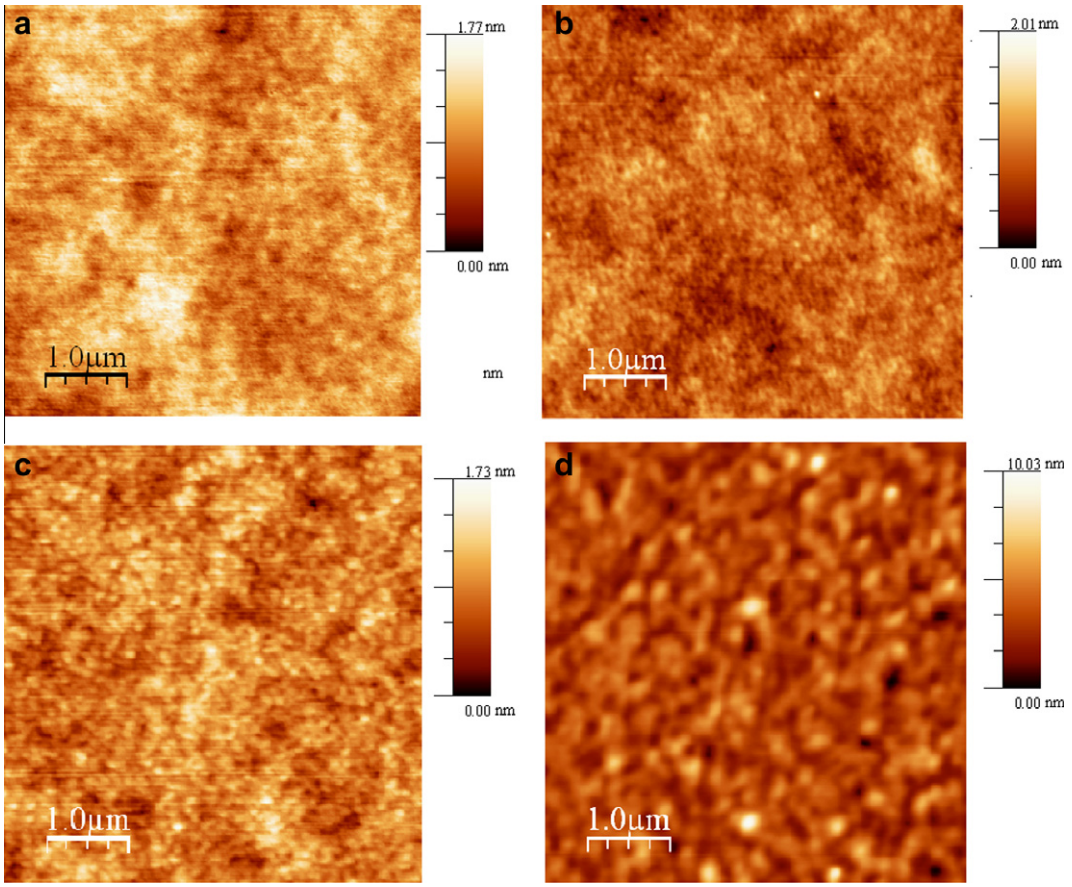

Fig. 2. AFM images of spin coated PVT films on Al gate with glass substrate: (a) 720 nm; (b) 960 nm; (c) 90 nm; (d) 90 nm film on anodized AlO_x surface.

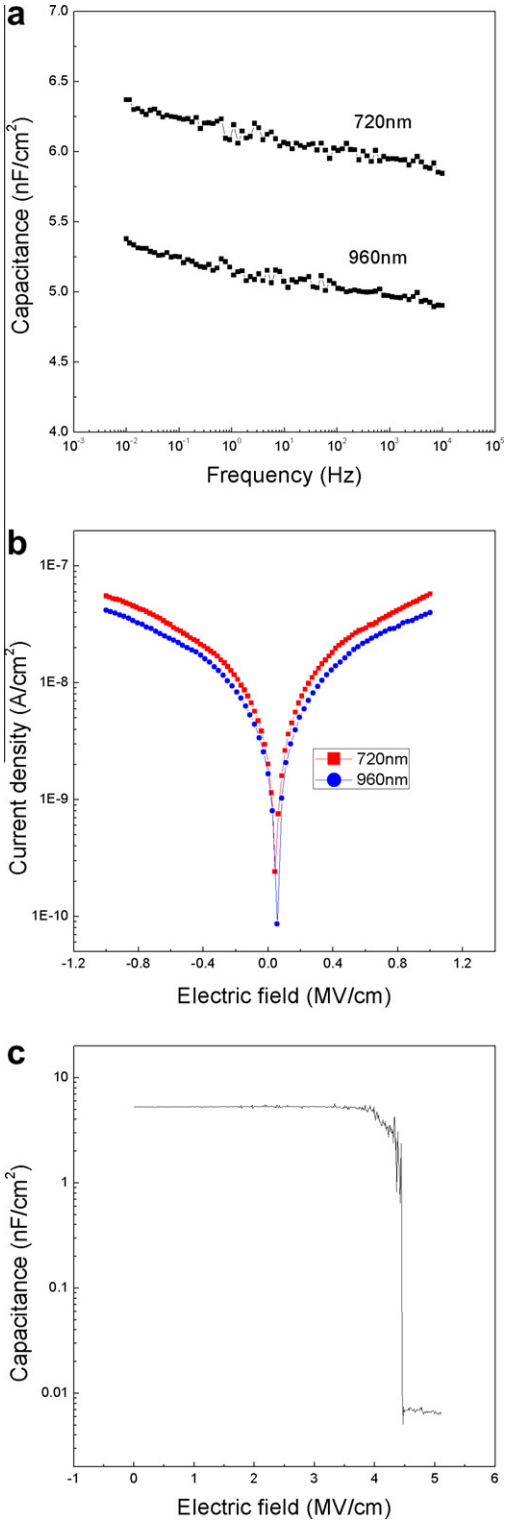

Fig. 3. Dielectric characterization of PVT films (720 nm and 960 nm) as in Al/PVT/Al structure: (a) frequency dependence of the capacitance; (b) leakage current versus applied DC voltage; (c) capacitance versus applied electric field at 10 Hz for the sample with the thickness of 720 nm.

0.01 Hz to 10 kHz, the capacitances of the films show dispersionless behaviour with rather low variance. Capacitance values at 10 Hz is used to determine the dielectric constant k, as given by $C_i = \varepsilon_0 k/d$, where C_i represents capacitance per unit area and d is the thickness of the dielectric layer. Linear fitting of the capacitance values versus different thicknesses yields dielectric constant of 5.1. Low leakage current is necessary to achieve high on/off ratio from an OFET. Leakage current versus applied electric field is shown in Fig. 3b. DC voltage is applied within ±110 V. At an electric field of 1 MV cm^{-1}, we have observed a leakage current density of around 5×10^{-8} A cm^{-2}. Dielectric strength of an insulator can be represented by the breakdown electric field, i.e. the sustainable voltage maximum before it loses its insulating character. It's a crucial parameter in achieving high capacitance by decreasing the thickness of the dielectric. Breakdown electric field of PVT is higher than 4 MV cm^{-1} as shown in Fig. 3c for the 720 nm thick sample, where capacitance were measured by ramping up the applied voltage at a frequency of 10 Hz.

Fig. 4a shows typical transfer characteristics of PVT in a p-channel device with pentacene as active layer. Gate leakage current is about −0.2 nA at −15 V. No hysteresis is observed with forward and reverse gate voltage sweep for the transfer curve. In the gradual channel approximation, drain current dependence on the gate voltage can be given by the following equation in saturation regime (given mobility is independent of the gate voltage):

$$I_{DS} = (W/2L)\mu_{sat}C_i(V_{GS} - V_{th})^2$$

where I_{DS} is the drain current; μ_{sat} is the mobility; V_{GS} is the gate voltage; V_{th} is the threshold voltage; W is the channel width and L is the channel length. The square root of drain current versus gate voltage of the saturation curve can be linearly extended to the "off" current to determine the threshold voltage. Rather low threshold voltage of −2.2 V is obtained. Considering the flat band potential of Al gate and pentacene work function, and also quite low dielectric capacitance of around 5 nF cm^{-2}, this value implies very low trap density. We have estimated the total trap density of 2.3×10^{10} cm^{-2} using $N_{trap} = C_i|V_{th} - V_{to}|/e$, where C_i is the capacitance per unit area; V_{th} is threshold voltage as determined above; V_{to} is the turn-on voltage which refers to applied gate voltage at the onset of the drain current [22]. Sub-threshold swing of 1.75 V dec^{-1} is derived. It reflects "turning on" speed of the device and correlates to the interface trap capacitance C_{it} through the equation [2]: $S = (K_B T/e)\ln(10)(1 + C_{it}/C_i)$. On/off ratio is higher than 10^3. The device sustained −200 V gate voltage without breakdown and further scaled up on/off ratio. Good linear and saturation behaviour is observable from the output curves (Fig. 4b). Mobility can be estimated from the linear regime where the charge carriers are uniformly distributed as given in the equation below:

$$I_{DS} = W/L\mu_{lin}C_i(V_{GS} - V_{th})V_{DS}$$

where V_{DS} is the drain voltage. Calculated hole mobility is 0.002 cm^2 V^{-1} s^{-1}. Dielectrics are more critical for the performance of n-channel OFETs, as the hydroxyl groups in organic dielectrics tend to trap electrons easily. However, it is essential for the dielectric to perform in an equal manner for both p- and n-channel devices if ambipolar and light

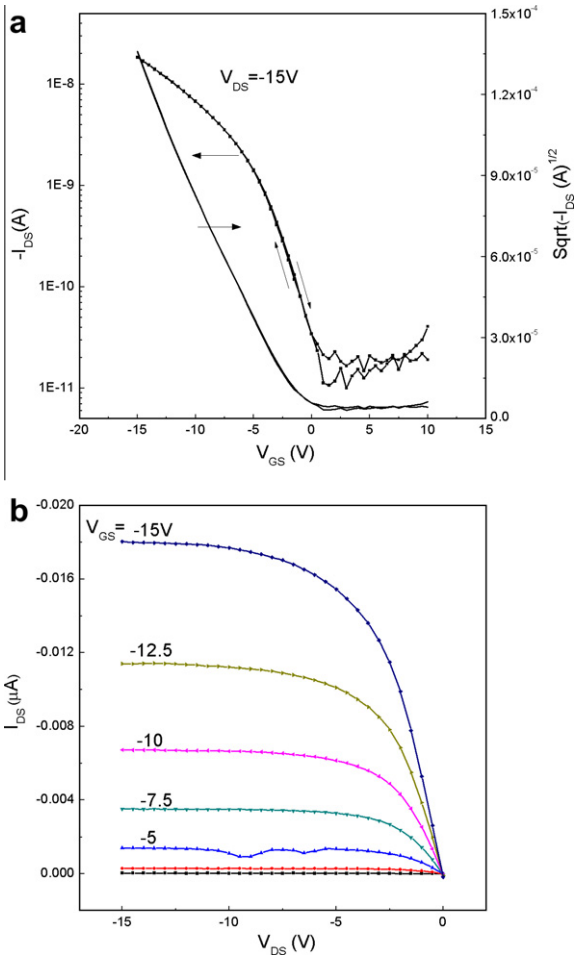

Fig. 4. Transfer (a) and output (b) characteristics of pentacene as p-channel OFET device with PVT dielectric layer. Au source/drain contacts were used with channel length of 0.06 mm and channel width of 2 mm.

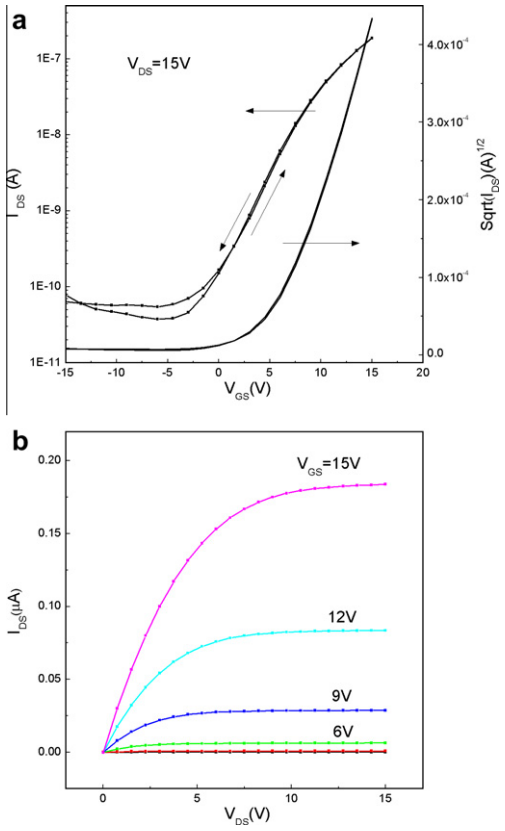

Fig. 5. Transfer (a) and output (b) characteristics of fullerene as n-channel OFET device with PVT dielectric layer. LiF/Al source/drain contacts were used with channel length of 0.06 mm and channel width of 2 mm.

emitting OFETs are pursued for various purposes. We investigated PVT in n-channel OFET, where C_{60} is used as active layer. Fig. 5a shows typical transfer characteristics of such an OFET device. Transfer curve again shows almost hysteresis free behaviour with forward and reverse gate voltage sweep. Slightly higher off currents can be due to the higher conductivity of C_{60} at drain voltage of 15 V as compared to the pentacene device. On/off ratio is higher than 10^3 and further scaling up is possible without breaking the dielectric. Gate leakage current is about 0.9 nA at 15 V. Derived threshold voltage is around 5.5 V. Comparing to p-channel OFET, this value suggests total trap states for electrons are slightly higher. Estimated total trap density from the difference between threshold voltage and turn-on voltage is about 6.6×10^{10} cm^{-2}. Compared to the C_{60} n-channel OFET based on dialysis grade PVA [8], using PVT as dielectric gives superior parameters. Sub-threshold swing is about 3.2 V dec^{-1}. Again, clear linear and saturation behaviour is observable from the output curves (Fig. 5b). Estimated electron mobility from the linear regime is 0.02 cm^2 V^{-1} s^{-1}.

Low voltage operation of OFETs is required for their practical application. Increasing capacitance of the dielectric layer is a direct approach. By decreasing the thickness of the film, one can obtain higher capacitance, thus lower operating voltage. Main problems can be that polymer dielectrics may not form homogenous films when solution concentration is lowered; leakage current may be comparable to the drain current or it can be easily breakdown. Cross linking of the thin polymer dielectrics is a viable approach. However, it will introduce additional processing step and impurities left from the cross linking agents might affect the performance of the devices. AFM study evidenced very good film formation property of PVT. When thinner films are prepared with low solution concentration, PVT still forms homogeneous films without defects or pinholes (see Fig. 2c). We attempted to fabricate n-channel OFET devices with dielectric thickness as low as 90 nm (capacitance around 50 nF cm^{-2}). Among more than 16 devices, almost all the devices worked below 1 V, with two orders of magnitude on/off ratio and well defined linear-saturation behaviours. Despite such a high yield, when gate voltage is applied more than 1 V to achieve comparable on/off ratios, leakage current becomes higher than those of the devices with thick PVT layer. In order to realize similar performance as of the thick PVT films, we fabri-

cated anodized AlO_x/PVT bi-layer dielectric to control the leakage current. Sixty-five nanometer AlO_x with capacitance around 120 nF cm^{-2} and 90 nm PVT with capacitance of 50 nF cm^{-2} yields a total capacitance of 35 nF cm^{-2}. Roughness of the film increased slightly due to the anodized AlO_x layer (see Fig. 2d) with root-mean-square roughness of about 1 nm. Fig. 6a shows the transfer characteristic of pentacene p-channel OFET based on such a bi-layer dielectric. At applied voltage of −3 V, the device performed in similar fashion as the thick PVT film based device. Gate leakage current is −0.4 nA at gate voltage of −3 V. Threshold voltage is about −1.5 V. Sub-threshold swing of 360 mV dec^{-1} is comparable to state of art low voltage operation OFET devices and direct result of low interface trap states. Linear and saturation trends in the output curves are evident (Fig. 6b). More impressive performance is attained in the C_{60} n-channel devices. Fig. 7a shows typical transfer curve. At applied voltage of 2 V, the device performed in a similar way as the thick PVT film based device with comparable on/off drain current ratio. Gate leakage current is 0.6 nA at gate voltage of 2 V. Threshold voltage is about 0.6 V and sub-threshold swing shows a very low value of 230 mV dec^{-1}. Output curves are shown in Fig. 7b.

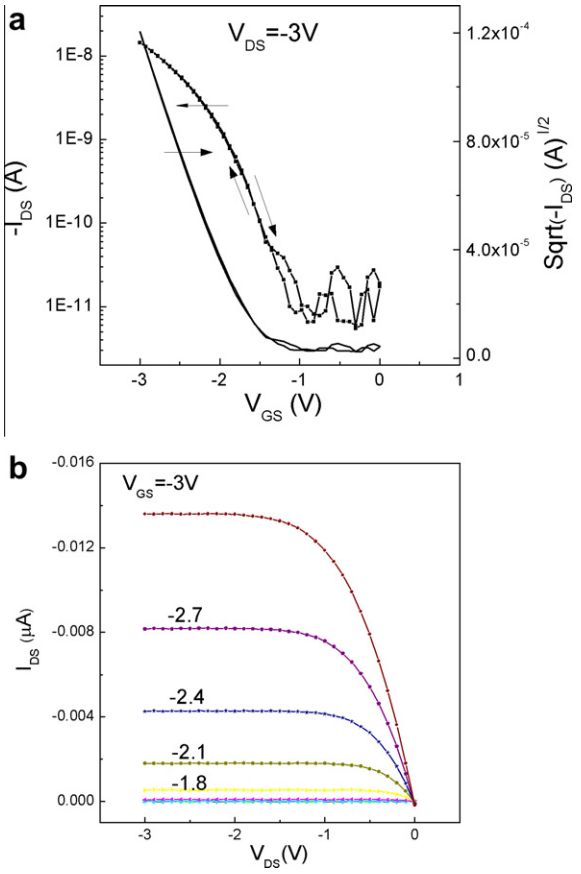

Fig. 6. Transfer (a) and output (b) characteristics of pentacene as p-channel OFET device with AlO_x (65 nm) and PVT (90 nm) dielectric bi-layer. Au source/drain contacts were used with channel length of 0.06 mm and channel width of 2 mm.

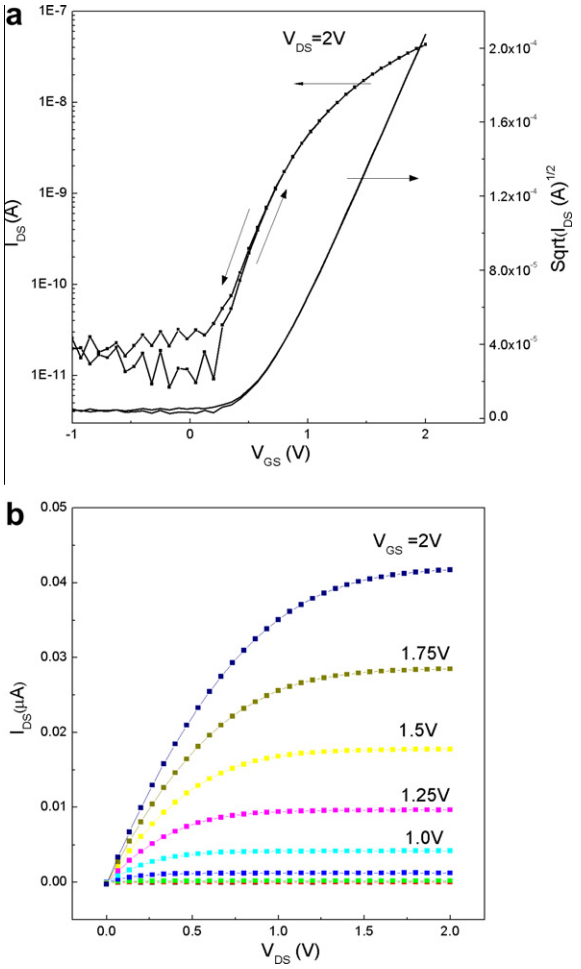

Fig. 7. Transfer (a) and output (b) characteristics of fullerene as n-channel OFET device with AlO_x (65 nm) and PVT (90 nm) dielectric bi-layer. LiF/Al source/drain contacts were used with channel length of 0.06 mm and channel width of 2 mm.

For all solution processed device, PVT, as a water soluble polymer dielectric, is suitable for most of the organic semiconductors. Here we used poly(2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene) (MEH–PPV) end capped with polyhedral oligomeric silsesquioxanes (POSS) as the active layer. Although its lower charge carrier mobility has not been appreciated for organic transistors, comparatively high photoluminescence efficiency is very promising for efficient light emission from organic transistor device. POSS renders relatively high air stability for the polymer without changing its absorption and photoluminescence [23]. MEH–PPV–POSS was directly spin coated on top of the PVT dielectric. Ca and Au source/drain electrodes were angle evaporated for efficient electron and hole injection. Typical transfer characteristics of such an ambipolar OFET device are shown in Fig. 8a. Both electron and hole enhancement is observed. This can also be confirmed by the output curves as displayed in Fig. 8b, where pronounced increase of drain current can be observed at low or reverse gate bias, a typical ambipolar current behaviour.

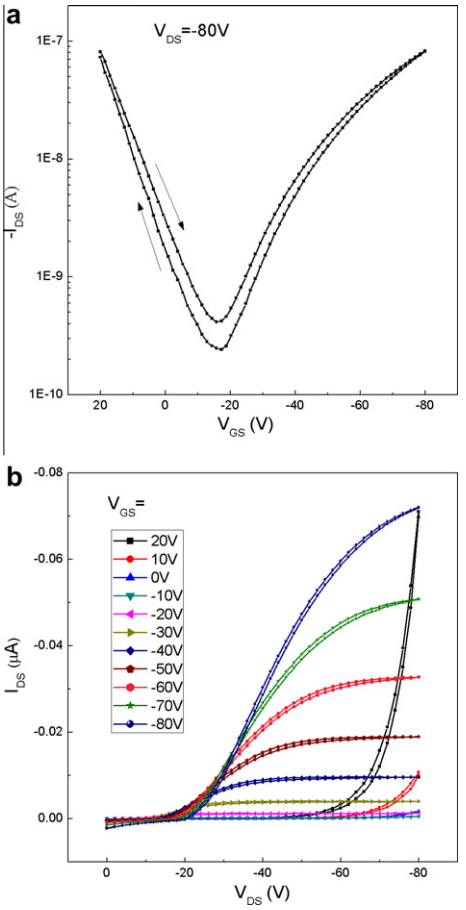

Fig. 8. Transfer (a) and output (b) characteristics of ambipolar OFET device with MEH–PPV–POSS active layer and PVT dielectric layer. Ca/Au asymmetric source/drain contacts were angle evaporated. Channel length is 0.05 mm and channel width is 3 mm.

4. Conclusions

In summery, we have investigated the dielectric property of PVT and its application for OFETs. PVT films showed considerably high breakdown voltage and low leakage current. Both n-channel and p-channel OFET devices are fabricated. Excellent performances are observed in both devices, with hysteresis free and very low threshold voltages. Owing to its good film formation property, using anodized AlO_x/PVT bi-layer dielectrics, both p-channel and n-channel OFET devices operated in low voltages with low threshold voltage and sub-threshold swing. Solution processed ambipolar device is fabricated with simple spin coating steps. Typical ambipolar characteristics were observed. Our results show that PVT can be a very promising polymer dielectric for OFET devices, especially for ambipolar and light emitting OFETs. Moreover, its solubility in water allows for a wide range of solution processed polymer based OFET devices directly fabricating layer by layer. Biocompatibility of PVT is another advantage of its application for bio-electronic devices.

Solution process

ABSTRACT

In the application of polymer light emitting diodes (PLEDs), to prevent etching of ITO by the acidic poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), the pH-neutral PEDOT:PSS was introduced as the hole injection layer (HIL). For the double layer PEDOT:PSS HIL, the pH-neutral PEDOT:PSS on top of ITO stops the indium migration into the polymer, while the regular acidic PEDOT:PSS beneath the light emitting layer keeps the efficient hole injection. The performance of the double layer HIL PLEDs is comparable to or even better than that of the single layer HIL light emitting device. To use pH-neutral PEDOT:PSS as a single layer HIL, the neutral PEDOT:PSS layer was treated by UV and oxygen plasma. Such treatments reduced the hole injection barrier between the HIL and the light emission layer to improve the hole injection, leading to a device performance better than that of the regular acidic PEDOT:PSS HIL device.

1. Introduction

Polymer light emitting diodes (PLEDs) generally have a bi-layer device structure, consisting of a hole injection layer (HIL) on top of an ITO coated glass substrate, and an electroluminescent (EL) layer between the HIL and low work function cathode [1–4]. The HIL helps the holes injected from the anode into the EL layer to radiatively recombine with the injected electrons from the cathode. So far, the most successful HIL material for the PLED devices is poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS). With PEDOT:PSS as HIL, the PLED devices show dramatically increased performances in terms of efficiency, brightness, lifetime, etc. [5,6] H.C. Starck GmbH offers two kinds of commercial PEDOT:PSS: Clevios™ P Al 4083 (4083) for PLED application and Clevios™ P CH 8000 (8000) for passive matrix display application [7]. Both PEDOT:PSS have a pH value between 1 and 3 at 20 °C, which make the interface between ITO and PEDOT:PSS unstable [8–10]. The instability comes from the fact that In_2O_3 has a relatively high solubility in acidic solution [11]. During the coating process, PEDOT:PSS can etch ITO causing indium migration into the PEDOT:PSS layer. The presence of indium in PEDOT:PSS could increase the hole injection barrier for PLED operation [12], and be responsible for device degradation [8]. Moreover, if indium diffused into the EL layer, as a quenching center for exciton, it would significantly reduce the luminous efficiency [13,14].

Recently, to lower the cost of the transparent electrodes in the display industry, zinc oxide based transparent conducting oxide (TCO), such as gallium-doped zinc oxide (GZO) and aluminum-doped zinc oxide (AZO), has progressed steadily in order to replace the expensive indium oxide based TCO, i.e. ITO [15–18]. Since ZnO has a higher solubility in the acid than In_2O_3 [11], it is anticipated that the acidic PEDOT:PSS 4083 and 8000 will etch ZnO based TCO even more. Therefore, finding the right HIL materials becomes necessary for the success of the PLED technology.

Different approaches have been attempted to protect the organic layers from indium contamination, including the insertion of a self-assembly monolayer between ITO anode and HIL to stop indium from penetrating into HIL

[10,19], the mixture of a silane material with PEDOT:PSS to block the indium dissolution in PEDOT:PSS [20,21], and the introduction of an interlayer between PEDOT:PSS and EL layer to prevent indium's diffusion into the EL layer [22,23]. In this contribution, first, we introduced a thin layer of pH-neutralized PEDOT:PSS before the deposition of the acidic PEDOT:PSS to make a double layer HIL for PLED application. The double layer HIL not only stops the etching of indium species due to the pH-neutral layer on top of ITO, but also retains the PLED performance due to the regular PEDOT:PSS beneath the EL layer. Second, we utilized the pH-neutral PEDOT:PSS without any acidic PEDOT:PSS as the single layer HIL. By applying the surface UV and plasma treatment on the pH-neutral PEDOT:PSS HIL, the PLED's performance is improved 10-fold than the device without any HIL treatment due to the reduction of the hole injection barrier. The performance is even better than the device with the regular acidic PEDOT:PSS HIL. As expected, the neutral PEDOT:PSS stops the etching of indium species protecting both the ITO anode and the EL layer. In addition, the utilization of pH-neutral PEDOT:PSS keeps the solution processability of the PLED device, which is regarded as a low cost process compared to the vacuum evaporation process.

2. Experimental

2.1. XPS measurements

The pH-neutralized version of PEDOT:PSS with a pH value of 5–8 at 20 °C is Clevios™ P Jet N (Jet N), developed by H.C. Starck GmbH for the printing of conductive patterns and particularly designed for the use in ink-jet-processes [7]. No application of Jet N in PLED has ever been reported. The three types of PEDOT:PSS, i.e. Jet N, 4083, and 8000, have the same chemical structure as shown in Fig. 1(a).

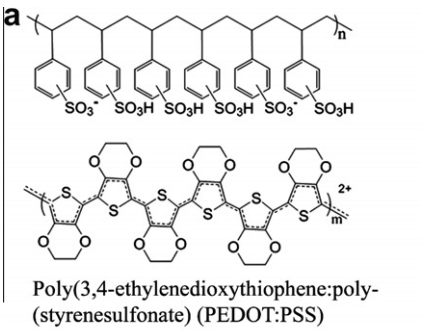

Fig. 1. Chemical structures of: (a) PEDOT:PSS and (b) P-PPV.

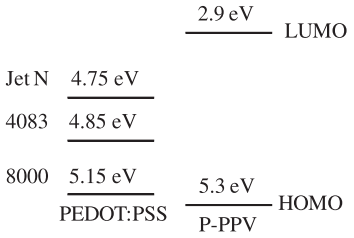

Fig. 2. Schematic illustration of the work function of different kinds of PEDOT:PSS, and the LUMO and HOMO energy levels of P-PPV.

The PEDOT to PSS ratio in those PEDOT:PSS is 1:2.5, 1:6, and 1:20, respectively [7], leading to different work functions of each kind of PEDOT:PSS (schematically illustrated in Fig. 2), i.e. $W_{8000}(5.15\ \text{eV}) > W_{4083}(4.85\ \text{eV}) > W_{\text{Jet N}}(4.75\ \text{eV})$ [24]. To investigate the etching effects of PEDOT:PSS, X-ray photoelectron spectroscopy (XPS) measurements were carried out on PEDOT:PSS coated ITO glass substrate and SiO_2/Si substrate.

Prior to the deposition of PEDOT:PSS, the ITO glass and SiO_2/Si substrates were thoroughly cleaned in sequence in an ultrasonic bath of acetone, isopropyl alcohol, detergent, de-ionized water, isopropyl alcohol, and went through O_2 plasma for 20 min. PEDOT:PSS was spin-cast in air followed by 10 minutes' baking at 200 °C in nitrogen. Five different devices were prepared: single layer Jet N and 4083 on both ITO glass and SiO_2/Si, plus UV and plasma treated Jet N film on ITO glass. The thickness of Jet N film, 4083 film, and UV and plasma treated Jet N film is 20 nm, 40 nm, and 10 nm, respectively, determined by a surface profiler (VEECO-D150). After the completion of the devices, all the devices and a bare ITO glass substrate were loaded into an ultrahigh vacuum chamber for XPS experiment. XPS was performed with a base pressure in the range of 10^{-9} mbar, using Mg Kα radiation (1253.6 eV) with the energy resolution of 0.48 eV. The X-ray survey spectra were acquired in the 0–1110 eV binding energy region at the power of 75 W (15 kV, 5 mA), with a pass energy of 160 eV. Narrow scans of C 1s, O 1s, N 1s, S 2p, Na 1s, In 3d, Sn 3d were obtained at 40 eV pass energy.

2.2. PLED fabrication

To fabricate the PLED devices, green light emitting conjugated polymer poly[2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-p-phenylenevinylene] (P-PPV) (chemical structure in Fig. 1(b), purchased from Canton OLedking Optoelectric Materials Co., Ltd.) was used as the light emission material. Six different HIL structures were made: (A) single layer Jet N; (B) single layer 8000; (C) single layer 4083; (D) double layer Jet N/8000; (E) double layer Jet N/4083; and (F) UV and plasma treated single layer Jet N. The optimal HILs' thickness are, respectively: (A) 10–20 nm; (B) 10–40 nm; (C) 40 nm; (D) 15/40 nm; (E) 15/40 nm; and (F) 5–10 nm. Three single layer HIL devices A, B, and C were prepared following the procedures described early. To make the double layer HIL devices D and E, the second PEDOT:PSS (8000 or 4083) layer was spin-coated on top of the Jet N layer immediately after the baking of Jet N. Directly

afterwards, the double layer HIL was baked at 200 °C for 10 min in nitrogen. For UV and plasma treated single layer Jet N HIL device F, the Jet N film was prepared by the process as same for device A, followed by 5 min exposure under a 120 W UV lamp, and five minutes' oxygen plasma treatment with a power of 80 W at 150 sccm oxygen flow (Shenyang Tiancheng Vacuum Technology Co., Ltd.).

After the completion of HILs, the EL polymer layer was prepared by spin-casting P-PPV solutions in *p*-xylene with the concentration of 8 mg/ml on top of the HIL. The resulted P-PPV layer was about 80 nm thick. The cathode layer consisting of 3 nm barium (Ba) and 200 nm aluminum (Al) was thermally evaporated on top of the organic layers in vacuum at a pressure below 1×10^{-6} Torr. The device performances were characterized in a nitrogen filled glove box by a Keithley 236 source meter and a silicon photodiode calibrated by a Chroma Meter CS-200 (Konica Minolta).

3. Results and discussion

Table 1 summarizes the XPS testing results, and the XPS spectra are shown in Fig. 3. For the bare ITO substrate, the indium atomic concentration reaches 34.7%, which is predictably the highest among all the devices. For PEDOT:PSS on Si/SiO_2 substrate, as expected, there is no In detected, since Si/SiO_2 substrate does not have any indium composition. However, 0.13% In is observed in the device of 4083 on ITO glass, while in the device of Jet N on ITO glass, only 0.02% In is found. The results clearly show that by replacing the acidic PEDOT:PSS with a neutral one, the ITO etching effect is dramatically reduced by a factor of 6.5, which will lead to the long operation stability of PLED. After the UV and oxygen plasma treatment, 0.05% In content is detected in the Jet N on the ITO device. The reason why In content doubles after UV and plasma treatment is not clear at the current stage. Lau's group reported an In concentration of 1.7% in acidic PEDOT:PSS coated ITO glass [10]. The difference is explained by the film preparation method. In Lau's work, the film was dried slowly at room temperature in nitrogen, while in our work, the film was hard baked at high temperature (200 °C) in nitrogen. Using a similar fast-drying method, de Jong's group observed an indium content of 0.02% via Rutherford backscattering spectrometry [9]. The fact that different PEDOT:PSS film preparation methods leading to different In concentrations, verifies that the main ITO etching mechanism is coming from the dissolution of In_2O_3 in an acidic solution. The prolonged PEDOT:PSS drying process in PLED fabrication is detrimental to the PLED performance and stability.

Table 1
Atomic concentration of indium in PEDOT:PSS by XPS analysis.

Type	Atomic concentration (%) by XPS						
	C 1s	O 1s	N 1s	S 2p	Na 1s	In 3d	Sn 3d
ITO glass	10.85	51.71	0.00	0.00	0.00	34.70	2.74
ITO/4083	72.27	17.92	3.47	5.15	1.06	0.13	0.00
ITO/Jet N	71.54	18.99	2.72	4.94	1.79	0.02	0.00
SiO_2/Jet N	65.64	21.67	2.65	8.63	1.41	0.00	0.00
SiO_2/4083	66.44	21.08	2.59	8.44	1.46	0.00	0.00
ITO/UV-plasma-Jet N	62.45	25.84	4.32	5.73	1.60	0.05	0.00

Though it effectively stops the indium diffusion, Jet N does not succeed as a single layer HIL in PLED application. Fig. 4(a) shows the current density (*J*)–bias (*V*)–luminance (*L*) characteristics and (b) shows the luminous efficiency (LE) vs. the current density. Among the three single layer HIL devices A, B, and C, the 8000 device exhibits the best performance, while the single layer Jet N device A exhibits the worst performance with the turn-on voltage of 4 V, the maximum luminance of 14,942 cd/m^2, and the highest LE of 2.24 cd/A. It demonstrates that Jet N is a rather poor HIL material. As shown in Fig. 2, the hole injection barrier between Jet N and P-PPV is substantially larger than that between 8000 and P-PPV, which may be responsible for the difference in the devices' performance.

By applying the regular PEDOT:PSS on top of Jet N, double layer HIL devices D and E greatly improve the device

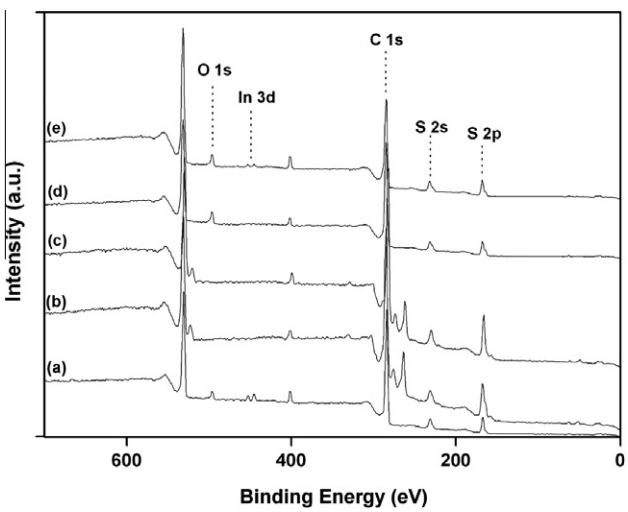

Fig. 3. XPS spectra of (a) ITO/4083, (b) ITO/Jet N, (c) SiO_2/Jet N, (d) SiO_2/4083, and (e) ITO/UV-plasma-Jet N.

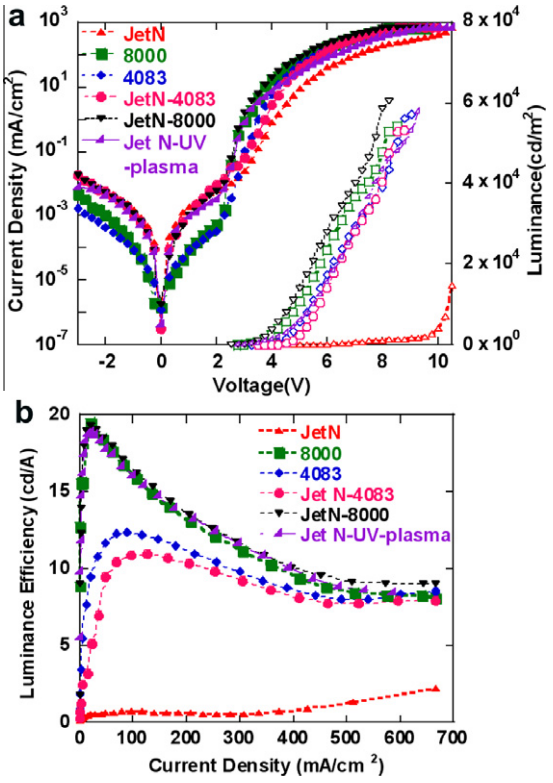

Fig. 4. (a) *J–V–L* characteristics, and (b) EL efficiency vs. current density of PLEDs with different HIL.

performances to the level comparable to or even better than the single acidic PEDOT:PSS HIL devices B and C. For example, the Jet N/8000 double HIL device D displays the highest LE of 19.3 cd/A at a current density of 19.1 mA/cm^2 with a luminance of 3685 cd/m^2. At the same current density, the 8000 single HIL device B has the same LE of 19.3 cd/A with a luminance of 3682 cd/m^2. In addition, the maximum brightness of device D reaches 60,374 cd/m^2, better than that of device B, which is 54,111 cd/m^2. Comparing Jet N/4083 double layer HIL device with 4083 single HIL device, the 4083 device has a maximum LE of 12.4 cd/A and a maximum luminance of 57,337 cd/m^2, while the Jet N/4083 device has a maximum LE of 11.0 cd/A and a maximum luminance of 53,128 cd/m^2. All the devices' performance is summarized in Table 2.

By using the double layer PEDOT:PSS HIL device structure, we successfully deal with the ITO/HIL interface via the pH-neutral PEDOT:PSS, and the HIL/light emitting polymer interface through the acidic PEDOT:PSS. However, adding another layer of HIL complicates the device fabrication process. It is desirable that a single layer HIL could not only prevent the ITO etching, but also retain the PLED performance. As demonstrated earlier, Jet N is a poor HIL material for PLED. Some groups reported that the work function of the acidic PEDOT:PSS could be tuned by UV and/or oxygen plasma treatment [25,26]. To modify the interface between Jet N and the EL layer, we applied the UV and the oxygen plasma treatment to the Jet N layer. After the treatments, the device performance was enhanced to a level even better than the regular PEDOT:PSS device. As shown in Fig. 4 and listed in Table 2, the UV and plasma treated Jet N HIL device F exhibits the highest LE of 18.8 cd/A at a current density of 20.3 mA/cm^2 with a luminance of 4462 cd/m^2. At the same current density, the 8000, 4083, Jet N HIL devices' LE are 19.5 cd/A, 9.5 cd/A, and 0.56 cd/A with a luminance of 3942 cd/m^2, 1932 cd/m^2, and 110 cd/m^2, respectively. In addition, the maximum brightness of the UV and plasma treated device reaches 57,855 cd/m^2, better than those of the 8000, and the 4083 devices, which are, respectively, 54,111 cd/m^2, and 57,335 cd/m^2. Another important feature of the UV and plasma treated device is that it has a turn-on voltage of 2.75 V, even lower than that of the 4083 device, which is 3.25 V.

To further understand the functions of the treated Jet N HIL, hole only device was fabricated with the device structure of ITO/treated Jet N/P-PPV/Au. The *J–V* characteristics are depicted in Fig. 5. It is revealed that with the UV and

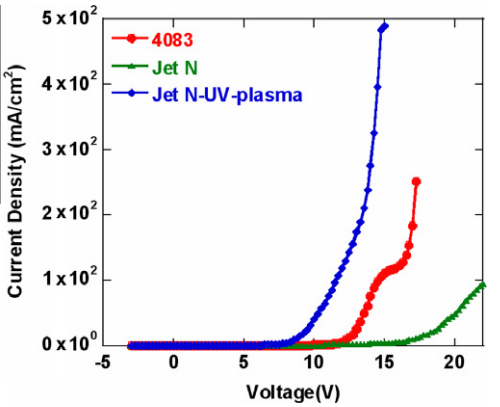

Fig. 5. *J–V* characteristics of hole-only devices with different HIL.

Table 2
Performance of PLED with different HIL.

HIL	Turn-on voltage (V)	*L* (max) (cd/m^2)	LE (max) (cd/A)	Performance at 19.1 mA/cm^2		
				V	*L*	LE
Jet N	4.00	14,942	2.24	5.6	106	0.5
8000	2.75	54,111	19.5	4.2	3682	19.3

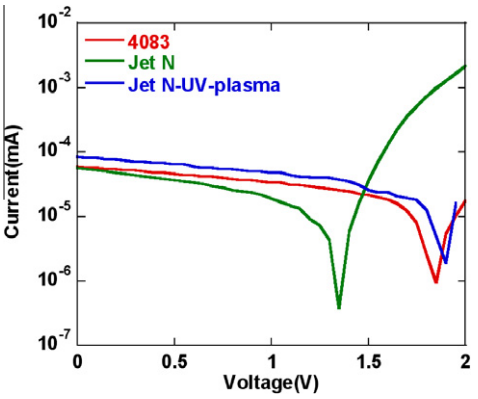

Fig. 6. Photovoltaic characteristics of the PLED devices with different HIL.

plasma treatment, Jet N device shows much higher hole current and lower turn-on voltage than both the device without the treatment and the regular 4083 device. The data demonstrates that the pH-neutral PEDOT:PSS with the UV and plasma treatment serves better as HIL in PLED than the acidic species.

The hole injection improvement is probably due to the reduction of the hole injection barrier between the HIL and the EL layer. Photovoltaic measurement is a direct measurement of the built-in potential, which scales with the hole injection barrier height on the anode side, when the cathode and the organic layers are same for all the devices [27]. Fig. 6 shows the Current (I)–Voltage (V) characteristics of the devices with different HIL under white-light illumination (80 mW cm^{-2}). The open-circuit voltage (V_{OC}) increased from 1.35 V for the non-treated Jet N device to 1.90 V for the treated Jet N device. For comparison, V_{OC} of the 4083 device is 1.85 V. The significant enhancement of V_{OC} confirms that the hole injection barrier is substantially lowered by Jet N HIL after treatment. Reducing hole injection barrier helps hole injections and makes electron and hole density balanced inside the device, therefore, improving the device performance.

4. Conclusions

We have demonstrated the utilization of pH-neutral PEDOT:PSS as the hole injection layer in the PLED devices. In a double layer HIL device structure, the neutral PEDOT:PSS on top of ITO prevents the acidic PEDOT:PSS from etching ITO, while the acidic PEDOT:PSS beneath the EL layer keeps the efficient hole injection from the anode to the light emission layer for the PLED operation. The double layer HIL structure not only reduces the ITO etching effect by a factor of 6.5, but also stops the indium penetration into the polymer layer. The performance of such a device is comparable to or even better than that of the single layer HIL device.

To simplify the double layer HIL structure, the neutral PEDOT:PSS as a single layer HIL in PLED was successfully achieved. Through the UV and the oxygen plasma treatment, the hole injection barrier between the HIL and the EL layer is reduced to improve the hole injection. The performance of the single layer Jet N HIL device is better than that of the regular acidic PDDOT:PSS HIL device. Furthermore, neutralized PEDOT:PSS serving as HIL has a process advantage over inorganic HIL. While the application of inorganic HIL generally requires high vacuum, the solution processability of the PEDOT:PSS retains the simplicity of the PLED process.

ABSTRACT

We report an ambipolar to n-type transformation in pentacene-based organic field-effect transistors (OFETs) of aluminum (Al) source–drain electrodes. The hole currents of the ambipolar OFETs were decreased by over two orders of magnitude within 24 h after the device fabrication, but the electron currents remained unchanged, which makes the devices present n-type only characteristics. The transformation is correlated with the interfacial interactions between Al electrodes and pentacene, as characterized by analyzing near-edge X-ray absorption fine structure spectra and Micro-Raman spectra. This study highlights the importance of metal/organic interfaces in the performance of OFETs, and demonstrates decent n-type pentacene-based OFETs with electron mobility of 0.1 $cm^2/V/s$ with proper annealing treatment.

A significant progress has been achieved in materials, device architectures, and fabrication processes of organic field-effect transistors (OFETs) [1,2]. Pentacene is one of the most promising materials for high performance p-type OFETs [3]. Besides p-type, the ambipolar [4–6] and n-type [7–9] conduction of pentacene-based OFETs were also observed when metal electrodes of low work function and trap-free dielectrics are used. Ambipolar OFETs could be deployed in organic circuits, such as inverters, oscillators, logic circuits, [10,11] and even organic light-emitting field-effect transistors recently [12,13].

In consideration of charge injection barriers, aluminum (Al) is a suitable metal as source–drain (S–D) electrodes in ambipolar pentacene-based OFETs, because the energy barriers for the injection of electrons and holes from Al S–D electrodes to pentacene are comparable. Therefore, the studies of ambipolar pentacene-based OFETs using Al S–D electrodes were reported [5,6]. However, we recently disclosed the pentacene-based OFETs of Al S–D electrodes only perform the decent n-type performance [8]. In this paper, the output characteristics of the OFETs were ambipolar initially. Within 24 h after the device fabrication, the hole currents decreased by over 2 orders of magnitude, but the magnitude of the electron currents remained the same. We attributed the time-dependent ambipolar to n-type transformation in pentacene-based OFETs of Al S–D electrodes to the specific interfacial interaction at the Al–pentacene junction, which presumably functioned as the hole blocking layer and was characterized by the near-edge X-ray absorption fine structure (NEXAFS) spectra and Micro-Raman spectra.

The device configuration, as shown in the inset of Fig. 1(d), is composed of the indium-tin-oxide (ITO) (as gate electrode) glass substrate/poly(3,4-ethylenedioxythiophene): polystyrenesulfonate (PEDOT:PSS)/crosslinked poly(4-vinyl phenol) (PVP) (as bottom dielectric)/polystyrene (PS) (as top dielectric)/pentacene (as active layer)/Al (as source and drain electrodes). The fabrication details

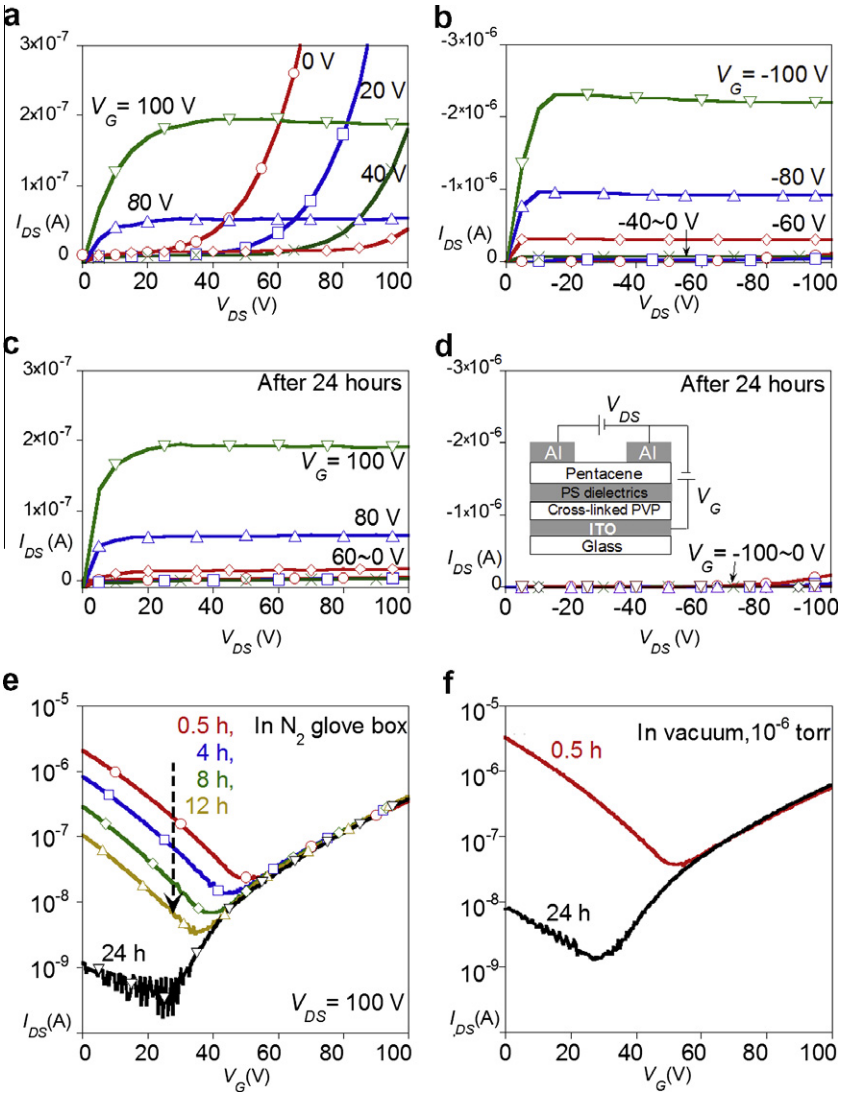

Fig. 1. The output characteristics of I_D vs. V_{DS} plot of pentacene-based OFETs with Al source–drain electrodes, (a) measured at 0.5 h after the fabrication of OFETs at V_G of (○) 0 V, (□) 20 V, (×) 40 V, (◇) 60 V, (△) 80 V, and (▽) 100 V in n-type operation regime (b) measured at 0.5 h at V_G of (○) 0 V, (□) −20 V, (×) −40 V, (◇) −60 V, (△) −80 V, and (▽) −100 V in p-type operation regime, (c) measured at 24 h in n-type operation regime, and (d) measured at 24 h in p-type operation regime. The inset is the structure of a pentacene-based OFET used in this study. (e) Transfer characteristics (I_{DS} vs. V_G) in nitrogen-filled glove box at (○) 0.5, (□) 4, (◇) 8, (△) 12, and (▽) 24 h and (f) in vacuum of 10^{-6} torr after fabrication at V_{DS} = 100 V.

were reported in a previous study [9]. PS was dissolved in toluene at a concentration of 5.0 wt.% and then spun on the substrate as top layer dielectric. The thicknesses of cross-linked PVP, PS dielectric, and pentacene layer were 160, 120, and 80 nm, respectively. The channel length (L) and width (W) were 100 and 1000 μm, respectively. The completed OFETs were stored in nitrogen-filled glove box at the oxygen and moisture level <1 ppm, or in vacuum at 10^{-6} torr. The output electrical characteristics were measured inside the glove box using HP4145B semiconductor parameter analyzer. The NEXAFS spectra were taken in radiation normal to sample substrates at the X-ray photoemission electron microscopy station with an energy resolution of 100 meV at the K-edge in National Synchrotron Radiation Research Center (NSRRC), Hsin-Chu, Taiwan. The Micro-Raman scattering spectra were recorded in backscattering configuration using Bruker SENTERRA Raman Microscope at room temperature through 50× objective with excitation by a 532 nm laser. The height images of atomic force microscopy (AFM) were taken by Veeco D5000 in tapping mode.

The output characteristics and transfer characteristics of pentacene-based OFETs with Al S–D electrodes are measured from originally ambipolar to n-type in 24 h. Fig. 1(a) plots the output characteristics, S–D current (I_{DS}) vs. S–D voltage (V_{DS}) of one device operated at positive gate voltage (V_G) from 0 to +100 V, n-channel accumulation regime, at 0.5 h after the fabrication. When V_G was from 0 to 60 V, the output currents did not exhibit the output characteristics of a transistor, but of a diode. These diode-like output

currents were decreased as positive V_G was increased which are contributed by hole carriers. When V_G was from 80 to 100 V, the curves presented saturated S–D output currents were increased as positive V_G was increased which are dominated by electron carriers. Fig. 1(b) shows the output characteristics of the same device operated at negative V_G of p-channel accumulation regime. It shows this device is p-type of output characteristics under negative V_G bias. In comparison of Fig. 1(a) and (b), the ambipolar conduction of the device is valid in both n-type and p-type operations with clear saturated electron currents and hole currents. Electron mobility and hole mobility are calculated as 2.43×10^{-3} and 2.18×10^{-2} $cm^2/V/s$ respectively in saturation region. Fig. 1(c) shows the output characteristics of the same device after 24 h of storage in nitrogen-filled glove box (oxygen and moisture level <1 ppm). The diode-like currents which are shown in Fig. 1(a) were not detected, but the saturated currents were remained. In Fig. 1(d), the p-type saturated currents are decreased about to the noise level of measurement system. According to the data of Fig. 1(c) and (d), the electron mobility after 24 h remains 2.43×10^{-3} $cm^2/V/s$, but the hole mobility is too low to be calculated correctly. Fig. 1(e) displays the evolution of transfer characteristics measured at 0.5 to 24 h after the fabrication of OFETs in a nitrogen-filled glove box. The I_{DS} of OFETs illustrates the ambipolar characteristics with hole current of 10^{-6} amp at $V_G = 0$ V and electron current of 10^{-7} amp at $V_G = 100$ V at 0.5 h. As the storage time increases, the hole current decreases to 10^{-9} amp after 24-h of storage, but the magnitude of the electron current remains unchanged. The originally ambipolar pentacene-based OFET becomes a n-type device in the inert atmosphere at the oxygen and moisture levels <1 ppm without any post treatment.

In order to find the origins of this phenomenon of the decreased hole currents, storage environments, annealing effect, gate dielectrics, metals of S–D electrodes, and the contact of S–D electrodes and pentacene layer were investigated systemically. By comparing Fig. 1(e) and (f), the hole current of the device stored in a vacuum of 10^{-6} torr is still decreased by over two orders of magnitude within 24 h. Although the oxygen and moisture inside the glove box and a vacuum of 10^{-6} torr is very low, we still cannot completely exclude the possible influence of the residual atmosphere to the device performance. When OFETs fabricated in this study were exposed to the air atmosphere or dry oxygen gas in 0.5 h, both the hole current and the electron current were decreased remarkably by few orders of magnitude. Full details of environmental experiments are presented in the Supporting Information S1. According to the results, oxygen and moisture in ambient atmosphere damage both n-type and p-type operations, but the levels of oxygen and moisture inside the glove box or a vacuum of 10^{-6} torr did not cause the decreasing of electron currents in Al pentacene-based OFETs.

To clarifying the correlation of this transformation and annealing effect on pentacene, annealing of 100 °C 0.5 h right after the device fabrication was applied. Fig. 2 presents the transfer curves of one annealed device measured at 0.5 and 24 h after the fabrication. The inset is the output characteristics of the device at 24 h. Firstly, the hole current of 10^{-6} amp at $V_G = 0$ V still existed right after annealing. Secondly, the hole current was decreased by over two orders of magnitude within 24 h. Thirdly, the electron current of the annealed device at $V_G = 100$ V was increased over 1.5 orders of magnitude, and its calculated electron mobility in saturation region is improved, up to 0.1 $cm^2/V/s$. The influence of annealing treatment of pentacene-based OFETs has been studied by several groups. Annealing effects include improving mobility as increasing crystallinity [14–16], keeping durability under continuous bias stress [15], and causing a shift in threshold voltages of the ambipolar pentacene OFETs [17]. As a result of this experiment, annealing treatment improves the electron currents of the Al pentacene-based OFET, and the phenomenon of decreased hole currents with time remains regardless of applying annealing treatment or not.

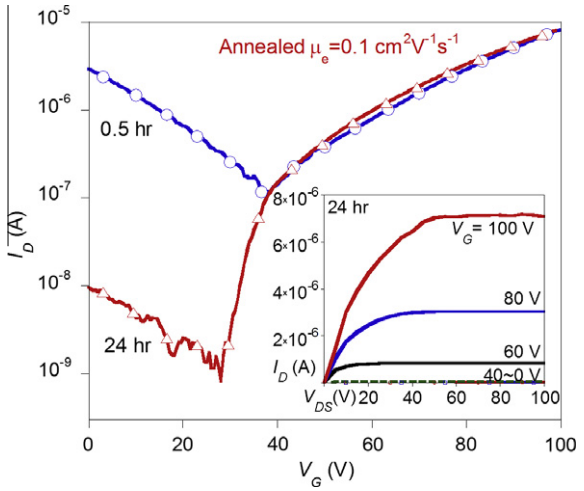

Fig. 2. Transfer characteristics of one pentacene-based OFET with Al S–D electrodes with annealing of 100 °C 0.5 h, then measured at (○) 0.5 and (△) 24 h after the fabrication. The inset is the output characteristics of the device at 24 h.

The influence of gate dielectrics such as poly(methyl methacrylate) (PMMA), PVP, polyvinyl alcohol (PVA), and PS, were surveyed which affects the morphologies of pentacene films. Fig. 3(a) presents the normalized hole currents at $V_G = 0$ V and $V_{DS} = 100$ V vs. time from 0.5 to 24 h for devices of different gate dielectrics. The hole currents for all pentacene-based OFETs of Al S–D electrodes comprising different gate dielectrics are decreased with time. Noted that the pentacene-based OFETs of Al S–D electrodes have the maximum decline in hole current after 24 h of fabrication, when PS is used as the gate dielectric. The variations in the decline of hole currents for OFETs of different gate dielectrics are probably related to the interfacial morphologies between different pentacene films and Al electrodes. The root-mean-square (rms) roughness as characterized by AFM of 80 nm thick pentacene films on PMMA, PVP, PVA, and PS are 15.5, 16.3, 10.4, and 7.6 nm, respectively. The difference of surface topography for 80 nm thick pentacene films on PMMA and PS can be identified by AFM height images as shown in Fig. 3(b).

Fig. 3(a) also summarizes the normalized hole currents vs. time for OFETs made of Au and Ag, as S–D electrodes to

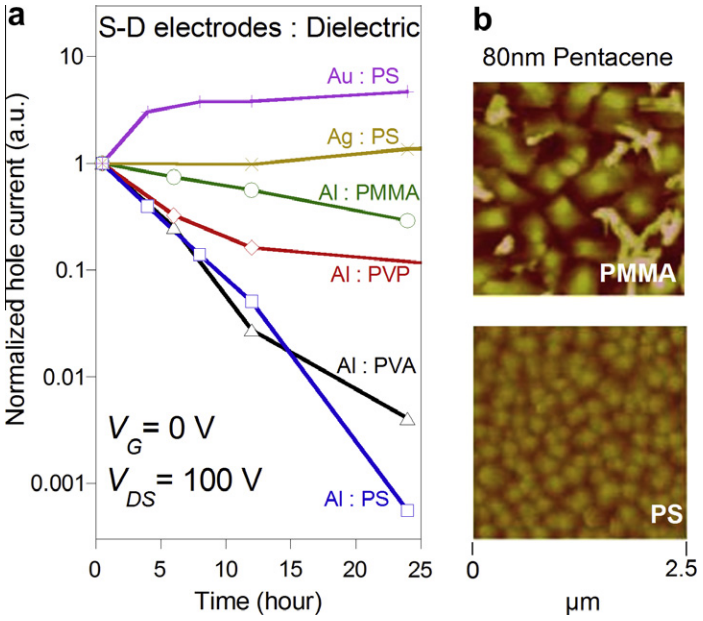

Fig. 3. (a) The normalized hole currents as a function of storage time (hours) in pentacene-based OFETs of (+) Au, (×) Ag S–D electrodes with PS as gate dielectric, and Al S–D electrodes with (○) PMMA, (◇) PVP, (△) PVA, and (□) PS as gate dielectrics at V_{DS} = 100 V and V_G = 0 V. (b) AFM height images (2.5 × 2.5 μm) of pentacene films (80 nm) on PMMA and on PS dielectrics.

investigate the correlations of the decreased hole currents with metal S–D electrodes. When Au was applied as S–D electrodes, the hole current increased initially, and it became stable after 4 h. Such an initial increase was attributed to the defect healing effect of pentacene-based OFETs at room temperature as reported by Kalb et al. [18]. The hole current of the OFET with Ag as S–D electrodes is also slightly increased. The marked decrease in the hole current can only be observed for OFETs of Al S–D electrodes. As a result, Al metal S–D electrodes are critical to the decline of hole currents, and the Al-pentacene interface should be characterized essentially.

To investigate the contact of S–D electrodes and pentacene layer, two approaches were utilized. One was S–D contact resistance by the transmission line model (TLM), and the other was the separation of Al and pentacene by inserting a buffer layer. First, TLM is a useful approach to identify the variation of hole currents on the S–D contact region or on the field-effect channel region by deriving contact resistance (R_C) and channel resistance (R_{Ch}) [19–21]. The total resistance (R_T) is equal to the sum of R_C and R_{Ch} according to

$$R_T = \left.\frac{\partial V_{DS}}{\partial I_{DS}}\right|_{V_{DS\to 0}}^{V_G} = R_{Ch} + R_C = \frac{L}{W\mu C(V_G - V_T)} + R_C, \qquad (1)$$

where L, μ, and V_T are the channel length, mobility, and threshold voltage, respectively. The R_C is given by the intercept of the total resistance, R_T, vs. L plot at L = 0, and is the sum of contact resistance of the source and the drain.

To apply TLM approach, the S–D total resistances of hole currents are measured at V_G = −100 V and V_{DS} = −1 V, and those of electron currents are measured at V_G = +100 V and V_{DS} = +1 V for OFETs made of different channel length L, 50, 100, 150, and 200 μm. From 0.5 to 48 h, the total resistance of hole currents increases by 2 orders of magnitude regardless of channel lengths. Accordingly, the contact resistance of hole currents dominates the total resistance, which was increased at the range from 6×10^6 to 10^9 Ω approximately as the storage time of OFETs was increased from 0.5 to 48 h. For the resistance of electron currents from 0.5 to 48 h, the contact resistance is slightly decreased from 8×10^6 to 5×10^6 Ω, and the channel resistance is also decreased from 3.3×10^6 Ω per 10 μm to 1.3×10^6 Ω per 10 μm, according to Eq. (1). More detail results on TLM approach are presented in the Supporting Information S2. The variations of the contact and channel resistance of electron currents are relatively small as compared to the increase in the contact resistance of hole currents. Therefore, the decrease of hole currents is a result of the increase of contact resistance at the Al–pentacene junction which determines the injection of charge carriers.

The second approach to investigate the contact of S–D electrodes and pentacene layer is inserting a buffer layer to prevent the direct contact of Al and pentacene without influencing the injection of charge carriers. Fig. 4(a–c) compare the transfer characteristics of one original pentacene-based OFET, with a buffer layer of molybdenum trioxide (MoO_3) which favors the injection of holes [22], and with lithium fluoride (LiF) layer which favors the injection of electrons and the blocking of holes [6,23]. Fig. 4(a) shows one pentacene-based OFET without a buffer layer inserted between pentacene and Al, which is the same device shown in Fig. 1(e), for comparison with those inserted a buffer layer. When the MoO_3 layer of 10 nm thickness was applied, it shows both hole and electron currents keep the same level within 24 h without the significant decreas-

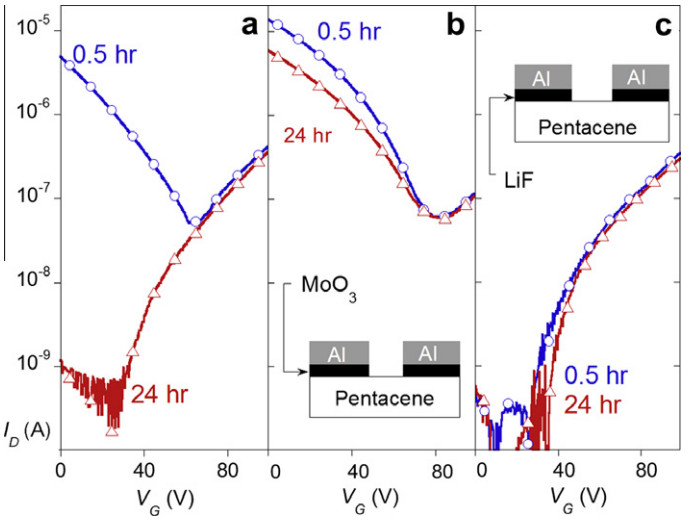

Fig. 4. Transfer characteristics of (a) one pentacene-based OFET with Al S–D electrodes, (b) one with MoO_3 of 10 nm thickness, and (c) one with LiF of 5 nm thickness as a buffer layer between pentacene layer and Al electrodes.

ing of hole currents in Fig. 4(b). When the buffer layer was replaced by LiF of 5 nm thickness, hole currents are blocked in the level of 10^{-9} A without delay in Fig. 4(c). Therefore, when Al and pentacene are separated, the time-dependant decreasing of hole currents does not happen. It indicates the main cause of the decreased hole currents is presumably the junction of Al and pentacene.

The injection barrier heights of hole carriers are examined by Fowler–Nordheim (FN) tunneling theory [24,25] $I \propto F^2 \exp(-\kappa/F)$, where I is the current of a diode, F is the electric field under bias V, and κ is a parameter which is related to the shape of the barrier height (φ). Fig. 5(a) shows the decrease of hole currents with time for a diode of ITO/PEDOT:PSS/pentacene/Al configuration at hole-dominated operation regime. For the matching of energy levels of hole transport, PEDOT:PSS/pentacene interface is considered as an Ohmic contact, but pentacene/Al interface is as a Schottky contact. The diode in this configuration is one hole-dominated device. The tunneling of hole carriers is mainly attributed at pentacene/Al interface. Fig. 5(b) presents the FN plots of $\ln(I/F^2)$ vs. $1/F$ for the same device. The slope of FN curves, κ, is proportional to $\varphi^{3/2}$. The increased slopes of FN curves in positive voltage with time probably suggest the barrier height of hole carriers through the tunneling process at Al–pentacene junction was increased due to the interfacial interaction, which block hole carriers and results a time-dependent output characteristics. There is no change in PEDOT:PSS/pentacene interface according to the similarity of the slopes of FN curves in negative voltage region in 48 h shown in Supporting Information S3.

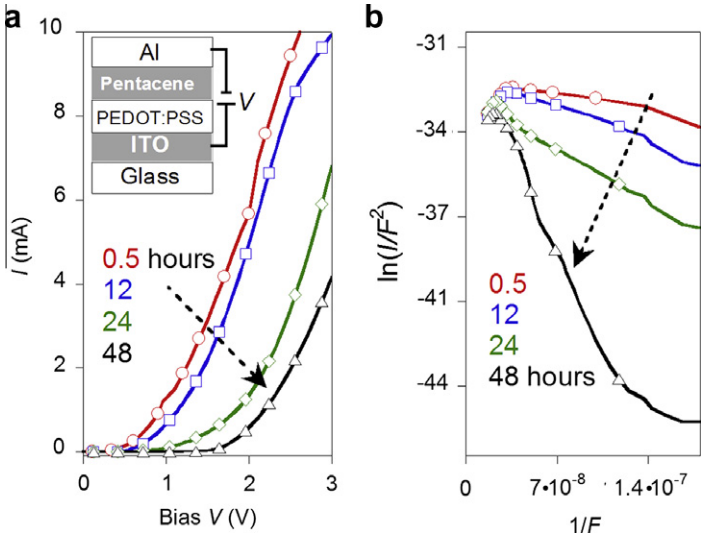

Fig. 5. (a) I–V characteristics for a diode of ITO/PEDOT:PSS/pentacene/Al configuration from 0.5 to 48 h after fabrication and (b) Fowler–Nordheim plots, $\ln(I/F^2)$ vs. $1/F$, for the same diode. F is the electric field under bias V.

Fig. 6(a) shows the NEXAFS spectra of pentacene films covered with ultra thin metals, such as Al and Ag. In Fig. 6(a) the signals of LUMO (282–283.7 eV) and LUMO + 1 (283.7–285.5 eV) groups of pristine pentacene in the π^*-transition region were apparent and the signal of σ^* (C–H)/Rydberg resonances region (287–288 eV) was very small [26,27]. The spectrum of the pentacene film deposited with 3 nm Ag was almost identical to that of pristine pentacene film in Fig. 6(a). The spectra of the pentacene film deposited with 1 nm Ag, 1 nm Au, and 3 nm Au are the same (not shown here). However, in the spectra for pentacene deposited with 1- and 3-nm-thick Al, the intensities of LUMO and LUMO + 1 were decreased and the signal of σ^* (C–H) was markedly enhanced with the thickness of Al. These results suggest that the change from carbon double bonds into carbon–hydrogen-like single bond is due to the deposition of Al on pentacene. The σ^* signal regarding the Al-related carbon single bond indicates the existence of Al–pentacene interactions.

The affected vibration mode of the Al–pentacene interactions is observed in Raman spectroscopy. Fig. 6(b) shows Raman spectra of a 10-nm-thick pentacene film and a 10-nm-thick pentacene film deposited with 8-nm-thick Al. The 1596 cm^{-1} Raman signal is enhanced in the as deposited 8-nm-thick Al over pentacene, which corresponds to a quadrant stretching mode of benzene rings. The relative intensity of the peak at 1596 cm^{-1} to the one at 1533 cm^{-1} was enhanced from 0.2 ($I_{1596\ cm^{-1}}/I_{1533\ cm^{-1}}$) for pristine pentacene film to 0.9 for one covered with Al. There are few possible mechanisms to change the quadrant stretching mode of pentacene molecules, such as the variation of the orientation of pentacene molecules [28] and the formation of humidity-induced pentacene–water interaction [29]. In our experiment, we suggest that the changes of 1596 cm^{-1} quadrant stretching mode are correlated with the specific Al–pentacene interfacial interactions as characterized in NEXAFS spectra. Although a time-dependent chemical analysis of Al–pentacene interface to examine the detailed hole blocking mechanism is still in progress currently, the decrease of hole currents in pentacene-based OFETs associated with the Al–pentacene interactions is quite apparent in our studies.

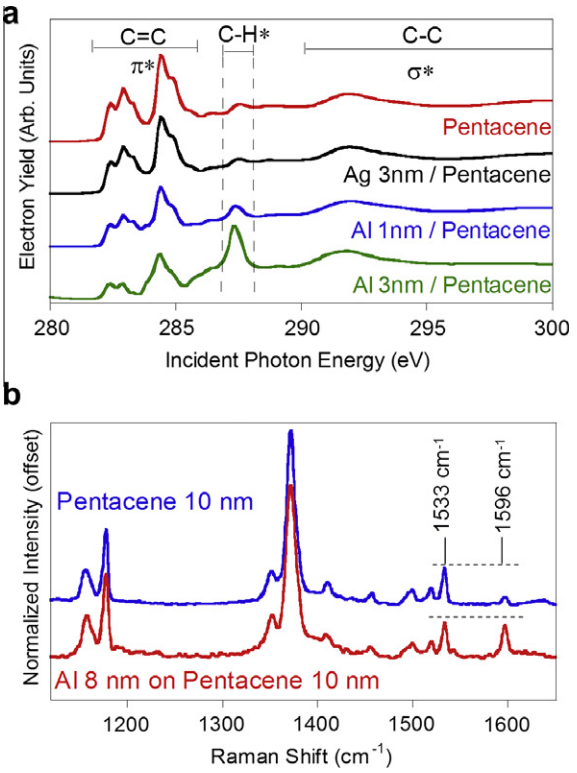

Fig. 6. (a) NEXAFS spectra of a pristine 200 nm thick pentacene film, and ones deposited with 3 nm Ag, 1 nm Al, and 3 nm Al. (b) Raman spectra of a pristine 10 nm pentacene film and one deposited with 8 nm Al.

In summary, we fabricated ambipolar pentacene-based OFETs with Al S–D electrodes initially, but the output characteristics of devices are transformed from ambipolar into n-type within 24 h. This transformation is due to the decrease of hole currents and correlated with the markedly increased contact resistance of hole currents. It is suggested that the interface at the Al–pentacene junction, after storing the OFETs in inert environment for 24 h, functions as an effective hole blocking layer to interfere the injection of the hole currents in ambipolar OFETs. This study highlights the importance of metal/organic material interface in the output performance of OFETs and indicates that Al S–D electrodes are suitable for the fabrication of decent n-type pentacene-based OFETs with electron mobility of 0.1 $cm^2/V/s$ with proper annealing treatment. The time-dependent *in situ* chemical analysis of the Al–pentacene interactions with the OFETs performance is currently in progress.

ABSTRACT

We demonstrate the use of n-type *N*,*N*′-ditridecyl-3,4,9,10-perylenetetracarboxylic diimide (PTCDI-C13) bottom contact organic field-effect transistors that employ photopatternable highly conductive poly(3,4-ethylenedioxythiophene):tosylate (PEDOT:Tos) source/drain electrodes characterized by a very low work function (4.3 eV). Due to the low work function of this material, the electron injection barrier between PTCDI-C13 and PEDOT:Tos was 0.25 eV lower than that between PTCDI-C13 and gold. The low injection barrier reduced the contact resistance, yielding a high field effect mobility in transistors based on PEDOT:Tos (0.145 cm^2/Vs); the field effect mobility was 16 times higher than that in transistors based on gold (0.009 cm^2/Vs).

Organic field-effect transistors (OFETs) have attracted considerable attention in recent years due to their potential applications in low-cost, flexible, and light-weight electronic integrated circuits used in portable displays, disposable radio frequency identification tags, and smart cards [1,2]. In logic circuit designs, complementary metal-oxide semiconductor-like logic elements consisting of p-type and n-type organic transistors are preferred due to their very low power consumption and the simplifications they bring to the logic circuits. Metals with a low work function, such as calcium (2.9 eV) and aluminum (4.3 eV), have been used as source/drain (S/D) electrode materials in n-type OFETs because their work functions match the lowest unoccupied molecular orbital (LUMO) energy level of the semiconductor, leading to a lower electron injection barrier between n-type organic semiconductors and the electrodes. However, metals are easily oxidized in air, which degrades the performance of OFETs. Therefore, the use of metals is limited to micron-scale logic circuits fabricated by photolithographic process in air. Despite the high work function of gold (5.1 eV), it is widely used due to its good air stability [3,4]. However, gold is not appropriate for organic devices because fabrication via vacuum deposition methods has a high associated cost, and the opaqueness and high contact resistance between gold and n-type semiconductors in OFETs are not favorable.

Poly(3,4-ethylenedioxythiophene) (PEDOT) is a promising electrode material for use in OFETs due to its high optical transparency in the visible region, its flexibility, low fabrication cost, and high conductivity [5]. PEDOT doped with the polyelectrolyte poly(4-styrene sulfonate) (PSS) has a conductivity that can vary from 0.03 to 900 S/cm [6]. Many reports have demonstrated good device performances of p-type OFETs based on PEDOT:PSS S/D electrodes due to the material's high work function, between 4.75 and 5.15 eV [7,8]. Recent reports have shown that vapor-polymerized PEDOT doped with the monomeric arylsulfonate, tosylate (Tos), has a very high conductivity of

doi:10.1016/j.orgel.2010.12.022

up to 4500 S/cm, comparable with that of indium tin oxide electrodes [9]. The studies also reported a work function of 4.30 eV, which is one of the lowest values among conductive polymers [10]. This work function is sufficiently low that the material may be used in S/D electrodes in n-type OFETs. In this letter, we describe n-type *N,N′*-ditridecyl-3,4,9,10-perylenetetracarboxylic diimide (PTCDI-C13) bottom contact OFETs using photopatterned PEDOT:Tos as S/D electrodes. We found that the electron field effect mobility of transistors based on PEDOT:Tos S/D electrodes was 16 times higher than that of devices composed of gold S/D electrodes. The mechanism underlying this higher device performance was examined by characterizing the crystallinity of PTCDI-C13 on electrodes at the interface between the channel and the electrodes, and the electron injection barrier between the electrodes and PTCDI-C13.

Bottom contact OFETs were fabricated on heavily doped silicon wafers covered with thermally grown 300 nm thick silicon dioxide layers. Polystyrene (Aldrich, Mw ≈ 192,000) was spin-coated onto silicone oxide substrates (to a thickness of 150 nm). Fe (III)-tosylate (FTS, 40 wt.%) was dissolved in 1-butanol, and the basic inhibitor, imidazole, was added to the solution at a concentration of 0.048 g/g, which enhanced the conductivity of PEDOT [5]. The solution was spin-coated onto the substrate. The coated substrate was subsequently exposed to UV light (λ = 255 nm, power = 50 W) (G15T8, Sankyo Denki) through a photomask for 5 min. Within the area exposed to UV light, the oxidant Fe^{3+} became Fe^{2+} by the photo-Fenton reaction [11]. Because Fe^{2+} does not oxidize 3,4-ethylenedioxythiophene (EDOT), oxidative polymerization of PEDOT did not occur [12]. By contrast, Fe^{3+} in the unexposed areas oxidized EDOT, leading to oxidative polymerization (Fig. 1a). Thus, the substrate was exposed to EDOT vapor for 3 min in a closed jar with heating at 60 °C, followed by rinsing with methanol to obtain S/D patterned PEDOT:Tos substrates (Fig. 1b). The PEDOT:Tos could be photopatterned with a spatial resolution of 50 μm in our laboratory, and the conductivity of the fabricated PEDOT:Tos film was about 600 S/cm. A 50 nm thick PTCDI-C13 (Aldrich) film was then deposited as the active layer. Fig. 1c shows a schematic representation of the fabrication process. In order to compare with transistors based on PEDOT:Tos, we prepared transistors composed of gold S/D electrode deposited on PS-coated substrates by thermal evaporation with a shadow mask.

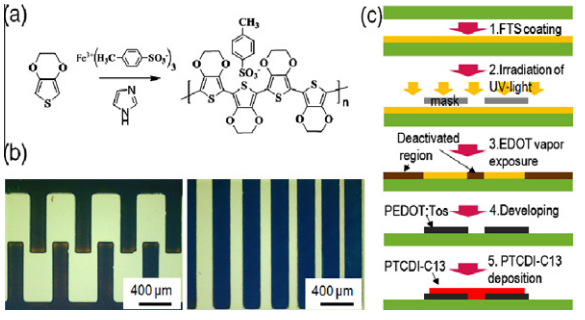

Fig. 1. (a) Polymerization scheme for producing poly(3,4-ethylenedioxythiophene):tosylate (PEDOT:Tos); (b) optical microscopy images of the photopatterned PEDOT:Tos electrodes, and (c) schematic representation of the photopatterning of PEDOT:Tos.

Fig. 2b and c shows the transfer and output characteristics, respectively of the fabricated OFETs, shown schematically in Fig. 2a. The electron mobility was calculated in the linear regime using the slope of a plot of the drain current versus gate voltage by fitting the data to the following equation: $I_D = (WC_i/L)\mu(V_G - V_{th})V_D$, where I_D is the drain current, μ is the carrier mobility, V_G is the gate voltage, V_{th} is the threshold voltage, and V_D is the drain voltage (6 V) [13]. The measured capacitance, C_i, was 6.4 nF/cm^2. The channel length (L) and width (W) were 150 and 1000 μm, respectively. The average electron mobility of twenty PTCDI-C13 transistors composed of PEDOT:Tos was 0.145 ± 0.017 cm^2/Vs, which was 16 times higher than that of devices containing gold S/D electrodes (0.009 ± 0.001 cm^2/Vs). As shown in Fig. 2c, ohmic contact behavior was observed for the devices based on PEDOT:Tos electrodes. Transistors based on gold exhibited non-ohmic contact characteristics, indicating a high contact resistance in these devices. Fig. 1d shows the width-normalized total resistance, *RW*, of transistors fabricated using gold and PEDOT:Tos S/D electrodes. *RW* is the sum of the channel resistance and the contact resistance as a function of V_G, at a V_D of 6 V. *RW* is given by

$$RW = R_C W + \frac{L}{\mu C_i (V_G - V_{th})}$$

where $R_C W$ is the width-normalized contact resistance [14]. When V_G was varied from 0 to 20 V, the *RW* of the device fabricated with gold decreased because the channel resistance decreased (channel resistance is inversely proportional to V_G). However, beyond a V_G of 20 V, *RW* became nearly constant, despite further increases in V_G, because $R_C W$ was too large and therefore the changes in channel resistance as a function of V_G were negligible compared to $R_C W$. Therefore, the transistor showed typical contact-limited device performance, and the average value of $R_C W$ was approximately 7×10^6 Ω cm at a V_G of 60 V. In contrast, *RW* for the device containing PEDOT:Tos decreased consistently during the sweep across V_G, from 0 to 60 V, indicating that *RW* was dominated by the channel resistance rather than by $R_C W$. For this device, $R_C W$ was less than 6×10^4 Ω cm at a V_G of 60 V. Thus, the higher performances of devices composed of PEDOT:Tos arose from a contact resistance that was smaller than that of transistors based on gold.

Atomic force microscopy (AFM) images of PEDOT:Tos and gold surfaces (Fig. 3a and b) showed that the surface of PEDOT:Tos was much rougher (surface roughness of 5.04 nm) than that of gold (surface roughness of 0.81 nm). Despite the pronounced differences between the two surfaces, the morphology of PTCDI-C13 on PEDOT:Tos was not distinctly different from that of gold (Fig. 3c and d). Most likely, the strong interactions between gold and PTCDI-C13 and the largely rough surface of PEDOT:Tos significantly hindered crystallization of PTCDI-C13, yielding 100 nm-sized small PTCDI-C13 grains on either surface [15,16]. The in-plane GIXD patterns shown in Fig. 3e were used to derive the coherence length in the

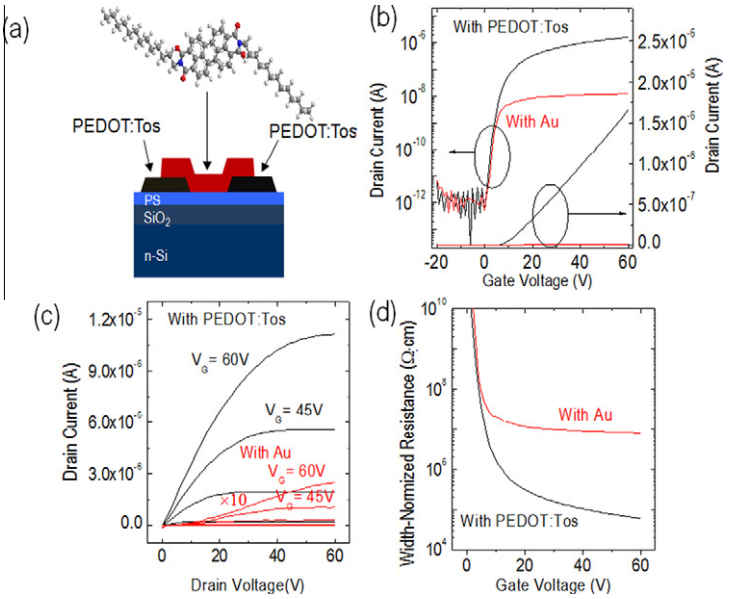

Fig. 2. (a) Schematic diagram of a bottom-contact PTCDI-C13 OFET fabricated using PEDOT:Tos; (b) transfer characteristics in the linear regime (V_D = 6 V) for OFETs prepared using PEDOT:Tos and gold; (c) output characteristics of OFETs with PEDOT:Tos and gold; (d) width-normalized total resistance, including channel and contact resistances, in an OFET as a function of gate voltage.

PTCDI-C13 films (i.e., the distance over which order was maintained). In the (1 0 0) direction, this length was determined to be 28 nm on the gold substrate and 32 nm on the PEDOT:Tos surface. The coherence lengths were determined from the half-widths of the (1 0 0) peaks using Scherrer's formula (Fig. 3f) [17]. Given that the coherence length is proportional to the size of the crystallites over which structural order is maintained, the PEDOT:Tos surface crystallites were only slightly larger than on the gold substrate, representing that the crystallinity of PTCDI-C13 on PEDOT:Tos was almost the same as that on the gold, consistent with the AFM results.

Fig. 4a shows the ultraviolet photoemission spectra (UPS, He(I): 21.2 eV) of PEDOT:Tos and gold, and Fig. 4b shows the C K-edge near-edge X-ray absorption fine structure (NEXAFS) spectra of 6.4 nm thick PTCDI-C13 films on PEDOT:Tos and gold. During the UPS measurements, a bias of −5.0 eV was applied to improve the transmission of low-kinetic-energy electrons and to ensure determination of the energy of the low-kinetic-energy edge. Angle-independent NEXAFS spectra of PTCDI-C13 were obtained using a fixed photon incidence angle of 55° from the surface normal (approximately equal to the magic angle of 54.7°). These spectra allowed calculation of the work function of each electrode and the relative position of the LUMO, as summarized in Fig. 3c [19,20]. The work function of PEDOT:Tos was 4.30 eV, which was 0.72 eV smaller than that of gold (5.02 eV). Owing to this low work function of PEDOT:Tos, the electron injection barrier between PTCDI-C13 and PEDOT:Tos was 0.25 eV lower than that between PTCDI-C13 and gold. The differences between the work functions (0.72 eV) and between the electron injection barriers (0.25 eV) is likely due to the larger downward vacuum level shift between gold and PTCDI-C13. The vacuum

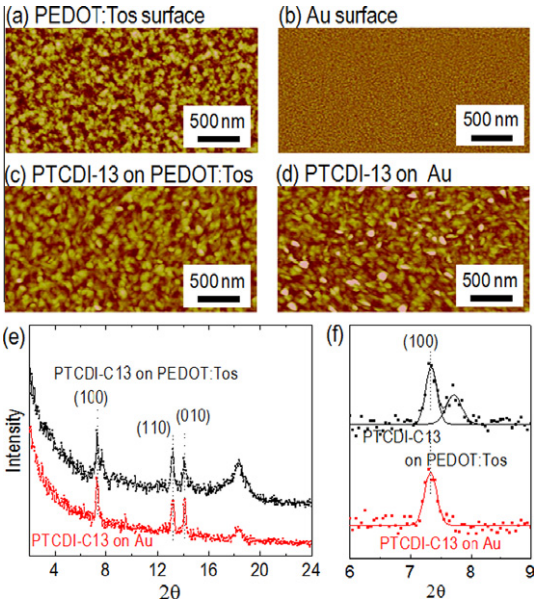

Fig. 3. (a) AFM images (3 × 3 μm) of the PEDOT:Tos surface and (b) gold surface. AFM images of 50 nm thick PTCDI-C13 films deposited on (c) a PEDOT:Tos surface and (d) a gold surface. (e) In-plane GIXD patterns of a 50 nm thick PTCDI-C13 film deposited on a PEDOT:Tos surface and on gold (λ = 1.075 Å). (f) The (100) peaks are shown in greater detail (the baselines of the GIXD pattern were subtracted and the peaks were fit to a Gaussian distribution). The peak at 7.7° corresponded to a diffraction peak (2 0 0) of the PEDOT [18].

level shift can be explained in terms of the high induced density of the interface states of PTCDI-C13 at the interface between gold and PTCDI-C13, which originates from the strong local orbital exchange and the potential correlations between the metal and the semiconductor [16,21].

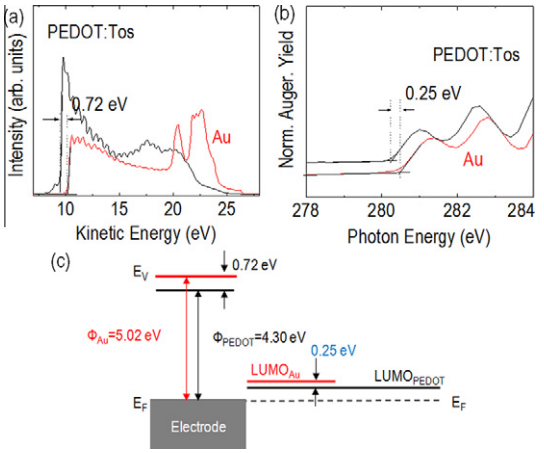

Fig. 4. (a) ultraviolet photoemission spectra of PEDOT:Tos and gold, (b) NEXAFS spectra of 6.4 nm thick PTCDI-C13 films on gold and PEDOT:Tos, and (c) band diagrams of the interface between gold and PTCDI-C13 and between PEDOT:Tos and PTCDI-C13.

In organic transistors, low electron injection barriers and highly crystalline organic semiconductor structures at the interface between the channel and S/D electrodes lead to a lower contact resistance [16]. AFM, GIXD, UPS and NEXAFS results demonstrated that the crystallinity of PTCDI-C13 on PEDOT:Tos was almost the same as that on gold, but the electron injection barrier between PTCDI-C13 and PEDOT:Tos was 0.25 eV lower than that between PTCDI-C13 and gold. Therefore, the lower contact resistance of OFETs based on PEDOT:Tos can be attributed to the lower electron injection barrier, which originates from the low work function of PEDOT:Tos.

We fabricated n-type PTCDI-C13 organic transistors by applying photopatternable highly conductive PEDOT:Tos S/D electrodes. Because PEDOT:Tos has a very low work function of 4.30 eV, the electron injection barrier between PTCDI-C13 and PEDOT:Tos was 0.25 eV lower than that between PTCDI-C13 and gold, leading to a reduced contact resistance in the transistor. The reduced contact resistance resulted in a high field effect mobility in transistors based on PEDOT:Tos (mobility of 0.145 cm^2/Vs) that was much greater than that in transistors based on gold (0.009 cm^2/Vs).

ABSTRACT

We have recently proposed that improvement of device performance using a buffer layer of molybdenum trioxide (MoO_3) originates from interfacial charge generation at an interface of MoO_3 and an organic hole-transport layer [17]. However, there is no clear experimental evidence enough to support the charge generation in our recent report. In this study, from comparison of current density–voltage characteristics of organic hole-only devices and ultraviolet/visible/near-infrared absorption spectra of composite films, we can conclude that the interfacial charge generation surly occurs to realize space-charge-limited currents of a wide variety of organic hole-transport layers. Moreover, a drastic increase in current density of a bilayer device of *n*-type C60 and *p*-type *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthyl)-1,1′-biphenyl-4,4′-diamine (α-NPD) by using a MoO_3 layer can provide the evidence of the charge generation.

1. Introduction

Large charge injection barriers are frequently present at electrode/organic heterojunction interfaces in organic electronic devices, making precisely clarifying charge transport mechanisms of organic thin films difficult because observed current density–voltage (*J*–*V*) characteristics are controlled by both charge injection and transport processes [1–3]. Also, the charge injection barriers are problematic for overall performance of organic electronic devices [4,5]. To solve the injection barrier problem, transition metal oxide, molybdenum trioxide (MoO_3) has been used as a buffer layer between a metal electrode and an organic layer in organic electronic devices, such as organic light-emitting diodes (OLEDs) [6,7], organic solar cells [8,9], and organic thin-film transistors [10,11]. Previously, we have demonstrated that use of a MoO_3 buffer layer with a specific thickness of 0.75 nm between an anode layer of indium tin oxide (ITO) and a hole-transport layer (HTL) of *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthyl)-1,1′-biphenyl-4,4′-diamine (α-NPD) leads to an increase in current density by about four orders of magnitude and appearance of a space-charge-limited current (SCLC) of α-NPD [12], indicating that the injection barrier at the ITO/α-NPD interface is completely negligible. This specific MoO_3 thickness of 0.75 nm is much smaller than those previously used for OLEDs. Power consumption and operational lifetimes of OLEDs are markedly improved by using the 0.75 nm MoO_3 buffer layer as well [5]. Thus, the very thin MoO_3 buffer layer is useful for establishing fundamental physics of charge transport in organic films and for developing the organic electronic devices.

Electronic states of multilayer films and composite films of organic and MoO_3 have been intensively investigated using ultraviolet photoelectron spectroscopy, inverse photoelectron spectroscopy, and X-ray photoelectron spectroscopy [13–16]. These leading papers have shown that: (1) charge transfer between electrode/MoO_3/organic interfaces induces large vacuum level shifts, minimizing a hole injection barrier height, (2) gap states are generated inside band gaps of α-NPD and MoO_3, and (3) a vacuum-deposited

doi:10.1016/j.orgel.2011.01.001

MoO_3 layer works as an electron conductor due to donating electrons from gap states to a conduction band. We have recently proposed that the improved device characteristics originate from interfacial charge generation at a MoO_3/HTL interface [17]. However, there is no clear experimental evidence enough to support the charge generation in our recent report. In this study, from comparison of *J*–*V* characteristics of organic hole-only devices and ultraviolet/visible/near-infrared (UV–vis–NIR) absorption spectra of composite films, we can conclude that the interfacial charge generation surly occurs to realize SCLCs of a wide variety of organic HTLs. Moreover, a drastic increase in current density of a bilayer device of *n*-type C60 and *p*-type α-NPD by using a MoO_3 layer can provide the evidence of the charge generation.

The interfacial charge generation mechanism we have recently proposed [17] is composed of (i) electron transfer from a lower-ionization-energy HTL to a higher-work-function MoO_3 layer to form electron–hole pairs at the MoO_3/HTL interface, (ii) separation of the electron–hole pairs under an external electric field, (iii) transit of resultant electrons and holes to corresponding electrodes through a conduction band (or gap states) of MoO_3 and a hole-transport level of α-NPD, and repetition of the charge transfer (i), the charge separation (ii), and the charge transit (iii) for steady-state current flow (Fig. 1). For a well-known standard hole injection mechanism without a MoO_3 buffer layer, HTL-to-ITO electron extraction (transfer) under a local high electric field and separation of electron–hole pairs are repeated in a manner almost similar to the charge generation mechanism mentioned above [15]. The difference between the charge generation and the charge injection is whether the charge transfer occurs or not under no electric field condition. Using the charge generation mechanism, a well-known charge injection barrier is no longer considered important and *J*–*V* characteristics are controlled by a SCLC. Since the HTL-to-MoO_3 electron transfer characteristics are expected to be related to a difference between an ionization energy of an HTL and a work function of a MoO_3 layer, a relationship between *J*–*V* characteristics and electron transfer characteristics is investigated in this study when ionization energies of HTL materials are systematically changed (see Fig. 2).

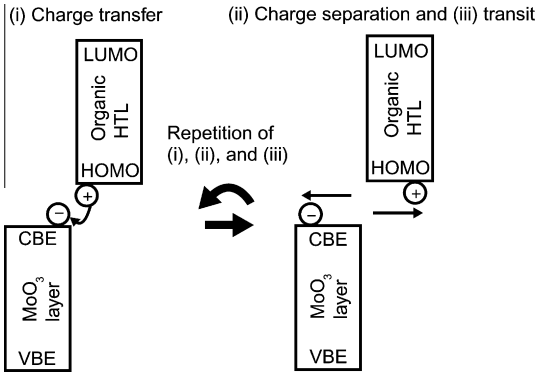

Fig. 1. Illustrations of energy-level diagrams showing charge generation mechanism, which is composed of (i) charge transfer, (ii) charge separation, and (iii) charge transit. These processes (i), (ii), and (iii) are repeated for steady-state current flow. CBE, VBE, HOMO, and LUMO stand for conduction band edge, valence band edge, highest occupied molecular orbital, and lowest unoccupied molecular orbital, respectively.

2. Experimental

HTL materials used in this study are 4,4′,4″-tris(*N*-3-methylphenyl-*N*-phenyl-amino)triphenylamine (m-MTDATA), *fac*-tris(2-phenylpyridinato)iridium(III) [Ir(ppy)$_3$], 4,4′,4″-tris(*N*-2-naphthyl-*N*-phenyl-amino)triphenylamine (2-TNATA), *N*,*N*′-di(m-tolyl)-*N*,*N*′-diphenyl benzidine (TPD), rubrene, α-NPD, 2,4,6-tricarbazolo-1,3,5-triazine (TRZ-2), and 4,4′-bis(carbazol-9-yl)-2,2′-biphenyl (CBP) (the chemical structures of the HTL molecules are shown in Fig. 2). Hole-only device structures and bilayer device structures of C60 and α-NPD are glass substrate/ITO anode (150 nm)/MoO_3 buffer layer (*X* nm)/m-MTDATA, Ir(ppy)$_3$, 2-TNATA, TPD, rubrene, α-NPD, TRZ-2, or CBP HTL (100 nm)/MoO_3 electron-blocking layer (EBL) (10 nm)/Al cathode (100 nm) and glass substrate/ITO anode (150 nm)/*n*-type C60 layer (30 nm)/MoO_3 buffer layer (0 or 5 nm)/*p*-type α-NPD HTL (100 nm)/MoO_3 EBL (10 nm)/Al cathode (100 nm), respectively. Source materials of m-MTDATA (Luminescence Technology), 2-TNATA (Luminescence Technology), rubrene (Aldrich), TRZ-2 (Luminescence Technology), and C60 (Materials Technologies Research) were purchased and purified twice using a vacuum train sublimation technique prior to evaporation. High-purity source materials of Ir(ppy)$_3$ (Nippon Steel Chemical), TPD (Tokyo Chemical Industry), α-NPD (Nippon Steel Chemical), CBP (Nippon Steel Chemical), MoO_3 (Mitsuwa Chemicals), and Al (Nilaco) were purchased and used as-received. The glass substrates coated with the 150 nm ITO anode layer with a sheet resistance of 10 Ω sq^{-1} (SLR grade) were purchased from Sanyo Vacuum Industries and the ITO layers were patterned by conventional photolithography. The substrates were cleaned using ultrasonication in acetone, followed by ultrasonication in detergent, pure water, and isopropanol. Then, the substrates were placed in an UV-ozone treatment chamber for 30 min. After the cleaning, the substrates were set in an evaporation chamber. The chamber was evacuated to a base pressure of $\approx 10^{-4}$ Pa. The layers of the MoO_3 and the organic materials were thermally deposited on the ITO surface from an alumina crucible (MoO_3) and individual carbon crucibles (organic materials). To complete the devices, the Al cathode layer was thermally deposited from a tungsten basket through a shadow mask with openings. The deposition rates were precisely controlled at 0.05 nm s^{-1} (MoO_3), 0.1 nm s^{-1} (organic materials), and 0.5 nm s^{-1} (Al) using a calibrated quartz crystal microbalance. The active device area was defined at 4 mm^2 by the overlapped area of the ITO layer and the Al layer. The completed devices were transferred to a nitrogen-filled glove box (O_2 and H_2O levels are less than 2 ppm) without exposing the devices to ambient air and encapsulated using a glass cap and an UV curing epoxy resin together with a desiccant sheet. The steady-state *J*–*V* characteristics of the devices were measured using a semiconductor characterization system (SCS4200, Keithley) at room tempera-

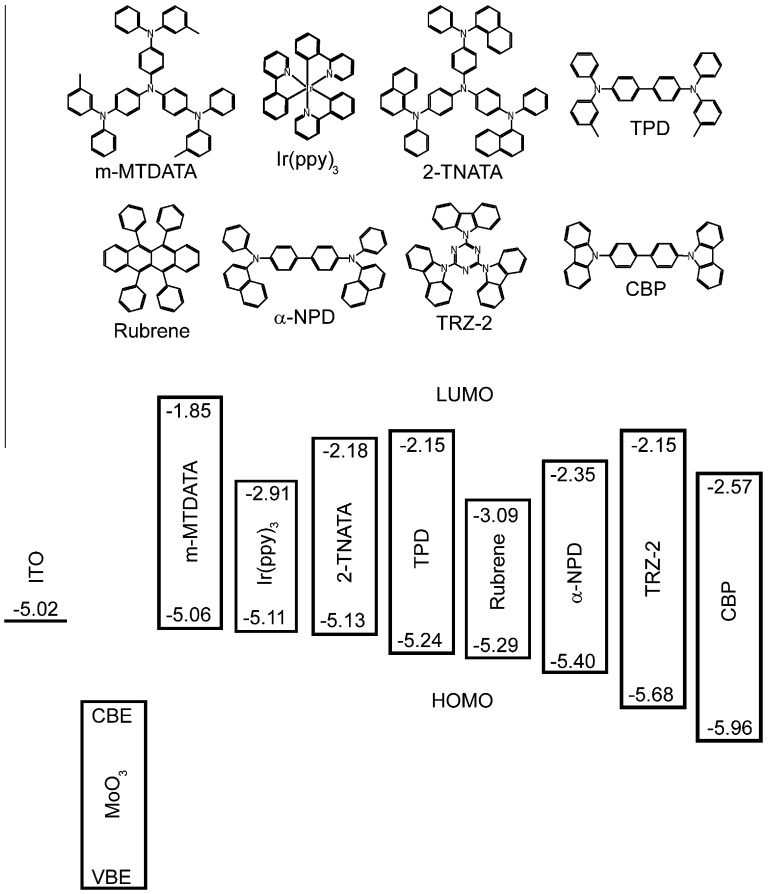

Fig. 2. Chemical structures of organic molecules and energy-level diagrams.

ture when the MoO_3 thicknesses (X) and the HTL materials are systematically changed. Since no electroluminescence was observed during the J–V measurements, it was confirmed that holes are dominant charge carriers in our devices.

A 50 nm organic layer, a 50 nm MoO_3 layer, and a 50 nm Al layer were thermally deposited on the cleaned ITO substrates using the preparation conditions described above. The ionization energies and the work functions of the layers were measured using an UV photoelectron spectrometer in air (AC-2, Riken Keiki). The work function of ITO was measured from the UV–ozone-treated bare ITO surface using the AC-2. The electron affinities of the organic layers were estimated by subtracting their absorption onset energies from the ionization energies.

Devices with a structure of glass substrate/Al electrode (100 nm)/organic layer (200 nm)/Al layer (100 nm) were fabricated using the preparation conditions described above. To calculate the relative permittivities, the capacitance of the organic layers was measured using an LCR meter (4284A, Agilent). The input voltage and the amplitude of the input signal were set at 0.1 V and ±0.005 V, respectively. No current flow was confirmed under the capacitance measurements. The capacitance of the organic layers remained constant in a frequency range from 20 Hz to 100 kHz.

Fifty nanometer intrinsic organic films and 50 nm composite films of organic and MoO_3 were thermally deposited on cleaned quartz substrates. The deposition ratio of organic to MoO_3 was controlled at 1:1 by mol using a calibrated quartz crystal microbalance. The total deposition rate was fixed at $\approx$0.1 nm s^{-1}. The UV–vis–NIR absorption spectra of the intrinsic films and the composite films were measured using an absorption spectrometer (V670, JASCO).

3. Results and discussion

3.1. Current density–voltage characteristics

The ionization energies of the HTL materials are measured as summarized in Table 1. The work functions of ITO, MoO_3, and Al are also measured respectively to be 5.02 ± 0.02, 5.68 ± 0.03, and 3.58 ± 0.02 eV. The work function of MoO_3 corresponds to a difference between a vacuum level and a Fermi level right below a conduction band edge [16]. The ionization energies and the work functions we measured here may be slightly different from actual values because they are measured in air [18]. In fact, the work function of a fresh Al surface has been measured to be $\approx$4.0 eV in an ultra-high vacuum condition [19]. The corresponding energy-level diagram with these values is shown in Fig. 2.

Table 1
Ionization energies (IE), relative permittivities (ε_r), zero field hole mobilities (μ_0), and field dependence parameters (β) of HTLs with thickness of 200 nm.

HTL material	IE (eV)	ε_r	SCLC		TOF	
			μ_0 ($cm^2\ V^{-1}\ s^{-1}$)	β ($cm^{0.5}\ V^{-0.5}$)	μ_0 ($cm^2\ V^{-1}\ s^{-1}$)	β ($cm^{0.5}\ V^{-0.5}$)
m-MTDATA	5.06 ± 0.02	2.76 ± 0.02	$2.2 \pm 0.2 \times 10^{-6}$	$4.3 \pm 0.4 \times 10^{-3}$	1.6×10^{-5} [23]	1.8×10^{-3} [23]
$Ir(ppy)_3$	5.11 ± 0.02	3.35 ± 0.05	$2.2 \pm 0.2 \times 10^{-8}$	$1.0 \pm 0.1 \times 10^{-2}$	No data reported	
2-TNATA	5.13 ± 0.02	2.77 ± 0.04	$6.8 \pm 0.5 \times 10^{-6}$	$3.1 \pm 0.2 \times 10^{-3}$	1.8×10^{-5} [22]	2.0×10^{-3} [22]
TPD	5.24 ± 0.02	3.38 ± 0.03	$1.4 \pm 0.1 \times 10^{-4}$	$2.0 \pm 0.2 \times 10^{-3}$	6.6×10^{-4} [24]	1.0×10^{-3} [24]

α-NPD	5.40 ± 0.01	3.42 ± 0.02	$3.3 \pm 0.3 \times 10^{-4}$	$8.0 \pm 0.6 \times 10^{-4}$	4.0×10^{-4} [24]	1.1×10^{-3} [24]
TRZ-2	5.68 ± 0.02	3.24 ± 0.05	No SCLC observed			
CBP	5.96 ± 0.02	2.62 ± 0.03	No SCLC observed			

If an Ohmic contact is formed at an electrode/organic interface and a free charge density is negligible in comparison to an injected charge density, a SCLC with field-dependent mobilities is expressed as the equation [20]:

$$J = \frac{9}{8}\varepsilon_r\varepsilon_0\mu_0 \exp\left(0.89\beta\frac{V^{0.5}}{L^{0.5}}\right)\left(\frac{V^2}{L^3}\right) \quad (1)$$

where ε_r is the relative permittivity, ε_0 is the vacuum permittivity, μ_0 is the zero field mobility, β is the field dependence parameter, and L is the film thickness. The relative permittivities of the HTLs are determined as summarized in Table 1 by measuring their capacitance. By fitting the obtained J–V characteristics with the SCLC Eq. (1), the zero field hole mobilities and the field dependence parameters can be determined at the same time.

The J–V characteristics of m-MTDATA, $Ir(ppy)_3$, and 2-TNATA are independent of the MoO_3 thicknesses X and are well fitted with the SCLC Eq. (1) (Figs. 3a–c), indicating that the J–V characteristics are controlled by the SCLCs and the junctions of ITO/m-MTDATA, ITO/$Ir(ppy)_3$, and ITO/2-TNATA are already Ohmic contacts without the MoO_3 buffer layer. We assume that the small barrier heights less than ≈0.1 eV no longer affect the J–V characteristics. Indeed, it has been shown that ITO forms ideal hole-injecting contacts with m-MTDATA [21] and 2-TNATA [22], which agree with our results.

On the other hand, the J–V characteristics of TPD, rubrene, and α-NPD are markedly dependent upon the MoO_3 thicknesses X (Figs. 3d–f). The current densities at the MoO_3 thickness of 0 nm are very small due to the relatively large hole injection barrier heights ranging from ≈0.2 to ≈0.4 eV. The current densities increase $\approx 10^4$ times and then decrease $\approx 10^1$ times as the MoO_3 thicknesses are increased. Details of the changes in the J–V characteristics have been discussed in our recent paper [17]. The optimized MoO_3 thicknesses are 1.0 nm for rubrene and 0.75 nm for TPD and α-NPD, which provide the highest current densities for the devices. Since the electron transfer from these HTLs to the MoO_3 layer can be confirmed (the electron transfer characteristics will be discussed later), the marked increase in current density by using the MoO_3 buffer layer is attributable to the interfacial charge generation mechanism as illustrated in Fig. 1. The J–V characteristics at the optimized thicknesses can be fitted with the SCLC Eq. (1).

The J–V characteristics of TRZ-2 and CBP slightly shift to higher current densities by using the MoO_3 buffer layer maybe due to a reduction in hole injection barrier height caused by the high-work-function MoO_3, but cannot be fitted with the SCLC Eq. (1) (Figs. 3g and h), indicating that the J–V characteristics are still controlled by injection-limited currents. Since the ionization energies of TRZ-2 (≈5.68 eV) and CBP (≈5.96 eV) are equal to or higher than the work function of MoO_3 (≈5.68 eV), no charge transfer and no charge generation occur at the HTL/MoO_3 interfaces.

The J–V characteristics of the hole-only devices with various HTL thicknesses (L) ranging from 50 to 800 nm are investigated (see Fig. 4). The optimized MoO_3 thicknesses (X) are used for the devices (0 nm for m-MTDATA, $Ir(ppy)_3$, and 2-TNATA, 0.75 nm for TPD and α-NPD, and 1 nm for rubrene). The J–V characteristics of all the devices can be fitted with the SCLC Eq. (1) when the field dependence parameters summarized in Table 1 are used for the SCLC fitting. The zero field hole mobilities estimated from the SCLC regions are plotted versus the HTL thicknesses in Fig. 5. The zero field hole mobilities are found to gradually increase as the thicknesses of the HTLs are increased.

The zero field mobilities and the field dependence parameters estimated from the SCLC regions are compared with those of m-MTDATA [23], 2-TNATA [22], TPD [24], rubrene [25], and α-NPD [24] measured using a time-of-flight (TOF) technique (Table 1). In this table, we summarize the zero field hole mobilities and the field dependence parameters of the 200 nm HTLs because the zero field hole mobilities are dependent on the film thicknesses and the mobility of the 100 nm α-NPD HTL does not still reach a saturation value. While the SCLC field dependence parameters are almost similar to the TOF field dependence parameters, the SCLC zero field mobilities are about one order of magnitude lower than the TOF zero field mobilities. It has been shown that electron mobilities of tris(8-hydroxyquinoline)aluminum (Alq_3) [26] and 4,7-diphenyl-1,10-phenanthroline (Bphen) [27] and hole mobilities of α-NPD [3] and 2-TNATA [28] depend on their film thicknesses. Chu and Song have attributed the thickness-dependent mobilities to a change in hole trap concentration in organic films [3].

While the J–V characteristics of TPD, rubrene, and α-NPD are dependent upon the MoO_3 thicknesses, the J–V characteristics of m-MTDATA, $Ir(ppy)_3$, and 2-TNATA

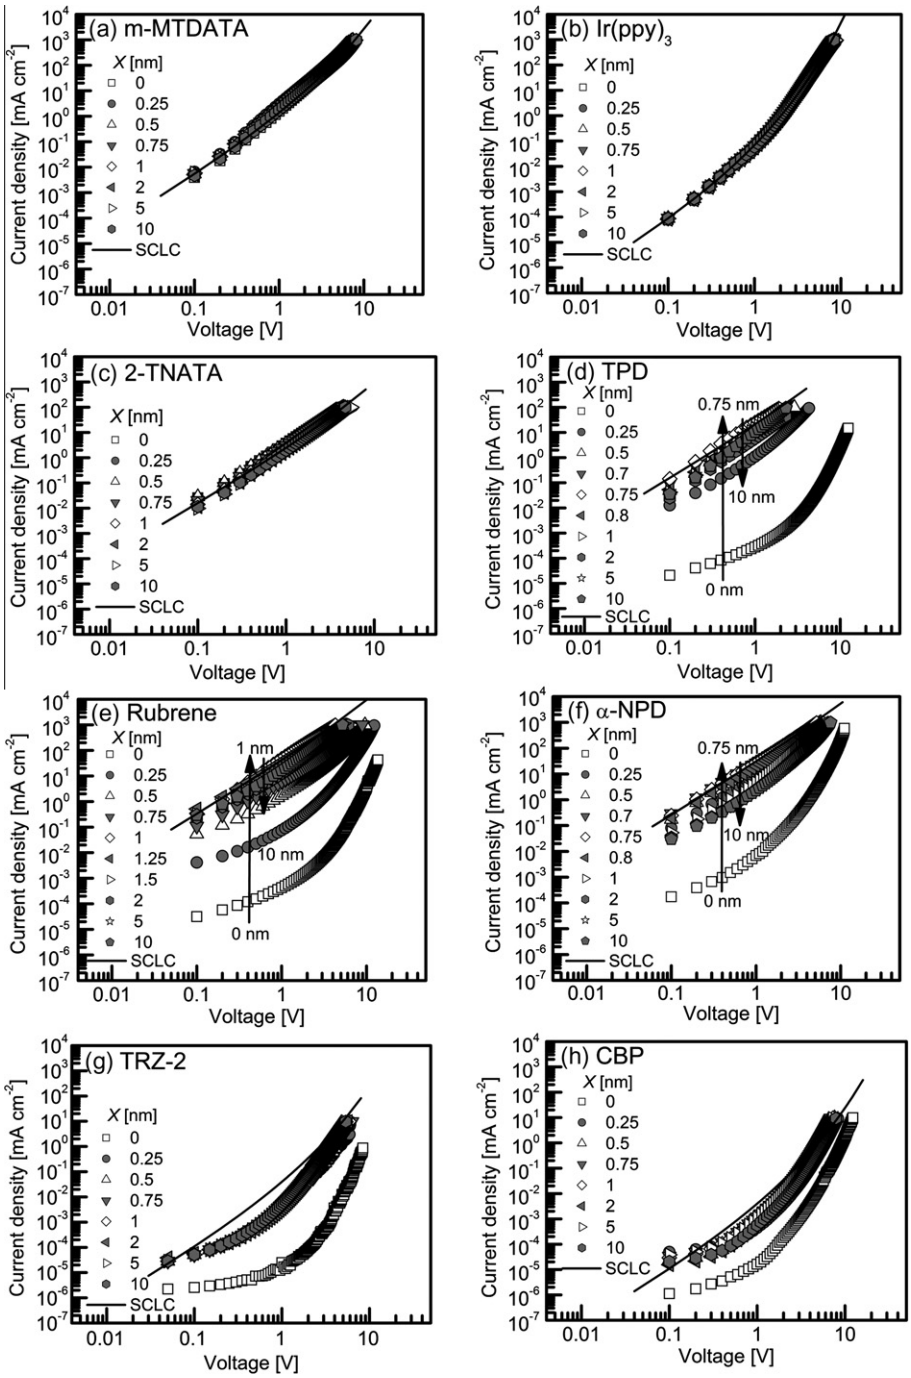

Fig. 3. *J–V* characteristics of hole-only devices, where 100 nm HTL layers are changed from (a) m-MTDATA, (b) $Ir(ppy)_3$, (c) 2-TNATA, (d) TPD, (e) rubrene, (f) α-NPD, (g) TRZ-2, and (h) CBP and MoO_3 thicknesses (*X*) are changed from 0 to 10 nm. Solid lines represent SCLCs.

are independent of the MoO_3 thicknesses as shown in Fig. 3. One possible explanation for the independent and dependent *J–V* characteristics is a difference in hole mobility between the organic layers. The layers of m-MTDATA, $Ir(ppy)_3$, and 2-TNATA have lower hole mobilities than the other layers of TPD, rubrene, and α-NPD have as summarized in Table 1. Thus, the *J–V* characteristics of m-MTDATA, $Ir(ppy)_3$, and 2-TNATA are strongly limited by a bulk hole transport process due to their lower mobilities, thereby obscuring the dependency of the *J–V* characteristics of m-MTDATA, $Ir(ppy)_3$, and 2-TNATA.

Built-in potential (a difference between Fermi levels of an anode and a cathode) sometimes makes difficult to analyze charge injection and transport characteristics of or-

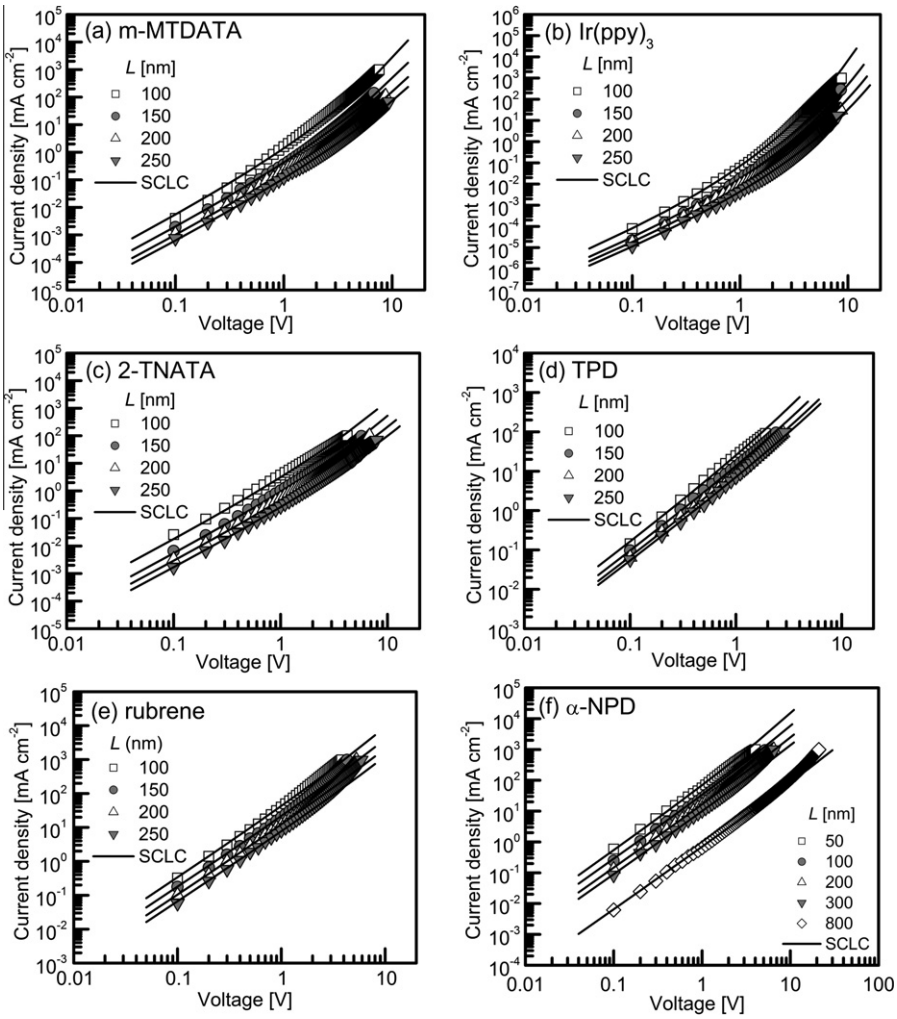

Fig. 4. *J–V* characteristics of hole-only devices with structures of glass substrate/ITO anode (150 nm)/MoO_3 buffer layer (*X* nm)/(a) m-MTDATA, (b) Ir(ppy)$_3$, (c) 2-TNATA, (d) TPD, (e) rubrene, or (f) α-NPD HTL (*L* nm)/MoO_3 EBL (10 nm)/Al cathode (100 nm). HTL thicknesses (*L*) are changed in range from 50 to 800 nm. Optimized MoO_3 thicknesses (*X*) are used (0 nm for m-MTDATA, Ir(ppy)$_3$, and 2-TNATA, 0.75 nm for TPD and α-NPD, and 1 nm for rubrene). Solid lines represent SCLCs. Field dependence parameters (β) summarized in Table 1 are used for SCLC fitting. Estimated zero field hole mobilities are shown in Fig. 5.

ganic electronic devices [29,30]. To investigate whether the built-in potential is present or not in our devices, the *J–V* characteristics of the hole-only devices with the structures of glass substrate/ITO anode (150 nm)/2-TNATA HTL (100 nm)/MoO_3 EBL (0 or 10 nm)/Al cathode (100 nm) are compared in the forward and reverse bias directions (Fig. 6). The reverse biased ITO/2-TNATA/Al device has much smaller current densities than the other devices have due to large charge injection barriers for both electrons and holes. No current flow is observed in a low voltage region of the forward biased ITO/2-TNATA/Al device due to the presence of the built-in potential. The built-in potential is roughly estimated to be ≈1.0 eV from a difference between the work functions of ITO (5.02 ± 0.02 eV) and Al (≈4.0 eV [19]). However, the estimated value is larger than the observed turn-on voltage (≈0.6 V), perhaps resulting from that actual built-in potential is slightly changed by a vacuum level shift [19].

Otherwise, the *J–V* characteristics of the forward and reverse biased ITO/2-TNATA/MoO_3/Al devices are completely overlapped and well explained with the SCLC Eq. (1), indicating that the influence of the built-in potential on the *J–V* characteristics is completely negligible by using the MoO_3 EBL. We assume that a Fermi level of MoO_3 is pinned near a hole-transport level of 2-TNATA due to the electron transfer from the 2-TNATA HTL to the MoO_3 layer, resulting in the completely overlapped *J–V* characteristics in both bias directions.

3.2. Electron transfer characteristics

To confirm the HTL-to-MoO_3 electron transfer under no electric field, the UV–vis–NIR absorption spectra of the 50 nm intrinsic organic films and the 50 nm composite films of organic:MoO_3 (1:1 by mol) on the quartz substrates are measured (Fig. 7). The absorption peaks appear

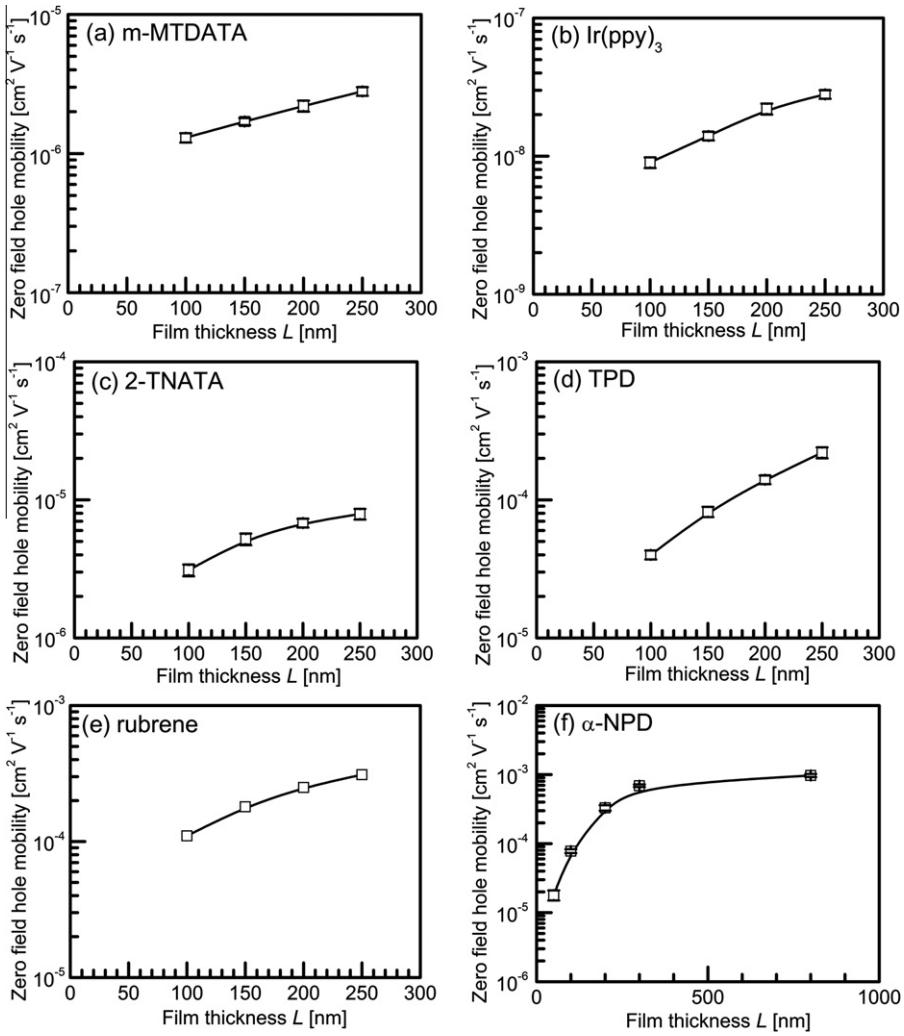

Fig. 5. Zero field hole mobility (μ_0)–film thickness (L) characteristics of (a) m-MTDATA, (b) Ir(ppy)$_3$, (c) 2-TNATA, (d) TPD, (e) rubrene, and (f) α-NPD. Zero field hole mobilities of HTLs are estimated by fitting J–V characteristics shown in Fig. 4 with SCLC Eq. (1).

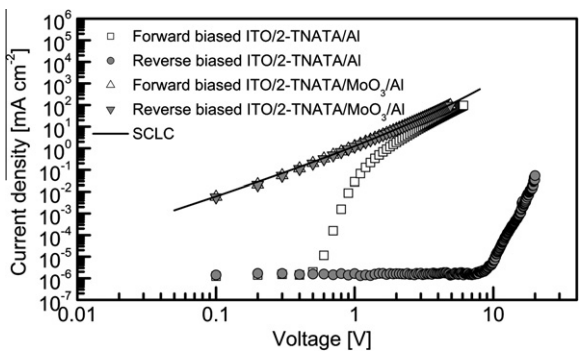

Fig. 6. J–V characteristics of 2-TNATA hole-only devices in forward and reverse bias directions. Solid line represents SCLC.

in the NIR region for the composite films (m-MTDATA, Ir(ppy)$_3$, 2-TNATA, TPD, rubrene, and α-NPD) when compared with their intrinsic films. The NIR peaks are attributable to generation of radical cations of HTL molecules, resulting from the electron transfer [31,32]. On the other hand, there is no absorption peak in the NIR region for the other composite films (TRZ-2 and CBP). These results indicate that the ionization energies of the HTLs must be lower than the work function of MoO_3 to induce the HTL-to-MoO_3 electron transfer.

A reduction in hole injection barrier height by using a MoO_3 buffer layer has been reported by analyzing electronic structures of electrode/MoO_3/organic interfaces using photoelectron spectroscopy [13–16] although it is still difficult to estimate actual hole injection barrier heights under operation of devices. Thus, the standard hole injection mechanism from the ITO anode to the HTL through the MoO_3 layer cannot be ruled out. However, since the electron transfer characteristics (Fig. 7) are in good agreement with the SCLC characteristics (Figs. 3 and 4), the interfacial charge generation mechanism surely occurs in addition to the hole injection mechanism. Since the charge generation rate is found to be high enough to real-

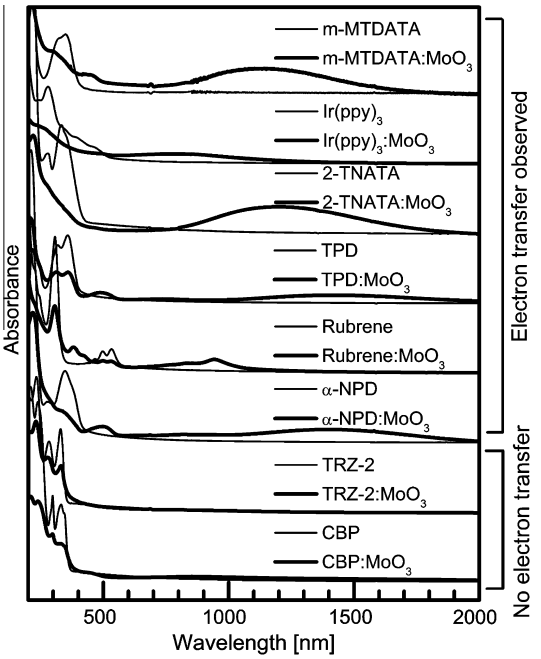

Fig. 7. UV–vis–NIR absorption spectra of intrinsic organic films and composite films of organic and MoO_3 (1:1 by mol).

ize the SCLCs (this evidence will be presented in the next section), we are able to conclude that the charge generation is a more dominant mechanism than the hole injection when the MoO_3 buffer layer is used.

The work functions of MoO_3 reported thus far are in a wide range from 5.3 to 6.86 eV [11,12,14–16,33]. Also, CBP-to-MoO_3 electron transfer has been confirmed from photoelectron spectroscopy under an ultra-high vacuum condition [14], which is in contrast to no CBP-to-MoO_3 electron transfer observed here. It has been shown that a major molecular species vaporizing is polymeric, $(MoO_3)_n$ [15,34] and oxygen vacancy defects are present in the resulting oxide films [16,33,35]. We assume that preparation conditions of the oxide films (such as a deposition rate and a partial pressure of oxygen inside a vacuum evaporator) affect degrees of the clustering and the oxygen vacancy defects, which further affect the work functions and the electron transfer characteristics. It has been shown that the amount of the oxygen vacancy defects are changed by annealing the oxide films in a vacuum [16] and exposing the oxide films to ambient air [35]. Also, Meyer et al. have reported that contamination by air exposure of the oxide film reduces its work function by about 1 eV [36]. We suggest that the charge generation is possible for the higher-ionization-energy materials (such as TRZ-2 and CBP) if the preparation conditions are favorably controlled and/or other higher-work-function metal oxide is used (such as WO_3 (6.4 eV) [37]).

3.3. Interfacial charge generation

To obtain the evidence of the interfacial charge generation, the *J–V* characteristics of two types of the devices are measured and compared (glass substrate/ITO anode (150 nm)/*n*-type C60 layer (30 nm)/MoO_3 buffer layer (0 or 5 nm)/*p*-type α-NPD HTL (100 nm)/MoO_3 EBL (10 nm)/Al cathode (100 nm)) (Fig. 8). Although it has been reported that a thin C60 layer (2.5 nm) improves hole injection from ITO [3], the use of the thick C60 layer (30 nm) between the ITO layer and the α-NPD layer extremely lowers the current densities of the C60/α-NPD device (Fig. 8a) due to effective blocking of hole injection from the ITO layer to the high-ionization-energy C60 layer (Fig. 8b). Surprisingly, the current densities markedly increase by inserting the MoO_3 layer between the C60 layer and the α-NPD layer. This increase in current density originates from the interfacial charge generation mechanism, which is composed of α-NPD-to-MoO_3 electron transfer to form electron–hole pairs, separation of the electron–hole pairs under an electric field, and transit of electrons and holes to corresponding electrodes through a conduction band (or gap states) of MoO_3, an electron-transport level of C60, and a hole-transport level of α-NPD (see Fig. 8b). A similar phenomenon has been observed in stacked OLEDs with a charge generation layer consisting of alkali metal and transition metal oxide [33,38,39]. Since there is negligible hole injection from the ITO layer for these devices, it

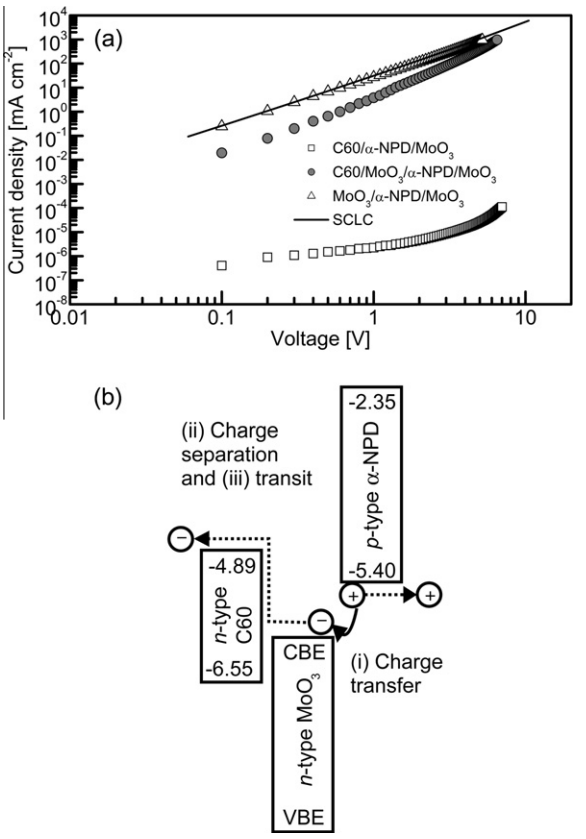

Fig. 8. (a) *J–V* characteristics of devices based on C60 and α-NPD. Solid line represents SCLC. (b) Energy-level diagrams showing charge generation mechanism of this device. Electron injection barrier at C60/MoO_3 interface is roughly estimated to be ≈0.79 eV from difference between electron affinity of C60 (≈4.89 eV) and work function of MoO_3 (≈5.68 eV).

is suggested that the charge generation rate is high enough to realize the SCLC. The current densities of the C60/MoO_3/α-NPD device are slightly lower than a SCLC level observed in the α-NPD device with the optimized MoO_3 thickness (glass substrate/ITO anode (150 nm)/MoO_3 buffer layer (0.75 nm)/α-NPD HTL (100 nm)/MoO_3 EBL (10 nm)/Al cathode (100 nm)). The lower current densities would be due to the presence of an electron injection barrier at the C60/MoO_3interface as shown in Fig. 8b.

4. Conclusions

J–V characteristics of organic hole-only devices having a MoO_3 buffer layer and UV–vis–NIR absorption spectra of composite films of organic and MoO_3 are investigated when HTL materials with different ionization energies are systematically changed. We find that SCLCs of a wide variety of HTLs are observed and their hole mobilities can be estimated using a SCLC analysis when ionization energies of HTLs are lower than a work function of MoO_3. From comparison of the *J–V* characteristics and the UV–vis–NIR absorption spectra, the HTL-to-MoO_3 electron transfer is crucial to realizing the SCLCs. Thus, we can attribute the observation of the SCLCs by using the MoO_3 buffer layer to an interfacial charge generation mechanism (composed of charge transfer, separation, and transit as shown in Fig. 1). Finally, we would like to mention that the interfacial charge generation is a versatile technique used to eliminate an influence of hole injection barriers on *J–V* characteristics of organic electronic devices.

ABSTRACT

An alternating current driven electroluminescence (EL) device consisting of a phosphor dispersed in a polymer matrix device was fabricated as a tandem structure. This structure can be formed by duplicating the emitting and conducting layers. The EL device with the tandem structure, particularly the device with the triple emitting layer, was six times brighter than (1460 cd/m^2 at an alternating voltage application of 50 V) the structure with a single emitting layer. This tandem structure plays important roles by increasing the chance of electron–hole tunneling into the phosphor with leading to an increase in brightness by combining the light emitted from several emitting layers in a device. In addition, the adoption of a spin-coating method for the deposition of an emitting layer can allow the production of a dielectric part on the lower-lying emitting phosphor powder particles. The implementation of a dielectric part and emitting part by one spin-coating procedure simplifies the overall fabrication process, particularly for the tandem structure. The significant increase in brightness with each additional emitting layer as well as a facile fabrication process would help to make the EL device a competitive candidate in future displays and lightings.

1. Introduction

Recently, considerable research effort has been poured into future potential flat panel displays [1–5] beyond liquid crystal displays and plasma display panels, which are both commercially available. Among these candidates, alternating current (AC) thick-film powder electroluminescence (EL) devices have attracted interest owing to their low cost and a simple fabrication process with the ability for mass production [6–9]. This EL structure is composed of a top electrode, an emitting layer, a dielectric layer, and a transparent electrode. Since AC EL is light emission under a high electric field, a dielectric layer is needed to prevent catastrophic dielectric breakdown in the device. Despite the merits of EL devices, such as an easy fabrication process and scalability to a large size for EL displays, the practical applications of AC thick-film EL devices are currently limited to backlighting in cellular phones. This is mainly due to the insufficient brightness of EL devices compared to other types of flat panel displays. More research on materials and structures for these devices will help overcome the key issues in EL, such as low brightness, relatively short lifetime and high operation voltages [10–13].

In this paper, we propose a tandem structure for an AC thick-film EL device with a multiple emitting layer. This tandem structure can help overcome one of the main weak

doi:10.1016/j.orgel.2010.12.020

points of the EL device, i.e., low brightness. This structure enhances the brightness of an EL device by combining the light emitted from several emitting layers (in this study up to three layers), which is similar to semiconductor multiple quantum wells or tandem solar cells [14,15]. In addition, since the capacitance of a device is increased by the parallel connection of the component emitting layers, the tandem structure would increase the chance of electron–hole tunneling in the phosphor leading to an increase in brightness. To simplify the fabrication process, a spin-coating method was also used to deposit the emitting layer. Since the dielectric part was formed on the phosphor powder particles during spin-coating, the spin-coating method can reduce the fabrication process to a single processing step instead of the two steps generally required [16].

2. Experimental

Fig. 1 shows the structure of the tandem EL device. The emitting layers are multiply stacked and the transparent conducting electrode layers are sandwiched between the adjacent emitting layers. The fabrication process for the tandem structure is as follows. An emitting layer was spin-coated on an indium doped tin oxide (ITO)-coated glass substrate at 1000 rpm for 40 s using the emitting paste composed of ZnS:Cu,Cl EL green phosphor powder (Sylvania, GG44) and an organic binder (EL-Korea, ELPR530) as a polyvinylidene fluoride (PVDF) based polymer [17]. The phosphor to binder weight ratio is 1/2. The spin-coated emitting layer was dried at 130 °C for 30 min, which yielded two separate layers by gravitation. The organic-based dielectric part was positioned on the emitting part, which was composed of phosphor particles. This spin-coating process simplified the fabrication of a tandem structure which will be explained later. An ITO transparent conducting layer was sputtered on top of the emitting layer. For a tandem structure, the coating process for the emitting and conducting layers was carried out repetitively. In this study, three different tandem structures were prepared – one, two, and three emitting layer(s). After forming the multiple emitting layer, an aluminum thin film as a top electrode was deposited on it by DC sputtering.

The light emission characteristics of the three different structured EL devices were measured under ambient conditions by varying the applied AC voltage and frequency.

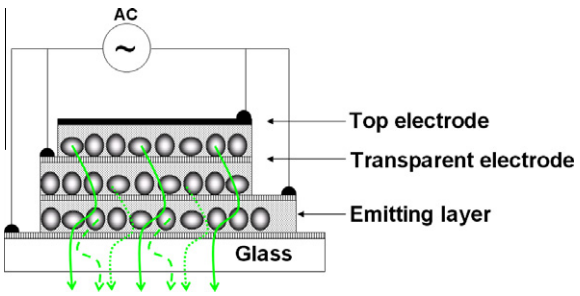

Fig. 1. Schematic diagram of an EL device with a triple emitting layer. The component emitting layers were connected to a power supply in parallel.

Fig. 1 shows the measurement system providing the electrical power to the device. In the tandem structure, the electrical wiring was connected in parallel to each emitting layer. The middle transparent electrode was shared by the neighboring upper and lower emitting layers. A sinusoidal AC voltage generated by the combination of a conventional function generator (Agilent, 33250A) and amplifier (Trek, P0610B-K) was applied to the device. An oscilloscope (Hewlett–Packard, 400D) was used to monitor the applied voltage. All AC readings are the peak-to-peak values. The absolute brightness was measured using a luminance colorimeter (Topcon, BM-7). After measuring the light emission, the morphology of the tandem structure of the emitting layers and intervening conducting layers was examined by field emission scanning electron microscopy (FE-SEM, Hitachi S-4200).

3. Results and discussion

The spin-coating method allows the deposition of two parts (an emitting phosphor part and a dielectric part in an emitting layer) in only one spin-coating because the tandem structure inherently requires the deposition of many component layers compared to the conventional single emitting layered EL structure. After spin-coating and consecutive drying of the emitting layer, most of the remaining organic binder, which would become an organic-based dielectric part, was located on and beside the phosphor powder particles due to the low viscosity of the emitting paste. However, virtually no organic binder was located under the phosphor powder particles due to the difference in density between the powder (4.1 g/cm^3) and binder (1.8 g/cm^3) during the spin-coating process. As shown in Fig. 2, this separation yielded the simultaneous formation of a phosphor-based emitting layer part at the low region and an insulating dielectric layer part at the upper region. Therefore, the deposition of a dielectric layer can be omitted when this spin-coating process is used. This omission is difficult to obtain using the screen-printing method because the high-viscosity nature of the emitting paste for printing results in incomplete coverage over the phosphor particles. This incompleteness in coverage leads to the formation of pinholes in the emitting layer, which is a serious failure mechanism in EL devices [3]. This can be explained by the fact that the paste for the spin-coating method is thinner, i.e., lower viscosity, than that for the screen-printing method due to the difference in the film deposition mechanism. The screen-printing method has practical problems for the fabrication of a tandem structure because many deposition processes are necessary for the deposition of dielectric layers. Furthermore, a transparent electrode can be broken easily by the squeeze pressure during the deposition of emitting and dielectric layers in the screen-printing method. Consequently, the spin-coating is a suitable method for the tandem structure of an EL device.

In AC thick-film EL devices, the total thickness of the emitting and dielectric layers is important because it determines the intensity of the electric field for a given voltage. Since the brightness of an EL device is a function

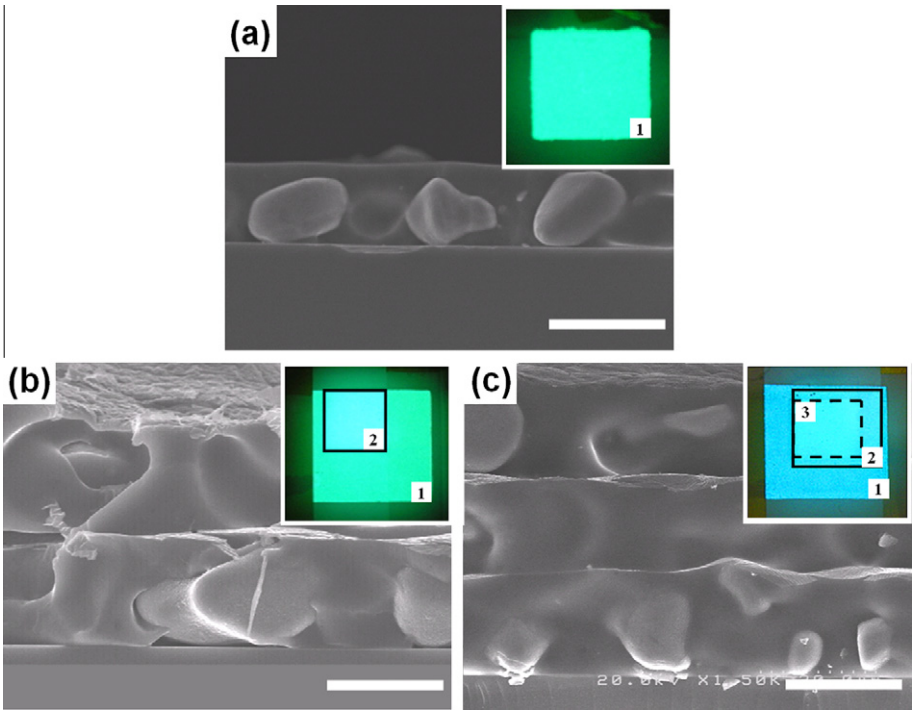

Fig. 2. SEM images of (a) single-, (b) double-, and (c) triple-layered structures on an ITO substrate by the spin-coating method. The scaling bars in the lower part of three SEM images correspond to 20 μm. The insets show optical images of light emission for the single-, double-, and triple-layered structure taken by a digital camera, where the Arabic numeral corresponds to the number of emitting layers. Although the emission colors of the EL device were taken by a digital camera, they have the same color (505 nm). This was caused by the automatic settings in the digital camera, which failed to match the precise color.

of the applied electric field, the brightness can be strongly affected by the layer thickness [18,19]. This suggests that using small phosphor powder particles, i.e., reduced thickness of the emitting layer, would result in high brightness. For this reason, an emitting layer as thin as possible was fabricated, i.e. one monolayer of phosphor particles. Fig. 2(a) shows a cross-sectional SEM image of the single emitting layer structure, where the mean thickness of the layer was approximately 15 μm. The average thickness of the two components in the emitting layer, i.e., the phosphor particles part and dielectric part, which was formed mostly on and beside the phosphor particles, were approximately 13.5 and 1.5 μm, respectively (see Fig. 2). The same AC voltage was applied to each emitting layer of the EL device due to the *parallel* electrical wiring to the layers, as shown in Fig. 1, despite the serial geometric stacking of the layers. Therefore, the brightness of a tandem structure was the combination of the similar brightness of each emitting layer. The insets in Fig. 2 show emission images of a single, double and triple emitting layered structure taken by a digital camera. The emission images of Arabic numerals 1, 2 and 3 are for the single-layered, double-layered (regions marked by the solid line in Fig. 2(b) and (c)) and triple-layered structure (region marked by the dotted line in Fig. 2(c)), respectively. The brighter image comes out from the structure with an additional layer (see the insets in Fig. 2), which is explained quantitatively in Fig. 3.

Fig. 3 shows a plot of the brightness as a function of the voltage (the frequency) at a fixed frequency (voltage) at 400 Hz (50 V) for the tandem structures. Although the brightness of the single-layered structure was 100 cd/m^2, that of the double- and triple-layered structures was 170 and 230 cd/m^2, respectively, at 150 V and 400 Hz, as shown in Fig. 3(a). This does not follow the increase in brightness with increasing number of emitting layers precisely. This may be caused by the fact that the light was absorbed or scattered by other components when the light passed through the other component layers. However, when the operation of the tandem structures moved to a high frequency of 12 kHz, the brightness increased substantially to 830 cd/m^2 (1460) for the double- (triple-) layered structure, even at a low voltage of 50 V (see Fig. 3(b)). In contrast, the single-layered structure showed a brightness of only 230 cd/m^2, indicating a more than threefold increase for the tandem structure. Since the emission mechanism in ZnS:Cu,Cl phosphor is different at low and high frequencies [20–23], this might affect the different multiple increases in brightness of the tandem structure. At the low frequency, a green emission (520 nm) transition occurred from Cl on a S site (Cl_S) to Cu on a Zn site (Cu_{Zn}) [6]. However, at high frequency, a blue transition (440 nm) occurred from Cl_S to interstitial Cu (Cu_i) [23].

All the devices in Fig. 4(a) showed a decrease in capacitance, as measured using a LCR meter at 0.1 V, with increasing frequency. The magnitude of the capacitance at the actual driving voltage of the EL device ranged from 30 to 150 V, which might be different from the measured

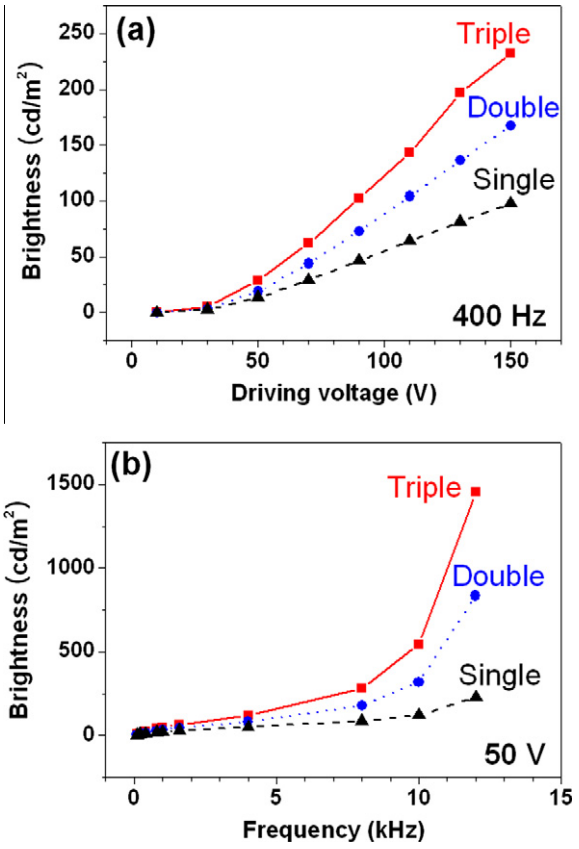

Fig. 3. (a) Brightness vs. voltage and (b) brightness vs. frequency curves of the tandem EL device using the emitting paste.

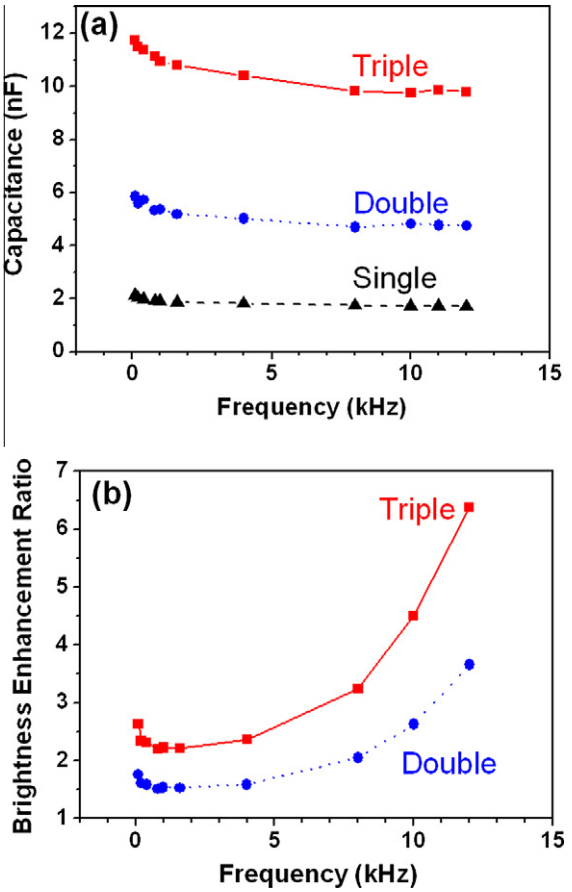

Fig. 4. (a) Capacitance vs. frequency curves of the tandem EL device at 0.1 V. (b) The ratio of brightness enhancement vs. frequency curve using the single to double and single to triple ratios in the tandem EL device.

capacitance at 0.1 V. However, it is reasonable to assume that the tendency of the measured capacitance reflects the qualitative behavior of the actual capacitance among the devices operated at 30–150 V. The capacitance of the single, double and triple emitting layer at a frequency of 12 kHz was 1.7, 4.7 and 9.8 nF, respectively. This can be explained by considering the capacitive characteristics of the emitting layer in the EL device. The capacitance was increased by the emitting layer due to their parallel connection in the electrical wiring. Fig. 4(b) presents the brightness enhancement ratios of the double-layered (circular line) and triple-layered (square line) structures to the single-layered structure. At frequencies <1 kHz, the enhancement ratio was decreased slightly, where the range of brightness enhancement of the single-layered to double- (triple-) layered structures was 1.5–1.7 (2.1–2.6). The ratios of the brightness enhancement increased at frequencies >1 kHz (the range of double to single: 2.1–3.7 and triple to single: 3.2–6.3). The brightness enhancement of the tandem structured EL device at the high capacitance and frequency can be interpreted as follows. In the ZnS:Cu,Cl phosphor, Cu_xS conducting needles are formed by the Cu concentration exceeding the solubility limit in ZnS. Electrons and holes are injected into the host lattice (ZnS) at opposite ends of each Cu_xS needle in the ZnS–Cu_xS interface by the high local electric field [24,25]. Electrons are trapped in the shallow Cl_S donor site, whereas holes are trapped by the Cu recombination centers. When the electric field is reversed, the emitted electrons recombine with the trapped holes to produce light. Therefore, the increase in capacitance of the tandem EL device led to a high probability of tunneling charge carriers at the interface between the ZnS–Cu_xS interface. This large charge density due to the increased capacitance based on the equation of charge, $Q = CV$, would increase the brightness of an EL device. Furthermore, the high frequency applied to an EL device would increase the chance of electron–hole pair recombination because light emission from an EL device normally occurs at the moment of the field reversal [3]. As a result, the brightness of the tandem EL devices is proportional to the capacitance by the increased electron–hole tunneling and recombination at a high frequency of 12 kHz. This would lead to large increase in the brightness of the tandem EL devices. The ratio of the increment brightness of single-layered to double- (triple-) layered structure was 3.6 (6.3) at a frequency of 12 kHz. At the same frequency, the ratio of the increment capacitance of the single-layered to double- (triple-) layered structure was 2.8 (5.7).

The capacitive reactance, X_C, was calculated to further examine the dependency of the brightness on the

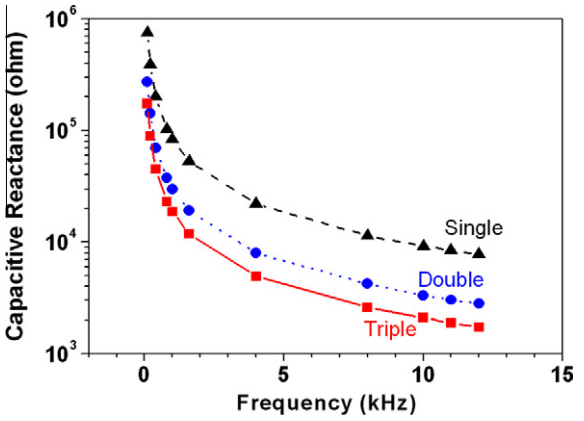

Fig. 5. Capacitive reactance vs. frequency curve with the *y*-log scale for the tandem EL device.

capacitance and frequency in the tandem structure. X_C can be written as $X_C = 1/(2\pi fC)[\Omega]$, where f is the frequency of an applied voltage and C is the capacitance of an EL device. This X_C value has a strong influence on the brightness of an EL device [10]. A decrease in X_C (high capacitance and frequency) can lead to an increase in the tunneling charge carriers at the ZnS–Cu_xS contact. Fig. 5 shows the capacitive reactance as a function of the various frequencies at a fixed voltage of 50 V. X_C for the single, double, and triple emitting layer was found to be 7.8×10^3, 2.8×10^3, and $1.7 \times 10^3\,\Omega$, respectively, at a frequency of 12 kHz. Figs. 3(b) and 5 show that the brightness increased rapidly with a substantial decrease in X_C. Similar results were reported in Ref. [10]. The EL device suggests that a low X_C value generally results in high brightness. The enhancement in the brightness of the double and triple emitting layer along with the simple lamination process of the spin-coating has potential for EL devices in flat panel displays.

4. Conclusion

A tandem structure for powder EL devices was fabricated by spin-coating an emitting paste composed of ZnS:Cu,Cl green phosphor powder particles and a PVDF based organic binder. Three different structures were prepared with one, two, and three emitting layer(s). The capacitance of the tandem EL device increased due to their parallel connection in the electrical wiring. This tandem structure EL device increases the probability of electron–hole tunneling into ZnS lattice and recombination electron–hole, and combines the light emission from each emitting layer. An approximately six fold increase in brightness for triple emitting layer was obtained at the high frequency regime. In addition, the tandem EL device was fabricated using a fast and simple process because the emitting phosphor part and dielectric part in the emitting layer were deposited by a single spin-coating process. This tandem structure can be a potential candidate for flat panel EL displays.

ABSTRACT

We investigate the energy level alignment and the Fermi level pinning mechanism at organic donor–acceptor heterojunctions interfaces by using the model organic–organic heterojunctions (OOHs) with well-defined molecular orientation of the standing copper (II) phthalocyanine (CuPc) and zinc phthalocyanine (ZnPc) films on the standing copper-hexadecafluoro-phthalocyanine (F_{16}CuPc) thin films on SiO_2. We identify two distinct regions for the energy level alignment by *in situ* ultraviolet photoelectron spectroscopy investigation. In region (I) where the work function (WF) of the underlying substrate is larger than the ionization potential (IP) of the top organic layers, the substrate Fermi level is pinned at the leading edge of the HOMO peak accompanied by a decreasing of the WF; in region (II) where the WF is smaller than the IP of the top organic layers, a downward shift of both the HOMO and vacuum level is observed. In connection with the defect induced gap states, we provide a detailed explanation for this thickness dependent energy level alignment and Fermi level pinning mechanism at the organic donor–acceptor OOH interface.

1. Introduction

Understanding the energy level alignment at organic–organic heterojunction (OOH) interfaces is crucial for organic electronic devices, such as OOH-based organic photovoltaic cells (OPVs), organic photodiodes and organic light-emitting diodes (OLEDs). It is of key importance for determining the electron and hole injection barriers in OLEDs or open circuit voltages and charge collection in OPVs [1–6]. Intensive research efforts have been devoted to establishing a general mechanism that governs the energy level alignment at these interfaces with limited success [4–14]. Various models, including the integer charge transfer (ICT) [10] model and the induced density of interface states (IDIS) [8,15] model, have been proposed. It is also argued that the tiny density of gap states, which is induced by defects and/or disorder in the molecular packing structure, determine the interfacial energy level alignment as well as the position of the highest-occupied-molecular-orbital (HOMO) with respect to the Fermi level [8,12,16,17]. Moreover, the highly anisotropic nature of π-conjugated organic molecules leads to the orientation dependent charge transport, as well as the electronic structures of highly ordered organic thin films, such as ionization potential (IP) of organic films and the interfacial dipole formation at the donor–acceptor OOH interfaces [18–22]. These can further complicate the understanding of the energy level alignment at the OOH interfaces. Therefore, it is necessary to carry out detailed investigation to understand the energy level alignment mechanism at the OOHs with well-defined supramolecular arrangement or molecular orientation.

Using well-oriented polar phthalocyanine (Pc) monolayers on graphite surface to control the substrate work function, Fukagawa et al. [12] have demonstrated the role of the IP in vacuum-level alignment at organic semiconductor interfaces. When work function of substrate is smaller than the IP of the standing pentacene films, the vacuum-level alignment can be observed; whereas for substrate work functions exceed the IP of the pentacene films, the Fermi level of the substrate is pinned with the HOMO of the pentacene films due to spontaneous electron transfer under thermodynamic equilibrium. Similar pinning effect relative to the substrate Fermi level was also observed by Koch et al. [23] for pentacene on several polymer substrates with different work functions, due to a charge transfer reaction between neutral pentacene molecules and poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonic acid) (PEDT/PSS) substrate cations in the presence of sulfonate moieties. However, in both cases the thickness of the pentacene thin films is no more than 2.0 nm corresponding to one or two monolayer of the standing

pentacene films. On the other hand, according to the ICT model [10], with the increasing thickness of the organic thin films (bulk structure, more than 10 nm), the Fermi level of the substrate is found to be pinned with the positive (negative) integer charge transfer states, which usually lies a few hundred meV above (below) the HOMO (LUMO) edge. In this article, in order to answer this discrepancy, we use *in situ* high resolution ultraviolet photoelectron spectroscopy (UPS) to study the energy level alignment mechanism at selected donor–acceptor OOH interfaces with different thickness, including the model OOHs with well-defined molecular orientation of the standing copper (II) phthalocyanine (CuPc) and zinc phthalocyanine (ZnPc) films on the standing copper-hexadecafluoro-phthalocyanine (F_{16}CuPc) thin film on SiO_2.

2. Experiment

Synchrotron-based *in situ* UPS experiments were carried out at the SINS beamline of the Singapore Synchrotron Light Source (SSLS) [24]. Vacuum level (VL) shifts were determined from UPS spectra at the low-kinetic energy onset (secondary electron cut-off) using photon energy of 60 eV with −5 V sample bias. Vacuum-sublimation purified F_{16}CuPc, CuPc and ZnPc molecules were thermally evaporated onto a substrate of Si(1 1 1) with native oxide (referred as SiO_2) held at room temperature in the growth chamber. The experimental details can be found elsewhere [24,25]. In order to better resolve the weak density of states near Fermi level, a novel high-precision and low-background UPS system with an electron energy analyzer (MBS, A-1) and a monochromatic Xe Iα source ($h\upsilon$ = 8.437 eV) were employed, while for UPS spectra at the low-kinetic energy onset, −7 V sample bias was applied [16,17]. All the UPS measurements were carried out at normal electron emission mode with the sample held at room temperature.

3. Results and discussion

As previously reported, the CuPc/F_{16}CuPc OOH (on SiO_2) can be considered as a standing OOH, where both CuPc and F_{16}CuPc molecules adopt a standing-up configuration with their molecular π-planes oriented nearly perpendicular to the substrate surface [22]. The evolution of the UPS spectra of CuPc on 5 nm standing F_{16}CuPc film on SiO_2 as a function of CuPc nominal thickness is shown in Fig. 1 for the HOMO (Fig. 1(a) and (b)) and VL (Fig. 1(c)) regions. In order to better reveal the weak density of states near the Fermi level, we plot the valence band spectra on a log intensity scale as displayed in Fig. 1(a) and (b). It is clear that the Fermi level is pinned at the leading edge of the CuPc HOMO for the CuPc thickness below 2 nm. This is accompanied by a downward shift of VL by 0.7 ± 0.02 eV or the reduction of the substrate work function (WF) from 5.25 ± 0.02 to 4.55 ± 0.02 eV, as shown in Fig. 1(c). Above the CuPc thickness of 2 nm, this Fermi pinning is no longer observed and the HOMO peak moves towards the higher binding energy together with a further downward shift of the VL with increasing thickness of CuPc films. As compared to the 2 nm CuPc coverage, both VL and CuPc HOMO edge show downward shift by 0.6 ± 0.02 eV and saturate when the thickness reaches to 12 nm. Similar behaviors have been reported by Hwang et al. previously, who demonstrated that the interface position of molecular levels with respect to the substrate Fermi level can be different from the position deeper in the bulk of the layer. This is attributed to states extending into the organic band gap [26]. The substrate WF, binding energy of CuPc HOMO edge and HOMO peak maximum, and IP (sum of WF and HOMO edge binding energy) of CuPc top layers are summarized in Table 1. Their changes as a function of CuPc nominal thickness are also plotted in Fig. 1(d).

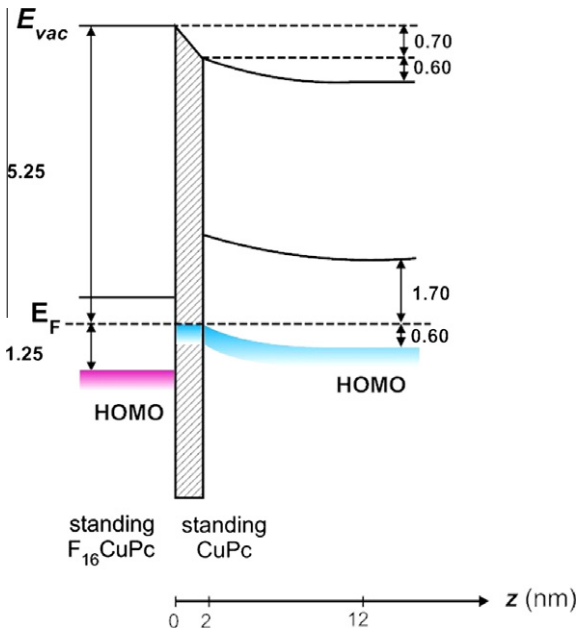

Fig. 2. The energy diagram of the CuPc/F_{16}CuPc interface.

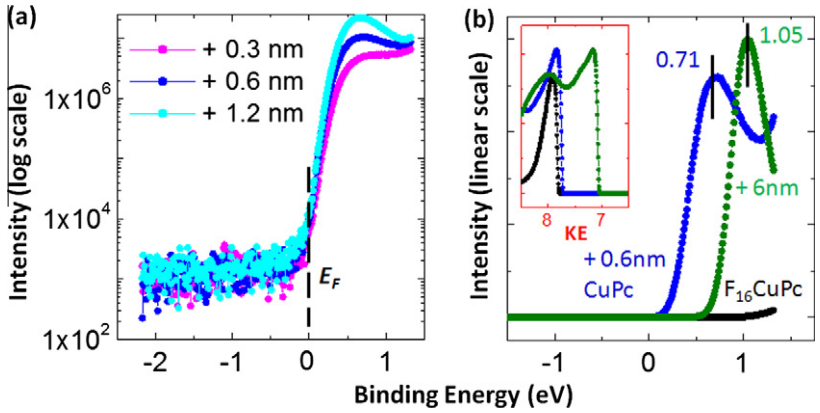

Fig. 3. (a and b) High-precision and low-background UPS spectra with monochromatic Xe Iα source (8.437 eV) during the deposition of CuPc on F_{16}CuPc film on SiO_2 at the low-binding energy part near the E_F region. The intensity in panel (a) is plotted on a log scale to better reveal the HOMO reaching the Fermi edge, while panel (b) is plotted in linear scale. The inset in panel (b) showing the corresponding UPS spectra at the low-kinetic energy region with a sample bias of −7 V.

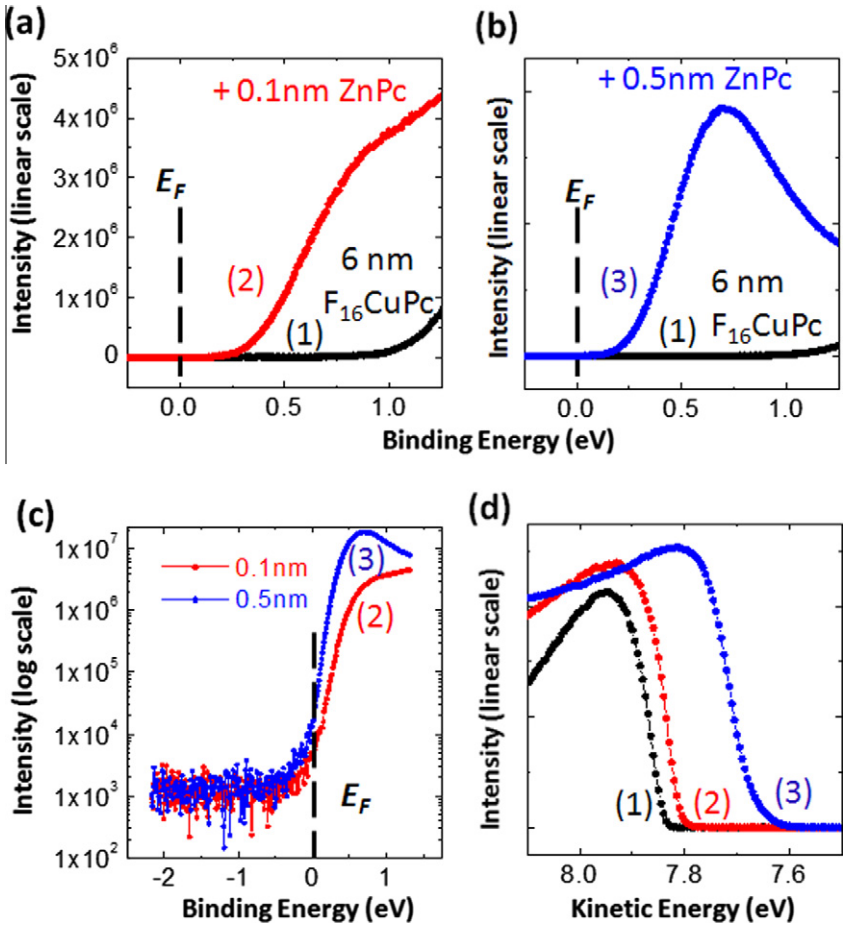

Fig. 4. UPS spectra during the deposition of 0.1 and 0.5 nm ZnPc on F_{16}CuPc film on SiO_2 at (a–c) the low-binding energy part near the E_F region and (d) at the low-kinetic energy part (secondary electron cut-off and the intensity is on a linear scale) with sample bias of −7 V. The intensity in panels (a) and (b) is plotted on a linear scale, while the intensity in panel (c) is plotted on a log scale to better reveal the HOMO reaching the Fermi edge. All spectra are measured with monochromatic Xe Iα source (8.437 eV).

As shown in Fig. 1(d), the energy level alignment at the CuPc/F_{16}CuPc interface can be divided into two regions. Region (I) represents the initial formation stage of the CuPc/F_{16}CuPc heterojunction with the CuPc thickness no more than 2 nm. In this region, the substrate WF is larger than the IP of the standing CuPc film (~4.55 eV) [21,22].

If assuming that the vacuum level is aligned at the heterojunction interface, this leads the HOMO of CuPc lies above the Fermi level, thereby facilitating a spontaneous charge (electron) transfer from CuPc top layer to the substrate Fermi level. This results in a downward shift of the substrate VL or reduction of substrate WF due to the interfacial charge transfer; while at the same time, the substrate Fermi level is pinned at the CuPc HOMO edge. In region (II) where the CuPc thickness is above 2 nm, the substrate WF is smaller than the IP of the standing CuPc film. We observe a downward shift for VL, CuPc HOMO edge and HOMO peak maximum at higher CuPc thickness, i.e., a "band-bending like" feature. For better illustration, the energy level diagram at the interface of CuPc/F_{16}CuPc heterojunction is shown in Fig. 2.

To better demonstrate the pinning of the Fermi level to the CuPc HOMO edge at low CuPc thickness, we used an ultrahigh sensitive and ultralow background UPS system to investigate this OOH [16,17]. Fig. 3(a) shows the UPS spectra with low CuPc coverage (0.3, 0.6 and 1.2 nm, in region (I)) near the E_F region on a log intensity scale. It clearly reveals the Fermi level pinning at the CuPc HOMO edge. By increasing the CuPc coverage to 6 nm (region (II)), the CuPc HOMO peak shifts to the higher binding energy from 0.71 ± 0.02 eV (0.6 nm CuPc coverage) to 1.05 ± 0.02 eV, as shown in Fig. 3(b), which is consistent with our observation of the energy level alignment at the OOH interface in Fig. 1(d).

Similar pinning behavior can be also found for the OOH of ZnPc on the standing F_{16}CuPc film on SiO_2 as shown in Fig. 4. After the deposition of 0.1 nm (Fig. 4(a)) and 0.5 nm (Fig. 4(b)) ZnPc, the substrate WF is 5.20 ± 0.02 and 5.05 ± 0.02 eV (Fig. 4(d)), respectively. It is reported that the IP for ZnPc thin film on C_{60} is 4.79 eV [27]. This

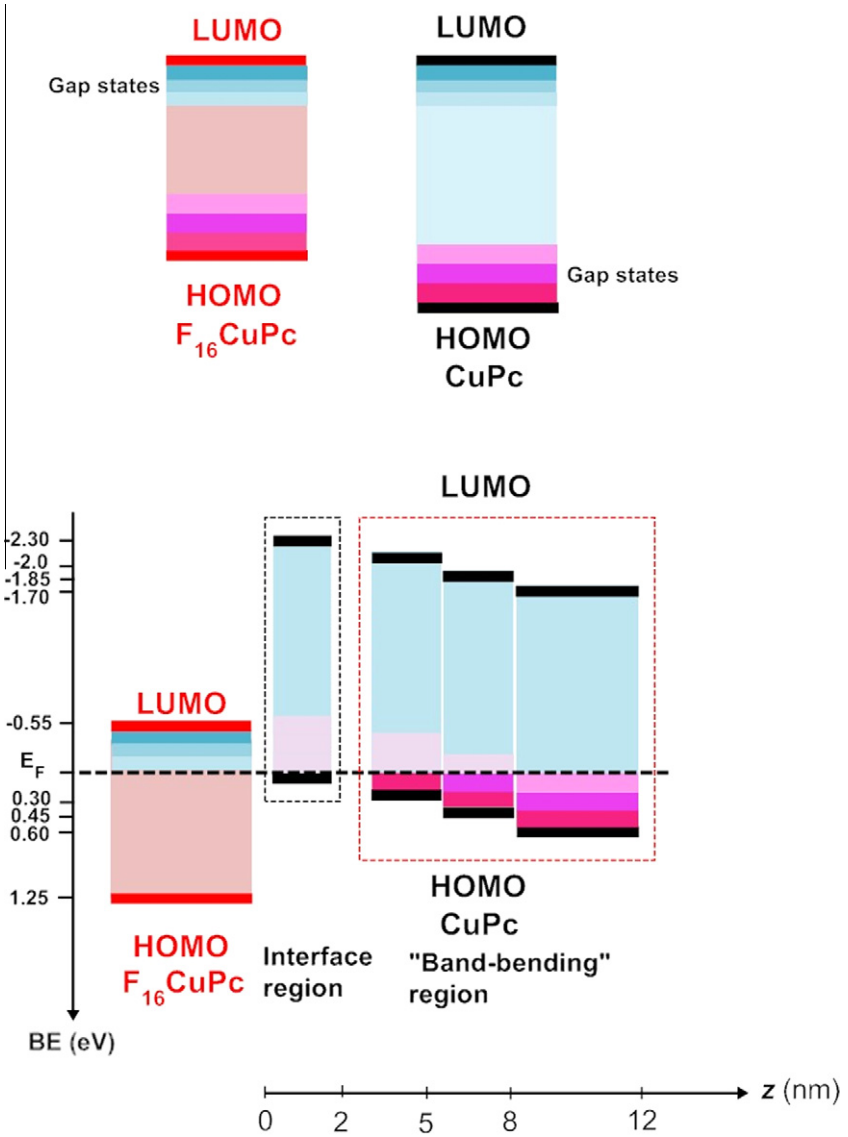

Fig. 5. Schematic illustration of the Fermi level pinning mechanism and the "band-bending" like feature at the CuPc/F_{16}CuPc heterojunction interface.

is smaller than the substrate work function of the standing F_{16}CuPc film on SiO_2. Compared to the experimental results for standing CuPc on F_{16}CuPc, the substrate Fermi level should be pinned at the ZnPc HOMO leading edge, in consistent with our experimental observations as shown in Fig. 4(a) and (b). This pinning effect can be seen more clearly in Fig. 4(c) using the plot on a log intensity scale. As such, we can conclude that the Fermi level will be pinned at the organic HOMO edge if the substrate work function is larger than the IP of the molecule at the OOH interfaces.

Recently, Kalb et al. examined the defects induced gap states extending from the valence-band edge into the band gap for small organic molecules as derived from electrical characteristics of organic field-effect transistors or from space-charge-limited current measurements [28]. Such gap or trap states exist not only in poly-crystalline films but also in crystalline thin films [29–32], even in molecular single crystals [33–35]. For the thermally evaporated CuPc thin films in the present work, there is no doubt that such defects induced gap states exist in the film, as shown by the schematic in the top panel in Fig. 5. The density of these gap states (DOGS) decays exponentially as a function of the energy from the HOMO, i.e., the larger the energy, the weaker the DOGS. It is found that these gap states have a significant effect on the energy level alignment at the OOH interface. As shown in the bottom panel in Fig. 5, when the thickness of CuPc thin films is below 2.0 nm (region I: WF > IP), the work function of the F_{16}CuPc substrate is larger than the ionization potential of the CuPc film. As a result, electrons from the CuPc layer (gap states + HOMO electrons) spontaneously transfer to the underlying F_{16}CuPc layer upon contact. When the integrated electrons over all occupied gap states of the CuPc layer are not sufficient to achieve the thermodynamic equilibrium, electrons in the HOMO of the CuPc layer are also transferred to the F_{16}CuPc layer until the thermodynamic equilibrium is achieved. As the density of states (DOS) of the HOMO is very large and increases steeply with energy near the HOMO leading edge, the Fermi level looks pinned at the HOMO edge after the depletion of all the gap states. It is worthy noting that the Fermi level is actually not pinned at a discrete energy level, but looks pinned at the HOMO leading edge relying on the energy dependence of the DOS. The Fermi level can move but only very slightly with increase in thickness (below 2 nm).

With increasing CuPc thickness above 2 nm (region II: WF < IP), upper part of the gap states of the newly deposited CuPc still locates above the Fermi level, allowing the electron transfer from the upper gap states to the underlying film. However, the degree of the charge transfer is weaker compared to that at the interface region (region I, CuPc thickness below 2 nm). In this case, the integration (or depletion) of a necessary smaller energy range of the occupied gap states can be sufficient for the thermodynamic equilibrium at the interface. As shown in the bottom panel in Fig. 5, the Fermi level can thus be pinned (or located) at an energy position in DOGS above the CuPc HOMO. Further increasing CuPc thickness, the interfacial charge transfer is even weaker, hence the integration of the DOGS over a much smaller energy range is enough to provide necessary electrons to reach the thermodynamic equilibrium at the interface, which result in the Fermi level location/pinning at a position even further away from the HOMO. As a result, the Fermi level moves in the band gap of the CuPc film depending on the distance from the CuPc/F_{16}CuPc interface as shown in Fig. 5. This can well explain the Fermi level pinning observed for the CuPc thickness below 2 nm (region I) and the "band-bending like phenomenon" above 2 nm (region II).

4. Conclusion

Organic donor heterojunctions of CuPc and ZnPc on F_{16}CuPc films on SiO_2 have been used as model systems to understand the interfacial energy level alignment mechanism. By using *in situ* high-resolution UPS measurements, we identify two regions for the interfacial energy level alignment: in region I (low thickness) where the WF of the underlying film is larger than the IP of the top organic layers, the Fermi level is pinned at the HOMO peak leading edge of CuPc or ZnPc and the WF is decreased due to the interfacial charge transfer; in region II (large thickness) where the WF is smaller than the IP of the top organic layers, a downward band-bending like feature is observed at the OOH interface. This observed thickness-dependent Fermi pinning behavior could account for the discrepancies on the Fermi pinning energy often found in literatures (i.e., integer charge transfer state *vs*. tailing gap states), as they essentially were looking into different thickness of the organic films. In connection with the defect induced gap states, we provide a detailed explanation for this thickness dependent energy level alignment and Fermi level pinning mechanism at the organic donor–acceptor OOH interface. The present study can help better understand the energy level alignment mechanism at various OOH interfaces, and hence facilitate the practical applications of organic heterojunction based electronic devices, such as organic light-emitting diodes, bipolar organic field transistors and organic photovoltaic cells.

ABSTRACT

Two carbazole–pyrene derivatives, namely 3,6-dipyrenyl-9-(4′-*tert*-butylphenyl) carbazole (BPyC) and 3,6-dipyrenyl-9-(4′-pyrenylphenyl) carbazole (TPyC), have been designed and synthesized for application in organic light-emitting devices (OLEDs). While the two compounds have similar chemical structures and photoluminescent properties, OLEDs based on them show distinct electroluminescence (EL) spectra. The BPyC-based devices show a single peak saturated blue emission with CIE coordinates of (0.15, 0.18); whereas the TPyC-based devices exhibit two emission peaks at blue and yellow hues with CIE coordinates of (0.22, 0.29). The difference in their EL spectra is attributed to the substitution of the *t*-butyl unit of BPyC with a pyrenyl group to form TPyC, which effectively increases the electron-donating property and results in exciplex formation at its interface with the electron-accepting TPBI. A high external quantum efficiency of 3.11% is achieved in the TPyC-based devices. Influences of chemical structure and fluorescent quantum yield on the efficiency of exciplex emission are discussed.

1. Introduction

Organic light-emitting device (OLED) is emerging as a leading next generation technology for full-color flat-panel displays and ambient illumination sources because of its huge market potential and excellent performance in terms of brightness, operating voltage and color gamut. Incorporation of extrinsic dyes into conductive hosts is an effective way to customize emitting color of OLEDs that is particularly useful for fabricating white OLEDs with two complementary or three primary colors [1,2]. Electroluminescence (EL) in terms of Commission Internationale de L'Eclairage (CIE) coordinates can be fine-tuned and optimized through precise control of dopant concentration and thickness for each light-emitting layer (EML). However, this approach would complicate device configuration as well as fabrication process, and inevitably increases the total manufacturing cost. In addition, the shortened device lifetime due to morphological phase separation caused by operation induced heating is another challenge for doped OLEDs.

Recent studies [3–9] have demonstrated a simple way to tailor the emitting color via interfacial excited-state charge-transfer complex (termed exciplex) formation to control emission peak location and/or intensity by using different binary combinations of electron-donor/hole-transporting materials (HTMs) and electron-acceptor/electron-transporting materials (ETMs), i.e., $h\nu_{\text{exciplex}} = E_{\text{LUMO}}$ (ETM) $- E_{\text{HOMO}}$ (HTM), ignoring the band bending at the organic/organic interface [10]. In the equation, E_{HOMO} and E_{LUMO} are the energies of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), respectively. However, only certain combinations of materials were reported to be capable of giving

doi:10.1016/j.orgel.2010.12.026

exciplex emission and their external quantum efficiencies (η_E) are usually low (e.g., m-MTDATA/Alq_3 (0.22%) [4], 2-TNATA/Alq_3 (0.30%) [5] and TPD/PBD (1.10%) [6]). Thus, the appearance of exciplex is often considered as one of the main reasons responsible for poor device performance. On the other hand, Palilis et al. recently reported exciplex-based OLEDs using NPB/PPSPP, and achieved an exceptionally high η_E of 3.40% [7]. Later, our group demonstrated the TPyPA/BPhen based exciplex emitting devices with η_E as high as 3.93% [8]. It is proposed that matched carrier mobilities, high photoluminescence quantum yield (Φ_{PL}), and suitable electron energy levels of organic materials are the prerequisites for efficient exciplex-based OLEDs [8]. These findings provide guidelines for designing organic materials with desirable physical properties to facilitate high efficiency exciplex emission.

In addition to triphenylamine [4,5,8], both pyrene [8,11] and carbazole [9,12] and their derivatives have also been employed for exciplex emission, owing to their excellent luminescence characteristics, structural stabilities, and particularly their strong electron-donating tendencies when contacting with different electron-acceptors. However, the influences on how the chemical structures of organic materials affecting the nature of exciplex emission have seldom been studied. In this work, two carbazole-based compounds end-capped with one *t*-butyl and two pyrene groups, namely 3,6-dipyrenyl-9-(4′-*tert*-butylphenyl) carbazole (BPyC) and three pyrene groups, namely, 3,6-dipyrenyl-9-(4′-pyrenylphenyl) carbazole (TPyC) have been synthesized. While the two compounds have very similar structures and photoluminescent spectra, OLEDs using them as host emitters show distinct EL characteristics. Particularly, the BPyC-based devices (η_E = 2.21%) show only a single blue emission peak while the TPyC-based devices show two emission peaks with higher maximum η_E of 3.11%. Reason for these differences is attributed to the higher degree of electron-donating property with increasing number of pyrene groups. This results in the formation of the yellow exciplex emission which shifts the EL spectrum from saturated blue (BPyC) to near white (TPyC). It is worth noting that both carbazole derivatives have Φ_{PL} of about 95%, which are much higher than that of our previously reported triphenylamine TPyPA (Φ_{PL} = 80%) [8]. This results in a higher maximum η_E of the TPyC-based devices, as compared to that of a similarly structured TPyPA-based OLED (η_E = 2.83%). Based on these results the influences of chemical structures and Φ_{PL} on the efficiency of exciplex emission are discussed.

2. Experimental

2.1. Materials and instruments

All reagents and solvents for the synthesis of BPyC and TPyC were purchased from either Sigma–Aldrich or Acros Organics and used as received without further purification. ^{1}H NMR spectra were recorded with the use of a Bruker DPX-400 spectrometer (400 MHz). Mass spectrometry was performed on a PE SCIEX LC/MS spectrometer. Elemental analyses were carried out on a Vario EL Elementar by the Flash EA 1112 method. Modulated differential scanning calorimetry (MDSC) and thermogravimetric analysis (TGA) were performed under a nitrogen atmosphere at a heating rate of 10 °C min^{-1} on a TA Instruments MDSC 2910 and TGA Q50, respectively. Solution Φ_{PL} were determined by using the method of Demas and Crosby [13] with a degassed aqueous solution of quinine sulfate as a reference. Optical absorption and photoluminescence (PL) spectra were measured with a Perkin-Elmer Lambda 2S UV/vis spectrometer and a Perkin-Elmer LS 50B luminescence spectrometer, respectively. Ultraviolet photoelectron spectroscopic (UPS) studies were performed in a VG ESCALAB 220i-XL surface analysis system with an unfiltered He I (21.22 eV) gas discharge lamp under a base vacuum of 10^{-10} Torr.

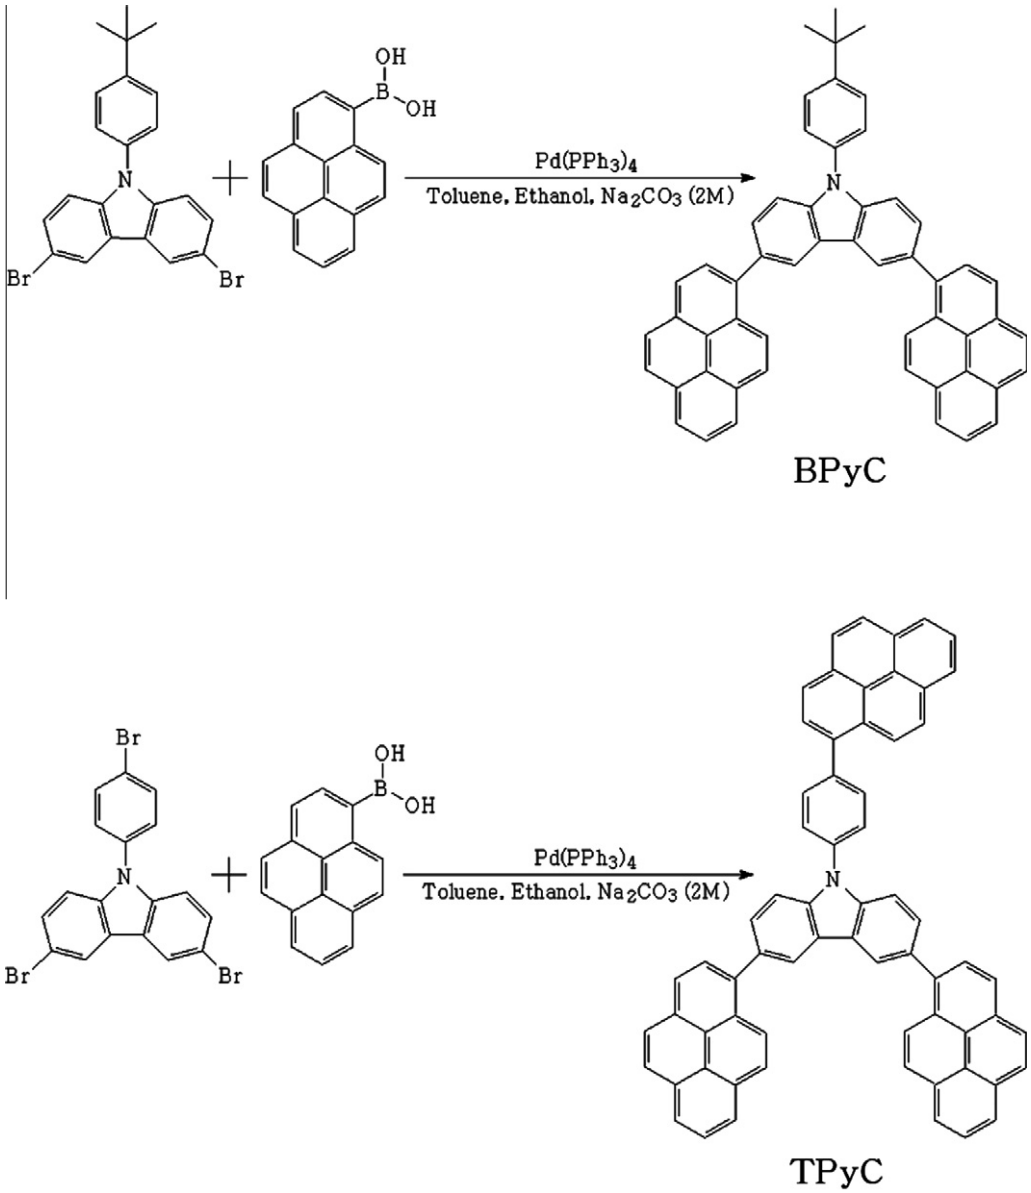
2.2. Fabrication and characterization of OLEDs

Transparent indium tin oxide (ITO) pre-coated and patterned glass slides with a sheet resistance of 30 Ω square^{-1} were used as anodic substrates. Prior to successive film deposition, they were thoroughly cleaned with Decon 90, rinsed in de-ionized water, dried in an oven, and finally treated in an ultraviolet–ozone cleaner. OLEDs consisting of a hole-transporting layer (HTL) of *N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB), a hole-transporting light-emitter of BPyC or TPyC, an electron-transporting layer (ETL) of 1,3,5-tris(*N*-phenylbenzimidazol-2-yl) benzene (TPBI) or 4,7-diphenyl-1,10-phenanthroline (BPhen), and a LiF/Al cathode. All films were thermally deposited sequentially without vacuum break in an evaporation chamber under a base pressure of ~10^{-6} Torr. Deposition rates were monitored with quartz oscillation crystals and controlled at a rate of 0.1–0.2 nm s^{-1} for both organic and metal layers. A shadow mask was used to define the cathode and to make four 0.1 cm^2 devices on each substrate. Current density–voltage–luminance (*J*–*V*–*L*) characteristics, EL spectra, and CIE coordinates were measured simultaneously with a programmable Keithley model 237 power source and a Photoresearch PR650 spectrometer. All measurements were carried out at room temperature under ambient atmosphere without any encapsulation.

3. Results and discussion

3.1. Material syntheses

Molecular structures of BPyC and TPyC and their synthetic routes are shown in Scheme 1. Incorporation of the 9-phenylcarbazole group is expected to enhance hole-transporting properties of the two compounds. BPyC and TPyC can be easily prepared with high yields using typical Suzuki coupling reactions from 3,6-dibromo-9-(4-*tert*-butylphenyl)-9*H*-carbazole [14], 3,6-dibromo-9-(4-bromophenyl)-9*H*-carbazole [15], and commercial starting material pyrene-1-boronic acid, respectively, according to reported procedures [16]. Molecular structures of the final compounds were confirmed by ^{1}H nuclear magnetic resonance, mass spectrometry, and elemental analysis.



Scheme 1. Synthetic routes and molecular structures of 3,6-dipyrenyl-9-(4′-*tert*-butylphenyl) carbazole (BPyC) and 3,6-dipyrenyl-9-(4′-pyrenylphenyl) carbazole (TPyC).

3.2. Chemical and photophysical properties

The rigid molecular structures in the two carbazole derivatives are beneficial to thermal stability, as manifested by their high decomposition temperatures (T_d) of 496 and 516 °C, and melting temperatures (T_m) of 293 and 245 °C for BPyC and TPyC, respectively (T_d corresponds to 5% weight loss in the TGA measurements whereas T_m was determined by MDSC) although no obvious glass transitions were observed.

Optical absorption and PL spectra of BPyC and TPyC vacuum-deposited solid thin-films on quartz plates are depicted in Fig. 1. The longest wavelength absorption maxima ($\lambda_{abs,\,max}$) appear at 358 and 369 nm for BPyC and TPyC, respectively, while the PL spectra show intense blue emissions peaked at 443 nm (BPyC) and 465 nm (TPyC) under excitation at 385 nm. It is well recognized that an increase in conjugation length would generally result in red-shifts in both λ_{abs} and PL. Indeed, the addition of a pyrene arm (from BPyC to TPyC) does red-shift the absorption and PL peaks by respectively 11 and 22 nm. From the PL quantum yield measurement, Φ_{PL} of BPyC and TPyC in solution are 94.8% and 95.0%, respectively. These high Φ_{PL} values may be attributed to large Stoke shifts (difference between positions of band maxima of the absorption and emission spectra) in both organic materials that can effectively avoid re-absorption of the emitted photons during the PL process.

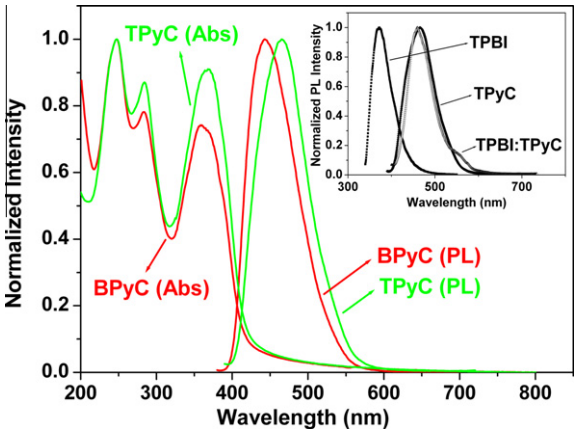


Fig. 1. Optical absorption (Abs) and photoluminescence (PL) spectra of BPyC and TPyC solid thin-films on quartz substrates. Inset: PL spectra of 10% TPBI:TPyC, TPBI, and TPyC thin-films, respectively.

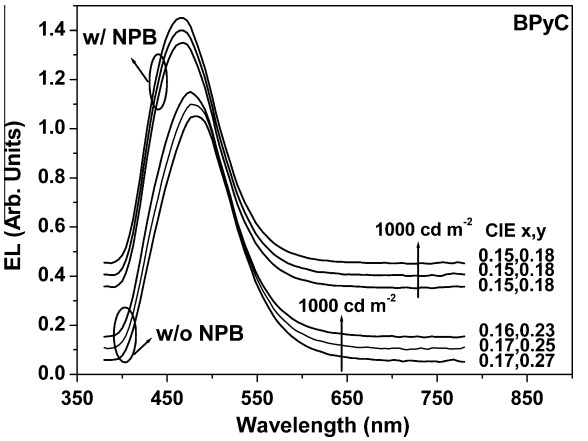

Fig. 2. Electroluminescence spectra of the BPyC-based OLEDs without (lower) and with (upper) NPB viewed in the normal direction at the luminance of 10, 100, and 1000 cd m^{-2}, respectively.

UPS was employed to measure the E_{HOMO} values of the carbazole derivatives, in which they are found to be 5.57 and 5.67 eV for BPyC and TPyC, respectively. By subtracting from the optical band gaps determined from long wavelength onsets of the absorption bands, E_{LUMO} are estimated to be 2.58 eV (for BPyC) and 2.71 eV (for TPyC). Table 1 summarizes the thermal and photophysical data of BPyC and TPyC.

3.3. Device characteristics

Devices with the structures of ITO/EML (100 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm) (w/o NPB) and ITO/NPB (70 nm)/EML (30 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm) (w/NPB) were fabricated to evaluate the properties of BPyC or TPyC as hole-transporting EML. Fig. 2 depicts EL spectra of the BPyC-based OLEDs with (upper) and without (lower) the NPB layer viewed in the normal direction at the luminance of 10, 100, and 1000 cd m^{-2}. Both devices exhibit similar pure blue emissions with mild change in CIE coordinates of (0.17, 0.25) (Device w/o NPB) and (0.15, 0.18) (Device w/NPB) over a wide range of luminance from 10 to 1000 cd m^{-2}. This suggests that the hole and electron recombination is well confined within the emissive BPyC layer. In addition, these undoped blue-emitting devices show high efficiencies (as shown in Fig. 3) and low operating voltages (as shown in Fig. 4) in which current and power efficiencies (η_C and η_P), and η_E and operating voltage at 20 mA cm^{-2} are 4.3 cd A^{-1}, 4.5 lm W^{-1}, 2.49%, and 3.7 V for device without NPB, and are 2.9 cd A^{-1}, 2.7 lm W^{-1}, 2.21%, and 3.5 V for device with NPB. After

Table 1
Thermal and photophysical properties of BPyC and TPyC. T_d and T_m were determined by thermogravimetric analysis (TGA) and modulated differential scanning calorimetry (MDSC) measurements at a same heating rate of 10 °C min^{-1} under a nitrogen atmosphere whereas T_d corresponds to 5% weight loss. λ_{abs} and λ_{PL} were measured with solid thin-film. E_{opt} was estimated from the long wavelength onset of the absorption band. E_{HOMO} was defined by ultraviolet photoelectron spectroscopy (UPS) while E_{LUMO} was estimated by $E_{LUMO} = E_{HOMO} - E_{opt}$. Φ_{PL} was measured in solution.

Compound	T_m/T_d (°C)	$\lambda_{abs,\ max}$ (nm)	λ_{PL} (nm)	Stokes shift (nm)	$\lambda_{abs,\ onset}$ (nm)/E_{opt} (eV)	E_{HOMO}/E_{LUMO} (eV)	Φ_{PL} (%)
BPyC	293/496	358	443	85	415/2.99	5.57/2.58	94.8
TPyC	245/516	369	465	96	419/2.96	5.67/2.71	95.0

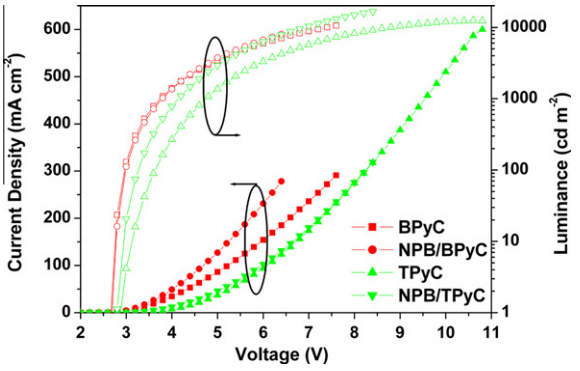

Fig. 4. Current density and luminance characteristics as a function of voltage in various devices. Device configurations: ITO/TPyC (100 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm); ITO/NPB (70 nm)/TPyC (30 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm); ITO/BPyC (100 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm); ITO/NPB (70 nm)/BPyC (30 nm)/TPBI (20 nm)/LiF (0.5 nm)/Al (100 nm).

insertion of NPB at the ITO/BPyC interface, the E_{HOMO} of NPB can function as a stepping-stone for hole-injection, similar to the case of ITO/m-MTDATA/NPB [17]. This improvement for hole-injection definitely reduces the driving voltage. It is believed that the amounts of hole and electron are balanced inside the device w/o NPB. However, the excess of holes in the device w/NPB eventually reduces the device efficiency. Nevertheless, these relatively high device efficiencies and low driving voltage are comparable or even better than current state-of-the-art undoped emitters with saturated blue fluorescence [18–20].

Unexpectedly, the extra pyrene arm in TPyC leads to large difference in EL properties. Fig. 5 depicts EL spectra of the TPyC-based OLEDs with (middle) and without (lower) NPB viewed in the normal direction at the luminance of 10, 100, and 1000 cd m^{-2}. In contrast with the PL spectrum of neat thin-film, both devices demonstrate two broad emission peaks at ca. 475 and 558 nm. The blue emission peak at 475 nm is contributed from the TPyC emission,

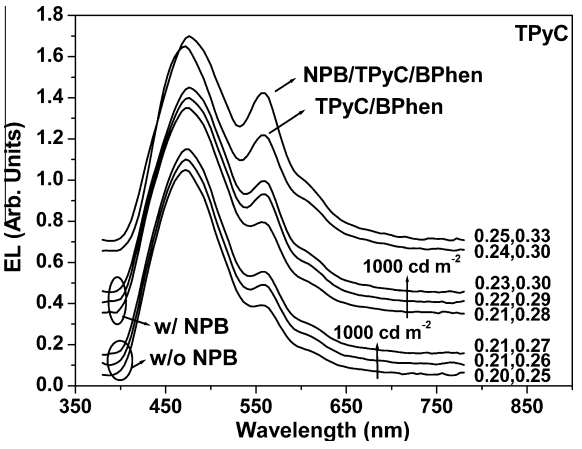

Fig. 5. Electroluminescence spectra of the TPyC-based OLEDs without (lower) and with (middle) NPB viewed in the normal direction at the luminance of 10, 100, and 1000 cd m^{-2}, respectively. Electroluminescence spectra for devices with the structures of ITO/TPyC/BPhen/LiF/Al and ITO/NPB/TPyC/BPhen/LiF/Al (upper) are also inserted.

whereas the red-shifted band centered at 558 nm appears to be arising from the exciplex emission formed at the TPyC/TPBI interface. This can be confirmed with the PL spectrum of the TPBI:TPyC blended film as shown in the inset of Fig. 1. It is considered that coupling between the strong electron-donating TPyC and the strong electron-accepting TPBI results in exciplex emission at their interface. Combining with the intrinsic blue emission at 475 nm, near white light emission with CIE coordinates of (0.21, 0.26) and (0.22, 0.29) were obtained for the devices without and with the NPB layer, respectively. In fact, the CIE coordinates change even closer to white emission of (0.24, 0.30) and (0.25, 0.33) when the ETL (i.e., TPBI) is replaced by BPhen (as shown in the two top-most spectra of Fig. 5).

Fig. 6 demonstrates efficiencies of the TPyC-based devices as a function of current density. With the insertion of NPB layer, η_C, η_P, and η_E dramatically increase to 6.4 cd A^{-1}, 5.3 lm W^{-1}, and 3.11%, respectively, much higher than those of device without the NPB layer (3.8 cd A^{-1}, 3.3 lm W^{-1}, and 2.01%). More importantly, the η_E of TPyC-based device is considerably higher than that of our previously reported triphenylamine TPyPA-based device (η_E = 2.83%) with the same device configuration. One possible explanation for this difference is that the Φ_{PL} of TPyC (95%) is much higher than that of TPyPA (80%). It should be noted that as Φ_{PL} of both TPyC and TPyPA materials are very high in solution, various solid-state quenching effects could be much more important than the yields in solution. The exact solid-state quenching effects in both

thin-films are now under investigation. Nevertheless, the discrepancy of Φ_{PL} on the device performance is in consistent with our previous study [8] and underscores the importance of high Φ_{PL} in organic materials for achieving highly efficient exciplex-based OLEDs. Characteristics of all BPyC- and TPyC-based devices are summarized in Table 2.

It is interesting to note that, in our previous study, the use of a better ETL (i.e., BPhen) would effectively increase the intensity of exciplex emission and, in turns, results in a better balanced white emission. In particular, the CIE coordinates change from (0.18, 0.25) for devices with TPBI as ETL to (0.31, 0.35) for the BPhen-based TPyPA device. In addition, the replacement of BPhen results in a high η_E of 3.93%, much higher than that of the TPBI-based device (2.83%). These enhancements have been attributed to the different carrier mobility of BPhen and TPBI. Indeed, the intensity of exciplex emission is determined by the charge accumulation densities, which in turns depends on the relative hole mobility and electron mobility in HTL and ETL. In particular, the use of ETL with higher electron mobility would lead to higher exciplex emission intensity. As the electron mobility in TPBI is two orders of magnitude lower than that in BPhen, the relatively small electron mobility in TPBI would inevitably reduce the number of electron–hole pairs formed for exciplex emission, and in turns leads to a weak exciplex emission. However, it is not the case in our present study, in which there is only a mild shift on the CIE coordinates from (0.22, 0.29) to (0.25, 0.33) and a small increase on η_E from 3.11% to 3.16% when the ETL is replaced by BPhen. Such minor device performance improvement for the TPyC-based devices may be ascribed by the lower mobility in TPyC than that in TPyPA. Particularly, it is expected that the hole mobility of TPyC is much lower than that of TPyPA, and thus the use of better electron-transporting materials, e.g., BPhen, would not result in a dramatic increase on the interfacial charge accumulation density at the HTL/ETL interface. It is also the reason for the larger driving voltage for the TPyC-based devices. For instance, to generate a current density of 20 mA cm^{-2}, the driving voltages of the TPyC-based device with TPBI or BPhen as ETL are 4.34 and 3.76 V, respectively, while those of the TPyPA-based device with TPBI or BPhen as ETL are 3.60 and 3.31 V, respectively [8].

4. Conclusions

We have designed and synthesized two carbazole–pyrene based fluorophores, namely BPyC and TPyC, to investigate how chemical structures of organic materials affecting exciplex emission. By employing the carbazole derivatives as emitters in contact with the electron-transporting TPBI, both devices exhibit distinct EL properties. Particularly, the TPyC-based devices display two emission peaks with CIE coordinates of (0.22, 0.29); while the BPyC-based devices show a single blue emission peak with CIE coordinates of (0.15, 0.18). More importantly, a relatively high η_E of 3.11% can be obtained for the TPyC-based device. This discrepancy on the device performance is attributed to the substitution of *t*-butyl unit of BPyC with a pyrenyl group, resulting in an increase on the degree of electron-donating property and hence the presence of exciplex emission at the HTL/ETL heterojunction.

White organic light-emitting devices
Color stability
Selectively doped profile

ABSTRACT

A white organic light-emitting device (WOLED) with ultra-high color stability was achieved by introducing an appropriate emitting layer (EML) structure with a spacer, and engineering a blue EML (B-EML) with a selectively doped profile. The advantage of the selectively doped profile over the conventional, uniformly doped profile was to minimize direct exciton formation on dopants with lower exciton energies to suppress electroluminescence (EL) spectrum variations. The recombination zone was found to be located at the spacer/B-EML interface, with a width of 4.5 nm. With the selectively doped profile, the WOLED exhibited ultra-high color stability, with the CIE coordinates shifting from (0.399, 0.483) to (0.395, 0.479) as the luminance increased from 145 to 12,100 cd/m^2 and from (0.401, 0.481) to (0.400, 0.479) as the luminance increased from 1240 to 4850 cd/m^2, the practical luminance range for display and lighting applications. In addition to the small CIE coordinates variation of (−0.004, −0.004) over the broad luminance range of about two orders of magnitude, we also achieved a high device efficiency of 34.1 cd/A, which stayed larger than 30 cd/A below 2000 cd/m^2.

1. Introduction

Owing to almost three decades of development, the power efficiency of organic light-emitting devices (OLEDs) has leapfrogged to several lm/W for monochromatic emission and over one hundred lm/W for white emission [1–5]. In addition to the marked improvement in the efficiency, which is obviously an important breakthrough as well as a prerequisite for practical applications, another issue concerning the user experience has been attracting attention, namely the color performance. For a monochromatic OLED, its color performance under different driving conditions is of less concern since only one kind of emitting sites is responsible for the emission. However, for a broadband white OLED (WOLED), its color performance, as quantified by factors such as the Commission Internaionale de l'Eclairage (CIE) coordinates and color rendering index (CRI), is of utmost importance because typically more than two different types of emitting sites are involved in the light generation. In this case, different dopants can conceivably compete with one another under different driving conditions due to differences in the exciton energy and shifts in the recombination zone [6–11]. As a result, the color performance will vary with different driving conditions, luminance levels and degrees of device degradation. This phenomenon inevitably presents additional difficulties for lighting applications and down-conversion displays with backlight units of WOLED and color filters. For lighting applications, CIE coordinates variation during operation will distort the color of the illuminated object. For down-conversion displays, the panel will suffer from distortions of the pixel emitting color and non-uniform color distribution over the panel under the same driving conditions. Therefore, for the sake of competitiveness in the

market, WOLED must be developed with high color stability, on top of high efficiency.

To suppress the CIE coordinates variation, the use of a single dopant to generate broadband emission for white light through bimolecular interactions holds promise as a viable solution, due to the absence of competition among the different kinds of dopants [12,13]. However, the difficulty lies in finding such organic materials. In contrast, stacking different EMLs or mixing different dopants in the same EML to yield white EML is a simpler way to generate white emission and obtain efficient devices. Direct stacking without introducing additional functional organic layers usually leads to electroluminescent (EL) spectral variations due to differences in the electric field dependence of carrier mobilities in different EMLs and saturation of the emitting sites as the injected carriers increase in number [6,7,10,14,15]. This directly stacked EML structure also results in lower efficiency as compared to its reference monochromatic OLED, since exciton competition will obviously arise due to the different exciton energies of the different emitting dopants. To ease the energy difference induced exciton competition, position control methods by which the recombination zone is deliberately allocated in the appropriate region have been suggested [4,16–24]. The crux of the approach is that excitons with lower energies are fed via energy transfer or diffusion from regions with high energies. Since the energy transfer is nearly independent of the carrier and exciton concentration, the EL spectrum is also independent of the driving conditions and luminance level. In this paper, we demonstrate how a spacer and a selective doping method were applied to achieve an ultra-high color stability WOLED, which exhibited a rather slight CIE coordinates variation of $(-0.004, -0.004)$ from 145 to 12,100 cd/m^2. Within the luminance range of lighting or backlight applications, this WOLED exhibited a negligible CIE coordinates variation of $(-0.001, -0.002)$ from 1240 to 4850 cd/m^2. This optimal WOLED further achieved peak efficiencies of 34.1 cd/A and 26 lm/W.

2. Experiments

The OLED fabrication and encapsulation followed similar procedures as outlined in our previous studies [24]. In our carrier transporting system, *N*,*N*′-diphenyl-*N*,*N*′-bis(1-napthyl)-1,1′-biphenyl-4,4′-diamine (NPB) was used as a hole-transporting layer (HTL) and 4,7-diphenyl-1,10-phenanthroline (BPhen) as an electron-transporting layer (ETL) beneath a LiF/Al cathode. An EML sandwiched between the HTL and ETL consisted of red-emitting tris(2-phenyl-1-quinoline)iridium(III) ($Ir(phq)_3$) [25], green-emitting tris(phenylpyridine)iridium ($Ir(ppy)_3$) and blue-emitting [(4,6-di-fluoropheny)-pyridinato-*N*,$C^{2'}$]picolinate (FIrpic), which were doped in the same host of *N*,*N*′-dicarbazolyl-3,5-benzene (mCP). The device structures under investigation were listed in Table 1. The current density–voltage (*J*–*V*) characteristics and EL spectrum were measured and recorded by a testing setup comprising of a Keithley 2400 source-meter and a Minolta CS-1000 spectrometer.

3. Results and discussions

3.1. Uniformly doped profile in EML

Although devices with thinner EML structures exhibited improved power efficiencies [22], the efficiencies of these devices nonetheless dropped rapidly at higher luminance levels due to more severe triplet–triplet annihilation (TTA) [23]. Therefore, thicker EML structures were proposed for high luminance applications as investigated in this study [24]. By deliberately manipulating the exciton distribution and energy transfer, we arrived at a backbone EML structure of 9% $Ir(ppy)_3$:mCP (30 nm) (G-EML)/mCP (4.5 nm)/9% FIrpic:mCP (18 nm) (B-EML) which exhibited a high color stability, with the adoption of an appropriate layer thickness to suppress the sensitivity of the electric field dependent carrier injection and transport [24].

A WOLED following this EML structure could be implemented by doping red-emitting molecules such as Ir(phq)$_3$. Naturally, the next question to be addressed is where to dope the red dopants in order to inherit the high color stability of the OLED with the backbone of G + B EML. In previous study [24], the Ir(phq)$_3$ was uniformly doped in the G-EML. To lessen the effect on the performance of the backbone EML, the Ir(phq)$_3$ was lightly doped to avoid obvious exciton catching events by this low-energy dopant, instead of the desired Ir(ppy)$_3$. Excitons caught by the Ir(phq)$_3$ would result in lower color stability, since a saturation of the emitting sites with an increase in the number of injected carriers would occur and alter the exciton relaxation paths.In addition to the G-EML, the Ir(phq)$_3$ could be also doped in the B-EML. However, doping the low-energy molecules in the main recombination zone (e.g. B-EML) will increase the probability of direct exciton formation on the Ir(phq)$_3$, thereby compounding the drawback of large EL spectrum variation. A device with the backbone of G + B EML was referred as to Device A1 as listed in Table 1. Devices with 0.5% Ir(phq)$_3$ doped throughout the G-EML and both the G- and B-EML were labeled as Devices A2 and A3, respectively. Fig. 1(a) shows the *J*–*V* and external quantum efficiency (EQE) versus *J* characteristics of Devices A1–A3. These three devices exhibited similar *J*–*V* characteristics, suggesting that the low concentration of Ir(phq)$_3$ had little impact on the electrical properties. On the other hand, with the introduction of the high-efficiency red dopants, the EQE were improved in Devices A2 and A3. The EQE of A3 was higher than that of A2 because the emission efficiency of the FIrpic is lower than that of the Ir(ppy)$_3$ [10,26]. Fig. 1(b)–(d) shows the spectra under different driving voltages for Devices A1, A2, and A3, respectively. It should be noted that the spectra were very stable in Devices A1 and A2 although there was a small increase in the red emission with increasing voltage for Device A2. In Device A3, the red emission was stronger than the green and blue emission, because the red dopants were doped in the main recombination zone. Contrary to the case of Device A2, the spectral variation was obvious, and the blue and green emission increased with increasing driving voltage in Device A3. Since the CIE is a measure of both the EL spectrum and human eye sensitivity, a more straightforward parameter is required to quantify the differences in the EL spectra without taking into consideration the human eye sensitivity. For this purpose, we have defined an EL spectrum area variation ratio (Ψ) as $\frac{\sum |P_{H(\lambda)} - P_{L(\lambda)}|}{\sum P_{L(\lambda)}}$, where $P_{H(L)}(\lambda)$ is the power distribution of the EL spectrum, normalized to its total radiation power and driven by a higher (lower) applied voltage. The newly defined Ψ without involving the human eye sensitivity will likely provide a more precise indicator for determining what really transpires in a high color stability OLED.

The electrical and optical performances of Devices A1–A3 were summarized in Table 2. Here, $P_L(\lambda)$ was chosen to be the EL spectrum at 4.5 V as a common reference level for Devices A1–A3 since these devices exhibited similar

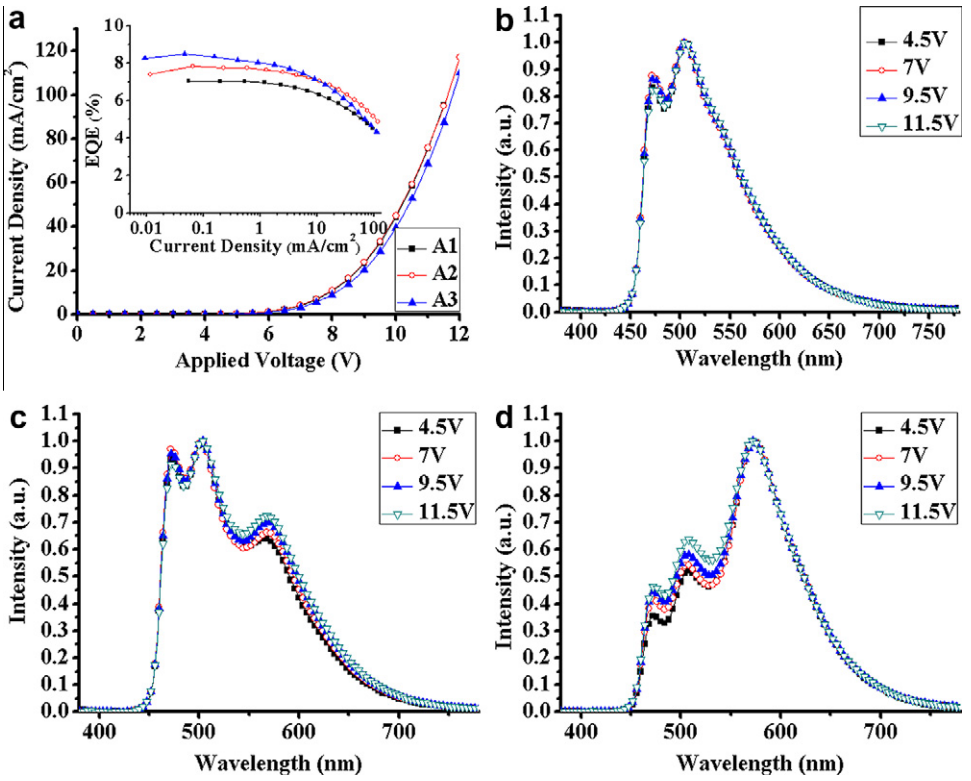

Fig. 1. *J*–*V* characteristics (a) and EQE (Inset in (a)) of Devices A1–A3, and EL spectra of Devices A1(b), A2(c), and A3(d) under applied voltage of 4.5, 7, 9.5, and 11.5 V. Emissions around 470, 520, 575 nm were generated by FIrpic, Ir(ppy)$_3$, Ir(phq)$_3$, respectively.

electrical characteristics (driving voltage variation within 0.5 V at 100 mA/cm^2, as can be seen from Fig. 1(a)). This suggested that light red dopant concentration did not dramatically alter the carrier transporting properties regardless of the regions doped.

Within the range from 4.5 to 11.5 V, the maximum Ψ values were 2.8%, 7.12%, and 8.96% for Devices A1, A2, and A3, respectively. The stable EL spectrum for Device A1 was ascribed to its mCP spacer and the low sensitivity of the electric field to carrier injection and transport [24]. For Device A3, doping Ir(phq)$_3$ in the entire B-EML further raised the Ψ value since the location of the main recombination zone within the B-EML made the saturation-induced EL spectrum variation more significant.

For extracting information on exciton behaviors in the different EMLs, the spectra of the WOLEDs were decomposed into their red (R, Ir(phq)$_3$), green (G, Ir(ppy)$_3$) and blue (B, FIrpic) emission components, respectively, as shown in Table 3 [24]. The different variations of the emission components in the EL spectra at different driving voltages for Devices A2 and A3 suggested that the EL spectral shifts were dominated by different mechanisms. For Device A2, as the applied voltage was increased from 4.5 to 11.5 V, the R component increased from 20.46% to 23.92%, while the B component decreased from 52.84% to 49.45%. The growth of the R component was likely due to the extension of the minor recombination zone, which could in turn be attributed to electron leakage out of the B-EML. On the other hand, the reduction of the B component could result from typical TTA in the B-EML, by which the FIrpic excitons in the main recombination zone were quenched. For Device A3 with the Ir(phq)$_3$-doped B-EML, the composition variation was reversed. In this case, the R component decreased from 55.27% to 48.80%, while the B component increased from 23.02% to 27.71%. In the main recombination zone, the Ir(phq)$_3$, with lower exciton energy than the FIrpic, made itself a preferred exciton formation site in the B-EML. As the number of injected carrier increased, the low concentration of Ir(phq)$_3$ was unable to provide sufficient exciton formation sites, and became saturated. Once the increasing number of carriers exceeded this saturation level, the number of excitons formed and released from the higher energy FIrpic would increase. Accordingly, the compositional variation in the EL spectra for Device A3 was a function of the degree of saturation of the Ir(phq)$_3$ molecules.

3.2. Selectively doped profile in EML

For Device A3, doping Ir(phq)$_3$ in the entire B-EML further raised the Ψ value since the main recombination zone was located in the B-EML. In order to increase the color stability, the selective doping method could be applied to modify this R:B-EML [16,21]. The prerequisite for applying the selective doping method was to ascertain the location of the maximum recombination zone.

Therefore, the P-series devices listed in Table 1 were designed to investigate the location of the recombination zone. By analyzing the EL spectra, it was possible to understand the exciton formation and diffusion characteristics [27–29]. Fig. 2 showed the red and green percentage and EL spectrum area variation ratio (Ψ) of the four devices (P1–P4). The green component was nearly the same, so the (blue + red) component was also nearly constant. Red component was highest at P1, with red dopant within 4.5 nm from the spacer/B-EML interface. And it decreased and then reached another local maximum within 4.5 nm from the B-EML/ETL interface. The Ψ value was very high for P1 device, which was due to serious carrier trapping of red dopant at the main recombination zone. Then it reached minimum at P2 and slightly increased toward P4. Although the red component in P4 was 8.8%, which was only slightly lower than that in P1 (11.7%), the Ψ value was greatly reduced from 19.79% (P1) to 5.79% (P4). Because the exciton lifetime in phosphorescent OLED was typically long, excitons might diffuse to the B-EML/ETL interface and be blocked (and partially quenched) by BPhen. When red dopants were inserted at this interface, energy would be transferred to red emitters for stable light emission, with significant reduction of Ψ value compared with P1. We can also note that green emission in P4 was slightly lower than P1–P3. Actually, it came from the stronger red emission near B-EML/ETL interface, which was transferred from blue emission. It provided another radiative pathway for light emission and decreased the BPhen quenching. Hence, the (red + blue) components increased, and the green percentage decreased. From discussion above, the major recombination zone should be located was within 4.5 nm from the spacer/B-EML interface, which resulted in a strong red emission, accompanying large spectral variation with different driving voltages in Device P1.

In the B-series devices shown in Table 1, the 0.5% Ir(phq)$_3$:mCP EML (R:B-EML) extended from the BPhen ETL. As long as this doped region extended toward and encompassed the recombination zone, an increasingly red emission would be observed [29]. In addition, a distinct EL variation with voltage would be observed [21]. As can be seen in Fig. 3, the red emission component from the Ir(phq)$_3$ in the EL spectrum increased as the selectively doped Ir(phq)$_3$ region extended to the spacer/B-EML

Table 2
Performances of Devices A1–A3.

Device	[a]Driving voltage (V)	Max. efficiency			CIE coordinate		Max. Ψ (%)
		lm/W	cd/A	EQE (%)	[b]Low luminance	[c]High luminance	
A1	11.6	17.4	24.9	7.05	(0.259, 0.468) (13.5 cd/m^2)	(0.259, 0.468) (15,200 cd/m^2)	2.80
A2	11.31	19.8	26.4	7.82	(0.305, 0.447) (16.9 cd/m^2)	(0.321, 0.451) (16,600 cd/m^2)	7.12
A3	11.77	22	28.7	8.50	(0.423, 0.476) (13.2 cd/m^2)	(0.404, 0.475) (13,700 cd/m^2)	8.96

Measurement conditions: [a]100 mA/cm^2; [b]4.5 V; [c]11.5 V.

Table 3
$Ir(phq)_3$ (R), $Ir(ppy)_3$ (G), and FIrpic (B) emission percentages of the EL spectra at 4.5 and 11.5 V.

Device	Driving voltage (V)	R (%)	G (%)	B (%)
A1	4.5		39.40	60.60
	11.5		39.86	60.14
A2	4.5	20.46	26.70	52.84
	11.5	23.92	26.63	49.45
A3	4.5	55.27	21.71	23.02
	11.5	48.80	23.49	27.71
B1	4.5	28.57	23.98	47.45
	11.5	31.53	24.63	43.84
B2	4.5	33.17	24.04	42.79
	11.5	34.93	23.92	41.15
B3	4.5	43.41	21.98	34.61
	11.5	44.13	22.35	33.52

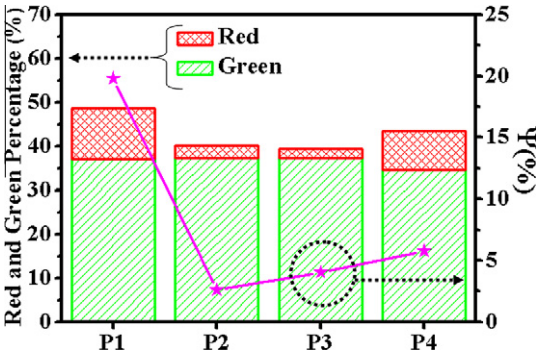

Fig. 2. Red and green percentage and EL spectra variations (Ψ values) of devices P1–P4. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

interface from the ETL. Therefore, this suggested that the recombination zone was located primarily at the spacer/B-EML interface. It also illustrated that the FIrpic molecules (2.9 eV), with similar LUMO to the BPhen (3.1 eV), could provide an electron injection pathway at the B-EML/BPhen interface to avoid electron accumulation and thus carrier recombination at this interface.

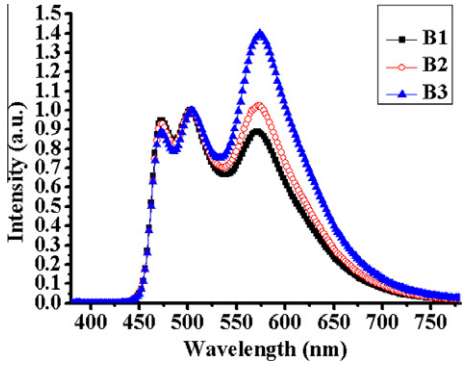

Fig. 3. EL spectra, measured at an injected current density of 2.5 mA/cm^2 and normalized to the green emission peak at 520 nm, of Devices B1–B3. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

As shown in Fig. 4(a), Devices B1–B3 exhibited similar electrical characteristics (with driving voltage variation within 0.5 V at 100 mA/cm^2), suggesting that the $Ir(phq)_3$ had little effect on the carrier transporting properties in the B-EML. The EQE values of B1, B2, B3, and A3 were similar because of the presence of the efficient red dopants. Fig. 4(b)–(d) illustrates the behaviors of EL spectrum variations under different voltages for the B-series devices, from which Ψ could be calculated. Under similar driving conditions, from 4.5 to 11.5 V, as listed in Table 4, the maximum Ψ values for Devices B1, B2, and B3 were 5.57%, 4.02% and 3.77%, respectively, all below that of Device A3 (Ψ: 8.96%) with a conventional, uniformly doped R:B-EML. In the B-series devices, the $Ir(phq)_3$ in the B-EML was located some distance away from the spacer/B-EML interface. In this regard, the emitting site saturation of the $Ir(phq)_3$ in the B-EML was automatically averted since the excitons were formed on the mCP or FIrpic in the absence of the $Ir(phq)_3$, and part of the excitons were sequentially diffused out or transferred to the $Ir(phq)_3$ to complete the EL spectrum. Since the energy transfer is nearly independent of the driving voltage and number of injection carriers, the EL spectra was expected to be stable under different driving conditions, thereby leading to lower Ψ values for the B-series devices as compared to the reference Device A3. According to the high color stability (lower Ψ) of Device B3, we inferred that the recombination zone was within 4.5 nm from the spacer/B-EML interface.

For the composition variations of the B-series devices (shown in Table 3), their B components decreased as the applied voltage was increased. This phenomenon could be a result of typical TTA in phosphorescent devices such as Device A2. In addition, according to the different extents of B component reduction among the B-series devices, we could infer that the $Ir(phq)_3$-doped EML played an important role in the TTA process. Since TTA is related to the exciton lifetime and rate constant of the TTA process [30], the behaviors of the TTA in B-EML (9% Firpic:mCP), R:B-EML (0.5% $Ir(phq)_3$:9% FIrpic:mCP), and even different combinations of both B-EML and R:B-EML may be different. According to similar TTA behaviors indicated by small B composition reductions for Devices B2 (42.79–41.15%) and B3 (34.61–33.52%), we postulated that the R:B-EMLs in these two devices were within the energy transfer radius of the FIrpic dopants, which therefore led to similar influence on the TTA. In Device B1, with the red doped region situated away from the recombination zone, the influence of the $Ir(phq)_3$ on the TTA in the B-EML was relatively weak due to the absence of $Ir(phq)_3$ within the energy transfer radius of the FIrpic dopants, thereby leading to a larger B component reduction (47.45–43.84%). In Ref. [24], we found that the TTA affected the color stability in G + B OLED (e.g. Device A1). Here, we found that the different $Ir(phq)_3$-doped regions altered the color balance between the red and blue emission in the B-EML/R:B-EML. If the energy transfer from the FIrpic to $Ir(phq)_3$ were efficient, as in the cases with Devices B2 and B3, the exciton concentration of the FIrpic emitting sites would not be as high as that in Device B1, thus alleviating the TTA events of FIrpic excitons. However, for Device B1, the energy transfer from the FIrpic to $Ir(phq)_3$ was not efficient

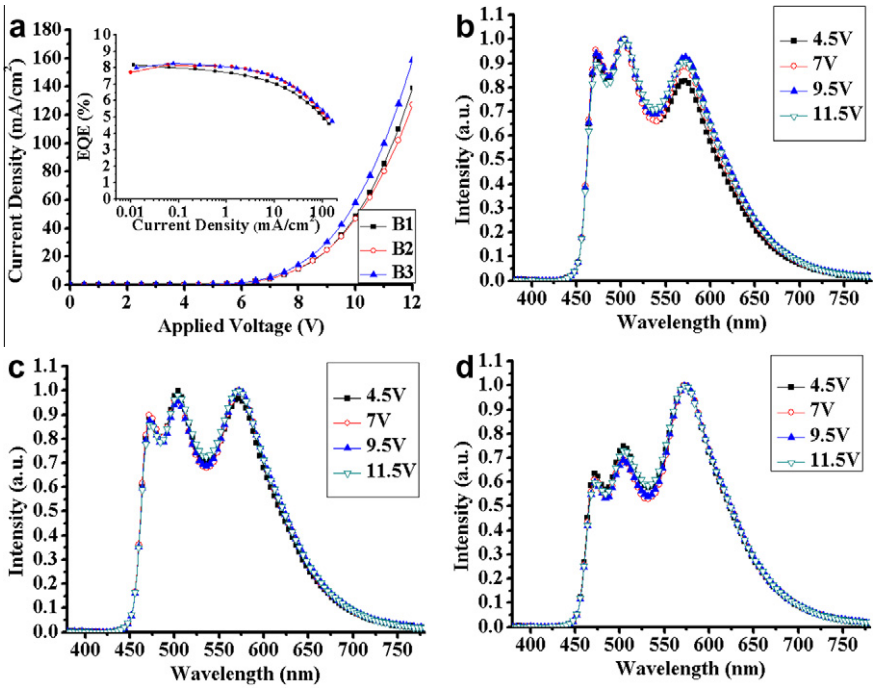

Fig. 4. *J–V* characteristics (a) and EQE (inset of (a)) of Devices B1–B3; EL spectrum variations of Devices B1(b), B2(c), and B3(d) from 4.5 to 11.5 V.

Table 4
Performances of Device B1–B3. Driving voltage was measured at current density of 100 mA/cm^2.

Device	Driving voltage (V)	Max. efficiency			CIE coordinate		Max. Ψ (%)
		lm/W	cd/A	EQE (%)	Low luminance	High luminance	
B1	11.3	21.4	27.5	8.15	(0.335, 0.449) (17.4 cd/m^2)	(0.346, 0.455) (18,700 cd/m^2)	5.57
B2	11.46	21.1	28.2	8.18	(0.353, 0.456) (17 cd/m^2)	(0.359, 0.459) (18,500 cd/m^2)	4.02
B3	11	22	28.7	8.24	(0.387, 0.461) (22.1 cd/m^2)	(0.390, 0.465) (22,500 cd/m^2)	3.77

(outside the energy transfer radius of the FIrpic) due to the large spacing between the recombination zone and R:B-EML. In this regard, the FIrpic dopants would be rapidly occupied by excitons and hence suffer from TTA at lower current densities, as can be seen from its EQE performance in the inset of Fig. 3(a). As compared with Device A2 with the absence of Ir(phq)$_3$ in B-EML, the B-series devices exhibited lower Ψ values since the presence of Ir(phq)$_3$ would prevent FIrpic excitons from being quenched by TTA. For the most color-stable Device B3, its CIE coordinates over the wide luminance range of 204–12,200 cd/m^2 varied from (0.389, 0.459) to (0.394, 0.462) with CIE coordinates variation of (0.005, 0.003). In addition, over the practical luminance range of 1430–5040 cd/m^2 for display and lighting applications, Device B3 exhibited a rather low CIE variation of (0.002, 0.001). Therefore, the replacement of a single R:B-EML by a two layer structure of B-EML/R:B-EML successfully led to satisfactory red emission and high color stability.

Before further optimization to achieve high efficiency and high color stability WOLED, the energy transfer paths of Device B3 with EML should be discussed. According to the previous study [24] and discussions above, the main recombination zone of Device B3 was located within the B-EML in the B-EML/R:B-EML region as indicated in Fig. 5, while a minor recombination zone was found in the R:G-EML. As illustrated in Fig. 5, excitons were first formed on mCP and FIrpic molecules in the B-EML, and subsequently on the Ir(ppy)$_3$ and Ir(phq)$_3$ molecules in the R:G-EML. The function of the spacer was to stabilize the emission ratio of B-EML to R:G-EML by interrupting the Dexter energy transfer of FIrpic to Ir(ppy)$_3$ and FIrpic to Ir(phq)$_3$, as indicated by the dashed lines in Fig. 5, in a way of separating the two different dopants in the spatial domain because Dexter energy transfer results from electronic orbital coupling. The Förster energy transfer ($D^{3*} + A^1 \rightarrow D^1 + A^{3*}$) path of the dashed lines were originally prohibited by spin conservation. A portion of the excitons on the mCP in the B-EML diffused out to either the R:G-EML or R:B-EML due to the relatively higher triplet exciton concentration in the main recombination zone. Therefore, in the R:G-EML, the Ir(phq)$_3$ emission was attributed to either direct exciton formation or energy transfer from higher energy molecules. In contrast, in the EML of the B-EML/R:B-EML, the Ir(phq)$_3$ emission originated purely from the energy transfer from the mCP and

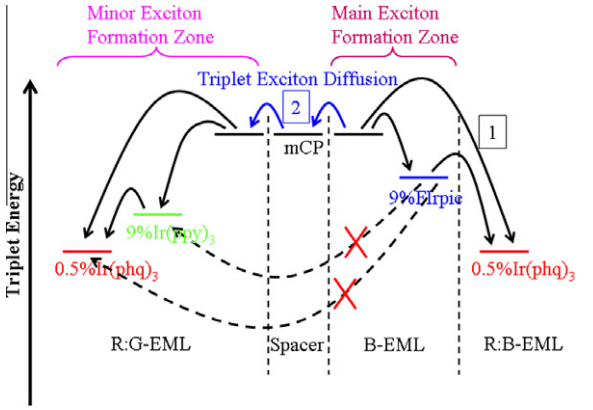

Fig. 5. Energy transfer diagram of molecules in R:G-EML/spacer/B-EML/R:B-EML structure. Main exciton formation zone was within B-EML while minor recombination zone was within R:G-EML and close to the spacer interface. Solid (dashed) lines indicate allowed (forbidden) energy transfer paths.

FIrpic in the B-EML. Since the $Ir(phq)_3$ in the R:B-EML were not located in the main recombination zone, direct exciton formation on the $Ir(phq)_3$ was technically prohibited. This absence of direct exciton formation on the $Ir(phq)_3$ in the B-EML resulted in the stable EL spectra in our WOLED devices.

Analysis of Devices A2, A3, B1, B2, and B3 revealed the role of the $Ir(phq)_3$ molecules in the B-EML. As shown in Fig. 6, Ψ decreased as the R:B-EML extended from the BPhen ETL until the red dopants were fully doped in the B-EML, as was the case with Device A3. In Device A2, the EL variation was attributed to the extension of the recombination zone toward the R:G-EML and TTA in the B-EML. For Device A3 with the single R:B-EML, the higher Ψ value arose from the saturation of the red emitters. Among the B-series devices, the competition between paths 1 and 2 in Fig. 5 led to lower Ψ values than that in Device A2.

Increasing the efficiency of the energy transfer via path 1 decreased the exciton diffusion toward the R:G-EML via path 2. In this regard, the main contributor to the exciton source supplying the R:G-EML was the recombination zone

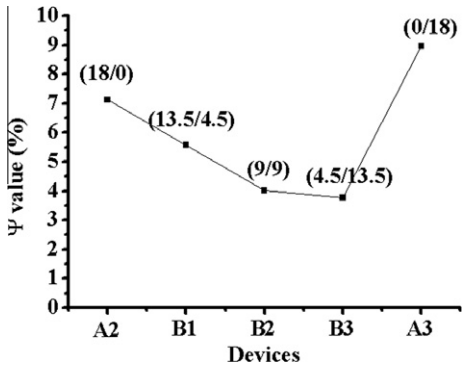

Fig. 6. EL spectra variations (Ψ values) of Devices A2, A3, B1, B2, and B3. Different EML structures between the spacer and BPhen ETL were indicated in parentheses as (B-EML thickness/R:B-EML thickness).

extension. For instance, the larger number of mCP excitons transferred to the $Ir(phq)_3$ in Devices B2 and B3 than that in Device B1 due to the closer spacing between the R:B-EML and recombination zone suppressed the mCP exciton diffusion via path 2, thereby lowering Ψ values as compared with Devices B1 and even A2.

3.3. Optimization of WOLED

As can be seen in Fig. 4(d), the 0.5% $Ir(phq)_3$-doped B-EML enabled significant red emission. Therefore, red-emitting $Ir(phq)_3$ in the R:G-EML (e.g. the B-series devices) could be removed (e.g. Device C1) to further simplify the device fabrication. Based on Device C1, the thickness of B-EML/R:B-EML and ETL were made thicker in Devices C2 and C3 (listed in Table 1) for the purposes of alleviating the TTA in the B-EML/R:B-EML, reducing metal quenching by the cathode, and adjusting the charge balance. For even thicker EMLs, increases in the driving voltage would lead to lower power efficiencies. After ascertaining the proper ETL thickness to avoid metal quenching and improve the charge balance, a WOLED structure optimized for high efficiency (e.g. Device C1 in Table 1) and with thicker layers of 0.5% $Ir(phq)_3$:9% FIrpic:mCP (18 nm) and BPhen (40 nm) was obtained. Fig. 7 shows the electrical and optical characteristics of Devices C2 and C3. Improvement in the efficiency due to the microcavity effect was ruled out, since the EL spectra for Devices C2 and C3 were almost identical.

In terms of efficiency as shown in Fig. 7(b), Device C2 exhibited the maximum efficiency of 26 lm/W and 34.1 cd/A, which stayed >30 cd/A until 2000 cd/m^2. As shown in Table 5, the maximum quantum efficiency of Device C3 was 9.93%, still lower than 10%. In terms of maximum quantum efficiency, this value was not high under similar phosphorescent dyes [22]. In our experiment, BPhen was used as ETL due to its comparable carrier mobility with NPB [24]. In this case, we could possibly achieve better charge balance and lower driving voltage. Although higher electron mobility could shift the recombination zone away from the B-EML/ETL interface, the excitons were able to diffuse to the ETL interface. Therefore, lower triplet exciton state (2.6 eV) of BPhen than that (2.7 eV) of FIrpic leaded to the occurrence of exciton quenching at this interface [31,32]. In order to avoid this exciton quenching, ETL with sufficiently higher triplet states were introduced [33,34]. Similar situation happened at the HTL/G-EML interface. The triplet state of NPB was 2.4 eV, and that of $Ir(ppy)_3$ was also 2.4 eV [31,35]. The almost equal triplet states of these two materials could make $Ir(ppy)_3$ transfer to NPB, thus leading to the fact that emitting triplet excitons were quenched by HTL. To well confine excitons in EML, 4,4′,4″-tris-(*N*-carbazolyl)-triphenylamine (TCTA), for example, with higher triplet state (2.8 eV) was inserted in between HTL and EML [34,36]. As for the blue-emitting material system, the host of FIrpic was continuously developed to extract more photons from FIrpic [33,34,37]. Since these adverse factors (exciton quenching at two interfaces of HTL and ETL, and inefficient blue host materials) in our material system, the EQE of our devices were below the level 10%. The main purpose of this study was to propose a methodology to manage EML for

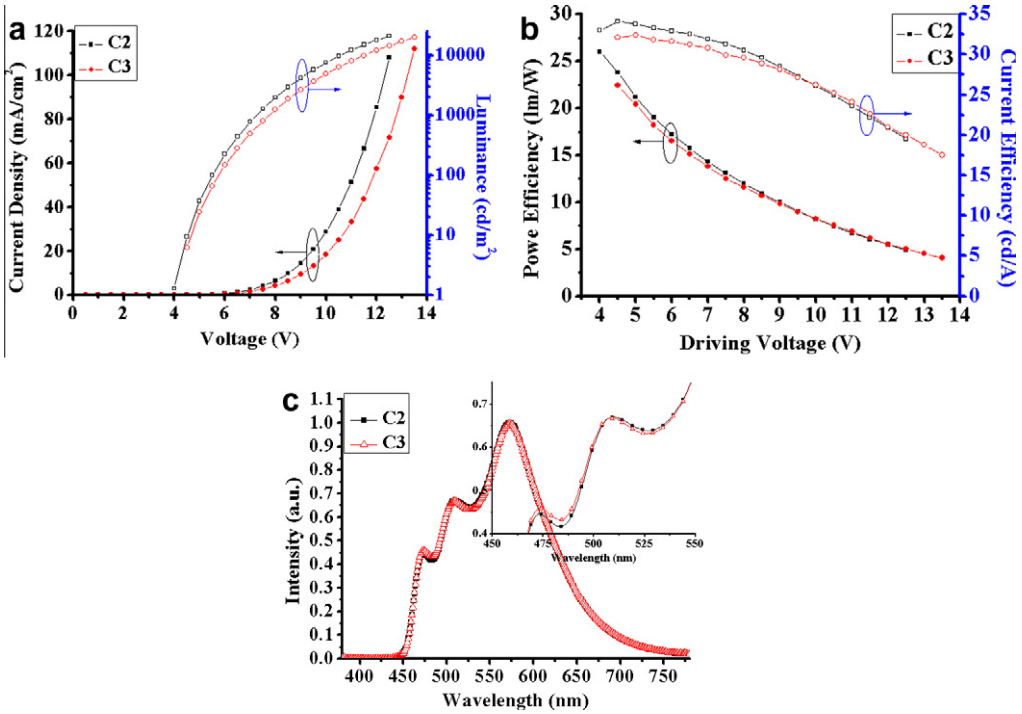

Fig. 7. The electrical and optical performances of optimized Devices C2 and C3. (a) *B–J–V* characteristic. (b) Current and power efficiency. (c) Normalized EL spectra measured at an injected current density of 2.5 mA/cm^2.

Table 5
Performance of Devices C1–C3. Driving voltage was measured at current density of 100 mA/cm^2.

Device	Driving voltage (V)	Max. efficiency			CIE coordinate		Max. Ψ (%)
		lm/W	cd/A	EQE (%)	Low luminance	High luminance	
C1	11.36	21	29.4	8.52	(0.355, 0.481) (19.1 cd/m^2)	(0.354, 0.487) (10,400 cd/m^2)	4.22
C2	12.35	26	34.1	9.93	(0.399, 0.485) (9.37 cd/m^2)	(0.404, 0.484) (12,100 cd/m^2)	4.41
C3	13.20	22.4	32.4	9.83	(0.401, 0.486) (24.1 cd/m^2)	(0.395, 0.479) (12,100 cd/m^2)	3.19

achieving white OLEDs with stable CIE coordinates by using commercial organic materials and suitable carrier mobility. Here, high electron mobility for ETL and not-too-high hole mobility for HTL were mostly desired. Transporting layer materials with higher triplet energy together with better host material in the EML would be most desired for further boosting up the OLED efficiency.

The efficiency roll-off beyond 2000 cd/m^2 was a typical phenomenon of triplet exciton quenching possibly due to increasing triplet excitons and polarons, leakage of charges, and non-radiative recombination at the transporting layers. Reineke et al. showed that triplet-polaron annihilation (TPA) only quenched excitons by ~20% at 200 mA/cm^2 [38] and the rate constant of TPA was 10 times lower than that of TTA [39] in Ir(ppy)$_3$-doped devices. Leakage of charges and non-radiative recombination at the transporting layers would lead to unstable EL spectrum at different injection conditions [24]. However, the performance of stable EL spectrum in our devices naturally ruled out these two factors. As a consequence, we suggested TTA dominated the efficiency roll-off in our cases. The stable EL spectra (maximum Ψ = 4.41% from 4.5 to 11 V) under different driving conditions suggested that the recombination zone was located in the same region as in Devices B3 and C1. As for the CIE coordinates so crucial to display and lighting applications, Device C2 exhibited a slight variation from (0.396, 0.484) at 100 cd/m^2, to (0.406, 0.483) at 5670 cd/m^2, finally approaching (0.404, 0.484) at 12,100 cd/m^2. Over the practical luminance range for backlight and lighting applications, Device C2 exhibited an ultra-high color stability, namely, a more or less fixed CIE coordinates from 1270 cd/m^2 with (0.403, 0.483) to 5670 cd/m^2 with (0.406, 0.483). Device C3, with 50 nm BPhen as the ETL, exhibited a slightly lower efficiency (shown in Fig. 7(b) and Table 5) than Device C2, but also a higher color stability (maximum Ψ = 3.19% from 5 to 12 V). In Device C3, the CIE coordinates shifted from (0.399, 0.483) at 145 cd/m^2, to (0.401, 0.481) at 1240 cd/m^2, finally reaching (0.395, 0.479) at 12,100 cd/m^2. The maximum δ was (−0.004, −0.004) over a wide luminance variation of about two orders of magnitude. In the practical luminance range, we observed almost unchanged CIE

coordinates, (0.401, 0.481) and (0.400, 0.479) for 1240 and 4850 cd/m^2, respectively. As compared with Device C2, the reduced EL spectrum and CIE coordinates variation could be attributed to the decreased sensitivity of the electric field to the carrier injection and transport as discussed in Ref. [24], since the thicker BPhen ETL (50 nm) would result in a greater voltage drop. The larger voltage drop across the thicker BPhen ETL possibly resulted in the lower voltage drop across the B-EML/R:B-EML, thereby lowering the electric field. In this regard, the electrons could not obtain sufficient energy to traverse the mCP spacer and leak to the G-EML. The result of the carrier confinement was the increasingly blue emission, as shown in Fig. 7(c).

4. Conclusion

The WOLED with ultra-high color stability both in the practical and over a rather wide luminance range was implemented by the selection of an appropriate EML layer thickness to reduce the sensitivity of electric field to the carrier injection and transport, a spacer to implement the desired exciton dynamics, and a selectively doped profile to generate red emission via complete energy transfer from the blue excitons. The combined effects of the abovementioned efforts were that the WOLED exhibited a rather small CIE coordinates variation of (−0.004, −0.004) over hundred-time luminance variation and an ultimately negligible variation of (−0.001, −0.002) in a commonly used luminance range for display and lighting applications. The efficiency reached a maximum value of 34.1 cd/A (26 lm/W) and stayed >30 cd/A until 2000 cd/m^2.

ABSTRACT

A nanostructured antireflection coating has been fabricated on glass side of an indium tin oxide (ITO) coated glass by self-assembling a monolayer of nano-silica spheres. Significant reduction in the weighted reflectance from 10.2% to 7.2% at 5° incident angle is observed. At 60° incident angle, the weighted reflectance of ITO glass with antireflection coating is still about 3% lower than that of bare ITO glass. This nanostructured antireflection coating has been applied on the glass surface of the ITO substrate in a polymer photovoltaic cell. Improvement in the power conversion efficiency from 1.80% to 2.05% at normal incidence has been demonstrated. The relative enhancement in the conversion efficiency is almost independent of the incident angles.

1. Introduction

Polymer photovoltaic technology has been getting more important nowadays due to the low cost and simple manufacturing process, and its compatibility to low cost plastic substrates. A lot of research has been conducted around the world [1–10]. Most of the works have been devoted to novel materials development [1–4] and process optimization [5–9]. However, investigations on the optical confinement and antireflection coatings for polymer photovoltaics have been scarce [10–13].

Various light trapping techniques are available for inorganic solar cells such as texturing [14,15]. Textured surfaces enhance scattering and, thus, the light is trapped in the device. Normally, the features of the conventional textured transparent conductive oxide is in the range of several hundreds nanometers, which are comparable or larger than the usual thickness of an active layer in a polymer photovoltaic cell (~100 nm). These large features would generate defects in polymer photovoltaic cells and degrade its performance and yield. Different new methods have been investigated to confine the photons within a thin polymer active layer. Rim et al. [12] proposed to fabricate the polymer solar cell on a V-shape indium tin oxide (ITO) substrate. They demonstrated an efficiency improvement by 52%. However, shunt defects might be generated from the sharp V-shape substrate, which have been discussed by Leo et al. [11]. Nanostructured polymer active layer was investigated for the light trapping in polymer solar cells [10]. By using nano imprint process, they replicated the pattern with nano-scale features on the polymer layer, poly(3-hexylthiophene) (P3HT): poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthien-5-yl)-2,1,3-benzothiadiazole] -2′,2″-diyl). They observed that the power conversion efficiency was increasing by decreasing the sizes of nanodots. The best efficiency was 1.85%, obtained with 25 nm nanodot pattern [10]. The efficiency was just comparable to the polymer solar cell fabricated with the representative materials consisted of P3HT and

doi:10.1016/j.orgel.2010.12.024

[6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM). Ko et al. [13] suggested using photonic crystal structure to trap light in a polymer active layer. Their photonic crystal structure was fabricated in the polymer active layer by Pattern Replication in Nonwetting Templates. The power conversion efficiency was improved, although the efficiency was still below 1% [13]. In their method, the photonic crystal polymer layer had to be thermally cured [13]. Therefore, not all polymer materials are compatible to this method. The choice of materials may be one of the reasons for the relatively low efficiency even after the incorporation of the photonic crystal. The pattern replication also increases the complexity of the device structure and the fabrication process.

In this work, we have used a simple method to fabricate antireflection coating on a polymer photovoltaic cell without any addition step involved before the completion of polymer photovoltaic cell fabrication. Our process is kept in room temperature, so that most of the polymer materials are compatible. Using this antireflection coating, we have demonstrated a 13% relative improvement in power conversion efficiency of a polymer photovoltaic cell.

2. Experimental details

2.1. Fabrication of polymer photovoltaic cell

The polymer photovoltaic cell was fabricated on a thoroughly cleaned ITO glass substrate. The structure of the polymer photovoltaic cell is ITO/poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS, 70 nm)/P3HT:PCBM (1:1, 100 nm)/Al (100 nm). PEDOT:PSS and P3HT:PCBM thin films were fabricated by spin coating, while Al was thermally evaporated under high vacuum. Finally, the device with active area of 16 mm^2 was encapsulated in a nitrogen box with desiccant and encapsulation glass.

2.2. Fabrication of nanostructured antireflection coating

After completion of the polymer photovoltaic cell, the glass side of the ITO coated glass was then cleaned by rubbing with acetone and ethanol. Then nanostructured antireflection coating (nano-ARC) was fabricated on glass side of ITO glass of the polymer photovoltaic cell at room temperature by self-assembly 100 nm nano-silica spheres supplied by Nissan Kagaku, Japan. The completed device was immersed in 1% v/v 3-aminopropyltrimethyoxysilane (APTMS), in anhydrous toluene solution at room temperature for 30 min and rinsed with deionized water [16,17]. Then the glass surface was silanized. It was then immersed into the negatively charged mono-dispersed nano-silica colloidal solution (MP1040 with ~126 nm in diameter, supplied by Nissan Kagaku, Japan) for 5 min, rinsed with deionized water twice and blow dried. The nano-silica spheres were self-assembled on the glass surfaces of the polymer photovoltaic cell. Detailed description of the preparation procedure and properties of the coatings with different sphere sizes are given in Ref. [17].

2.3. Characterization

SEM was used to characterize the morphology of the nano-ARC. Si wafer with native oxide was used as the substrate due to its better conductivity. The direct transmittance and the specular reflectance were measured by Perkin Elmer Lambda 750 UV/Vis/NIR Spectrophotometer. The polymer photovoltaic cell was characterized by current–voltage (J–V) measurement under air mass (AM) 1.5 conditions (100 mW/cm^2). The J–V curve of polymer photovoltaic cell with the nano-ARC was measured first. Then the nano-ARC was removed by rubbing with clean room tissue. The J–V curve of the same polymer photovoltaic cell was measured again. The efficiency data were compared.

3. Results and discussion

Fig. 1 shows the SEM images of the nano-ARC coating on glass. The monolayer of nano-silica spheres are self-assembled in a random non-close packed manner, which is in agreement with previous work [17,18]. The direct transmittance, specular reflectance and weighted reflectance of ITO coated glass with and without nano-ARC are shown in Fig. 2.

Fig. 2a shows the transmittance of ITO glasses with or without nano-ARC and the absorption of P3HT:PCBM. The transmittance is enhanced in the whole spectrum for glass with nano-ARC compared to that of the bare glass, which is beneficial to our polymer photovoltaic cells with absorption in the visible region. The peak transmittance of

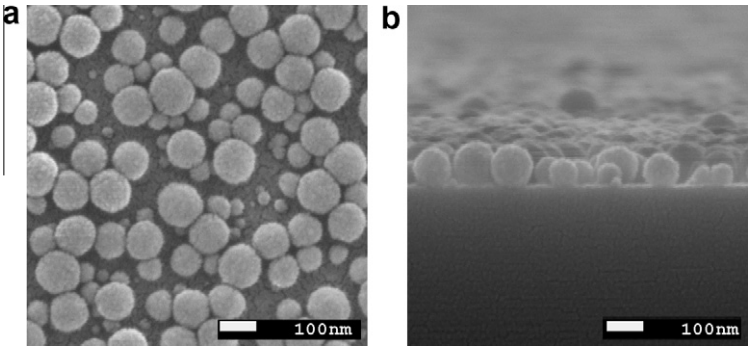

Fig. 1. SEM images show the morphology of nano-ARC (a) top view and (b) corresponding cross-sectional image.

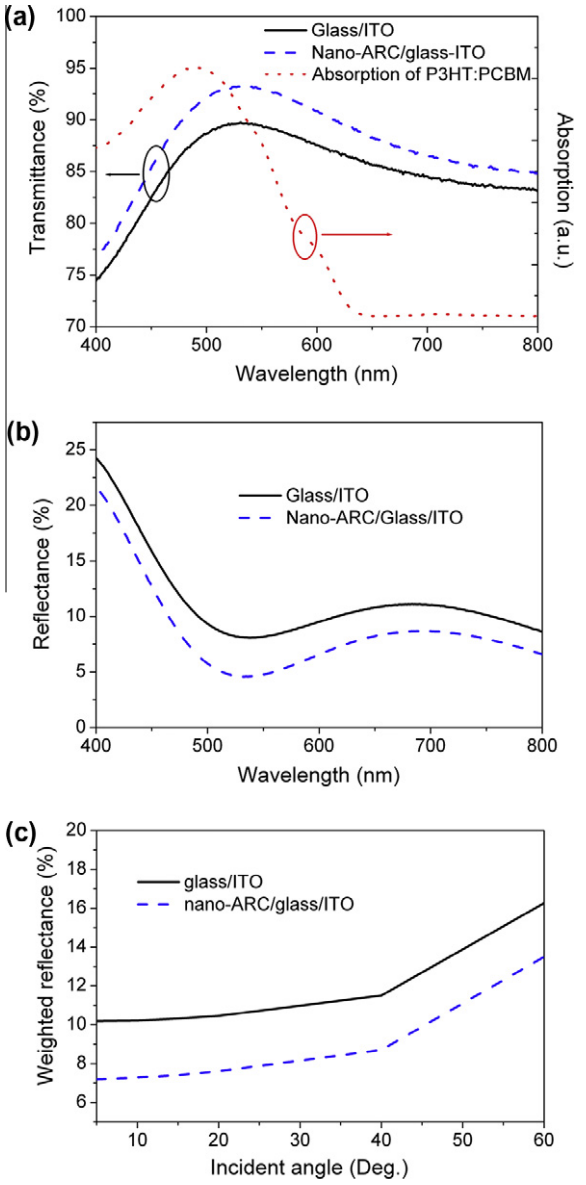

Fig. 2. (a) Transmission spectra and absorption spectrum of P3HT:PCBM, (b) spectral reflectance, and (c) angular dependent weighted reflectance of nano-ARC coated ITO and bare ITO glass.

93.3% is obtained at 532 nm for nano-ARC ITO glass, while it is 89.6% for ITO glass.

The reflectance spectra shown in Fig. 2b and c are measured by Perkin Elmer Lambda 750 UV/Vis/NIR Spectrophotometer. The spectral reflectance is measured at 5° incident angle. For angular dependent reflectance measurements, the samples are mounted in vertical plane and the reflectance are measured at 20°, 40°, and 60°. For the best reduction in reflectance, the refractive index of the antireflection coating should be equal to $\sqrt{n_{air} n_{glass}}$. In our work, the refractive index of the glass is 1.47. Therefore, for the best antireflection properties, the refractive index of the nano-ARC should be $n_{nano\text{-}ARC} = 1.21$. We have attempted to control the coverage percentage of nano-silica spheres to control the refractive index of the nano-ARC. Fig. 2b shows the reflectance measured at 5°. It can be seen that the reflectance of nano-ARC coated ITO glass is decreased compared to that of the bare ITO glass in the whole spectrum from 400 to 800 nm. The minimum reflectance is occurred at around 530 nm. The reduction in the reflectance could be attributed to the lower effective refractive index of the nano-ARC, which is about 1.38 calculated by effective medium theory with 74.5% coverage of nano-silica [19,20]. The optical thickness of the nano-ARC for the minimum reflectance at 532 nm should be equal to $\lambda/4$ (~133 nm). This value is in consistent with the diameter of the nano-silica (~126 ± 13 nm). Fig. 2c shows the weighted reflectance at different incident angles calculated according to Eq. (1).

$$R_w = \int_{400}^{800} R(\lambda) I(\lambda) d\lambda / \int_{400}^{800} I(\lambda) d\lambda \quad (1)$$

where R_w is the weighted reflectance, R is the reflectance from 400 to 800 nm, and $I(\lambda)$ is the intensity of light at particular wavelength, and measured $R(\lambda)$ is the reflectance at particular wavelength. The weighted reflectance of nano-ARC ITO glass is 3% below that of the bare ITO glass. The reduction in the weighted reflectance is almost constant for any incident angle, due to the omnidirectional antireflection properties at the air/nano-ARC/glass interface. The reduction in reflectance over the wide range of incident angles might be attributed to both the lower effective refractive index and the graded-index profile due to the spherical shape of the silica [21–27]. Similar independency of antireflection properties against incident angles was reported by other research groups [26,28,29]. Chang et al. reported that the reflectance of ITO nanocolumns on top of a silicon wafer was independent on the incident angles due to the gradient of refractive index [26]. Zhou et al. also studied the fabrication of various microstructures as antireflection coating on a solar cell. They found that microspheres on top of the substrate can results in significantly reduction in reflectance up to 60° due also to the gradient in the refractive index, and spherical nature of the micro-size silica [29]. Comparing to our previous work on double-side nano-ARC on glass substrate, the reflectance increases more sharply for a single side nano-ARC ITO glass [17]. The reason is the additional planar ITO thin film, which causes addition reflection at the glass/ITO interface and ITO/air interface, especially at large incident angle. Nevertheless, the reduction in reflectance or the enhancement in transmittance at any incident angle is particular important in photovoltaic applications.

Table 1 summarizes the performances of the polymer photovoltaic cells with and without nano-ARC measured under AM1.5G one-sun condition. It is obvious that only

Table 1
Comparison of the polymer photovoltaic performance with and without nano-ARC under AM1.5G irradiation at normal incidence.

	V_{OC} (V)	J_{SC} (mA/cm^2)	FF	η (%)
Without nano-ARC	0.45	12.64	0.32	1.80
Nano-ARC	0.46	13.83	0.33	2.05

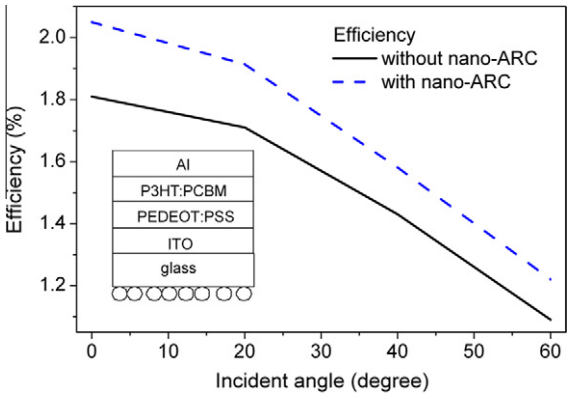

Fig. 3. Angular dependent power conversion efficiency of a polymer photovoltaic cell with and without nano-ARC, the inset shows the structure of polymer photovoltaic cell with nano-ARC.

short circuit current density has been affected by the antireflection coating, which agrees well with the Ref. [30]. It is simply because the fabrication of our nano-ARC does not modify any fabrication process nor the device structure. Therefore, it is reasonable that only short circuit current density is increased due to the increase in the light coupling into the solar cell [30]. The current density has been improved to 13.83 mA/cm^2 from 12.64 mA/cm^2 at normal incidence. This results in an improvement of power conversion efficiency to 2.05% from 1.80%. We have also measured the power conversion efficiency at different incident angles, which is shown in Fig. 3. Upon increasing the incident angles, the relative conversion efficiency improvement drops slightly from 13.3% at normal incident to 12.0% at 60°. The trend of efficiency enhancement disagrees with the reference [30], in which they obtained larger efficiency enhancement at larger incident angle for the omnidirectional antireflection coating. One possible reason may be due to the different in the device structure. Their device structure is antireflection coating/ITO/amorphous silicon, while our device structure is nano-ARC/glass/ITO/polymer. The higher number of planar interfaces in our device structure may result in larger reflectance at larger incident angle, which results in decrease in efficiency enhancement with increasing incident angles. Nevertheless, the power efficiency enhancement is quite obvious from 0° to 60° due to the omnidirectional antireflection properties of the nano-ARC, which could be attributed to the gradient of refractive index of the antireflection coating and the spherical nature of our nano-silica [29].

4. Conclusion

In summary, broadband nanostructured antireflection coating has been fabricated by a simple self-assembly method on a glass substrate of a polymer photovoltaic cell. The fabrication process is fully compatible with any polymer photovoltaic cell, which does not involve any additional fabrication step prior to the completion of the polymer solar cell. The reflectance of the nano-ARC coated ITO glass has been reduced in a broad spectrum from 400 to 800 nm. The weighted reflectance of nano-ARC coated ITO glass has been reduced by 3% at incident angle from 5° to 60°. With the broadband antireflection property, the power conversion efficiency of the polymer photovoltaic cell with nano-ARC increases to 2.05% from 1.80% of the polymer photovoltaic cell without nano-ARC at normal incidence. Due to the omnidirectional property, the relative enhancement of the power conversion efficiency with the nano-ARC is almost independent of the light incident angles.

ABSTRACT

The improvement of current injection efficiency in organic light emitting diodes is demonstrated with incorporation of lithium fluoride (LiF) mixed with subphthalocyanine (SubPc) as electron injection layers. The photoemission spectra indicate that the lithium released from LiF would remove chlorine atoms from SubPc molecules and create large density of gap states at the interfaces. These gap states, resulted from the addition of SubPc in conventional aluminum/LiF/ tris-(8-Hydroxyquinoline)-aluminum (Alq_3) cathode structures, further enhance the electron injection efficiency in OLEDs. The results demonstrate a relatively unique feature of SubPc which can be used to improve both electron and hole injection efficiency.

1. Introduction

Thin film organic light-emitting diodes (OLEDs) have attracted huge attentions in both academic research and industrial development due to their potential applications for future display and lighting [1]. However, the unbalanced carrier mobilities for electrons and holes in organic materials lead to the carrier accumulation at the organic-organic interfaces and device instability [2,3]. In general, the current efficiency can be improved by insertion of electron injection layers (EILs), such as lithium fluoride (LiF) between aluminum cathodes and electron transport layers (ETLs) [4,5]. The chemical reaction mechanism of such a cathode structure has been studied extensively [6–8]. In this letter, we reports an effective cathode structure consisting of a mixture of chlorosubphthalocyaninato boron(III) (SubPc) [9,10] and LiF as electron injection layers and an aluminum cathode, which improves the electron injection current by an order of magnitude as compared to the conventional LiF/Al cathode. The molecular structure of SubPc is shown in Fig. 1. It has already been reported that SubPc can be used as a hole injection layer or be mixed with *N*,*N*′-di(naphthalene-1-yl)-*N*,*N*′-diphenyl-benzidene (NPB) to improve the hole injection efficiency [11,12]. These results demonstrate a rather unique feature of SubPc, which can be used to improve carrier injection efficiency for both holes and electrons in OLEDs. The electronic structures of SubPc/LiF at the cathode interfaces were also studied via photoemission spectroscopy and quantum chemistry calculation to understand the mechanisms leading to the carrier injection improvements.

2. Experimental

Photoemission spectroscopy experiments, including valence band and core level spectra, were carried out at the National Synchrotron Radiation Research Center (NSRRC). The detail specifications of the experimental setups at NSRRC are described in the previous report [13]. The OLEDs investigated in this study were fabricated with the following procedures. The glass substrate coated with ITO

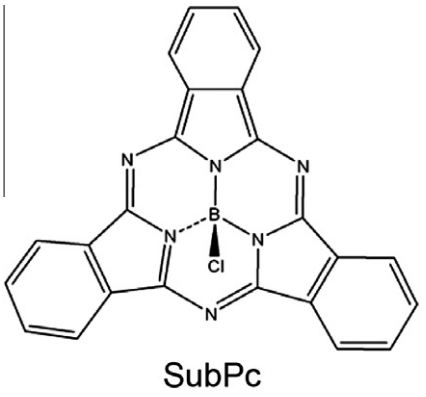

Fig. 1. Molecular structures of SubPc.

was cleaned with acetone, methanol, and UV ozone, sequentially, before being loaded into a thermal evaporation chamber. The deposition rate and thickness of the films were monitored by quartz crystals calibrated with depth profilers. The thermal evaporation chamber was designed to enable mask-change *in situ* so that the devices can be fabricated without exposure to ambient environment in order to minimize the contamination at the electrode-organic interfaces. Furthermore, the sample holder was rotated with constant speed during deposition to ensure good uniformity of films. The current density–voltage (*J*–*V*) characteristics were measured by a Keithley 2400 source-meter. Theoretical simulations with density functional theory (DFT) methods [14] were used to compute density of states. The optimized geometric structures were obtained with the method of B3LYP [15,16] using the basis set of 6-31G, and the single-point energy was then applied to retrieve the detail information of molecular energy using Gaussian03 software [17]. The simulated valence band spectra were extracted via GaussSum [18] with full-width-at-half-maximum of 0.4 eV [19].

3. Results and discussion

To investigate the efficiency of electron injections, a set of multilayer devices consisting of SubPc, LiF, or LiF mixed with SubPc (1:1 ratio) as EILs were fabricated in our customized evaporation chamber. The device structures are indium tin oxide (ITO)/NPB (80 nm)/Alq_3 (80 nm)/EIL (1 nm)/Al (150 nm). Fig. 2(a) shows the current density versus voltage (*J*–*V*) characteristics of the OLEDs with combinations of SubPc and LiF as the EILs. With SubPc inserted in the devices as an EIL between Alq_3 and Al, the current density at operation voltages is only slightly better than that of the device without an injection layer, but is much lower than that of the conventional device with LiF as an EIL. When the 1:1 mixture of SubPc and LiF is used to replace LiF as an EIL, however, the current density of the devices is improved as compared to that of the devices using just LiF as an EIL. The optimized percentages of SubPc in the mixture layers are about 25% to 50% and the device performances are similar when the mixture ratios are in this range. The luminance–voltage (*L*–*V*) data shown in Fig. 2(b) also

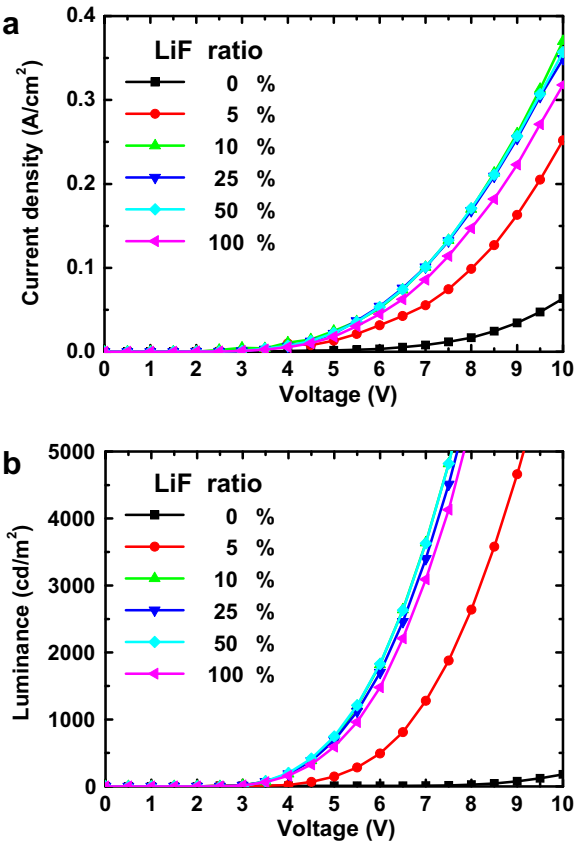

Fig. 2. (a) The *J*–*V* characteristics and (b) the *L*–*V* characteristics of the devices with SubPc and LiF of different ratios as EILs.

demonstrate similar improvement. These results show that LiF:SubPc mixtures are more efficient than the conventional LiF as EILs. Since the cathode structures only consist of EILs about 1 nm between the electron transport layers and cathodes, the electronic structures and the chemical interaction at the Al/LiF:SubPc/Alq_3 interface would be the origins related to the performance improvement of the devices and were therefore further investigated.

It is well known that in Al/LiF/Alq_3 cathode structures chemical reactions between aluminum and LiF lead to the release of lithium from LiF to Alq_3 matrix at the interfaces [5]. In this study with cathode structures consisting of Al/LiF:SubPc/Alq_3, the interactions between SubPc and lithium were investigated via photoemission spectroscopy. Fig. 3 shows the valence band spectra of SubPc with incremental deposition of lithium. The valence band shifts to lower binding energy with very low lithium coverage of 0.2 Å. More importantly, there are new states emerging in the forbidden gap and extending to the Fermi level. These new states close to the Fermi level reaches the maximum intensity at about 2.5 Å of lithium coverages and disappears when the valence band spectra are dominated by lithium with thickness of 10 Å. The result demonstrates that these gap states only appear at the interfaces of lithium and SubPc. The formations of the gap states were further investigated via core level photoemission spectroscopy.

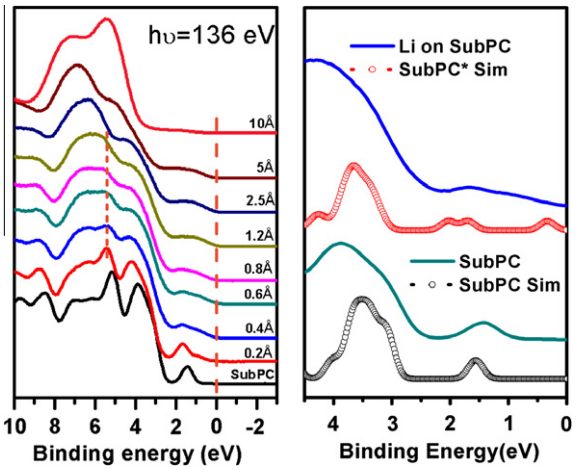

Fig. 3. The valence band spectra of SubPc with incremental deposition of lithium on the surfaces.

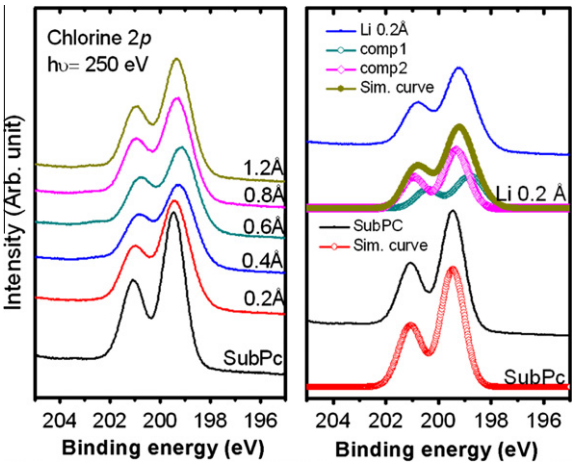

Fig. 5. The chlorine 2p core level spectra of SubPc with incremental deposition of lithium on the surfaces. The figure on the right hand side is the deconvolution of chlorine 2p core levels.

Fig. 4 shows the boron 1s core-level spectra of SubPc with incremental deposition of lithium. It is clear that a new component of boron 1s emerges at the lower binding energy when lithium is mixed with SubPc. The spectra of SubPc with 0.2 Å coverage of lithium is decomposed and shown on the right hand side of Fig. 4. The full-width-at-half-maxima (FWHM) of all the decomposed components are about 1 eV. The new component of the boron 1s core level is at the binding energy of 191 eV. This emerging peak at lower binding energy of boron 1s core level spectra implies that chlorine atoms are detached from the boron in SubPc molecules with the presence of lithium at the interfaces [11].

The core-level spectrum of chlorine 2p was also investigated with excitation photon energy of 250 eV. As shown in Fig. 5, the binding energies of chlorine 2p core levels in pristine SubPc are 199.45 eV for $2p_{3/2}$ and 201.05 eV for $2p_{1/2}$. When lithium is mixed with SubPc, the chlorine core-level spectra are broadened and there is a new feature appearing at the lower binding energy. To clearly identify the energy of the new components, the spectra of pristine SubPc and SubPc with lithium of 0.2 Å are decomposed and shown on the right hand side of Fig. 5. The new features are located at 198.8 and 200.4 eV for chlorine $2p_{2/3}$ and $2p_{1/2}$ core levels, respectively, which are the binding energies of chlorine 2p core-levels in lithium chloride [20]. Fig. 6 shows the Li 1s core level spectra on SubPc films with incremental deposition of lithium. In Fig. 6, at low coverage of Li, the binding energy of Li 1s peak is about 56 eV, which is consistent with the binding energy of Li 1s electron in LiCl [21]. The metallic Li peak begins dominating at high coverage. These results indicate that lithium would take away chlorine atoms from SubPc molecules and form a new radical SubPc*, i.e. SubPc molecules with chlorine atoms detached.

From DFT calculation, SubPc would react with lithium and the products are SubPc* and LiCl and the heat of formation of this reaction is about −27 kcal/mol, which is about the same as the reaction heat of $Alq_3 + Li \rightarrow Li+ Alq_3^-$. The simulated valence band spectra of SubPc and

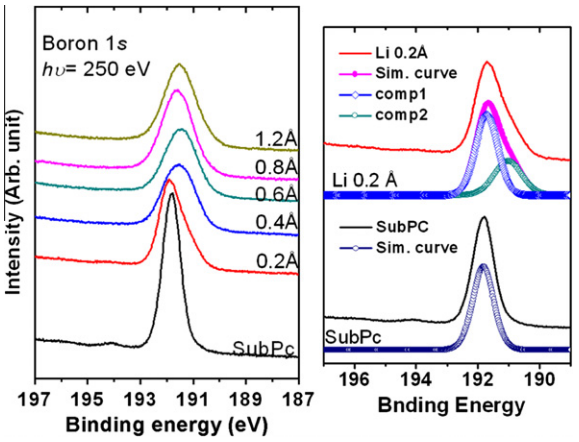

Fig. 4. The boron 1s core level spectra of SubPc with incremental deposition of lithium on the surfaces. The figure on the right hand side is the deconvolution of boron 1s core levels.

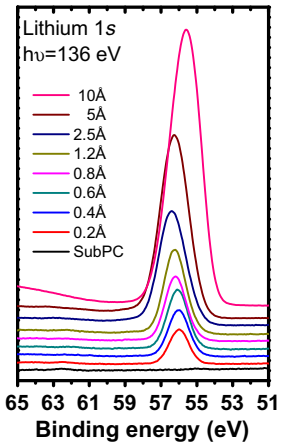

Fig. 6. The lithium 1s core level spectra of SubPc with incremental deposition of lithium on the surfaces.

SubPc* are shown on the right hand side of Fig. 3, which agree fairly well with the experimental spectra. The results indicate that the gap states shown in Fig. 3 are derived from the SubPc* radical. It is known that LiF can react with Al and release lithium atoms. Therefore with SubPc being added in the Al/LiF/Alq_3 cathode structures, other than forming a complex with Alq_3 and resulting *n*-doped Alq_3, lithium could also react with SubPc and create gap states at the interfaces. As a result, the electron injection efficiency would be improved through not only the lowering of injection barriers but also the formation of gap states with SubPc:LiF as EILs, which is consistent with the device characteristics shown in Fig. 2(a).

4. Conclusion

In summary, the improvement of current injection efficiency in organic light emitting diodes is demonstrated with incorporation of LiF:SubPc as electron injection layers. The photoemission spectra indicate that the lithium released from LiF would remove chlorine atoms from SubPc molecules and create large density of gap states at the interfaces. These gap states, resulted from the addition of SubPc in conventional aluminum/LiF/Alq_3 cathode structures, further enhance electron injection efficiency in OLEDs. Combined with the previous report showing SubPc as an efficient hole injection layer, the results demonstrate a unique feature of SubPc which can be used to improve both electron and hole injection efficiency.

ABSTRACT

Manufacturing of flexible ITO-free polymer solar cell modules by roll-to-roll methods (R2R) is described. Inverted devices with top illumination were built on a Kapton foil and an Aluminum/Chromium bi-layer system was used as electron contact. The layer structure was Kapton/Al/Cr/P3HT:PCBM/PEDOT:PSS/Ag (printed) and devices were encapsulated. Small area cells (3 cm^2 active area) were first carefully optimized investigating the influence of a number of discrete parameters on performance. A maximum power conversion efficiency of 1.4% was achieved under 1 sun illumination (AM 1.5G, 1000 W m^{-2}). Optimized lab-scale single devices were then transferred to a full R2R process combining slot-die coating and screen printing. All the layers were processed from solution under ambient conditions. Two different concepts were explored: (i) serially connected stripe modules (to reduce the Ohmic losses) and (ii) monolithic modules (to achieve high geometric fill factor and increase the flexibility of the process). For this second concept, the only layer that needs to be patterned is the silver grid electrode and the grid pattern design can then be readily tuned. As an example, four different patterns were used and the resultant performances compared. Modules comprising 16 serially connected cells gave total area efficiencies up to 0.5% (235 cm^2 – 1% on the active area) while the best monolithic ones gave 0.35% (100 cm^2 – 0.4% on the active area). The freshly prepared devices consistently showed an inflection point in the *IV* curve indicative of a rather poor photovoltaic behavior. Upon light exposure and repeated *IV* scans the inflection point partially disappeared, and performance significantly increased.

1. Introduction

Polymer solar cells (PSC) are emerging as a very promising alternative for solar energy conversion. They ideally present a unique combination of attractive features (low-cost, light weight, flexibility etc.) and are characterized by an incomparable ease of processing [1]. The current state-of-the-art devices rely on a photoactive layer sandwiched between a transparent ITO-based bottom electrode deposited on glass and an evaporated metallic back contact [2]. These so-called "normal geometry" cells are successfully prepared on the lab scale and efficiencies greater than 8% have been reported [3]. As encouraging as these results are, such devices fail to meet most of the prerequisites for a commercially viable device. This is mainly due to the fact that requirements regarding upscaling of fabrication are not taken into consideration. For example, the low-cost potential of PSC is based on high production speeds. This is anticipated to be accomplished by roll-to-roll processing, which totally excludes the use of rigid glass substrates. Vacuum-free processing also seems beneficial as each vacuum step is likely to be cost-increasing unless very high speeds can be accomplished. This point can be addressed by switching from "normal" to "inverted geometry" devices that allow for the use of a solution-processed back electrode. Such devices can be manufactured on a large

doi:10.1016/j.orgel.2011.01.009

scale under ambient conditions following a full solution R2R process [4,5]. This has already led to various demonstration projects confirming the feasibility of the approach [6–8]. Detailed cost analysis of these projects interestingly revealed that ITO is one of the major cost-driving factors [9] and because of the cost of Indium and its scarcity, alternative solutions are highly desirable. This has motivated some attempts to prepare PSC without the use of ITO and different ITO-free working concepts have already been described [10–15]. The replacement of ITO by a highly conductive pure PEDOT:PSS layer or by a composite electrode associating PEDOT:PSS and a metal grid has for instance been investigated [10,11]. Inverted geometries employing a multi-layer system (metal/metal or metal/oxide) as electron contact have also been reported [12–15]. Efficiencies up to 3.1% and excellent stability have for example been obtained by Zimmerman et al. using a Chromium/Aluminum/Chromium stack (hereafter referred to as the Fraunhofer-approach) [13].

In this manuscript, the transfer of the suitably modified Fraunhofer-type approach from the lab scale to a full R2R process is presented. An Aluminum/Chromium bottom electrode deposited on a Kapton foil is used in conjunction with a printed silver grid as the top electrode (Fig. 1). The performances of small model devices were first optimized and a new R2R process was then developed where all the layers except the electron contact were processed from solutions under ambient conditions. Both serially connected modules and monolithic solar cells were prepared. This second approach greatly simplifies the processing as the only patterning requirement concerns the top grid [14].

2. Materials and methods

2.1. Materials

Poly(3-hexylthiophene) was purchased as Sepiolid P200 from BASF and [60]PCBM was purchased from Solenne BV (purity of 99%). PEDOT:PSS was purchased as Orgacon EL-P 5010 from Agfa and was diluted with isopropanol until a viscosity of 270 mPa s was obtained. The silver ink was a heat curable one (Dupont PV410) and used as received. The barrier foil was purchased from Amcor.

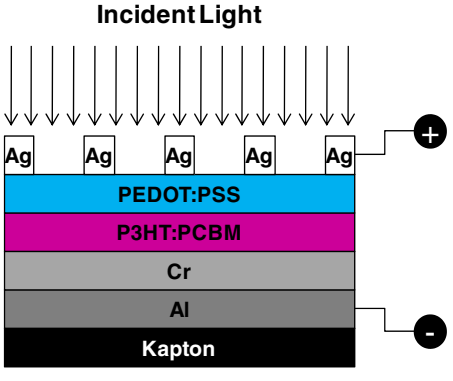

Fig. 1. Illustration of the device architecture employed in this study.

2.2. R2R processing of the electron contact

Kapton foil was purchased from Skultuna Flexibles AB (Sweden) and trimmed to a web of 290 mm. It was chosen owing to its higher thermal stability and better mechanical properties. Deposition of the Aluminum/Chromium stack was performed using a roll-to-roll evaporator. The bare foil was introduced into a R2R sputtering system employing two DC magnetrons with two different targets (Aluminum and Chromium). After pumping down, 100 nm of Aluminum were first sputtered then followed by 15 nm of Chromium on the next target. The web speed was 1 cm min^{-1}. The Al/Cr stack on top of Kapton was obtained either as 16 stripes, each 13-mm-wide and separated from each other by a 2-mm-wide gap (hereafter referred to as striped foil) or as a 200-mm wide band (hereafter referred to as plain foil). The two different patterns are pictured in Fig. 2. Two different kinds of plain foil were also prepared changing the pumping time preceding the stack deposition. The respective sheet resistances of the foils used within this study are collected in Table 1.

2.3. Model devices preparation

Small pieces of the plain foils were first cut manually (25 × 50 mm) and 15 mm of the electrode was then removed from one end by dipping the sample into a 1 M NaOH solution. The as-obtained substrates were rinsed with deionized water and isopropanol. A P3HT:PCBM layer was spin-coated at 600 rpm from a chlorobenzene solution (polymer:fullerene weight ratio 15:10, 30:20, 21:14, 21:18.5 or 21:21 mg/mL of chlorobenzene). The active layer surface was wetted with isopropanol and a PEDOT:PSS layer was then spin-coated at 700, 1000, 1250, 1400 or 2000 rpm. A 5 min thermal annealing was subsequently performed either at 110 or 140 °C on a hot plate. The silver grid was printed using a small laboratory screen printer and dried immediately after printing for 3 min at 140 °C on a hot plate. Finally, the devices were manually encapsulated. All preparative steps were carried out in air and the device active area was 3 cm^2.

2.4. R2R processing

2.4.1. Geometrical considerations

2.4.1.1. 16-Stripe modules. Fig. 3 shows the principle whereby the Al/Cr bilayer is patterned into endless stripes. All the stripes are then serially connected via the ensuing silver printing process.

2.4.1.2. Monolithic modules. In principle, devices as wide as 200 mm could have been made, but here we chose to work on 85 mm wide stripes so that two monolithic modules can fit on the width of the foil.

2.4.2. R2R slot-die coating of P3HT:PCBM and PEDOT:PSS

The R2R slot-die coating was performed on a BC30 basecoater from Solarcoating Machinery GmbH (Germany). The equipment has already been extensively described elsewhere [16]. The active layer was coated from a chlorobenzene solution having the following composition:

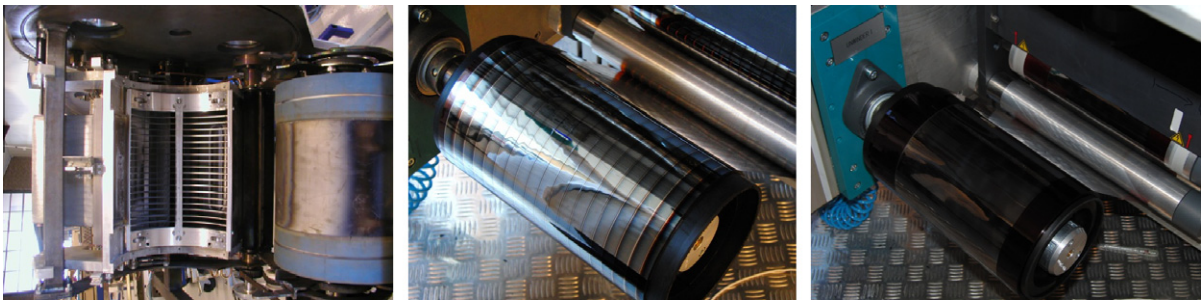

Fig. 2. Photograph of the R2R evaporator setup showing the drum and the mask in front of the two targets (Al and Cr). Courtesy of Susanne Libergreen (left). The two different electron contact patterns are also shown as the striped pattern (middle) and the plain foil (right).

Table 1
Characteristics of the foils employed in this study.

Foil	Pumping time (h)	Sheet resistance (Ω square^{-1})
Stripes	15	0.5
Plain A	2	10–15
Plain B	15	0.5

21 mg mL^{-1} for P3HT and 18.5 mg mL^{-1} for PCBM (Fig. 4). The typical coating speed was 2 m min^{-1} and the active layer was subsequently dried at 90 °C with a residence time in the oven of around 30 s. The wet and dry layer thicknesses were about 8 μm and 300 nm, respectively. The PEDOT:PSS solution was then slot-die coated at a typical speed of 0.3 m min^{-1} and the material was dried at 110 °C with a residence time in the oven of around 3 min. The wet layer thickness was about 70 μm and the dry one about 20 μm. To avoid dewetting of the PEDOT:PSS layer prior to drying, the active layer was wetted with isopropanol immediately before coating.

In the case of the striped foil, P3HT:PCBM was coated as 16 13-mm-wide stripes on top of the Al/Cr stripes with a 1-mm offset allowing for contact between the printed silver and the Al/Cr in the serial connection. Sixteen stripes of PEDOT:PSS were coated on top of the active layer with a 1-mm offset to avoid contact with the Al/Cr layer.

As for the plain foil, two 96-mm wide P3HT:PCBM stripes were coated on top of the Al/Cr (Fig. 4). The two stripes were separated by a 20-mm wide gap allowing for final contacting of the Al/Cr electrode. Two 94-mm wide PEDOT:PSS stripes were coated on top of the active layer with a 1-mm offset to avoid contact with the Al/Cr system.

2.4.3. R2R screen printing of the silver back electrode

This step was carried out on a flat bed R2R screen printer from Alraun [5]. The printing speed of the squegee was 550 mm s^{-1} and the web speed was 1 m min^{-1}. The drying was carried out immediately after printing in a hot air oven. The temperature was set to 140 °C and the total drying time was around 1.2 min (oven length 120 cm). The printed silver pattern used for the 16-stripes modules has already been described elsewhere [5]. In the case of the monolithic devices, four different patterns were employed (Figs. 5 and 6). Four monolithic modules were thus made in one print, each of them having a different silver grid pattern.

2.4.4. R2R lamination

Device encapsulation was achieved on both sides of the completed solar cells by cold lamination of the barrier foil carrying an adhesive. The barrier on the top side was made such that a part of the printed silver electrode was exposed ensuring reliable contact with the electrodes during electrical characterization. The modules were finally cut manually into individual devices prior to electrical characterization. The illuminated area and active area of the final modules are reported in Table 2 for both approaches. For monolithic devices the active area corresponds to the illuminated area minus the silver electrode area (shadow loss).

2.5. Devices characterization

IV-characteristics were recorded under illumination with a Keithley 2400 source-measure unit. The illumination was provided by a KHS575 solarkonstant from Steuernagel Lichttechnik (AM 1.5G, 1000 W m^{-2}) and the intensity regularly controlled. The temperature was 72 ± 2 °C. Photo-annealing studies were also performed by light-soaking the devices under simulated sunlight (AM 1.5G, 1000 W m^{-2}, 72 ± 2 °C) and recording *IV*-curves at fixed interval over an extended period of time.

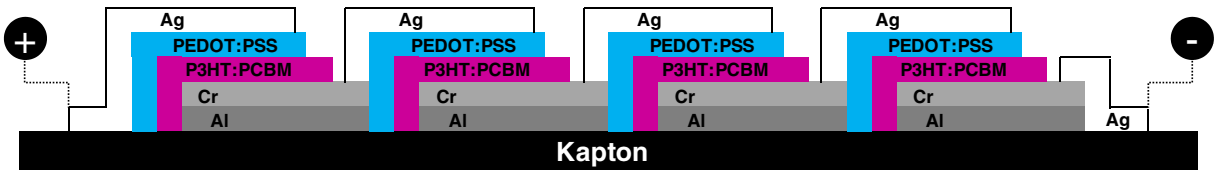

Fig. 3. Schematic cross section of the device showing the layers stacking and their position (view along the stripes).

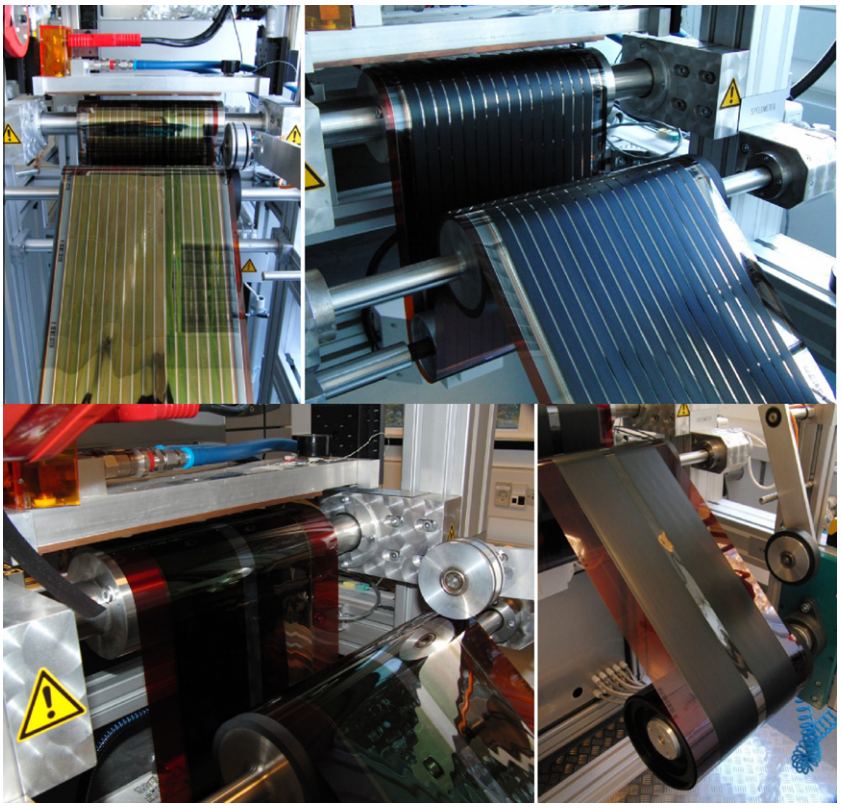

Fig. 4. The slot-die coating of P3HT:PCBM (left) and PEDOT:PSS (right) using the striped foil (top) or the plain foil (bottom).

Light Beam Induced Current (LBIC) experiments were carried out using a custom made setup previously described [17].

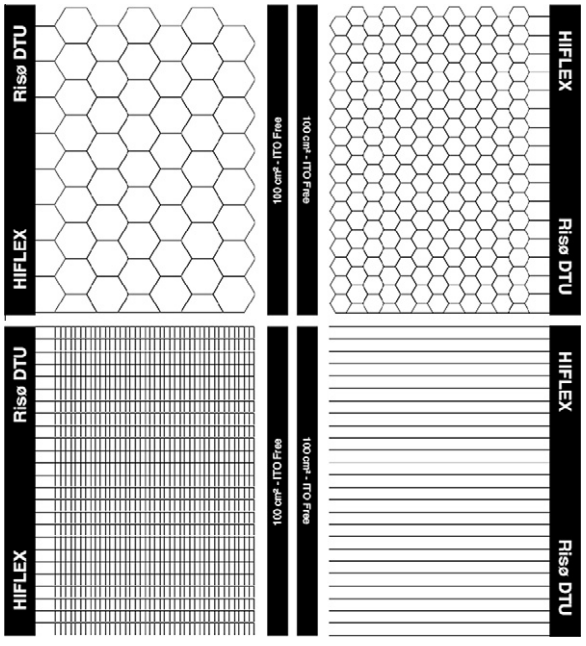

Fig. 5. Drawings of the four silver patterns used for the monolithic devices. Large honey-comb (top left), small honey-comb (top right), grid (bottom left) and simple comb (bottom right).

3. Results and discussion

3.1. Model devices (3 cm^2)

Before preparing the large modules, initial studies were performed on small area model devices. This was done both to evaluate the potential of the approach and to optimize a range of discrete parameters. All the results are collected in the Table 3, together with the experimental details. All the values reported are obtained from an average of four photovoltaic cells.

3.1.1. Influence of the active layer composition

A first series of devices have been fabricated to optimize the solution concentration. The various P3HT concentrations tested were 15, 21 and 30 mg mL^{-1} while the P3HT:PCBM ratio was set to 1.5:1 (w/w). In these conditions, the highest performances were obtained with the intermediate P3HT concentration (21 mg mL^{-1}). A second set of experiments was performed to investigate the influence of the P3HT:PCBM ratio. Three compositions were used – 21:14, 21:18.5 and 21:21 mg mL^{-1} – and very similar performances were recorded. This is not completely surprising as a recent study evidenced that a relatively broad range of P3HT:PCBM mixing ratio affords the optimal device performances [18]. The optimized devices gave V_{OC} = 0.37 V, J_{SC} = −7.3 mA cm^{-2}, and a fill factor (FF) of 0.30, resulting in an aperture efficiency of 0.8% (average value). An inflection point was systematically observed in

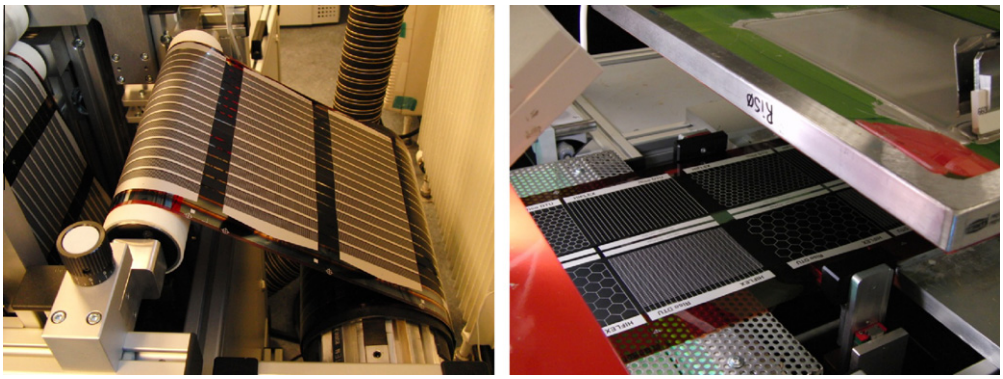

Fig. 6. Silver screen printing for the 16-stripes devices (left) and the monolithic devices (right).

Table 2
Illuminated and active area of the different modules prepared in this study.

Module types	Total illuminated area (cm^2)	Active area (cm^2)	Ratio active/total
16-Stripes	235	160	68.1
Monolithic	100		
Comb		95.8	95.8
Grid		87.8	87.8
Honey comb		94.7	94.7
Large honey comb		97.3	97.3

Table 3
Overview of processing of small area model devices together with the corresponding photovoltaic properties.

Foil	P3HT:PCBM (mg mL^{-1})	PEDOT:PSS		V_{oc} (V)	J_{sc} (mA cm^{-2})	FF	PCE (%)
		Spinning speed (rpm)	Drying				
A	15:10	1000	5 min/110 °C	0.35	3.9	0.31	0.42
	21:14			0.35	5.9	0.35	0.72
	30:20			0.32	3.4	0.24	0.26
	21:21			0.36	7.4	0.3	0.8
	21:18.5			0.37	7.3	0.3	0.8
B	21:18.5	1000	5 min/110 °C	0.43	8.0	0.3	1
			5 min/140 °C	0.39	5.4	0.31	0.65
		700	5 min/110 °C	0.41	6.4	0.35	0.9

		1400		0.4	8.0	0.33	1.1
		2000		–	–	–	–

the *IV*-curves of the devices explaining the low fill factor (Fig. 7, dashed curved). This behavior has been frequently observed in a wide range of devices and is generally attributed to poor carrier transport in one of the layers or interfaces [19].

3.1.2. Influence of the electron contact preparation

The influence of Al/Cr deposition conditions was then studied. Two kinds of foils were used (Table 1) and the resultant performances of the devices were compared (Table 3). As expected, the best results were obtained with the low resistance foil as a 25% efficiency increase was recorded using it. The optimized device gave V_{OC} = 0.43 V, J_{SC} = −8.0 mA cm^{-2}, a fill factor (FF) of 0.30 and an aperture efficiency of 1% (on average).

3.1.3. Influence of the PEDOT:PSS

Further experiments were then conducted to optimize the thickness and the drying conditions of the hole-transporting layer. PEDOT:PSS thickness is especially critical as the use of non-transparent substrate imposes to illuminate the device through the PEDOT:PSS layer. The use of a too thick layer leads to low current densities because of significant transmission loss. In principle, reducing the layer thickness increases transmission of light and subsequently the current density. However, a too thin layer has already been shown to lead to short circuit, a phenomenon ascribed to the destruction of the active layer by the solvent of the silver paste [4]. Increasing the layer thickness solves this problem as solvent diffusion is then prevented. A good balance has thus to be found to get working devices that

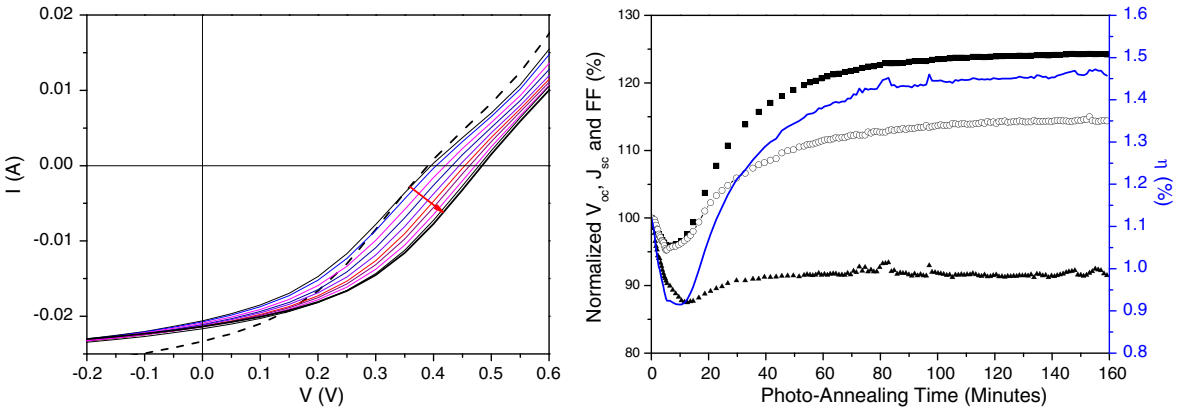

Fig. 7. (Left) *IV*-curve typical evolution during photo-annealing of an encapsulated model device at 1000 W m^{-2}, 72 ± 2 °C (- - -) as-produced (–) after photo-annealing. The curves corresponding to the first phase are omitted; (right) evolution of the photovoltaic parameters versus photo-annealing time (■) V_{oc}, (▲) J_{sc}, (○) FF and (–) η. Device was processed using foil B and PEDOT:PSS was spin-coated at 1250 rpm.

remain as efficient as possible. To adjust the PEDOT:PSS layer thickness, different spinning speeds were employed (700, 1000, 1250, 1400 and 2000 rpm, see Table 3). A practical optimum was obtained processing the PEDOT:PSS in the range 1000–1400 rpm as efficiencies around 1.1% were achieved in these conditions. Lower spin speed yielded lower current while higher spin speed led to reduced voltage.

A last series of experiments were made to study the influence of the drying conditions on the device efficiency. The PEDOT:PSS layer was dried either at 70, 90, 110 or 140 °C. The two lower ones were proved to be practically irrelevant as the time needed to complete a proper drying was extremely long (>45 min at 70 °C). It was also observed that annealing at 140 °C causes a significant efficiency decrease (ca 35%) and 110 °C consequently appeared to be the best drying temperature.

3.1.4. Device photo-annealing

The effects of illumination on the cells photovoltaic properties were studied by measuring the electrical properties of encapsulated devices all along ageing. An instantaneous but rather limited decrease in efficiency was initially observed and immediately followed by a drastic performance increase. A characteristic experiment is shown in Fig. 7. V_{oc}, J_{sc} and FF data have been normalized by their respective initial values for the sake of clarity. One can clearly observe the progressive removal of the inflection point in the *IV*-curve that leads to a sharp increase in the fill factor (FF) and the open-circuit voltage (V_{oc}) while the short-circuit current density is reduced by ca. 10%. A very similar behavior has already been observed and recently described in the case of inverted devices including a ZnO layer [19]. In our case, for the best performing devices a 30% increase was observed and final efficiency as high as 1.4% was obtained (Table 4). This peculiar behavior was systemically observed, but the maximum efficiency varied considerably with the PEDOT:PSS processing conditions (Table 4). Indeed, for devices comprising a thicker PEDOT:PSS layer, the efficiency of photo-aged devices remained inferior to their initial one. This places further evidence on the critical influence of the PEDOT:PSS layer thickness.

Table 4
Overview of the initial and final power conversion efficiencies for different PEDOT:PSS processing conditions.

PEDOT:PSS spinning speed (rpm)	η As-produced (%)	η After photo-annealing (%)
700	0.9	0.85
1000	1	1.2
1250	1.1	1.4
1400	1.1	1.35

3.2. R2R devices

Once the lab-scale experiments completed, the next step was to transfer the optimized devices to a full R2R process allowing for large area modules production. Whatever the module geometry – 16-stripes or monolithic – active layer and PEDOT:PSS were slot-die coated and the silver grid was screen-printed. Of course, when going from spin-coating to slot-die coating some adjustments have to be made (e.g. the active layer has to be dried). But, to the best of our ability, we tried to limit them as much as possible. There was no particular wetting problem of the P3HT:PCBM ink on the electron contact and the active layer coating proceeded well. After isopropanol pre-washing, the PEDOT:PSS was slot-die coated on top of the active layer and subsequently dried. Here again, no particular technical difficulty was encountered during this step.

3.2.1. 16-Stripe modules (235 cm^2)

In this first case, the total length of the material processed was 6 m, giving 20 print repetitions, corresponding to a total of 40 cells. The screen printing of the silver grid being a non continuous process – as opposed to the slot-die coating – it is possible to adjust the position of the mask only between two prints. One prerequisite to making a good print is that all the stripes are perfectly straight and regularly spaced, at least over the repetition length of the

print. Otherwise, some stripes could be shorted after silver printing which of course reduces the module voltage. Unfortunately, this requirement was not always satisfied and difficulties were encountered during the printing step. These alignment problems resulted in strong variations of modules voltage. According to the results obtained with the model devices and assuming that all the stripes perform equally, a V_{oc} as high as 6.4 V could have been expected while the highest voltage achieved was around 5.2 V. The average properties of the devices showing a V_{oc} > 3.5 V (21 devices out of 40) are reported in Table 5 together with the characteristics of the best device. The fill factor is very close to the one reached with model devices whereas the current density is much lower by a factor 5-6. LBIC analysis was performed and revealed that in each module, some of the stripes were performing poorly (Fig. 8) thus limiting the whole efficiency. As observed on Fig. 8, seven out of the 16 stripes show no or limited photovoltaic behavior. This clearly explains the efficiency difference between the lab-scale and the R2R processed devices.

The effects of photo-annealing on the device properties were also examined. As observed for the model cells, large modules required light soaking for some time to reach the optimum performance (Fig. 9). While the fill factor remained almost unchanged, both the short-circuit current density and the open-circuit voltages largely increased. The efficiency recorded after light-soaking was more than doubled and the top performance reached was 0.5%.

Table 5
Overview of the results obtained for the 16-stripes modules showing a V_{oc} > 3.5 V. The highest performance obtained are indicated in brackets.

	V_{oc} (V)	J_{sc} (mA cm^{-2})	FF	η (%)
As-prepared	4.3 (5.1)	0.12 (0.14)	0.35 (0.41)	0.19 (0.29)
After photo-annealing	5.9 (6.1)	0.17 (0.21)	0.41 (0.41)	0.41 (0.53)

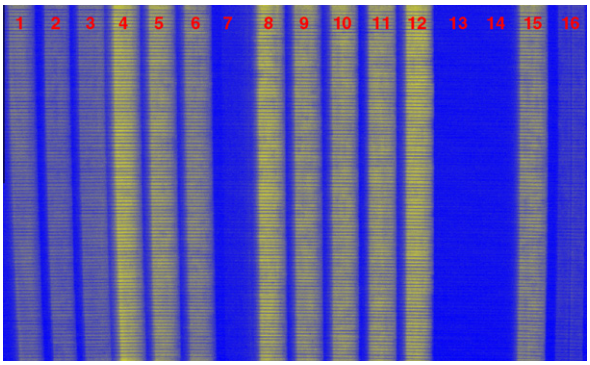

Fig. 8. LBIC image of a typical 16-stripe module where bright yellow represents the highest absolute current extracted while blue represents the lowest current. Stripes nos. 7, 13 and 14 exhibit no photovoltaic behavior. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

3.2.2. Monolithic devices (100 cm^2)

When a process is up-scaled and large-area solar modules produced, large electrical currents are encountered that have to be extracted. When ITO is used, the distance over which the current can be efficiently transported – i.e. without significant Ohmic loss – is strongly limited by the non negligible electrode sheet resistivity (>5 Ω square^{-1} minimum). The situation is even more problematic when ITO is deposited on flexible polymeric substrates where the sheet resistivity is often much higher (around 60 Ω square^{-1}). It is then necessary to pattern the ITO into stripes that can be serially connected. In this way, Ohmic losses are reduced but this is achieved at the expense of the active area (Table 2). In addition, some extra processing steps are needed and this also implies that a great part of the initial amount of ITO is lost [9]. It thus seems attractive to use a high conductivity metal bottom electrode allowing for the processing of large area monolithic devices [14]. Another advantage of this approach is that there is no requirement as for a patterning of the active layer or the PEDOT:PSS. The only patterning constraints reside in the front grid, but this can be easily varied. The whole processing is then simplified to a great extent as this approach does not rely on an extremely accurate patterning which can be a serious issue otherwise, as exemplified in the former paragraph.

Ten meters of Al/Cr foil were processed and a total of 200 cells were obtained. As expected, it was necessary to light-soak the modules in order to reach the highest efficiency. The results obtained for the four different grid patterns are collected in Table 6. From these data it is clear that the grid pattern provides the best results as it provides the highest current density and consequently the maximum performance after light-soaking was 0.36% (0.4% on the active area). This finding is due to the higher surface coverage of this pattern (Table 2 and Fig. 5). Indeed, the rather low conductivity of the PEDOT:PSS limits the distance over which the holes can be transported. If this distance is increased – i.e. if the "density" of the grid is reduced – some of the holes are not extracted and the collected current is lowered. Of course, the grid density must be limited as well. Because of the shadow losses, the amount of light reaching the active layer diminishes when the grid density increases. At some point, this second effect would overbalance the former leading to an efficiency decrease.

One can notice that in comparison to model devices, the efficiency of these cells is strongly limited by a low fill factor (ca 0.25) and a reduced current density (ca. −3 mA cm^{-2}) while the voltage is close to the one obtained for the small devices (ca 0.4–0.45 V). Modules were finally characterized by LBIC and two examples are given below (Fig. 10). From these pictures it is clear that current is collected from the whole device area and one can easily see the shape of the grid.

3.3. Comments and outlook

While ITO has accompanied the PSCs development from the very beginning of the field and is now used worldwide in almost all the devices, its alleviation is commonly seen

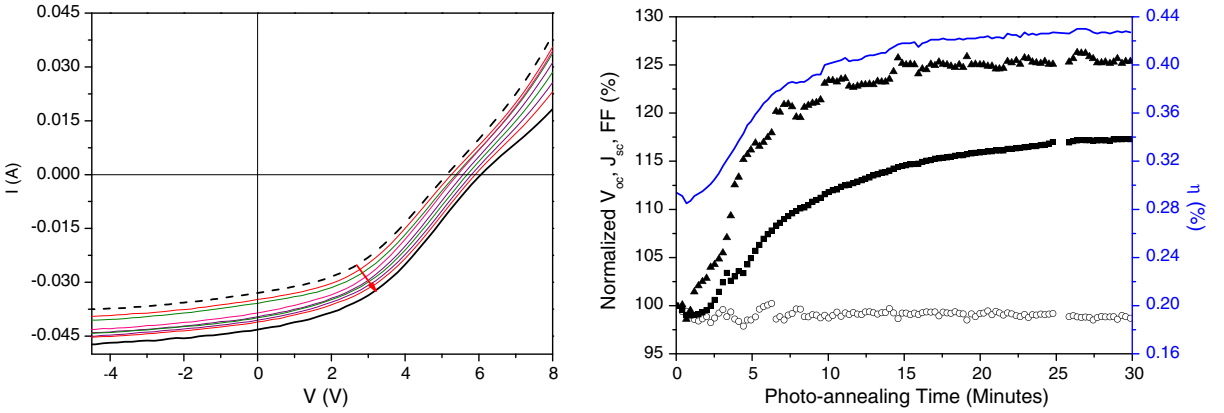

Fig. 9. (Left) *IV*-curve typical evolution during photo-annealing of an encapsulated 16-stripe module at 1000 W m^{-2}, 72 ± 2 °C (- - -) as-produced (–) after photo-annealing; (right) evolution of the photovoltaic parameters versus photo-annealing time (■) V_{oc}, (▲) J_{sc}, (○) FF and (–) η.

	After photo-annealing	0.42 (0.43)	2.01 (2.30)	24.2 (24.1)	0.20 (0.24)

as a prerequisite for commercially viable devices. This is of course very challenging as it requires developing totally different approaches that lie outside the trotted path. To the best of our knowledge, very few studies have been published where processes enabling large-scale R2R manufacture of ITO-free solar cells are described [14,15]. In a context where new concepts are highly sought, the efforts reported here are then valuable. The achievability of the approach we followed has indeed been demonstrated even if it implies a significant sacrifice in performance in comparison to the state-of-the-art [8]. It is obvious that new strategies allowing for the removal of ITO can only be successful if they solve more problems than they create. From this point of the view, two main shortcomings can already be pointed out in this work. The use of Kapton is a first drawback owing to its cost alone (40 times more expensive than PET). However, as there is no need for a transparent substrate, solar modules could potentially be built on any flexible substrate. The vacuum-deposition of the metallic electron contact is a second negative aspect, although it is completely feasible to do it on a large scale using R2R methods (cf. the example of the food packaging industry). Solution-processed electrodes are much more attractive as they can be prepared in higher cadence and potentially with a reduced cost. Besides, a successful attempt has already been reported where PSCs were prepared using a process free from ITO and vacuum coating steps [15].

4. Conclusion

In this work, the preparation of large area ITO-free flexible polymer solar cells has been described. The device structure comprised Kapton/Al/Cr/P3HT:PCBM/PEDOT:PSS/Ag with illumination through the top electrode. The performances of small area model cells were first optimized and the efficiency that could be reached was 1.4% as tested under standard conditions (AM 1.5G, 1000 W m^{-2}). The process was subsequently up-scaled using full roll-to-roll processing and two different concepts were developed: (i) serially connected stripe modules and (ii) monolithic modules. The feasibility of both approaches has been demonstrated and their respective photovoltaic properties presented. Efficiencies up to 0.5% were achieved with the 16-stripe modules (total area 235 cm^2) while the best monolithic ones gave 0.35% (100 cm^2). This second approach provides strong additional advantages in terms of processing as the module shape can be chosen when the silver grid – i.e. the last layer – is printed. Finally, the current limitations of the strategy we followed were outlined. First of all, while the problem of the use of ITO is addressed, a sacrifice in performance was also observed. In addition the upscaling to larger area devices brings along with it challenges in alignment of layers during coating and printing leading to large defective areas (stripes) limiting the performance. More control over the coating and printing process is thus warranted before detailed physical insight can be gained. Other shortcomings are the vacuum coating of Aluminum and Chromium and the use of Kapton. Possible solutions to these hindrances were finally discussed.

ABSTRACT

In this study we used a known host material diphenylbis[4-(9-carbazoyl)phenyl]silane (SiCa) to realize a highly efficient bis[4,6-(difluorophenyl)-pyridinato-N,$C^{2'}$]picolinate (FIrpic)–based blue phosphorescent device exhibiting high efficiencies of up to 18.3%, 41.5 cd/A, and 31 lm/W in a carrier- and exciton-confined device structure. At a practical brightness of 1000 cd/m^2, the device performance (η_{ext}) remained as high as 16.7%. The enhanced efficiency and reduced roll-off resulted mainly from the introduction of (a) DTAF as an HTL that efficiently blocked and confined excitons within the FIrpic-doped emissive layer, and (b) a thin layer of DPPS between the EML and TAZ, serving as an exciton- and hole-blocking layer to suppress exciton quenching by FIrpic at the EML–ETL interface. In addition, we incorporated a red phosphorescent dopant ($Mpq_2Iracac$) into the blue device to fabricate a white phosphorescent organic light-emitting device, which exhibited satisfactory efficiencies (11.6%, 21.2 cd/A, 14.2 lm/W) with the Commission Internationale de L'éclairage (CIE) coordinates of (0.35, 0.38).

1. Introduction

Phosphorescent organic light-emitting devices (PhOLEDs) featuring emissive layers comprising transition metal–centered dyes doped into appropriate host materials are attracting much research attention because they can achieve internal efficiencies as high as 100% [1]. Unlike the reported efficient green- and red-PhOLEDs, the realization of highly efficient blue PhOLEDs remains a great challenge because the triplet energy (E_T) of host molecules must be sufficiently high (i.e., $E_T \geqslant 2.7$ eV) to confine the triplet excitons within the emitting layer [2–5]. In addition, the tendency of triplet excitons to diffuse into the nonradiative levels of the neighboring hole transport layer (HTL) and/or electron transport layer (ETL) must also be avoided. In this regard, Zheng et al. demonstrated highly efficient blue PhOLEDs using 1,1-bis[(di-4-tolylamino)phenyl]cyclohexane (TAPC) as the HTL, obtaining a maximum external quantum efficiency (η_{ext}) of 18.1%, which is approximately 50% higher than the value obtained (12%) for a previously reported device featuring bis[*N*-(1-naphthyl)-*N*-phenylamino]biphenyl (NPB) as the HTL [6]. The Kido group recently reported several ETLs exhibiting hole-blocking ability that improve the performance of bis[4,6-(difluorophenyl)-pyridinato-N,$C^{2'}$]picolinate (FIrpic)–based blue PhOLEDs [7–9]. For example, a device incorporating diphenylbis[4-(pyridin-3-yl)phenyl]silane (DPPS) as the ETL provided a maximum value of η_{ext} of 22%, which is much higher than the value obtained (15.3%) when using 3-(4-biphenylyl)-4-phenyl-5-(4-*tert*-butylphenyl)-1,2,4-triazole (TAZ) as the ETL [9]. It appears that achieving highly efficient blue PhOLEDs requires improvements in the charge recombination efficiency by

doi:10.1016/j.orgel.2011.01.012

using efficient charge-transporting materials to maintain the charge balance as well as to confine the generated triplet excitons within the emissive layer. The neighboring hole- and electron-transport materials (HTMs and ETMs) require: (a) the higher triplet energy than that of blue dye to suppress the triplet exciton quenching of the emitter, (b) the carrier blocking ability to confine the carriers within EML and (c) the high carrier transport/injection property to reduce the driving voltage of devices.

Among the many silicone-based wide-bandgap host materials that have been developed, tetraphenylsilane-functionalized ultrahigh-energy-gap hosts (UGHs) are particularly useful for fabricating deep blue PhOLEDs [3,10,11]. Unfortunately, tetraphenylsilane has an undesirably low glass transition temperature (T_g), which limits its practical applicability. To solve this problem, Kim et al. developed a new host material, diphenylbis[4-(9-carbazoyl)phenyl] silane (SiCa) [12], by appending carbazole moieties through their 9-positions (i.e., the nitrogen atom) to a tetraphenylsilane core. The design of SiCa was based on the fact that both tetraphenylsilane and carbazole possess large triplet energy gaps (3.5 and 3.0 eV, respectively) [10,13]. The tetrahedral Si center serves as an effective spacer that blocks the π-conjugation of the carbazole substituents, thereby maintaining a high triplet energy (E_T = 3.0 eV) and enhancing the thermal stability (T_g = 109 °C). These values suggest that SiCa might be a promising host material for blue electrophosphorescent devices. Unfortunately, the use of SiCa as a host for tris[(3,5-difluoro-4-cyanophenyl)pyridine]iridium (FCNIr) [12,14] resulted in a low quantum efficiency (4.9% at 300 cd/m^2), presumably because of poor energy transfer in the host/guest system, poor triplet exciton confinement, and/or unbalanced charge recombination in the emitting layer.

In this report, we demonstrate that high efficiency can be achieved in a carrier- and exciton-confined device structure. Indeed, we achieved a maximum value of η_{ext} of 18.3% when using the well-established blue phosphorescent iridium complex FIrpic as the dopant dispersed in SiCa by using efficient charge-transporting materials (DTAF and DPPS) to maintain the charge balance as well as to confine the generated triplet excitons within the emissive layer. These results can provide the basic guidelines for the device design of FIrpic-based OLEDs. We have also used SiCa in conjunction with a red phosphorescent dopant ($Mpq_2Iracac$) [15] to fabricate a white PhOLED that exhibited satisfactory efficiency (11.6%, 21.2 cd/A, 14.2 lm/W) with the Commission Internationale de L'éclairage (CIE) coordinates of (0.35, 0.38).

2. Results and discussion

We adopted two approaches to improve the performance of the previously reported device incorporating SiCa as the blue host: (1) employing a dopant material having a lower triplet energy and (2) optimizing the device structure so that it featured charge transport layers with high triplet energies [16]. Because the triplet energy of SiCa (E_T = 3.0 eV) is 0.2 eV higher than that of FCNIr (E_T = 2.8 eV), it should serve as a host for FCNIr, except that the neighboring charge transport layers – bis[*N*-(1-naphthyl)-*N*-phenylamino]biphenyl (NPB) and 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) with low triplet energies are strong quenchers of the blue phosphorescence of FCNIr. We anticipated that selecting the popular blue emitter FIrpic, which has a lower triplet energy (E_T = 2.62 eV) [2], as the dopant would prevent back energy transfer from the dopant to the adjacent functional layers. Therefore, we employed the phosphor FIrpic to replace FCNIr in the emitting layer having the original structure reported by Kim [12]. By changing the doping concentration of FIrpic, we prepared three devices (**A1–3**) having the following configuration: indium tin oxide (ITO)/ *N*,*N*′-diphenyl-*N*,*N*′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/NPB (30 nm)/SiCa:FIrpic (**A1**: 5%; **A2**: 10%; **A3**: 15%) (30 nm)/BCP (5 nm)/tris(8-hydroxyquinoline) aluminium (Alq_3, 20 nm)/LiF (1 nm)/Al (200 nm). Fig. 1 presents the current

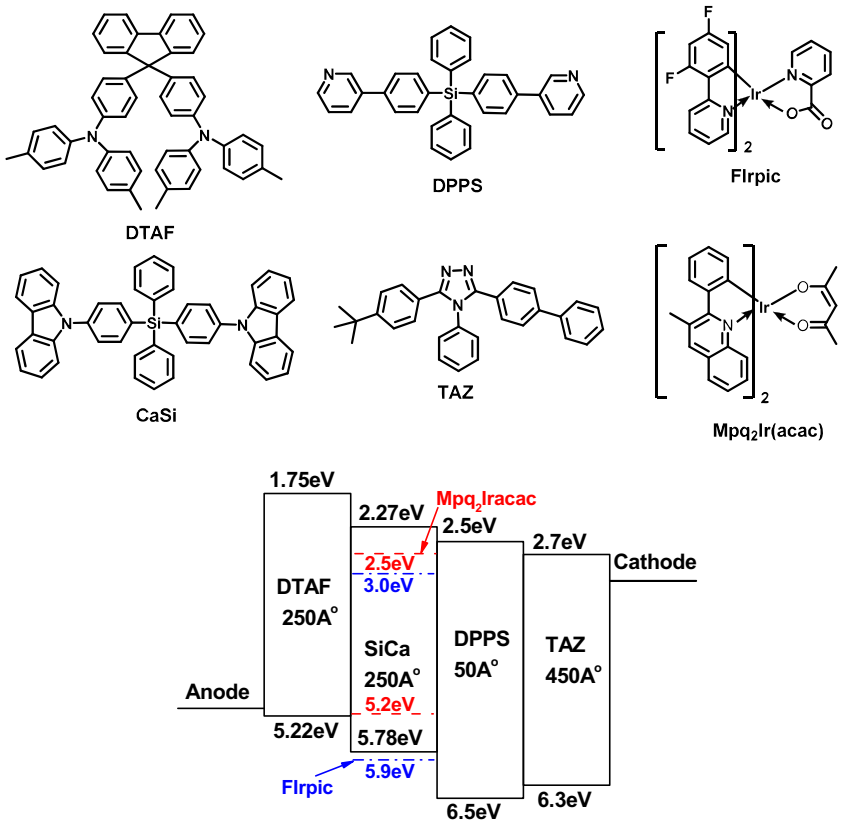

Fig. 2. Energy level diagram and molecular structures of the materials used in device **D1**.

density–voltage–luminance (*I–V–L*) characteristics and EL efficiencies of devices **A1–3**. Notably, the brightnesses (39,400–43,100 cd/m^2) and current densities (1880–2380 mA/cm^2) of our devices were significantly higher than those reported previously [12], suggesting that SiCa is capable of effectively confining the triplet energy of FIrpic. Nevertheless, the EL efficiencies (3.6–2.3% or 4.3–1.7 lm/W) of devices **A1–3** were low relative to those reported previously, presumably because we used NPB, which has a low triplet energy (E_T = 2.3 eV), as the HTL [17], which could not efficiently prevent exciton diffusion.

To improve the EL efficiencies of devices **A1–3**, we used 1,1-bis[(di-4-tolylamino)phenyl]-9,9′-fluorene (DTAF) to replace NPB as the HTL [18,19]. The molecular design of DTAF endows it with several advantageous properties: (1) high morphological and thermal stability (T_g = 124 °C); (2) an appropriate HOMO energy level (−5.22 eV) to provide a low hole injection barrier from the anode and a low-lying LUMO energy level (−1.75 eV) to block electrons injected from the cathode; (3) high hole transport properties ($\mu_h > 10^{-3}$ cm^2/Vs); and (4) a high triplet energy gap (E_T = 2.87 eV) relative to that of NPB, allowing triplet excitons to be confined in the EML. In addition, we adopted a 5-nm-thick layer of diphenylbis[4-(pyridin-3-yl)phenyl]silane (DPPS), inserted between the EML and the ETL (TAZ), to serve as an exciton- and hole-blocking layer (HBL) for suppressing the FIrpic exciton quenching at the EML–ETL interface. Chemical structures of related compounds and their energy levels are shown in Fig. 2, in which HOMO levels of compounds in films are determined here by Riken AC-2 photoemission spectrometer while the HOMO levels of DPPS and TAZ are taken from the literature [9]. The LUMO levels of all compounds are derived by subtracting the HOMO levels from the optical energy gaps.

To evaluate the feasibility of using DTAF as an HTL and DPPS as an HBL, we designed three different devices **B1–3** having the following configuration: ITO/poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonic acid) (PEDOT:PSS) (30 nm)/HTL (25 nm)/SiCa:12 wt% FIrpic (25 nm)/ETL (50 nm)/LiF (0.5 nm)/Al (100 nm). In device **B1**, NPB (20 nm)/TCTA (5 nm) was used as the HTL; in devices **B2** and **B3**, DTAF (25 nm) was employed as the HTL. In addition, TAZ (50 nm) was employed as the ETL in devices **B1** and **B2**, whereas DPPS (5 nm)/TAZ (45 nm) was adopted in device **B3** as the ETL. In device **B1**, we inserted a thin layer of 4,4′,4″-tri(*N*-carbazolyl)triphenylamine (TCTA, 5 nm), which has a high triplet energy (E_T = 2.76 eV) [20], between NPB and the EML to serve as the exciton-blocking layer. In device **B3**, we inserted a 5-nm-thick layer of DPPS, which has a HOMO energy level of 6.5 eV, between the EML and TAZ to bolster the hole-blocking capability of TAZ (HOMO = 6.3 eV) and to confine the excitons within the EML.

Fig. 3 displays the electroluminescence (EL) characteristics of devices **B1–3** featuring this new device structure;

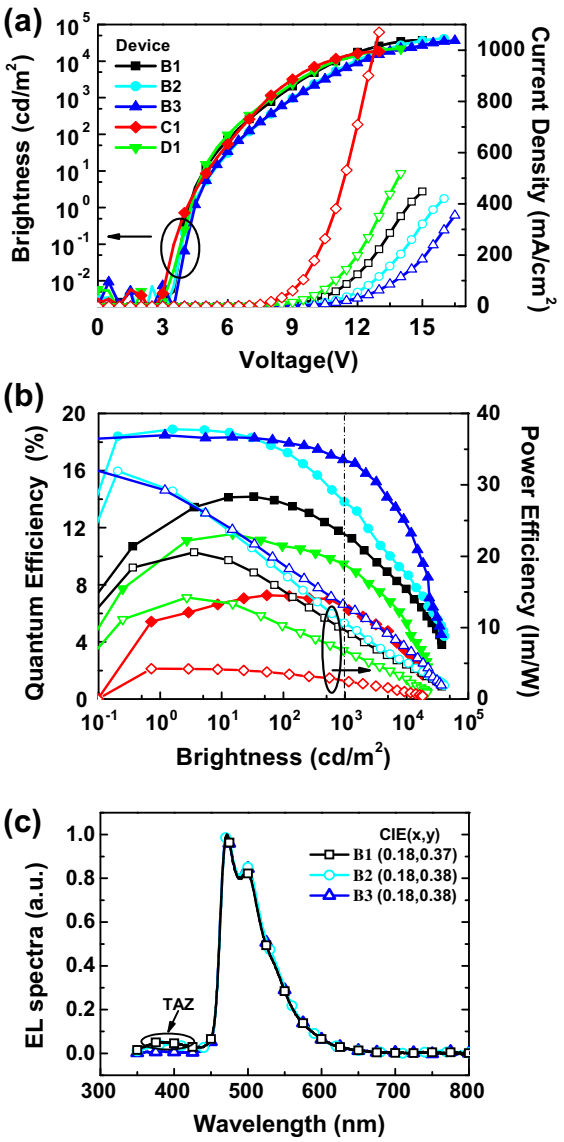

Fig. 3. (a) Current density–voltage–luminance (*I–V–L*) characteristics, (b) external quantum (η_{ext}) and power (η_p) efficiencies plotted as a function of brightness, and (c) EL spectra of devices.

Table 1 summarizes the data. Although devices **B1–3** exhibited similar turn-on voltages (ca. 3.5 V) and similar brightnesses (37,300–40,900 cd/m^2) relative to those of devices **A1–3**, the current densities (360–450 mA/cm^2) had obviously decreased. The *I–V* characteristics revealed that the device **B2** incorporating DTAF as HTL exhibited a slightly lower current density at high voltage relative to device **B1** incorporating NPB/TCTA as HTLs. The lower current density may be due to a large barrier of 0.5 eV between DTAF/CaSi. (see the schematic energy level diagram in Fig. 2). The large energy mismatch should enable a lot of holes accumulate at the HTL/EML interface and lead to a direct trap of charge carriers by FIrpic. In addition, the high triplet energy of DTAF (E_T = 2.87 eV) also enables the efficient confinement of excitons within the EML. Combining these effects together, the DTAF-based device **B2** exhibited efficiencies [a maximum η_{ext} of 18.9% (41.7 cd/A) and a value of η_P of 30 lm/W] that were much higher than those of the traditional NPB/TCTA-based device **B1** (14.2%, 31 cd/A, and 20.6 lm/W, respectively; Fig. 3b). These results indicate that the exciton-confined ability is more crucial than hole injection, because of the greater number of holes than electrons in the OLED. Therefore, the charge balance in the DTAF-based device **B2** might be better than that of the NPB/TCTA-based device **B1**, and results in a higher charge-recombination efficiency.

Careful analysis of the electroluminescence (EL) spectra of devices **B1** and **B2** revealed the presence of short wavelength (λ = 360–410 nm) emissions (Fig. 3c), which presumably arose from a portion of the holes that overcame the barrier at the EML–TAZ interface recombining with electrons in TAZ. Thus, we inserted a 5-nm-thick layer of DPPS between the EML and TAZ in device **B3** to serve as the exciton- and hole-blocking layer to prevent exciton quenching and hole leakage into the TAZ. Obviously, the emission of device **B3** occurred only from FIrpic, without any other emission from its neighboring materials. The quantum efficiency roll-off of device **B3** was suppressed after the introduction of the 5-nm-thick DPPS layer (Fig. 3b). When the brightness reached 1000 cd/m^2, the value of η_{ext} of device **B3** remained as high as 16.7%, with an efficiency roll-off as low as 9%. This result indicates that DPPS can be more effectively blocked the holes within the EML, owing to the wider energy gap, that is, the HOMO level (6.5 eV) is greater than that of TAZ. To gain further insight into the emission mechanisms, three testing devices with doping in only a portion of the 25 nm SiCa emitting layer under B3 device structure (device B3a: doping 8 nm next to DTAF; device B3b: doping 8 nm at the center;

[a] Defined as the voltage at which the EL is rapidly enhanced.

device B3c: doping 8 nm next to DPPS) were also fabricated and tested. Although all three devices showed emission dominantly from FIrpic, device B3b showed much lower quantum efficiency (4%) than devices B3a and B3c (7.8% and 8.7%, respectively). The results indicate that the emitting zone mainly takes place near the HTL/EML and EML/ETL interfaces. The holes accumulate at the HTL/EML interface due to a large barrier of 0.5 eV between DTAF/CaSi. FIrpic is an emitting ET material [21], therefore, localization of excitons on FIrpic can occur through direct charge trapping at the HTL/EML interface. The emitting zone also takes place near the EML/ETL interface, where electrons inject either onto CaSi or directly onto FIrpic.

We confirmed this hypothesis by exploring the carrier transport properties of SiCa, probed using time-of-flight (TOF) techniques [22]. The device used for TOF measurement was prepared through vacuum deposition with the structure ITO glass/SiCa (2.1 μm)/Ag (150 nm) and then it was placed inside a cryostat under vacuum. Fig. 4a display representative TOF transients for holes measured at ambient temperature under an applied field of 9.7×10^4 V/cm. The observed photocurrents did not display any distinct constant current plateaus; instead, the current decayed significantly, resulting in *dispersive* charge transport. This result suggests that the charge carriers in SiCa were trapped and could not attain dynamic equilibrium while migrating across the sample. We obtained the transit times (t_T) from the intersection points of two asymptotes in the double-logarithmic representations (insets to Fig. 4a). The hole mobility was determined using the equation $\mu = d^2/Vt_T$ where d is the thickness of the organic film, V is the applied voltage, and t_T is the transit time. Fig. 4b plots the calculated field-dependent hole mobility of SiCa as a function of $E^{1/2}$. The hole mobilities exist in the range from 1.2×10^{-4} to 5.4×10^{-4} cm^2/Vs for fields varying from 9.7×10^4 to 5.3×10^5 V/cm. Conversely, the electron mobility of SiCa was too low to be measured. The preferential hole mobility of SiCa agrees with the results observed for devices.

In addition to acting as a blue host, SiCa can also be used as the host for red phosphorescent dopants. Using the structure of device **B3**, we introduced $Mpq_2Iracac$ [15] as a red phosphorescent emitter to obtain device **C1**, which exhibited a maximum brightness of 18,200 cd/m^2 at 1070 mA/cm^2 with CIE coordinates of (0.66, 0.34). The *I–V* characteristics of device **C1** revealed a higher current density (1070 mA/cm^2 at 13 V) than that of device **B3** (Fig. 3a). This result can be rationalized by considering that the HOMO energy level of $Mpq_2Iracac$ is close to that of DTAF, thereby reducing the hole injection barrier at the interface. Notably, however, device **C1** provided relatively low values of η_{ext}, η_l, and η_P (7.3%, 7.3 cd/A, and 4.2 lm/W, respectively), due to the intrinsic lower quantum yield of red triplet emitter.

To take advantage of the double confinement strategy used in device **B3**, we fabricated a white PhOLED (device **D1**) by doping the emitting layer in device **B3** with the red phosphor $Mpq_2Iracac$. The CIE coordinates of device **D1** (Fig. 5a) reveal the complementary nature of these

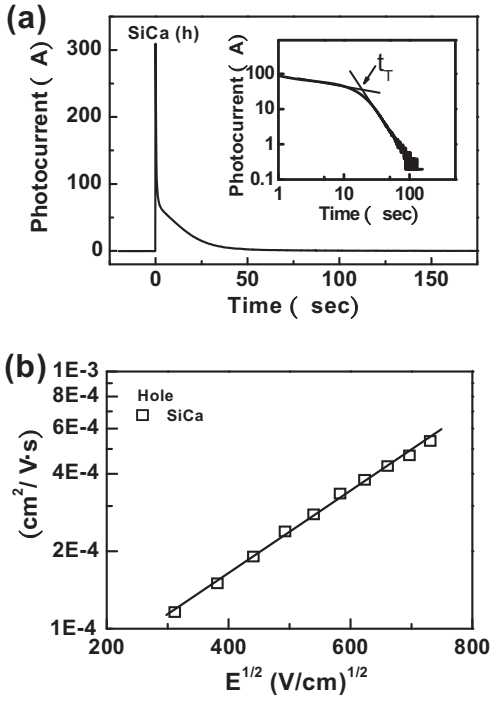

Fig. 4. (a) Representative TOF transients for holes of SiCa (d = 2.1 μm) at a value of E of 9.4×10^4 V/cm. (b) Hole mobility plotted with respect to $E^{1/2}$ at ambient temperature.

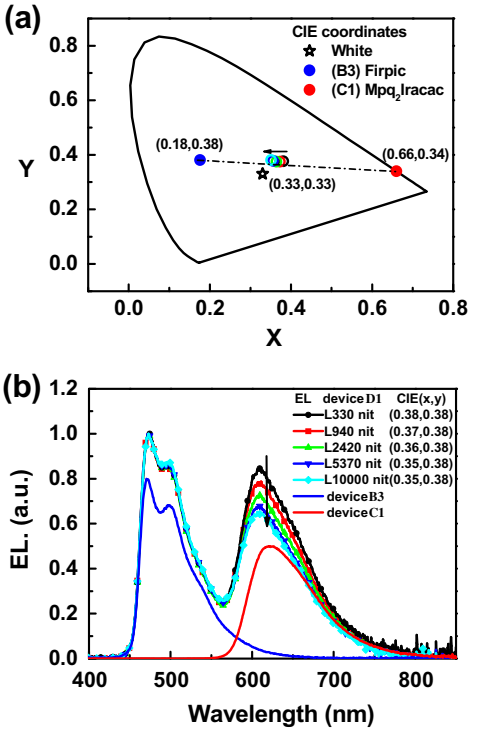

Fig. 5. (a) Chromaticity diagram (CIE coordinates), and (b) EL spectra of devices **B3** (blue), **C1** (red), and **D1** (white) at various luminance (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

two phosphors for white light emission. White emission with CIE coordinates close to (0.33, 0.33) could be achieved if appropriate combinations were made [23–25]. For the two-dopant single-EML device, the EL was strongly influenced by the ratio of the two dopants. Through systematic tuning of the dopants' concentrations, we fabricated a white light-emitting device **D1** incorporating 12 wt% of FIrpic and 0.2 wt% of $Mpq_2Iracac$ doped into the host SiCa. The proportion of red dopant required to produce balanced emission in this device is relatively low because the red emission occurred from the combined effects of efficient energy transfer from the blue phosphor and exciton formation by charge trapping on the red dopant. The maximum brightness of 21,600 cd/m^2 was achieved at 14 V, with maximum efficiencies (η_{ext}, η_l, and η_p) of 11.6%, 21.2 cd/A, and 14.2 lm/W. Fig. 5b displays the EL spectra of device **D1** recorded at various brightnesses. The relative intensity of the red emission decreased slightly when the brightness increased, leading to a slight shift in the CIE coordinates from (0.38, 0.38) at a value of L of 330 cd/m^2 to (0.35, 0.38) at 10,000 cd/m^2. This color shift originated from the shifting of the recombination zone upon increasing the applied voltage and from the easier formation of high-energy excitons at higher voltage [26]. Compared with multi-EML white organic light emitting diodes (WOLEDs) [27–29,24], our two-dopant single-EML device exhibits higher color stability, which we attribute to the more-uniform distribution of the two dopants in the EML [30].

3. Experimental

We study of carrier-transport properties in the organic materials by the time-of-flight (TOF) transient photocurrent technique. The samples for the TOF measurement were prepared by vacuum deposition using the structure: ITO glass/SiCa (2.1 μm)/Ag (150 nm), and then placed inside a cryostat and kept under vacuum. The thickness of organic film was monitored in situ with a quartz crystal sensor and calibrated by a Thin Film Thickness Measurement (K-MAC ST2000). A pulsed nitrogen laser was used as the excitation light source through the transparent electrode (ITO) induced photogeneration of a thin sheet of excess carriers. Under an applied dc bias, the transient photocurrent was swept across the bulk of the organic film toward the collection electrode (Ag), and then recorded with a digital storage oscilloscope. Depending on the polarity of the applied bias, selected carriers (holes or electrons) are swept across the sample with a transit time of t_T. With the applied bias V and the sample thickness D, the applied electric field E is V/D, and the carrier mobility is then given by $\mu = D/(t_T E) = D^2/(Vt_T)$, in which the carrier transit time, t_T, can be extracted from the intersection point of two asymptotes to the plateau and the tail sections in double-logarithmic plots.

The PHOLEDs were fabricated on a clean glass substrate precoated with an ITO layer having a sheet resistance of 20 Ωsq. Prior to use, the substrate was degreased with solvents and cleaned in a UV-ozone chamber. To improve the hole injection from the anode, PEDOT:PSS was spun onto the pre-cleaned substrate to form a 30-nm-thick polymer buffer layer. The other organic layers were sequentially deposited onto the substrate without breaking vacuum at a pressure of ca. 10^{-6} torr. All materials were purified by train sublimation prior to used. The I–V–L characteristics of the devices were measured simultaneously in a glovebox using a Keithley 6430 source meter and a Keithley 6487 picoammeter equipped with a calibration Si-photodiode. EL spectra were measured using a photodiode array (OTO SD1000).

4. Conclusion

We have fabricated a highly efficient FIrpic-based blue PhOLED, exhibiting a decreased efficiency roll-off that possesses a carrier-balanced and exciton-confined device structure. This device exhibited a maximum external quantum efficiency (η_{ext}) of 18.3% (41.5 cd/A) and a power efficiency of 31 lm/W; the quantum efficiency roll-off was minimal: the value of η_{ext} remained as high as 16.7% at a brightness of 1000 cd/m^2. The enhanced efficiency and reduced roll-off resulted mainly from the introduction of (a) DTAF as an HTL that efficiently blocked the injected electrons and confine excitons within the FIrpic-doped emissive layer, and (b) a thin layer of DPPS between the EML and TAZ, serving as an exciton- and hole-blocking layer to suppress exciton quenching by FIrpic at the EML–ETL interface. By incorporating a red phosphorescent dopant ($Mpq_2Iracac$) into the blue device, we fabricated a white PhOLED that exhibited satisfactory efficiencies (11.6%, 21.2 cd/A, 14.2 lm/W) with CIE coordinates of (0.35, 0.38).

ABSTRACT

Delayed EL measurements are used to elucidate carrier recombination and light emission mechanism in phosphorescent organic light emitting devices (PhOLEDs) based on 4,4′-bis(9-carbazolyl)-1,1′-biphenyl (CBP) and fac-tris(2-phenylpyridine) iridium ($Ir(ppy)_3$) host:guest system. The results show that changing the thickness of the emitting layer (EML) leads to marked changes in charge-trapping and host–host triplet–triplet-annihilation (TTA) patterns, suggesting that carrier transport and recombination processes change depending on EML thickness. The results suggest a change in carrier recombination and exciton formation mechanism, depending on EML thickness, from a scenario (for EMLs <20 nm) in which recombination occurs mostly on the guest rather than the host thus creating excitons directly on the guest, and hence is not strongly influenced by host-to-guest energy transfer; to another scenario (for EMLs >20 nm) where carrier recombination and exciton creation on the host is not negligible, and hence also the role of host-to-guest energy transfer.

1. Introduction

Phosphorescent materials are widely used in organic light emitting devices (OLEDs) for their capacity to realize higher efficiencies [1–4]. These phosphorescent materials are usually used in the emitting layer (EML) of a device in the form of a guest doped into a host, the latter typically a fluorescent material. A higher device efficiency favors that the recombination of electrons and holes will occur directly on the phosphorescent guest rather than on the host material [5], and therefore requires that the guest sites act as carrier recombination centers within the EML [5]. This, in turn, requires that the EML will be able to transport both carriers within its bulk; a role that is believed to be generally taken by the host material rather than the guest, owing to the higher carrier mobility of the earlier. Understanding carrier transport and recombination processes in phosphorescent OLEDs (PhOLEDs) utilizing these host:guest systems is therefore crucial for optimizing their performance.

Fac-tris(2-phenylpyridine) iridium ($Ir(ppy)_3$) is a widely used phosphorescent emitter and is considered to be the benchmark emitter for green PhOLEDs. In these devices, 4,4′-bis(9-carbazolyl)-1,1′-biphenyl (CBP) is usually the material of choice for the host, owing to their demonstrated superior performance. Despite their wide utilization, the carrier transport and recombination processes in CBP: $Ir(ppy)_3$ remain not very well understood. For example, the superior efficiency performance of CBP: $Ir(ppy)_3$ is widely attributed to CBP's bipolar charge transport characteristics and efficient energy transfer to $Ir(ppy)_3$ [1,2,6,7]. However, some studies show that light emission in CBP: $Ir(ppy)_3$-based PhOLEDs originates primarily from excitons that are directly created on $Ir(ppy)_3$ sites by the recombination of electrons transported on CBP lowest unoccupied molecular orbitals (LUMO) and holes injected and transported on $Ir(ppy)_3$ highest occupied molecular orbitals

(HOMO) [10]; entailing that the light emission mechanism should not strongly depend on host-to-guest energy transfer. Furthermore, time of flight studies reveal that holes have much lower mobility in CBP: $Ir(ppy)_3$ in comparison to electrons [8,9] indicating that transport is not bipolar, and suggesting that the transport of holes via hopping between $Ir(ppy)_3$ [10] sites can not be efficient.

In this work, we study and compare prompt and delayed electroluminescence (EL) from CBP: $Ir(ppy)_3$ PhOLEDs of various architectures to elucidate charge transport and recombination mechanisms. The results show that changing the EML thickness leads to marked changes in charge-trapping and host–host TTA patterns, suggesting that carrier transport and recombination processes change depending on EML thickness.

2. Experimental

In this study, two series of PhOLEDs in two different structures and various layer configurations are investigated. The general device structures are:

Series I: ITO/NPB (40 nm)/CBP: 4 wt% $Ir(ppy)_3$ (x nm)/BPhen (30 nm)/Mg/Ag.
Series II: ITO/NPB (40-y nm)/TAPC (y nm)/CBP: 4wt% $Ir(ppy)_3$ (x nm)/CBP(40-x nm)/BPhen (30 nm)/Mg/Ag.

where NPB represents *N*,*N*′-di(naphthalene-1-yl)-*N*,*N*′-diphenyl-benzidine and is used as a hole transport material; BPhen represents 4,7-diphenyl-1,10-phenanthroline and is used as a hole blocking and electron transport material; and TAPC represents 1,1′-bis(di-4-tolylaminophenyl) cyclohexane, and is used as a hole transport and electron blocking material. ITO and Mg/Ag are employed as the anode and cathode, respectively. "x" represents the thickness of the EML, and ranges from 5 to 40 nm, as is typically the case in PhOLEDs. In series II devices, "y" represents the thickness of the TAPC layer, and is either 0 or 10 nm. All devices are fabricated by the deposition of organic materials and metals at a rate of 1–2 Å/s by using thermal evaporation in vacuum at a base pressure of about 5×10^{-6} Torr on UV ozone-cleaned ITO-coated glass substrates. Current–Voltage–Luminance (J–V–L) measurements are carried out using Agilent 4156C and Minolta Chroma Meter CS-100. The setup for delayed EL measurements is as described in our previous work [11–12]. The devices are kept in a nitrogen atmosphere during all tests.

3. Results and discussions

First, we measure the J–V–L characteristics in series I devices of various EML thicknesses. Fig. 1a shows the dependence of driving voltage on EML thickness whereas Fig. 1b shows the dependence of current efficiency (in cd/A) on current density for the different devices. As expected, for any given current, the driving voltage increases with EML thickness. The dependence of current efficiency on current density in the low current (<20 mA/cm^2), on the other hand, displays different trends in thin (<20 nm) versus thick (>20 nm) EMLs regime, displaying, in case of thin EMLs, an initial increase in efficiency with current density before the expected efficiency roll-off trend is attained.

In order to obtain some insights about the change in current efficiency trends with EML thickness, we carried out delayed EL measurements on the same devices. In this technique, the devices are driven using a square pulse driving scheme, with a forward bias pulse width of 0.5 ms, which is sufficiently long for prompt EL to reach its steady-state intensity. A photomultiplier tube is used to collect any persistent (i.e. delayed) electroluminescence from the devices that persists after the end of the forward bias. An optical chopper allows signal collection to begin only after a delay of about 0.3 ms following the end of the forward bias pulse, which is significantly longer than host singlet lifetime (typically <20 ns) and $Ir(ppy)_3$ triplet lifetime ($\sim$1 μs), to ensure the absence of any contributions from prompt EL (i.e. from the relaxation of excitons created *during* the forward bias pulse) in the collected signal. Fig. 2a shows a schematic diagram of the driving and signal collection timing scheme, whereas Fig. 2b shows the delayed EL signal collected from the devices versus time elapsed from the end of the forward bias pulse. As can be seen from the figure, the intensity of delayed EL collected from the devices varies significantly depending on the thickness of the EML, where PhOLEDs with the thicker EMLs (i.e. 30–40 nm) produce 2–3 times stronger delayed EL than their counterparts with the thinner EMLs (i.e. 5–10 nm). It should be pointed out that, like prompt EL, delayed EL arises from $Ir(ppy)_3$ triplet state, evidenced in the essentially identical delayed and prompt EL spectra (Fig. 2b inset). It is noteworthy to point out that the relative intensities of delayed EL do not correlate with the prompt EL intensities (Table 1) measured at the same current density, indeed proving that they must have different origins, and that there are no significant contributions from the prompt EL in the collected delayed EL signal as maintained above.

In general, prompt EL arises from the radiative decay of $Ir(ppy)_3$ triplet excitons produced by the recombination of electrons and holes *during* electrical excitation either directly on $Ir(ppy)_3$ sites, or on CBP sites followed by host to guest energy transfer. In this regard, its intensity is primarily governed by the carrier recombination efficiency on the guest in case of the former, or on the concentration of excitons (both singlet and triplet) on the host as well as the efficiency of their transfer to the guest in case of the latter. In comparison, the delayed EL can be the product of one or several of the following processes [11–13]: (i) recombination of trapped charges that get released after the end of the forward bias pulse; (ii) slow migration of host triplet excitons that are generated during the electrical excitation and their late arrival to the proximity of guest sites where energy transfer to the guest can take place; and (iii) triplet–triplet-annihilation (TTA), which in this case will be primarily due to the fusion of host triplet excitons (i.e. host–host TTA). Unlike in fluorescent OLEDs, any contributions from guest–guest TTA to delayed EL in the milliseconds time frame, as is used in our measurements here, will be insignificant in case of PhOLEDs. This is due to the much shorter lifetime of phosphorescent guest triplet excitons, (because of the efficient intersystem crossing),

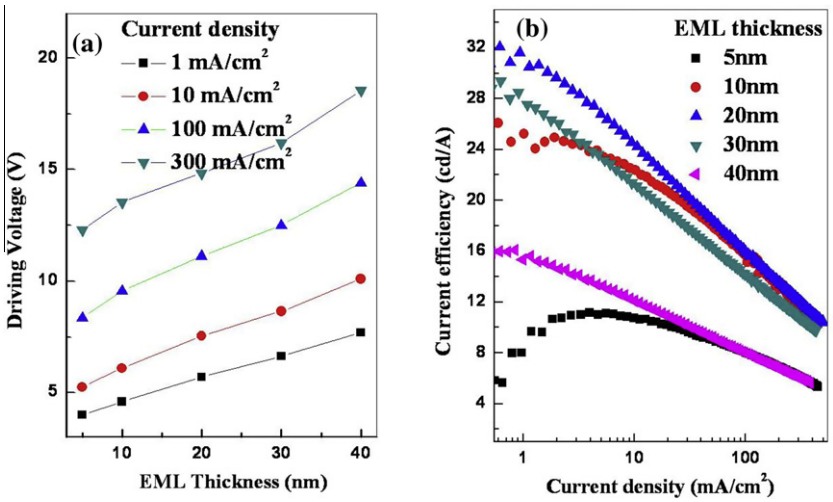

Fig. 1. Dependence of operating voltage on EML thickness from devices in series I with a device structure of ITO/NPB (40 nm)/CBP: 4wt% $Ir(ppy)_3$ (x nm)/BPhen (30 nm)/Mg/Ag.

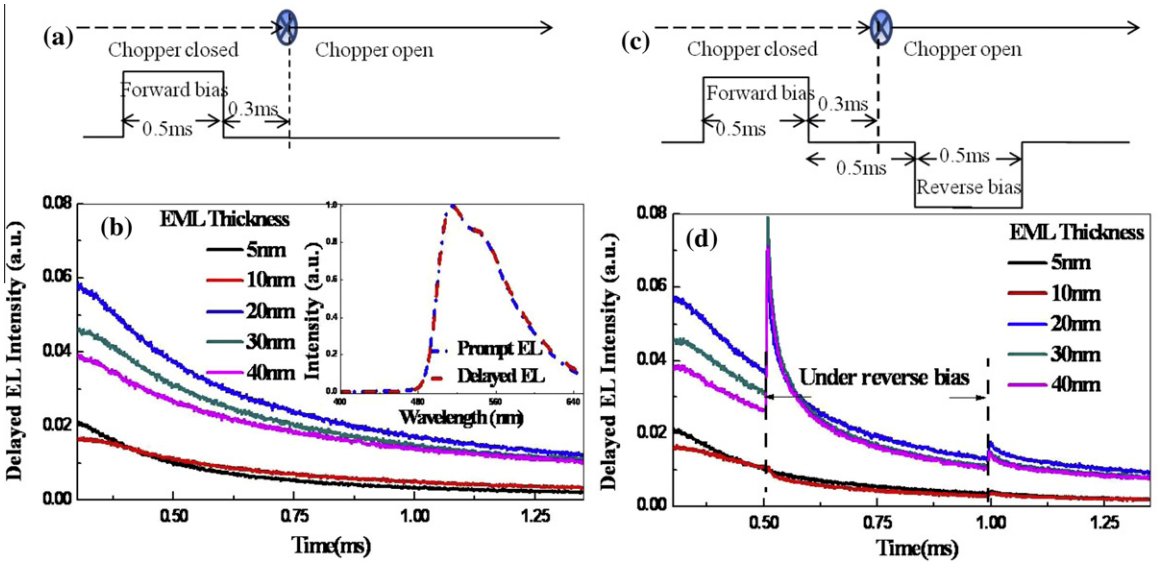

Fig. 2. (a) A schematic time setup of delayed EL measurement. A forward current density of 20 mA/cm² was removed at t = 0 ms and at t = 0.3 ms, the optical chopper open and the emission was recorded. (b) The time evolution of delayed EL emission from devices in series I. Inset: spectral distribution of prompt and delayed EL emission. (c) A schematic time setup of delayed EL measurement with reverse bias. At t = 0.5 ms, a reverse bias of −8 V was applied for another 0.5 ms and removed at t = 1 ms. (d) The time evolution of delayed EL emission from devices in series I with reverse bias.

Table 1
Prompt and delayed EL intensity at different EML thicknesses.

EML thickness	5 nm	10 nm	20 nm	30 nm	40 nm
Brightness (in cd/m²) at 20 mA/cm²	2050	4100	4500	3750	2180
Delayed EL intensity (normalized to delayed EL of PhOLED with 20 nm EML)	0.363	0.284	1	0.789	0.660

which requires that any such processes must occur in a much shorter time scale (i.e. <1 ms). Therefore, the intensity of delayed EL strongly correlates with the concentrations of trapped charges and CBP triplet excitons. Processes (ii) and (iii) can generally be described by the following multi step mechanistic schemes [13]:Process ii:

$$H_3^* + G_o \rightarrow H_o + G_3^* \text{(Energy transfer)} \quad \text{(ii-1)}$$

$$G_3^* \rightarrow G_o + h\nu \text{ (Phosphorescence)} \quad \text{(ii-2)}$$

Process iii:

$$H_3^* + H_3^* \rightarrow H_1^* + H_o \text{(Host—host TTA)} \quad \text{(iii1)}$$

$$H_1^* + G_o \rightarrow H_o + G_1^* \text{(Energy transfer)} \quad \text{(iii2)}$$

$$G_1^* \rightarrow G_3^* \text{ (Intersection crossing)} \quad \text{(iii3)}$$

$$G_3^* \rightarrow G_o + h\nu \text{ (Phosphorescence)} \quad \text{(iii4)}$$

where H_1^*, H_3^*, G_1^*, G_3^*, H_o and G_o denote host singlet exciton, host triplet exciton, guest singlet exciton, guest triplet exciton, host ground state and guest ground state, respectively.

In order to differentiate between these processes, a 0.5 ms reverse bias pulse is applied on the devices during the delayed EL signal collection, and subsequent changes in delayed EL characteristics are recorded. Fig. 2c shows a schematic diagram of the driving and signal collection timing scheme used in this case, whereas Fig. 2d shows the delayed EL characteristics under these conditions. As can be seen from the figure, the application of the reverse bias leads to the appearance of a strong spike followed by a decrease in delayed EL intensity in devices with 20–40 nm EML, and a subsequent partial recovery at the end of the pulse. In contrast, the reverse bias pulse has negligible effect on delayed EL from the devices with the thinner EMLs (5–10 nm). The observed spike at the beginning of the reverse bias is an indication of a sudden release of trapped charges by the reverse bias field, after which they recombine producing the delayed EL spike [11,12]. The observations therefore indicate that the number of trapped charges increases with EML thickness, suggesting it is a bulk effect, and that only thick (i.e. $\geqslant$20 nm) EMLs contain a significant number of trapped charges. The partial recovery in delayed EL at the end of the reverse bias pulse, on the other hand, is indicative of host–host TTA [13], as the fusion of two triplet excitons can lead to the production of a singlet intermediate (entity H_1^* in step iii-1 in the above scheme) that can be easily dissociated by the electric field, hence its susceptibility to quenching by the reverse bias. It should be noted that in contrast to singlet excitons, triplet excitons are much less susceptible to electric field induced quenching [11,12], due to their lower energy, and therefore do not themselves contribute to the quenching effect of the reverse bias aside from their role in creating singlets through the TTA process. The partial recovery in delayed EL at the end of the reverse bias pulse in Fig. 2d in case of thicker EML is therefore indicative of significant host–host TTA, suggesting the concentration of host triplet excitons must be significantly higher in these devices for efficient TTA to occur. The results in Fig. 2d therefore indicate that the higher delayed EL intensity in devices with thicker EMLs (Table 1) arises from higher concentrations of trapped charges and host triplet excitons in these devices.

From an energy levels standpoint, $Ir(ppy)_3$ sites can be expected to act as traps for carriers in a CBP: $Ir(ppy)_3$ EML, especially for holes. This is due to the differences between CBP and $Ir(ppy)_3$ HOMO and LUMO levels (CBP HOMO and LUMO are 6.0 and 2.9 eV, respectively, $Ir(ppy)_3$ HOMO and LUMO are 5.6 and 3.0 eV, respectively [14]), which suggest that $Ir(ppy)_3$ should efficiently trap holes in a CBP: $Ir(ppy)_3$ mixture. To test if this is indeed the case, we compare J–V characteristics of devices with or without $Ir(ppy)_3$ dopant. Fig. 3a shows J–V characteristics from standard devices of structure as shown in the inset. It can be seen that the device with $Ir(ppy)_3$ doping displays lower current density for a given driving voltage in comparison to the device with the neat CBP layer (i.e. without the dopant), suggesting that $Ir(ppy)_3$ indeed acts as charge traps. However, as the transport of electrons is known to be efficient in a CBP host, and therefore may strongly influence the J–V characteristics, it is important to rule out possible variations in electron currents among these devices. We therefore also test hole-only devices that include a CBP layer with or without $Ir(ppy)_3$, following the general approach adopted by Murata et al. [15]. In these devices, the CBP layer is sandwiched between two NPB layers, rendering it a hole-only device due to the limited electron injection capacity of NPB/Mg:Ag interface. The J–V characteristics from these devices and the device structure are depicted in Fig. 3b. As can be seen, hole currents at a given voltage are significantly lower in device with $Ir(ppy)_3$ doping, convincingly verifying the hole trapping role of $Ir(ppy)_3$ in a CBP host. Therefore, the increase in the delayed EL spike intensity with EML thickness in Fig. 2d can be readily explained in terms of the larger number of $Ir(ppy)_3$ sites in the thicker layers, which would expectedly increase the number of trapped charges. To explain the marked differences between the thin (5–10 nm) versus thick (30–40 nm) EMLs in terms of the amount of trapped charges and the magnitude of host–host TTA (hence the concentration of triplets on CBP), we propose the following as a possible charge transport and recombination model, which is also depicted, pictorially, in Fig. 4.

Due to the small difference in energy between BPhen and CBP LUMO levels ($\sim$0.1 eV), electrons are easily injected from the BPhen electron transport layer into the LUMO of CBP, and are transported mostly on CBP sites (processes 1 and 2 on the diagram) [13,16]. On the other hand, due to the relatively large barrier ($\sim$0.6 eV) for hole injection from NPB to CBP, the injection of holes onto CBP is difficult [17], and therefore, the majority of holes are injected directly into $Ir(ppy)_3$ sites (process 3 on the diagram) [6]. When the EML is thin (5–10 nm), (the scenario depicted in Fig. 3a), electrons transported onto the LUMOs of CBP will be able to drift across the EML rather quickly, thereby reaching the hole transport layer (HTL)/EML interface, where they recombine with the holes on $Ir(ppy)_3$ sites. As a result, the excitons are formed mainly directly on $Ir(ppy)_3$ sites in this case, and the CBP host will be deficient in holes and excitons, hence the absence of the host–host TTA characteristic "finger print" (i.e. the partial recovery in delayed EL at the end of the reverse bias pulse in Fig. 2d). However, in case of the thicker EMLs (the scenario depicted in Fig. 4b), the electrons will take longer times to drift across the EML (the electron mobility of CBP is only about 10^{-3} cm^2 V^{-1} s^{-1} [8]). As such, holes will have the time to drift from the HTL/EML interface deep into the EML bulk. Although the transport of holes in the EML can proceed via hopping between $Ir(ppy)_3$ sites (process

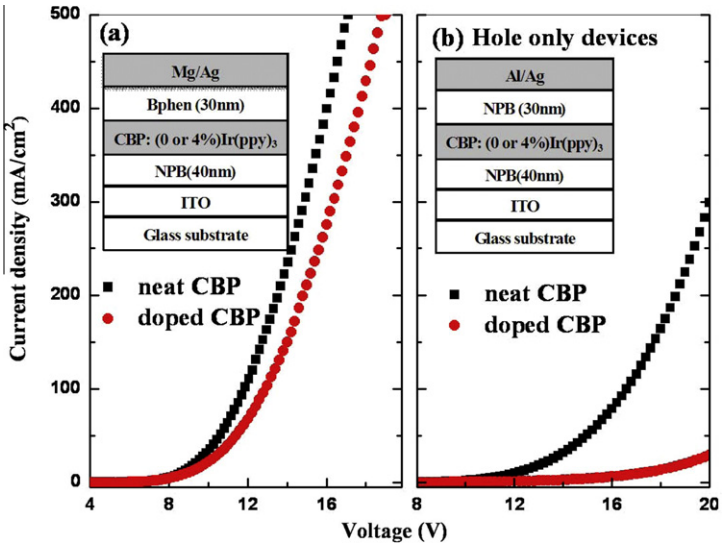

Fig. 3. (a) J–V characteristics from devices with 40 nm neat CBP EML and CBP: 4%Ir(ppy)$_3$ EML, respectively. (b) J–V characteristics from hole-only devices with 40 nm neat CBP EML and CBP: 4%Ir(ppy)$_3$ EML, respectively. Insets: the schematic device structures.

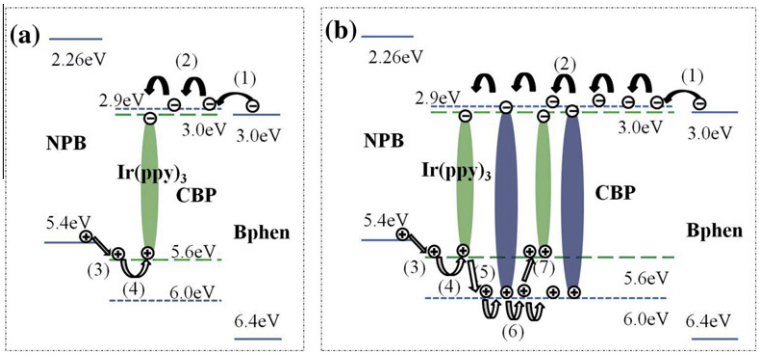

Fig. 4. Schematic energy level diagram of charge carrier injection and transport for electrons and holes in thinner EML (a) and thicker EML (b), respectively. (1) Electron injection from ETL into CBP and Ir(ppy)$_3$, (2) Electron transport through LUMO of CBP, (3) hole injection from HTL into Ir(ppy)$_3$, (4) direct hopping of holes between Ir(ppy)$_3$ sites, (5) hole injection from HOMO of Ir(ppy)$_3$ to that of CBP, (6) hole transport through HOMO of CBP, and (7) hole trapping at Ir(ppy)$_3$ sites. Values for HOMO and LUMO levels are taken from references [14,16,17].

4 on the diagram), the large intermolecular distances between the guest sites makes this process inefficient [8,18], and allows for a fraction of the holes to be injected onto CBP where they can be transported more easily via CBP HOMOs (processes 5 and 6 on the diagram), where their mobility can be higher (about 10^{-2} cm^2 V^{-1} s^{-1} [8]). With the increase in the hole population on CBP, electron–hole recombination on the host rather than the guest becomes increasingly prominent, hence the larger concentration of CBP triplet excitons, evident from the clear host–host TTA "finger print" observed in only the thick EMLs. As, in case of the thin EMLs, holes recombine with electrons very close to the HTL/EML interface, only very few holes will penetrate deeper into the EML where they may become trapped on Ir(ppy)$_3$ sites, hence the absence of the characteristic "trapped charges" spike in these devices on Fig. 2d. The results are therefore consistent with a charge transport and recombination mechanism that depends on the EML thickness, and can change from a scenario (for EMLs <20 nm) in which carrier recombination occurs mostly on the guest rather than the host thus creating excitons directly on the guest, and hence is not strongly influenced by host-to-guest energy transfer; to another scenario (for EMLs >20 nm) where carrier recombination and exciton creation on the host is not negligible, and hence also the role of host-to-guest energy transfer. In this regard, the initial increase in the current efficiency with current observed only in case of the PhOLEDs with the thin EMLs (Fig. 1b) can be attributed to improved charge balance with increasing the bias, which alleviates the higher initial concentration of electrons in the recombination zone (due to the facile transport of electrons across the thin EML as pointed to above).

Although the above model can fully explain the experimental results described above, it necessitates that the injection of holes from Ir(ppy)$_3$ HOMO to CBP HOMO (pro-

cess 5 on Fig. 4b) is non negligible in the thicker EMLs, a process whose likelihood could be questionable due to the significant hole injection barrier, as is also suggested by some reports [8]. Therefore, in order to see if injection of holes from $Ir(ppy)_3$ to CBP can indeed be significant, we fabricate and test a second series of devices (series II). In these devices, only one part of the EML (the one adjacent to the HTL interface) is doped with $Ir(ppy)_3$, whereas the other part comprises neat CBP. The total thickness of the EML is maintained at 40 nm in all devices, but the thickness of the doped part is varied from 5 to 40 nm (the latter being a fully doped EML, hence is the same as in series I above). Fig. 5 shows the normalized prompt EL spectra, respectively, collected from these devices. Clearly, both sets of spectra show the $Ir(ppy)_3$ characteristic emission (the 514 and 540 nm bands, where the small variations in the 540–514 nm relative intensities are due to the known micro-cavity effects [14] resulting from variations in the distance between the emission zone and the reflective metal cathode due to differences in the thickness of the neat CBP part). Aside from $Ir(ppy)_3$ emission, the prompt EL spectra show some weak blue emission in the blue range, with bands peaking at around 400 and 450 nm. Introducing a thin layer of TAPC at the HTL/EML interface leads to the disappearance of the 450 nm band, indicating it arises from NPB emission. As the 400 nm band coincides with CBP singlet emission, is only visible in devices with a neat CBP layer, and its intensity increases with the thickness of the neat CBP layer, it must be due to CBP singlet emission from the neat layer [19]. Obviously, the detection of CBP emission from the neat layer indicates that the injection of holes from the $Ir(ppy)_3$-doped part of the EML to the neat CBP part is possible, proving that the injection of holes from $Ir(ppy)_3$ to CBP can indeed take place. In fact, the ability to detect emission from the neat part indicates that some of the underlying CBP singlets do not undergo complete energy transfer to $Ir(ppy)_3$, suggesting they must be created at least a few molecular monolayers into the neat part, away from the interface with the $Ir(ppy)_3$-doped part.

Fig. 6 shows normalized time resolved delayed EL characteristics of the same devices (i.e. of the same type II devices described in the previous paragraph), under the driving scheme depicted in Fig. 2c (i.e. with the additional reverse bias component). As can be seen from the figure, the height of the spike at the beginning of the reverse bias pulse increases with the thickness of CBP:$Ir(ppy)_3$ layer, similar to series I devices (Fig. 2a) despite the fact that the thickness of the entire EML remains the same in all the devices. These results show that the trapped charges are mainly present in the $Ir(ppy)_3$-doped part, confirming our earlier supposition that they are indeed mostly trapped on $Ir(ppy)_3$ sites. As can also be seen from the figure, the partial recovery at the end of the pulse also increases with the thickness of CBP:$Ir(ppy)_3$ layer in this case. This suggests that most of the host–host TTA still occurs in the $Ir(ppy)_3$-doped part of the EML. This may perhaps be due to the easier transport of holes across the neat CBP layer, which would cause their capture cross section to electrons to be smaller, hence leads to a lower electron–hole recombination rate, and, as a result, a lower exciton concentration in the neat CBP.

4. Conclusions

In conclusion, delayed EL measurements are used to elucidate carrier recombination and light emission mechanism in PhOLEDs based on CBP: $Ir(ppy)_3$. The results show that changing the EML thickness leads to marked changes in charge-trapping and host–host TTA patterns, suggesting that carrier transport and recombination processes change depending on EML thickness. The results suggest a change in carrier recombination and exciton formation mechanism, depending on EML thickness, from a scenario (for EMLs <20 nm) in which recombination occurs mostly on

the guest rather than the host thus creating excitons directly on the guest, and hence is not strongly influenced by host-to-guest energy transfer; to another scenario (for EMLs >20 nm) where carrier recombination and exciton creation on the host is not negligible, and hence also the role of host-to-guest energy transfer.

ABSTRACT

The model of metallic type or enhanced hopping conductivity with reduced activation energy at the donor–acceptor interface formed by organic dielectrics is suggested. High density of electrons and holes at the interface arises due to the integer charge transfer from donor to acceptor molecules. Significant part of charge carriers can avoid thermal activation and tunneling in course of their transport if the interfacial energy barrier is low enough. The critical value of an interfacial energy barrier, density of free electrons, the values of two-dimensional mobility and conductivity of charge carriers are estimated by numerical modeling and compared with experimental data.

1. Introduction

Electric conduction along organic interfaces attracts much attention since electronic processes at organic–organic and organic–metal interfaces can differ from those in the bulk of organic layers, and interfacial properties have a profound impact on device performance [1–4]. High conductivity is required to maintain superior device characteristics. Electronic transport at organic interfaces, as well as in organic layers, is known to be restricted typically by localization and low concentration of mobile charge carriers [5]. Typically, improvement results from electrochemical doping [6,7] and field effect [7–9]. The latter increases concentration of carriers and their mobility within a thin ($\cong$ 1 nm) layer at the polymer–gate interface due to filling of deep fraction of localized states.

High mobility and conductivity in organic structures involving interface of electron donor (D) and acceptor (A) materials has been recently reported (see, for examples, [10–13]). In original materials, conductivity was found to be lower by several orders of magnitude than that in the interface structure. An important result of Ref. [11] was the saturation of conductivity with thickness of the top A-layer as soon as its thickness exceeded ca. 2 nm in the course of formation of D–A interface. The Hall mobility of both electrons and holes above 1 $cm^2\ V^{-1}s^{-1}$ was measured, suggesting the sheet density of *delocalized* charge carriers up to $5 \times 10^{10}\ cm^{-2}$ at the copper phthalocyanine (CuPc)/copper hexadecafluoro phthalocyanine ($F_{16}CuPc$) interface. In those experiments [13], the conductivity was trap-controlled hence thermoactivated one. In [10], two-dimensional (2D) conductivity above the minimal metallic level, e^2/h, characterized by metallic temperature dependence, along the interface formed by two organic crystals of tetrathiofulvalene (TTF) and 7,7,8,8-tetracyanoquinodimethane (TCNQ) has been demonstrated and attributed to the formation of 2D electronic gas, resulting from electron transfer from TTF to TCNQ. The question about the occurrence of *complete* (integer) or *partial* charge transfer at the concrete donor–acceptor organic interface is under debate. The complete electron transfer at the interface between two dielectrics, including organic ones, is known for a rather long time; in particular, this effect

is responsible for the charging of dye particles in a mixture of powders used in xerography [14]. Recent work on modeling of organic–metal and organic–organic interfaces has been summarized in the review [15]. Obviously, none of the existing models describe the whole variety of organic–organic interfaces. However, strong arguments has been reported, that integer electron transfer from donor to acceptor molecule occurs at the organic–organic interface, if (i) chemical interaction of these molecules is rather weak in order to prevent considerable hybridization of electronic molecular orbitals and (ii) this transfer is profitable energetically, i.e. the energy of highest occupied molecular orbital (HOMO) of a donor lies high enough relative to the position of lowest unoccupied molecular orbital (LUMO) of an acceptor. In particular, integer charge transfer in the structure involving TTF and TCNQ has been approved. On the other hand, many experimental and theoretical works have pointed to partial charge transfer at organic–organic interfaces, including TTF–TCNQ interface (see, for example, [16]). Perhaps, the reason of this uncertainty is the dependence of the relative energetic positions of electrons and holes at the interface on the choice of the conductive substrate (electrode) [15]. In this work, we assume that an integer charge transfer is the case for the analyzed interface, because this case (weak chemical intermolecular interaction), which is typical for organics, seems to be most questionable in view of 2D-electronic gas formation.

The primary step in this case is the formation of an electron–hole (e–h) pair in which the charges are separated by the distance ca. 1 nm and localized by mutual Coulomb interaction. Formation of 2D e-gas needs in rather high area density of pairs, in order to delocalize charge carriers by means of interaction with charges from adjacent pairs. However, the microscopic nature of the huge enhancement of conductivity along the D–A interface with respect to the bulk conductivity of the materials remains unclear. One has to clarify the mechanism of 2D e-gas formation at such an interface and quantify the critical parameters of the interface. The mechanism of conductivity exploited for the interfaces of perovskite transition metal oxides ABO_3 [17] seems to be not appropriate for the organic structures, in which sequential polar layers are absent.

The concept of sequence of charge carrier transfers from charge-transfer states (CTSs) to the neighboring unpaired charge (“Coulomb hole”) was suggested earlier to explain the sharp increase in the bulk conductivity of electrochemically doped polymers [18] and the electronic switching in polymers [19]. In the present paper, we show that the concept provides a mechanism describing both enhanced hopping conductivity with reduced activation energy and metallic conductivity along the D–A interface. We quantify the conditions of 2D e-gas formation as well.

2. Model

The integer charge transfer of an electron from donor to acceptor molecule produces a pair of positive (donor) and negative (acceptor) CTSs, having energies E^+_{ICT} and E^-_{ICT}, respectively. The energy $E^+_{ICT}(E^-_{ICT})$ is defined as the energy required to withdraw an electron (respectively, the energy gained when an electron is added to the molecule) producing a fully relaxed state, i.e. both electronic and geometrical relaxation and interaction of charges are taken into consideration. These energies differ from respective energies of neutral HOMO and LUMO states [15]. The electron donated at the interface is transferred to the nearby molecule of an acceptor enabling significant Coulomb interaction with the energy $U_a = e^2/4\pi\varepsilon\varepsilon_0 a$, where e is the elementary charge, ε is an effective permittivity, ε_0 is the electric constant and a is the mutual electron–hole distance. Thus, the recombination of an (isolated) electron–hole pair at the interface is suppressed by the energy barrier $\Delta E = U_a + E^{don} - E^{acc}$, where E^{don} and E^{acc} are the energies of an electron, being located at donor and acceptor molecules, respectively (see Fig. 1). Charge transfer can be energetically beneficial, i.e. $\Delta E > 0$, even if $E^{don} < E^{acc}$, due to Coulomb interaction of the pair. An electron (e) and a hole (h) in an isolated pair should be localized by this interaction.

Yet, an e–h pair is not isolated at interface. If the distance between the neighboring pairs is comparable with the spacing of charges inside the pair, it is necessary to take into account the interaction of charges with the environment consisting of dipoles (e–h pairs), “vacancies” (pairs of neutral molecules) formed due to the recombination of a fraction of e–h pairs, and unpaired charges of both signs (i.e. dissociated pairs). The random arrangement of e–h pairs, vacancies and unpaired charges produces the potential fluctuations around each e–h pair. In average, the energy barrier ΔE is compensated by the drop of the electrostatic energy ΔU in equilibrium state, hence the energy level alignment of integer CTSs, E^+_{ICT} and E^-_{ICT}, is established at the interface [15] (see Fig. 1).

One has to note that organic–organic interface is a complex of interacting molecules of both materials. Hence, the morphology of the interface can differ from the morphology in the bulk of both materials. We perform model calculations under the simplifying assumption that the pairs of molecules of both materials at the interface form a square lattice with the parameter $b \geqslant a$, and all pairs of molecules

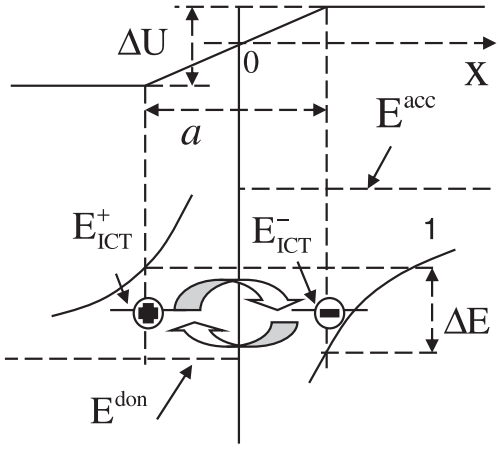

Fig. 1. Energy diagram of the interface between two organic materials. Curve 1 shows the function $E^{acc} - e^2/4\pi\varepsilon\varepsilon_0 x$.

are able to form e–h pairs. Vacancies, e–h pairs and dissociated pairs of charges were randomly arranged over the sites of a square lattice filling a square with dimensions $m \geqslant 20$ in any direction from the given pair with the relative concentrations $n_{\pm}$, n_0 and n, respectively. The contribution of distant electrons and holes was taken into account in the approximation of point dipoles forming a square lattice with the effective lattice parameter $b_{eff} = b/\sqrt{1-n_0}$. Relative concentrations of e–h pairs and vacancies are equal [20,21], because rates of separation and recombination of pairs seems to be equal under the presumed condition $E^{+}_{ICT} = E^{-}_{ICT}$, hence the normalizing condition $n_0 + n + n_{\pm} = 1$ yields

$$n_0 = n_{\pm} = (1-n)/2. \tag{1}$$

The spatial profile of the Coulomb energy of electron interaction with surrounding electrons and holes is calculated as follows,

$$U(x,y) = -\chi^{+}_{00}U_C(x,y,a/b) + \sum_{r_{ij}\neq 0}\left[\chi^{-}_{ij}U_C(x-i,y-j,0) - \chi^{+}_{ij}U_C(x-i,y-j,a/b)\right], \tag{2}$$

where $U_C(x,y,z) = U_b/\sqrt{x^2+y^2+z^2}$ is the energy of Coulomb repulsion, $U_b = e^2/4\pi\varepsilon\varepsilon_0 b$, $r_{ij} = \sqrt{i^2+j^2}$; x, y and z are coordinates in units of b (an electron is located at the zero point), the z axis is orthogonal to the interface; equations $z = 0$ and $z = a/b$ define the "plane of electrons" and "plane of holes", respectively. The pair of integers $\{i,j\}$ gives the position of a site (i.e. a pair of molecules) in the x–y plane, and χ^{+}_{ij}, χ^{-}_{ij} are random numbers. These numbers take the values 1 or 0, if the site is occupied or not occupied by positive and negative charge, respectively. A combination $\chi^{+}_{ij} = \chi^{-}_{ij} = 1$, i.e. an e–h pair, is realized with the probability $n_{\pm}$; a combination $\chi^{+}_{ij} = 0$ and $\chi^{-}_{ij} = 1$, i.e. an unpaired electron, occurs with the probability $n/2$, ets. Eq. (2) shows that the random spatial profile of electron potential energy, U/U_b, is affected by the unique parameter b/a. It is instructive to relate this parameter and the energy offset Δ, $\Delta = E^{don} - E^{acc}$ (the value of Δ is negative on Fig. 1). Taking into account the energies of electron's interaction with surrounding electrons and holes, namely

$$E^{+}_{ICT} = E^{don} + U^{don},\ E^{-}_{ICT} = E^{acc} + U^{acc} - U_a, \tag{3}$$

$$U^{don} = U_b\sum_{r_{ij}\neq 0}\left[\chi^{-}_{ij}/\sqrt{r_{ij}^2 + (a/b)^2} - \chi^{+}_{ij}/r_{ij}\right], \tag{4a}$$

$$U^{acc} = U_b\sum_{r_{ij}\neq 0}\left[\chi^{-}_{ij}/r_{ij} - \chi^{+}_{ij}/\sqrt{r_{ij}^2 + (a/b)^2}\right], \tag{4b}$$

one obtains the following equation from Eqs. (3) to (4) and from the condition $E^{+}_{ICT} = E^{-}_{ICT}$,

$$\frac{\Delta}{U_b} = -\frac{b}{a} + \sum_{r_{ij}\neq 0}\left(\chi^{+}_{ij} + \chi^{-}_{ij}\right)\left(\frac{1}{r_{ij}} - \frac{1}{\sqrt{r_{ij}^2 + (b/a)^{-2}}}\right), \tag{5}$$

Eq. (5) connects the ratio b/a with the energetic characteristic of an interface, i.e. the dimensionless energy Δ/U_b. It is instructive to relate Δ and such measurable values as energies of HOMO and LUMO states, E^{don}_{HOMO} and E^{acc}_{LUMO}. These energies include a "molecular" term which can be measured as ionization potential, I_G, and electron affinity, A_G, in gaseous phase, and energy of polarization of surrounding molecules by an electron (a hole), P_e (P_h): $E^{don}_{HOMO} = -I^{don}_G + P^{don}_h$, $E^{acc}_{LUMO} = -A^{acc}_G - P^{acc}_e$. It is conventional to consider the terms I, A, P as positive values [22]. The contribution of polarization energy at the interface differs from that in the bulk of both materials because ca. half of surrounding molecules belongs to another material. Therefore, one-can estimate the energies as following: $E^{don} = -(I^{don}_G - 0.5P^{don}_h - 0.5P^{acc}_h)$, $E^{acc} = -(A^{acc}_G - 0.5P^{acc}_e - 0.5P^{don}_e)$. Consequently,

$$\Delta = \left(E^{don}_{HOMO} - E^{acc}_{LUMO}\right) + 1/2\left(P^{acc}_h - P^{acc}_e\right) + 1/2\left(P^{don}_e - P^{don}_h\right). \tag{6}$$

Thus, the energy offset Δ can be equal to the difference of donor HOMO energy and acceptor LUMO energy at the interface, $\Delta = E^{don}_{HOMO} - E^{acc}_{LUMO}$, in the typical case of symmetry of polarization caused by electrons and holes, $P_h = P_e$ [22].

The result of numerical solution of Eq. (5) is a distribution function of the ratio $p = b/a$ for the definite value of Δ/U_b because of the random arrangement of a given e–h pair. The distribution is well fitted by Gaussian function,

$$\Phi(p) = \exp\left[-(p - \langle p\rangle)^2/2\sigma^2\right]/\sqrt{2\pi\sigma^2}, \tag{7}$$

where the mean value $\langle p\rangle = \langle b/a\rangle$ is well fitted by the universal (i.e. the parameter less) function of Δ/U_b in the investigated interval $-0.4 < \Delta/U_b < 0.8$:

$$\langle b/a\rangle = 0.57 + \exp[-(\Delta/U_b)/2.75]. \tag{8}$$

The variance σ is practically independent on the energy Δ, $\sigma = 0.11 \pm 0.01$, and both the values $\langle b/a\rangle$ and σ are practically independent on the relative concentration n, $0 \leqslant n \leqslant 1/3$.

The mechanism of thermally non-activated dissociation of e–h pairs is important for consideration of metal-type conductivity. Interaction of a pair with neighboring "vacancy", i.e. the process $n_0 + 2n_{\pm} \rightarrow n + n_{\pm}$ (Fig. 2a) has been analyzed previously [20,21]. The process is cooperative. For example, the shift of an electron toward the right

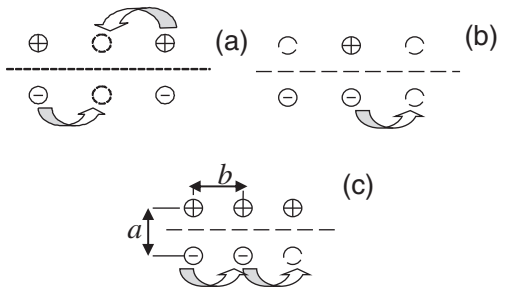

Fig. 2. Schematics of processes at the interface (broken lines): (a) Dissociation of e–h pairs by interaction with a "vacancy"; (b) dissociation by interaction with neighboring unpaired charge; and (c) transport of a "Coulomb hole".

stimulates the hopping of a hole in the opposite direction (Fig. 2a). This process, however, becomes inefficient if $b/a > 1.2$, that seems to be a typical case [20,21]. In such a case, dissociation of an e–h pair caused by Coulomb repulsion of one of the charges from neighboring unpaired charge, which is injected from an electrode or photogenerated (Fig. 2b), is the most likely process. An electron, being injected, can produce a lot of dissociated pairs in the course of its motion towards counter electrode. The value of n is limited by the reverse process, i.e. recombination. Using the steady-state relation $n = \varphi_{dis} n_{\pm}$ and Eq. (1) one obtains

$$n = \varphi_{dis}/(2 + \varphi_{dis}), \tag{9}$$

where the dissociation probability, φ_{dis}, is calculated by Monte–Carlo simulation as the ratio of the number of dissociation events to the total number of attempts, providing that the configuration shown in Fig. 2b is realized. The results of the simulation are exhibited in Table 1.

It is assumed that dissociation event occurs provided that the minimum of electron potential energy (see Eq. (2)) is shifted from the point {0,0} by more than $b/2$ in the x–y plane due to both the dynamic character of the interaction and the possibility of cooperative processes. This criterion yields the probability of dissociation which is free from thermal activation and from tunneling possibly. Condition for the latter is discussed below.

3. Results and discussion

The value of φ_{dis} depends only on the ratio $p = b/a$ because only this parameter affects the profiles of potential energy, see Eq. (2). Numerical simulations of φ_{dis} and Eq. (9) yield the value of n for a given p. It is important that (i) the values of p are distributed in accordance with Eq. (7) and (ii) random potential of dipoles and unpaired charges produces energetic disorder. Really, it is correlated disorder, i.e. charge carriers in neighboring states tends to obtain similar energies [23]. Therefore, the value of n should be calculated as the average of $n(p)$ values which are determined by *local* values of p:

$$n = \langle n \rangle = \int n(p)\Phi(p)dp \tag{10}$$

Practically, the value of $\langle n \rangle$ is estimated as a sum of the products $n(p_i)\Phi(p_i)\Delta p_i$ by the use of Eqs. (7)–(9) and the values of $\varphi_{dis}(p_i)$, see Table 1. The result is as following: $\langle n \rangle = 0.04$, $\Delta/U_b = 0.2$, and $\langle n \rangle = 0.02$, $\Delta/U_b = 0.0$. Eventually, the value of n is determined by the normalized energy offset Δ/U_b. The value of n is critical for the mechanism of charge carrier transport as it is shown below.

Table 1
Results of numerical modeling.

Δ/U_b	$\langle b/a \rangle$	φ_{dis}	φ	$\bar{\varphi}$ (0.2)
0.8	1.32	0.18	0.61	0.44
0.4	1.44	0.03	0.58	0.35
0.2	1.5	0.01	0.55	0.33
0.0	1.57	0.005	0.52	0.26
−0.4	1.73	<0.001	0.45	0.15

Energy of an electron at the interface, both paired and unpaired, is the subject of random temporal (as well as spatial) fluctuations which are related to variations of numbers χ_{ij}^{+}, χ_{ij}^{-} because of the recombination and dissociation events. Therefore, the electron energy is uncertain. We calculated the distribution function of the energy of paired and unpaired electrons ($E_{\pm}$ and E_0, respectively) in order to estimate the uncertainty. The energies $E_{\pm}$ and E_0 are calculated as $U(0,0)$ from Eq. (2), providing that $\chi_{00}^{+} = 1$ and $\chi_{00}^{+} = 0$ in the former and the latter case, respectively. One obtains the Gaussian distribution functions in both cases, see examples in the Fig. 3. The energy offset Δ and the relative concentration of dissociated pairs, n, are considered as independent variable parameters, operationally. One obtains that the mean energies, $\langle E_{\pm} \rangle$ and $\langle E_0 \rangle$, are independent of n, see Fig. 3, while their mutual displacement increases slightly with the decrease of Δ ($\langle E_0 \rangle - \langle E_{\pm} \rangle = 1.31$, $\Delta = 0.8$, and $\langle E_0 \rangle - \langle E_{\pm} \rangle = 1.57$, $\Delta = 0.0$, in units of U_b). Vice versa, the Gaussian variances, $\sigma_{\pm} \approx \sigma_0$, are independent of Δ and increases strongly with the increase of n, see Fig. 4:

$$\sigma_{\pm}/U_b \approx 5 \cdot n^{0.55}, 0.01 \le n \le 0.33. \tag{11}$$

Their values are minimal if $n = 0$: $\sigma_{\pm} \approx \sigma_0 \approx 0.06U_b$. Strictly speaking, the calculation of energies is complicated by the Gaussian energy disorder that is caused by interactions of the charge with molecular dipole moments [5,23]. However, one can neglect this disorder if the respective variance does not exceed the value which is predicted by Eq. (11).

Two different physical situations arises at small and large ($n \ge 0.02$) concentration of unpaired charges. In the latter case, energy bands of paired and unpaired charge carriers are broad and effectively overlapped, see Fig. 3. The band width, $\sqrt{2}\sigma_{\pm}$, exceeds 0.8 relative to U_b. Providing $b \approx 1$ nm and $\varepsilon = 3.5$, one obtains $U_b \approx 0.4$ eV, hence $\sqrt{2}\sigma_{\pm} \ge 0.3$ eV. The latter value is comparable with the band width of organic conductor TTF–TCNQ, 0.5 eV [24]. The intersite transfer time is $t_0 \cong \hbar/\sqrt{2}\sigma_{\pm} \approx 10^{-15}$ s, that is not larger than typical time of electronic polarization in organics. One can consider nb^{-2} as the area density of

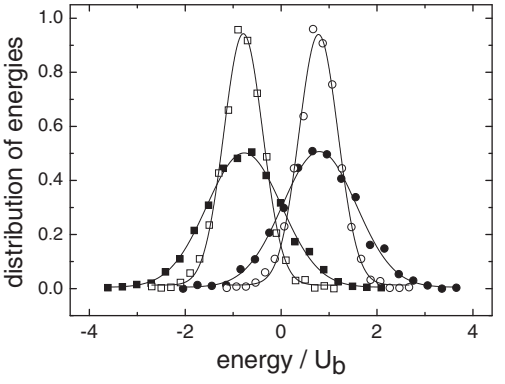

Fig. 3. Distribution functions of energy of an electron, which belongs to e–h pair (squares) and the same of a single electron (circles). Gaussian fits are also shown. $\Delta = 0.0$. The relative concentration of dissociated pairs, n, is 0.03 (filled symbols) and 0.01 (open symbols).

free (delocalized) charge carriers (2D e-gas). The critical concentration of unpaired charges, $n \approx 0.02$, corresponds to $\Delta \approx 0$, as mentioned above. This value seems to be reasonable for the TTF–TCNQ interface (the offset of energy levels in the bulk, $E^{don}_{HOMO} - E^{acc}_{LUMO} = -0.2$ eV [24], yet this value can be reduced due to quantum splitting of energy levels at the interface [25]). Recently, the energy level alignment, $E^{+}_{ICT} = E^{-}_{ICT}$, has been reported for TTF–TCNQ D–A interfaces [15,26], hence $\Delta E = \Delta U$. Basing on the value of an interfacial electrostatic energy from the Ref. [26], $\Delta U = 0.6$ eV, and providing that, again, $U_b \approx 0.4$ eV and $b/a \approx 1.5$, one obtains $\Delta = \Delta E - U_a \approx 0$.

In order to approve the possibility of metal-type conductivity, we calculated the probability φ (by means of the same criteria which was used in calculations of φ_{dis}) of thermal activation- and tunneling- free electron's transfer caused by an adjacent unpaired hole (see Fig. 2c). If $\varphi \geq 0.5$, that relates to $\Delta/U_b \geq 0.0$, see Table 1, each unpaired charge can initiate sequential transfers of opposite charge (motion of a "Coulomb hole") [20,21] because the number of "open bonds" in a 2D square lattice exceeds two, hence the criterion of percolation is fulfilled [27]. One can estimate the mobility, μ, and the surface (2D) conductivity, $\sigma_{2D} = e\mu n b^{-2}$, as follows: $\mu = (e/kT)b^2/t_0$, $\sigma_{2D} = (e^2/kT)n/\ t_0$, where T is the temperature, and k is the Boltzmann constant. The value of σ_{2D} exceeds the threshold of metallic 2D conductivity [28], $\sigma_{\min} \approx e^2/h \approx 0.4 \cdot 10^{-4}$ S at $T \leq 300$ K, provided that $n \geq 0.02$ (hence $t_0 \leq 10^{-15}$ s^{-1}), and $b \leq 1$ nm: $\sigma_{2D} \geq 10^{-4}$ S. This value is in good agreement with the experimental result of Alves et al. $\sigma_{2D} \leq 10^{-3}$ S [10].

If the concentration of dissociated pairs is rather small, $n \leqslant 0.01$, energy bands of paired and unpaired charge carriers are narrow (<0.05 eV) and separated by energy gap. Charge carriers are localized on molecules, and the transport of "Coulomb holes" occurs via hopping in this case. However, Coulomb interaction between oppositely charged carriers from adjacent pairs can substantially reduce activation energy of hops and hence increase mobility. Table 1 shows the probability $\tilde{\varphi}$ that potential drop on the distance b compensates energy difference of initial and final localized states, which is more than $0.2 \cdot U_b \cong 0.1$ eV. The reciprocal value, $\tilde{\varphi}^{-1}$, yields the frequency of attempts of the hops relative to typical frequency of fluctuations of potential. The latter seems to be the typical frequency of recombination of the e–h pairs, i.e. the frequency of non-activated tunnel charge transfers.

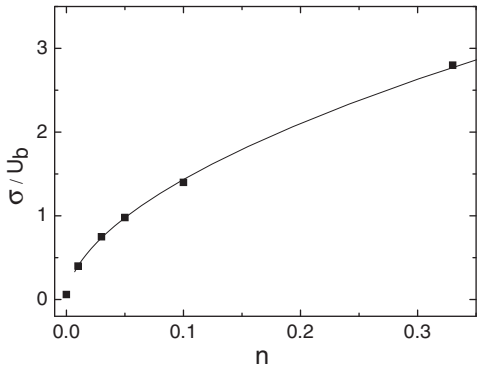

Fig. 4. Gaussian variances of electron's energy distributions, see Fig. 3, in dependence of the relative concentration of dissociated pairs, n. Solid curve shows the fit by Eq. (11).

As an example of the above reasoning one can consider the charge carrier transport in polymer composites based on either poly-N-vinylcarbazole (PVK) or aromatic polyimide derivative (API) incorporating either carbon single-walled nanotubes (SWNT) or nanocrystals of J-aggregated cyanine dye molecules (CD) [29–32]. In the polymer composites, one of the components (anthracene moiety in API, carbazole in PVK) acts as an electron donor and another one (carbocyanine core in J-aggregate, semiconducting SWNT) exhibits electron-acceptor behavior. The difference of energy levels between donor HOMO and acceptor LUMO (−5.8 and −4.8 eV [33], for the case of PVK/SWNT composite; −5.2 [34] and −3.7 eV [32] for the case of API/CD composite, respectively) is much higher than those for TTF and TCNQ. However, the formation of D–A interface is reasonable even if the barrier is as high as 1 eV [12]. The transport is shown to exhibit a similar behavior in the mentioned composites, namely: (1) the drift mobility of charge carriers in the composite is higher than that in the undoped polymer by 1–1.5 order of magnitude although the SWCNT or CD concentration is below that of percolation threshold; (2) the mobility of electrons is higher than that of holes, vice versa than in the pristine polymers; (3) the field dependence of the mobility is linear in Poole–Frenkel coordinates. The third feature is a manifestation of hopping transport [5,23], while the second one can be an evidence of transport by mean of "Coulomb holes".

4. Conclusion

Integer charge transfer over D–A organic interface can produce a high area density ($\cong 10^{14}$ cm^{-2}) of strong and fluctuating dipoles (pairs of CTSs). Moreover, the high density of single electrons and holes arises due to dissociation of the pairs, if $\Delta/U_b \geq 0.0$. Strong Coulomb interaction results in intermolecular transfer time of charge carriers which is less than the time of electron polarization. Hence, metal-type band transport along the interface, at least through some fractal areas, is achieved. If the density of CTSs is too low (e.g., the D–A interface is not perfect, or HOMO–LUMO barrier is too high), an increase of mobility can originate from the reduction of the energy barrier for hopping of "Coulomb holes" by Coulomb attraction.

Organic light-emitting devices

ABSTRACT

A series of novel host blue-emitting materials based on anthracene have been synthesized and investigated in which, a π-electron-rich dibenzothiophene moiety was introduced as a side group to fine adjust the HOMO/LUMO levels of the anthracene and enhance the ability of hole-transport and electron-injection. These materials exhibit good film-forming capabilities, and display strong blue fluorescence in solution. To explore the electroluminescent properties of these materials, sky blue devices of 2-TNATA (60 nm)/NPB (10 nm)/Host: BUBD-1 (40 nm)/Alq_3 (15 nm)/LiF (1 nm)/Al (150 nm) were fabricated. For the device with 9, 10-bis(dibenzothiophen-4-yl)anthracene as the host, an electroluminescence efficiency of 13.14 cd/A and 6.76 lm/W at 20 mA/cm^2 and 6.09 V were achieved, with Commission Internationale d'Eclairage ($CIE_{x,y}$) color coordinates of (x = 0.15, y = 0.30).

1. Introduction

Organic light emitting diodes (OLEDs) have been a subject of intense academic and industrial research for the last decades due to their potential application in displays and solid state lighting [1–3]. Until now, among the three primary colors, green and red phosphorescent material have been studied intensively, and high efficiency and long lifetime red and green devices have been obtained [4–7]. However, it is very difficult to get high efficiency and long lifetime blue phosphorescent devices in spite of many relevant studies related to blue phosphorescent devices. Therefore, blue fluorescent material is still of prime importance for application in full-color flat-panel displays. To date, several derivatives of anthracene [8], binaphthol [9,10], spirobifluorene-linked bianthracene [11] and biaryl have been developed and subsequent attempts were made to improve their electroluminescent (EL) properties.

Among them, anthracene derivatives are one of the earliest luminescent materials reported [9] and they emit violet light both in the solid state and in solution. Derivatives such as 9, 10-di-2-naphthylanthracene (**ADN**) and 2-*tert*-butyl-9, 10-di-2-naphthylanthracene (**m-ADN**) have been used successfully as blue emitters in commercial OLED products (Scheme 1). Recently, Park et. al have reported anthracene derivatives bearing bulky side groups with an excellent external quantum efficiency (EQE) of 7.18% and Commission Internationale d'Eclairage (CIE) coordinates of (0.156, 0.088) [12]. Char and coworkers reported anthracene derivatives bearing non-planar diarylsilyl groups exhibiting high external quantum efficiency (EQE) (6.3%)

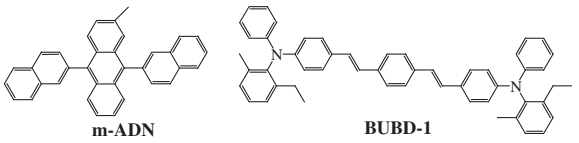


Scheme 1. The molecular structure of **m-ADN** and **BUBD-1**.

and good CIE coordinates (0.142, 0.149) [13]. Additionally, it was found that the introduction of *m*-dibenzothiophene into the polyfluorene backone could effectively suppress the long-wavelength emission [14]. Furthermore, dibenzothiophene-S, *S*-dioxide was incorporated into the small molecules owing to its high fluorescence efficiency and electron affinity energy [15]. However, to our knowledge, there is no report on the blue-emitting materials based on anthracene with dibenzothiophene as the wing to increase the charge transporting properties.

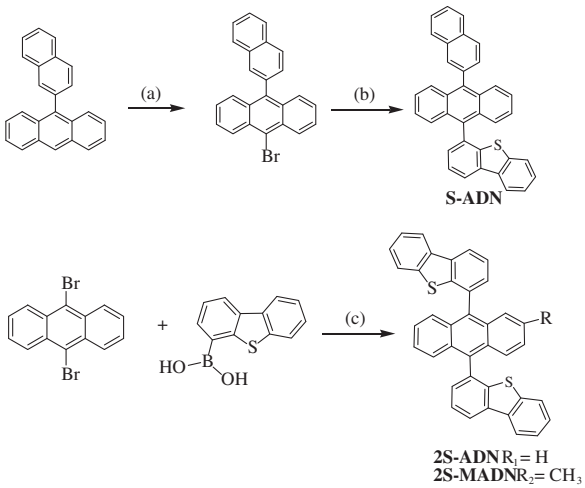
In this work, a series of high efficiency blue-emitting dibenzothiophenyl-anthracene derivatives were designed and synthesized. The design concept is to attach the π-electron-rich dibenzothiophene moiety to the 9, 10 positions of anthracene and therefore to facilitate the ready manipulation of its electronic structure (HOMO/LUMO levels) and tune the resulting physical properties. We anticipated that these new anthracene derivatives would reconstitute the properties of the **ADN** derivatives for the following two reasons: (1) The π-electron-rich benzothiophene substitution would offer the resulting new molecule with better hole transport properties. (2) The introduction of sterically hindered dibenzothiophene group at the side of anthracene would reduce the LUMO of the anthracene, which will be beneficial for the injection of electrons. At the same time, the PL emission of these benzothiophene derivatives will be blue-shifted as compared to **m-ADN**.

Because the use of sky blue light represents an efficient way to obtain the favorable white light [16,17], multilayered sky blue OLEDs were fabricated using these new blue host materials and BUBD-1 as the dopant (BUBD-1 = (*N*-(4-((1*E*,8*E*)-4-((*E*)-4-((2-ethyl-6-methylphenyl)(phenyl) amino)styryl)styryl)phenyl)-2-ethyl-6-methyl-*N*-phenylbenzenamine)) in investigating the EL properties of these materials (Scheme 2). As will be demonstrated below, devices using materials **2S-ADN** exhibited highly efficient sky blue emissions.

2. Experimental section

2.1. Material and methods

All reagents and solvents were used as purchased from Aldrich and were used without further purification. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker-AF301 AT 400 MHz NMR spectrometer. Mass spectra were obtained on a Finnigan MAT SSQ-710 in FAB (positive) mode. Fluorescence spectra were obtained on a Perkin-Elmer LS55 luminescence spectrometer. The differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA) experiments were performed under a nitrogen atmosphere on a TA Instruments DSC 2920 or DSCQ2000. Elemental



Scheme 2. Synthesis of compounds **S-ADN**, **2S-ADN** and **2S-MADN**. Conditions: (a) hυ, NBS, CH_2Cl_2; (b) $PdCl_2(PPh_3)_2$, toluene, 2 M K_2CO_3, 4-dibenzolthiophene boronic acid; (c) $Pd(PPh_3)_4$, toluene, 2 M K_2CO_3.

analyses were determined by a Finnigan FLASH 1112 SERIES EA elemental autoanalyzer. Cyclic voltammetric measurements were carried out in a conventional three electrode cell using a Pt button working electrode of 2 mm in diameter, a platinum wire counter electrode, and a SCE reference electrode on a computer-controlled EG&G Potentiostat/Galvanostat model 283 at room temperature. Reduction of all compounds was performed in dichloromethane containing Bu_4NPF_6 (0.1 M) as the supporting electrolyte.

9-(2-naphthyl)anthracene and 9-(2-naphthyl)-10-(bromo)-anthracene were prepared by the process reported in the literature [18]. Suzuki coupling reaction was conducted under a nitrogen atmosphere in the absence of light exposure.

2.2. Preparation of compounds

2.2.1. Synthesis of 9-(2-naphthyl)anthracene

It was synthesized by the method reported in the literature [18]. Yield: 89%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.52 (s, 1H, Ar), 7.99–8.09 (m, 4H, Ar), 7.88–7.93 (m, 2H, Ar), 7.66–7.69 (m, 2H, Ar), 7.54–7.61 (m, 3H, Ar), 7.44–7.49 (m, 2H, Ar), 7.29–7.34 (m, 2H, Ar).

2.2.2. Synthesis of 9-(2-naphthyl)-10-(bromo)anthracene

It was synthesized by the method reported in the literature [18]. Yield: 91%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.61–8.63 (d, 2H, Ar), 7.99–8.075 (m, 2H, Ar), 7.84–7.89 (m, 2H, Ar), 7.64–7.66 (d, 2H, Ar), 7.56–7.60 (m, 4H, Ar), 7.50–7.52 (m, 1H, Ar), 7.32–7.35 (m, 2H, Ar).

2.2.3. 4-(10-(Naphthalen-2-yl)anthracen-9-yl) dibenzothiophene (***S-ADN***)

A mixture of 4-dibenzothiophene boronic acid (2 mmol, 456 mg), 9-(2-naphthyl)-10-(bromo)anthracene(**2**) (2 mmol, 760 mg), $PdCl_2$ $(PPh_3)_2$ (0.06 mmol), toluene (30 mL), and K_2CO_3 (10 mL, 2 M) was flushed with N_2 for 10 min under

stirring. The reaction mixture was heated at 120 °C for 12 h under a N_2 atmosphere. After cooling to room temperature, the organic layer was evaporated to dryness under reduced pressure. The residue was purified by flash column chromatography on silica gel using CH_2Cl_2: hexane = 1:3 (v/v). Yield: 85%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.36–8.36 (m, 1H, Ar), 8.28–8.30 (m, 1H, Ar), 8.0–8.11 (m, 3H, Ar), 7.91–7.96 (m, 1H, Ar), 7.59–7.78 (m, 10H, Ar), 7.47–7.51 9 (m, 1H, Ar), 7.39–7.43 (m, 1H, Ar), 7.26–7.33 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$) δ 141.83, 139.96, 138.0, 136.5, 136.47, 136.43, 135.94, 135.76, 134.52, 133.41, 133.37, 132.79, 130.3, 130.23, 129.56, 129.48, 128.15, 128.09, 127.98, 127.95, 127.92, 127.90, 127.31, 126.85, 126.47, 126.45, 126.38, 126.26, 125.57, 125.31, 124.94, 124.43, 122.87, 121.86, 120.97 (Ar). FAB-MS: 486.1 (*m/z*), calcd for $C_{36}H_{22}S$: 486.6. Anal.calcd for $C_{36}H_{22}S$: C 88.85, H 4.56, S 6.59; found: C 88.80, H 4.58, S 6.51.

*2.2.4. 9, 10-Bis(dibenzothiophen-4-yl)anthracene (**2S-ADN**)*

The compound was synthesized using a similar procedure as for compound **S-ADN**. Yield: 80%. ^{1}H NMR (400 MHz, $CDCl_3$): 8.36–8.39 (m, 2H, Ar), 8.29 (d, 2H, Ar), 7.59–7.76 (m, 10H, Ar), 7.44–7.52 (m, 2H, Ar), 7.40–7.44 (m, 2H, Ar), 7.27–7.29 (m, 4H, Ar). ^{13}C NMR ($CDCl_3$) δ 142.0, 140.3, 136.2, 136.0, 134.0, 129.9, 129.7, 127.1, 126.0, 125.1, 124.7, 123.2, 123.1, 122.1, 121.3 (Ar). FAB-MS: 543.2 (*m/z*), calcd for $C_{38}H_{22}S_2$: 542.7. Anal.calcd for $C_{38}H_{22}S_2$: C 84.10, H 4.09, S 11.82; found: C 84.0, H 4.15, S 11.72.

*2.2.5. 2-Methyl-10-bis(dibenzothiophen-4-yl)anthracene (**2S-MADN**)*

The compound was synthesized using a similar procedure as for compound **S-ADN**. Yield: 76% ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.37–8.40 (m, 2H, Ar), 8.29–8.32 (m, 2H, Ar), 7.74–7.79 (m, 2H, Ar), 7.48–7.69 (m, 9H, Ar), 7.42–7.45 (m, 2H, Ar), 7.37 (s, 1H, Ar), 7.25–7.28 (m, 2H, ar), 7.12–7.15 (m, 1H, Ar), 2.3 (s, 3H, Ar). ^{13}C NMR ($CDCl_3$): 141.78, 140.01, 139.96, 135.91, 135.84, 135.78, 135.53, 135.28, 134.38, 134.0, 133.92, 129.95, 129.80, 129.63, 129.57, 129.13, 128.65, 128.30, 126.83, 126.82, 126.60, 126.50, 125.65, 125.32, 124.98, 124.94, 124.70, 124.43, 122.87, 121.86, 120.96, 120.94, 22.06 (Ar). FAB-MS: 557.4 (*m/z*), calcd for $C_{39}H_{24}S_2$: 556.7. Anal.calcd for $C_{38}H_{24}S_2$: C 84.14, H 4.35, S 11.52; found: C 84.12, H 4.39, S 11.42.

2.3. Device fabrication

The device structure used for the evaluation of **S-AND**, **2S-ADN**, and **2S-MADN** as a host material was indium-tin-oxide (ITO)/2-TNATA (60 nm)/NPB (10 nm)/Host: BUBD-1 (40 nm)/Alq_3 (15 nm)/LiF (1 nm)/Al (150 nm) and the energy level diagram is shown in Fig. 4. Prior to the deposition of organic materials, the indium-tin-oxide (ITO)/glass was cleaned with a routine cleaning procedure and pretreated with UV-ozone. Devices were fabricated under a base vacuum of about 10^{-6} torr in a thin-film evaporation coater following a published protocol [19]. The current density–voltage–luminance characteristics of the devices were measured with a diode array rapid scan system using a Photo Research PR650 spectrophotometer and a computer-controlled, programmable, direct-current (DC) source.

Goodness-of-fit on F^2	0.815	1.032

2.4. X-ray crystallography

Pertinent crystallographic data and other experimental details are summarized in Table 1. Diffraction data were collected at 293 K using graphite monochromated Mo Kα radiation (λ = 0.71073 Å) on a Bruker Axs SMART 1000 CCD diffractometer. The collected frames were processed with the software SAINT+ [20] and an absorption correction (SADABS) [21] was applied to the collected reflections. The structure was solved by the Direct methods (SHELXTL) [22] in conjunction with the standard difference Fourier techniques and subsequently refined by full-matrix least-squares analyses on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated in their idealized positions and allowed to ride on their respective parent carbon atoms. CCDC reference numbers 794330 and 794331.

3. Results and discussion

The chemical structures and synthetic routes of the three new compounds are shown in Scheme 2. They were synthesized by the Pd-catalyzed Suzuki cross-coupling of the 4-dibenzothiopheneboronic acid and the corresponding bromide with high yields. All of the newly synthesized compounds were fully characterized with ^{1}H-NMR spectroscopy and FAB-MS spectrometry and found to be in good agreement with their structures.

In order to look into the conformation of the benzothiophene-substituted derivatives, the crystal structure of **S-ADN** and **2S-ADN** were determined. As shown in Fig. 1

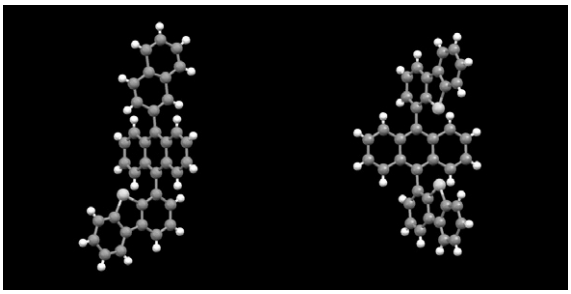

Fig. 1. The ORTEP drawings of **S-ADN** (left), and **2S-AND** (right).

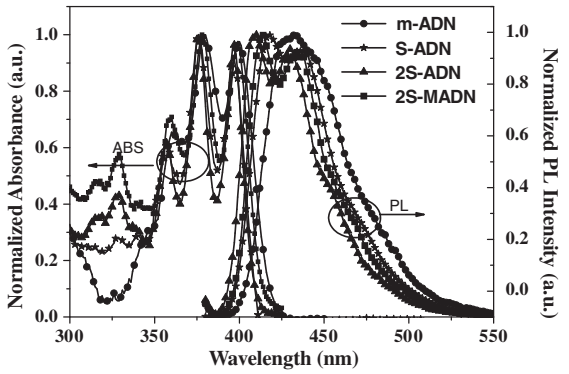

Fig. 2. Photoluminescence (PL) (λ_{ex} = 376 nm) and absorption spectra of compounds **m-ADN**, **S-ADN**, **2S-ADN**, and **2S-MADN** in toluene.

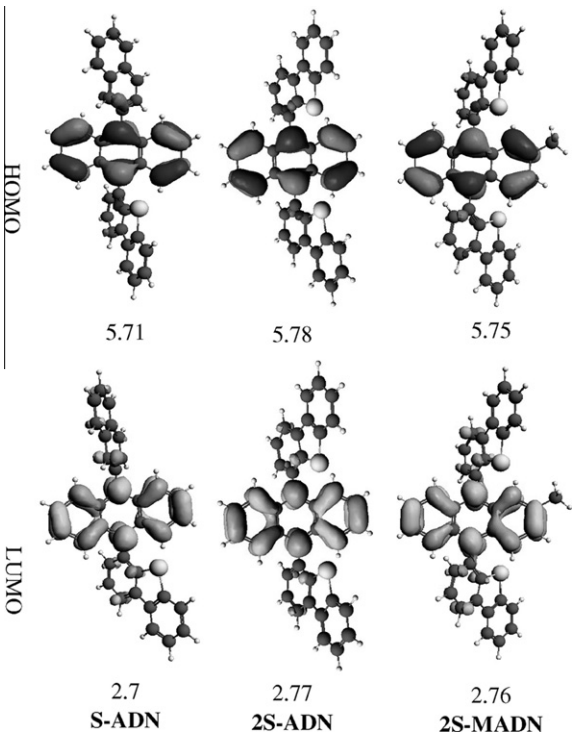

Fig. 3. The B3LYP/6-31-G calculated HOMOs and LUMOs for **S-ADN**, **2S-ADN**, **2S-MADN**.

(left), the twisted angle between the anthracene main core and the dibenzothiophene side unit is 86.55°, whereas the twisted angle between 2-naphthyl and anthracene is 77.02°. For the compound **2S-ADN**, the corresponding twist angles between the dibenzothiophene and anthracene groups are 74.14° and 76.45°. The results suggest that the obtained **2S-ADN** has a non-coplanar structure which bears bulky substituents for the purpose of disrupting the intermolecular interaction and suppressing the problematic recrystallization that would eventually reduce self-aggregation, which in turn, improves the morphological stability of the thin film of the OLED devices.

Thermal properties of these new blue host materials were studied using DSC and TGA. In Table 2, the glass transition temperature (T_g) and onset decomposition temperature (T_d) of the compounds are given. The compounds **S-ADN**, **2S-ADN,** and **2S-MADN** posses high (T_g's) at 177 °C, 115 °C and 149 °C in the DSC heating cycle, respectively. As we know, the high T_g will be beneficial for the performance of OLED device. TGA measurements showed that all the compounds exhibit high T_d (5% weight loss) at 411, 437, and 454 °C, respectively. It means that these materials are stable enough to endure the temperature of the vacuum vapor deposition.

Absorption and photoluminescence (PL) spectra of **S-ADN**, **2S-ADN**, **2S-MADN**, and **m-ADN** were recorded to compare the photophysical properties of the three blue-emitting host materials. Fig. 2 shows the UV absorption and PL spectra of **S-ADN**, **2S-ADN**, **2S-MADN**. In the toluene solution, the peak positions of UV absorption spectra of the three compounds are similar to anthracene except for a new peak at 329 nm. The new peak can be ascribed to the absorption of dibenzothiophene. From **S-ADN** to **2S-ADN** and **2S-MADN**, the intensity of the new peak increased with the number of dibenzothiophene. The absorption band in the 330–400 nm region is assigned to the $S_1 \leftarrow S_0$ transition of the anthracene moiety [23,24]. On irradiation at 376 nm in toluene, all of the compounds show intense blue fluorescence, with an emission peak centred at 410–440 nm. There is a distinct blue shift in the PL maxima emission of **S-ADN**, **2S-ADN** and **2S-MADN** as compared to **m-ADN**, and this is likely due to a decrease

Table 2
The optical, photophysical and thermal properties of **S-ADN**, **2S-ADN**, and **2S-MADN**.

	λ_{max}/nm (abs)	λ_{max}/nm (PL)	E_{gap}/eV	HOMO/LUMO	T_d/T_g (°C)	Φ_f
m-ADN	360, 380, 399	432	2.96	−5.49/−2.53	397/120	1
S-ADN	328, 356, 376, 396	418, 436	2.95	−5.50/−2.55	411/177	0.78
2S-ADN	329, 357, 376, 397	410, 430	3.03	−5.67/−2.64	437/115	0.74
2S-MADN	329, 360, 378, 398	414, 434	3.0	−5.61/−2.61	454/149	0.87

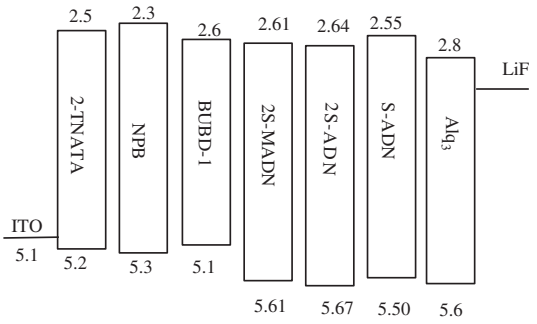

Fig. 4. Configuration and energy level diagram of blue-doped device.

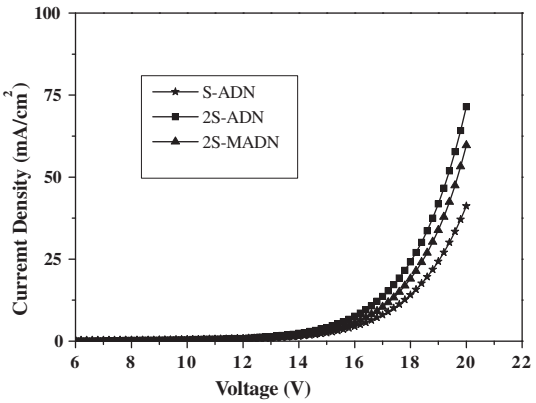

Fig. 6. Current density–voltage (*J*–*V*) curve of hole-only device for **S-ADN**, **2S-ADN**, and **2S-MADN** in device ITO/2-TNATA (40 nm)/blue host (20 nm)/Al (150 nm).

in conjugation because of a higher steric hindrance of the dibenzothiophene ring. The fluorescent quantum yields (0.78, 0.74, and 0.87, respectively) of **S-ADN**, **2S-ADN** and **2S-MADN** are listed in Table 2, which are measured using **m-ADN** as the reference. The optical and photophysical properties of **S-ADN**, **2S-ADN**, and **2S-MADN** are also summarized in Table 2.

The electrochemical behavior of **S-ADN**, **2S-ADN** and **2S-MADN** were investigated by cyclic voltammetry. From the electrochemical data and optical band gap (E_{gap}), the HOMO and LUMO energies were calculated as −5.50 and −2.55 eV for **S-ADN**, −5.67 and −2.64 eV for **2S-ADN**, −5.61 and −2.61 eV for **2S-MADN**. In our design, we introduce the dibenzothiophene group to reduce the LUMO level of **ADN**, and it is clear that the LUMO of **2S-ADN** is 0.09 eV lower than that of **S-AND**. As we know, the lower LUMO level will favor the injection of electron. The band gap, HOMO and LUMO of **S-ADN**, **2S-ADN**, and **2S-MADN** were calculated from the absorption spectra and cyclic voltammetric measurements. The E_{gap} are 2.95 eV for **S-ADN**, 3.0 eV for **2S-MADN** and 3.03 eV for **2S-ADN**. The increase of E_{gap} can be attributed to the larger torsional angle between anthracene and the attached side group. The effect of the dibenzothiophene side group in fine adjusting the photophysical properties and the HOMO/LUMO level of anthracene is clear.

In order to investigate the origin of this observation, molecular simulations of **S-ADN**, **2S-ADN** and **2S-MADN** were carried out to understand their physical properties at the molecular level. Ab initio calculations were performed using a suite of Gaussian programs, and the chemical structures of **S-ADN**, **2S-ADN**, and **2S-MADN** were fully optimized by density functional theory (DFT) using PBE ADF2009. The optimized structures and the HOMO/LUMO orbitals for **S-ADN**, **2S-ADN** and **2S-MADN** are shown in Fig 3. The HOMO and LUMO orbitals of these compounds are mostly distributed over the anthracene unit and the dibenzothiophene group only plays an accessory role. The calculated HOMO/LUMO values are in the range of 5.71–5.78 eV/2.7–2.77 eV, which also correlate well with the experimental data considering the approximations employed. By the way, in the compounds **S-ADN**, the two dihedral angles between the 2-naphthyl unit and the adjacent anthracene ring as well as dibenzothiophene unit and anthracene ring are 73.1° and 83°, respectively, which are close to the experimental values of 77.02°/86.55° obtained from the single-crystal X-ray structural analysis. The larger dihedral angles will shift the emission peak toward the blue, (see Fig. 2).

To investigate the performance of **S-ADN**, **2S-ADN** and **2S-MADN** as a blue host emitting material, the relevant OLED devices were fabricated. The device configuration

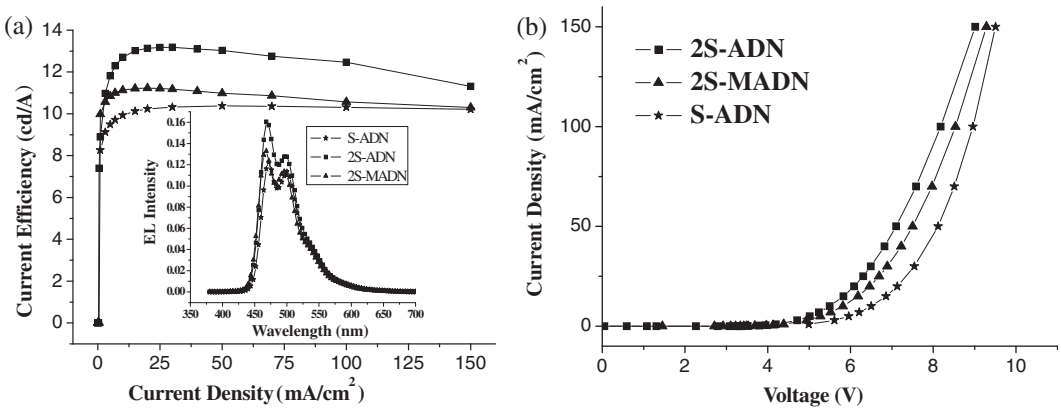

Fig. 5. (a) Dependence of the current efficiency on the drive current density for **S-ADN**, **2S-ADN**, and **2S-MADN** based devices (Insert: The EL spectrum of the device at 20 mA/cm^2). (b) Current density–voltage (*J*–*V*) curve.

Table 3
The EL performance of **S-AND, 2S-AND** and **2S-MADN** in the tri-layer device[a].

	Voltage (V)	Current density (mA/cm^2)	CE (cd/A)	PE (lm/W)	EQE (%)	CIE
S-ADN	7.13	20	10.24	4.51	5.01	(0.18, 0.31)
2S-ADN	6.09	20	13.14	6.76	6.86	(0.152, 0.304)
2S-MADN	6.40	20	11.24	5.51	5.70	(0.15, 0.312)

[a] CE = current efficiency, PE = power efficiency, EQE = external quantum efficiency.

used for the blue host material test was ITO/2-TNATA (60 nm)/NPB (10 nm)/Blue Host: BUBD-1 (40 nm)/Alq_3 (15 nm)/LiF (1 nm)/Al (150 nm). In the device, 4,4′,4″-*tris* [*N*-(1-naphthyl)-*N*-phenylamino]triphenylamine (2-TNATA), *N*,*N*′-bis-(1-naphthyl)-*N*,*N*′-diphenyl,1,1′-biphenyl-4,4′-diamine (NPB), tris(8-quinolino-lato)aluminium (Alq_3) and LiF were used as the hole injection, hole transport and electron transport materials, respectively. The emission layer consists of a sky blue styrylamine-type fluorescent material, BUBD-1, uniformly doped in the new blue host material [25,26]. Devices at different dopant concentrations have been fabricated (see SFig. 1), and the optimal BUBD-1 concentration in these hosts is 5%.

The current efficiency of **S-ADN**, **2S-ADN** and **2S-MADN** devices was plotted against current density in Fig. 5(a). The current efficiency increased in turn with **S-ADN**, **2S-MADN**, and **2S-ADN**, which can be ascribed to the increased hole-transporting and electron injection ability. Meanwhile, their EL spectra showed a slight blue-shift, which can be ascribed to the larger steric hindrance of dibenzothiophene. For the **2S-ADN**, an EL efficiency of 13.14 cd/A and 6.76 lm/W at 20 mA/cm^2 and 6.09 V was observed, with $CIE_{x,y}$ coordinates of (x = 0.15, y = 0.30), which is amongst the best sky-blue emitting devices reported so far in the current available literature. Fig. 5(b) shows the current density–voltage curves of **S-ADN**, **2S-ADN**, and **2S-MADN** devices. At the same driving voltage, the current density of **2S-ADN** is higher than that of **S-ADN**, which may be ascribed to the better charge injection and transport properties of the added dibenzothiophene. For **2S-MADN**, the current density is between those of **S-ADN** and **2S-MADN**, and it is a manifestation of the methyl substituent in the 2-position in increasing the distance between molecules and reducing the transport properties as compared to **2S-ADN**. In order to corroborate this prediction, the hole-only devices of these materials were fabricated. The device configuration was ITO/2-TNATA (40 nm)/blue host (20 nm)/Al (150 nm). From the current density–voltage (J–V) curve (Fig. 6), it is obviously that the charge injection of **2S-ADN** is the best, and at the same current density, the voltage increased in turn from **2S-ADN**, **2S-MADN** to **S-ADN**. The EL properties of sky blue devices based these new materials are summarized in Table 3, with all devices showing good sky blue light.

4. Conclusions

Some anthracene-based blue light-emitting materials, composed of anthracene as the main unit and dibenzothiophene group as side wings were developed and characterized. The introduced rigid and dibenzothiophene wings inhibited intermolecular interactions and increased the hole transport ability. Single-crystal diffraction analysis has shown that the obtained material has a non-coplanar structure, which results in high PL efficiency, thin film of a high quality, and high thermal stability with a high T_g. In the guest/host emitting system, the sky blue devices 2-TNATA (60 nm)/NPB (10 nm)/Host: BUBD-1 (40 nm)/Alq_3 (15 nm)/LiF (1 nm)/Al (150 nm) were fabricated for the **2S-ADN**, achieving an EL efficiency of 13.14 cd/A and 6.76 lm/W at 20 mA/cm^2 and 6.09 V, with $CIE_{x,y}$ color coordinates of (x = 0.152, y = 0.30).

ABSTRACT

In this study, a series of trifluoromethyl-terminated alkanethiols with different chain length ($CF_3(CH_2)_nSH$, n = 5, 6, 10, 11, 12 and 13), were used to form self-assembled monolayers(SAMs) on silver and gold surfaces. The SAM modulates the metal work function as a result of the different orientation of the terminal dipolar CF_3 group due to different chain tilt of the SAM on Au and Ag surfaces, respectively. The SAM-modified Ag and Au were used as the anode in the fabrication of hole-only devices as well as top-emitting organic light-emitting diodes (TOLEDs) with different hole-transporting layers. The correlation between current density/luminous efficiency and the SAM chain length/work function were analyzed to provide information on charge balance. Thus with NPB as the hole-transporting layer, where little difference between the HOMO energy level and the work function of the SAM-modified electrode, the charge injection is modulated by the chain length (tunneling distance-dependent) of the SAM used for modification, decreasing with increasing chain length. With BPAPF as the HTL, where a barrier is present, the charge injection is modulated more by the work function (injection barrier-dependent), which shows an odd–even alternation.

1. Introduction

A metal/organic (M/O) interface is involved in most of organic electronic devices, including organic light-emitting diodes (OLEDs), organic solar cells, and organic field-effect transistors. In general, these interfaces involve an abrupt shift of the vacuum level between materials, i.e. an interface dipole barrier (Δ), usually with negative charges on the metal side and positive charges on the organic side, due to different carrier density between metal and organic materials. In addition, a barrier may also exist due to different alignment of the metal work function and the molecular orbital energy level. The magnitude of these barriers determines how efficient the charges can across the interface, which in turn influences the device performance in a major way. For example, the hole/electron charge balance is one important contributing factor in the current efficiency in a light-emitting device [1]. An understanding and further modulating the barrier is of great interest in fabricating various devices.

Considerable efforts have been devoted to reducing the charge injection barrier in order to improve the current density in organic electronic devices. These include various surface treatments and/or adsorption of specific species to create a new dipolar layer for better charge injection [2]. Among these, self-assembled monolayers [3] (SAMs) provide a systematic way of modulating the M/O interfacial barrier by varying the functional group and/or the chain length of the molecule [4]. The size and direction of the

doi:10.1016/j.orgel.2011.01.004

molecular dipole introduced by the SAM adsorption lead to change in the work function of the metal on which it is adsorbed [5]. Improvement in charge injection can be achieved with a proper work function modification. Nevertheless, increasing the current density by reducing injection barrier does not always lead to improved luminous efficiency because increasing carriers which is already in excess will reduce the recombination ratio and thus the luminous efficiency [6]. Besides introducing an oriented dipole, the SAM also imposes a tunneling barrier through which the charges have to pass to reach the organic layer. It was demonstrated that within the same series of SAM-forming molecules (alkyl chain carrying the same terminal molecular dipole) modifying the anode, the current injection decreases with increasing chain length. The corresponding trend in luminous efficiency provides insights to the charge balance situation in an organic light-emitting device [7]. Thus in the case of a hole-dominating device, increasing the chain length (and thus decreasing the hole injection) would improve the hole/electron charge balance and results in increasing luminous efficiencies. Whereas in the case of a hole-deficient device, increasing the chain length would further the charge imbalance and results in decreasing luminous efficiency [7]. However, the work function and the molecular chain length may have different impact on the charge injection, depending on the energy level of the organic material in contact with the electrode.

In this work, we use a series of dipole-carrying ω-trifluoromethylalkanethiols of different chain length as modifiers and focus on the effect of the dipole direction due to odd–even chain length alternation on the work function and charge injection in an organic light-emitting device. The efficiency of charge injection and device performance in hole-only diodes and top-emitting organic light-emitting diodes (TOLEDs) were analyzed to show that depending on the electrode (Au or Ag) and the hole-transporting material used (and thus the injection barrier involved), different current responses were observed. This can shed light on the charge balance picture in a device and help in looking for strategy to improve the luminous efficiency.

2. Experimental

The silver or gold substrates were prepared by thermally evaporating 150 nm of silver or gold on a 2-inch silicon wafer primed with 10 nm chromium. The substrates were immersed in a 1 mM ethanolic solution containing various alkanethiols ($CF_3(CH_2)_nSH$, n = 5, 6, 10, 11, 12 and 13, designated as CF_3C5, CF_3C6, CF_3C10 and so on) for 2 h. The substrates were then removed from the solution, rinsed with absolute ethanol, acetone, and finally spun-dried on a spinner. Reflection–absorption IR spectra were taken with a Biorad FTS-60 Infrared spectrometer equipped with a DTGS detector, and a custom-designed optics unit with 86° incidence angle and p-polarized light were employed. Plasma-cleaned gold was used as reference for all spectra. Contact angle was taken with a GBX DIGIDROP Goniometer, and Teflon-coated needles were used to dispense water and hexadecane as the contacting liquids onto the surface of the monolayers. Atomic force microscopy (AFM) measurements were carried out under ambient conditions using a Digital Instruments Nanoscope IIIa microscope. Topography images were captured by tapping mode with silicon tip at 300 kHz frequency.

For device fabrication, the anodes were prepared by thermally evaporating 150 nm of Ag or Au on the soda glass primed with 10 nm chromium, with the area (4 mm^2) defined by a shadow mask. The Au or Ag substrates modified with SAMs of various alkanethiols were placed in a custom-designed rotating substrate holder in a vacuum chamber for device fabrication. Layers of naphthylphenylbiphenyldiamine (NPB) or 9,9-bis{4-[di-(p-biphenyl)aminophenyl]}fluorene (BPAPF) [8] as the hole-transporting layer (HTL), tris-(8-hydroxyquinoline) aluminum (Alq) as emitting and electron transporting layer (ETL), and the cathode were deposited sequentially in the same vacuum to give either the hole-only devices of metal/SAM/NPB(120 nm)/Al or TOLED devices of metal/SAM/NPB or BPAPF (50 nm)/Alq (50 nm)/LiF (1 nm)/Al (2 nm)/Ag (25 nm). The devices were encapsulated with UV-cured epoxy glue "*in situ*" before property measurement. The luminance–current density–voltage characteristics (L–J–V) of the devices were measured by a computer-controlled Keithley 2400 Source meter connected with a PR650 spectrometer. The work functions of SAM-modified metal electrodes were measured by a photoelectron spectrometer (AC-2, RIKEN KEIKI, Japan) in ambient with a UV source.

3. Results and discussion

3.1. Odd–even effect on the structure of orientated SAMs on Au and Ag surface

n-Alkanethiols are known to form well-ordered and closely packed monolayers on both Au and Ag surfaces, with a slight structural difference in that a higher chain tilt is obtained on Au (~30°) than on Ag (~11°) because of different binding lattices on the two metals [6]. An odd–even effect in the infrared absorption intensity was observed for the terminal methyl group as a result of orientation alternation between odd and even chain length [9]. An odd–even effect in the wetting property was also observed due to the different interaction of the very outer surface with wetting liquids [10]. When the terminal methyl group is changed to a strongly dipolar group of CF_3, the dipole component along the surface normal direction is expected to alternate between odd and even chain thiols (Fig. 1), which may contribute to the work function modulation. Vibration signatures in the reflection absorption IR spectra of SAMs of CF_3-terminated alkanethiol on Au and Ag surfaces (Fig. 2) provide the evidences for the alternation in the orientation of terminal CF_3 group. The absorption peak intensities of CF_3 group (at ~1170 and ~1385 cm^{-1} for ν_{as} and $\nu_{as\ ip}$, respectively, and ~1265 cm^{-1} for ν_s [11]) alternate clearly depending on the chain length (odd versus even) for SAM on Au (Fig. 2a), but less so for SAM on Ag, presumably due to a lower chain tilt in SAMs on Ag surface (Fig. 2b). However, the $\nu_{as}(CF_3)$ and $\nu_{as\ ip}(CF_3)$ are stronger for odd chain, which is opposite to that of *n*-alkanethiol, where

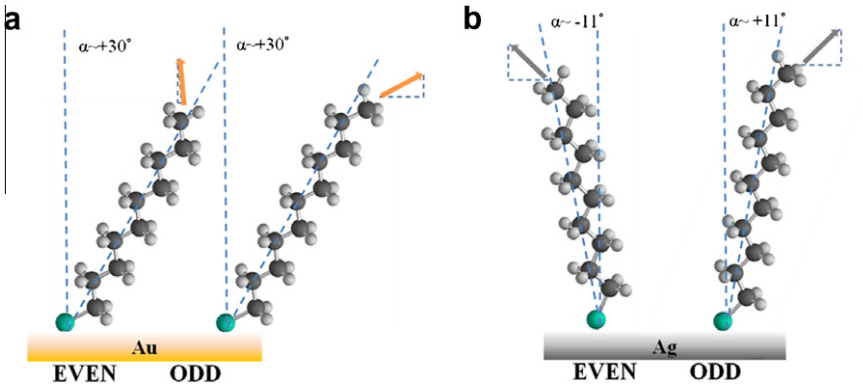

Fig. 1. Schematic diagram of monolayer of *n*-alkanethiol on (a) Au and (b) Ag surfaces.

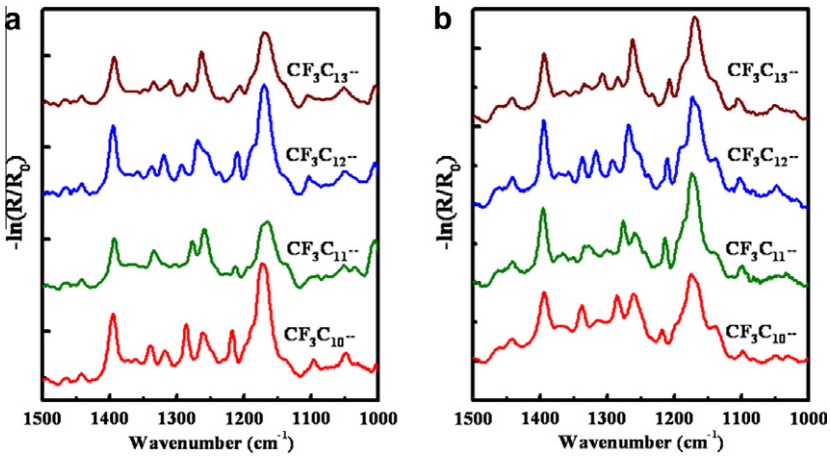

Fig. 2. Reflection adsorption IR spectra of ω,ω,ω-trifluoroalkanethiol on (a) Au and (b) Ag surfaces.

$\nu_{as}(CH_3)$ and $\nu_{as\ ip}(CH_3)$ are stronger for even chains [9]. Contact angle measurement on the SAMs using water and hexadecane as wetting liquids also showed different trends for the SAMs on different metal surfaces. On Au surface, both water contact angle and hexadecane contact angle show alternation with the chain length (Fig. 3), presumably due to different dispersive and polar interaction of the wetting liquid with the terminal CF_3 groups pointing at different directions for odd chain and even chain. Again the contact angle values are slightly higher for odd chain than on even chain. This is also opposite to that for *n*-alkanethiol on Au [9]. It is noted that an opposite odd–even trend in contact angle was observed for polar liquids on such series of thiols on Au was observed [12]. Whereas on Ag surface, little alternation was observed for the same series of SAMs, again due to a lower chain tilt in the SAMs on Ag. This is in corroboration with the IR results.

The effect of adsorbed dipole on work function ($\Delta\Phi$) is related [13] to $N\mu_\perp/\varepsilon_0\kappa$, where the N is the density of dipoles, $\mu_\perp$ is the dipole moment along the surface normal on the substrate, ε_0 is the permittivity of free space, κ is the dielectric constant of the SAM. Assuming same surface density and dielectric constant for the same series of SAM, the work function will be sensitive to the orientation of the dipole. The work function ω measured on SAM-modified

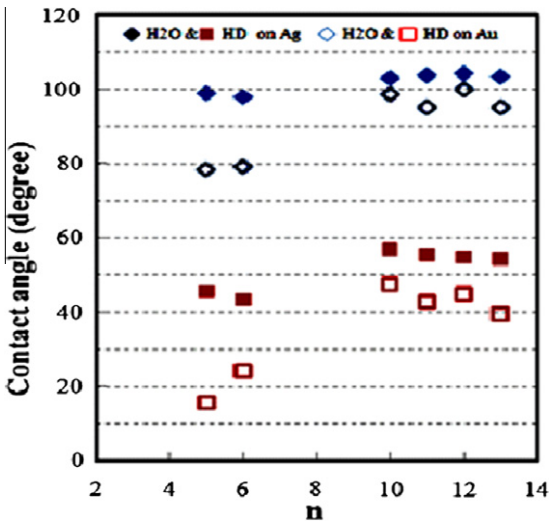

Fig. 3. The contact angles on ω,ω,ω-trifluoroalkanethiol-modified Ag and Au surfaces.

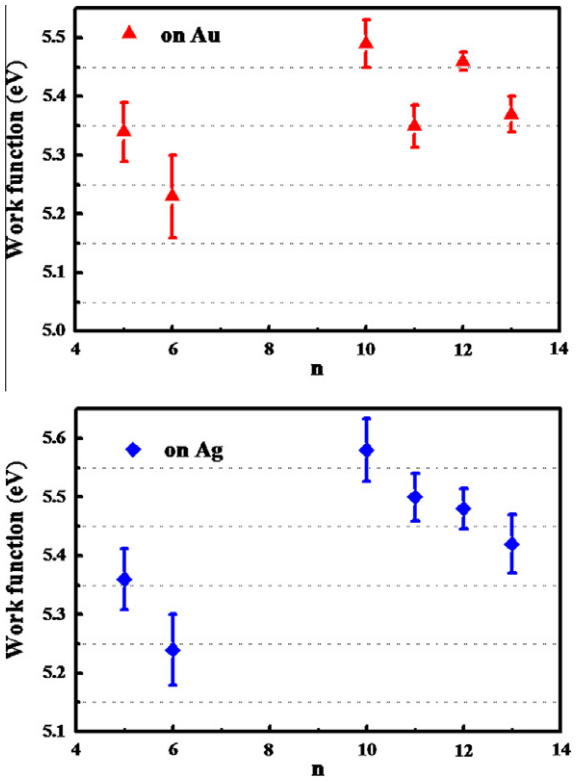

Fig. 4. The work function of ω,ω,ω-trifluoroalkanethiol-modified Ag and Au surfaces.

Au exhibits a clear odd–even effect (Fig. 4) for chain length longer than C11, presumably due to the alternating direction of the terminal CF_3 group of the monolayer. Yet there is no clear alternating trend for work function measured on Ag. It is noted that the odd chain length ($n + 1$ is odd-numbered) produces higher effective work function than the even chain length, which is in contrast with the trend expected based on Fig. 1, where a bond angle of Au–S–C of ~110° is depicted and the odd chain should have CF_3 group pointing away from the surface normal. The trend observed here is similar to the trend observed by UPS for chain length from C10–C18 [14]. It is known that *n*-alkanethiol on Au and Ag exhibit opposite odd–even alternation trend in contact angles and IR peak intensities. Different binding angle for sulfur atom at the surface was suggested: bent Au–S–C angle (~110°) on Au and linear Au–S–C angle on Ag (180°).[15] In the current case, the CF_3-terminated alkanethiols result in an opposite trend could imply a different binding angle for sulfur at the Au surface due to the perturbation of the polar CF_3 group. This bond angle change also can explain the opposite odd–even trend observed for IR intensity and contact angle above. It is also noticed that the data for short chain ones like CF_3C5 and CF_3C6 fall off the line and the trend. We assume these short chain SAMs are disordered and the CF_3 group is too close to the substrate to be free from influence from the underlying substrate.

The SAM-modified Ag and Au appear to give work functions of similar range even though the bare metals have very different work function (4.3 and 5.2 eV, respectively) [2c,4c]. Similar observation for SAM-modified metal substrates was reported [16]. This can be a collective result of the packing density, chain tilt in the SAM, as well as the metal-sulfur bond dipole, which are all different on Au and Ag surfaces. All these factors contribute to the overall interfacial dipole. It is also noted that while the same work function was extracted for the SAM-modified Ag metal and SAM-modified Au (for example, ~5.5 eV for CF_3C11-modified Ag and CF_3C10-modified Au), the Ag metal gives off more electron density than Au, as reflected in the slope of electron yield upon UV-irradiation (Fig. 5). The roughness of the two metals are also quite different (Fig. 6a and b). It is suggested that the electron fluxes from different metal surfaces depend not only on the work function, but also on the effective area of electrode (roughness).

Hole-only devices with SAM-modified Ag or Au as anode and NPB as HTL, Al as cathode were fabricated. The *I–V* characteristics are shown in Fig. 7(a and b). The devices based on SAM-modified Au gave much lower currents. With both electrodes, similar trend in that the current density decreased with increasing alkyl chain length was observed. No odd–even effect was detected for devices with Au as anode, even though the ω value showed odd–even alternation. It is suggested that the modified surfaces (Ag or Au) have Fermi level similar or lower than the HOMO level of NPB (~5.2 eV) [17] so that there is no energy barrier and the hole injection is influenced mainly by the chain length, which imposes a tunneling distance for charges to overcome. The shorter the monolayer chain length, the higher the current. Hole-only devices with SAM-modified Au as anode and BPAPF as the HTL exhibited a very different *I–V* trend, as shown in Fig. 7(c). The currents decrease in the order of $CF_3C10 > CF_3C12 > CF_3C11 > CF_3C13 > CF_3C5 > CF_3C6$, which parallels to the trend of work function approximately: higher work function anodes gave higher currents. For the pair of odd chain (and even chain), the shorter chain gave higher currents. BPAPF has a lower-lying HOMO level (5.62 eV) than NPB does. A substantial injection barrier exists in the M/O interface and the charge injection is influenced mainly by the work function (with a

minor effect from chain length), which shows an odd–even effect.

The TOLEDs with NPB as HTL and SAM-modified Ag as anode showed similar trend in current as in the hole-only devices in that the longer chain SAM-modified anodes result in lower currents (Fig. 8a). The luminous efficiency, on the other hand, showed a monotonous yet opposite trend in that the higher the current density, the lower the luminous efficiency (Fig. 8b). This is ascribed to the hole-dominating nature of these devices. The hole/electron carriers are imbalanced, with hole charges in excess. Diminishing the hole charges by imposing a longer insulating organic layer improves the charge balance (or alleviate the imbalance) and thus enhances the luminous efficiency.

TOLEDs with BPAPF as HTL and SAM-modified Au as anodes were also fabricated. The *I–V* characteristics (Fig. 9) showed similar chain length-dependence as in hole-only devices, that is, the current is higher for odd chain

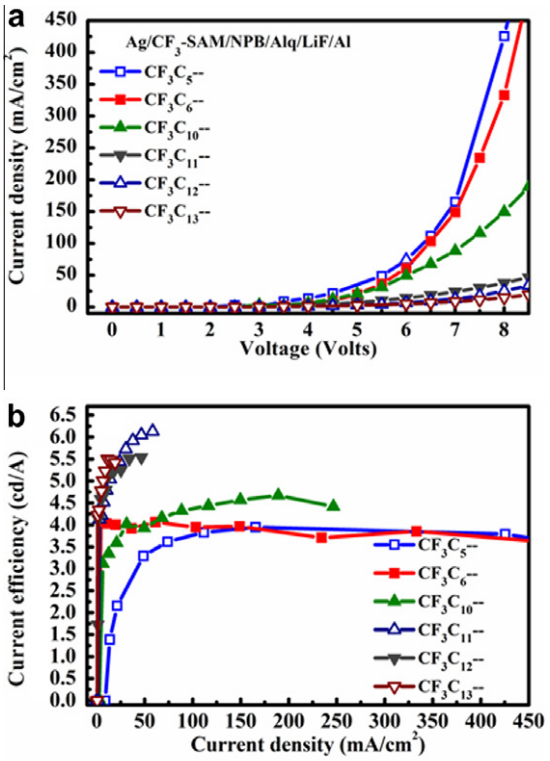

Fig. 8. (a) *I–V* characteristics and (b) current efficiency for TOLEDs using NPB as the HTL and SAM-modified Ag as the anode.

derivatives than for even chain derivatives. However, the luminous efficiency varies in a non-monotonous fashion: the device with the highest current (and the hole injection, i.e. CF_3C10) yielded the lowest efficiency (~3.6 cd/A). Decreasing the current (CF_3C12) enhanced the efficiency. Further decrease in current (CF_3C11) gave a maximum (~5.6 cd/A). Then the efficiency decreased again with further decrease in current (CF_3C13, CF_3C6, CF_3C5). It is suggested that in the current device, a switch in charge balance occurred, from hole-dominating to more balanced carriers and then to electron-dominating as a result of the systematic variation in the hole injection. Thus in order to balance the electron charges from the LiF/Al cathode into Alq, a specific work function and injection barrier exist. Further decreasing the barrier and increasing the hole current will not help the luminous efficiency. It should be noted that the power efficiency (lumen/watt) of the devices have different trend as the luminous efficiency. At a reduced current density to reach a balanced charge, a higher voltage is needed to reach similar brightness. This will reduce the power efficiency.

4. Conclusions

In summary, it is demonstrated here that both dipole moment and chain length of the monolayer can be used to modulate the charge injection. The importance of either depends on the energy barrier between the M/O interfaces. Where there is little energy gap between the metal and the HOMO of organic layer, the current is influenced by the chain length of the SAM (tunneling distance-dependent). Where there is a barrier between the metal and the HOMO of organic layer, the current is dominated by the work function (injection barrier-dependent). The trend in the current efficiency provides further information regarding the charge balance in the devices. It is demonstrated that excessive charge injection does not necessarily benefit the luminous efficiency. This will help in approaching the charge balance through proper interfacial modification and improve the device efficiency.

ABSTRACT

The characteristics of organic–inorganic multi-barriers were investigated in this study. Polymerized cycloaliphatic epoxy hybrid materials (hybrimers), synthesized by a sol–gel method and MgO were used as an organic and inorganic material, respectively. We performed a Ca test at 30 °C and 90% R.H. A multi-barrier of 6 dyads on 100 μm thick PET resulted in a water vapor transmission rate (WVTR) of 4.9×10^{-5} g/m^2 day and optical transmittance of 81.8% in the visible region (350–850 nm). We suggested relatively simple passivation method with a solution process involving an organic material coupled with low temperature deposition of MgO using an electron beam evaporator. Due to the solution process of the organic layer, the OLEDs were passivated without dark spots or an additional protective layer. After driving of 740 h with a constant current source under ambient conditions, a half-life time of 15,000 h was estimated by the stretched exponential decay (SED) model with an initial luminance value L_0 = 1000 cd/m^2.

1. Introduction

Organic light-emitting diodes (OLEDs) have great potential for use in next-generation flat-panel displays due to their many advantages, such as their fast response, low power consumption and potential for use with flexible displays. However, reliability issues remain as a major challenge for mass production at present. The organic materials used in OLEDs are very sensitive to oxygen and water vapor. The water vapor transmission rate (WVTR) requirements in organic electronics are stricter than those of any other packaging application [1]. In an OLED, the WVTR must be less than 10^{-6} g/m^2 day. To reduce the weight of the device and realize a full potential of OLEDs, a technology that replaces glass encapsulation is indispensable. Although polymers have been considered as promising candidates for these substrates, the enormously rapid permeation of this setup is known to be a major obstacle [2]. Therefore, a barrier-coating technique is essential before the great potential of OLEDs can be realized. The permeation properties of multi-barriers were discussed by Graff et al. using classical Fickian diffusion models [3]. The effective diffusion path was increased using an alternating layer design.

The lifetime and electroluminescence of OLEDs are directly affected by the formation of non-emitting areas known as dark spots, which accelerate with continuous operation. Various mechanisms of the dark spots have been studied. Crystallization of the organic material by Joule heating and local decomposition of the ITO/organic interface have been reported as possible origins of the dark spots [4,5]. It was also revealed by Liew et al. that cathode delamination is a primary factor in the growth of the dark spots [6]. The growth of the dark spots due to external factors can be blocked by a reliable encapsulation method. Research in relation to the multi-barrier encapsulation

doi:10.1016/j.orgel.2011.01.007

method has been done in which a vacuum process was utilized. Atomic layer deposition (ALD) and chemical vapor deposition (CVD) have also been shown to provide a high-quality layer [7,8]. However, a vacuum-based deposition process requires considerable time and lowers the price competitiveness. Although a multi-barrier design provides high performance with low WVTR values, encapsulation without dark spots is quite challenging. A protective layer for passivation using a vacuum process is crucial for avoiding damage during the passivation process [9].

In this work, we report a simpler multi-barrier encapsulation method for OLEDs involving the use of a solution process, prepared UV-curable epoxy hybrid materials and the low-temperature deposition of MgO. Directly coated hybrid materials on top of the devices serve as a protective layer in the passivation process. They also function as permeation barrier. A passivated device using the multi-barrier design showed no dark spots. It also demonstrated performance identical to that of glass-lid encapsulation devices.

2. Experimental setup

2.1. Preparation of organic–inorganic hybrid materials

In an earlier study, we prepared a UV-curable epoxy hybrid material (hybrimer) in a sol–gel method [10]. Cycloaliphatic-epoxy oligosiloxane resins were synthesized in a condensation reaction between [2-(3,4-epoxycyclohexyl)ethyl]trimethoxysilane (ECTS, Fluka, USA) and diphenylsilanediol (DPSD, Gelest, USA). Polyethylene glycol methyl ether acetate (PGMEA, Aldrich, USA) and arylsulfonium hexafluorophosphate salt (Aldrich, USA) were used as a solvent and a photo initiator respectively.

The characteristics of the cycloaliphatic-epoxy oligosiloxane resins were also studied [11]. The WVTR value was affected by the siloxane and epoxy network density, and the surface energy of the coating. Higher packing density, greater transparency and lower surface energy were obtained in accordance with increasing the DPSD content of the hybrimer. An optimized hybrimer applicable to the passivation of an OLED was used for the multi-barriers.

2.2. Organic–inorganic multi-barrier coating

In the multi-barrier structure, polymerized cycloaliphatic epoxy hybrid materials (hybrimers) and MgO were used as an organic and inorganic material, respectively. A diluted cycloaliphatic-epoxy oligosiloxane solution with a predetermined amount of solvent (PGMEA) was spin-coated at 2000 rpm for 15 s to create a 1 μm thick layer on 100 μm PET. The coated film was cured by I-line UV light ($\lambda = 365$ nm, optical power density = 11 mW/cm^2) for 360 s. Following this process, thermal curing at 60 °C was conducted in a vacuum chamber for 1.5 h to remove the remaining solvent. 100 nm thick MgO was then deposited using an electron beam evaporator at 2×10^{-6} torr. To prevent the deformation of the film and thermal degradation of the organic materials, a low temperature of 60 °C was maintained, throughout the MgO deposition process. These processes were successively repeated to create the organic–inorganic multi-barrier structure.

2.3. Device fabrication

The OLED was fabricated on a glass substrate coated with indium tin oxide (ITO) in a bottom-emission type. After an O_2 plasma treatment, the 150 nm thick ITO had a sheet resistance of 10 Ω/□. The OLED device had a configuration of ITO(150 nm)/2-TNATA(60 nm)/NPB(30 nm)/Alq$_3$-MADN doped with DCJTB (35 nm)/Alq$_3$(30 nm)/LiF(0.8 nm)/Al(150 nm), wherein 4,4′,4″-tris(2-naphthylphenyl–phenylamino)-triphenylamine (2-TNATA) and *N*,*N*′-bis(1-naphthyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB) independently functioned as a hole injection layer (HIL) and a hole transport layer (HTL). The emitting layer was co-deposited with tris(8-hydroxyquinolinato)aluminum (Alq3) of 20% and 2-methyl-9,10-di(2-naphthyl) anthracene (MADN) of 80% as the co-host materials, and this was doped with 4-(dicyanomethylene)-2-t-butyl-6-(1,1,7,7-tetramethyl-juloli-dyl-9-enyl)-4*H*-pyran (DCJTB) of 2% as a red dopant. Alq$_3$ was subsequently used as an electron transport layer (ETL), and LiF/Al was used as a cathode [12]. Each layer was deposited by a thermal evaporator at 8×10^{-8} torr. Following the fabrication process, the organic–inorganic layers were coated alternatively for passivation via an identical multi-barrier coating method. After the passivation process, silver paste was used to ensure contact. The photograph in Fig. 5 (iii) shows the passivated device.

3. Results and discussion

The WVTR measurements were carried out in a Ca test using the electrical corrosion method involving a Ca sensor at 30 °C and 90% R.H [13]. 100 μm PET was employed as a substrate for the film. A 1.5 cm^2 area of the 250 nm Ca was encapsulated by barrier-coated film with a UV sealant. Al at a thickness of 100 nm was used as an electrode (Fig. 2(a)-(i)). For greater accuracy, a four-point probe system was also utilized during the Ca test. The WVTR value was determined using the following equation:

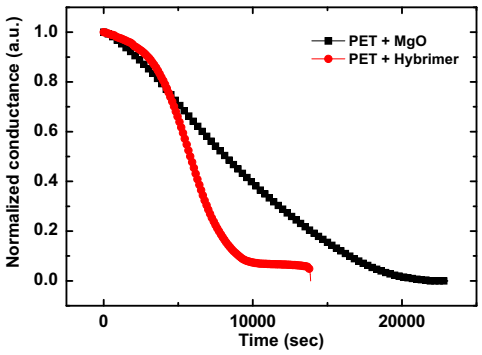

Fig. 1. The permeation test results for the single layer of 1 μm hybrimer and 100 nm MgO on PET substrate.

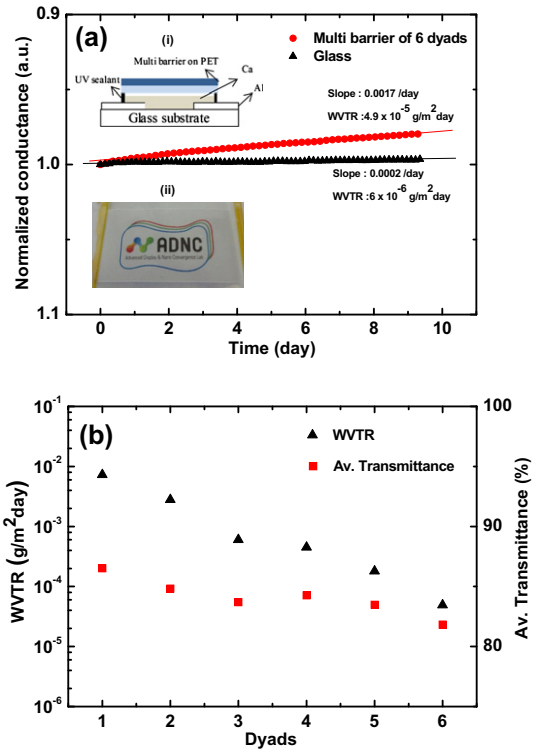

Fig. 2. (a) The results of the Ca test for the 6-dyad multi-barrier on 100 μm PET and glass. Inset: (i) Schematic diagram of the Ca test. (ii) Photograph of a logo image under the 6-dyad multi-barrier on PET. (b) Change in the WVTR and optical transmission (350–850 nm) of the multi-barriers on a 100 μm PET substrate after an increase in the number of dyads.

$$P = -n\left(\frac{1}{R_0}\right)\frac{\mathrm{M}(\mathrm{H_2O})}{\mathrm{M}(Ca)}\delta\rho\frac{l}{b}\frac{d(R_0/R)}{dt}$$

Here, n is the molar equivalent of the degradation reaction, $\mathrm{M}(\mathrm{H_2O})$ and $\mathrm{M}(\mathrm{Ca})$ are the molar masses of H_2O and Ca, respectively. Additionally, δ is the density of the Ca, ρ is the Ca resistivity, l is the length and b is the width of the Ca layer. The slope of the conductance curve R_0/R could be extracted by a Ca test and R_0 is the initial resistance.

Fig. 1 shows the normalized conductance curve of the 1 μm of hybrimer and the 100 nm of MgO on the PET substrate. A WVTR value of 0.79 g/m^2 day for the 1 μm hybrimer and 0.46 g/m^2 day for the single layer of 100 nm MgO was obtained. These WVTR values do not meet requirements of OLED passivation. The WVTR value can be effectively reduced by applying organic–inorganic multi-barriers. Because the permeability is controlled by defects, the diffusion path of oxygen and water vapor can be increased by alternating the layers. To achieve a low WVTR value, each single layer was coated, alternatively, to make a multi-barrier structure.

The Ca test was conducted in accordance with the number of dyads. For the 6-dyad multi-barrier and the glass, the change in the normalized conductance of the Ca sensor is shown in Fig. 2(a). A 1.7% change of the conductance and a WVTR value of 4.9×10^{-5} g/m^2 day were recorded for the multi-barrier. The glass was tested with an identical sealing method. The WVTR value was 6×10^{-6} g/m^2 day with a 0.2% change in the conductance after 10 days. Fig. 2(b) illustrates the performance of the multi-barrier for a set of hybrimer (1 μm)/MgO (100 nm) layers. The WVTR values of multi-barriers, from 1 to 5 dyads, were determined to be 0.0073, 0.0028, 0.0006, 0.00045, and 0.00018 g/m^2 day, respectively. Suppression of the permeation was verified by increasing the number of pairs of layers. The optical transmission of the film was measured using a Shimadzu spectrophotometer (UV-2550). An average transmittance of 81.8% was obtained with 6 dyads on PET in the visible region (350–850 nm) with air used for the baseline. As shown in Fig. 2(a)-(ii), the logo image shows that the transparency of the barrier-coated film is comparable to that of the glass.

Fig. 3 depicts a scanning electron microscope (SEM) image of an individual layer. The cross-section image was taken by a Hitachi instrument (S-4800). A Si wafer was used as the substrate. The film is composed of 100 nm of MgO and 1 μm of hybrimer. Each layer is well defined in the barrier structure. Due to the quality of the spin-coating process, the error range in the thickness of the hybrimer was observed to range from 924 to 1050 nm. However, the effect of the errors did not significantly influence the performance of overall barrier system compared to a 6.6 μm perfect film.

Fig. 4(a) shows the I–V–L characteristics of the multi-barrier passivated OLED and a glass-lid encapsulated device with a desiccant. A 4 mm^2 active area of the devices is defined with an insulator (inset Fig. 4) to eliminate the edge effect by the mask. After encapsulation, the I–V–L results were automatically accumulated by a measurement system with a source meter (Keithley 2400) and a spectrophotometer (TOPCON BM7-A). The maximum luminance of the thin-film passivated OLED showed a luminance value of 33205 cd/m^2 at 24.5 mA according to a dc-current sweep measurement (Fig. 4(b)). These results indicate that no significant differences exist between the two devices.

To evaluate the performance of the multi-barrier, a lifetime test was carried out. The devices were driven by a constant current source of 0.76 mA. The measurements started with an initial luminance value of L_0 = 1000 cd/m^2 under ambient conditions, as shown in Fig. 5. After driving

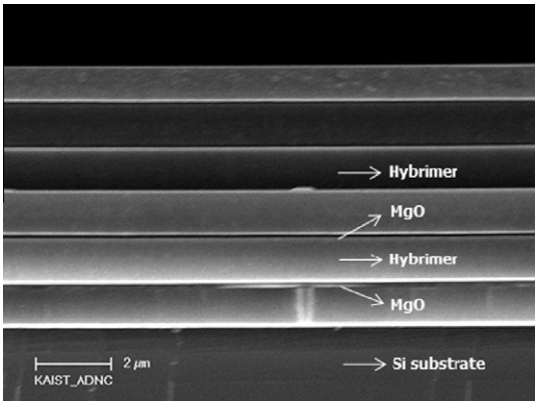

Fig. 3. Cross-sectional SEM image of MgO (100 nm)/hybrimer (1 μm) on a Si substrate.

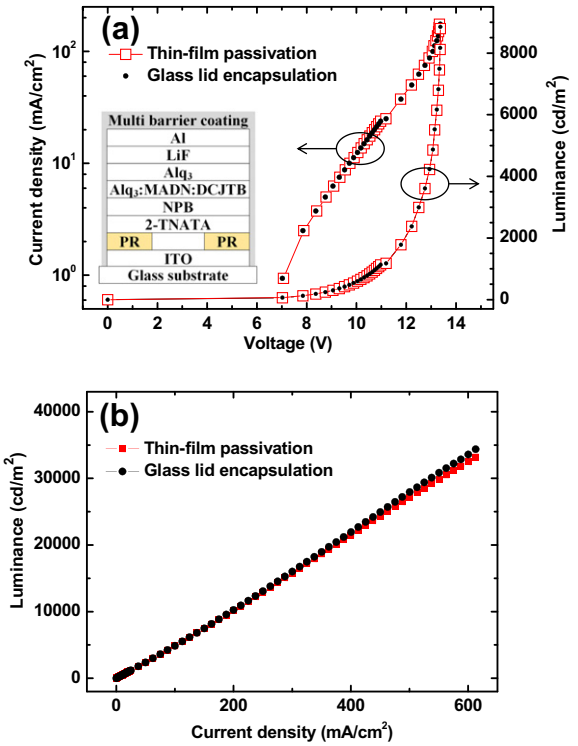

Fig. 4. (a) A comparison of I–V–L characteristics of the encapsulated OLEDs. Inset: Structure of the device. (b) Plot of the luminance versus current density.

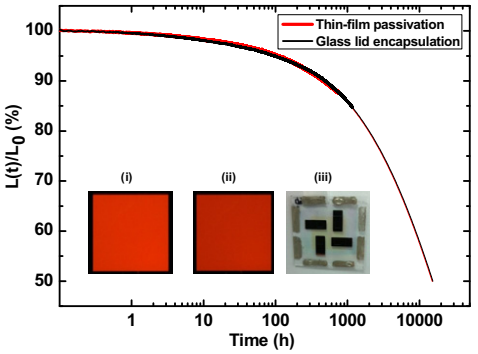

Fig. 5. Half-life time of devices with an initial luminance value $L_0 = 1000$ cd/m^2. The bold lines are the experimental data and the other lines are the exponential fitting data. The inset shows the 4 mm^2 active areas. (i) Before driving, (ii) After driving, (iii) The passivated device. There was no damage during the passivation process and during actual operation.

of 740 h for the thin-film passivated device and at 1182 h for the glass-lid encapsulated device, the lifetime was fitted using the stretched exponential decay (SED) model to consider the half-life time [14,15]. It is known that the luminance of OLEDs decreases exponentially over time. The lifetime was fitted using following equation:

$$L(t) = L_0 \exp\left[-\left(\frac{t}{\tau}\right)^{\beta}\right]$$

In this equation, $L(t)$ is the luminance at time t, L_0 is the initial luminance, and β and τ were obtained from the experimental data. The luminance of the OLEDs decreased to 87.8% of the initial value after operation for 740 h. The lifetime was extrapolated to 15,000 h for the multi-barrier passivation and 15,300 h for the glass-lid encapsulation, respectively, using a constant value for $\beta = 0.556$. In the case of the non-passivated device, the half-decay time was only 5.7 h (not shown in the figure). The microscope image shown in the inset of Fig. 5(i) and (ii) reveals that the OLED did not degrade during the passivation process or during its operation test. The OLED was seriously degraded during the inorganic deposition vacuum process without a protecting layer. When MgO was deposited on top of the device, no light emission was observed. The first layer should serve as a buffer layer during the passivation process. The hybrimer was sufficient to protect the OLED from damage. Due to the solution process of the hybrimer layer, a low-cost and relatively simple OLED passivation process was achieved. The surface roughness of the hybrimer had a RMS value of 0.5 nm in a previous work. We believe that, for the MgO/Hybrimer multi-barrier structure, the MgO surface was planarized in each step. Consequently, the possibility of the formation of the defects and pinholes was reduced effectively at the organic–inorganic interface.

4. Conclusion

We demonstrated the performance of the multi-barriers composed of MgO and UV-curable epoxy hybrid materials (hybrimers). A low WVTR value for the 6-dyad multi-barrier is adequate for encapsulation of the OLED to protect it from water vapor and oxygen. Due to the spin-coated hybrimer layers and the use of MgO deposited at a low temperature, the device was encapsulated without dark spots. The passivated OLED showed stable operation and feasible I–V–L characteristics comparable to those of the glass-lid encapsulated devices. Furthermore, the optimization processes of the barrier structure and composition are practical for application to flexible displays with high transmittance in the visible region. This can be applied to other fields, for instance, to organic thin-film transistors and organic solar cells.

ABSTRACT

Three solution-processable triphenylamine (TPA)-containing low band gap D-A-D molecules with benzothiadiazole (BT) as acceptor unit and TPA-(4-hexyl)thiophene (TPA-HT), TPA-(4-hexyl)thieno[3,2-b]thiophene (TPA-HTT) and bis(octyloxy)TPA-(4-hexyl)thieno[3,2-b]thiophene (boTPA-HTT) as donor units, TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT, have been designed and synthesized for the application in the bulk-heterojunction organic solar cells (OSCs). The molecules show broad absorption band in the visible range and appropriate HOMO energy levels for the donor materials in OSCs. The OSC devices were fabricated with the molecules as donor and $PC_{70}BM$ as acceptor. The power conversion efficiencies of the OSCs based on TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT reached 1.44%, 1.44% and 0.75%, respectively, under the illumination of AM.1.5, 100 mW/cm^2.

1. Introduction

Solution-processable organic small molecules have attracted much interest recently for the applications as donor in bulk-heterojunction organic solar cells (OSCs) [1–16], because they exhibit the advantages of high purity and definite molecular weight in comparison with polymers, and low-cost solution processability in comparison with common vacuum-deposition of organic molecules. The organic molecules reported in literatures include branched oligothiophenes [4,5], linear D-A molecules [2,3,10–14] and triphenylamine (TPA)-containing molecules [14–22]. Nguyen et al. synthesized a series of linear D-A-D molecules with oligothiophenes as donor and diketopyrrolopyrrole (DPP) as acceptor unit. The molecules show narrow band gap of ca. 1.8 eV and broad visible absorption. The power conversion efficiency (PCE) of the bulk-heterojunction OSCs based on the molecules as donor and PCBM as acceptor reached 3–4% [12,13]. TPA-containing organic molecules possess good solution-processibility because of its 3-dimensional spatial structure. Therefore, the TPA-containing molecules have been designed and synthesized for the application in solution-processed organic light-emitting diodes (OLEDs) and OSCs in recent years. Our group has reported various TPA-containing D-A structured organic molecules as donor materials, and the highest PCE reached 3% [22].

For further study of the relationship of the molecular structure and photovoltaic properties of the solution-processable organic photovoltaic materials, we synthesized three new TPA-containing linear D-A-D molecules with benzothiadiazole (BT) as acceptor unit and TPA-(4-hexyl)thiophene (TPA-HT), TPA-(4-hexyl)thieno[3,2-b]thiophene (TPA-HTT) and bis(octyloxy)TPA-(4-hexyl)thieno[3,2-b]thiophene (boTPA-HTT) as donor units, TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT. The design of the molecular structure was from the following consider-

doi:10.1016/j.orgel.2011.01.013

ations: (1) the D-A-D structure of the molecules is to reduce the band gap of the materials for improving the absorption; (2) (4-hexyl)thieno[3,2-b]thiophene is introduced in TPA-HTT-BT and boTPA-HTT-BT for enhancing the hole mobility and improving absorption of the compounds, because fused thiophenes usually show larger π-conjugation and higher hole mobility [23–25]; (3) the terminal alkoxy group in boTPA-HTT-BT is to strengthen the electron donating effects of TPA unit to make the absorption broader. TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films show broad absorption band in the range of 350–700 nm, lower band gap and good thermal stability. The solution processed bulk-heterojunction OSC devices based on the blend of TPA-HT-BT or TPA-HTT-BT as donor and $PC_{70}BM$ as acceptor (the weight ratio of donor/acceptor is 1:3), reached 1.44% under the illumination of A.M. 1.5 G, 100 mW/cm^2, which indicates that TPA-HT-BT and TPA-HTT-BT are promising organic donor photovoltaic materials.

2. Experimental section

2.1. Chemicals

Triphenylamine, 3-hexylthiophene, *n*-butyllithium (2.5 mol/L in hexane), tri-*n*-butyltin chloride, 4,7-dibromo-2,1,3-benzothiadiazole, $Pd(PPh_3)_2Cl_2$, methyltriphenylphosphonium bromide, tetrabutylammonium bromide, sodium acetate, palladium acetate and *N,N*-dimethyl formamide (DMF) were purchased from Acros Organics. Tetrahydrofuran (THF) was dried over Na/benzophenoneketyl and freshly distilled prior to use. Thieno[3,2-b]thiophene and 1-*n*-octyloxy-4-iodobenzene, 4-Formyltriphenylamine (1), monomer C were synthesized as reported in the literatures [26–29]. Other chemicals were common commercial level and were used as received.

2.2. Synthesis of compounds

2.2.1. Monomer (A)

N,N-Diphenyl-N-(4-vinylphenyl)amine(A): To a solution of methyltriphenylphosphonium bromide (7.19 g, 20 mmol) in dry THF (250 ml) at −78 °C was added *n*-butyllithium (8 ml, 2.5 M, 20 mmol) by syringe. The mixture was warmed to room temperature slowly. Compound 1 (5 g, 18 mmol) in dry THF (50 ml) was added dropwise to the mixture, and the resulted mixture was kept at room temperature for 12 h. The mixture was poured into water and extracted into dichloromethane (3 × 150 ml). The combined organic extracts were washed with brine and dried by anhydrous magnesium sulfate. After evaporation of the solvent, the crude product was purified by column chromatography (hexane) to get monomer A as white solid. Yield 4.33 g (87%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 7.30–7.25 (m, 6H), 7.23 (d, 4H), 7.03 (d, 4H), 6.67 (q, 1H), 5.62 (d, 1H), 5.14 (d, 1H). MS: m/z = 271 (M^+).

2.2.2. Monomer (B)

N,N-Di(n-octyloxyphenyl)-pheneylamine (2): 1-*n*-Octyloxy-4-iodobenzene (13 g, 39 mmol), phenylamine (1.65 g, 17.7 mmol), cuprous chloride (0.142 g, 1.42 mmol), phenanthroline (0.257 g, 1.42 mmol) and potassium hydroxide (17.44 g, 311 mmol) were dissolved in toluene (28 ml) and refluxed for 24 h. The reaction mixture was poured into ice water. The product was extracted into dichloromethane (5 × 150 ml) and the combined organic extracts were washed by brine and dried by anhydrous magnesium sulfate. The crude product was purified by column chromatography (petroleum) to give compound 2 as colorless liquid. Yield 3.75 g (39.14%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 7.28 (q, 1H), 7.17 (t, 2H), 7.04 (d, 4H), 6.94 (d, 2H), 6.82 (d, 4H), 3.95 (t, 4H), 1.78 (m, 4H), 1.43 (m, 4H), 1.31 (m, 16H), 0.90 (t,6H). MS: m/z = 501 (M^+).

N,N-Di(n-octyloxyphenyl)-4-(formylphenyl)amine (3): Phosphorus oxychloride (11.1 ml, 121 mmol) was added dropwise into a stirred *N,N*-dimethyl formamide (18.6 ml, 242 mmol), under argon at 0 °C. After addition, the reaction mixture was stirred at 0 °C for 1 h and at room temperature for 1 h. Compound 2 (10 g, 19.9 mmol) in 1,2-dichloroethane was added dropwise to the mixture and the resulted mixture was kept at 90 °C over night. The reaction mixture was cooled to room temperature, poured into ice water and neutralized with sodium hydroxide (2 M). The product was extracted into dichloromethane (5 × 150 ml) and the combined organic extracts was washed with brine and dried by anhydrous magnesium sulfate. The crude product was purified by column chromatography (petroleum:ethyl acetate, 5:1) to give compound 3 as yellow liquid. Yield 6.6 g (66.2%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 9.74 (s, 1H), 7.63 (d, 2H), 7.10 (d, 4H), 6.88 (m, 6H), 3.88 (t, 4H), 1.79 (m, 4H), 1.44 (m, 4H), 1.33 (m, 16), 0.90 (t, 6H). MS: m/z = 529 (M^+).

N,N-Di(n-octyloxyphenyl)-4-(vinylphenyl)amine (B): To a solution of methyltriphenylphosphonium bromide (4.1 g, 11.5 mmol) in anhydrous THF (250 ml) at −78 °C was added *n*-butyllithium (4.6 ml, 2.5 M, 11.5 mmol) by syringe. The mixture was warmed to room temperature slowly. Compound 3 (5 g, 9.5 mmol) in anhydrous THF (100 ml) was added dropwise to the mixture, and the resulted mixture was kept at room temperature for 12 h. The mixture was poured into water and extracted into dichloromethane (5 × 100 ml). The combined organic extracts were washed with brine and dried by anhydrous magnesium sulfate. After evaporation of the solvent, the crude product was purified by column chromatography (hexane) to get monomer B as yellow liquid. Yield 4.85 g (97%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 7.21 (d, 2H), 7.04 (d, 4H), 6.88(d, 2H), 66.84 (d, 4H), 6.66 (m, 1H), 5.60 (d, 1H), 5.10 (d, 1H), 3.92 (t, 4H), 1.80 (m, 4H), 1.49 (m, 4H), 1.29–1.34 (m, 16H), 0.89 (t, 6H). MS: m/z = 527 (M^+).

2.2.3. Monomer (D)

4,7-Di(6-hexyl-thieno[3,2-b]thiophen-2-yl)-2,1,3-benzothiadiazole (5): *n*-Butyllithium (17.8 ml, 2.5 M in hexane, 44.6 mmol) was added dropwise to a stirred solution of 3-hexylthieno[3,2-b]thiophene (10 g, 44.6 mmol) in anhydrous THF (200 ml), under argon at 0 °C. The reaction mixture was maintained under these conditions for a further 2 h before tri-*n*-butyltin chloride (12 ml, 44.6 mmol) was added dropwise. The mixture was allowed to warm to room temperature and stirred for another 6 h. 4,7-bib-

romo-2,1,3-benzothiadiazole (5.9 g, 20.3 mmol) and $PdCl_2(PPh_3)_2$ (853 mg, 1.2 mmol) were added to the stirring mixture. After the solution was stirred for 12 h at 80 °C, hydrochloric acid (3%, 50 ml) was added to the solution to quench the reaction. The product was extracted into dichloromethane (3 × 150 ml) and the combined organic extracts were washed with brine and dried by anhydrous magnesium sulfate. The crude product was purified by column chromatography (petroleum) to give compound 5 as red powder. Yield 8.2 g (69%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 8.45 (s, 2H), 7.88 (s, 2H), 7.06 (s, 2H), 2.78 (t, 4H), 1.87–1.54 (m, 4H), 1.35 (m, 12H), 0.90(t, 6H). MS: m/z = 580 (M^+).

4,7-Di(5-bromo-6-hexyl-thieno[3,2-b]thiophen-2-yl)-2,1,3-benzothiadiazole (D): To a solution of compound 5 (3 g, 5.17 mmol) in 100 mL anhydrous DMF was added NBS (1.93 g, 10.8 mmol) in one portion at room temperature and stirred for 24 h. The precipitate was filtered and washed with methanol and water to give monomer D as dark red powder. Yield 2 g, 63%. ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 8.15 (s, 2H), 7.6 (s, 2H), 2.53 (t, 4H), 1.53 (m, 4H), 1.09 (m, 12H), 0.65 (t, 6H). MALDI-TOF MS: 738.1, calcd for $C_{30}H_{30}Br_2N_2S_5$ 738.71.

2.2.4. TPA-HT-BT

Monomer C (1 g, 1.6 mmol), monomer A (0.95 g, 3.52 mmol), palladium (II) acetate (10 mg), tetra-*n*-butylammonium bromide (161 mg, 0.5 mmol), and sodium acetate anhydrous (2.62 g, 32 mmol) were dissolved and kept in degassed *N*,*N*-dimethyl formamide (30 ml) under argon at 100 °C for 24 h. The mixture was poured into water (30 ml). The precipitate was filtered, washed with water and dissolved in dichloromethane, then dried by anhydrous sodium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (petroleum/dichloromethane, 1:1). Yield 600 mg (37%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 7.68 (s, 2H), 7.55 (s, 2H), 7.13 (d, 4H), 7.01 (t, 8H), 6.87 (t, 8H), 6.78 (t, 8H), 6.73 (d, 4H), 2.48 (t, 4H), 1.43 (m, 4H), 1.08 (m, 12H), 0.64 (t, 6H). MALDI-TOF MS: 1006.8, calcd for $C_{66}H_{62}N_4S_3$ 1006.41. Anal. Calcd for $C_{66}H_{62}N_4S_3$: C, 78.88; H, 5.98; N, 5.58. Found: C, 78.02; H, 6.32; N, 5.36.

2.2.5. TPA-HTT-BT

Monomer D (1 g, 1.3 mmol), monomer A (808 mg, 2.98 mmol), palladium (II) acetate (15 mg), tetra-*n*-butylammonium bromide (140 mg, 0.43 mmol), and sodium acetate anhydrous (2.2 g, 27 mmol) were dissolved and kept in degassed *N*,*N*-dimethyl formamide (30 ml), under argon at 100 °C for 24 h. The mixture was poured into water (30 ml). The precipitate was filtered, washed with water and dissolved in dichloromethane, then dried by anhydrous sodium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (petroleum/dichloromethane, 1:1). Yield 500 mg (33%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 8.45 (s, 2H), 7.81 (s, 2H), 7.37 (d, 4H), 7.29 (t, 2H), 7.21 (d, 2H), 7.13 (d, 10H), 7.06 (t, 10H), 6.93 (d, 4H), 2.94 (t, 4H), 1.78 (m, 4H), 1.43 (m, 4H), 1.35 (m, 8H), 0.92 (t, 6H). MALDI-TOF MS: 1118.5, calcd for $C_{70}H_{62}N_4S_5$ 1118.36. Anal. Calcd for $C_{70}H_{62}N_4S_5$: C, 75.1; H, 5.54; N, 5.0. Found: C, 73.53; H, 5.82; N, 4.54.

2.2.6. boTPA-HTT-BT

Monomer D (1 g, 1.3 mmol), monomer B (1.57 g, 2.98 mmol), palladium (II) acetate (15 mg), tetra-*n*-butylammonium bromide (140 mg, 0.43 mmol), and sodium acetate anhydrous (2.2 g, 27 mmol) were dissolved and kept in degassed *N*,*N*-dimethyl formamide (30 ml), under argon at 100 °C for 24 h. The mixture was poured into water (30 ml). The precipitate was filtered, washed with water and dissolved in dichloromethane, then dried by anhydrous sodium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (petroleum/dichloromethane, 1:1). Yield 490 mg (28%). ^{1}H-NMR ($CDCl_3$, 400 MHz, δ/ppm): 8.36 (s, 2H), 7.81 (s, 2H), 7.31 (d, 4H), 7.16 (d, 2H), 7.06 (d, 8H), 6.99 (d, 4H), 6.84 (d, 10H), 3.95 (t, 8H), 2.83 (s, 4H), 1.82 (m, 12H), 1.46 (m, 12H), 1.34 (m, 40H), 0.91 (t, 18H). MALDI-TOF MS: 1631.2, calcd for $C_{102}H_{126}N_4O_4S_5$ 1632.44. Anal. Calcd for $C_{102}H_{126}N_4O_4S_5$: C, 75.18; H, 7.62; N, 3.43. Found: C, 75.16; H, 7.92; N, 3.29.

2.3. Measurements and instruments

Nuclear magnetic resonance (NMR) spectra were taken on a Bruker DMX-400 spectrometer. MALDI-TOF spectra were recorded on a Bruker BIFLEXIII. Absorption spectra were taken on a Hitachi U-3010 UV-vis spectrophotometer. The film on quartz used for UV measurements was prepared by spin-coating with 1% chloroform solution. The TGA measurement was performed on a Perkin-Elmer TGA-7 apparatus. The electrochemical cyclic voltammograms were obtained using a Zahner IM6e electrochemical workstation in a 0.1 mol/L tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) acetonitrile solution. A Pt electrode coated with the sample film was used as the working electrode; a Pt wire and Ag/Ag^+ (0.01 M $AgNO_3$ in acetonitrile) were used as the counter and reference electrodes respectively.

2.4. Fabrication and characterization of organic solar cells

Organic solar cells (OSCs) were fabricated in the configuration of the traditional sandwich structure with an ITO positive electrode and a metal negative electrode. Patterned ITO glass with a sheet resistance of 30 Ω sq^{-1} was purchased from CSG Holding Co. Ltd (China). The ITO glass was cleaned in an ultrasonic bath of acetone and isopropanol, and treated by UVO (ultraviolet ozone cleaner, Jelight Company, USA). Then a thin layer (30 nm) of PEDOT:PSS (poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate)) (Baytron PVP AI 4083, Germany) was spin-coated on the ITO glass. Subsequently, the photosensitive layer was prepared by spin-coating the blend solution of the linear molecules and $PC_{70}BM$ (1:3 w/w) on the top of the PEDOT:PSS layer (ca. 60 nm thickness) and baked at 80 °C for 0.5 h. The concentration of the solution was 10 mg/mL in chlorobenzene. The thickness of the photoactive layer was measured using an Ambios Technology XP-2 profilome-

ter. Finally, Al electrode (ca. 120 nm) was vacuum evaporated on the photoactive layer under a shadow mask in the vacuum of ca. 10^{-4} Pa. The active area of the devices is 4 mm^2. The current–voltage (I–V) measurement of the devices was conducted on a computer-controlled Keithley 236 Source Measure Unit. A xenon lamp coupled

with A.M. 1.5 solar spectrum filters was used as light source, and the optical power at the sample was ca. 100 mW/cm^2.

3. Results and discussion

3.1. Synthesis and thermal stability of the molecules

The three linear molecular materials were synthesized by the route shown in Scheme 1. Monomer A reacted with C or D, B reacted with D by a palladium-catalyzed Heck reaction to get linear molecules of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT, respectively [15,17].

The three linear compounds are soluble in common organic solvents, such as $CHCl_3$, THF, chlorobenzene and toluene. The thermal stability of the compounds was investigated by thermogravimetric analysis (TGA). The temperatures with 5% weight loss are at 367, 338 and 378 °C for TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT respectively, as shown in Fig. 1. The thermal stability of the materials is good enough for the application in optoelectronic devices. As compared to TPA-HT-BT, TPA-HTT-BT, the char yield of boTPA-HTT-BT is much lower, which should be attributed to the thermally instable alkoxy groups in boTPA-HTT-BT (Fig. 1).

3.2. Absorption spectra

Fig. 2 shows the UV-vis absorption spectra of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT in chloroform solution and film state. The optical absorption maxima (λ) were summarized in Table 1. Benefited from their D-A molecular structures, the absorption spectra of the three linear molecules in chloroform solutions exhibit strong absorption in the wavelength range from 300 to 700 nm. And because the similar structure of the three linear molecules, the absorption spectra of them are similar with three peaks. By comparing the λ_{max} of the similar molecules in our previous work [15,17,21], the two peaks at ca. 310 nm and at ca. 410 nm correspond to the $\pi-\pi*$ transition absorption of the molecules, and the visible absorption peak located at longer wavelength centered at ca. 580 nm could be assigned to the intramolecular charge transfer transition between the TPA donor moiety and the BT acceptor unit.

For all of the three linear molecules, in comparison with absorption spectra of their dilute solutions, the three absorption peaks of the films red-shifted a little, which indicates some aggregation of the molecules in the film state exists. The absorption spectra of TPA-HTT-BT and boTPA-HTT-BT solutions and films are broader than that of TPA-HT-BT, due to the planar and larger π-conjugation of the thieno[3,2-b]thiophene unit in TPA-HTT-BT and boTPA-HTT-BT than the thiophene unit in TPA-HT-BT. This phenomenon was also observed in literature [23]. In addition, benefitted from the electron-donating alkoxy groups on the TPA unit in boTPA-HTT-BT, the three absorption peaks of boTPA-HTT-BT solution and film red shifted a little in comparison with TPA-HTT-BT. The absorption edge of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films are at ca. 715, ca. 754, and ca. 766 nm, corresponding to the band gap of 1.73, 1.64 and 1.61 eV, respectively.

3.3. Electrochemical properties and electronic energy levels

Electrochemical cyclic voltammetry was carried out for TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films on Pt electrode, in order to estimate their HOMO and LUMO energy levels. Fig. 3 shows the cyclic voltammograms of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films. The HOMO energy level, the LUMO energy level, and the electrochemical band gaps (E_g^{ec}) of the polymers were calculated from onset oxidation potentials (E_{onset}^{ox}) and onset reduction potentials (E_{onset}^{red}) according to the following equations [30]: $E_{HOMO} = -e\ (E_{onset}^{ox} + 4.71 + 4.71)$ (eV), $E_{LUMO} = -e\ (E_{onset}^{red} + 4.71)$(eV) and $E_g^{ec} = E_{LUMO} - E_{HOMO}$. The detailed results of electrochemical measurement of the three compounds were listed in Table 1. The calculated HOMO and LUMO energy levels of TPA-HT-BT are −5.14 and −3.37 eV, respectively, which is similar to that of TPA-th-TPA [15]. The HOMO levels of TPA-HTT-BT and boTPA-

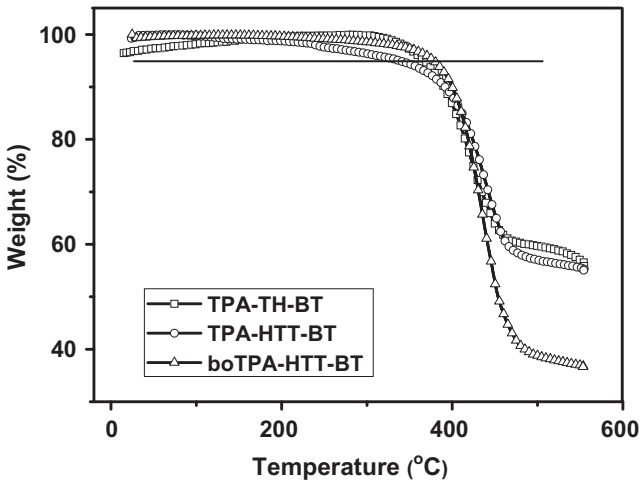

Fig. 1. TGA plots of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT.

HTT-BT are 0.04 and 0.09 eV higher than that of TPA-HT-BT respectively, which could result from the planar and large π-conjugation of the thieno[3,2-b]thiophene unit in the molecules. The further up-shift of the HOMO of boTPA-HTT-BT than TPA-HTT-BT should be due to the electron-donating alkoxy groups attached to TPA in boTPA-HTT-BT. Compared with the HOMO and LUMO energy levels (−5.87 and −3.91 eV respectively [31]) of $PC_{70}BM$, the three compounds are suitable to be used as the photovoltaic donors blended with $PC_{70}BM$ as acceptor in bulk-heterojunction OSCs.

3.4. AFM morphology and hole mobility

Morphology of the photoactive layer is very important for the photovoltaic performance of OSCs [32,33]. We used atomic force microscopy (AFM) to investigate the morphology of the linear molecules: $PC_{70}BM$ (1:3, w/w) blend films. All of the AFM images of the blend films exhibit typical amorphous morphology without any crystalline domains, as shown in Fig. 4. We can see intuitively that the interpenetrating network was formed on the surface of the blend films of TPA-HT-BT/$PC_{70}BM$ and TPA-HTT-BT/$PC_{70}BM$,

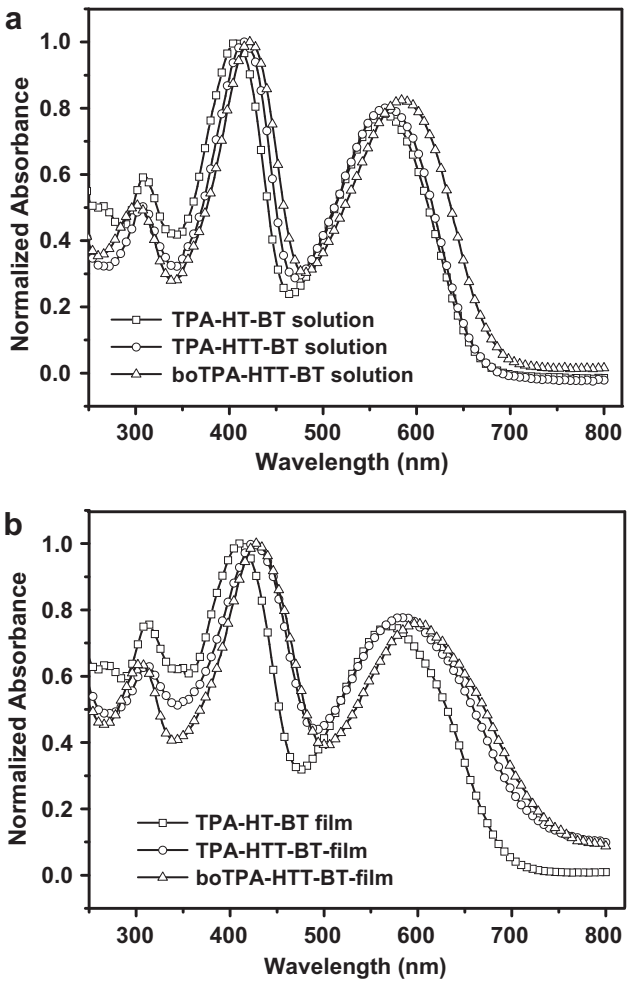

Fig. 2. UV-vis absorption spectra of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT in chloroform solutions (a) and in film state (b).

Table 1
Absorption and electrochemical properties, HOMO and LUMO energy levels of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT.

Compounds	$\lambda_{solution}$(nm)	λ_{film}(nm)	λabs_{edge} (nm)	E_g^{opt}(eV)	E_{onset}^{ox}(V[a])/HOMO (eV)	E_{onset}^{red}(V[a])/LUMO(eV)	E_g^{ec} (eV)
TPA-HT-BT	308/405/564	311/409/569	715	1.73	0.43/−5.14	−1.34/−3.37	1.77
TPA-HTT-BT	306/414/568	311/425/581	754	1.64	0.39/−5.10	−1.29/−3.42	1.68
boTPA-HTT-BT	300/420/585	305/428/596	766	1.61	0.30/−5.01	−1.35/−3.36	1.65

[a] Reference electrode is Ag/Ag^+.

which should be beneficial to the charge separation and charge transport in the OSC devices. However, the blend film of boTPA-HTT-BT/$PC_{70}BM$ exhibit rougher morphology and big aggregates, which could lead to decrease in the D-A interfacial area for efficient charge separation [34,35], and result in lower short circuit current in the OSCs with boTPA-HTT-BT/$PC_{70}BM$ as active layer.

Hole mobility of the molecules was measured by space-charge-limited-current (SCLC) method with the device structure of ITO/PEDOT:PSS/linear molecule film/Au. The hole mobilities of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT are 1.04×10^{-4}, 1.48×10^{-4} and 2.78×10^{-5} $cm^2\ V^{-1}\ s^{-1}$ respectively. Obviously, replacement of the thiophene unit in TPA-HT-BT by thienothiophene unit in TPA-HTT-BT increased the hole mobility, but the four alkoxy groups in boTPA-HTT-BT decreased the hole mobility significantly which could be related to its poorer morphology mentioned above.

3.5. Photovoltaic properties

Bulk-heterojunction OSCs were fabricated by using the three linear molecules as donor materials, $PC_{70}BM$ as acceptor materials [36–38] and Al as the negative electrode. The device structure is ITO/PEDOT: PSS/photoactive layer (60 nm)/Al. The photoactive layers are composed of the blend of the linear molecule and $PC_{70}BM$. For the donor/acceptor weight ratios in the photoactive layers, the optimized weight ratio is 1:2 [20,22] or 1:3 [17,21] in our previous papers for the TPA-containing molecule donors. To determine the optimized weight ratio for the three linear molecules, the blend of TPA-HT-BT/$PC_{70}BM$ was investigated with different weight ratios of 1:1, 1:2 and 1:3. Table 2 lists the photovoltaic performance of the OSCs. It can be seen from Table 2 that the OSC with the TPA-HT-BT/$PC_{70}BM$ weight ratio of 1:3 shows the best photovoltaic performance with I_{sc} of 5.71 mA/cm^2 and power conversion efficiency (PCE) of 1.44%.

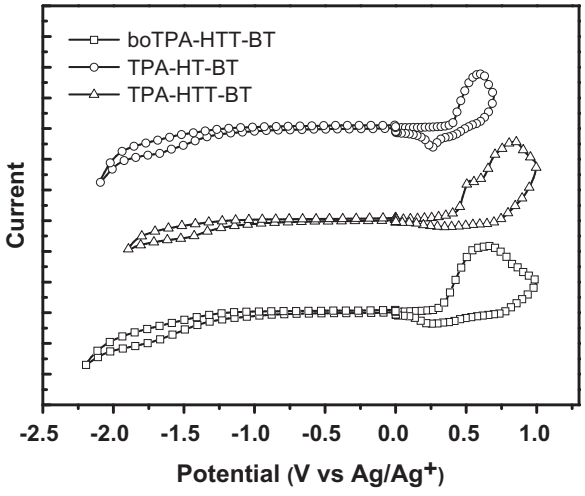

Fig. 3. Cyclic voltammograms of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films on Pt electrode in an acetonitrile solution of 0.1 mol/L Bu_4NPF_6 (Bu = butyl) with a scan rate of 100 mV/s.

Based on the above optimization of weight ratio, we studied the photovoltaic properties of the three linear molecules by fabricating the OSCs with the donor/acceptor weight ratio of 1:3. Fig. 5 shows the typical current–voltage curves of the OSCs based on the linear molecules/$PC_{70}BM$ (1:3, w/w) at dark and under the illumination of

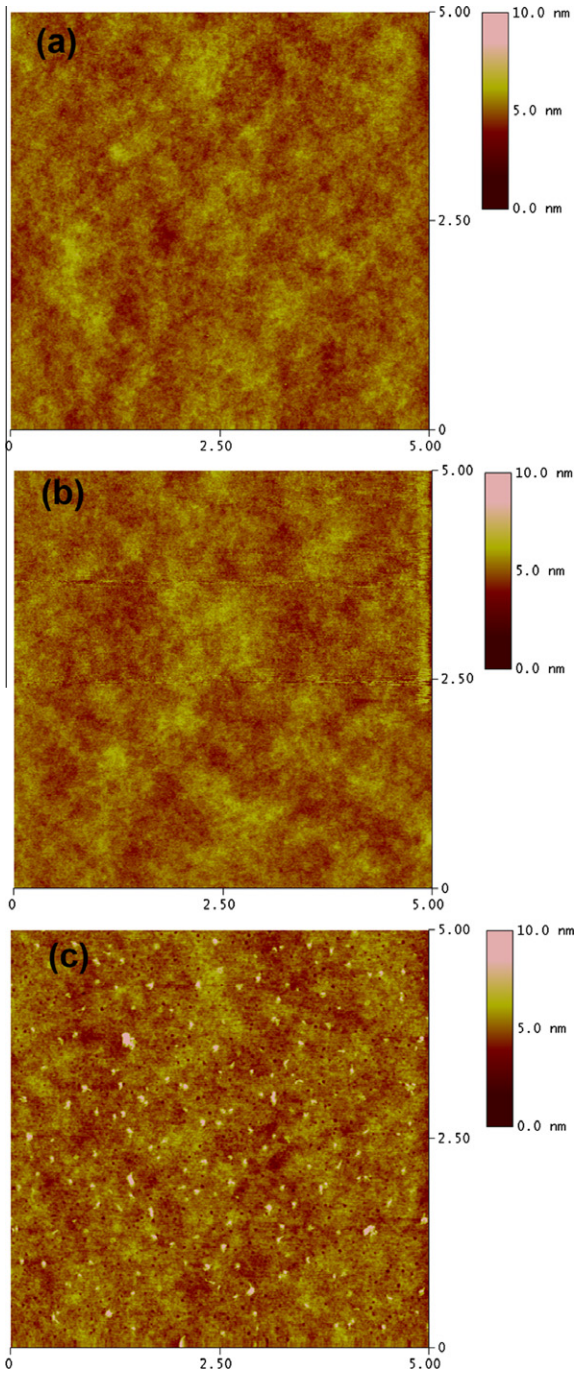

Fig. 4. AFM images of linear molecules: $PC_{70}BM$ films spin-coated from the blend solutions: (a) TPA-HT-BT/$PC_{70}BM$, (b) TPA-HTT-BT/$PC_{70}BM$, (c) boTPA-HTT-BT/$PC_{70}BM$. All films were spin-coated on ITO/PEDOT: PSS substrates and the scan size for all images is 5 μm × 5 μm.

Table 2
Photovoltaic performance of the OSCs based on TPA-HTT-BT: $PC_{70}BM$ with different weight ratios under the illumination of AM 1.5, 100 mW/cm^2.

TPA-HTT-BT:PC70BM	Voc (V)	Isc (mA/cm2)	FF (%)	η (%)
1:1	0.79	1.68	29	0.40
1:2	0.71	4.78	36	1.22
1:3	0.74	5.71	34	1.44

AM 1.5, 100 mW/cm^2. The photovoltaic performance data of the OSCs, including the open circuit voltage (V_{oc}), short circuit current (I_{sc}), fill factor (FF) and power conversion efficiency (PCE) values, are summarized in Table 3. V_{oc} of the OSC based on TPA-HT-BT reached 0.79 V, which should be benefitted from the lower HOMO energy level of the compound. V_{oc} value of 0.61 V for the OSC based on boTPA-HTT-BT is much lower than that of TPA-HT-BT (0.79 V) and TPA-HTT-BT (0.74 V), which should mainly result from its higher HOMO level (see Table 1), since V_{oc} is proportional to the difference of the LUMO of the acceptor (PCBM) and the HOMO of the donor [30]. The replacement of (4-hexyl) thiophene (HT) in TPA-HT-BT with TPA-(4-hexyl)thieno[3,2-b]thiophene (HTT) in TPA-HTT-BT enhanced the I_{sc} value from 4.84 to 5.71 mA/cm^2, which is consistent with the broader absorption of TPA-HTT-BT in visible region and higher hole mobility mentioned above. PCE values of the OSCs based on TPA-HTT-BT is 1.44% which is the same with that of TPA-HT-BT because of its lower V_{oc}. The OSC based on boTPA-HTT-BT exhibited lower I_{sc} and lower PCE than that of TPA-HTT-BT, due to the poorer morphology (as shown in Fig. 4) which could result from the introduction of terminal alkoxy groups on TPA.

Table 3
Photovoltaic performance of the OSCs with the device structure of ITO/PEDOT: PSS/Liner molecules: $PC_{71}BM$ (1:3, w/w)/Al under the illumination of AM 1.5, 100 mW/cm^2.

Donor Compounds	V_{oc} (V)	I_{sc} (mA/cm^2)	FF (%)	PCE (%)
TPA-HT-BT	0.79	4.84	37.5	1.44
TPA-HTT-BT	0.74	5.71	34	1.44
boTPA-HTT-BT	0.61	3.61	34.2	0.75

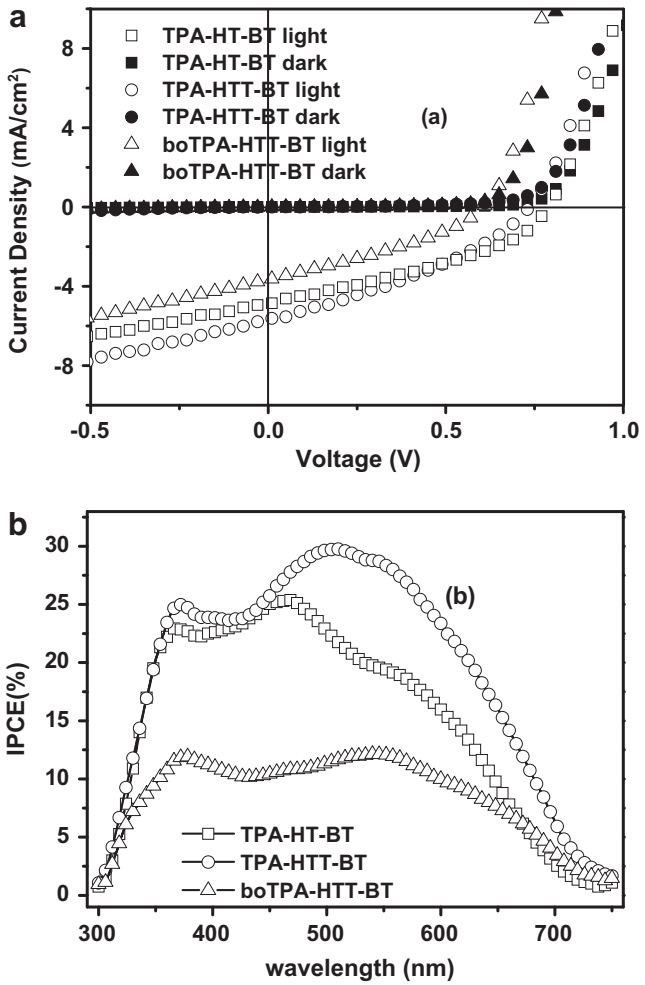

Fig. 5. (a) Current density–voltage characteristics of the OSC devices based on the blends of liner molecules/$PC_{70}BM$ (1:3, w/w) with Al as the negative electrode at dark and under the illumination of AM 1.5, 100 mW/cm^2; (b) IPCE spectra of the OSC devices.

Higher HOMO level, poorer miscibility with $PC_{70}BM$ and lower hole mobility should be the main reasons for the lower PCE value of the OSCs based on boTPA-HTT-BT. The results indicate that the introduction of the terminal alkoxy groups to the TPA seems not a good strategy in the molecular design for high performance photovoltaic molecules.

The incident photon-to-converted current efficiency (IPCE) spectra (see Fig. 5b) shows similar shapes as those of the absorption spectra of the three linear molecules, indicating that all the visible light absorption of TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT contributed to the photovoltaic conversion. The maximum IPCE value of the OSC based on TPA-HTT-BT reached 30%, which is higher than those of the devices based on TPA-HT-BT and boTPA-HTT-BT. The higher IPCE value of TPA-HTT-BT agrees with the higher I_{sc} of the OSC based on it. The significant decrease of the IPCE values from TPA-HTT-BT to boTPA-HTT-BT should result from inefficient charge transfer due to the poor miscibility of boTPA-HTT-BT with $PC_{70}BM$ as explained above.

4. Conclusions

A series of TPA-containing linear D-A-D structured molecules with BT as acceptor unit and TPA-HT, TPA-HTT or boTPA-HTT as donor unit, were synthesized through palladium-catalyzed Heck reaction for the application in bulk-heterojunction OSCs. TPA-HT-BT, TPA-HTT-BT and boTPA-HTT-BT films show broad absorption band in the range of 350–700 nm, lower band gap at 1.6–1.7 eV and good thermal stability. The OSC devices were fabricated by spin-coating the blend solution of the three linear molecules as donor and $PC_{70}BM$ as acceptor. The OSC devices based on TPA-HT-BT/$PC_{70}BM$ (1:3, w/w) exhibited a V_{oc} of 0.79 V, an I_{sc} of 4.84 mA/cm^2, and a PCE of 1.44%, under the illumination of AM.1.5, 100 mW/cm^2. The devices based on TPA-HTT-BT/$PC_{70}BM$ (1:3, w/w) show a higher I_{sc} of 5.71 mA/cm^2 but lower V_{oc} of 0.74 V, leading to the same PCE of 1.44%. The results indicate that broadening the absorption with remaining the lower HOMO energy level should be considered in the design of high performance organic photovoltaic donor materials.

Conjugated polymer devices

ABSTRACT

Indium tin oxide (ITO), Au and Pt are materials of interest as high work function contacts for organic semiconductor devices. In this paper the relative energy level line-up of these materials is investigated both as bare surfaces or part of a polymer/conductor interface. Kelvin probe (KP) measurements show that the estimated work function for Au and Pt surfaces, evaporated under normal high vacuum (HV) fabrication conditions and measured in air, can be significantly lower (by ~0.2 to 0.9 eV) than those of clean surfaces evaporated and measured in the more demanding and clean ultra high vacuum (UHV), that are often used as reference values. The work function of all surfaces increases significantly (from ~0.4 to >1 eV) after an oxygen plasma, but then decreases upon air exposure, with different rates for different materials. The effect of the plasma wears off most rapidly for Au whilst it is more resilient for ITO. Most interestingly, via KP and electroabsorption measurements of the built-in potential on polymer/conductor and conductor/polymer/conductor structures, we demonstrate that a plasma-induced enhancement of the work function is "frozen in" by the application of a polymer semiconductor layer over the plasma-treated surfaces and can be made to last for years by proper device encapsulation. These results have strong implications on the understanding, fabrication, design and stability of organic semiconductor devices.

1. Introduction

Fabrication of efficient organic semiconductor optoelectronic devices often requires the identification and development of high work function conducting materials for use as electrical contacts. The relative energy level alignment [1–6], and the matching of the work function of these materials with the highest occupied molecular orbitals (HOMOs) or polaron levels of the active semiconductor layer is important to improve hole injection in light-emitting diodes (LEDs) and (p-type) thin film transistors (TFTs), and to increase the built-in potential and carrier extraction in photodiodes and photovoltaic cells. To obtain an ohmic contact it is necessary to minimise injection barriers. Since the ionisation potential of many organic semiconductors is $\geqslant 5$ eV, contact materials with a work function close to or higher than 5 eV are often sought.

The work function is a parameter that depends very strongly on the condition of the surface it relates to: namely, on different deposition conditions, treatments and environments it is subjected to. Prevalent reference values for the work function of mono-atomic metals [7],

including high work function metals such as Au and Pt, are typically extracted from samples that are as close as possible to ideal, prepared and measured under ultra high vacuum (UHV). However, the conditions used in the fabrication of conjugated polymer devices are often far from these. For example, evaporation of contacts occurs mainly in the high vacuum range (10^{-7}–10^{-5} mbar) rather than in UHV (<10^{-9} mbar). Furthermore, for bottom contacts, the deposition of the overlaying organic semiconductor often occurs after the contact surface has seen a glove-box environment or air at some stage of the fabrication process. Processing in air is attractive commercially since fabrication costs are greatly reduced. However, contact with air over time, as we confirm, can reduce the work function considerably.

In the case of transparent anodes, typically indium tin oxide (ITO), the work function of the untreated surface is initially a few tenths of electron volts below 5 eV. As we show in this manuscript, the work functions of evaporated Au and Pt surfaces exposed to air are also below 5 eV. It becomes therefore often necessary to increase the work function of the contact after its deposition. Different strategies have been developed, including treating the surface with self assembled monolayers [8–13], overlaying a hole-injecting layer [14,15] like poly(3,4-ethylene dioxythiophene):poly(styrene sulfonate) PEDOT:PSS, that has a high work function [16] or subjecting the electrode to an oxygen plasma or ozone treatments which is also used as a cleaning procedure [17–29]. The latter two procedures, which also clean the surfaces from contaminants, have now become a common strategy in a wide variety of organic semiconductor device heterostructures.

In this work we investigate three different surfaces that have been widely used as anodic contacts: ITO, Au and Pt. Using a Kelvin probe (KP) we have monitored the enhancement of the work function of the contacts as a result of exposure to oxygen plasma. We see that the enhancement is not permanent but decreases over time if the surface is left bare in air. Via a combination of Kelvin probe and electroabsorption (EA) measurements on polymer/conductor and conductor/polymer/conductor sandwich heterostructures, we give direct evidence that the effect of increasing the work function, is made to last considerably longer by depositing a conjugated semiconducting polymer over the contact soon after it has been subjected to the plasma treatment. Furthermore, with an effective encapsulation of the diodes, EA results show that this O_2 plasma effect on the energy levels endures stably over the time scale of the over two years of our investigation. These results have strong implications on the understanding, fabrication, design and stability [30,31], of organic semiconductor devices.

2. Experimental

The results presented here are the outcome of KP and EA investigations of three different sample batches: (1) Au, Au* study, (2) Pt, Pt* study and (3) ITO, ITO* study. The symbol "*" here denotes a surface that has been subjected to an oxygen plasma. ITO was provisioned commercially on glass substrates. Au and Pt were thermally evaporated as detailed below. The samples prepared include bare conducting electrode surfaces, polymer-semiconductor/electrode and full electrode/semiconductor/electrode device structures.

Contact potential difference (CPD) measurements were carried out using a gold mesh Kelvin probe (Besocke Delta-Phi) in air. Description of the EA apparatus used for this experiment can be found in reference [32]. The sample fabrication details were the following.

2.1. Au/Au* study

Fifty nanometer films of Au were thermally evaporated on 12.5 mm × 12.5 mm glass substrates previously ultrasonically cleaned in acetone and propan-2-ol(IPA) and blow dried in N_2. Two sets were prepared: Au(1) evaporated at ~1×10^{-6} mbar and Au(2) evaporated at 4–5 × 10^{-6} mbar. Evaporation rates were 0.03–0.05 nm/s. After evaporation the samples were kept in a plastic box in air for over 12 h before measurement. After a first set of Kelvin probe measurements on untreated surfaces, the samples underwent an oxygen RF plasma treatment and a new series of KP measurements were carried out. The plasma was created in a Harrick plasma cleaner (PDC-002) at pressures of 4–7 × 10^{-2} mbar for 5 min and at a plasma power of 100 W.

A third sample, equivalent to Au(1), was covered with a 75 nm film of poly(9,9-dioctylfluorene), F8, spun from a 2% (wt.) xylene solution at 1500 rpm for 180 s, straight (i.e. ~2 min) after completion of the plasma treatment. The samples see air after completion of the plasma. The symbol "*" after Au (and the other surfaces) indicates that the surface has been subjected to an oxygen plasma.

2.2. Pt, Pt* study

2.2.1. Surfaces

The first sample of this set, (i), consisted of a bare ITO surface (on glass substrate) provisioned from Asahi. A second sample, (ii), had a 1 nm-thick semitransparent Pt layer evaporated onto the ITO layer. A third sample (iii) was the same as sample (ii), after the surface was treated with an oxygen plasma. We made sample (ii) and (iii) semitransparent as EA measurements require a (semi)transparent contact. For work function measurements we also prepared a fourth sample (iv), consisting of a thicker opaque Pt layer (several nm thick) evaporated on a glass substrate. A fifth sample (v) consisted of sample (iv) after being treated with an oxygen plasma (i.e. Pt*). The final sample (vi) had a Au layer evaporated on it at pressures in the 10^{-6} mbar range. The ITO substrates were subjected to the wet cleaning procedure of two successive ten minute ultrasonic baths in acetone and in IPA, and were then dried with nitrogen: before measurement for sample (i) and before deposition of Pt for sample (ii). Thermal evaporation of Pt was realized by winding a Pt wire around a tungsten filament heated by the Joule effect. Although great care was taken in cleaning the chamber to avoid degassing of contaminants, the pressures during thermal evaporation went up to 1×10^{-5} mbar due to the high temperatures necessary to evaporate Pt (melting temperature of Pt is 1768 °C compared to 1064 °C for Au and the vapour pressure for Pt is

0.0312 Pa at 2045 K and 0.000237 Pa at 1337 K for Au. Heat of vaporization is 510 kJ/mol for Pt and 334.4 kJ/mol for Au).

2.2.2. Diodes

Single-layer sandwich structures were also fabricated using bottom contacts equivalent to (i), (ii), and (iii) described above; a 120 nm layer of poly(dioctyfluorene-alt-benzothiadiazole), F8BT, was subsequently spun over these semitransparent electrode surfaces. The diodes were completed by thermally evaporating 14 mm^2 and 15 nm-thick gold top electrodes at a pressure in the $\sim 1 \times 10^{-6}$ mbar range.

2.3. ITO/ITO∗ study

2.3.1. Surfaces

One hundred nanometer thick ITO-covered glass substrates were obtained from Merck KGaA. The substrates were cleaned in two 10-min ultrasound baths (acetone and IPA) before undergoing KP measurements. After the first set of measurements, the samples underwent an oxygen plasma treatment in a Harrick plasma cleaner (PDC-002) at pressures of $\sim 1 \times 10^{-1}$ mbar for 5 and 10 min. Plasma powers used were 60 W and 100 W. Varying these treatment conditions (time and power) does not lead to variations in the results greater than the reproducibility. Here, we show two representative results over a set of measurements: it is likely that the variations shown in the work function of the ITO soon after plasma treatment between samples are due to the difficulty in maintaining a constant and reproducible pressure in the plasma chamber. An oxygen-plasma treated-ITO sample (5 min, 60 W power, 1×10^{-1} mbar) was covered by a 75 nm F8 film [spun at 1500 rpm from a 2% (wt.) xylene solution] 2 min after completion of the plasma treatment.

2.3.2. Diodes

Indium tin oxide (ITO) substrates were cleaned in acetone and isopropanol. One of them was treated with oxygen plasma. Subsequently, the substrates were transferred in a nitrogen glove-box for all subsequent processing steps. A 70 nm thick layer of a polyfluorene-based blue-emitting polymer was spin coated over the substrates from a xylene solution [33,34]. The cathode was Al (400 nm) evaporated at pressures between 10^{-6} and 10^{-7} mbar. The finished devices were encapsulated with metal cans and epoxy resin, and contact pins were attached to allow characterization outside the glove-box.

3. Results

We utilised the Kelvin probe technique [35,36] to measure the contact potential difference (CPD), or work function difference, between the gold mesh of the experimental apparatus and the conductive surface samples we prepared (i.e. (1) Au, Au∗; (2) Pt, Pt∗; (3) ITO, ITO∗ where "∗" is an oxygen-plasma treated sample).

In the literature, the reported gold work function values vary between 4.2 eV and 5.4 eV, depending strongly on the environment and state of its surface [7,37,38]. We chose a freshly cleaned (10 min acetone + 10 min IPA ultrasound rinse) ITO substrate as our daily reference for all KP measurements as the readings are stable over that time period (and even longer as we show in Fig. 1) and is more practical than dismounting the gold mesh and cleaning it before each measurement. This is evident from Fig. 1 in which we have plotted the work function of 100 nm thick ITO/glass substrates (Merk KGaA) treated in ultrasonic baths of acetone and IPA and blow dried with nitrogen. The absolute value of the work function of the ITO samples was extracted by also measuring the CPD of a surface of highly oriented pyrolytic graphite, HOPG, monochromator grade ZYH (supplied by GE advanced ceramics) for each data point. The work function was monitored over a time span of 10 weeks. HOPG surfaces are customarily utilised for calibration of work function values since its own work function (4.475 ± 0.005 eV) is known to be reliable and sufficiently stable as measured against standard calomel electrodes (SCE) [39]. Over the 10 week time span the mean value of the ITO sample was 4.70 with a standard deviation of 0.05 V (also equivalent to the CPD difference measurement error) with a minimum (maximum) reading of 4.62 eV (4.76 eV). A second sample (2 min baths in acetone and IPA) showed similar behaviour over the 10 week timeframe with a mean work function of 4.74 eV (standard deviation of 0.04 eV).

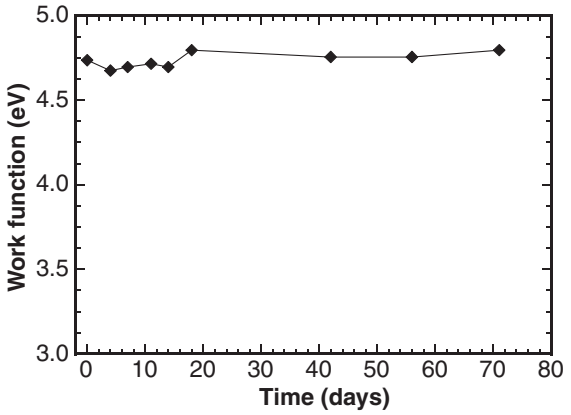

Fig. 1. Work function of ITO/glass sample cleaned in 5 min baths of acetone and IPA prior to each measurement calibrated utilizing a highly oriented pyrolytic graphite surface (Kelvin probe contact potential difference measurements). The mean value is 4.70 eV with a standard deviation of 0.05 eV.

Thus, in order to report measurements that can be compared with the energy levels of a variety of organic semiconductors and of other conductor surfaces, we have converted experimental CPD measurements to a work function (ϕ) using the following equation: $\phi(\text{sample}) = e{\cdot}\text{CPD} + \phi(\text{ITO})$, where we assigned: $\phi(\text{ITO}) = 4.7$ eV. Photoelectron spectroscopy is usually utilised to measure absolute values for work functions (see for example distinctions compared to the KP technique in reference [40]). Work function values for ITO are typically between 4.6 and 4.8 eV [16,40] depending also on the ITO supplier. We found that the ITO substrates from the particular

batches in our possession gave the same KP readings within 0.05–0.1 V (differences may be higher between different ITO materials/suppliers). We consider ϕ(ITO) = 4.7 eV to be a satisfactory estimate as this value is also supported by EA measurements of the built-in potential [16,41]. Note however that irrespective of the choice of reference surfaces, work function differences are independent of any reference value used. Furthermore, the original CPD difference (referenced to the reference ITO sample) can be traced back from the work function data reported here by subtracting 4.7 eV. Due to error propagation, the experimental error on the reported work function values we present here, apart from that on the HOPG reference and the oscillations in the CPD (±0.05 eV), will have to include the variability between ITO substrates giving an estimated total error of 0.1–0.15 eV.

In this manuscript we report KP measurements not only on bare conducting surfaces, but also on conducting surfaces covered by either a F8 or F8BT polymer overlayer. F8 and F8BT are polyfluorenes employed in the fabrication of efficient optoelectronic devices [42]. Here they were chosen mainly for their high purity and high ionisation potential (HOMO(F8) = 5.8 eV [43], HOMO(F8BT) = 5.9 eV [44]) so that space charge in the semiconductor, band bending and/or strong pinning of the conductor Fermi level occurring at the HOMO (bi)polaronic levels of the semiconductor [45] would not occur. Polyfluorenes have in fact been shown to be high purity materials devoid of significant charge over the film thicknesses $\leqslant$100 nm under consideration [32,41,46]. No evidence for band bending in pristine polymer layers was detected for distances as long as 110 nm from the interface [32]. Thus, for fresh samples, we are confident that CPD measurements probe the work function of the contact/polymer structure, which to a first approximation is the sum of the work function of the underlying conductor and any interfacial dipole contribution at the conductor/polymer interface. All KP measurements reported here were taken in air.

Electroabsorption spectroscopy measures the normalized variation of the transmission of light ($\Delta T/T$) through a sample upon application of a periodic electric field of frequency ω. As described by Campbell and coworkers [45], the signal measured at the fundamental frequency ω:

$$\Delta T/T(\omega) \propto \xi(h\nu) \times V_0 V_{AC} \cos(\omega t) \propto (V_{DC} - V_{BI}) V_{AC} \cos(\omega t), \quad (1)$$

can be used to extract the built in potential (V_{BI}) by monitoring at which applied bias (V_{DC}) the EA response is zero.

The built-in potential originates from the equilibration of the Fermi level throughout the heterostructure. Without significant charge (extrinsic or intrinsic) accumulation inside the polymer film, the electric field is essentially uniform in the bulk of the polymer layer. As shown in Fig. 2, EA can be a powerful tool as it can provide a direct measurement of V_{BI} enabling to gauge the energy level alignment of different contacts by measuring the V_{BI} on a series of diodes that differ only by the anode material (keeping the cathode and polymer layer unaltered). Further and more detailed considerations on the EA technique can be found in references [32,47].

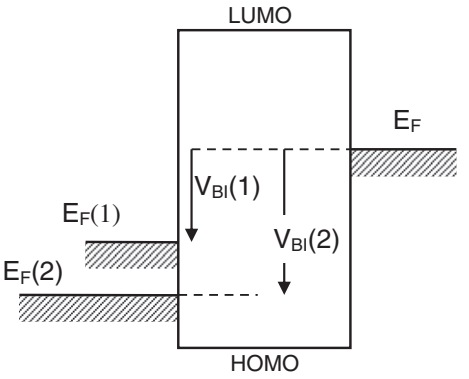

Fig. 2. Schematic diagram of the energy levels of a diode structure at flat band. The distance between the Fermi levels of the two electrodes will generate a built-in potential at equilibrium. In the case of two heterostructures having the same cathode and semiconductor and differing only by the anode material (1) and (2), V_{BI} becomes a useful quantitative measure of the relative alignment of the two electrodes. A positive and higher V_{BI} extracted from electroabsorption data indicates that the Fermi level of the bottom electrode (2) lies closer to the HOMO level of the semiconductor resulting in a lower barrier to hole injection.

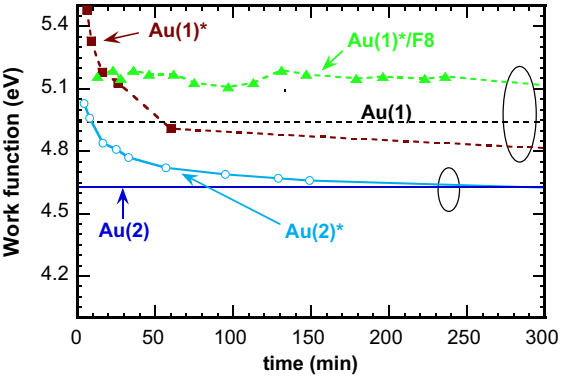

Fig. 3. Kelvin probe work function measurements in air over the first 5 h of: (1) a gold surface evaporated at a pressure of <1.8 × 10^{-6} mbar before [Au(1) – dashed line] and after an O_2 plasma [Au(1)* – squares]; 2) a gold surface evaporated at a pressure of 4–5 × 10^{-6} mbar before [Au(2) – full line] and after an O_2 plasma [Au(2)* – circles]; 3) Au(1) surface evaporated at a pressure of <1.8 × 10^{-6} mbar and subjected to an O_2 plasma and covered by an F8 polymer semiconductor overlayer spun cast 3 min after completion of the plasma treatment (triangles). The plot lines connect data points (some with data points located beyond the 300 min shown in the figure). The symbol "*" indicates that the surface has been subjected to an oxygen plasma.

3.1. Au, Au* study

Fig. 3 shows the work function of the two gold surfaces we evaporated, Au(1) and Au(2), obtained by measuring the CPD with the Kelvin probe and referencing the result to the work function of the reference ITO sample (ϕ = 4.7 eV). The straight horizontal lines correspond to the work function of the two surfaces measured after having rested in air for a period between 12 and 24 h after evaporation.

The dashed horizontal line represents the work function of Au(1) which was evaporated at pressures of 1 × 10^{-6} mbar.

The CPD of Au(1) is 0.24 V higher than the reference ITO sample giving an estimated work function of ϕ[Au(1)] = 4.94 eV. The continuous horizontal line represents the work function of Au(2) which was evaporated at (4–5) $\times$ 10^{-6} mbar. The CPD of Au(2) (relative to the ITO surface) is -0.07 V, yielding ϕ[Au(2)] = 4.63 eV. We have seen that although the CPD reading (vs. the ITO reference) of untreated Au surfaces in air can stray by a more than a tenth of a volt on the time scale of several weeks, it stays constant (±0.05 eV) on the time scale of a day and has hence been represented as horizontal lines in Fig. 3.

After the initial set of KP measurements represented by the horizontal lines of Fig. 3, both Au(1) and Au(2) were subjected to an oxygen plasma as described in the experimental section. The samples were then taken out of the etcher and their work function measured in air with the Kelvin probe. A significant enhancement in the work function of both surfaces was measured. The work function of the gold surfaces, with respect to their initial untreated values, increased by 0.54 eV for Au(1) (first measurement taken 6 min after completion of the O_2 plasma treatment) and by 0.40 eV for Au(2) (first measurement taken 4.5 min after the plasma treatment). We then continued monitoring the CPD of the plasma treated Au surfaces over time while left resting in air. We found that the plasma effect on the work function is not permanent in these conditions: the work function decreases appreciably with time (Au(1)$*$ and Au(2)$*$ in Fig. 3) when the surfaces are left in air. Not only does ϕ reach its initial value (prior to the plasma treatment) within an hour for Au(1) and 4 h for Au(2), but it tailors off to values which are even lower than the initial ones.

The work function for the third gold sample [Au$*$/F8], which was covered by a 75 nm-thick F8 film 2 min after completion of the oxygen plasma treatment, is ϕ = 5.15 eV, This corresponds to an increase of 0.2 eV with respect to the initially untreated surface, a value that remains constant (within experimental error) over the period of 5 h shown in Fig. 3.

3.2. Pt, Pt$*$ study

3.2.1. Surfaces

Table 1 reports CPD measurements and work function values taken in air of the electrodes (i)–(v), described in the experimental section: (i) ITO, (ii) ITO/Pt, (iii) ITO/Pt$*$, (iv) Pt, (v) Pt$*$ and (vi) Au. Untreated Pt, samples (ii) and (iv), show the same work function as ITO. The work function of sample (vi) Au is 0.2 eV lower than that of ITO. After the oxygen plasma treatment, the work function of both Pt surfaces (iii) and (v) increases by a large amount (by 0.8–0.9 eV) yielding a value of ϕ = 5.5–5.6 eV. Table 1 also shows that the work function of the thinner ($\sim$1 nm) semi-transparent (ii)–(iii) and thicker opaque (iv)–(v) Pt layers coincide within 0.1 eV.

The evolution of the Pt$*$ CPD over time in air showed a 0.3 eV decrease between a measurement taken at t = 15 min after the plasma treatment and the last measurement at t = 120 min.

Table 1
The values of contact potential difference (CPD) relative to an ITO reference sample measured with the Kelvin probe in air. The work function, ϕ, can be estimated by adding 4.7 eV to e·CPD. Fabrication details of the surfaces can be found in the experimental section. The symbol "$*$" indicates that the surface has been subjected to an oxygen plasma.

Surface	(i)	(ii)	(iii)	(iv)	(v)	(vi)
Materials	ITO	ITO/Pt	ITO/Pt$*$	Pt	Pt$*$	Au
[CPD ± 0.1]V	–	0	0.8	0	0.9	−0.2

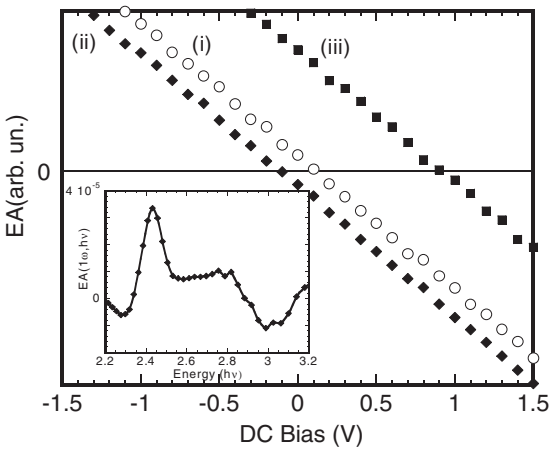

Fig. 4. Electroabsorption response at hν = 2.41 eV and V_{AC} = 0.5 V as a function of applied bias for: (i) ITO/F8BT/Au, (ii) ITO/Pt/F8BT/Au and (iii) ITO/Pt$*$/F8BT/Au diode structures. The spectral dependence of the EA signal, originating from F8BT, is shown in the inset. The large shift ($\sim$1 V) in curve (iii) compared to curve (ii) indicates that the plasma treatment on the platinised surface (ITO/Pt$*$) has pulled the anode's work function closer to the F8BT's HOMO by an equivalent amount ($\sim$1 eV) as schematised in Fig. 2.

3.2.2. Diodes

Electroabsorption measurements on diodes consisting of contact/F8BT/Au [bottom contact $\equiv$ (i) ITO, (ii) ITO/Pt or (iii) ITO/Pt$*$] are reported in Fig. 4. The EA spectrum (Eq. (1)) at the fundamental frequency of the F8BT, sandwiched between the two contacts, is shown in the inset. The latter shows a prominent peak at $\sim$2.43 eV. The absorption spectrum of F8BT can be found in Ref. [42]. In order to measure the built-in potential across the F8BT diode structures, the photon energy (hν = 2.41 eV) and the amplitude (V_{AC} = 0.5 V) were kept fixed and the dependence of the EA signal upon DC bias was monitored. The results for the three devices, (i), (ii) and (iii), are shown in the

Table 2
The values of the built-in potential for the three different F8BT-based diode structures measured with electroabsorption (extracted from Fig. 4). A positive V_{BI} is an indication that the Fermi level of the bottom electrode lies lower than that of Au (i.e. further away from the vacuum level) at flat band as shown in Fig. 2. The symbol "$*$" indicates that the surface has been subjected to an oxygen plasma.

Device	(i)	(ii)	(iii)
Top electrode	Au	Au	Au
Bottom electrode	ITO	ITO/Pt	ITO/Pt$*$
V_{BI}	0.1 V	−0.1 V	0.9 V

main panel of Fig. 4. The values at which the electroabsorption signals of Fig. 4 intersect the zero axis correspond to V_{BI}. These values are reported in Table 2. (i) V_{BI} = 0.1 V for the ITO/F8BT/Au diode; (ii) V_{BI} = −0.1 V for ITO/Pt/F8BT/Au; (iii) V_{BI} increases very significantly (V_{BI} = +0.9 V) when the Pt surface is subjected to an oxygen plasma prior to the deposition of the organic semiconductor, i.e. for ITO/Pt∗/F8BT/Au. As discussed earlier the use of a material with such a deep HOMO (∼5.9 eV below vacuum) as F8BT ensures that hole injection is negligible in the LEDs during electroabsorption experiments in the range of applied DC voltages used here.

3.3. ITO, ITO∗ study

3.3.1. Surfaces

Emission KP measurements of the ITO surfaces are reported in Fig. 5. The work function of the untreated surface was set at 4.7 eV and is shown as a horizontal dashed line. After plasma treatment, the CPD measured by the KP increases by ∼1.3–1.6 eV. Two ITO∗ surfaces are included in Fig. 5 to show that the reproducibility of the CPD enhancement due to the plasma treatment, just after its completion, is within a few tenths of an eV. Once the ITO∗ surfaces are left in air, the CPD decreases quite rapidly (within 100–400 min) by ∼0.7–1 V towards a more stable value. Note that this plateau in the work function is still 0.5–0.7 eV higher than the work function of the initial untreated surface. The work function (t > 1000 min, not shown) actually continues to decrease slowly with time. Indeed, after four months (right panel of Fig. 5), the work function of both ITO∗ surfaces has reached, within 0.05 eV, its "initial" value (i.e. CPD ≅ 0 V, i.e. ϕ = 4.7 eV, before either surface was subjected to an ITO plasma).

Also shown in Fig. 5 is the ITO surface which was covered with a 75 nm film of F8 two minutes after being

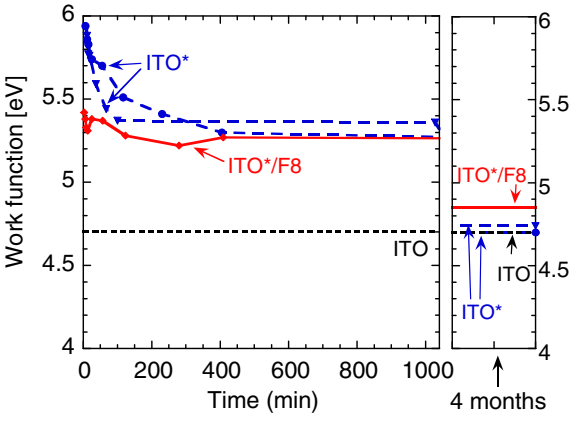

Fig. 5. Left panel: Kelvin probe work function measurements of two oxygen-plasma treated ITO surfaces (ITO∗) as a function of time after completion of the plasma treatment (dashed curves, diamond and circles treated for 5 and 10 min, respectively). Also shown are the results for an oxygen-plasma treated sample covered by a 75 nm film of F8 (continuous curve). Measurements were taken in air. Right panel: work function of the same samples after they were left in air for four months. The horizontal line at 4.7 eV represents the work function of the ITO surface before plasma treatment.

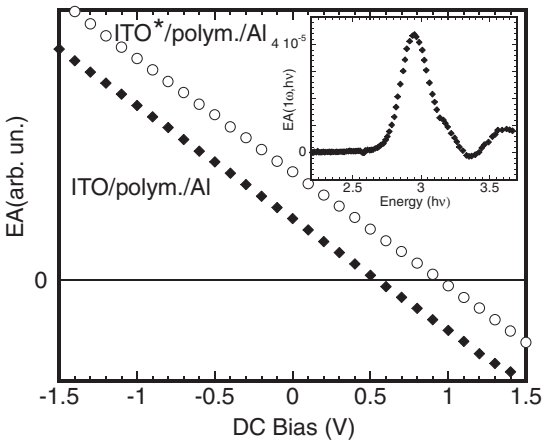

Fig. 6. Electroabsorption (EA) response at hν = 2.9 eV and V_{AC} = 1 V as a function of applied bias for the following encapsulated diodes: ITO/polymer/Al (left, black diamonds, V_{BI} = 0.51 V), and ITO∗/polymer/Al (right, circles, V_{BI} = 0.99 V). The difference in V_{BI} between the two samples is a direct verification that the Fermi energy level of the plasma treated ITO* sample is 0.48 eV closer to the HOMO level of the semiconductor compared to the untreated surface. The measurements (only one shown for each heterostructure) were taken shortly (0 months) and repeated 20 months and 25 months after fabrication and encapsulation of the diodes, with no appreciable change in the EA response. The spectral dependence of the EA signal is shown in the inset.

treated with the oxygen plasma. Here the initial CPD enhancement due to the plasma is still significant (0.6–0.7 V) but reduced compared to the "free" ITO∗ surface. There is also some CPD evolution – an overall small decrease (0.1–0.15 V) within the first 400 min. The work function tends to a plateau value ∼0.5 eV higher than the untreated ITO surface before decreasing further after 4 months (CPD = 0.15 eV).

3.3.2. Diodes

The inset of Fig. 6 shows the EA spectrum of the ITO/polymer/Al device described in the experimental section. The energy of the incident photon was kept at 2.9 eV and the EA signal monitored as a function of the applied bias for both the ITO/polymer/Al and the ITO∗/polymer/Al encapsulated devices. The zero crossing of the plots are: V_{BI} = 0.51 V for ITO/polymer/Al diode; V_{BI} = 0.99 V for the ITO∗/polymer/Al diode. Note that the electroabsorption measurements of V_{BI} were taken straight after fabrication (∼0 months) and then repeated 20 and 25 months (left idle – i.e. without being driven) after the devices were fabricated and encapsulated in nitrogen atmosphere, without any noticeable change in the V_{BI} over this entire period.

4. Discussion

4.1. Au, Au∗ study

Fig. 3 shows clearly that both the gold surfaces under study Au(1) and Au(2), in an air environment, possess a work function that can be significantly lower than that of a gold surface formed and measured in ultra high vacuum (despite even the tendency of photoemission techniques to

provide smaller values than KP [40]). Typically, ϕ [Au] $\geqslant$ 5.1 eV in UHV [7]. Adventitious species that are adsorbed on (or co-evaporated with) the gold surfaces in the evaporation chamber [21] (in high vacuum conditions rather than UHV) and when the surfaces are left resting in air [20], are the reported causes of the lower work function we measured: ϕ = 4.94 eV for Au(1) and ϕ = 4.63 eV for Au(2). Au(1) was evaporated at pressures of $<1.8 \times 10^{-6}$ mbar and Au(2) at higher pressures $\leqslant 5 \times 10^{-6}$ mbar. We believe that the lower work function for Au(2) is caused by a higher partial pressure of hydrocarbons [7,18,21,22,48,49] and other contaminants [50], present in the evaporation chamber (in which a variety of other materials are also routinely evaporated).

The O_2 plasma treatment initially increases the work function of the Au surfaces by 0.4–0.54 eV (Fig. 3). Chemically sensitive techniques such as photoemission spectroscopy [3,51,52] would be required to gauge the chemistry of the Au* surface (although outside the scope of this work), but the enhancement in work function may be in part ascribed to the plasma ablation of adventitious adsorbed contaminant layers, as also occurs, at least partially, in less chemically stable surfaces such as ITO [18,20–22,24,48,49] and also to the adsorption or chemisorption of more reactive species such as oxygen [27,53]. Leaving the plasma treated Au surfaces in air ambient causes the work function to decrease in time to values that are even lower than those of the same surfaces prior to the plasma (Fig. 3). While there are a number of possible explanations, this behaviour may mean that the plasma creates a more reactive surface (through the generation of reactive chemical surface species) which then attracts a higher concentration of adsorbed hydrocarbons and contaminants from the air environment, over the time scale of hundreds of minutes. The above results confirm that Au is not a good standard in air [38,39] since its work function depends strongly on the evaporation conditions and on the environment it sees before and during measurement.

Beierlein et al. [20] have reported that the reduction of the work function of metals upon exposure to air may be strongly mitigated by putting samples in an inert atmosphere. In Fig. 3 we show that by overlaying an F8 film over the O_2 plasma-functionalised Au surface (Au*/F8), the enhancement in the work function is "frozen-in". The fact that this enhancement is stabilised at a lower value compared to the equivalent work function of the bare plasma treated surface (cf. Fig. 3 squares) may potentially be ascribed to a significantly large dipole forming at the Au/F8 interface [2,3,6], and/or to the fact that the more reactive (but unstable) species that may be produced initially by the plasma on the gold surface are then passivated/eliminated by the spin coating of the film; a partial contribution from band bending cannot be excluded. However, since the polymers utilised in this work are of high purity, we believe this effect to be marginal in this case, as also confirmed by subsequent EA measurements on diodes; recent photoemission studies on polymer/Au interfaces by Osikowicz et al. [54] have related this effect to a compression of the metal electron density tail in the presence of an organic layer. Fig. 3 shows that the work function of the Au*/F8 sample is constant (±0.05 eV) over the time scales of the 10^2–10^3 min under study and is $\phi \cong 5.15$ eV: a significant value in that it is very close to the ones reported for Au formed and measured in UHV (i.e. a clean surface). Note that although in principle strong pinning of the anode work function (and thus V_{BI}) cannot be excluded as recent photoemission experiments show instead a large relaxation energy for the polaronic energy levels (placed at ~5.2 eV [55] that can pin the Fermi level, here it is improbable as in the results using F8BT (see next section) which has an IP similar to that of F8, the built-in potential measured is greater than would be expected if strong pinning were occurring at a polaronic energy level with a relaxation energy of 0.4–0.7 eV. In previous EA experiments pinning was shown to occur closer to the ionization potential of F8, i.e. 5.8 eV) [56]; photoemission studies and EA techniques may inherently give rise to differences [33], for reasons similar to those encountered when comparing photoemission studies to KP measurements [40].

4.2. Pt, Pt* study

4.2.1. Surfaces

Table 1 shows that the work function of evaporated Pt layers (i) and (iv) measured in air is 4.7 eV. An oxygen plasma treatment brings the work function of the Pt surfaces to ϕ = 5.5–5.6 eV. This value corresponds to the work function of a UHV clean Pt surface [7]. The ϕ of the untreated Pt is much lower because of species adsorbed in air but also because of the relatively elevated pressures reached in the evaporation chamber during the thermal evaporation (1×10^{-5} mbar) which can contaminate [20,21] the surface with species degassing from the crucible and chamber.

The increase in work function after the plasma suggests that it is the surface contamination that is removed by the plasma although there may also be a contribution from oxygen adsorbed or chemisorbed on the Pt surface [53]. The reduction in the work function of 0.3 eV over the time period of 2 h (measured 15 min and 2 h 15 min after the plasma treatment in air) confirms that bare clean Pt may have a similar (although improved) [21] stability trend compared to the Au surface. It is also interesting to note that the thin Pt layers where a contribution from the underlying ITO* sample (island growth) may also be present give the same result as the thicker opaque Pt layers.

4.2.2. Diodes

Fig. 4 and Table 2 show that the V_{BI} of the diode with a plasma treated Pt contact (ITO/Pt*/F8BT/Au) is ~1 eV higher compared to the device with an untreated Pt anode (ITO/Pt/F8BT/Au) (see Fig. 4 and Table 2). This means that the barrier to hole injection from the anode into the F8BT has been reduced by a similar amount (see Fig. 2). This O_2 plasma-induced enhancement in V_{BI} is ~ equal (within ± 0.1 eV) to that in the work function, ϕ, of the bare platinum surface (Table 1). The ensuing barrier height lowering of the same magnitude (see Fig. 2) is responsible for the improvement in hole injection in diodes with ITO/Pt anodes as reported by Shen et al. [57]. Note that among the ITO*/polymer, Au*/polymer and the Pt*/polymer samples, it is the latter that yields the largest increase in ϕ or V_{BI}. Also, unlike the Au*/F8 case, where a significant dipole

may have formed at the metal/semiconductor interface, the remarkable consistency between the V_{BI} of Table 2 and the work function data of Table 1 indicates that: (a) the Schottky–Anderson model for the interface between F8BT and Pt (ii) and (iii), and also ITO (i), constitutes a good approximation in describing the energy level alignment at these electrode–polymer interfaces, (b) the plasma is not likely to generate a significant concentration of unstable reactive species at the Pt∗ surface, (c) that the zero crossing voltage difference can be utilised to gauge the variation on barrier height (NB ionisation potential of F8 > estimated work function of anode) [32,58]. It is interesting to note that the case of Pt is in contrast to Au for which the original work function enhancement due to the plasma is reduced by spinning an organic overlayer on top. Furthermore, the F8BT film of the LEDs of Table 2 was spun minutes after completion of the plasma treatment of the anode, but the EA measurements were taken over 24 h later. Thus, on this timescale, overlaying a polymer layer over an oxygen-plasma treated Pt surface "preserves" the V_{BI}, and thus the original work function of the surface.

Finally, we consider that the gold interface with F8BT for all the diodes of Fig. 4 and Table 2, is evaporated directly over the polymer film in vacuum and has thus never seen air. V_{BI} for sample (i) ITO/F8BT/Au is −0.1 V. This implies that, at flat band, the Fermi level of the Au top-contact is 0.1 eV closer to the vacuum level than that of ITO (Fig. 2); if the Schottky–Anderson vacuum-level alignment model ruled, the work function of the Au would be 4.6 eV [ϕ (ITO) = 4.7 eV]. This is far lower than the expected work function of Au in a good vacuum [7], indicating that estimates of charge injection barriers based on the work function of atomically clean gold surfaces can lead to errors as also outlined in recent photoemission experiments by Osikowicz et al. [54] for which a decrease of the vacuum energy levels of Au in contact with a polymer layer is consistently observed and due to the compression of the metal electron density tail in the presence of an organic contact layer. Note also that the Au contact of Table 2, evaporated over the conjugated polymer, may give rise to quantitatively different energy level alignment compared to the situation in which the organic layer is spun over a previously deposited (and cleaned) Au surface.

4.3. ITO, ITO∗ study

4.3.1. Surfaces

The work function of the plasma treated ITO surface (Fig. 5) has a similar time dependence to that of the Au surfaces of Fig. 3 with two main differences: (a) the increase and absolute value for ITO* are significantly higher just after the plasma treatment and (b) the decrease with time when the surfaces are left in air reaches an initial plateau after 100–400 min which is still sizeably higher than the initial untreated ITO.

Although higher than that of the untreated ITO, the work function of the ITO∗/F8 sample is lower (by ∼0.5 eV) than that of the ITO∗ shortly after the plasma treatment (but before F8 deposition). This suggests that either: (a) a simple Schottky vacuum-level alignment does not occur and a significant dipole (that shifts the levels by 0.5 eV) is formed at the ITO∗/F8 interface, and/or (b) that any reactive chemical species [27] present on the ITO∗ surface after the oxygen-plasma, which could induce a work function increase, are quenched much more rapidly by application of the polymer layer, and/or (c) that the polymer film causes a reduction of the electron tail density that extends outside the metal surface [54]. A partial contribution from band bending cannot be excluded. However, since the polymers utilised in this work are of high purity, we believe this to be low in this case as also confirmed by subsequent EA measurements on diodes, and by the perfect linearity of the EA vs. V_{DC} characteristics. Fig. 5 shows that any chemical, physical and electronic process or interaction between F8 and ITO∗ continue even some time (∼200 min) after deposition of the polymer overlayer. Although in previous work [18,22,24,29,49,59] the increase of the ITO work function upon plasma treatment has mainly been ascribed to the removal of surface contaminants such as hydrocarbons and to chemical modification (e.g. oxidation) of the ITO, recently Kim et al. [27] proposed that a dipole layer of O^- ions is formed on the ITO surface, which increases the work function of the ITO. We consider that the role of reactive, unstable species left on the surface after an oxygen plasma and the evolution of these in time has received little attention, and that would deserve a dedicated investigation with chemistry-sensitive techniques such as X-ray photoelectron spectroscopy (XPS).

A consideration that arises when analysing these results is that the time elapsed between the completion of the plasma treatment and the deposition of F8 can be crucial in determining the energy level alignment, since a dipole that actually decreases the separation of the semiconductor HOMO and the Fermi level of the high work function conductor are rare [6]. It thus becomes important to overlay the organic semiconductor before the work function of the underlying contact has decreased much beyond the ionization potential of the semiconductor in order to minimise the hole injection barrier.

Although the effect of the plasma is longer lasting in the case of ITO compared to gold surfaces, Fig. 5 shows that the work function of the ITO∗ surfaces has returned to its initial value after leaving the samples 4 months idle in air. Even the work function of the ITO∗/F8 sample has decreased very sizeably, although it remains 0.15 eV higher than untreated ITO surface. The F8 layer carries out some protective action on the electronic properties of the underlying interface, but not on the time scale of months. This large decrease in the KP reading over time can either be ascribed to chemical/electronic variations at the electrode/polymer interface (as seen in electrically stressed PLEDs with a PEDOT:PSS anodes for example) [60], and/or polymer/air interface and/or polymer/air interface and/or in the bulk of the semiconductor. Either way, this will have a strong and detrimental impact on the performance and lifetime of any device built with these materials and is mainly due to molecules from the air environment diffusing into and through the semiconducting polymer.

4.3.2. Diodes

Very significantly, however, proper encapsulation of the diodes results in a dramatic improvement on the lifetime

of the plasma-induced work function enhancement (Fig. 6). EA measurements were taken soon after fabrication and also 20 and 25 months after fabrication and encapsulation of the samples (no getter included). No change during this time period of over two years was detected in the V_{BI} for either ITO/polymer/Al or ITO∗/polymer/Al samples. The relative energy levels have therefore remained unaltered over this time. Using the top Al electrode as the reference and assuming a work function of 4.2 eV (and a Schottky type alignment at the Al/polymer interface as determined in a previous paper) [32], the Fermi level of the untreated ITO sample would lie 0.5 eV (V_{BI} = 0.51 V) higher than Al (see Fig. 2), i.e. at 4.7 eV from the vacuum level. This value also coincides with the measured value for ITO (see Fig. 1) meaning that Schottky–Anderson vacuum-level alignment is valid at this ITO/polymer interface as well. For the ITO∗ anode, V_{BI} = 0.99 V. This is a direct verification, on a working diode structure, that the Fermi energy level of the ITO∗ sample is 0.48 eV closer to the HOMO level of the semiconductor compared to the untreated surface (i.e. ϕ(ITO∗) ≈.5.18 eV). The resulting barrier lowering leads to improved injection of holes in organic semiconductor diodes as detailed in a number of studies [17,24,61].

The above results also shed some light on the issue of poor reproducibility that can affect the fabrication of organic semiconductor devices. The electronic properties of an interface, including the energy level positioning and formation of interfacial dipoles, depend obviously and critically on the choice of contact and semiconductor materials. Not only do they depend on the different fabrication processes, conditions, and environments, but also on more subtle and sometimes less controllable parameters such as variations in the chamber pressure during evaporation and the time elapsed between the treatment of the contacts and the actual deposition of the semiconducting layers.

5. Conclusions

Evaporating films of Au and Pt in high vacuum conditions and leaving the samples in an air environment leads to a work function that can be considerably lower than the equivalent reference surfaces formed and measured in UHV conditions. For Au and Pt surfaces, it is desirable to keep the pressures in the evaporation chambers as low as possible ($\leqslant 1 \times 10^{-6}$ mbar) as higher pressures lead to a lowering of the work function which can be detrimental to the operation of optoelectronic devices.

We have shown that treating Au, Pt and ITO surfaces with an oxygen plasma can increase their work function by up to over 1 eV. This enhancement is however not permanent when the samples are left in air as the work function starts to decrease when exposed to air. For Au surfaces the work function can fall back to the pre-treated value (and lower) within a few tens of minutes. For ITO there is a similar initial reduction but the work function plateaus (on the time scale of 10^3 min) to a value which is still considerably higher than its initial one. This difference compared to the metallic Au electrode suggests that for the ITO surface the plasma has not only a superficial effect (e.g. removing hydrocarbons, impurities and adding adsorbed species (e.g. O^-)) but also more lasting chemical modifications. Ultimately however, after 4 months we see that the work function of ITO has gone back to its initial untreated value, ϕ (ITO) = (4.7 ± 0.1 eV), as measured utilizing a highly oriented pyrolytic graphite surface for calibration.

By spinning a semiconductor polymer layer over the plasma treated Au, Pt, and ITO surfaces, we show that the enhancement of the work function brought about by the plasma is at least partially preserved even in air: in its entirety for the Pt∗ surface covered with F8BT (which suggests a vacuum-level alignment); somewhat reduced for the Au∗ and ITO∗ surfaces when covered with an F8 film, which may indicate that a significant dipole has formed at those semiconductor/electrode contacts or that the more reactive species generated by the plasma have been removed/passivated by the film. Nevertheless, for all the plasma-treated surfaces (Au, Pt and ITO), the Fermi level of the conductor has been brought closer to the HOMO levels of the semiconducting polymers decreasing the barrier to hole injection significantly, by between 0.2 eV and 1 eV. The electroabsorption results on complete diode structures confirm this. The estimated "effective" work functions (∼ ± 0.15 eV) of these plasma treated electrodes are 5.15 eV for Au∗, 5.18 eV for ITO∗ and 5.6 eV for Pt∗. For the untreated surfaces the initial values in air are much lower: 4.5–4.9 eV for Au, 4.7 eV for ITO (the reference sample) and 4.6–4.7 eV for evaporated Pt.

Although the polymer overlayer keeps the work function of plasma-treated surfaces steady over the times scale of a day, it does not preserve it on the time scale of a few months with detrimental effects on the lifetime of a device. On the other hand, if devices are properly encapsulated in inert atmosphere, we have also proven that the relative energy level alignment of the contact and semiconductor materials (and thus of the ensuing injection barriers) is completely and firmly frozen over the time scale of the 25 months of our study.

Although it would be desirable to offer a more detailed analysis of the underlying mechanisms for the measured work-function deepening, recovery and stabilisation, this would require a number of studies which fall beyond the scope of this communication, owing to their complexity and length. An obvious explanation of the stabilisation may be the suppression of diffusion of polar atmospheric contaminants to the metal/polymer interface. However, the identification of the nature of the contaminants that are likely to be adsorbed and responsible for the observed effects is a particularly demanding task, which requires a separate and dedicated study.

While these results have been obtained with a particular class of materials (polyfluorenes) that are significantly stable, we consider that the results are more general to well – encapsulated electrode/organic-semiconductor/electrode devices. For example, recently devices with a different class of materials, have currently been reported with optical and electroluminescent properties that are stable over a period of ∼10 years when stored in the dark [13]. We suggest therefore that our results have strong implications

for the understanding, design, fabrication strategies, processing timings, and lifetimes of un-encapsulated surfaces and electrode-organic heterostructures and ultimately of completely encapsulated devices. For the latter, the fact that the high work function electrode/semiconductor alignment stays constant on the timescale of years contributes in explaining the observations of correspondingly long shelf lives and lifetimes seen in organic semiconductor devices including OLEDs [62–66], TFTs [67], and photovoltaic cells [68–73].

Acknowledgements

The Pt, Pt∗ investigation was carried out at the Cavendish Laboratory, Cambridge University. The ITO, ITO∗ diodes were fabricated at Cambridge Display Technology. TMB wishes to thank MIUR for a "Incentivazione alla mobilità di studiosi residenti all'estero" fellowship and financial support "Polo Solare Organico Regione Lazio" from Regione Lazio. We also thank the EC Marie Curie RTN-THREADMILL (MRTN-CT-2006-036040) and ITN-SUPERIOR (PITN-GA-2009-238177), EPSRC, the EC FP7 ONE-P large-scale project N. 212311 for financial support.

ABSTRACT

In the present study, we demonstrate inkjet-printed n-type organic field-effect transistors (OFETs) and their complementary inverters with high performance uniformity, using soluble *N*,*N*′-bis(*n*-octyl)-(1,7&1,6)-dicyanoperylene-3,4:9,10-bis(dicarboximide) (PDI8-CN_2). The device performance and uniformity were improved by ink-jet printing a PDI8-CN_2 solution onto a heated substrate (60 °C). The printed features, which were discontinuous crystalline films at RT, were uniform films when the substrate temperature was increased to 60 °C. Optimized n-channel PDI8-CN_2 FETs showed a high field-effect mobility of 0.05–0.06 cm^2/Vs, a high on/off ratio of $\sim 10^6$, and a high uniformity that was within 10% with a bottom-gate/bottom-contact device configuration. Inkjet-printed organic complementary inverters were constructed by direct inkjet-printing of n-channel (PDI8-CN_2) and p-channel (6,13-bis(triisopropyl-silylethynyl)-pentacene or poly(3-hexylthiophene)) organic semiconductors onto silicon dioxide gate dielectrics. The inkjet-printed organic complementary inverters exhibited a high voltage gain of more than 15 and small standard deviation of inverting voltage and gain of ±0.95 V and ±0.56, respectively, for measuring 12 samples from four difference batches.

1. Introduction

Complementary metal–oxide–semiconductor (CMOS) inverters, which are composed of both p-type and n-type transistors, are fundamental logic circuits in current microprocessors and most advanced integrated circuits. The advantages of CMOS inverters include both higher noise immunity and lower static power consumption than n-type-only or p-type-only MOS inverters [1–3]. Currently, solution-processible organic field-effect transistors (OFETs) and complementary circuits are being developed to realize large-area flexible electronics, such as digital processors in radio-frequency identification (RFID) tags and driver circuits in full color flexible displays, via cost-effective graphic art printing techniques [4–6]. To achieve these low-cost and high-speed organic complementary circuits, high performance n- and p-channel OFETs that have well-balanced charge carrier mobility must be realized by direct printing methods. Earlier studies that aimed to develop soluble conjugated molecules as the active layer of OFETs were focused mainly on high-performance p-type organic semiconductors because of their facile chemical synthesis [7–10]. These previous studies resulted in the development of state-of-the-art, soluble p-type organic small molecules and polymers that exhibit field-effect mobilities, μ_{FET} ($\sim$1 cm^2/Vs), comparable to those of amorphous silicon transistors [9,10]. In recent years, research has focused on the development of high-performance and air-stable n-type conjugated molecules [6,11].

Inkjet-printing is a promising patterning method for the formation of active layers in OFETs and their integrated circuits. Inkjet-printing, which is an alternative to conventional photolithography, was recently applied in various processes required for the manufacture of microelectronic devices, such as formation of the color filter of a liquid crystal display and patterning of a luminescent polymer for an organic light-emitting display [12]. The direct-write ability and precise production of droplets with a constant volume enables to decrease device manufacturing costs due to simplification of the patterning process and minimization of material waste and contamination. Several groups have demonstrated inkjet-printed OFETs and inverters using conjugated small molecules or polymers [4–6,13]. OFETs fabricated by inkjet-printing of these small molecules typically have slightly superior μ_{FET} compared with conjugated polymers because highly crystalline films are readily formed. Inkjet-printing of one prototype molecule, 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene), resulted in a μ_{FET} as high as >1 cm^2/Vs [2,13]. The ability to control the features of the inkjet-printed film is very important for microelectronic applications, including OFETs, since the device functionality depends on well-defined and highly uniform deposits. For example, OFETs inkjet-printed with small molecules suffer from large differences in device performance due to non-uniform semiconducting films. The most common causes of non-uniform films are the relatively lower viscosity of the semiconducting ink and inhomogeneous drying of liquid droplets on a non-absorbing substrate, e.g., the coffee-ring effect [14]. Consequently, the conjugated solute localized near the boundary of the inkjet-printed deposits. The coffee-ring effect is typically minimized by using a mixture of high- and low-boiling-point solvents with different surface tension energies, which reduces the rate of evaporation at the boundary of the liquid deposit. Alternatively, increasing the substrate temperature also reduces the coffee-ring effect [15,16]. Lim et al. used the solvent-mixture approach to improve the performance and uniformity of inkjet-printed TIPS-pentacene OFETs [13]. However, this method was effective only for transistor channels with an abnormal circular geometry and is difficult to apply for poor solubility molecules to various organic solvents. Indeed organic semiconductors typically have poor solubility in low-surface-tension solvents.

Here, we report highly uniform OFETs that were inkjet-printed with an n-channel small molecular semiconductor, *N*,*N*′-bis(*n*-octyl)-(1,7&1,6)-dicyanoperylene-3,4:9,10-bis(dicarboximide) (PDI8-CN_2). The performance and uniformity were improved by inkjet-printing a PDI8-CN_2 solution onto a substrate that had been heated to 60 °C to enhance solvent evaporation. The printed features were changed from a discontinuous film composed of crystals of PDI8-CN_2 at room temperature (25 °C) to a uniform film as a result of heating the substrate. Optimized n-channel PDI8-CN_2 OFETs with a bottom-gate/bottom-contact (TG/BC) device configuration showed a reasonably high μ_{FET} of 0.05–0.06 cm^2/Vs with a gold source and drain electrode and a high uniformity within 10%. In addition, inkjet-printed organic complementary inverters were constructed by direct inkjet-printing of n-channel (PDI8-CN_2) and p-channel {small molecule (TIPS-pentacene) or polymer (poly(3-hexylthiophene), P3HT} organic semiconductors onto silicon dioxide gate dielectrics. The inkjet-printed organic complementary inverters using PDI8-CN_2 and P3HT showed a high voltage gain of more than 15 and small standard deviation of inverting voltage and gain of ±0.95 V and ±0.56, respectively, for measuring 12 samples from four difference batches.

2. Experimental

The soluble n-channel organic semiconducting material, PDI8-CN_2 (Polyera, ActivInk N1200), was used as received. The chemical structure of PDI8-CN_2 is shown in Fig. 1. The PDI8-CN_2 was dissolved in anhydrous chlorobenzene (CB) and 1,2-dichlorobenzene (DCB) to obtain a concentration of ca. 2–5 mg/ml, and the solution was filtered using a 0.2 μm PTFE syringe filter. By using a piezoelectric-type inkjet head (50 μm orifice diameter, Microfab, Inc.), uniformly sized droplets of the PDI8-CN_2 solution were made by controlling the voltage pulses at an operating frequency of 1 kHz. The formation of inkjet droplets was verified using a built-in CCD camera. Silicon wafers with a 300 nm-thick thermal oxide layer were used as substrates after cleaning in an ultrasonic bath using a series of solvents: de-ionized water, acetone, and isopropanol for 10 min each. The gold/nickel (Au/Ni) patterns for the source and drain (S/D) electrodes (Ni, adhesion layer) were fabricated using a conventional lift-off photolithography technique. The PDI8-CN_2 solutions were inkjet-printed onto the as-cleaned substrate at a temperature of 25, 40, 50, 60, or 70 °C in air. The substrate temperature (T_s) means the temperature of SiO_2 surface measured by a digitalized thermo-couple type thermometer. The inkjet-printed PDI8-CN_2 films were annealed at 110 °C for 20 min in a nitrogen-filled glove box with low oxygen and moisture levels (<5 ppm) to remove any residual

solvent and obtain an ordered crystalline morphology, which were verified by optical microscopy. The electrical characteristics were measured using a Keithley 4200-SCS in a nitrogen-filled glove box. The transistor parameters, such as the μ_{FET} and threshold voltage (V_{Th}) were calculated in the saturation regime using the standard formula for FETs.

3. Results and discussion

The formation of stable and uniform droplets with no satellite drops is the first step in the fabrication of OFETs by inkjet-printing. Fig. 2a shows captured images of PDI8-CN_2 droplets with chlorobenzene (CB) solvent at propagation delay times of 80 μs. The diameter, volume, and velocity of the PDI8-CN_2 droplets were measured as ca. 30–35 μm, 15–20 pl and 3.0–3.6 m/s, respectively. It is worth noting that selection of the appropriate PDI8-CN_2 solvent for use in inkjet-printing is the key to obtaining uniform printed features. PDI8-CN_2 showed good solubility in chloroform, which is not a suitable solvent for inkjet-printing due to its very low boiling point (BP) (61 °C). PDI8-CN_2 dissolved in high BP solvents, such as CB or 1,2-dichlorobenzene (DCB) at a low concentration (2–5 mg/ml). As shown in Fig. 2b, when a high BP and high surface tension energy solvent (DCB, BP = 161 °C, surface tension = 33.6 mN/m at 20 °C) was used, the crystalline feature of the printed single drops were well defined. Although the printed single drops using DCB appeared to have a crystalline domain with, typical crystal sizes (on average a few μm in diameter) were not large enough to permit their direct use as the active channel area. The typical channel length of the OFETs in the present study was ca. 2–20 μm. Therefore, uniform single lines, or overlapped inkjet-printed lines, are more desirable for complete interconnectivity between the S/D electrodes. Multi-drop inkjet-printing of the PDI8-CN_2 DCB solution at T_s = 25 °C created stacked single crystals with diameters of a few μm (Fig. 2c). It was very interesting that the organic single crystals formed immediately after dropping the PDI8-CN_2 solution onto the SiO_2/Si(n+) substrate. Presumably this happened because of the slow evaporation rate of the solvent and because the solubility of PDI8-CN_2 in DCB is only marginal (up to ca. 2 mg/ml). The PDI8-CN_2 single crystals are expected to show excellent performance in n-channel OFETs with high μ_{FET}. Although we are investigating inkjet-printed single crystalline PDI8-CN_2 FETs using DCB solvent, currently it is difficult to use the individual crystals as an active layer of OFETs, because sizes of single crystals are a relatively smaller than channel length. Therefore, we changed DCB to CB solvent providing more uniform and continuous PDI8-CN_2 films due to a relatively lower BP (131–132 °C) and better solubility.

Continuous and uniform inkjet-printed PDI8-CN_2 lines and films were obtained by using CB solvent Fig. 2d on a heated substrate (T_s = 40–70 °C). Fig. 3a and b show the typical output and transfer characteristics of an inkjet-printed PDI8-CN_2 OFET with a Au S/D electrode (channel width/length = 1 mm/20 μm). The transistor parameters, such as the μ_{FET} and the threshold voltage (V_{Th}), were calculated in the saturation or linear regime using the standard formula for FETs [17]. The best device, which was constructed using a substrate heated to 60 °C and no

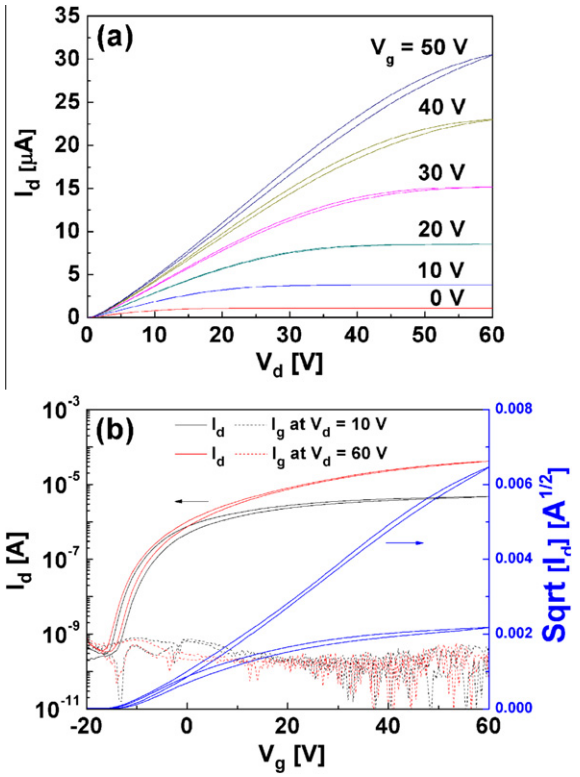

Fig. 3. (a) Output and (b) transfer characteristics of inkjet-printed PDI8-CN_2 transistors (W/L = 1 mm/20 μm). PDI8-CN_2 films were printed with CB solvent at T_s = 60 °C.

hydrophobic surface treatment, showed a high saturation μ_{FET} of 0.05–0.06 cm^2/Vs and a high on/off-current ratio of ~10^6. The device parameters are summarized in Table 1. The transfer curve showed a small bias hysteresis between forward and backward sweep which may be resulted from trapping of electrons in hydroxyl groups of SiO_2 surface and polycrystalline morphology of printed PDI8-CN_2 films. The gate leakage current was a few orders of magnitude smaller than unpatterned spin-coated devices due to patterned PDI8-CN_2 films by ink-jet printing.

In bottom-gate/bottom-contact (BG/BC) OFETs, the charge injection is highly dependent on the contact resistance (R_c), which includes the injection resistance of the charge (R_{inj}) at the metal–semiconductor interface and the bulk resistance (R_{bulk}) of the semiconductor [18]. R_{inj} is a function of the injection barrier height, which is primarily determined by the difference between the work-function of the injecting metal and the electron affinity/ionization potential of the semiconductor. R_{bulk} is largely determined by the local conductivity of the organic semiconducting film at the metal–semiconductor interface [4,19]. Therefore, the slightly reduced performance of a BG/BC device is mainly due to both the large electron injection barrier height (~0.7 eV) between work-function of gold electrode and lowest unoccupied molecular orbital (LUMO) energetic level of PDI8-CN_2 and the smaller charge injection area of a coplanar OFET compared with that of a staggered configuration. The slight deviation from linear for the BG/BC PDI8-CN_2 OFETs in the typically linear region of the output characteristics indicates a large R_c (Fig. 3a). Device performance can be improved by insertion of a specific self-assembly monolayer, which decreases the work-function of the injection electrode [20,21].

Fig. 4a shows the plot of μ_{FET} versus channel length (L) at various substrate temperatures (T_s) between 40 and 70 °C. All devices showed better μ_{FET} at the devices with L > 10 μm than devices with L < 10 μm due to the aforementioned decrease in the R_c between charge injection

Table 1
Device parameters of the inkjet-printed OFET at various substrate temperatures (T_s). The field-effect mobilities were calculated in the saturation region (drain voltage = ±60 V) using a standard device formula [5].

electrode and PDI8-CN_2. The relationship between the resistances of a FET and L is given by;

$$R_{on}(L) = R_{ch}(L) + R_p = \frac{L}{W\mu Ci(V_G - V_T)} + R_p \quad (1)$$

where R_{on}, R_{ch}, and R_p are the total, channel, and parasitic resistance of a transistor, respectively. W is the channel width, C_i is the gate capacitance per unit area. The parasitic resistance (R_p), which is mainly composed of R_c, exceeds R_{ch} and dominates R_{on} when L is small. Therefore, PDI8-CN_2 transistors showed inferior μ_{FET} when $L < 5$ μm. The threshold at which L has a significant impact on R_c is between 5 and 10 μm. The best PDI8-CN_2 device, which was achieved at $T_s = 60$ °C, showed very high performance uniformity with only a 10% deviation from the average μ_{FET} obtained for 50 measured devices with four different substrates and showed 100% yield. Although printed PDI8-CN_2 lines showed the coffee-ring effect at $T_s = 60$ °C as shown in Fig. 2d, devices showed very uniform characteristics since charges mainly transport through one and two monolayers placed at embedded semiconductor-SiO_2 dielectric interface not uneven top surfaces of printed films. The high performance uniformity might be attributed to the uniform printed features at the high T_s. By contrast, devices with an active layer that was inkjet-printed at low T_s showed a lower μ_{FET} with a large deviation in performance uniformity due to the inhomogeneous drying of the liquid droplets. The low rate of solvent evaporation resulted in the formation of micro-sized crystals (Fig. 2b). However,

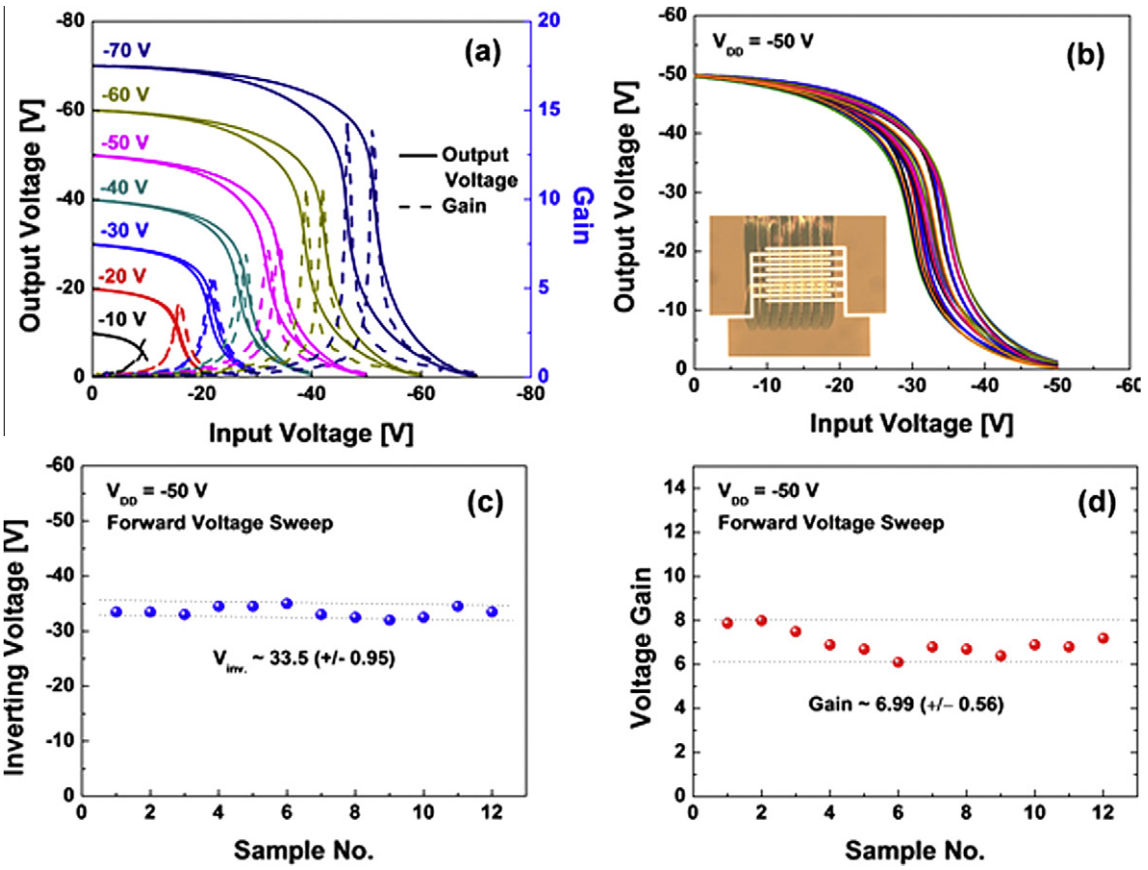

Fig. 5. Complementary organic inverter characteristics using the inkjet-printed PDI8-CN_2 and P3HT [SiO_2 300 nm, $L = 20$ μm, $W_n/W_p = 1$ mm/10 mm]. PDI8-CN_2 and P3HT were inkjet-printed at $T_s = 60$ °C and RT, respectively. (a) Voltage transfer characteristics (VTC) curves at various supplied voltages (V_{DD}) from −10 V to −70 V. Statistical characteristics of the organic inverters, (b) VTC curves [inset: optical microscope image of inkjet-printed P3HT film feature], (c) inverting voltages, and (d) voltage gains at the $V_{DD} = -50$ V during forward voltage scan.

device performance did not increase further when higher T_s were used (>70 °C), because too rapid evaporation of the solvent caused poor crystallinity in the semiconducting film.

The PDI8-CN_2 FETs were incorporated with different types of p-channel semiconductors {soluble small molecule (TIPS-pentacene) or polymer (P3HT)} into complementary inverters. TIPS-pentacene and P3HT were used as-received and were dissolved in anhydrous toluene (10 mg/ml) and CB (5 mg/ml), respectively. TIPS-pentacene and P3HT solutions were inkjet-printed onto a clean SiO_2/Si(n++) substrate at T_s = 60 °C and RT, respectively, followed by a thermal annealing at 110 °C for 20 min in N_2. The TIPS-pentacene transistors (0.005–0.01 cm^2/Vs) typically showed a higher μ_{FET} and better balanced performance with PDI8-CN_2 than those of P3HT (ca. 1×10^{-3} cm^2/Vs). The TIPS-pentacene/PDI8-CN_2 inverters showed a high voltage gain as high as 30 and had the inverting voltage (V_{int}) near half point of the supplied voltage (½V_{DD}) (not shown here) after adjustment of W/L ratio to 5:1 for those p- and n-type transistors. However, it was observed that the relatively large standard deviation of the V_{int} (±1.9 V) and voltage gains (±4.78) was induced mainly from TIPS-pentacene OFETs, which showed a large bias hysteresis and μ_{FET} and V_{Th} fluctuation presumably due to less optimized film morphology of the inkjet-printed p-type small molecular semiconductor.

Statistical characteristics and its standard deviation of the inkjet-printed organic complementary inverters can be improved by using p-channel polymer semiconductors, since polymer semiconductors typically exhibited better device-to-device printed-film uniformity (see inset in Fig. 5b) than those of small molecules. Inkjet-printed P3HT OFETs showed lower μ_{FET} (ca. 1.3×10^{-3} cm^2/Vs) than TIPS-pentacene, as shown in Fig. 5a, so that voltage transfer characteristics curve of the PDI8-CN_2/P3HT inverters still shifted from ½V_{DD} in the negative direction even after adjustment of W/L ratio of p-type and n-type transistors up to 10:1. The voltage gain was up to 15 by proportional to increase in the V_{DD}. Statistical characteristics of complementary inverters exhibited much improved by reduction of standard variation of the p-channel transistor properties. PDI8-CN_2/P3HT CMOS inverters showed average inverting voltage ($V_{inv.}$) and voltage gains of −33.5 V and 6.99 with the small standard deviation of ±0.95 V and ±0.56, respectively, for measuring 12 samples from four difference batches. Consequently, this inkjet-printed n-type OFETs can be utilized in a variety of organic electronic applications, such as drivers for display backplanes, digital or analog circuits in printed RFID tag, organic memory, and sensors [22–26].

4. Conclusion

In conclusion, we have demonstrated high performance inkjet-printed n-type organic transistors and their complementary inverters. The device performance and uniformity were improved by inkjet-printing a PDI8-CN_2 solution onto a heated substrate (60 °C) and by selection of the optimal organic solvent (CB). The inkjet-printed features, which were initially discontinuous crystalline domains at RT, were converted to continuous films when the substrate temperature was increased to 60 °C. When we measured more than 50 n-type OFETs, those devices showed highly uniform μ_{FET} and V_{Th} within 10% standard deviation. The optimized n-channel PDI8-CN_2 FETs were integrated into inkjet-printed organic complementary inverters in combination with TIPS-pentacene or P3HT OFETs. The inkjet-printed PDI8-CN2/P3HT inverters exhibited a high voltage gain of more than 15 and small standard deviation of inverting voltage and gain of ±0.95 V and ±0.56, respectively, for measuring 12 samples from four difference batches.

ABSTRACT

Enhanced performances of hybrid polymer solar cells based on a blend of poly[2-methoxy-5-(2′-ethyl-hexyloxy)-1,4-phenylene vinylene] (MEH-PPV) and *p*-methoxybenzoic acid (MBA) modified zinc oxide (ZnO) nanoparticles were reported. Both the short-circuit current and open-circuit voltage of solar cells were improved by using MBA modified ZnO nanoparticles as electron acceptor. The overall power conversion efficiency was increased from 1.09% to 1.52% under AM 1.5 G 100 mW/cm^2 illumination after ZnO was modified with MBA at 0.1 wt.%. It was found that modification of ZnO with 0.1 wt.% of MBA did not affect electron and hole transport properties of the active layer. However, a fine phase separation between MEH-PPV donor and MBA-modified ZnO acceptor was obtained. The fine phase separation enhanced the exciton dissociation efficiency and hence the power conversion efficiency of solar cells.

1. Introduction

Hybrid solar cells using conjugated polymers as electron donors and inorganic semiconductor nanocrystals as electron acceptors have attracted a lot of attention in recent years due to the combined merits of both materials: solution processability of conjugated polymers, high electron mobility and low-cost fabrication of inorganic semiconductor nanocrystals. By far, several kinds of hybrid polymer solar cells have been reported using CdSe [1–5], CdS [6], TiO_2 [7–12] and ZnO nanocrystals [13–17] as electron acceptors. Efficient hybrid solar cells with power conversion efficiency (PCE) over 2% have been obtained by using CdSe and TiO_2 nanocrystals as electron acceptors [5,9]. However, CdSe nanocrystal has high toxicity and TiO_2 nanocrystal has high crystallization temperature. ZnO nanocrystal is a more promising candidate for electron acceptor due to its non-toxicity and low crystallization temperature properties.

Because of short exciton diffusion length (less than 10 nm) in semiconducting polymers, only excitons generated within 10–20 nm distance from the donor/acceptor interface can diffuse to the interface and dissociate into free carriers [18–20]. Therefore, a bulk heterojunction structure with nanoscale donor–acceptor phase separation is required to realize efficient exciton dissociation [21]. The main challenge for hybrid polymer solar cells is the large phase separation between polymer donors and inorganic semiconductor acceptors due to the high surface polarity of inorganic nanocrystals [22,23]. Studies have been done to achieve hydrophobic surfaces of inorganic semiconductor nanocrystals via surface modification with conductive ligands to reduce the polymer/inorganic nanocrystal phase separation in hybrid polymer solar cells [24,25]. However, few result has been reported on simultaneously reducing the phase separation and enhancing the PCE of ZnO-based hybrid polymer solar cell. Ravirajan et al. reported enhanced charge separation yield in hybrid polymer solar cell

based on poly(3-hexylthiophene) (P3HT) and amphiphilic ruthenium complex (Z907) modified ZnO nanorods, whereas the PCE of the cell was only 0.2% [26]. Said et al. reported recently a hybrid solar cell based on P3HT and porphyrin-modified ZnO nanorods in which the phase separation between P3HT and ZnO nanorods was increased, the short-circuit current (J_{sc}) and PCE were reduced [27].

In this work, we report enhanced performances of hybrid polymer solar cells using poly[2-methoxy-5-(2′-ethyl-hexyloxy)-1,4-phenylene vinylene] (MEH-PPV) as donor and *p*-methoxybenzoic acid (MBA) modified ZnO nanoparticles as acceptor. MBA was selected as the ZnO surface modifier because its small size may not influence the charge transport between ZnO nanocrystals. Moreover, the MBA may possess good compatibility with MEH-PPV since both of them have alkoxy groups. Compared to the control solar cell based on MEH-PPV: as-prepared ZnO blend, solar cells with MBA-modified ZnO showed improvements on both the J_{sc} and open-circuit voltage (V_{oc}) and the resulted 50% increasing on PCE. The effect of MBA modification on the film morphologies and the charge transport properties of the MEH-PPV:ZnO composite film was discussed in detail.

2. Experimental section

The MEH-PPV (Fig. 1) was purchased from Canton OLEDKING Optoelectronic Materials Co., Ltd. and used as received. ZnO nanocrystal with a diameter of about 5 nm was prepared according to the literature [16]. Zinc acetate dihydrate (2.95 g, >99%) was dissolved in methanol (120 mL) at 60 °C under vigorous stirring. 1.48 g of KOH (>85%) was dissolved in methanol (60 mL). The KOH solution was dropped into the zinc acetate dihydrate solution in 10 min under vigorous stirring. The solution temperature was held at 60 °C and stirred for 4 h, and then the heating and stirring were removed to allow particles to precipitate for additional 12 h. The precipitate was cleaned by centrifugation of the dispersion and washed twice with 50 mL of methanol. The washed ZnO nanoparticles were dissolved in 5 mL of chlorobenzene and were formed ZnO solution with a concentration of 120 mg mL^{-1}. The surface modification of ZnO was done by adding quantitative MBA into ZnO chlorobenzene solution.

The hybrid polymer solar cells with a structure of indium–tin oxide (ITO) anode/PEDOT:PSS/MEH-PPV:ZnO/Al cathode were prepared as shown in Fig. 1. The ITO-coated glass substrate with a sheet resistance of 10 Ohm/square was cleaned with detergent and deionized water in sequence and then dried at 120 °C for 30 min. The ITO substrate was treated with UV ozone cleaner for 10 min. A 40-nm-thick PEDOT:PSS layer was spin-coated onto the ITO substrate and baked at 120 °C for 30 min in ambient. A solution comprising MEH-PPV and ZnO nanocrystal (with or without MBA modification) with a weight ratio of 1:3.3 in chlorobenzene was spincoated on top of the PEDOT:PSS layer to produce a 100-nm-thick active layer. Finally, the device was completed by depositing a 100 nm Al cathode on top of the active layer in vacuum chamber under a base pressure of 4×10^{-4} Pa. The illuminated current density–voltage (*J–V*) characteristics of the solar cells were tested using a Keithley 236 source meter under AM 1.5 G 100 mW/cm^2 illumination from a calibrated solar simulator filtered with GG420 filter to remove UV irradiation. The external quantum efficiency (EQE) was measured under short-circuit condition with a lock-in amplifier (SR830, Stanford Research System) at a chopping frequency of 280 Hz during illumination with the monochromatic light from a Xenon lamp.

Fourier transformed infrared (FTIR) spectroscopy in absorption mode was recorded with a BRUKER Vertex 70 FTIR spectrometer using pressed KBr tablets. The samples for FTIR analysis were obtained by drying the ZnO nanoparticles just after the washing process (as-prepared ZnO) or surface modification procedure (2% MBA-modified ZnO is used due to the detecting sensitivity of the FTIR spectrometer). Water contact angle test was performed on a DSA10 Control UNIT. Transmission electron microscopy (TEM) of the MEH-PPV:ZnO blend films was conducted on a JEM-1011 transmission electron microscope operated at an acceleration voltage of 100 kV. The samples for TEM observation were obtained by stripping the active layer off the underlying PEDOT:PSS layer and then transferred onto a carbon-coated copper grid. Ultraviolet photo-

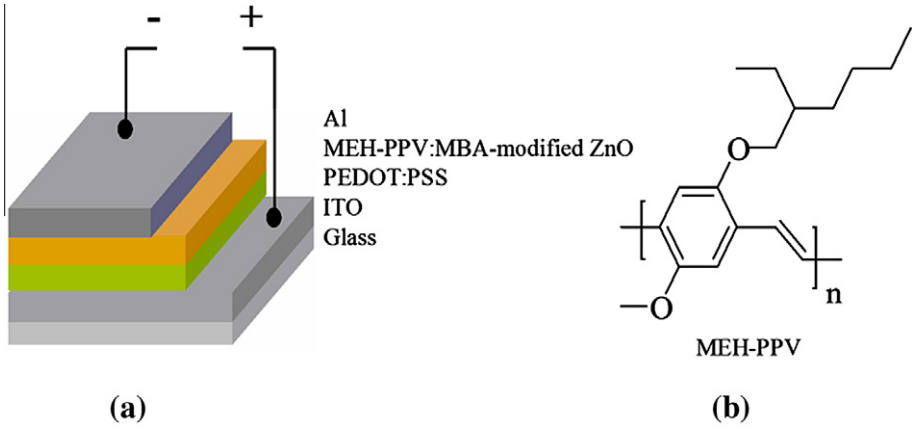

Fig. 1. (a) The device configuration of MEH-PPV:MBA-modified ZnO hybrid solar cell and (b) the chemical structure of MEH-PPV.

electron spectroscopy (UPS) measurement of as-prepared and 0.1% MBA-modified ZnO were performed on Thermo ESCALAB 250 with HeI (21.2 eV) as monochromatic light source. The absorption spectra of as-prepared and 0.1% MBA-modified ZnO were measured using a Perkin–Elmer 35UV–vis spectrophotometer on quartz substrates.

3. Results and discussion

To verify the adsorption of MBA ligand onto the ZnO surface, FTIR spectroscopy of the MBA-modified and as-prepared ZnO samples was recorded in absorption mode. Fig. 2 showed the FTIR spectra of the MBA, as-prepared ZnO and 2% MBA-modified ZnO. The main bands and their assignments for MBA were as follows: stretching vibration of the aromatic ring ν(C=C)/ν(C–C) at 1603 and 1516 cm^{-1}, the symmetric and asymmetric stretch of CO in OCH_3 group ν_s(C–O) at 1261 cm^{-1} and ν_{as}(C–O) at 1027 cm^{-1}, the ν(C=O) stretch in COOH at 1686 cm^{-1}, the bending vibration of CH in aromatic ring γ(C–H) at 845 and 773 cm^{-1}, and the ν(O–H) in COOH at 2500–3000 cm^{-1}. For the as-prepared ZnO sample, the band at 441 cm^{-1} was attributed to the stretching vibration of ZnO. The $\nu_{as}(COO^-)$ at 1582 cm^{-1} and $\nu_s(COO^-)$ at 1416 cm^{-1} were characteristics for a carboxylic group being coordinated to a metal. They were assigned to the acetates adsorbed on ZnO surface. The stretch ν(O–H) at 3420 cm^{-1} was assigned to hydroxyl group of methanol adsorbed on ZnO surface. In the case of the MBA-modified ZnO sample, the stretching vibration of the aromatic ring ν(C=C)/ν(C–C) at 1608 and 1512 cm^{-1}, the ν_s(C–O) and ν_{as}(C–O) of OCH_3 group at 1257 and 1032 cm^{-1}, the γ(C–H) of aromatic ring at 853 and 785 cm^{-1} were observed. However, the characteristic bands of carboxylic group, namely, ν(C=O) stretch at 1686 cm^{-1}, and the wide band located around 2500–3000 cm^{-1} of the ν(O–H) in COOH disappeared. The asymmetric stretch, $\nu_{as}(COO^-)$ at 1561 cm^{-1}, and symmetric stretch, $\nu_s(COO^-)$ at 1421 cm^{-1} were presented, indicating

that the carboxylic group in MBA was coordinated to ZnO nanocrystals and formed carboxylate complexes.

The illuminated *J–V* characteristics of the hybrid polymer solar cells based on MEH-PPV:MBA-modified ZnO composites with different weight ratios of MBA to ZnO (0%, 0.01%, 0.1% and 0.5%) are shown in Fig. 3a. The MEH-PPV: ZnO solar cell shows a V_{OC} of 0.82 V, a J_{SC} of 2.89 mA cm^{-2}, and a fill factor (*FF*) of 0.46, respectively. The overall PCE of this cell is about 1.09%. It is noted that the MEH-PPV:MBA modified ZnO solar cells show enhanced V_{OC}, J_{SC} and *FF* compared to the MEH-PPV: as prepared ZnO control cell. Interestingly, the J_{SC} of the solar cells based on MEH-PPV:MBA-modified ZnO blends increases initially at low content of MBA and then decreases at high content of MBA. The highest J_{SC} of 3.45 mA cm^{-2} is achieved for the MEH-PPV: 0.1 wt.% MBA modified ZnO solar cell. This cell also shows a V_{OC} of 0.88 V and an *FF* of 0.5, leading to a maximum PCE of 1.52%. When the weight percentage of MBA is increased to 0.5%, the J_{SC} of the resulted solar cell drops but the V_{OC} keeps unchanged. The EQE curves of the hybrid solar cells are shown in Fig. 3b. The MEH-PPV:0.1% MBA-modified ZnO solar cell shows a maximum EQE of 49%, much higher than 39% of the MEH-PPV:ZnO solar cell.

To understand the variation in J_{SC}, the effect of MBA surface modification of ZnO on the morphology of

MEH-PPV:ZnO composites was studied. TEM images of the MEH-PPV:MBA-modified ZnO composite films with various weight ratios of MBA to ZnO are shown in Fig. 4. The dark regions in the images are assigned to ZnO-rich domains and the bright regions are assigned to MEH-PPV-rich domains based on larger mass density of ZnO nanocrystal than that of MEH-PPV. It can be seen that the MEH-PPV:MBA-modified ZnO composite films show smaller ZnO aggregates than those in the MEH-PPV:ZnO composite film. It may be attributed to reduced surface polarity of ZnO nanocrystals by MBA modification. This is also supported by the water contact angle results of the as-prepared and 0.5 wt.% MBA-modified ZnO films as shown in Fig. 5. It can be seen that the water contact angle of ZnO nanocrystal film is increased from 30° to 51° after MBA surface modification. The result demonstrates that a more hydrophobic ZnO surface has formed. As mentioned before that the exciton diffusion length in conjugated polymers is merely about 10 nm, the fine phase separation between the MEH-PPV donor and ZnO acceptor is favorable for efficient exciton dissociation and for enhancement of J_{SC}. Thus, it is understandable that the MEH-PPV:0.01 wt.% MBA-modified ZnO solar cell only shows a slightly increased J_{SC} due to insignificant improvement of the MEH-PPV:ZnO composite morphology. The maximum J_{SC} is obtained in the MEH-PPV:0.1 wt.% MBA-modified ZnO solar cell, although the MEH-PPV:0.5% MBA-modified ZnO composite film demonstrates a more uniform phase separation at nanoscale.

To gain further insight into the variation in J_{SC}, the charge transport characteristics in MEH-PPV:ZnO composite films was investigated by single carrier devices. Fig. 6 shows the experimental dark J–V curves of the electron-only and hole-only devices. For electron-only devices, Al

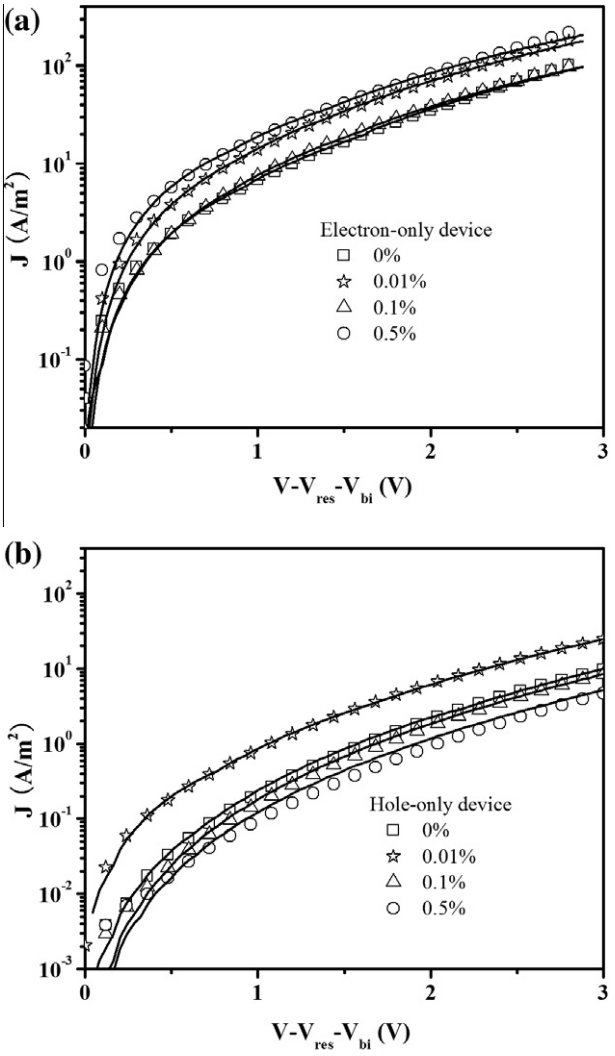

Fig. 6. The dark J–V characteristics, corrected for built-in voltage (V_{bi}) and series resistance (V_{res}), of the electron- and hole-only devices: (a) electron-only devices with a structure of Al/MEH-PPV:ZnO (x_1 nm)/Al, where x_1 equals 210, 165, 210 and 150 nm for devices based on 0%, 0.01%, 0.1% and 0.5% MBA-modified ZnO and (b) hole-only devices with a structure of ITO/PEDOT:PSS/MEH-PPV:ZnO (x_2 nm)/MoO_3/Al, where x_2 equals 170, 150, 170 and 160 nm for devices based on 0%, 0.01%, 0.1% and 0.5% MBA-modified ZnO. The experimental data are fitted (shown by solid lines) with a space–charge-limited current.

was used as bottom electrode to suppress hole injection into the MEH-PPV:ZnO active layer. For hole-only devices, the top cathode Al was replaced by MoO_3/Al to suppress electron injection. The electron and hole mobilities in MEH-PPV:ZnO composite films are calculated by space-charge-limited current (SCLC) in the hole- and electron-only devices [28]:

$$J_{e(h)} = \frac{9}{8}\varepsilon_r\varepsilon_0\mu_0\frac{V^2}{L^3}\exp\left(0.89\beta\sqrt{\frac{V}{L}}\right) \quad (1)$$

where $J_{e(h)}$ is the electron (hole) current density, μ_0 the zero-field mobility of electron (hole), β is the field activation factor, ε_0 is the permittivity of free space, ε_r is the relative permittivity of the material, and L is the thickness of the active layer. The experimental data in Fig. 6 were fitted using Eq. (1) and the results were shown by the solid lines. Electron mobilities of 1.06×10^{-9}, 1.15×10^{-9}, 1.02×10^{-9}, 1.6×10^{-9} $m^2\,V^{-1}\,s^{-1}$ and hole mobilities of 8.7×10^{-11}, 9.2×10^{-11}, 7.2×10^{-11} and 1.9×10^{-11} $m^2\,V^{-1}\,s^{-1}$ were obtained for the MEH-PPV:MBA (0%, 0.01%, 0.1% and 0.5%)-modified ZnO composite films. It was noted that the electron mobility in the MEH-PPV: 0.5 wt.% MBA-modified ZnO composite film was slightly higher than electron mobility in other devices. This was attributed to smaller ZnO aggregates in that composite film, which reduced the distance between ZnO aggregates and led to favorable electron hopping between them. It also indicated that low content of MBA ligands did not hinder the electron transport between ZnO aggregates. The average numbers of MBA molecule attached to each ZnO nanoparticle were calculated to be 0.13, 1.3, 6.5 for 0.01, 0.1 and 0.5 wt.% of MBA, respectively. It corresponded to a coverage of 0.04%, 0.4% and 2% of ZnO surface by MBA molecules, assuming a perpendicular orientation of MBA molecules relative to ZnO surface and an occupied surface area of 0.25 nm^2 [29]. Although electron hopping between ZnO aggregates had not been hindered by MBA ligands, the hole mobility in MEH-PPV:0.5 wt.% MBA-modified ZnO composite film was reduced to about one fifth of that in MEH-PPV: as prepared ZnO composite film. The decreasing of hole mobility may be attributed to the restrained packing of MEH-PPV polymer chains in ZnO dispersed matrix. Hence, it was concluded that the decreased J_{SC} for the solar cell based on MEH-PPV:0.5% MBA-modified ZnO composite film resulted from the decreasing of hole mobility. The highest J_{SC} of the MEH-PPV:0.1 wt.% MBA-modified ZnO solar cell was resulted from a tradeoff between the exciton dissociation and charge collection in MEH-PPV:ZnO composite film.

In addition to the enhanced J_{SC}, the V_{OC}s of the MEH-PPV:MBA-modified ZnO solar cells were also improved compared to the MEH-PPV:ZnO solar cell. In order to clarify the origin of the increased V_{OC}, both absorption and UPS experiments were carried out to determine the effect of MBA modification on ZnO electronic energy levels. The absorption spectra for both ZnO and 0.1% MBA-modified ZnO (the inset of Fig. 7a) showed the same absorption onset at 360 nm, indicating an unchanged band gap of 3.44 eV. The UPS spectra for ZnO and 0.1 wt.% MBA-modified ZnO displayed the same spectrum width of 13.53 eV

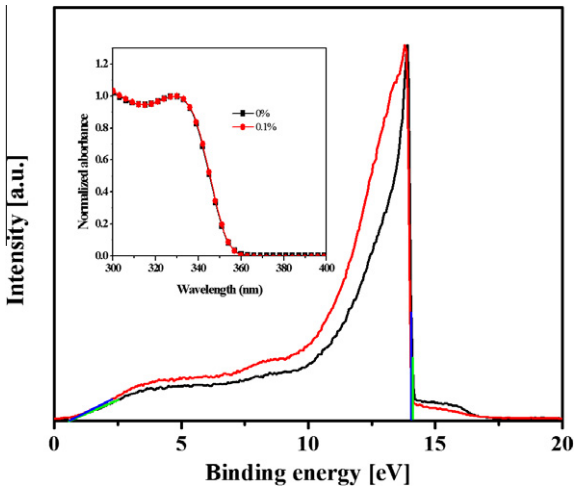

Fig. 7. UPS spectra for ZnO and 0.1% MBA-modified ZnO samples. The inset shows normalized absorption spectra for ZnO and 0.1% MBA-modified ZnO.

(Fig. 7). The same highest occupied molecular orbital (HOMO) of 7.67 eV and the same lowest unoccupied molecular orbital (LUMO) level of 4.23 eV were estimated for ZnO and 0.1% MBA-modified ZnO. Vandewal et al. reported that V_{OC} of polymer-fullerene solar cells scaled linearly with the band gap of charge-transfer state ($E_{eff,g}$, effective bandgap of donor and acceptor blends) which was determined by the difference between the HOMO energy level of donor and LUMO energy level of acceptor [30]. They pointed out that $E_{eff,g}$ was influenced by the active layer morphology for a given donor and acceptor blends with constant composition ratio. In our case, the packing of MEH-PPV chains was restrained by improved dispersion of MBA modified ZnO in matrix. The restrained packing of polymer chains may lower the HOMO energy level of MEH-PPV and thus resulted in increasing of V_{OC}.

4. Conclusions

In summary, hybrid polymer solar cells using MBA-modified ZnO nanocrystal as electron acceptor are fabricated. The poor compatibility between MEH-PPV and ZnO is well resolved via ZnO surface modification by MBA. The methoxyl group in MBA molecule renders ZnO surface more hydrophobic that improves the dispersion of ZnO nanocrystals in MEH-PPV matrix. The electron transport between ZnO aggregates is not influenced by MBA surface modification of ZnO, while the hole transport in MEH-PPV domains is reduced with high content of MBA. The highest J_{SC} can be achieved by coordinately optimizing the composite film morphology and charge transport properties. The power conversion efficiency of the hybrid solar cell with MBA-modified ZnO has increased up to 50% compared to solar cell with as-prepared ZnO.

ABSTRACT

A simple, low cost, and scalable process based on sandblasting to modify the OLED substrate's surface, has been successfully developed. The rough surface produced by sandblasting efficiently suppressed the internally generated photons' waveguide mode, and enhanced the white OLED's EQE from 9% to 11.6% without changing the emission spectrum and the Lambertian emitter property. The improvement of the EQE was found to monotonically decrease with the surface roughness within the roughness range from around 1 μm to 3 μm. The white OLED's luminous efficiency was increased from 15.5 cd A^{-1} to 20 cd A^{-1}. Furthermore, the realization of rough surface on a 3.5 inch white lighting panel not only improved the 9-point uniformity from 80% to 90%, but also demonstrated the manufacturing scalability of the sandblasting technique.

1. Introduction

Due to their promising applications in full-color flat-panel displays, backlights for liquid-crystal displays (LCD), and solid-state lighting sources, organic light-emitting diodes (OLED) have attracted considerable interests since their discoveries [1–5]. Through collective efforts by world-wide researchers, and heavy investments by display companies, OLED technology has been commercialized in the display industry in the past decade. Recently, the development of white OLEDs (WOLEDs) for the application in the solid-state lighting became the focus of OLED researches. The power efficiency (PE) of WOLEDs based on small molecules has been reported to reach 90 lm W^{-1} [6], while the PE of WOLEDs based on semiconducting conjugated polymers has exceeded 20 lm W^{-1} [7,8], for the devices without any substrate's surface modifications. Since the internal quantum efficiency almost reached 100% [9–11], how to improve the external quantum efficiency is critical for WOLEDs' success in the lighting industry.

The relationship between the internal quantum efficiency (IQE) defined as the number of generated photons per injected carrier, and the external quantum efficiency (EQE) defined as the number of photons emitted into the viewing direction per injected carrier [12], is expressed in the following equation:

$$\eta_{EQE} = \eta_{IQE} \times \eta_{OUT} \quad (1)$$

where η_{OUT} is the light output coupling efficiency. As schematically illustrated in Fig. 1a, a large portion of internally generated lights can not exit the OLED devices' forward viewing side, due to the total reflection at the interface between the air and the transparent device substrate which generally has a high refraction index value. The light output coupling efficiency determines how much lights can escape from the device in the forward viewing direction. For a smooth plane device surface, the η_{OUT} is given by [13]:

$$\eta_{OUT} = 1 - \frac{3}{4}\left\{\sqrt{1-\frac{1}{n^2}} + \frac{1}{3}\left(1-\frac{1}{n^2}\right)^{\frac{3}{2}}\right\} \approx 0.75n^{-2} \quad (2)$$

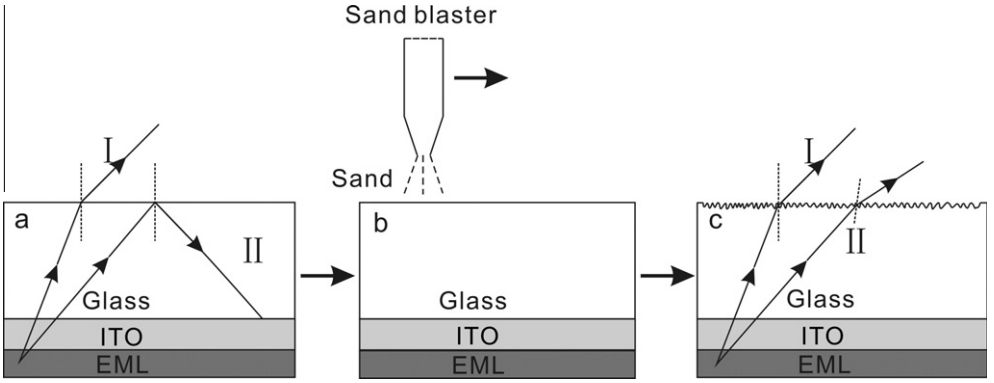

Fig. 1. Schematics of (a) the propagation of lights from an OLED device with smooth surface substrate. I represents the escaped lights, and II represents the trapped lights; (b) sandblasting process; and (c) the propagation of lights from an OLED device with rough surface substrate. Both lights I and II can escape from the OLED surface.

where n is the refraction index of the substrate. Taking the refraction index of the glass ($n \sim 1.5$), the η_{OUT} is only 0.33, meaning that two thirds of the generated lights are trapped inside.

To address the output coupling issue, two directions are generally considered: lowering the substrate's refraction index, or modifying the light's incident angle at the substrate–air interface. Tsutsui's group used silica aerogel with n around 1 as the device substrate to double the EQE [14]. However, the fragility and porosity of the silica aerogel prevents its use in real applications. To modify the light's incident angle, various approaches have been attempted, such as mesa structures [15], spherical substrate [6,16,17], microlens array [18], Bragg grating [19–21], corrugated structures [22–24], textured surface [25,26], and so on. However, all the methods aforementioned required complicated substrate process, including precise photolithography [15,18–23,25,26], lamination [6,16], stamping [18,24], self assembly [17], etc. Moreover, some of the device structures like spherical substrate, or mesa structure are impractical in the application of large area, plane light source. It's clear that a simple, scalable, and low cost process suitable for large size substrate in the industrial manufacturing facility is critical for the success of WOLED as solid-state lighting source.

In our contribution, we developed a novel process to roughen the substrate surface via sandblasting. The sandblasting technique, was first mentioned by Prof. Baldo's group [27], and was realized in a green small moledule OLED by Prof. Kwok's group [28]. The rough surface on OLED device will change the emitted lights' incident angle at the substrate–air interface, leading to more escaped photons in the forward viewing direction as illustrated in Fig. 1(c). By employing the sandblasting method, the maximum brightness of the WOLED was enhanced 42.5%, and the external quantum efficiency was increased 28.9%. Through the accurate control of the surface roughness, we found a linear dependence of the EQE improvement on the surface roughness in the roughness range from around 1 μm to 3 μm. The successful demonstration of the sandblasting technique on a 3.5 inch WOLED lighting panel shows the great potential of such technology in real manufacturing.

2. Experiments

To demonstrate the rough surface effects on the external quantum efficiency, solution processed WOLEDs with the device configuration of ITO/poly(ethylendioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS)(50 nm)/poly(*N*-vinylcarbazole) (PVK)(40 nm)/light emitting layer (60 nm)/Ba(4 nm)/Al(200 nm) were fabricated. The white light emission was achieved by doping a blue emitting conjugated dendrimer G0 with phosphorescent green emitter Ir(mppy)$_3$, and red emitter Ir(piq)$_2$acac. The blue light device was made with G0 only, while the red and green devices were obtained by doping PVK with Ir(piq)$_2$acac and Ir(mppy)$_3$, respectively. The molecular structures of the materials and the device structures are detailed in our early publication [29,30]. All chemicals and materials were purchased and used as received. PVK was purchased from Aldrich. Ir(piq)$_2$acac and Ir(mppy)$_3$ were purchased from American Dyes Sources. PEDOT:PSS was CleviosTM P Al 4083 from H. C. Starck GmbH. G0 was provided by Prof. Jian Pei in Peking University, Beijing, China [29]. Device fabrication followed well-established processes that have been described elsewhere [30]. The current density (J)-voltage (V)-luminance (L) characteristics were obtained using a Keithley 236 source meter and a silicon photodiode calibrated by a Chroma Meter CS-200 (Konica Minolta). The EL spectra and CIE coordinates were recorded by a PR-705 SpectraScan Spectrophotometer (Photo Research). The EQEs were obtained in an integrating sphere (IS-080, Labsphere). To measure the forward viewing EQE, the edges of the devices were covered by the black ink. No lights escaped from the device edges.

Sandblasting is one of the abrasive blasting techniques, which uses high-pressure air to blow a stream of sands against a surface. It's widely used for refurnishing buildings, creating art works, cleaning surfaces, etc. In display industry, as a low cost and scalable process, sandblasting is adopted for making barrier ribs on the rear panel of the plasma display panel. Fig. 2 shows the three dimensional pictures of the glass substrate's surface before and after sandblasting. The glass surface became textured from smooth after sandblasting. To characterize the rough

surface topology, Average Roughness, universally called Ra, is the standardized parameter. It is defined as arithmetic mean of the departures of the profile from the mean line over a given length [31]. In the following experiments, Ra is specified and measured by a confocal laser scanning microscope (OLYMPUS-OLS3100) for the roughness characterization.

Sandblasting provides a variety ways to modify the surface morphology, for example: the sand injection pressure, the blasting frequency, the size of the sand, the spraying angle, the distance between the spray nozzle and the substrate, etc. In our experiment, we set the distance from the nozzle to the glass substrate at 10 cm, the spraying angle at zero degree (perpendicular to the substrate surface), the sand injection pressure at 3.92×10^4 Pa, and the blasting frequency at 1 Hz. While fixing all the other parameters, we changed the size of the white corundum sand (from 20 μm to 60 μm) to obtain different but reproducible surface roughness. The sandblasting machine is Model 6090B from Jichuan International (Hong Kong) Co., Ltd. The sands were purchased from Zhengzhou Fengda Abrasive Materials (China) Co., Ltd.

3. Results and discussion

The WOLED device with smooth substrate surface (W1) has a peak PE of 9.0 lm W^{-1} at 5.0 V, and a peak luminous efficiency (LE) of 15.5 cd A^{-1} at the current density of 0.334 mA cm^{-2}. The maximum luminance reaches 30,151 cd m^{-2}. By introducing the rough surface substrate with Ra = 1.266 μm, the device performance is significantly enhanced. As summarized in Table 1, the WOLED device with rough substrate surface (W2) has a peak PE of 11.1 lm W^{-1} at 5.25 V, a peak LE of 20 cd A^{-1} at the current density of 0.654 mA cm^{-2}, and a maximum brightness of 42,978 cd m^{-2}. The performance improvements in terms of PE, LE and brightness are 23.3%, 29% and 42.5%, respectively. More important, the EQE is enhanced by 28.9%, from 9% to 11.6%.

By carefully examining the *J–V–L* characteristics of the two WOLED devices (Fig. 3a), it's clear that the EQE enhancement by the rough surface is totally due to the optical output coupling efficiency, because the electrical properties (*J–V* curves) of W1 and W2 are identical. It's worth to note that the turn-on voltage (defined as the operation voltage at which 1 cd m^{-2} is collected in the forward viewing direction) of W2 is 0.25 V lower than that of W1, which also confirms that more lights pass through the rough surface than the smooth surface. Under the operation brightness of 3000 cd m^{-2}, W2 has a smaller current density of 18.6 mA cm^{-2}, and a lower operation voltage of 8.5 V, compared to those of W1 which are 21.7 mA cm^{-2} and 8.75 V, respectively. As a result, rough surface device W2 has a higher PE of 6 lm W^{-1} at the operation brightness, leading to reduced power consumption. The comparison of the two devices' LE and PE's dependence on the current density are shown in Fig. 3b and c.

Table 1
The device performance of WOLEDs. W1: smooth surface device. W2: rough surface device.

Device	CIE [X, Y]	Turn-on voltage [V]	Max L [cd/m^2]	Max LE [cd/A]	Max EQE [%]	Max PE [lm/W]
W1	0.340, 0.366	4.5	30,151	15.5	9	9.1
W2	0.326, 0.362	4.25	42,978	20	11.6	11

To study the rough surface's influence on the emitting spectrum, the spectra of W1 and W2 under the same current density of 6.7 mA cm^{-2}, are collected and normalized to the W2 spectrum's peak value. As revealed in Fig. 3d, Device W2 shows intensity enhancement across the whole visible spectrum, which suggests that at the roughness of Ra = 1.266 μm, all the primary color emissions, i.e. red, green, and blue, have more outputs than at zero roughness (smooth surface). However, the blue (432 nm) and green (512 nm) peaks have big increases of 17.5% and 16.6%, respectively, while the red light (618 nm) exhibits only 2.8% intensity increase. To investigate why the blue and green peaks have more pronounced improvement than the red peak, we made individual red, green, and blue devices based on the material set of the white device to guarantee the same emission peaks as those from the white, i.e. red (PVK doped with $Ir(piq)_2acac$), green (PVK doped with $Ir(mppy)_3$), and blue (G0). At the roughness of 1.219 μm, the EQE improvements for red, green, and blue devices

are 8.46%, 42.3%, and 36.4%, respectively, among which the improvement of red device is the lowest, consistent with the findings in the white color device. The underlying mechanism on why the same surface roughness have different effects on different color is currently under investigation.

It's known that when the trichromatic color mixture has the same color coordinates and the same brightness as the equal-energy radiator Illuminant E does, the brightness ratio of the three standard primary colors emitters is $\tilde{r} : \tilde{g} : \tilde{b} = 1.0000 : 4.5907 : 0.0601$ [32]. The equation reveals that the green emission counts more in producing a white light [33], since the human eyes are most sensitive to the green color. The big increase of the green portion in Device W2 is preferable in improving the white light efficiency. Unfortunately, the uneven light intensity improvements among the three primary emissions shift the color coordinates from (0.340, 0.346) to (0.326, 0.362). Nonetheless, the color coordinates are still in the center of the white light region specified in the CIE 1931 Chromaticity Diagram [32].

For the lighting application, either solid-state lighting source, or backlights panel in LCD, Lambertian emitter is always required. Plane structure OLED with smooth substrate surface is theoretically-proven ideal Lambertian emitter [13]. After the surface was modified by sandblasting, it's important to test if the Lambertian emission still remains. The angular dependence of the light intensity of Device W2 is plotted in Fig. 4a. The zero degree denotes the viewing direction normal to the substrate plane as illustrated in Fig. 4a inset. The light intensity is normalized to the intensity at zero degree. The dashed line is the plot of an ideal Lambertian emitter's normalized light intensity vs. the viewing angle, following the equation [34]:

$$L(\theta) = L_0 \cos\theta \tag{3}$$

where L_0 is the light intensity at zero degree. The superposition of the experimental data and the theoretical curve demonstrates that the rough surface WOLED is a perfect Lambertian emitter.

It's important to optimize the surface roughness of the WOLED substrate to achieve the highest external quantum efficiency. Though it is a simple technology, sandblasting provides a variety ways to modify the surface morphology (Section 2). The dependences of the EQE improvement on the surface roughness is illustrated in Fig. 4b. In the roughness range from around 1 μm to 3 μm, the smaller the roughness, the higher the EQE. Since the smallest roughness is 0 meaning smooth surface, it suggests that the EQE will have a peak value between 0 and 1 μm. Some works by other groups demonstrated that when the surface scattering medium has the size of half the light wavelength, the EQE has its largest value [25]. For our white emission with three primary colors, it's therefore, expected that when the roughness of the substrate approaches 256 nm, the EQE will reach its maximum. To produce sub-micrometer roughness, special sandblasting machine equipped with much smaller sands is needed.

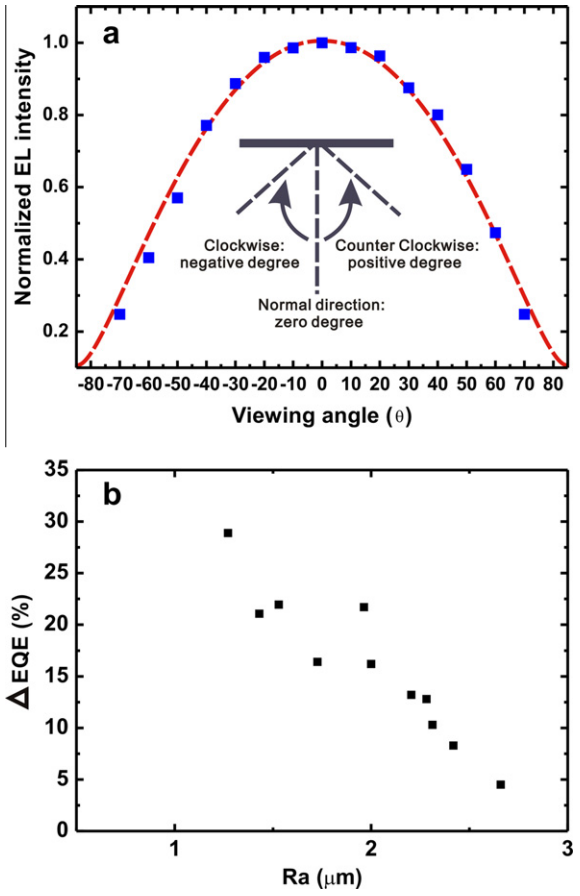

Fig. 4. (a) The dependence of luminance on the viewing angle. Square: the normalized luminance from a rough surface WOLED. Dashed line: the theoretical plot of an ideal Lambertian emitter. Inset: the illustration of the measurement. (b) The dependence of the EQE improvement on the surface roughness Ra.

For large size plane light source, the uniformity is a crucial parameter. Since the rough surface scattered the internally generated photons out of the surface randomly as schematically illustrated in Fig. 1c, the roughness is expected to improve the uniformity of the large area plane light source. To confirm the uniformity improvement and demonstrate the manufacturing scalability of the sandblasting technique, a 3.5 inch diagonal white lighting panel was fabricated. The 3.5 inch substrate is 2.7 inch long, and 2.2 inch wide. On the ITO surface, a group of Cr lines with the width of 40 μm were patterned using standard photolithography. The Cr lines help conduct the current from the edge to the center. The white emission of the panel was achieved by doping G0 with the green emitting conjugated polymer poly [2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-*p*-phenylenevinylene] (P-PPV), and orange emitting polymer poly[2-methoxy-5-(2′-ethyl-hexyloxy)-1,4-phenylenevinylene] (MEH-PPV), which were purchased from Canton OLedking Optoelectric Materials Co., Ltd. The lighting panel with smooth surface has a 9-point uniformity [35] of 80%, while after sandblasting the substrate, the uniformity improves to 90%. The panel picture is shown in Fig. 5.

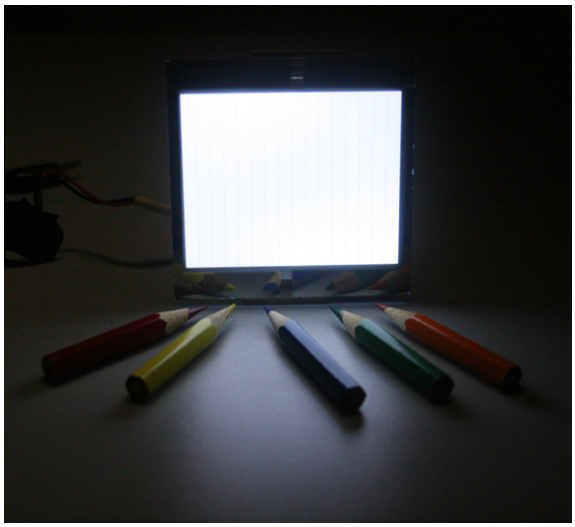

Fig. 5. The picture of a 3.5 inch white light panel.

4. Summary

In summary, we have successfully developed a simple, low cost, and scalable process to modify the WOLED substrates' surface. The rough surface created by the sandblasting technique efficiently suppressed the optical waveguide mode of the internally generated photons, and significantly enhanced the output coupling efficiency. For a white emission OLED, the EQE was improved from 9% to 11.6%. The surface roughness can be accurately controlled and reproduced. In the roughness range between about 1 μm and 3 μm, the EQE improvement is inversely proportional to the surface roughness. Moreover, neither the emission spectrum, nor the angular dependence of the light intensity, were altered by the rough surface. The realization of rough surface on a 3.5 inch white lighting panel not only improves the 9-point uniformity from 80% to 90%, but also demonstrates the feasibility of sandblasting technique in real manufacturing.

Loss-channel analysis

ABSTRACT

A new approach for the simulation of OLEDs based on a plane wave field expansion is proposed. Exact general formulae are given that allow for the calculation of their optical characteristics including losses in all layers in an arbitrary OLED structure. The S-matrix approach is used which ensures numerical stability of the algorithm. A simple way is proposed to take into consideration non-coherent reflections in a thick substrate. The validity of the model is demonstrated by comparing with experimental data.

1. Introduction

The development of light-emitting devices and displays based on organic light-emitting diodes (OLEDs) is an important area of modern optics since such devices have important advantages in comparison with their conventional inorganic analogs [1]. Usually an OLED structure is composed of a stack of plane layers, whose thickness and optical properties crucially influence the behavior of the whole device. The properties include the external efficiency, color, spectral and angular distribution of the emission. The manufacturing of experimental samples is an involved and expensive technological process therefore, it is important to first carry out an optimization of an OLED structure by means of rigorous modeling.

A number of models have been proposed for the description of the optical behavior of OLED devices. Considering only those which implement a rigorous electromagnetic analysis, one can divide these models into two groups. The models of the first group are based on field decomposition into a set of cylindrical harmonics [2,3], and the second group includes models which are based on a plane wave representation of the electromagnetic field [4–6]. Note that both groups of approaches use the dipole emission rate calculation in a plane layered medium. The first approach was proposed in [7] and further developed for an arbitrary multilayer system in [8]. Regarding the dipole emission in a layered structure described in terms of plane waves, important developments were made in [9,10] where also the links can be found to papers concerning the wave propagation in a plane layered media.

All the models elaborated for the calculation of the electromagnetic properties of OLED structures are aimed at estimating both the internal fields and waves outgoing from a structure. The capability of an exact calculation of the electromagnetic fields in all layers of a device, and hence the power flux and losses inside, is a prerequisite for the optimization of the performance of a device. The mentioned approaches as they are usually presented suffer however from a lack of a clear, simple and precise way of calculation of these physical quantities. Simplified equations solving this problem were given in [3] for the model using a cylindrical harmonic representation. For the plane-wave-representation approach, authors usually give only

doi:10.1016/j.orgel.2011.01.019

the expressions for the energy flux outside the layers to calculate the emission from the whole structure [11,12]. Reference [13] might have given the required solution, but the authors place dipoles at the interfaces between different media which cannot be justified neither from physical nor from mathematical points of view.

The present work aims at giving exact formulae in the frame of the plane-wave approach that describes in the most general way the power flux inside an OLED device containing an arbitrary number of emitting layers. To complete the model, an S-matrix propagation algorithm (instead of T-matrices) is used for sake of numerical stability [14] and a simple way of accounting for non-coherent reflections in a thick substrate is introduced.

2. Plane wave expansion model

Before giving the details of the method it is necessary to define the considered structure. A conventional OLED is composed of a stack of plane layers comprising a metal cathode and several lossy dielectric layers: an active layer, an anode and possibly electron/hole transport and blocking layers [15]. The sketch representing the general structure of the device can be seen in Fig. 1. The numeration of all layers starts from the semi-infinite medium under the cathode. Each layer is considered to be homogeneous of complex dielectric permittivity ε_i and thickness h_i. All plane layers and interfaces are parallel to the plane XOY in a Cartesian system XYZ.

Dealing with plane wave propagation seems to be the most natural way when describing a plane layered structure. The field emitted by a point source is decomposed into a set of plane harmonics. As usual, the active layer is represented as an infinite layer with point dipoles. Note that while studying propagation of plane harmonics found by decomposition of a point source field we implicitly deal with an infinite plane layer of sources instead of a single dipole. Additionally, no absorption is supposed in the surrounding dipole medium since the dipole field tends to infinity in the vicinity of the dipole. However the medium can absorb at some nonzero distance from the dipole.

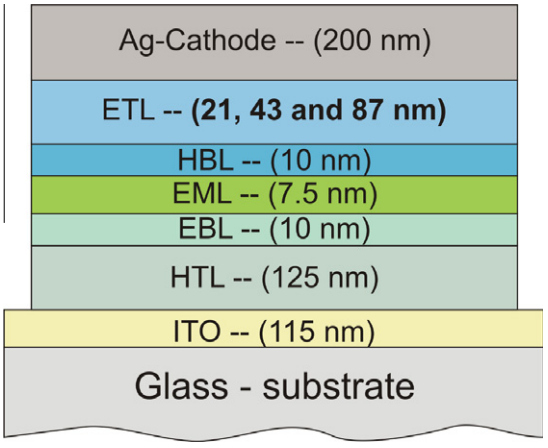

Fig. 1. Structure of the green-emitting electrophosphorescent OLEDs used in this study.

3. Dipole emission in a homogeneous medium

Consider first a monochromatic point Dirac dipole with polarization amplitude $\mathbf{p}_0$ located at point $\mathbf{r}_0 = (x_0, y_0, z_0)$ in a homogeneous medium of permittivity ε_p:

$$\mathbf{p}(\mathbf{r}, t) = \mathbf{p}_0 \delta(\mathbf{r} - \mathbf{r}_0) \exp(-i\omega t) \tag{1}$$

Monochromatic source (1) is considered as a Fourier decomposition of a real broadband source whose spectrum has to be integrated to obtain the final temporal response. All the fields produced by source (1) are proportional to the term $\exp(-i\omega t)$ which will be omitted hereunder for sake of brevity.

Denote the wavevector of a plane harmonic as

$$\mathbf{k}_i^{\pm} = (k_x, k_y, \pm k_{zi}) \tag{2}$$

where

$$k_{zi} = \sqrt{k_i^2 - k_x^2 - k_y^2} \tag{3}$$

is the wavenumber in the i-th layer $k_i = \omega\sqrt{\mu_0 \varepsilon_i}$ and signs "plus" and "minus" correspond to the waves propagating in half-spaces $z > z_0$ and $z < z_0$, respectively. Introduce also an in-plane wavevector modulus $\gamma = \sqrt{k_x^2 + k_y^2}$. Then the amplitudes of TE and TM polarized harmonics of the field propagating upwards and downwards with respect to the z axis write (see, for example [13]):

$$a_{TE}^{(S)\pm} = \frac{i\omega^2 \mu_0 k_0^2}{8\pi^2 \gamma k_{pz}} (k_y p_{0x} - k_x p_{0y}) \tag{4}$$

$$a_{TM}^{(S)\pm} = \frac{i\omega k_0^2}{8\pi^2 \gamma k_{pz}} (\mp k_x k_{pz} p_{0x} \mp k_y k_{pz} p_{0y} + \gamma^2 p_{0z}) \tag{5}$$

Here the factor k_0^2 is introduced to keep the same dimension of the real field and of the plane harmonic amplitudes. Note that in derivation of Eqs. (4) and (5) we have used the following relation between field components and the amplitudes of TE- and TM-polarized waves:

$$E_x^{\pm} = \frac{k_y}{\gamma} a_{TE}^{\pm} \mp \frac{k_x k_z}{\omega \varepsilon_i \gamma} a_{TM}^{\pm};\ E_y^{\pm} = -\frac{k_x}{\gamma} a_{TE}^{\pm} \mp \frac{k_y k_z}{\omega \varepsilon_i \gamma} a_{TM}^{\pm};$$
$$E_z^{\pm} = \frac{\gamma}{\omega \varepsilon_i} a_{TM}^{\pm} \tag{6}$$

$$H_x^{\pm} = \pm \frac{k_x k_z}{\omega \mu_0 \gamma} a_{TE}^{\pm} + \frac{k_y}{\gamma} a_{TM}^{\pm};\ H_y^{\pm} = \pm \frac{k_y k_z}{\omega \mu_0 \gamma} a_{TE}^{\pm} - \frac{k_x}{\gamma} a_{TM}^{\pm};$$
$$H_z^{\pm} = -\frac{\gamma}{\omega \mu_0} a_{TE}^{\pm} \tag{7}$$

The power flux through any interface parallel to XY plane is found as the real part of the Poynting vector z-projection. In terms of the TE and the TM amplitudes $a_{TE}^{\pm}$ and $a_{TM}^{\pm}$ it has the form:

$$S_z(k_x, k_y) = \begin{bmatrix} \frac{1}{2}\left\{\frac{\mathrm{Re}(k_z)}{\omega\mu_0} \left|a_{TE}^{+}\right|^2 + \mathrm{Re}\left(\frac{k_z}{\omega\varepsilon_m}\right)\left|a_{TM}^{+}\right|^2\right\}, & z > z_0 \\ -\frac{1}{2}\left\{\frac{\mathrm{Re}(k_z)}{\omega\mu_0} \left|a_{TE}^{-}\right|^2 + \mathrm{Re}\left(\frac{k_z}{\omega\varepsilon_m}\right)\left|a_{TM}^{-}\right|^2\right\}, & z < z_0 \end{bmatrix} \tag{8}$$

Therefore, the total power emitted by the dipole into a given harmonic is found as:

$$I_d(k_x,k_y) = \lim_{z\to z_0+0} S_z(k_x,k_y) + \lim_{z\to z_0-0} S_z(k_x,k_y)$$
$$= \frac{1}{2}\left\{\frac{\mathrm{Re}(k_z)}{\omega\mu_0}\left(\left|a_{TE}^{(S)+}\right|^2 + \left|a_{TE}^{(S)-}\right|^2\right)\right.$$
$$\left. + \mathrm{Re}\left(\frac{k_z}{\omega\varepsilon_m}\right)\left(\left|a_{TM}^{(S)+}\right|^2 + \left|a_{TM}^{(S)-}\right|^2\right)\right\} \quad (9)$$

Eqs. 4, 5, 8, and 9 lie in the core of the model. They allow for the calculation of all electromagnetic properties of the OLED structure including losses in layers and the effective source emission.

4. Plane wave propagation in a multilayer stack

As was stated in the introduction the S-matrix propagation algorithm was implemented to trace and relate fields in all layers of a structure instead of the T-matrices. Consider a plane structure perpendicular to the z axis and suppose that the reflection and transmission coefficients are found for it. Denoting by $a_1^{\pm}$ the plane wave amplitudes below the structure and by $a_2^{\pm}$ above the structure the S-matrix relates them as follows:

$$\begin{pmatrix} a_1^- \\ a_2^+ \end{pmatrix} = S\begin{pmatrix} a_1^+ \\ a_2^- \end{pmatrix} = \begin{pmatrix} S_{11} & S_{21} \\ S_{12} & S_{22} \end{pmatrix}\begin{pmatrix} a_1^+ \\ a_2^- \end{pmatrix} \quad (10)$$

Further, we need to specify explicitly two elementary types of S-matrices. The first one is an S-matrix of an interface between two media of permittivities ε_1 and ε_2. It consists of the Fresnel reflection and transmission coefficients and depends on the polarization:

$$S_{TE} = \begin{pmatrix} \frac{k_{1z}-k_{2z}}{k_{1z}+k_{2z}} & \frac{2k_{2z}}{k_{1z}+k_{2z}} \\ \frac{2k_{1z}}{k_{1z}+k_{2z}} & \frac{k_{2z}-k_{1z}}{k_{1z}+k_{2z}} \end{pmatrix} \quad (11)$$

$$S_{TM} = \begin{pmatrix} \frac{\varepsilon_2 k_{1z}-\varepsilon_1 k_{2z}}{\varepsilon_2 k_{1z}+\varepsilon_1 k_{2z}} & \frac{2\varepsilon_1 k_{2z}}{\varepsilon_2 k_{1z}+\varepsilon_1 k_{2z}} \\ \frac{2\varepsilon_2 k_{1z}}{\varepsilon_2 k_{1z}+\varepsilon_1 k_{2z}} & \frac{\varepsilon_1 k_{2z}-\varepsilon_2 k_{1z}}{\varepsilon_2 k_{1z}+\varepsilon_1 k_{2z}} \end{pmatrix} \quad (12)$$

where $k_{z1,2}$ are defined by (3) for lower and upper media, respectively. The second type is an S-matrix of a homogeneous layer of permittivity ε_l and thickness h_l. It contains only the exponential factors expressing the plane wave propagation and regardless of polarization writes

$$S = \begin{pmatrix} 0 & \exp(ik_{lz}h_l) \\ \exp(ik_{lz}h_l) & 0 \end{pmatrix} \quad (13)$$

Note that in the case of a homogeneous layer both exponents in (13) have the "plus" sign. Such property is quite opposite to that of T-matrix and leads to the numerical stability of S-matrices.

We define next the basic S-matrix relations that give means to calculate the field amplitudes at any point of the structure. If a plane layered structure consists of two substructures characterized by S-matrices $S^{(L)}$ and $S^{(U)}$ (the first corresponds to the lower substructure and the second – to the upper one) then one can find the resulting S-matrix S of the whole structure by applying the following multiplication rule:

$$\begin{aligned} S_{11} &= S_{11}^{(L)} + S_{12}^{(L)}S_{11}^{(U)}(I - S_{11}^{(U)}S_{22}^{(L)})^{-1}S_{21}^{(L)} \\ S_{12} &= S_{12}^{(L)}(I - S_{11}^{(U)}S_{22}^{(L)})^{-1}S_{12}^{(U)} \\ S_{21} &= S_{21}^{(L)}(I - S_{11}^{(U)}S_{22}^{(L)})^{-1}S_{21}^{(U)} \\ S_{22} &= S_{22}^{(U)} + S_{21}^{(U)}S_{22}^{(L)}(I - S_{11}^{(U)}S_{22}^{(L)})^{-1}S_{12}^{(U)} \end{aligned} \quad (14)$$

By successively applying Eq. (14) one can obtain the S-matrix components for a whole stack containing any number of layers.

5. Dipole emission in a layer

We proceed with considering a dipole source placed between two structures characterized by S-matrices $S^{(L)}$ and $S^{(U)}$. When the source emits plane waves of amplitudes $a_s^{\pm}$ the effective wave amplitudes differ from those of emitted waves because of the interference with reflected waves. This effect is very important since it describes the modifications in a spectrum emitted by a source placed in a layered structure.

Denote the z coordinates of two interfaces that bound a layer containing a dipole by z_1 and z_2, and the dipole position by z_s as shown in Fig. 2. The harmonic amplitudes emitted by the dipole $a_s^{\pm}$ are found in accordance with (4) and (5). The effective amplitudes $a^{\pm}(z_s)$ in the plane of the source are different from $a_s^{\pm}$. They are found as a result of the interference of all emitted and reflected waves:

$$\begin{aligned} a^+(z_s) &= (I - S_{22}^{(L)}S_{11}^{(U)})^{-1}(S_{22}^{(L)}a^{(S)-} + a^{(S)+}) \\ a^-(z_s) &= (I - S_{11}^{(U)}S_{22}^{(L)})^{-1}(S_{11}^{(U)}a^{(S)+} + a^{(S)-}) \end{aligned} \quad (15)$$

At any plane $z = const$ that does not coincide with the layer of dipoles the amplitudes of both up- and down-propagating harmonics are then found $a_{TE,TM}^{\pm}(z)$ and the correspondent power flux writes

$$S_z(k_x,k_y,z) = \frac{1}{2}\left\{\frac{\mathrm{Re}(k_z)}{\omega\mu_0}\left(\left|a_{TE}^+\right|^2 - \left|a_{TE}^-\right|^2\right)\right.$$
$$\left. + \mathrm{Re}\left(\frac{k_z}{\omega\varepsilon_m}\right)\left(\left|a_{TM}^+\right|^2 - \left|a_{TM}^-\right|^2\right)\right\}$$
$$- \frac{\mathrm{Im}(k_z)}{\omega\mu_0}\mathrm{Im}(a_{TE}^+ a_{TE}^{-*}) - \mathrm{Im}\left(\frac{k_z}{\omega\varepsilon_m}\right)\mathrm{Im}(a_{TM}^+ a_{TM}^{-*}) \quad (16)$$

The latter relation follows directly from (8). The effective power emitted by a dipole source layer located in the plane $z = z_s$ is found from (16) by substituting the corresponding field amplitudes in the vicinity above and under the layer:

$$I_s = \lim_{z\to z_s+0} S_z + \lim_{z\to z_s-0} S_z$$
$$= \frac{1}{2}\left\{\frac{\mathrm{Re}(k_z)}{\omega\mu_0}\left(|a_{TE}^+(z_s)|^2 - |a_{TE}^+(z_s) - a_{TE}^{(S)+}|^2 + |a_{TE}^-(z_s)|^2\right.\right.$$
$$\left. - |a_{TE}^-(z_s) - a_{TE}^{(S)-}|^2\right) + \mathrm{Re}\left(\frac{k_z}{\omega\varepsilon_m}\right)\left(|a_{TM}^+(z_s)|^2 - |a_{TM}^+(z_s)\right.$$
$$\left.\left. - a_{TM}^{(S)+}|^2 + |a_{TM}^-(z_s)|^2 - |a_{TM}^-(z_s) - a_{TM}^{(S)-}|^2\right)\right\}$$
$$- \frac{\mathrm{Im}(k_z)}{\omega\mu_0}\mathrm{Im}[a_{TE}^{+*}(z_s)a_{TE}^{(S)-} + a_{TE}^{-*}(z_s)a_{TE}^{(S)+}]$$
$$- \mathrm{Im}\left(\frac{k_z}{\omega\varepsilon_m}\right)\mathrm{Im}[a_{TM}^{+*}(z_s)a_{TM}^{(S)-} + a_{TM}^{-*}(z_s)a_{TM}^{(S)+}] \quad (17)$$

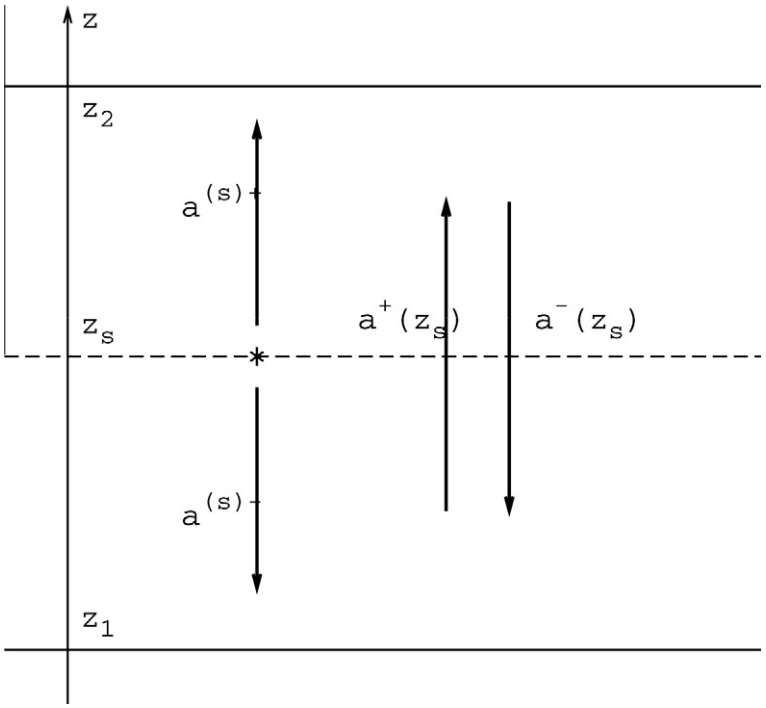

Fig. 2. Schematic picture of a layer with emitting dipole.

The "asterisk" indicates complex conjugation. The last two terms of expression (17) represent the power flux in the evanescent components of the emission of point sources. Finally the power emitted (or lost if there is no sources) in a layer is found as

$$I_l = \left| \lim_{z \to z_u - 0} S_z - \lim_{z \to z_d + 0} S_z - I_s \right| \tag{18}$$

An important practical significance of this formula is that it gives losses in a layer regardless of the presence of sources inside it.

The only thing left is the definition of unknown amplitudes in (16) and (17). Equations (13) allow for obtaining output amplitudes from the whole structure:

$$\begin{aligned} a^-(z_1) &= S^A_{12} a^-(z_s) = S^A_{12}(I - S^B_{11} S^A_{22})^{-1}(S^B_{11} a^{(S)+} + a^-_s) \\ a^+(z_2) &= S^B_{21} a^+(z_s) = S^B_{21}(I - S^A_{22} S^B_{11})^{-1}(S^A_{22} a^{(S)-} + a^+_s) \end{aligned} \tag{19}$$

In order to trace the fields in different layers we use the solution to the following problem. Given a structure composed of two elements characterized by S-matrices $S^{(L)}$ and $S^{(U)}$ and two incident plane waves with amplitudes $a^+(z_1)$ and $a^-(z_2)$ (under and above the structure), the incident waves have the same temporal and spatial frequencies, therefore, wave amplitudes $a^{\pm}(z_3)$, $z_1 < z_3 < z_2$ between elements are found as result of the interference between all transmitted and reflected waves:

$$\begin{aligned} a^+(z_3) &= (I - S^{(U)}_{11} S^{(L)}_{22})^{-1}[S^{(L)}_{21} a^+(z_1) + S^{(L)}_{22} S^{(U)}_{12} a^-(z_2)] \\ a^-(z_3) &= (I - S^{(U)}_{11} S^{(L)}_{22})^{-1}[S^{(U)}_{11} S^{(L)}_{21} a^+(z_1) + S^{(U)}_{12} a^-(z_2)] \end{aligned} \tag{20}$$

Formulae (15)–(20) are sufficient for the description of plane wave emission and propagation in an arbitrary plane layered structure. By using them one can find the energy flux and losses at every point of the structure.

6. External reflections and non-coherent return of light

In many cases, the light is extracted from the structure to the air through a substrate. The substrate is too thick to preserve light coherence and therefore waves reflected back from the air-substrate interface do not interfere with emitted waves. A correct analysis of such situation includes the calculation of light emission to the substrate by means of the techniques developed in the previous sections. Then, the air-substrate interface is introduced which modifies the intensities.

The presence of the air-substrate interface leads to two main consequences: first, all waves with in-plane wave vector projection $\gamma \geqslant k_{air}$ will be totally reflected back and guided in the substrate; secondly, in the case $\gamma \leqslant k_{air}$, the emitted waves will be partially reflected at the interface resulting in decreasing output efficiency. Let R_a and T_a be the reflection and transmission power coefficients at the air-substrate interface

$$R_{aTE} = \left|\frac{k_{sz} - k_{az}}{k_{sz} + k_{az}}\right|^2,\ R_{aTM} = \left|\frac{\varepsilon_a k_{sz} - \varepsilon_s k_{az}}{\varepsilon_a k_{sz} + \varepsilon_s k_{az}}\right|^2,\ T_a = 1 - R_a \tag{21}$$

The reflection coefficient $R_s$from the structure is found as the square modulus of element $S_{22}$of the structure's

S-matrix. Then, the total intensity transmitted into the air after N reflections is found

$$I_a = I \cdot T_a \frac{1-(R_a R_s)^N}{1-R_a R_s} = I \cdot (1-R_a)\frac{1-(R_a R_s)^N}{1-R_a R_s} \quad (22)$$

where I is the intensity calculated in the absence of the air-substrate interface. The intensity lost due to re-absorption in the structure is

$$I_l = I \cdot R_a(1-R_s)\frac{1-(R_a R_s)^N}{1-R_a R_s} \quad (23)$$

The rest of intensity is "guided" by the substrate:

$$I_s = I - I_a - I_l = I \cdot (R_a R_s)^N \quad (24)$$

The effective number of reflections N depends on the structure geometry and on the wave vector projections k_x, k_y which determine the angles of wave propagation in the substrate.

7. Calculation examples

To demonstrate the functioning of the model we compared the experimental data on the spectral and angular characteristics of OLED devices with corresponding results obtained with numerical simulation. For this study three green bottom-emitting devices with an active area of 1.6 cm^2 and 4 mm^2 were fabricated. The structure of the devices was glass-substrate/115 nm indium tin oxide (ITO)/125 nm hole transporting layer (HTL)/10 nm electron blocking layer (EBL)/7.5 nm green emitting layer (EML) consisting of host and a green dye/10 nm hole blocking layer (HBL)/electron transporting layer (ETL)/200 nm Ag-cathode. The stack was fabricated with three different ETL thicknesses (21, 43 and 87 nm). Using standard evaporation techniques the organic layers were deposited on an ITO coated glass substrate. For better electron and hole transport, doped ETL and HTL were used. The dopant was applied by co-evaporation. This technique was also used for depositing the green dye inside the host. The evaporation rate was 0.5 Å/s at a base pressure of 10^{-7} mbar. After the evaporation of the Ag-cathode the devices were encapsulated with a glass lid and getter. The scheme of the stack is shown in Fig. 1.

The measurements were performed with a Keithley 2400 Source-Measurement Unit and an Instrument Systems fiber spectrometer (CAS 140) on a rotational stage for measurements at different angles.

For determination of the integral spectrum the measurements were performed in an integrating sphere, which was connected to the Keithley 2400 Source-Measurement Unit and the Instrument Systems fiber spectrometer. Prior to the measurement a calibration with a halogen lamp was performed with and without device in order to obtain the absorption spectra of the OLED. The substrate edges were blackened in order to avoid an influence of the side emission. For the measurement of the light trapped in the substrate an index matched half-ball lens with a diameter of 25 mm was optically coupled with an index matching gel from Cargille laboratories. The lens has a refractive index of $n = 1.52$, matching the substrate refractive index exactly. For these measurements the devices with an active area of 4 mm^2 were used.

In order to ensure accurate simulation the complex refractive indices as a function of wavelength were determined by means of reflection-transmission spectroscopy of single supported films for all used materials [16]. The emission spectrum of the phosphorescent dye in free space has been extracted from the electroluminescence (EL) spectrum emitted in the direction normal to the substrate (zero angle) by applying optical simulations based on [7] on the measured data. We first simulated the zero angle emission spectra from the OLED using a white spectrum (constant intensity over all wavelengths) and subsequently multiplied the outcome by the measured EL-spectrum.

Fig. 3 shows devices spectra measured at zero angle. Very good agreement is seen not only in the curves shape but also in the relative positions of the curves corresponding to the different devices on the whole visible spectrum. Next, angular properties of the emitted radiation are presented in Fig. 4 demonstrating dependence of the color coordinates from the viewing angle with angle step 5°. Both in experimental and theoretical characterization color coordinates were obtained with the CIE coefficients 1931 standard observer via known power flux of emitted radiation in different directions. The shape of the simulated curve well suites to the experimental one, their positions however slightly differ, this can be explained by the finite size of the detector aperture and relatively fast decrease of the emitted light intensity at high viewing angles. To demonstrate the influence of the substrate on the decrease of the external efficiency there were measured integral spectra of the usual device and the device with an optically coupled half-ball lens placed atop the substrate. Collection of the radiation from the OLED with the half-ball lens gives the total power emitted into the substrate. The results of measurement and simulation for the device with an ETL-thickness of 87 nm are shown in Fig. 5. It can be seen that the radiation in air and in the substrate can be calculated very well. The power emitted to the substrate and to the air can be also compared with theoretically calculated total effective emitted power and power losses in layers. This is done via expressions (17), (18) and the resulting spectral

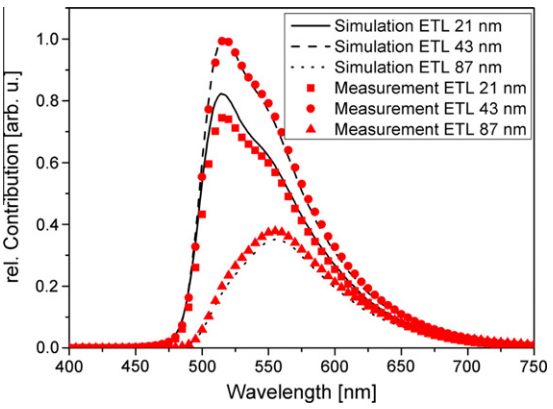

Fig. 3. Zero-angle spectra for the three devices as a function of wavelength.

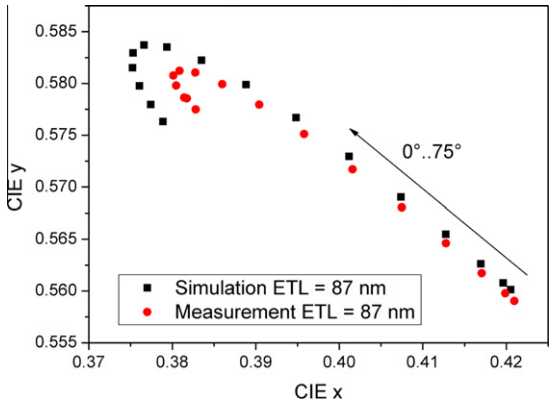

Fig. 4. Angular dependent Color coordinates of the device with an ETL-thickness of 87 nm.

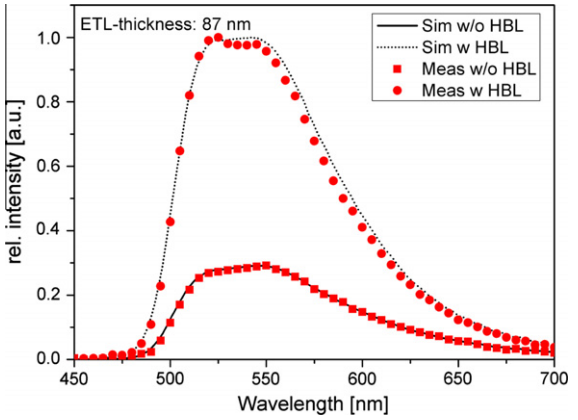

Fig. 5. Spectra with and w/o Half-Ball Lens measured in an integrating sphere as a function of wavelength.

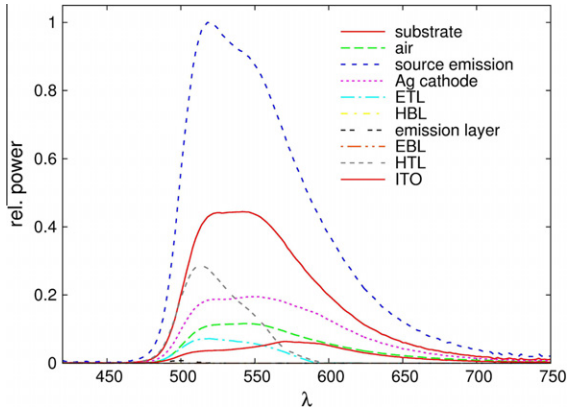

Fig. 6. Effective emission, outgoing power and losses in each layer.

dependencies are shown in Fig. 6. The analysis of losses in each layer of the structure presented in Fig. 6 may be very important in general for optimization of OLED structures. It immediately shows the layers with main losses in different parts of the spectrum, and allows the accurate tuning of the output efficiency.

8. Conclusions

The plane wave propagation model of OLEDs was revised and its ability to rigorously simulate all electromagnetic properties of devices was demonstrated. The important exact relationships for the power flux and losses in OLED layers were given. The presence of a substrate was accounted for via non-coherent reflection and transmission. The applicability of this model was confirmed by a comparison with the experimental data obtained by the measurement of the optical properties of fabricated green OLEDs.

ABSTRACT

Measuring the current density to voltage (*J–V*) characteristics of the separate subcells in two-terminal polymer tandem solar cells enables assessing the individual contributions of the two subcells to the total performance. We present two different methods to determine the *J–V* characteristics of the subcells in a two-terminal tandem cell without interfering with the light incoupling of the cell. The first method employs an extra proximity metal electrode that acts as a voltage probe. The proximity electrode is in contact with the recombination layer that separates the two subcells, but is positioned outside the illuminated area of the tandem cell. The second method uses bias-dependent external quantum efficiency measurements of two-terminal tandem solar cells and subsequent integration with the solar spectrum to determine the *J–V* curves of the subcells. The methods show good mutual agreement. For a 4.7% efficient solution processed two-terminal polymer tandem cell, based on PFTBT:PCBM as wide band gap and pBBTDPP2:PCBM as small band gap layer, we find that the subcells contribute with efficiencies of 2.9% and 1.8%.

1. Introduction

Employing wide and small band gap semiconductors in a tandem solar cell reduces the energy losses inherent to single junction cells. The wide band gap subcell lowers the thermalization losses associated with absorption of high energy photons in a small band gap cell and on the other hand the small band gap subcell absorbs the low energy photons for which a wide band gap cell is not sensitive. Hence in a tandem solar cell the photon energy can be better preserved. Recently semiconducting organic molecules and polymers are being considered for tandem solar cells, resulting in power conversion efficiencies over 5% [1–14]. Most organic and polymer tandem solar cells use a series connection in which the two subcells are electrically connected via a thin metallic interlayer or a stack of doped organic, polymer, or metal oxide electron and hole transporting layers.

The performance of a tandem cell can be determined from the current density to voltage (*J–V*) characteristics under (simulated) solar illumination but this does not allow obtaining a deeper insight in the functioning of individual layers in the tandem cell. Measuring the *J–V* characteristics of the subcells can provide better understanding of the interplay of the two subcells and assess their individual contributions. Such measurements have been demonstrated in three-terminal devices, where an intermediate metallic contact is available [6,10,15,16]. Also polymer tandem solar cells connected in a parallel configuration allow determining the *J–V* characteristics of the subcells [17,18].

A solution processed intermediate contact is, however, commercially the most interesting cell configuration because printing techniques are less time and energy consuming and eventually allow roll-to-roll processing [19]. Recently, polymer tandem solar cells with electron transporting (ET) and hole transporting (HT) layers processed from solution in a two-terminal configuration have been reported [8,9,11,12]. The conductivity of the solution

processed intermediate contact, or recombination ET–HT layer, parallel to the surface is, however, too low to use it for external *J–V* measurements.

Here, we present two methods to measure the *J–V* characteristics of the subcells of a polymer tandem solar cell with an electrically inaccessible intermediate contact. We apply these to a solution processed polymer tandem solar cell that we described recently [12]. Both methods preserve the exact layout of the tandem cell such that the optical electric field inside the device remains identical. In the first method an extra metal proximity electrode (Fig. 1a and b), located just outside of the active area, is evaporated between the ET and HT layers creating a pseudo three-terminal device that allows assessing the voltage difference between the intermediate contact and one of the two terminal electrodes. The second technique exploits bias-dependent external quantum efficiency (*EQE*) measurements of the polymer tandem solar cell in a two-terminal device as described recently [20]. Varying the bias voltage over the tandem cell allows determining the *J–V* curve of the subcells under appropriate bias illumination.

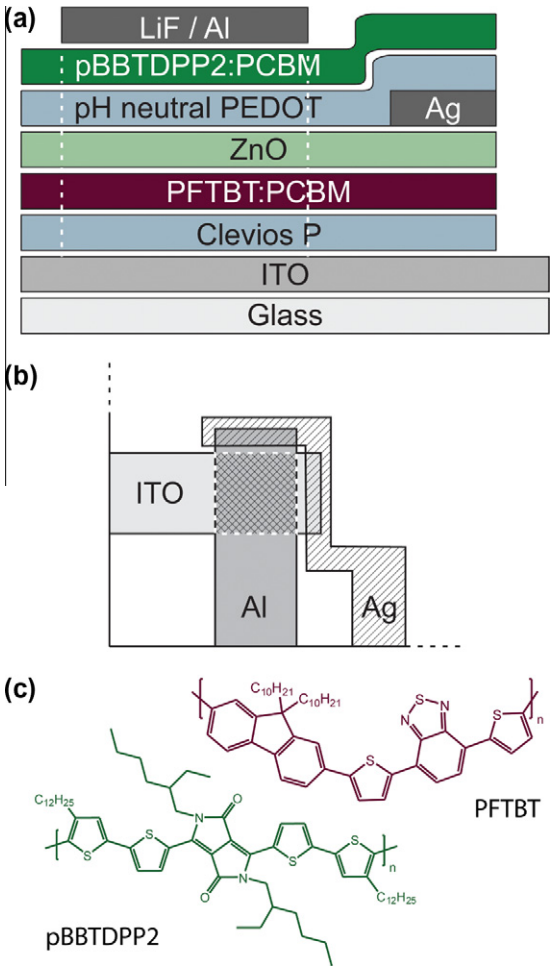

Fig. 1. Schematic side (a) and top (b) view of the device structure for a polymer tandem solar cell with an accessible intermediate contact situated just outside of the active area. The layer thickness is 180 nm for PFTBT:PCBM, 30 nm for ZnO, 15 nm for pH neutral PEDOT, and 115 nm for PBBTDPP2:PCBM. The active area, defined by the overlap of the ITO and LiF/Al electrodes, is 3×3 mm^2 and indicated by white dashed lines. The lateral distance of the Ag electrode to the actual device is 0.5 mm and the Ag layer is 30 nm thick. Panel (c) shows the chemical structures of the two polymers used.

2. Experimental

The tandem cell studied is based on poly[2,7-(9,9-didecylfluorene)-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)] (PFTBT) as wide band gap polymer and poly[3,6-bis(4′-dodecyl-[2,2′]bithiophenyl-5-yl)-2,5-bis(2-ethylhexyl)-2,5-di-hydropyrrolo[3,4-]pyrrole-1,4-dione] (pBBTDPP2) as small band gap polymer (Fig. 1c), both in combination with [6,6]-phenyl-C_{61}-butyric acid methyl ester ([60]PCBM or PCBM in short) [12,20]. The recombination layer that separates the two subcells consists of a 30 nm ET layer of ZnO nanoparticles and a 15 nm HT layer of pH neutral PEDOT:PSS, both deposited from solution on the wide band gap photoactive layer [8]. When sandwiched between a ITO/PEDOT:PSS bottom electrode and a LiF/Al top electrode the entire tandem structure with a 180 nm thick PFTBT:PCBM front cell and a 115 nm thick pBBTDPP2:PCBM back cell resulted in an overall efficiency of 4.7% under simulated AM1.5G (global air mass 1.5, 100 mW/cm^2) solar light. The fabrication and optimization of these devices have been described in detail in Ref. [12]. Fig. 2 shows the AM1.5G spectrum together with the normalized absorption spectra of the two active layers and the lamp spectrum used in this study.

For the accessible intermediate contact, 30 nm Ag was evaporated through a shadow mask on top of the ZnO layer prior to the deposition of the pH neutral PEDOT. The mask was designed such that the Ag layer was placed 0.5 mm from the 3×3 mm^2 active area of the cell defined by the overlap of ITO and LiF/Al electrodes (Fig. 1b). *J–V* measurements were performed under simulated AM1.5G solar light from a tungsten-halogen lamp filtered by a Schott GG385 UV filter and a Hoya LB120 daylight filter using a Keithley 2400 source meter. Illumination was done through a mask

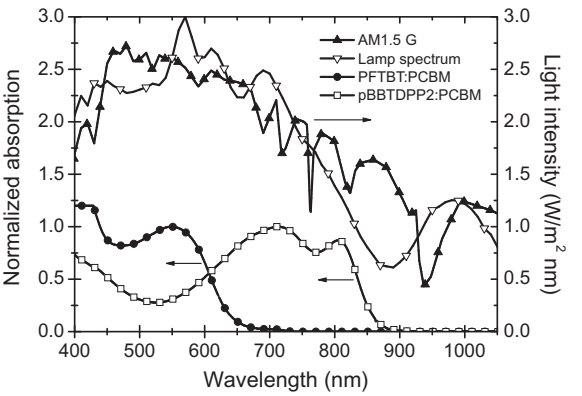

Fig. 2. Normalized absorption spectra of the two active layers (PFTBT:PCBM and pBBTDPP2:PCBM) together with the AM1.5G spectrum and the lamp spectrum of the solar simulator used in the present investigation.

with an aperture of 3×3 mm^2 that is equal to the nominal device area defined by the overlap of the ITO and LiF/Al electrodes to avoid parasitic photocurrents. The voltage difference between the accessible intermediate contact and one of the two electrodes was determined with a Keithley 6512 programmable electrometer. The high input resistance (200 TΩ) of the Keithley 6512 exceeds the lateral series resistance of the recombination layer to the Ag contact of <10 MΩ that can be inferred from the measured lateral conductivity of the pH neutral PEDOT:PSS of 0.2 S/cm and the dimensions of the device layout.

The *EQE* measurements were done in a home-built setup [20]. Modulated monochromatic (Oriel Cornerstone 130 1/8 m, Newport) probe light (Halotone halogen lamp, Philips) was mechanically chopped at a frequency of 165 Hz with an optical chopper (SR 540, Stanford Research). The bias illumination was provided by a 532 nm (B&W, Tek Inc., 30 mW) and 780 nm (B&W, Tek Inc., 21 mW) solid state laser. The sample was stored in a nitrogen filled container during the measurements and illuminated through a circular aperture of 2 mm which is slightly smaller than the device area to avoid errors. This aperture was used for the sample cell and for the calibrated Si reference cell used in the measurements. The measurements were executed with a lock-in-amplifier (SR 830, Stanford Research) over a load of 50 Ω. All data were recorded by a Labview program on a computer. The electrical bias over the tandem cell was provided by the lock-in-amplifier. Details of the measurement procedure of the *EQE* of polymer tandem solar cells have been described in detail recently [20].

3. Results and discussion

3.1. Method 1: tandem cell configuration with a proximate middle electrode

In the first method a Ag proximity electrode is evaporated after the deposition of the ZnO ET layer and prior to deposition of the pH neutral PEDOT HT layer just outside of the active area of the solar cell defined by the geometrical overlap between the patterned indium tin oxide and evaporated Al electrode (Fig. 1a and b) to create a three-terminal device. In this layout the light incoupling in the stack of the layers is not disturbed and the additional middle contact does not affect the performance of a device with optimal active layer thicknesses [12].

Measuring a *J–V* curve directly with this intermediate Ag proximity contact is not possible due to the low conductivity of the ET and HT layers parallel to the surface, which makes it impossible to pass a lateral current through the intermediate contact without significant resistance losses. However, this set-up does allow for measuring the voltage difference between the intermediate contact and one of the two electrodes. The internal impedance of the measuring unit is preferentially large to minimize current and voltage losses in the tandem cell (see Section 2). By sweeping the voltage over the entire tandem cell and recording the current density of the tandem cell and the voltage difference between the intermediate contact and one of the two electrodes, one can determine the *J–V* characteristics of the subcells in a tandem cell (Fig. 3). Apart from ensuring that the lateral series resistance is small compared to the input resistance of the voltmeter, this method only requires that there is no voltage drop at the recombination layer.

From these measurements the contribution of both subcells to the performance of the tandem cell can easily be deduced. The power density of the tandem cell in the maximum power point (*MPP*) is 4.7 mW/cm^2. For the current density corresponding to the *MPP* of the current tandem cell, the power densities of the subcells are 2.9 and 1.8 mW/cm^2 for the front and back cell, respectively. These power densities are very close to the *MPPs* of the two subcells in the tandem device (3.0 and 1.7 mW/cm^2), but in general this need not to be true. We note that Method I works best for subcells that provide rather similar current densities under illumination, because the limiting subcell sets the maximum current that can be achieved in the device. As a result, the *J–V* curve of the nonlimiting subcell cannot be measured beyond this value. This is shown in Fig. 3 where *J–V* curve of the back cell is only accessible down to −0.35 V.

3.2. Method 2: electrical bias sweep in the EQE measurement

The extra proximity contact requires an additional evaporation step during the processing of the device. The second method exploits the spectral response measurement of the polymer tandem solar cell without the need for additional processing or contacts. To allow direct comparison, the second technique has been performed on the same device as used for the first method. We have recently shown that the exact determination of the *EQE* of the subcells requires, besides a specific optical bias illumination, a forward electrical bias on the entire cell to measure the

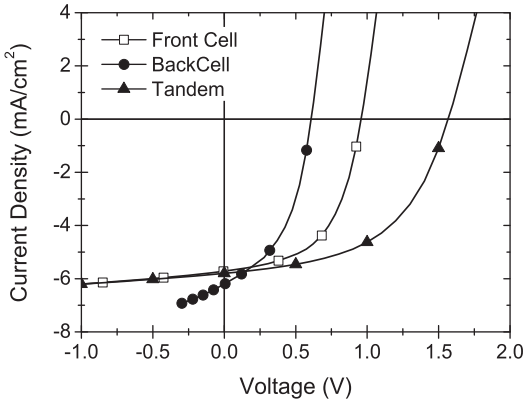

Fig. 3. Method 1. *J–V* characteristics of the front, back, and tandem cell measured with an intermediate contact situated just outside of the active area under simulated solar light. In the experiment the voltage over the tandem cell was set by the source unit and the voltage over the back cell was measured between the intermediate Ag contact and the LiF/Al contact. The data for the front cell were calculated from the two measured curves. Virtually identical results were obtained when the voltage over the front cell was measured directly between the ITO contact and the intermediate Ag contact in a separate experiment.

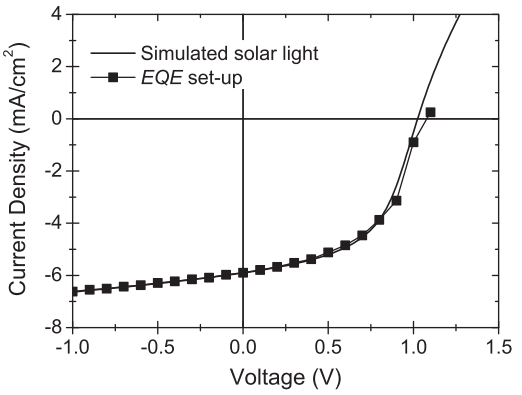

Fig. 4. Comparison of J_{photo}–V characteristics of a single junction PFTBT:PCBM solar cell measured under simulated solar light and after integration of the *EQE*, measured at different electrical bias, with the AM1.5G solar spectrum.

subcell under short-circuit conditions [20]. To correctly determine the amount of optical and voltage bias in the *EQE* measurement, the refractive index and extinction coefficient of all layers must be known as function of wavelength together with the thickness of each individual layer and the behavior of the corresponding single junction cells as function of light intensity. Integration of the experimental *EQE* at the correct bias voltage with the AM1.5G solar spectrum results in the J_{sc} of the subcell in the tandem cell.

The second methods relies on measuring the *EQE* of the subcell at variable bias voltages *V*. Integration of the resulting *EQE*(*V*) with the AM1.5G solar spectrum for each value of *V* corresponds to measuring the *J*–*V* characteristics of the subcells under simulated solar light. This is first demonstrated by measuring the *J*–*V* characteristics of a single junction PFTBT:PCBM solar cell. The *J*–*V* curve measured under simulated solar light and the *J*–*V* curve obtained from the *EQE* with varying electrical bias showed a good correspondence for the single junction cell (Fig. 4). In an *EQE* measurement only the photocurrent is determined as the response of the cell to modulated light is measured. Therefore, the J_{photo}–V curve obtained from $J_{photo} = J_{light} - J_{dark}$ measured under simulated solar light is compared to the curve from the *EQE* measurement. We note that the relation $J_{photo} = J_{light} - J_{dark}$ is only approximate because the different light intensities used in measuring J_{light} and J_{dark} cause temperature differences in the active layer [21].

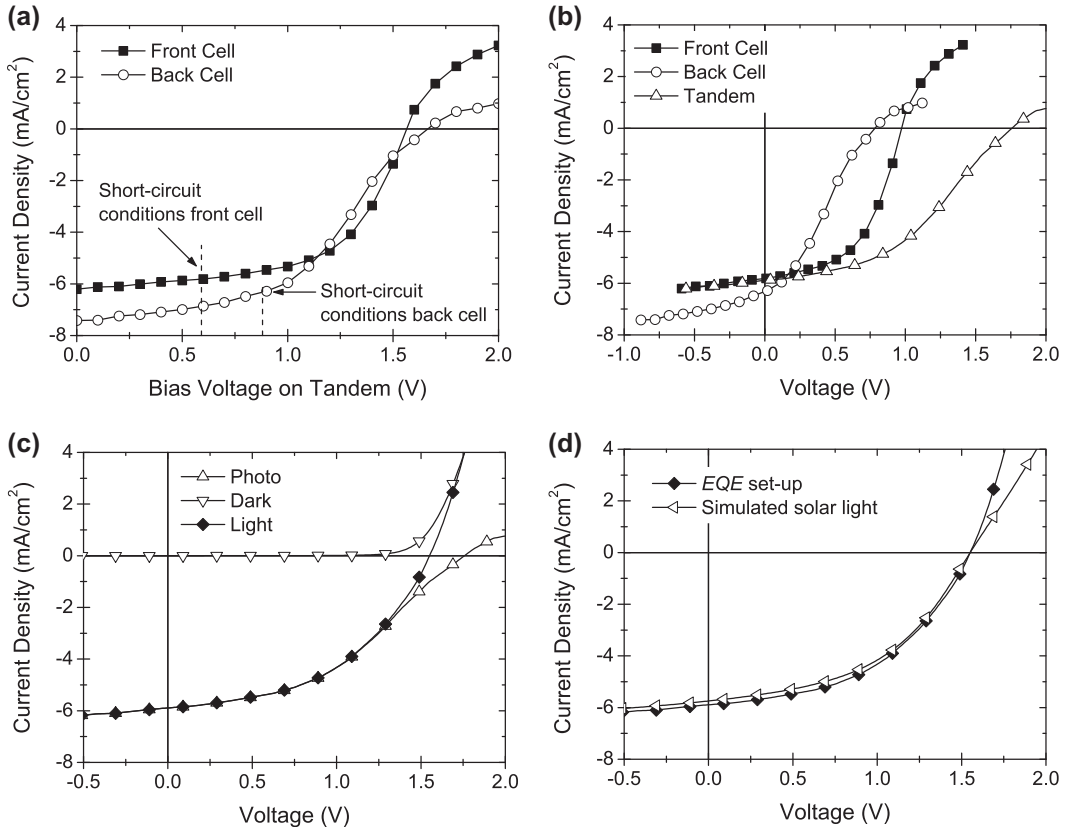

Fig. 5. Method 2. (a) Current density vs. bias voltage on the polymer tandem solar cell of the front and back cell obtained from the *EQE* measurement after integration of the *EQE* with the AM1.5G solar spectrum. The dotted line represents the electrical bias required for measuring under short-circuit conditions. (b) J_{photo}–V characteristics of the front and back cell. The J_{photo}–V curve of the tandem cell is the addition of photo *J*–*V* curves of the subcells. (c) The photo, dark, and light *J*–*V* curve of the tandem cell. (d) Comparison between the constructed *J*–*V* curve obtained from *EQE* measurements and the measured *J*–*V* curve under simulated solar light after the series of *EQE* measurements.

Table 1
Performance parameters of the front, back, and tandem cell measured with a proximity electrode (Method 1) and measured via the EQE measurement of the subcells (Method 2).

Cell	J_{sc} (mA/cm^2)	V_{oc} (V)	*FF* (–)	*MPP* (mW/cm^2)
Method 1				
Front cell (PTFBT:PCBM)	5.7	0.96	0.54	3.0
Back cell (pBBTDDP2:PCBM)	6.3	0.61	0.46	1.7
Measured tandem cell	5.8	1.57	0.52	4.7
Method 2				
Front cell (PTFBT:PCBM)	5.8	0.94	0.53	2.9
Back cell (pBBTDDP2:PCBM)	6.3	0.58	0.39	1.4
Constructed tandem cell	5.9	1.55	0.47	4.3
Measured tandem cell	5.7	1.55	0.48	4.2

The lower temperature in the dark measurement may cause an overestimation of J_{photo}. This effect is mainly present at $V > V_{oc}$ where J_{dark} steeply increases and can be seen as small deviation of the two curves in Fig. 4.

This experiment was also performed for the tandem cell used in the experiments of the first technique. For the PFTBT:PCBM front cell, all *EQE* curves at the different electrical biases were measured under a 780 nm bias illumination that ensures that the small band gap cell is not current limiting. The *EQE* was subsequently mathematically corrected for the sub-linear light intensity dependence of the current. Without this correction, the *EQE* would be overestimated because it is measured at low monochromatic light intensity. The necessity for the correction strongly depends on the light intensity (I) dependence of the short-circuit current. For many polymer solar cells this can be described by $J_{sc} = I^{\alpha}$, with the exponent α being in the range of 0.95–1.00. For example when $\alpha = 0.98$ and the monochromatic light intensity is 1% of AM1.5G intensity, the error in J_{sc} can be as large as 10%. In the Ref. [20] we have shown that for the PFTBT:PCBM cell and the present *EQE* setup the required correction factor is about 0.93.

For determining the *EQE* of the pBBTDPP2:PCBM back cell, the sample was illuminated by 532 nm light, which serves simultaneously as flood light for the back cell and as bias illumination for the front cell during the measurements. Under these conditions, the short-circuit condition in the subcells was obtained at an applied electrical bias of 0.59 V and 0.88 V for the front and back cell, respectively. This resulted in a $J_{sc} = 5.8$ mA/cm^2 for the front cell and $J_{sc} = 6.3$ mA/cm^2 for the back cell.

After integration of the *EQE* with the AM1.5G solar spectrum for variable electrical bias, the current densities of front and back cell were plotted vs. the bias voltage on the tandem cell (Fig. 5a). These curves were rectified with the appropriate forward bias voltage on the tandem cell, shifting the curves, so that the short-circuit current densities end up at 0 V (Fig. 5b). The *J–V* curves of the subcells were summed using Kirchhoff's law to obtain the *J–V* curve of the tandem cell (Fig. 5b). Addition of this photocurrent curve of the tandem cell to the measured dark curve ($J_{light} = J_{photo} + J_{dark}$) led to the *J–V* curve of the tandem cell under illumination (Fig. 5c). This *J–V* curve obtained from the *EQE* of the subcells in the tandem shows an excellent agreement with the *J–V* curve measured under simulated solar light, recorded after completing the series of spectral response measurements (Fig. 5d).

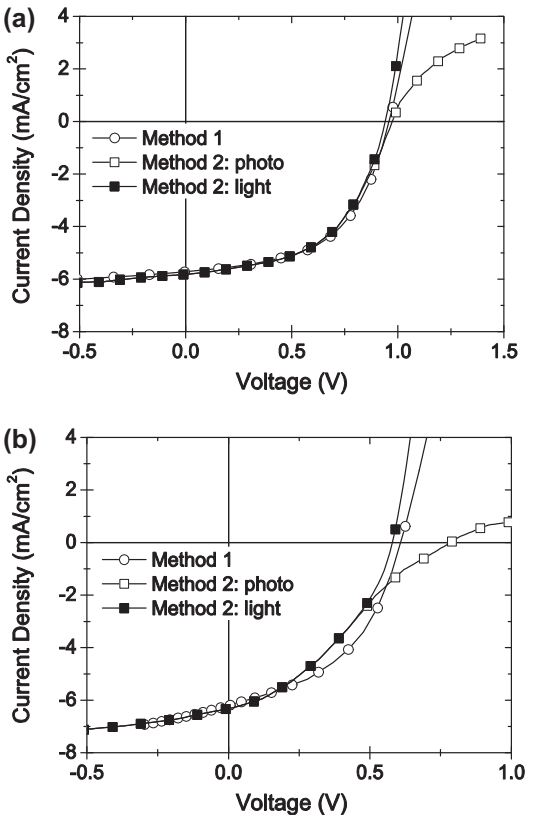

Fig. 6. Comparison between the *J–V* characteristics determined by Method 1 and Method 2 for the PFTBT:PCBM front cell (a) and the pBBTDPP2:PCBM back cell (b) in the polymer tandem solar cell. The light curve for Method 2 is defined as $J_{light} = J_{photo} + J_{dark}$, see text.

3.3. Comparison of the J–V curves of the subcells from methods 1 and 2

The two methods both allow determining the *J–V* characteristics of the subcells in a polymer tandem solar cell with a solution processed intermediate contact. Fig. 6 plots the *J–V* curves of the front and back cell obtained using the proximity electrode (Method 1) and via the *EQE* measurement (Method 2). The performance parameters of the subcells are summarized in Table 1. For the determination of the V_{oc} of the subcells in Method 2, the photocurrent curve is summed with a measured dark curve of a single junction 'dummy' cell, identical to the subcell.

For the PFTBT:PCBM front cell, the *J–V* curves of the two methods match well (Fig. 6a). On the other hand, the *J–V* curves of the pBBTDPP2:PCBM back cell diverge slightly in the region of 0.2–0.5 V (Fig. 6b). Only the fill factor (*FF*) of the back cell deviates. Because this subcell is not current-limiting, this has little to no influence on the performance of the tandem cell. The main reason for the difference is the stability of the tandem cell during the

spectral response measurements. Table 1 shows that the tandem cell has degraded from 4.7% to 4.2% as a result of the long (several hours) and intense illumination (up to 3 sun bias illumination for the PFTBT:PCBM cell) during the bias dependent *EQE* measurements.

4. Conclusions

We have developed two methods to measure the *J–V* curves of the subcells in a solution processed tandem polymer solar cell. In these devices a third middle contact that extracts current cannot be used because the conductivity parallel to the surface in the intermediate recombination layer is too limited. In the first method an additional Ag electrode was evaporated between the ET and HT layers that form the recombination layer. The Ag electrode was positioned just outside of the active area to prevent interference with the optical electric field in the stack. This extra proximity contact allows the determination of the voltage difference between the intermediate contact and one of the two electrodes. The second method employs the *EQE* measurement of the subcells in the tandem configuration and varying the electrical bias over the tandem cell. After integration with the AM1.5G solar spectrum, the current density as a function of the voltage over the tandem cell is determined for both subcells and can be transformed in the *J–V* curves of the subcells of the tandem cell. The results of the two methods are in mutual agreement and enable characterizing the individual cells in the tandem stack.

Acknowledgements

We thank Frank Louwet and Dirk Bollen (Agfa Gevaert NV) for providing a sample of the pH neutral Orgacon PEDOT. We acknowledge Jörgen Sweelssen (Dutch Organization for Applied Scientific Research, TNO) and Mathieu Turbiez (BASF) for the synthesis of PFTBT and pBBTDPP2, respectively. ABSTRACT

A series of novel arylvinylene substituted phenanthroline derivatives has been synthesised and their application as electron transporting materials in organic light emitting diodes (OLEDs) has been investigated. One particular derivative, namely, 2,9-bis-(2-thiophen-2-yl-vinyl)-[1,10]phenanthroline (C-4) shows significantly lower operating voltage (36% reduction) and increase of power efficiency of up to 83% compared to tris (8-quinolinolato)aluminium (III) (Alq_3). C4 also shows substantially longer (nearly 6-fold) life-time than bathophenanthroline (BPhen) in blue devices. Doping of C4 with electron donors such as m-MTDATA, α-NPB and lithium quinolinolate (Liq) further reduces the turn-on voltage and operating voltage.

1. Introduction

Organic light emitting diode (OLED) based displays have become one of the significant flat panel display technologies as evidenced by the production of active matrix OLEDs for mobile phones by Samsung SDI and the introduction of 11″ AM-OLED TV (XEL-1) to the market by Sony. Recent announcement by Samsung of its intention to invest US Dollars 2.2 billion into active matrix OLED Television (AM-OLED) to bring them into mainstream TV market has given considerable impetus to the scientists developing materials for the OLED devices [1–9].

Since Tang et al. reported an organic light emitting device (OLED) using tris (8-quinolinolato)aluminium (III) (Alq_3) as an electron transporting material (ETM) in 1987, Alq_3 has widely been employed both in commercial production and research because of its low cost and acceptable life-time [2]. However, Alq_3 has three disadvantages: (i) poor mobility, therefore high operating voltage and reduced luminous efficiency. (ii) It leaves behind considerable amount of residue and ash under production condition (during vacuum thermal evaporation). (iii) Perceived toxicological properties of aluminium compounds. Considerable research effort has been expended to develop high mobility materials which would reduce the operating voltage without diminishing the efficiency and life-time [8,9]. In addition to metal quinolates, oxadiazole(s), oxazole(s), thiazole(s), imidazole(s), pyridyl compounds, silole(s), perfluorinated oligophenylene(s), phenanthroline(s), pyrimidone(s) and triazine(s) have been reported by several authors [3–8,10–14,19,28–31].

Amongst the phenanthroline derivatives, bathophenanthroline (BPhen), bathocuproine (BCP) have been extensively studied because of their high mobility (1×10^{-4} $cm^2 V^{-1} s^{-1}$) compared to that of Alq_3 (1×10^{-6}–1×10^{-7} $cm^2 V^{-1} s^{-1}$) [6–7] and deep HOMO levels (typically, −6 eV to −6.9 eV) which make them excellent hole blockers. However, both virgin BCP and BPhen give significantly poorer life time compared to other hole blockers. The former tends to crystallize (BCP films crystallize upon

doi:10.1016/j.orgel.2010.12.025

storage) and the latter has a very low T_g of 62 °C [9,15–17]. Both BCP and BPhen were found to give acceptable life-time if they are doped or mixed with electron donors such as low work function metals (e.g. Li and Cs) or their complexes [10–13]. Kim and Im [15] reported that their devices with pristine BCP or BPhen lasted only a few hours even at an initial luminance of 150 cd m^{-2}. Another potential candidate, 1,3,5-tris(phenyl-2-benzimidazolyl)benzene (TPBI), has similar crystallisation problem [21].

Yan-Jun Li et al. recently reported some phenanthroline derivatives with superior performance to Alq_3 [11] for their device structure ITO/α-NPB (50 nm)/Alq_3 (40 nm)/ETL (30 nm)/LiF (1 nm)/Al where their best ETM gave a 21% reduction in operating voltage at 1000 cd m^{-2} and 32% increase in power efficiency (lm/W) compared to Alq_3 based devices. However, no life-time information was reported.

A good electron transporter (et) should have the following characteristics [7]: (i) high electron affinity to match with the workfunction (W.F.) of the cathode, thus reducing the energy barrier; (ii) high electron mobility ($\mu_e > 1 \times 10^{-5}$ cm^2 V^{-1} s^{-1}) to aid the transport of electrons into the emissive layer and efficiently confine the excitons in this layer; (iii) a reversible electrochemical reduction with a sufficiently high reduction potential;(iv) a high ionisation potential (I.P.) to serve as a hole blocker (I.P. > 6 eV); (v) a high glass transition temperature and melting point; (vi) thermal stability up to at least 250 °C (high $T_g/T_m/T_d$); (vii) stability under evaporation conditions for a period of at least 144 h if vacuum processing is employed as the manufacturers would like to run their production equipment at least for 6 days in a row without interruption; (viii) good stability to moisture and oxygen; (ix) capable of forming amorphous film so that crystallisation induced degradation is avoided; (x) photostability; (xi) if phosphorescent emitters are used, the triplet energy level of the et should be higher than that of the phosphorescent emitters; (xii) processability to produce uniform and pinhole-free films either by evaporation (small molecules) or by solution casting.

We have been interested in developing electron transporters cum hole blockers which would give long life-times. Here, we report the synthesis of some selected 2,9 substituted phenanthrolines, their physical properties and their performance as ETMs in blue OLEDs [14].

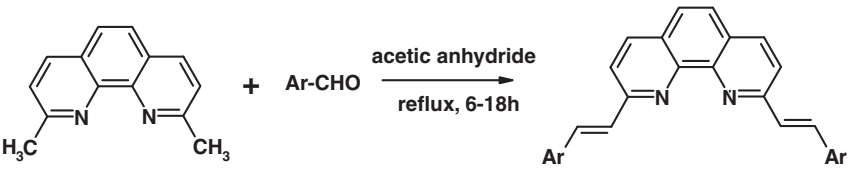
2. Experimental

2.1. Synthesis

The compounds were synthesized according to the general method as shown in Scheme 1. All the compounds were purified by double sublimation.

2.1.1. 2,9-Bis(styryl)-[1,10]-phenanthroline [C-1]

A mixture of neocuproine hydrate (5.0 g; 0.024 mol) and benzaldehyde (5.4 g; 5.2 mL; 0.050 mol) was refluxed



Scheme 1. Ar = phenyl (*C*-1), 4-trifluoromethylphenyl (*C*-2), 4-cyanophenyl (*C*-3) and thienyl (*C*-4).

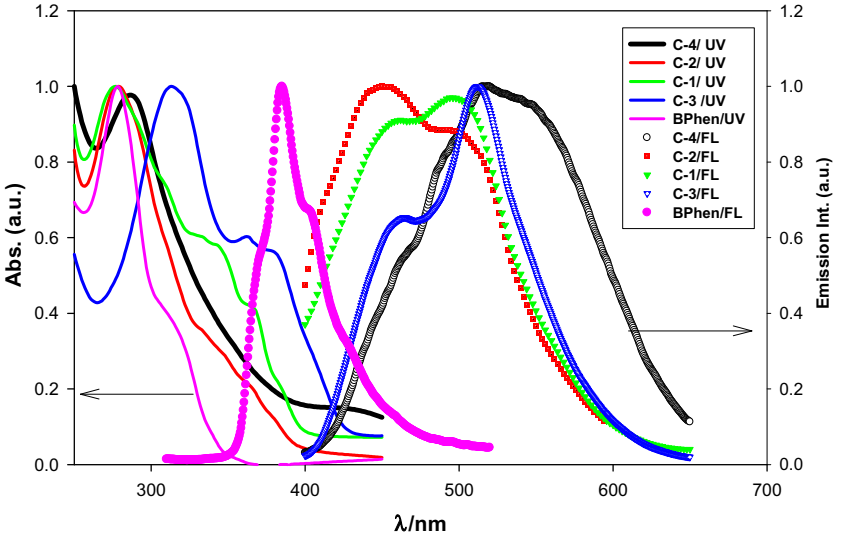


Fig. 1. Thin film UV–Vis absorption and fluorescence spectra of C-1, C-2, C-3, C-4 and BPhen. Excitation wavelengths: C-1 (360 nm), C-2 (360 nm), C-3 (350 nm), C-4 (350 nm) and BPhen (350 nm).

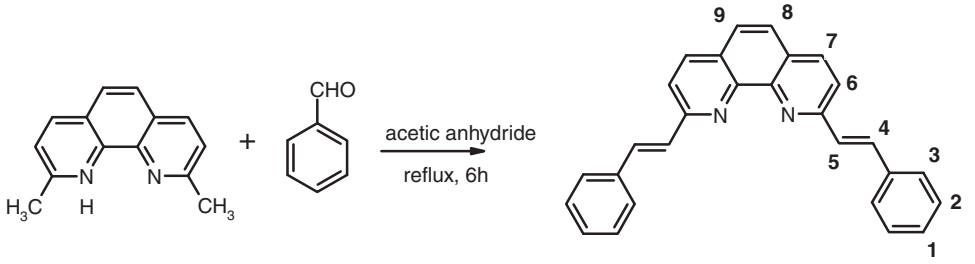
in acetic anhydride (20 mL) for 6 h and the cooled reaction mixture was poured into ice-cold water. The product was extracted into ethyl acetate. The organic phase was washed with water, dried over anhydrous magnesium sulphate and then the solvent removed. To the residue con. HCl was added and the yellow solid that obtained was again taken into dichloromethane and extracted with 5% NaOH solution. The organic phase was washed well with water, dried over anhydrous magnesium sulphate and solvent removed to give a yellow solid. The product was purified by column chromatography on silica gel (eluent: CH_2Cl_2–MeOH 49:1). The eluents containing the product was evaporated and by addition of ether and petroleum ether gave an analytically pure material 4.8 g (52%). *Anal.* Calc. for $C_{28}H_{20}N_2$: C, 87.47; H, 5.24; N, 7.28. Found: C, 87.14; H, 5.15; N, 7.20%. ^{1}H NMR ($CDCl_3$): 7.33(t, J = 7.4 Hz, H-1), 7.42(t, J = 7.4 Hz, H-2), 7.70(d, J = 8.3 Hz, H-3), 7.78(d, J = 16 Hz, H-4), 7.73(d, J = 16 Hz, H-5), 7.89(d, J = 8.4 Hz, H-6), 8.16(d, J = 8.4 Hz, H-8), 7.68 (s, H-8 and H-9).

2.1.2. 2,9-Bis(4,4′-trifluoromethylphenyl)vinyl-[1,10]-phenanthroline [C-2]

A mixture of neocuproine hydrate (5.0 g; 0.024 mol) and 4-(trifluoromethyl)benzaldehyde (8.8 g; 0.050 mol) was refluxed in acetic anhydride (20 mL) for 6 h and then allowed to cool for 18 h to give light pinkish crystals. Methanol and small amounts of water were added and the crystals were collected by suction filtration. The product was then washed thoroughly with methanol, water and diethyl ether before dried under vacuum at 80 °C for several hours to give (7.9 g; 63%) of product. Finally, the product was purified by sublimation (270 °C at 10^{-6} Torr) to give an analytically pure material as a light yellow solid, m.p. 279 °C (DSC, onset); 285 °C (DSC, peak). *Anal.* Calc. for $C_{30}H_{18}N_2F_6$: C, 69.23, H, 3.49; N, 5.38. Found: C, 69.54, H, 3.39, N, 5.40%; ^{1}H NMR (d-DMF): 7.88(d, J = 8 HZ, H-3, 4H), 7.93 (d, J = 16 Hz, H-5), 8.02 (s, H-9), 8.03 (s, H-8), 8.11(d, J = 8 Hz, H-2, 4H), 8.20 (d, J = 8.3 Hz, H-6), 8.26 (d, J = 16 Hz, H-4), 8.58 (d, J = 8.3 Hz, H-7).



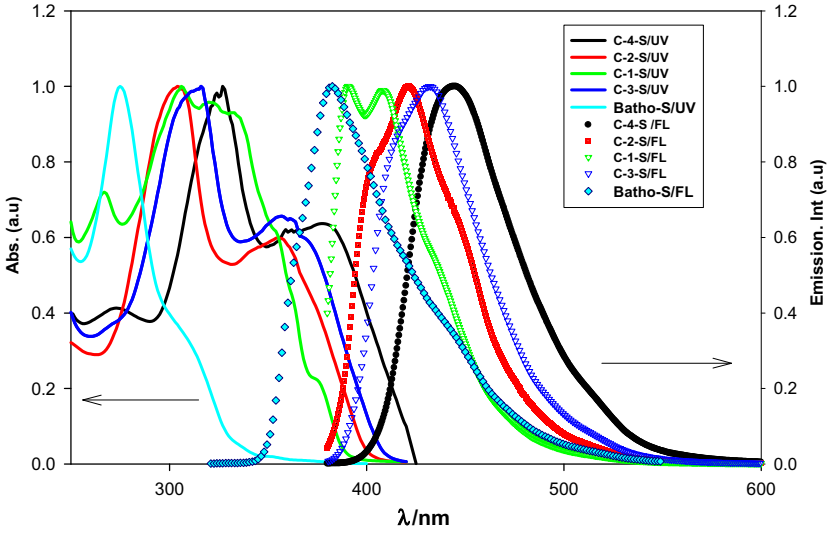


Fig. 2. UV–Vis absorption and fluorescence spectra of C-1 (4.16×10^{-5} M), C-2 (3.84×10^{-5} M), C-3 (5.06×10^{-5} M), C-4 (4.03×10^{-5} M) and BPhen (6.0×10^{-5} M) in CH_2Cl_2. Excitation wavelengths: C-1, C-2, C-3, C-4 (all 350 nm) except BPhen (300 nm).

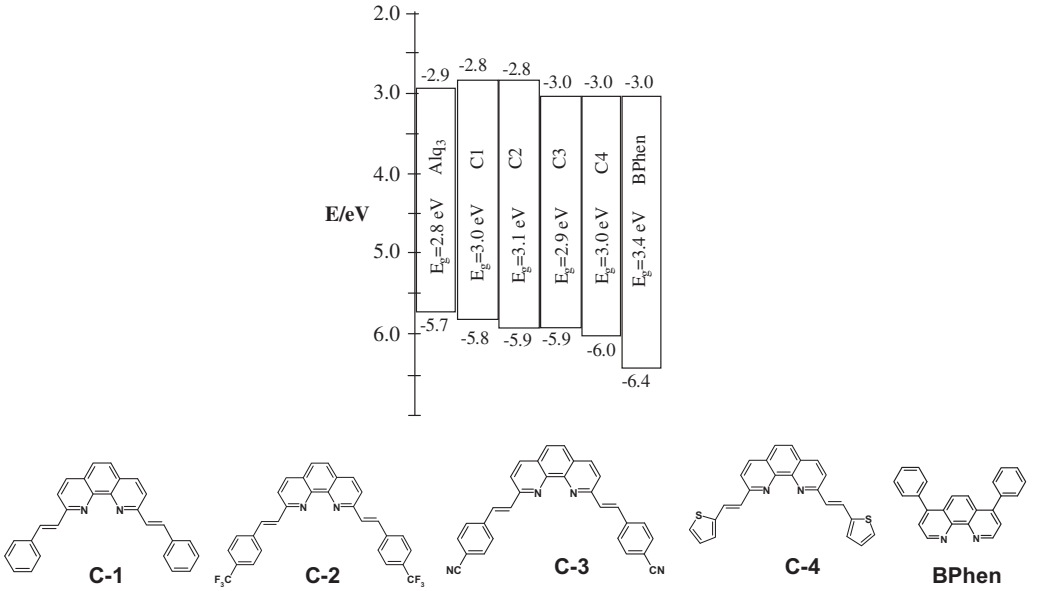

Fig. 3. HOMO–LUMO levels of Alq_3, C-1, C-2, C-3, C-4 and bathophenanthroline (BPhen).

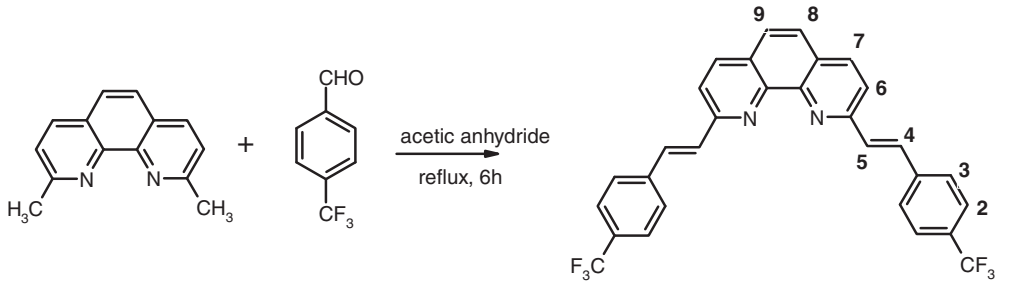
2.1.3. 2, 9-Bis(4,4′-cyanophenyl)vinyl-[1,10]-phenanthroline [C-3]

A mixture of neocuproine hydrate (5.0 g; 0.024 mol) and 4-cyanobenzaldehyde (6.6 g; 0.050 mol) was refluxed in acetic anhydride (30 mL) for 18 h under nitrogen and then allowed to cool to room temperature to give a yellow orange solid. The product was filtered off under suction and washed with petroleum ether (40–60 °C), methanol and finally with diethyl ether. The product was dried under vacuum at 80 °C to give a light yellow solid (7.9 g; 76%). Finally, the crude product was purified by sublimation (at 280 °C; 10^{-6} Torr) to give an analytically pure material, m.p. 289 °C (DSC, onset). *Anal.* Calc. for $C_{30}H_{18}N_4$: C, 82.93; H, 4.18; N, 12.82. Found: C, 82.67; H, 4.07; N, 12.82%. The compound was so insoluble in most of the organic solvents that ^1H NMR could not be carried out.



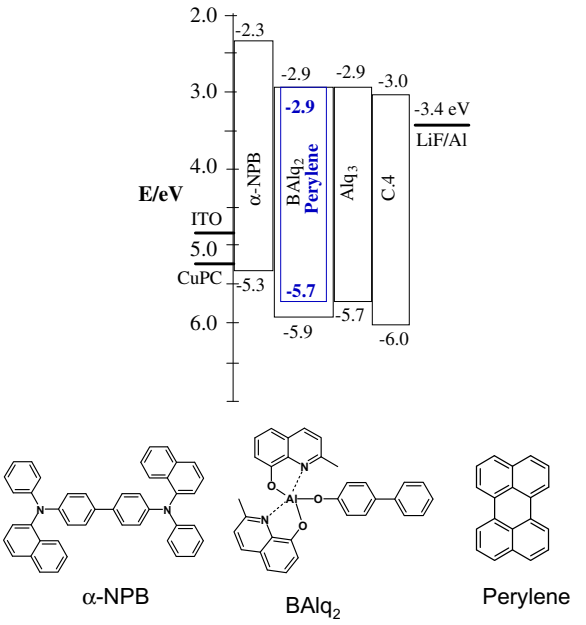


Fig. 4. Energy level diagram for the device: ITO/CuPc(50 nm)/a-NPB (75 nm)/$BAlq_2$ + perylene(50:0.1 nm)/ETL(20 nm)/LiF(0.5 nm)/Al where the ETL is either Alq_3 or C-4.

2.1.4. 2,9-Bis-(2-thiophen-2-yl-vinyl)-[1,10]phenanthroline [C-4]

A mixture of neocuproine hydrate (50 g; 0.24 mol) and 2-thiophene carboxaldehyde (46.5 mL; 0.50 mol) was refluxed in acetic anhydride (90 mL) for 6 h and then allowed to cool to room temperature over 20 h. Water (20 mL) and methanol (130 mL) were added to the reaction mixture and the product was collected by suction filtration to give a light yellow brown solid. The solid was washed with petroleum ether (40–60 °C), methanol followed by diethyl ether and dried under vacuum at 80 °C for several hours (>10 h) to give (46 g; 48%) of product . Finally, the product was further purified by sublimation (at 260 °C; 10^{-6} Torr) to give a golden yellow solid, m.p. 298 °C (DSC, onset); T_g 111 °C. *Anal.* Calc. for $C_{24}H_{16}N_2S_2$: C, 72.70; H, 4.07; N, 7.06; S, 16.17. Found: C, 72.85; H, 4.12: N, 7.10; S, 16.17%; ^{1}H NMR (d-DMF): 7.21(dd, H-2), 7.45 (d, J = 16 Hz, H-5), 7.52 (d, J = 3.5 Hz,H-3), 7.67 (d, J = 5 Hz, H-1), 7.95(S, H-8, 9), 8.15 (d, J = 8.3 Hz, H-6), 8.32 (d, J = 16 Hz, H-4), 8.49 (d, J = 8.3 Hz, H-7). MS (m/z) (%): 419 (100) (M^++Na), also peaks appeared at m/z 435, 472 and 499.

3. Characterisation

UV–Vis absorption spectroscopy (Shimadzu, UV-1601) and fluorescent spectroscopy (Perkin–Elmer LS55) were performed on evaporated thin films on quartz (spectrosil) and in dichloromethane solutions. The decomposition characteristics were examined under nitrogen atmosphere on a TGA equipment (Rheometric Scientific) and the Differential Scanning calorimetry was performed on Perkin Elmer (Pyris 6 DSC). Band gap was estimated from absorption spectroscopy of thin films produced by vacuum thermal evaporation.

HOMO–LUMO levels were determined by cyclic voltammetry (computer controlled potentiostat PAR 273 or CHI 600D, analyte = 0.5 mM, supporting electrolyte (tetrabutyl ammonium tetrafluoroborate = 10 mM in dichloromethane as the solvent). The working, counter and reference electrodes were Pt foil, Pt wire and Ag/AgCl electrodes, respectively.

The HOMO/LUMO levels were determined from the equation in the reference [26]:

$$\text{HOMO/LUMO} = -(E_{1/2}\text{vs.NHE} + 4.40)\ \text{eV} \quad (1)$$

(NHE: normal hydrogen electrode)

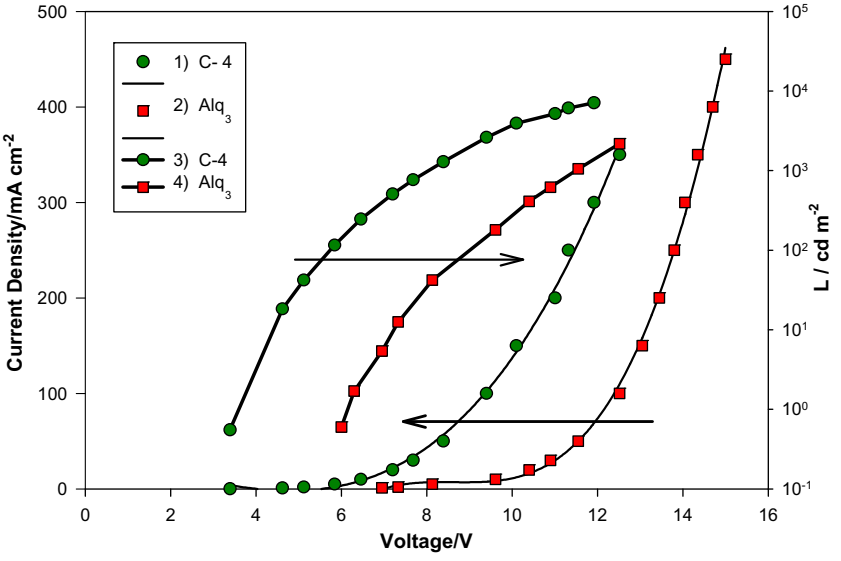

Fig. 5. Current density–voltage–luminance characteristics of ITO/CuPc(50 nm)/a-NPB(75 nm)/$BAlq_2$ + perylene(50:0.1 nm)/ETL(20 nm)/LiF(0.5 nm)/Al where the ETL is either Alq_3 or C-4.

Table 2
Performance of blue devices (Set A).

ETM	Turn-on voltage (V)	V_{op}/V at 1000 cd m^{-2}	V at 100 mA cm^{-2}	Eff./cd A^{-1} at 100 cd m^{-2}	Eff./lm W^{-1} at 100 cd m^{-2}	Eff./cd A^{-1} at 1000 cd m^{-2}	Eff./lm W^{-1} at 1000 cd m^{-2}	EQE (%)	Life-time ($t_{1/2}$)/h) initial luminance 100 cd m^{-2}

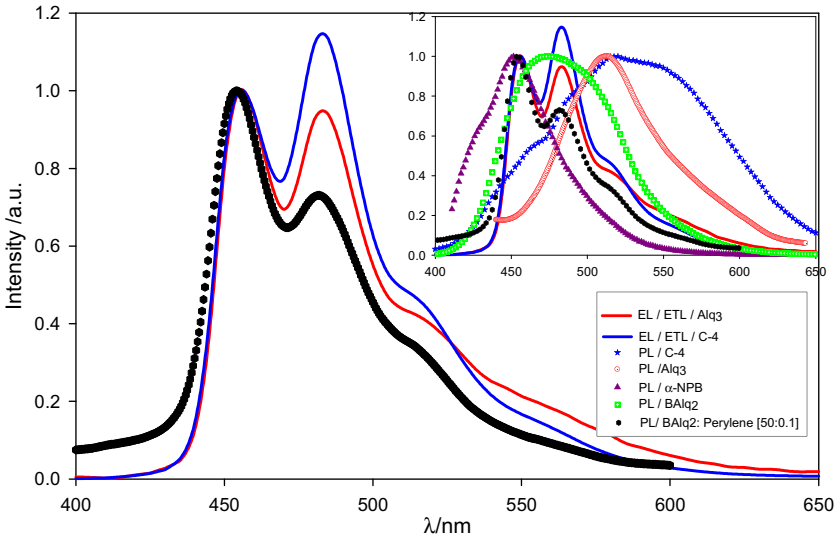

Fig. 6. EL spectra (solid lines) of ITO/CuPc(50 nm)/a-NPB(75 nm)/$BAlq_2$ + perylene (50:0.1 nm)/ETL(20 nm)/LiF(0.5 nm)/Al where the ETL is either Alq_3 or C-4. Thin film PL spectra of C-4, Alq_3, a-NPB, $BAlq_2$ and perylene (50:0.1).

The $E_{1/2}$ employed here were determined from the derivative of the cyclic voltammograms.

3.1. Device fabrication

Electroluminescent devices were fabricated by thermal evaporation method using a multi-chamber OLED pilot plant machine (Solciet, manufactured by ULVAC, Japan). The devices were fabricated on a patterned (pixelated ITO substrate (40 Ω per square surface resistance), Hitachi High Tech., Japan), cleaned with deionised water, acetone, isopropyl alcohol and water (in that order), then dried at 150 °C for 20 min and then subjected to ozone cleaning (UV irradiation, 185 nm) at 150 °C for 10 min. The substrate was then plasma cleaned in the presence of oxygen for 25 s and moved into the vacuum chamber from which the hole injector (copper phthalocyanine, CuPC), hole transporter [*N*,*N*′-bis-(1-naphthalenyl)-*N*,*N*′-bis-phenyl-(1,1′-biphenyl)-4,4′-diamine (α-NPB)]], host ($BAlq_2$ or BH-3)):dopant (perylene or BD-3), electron transporter (20 nm) were sequentially deposited under vacuum. The evaporation rates of CuPc, α-NPB, $BAlq_2$, perylene, BH-3, BD-3, Alq_3 and C-4 were 0.7, 1.5, 1, 0.002, 1, 0.1, 1 and 1 Å s^{-1}, respectively.

An electron injection layer (LiF, 0.5 nm) was deposited on top of the ETM before depositing the top contact (Al, 150 nm). All the devices were encapsulated with a UV curable adhesive (Nagase, Japan) with glass backplates in a glovebox under nitrogen atmosphere. The electrical and optical measurements were carried out by computer controlled Keithley 2400 Source Meter and Minolta (CS-1000) spectrometer, respectively. Life time measurements were carried out on encapsulated devices under constant current.

4. Results and discussion

4.1. Physical properties

The thin film absorption and fluorescence spectra of the compounds C-1-C-4 and bathophenanthroline (BPhen) are compared in Fig. 1. The absorbance and fluorescence in dichloromethane are shown in Fig. 2. All the compounds were found to be fluorescent, light blue as thin films and dark blue in solutions.

Table 1 summarises the physical properties of the compounds C-1, C-2, C-3 and C-4. All the compounds were purified by double sublimation.

HOMO–LUMO data are shown in Fig. 3. On substituting the phenyl ring of C-1 with electron withdrawing groups such as CF_3 (C-2), the HOMO level is depressed by 0.1 eV whilst LUMO level is unchanged. In contrast, both HOMO

and LUMO levels are lowered by 0.1 eV on substituting C-1 with the CN group (C-3). This is consistent with the postulation by Bredas and Heeger [20].

4.2. Device performance

As C-1 and C3 decompose on sublimation, they were not suitable for device fabrication under vacuum thermal evaporation. We report here the blue device performance of only compound 4 as our preliminary results showed that C4 was superior to C2 in terms of operating voltage, efficiency and life-time [22] with green OLEDs. Thus, we fabricated two sets of OLEDs. One (Set A), light blue based on $BAlq_2$ as host and perylene as dopant and the other (Set B) dark blue [(CIE (x, y): (0.15, 0.14)] based on host BH-3 (Kodak) and dopant BD-3 (Kodak).

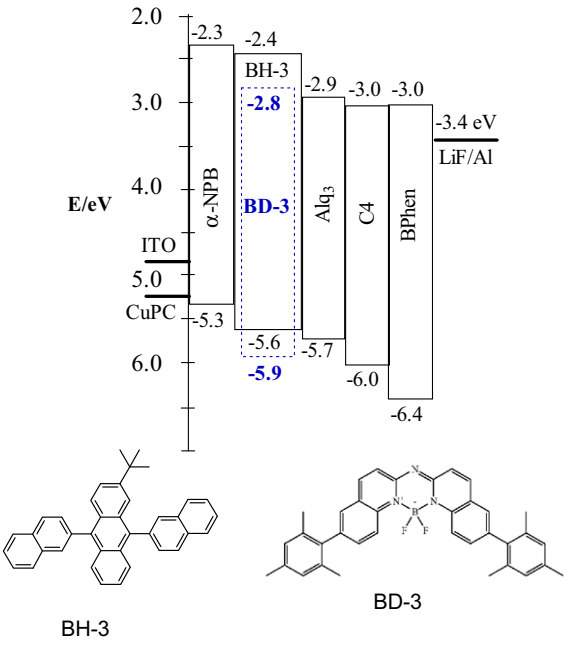

Fig. 7. Energy level diagram for ITO/CuPc (10 nm)/a-NPB(50 nm)/BH-3 + BD-3 (30:0.5 nm)/ETL (20 nm)/LiF(0.5 nm)/Al where the ETL is either Alq_3, C-4 or BPhen.

4.2.1. Device Set A

The device architecture of Set A is ITO/CuPC (50 nm)/α-NPB (75 nm)/$BAlq_2$ + perylene (50:0.1 nm)/ETL (20 nm)/LiF (0.5 nm)/Al where the ETL is either Alq_3 or C-4. The energy level diagram for the device under zero bias is shown in Fig. 4.

Fig. 5 shows the luminance vs. voltage and the current density vs. voltage plots for the Set A. From Fig. 5, it is obvious that the current injection and transport are much more efficient in the case of C-4 as opposed to Alq_3 as evidenced by the lower operating voltage presented by C-4 at any given luminance or current density. For example, the voltage required for devices with Alq_3 as ETM to give a luminance of 1000 cd m^{-2} was 11 V as opposed to those with C-4 was only 7 V, a reduction of nearly 36% in operating voltage. Correspondingly, the power efficiency for devices with Alq_3 as ETL was 0.6 lm/W and those with Compound C-4 was 1.1 lm/W at 1000 cd m^{-2}, representing an increase of 83% in efficiency. The device data are also summarised in Table 2. The colour co-ordinates obtained for devices with Alq_3 [(CIE (x, y): (0.173, 0.252)] and that for the devices with C4 is (0.150, 0.233). This is consistent with our expectation that the mobility of C-4 is much greater than that of Alq_3 and hence the electron/hole recombination would take place closer to the α-NPB interface for the devices with C-4 and hence more saturated blue colour co-ordinates. Fig. 6 compares the EL spectra of the devices

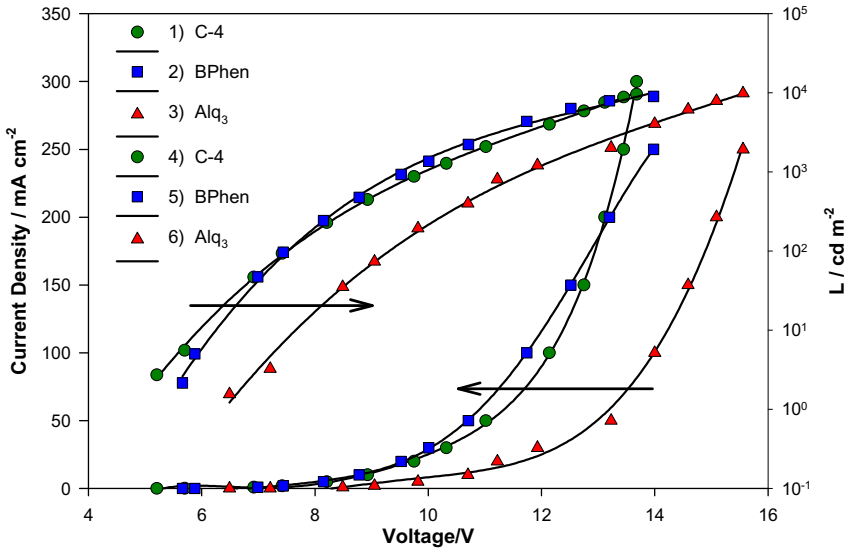

Fig. 8. Current density–voltage–luminance characteristics of ITO/CuPc (10 nm)/a-NPB(50 nm)/BH-3 + BD-3 (30:0.5 nm)/ETL (20 nm)/LiF(0.5 nm)/Al where the ETL is either Alq_3, C-4 or BPhe.

with C-4 and the Alq_3 as ETL and the PL of α-NPB, $BAlq_2$, a mixture of $BAlq_2$ with perylene (50:0.1) and Alq_3 and C-4. It is clear from Fig. 6 that the peak positions of the EL spectra and the PL of mixture of $BAlq_2$ and perylene are identical, but the relative ratios of the intensity of emission are slightly different. The second peak at 483 nm from the EL of the devices with C-4 as the ETL is slightly more intense than the first peak at 455 nm when compared with the EL from devices where Alq_3 is ETL. The EL spectra of devices with Alq_3 has a longer emission tail than the EL spectra of devices with C-4 as the ETL. This explains the differences in colour co-ordinates obtained here. Furthermore, the relative intensity differences could be due to the slight differences in the concentration of perylene in the host as the control of concentration at such a low level (0.2% of perylene) is not easy under the co-evaporation conditions.

The life-time of the devices with Alq_3 as ETM has significantly longer life-time than C-4. We attribute this to the high Tg (172 °C of Alq_3) as compared to C-4 (111 °C) and the fact that Alq_3 is a mixture of at least two isomers thus retaining a high degree of amorphicity [27].

It is well known that the nature of current injection of an electron transporter is dependent on its interfacial characteristics with the adjacent layer, namely, host + dopant.

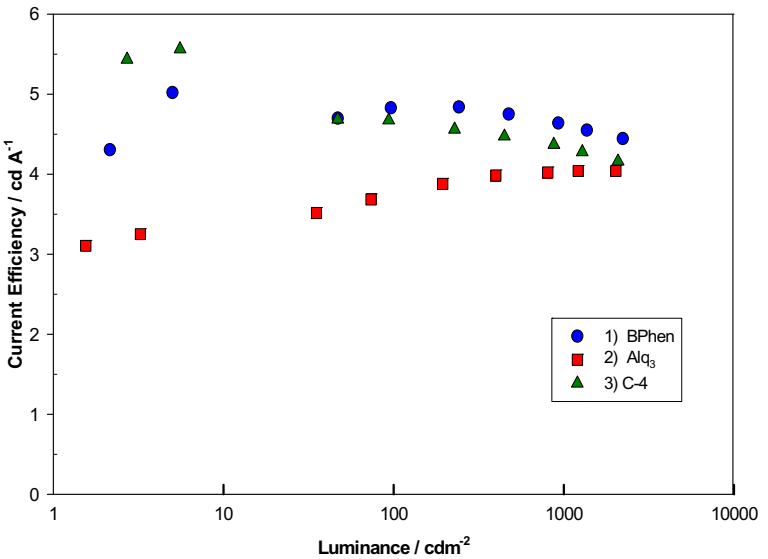

Fig. 9. Current efficiency vs. luminance characteristics of ITO/CuPc (10 nm)/a-NPB (50 nm)/BH-3 + BD-3 (30 + 0.5 nm)/ETL (20 nm)/LiF (0.5 nm)/Al, where the ETL is either Alq_3, C-4 or BPhen.

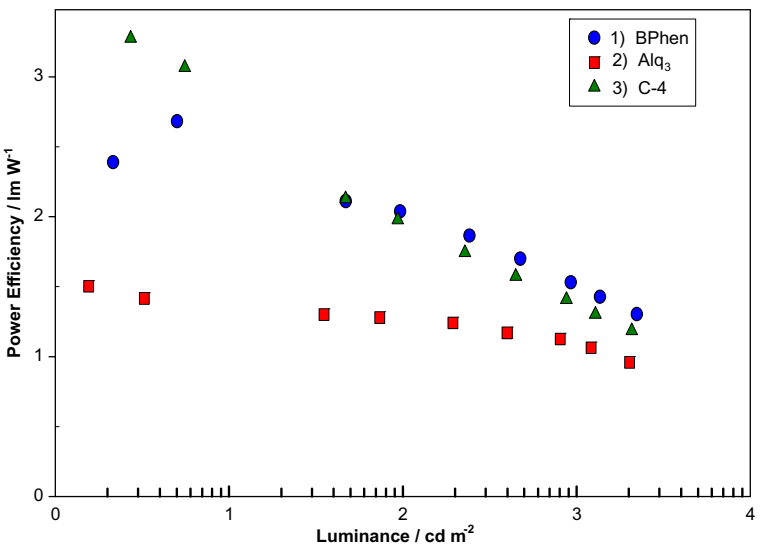

Fig. 10. Power efficiency vs. luminance characteristics of ITO/CuPc (10 nm)/a-NPB (50 nm)/BH-3 + BD-3 (30 + 0.5 nm)/ETL (20 nm)/LiF (0.5 nm)/Al, where the ETL is either Alq_3, C-4 or BPhen.

Table 3
Performance for Blue Devices from Set B.

ETM	Turn-on voltage (V)	V_{op}/V at 1000 cd m^{-2}	V at 100 mA cm^{-2}	Eff./cd A^{-1} at 100 cd m^{-2}	Eff./ lm W^{-1} at 100 cdm^{-2}	Eff./cd A^{-1} at 1000 cd m^{-2}	Eff./lm W^{-1} at 1000 cd m^{-2}	CIE (x, y) at 1000 cd m^{-2}	EQE(%)	Life-time ($t_{1/2}$) at 1000 cd m^{-2}
Alq_3	6.0 ± 0.2	11.5 ± 0.2	14.0	3.5	1.3	4.0	1.2	(0.152, 0.145)	3.3	1500
BPhen	5.0 ± 0.2	9.5 ± 0.2	12.0	4.5	2.0	4.4	1.4	(0.147, 0.157)	3.4	40
C-4	4.3 ± 0.2	9.5 ± 0.2	12.0	4.6	2.0	4.4	1.6	(0.151, 0.144)	3.6	250

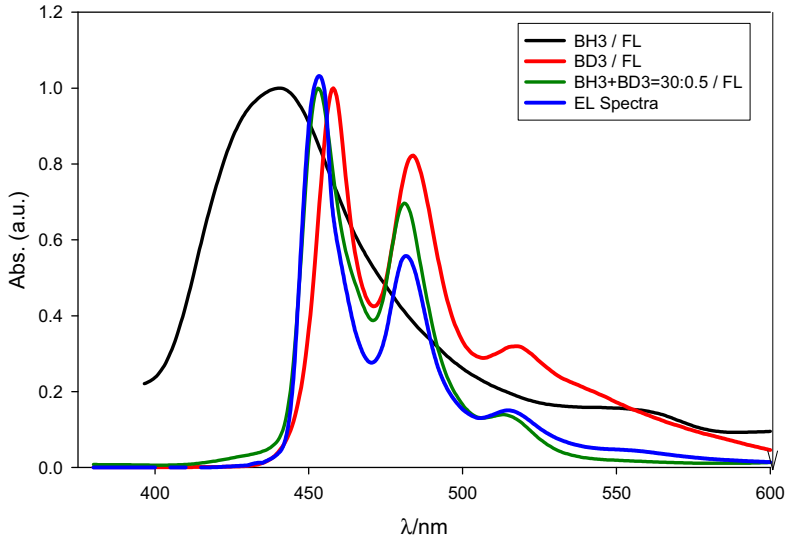

Fig. 11. Fluorescence and EL spectra of ITO/CuPc (10 nm)/ a-NPB (50 nm)/BH-3 + BD-3 (30 + 0.5 nm)/C-4 (20 nm)/LiF (0.5 nm)/Al.

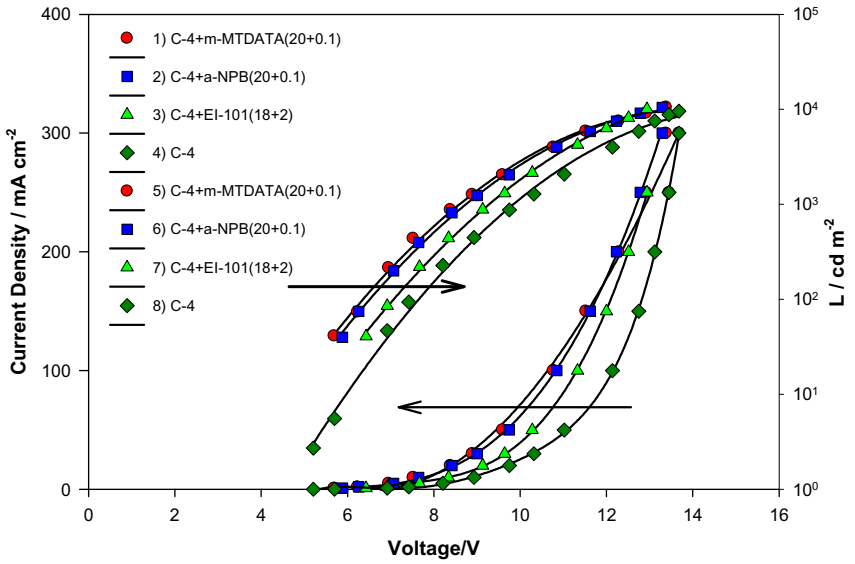

Fig. 12. Current density vs. voltage vs. luminance for ITO/CuPc (10 nm)/a-NPB (50 nm)/BH-3 + BD-3 (30 + 0.5 nm)/C-4 (20 nm)/LiF (0.5 nm)/Al where C-4 was doped with m-MTDATA (0.5%), a-NPB (0.5 %) and Liq (10%).

The question is whether C-4 would perform well in another system. Further, the comparison of the electron transporter, C-4 with Alq_3 alone is not sufficient as it is known that bathophenanthroline (BPhen) has much higher electron mobility and deeper HOMO level than Alq_3, any new ETM has to be compared with BPhen as well. Thus, we designed the device structure Set B to compare C-4 with BPhen and Alq_3.

4.2.2. Device Set B

ITO/CuPc (10 nm)/α-NPB (50 nm)/BH-3 + BD-3 (30:0.5 nm)/ETL (20 nm)/LiF (0.5 nm)/Al where the ETL is either Alq_3, C-4 or BPhen. The energy level diagram for the devices in Set B is shown in Fig. 7.

Figs. 8–10 show the luminance vs. voltage, current density vs. voltage, current efficiency (cd/A) vs. luminance and power efficiency (lm/W) vs. luminance for Set B. Reduction in operating voltage with C-4 is again substantial. The turn-on voltage for the devices with C-4, BPhen and Alq_3 are 4.3, 5.0 and 6.0 V, respectively (Table 3). A 17% reduction in operating voltage and 33% increase in power efficiency has been achieved by replacing Alq_3 with C-4 at 1000 cd m^{-2}. The current injection from C-4 is similar to that of BPhen.

We attribute the low turn-on voltage and operating voltage of C-4 to its high mobility. The EL and PL spectra of BH-3, BD-3 and a mixture of BH-3 and BD-3 (30.0:0.5) are shown in Fig. 11. The PL spectra of the mixture is blue shifted by 4 nm compared to virgin BD-3 as expected. The EL spectra of the devices in Set B are identical to the PL of the mixture. Thus, the same excited state is involved in both the cases.

It has to be stressed that interfacial effects dominate OLED performance and the electron transporter/host + dopant interface is no exception. Thus, a good electron transporter for one particular system may not be as good in another system even if the mobilities of the ETM's are high. What is required is a balanced injection of electrons and holes.

The life time at 1000 cd m^{-2} for C-4 is 6.25 times longer than that for BPhen as ETL. We attribute the enhanced life-time from devices with C-4 to its higher T_g of 111 °C as opposed to the lower T_g of 62 °C for BPhen.

Though, the life-time of devices with C-4 is longer than that with BPhen, they are not as long as Alq_3. It is general practice to dope the electron transporters with lithium quinolinolate (Liq) to improve the life time of devices [23]. Okumoto and Kanno reported that doping of the electron transporters with hole transporters such as m-MTDATA, α-NPB resulted in reduction in operating voltage and increased life-time [18]. We fabricated devices of the Type C (ITO/CuPc (10 nm)/ α-NPB (50 nm)/BH-3 + BD-3 (30:0.5 nm)/C-4 (20 nm)/LiF (0.5 nm)/Al) where the compound 4 is doped with m-MTDATA (0.5%), α-NPB (0.5%) and Liq (10%) and found that the turn-on voltage and the operating voltages are indeed reduced (Fig. 12). The performances of the devices are summarised in Table 4.

We found that m-MTDATA as the dopant was most effective in reducing the operating voltage, then α-NPB and Liq. However, there was no significant gain in either the current efficiency or power efficiency.

Fig. 13 shows the energy level diagram for device Type C. The turn-on voltage of the doped systems simply follow the energy difference between LUMO level of the dopants and LUMO level of the host ETM (C-4), The difference of energy between the LUMO levels of the dopants, m-MTDATA, α-NPB and Liq and C-4 are 1.1, 0.7 and 0.5 eV which correlate with the turn on-voltage of 3.8, 4.1 and 4.2 V, respectively. The diminution of the turn on voltage and operating voltage could be attributed to charge transfer from the donor molecules to the acceptor (C-4), thereby increasing the conductivity [24,25]. Life-time measurements of the doped systems are on going and will be reported elsewhere.

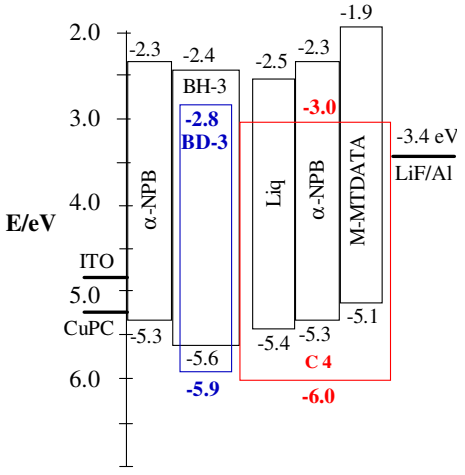

Fig. 13. Energy level diagram for ITO/CuPc (10 nm)/a-NPB (50 nm)/BH-3 + BD-3 (30 + 0.5 nm)/C-4 (20 nm)/LiF (0.5 nm)/Al where C-4 was doped with m-MTDATA (0.5%), a-NPB (0.5%) and Liq (10%).

Table 4
Device Performance of C-4 with m-MTDATA, α-NPB and Liq as dopants.

ETM	Turn-on voltage (V)	V_{op}/V at 1000 cd m^{-2}	V at 100 mA cm^{-2}	Eff./cd A^{-1} at 100 cd m^{-2}	Eff./lm W^{-1} at 100 cd m^{-2}	Eff./cd A^{-1} at 1000 cd m^{-2}	Eff./lm W^{-1} at 1000 cd m^{-2}	EQE (%)	CIE (x, y) at 1000 cd m^{-2}
Compound 4 (C-4)	4.3	9.5	12.0	4.6	2.0	4.4	1.6	3.6	(0.151, 0.144)

5. Conclusion

We have demonstrated that it is possible to produce phenanthroline derivatives for example, 2,9-bis-(2-thiophen-2-yl-vinyl)-[1,10]phenanthroline (C-4) which can act as good electron transporters and hole blockers with reasonably long life-times even in their virgin form. Further synthetic work is in progress to identify phenanthroline derivatives which would give much longer life-time than Alq_3 or doped BPhen.

ABSTRACT

We report top-emitting white organic light-emitting diodes (WOLEDs) by thermally evaporating non-doped (4-(4-(1,2,2-triphenylvinyl)phenyl)-7-(5-(4-(1,2,2-triphenylvinyl)phenyl) thiophen-2yl)benzo[c][1,2,5]thiadiazole) (BTPETTD) as a color conversion cap layer on top-emitting blue OLEDs. With a 240 nm cap layer, 74.5% of the blue photon energy are absorbed and converted to red emission with a conversion efficiency of 40%. By mixing the unabsorbed blue emission and red emission, the resulting top-emitting WOLEDs exhibit a broad band spectra with CIE coordinates of (0.34, 0.35), high color stability over a wide range of driving voltages, and peak efficiency of 17.7 cd/A and 8.7 lm/W.

1. Introduction

White organic light-emitting diodes (WOLEDs) are of considerable interests in recent years due to their potential applications in full color display and solid-state lighting [1–16,19]. Theoretically, the white color can be generated by additive mixing of three primary colors or two complementally colors. Thus, WOLEDs is mainly constructed by combining multiple color light emissive layers [1,2], or employing a single emissive layer doped simultaneously with different color dopants [3,4], as well as stacking several OLED units with each unit emitting different colors [5,6]. Although efficient and bright WOLEDs have been realized of adopting these methods, the fabrication process is somewhat complicated. The exciton distribution profile and the doping concentration should be carefully tuned to achieve a balanced exciton distribution in each emissive layer or among the light emitting dopants [7,8]. Furthermore, such WOLEDs suffer low color stability, i.e., the white spectra change with driving voltages and/or operation times, which is probably due to the shifting of the recombination zone and/or differential aging of different emitting materials [9,10].

WOLEDs by combining blue OLEDs with a color down conversion layer (CCL) have been proposed to simplify the fabrication process and achieve high color stability [11–16]. However, most reports focused on bottom-emitting WOLEDs, in which the CCL, typically composed by a host layer doped with an organic/inorganic dye, is spin-coated/laminated on the back glass side [11–14], or deposited as an internal hole-injection and conversion layer for the bottom-emitting blue OLEDs [15]. It is desirable to develop top-emitting WOLEDs since they promise large aperture ratio and can be fabricated on opaque substrates such as silicon and metal. Moreover, the combination of top-emitting blue OLEDs with CCL can easily yield broad band spectra, which is difficult to achieve in conventional top-emitting structures mainly due to the well-known microcavity effect [19].

To construct the top-emitting WOLEDs, the CCL should be thermally evaporated on top of top-emitting blue OLEDs in order not to damage the underneath OLEDs. Thus conventional CCL [11–14], which require spin-coating technique and/or thicker layer (~10 μm) are impractical. Ji

et al. employed thermal evaporated phosphors DPPO deposited on top-emitting blue OLEDs to construct top-emitting WOLEDs [16], but the efficiencies of the resulting WOLEDs are low. Tien et al. proposed color tunable double-emitting OLEDs by capping Alq_3: DCJTB/rubrene on the metal cathode to recycle a portion of the energy trapped by surface plasmon polariton [22]. In this work, we show that 4-(4-(1,2,2-triphenylvinyl)phenyl)-7-(5-(4-(1,2,2-triphenylvinyl)phenyl)thiophen-2yl)benzo[c][1,2,5]thiadiazole (BTPETTD) with aggregation-induced-emission (AIE) characteristics is an ideal CCL for top-emitting blue OLEDs. By thermally evaporating 240 nm BTPETTD on top of top-emitting blue OLEDs, 74.5% of the blue photon energy are absorbed and subsequently converted to red emission by photoluminescence (PL) with a conversion efficiency of 40%. Combining with the unabsorbed blue emission, the resulting top-emitting WOLEDs exhibit broad band spectra with 1931 Commision International de L'Eclairage (CIE) coordinates of (0.34, 0.35), demonstrate high color stability over a wide range of driving voltages, and perform peak efficiencies of 17.7 cd/A and 8.7 lm/W.

2. Experimental

The top-emitting blue OLEDs were fabricated in a multi-source vacuum chamber with a base pressure of around 5×10^{-7} Torr with structure glass/Al (100 nm)/MoO_3 (8 nm)/NPB 25 nm/TcTa 10 nm/CDBP:Firpic 12 wt.%, 20 nm/TAZ 10 nm/BPhen 20 nm/Yb 5 nm/Ag 20 nm, where Al, MoO_3 and NPB functions as reflective anode, hole-injection and hole-transporting layer, respectively, Firpic doped CDBP works as blue light-emitting layer, TcTa and TAZ servers as exciton-blocking layer, Bphen, Yb and Ag acts as electron-transporting, electron-injection layer and semi-transparent cathode, respectively. A 190 nm or 240 nm BTPETTD layer was further deposited on the top-emitting blue OLEDs without breaking vacuum as a non-doped CCL. The synthesized method and AIE characteristics of the BTPETTD were reported elsewhere [17]. The schematic illustration of the device structure is shown in the inset of Fig. 2(a). The current density–voltage–luminance characteristics of the devices were measured by the HP4145B semiconductor parameter analyzer and a calibrated UDT PIN-25D silicon photodiode. The electroluminescent (EL) spectra were obtained with the PR650 spectrophotometer.

3. Results and discussion

Fig. 1(a) shows the refractive index n and extinction coefficient k of BTPETTD as measured by spectroscopic ellipsometer. The molecular structure of BTPETTD is also shown in Fig. 1(a). The calculated absorption spectra based on the measured k value agree well with the measured absorption spectra as shown in Fig. 1(b). The absorption peak at 470 nm matches well with the EL spectra of the top-emitting blue OLEDs, signifying that BTPETTD may absorb the blue photon energy and convert to red emission effectively via the PL process. To verify this assumption, two devices, one with 190 nm and the other with 240 nm BTPETTD layer were fabricated; the EL spectra of the devices are shown in Fig. 2(a). The top-emitting blue OLEDs exhibit a single peak at 472 nm; however, by introducing a 240 nm BTPETTD cap layer, a secondary peak at 610 nm appeared, confirming that some of the blue photons are absorbed and converted to red photons by the cap layer. Interestingly, the devices with a 190 nm cap layer exhibit a secondary peak at 550 nm, which is neither the intrinsic emission of Firpic nor the PL emission of BTPETTD. This peak is likely due to the microcavity effect, since in top-emitting OLEDs, the thickness of the cap layer can alter the optical properties of the OLED film stacks and hence shift the resonant wavelength of the cavity [18,19].

To verify this assertion, we used a rigorous classical electromagnetic method to model the interference effect of the top-emitting blue OLEDs with different cap layer thicknesses [20,21]. The simulated spectra are shown in Fig. 2(a). They agree well with the experimental results, confirming the accuracy of the model. Based on the model, the emission of Firpic at 550 nm is enhanced by introducing a 190 nm cap layer, and thus the combination of the modified blue emission with PL emission of BTPETTD

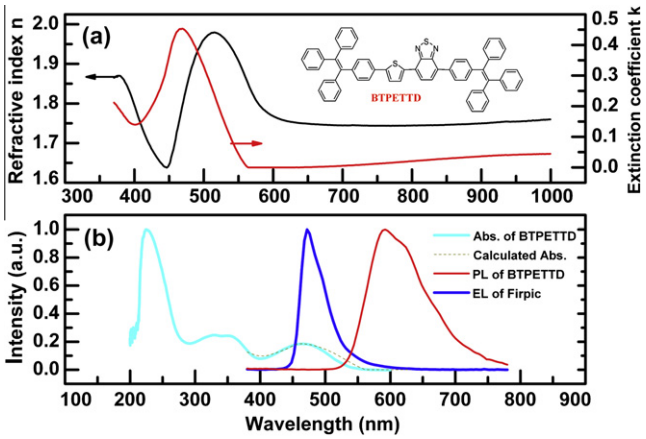

Fig. 1. (a) Refractive index n and extinction coefficient k of BTPETTD, inset: molecular structure of BTPETTD; (b) measured and calculated absorption spectra, PL spectra of BTPETTD, and EL spectra of top-emitting blue OLEDs based on Firpic emitter.

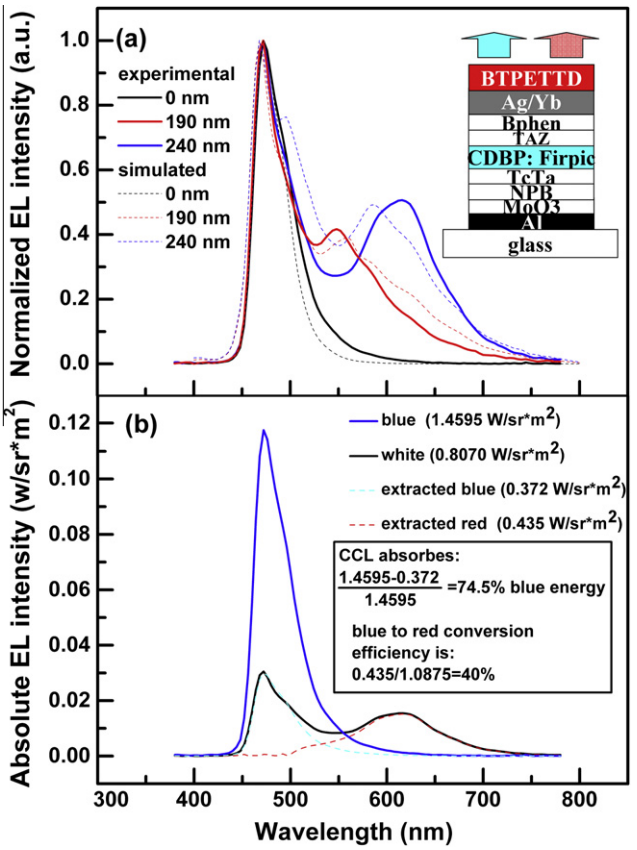

Fig. 2. (a) Normalized EL spectra of the devices with different thickness cap layer, inset: device structure; (b) absolute EL intensity of the devices without and with 240 nm cap layer.

exhibits a secondary peak at 550 nm. While with 240 nm cap layer, the resonant wavelength of the cavity is set equal to the peak intrinsic emission of Firpic, and hence the combination of the intrinsic emission of Firpic with PL emission of BTPETTD results in a secondary peak at 610 nm, similarly with the PL peak of BTPETTD. Therefore, to obtain pure white emission, the thickness of the cap layer should be carefully tuned to set the resonant wavelength equal to the peak intrinsic emission of Firpic, as well as to generate appropriate red emission intensity. As shown in Fig. 2(a), the mixture of the unabsorbed intrinsic blue emission of Firpic and the red PL emission of the 240 nm cap layer yields a white emission with CIE coordinates of (0.34, 0.35).

To evaluate the conversion efficiency of the cap layer, the absolute EL spectra of the top-emitting blue OLEDs without and with a 240 nm cap layer, operating at a driving current of 5 mA/cm^2 and luminance of 1165 cd/m^2, 857 cd/m^2, respectively, were tested. As shown in Fig. 2(b), the output blue emission intensity without cap layer is 1.4595 W/sr m^2, obtained by integrating the blue spectra. By introducing a 240 nm cap layer, the intensity is reduced to 0.8070 W/sr m^2 white emission, which can further be decomposed to 0.3720 W/sr m^2 unabsorbed blue emission intensity and 0.4350 W/sr m^2 red emission intensity by integrating the extracted blue and red spectra, respectively. Thus the cap layer absorbs 1.4595–0.3720 = 1.0875 W/sr m^2 (74.5%) blue emission and subsequently converts it to 0.4350 W/sr m^2 red emission. Therefore the blue to red watt to watt conversion efficiency can be calculated as 0.4350/1.0875 = 40%. Taking account the output red photon energy at 600 nm is ~80% of the input blue photon energy at 472 nm, the quantum efficiency of the cap layer is about 40%/80% = 50%, which agree well with 55% as measured by integrated sphere [17]. Obviously, to enhance the conversion efficiency, CCL with higher quantum yield should be employed.

Fig. 3(a) shows the EL spectra of the devices with 240 nm cap layer under different driving voltages. Obviously, no significant EL spectra change can be observed as the driving voltages increased from 6 V to 10 V, indicating that the top-emitting WOLEDs demonstrated here have excellent color stability. Fig. 3(b) shows the EL spectra normalized to 472 nm under different viewing angles. By setting the resonant wavelength equal to the peak intrinsic emission of Firpic, the blue emission shows minimal blue shift with increased viewing angles. While the red emission exhibits a slightly blue shift, with its peak changing from 610 nm at normal viewing angle to 584 nm at 60° viewing angle. Interestingly, the red emission is enhanced significantly as increased of viewing angles, which may be likely due to the light at oblique angles experiencing

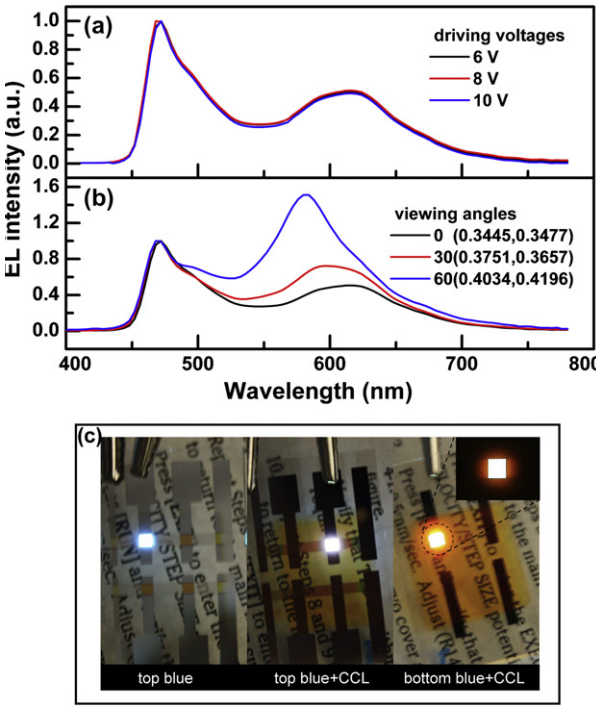

Fig. 3. (a) EL spectra under different driving voltages; (b) EL spectra under different view angles; (c) photos of the devices.

thicker CCL than its counterpart at normal angle; hence more blue photon energy are absorbed, resulting in an enhanced red emission and a shifting of CIE coordinates. As shown in Fig. 3(c), by depositing a 240 nm cap layer on top of top-emitting blue OLEDs, the blue emission has been modified as a uniform white emission. The photo of the bottom-emitting blue OLED with its back glass side covered by BTPETTD is also shown for comparison. Unlike the top-emitting WOLEDs with uniform white emission, the bottom-emitting WOLEDs are surrounded by a red ring, indicating that all the blue emission in the edges is absorbed and converted to red emission completely. Such phenomena may be mainly due to the light diffusing effect induced by thick glass substrate, resulting in a weak edges blue emission. The weak edges blue emission is subsequently converted to red emission by the CCL completely. To eliminate this effect, the CCL should be directly deposited on the blue OLEDs. Thus the combination of top-emitting blue OLEDs with CCL cap is superior to the bottom-emitting blue OLEDs with external CCL in terms of white lighting qualities.

Fig. 4 shows the luminance-voltage-current density and external quantum efficiency–luminance–power efficiency characteristics of the devices with different cap layer thickness. All devices show identical current density–voltage characteristics since the cap layer does not alter the electrical characteristics of the devices. Due to conversion loss, the luminance decreases as increased of cap layer thickness; for example, at a driving current of 5 mA/cm^2, the luminance decreases from 1165 cd/m^2 to 914 cd/m^2, 857 cd/m^2, corresponding to a external quantum efficiency of 10% (23 cd/A, 10 lm/W), 6.8% (18.3 cd/A, 7.2 lm/W) and 6% (17.1 cd/A, 6.6 lm/W), for the devices with 0 nm, 190 nm and 240 nm cap layer, respectively. The efficiency of the top-emitting WOLEDs can be further enhanced by developing efficient top-emitting blue OLEDs, employing high quantum yield CCL, as well as adopting light out-coupling techniques.

4. Summary

In summary, we have demonstrated an easily fabricated top-emitting WOLEDs by thermally evaporating a non-doped BTPETTD cap layer on top of top-emitting blue OLEDs. By carefully tuning the cap layer thickness, the top-emitting WOLEDs emit pure white light emission with CIE coordinates of (0.34, 0.35), exhibit extremely high color

stability over a wide range of driving voltages, and perform a peak efficiency of 6.6%, 17.7 cd/A and 8.7 lm/W.

Acknowledgments

The authors thank Dr. Zujin Zhao and Prof. Ben Zhong Tang for providing the BTPETTD. This work was supported by the Hong Kong Government Research Grants Council Grant Number AOE/P0308PG2.

ABSTRACT

An all-printed photosensor based on polyfluorene derivatives has been developed for high illuminance range detection (>100 klux). The active layer is a blend of hole-accepting poly(9,9′-dioctylfluorene-co-bis-*N*,*N*′-(4-butylphenyl)-bis-*N*,*N*′-phenyl-1,4-phenylenediamine) (PFB) and electron-accepting poly(9,9′-dioctylfluorene-co-benzothiadiazole) (F8BT). A top-absorbing architecture was used with poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) as the transparent electrode. The surface energy of the PEDOT:PSS ink was modified in order to allow printing directly onto the hydrophobic surface of the PFB:F8BT blend layer, placing the transparent electrode at the top of the light sensor structure. The all-printed photosensor shows a linear response over multiple measurements within the illuminance range of (100–400) klux.

High intensity light sensors are needed in order to monitor working environmental conditions and assist with the diagnosis of blast-related injuries [1] which include traumatic brain injury (TBI) [2]. Light-emitted from blasts or explosions can be of very high illuminance [3] (greater than 100 klux) and cause photo-stress, temporary blindness and disorientation [4]. We have been developing a monitoring system that could be worn by soldiers to collect daily information that can be incorporated as part of their medical record. This device is designed to be disposable, inexpensive and adhered directly to objects (including non-planar surfaces). This requires the development of light sensors with transparent top electrodes, high light intensity response and process compatibility with flexible substrates. In our approach we use ink-jet printing as a deposition and patterning technique and use solution processible materials such as conjugated polymers and metal nanoparticles as active layers in the device. Ink-jet printing has been previously used to print the active layers of photovoltaics [5], organic light emitting diodes [6], field effect transistors [7] and display backplanes [8].

Typically organic-based light sensors are fabricated on glass substrates with a sputtered layer of indium tin oxide (ITO) as the transparent anode [9], with light being absorbed through the glass. As described above, our application requires a top-absorbing device architecture with the transparent conductor deposited directly on top of the semiconducting material, which can sometimes damage the organic layer. The surface of the organic photoactive layer is hydrophobic and presents a challenge when fabricating top-absorbing devices from solution. We have been able to address this fabrication challenge by employing a modified conductive polymer ink as the transparent electrode in order to improve wetting and printing characteristics onto the photoactive layer.

A cross-sectional view of the all-printed light sensor is shown in Fig. 1. Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS from H.C. Starck) was used as the transparent anode as an alternative to conventional sputtered-ITO and ITO nanodispersions [10]. As illustrated in Fig. 1a, light absorption occurs directly through the top electrode PEDOT:PSS layer. The sessile drop contact angle of conventional PEDOT:PSS solution on the polyfluorene blend (photoactive layer) surface was $\theta = 104 \pm 5°$ (Fig. 1b). The surface tension of PEDOT:PSS ink was modified by mixing Zonyl fluorosurfactant (0.1–0.2 wt%) to the original formulation. This new ink composition reduced the contact angle to $\theta = 22 \pm 4°$

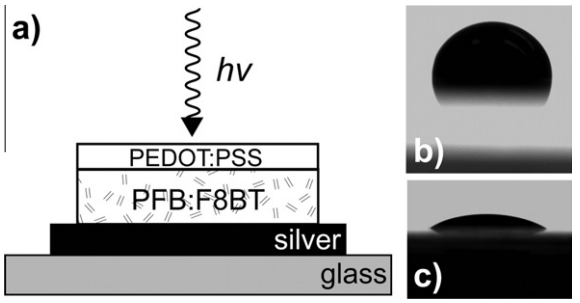

Fig. 1. (a) Cross-sectional view of the all-printed polyfluorene PFB:F8BT photosensor. Illumination is through the PEDOT:PSS top electrode layer. (b) PEDOT:PSS droplet on PFB:F8BT semiconducting film. (c) Modified PEDOT:PSS droplet with addition of Zonyl fluorosurfactant on a PFB:F8BT film.

(Fig. 1c) allowing printing of PEDOT:PSS (film thickness 25–30 nm) directly onto the semiconducting film surface. While making the PEDOT ink compatible with other layers of devices, the addition of the surfactant did not alter the PEDOT:PSS conductivity. The measured conductivity of films with and without the fluorosurfactant was 29 ± 4 and 31 ± 6 S/cm, respectively. The printed PEDOT:PSS electrode area defines the active area of the light sensor, and it varied from 6 to 9 mm^2 in the experiments described here.

The organic photoactive layer was composed of a blend of electron accepting poly(9,9′-dioctylfluorene-co-benzothiadiazole) (F8BT) and the electron donor poly(9,9′-dioctylfluorene-co-bis-*N*,*N*′-(4-butylphenyl)-bis-*N*,*N*′-phenyl-1,4-phenylenediamine) (PFB). The molecular weights of PFB and F8BT were 46 and 27 K, respectively. The PFB:F8BT blend layer was ink-jet printed, in air, from a 1:1 weight ratio solution in dichlorobenzene atop a printed silver nanoparticle electrode [8] using a previously described custom-built system [7]. Our printer system consists of a piezoelectric print head, translation stages, substrate holder and alignment camera. The printed silver nanoparticle electrode (Cabot Corporation) was annealed at 130 °C for 10 min, typically ≈50 nm thick. The printed PFB:F8BT layers were optically smooth thin films of ≈35 mm^2 area and thicknesses of 0.8–1.0 μm. We have adopted this thickness to ensure high yield and reproducibility in our fabrication process. As we are printing all layers in the device and PEDOT:PSS directly onto the photoactive blend layer, we need to take into account the roughness of the printed silver electrodes. This blended system has been used previously in polymer based photovoltaics [11], and it has been shown that the degree of phase separation of the polymer components influences the resulting morphology and device performance [11,12]. Methods used to vary the thin film phase separation include altering: polymer component ratio [11], selection of solvent based on boiling point [12], substrate temperature [12], molecular weight [13], and the formation of polymer nanospheres from a miniemulsion process [14]. These methods alter the domain size from nanometers to microns when observed by atomic force microscopy (AFM) or fluorescence microscopy. Compositional mapping via synchrotron-based scanning X-ray [15], scanning near-field optical [16], and electrostatic force microscopies [17] have shown that these micron-sized domains are not composed of a single phase but contain proportions of both PFB and F8BT. Using synchrotron-based scanning X-ray microscopy [15], McNeill et al. have mapped the composition of the enclosed domains to be PFB-rich (70 ± 3 wt%) and the surrounding majority phase to be F8BT-rich (95 wt%).

Ink-jet printing can also be used as a method to vary the thin film morphology that has lead to improved device performance over other processing methods such as spin-coating [18]. Xia and Friend observed increased external quantum efficiency (EQE) in ink-jet printed devices attributed to improved charge transport compared to spin-coated devices [18]. The external quantum efficiency of the printed PFB:F8BT photosensor is shown in Fig. 2. EQE was calculated by

$$\mathrm{EQE} = \frac{hcJ_{SC}}{e\lambda P} \tag{1}$$

where λ is the incident wavelength, J_{SC} is the short-circuit photocurrent density, e is the elementary charge, h is the Planck constant, c is the speed of light, and P is the incident light power. Spectral response was measured under zero bias using an Oriel Cornerstone Monochromator with Oriel Instruments Quartz Tungsten Halogen lamp (100 W). Photoresponsivity was at wavelengths below 550 nm and EQE reaches a maximum of 5.9% at 400 nm. The photocurrent increases at higher excitation energy, which has been explained by the theoretical analysis of the nature of excited states in PPV [19] and applied to the PFB:F8BT system [11], namely that excitons at higher excitation energies have smaller binding energies and greater number of delocalized wavefunctions, making disassociation more probable. For comparison, the absorption spectra measured by UV–vis spectroscopy of a printed blend layer (∼220 nm thickness) is also plotted in Fig. 2. The photoaction spectrum of the blend devices was mostly symbatic with the absorption curves for excitation energies below ∼3.75 eV.

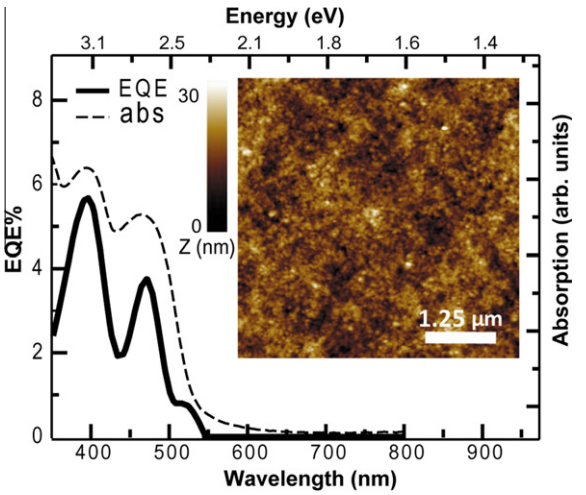

Fig. 2. External quantum efficiency (EQE) and UV–vis absorption spectra for printed PFB:F8BT photosensor. Atomic force micrograph (inset) of ink-jet printed film. *Z*-height scale is 30 nm and scale bar is 1.25 μm.

Examination of the printed surface topology by AFM (Veeco Dimension 3100) revealed a fine phase separation of the polyfluorene components as shown in the inset of Fig. 2. The ink-jet printed features are on the nanometer-scale measuring ≈60–150 nm in size. Xia and Friend observed device improvements and finer phase separation in ink-jet printed devices compared to spin-coated devices [18]. They observed little change in the photoluminescence (PL) efficiency between devices with micron-sized domains to nanometer-sized domains indicating almost no change due to charge dissociation and therefore attributed the improvement in EQE of their ink-jetted devices to improved charge transport. Ink-jet printed devices likely have finer phase separation because solvent drying rates are more rapid in ink-jet printing due to the small volumes of liquid (≈100 pL) being dispensed, allowing for less time for the polyfluorene blend components to phase-separate.

The printed high light intensity sensors were tested under illumination provided by a Newport 1600W solar simulator (Xenon short arc lamp). The illuminance was varied from 100 to 400 klux which was achieved by changing the vertical distance between the photosensor and the vertex of the light source since *illuminance* = I/d^2, where d is the distance from the sample to the illumination source and I is the intensity of the illumination source. Illuminance was measured by an Extech EA30 light meter. Fig. 3 shows current–voltage (I–V) characteristics for the all-printed sensor measured by a Keithley 6487 electrometer. The dark current at −1 V was 1 nA/cm^2. The photocurrent (measured at −1 V) increases linearly with light intensity and no current saturation is observed (Fig. 3 inset). For all sensors, the open circuit voltage (V_{oc}) was within the range of 0.1–0.2 V, however, for an individual sensor, the V_{oc} did not shift as illuminance increased. Previous researchers [20] observed a logarithmic increase in the V_{oc} in PFB:F8BT bilayer devices from increasing Argon-ion laser intensity (based on 458 nm line), but for those measurements, the V_{oc} saturated at radiometric intensities above 0.7 mW/cm^2, which is significantly lower than the testing conditions used in the experiments described here.

Further examination of the printed PFB:F8BT photosensors was completed under short illumination pulses. Light exposure from a explosion or blast was simulated by exposing the PFB:F8BT photosensor to light from the solar simulator for only 0.5–0.75 s, by toggling the mechanical shutter of the Newport solar simulator open and closed. The change in voltage was recorded by a Tektronix TDS2014B digital oscilloscope at different illuminance levels. The signal from the PFB:F8BT photosensor at zero bias was amplified by a Keithley 427 current amplifier (gain 10^7 V/A) and the oscilloscope was triggered using a calibrated silicon photodiode (Newport) from a secondary input channel. An example of the oscilloscope voltage readout of the PFB:F8BT photosensor is shown in Fig. 4a. Plotting the change of voltage (ΔV) from the initial background voltage ($V_o \approx 0$) versus illuminance (Fig. 4b) shows that the photosensor voltage increased ≈0.3 V per 100 klux, and linear photoresponse as a function of illuminance over multiple measurements. Future experiments will further examine the transient photocurrent response as well as device reliability, which is necessary to understand the dynamics of charge transport and charge separation at these high illuminance values.

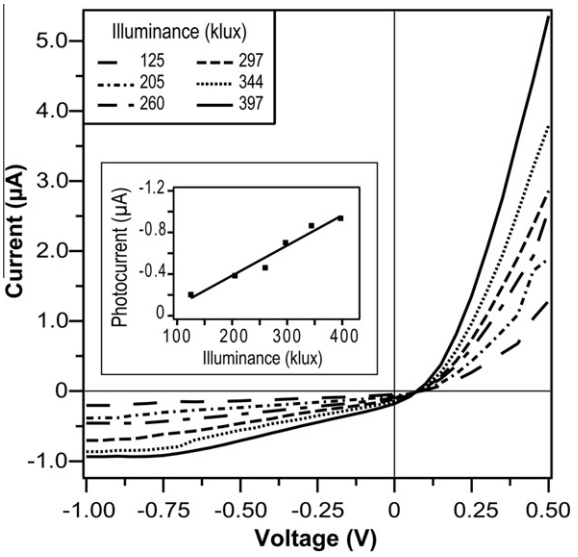

Fig. 3. Current–voltage (I–V) characteristics for the printed polymer blend photosensor collected at increasing illuminance values (inset legend, measured in klux, photocurrent measured at −1 V).

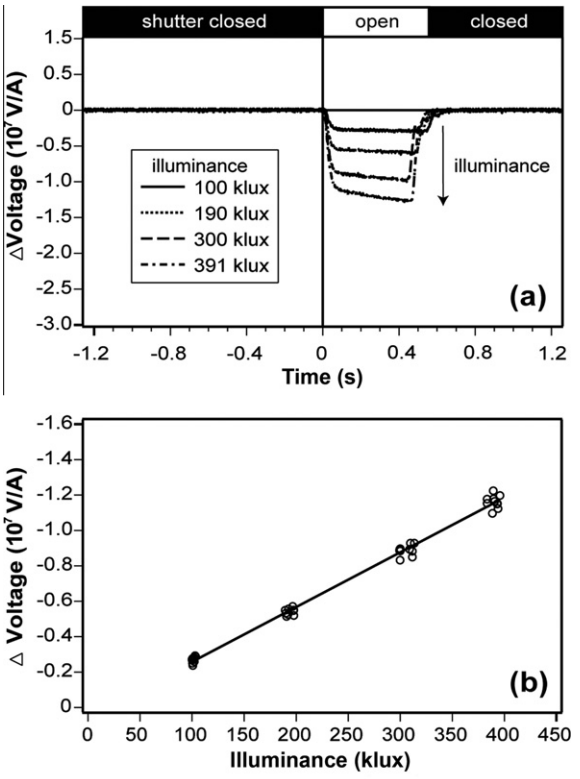

Fig. 4. (a) Change in voltage (ΔV) as the photosensor is exposed to ≈0.5 s of illumination from solar simulator at varying levels of illuminance (see inset legend). (b) Change in voltage (ΔV) from (a) plotted as a function of illuminance for multiple measurements.

In summary, we have demonstrated an all ink-jet printed top-absorbing photosensor fabricated from printed layers of a PFB:F8BT polymer blend, and Ag nanoparticles and PEDOT:PSS electrodes. Ink-jet printing of the PEDOT:PSS top electrode directly onto the hydrophobic PFB:F8BT layer was made possible by the addition of a fluorosurfactant to the PEDOT:PSS ink. The photosensors were examined under short illumination pulses (0.5–0.75 s), and showed good linearity in photoresponse over multiple measurements at high illuminance values of 100–400 klux.

ABSTRACT

In this study, we used thermal evaporation with a low sublimation temperature (42 °C) to deposit 1,5-diaminoanthraquinone (DAAQ) in various morphologies—including nanorods, nanocornerstones, and nanofibers—onto various substrates. Three major factors influenced the growth of vertically aligned DAAQ nanofibers on the electrodes: a low water contact angle (WCA) for the substrate and intermolecular hydrogen bonding and π–π interactions between the DAAQ molecules. On Au and Ti substrates (low-WCA), the DAAQ nanofibers **DAAQ-Au** and **DAAQ-Ti**, respectively, possessed great verticality and high aspect ratios; they also exhibited field emission characteristics, with maximum emission current densities of 0.31 and 0.65 mA/cm^2, respectively, at an applied electric field of 12 V/μm. The turn-on electric fields for producing a current density of 10 μA/cm^2 were 8.5 V/μm for **DAAQ-Au** and 8.25 V/μm for **DAAQ-Ti**. From the slopes of Fowler–Nordheim plots, we calculated the field enhancement factors (β) of **DAAQ-Au** and **DAAQ-Ti** to be 447 and 831, respectively. Field emission stability studies revealed that the DAAQ nanofibers possessed outstanding anti-degrading capability. The emission current did not decrease, but rather increased slightly, after 3000 s. Given the advantages of this simple low-temperature process and the impressive anti-degrading field emission characteristics, such DAAQ nanofibers have great potential for use in various electronics applications (e.g., as organic field emitters).

1. Introduction

Nanostructures based small organic molecules have become the focus of intensive research efforts because of their unique applications in nanoscale devices [1–3]. One-dimensional (1D) organic nanostructures, including nanorods, nanofibers, nanowires, and nanotubes, can be fabricated using a wide range of methods; they often exhibit unique material properties that make them suitable for use in organic electronics applications (e.g., solar cells [4–7], chemical vapor sensors [8], field emitters [9–15]) and in various optoelectronic devices [16–19]. Recently, several small organic molecules, including tris(8-hydroxyquinolinato) aluminum (Alq_3) [9,13,16,19], anthracene (AN), perylene (PY) [20], coronene [10], copper phthalocyanine (CuPc) [11], and 1,5-diaminoanthraquinone (DAAQ) [8], have been prepared in form of various nanostructures under conditions milder than those used to prepare related nanostructures from inorganic compounds. Because of their suitability for use in inexpensive, low temperature-processed, highly flexible optoelectronic devices, increasing attention is being drawn to the development of nanostructures of small-molecule organic materials.

Several fabrication methods have been reported for the preparation of organic 1D nanostructures [1–3,21]. Nanowires and nanorods have been prepared through thermal evaporation (solid state chemical reactions) [20]

at high temperatures (up to 280 °C). Solution processing of nanorods has been employed using a microemulsion route assisted by surfactants [19]. Self-polymerization and self-assembly process has been developed for production of supramolecular nanomaterials [22]. Thermal evaporation of nanotubes and nanotube junctions onto metal catalysts has been performed at 340 °C under a flow of Ar gas [23]. Vapor condensation has been used to prepare nanowires [9] and nanoparticles [24] under Ar atmospheres at temperatures of over 400 °C with the substrate placed under a N_2-cooled trap. Zhao et al. applied neutral aluminum oxide (or silica gel) in the adsorbent-assisted physical vapor deposition of nanoribbons and nanowires [25,26]. Vacuum sublimation, a form of vapor-phase deposition, has also been applied to the preparation of nanostructures, particularly for fabricating 1D organic nanofibers for organic field emission devices [10–12]. We have previously applied high vacuum processing to fabricate nanostructures with highly uniform distributions on targeting substrates, without the need for catalysts or high temperatures. Such simple one-step approaches not only eliminate the effects of impurities but also potentially lower the fabrication temperature.

Recent investigations of DAAQ-based optoelectronic devices, such as chemical sensors [8], optical waveguides [27], and organic solar cells [28], have led to a rapid development of DAAQ fabrication technologies. Zhao et al. [27] recently reported that this organic dye prefers to undergo vertical deposition on substrates having high surface energies (SEs) and hydrophilic domains. In this present study, we synthesized 1D DAAQ nanofibers through vacuum sublimation on selected substrates. We characterized these 1D DAAQ nanofibers using scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HRTEM). From investigations of the morphologies of DAAQ thin films formed on different substrates, we selected electrodes suitable for the vertical deposition of DAAQ nanofibers. To determine the practicality of employing DAAQ nanofibers as cathode materials in field emission devices, we evaluated their field emission characteristics using a vacuum emission measurement (VEM) system.

Stabilized by intermolecular hydrogen bonding and π–π interactions, DAAQ self-assembles onto substrates to form vertically out-of-plane nanostructures. Analogous to organic vapor-phase deposition (OVPD), the vacuum sublimation of small organic molecules is also a vapor-solid (VS) process. Because sublimation proceeds at lower temperatures in higher vacuums, relative to those used for OVPD, its use opens up a new area of study and potentially increases the applications of organic small molecules in flexible electronic devices.

2. Experimental

Commercially available DAAQ powder (purity: 92%; Tokyo Chemical Industry) and 1,1,1,3,3,3-hexamethyldisilazane (HMDS; Lancaster), for Si surface treatment, were used as received without further purification.

DAAQ films were deposited on various substrates (Ag, Al, Au, Ni, Si, Ti) using a thermal evaporator operated at a base pressure of 6×10^{-6} torr. The metal substrates were prepared by depositing metal films onto Si (1 0 0) substrates using an electron beam (E-beam) evaporator. Prior to E-beam evaporation of each metal thin film, a Ti layer (thickness: 200 Å) was deposited on the bare Si substrate as an adhesion layer. Without breaking the vacuum, a thin layer of Ag, Al, Au, Ni, or Ti (thickness: 1000 Å) was then deposited. The entire Si substrate was treated with HMDS vapor and then cured at 160 °C for 0.5 h, and the surface chemistry of the Si substrate was modified through the formation of a self-assembled monolayer of HMDS.

DAAQ nanostructure films were formed on the various substrates while maintaining the substrate temperature at 25 °C. The sublimation of DAAQ was performed at a temperature of 42 °C; the corresponding deposition rate, controlled by a quartz crystal microbalance, was 0.5 Å/s.

Top and cross-sectional views of the morphologies of the DAAQ nanostructure films were surveyed using a JEOL JSM-6500F scanning electron microscope. Ultraviolet–visible (UV–Vis) spectra (250–900 nm) were recorded using a Shimadzu UV-3600 spectrophotometer. Contact angles (CAs) and SEs were determined on each substrate using a Krüss universal surface tester (model GH-100), the geometric mean approximation, and three standard liquids: water (H_2O), diiodomethane (CH_2I_2), and ethylene glycol [$C_2H_4(OH)_2$]. The profiles and fine structure of nanofibers were imaged and analyzed using a JEOL-2010 high-resolution transmission electron microscope and an internal charge-coupled device (CCD) camera. The crystalline of DAAQ nanofibers was characterized by GIXRD, using Bruker D8 system and Cu Kα radiation. The incident angle of the X-ray beam was fixed at 0.2°. The field emission characteristics of the DAAQ nanofibers were determined under a base pressure of 8×10^{-6} torr. Indium tin oxide (ITO) plate glasses were used as anodes, positioned above the substrate surfaces at a distance of 80 μm. The field emission instrument featured a plate-to-plate geometry; the cathode comprised DAAQ nanofibers deposited on Au and Ti substrates (area: 0.06 cm^2). Current density–electric field (J–E) curves of the field emission devices were measured using a Keithley 237 instrument (accuracy: 10^{-13} A). The emission currents of the DAAQ nanofibers were monitored as a function of the sweep bias.

3. Results and discussion

Fig. 1(a) displays the molecular structure of DAAQ. Assemblies of DAAQ molecules feature both intramolecular charge transfer [29] and intermolecular hydrogen bonding [23]. Intramolecular charge transfer occurs between the amino (NH_2) and carbonyl (C=O) groups of the anthraquinone ring; intermolecular hydrogen bonding occurs between the oxygen atoms of the C=O group in one DAAQ molecule and the hydrogen atoms of the NH_2 group in another. For the nonpolar molecule coronene [10] to form 1D nanofibers, molecular stacking occurs mainly through π–π and van der Waals interactions. In the stacking of DAAQ molecules, we suspected that both intra- and intermolecular hydrogen bonds would coexist. In addition to π–π interactions and van der Waals contacts between

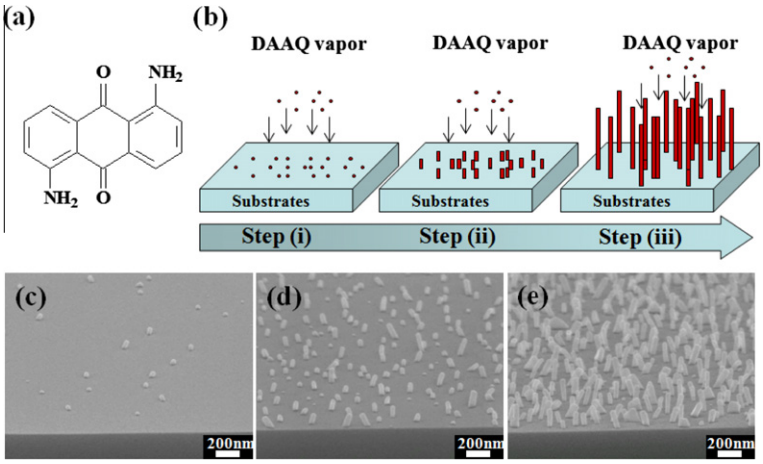

Fig. 1. (a) Chemical structure of DAAQ. (b) Schematic representation of the growth of 1D DAAQ nanofibers through vacuum sublimation. SEM images (cross-sectional view) of DAAQ thin films grown on a Si substrate for (c) 6 s, (d) 10 s, and (e) 60 s at a deposition rate of 0.5 Å/s.

stacking molecules, intermolecular hydrogen bond also plays an important role in 1D self-assembly.

The major advantage of vacuum sublimating DAAQ nanostructure films is the simplicity and accessibility of the process. No catalyst is used and no droplets of catalyst are found at the tips of the nanofibers; therefore, the growth mechanism of DAAQ nanostructure films is presumed to be similar to that of the physical vapor transport method [27]. One strategy for achieving 1D structures, reported by Xia et al. [30], is the use of various templates with 1D morphologies to direct the assembly process. The growth mechanism normally involves three steps (Fig. 1(b)) (i) as the concentration of DAAQ increases, the molecular building blocks begin to aggregate into small nuclei; (ii) these nuclei become seeds for the anisotropic packing of DAAQ molecules; (iii) with a continuous supply of DAAQ, vapor molecules self-assemble to form 1D morphologies with vertically aligned nanostructures on the substrates. In this study, we used vacuum sublimation of DAAQ to construct 1D nanostructures on selected substrates. We investigated the growth mechanism of these DAAQ thin films to develop guidelines for the design of suitable structures for field emitters. Fig. 1(c–e) present cross-sectional SEM images of the early stage (6, 10, and 60 s of deposition at a rate of 0.5 Å/s, respectively) products of the DAAQ nanofibers on a Si wafer. We observe a layer of vertically self-assembled and elongated nanoparticles, which acted as seeds for the anisotropic overgrowth of the nanofibers into columnar structures. Furthermore, varying the deposition time allowed us to adjust the length of the nanofibers on the substrates.

Fig. 2 presents SEM images (top and cross-sectional views) of the DAAQ nanostructure films formed on the Ag, Al, Au, Ni, Si, and Ti substrates. Clearly, the nature of the substrate influenced the morphology of its DAAQ thin film. Fig. 2(a and d) reveal entangled, in-plane, rod-like morphologies for the DAAQ films formed on the Ag and Ni substrates, respectively. In the top-view SEM images in Fig. 2(b, c and e, f) we observe that most of the DAAQ nanofibers grew perpendicularly (slightly slanting) from the substrates to form quasi-arrays. Repulsive forces among nuclei can result in a parallel-displaced conformation, leading to a tilted columnar structure [10,31]. In Fig. 2(c, e, and f), the high-density packing morphologies of the DAAQ nanofibers on the Si and Ti substrates are similar to those on the Au surface. The densities of these nanostructures on all of the substrates ranged from 10^8 to 10^9 cm^{-2} (Table 1). The DAAQ thin films deposited on the Ag and Ni substrates both possessed tilted out-of-plane and in-plane nanorod morphologies, as revealed in their cross-sectional SEM images (insets to Fig. 2(a and d), respectively). The short, tilted nanorods on the Ag surface had a mean radius of 48 nm and a mean length of 226 nm; those on the Ni substrate, however, had larger dimensions (90 and 843 nm, respectively). The DAAQ nanostructures deposited on the Al substrate (inset to Fig. 2(b)) had the largest average radius (100 nm) and length (883 nm); we suspect these oversized nanostructures comprised three or four nanofibers aggregated together in the form of nanocornerstones. In contrast, the DAAQ molecules packed on the Au, Si, and Ti substrates to present an out-of-plane morphology with uniform arrangement; these nanofibers had average lengths of 427, 794, and 587 nm, respectively (insets to Fig. 2(c, e, and f), respectively). The mean radii of these nanofibers, featuring smooth surfaces, ranged from 27 to 35 nm. The lengths of the nanofibers on these substrates could be adjusted by varying the deposition time. Table 1 summarizes the mean lengths (L), radii (r_m), and nanostructural types of the DAAQ assemblies deposited on the various substrates. The aspect ratios (ARs), defined as

$$\mathrm{AR} = L/r_m \tag{1}$$

of the 1D DAAQ nanofibers deposited on the Au, Si, and Ti substrates were 12.6, 29.4, and 16.8, respectively. The high ARs of these DAAQ nanofibers suggest that they are potentially applicable nanostructures for use as organic field emitters.

The selective growth of vertical DAAQ nanowires generally occurs through preferential deposition on geometrical

Ti	587	35	16.8	Nanofiber	1.6×10^9

chemically modified surfaces; for example, substrates featuring sharp tips or edges, silica beads, or hydrophilic domains [27]. To realize the effects of CAs and to select appropriate metals for use as electrodes for potential applicability in organic field emission, we selected Ag, Au, Al, Ni, Si, and Ti as substrates and investigated the morphologies of the DAAQ nanostructure films formed on these surfaces. Table 2 summarizes the CAs of the various substrates and their SEs, calculated using the Owens and Wendt method [32]. The water contact angles (WCAs) of the Ag, Al, and Ni substrates were 96.1°, 96.7°, and 100.9°, respectively, making them hydrophobic substrates. The majority of DAAQ molecules deposited on these substrates formed flat and entangled structures. In contrast, the DAAQ molecules deposited on the Au, Si, and Ti surfaces extended perpendicularly from the substrates, which had WCAs of 81.8°, 59.7°, and 78.8°, respectively (i.e., hydrophilic substrates). Therefore, it appears that the preferred growth of 1D vertical DAAQ nanofibers requires hydrophilic, rather than hydrophobic, surfaces. This result is similar to those reported by Zhao et al. [27] who studied the effect using UV–Vis absorption spectroscopy. Next, we performed surface treatment of the Si substrate to confirm our

Table 2
CAs and SEs of various substrates.

Substrate	CA (°)			SE[b] (mJ/m^2)
	H_2O	CH_2I_2	$C_2H_4(OH)_2$	
Ag	96.1	52.7	66.5	34.8

[a] Sample obtained after the bare Si substrate had been treated with HMDS vapor and annealed at 160 °C for 30 min.
[b] Calculated using the Owens method from the geometric mean approximation (GMA) measurements of the static CAs of H_2O, CH_2I_2, and $C_2H_4(OH)_2$.

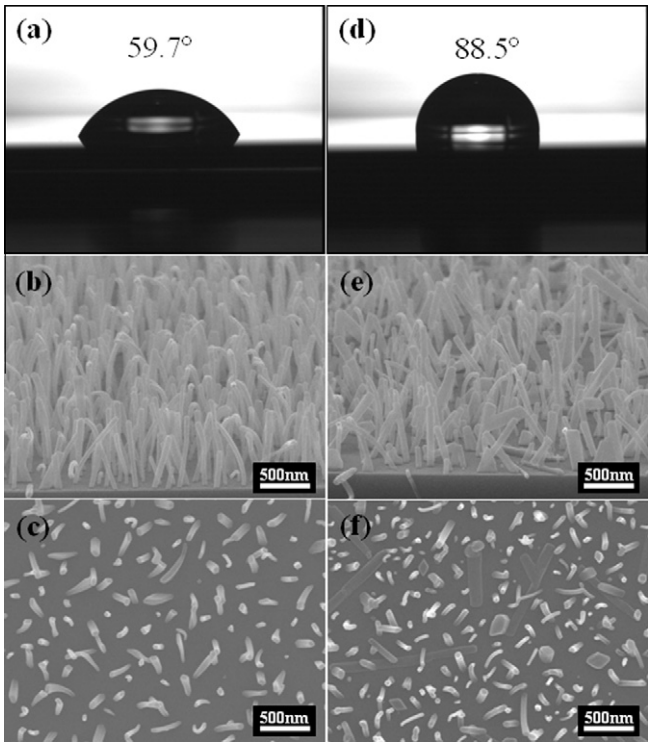

Fig. 3. (a, d) Photographs of water droplets on the (a) bare Si substrate (WCA: 59.7°) and (d) HMDS-treated SiH substrate (WCA: 88.5°). (b, c, e, f) SEM images of the DAAQ structures formed on the (b, c) bare Si and (e, f) SiH substrates; (b, e) cross-sectional views; (c, f) top views.

hypothesis. Fig. 3(a and d) present images of water droplets on the surfaces of bare Si and HMDS-treated Si (SiH), respectively; the WCAs were 59.7° and 88.5°, respectively. We suspect that the greater WCA for the SiH substrate resulted from a reduction in the density of interfacial trapping states and a lowering of the SE. Fig. 3(b and c) display SEM images of the DAAQ thin films deposited on the bare Si surface; as before, the structures extend away from the substrate. In contrast, some of the DAAQ nanofibers were deposited in-plane and entangled on the SiH substrate (Fig. 3(e and f)). This finding confirms that a low-WCA surface endows a preference for vertical deposition of 1D DAAQ nanofibers.

Fig. 4(a and c) present TEM images of the DAAQ nanofibers formed on the Au and Ti substrates, respectively; these nanofibers were very smoothly faceted and uniform in length. High-resolution TEM images of single nanofibers revealed (Fig. 4(b and d)) indistinct lattice fringe spacing. We suspect that the DAAQ molecules were oriented in short-range order at the edges of the nanofibers, but entangled randomly within the nanofibers. The selected area electron diffraction (SAED) pattern in the inset to Fig. 4(a) features only amorphous rings, rather than distinct diffractive spots, suggesting that an insignificant degree of crystallinity was responsible for the isotropic and randomly oriented molecules. Similarly, the electron diffraction pattern in the inset to Fig. 4(c) also reveals the amorphous features of the DAAQ molecules deposited on the Ti substrates. In addition, these HRTEM images do not reveal the presence of any metal catalysts at the tips of the fibers, confirming that the growth mechanism was different from that of carbon nanotubes (CNTs) [33]. In order to understand the lattice differences in our system, the XRD patterns of the DAAQ commercial powders and nanofiber arrays were used to further study (Fig. 4(e)). Although the DAAQ nanofiber arrays feature lower peak intensity than the commercial powders, the relative percentages of (1 0 0), (1 0 2) and (1 1 2) lattice planes show some changes. Comparison of our results with the previous report of DAAQ nanowires [8], the DAAQ nanofiber arrays (formed by vacuum sublimation in low-temperature process) also prefer to grow in the orientation of (1 0 0) lattice plane.

To determine the differences in energy levels between the electrodes and the DAAQ materials for potential field emission applications, we used photoelectron spectroscopy in air (PESA; Fig. 5(a)) and UV–Vis spectroscopy (Fig. 5(b)) to measure the energy levels of DAAQ. When we bombarded our surface materials under a slowly increasing amount of UV light, photoelectrons were emitted from the surface (from a depth of several to hundred angstroms) at a certain energy level, due to the photoelectron effect. These emitted photoelectrons were then counted by a detector and open counter. Using this approach, the valence band [highest occupied molecular orbital (HOMO)] of DAAQ obtained through linear fitting from the PESA data was 5.60 eV relative to the vacuum level. The UV–Vis absorption spectra of the DAAQ films revealed an absorption band in the region 300–800 nm. From the on set wavelength at 614 nm, we derived an energy gap

for the DAAQ of 2.02 eV. From this value, we estimated the energy of the conduction band [lowest unoccupied molecular orbital (LUMO)] to be 3.58 eV. Fig. 5(c and d) provide a schematic energy level diagram; the HOMO and LUMO states of DAAQ were 5.60 eV and 3.58 eV, respectively; the work functions of Au and Ti, for use as cathode substrates, were 5.1 and 4.33 eV, respectively. Therefore, electrons injected from the Au substrate into the LUMO state of the DAAQ layer must conquer a larger energy gap than those injected from the Ti substrate.

We examined the field emission properties of the DAAQ nanofibers using a parallel-plate configuration with the spacing of 80 μm in a vacuum chamber at a pressure of 8×10^{-6} torr. The anode ITO glass was connected to the source monitor unit (SMU) of a Keithley 237 instrument; the cathode of Au and Ti substrates were grounded. Fig. 6 displays the field emission characteristics (J–E curve) of the DAAQ nanofibers deposited on the Au (**DAAQ-Au**) and Ti (**DAAQ-Ti**) substrates. The turn-on fields (defined as the applied field required for a current density of 10 μA/cm^2) of **DAAQ-Au** and **DAAQ-Ti** were 8.5 and 8.25 V/μm, respectively; at an applied field of 12 V/μm, the maximum current densities were 0.31 and 0.65 mA/cm^2, respectively. The dependence of the emission current of a field emitter on the applied field is described by the Fowler–Nordheim (FN) equation [34]:

$$ln\left(\frac{J}{E^2}\right) = \ln\left(\frac{A\beta^2}{\phi}\right) + \left(\frac{-B\phi^{3/2}}{\beta}\right)\left(\frac{1}{E}\right) \quad (2)$$

where A and B are constants (1.54×10^{-6} A eV/V^2 and 6.83×10^3 V/eV$^{3/2}$/μm, respectively), J is the current density, E is the applied field, and ϕ is the local work function of the emitter material. By plotting $\ln(J/E^2)$ versus $1/E$, the slope of the line of best fit can be used to deduce the field enhancement factor (β):

$$\beta = -\frac{B\phi^{3/2}}{S} \quad (3)$$

where S is the slope of the FN plot. According to FN theory, β is strongly dependent on the geometric structure of the field emitter. The linear FN plots in the insets to Fig. 6(a and b) reveal that the J–E characteristics of the DAAQ nanofibers followed the FN field emission mechanism. The slopes of FN plots for **DAAQ-Au** and **DAAQ-Ti** were −103.5 and −55.67, respectively. Because the LUMO energy level (ϕ) of DAAQ was 3.58 eV, we estimated the values of β of **DAAQ-Au** and **DAAQ-Ti** to be 447 and 831, respectively. To understand why these values of β differed so dramatically, we must consider the effect of the geometry of the nanofibers. Tarntair et al. [35] reported that the field enhancement factor β could be approximated by the length-to-radius ratio of the 1D nanostructure, expressed as

$$\beta = \frac{l}{r} \quad (4)$$

where r is the radius of curvature of the tip and l is the length of the nanofiber. This equation suggests that emitters having longer lengths and smaller radii, resulting in larger values of β, would have better field emission characteristics. Because our low-WCA surfaces (Au and Ti) favored DAAQ molecules self-assembling into standing nanofibers and because the value of β of **DAAQ-Ti** was greater than that of **DAAQ-Au**, we suspected that the higher AR of the DAAQ nanofibers deposited on Ti would be superior, to those formed on Au, for use in field emission devices. Cho et al. [36] reported the effective radius (r_e) of an effective area at the tips of their Alq_3 nanostructural thin film; the calculated radius (r_e = 2.07 nm) was smaller than the measured radius (r_m = 40 nm). The DAAQ nanofibers of **DAAQ-Au** and **DAAQ-Ti** had effective radii of 0.96 and 0.7 nm, respectively (Table 3). From the differences between the values of r_m (34 nm for **DAAQ-Au**; 35 nm for **DAAQ-Ti**) and r_e, we suspect that the electrons were emitted from a localized area at the tip of a nanofiber, rather than from the entire measured area of the nanofiber. From the viewpoint of the energy levels, Fig. 5(c and d) reveal

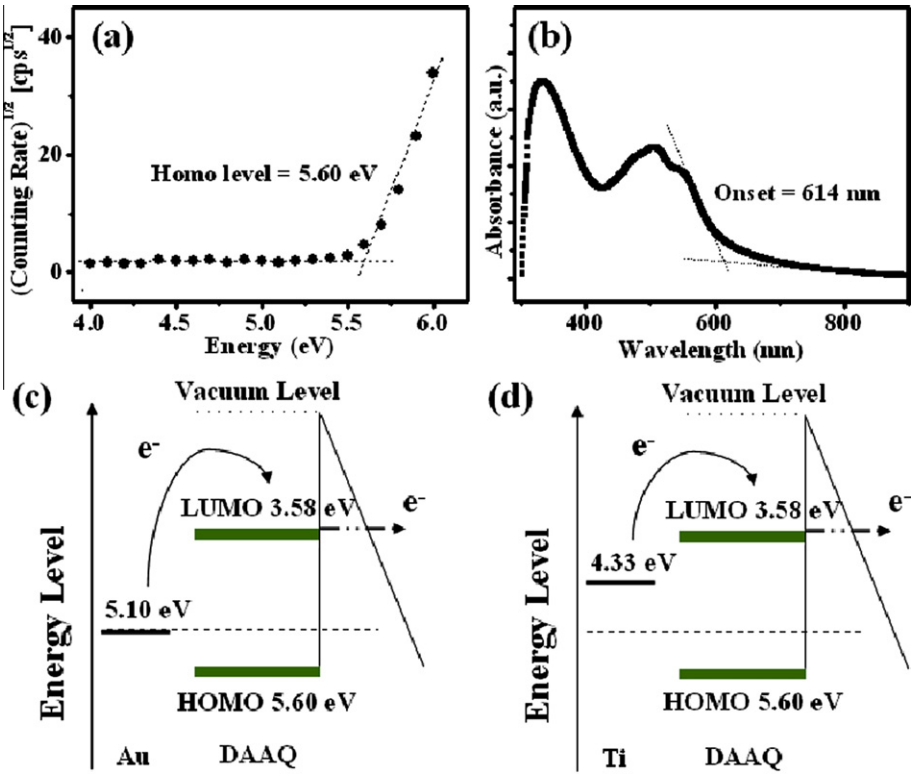

Fig. 5. (a) PESA analysis of the DAAQ thin films. (b) UV–Vis absorption spectra of DAAQ thin films. (c, d) Schematic representations of the energy levels and electrons field emitting through the DAAQ nanofibers of the (c) Au-DAAQ and (d) Ti-DAAQ contacts.

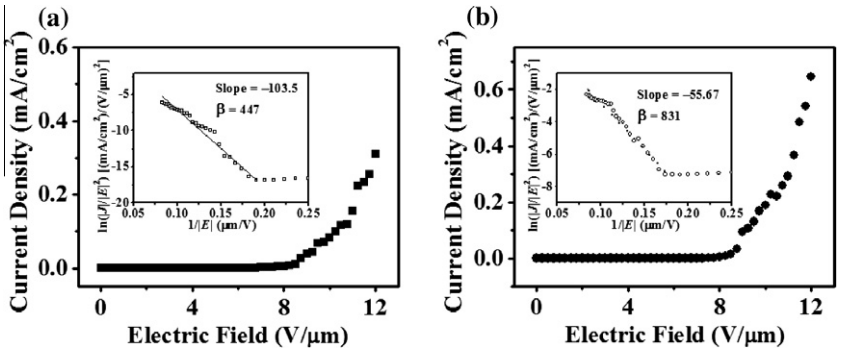

Fig. 6. Field emission *J*–*E* curves of (a) **DAAQ-Au** and (b) **DAAQ-Ti**. Insets: Corresponding FN plots.

Table 3
Values of $E_{turn\text{-}on}$, slopes of FN plots, field emission enhancement factors (β), and effective radii (r_e) for the DAAQ nanofibers.

Substrate	$E_{turn\text{-}on}$ (V/μm)	Slope	β	r_e (nm)
Au	8.50	−103.50	447	0.96
Ti	8.25	−55.67	831	0.70

that the work function (5.1 eV) of Au was much higher than that (4.33 eV) of Ti; therefore, the energy barrier (1.52 eV) at the Au-DAAQ interface was larger than that (0.75 eV) at the Ti-DAAQ contact. These energy barriers limited the injection of electrons from the conducting substrates to organic nanofibers; consequently, a higher applied field was required to reach the same level of emission current.

We performed stability tests of our DDAQ nanofibers under an applied field of 11 V/μm for 3000 s. The calculated mean current densities were ca. 0.07 mA/cm^2 for **DAAQ-Au** (Fig. 7(a)) and 0.19 mA/cm^2 for **DAAQ-Ti** (Fig. 7(b)), with perturbations of less than one order. In addition, we observed a slowly increasing **DAAQ-Ti** emission current over time and two apparent increasing **DAAQ-Au** emission currents from 150 to 250 s and from

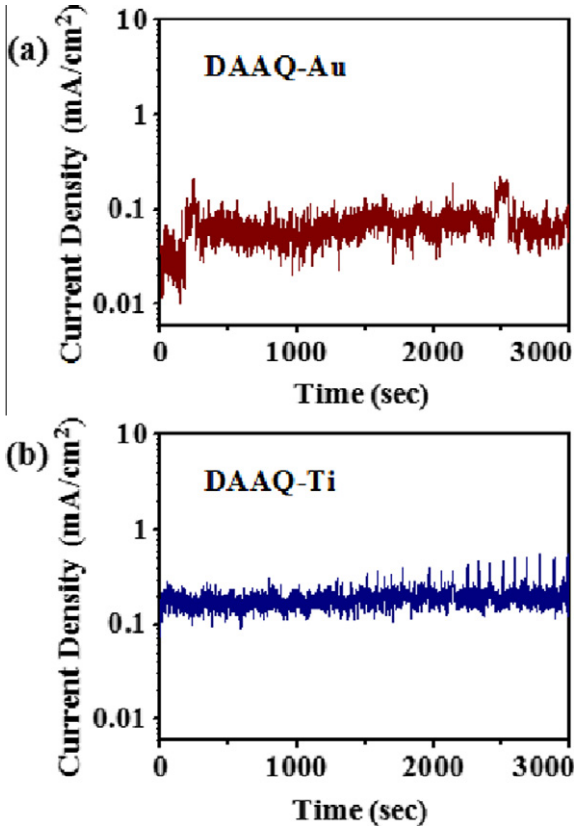

Fig. 7. Emission current stability plots recorded at a constant voltage for 3000 s: (a) **DAAQ-Au**; (b) **DAAQ-Ti**.

2440 to 2540 s. The latter presumably arose from a training effect [37,38]; that is, contaminants were expelled from the nanofibers after an adapted biasing on the nanofibers for a period of time. Thus, the organic semiconductor sustained a stable field emission current, without any decay, during the measurement period, demonstrating that DAAQ organic nanofibers have great potential for use in cold field electron-emitting devices.

4. Conclusions

By using DAAQ as a starting material, we prepared vertical organic nanofibers through low-temperature (42 °C) vacuum sublimation. The morphologies of the structures formed from the DAAQ molecules were controlled by the surface properties of the substrates, with vertically aligned 1D DAAQ structures growing preferentially on low-WCA surfaces, such as Au, Si, and Ti. The DAAQ nanofibers exhibited unique field emission characteristics and followed FN behavior. The maximum emission current densities of **DAAQ-Au** and **DAAQ-Ti** were 0.31 and 0.65 mA/cm^2 when biased at 960 V (E = 12 V/μm), respectively. The field enhancement factors β of the DAAQ nanofibers on the Au and Ti substrates were 447 and 831, respectively. In field emission stability tests, the field emission current was stable, without any decay, during the duration of the measurements. The stability of the emission current and the simplicity of the synthetic process suggest that this method of fabricating vertically aligned DAAQ nanofibers is suitable for application in the fabrication of electron-emitting devices.

9,10-di(2-naphthyl)anthracene (AND) [11], which is designed to be used as a host material because it also has the anthracene structure identical to the dopants. Here, both the host and guest contain the anthracene moieties which are supposed to increase the compatibility between guest and host as to have well-dispersed dopants in the host matrix, and lead to an increase in the emission efficiency.

The dopants (with sample code) for OLEDs fabrication were N,N,N′,N′-tetraphenyl-anthracene-9,10-diamine (TAD), N,N,N′,N′-tetra-*m*-tolyl- anthracene-9,10-diamine (T*m*AD), N,N,N′,N′-tetra-*p*-tolyl-anthracene-9,10-diamine (T*p*AD) and N,N,N′,N′-tetrakis-(3,4-dimethyl-phenyl)-anthracene-9,10-diamine (T*mp*AD). Among these compounds, the physical properties and device performances of TAD and T*p*AD were already reported as the host emitters [12]. Here, we present the first reported case in which the *N*-diaryl amino anthracenes were used as green dopant in ADN host system for OLED devices. We are reporting on the synthesis, characterization, fabrication and performance of OLED devices that incorporate the four dopant molecules described above in the emitting layer. The effects of substituted methyl group at different positions of aromatic *N*-aryl-substituted anthracene-9,10-diamine have been compared based on both materials and solid device evaluation. Moreover, the device performance of the dimethyl-substituted dopants/AND-based devices was also compared to a general guest/host system based on coumarin (C545T) as dopant and Alq_3 as host [13]. The improvement effect of guest/host both based on anthracence derivatives could be observed in this study.

2. Experimental

2.1. Materials and Instrumentations

Sodium tert-butoxide (*t*-BuONa, Merck), Tri-tert-butylposphine (P(t-Bu)$_3$, Strem), Palladium(II) acetate ($Pd(OAc)_2$, Strem), Tris(dibenzylideneacetine)dipalladium ($Pd_2(dba)_3$, Strem), 9,10-Dibromoanthracene (98%, Alfa), Diphenylamine (98%, Alfa), Di-*m*-tolyl-amine (98%, Alfa), Di-*p*-tolyl-amine (97%, Adrich), 4-Bromo-*o*-xylene (98%, Alfa), Benzylamine (99%, Acros), Palladium (10% on carbon, Alfa), Anthracene (98%, Acros), Ethanol (Merck), n-Hexane (Merck), Methanol (Merck) were used as received without further purification. Tetrahydrofuran (THF, Merck), Toluene (SHOWA), Dichloromethane (CH_2Cl_2, Merck) were dried and distilled under standardard procedure (THF and Toluene dried using Na/Ph_2CO; CH_2Cl_2 dried using CaH_2) and stored under nitrogen. For device fabrication, 9,10-di(2-naphthyl)anthracene (ADN), copper phthalocyanine (CuPc), N,N′-bis(naphthalene-1-yl)-N,N′-bis(phenyl)benzidine (NPB), 2,3,6,7-tetrahydro-1,1,7,7,-tetramethyl-1*H*,5*H*,11*H*-10(2-benzothiazolyl)quinolizine- [9,9a,1gh] coumarin (C545T), tris(8-hydroxyquinoline)aluminum (Alq_3) were received from a commercial source (Summit-Tech Co., Ltd.) and purified by a temperature programmated sublimation system. Tungsten boat (Summit-Tech Co., Ltd.), Alumina (Alfa) and LiF (Alfa) were used as received from commercial sources. Indium tin oxide (ITO)-coated glass subtrates with surface resistance 15 Ω/□ were bought from Ritek Co., Ltd.

The synthesized compounds were characterized by Nuclear Magnetic Resonance (NMR) and Mass spectrometer. NMR measurements were made using Bruker AMX 400 and 500 NMR spectrometer. Mass spectra were obtained with a MAT-95XL HRMS mass spectrometer. The UV–visible spectra were recorded using a Perkin Elmer Lambra 35 UV–visible spectrophotometer. Fluorescence spectra were recorded using a Hitachi F-4500 fluorescence spectrophotometer. Photo-electron spectra were obtained by a Riken Keiki Photo-electron Spectrometer model AC-2. Quantum yields were recorded using an integrating sphere and a HAMAMATSU photonic multi-channel analyzer C10027. All data were averaged from at least five raw data to ensure statistical significance. Device properties were monitored using a Keithley 2400 power supply with a 400 nm cut-off filter. An optical meter of model PR705 was used in this study. All of the products were purified by sublimation method with a temperature programmed condition using an upper opened sublimation system made by ULVAC. The high vacuum evaporation system was made by Branchy Technology Co., Ltd. for organic thin film deposition. Thin films were prepared by vacuum evaporation at a base pressure of 2×10^{-5} Torr or lower. The film thickness was measured with a calibrated quartz-crystal microbalance during deposition.

2.2. General procedure for the synthesis of diaryl-anthracene-9,10-diamine derivatives

The structure of as-synthesized diaryl-anthracene-9,10-diamine derivatives are illustrated in Fig. 1 with compound code TAD, T*m*AD, T*p*AD and T*mp*AD, respectively. The diaryl-anthracene-9,10-diamine derivatives were prepared in high yields, by palladium-catalyzed C–N cross-coupling [12,14–16] of the 9,10-Dibromoanthracence with the amine (Diphenylamine, Di-*m*-tolyl-amine, Di-*p*-tolyl-amine or Bis-(3,4-dimethyl-phenyl)-amine). 9,10-Dibromoanthracence (1 equiv.), $Pd(OAc)_2$ or $Pd_2(dba)_3$ (1 mol%), *t*-BuONa (2.5 equiv.), the amine (Diphenylamine, Di-*m*-tolyl-amine, Di-*p*-tolyl-amine or Bis-(3,4-dimethyl-phenyl)-amine) (2.4 equiv.) were weighted into a 500 ml double-neck round-bottom flask connected with a condenser under nitrogen. Dry toluene (200 mL) was then added under nitrogen with stirring to give a homogeneous mixture. A solution containing P(*t*-Bu)$_3$ (5 mol%) and dry toluene (3.4 mol%) was then added to the mixture and reacted under nitrogen for some hours at 130 °C. The endpoint of reaction was monitored by thin-layer chromatography. After complete consumption of starting materials, the resulting solution was cooled to room temperature; and *n*-hexane was added to precipitate the products. The products were collected by filtering and then dried under vacuum for overnight at 100 °C. The crude products were purified by sublimation method under the programmated condition (e.g. 280 °C for 90 min, 300 °C for 90 min, 320 °C for 90 min and then 100 °C). The detailed synthetic procedures of compounds TAD, T*m*AD, T*p*AD and T*mp*AD were described as follows:

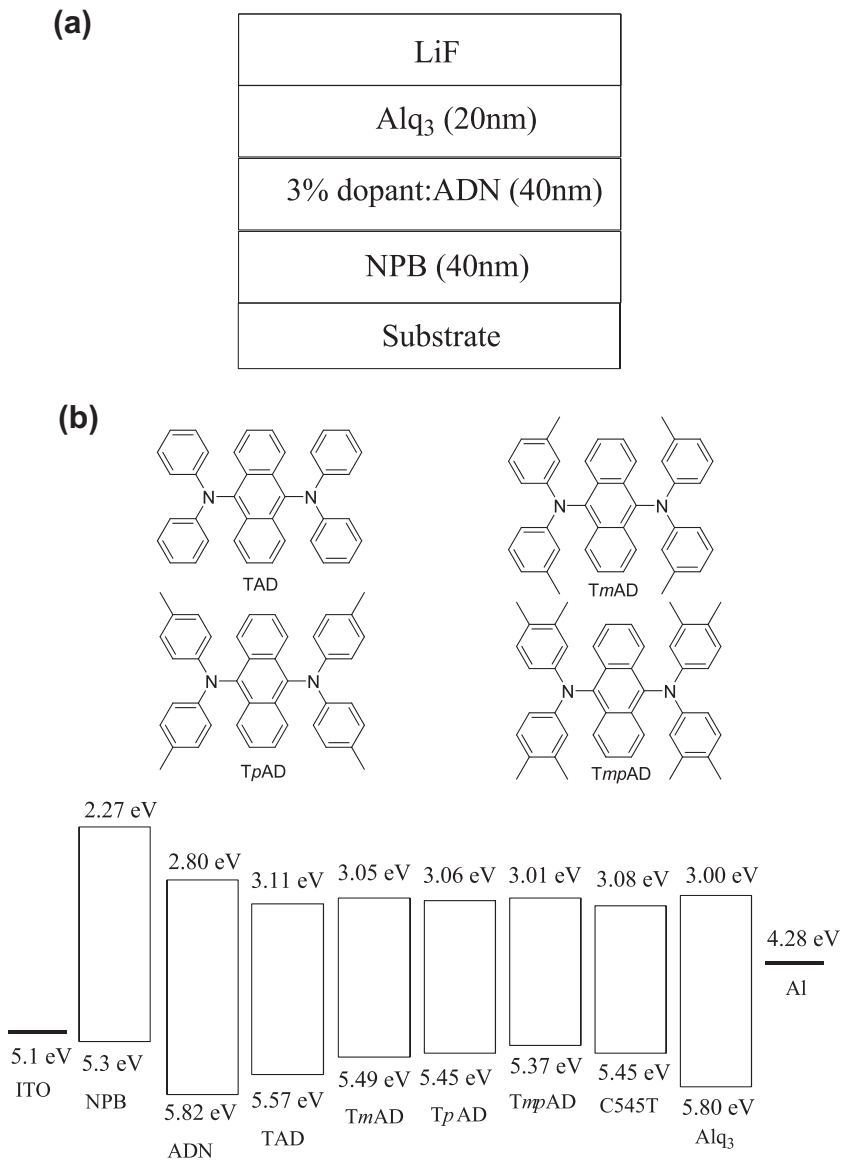

Fig. 1. (a) Schematic OLED device setup. (b) Molecular structure of as-synthesized dopants and relative energy diagram of materials used in all the devices.

2.2.1. N,N,N′,N′-tetraphenyl-anthracene-9,10-diamine (TAD)

From 9,10-Dibromoanthracence (10 g, 29.8 mmol) and Diphenylamine (12.09 g, 71.4 mmol), compound TAD was obtained as a yellow solid. The crude product was purified twice by sublimation to afford compound TAD in 78% yield. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 6.89–6.92 (*t*, *J* = 3.2 Hz, *J* = 7.2 Hz, 4 H), 7.10–7.12 (*d*, *J* = 4.4 Hz, 8 H), 7.18–7.22 (*t*, *J* = 7.2 Hz, *J* = 8.4 Hz, 8 H), 7.33–7.36 (*q*, *J* = 3.2 Hz, 4 H), 8.17–8.20 (*q*, *J* = 3.2 Hz, 4 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 120.3, 121.4, 125.1, 126.8, 129.3, 131.8, 137.4, 147.7; EI MS (m/e): 512 (M^+).

2.2.2. N,N,N′,N′-tetra-m-tolyl-anthracene-9,10-diamine (TmAD)

From 9,10-Dibromoanthracence (5 g, 14.9 mmol) and Di-*m*-tolyl-amine (7.05 g, 35.7 mmol), compound T*m*AD was obtained as a yellow solid. The crude product was purified twice by sublimation to afford compound T*m*AD in 79% yield. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.19 (s, 12 H), 6.70–6.72 (*d*, *J* = 7.2 Hz, 4 H), 6.86–6.88 (*d*, *J* = 9.84 Hz, 4 H), 6.94 (s, 4 H), 7.04–7.08 (*t*, *J* = 8.0 Hz, *J* = 7.6 Hz, 4 H), 7.33–7.34 (*q*, *J* = 3.2 Hz, 4 H), 8.17–8.17 (*q*, *J* = 3.2 Hz, 4 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 21.6, 117.7, 120.9, 122.1, 125.1, 126.6, 129.0, 131.9, 137.5, 138.9, 147.9; EI MS (m/e): 568 (M^+).

2.2.3. N,N,N′,N′-tetra-p-tolyl-anthracene-9,10-diamine (TpAD)

From 9,10-Dibromoanthracence (5 g, 14.9 mmol) and Di-*p*-tolyl-amine (7.05 g, 35.7 mmol), compound T*p*AD was obtained as a yellow solid. The crude product was purified twice by sublimation to afford compound T*p*AD

in 82% yield. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.24 (s, 12 H), 6.98–6.99 (*d*, *J* = 1.2 Hz, 16 H), 7.30–7.34 (m, 4H), 8.16–8.19 (m, 4H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 20.6, 120.1, 121.1, 126.6, 129.8, 130.3, 131.9, 137.5, 145.6; EI MS (m/e): 568 (M^+).

2.2.4. N,N,N′,N′-tetrakis-(3,4-dimethyl-phenyl)-anthracene-9,10-diamine (TmpAD)

For the synthesis of T*mp*AD, the Bis-(3,4-dimethyl-phenyl)-amine was first synthesized as the following procedure: 4-Bromo-*o*-xylene (2 g, 10.8 mmol), Benzylamine (2.54 g, 23.7 mmol), $Pd_2(dba)_3$ (0.1 g, 1 mol%), *t*-BuONa (2.4 g, 2.3 equiv.) were weighted into a 250 ml double-neck round-bottom flask connected with a condenser under nitrogen. About 50 mL of toluene was added and then stirred to give a homogeneous mixture. A solution of 5 mol% P(*t*-Bu)$_3$ in toluene (2.6 mL) was then added to the mixture and reacted at 130 °C. After overnight, the resulting solution was cooled to room temperature, and the solution was evaporated to dryness to afford a powder, which was adsorbed onto 4 g of silica gel and chromatographed with hexane to give 2 g (yield: 80%) of Benzyl-bis-(3,4-dimethyl-phenyl)-amine as a red-brown liquid. The as-prepared Benzyl-bis-(3,4-dimethyl-phenyl)-amine was further reduced to form Bis-(3,4-dimethyl-phenyl)-amine. A mixed solvent of ethanol and THF was added to a 100 mL double-neck round-bottom flask which contained Benzyl-bis-(3,4-dimethyl-phenyl)-amine (2 g, 6.34 mmol) and Pd/C (0.025 g, 2 mol%) and stirred under nitrogen. After the starting materials had dissolved, hydrogen gas was then bubbled into the solution and further reacted overnight. The reaction was monitored by thin-layer chromatography. After the reaction had completed, the resulting brown solution was evaporated to dryness to afford 0.83 g (yield: 58%) of Bis-(3,4-dimethyl-phenyl)-amine as a brown solid which was used as the starting material for the synthesis of compound T*mp*AD. Compound Benzyl-bis-(3,4-dimethyl-phenyl)-amine was identified by ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.08–2.19 (m, 12 H), 4.30 (s, 2 H), 6.40–6.43 (*q*, *J* = 2.4 Hz, 2H), 6.49–6.50 (*d*, *J* = 2.0 Hz, 2H), 6.93–6.95 (*d*, *J* = 80 Hz, 2H), 7.25–7.38 (m, 5H). Compound bis-(3,4-dimethyl-phenyl)-amine was identified by ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.19–2.20 (d, 12 H), 5.43 (s, 1 H), 6.78–6.82 (m, 4 H), 6.99–7.01 (d, 2H).

From 9,10-Dibromoanthracence (5 g, 14.9 mmol) and Bis-(3,4-dimethyl-phenyl)-amine (8.05 g, 35.7 mmol), compound T*mp*AD was obtained as an orange solid. The crude product was purified twice by sublimation to afford compound T*mp*AD in 81% yield. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.11 (s, 12 H), 2.15 (s, 12H), 6.77–6.80 (*q*, *J* = 2.4 Hz, 4 H), 6.91–6.93 (m, 8 H), 7.31–7.33 (*q*, *J* = 3.2 Hz, 4 H), 8.17–8.19 (*q*, *J* = 3.2 Hz, 4 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 18.9, 20.1, 117.8, 121.4, 125.2, 126.4, 129.0, 130.2, 132.0, 137.2, 137.5, 145.96; EI MS (m/e): 624 (M^+).

2.3. OLED fabrication

Indium tin oxide (ITO)-coated glass substrates were thoroughly cleaned and treated with oxygen plasma. OLEDs were fabricated by using a multiple source thermal evaporation system at a base pressure of 2×10^{-5} Torr or lower. The deposition rate was 1 Å/s for all organic films. The LiF film, with thickness of 15 Å, was evaporated at a rate of 0.1 Å/s. The Al cathode, with thickness of 200 nm, was deposited at a rate of 5 Å/s.

3. Results and discussion

3.1. Photo-physics studies

The photo-physics properties of as-synthesized methyl groups substituted N-aryl anthracene-9,10-diamine derivatives TAD, T*m*AD, T*p*AD and T*mp*AD were studied by UV–visible and fluorescence spectrophotometer. The absorption and emission spectra as illustrated in Fig. 2a and Table 1 show that these compounds in form of solid film have major absorption bands with wavelength maxima (λ_{max}) within 258–268, 296–297, 360–380 and 470–490 nm. The potoluminence (PL) emission band has λ_{max} located around 519–532 nm. As a result, compound TAD and T*m*AD have similar emission spectra with $\lambda_{max} \sim 520$ nm in solid state, whereas there are obvious bathochromic shift observed at $\lambda_{max} \sim 530$ nm for compound T*p*AD and T*mp*AD. The compound T*mp*AD, with methyl groups substituted in both *para*/*meta* position, also has similar emission spectra to that of T*p*AD. The result indicates the methyl group substituted at the *para* position of aromatic phenyl diamine has a greater electronic effect than *meta* position on the anthracene moiety. There is a strong solvent effect for these anthracene materials as illustrated in Fig. 2b and Table 1. Basically the emission color of these compounds exhibit a green color in non-polar solvents, i.e., toluene, and red shift to yellow-green color in polar solvents, i.e., CH_2Cl_2, for compound with methyl substuents. The solvent effect indicates there is an observable dipole moment between phenyl diamine and anthracene moieties. The dipole moment is strongly dependent on the position of methyl groups at the phenyl diamine, especially for the compound T*p*AD and T*mp*AD. The effects of methyl substituents for the comparison of λ_{em} in solvent phase showed the following sequence of T*mp*AD, T*p*AD and then T*m*AD.

A photoelectron spectrometer was used to evaluate the energy of the highest occupied molecular orbital (HOMO). The energy gap (E_g) was calculated by the formula: E_g (eV) = $hc/\lambda_{onset} = \sim 1241/\lambda_{onset}$, where h is Planck's constant and c is speed of light. The wavelength onset, λ_{onset}, was obtained by absorption spectra as illustrated in Table 1. The lowest unoccupied molecular orbital (LUMO) was derivated from the values of HOMO and E_g, and the data are listed in Table 1. The relative energy diagram of materials used for devices fabrication is compared in Fig. 1 The compound T*mp*AD has relatively the smallest value of HOMO, i.e. 5.37 eV, due to its higher donor ability than others. The delocalization degree of anthracene relatively decreased along with the donor ability of phenyl diamine moiety, and the energy band gaps become smaller. The energy band gaps follow the sequence: compound TAD > T*m*AD > T*p*AD > T*mp*AD, where the E_g values are 2.46, 2.44, 2.39 and 2.36 eV, respectively.

3.2. Devices fabrication

The as-prepared anthrancene-9,10-diamine materials TAD, T*m*AD, T*p*AD, and T*mp*AD were used as dopants of the emitting layer for the application of organic electroluminescent devices. Before device fabrication, compound T*p*AD was used as a dopant for doping concentration tests with devices fabricated as follows: ITO/CuPc (15 nm)/NPB (40 nm)/T*p*AD:AND (40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm), where the doping concentration of T*p*AD was changed between 1 and 4 mol%. It can be seen that the luminance efficiency and brightness of devices were relatively increased by changing the concentration from 1 to 4 mol% as the curves show in Fig. 3. The results show that

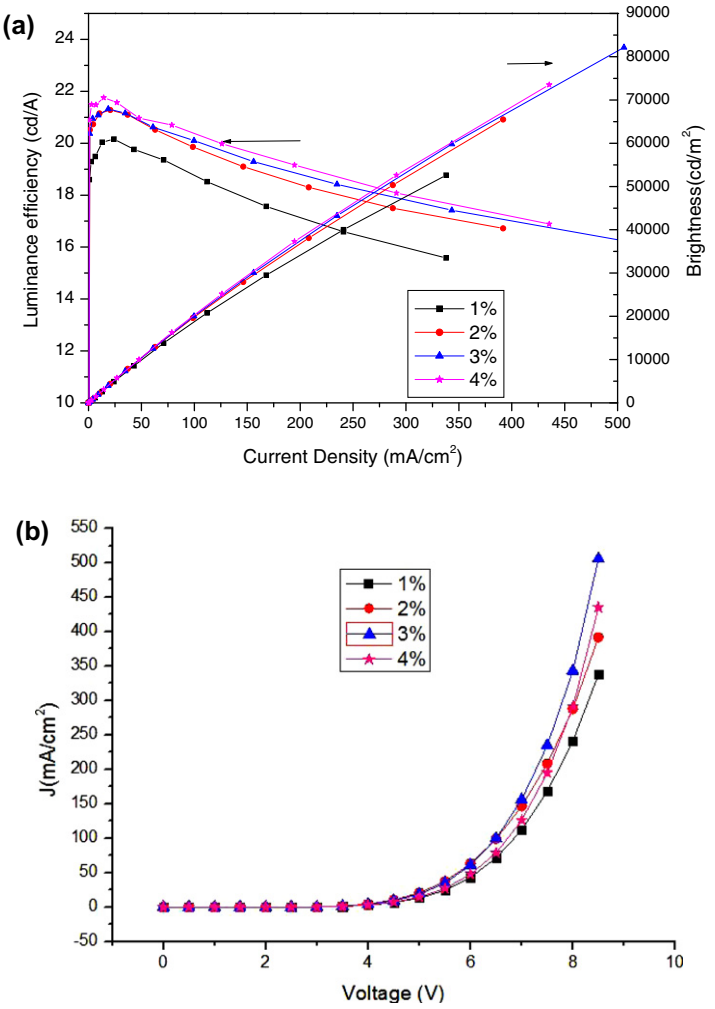

Fig. 3. The doping concentration test with devices fabricated as: ITO/CuPc (15 nm)/NPB (40 nm)/T*p*AD:AND (40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm), where the concentration of T*p*AD is changed between 1 and 4 mol%.

the devices have good luminance efficiency below a current density of 100 mA/cm^2. As the current density increased, the optimized concentration of T*p*AD doping in AND could be compared and selected, where the doping concentration of 3 mol% was the optimum value for considering the driving voltage, luminance efficiency and brightness over a wide range of current density. The result could be observed from the *J*–*V* curves for the doping concentration test as shown in Fig. 3b, in which 3 mol% of dopant shows relatively lower driving voltage, when compared at the same current density. Therefore, in this study, a series of solid state devices were fabricated by using 3 mol% dopant for the comparison in the effects of methyl substituents on the dopants.

The structure of devices using the as-prepared anthracene-9,10-diamine derivatives as dopants was designed and fabricated as ITO/NPB (40 nm)/3% dopant:AND (40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm) and schematic shown as Fig. 1 Herein, NPB was used as the hole transport layer (HTL). The wide band gap material of AND, which has a high energy band gap of 3.02 eV, was used as the host material because it might restrict the electron and hole in the emitting layer and was expected to improve the efficiency of emission during recombination. Moreover, the same structure of anthracene moieties for both dopant and the host AND was expected to have more compatible properties and be suitable as a good guest/host combination for the emitting layer. The electron transport layer (ETL) was tris(8-hydroxyquinoline)aluminum (Alq_3).

3.3. Devices properties studies

A comparative device based on a general guest/host system with coumarin (C545T)/Alq_3-based emitting layer was fabricated and named as device 1, which has the structure of ITO/NPB (40 nm)/2% C545T:Alq_3 (40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm). The devices based on the as-prepared compound TAD, T*mp*AD, T*m*AD, and T*p*AD were fabricated and named as device 2, device 3, device 4 and device 5, respectively. The device properties are summarized in Table 2. As the results show, device 3 exhibits the best performance with maximal external quantum

efficiency (E.Q.E.) reached to 8.2%. The E.Q.E. values of devices 1–5, which evaluated at 100 mA/cm^2, follow the sequence: device 3 > device 5 > device 4 > device 2 > device 1, where the E.Q.E. values are 6.91%, 6.37%, 5.40%, 5.33% and 3.52%, respectively. The effects of substituted methyl group at both *para/meta* positions of aromatic *N*-aryl-methyl-substituted 9,10-diaminoanthracene by fabricating the device using the T*mp*AD/AND based guest/host system have been observed with the power efficiency of 9.24 lm/W and current efficiency of 28.17 cd/A, evaluated at luminance of 10,000 cd/m^2. All of the devices have color coordinates located at the green region in the Commission internationale de l'éclairage (CIE) chromaticity diagram. The electroluminescent spectra of devices 1–5 are shown in Fig. 4. Evidently, the trends of emission for these devices are similar to that of solid films as shown in Fig. 2a. For the devices 1–5, the relationships of luminance (B) versus current density (*J*) are shown in Fig. 5. As shown in *B–J* curves, the brightness of devices using the dopants with methyl groups at both *para/meta* or *para* positions of *N*-aryl-methyl-substituted 9,10-diaminoanthracene, i.e., the devices 3 and 5, were better than that at *meta* position or non-substituted, i.e., devices 4 and 2. However, all of these developed devices based on the anthracene-9,10-diamine derivatives/AND based guest/host system were greatly enhanced in brightness as compared at the same current density to the system based on coumarin (C545T)/Alq_3 of device 1. Furthermore, as we study the current efficiency (cd/A) or power efficiency (lm/W) related to luminance (cd/m^2), we can find that the curve trends show the device efficiency as follows: device 3 is better than device 5, device 5 is better than devices 4 and 2; device 1 is the worst, as shown in Fig. 6. The improvement in optoelectronic properties of the guest/host system based on anthracene-9,10-diamine derivatives/9,10-di(2-naphthyl)anthracene (AND) as compared to the coumarin (C545T)/Alq_3 is obvious. In addition, the dopant T*mp*AD illustrated the effect of methyl groups substituted at both the *para/meta* positions could greatly improve in device performance. This may be attributed to the relative amorphous property of the emission film and the reduction of the self-quenching phenomena. The steric effect of the two methyl groups substituted at the *meta* and *para* position of phenyl diamine may make the molecules relatively difficult to aggregate with each other. Therefore the emission efficiency can be improved by developing these serials of 9,10-diaminoanthracene derivatives as the dopant T*mp*AD. However, the methyl substituents may decrease the carrier mobility and lead to a higher driving voltage as compared with the current density (mA/cm^2) versus driving voltage (*V*) curves of the fabricated devices as shown as Fig. 7. The driving voltage of device 1 is lower than device 2–5 because of the relatively lower energy barrier between the host

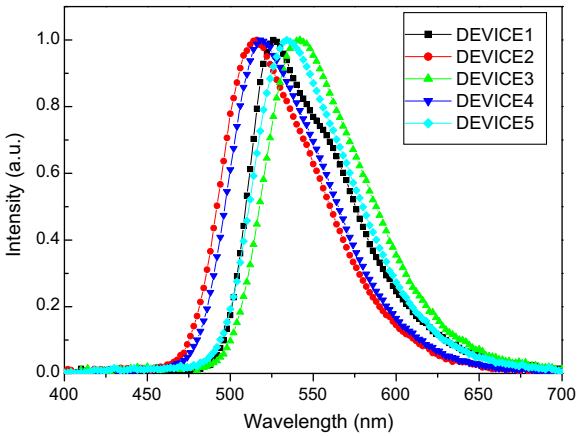

Fig. 4. The electroluminescent spectra of devices fabricated in this study, where device 2–5 with structure of ITO/NPB (40 nm)/dopants: AND (40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm), and device 1 (as a compared device) with structure of ITO/NPB (40 nm)/C545T: Alq_3(40 nm)/Alq_3 (20 nm)/LiF (1.5 nm)/Al (200 nm). The dopant of device 2, TAD; device 3, T*mp*AD; device 4, T*m*AD; Device 5, T*p*AD.

emitter layer and the electron transport layer (ETL) as illustrated in Fig. 1. Device 1 has both a host emitter layer and an ETL using material of Alq_3, while devices 2–5 had been fabricating the host emitter by using AND as to improve the properties of the organic devices. However, a little higher driving voltage is acceptable as compared to the voltages illustrated in Table 2, e.g., 10.23 volt of device 5 as compared to 9.9 V of device 1.

From the discussion above, we demonstrate the as-prepared compound TAD, T*m*AD, T*p*AD, and T*mp*AD, especially T*mp*AD, could be used as good dopants in the AND based host material for OLEDs fabrication, with excellent electroluminescent properties. In general, their performances are better than coumarins/Alq_3 based devices, although the driving voltage is a little worse. The methyl substituents on the aromatic ring of phenyl diamine also induce the emission red-shift to closer to the range of eye sensitive wavelength near 550 nm, e.g., 542 nm for T*mp*AD. Therefore, these methyl-substituted dopants are suitable when used as highly efficient green dopant materials for OLEDs.

As compared with device 2 for the effects of methyl substituents in devices efficiency, current efficiency was promoted about 2.9, 6.33, and 7.94 cd/A for dopants with the substituted methyl groups at *meta*, *para and both meta/para* position, for device 4, 5 and 3, respectively. In addition, the power efficiency was also significantly increased with 0.74, 2.26 and 3.02 lm/W for device 4, 5, and 3, respectively. When comparing the results, device 3, fabricated by T*mp*AD/AND-based emitter system, exhibits the best E.Q.E., luminance efficiency, power efficiency, and the most saturated green with CIE $x = 0.038$; $y = 0.59$ for OLED applications. We demonstrate that the as-prepared compound TAD, T*m*AD, T*p*AD and T*mp*AD, especially T*mp*AD, could be used as good dopants in the AND based host material for OLEDs fabrication, with excellent electroluminescent properties. In general, their performances are better than coumarins/Alq_3 based devices.

4. Conclusions

The methyl substuents on the *N*-diarryl rings of anthracene-9,10-diamine showed obvious effects in emission spectra as demonstrated in photo-studies, which observed a significant bathochromic shift followed by the sequence of compound T*mp*AD, T*p*AD, and T*m*AD as compared to TAD. The energy band gaps are relatively decreased as

the methyl groups substituted at the *N*-diarryl rings, especially significant for both on *para*/*meta* positions of compound T*mp*AD. Here we demonstrate the as-prepared compound TAD, T*m*AD, T*p*AD, and T*mp*AD, especially T*mp*AD, could be used as good dopants in the wide band gap AND based emitting layers for OLEDs farication, which have excellent performances better than coumarins/Alq_3 based devices. The effect of methyl groups substituted at both the *para*/*meta* positions of the *N*-diarryl rings of anthracene-9,10-diamine could show great improvement in device performance as compared to the non-substituent compound TAD.

ABSTRACT

Small molecular organic light-emitting diodes (SMOLEDs) were fabricated with an ink-jet printed film of 2-(*t*-butyl)-9,10-bis (20-naphthyl) anthracene (TBADN) doped with 4,4′-bis[2-{4-(*N*,*N*-diphenylamino)phenyl vinyl] (DPAVBi) as emitting layer. Dewetting behavior of ink-jet printed TBADN/DPAVBi solutions were restrained by adding cyclohexylbenzene or α-chloronaphthalene to the main solvent chlorobenzene. The high boiling point and high viscosity of cyclohexylbenzene and α-chloronaphthalene has increased the thickness of liquid films and the viscosity, which restrained the dewetting from thermodynamics and kinetics aspect. Uniform TBADN/DPAVBi films obtained by ink-jet printing from chlorobenzene/cyclohexylbenzene solution have been used in the fabrication of matrix display of SMOLEDs. The OLEDs has a turn-on voltage of 5.5 V, the maximum luminance of 289 cd/m^2 and the maximum current efficiency of 0.71 cd/A.

1. Introduction

Organic light-emitting diodes (OLEDs) have drawn much attention in flat-panel displays (FPD) because of their high brightness, low power consumption, wide viewing angle and good contrast [1–4]. Ink-jet printing provides an opportunity to gain large-area full color displays of OLEDs by high efficiency and low-cost process [5–7]. A lot of light-emitting polymers have been patterned by ink-jet printing and were used in full color display devices [8–13]. The ink-jetting behavior of polymer solutions has also been studied [14–17]. Recently solution-processed small molecular organic light-emitting diodes (SMOLEDs) have attracted more attention because of the simple film forming process and good performance of devices [18–20]. Printable phosphorescent organic light-emitting devices have been demonstrated to be able to exhibit high performance and long lifetime [21,22].

To gain a high-performance and long-lifetime device by wet-processing, a good film-forming property of the materials is necessary. But the small molecular materials usually have poor film-forming properties. The liquid films covered on the substrates can dewet from the substrate surface and cannot form continuous uniform films during the solidification. There are ways to improve the film-forming properties of the solution. Materials with large molecular volume and long alkyl-chain are properly designed and synthesized to improve the solubility and film-forming property [23,24]. Small molecular materials can also be mixed with polymers to form films [25,26]. Ultra-high molecular weight polystyrene (UHMW-PS) has been added to the small molecular solution to provide good film-forming characteristics and advantageous mechanical properties [27].

The film formation can also be improved by localizing the dewetting in the chemical or physical patterned substrates. Sirringhaus et al. gained high-resolution polymer electrodes through inkjet printing of water-based conducting polymer solution on hydrophilic glass with hydrophobic polyimide pattern [28]. Hendriks et al. produce silver tracks by ink-jet print nanoparticle ink on the

doi:10.1016/j.orgel.2011.01.027

hot-embossed structure, where ink can imbibe the corner of the channel as a consequence of the capillary forces when the contact angel is small [29]. However, the influences of the solvents on the film-forming properties of the small molecular materials are rarely investigated though binary solvents system have been used to gain uniform film morphology in ink-jet printing of organic semiconductor films [30–32].

In this paper, we choose the 2-(*t*-butyl)-9,10-bis (20-naphthyl) anthracene (TBADN) doped with 4,4′-bis [2-{4-(*N*,*N*-diphenylamino)phenyl vinyl] (DPAVBi) system to reveal the solvent effects on the film-forming property of the small molecular materials. The spin-coated films of TBADN doped with DPAVBi from toluene and chlorobenzene solutions have been used as emitting layer. The solution-processed devices have a high performance which is comparable with the vacuum-deposited ones [19]. The film forming property of ink-jet printed TBADN/DPAVBi solutions from different solutions were investigated on the substrate with low surface energy separators. We found that the solvents have great effects on the film-forming properties of TBADN/DPAVBi system. And an probable film-forming mechanism of the liquid film from different solvents were given. With the ink-jet printed pin-hole free film as emitting layer, a passive matrix display has been fabricated and the performance of the matrix was characterized.

2. Experimental

2.1. Materials

The positive photoresist was purchased from Suzhou Ruihong Electronic Chemical Co., Ltd., China. Polystyrene (PS, Mw: ~31600, PDI: ~2.02, T_g = 103 °C) and poly (4-vinylpyridine) (P4VP, Mw: ~60,000, PDI: ~2.96, T_g = 137 °C) were purchased from Aldrich. Polydimethylsiloxane (PDMS, Sylgard™ 184) was purchased from Dow Corning. ITO glass (glass slide with indium-tin-oxide films) was purchased from Chinese South Glass Holding (CSC) Co., Ltd. The hole-injection material of poly (styrene sulfonic acid)-doped poly (3,4-ethylenedioxythiophene) (PEDOT: PSS, Baytron P VP.AI4083) was purchased from H.C. Starck GmbH. 2-(*t*-Butyl)-9,10-bis (20-naphthyl) anthracene (TBADN) as the emitting host material and 4,4′-bis[2-{4-(*N*,*N*-diphenylamino)phenyl vinyl] (DPAVBi) as the dopant material were purchased from LumTech Corporation. α-Chloronaphthalene (ClNaph) and cyclohexylbenzene (CHB) were purchased from Aldrich without further purifying. The chlorobenzene (CB) and o-dichlorobenzene (oDCB) were purchased from Beijing Chemical Reagent Co. Ltd., China and were purified by reflux distillation in N_2 for 12 h.

2.2. Ink-jet printing of organic light-emitting films

The substrates with low surface energy separators are prepared from the method used in our previous work [12]. Transfer printed PS pattern was used as mask to realize selective deposition and patterning of Au/Ni metal film on P4VP/photoresist films. The metal film can be used as mask of photolithography to realize the patterning of photoresist and form separator with T shape cross-section. After self-assembling monolayer of fluorinated mercaptan on the patterned metal film, low surface energy separators were obtained.

The PEDOT:PSS served as the hole-injection layer was spin-coated on the substrate to give a thickness of 45 nm and then baked at 80 °C for 30 min in vacuum. TBADN doped with DPAVBi (95/5 wt/wt) was dissolved in CB or mixed solvents. The mixed solvents were obtained with a mixture of 70% CB and 30% other solvents by weight, such as CB and oDCB, CB and ClNaph, CB and CHB, etc. The solutions were ink-jet printed into the grooves between the separators by a home-built ink-jet printer to form films, as shown in Fig. 1a. The ink-jet printer was equipped with a piezoelectric print head to form and eject drops, an X–Y stage to move the substrate. The spatial and repeatable resolution of the stage is 10 and 5 μm. The print head with nozzle diameter of 70 μm was manufactured by Microdrop Technique GmbH. The spin-coated films from CB and CB/CHB solutions were also prepared. All the films were put into a vacuum oven at room temperature for 20 min and then at 80 °C for 2 h to remove the solvents.

2.3. Fabrication of OLEDs

The light-emitting layer of TBADN/DPAVBi (80 nm) from CB/CHB solutions were deposited by spin-coating or ink-jet printing. After removing the solvents in the vacuum oven, the electron-transporting layer TPBI (20 nm) and LiF (1 nm)/Al (100 nm) cathode were deposited by thermal evaporation with pressure of less than 4×10^{-4} Pa without breaking the vacuum.

2.4. Characterization of films and SMOLEDs

The ink-jet printed films were observed by Optical Microscopy (Leica DMLP, Leica Microsystems Ltd., Germany). The surface morphology of the films were investigated by Atomic Force Microscopy (SPA 300HV with a SPI 3800N Probe Station, Seiko Instruments Inc., Japan) in tapping model. The current–luminance–voltage characteristics were acquired through a Keithley source measurement unit (Keithley 2400) with a calibrated silicon photodiode. The PL spectra were recorded using a Perkin–Elmer LS 50B spectrofluorometer and the EL spectra were measured using a PR650 spectra colorimeter. The thickness profiles of the films were investigated by a Veeco Dektak 6M Stylus Profilometer.

3. Results and discussion

3.1. Film-forming property

For wet-processing procedure, the solvents have a great effect on the quality of the films, which leads to different performance of the devices. In spin-coating process, the solvents can influence the microstructure and the morphology of the films [19,33]. In the ink-jet printing process, coffee ring can be effectively prevented by using a

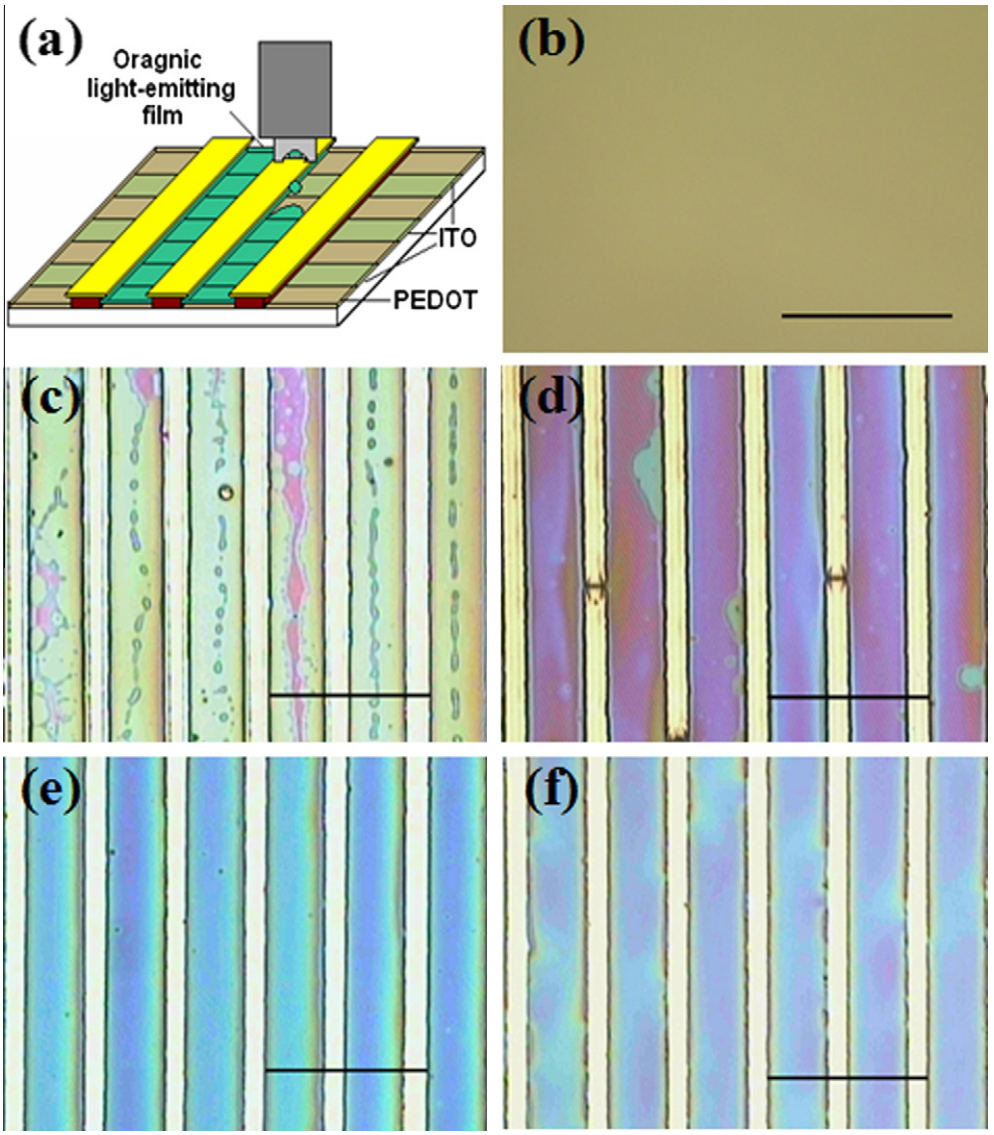

Fig. 1. (a) The schematic process of ink-jet printing. The optical images of TBADN/DPAVBi (95/5, w/w) films (b) spin-coated from CB and ink-jet printed from (c) CB, (d) CB/oDCB, (e) CB/ClNaph and (f) CB/CHB, respectively. The scale bar is 500 μm.

mixture of two solvents with great difference in boiling points and uniform films can be gained [30–32].

And the properties of the solvents can also influence the film-forming properties of the small molecular materials. The optical images of TBADN/DPAVBi (95/5, w/w) films by ink-jet printing from CB solution, CB/oDCB solution, CB/ClNaph solution and CB/CHB solution are shown in Fig. 1c–f. When only CB is used, each groove of the substrate is only partially covered by TBADN/DPAVBi films. As shown in Fig. 1c, discontinuous dots are dispersed at the middle of the grooves and most area of the substrate is not coated well by the films. But when CB solution is deposited by spin-coating, the TBADN/DPAVBi film is uniform in the vast, as shown in Fig. 1b. When oDCB is added to CB by 30% in weight, most area is covered by the film but there are a few holes as shown in Fig. 1d. The holes in the film can cause electrical shorts when voltage is applied. Fig. 1e and f shows the ink-jet printed films from CB/ClNaph and CB/CHB solutions, where all the grooves are fully coated by the emitting materials and uniform films are obtained.

3.2. Mechanism for restraining dewetting

The different film-forming behaviors of the same small molecular materials should result from the different properties of the solvents. The basic properties of the solvents used in our work are shown in Table 1. All the solvents are with relative high boiling points to prevent the clogging of nozzle of the print head during ink-jet printing process. As examples, we discuss the film forming

Table 1
The boiling point, viscosity and surface tension of the solvents.

Solvent	Boiling point (°C)	Viscosity (mPa s)	Surface tension (mN/m)
CB	131.7	0.730	32.93
oDCB	180.5	1.322	36.63
ClNaph	259.3	2.927	39.23
CHB	240.1	2.685	33.29

Data compiled from Yaws' Handbook of Thermodynamic and Physical Properties of Chemical Compounds© 2003 Knovel.

behaviors of the small molecular materials from CB and CB/CHB solutions by two aspects.

On the one hand, the thickness of the solution film reduces fast because of the evaporation of solvent. According to the dewetting theory, the rupture of a thin liquid film is initiated only when the film thickness is smaller than a certain value, namely the critical dewetting thickness e_c. The critical thickness e_c can be given by the equation $e_c = 2\kappa^{-1}\sin(\frac{\theta_E}{2})$, where κ^{-1} is the capillary length and θ_E is the static contact angle. The capillary length is defined by the equation $\lambda_{cap} = \sqrt{\gamma_{lv}/\rho g}$ [34,35], where γ_{lv} is the liquid/vapor surface tension and ρ the density of the liquid. Smaller than the critical dewetting thickness, molecular forces dominate over gravitational forces and the film may dewet [36,37]. The rupture, which may be initiated by the heterogeneous nucleation mechanism, would firstly take place on the areas where the thickness of liquid film is smaller and reaches the critical value firstly. Then the dewetted liquid flows away exposing the underlying substrate, as shown in Stages I and II in Fig. 2a. When the solvent with high boiling point, such as CHB, is used, the evaporating velocity will be slower. When the time scale for liquid droplet evaporation is much less than the time scale for solutes near the contact line to meet each other, the solutes have sufficient time to migrate to the contact line and form a monolayer to maintain a pinned contact line [38], thus the liquid film can evaporate without receding and cover the substrate well. Since low volatility of CHB, liquid films with relatively higher thickness will be stayed on the substrate in the ink-jet printing process. The thicker film is beneficial for preventing the dewetting behavior of the solution deposited in the grooves, as shown in Stages I and II in Fig. 2b. The improved film-forming property of CB/oDCB and CB/ClNaph solutions are the same reason.

On the other hand, the dewetting velocity of ink-jet printed liquid films is affected by the properties of the solvents. Solutions contained small molecular materials, in which there is not any inter-chain entanglement as polymers, belong to Newtonian fluids and can retain their initial viscosity as the solvents [21]. Eq. (1) shows the dewetting velocity of the ideal Newtonian fluids [39,40]:

$$V = \frac{dR}{dt} = k\frac{\gamma}{\eta}\theta e^3 \tag{1}$$

In which, V is the dewetting velocity, R is the radius of the rim and t is the time, γ is the surface tension, η is the viscosity and θ_e is the contact angle in the equilibrium state. When only CB is used, the solution cannot form continuous film in every groove. This may be due to the large value (~45.11) of $\frac{\gamma}{\eta}$, which results in a high dewetting velocity. When the CHB/CB solvent is used, the concentration of CHB in the solution will increase in the drying process because of its high boiling point and low volatility. Compared with CB, the value (~12.40) of $\frac{\gamma}{\eta}$ for CHB is much smaller. Thus the viscosity and surface tension of the solution will change and the value of $\frac{\gamma}{\eta}$ decreases. At last, the dewetting velocity of the liquid film will be much lower for the CB/CHB solution during the drying process. Combined with drying in vacuum condition, which reduce

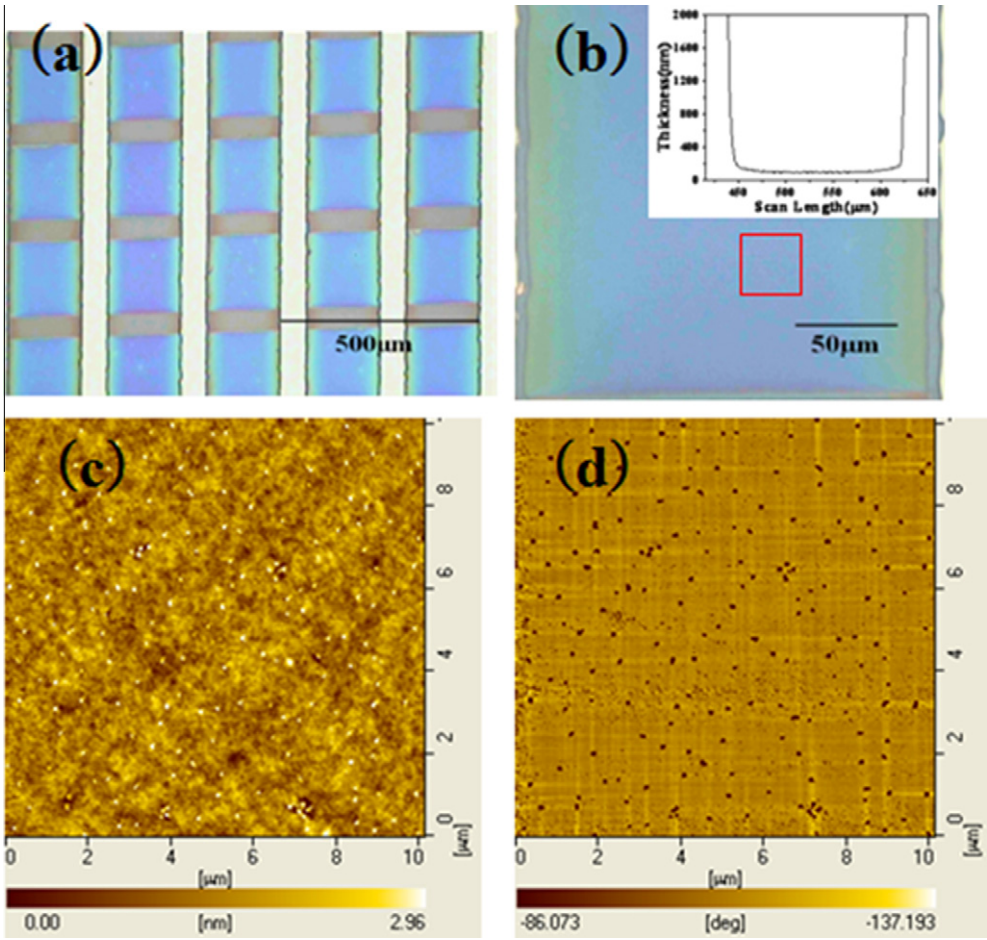

Fig. 3. The optical images of the ink-jet printed TBADN/DPAVBi film from CB/CHB (70/30, w/w) solution: (a) pixel array, (b) a single pixel and the inset is the thickness profile of the single pixel, (c) AFM height image of the center area (part of the selected area in (b)) of the ink-jet printed TBADN/DPAVBi film (RMS = 0.43 nm), and (d) AFM phase image of (c).

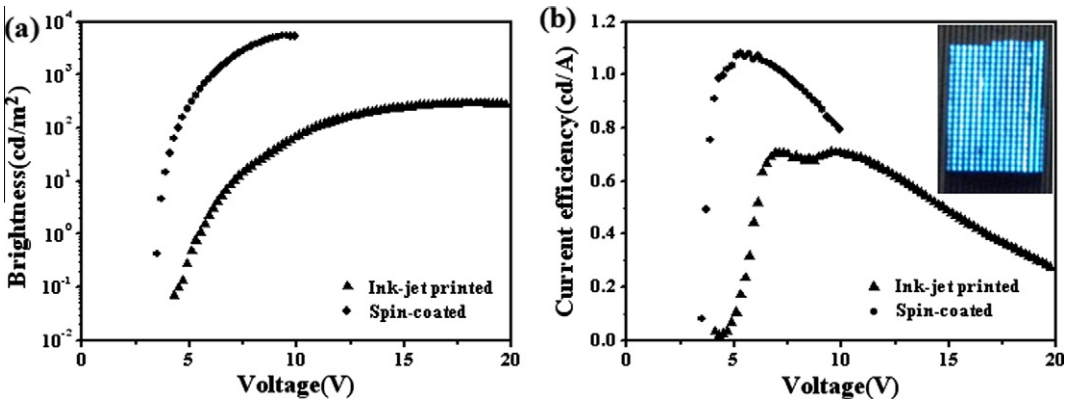

Fig. 4. (a) Luminance–voltage curve and (b) current efficiency–voltage curve of the ink-jet printed and spin-coated SMOLEDs from the CB/CHB solution. The inset in (b) is the optical image of matrix of the ink-jet printed SMOLEDs.

the drying time of deposited solution, the dewetting of liquid film is restrained effectively. At last, pinhole-free solid films were obtained by ink-jet printing, as shown in Fig. 1f. Likewise, we can know that the dewetting velocity from different solutions as following: $V_{CB/CHB} < V_{CB/ClNaph} < V_{CB/oDCB} < V_{CB}$.

3.3. Fabrication and performance of OLEDs

The device structure of the OLEDs is ITO/PEDOT:PSS (45 nm)/TBADN doped with DPAVBi (80 nm)/TPBI (20 nm)/LiF/Al. The films of TBADN doped with DPAVBi deposited on the substrates with low energy separators by ink-jet printing from CB/CHB solution were served as emitting layer. The low energy separators have a width of 50 μm with a space of 200 μm. The patterned ITO stripes have a width of 200 μm with a space of 50 μm. So the dimension of the light-emitting region in every pixel of the passive matrix was 200 × 200 μm. By comparison, a device with an 80 nm-thick emitting layer of TBADN doped with DPAVBi by spin-coating from CB/CHB solution also was fabricated.

The optical images of the ink-jet printed pixel array and a single pixel from CB/CHB (70 w/30 w) solution are shown in Fig. 3a and b. All the pixels are similar to each other in the whole. Most of the area in the single pixel is uniform from the Fig. 3b. The inset of Fig. 3b shows the profile of cross section of the ink-jet printed film. The thickness is a little higher at the edge than that at the center. It may be caused by the pinning of the solvent contact line and the faster evaporation at the edge than the center, as coffee-ring effect [41–43]. Fig. 3c and d shows the surface morphology of the ink-jet printed TBADN/DPAVBi film from CB/CHB (70/30, w/w). The RMS roughness value of the center area of the ink-jet printed TBADN/DPAVBi films is 0.43 nm, which indicates that the film is very smooth and without pinholes. But there are some aggregations in the film, which show a different phase from the bulk area as it shows in Fig. 3d. When TBADN only solution at the same condition is ink-jet printed, the aggregations are also observed (not show in the paper). So the aggregations are consisted of TBADN molecules.

Fig. 4a and b shows the brightness and current efficiency of the ink-jet printed and the spin-coated devices. For the ink-jet printed devices, the turn-on voltage (at 1 cd/m^2) is 5.5 V, the maximum luminance is 289 cd/m^2 and the maximum current efficiency is 0.71 cd/A. While the performance of the spin-coated devices is better than the ink-jet printed ones. In spin-coated OLEDs, the turn-on voltage is 3.7 V, the maximum luminance is 5400 cd/m^2 and the maximum current efficiency is 1.08 cd/A. The reason for the lower performance of the ink-jet printed devices need to be further investigated. The inset of Fig. 4b shows optical image of the matrix of ink-jet printed SMOLEDs. There is only one dead pixel which may come from the defect caused from the fabricating process. The ratio of the light-emitting area to the pixel area is high. So it is feasible to fabricate SMOLEDs by ink-jet printing.

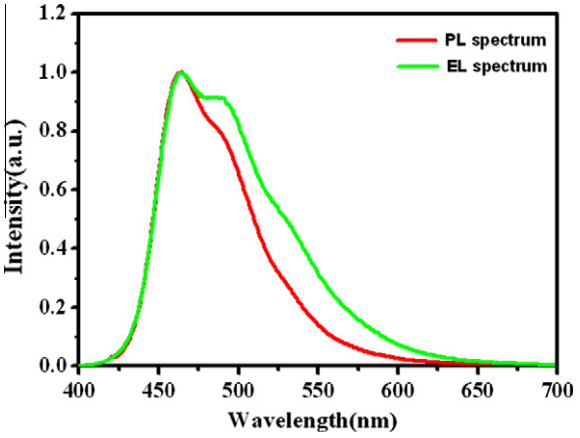

Fig. 5. The PL spectrum of spin-coated DPAVBi doped TBADN film and EL spectrum of SMOLED based on the ink-jet printed film under a bias of 7 V.

The color purity can be recognized from the EL spectrum of the device. Fig. 5 shows the PL spectrum of the ink-jet printed TBADN/DPAVBi film and EL spectrum of the SMOLEDs. It shows that films emit only at 464 and 483 nm from DPAVBi [44]. There is no emission of TBADN at all. It proves the energy transfer between host and dopant is complete. On the other hand, it indicates that the consistency property of TBADN and DPAVBi is good. And the aggregation behavior of TBADN molecules in the films has little influence on the energy transfer.

4. Conclusion

In conclusion, we have improved film-forming property of ink-jet printed small molecular materials by mixing chlorobenzene with α-chloronaphthalene or cyclohexylbenzene, a solvent with higher boiling point and higher viscosity. The mechanisms of the film-forming process from different solutions were also given. Higher boiling point of the solvent stays liquid films with higher thickness which restrains the dewetting of ink-jet printed films from thermodynamics aspect. Then the higher viscosity restrained the dewetting of ink-jet printed liquid films from kinetics aspect. Uniform and pinhole free TBADN/DPAVBi films were patterned by ink-jet printing from chlorobenzene/cyclohexylbenzene solution. The matrix display device of SMOLEDs was fabricated after deposition of electron-transport layer and cathode on the patterned films. The performance of the ink-jet printed devices is lower than the spin-coated ones in our experiments. Aiming to improve the performance of ink-jet printed devices, the techniques are under optimization and the reason need to be further investigated.

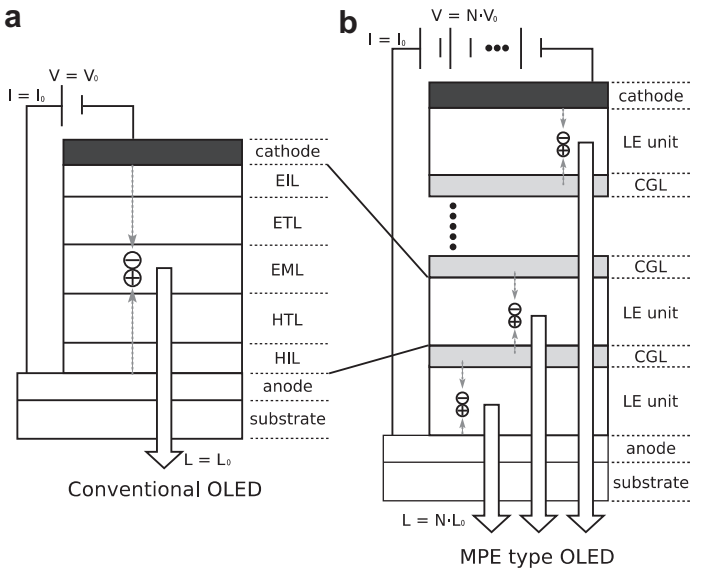

Fig. 1. Device structure. (a) Conventional OLED and (b) MPE-type OLED.

however, ITO results in sputtering damage to an organic layer, and its high conductivity causes crosstalk between each emitting pixels in display applications. On the other hand, CGL consisting of an electron-accepting and an electron-donating layer can be used as an intermediate layer, and its conductivity is enough low and almost insulating. In general, the electron-accepting components of CGL are metal oxides such as V_2O_5 [3,6], MoO_3 [7,9,11,16,19], WO_3 [8,14,15,21,22], and Lewis acids such as tetracyanoquinodimethane (TCNQ) [10,13], and the electron-donating components are arylamine derivatives. However, metal oxides also have some disadvantages such as high deposition temperature, resulting in complicated production line. Recently, the organic acceptor compound, 1,4,5,8,9,11-hexaazatriphenylene hexacarbonitrile (HAT-CN_6), was reported as a substitute of metal oxide in the CGL of MPE devices [17,20]. HAT-CN_6 has no absorption in visible range and has a deep lowest unoccupied molecular orbital (LUMO) level. Because of such a low LUMO level, HAT-CN_6 can accept one electron from highest occupied molecular orbital (HOMO) level of an adjacent donor compound such as *N*,*N*′-di(naphthalene-1-yl)-*N*,*N*′-diphenylbenzidine (NPD).

In this letter, we report the charge-generation characteristics of MPEs fabricated with organic CGLs that are free of metal oxides. These organic CGLs consist of the organic acceptor material HAT-CN_6 and the organic donor materials NPD or 1,1-bis-(4-bis(4-tolyl)-aminophenyl)cyclohexene (TAPC). The LUMO level of HAT-CN_6 is very deep, which makes it difficult for electrons, accepted from NPD, to be injected into the LUMO of adjacent ETL. To resolve this problem, we use a stack consisting of an ultra-thin 1 nm layer of the alkali halide LiF and of Al as an electron-injection layer (EIL). We applied this combination of LiF/Al as EIL and HAT-CN_6/NPD or TAPC as CGL to a fluorescent yellow MPE–OLED resulting in high luminance and a long operational lifetime, simultaneously, and to a phosphorescent green MPE–OLED resulting in an extremely high current efficiency over 250 cd/A.

2. Experimental

All organic materials were purified by temperature-gradient sublimation in vacuum. HOMO energy levels were estimated by the photoelectron yield spectroscopy (Sumitomo Heavy Industries, Ltd.) under atmospheric pressure of N_2 [23]. LUMO energy levels were calculated from the HOMO energy levels and the lowest-energy absorption edges of the UV–vis absorption spectra. Electrochemistry was performed using an BAS Electrochemical Analyzer 660B. All measurements were made at room temperature on samples dissolved in dry benzonitrile with 0.1 M tetra-*n*-butylammonium tetrafluoroborate as the electrolyte. The sample concentration was 1 mM, and a platinum working electrode, platinum counter electrode in 0.1 M tetra-*n*-butylammonium tetrafluoroborate in the same solvent as used for the sample, and a Ag/0.1 M $AgNO_3$ in acetonitrile reference electrode were used. The scan rate was 100 mV/s. The solutions were deoxygenated with argon. The ferricenium/ferrocene couple was used as standard. All potentials are quoted relative to the ferricenium/ferrocene couple. All devices were grown on glass substrates pre-coated with a ~110 nm thick layer of indium tin oxide (ITO) having a sheet resistance of 15 Ω/square. The substrates were cleaned with ultra-purified water and organic solvents, and then dry-cleaned for 30 min by exposure to an UV-ozone ambient. The organic compounds were deposited onto the ITO substrate under the vacuum (~10^{-5} Pa), successively. LiF and Al were patterned using a shadow mask with an array of 2 mm × 2 mm openings without breaking the vacuum (~10^{-5} Pa). All devices were encapsulated immediately after preparation under a nitrogen atmosphere using epoxy glue and glass lids. The EL

spectra were taken using an optical multichannel analyzer Hamamatsu Photonics PMA-11. The current density–voltage and luminance–voltage characteristics were measured using a Keithley source measure unit 2400 and a Minolta CS200 luminance-meter, respectively. External quantum efficiencies were calculated from the front luminance, current density, and EL spectrum. The device lifetimes were measured under a constant current density of 50 mA/cm^2.

3. Results and discussion

The CGL-only devices were fabricated to investigate charge generation of CGLs and electron injection from CGL to ETL (Fig. 2). In case of device A, which has no CGL, showed no current response under forward bias, which is an indication of the excellent ability of Alq_3 to block holes from the anode and of NPD to block electrons from the cathode. However, device B, which has the organic electron acceptor HAT-CN_6 between the Alq_3 and NPD layers exhibit a current response. The HOMO of HAT-CN_6 was estimated from 7.5 eV of the ionization potential (Ip), measured by the photoelectron yield spectroscopy of the thin film (50 nm) on ITO. The LUMO level was tentatively estimated to be 4.4 eV from the difference between Ip and optical energy gap from the absorption edge of the UV–vis spectra. In cyclic voltammetry measurement, redox potential of NPD, corresponding to the HOMO level, was 0.32 V. On the other hand, redox potential of HAT-CN_6, corresponding to the LUMO level, was −0.53 V. There was 0.85 V of the difference in the redox potentials, and this difference suggest that HAT-CN_6 cannot oxidize NPD in a solution environment. However, the LUMO level, 4.4 eV, was smaller than the reported value, 5.6 eV, from UPS measurement [24,25]. Further detailed discussion of interface between HAT-CN_6 and NPD will be necessary to understand the charge generation mechanism under electric filed. These results demonstrate that the CGLs HAT-CN_6/NPD internally generate current in response to an applied voltage and that the organic CGL HAT-CN_6/NPD may be used instead of an inorganic metal oxide. In device C, the thin Al layer did not act as CGL because the energy difference between the NPD HOMO and the work function of Al is too large to allow charge generation. We also investigated the influence of the electron-injection barrier between the LUMO of HAT-CN_6 in CGL and the adjacent Alq_3 layer. Thin layers of LiF and Al were used as the EIL to assist electron injection from CGL in device D. The EIL consisting of LiF and Al dramatically reduces the driving voltage. In conventional OLEDs, alkali halides such as LiF are widely used as efficient EILs and Al, deposited successively, is essential to activate the LiF in order to enhance electron injection [26]. In order to discuss the effect of LiF/Al in detail, we used a thin Al or LiF layer, independently, as EIL in devices E and device F, respectively. The current response of these device was much smaller than that of device D, having both of LiF and Al in EIL.

Based on a thin LiF/Al EIL and a HAT-CN_6/NPD CGL, we investigated the device lifetime of the fluorescent MPE device fabricated with NPD as a hole transporting layer, rubrene as a dopant, and Alq_3 as a host and an electron-transporting layer (Fig. 3(a)). A thin LiF/Al EIL was used, along with an HAT-CN_6/NPD CGL. Fig. 3(b) shows the EL spectra of conventional device and MPE device at a current density of 20 mA/cm^2. The narrower spectra of MPE device was due to optical interference between each emissions from each stacked LE unit. At a current density of 30 mA/cm^2, the driving voltage and luminance of the conventional (i.e. single-unit) device are 7.9 V and 2240 cd/m^2, respectively, whereas the driving voltage and luminance of the 2-unit MPE device are 13.4 V and 4111 cd/m^2, respectively, which are about twice that of the single-unit device (Fig. 4(a)). The current efficiencies of the 2-unit MPE device are also almost twice those of the single-unit device (Fig. 4(b)). At a luminance of 100 and 1000 cd/m^2, the 2-unit MPE device exhibited a current efficiency of 20.2 and 16.8 cd/A, respectively, which are two times higher than those of the single-unit device. In other words, to achieve a luminance of 1000 cd/m^2, 12.0 mA/cm^2 is required for the

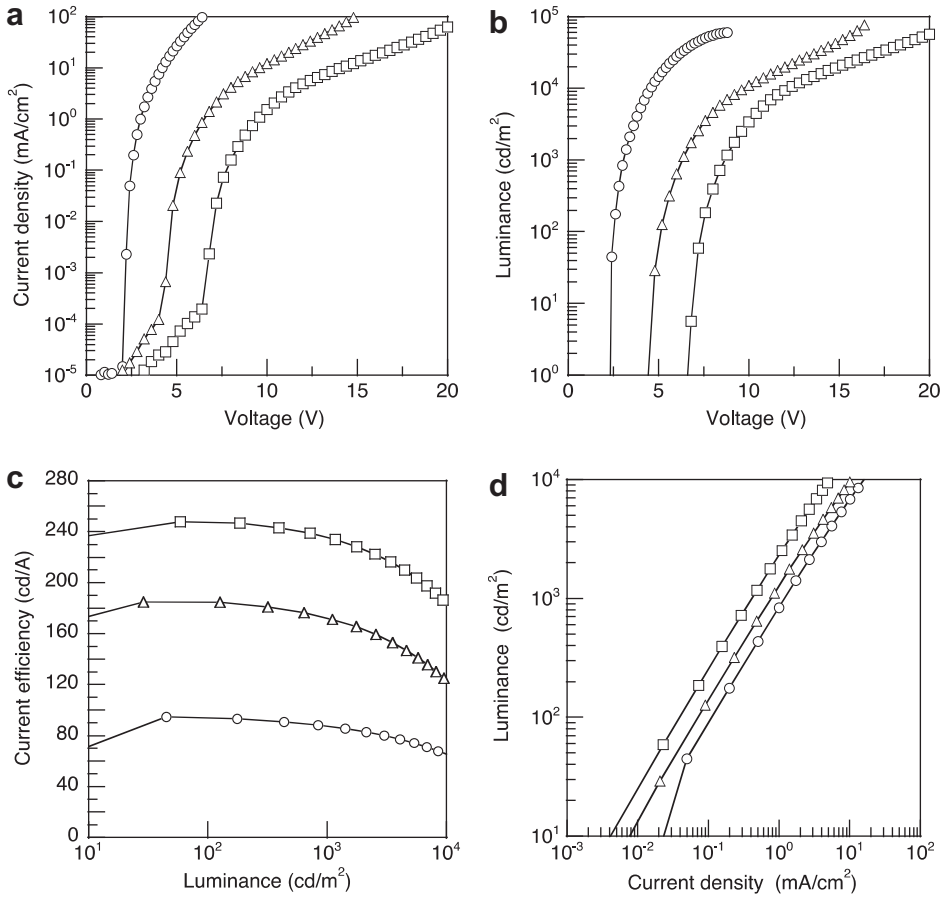

Fig. 6. Characterization of the phosphorescent devices (the 1-unit: circles, 2-unit: triangles, and 3-unit: squares). (a) Current density–voltage characteristics. (b) Luminance–voltage characteristics. (c) Current efficiency–luminance characteristics. (d) Luminance–current density characteristics.

($T_{85\%}$) of the conventional single-unit device, which began with a luminance of 3410 cd/m^2, was 98 h. Although the initial luminance of the 2-unit MPE device is twice 6600 cd/m^2 that of the single-unit device at the same

current density, the 2-unit MPE device $T_{85\%}$ was 190 h. This result demonstrates that, by exploiting the reduced current density in an MPE device, higher-luminance OLEDs can be achieved without deteriorating the device lifetime. The longer lifetime of the 2-unit MPE device than that of the single-unit device is considered to be resulted from the better stability of electron and hole injection from CGL into adjacent LE unit than the injections from electrode in the single device. Furthermore, power efficiencies (lm/W) of both conventional and MPE OLEDs are similar, which means that this new MPE structure does not suffer any penalties in terms of power consumption (Fig. 4(b)).

We also fabricated ultra-high efficiency green phosphorescent MPE devices based on a thin LiF/Al EIL and a HAT-CN_6/TAPC CGL with two or three LE units (Fig. 5(a)). The complex *fac*-tris(2-phenylpyridine) iridium [$Ir(ppy)_3$] was used as green phosphorescent dopant and TAPC was used as the HTL. The hole-transporting host material 4,4′,4″-tris(*N*-carbazolyl)triphenylamine (TCTA) and the bipolar host material, 4,4′-(*N*-carbazolyl)biphenyl (CBP) were used in the double emitting layers. Bis-4,6-(3,5-di-4-pyridylphenyl)-2-methylpyrimidine (B4PYMPM) [27] was used as an electron-transporting and hole-blocking layer. In the EL spectra (Fig. 5(b)) of the green phosphorescent MPE devices at a current density of 20 mA/cm^2, the peak on the shoulder of the spectrum near 542 nm increases in comparison with what is observed with a conventional single-unit device, because of optical interference between the emissions from each stacked unit. Fig. 6(a) and (b) shows the voltage–current–density and luminance characteristics of the devices. At the current density of 2.0 mA/cm^2, the conventional single-unit device requires a driving voltage of 3.26 V, whereas the 2- and 3-unit MPE devices require driving voltages of 7.19 and 10.35 V, which are 2.2 and 3.2 times that of the single-unit device, respectively. Simultaneously, the single-unit-device luminance is 1600 cd/m^2, whereas the luminances of the 2- and 3-unit MPE devices are 3100 and 4300 cd/m^2, which are 1.9 and 2.7 times that of the single-unit device, respectively. These linear increases in driving voltage and luminance with respect to the number of stacked LE units are important parameters that demonstrate that charges are efficiently generated in CGLs and injected into adjacent LE units in the MPE device. Fig. 6(c) shows current efficiency as a function of luminance for the three devices. At a luminance of 100 cd/m^2, the 2- and 3-unit MPE devices exhibit extremely high current efficiencies of 181 and 256 cd/A, which are 2.0 and 2.8 times the current efficiency of 90 cd/A measured for the single-unit device, respectively. Even at the high luminance of 1000 cd/m^2, high current efficiencies of 171 and 244 cd/A are achieved in the 2- and 3-unit MPE devices, which are 2.1 and 2.9 times the 83 cd/A of the single-unit device, respectively. These ultra-high current efficiencies result in low driving currents for these OLEDs. In the 3-unit MPE device, only one-third of the current density (i.e. 0.0395 and 0.404 mA/cm^2) is required to get 100 and 1000 cd/m^2 of luminance, respectively (Fig. 6(d)).

4. Conclusions

We investigated the effect of charge generation and electron injection characteristics of intermediate layer, based on a thin LiF/Al EIL and a HAT-CN_6/NPD CGL, for a stacked OLED. The EIL consisting of LiF and Al dramatically reduces the driving voltage, which are due to enhance of electron injection. This EIL–CGL combination was applied to an orange-emitting fluorescent MPE device and that exhibited a high luminance and a long operational lifetime. We also fabricated green phosphorescent MPE devices that exhibited extremely high current efficiency of over 250 cd/A. This intermediate layer can be a powerful tool for improvement MPE device performance.

microscopy, transmission electron microscopy, optical microscopy, and light-induced electron spin resonance (LESR) [11–17]. On the basis of these studies, it is now well established that the growth of PCBM clusters leads to the formation of percolation paths for electron carriers. On the other hand, the well-known lamellar structure of P3HT gradually disappears with increasing PCBM fraction. However, almost all previous research was focused only on bulk or surface morphology and not on the interfacial structure between active layers and insulators. In order to understand the fundamental properties of the accumulation and transport of charge carriers in FETs, it is necessary to develop a method suitable for the characterization of interfacial molecular structures.

Recently, we have developed a new method for studying organic field-effect devices, such as metal–insulator-semiconductor (MIS) diodes and FETs, that employs field-induced electron spin resonance (FI-ESR), and we were able to reveal microscopic properties of charge carriers at the device interface, including spin states, spatial extent of their wave functions, and charge carrier concentration, in regioregular poly(3-alkylthiophene) [18–22] and pentacene [23]. In addition, we also successfully observed field-induced ambipolar charge carriers in P3HT/C_{60} [24] and PCBM composites [25] using MIS diodes. It should be noted that FI-ESR is a powerful tool to investigate the interfacial molecular structure because the molecular orientation can be directly determined by the angular variation of FI-ESR signals through the anisotropic g-value and hyperfine-determined linewidth of unpaired π-electrons [18–23,26]. Moreover, FETs with controlled in-plane chain orientation have also been fabricated using Langmuir–Blodgett (LB) techniques by co-spreading liquid crystal molecules with P3HT [26]. Consequently, we have been able to directly determine orthorhombic anisotropies of g-values and hyperfine couplings of P3HTs for the first time. The use of such orthorhombic anisotropies makes it possible to precisely analyze the interfacial molecular orientations of P3HT and also complex composites of P3HT and PCBM.

In this study, in order to investigate interfacial molecular orientations of P3HT domains modulated by the introduction of PCBM molecules, we performed FI-ESR measurements on MIS devices using P3HT/PCBM composites with various PCBM mixing ratios as active layers, parylene as a gate insulator, and gold (Au) as top electrodes. In the case of pure P3HT devices, by applying a negative gate bias, clear FI-ESR signals were observed around $g = 2.0031$ with the external magnetic field normal to the substrate plane, where the g-value agrees well with that along the inter-lamellar direction [18–22,26]. This indicates that positive polarons localize at the domain of edge-on orientations of the P3HT lamellar structure. In the case of higher PCBM mixing ratios, on the other hand, a new additional peak was observed at $g = 2.0022$, which is characteristic of the $p\pi$-orbital axis, indicating the occurrence of flat-on structures. The intensity of this peak increased with increasing PCBM fraction above 50 wt.%. Using ESR spectrum simulations with anisotropic g-values, the fractions and orientation distributions of both edge-on and flat-on domains at the interface were determined. Ambipolar charge transport was also clearly observed in FETs using P3HT/PCBM. With increasing PCBM fraction from 0 to 100 wt.%, the field-effect mobility of holes decreased, while, that of electrons increased. These results demonstrate that the flat-on orientation strongly reduces charge carrier transport of holes because two-dimensional charge transport assisted by π–π interaction is interrupted by the presence of the flat-on structure.

2. Experimental

P3HT (Fig. 1a; regioregularity 98.5%) and PCBM (Fig. 1b; purity 99.5%) were purchased from Aldrich and Frontier Carbon Co., respectively. A schematic illustration of the MIS device with the P3HT/PCBM composite used in the present study is shown in Fig. 1c. Aluminum (Al) gates were patterned by vacuum deposition on polyethylenenaphthalate (PEN) films as substrates. The thickness of the PEN and Al gates were about 0.25 mm and 50 nm, respectively. Parylene insulator was deposited by chemical vapor deposition using a PDS 2010 LABCOTER (Speciality Coating System Inc.) [27]. The thickness and capacitance of the parylene were evaluated to be 850 nm and 3.4 nF/cm^2, respectively. We confirmed that the quality factor (Q-factor) of the ESR cavity does not decrease with the parylene insulator. The active semiconductor layer of P3HT/PCBM was deposited by drop-casting of chloroform solution with a concentration of 0.5 wt.%. We prepared devices with different mixing fractions of PCBM (0, 22, 50, 67 wt.%). The thickness of the active layer was about 0.5 μm. 30 nm-thick Au top electrodes were vacuum-deposited formed an effective area of 0.44 cm^2. Our previous studies showed that the Au electrode was not suitable for efficient injection of ambipolar carriers, in particular electrons, because of the energy level mismatch between PCBM LUMO (3.7 eV) and Au (5.1 eV) [4,25]. In this study, however, we did employ Au electrodes in order to specify

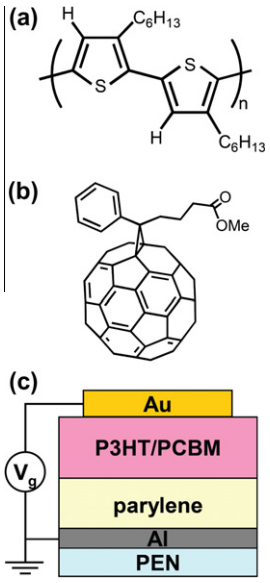

Fig. 1. Chemical structures of (a) P3HT and (b) PCBM. (c) Schematic illustration of the MIS device used in this work with a P3HT/PCBM composite and parylene insulator.

and characterize the accumulated holes at the interface between the active layers and insulators. FET devices with Au source and drain electrodes were fabricated on the same parylene insulator with a channel length (L) and width (W) of 100 μm and 2.2 mm, respectively. FET characteristics were measured under vacuum using Keithley 2400 and 6487 source meters with application of a gate voltage (V_g) and a drain-source voltage (V_{ds}), respectively. All the devices were annealed under a He atmosphere at 125 °C for 10 min before the measurements.

All ESR measurements were performed using a Bruker E500 X-band spectrometer at room temperature. ESR signals were obtained by subtracting the background ESR signal at V_g = +40 V. It should be noted that ESR signals from PCBM are observable only at low temperatures because the spin–lattice relaxation time is too short at higher temperatures [25]. Thus, the present FI-ESR signals describe those of hole carriers (polarons) in P3HT.

3. Results and discussion

3.1. Field-induced ESR of P3HT/PCBM composites

Fig. 2a shows the dependence of FI-ESR signals on the PCBM mixing ratio. All FI-ESR signals were measured by applying V_g of −60 V and an external magnetic field (H) perpendicular to the substrate at room temperature, except for the dotted plots shown at the top of Fig. 2a, where H was applied parallel to the substrate. The observed g-value ($g \sim 2.00310$), determined from the resonance field, and the peak-to-peak linewidth ($\Delta H_{PP} \sim 1.1$ G) of the field-induced signal for lower PCBM mixing fractions (up to 22 wt.%) with H perpendicular to the substrate agree well with those reported in our previous studies for pure P3HT MIS devices on SiO_2 and Al_2O_3 gate insulators [18–22,24–26]. The observed anisotropic spectra are consistent with an edge-on orientation as schematically shown in Fig. 3a. Here, the errors for the g-value and ΔH_{PP} are estimated to be ±0.00005 and ±0.05 G, respectively. This result indicates that the injected charge carriers are positive polarons of P3HT.

On the other hand, FI-ESR signals for higher PCBM fractions (above 50 wt.%) drastically changed with increasing PCBM fraction. The FI-ESR signal split into two components with different g-values (around 2.0030 and 2.0022). The signal is considered to originate not from PCBM anions but from polarons of P3HT, because the spin–lattice relaxation time for PCBM anions is short at room temperature [24,25]. In the case of our previous LESR study of cast films of the same composite system, LESR signals due to polarons on P3HT, which are generated in the bulk composites, never showed such splitting [17]. Thus, the splitting

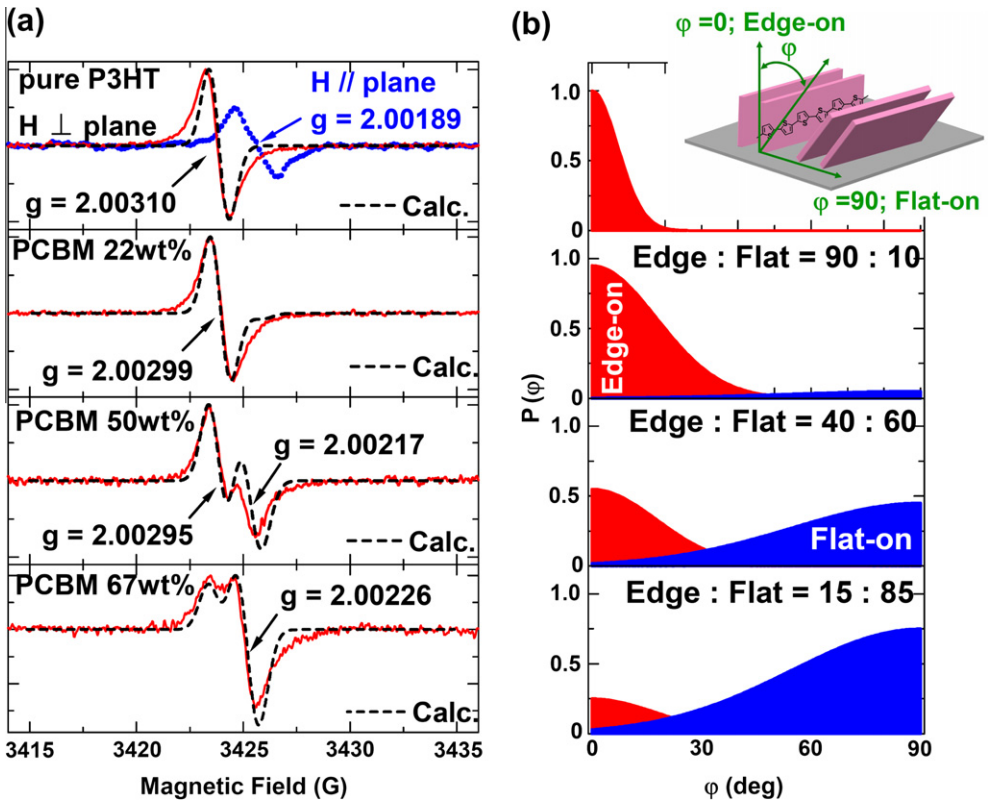

Fig. 2. (a) Dependence of FI-ESR signals on the PCBM mixing ratio. PCBM mixing fractions of 0, 22, 50, and 67 wt.% were used, as shown from the top to the bottom plots, respectively. All ESR signals were measured with a microwave power of 6.3 mW at 293 K. The solid and dotted lines represent FI-ESR signals with H perpendicular and parallel to the substrate, respectively. Dashed lines show the calculated spectra obtained by simulation with the distribution function $P(\varphi)$, whose angular distributions are shown in (b). The inset in (b) shows a schematic diagram of the ordered lamellar structure of P3HT. Alkyl-side chains are omitted. φ denotes the tilt angle between the short axis of the π-conjugated plane and the normal direction of the substrate, i.e., the edge-on and flat-on orientations correspond to φ = 0 and 90°, respectively.

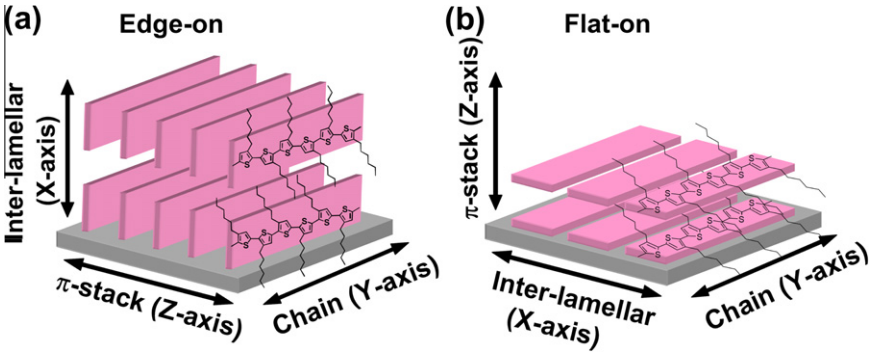

Fig. 3. Schematic illustrations of (a) edge-on and (b) flat-on orientations. In the actual devices, the chain axes are randomly oriented in both cases.

phenomenon can be considered to be a unique feature in FI-ESR measurements, which specifically detect the interfacial structure.

As mentioned in the introduction section, orthorhombic anisotropy of g-values and hyperfine-determined ESR linewidths have been directly determined using FI-ESR techniques on ultrathin-film FETs with controlled in-plane chain orientations [26]. According to this result, the anisotropy of g-values and ΔH were determined to be: $g_X = 2.00310$, $g_Y = 2.00152$, $g_Z = 2.00203$ and $\Delta H_X = 1.09$ G, $\Delta H_Y = 1.41$ G, $\Delta H_Z = 1.21$ G, respectively, where the X-, Y-, and Z-axes correspond to the directions of the inter-lamellar, polymer main-chain, and π-stack, respectively (see definitions in Fig. 3(a and b)). The observed g-value of around 2.0022 at a higher magnetic field is very close to the g_Z ($p\pi$-orbital) component, suggesting that the splitting of the FI-ESR signals could be caused by flat-on components at the interface, where the $p\pi$-axis is normal to the plane direction, as shown in Fig. 3b. These direct comparisons of the g-values suggest that FI-ESR signals obtained for a lower PCBM fraction (22 wt.%) originate from edge-on components ($H//X$-axis, that is, inter-lamellar direction) and splitting of FI-ESR originates in the co-existence of edge-on and flat-on components. This result indicates that mixing PCBM molecules could modulate the polymer orientation into a flat-on structure at the interface. We note that observations of such flat-on orientations in thin films of P3HT have been reported using X-ray diffraction measurements, which are considered to be related to substrate conditions and the degree of regioregularity [28–30]. Introducing PCBM molecules is considered to be a factor to provide poor regioregularity due to the molecular interactions between P3HT and PCBM domains, resulting in such unique co-existence of edge-on and flat-on regions. Thus, the differences in the film microstructure observed in this work may be the origin of charge transport properties of FET devices.

We also confirmed that the intensities of FI-ESR linearly increase with the application of a negative V_g up to −60 V. It should be noted that the number of injected charge carriers calculated by capacitance measurements was consistent with that of injected spins in the case of composite MIS devices at lower $|V_g|$. This result strongly suggests that all the injected charge carriers have spin 1/2 and accumulate at the insulator interface [18–22,24–26]. However, at a higher $|V_g|$ of 80 V, the intensities of these spectra tended to saturate, where the number of injected spins reached $\sim 3 \times 10^{12}$ spins/cm^2 and the spin concentration (doping level) was evaluated to be 0.3% per thiophene monomer unit. The observed spin saturation agrees well with our previous values for the onset of spin saturation [18–22, 24,25]. Such spin saturation strongly suggests the formation of a doubly charged spinless state, such as bipolarons or polaron-pairs.

3.2. Angular dependence of FI-ESR signals for composite MIS devices

Fig. 4a shows the angular dependence of FI-ESR signals of a PCBM composite (22 wt.%) MIS device, where θ denotes the angle between H and the normal to the substrate. The angular dependence of both g-values and FI-ESR linewidths are shown in Fig. 4b, representing circles and squares, respectively. As reported previously, FI-ESR signals of pure P3HT MIS devices show clear angular variations of g-values and ΔH_{PP} [18–22,24,25]. The observed g-anisotropy is well explained by that of π-electrons of a P3HT chain ($g_X > g_Y, g_Z$) having edge-on orientation due to the formation of a lamellar structure [18–22,24–26]. The angular dependence of FI-ESR signals thus shows the same behavior as that for pure P3HT MIS devices. This suggests that the edge-on orientation is still maintained for PCBM fractions of up to 22 wt.%.

In the case of higher PCBM mixing devices, the angular dependence of FI-ESR signals is clearly different from the above cases, reflecting the presence of the flat-on component. The case of the device with 67 wt.% mixing fraction is shown in Fig. 5. The solid and dashed curves represent peaks originating from edge-on and flat-on orientations, respectively, shown as guides to the eye. FI-ESR signals around $\theta = 0°$ show clear splitting of peaks. With increasing θ, to a mid-angle around 40–60°, the FI-ESR signal approaches a single component line and finally splits again around $\theta = 90°$. These behaviors provide evidence for the above assignment of edge-on and flat-on components through g-value anisotropy; smaller g-value gives higher magnetic field and *vice versa* [19]. The peak at the lower magnetic field for the FI-ESR signal obtained at $\theta = 0°$ seems to shift to a higher magnetic field, *i.e.* shifting from g_X to the averaged value between g_Y and g_Z, with increasing

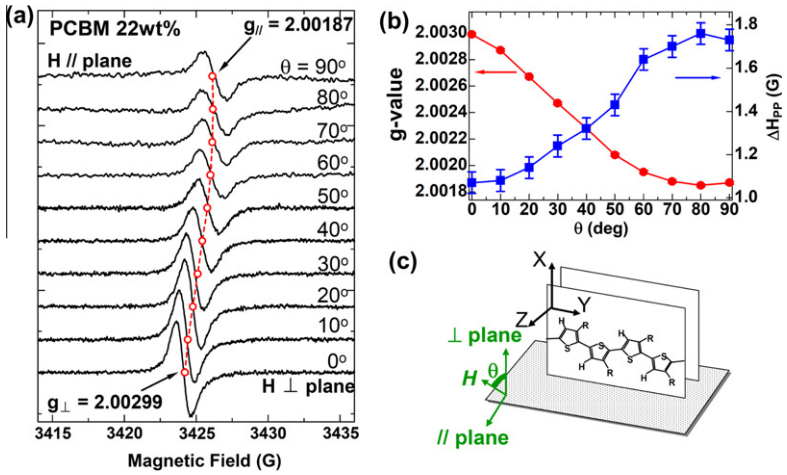

Fig. 4. (a) Angular dependence of the FI-ESR signal due to polarons for the PCBM composite (22 wt.%) MIS device. θ denotes the angle between H and the normal to the substrate, as defined in (c). Open circles represent the obtained g-values. (b) Angular dependence of the g-value and peak-to-peak linewidth (ΔH_{PP}) of the FI-ESR signals, denoted by circles and squares, respectively. (c) Schematic of the ordered lamellar structure of P3HT on the substrate. The X, Y, and Z axes are the principal axes of the g-value and linewidth due to proton-hyperfine coupling of a π-electron.

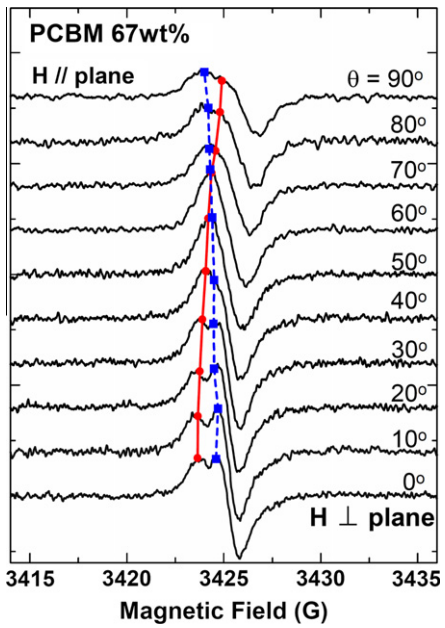

Fig. 5. Angular dependence of FI-ESR signals due to polarons for a PCBM composite (67 wt.%) MIS device. The angle is between H and the normal to the substrate. Solid and dashed curves are guides to the eye for the two peaks of the FI-ESR signals.

θ (solid line in Fig. 5). This indicates that the peak originates from the edge-on structure because the shift follows the anisotropy in the g-value ($g_X > g_Y$, g_Z). On the other hand, the other peak at $\theta = 0°$ with a higher magnetic field, ascribed to be the flat-on orientation, tends to shift to lower magnetic field, *i.e.* shifting from g_Z to the averaged value between g_X and g_Y, with increasing θ (see dashed line in Fig. 5). This is also consistent with g-anisotropy ($g_Z < (g_X + g_Y)/2$) and suggests that the peak originates from the flat-on structure. Thus these peak shifting and exchanging behaviors can be reasonably explained by considering g-anisotropy, consequently, we can assign these peaks as edge-on and flat-on components. Thus, the angular dependence of FI-ESR signals also provides clear evidence of the co-existence of both edge-on and flat-on structures.

3.3. ESR spectrum simulation for PCBM composite MIS devices

The observed dependence of the FI-ESR signals for various PCBM mixing ratios, shown in Fig. 2a, provides the basis for identifying the relative fractions of edge-on and flat-on components and their detailed molecular orientations. This can be achieved by an ESR spectrum simulation method, as described below. In this method, the ESR spectrum of either single or split peaks is calculated by employing a molecular orientation distribution function $P(\varphi)$ and convoluting a single Gaussian-type line-shape function $G[g(\varphi), \Delta H(\varphi)]$ centered at $g = g(\varphi)$ with linewidth $\Delta H(\varphi)$. The ESR spectrum $I(H)$ can be described by

$$I(H) = \int_0^{\pi/2} P(\varphi) G[g(\varphi), \Delta H(\varphi)] d\varphi \quad (1)$$

Here, $g(\varphi)$ and $\Delta H(\varphi)$ are given as,

$$g(\varphi) = \sqrt{g_X^2 \cos^2(\varphi) + g_Z^2 \sin^2(\varphi)} \quad (2)$$

$$\Delta H(\varphi) = \sqrt{\Delta H_X^2 \cos^2(\varphi) + \Delta H_Z^2 \sin^2(\varphi)} \quad (3)$$

where g_X, g_Z, ΔH_X, and ΔH_Z represent the X and Z components of the g-value and linewidth, respectively, whose values were also determined from previous studies [26]. Here, we limit ourselves to the calculation of the ESR spectrum with H perpendicular to the substrate because splitting of FI-ESR signals due to the two orientations are most clearly resolved along this direction. We also assume that the contribution of the Y-axis (chain-direction)

component is negligible in the calculation because the *Y*-axis is likely to be confined in the substrate plane. Indeed, corresponding peak of *Y*-component, which should be observed at a higher magnetic field given by g_Y, is not resolved, thus excluding the significant contribution of the *Y*-axis along the normal direction of the substrate. For the molecular orientation distribution function of $P(\varphi)$, the following form is adopted,

$$P(\varphi) = P^{\mathrm{Edge}} \exp\left\{-\left(\frac{\varphi}{\delta^{Edge}}\right)^2\right\} + P^{Flat} \exp\left\{-\left(\frac{\varphi - \pi/2}{\delta^{Flat}}\right)^2\right\} \quad (4)$$

where φ is the tilt angle between the *Z*-axis and the normal direction, (i.e., perfect edge-on and flat-on orientations correspond to $\varphi = 0$ and 90°, respectively; see the definition in the inset in Fig. 2b). P^{Edge} and P^{Flat} are the amplitudes of the edge-on and flat-on orientations, which determine the ratio between the edge-on and flat-on components. δ^{Edge} and δ^{Flat} are the widths of the orientation distribution of the molecules. It is reasonable to use this molecular orientation function (Eq. (4)) in the ESR spectrum simulation because single component ESR spectra for pure P3HT MIS devices are well reproduced with this simple function, as shown at the top of Fig. 2b. In this case, the distribution width is assumed to be ~10° at the maximum. Considering the surface roughness of the parylene insulator (root mean square: RMS ~ 10 nm), this value is reasonable [19,22,26].

It is noted that a little deviation of the line-shape from Gaussian is seen at wings of each signal. This may be ascribed to the fact that the ESR spectra exhibit certain extent of motional narrowing due to the thermal motion of carriers at room temperature, giving the intermediate line-shape between Gaussian and Lorentzian [19]. This is most clearly recognized from the fact that the spectrum of pure P3HT case at the top of Fig. 2 a already shows a deviation of the wings from Gaussian, where the y-axis is well-confined in the substrate plane, as is evidenced from ESR simulation and X-ray structural analyses. It should be also mentioned that the observed spectra with two split peaks in the composite case shown in Fig. 2a can not be well-reproduced by any other line-shape function such as pure Lorentzian. Therefore, applying single Gaussian line-shape is approximately reasonable.

The obtained molecular orientation distributions at each PCBM mixing ratio in this work are shown in Fig. 2b. By assuming these orientation functions, the split ESR spectra are well reproduced (see dashed lines in Fig. 2a). At a low PCBM mixing ratio (22 wt.%), the experimentally obtained *g*-value was slightly smaller than that for the pure P3HT device (shifted to a higher magnetic field) due to the broadening of ΔH_{pp}. This trend could be traced to the increasing distribution width δ^{Edge} (~20°) and the introduction of flat-on components, indicating that almost all molecular orientations of P3HT maintain the original edge-on structure. On the other hand, for higher PCBM mixing ratio, for example 67 wt.%, the split ESR spectrum is well reproduced by using the parameters δ^{Edge} of 25°, δ^{Flat} of 45°, P^{Edge} of 0.25, and P^{Flat} of 0.75, yielding a ratio between the edge-on and flat-on orientations of 15:85. This result indicates that the split ESR spectra, especially the peak obtained at a higher magnetic field, originated from spins localized on polymers with a flat-on orientation.

According to previous studies on X-ray structural analyses of bulk heterojunction solar cells of the P3HT/PCBM composites system, with increasing PCBM mixing fraction, the edge-on component of the P3HT lamellar structure gradually decreases and is interrupted by microcrystalline domains for a PCBM fraction above 70–80 wt.% [13,14]. In contrast to these structural analyses on the bulk or surface, FI-ESR revealed that some fractions of the edge-on orientation were maintained even at higher PCBM mixing ratios above 50–67 wt.%, consistent with results obtained by optical measurements [12–14] and LESR [17]. This indicates that highly-crystalline domains of the P3HT lamellar structure still remain even though phase separation between P3HT and PCBM is drastically enhanced. However, microcrystals of PCBM may strongly modulate P3HT lamellar domains into unique orientations at the device interface, where both the fraction and distribution width of such flat-on orientations increases up to around 85% and 45°, respectively, in the case of the higher PCBM mixing ratio (67 wt.%). Such flat-on orientations are a unique feature occurring only at the device interface, which has been revealed by using FI-ESR that can selectively observe interfacial orientations. The co-existence of two such components is regarded as a kind of disordering of the original P3HT lamellar orientations caused by mixing PCBM molecules. Therefore, the field-effect mobility for holes may be decreased within such a disordered structure [28].

3.4. Ambipolar characteristics of field-effect transistors using P3HT/PCBM composites

Finally, ambipolar operations of FET devices on a parylene insulator are discussed. Fig. 6 shows the transfer characteristics of FET devices with application of a (a) negative and (b) positive bias. Circles, squares, and triangles represent FET devices for pure P3HT, composite (67 wt.% PCBM), and pure PCBM, respectively. Clear *p*-type and *n*-type operations for pure P3HT and PCBM devices are observed on the parylene insulator with a relatively high on/off ratio above 10^3. The field-effect mobility (μ) was estimated by gradual channel approximation in the linear region. In the case of pure P3HT and pure PCBM FET, the mobilities for both holes and electrons were evaluated to be 7.6×10^{-4} and 4.9×10^{-3} cm^2/Vs, respectively. The transfer characteristics for PCBM composite (67 wt.%) devices were obtained for both hole and electron enhancement modes (squares in Fig. 6(a and b)). The mobilities of holes and electrons were evaluated to be 3.1×10^{-6} and 4.2×10^{-4} cm^2/Vs, respectively. We also observed ambipolar behavior for the 50 wt.% PCBM devices.

Fig. 7 shows the mobilities of both holes and electrons for various PCBM mixing ratios, represented by circles and squares, respectively. The two dashed lines in Fig. 7 are shown as guides to the eye. With increasing PCBM mixing fraction, the electron mobilities drastically increased (about two orders of magnitude) because percolation paths

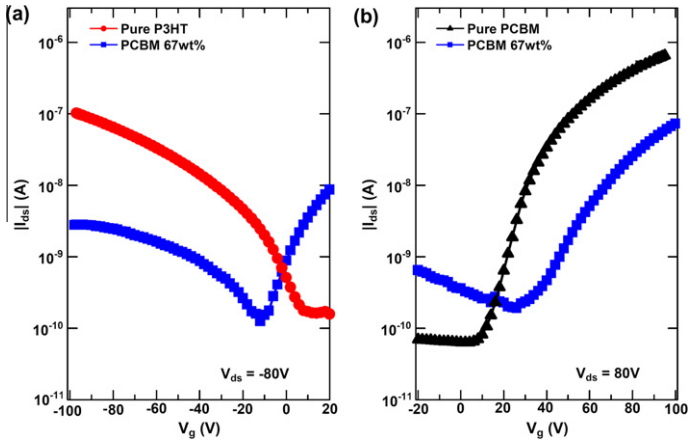

Fig. 6. Transfer characteristics of pure P3HT, pure PCBM, and PCBM composite (67 wt.%) devices, represented by circles, triangles, and squares, respectively. (a) p-type operation mode ($V_{ds} = -80$ V) and n-type operation mode ($V_{ds} = 80$ V).

for electrons grew at the interface. On the other hand, the hole mobility remained in the 10^{-4} cm^2/Vs range with increasing PCBM mixing fraction up to 22 wt.%, where only the edge-on component, though with higher distribution width, was seen. However, at higher PCBM mixing ratios, over 50 wt.%, the hole mobility steeply decreased to the 10^{-6} cm^2/Vs range. These shifts of both mobilities associated with mixing PCBM are consistent with previous reports [5,6,31,32]. In these studies, the decrease of hole mobility for higher PCBM mixing ratio has been ascribed to the decrease of percolation path of P3HT. On the other hand, FI-ESR measurements can spectroscopically reveal interfacial molecular orientations at lower PCBM mixing ratios (<50 wt.%) maintain well-known edge-on structures and at higher ratios (>50 wt.%) are gradually modulated to flat-on structures, although some fraction of the edge-on component still remains. Since the FI-ESR method gives the information about the sites where the carriers actually accumulate, such changes of molecular orientation will also correlate with the charge carrier mobility. Indeed, flat-on structure of P3HT gives smaller hole mobility than the case of edge-on structure [28].

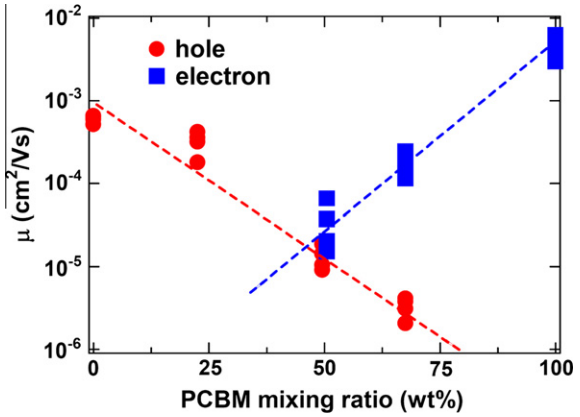

Fig. 7. PCBM mixing ratio dependence of hole and electron mobilities, represented by circles and squares, respectively. The dashed lines are shown as a guide to the eye.

The demonstrated flat-on structure may strongly reduce charge carrier transport for holes because two-dimensional charge transport assisted by overlap of π–π interaction on the edge-on structure is interrupted by the presence of flat-on structures. Indeed, it has been found that anisotropy of mobility between intra-chain and inter-chain (π-stack) is relatively small for P3HT, which has been confirmed from the mobility studies of in-plane oriented P3HT film combined with the detailed determination of in-plane orientations using ESR [25]. This means that charge carrier transport for P3HT can be supposed to be two-dimensional transport. Such two-dimensional charge transports can be reduced by flat-on orientations. Thus, the decrease of mobility within P3HT domain might be possibly crucial for hole transport as well as percolations.

4. Conclusions

In this study, FI-ESR measurements were performed on MIS devices using P3HT/PCBM composites with various PCBM mixing ratios on a parylene insulator. In the case of pure P3HT devices, a clear FI-ESR signal was observed around $g = 2.0031$ with H perpendicular to the substrate plane, indicating that positive polarons localize at the domain of edge-on orientations of the P3HT lamellar structure, as shown in previous studies on P3HT devices. The edge-on orientation of P3HT is maintained below 20 wt.% PCBM fraction. On the other hand, FI-ESR signals due to positive polarons clearly split into two components with $g = 2.0030$ and 2.0022 with increasing PCBM mixing fraction above 50 wt.%. The latter g-value is characteristic of the $p\pi$-orbital axis, indicating the occurrence of flat-on orientations, which was further confirmed by angular dependence of the FI-ESR signals. By ESR spectrum simulations using anisotropic g-values, the fractions and orientation distributions of both edge-on and flat-on domains at the interface were determined. We also observed clear ambipolar charge transport in field-effect transistors of P3HT/PCBM on parylene insulators. With increasing PCBM fraction, the field-effect mobility of holes decreased, while that

of electrons increased. A systematic study of both interfacial molecular orientation and charge transport properties demonstrates that the interfacial molecular orientation, such as edge-on and flat-on, strongly correlates with charge carrier transport properties in ambipolar field-effect devices.

quired to develop OBLED which can be processed in solution and have multilevel luminance control performance over wide luminance range. The luminance range which can be controlled in OBLED was around 100 cd/m^2.

In this work, a solution processed organic multistable light-emitting diode (OMLED) with nonvolatile multilevel luminance switching performances was developed. The integration of the solution processed OLED and solution processed OBD was carried out by a metal interlayer using a tandem structure and a stamp transfer printing of a common polyphenylenevinylene (PPV) based polymer. A high on/off ratio over 1000, a wide range luminance control over 300 cd/m^2 and four level luminance switching were demonstrated from the solution processed tandem OMLED.

2. Experimental

The device structure of the OMLED was indium tin oxide (ITO, 150 nm)/polyethylene-3,4-dioxythiophene:polystyrenesulfonate (PEDOT:PSS, 60 m)/PPV (50 nm)/LiF (1 nm)/Al (100 nm)/PPV (70 nm)/Al (100 nm). The ITO substrate was cleaned in deionized water and 2-propanol in ultrasonic bath for 30 min to remove particles on the substrate followed by cleaning in boiling 2-propanol to remove organic contaminants. After drying, the cleaned ITO substrate was exposed to ultraviolet/O_3 to modify the work function of the ITO. PEDOT:PSS was spin coated from water dispersion at a spin speed of 2000 rpm to obtain 60 nm thick PEDOT:PSS film. The PEDOT:PSS layer was baked at 200 °C for 10 min to remove residual solvent. The PPV layer on PEDOT:PSS was spin-coated from 0.7 wt.% toluene solution at a spin speed of 2000 rpm. The PPV layer on the Al was coated by spin-coating or stamp transfer printing. The spin-coating of the PPV layer was carried out at a spin speed of 1000 rpm from 0.7 wt.% toluene solution. The stamp transfer printing of the PPV layer was performed by transferring the PPV film spin-coated on Si wafer at a thickness of 70 nm. The PPV film on Si susbstrated was transferred to the polydimethylsiloxane (PDMS) stamp and the PPV film on the PDMS stamp was transferred on the Al electrode at 120 °C. The device structure of the OBD was Al (100 nm)/PPV (70 nm)/Al (100 nm) and the PPV was coated by the stamp transfer printing. The device structure of the OLED was ITO (150 nm)/PEDOT:PSS (60 nm)/PPV (50 nm)/LiF (1 nm)/Al (100 nm). The PPV was spin-coated from toluene solution.

Current density–voltage curves of the OBD, OLED and OMLED were obtained using a Keithley 2400 source measurement unit and the luminance performances were measured with CS 1000 spectroradiometer (Minolta Co.). The cross-section of the fabricated device was analyzed by transmission electron microscopy (TEM, model JEM-2100F, Jeol Co.) after sampling using a focused ion beam method. The stability of the luminance over cycles was measured using a Si photodiode.

3. Results and discussion

The OLED and the OBD units were integrated using a tandem device structure by connecting the two devices

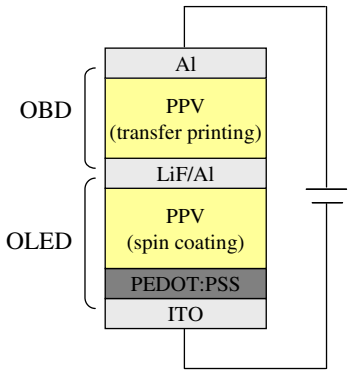

Fig. 1. Device structures of the OMLED.

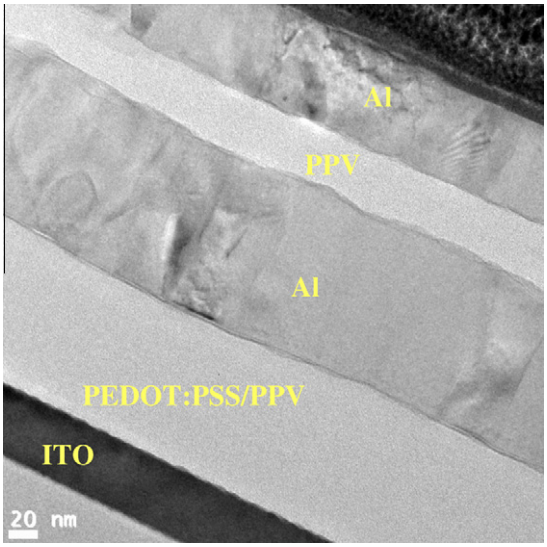

Fig. 2. Transmission electron microscopic pictures of the cross-section of the OMLED fabricated by the stamp transfer printing.

in series with a metal interlayer. Compared with the typical structure reported in earlier work [11–14], the tandem device structure with the metal interlayer is advantageous because two device units can function independently. In earlier work, the OBD unit was introduced as a layer inside the OLED unit and it was difficult to manage the OBD and OLED performances at the same time. In this work, the Al interlayer separates the OLED and OBD units and they can function separately. The device architecture of the OMLED is shown in Fig. 1. The OBD unit was stacked on the electrode of the OLED unit using the electrode as the interlayer. The PPV polymer was coated on the LiF/Al electrode of the OLED unit and the Al electrode of the organic memory unit was deposited on the PPV. Two devices with different PPV coating processes, spin coating and stamp transfer printing, were fabricated. The spin coating method is a conventional film coating method, but the solution can permeate through the pin hole of the Al electrode to the active layer of the OLED. Therefore, a stamp transfer printing method was also used to make the PPV active layer film of the memory unit. The stamp transfer printing method is a

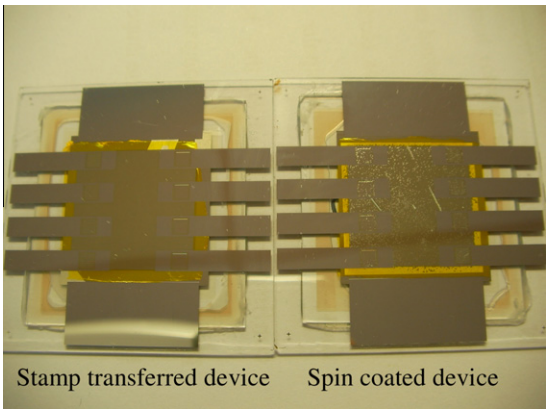

Fig. 3. Device pictures of the spin coated and stamp transfer printed device.

dry patterning method and does not affect the PPV active layer of the OLED unit and LiF/Al electrode [15–17]. Fig. 2 shows the transmission electron microscope (TEM) pictures of the OMLED prepared by the stamp transfer printing of the PPV active layer. In the case of the spin coated device, the spin coated PPV active layer penetrated into the LiF/Al cathode through the pin hole of the thermally evaporated Al as shown in Fig. 3. The active layer was damaged in the device with the spin coated PPV on LiF/Al. Compared with the spin coated device, the stamp transfer printed device showed clear boundary between the Al and the stamp transfer printed PPV film. Therefore, solution processed tandem OMLEDs with stable morphology could be fabricated using the stamp transfer printing process instead of the spin coating. Device pictures of the spin coated and stamp transfer printed tandem devices are shown in Fig. 3. It can be clearly seen from the picture that the PPV layer contaminated the active layer of the OMLED in the spin coating case, while the PPV layer did not affect the active layer of the OMLED in the stamp transfer printing case. Therefore, the active layer of the OBD in the OMLED was fabricated by stamp transfer printing process in this work, while the PPV layer of the OLED unit was spin coated. Detailed stamp transfer printing process was already reported in previous work [17].

Nonvolatile bistable switching performances of the memory unit are important for the nonvolatile bistable luminance control of the integrated OMLEDs as the OBD unit is directly connected to the OLED unit in the tandem structure. Therefore, the bistable behavior of the PPV memory device was investigated. Fig. 4**a** shows the current density–voltage curves of the OBD with the PPV active layer. PPV was stamp transfer printed on the Al electrode. The device structure of the OBD was Al/PPV/Al. The OBD exhibited bistable current state depending on the applied voltage to the device. The high current state (on state) was induced by applying 3 V (writing voltage), while the low current state (off state) was induced by applying a voltage above 5 V (erasing voltage). The bistable switching behavior of the PPV based OBD was already reported in other works and negative differential resistance (NDR) was observed [18,19]. It was reported that the bistable

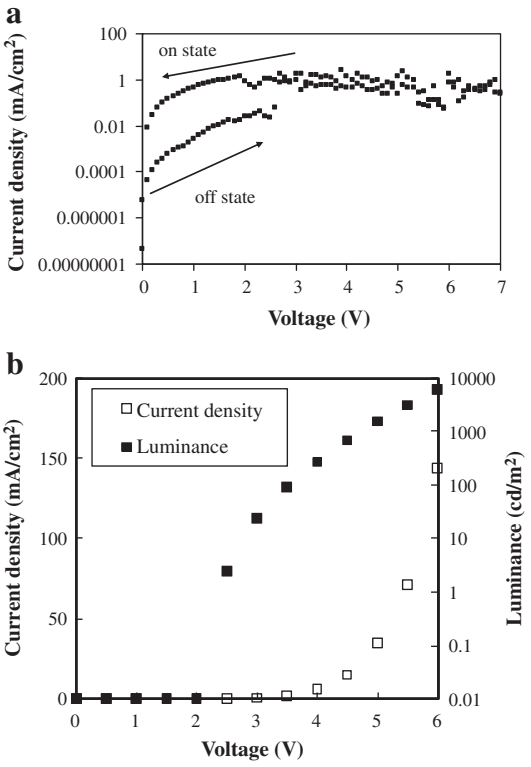

Fig. 4. Current density–voltage curves of the OBD (a) and current density–voltage–luminance curves of OLED (b).

stable switching behavior of the PPV OLED was originated from the electron trapping and freeing through the metal nanoclusters at the interface between the active layer and Al cathode [18]. Other than this, filament mechanism based on the aluminum oxide formation at the interface was also proposed as the origin of the bistability of the PPV based OBDs [19]. Aluminum oxide was generated during the deposition process of the OBD and it was responsible for the bistability of the device. Similar data were obtained in the PPV OBD fabricated in this work. A sharp increase of the current was observed at 2.7 V during forward scan from 0 to 7 V at low conductance state. The high conductance state could be maintained during reverse scan from 7 to 0 V. The high conductance state can return to the low conductance state by applying a voltage higher than 5 V. Therefore, the OBD showed bistable current state between 0 and 2.7 V. The on/off ratio of the OBD was over 100 and the on/off ratio was kept stable during multiple switching. The writing voltage of the OBD could be set as 3 V and the erasing voltage could be set as >5 V.

Current density–voltage-luminance performances of the OLED unit are also presented in Fig. 4b. The PPV based OLED showed typical light-emitting performances of the OLED. The turn-on voltage was 2.5 V and the voltage at 100 cd/m^2 was 3.6 V. Comparing the current level of the OBD and OLED, the current level of the OLED was higher than that of the OBD above 4 V, while it was lower than that of the OBD below 4 V. This indicates that the OBD has lower resistance than the OLED in the writing voltage

range and the OBD has higher resistance than the OLED in the erasing voltage range. This affects the bistable switching performances of the OMLED as the voltage applied to the OLED and OBD units is determined by the resistance of each device. The relative ratio of the resistance of the OLED and OBD at 3 V was R_{OLED}: R_{OBD} (2:1). Therefore, it can be expected that the voltage range for the bistable current state is widened compared with that of the OBD.

Fig. 5 shows the current density–voltage and luminance-voltage curves of the integrated OMLEDs. The integrated OMLED showed typical current density–voltage curves of the nonvolatile OBDs. The current density was sharply increased from 6 to 8.5 V and NDR characteristics of the OBD were observed at high voltage. The current density at high conductance state was higher than that at low conductance state below 8.5 V and similar NDR curve was obtained above 8.5 V. The on/off ratio of the OMLED was over 1000 at 6 V and it showed good device performances as the memory device. The bistability of the OMLED is due to the bistability of the OBD integrated into the device. The voltage range for the bistability of the OBD was from 0 to 2.7 V. The bistable voltage range was expanded in the OMLED as the voltage was applied both to the OBD and OLED units. At high conductance state, the current density was the same as that of the low conductance state up to 1.5 V, but high current density was obtained from 1.5 to 8.5 V. Therefore, the bistability was observed between 1.5 and 8.5 V although the on/off ratio was dependent on the reading voltage of the OMLED. The on state was induced at a writing voltage of 9 V and the off state was induced at an erasing voltage of 15 V. Therefore, the integrated OLBED device could play a role of the OBD over wide voltage range.

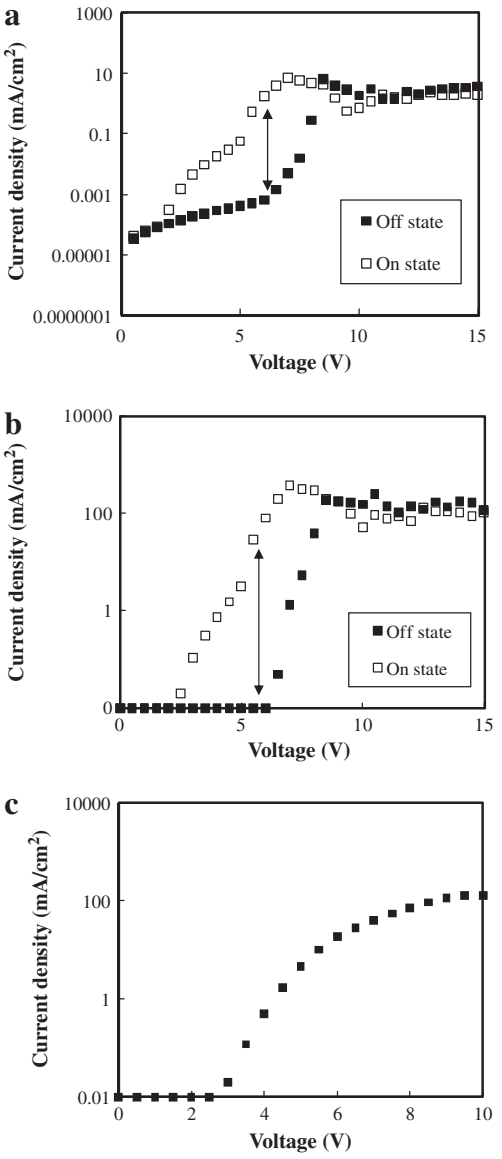

Fig. 5. Current density–voltage (a) and lumimance–voltage (b) curves of the OMLED at off state and on state. The erasing voltage for the off state was 15 V and the writing voltage for the on state was 9 V. Luminance–voltage (c) curve of the spin coated device is also shown.

As the current density was different depending on the applied voltage to the OMLED, it is expected that the luminance of the OMLED may be changed according to the switching voltage of the OMLED. As expected, the luminance of the OMLED was dependent on the switching voltage of the device. Within the bistable voltage range, the bitable luminance control of the OMLED was realized. The OMLED at low conductance state was not turned on until 6 V, while the OMLED was turned on from 2.5 V at high conductance state. The luminance of the OMLED at high conductance state at 6 V was 78 cd/m^2 compared with 0 cd/m^2 at low conductance state. The difference of the luminance was even higher at 7 V. The luminance at high conductance state was 369 cd/m^2, while that at low conductance state was only 1.3 cd/m^2. There was almost 300 times increase of the luminance at 7 V by changing the writing voltage of the OMLED. As the luminance is mainly determined by the charge density in the emitting layer, the increase of the current density increased the luminance of the OLED. The luminance of the OMLED at high and low conductance states was kept stable and the same luminance was obtained at the same voltage before applying different writing voltage. Therefore, nonvolatile bistable luminance switching behavior could be achieved in the tandem OMLED fabricated in this work. In the case of the spin coated device, no nonvolatile luminance switching behavior was observed and very low luminance level was observed. Luminance data of the spin coated device are shown in Fig. 5.

It is important to manage the current state at several levels to achieve multilevel luminance control in OMLED. Therefore, multilevel current control performance of the OMLED was investigated. Fig. 6 shows the current density of the OMLED depending on the writing voltage of the OMLED. The writing voltage of the OMLED was changed from 8 to 15 V to induce the multilevel current state in the OMLED. The reading voltage of the OMLED was 7 V. The OMLED showed low current level at a writing voltage of 8 V and high current level at a writing voltage of 9 V. Intermediate current level was observed at a writing voltage of 10 and 12 V. Therefore, four different current levels were clearly observed at different writing voltages.

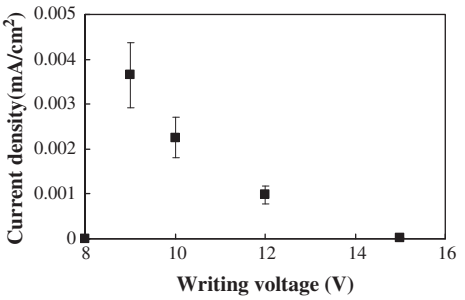

Fig. 6. Multilevel current density data of the OMLED according to the writing voltage.

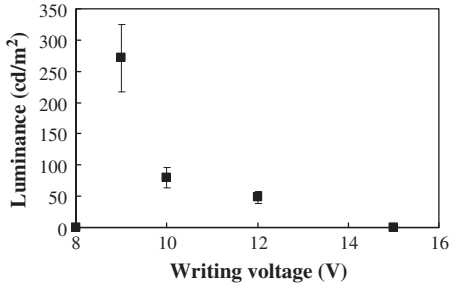

Fig. 7. Multilevel luminance data of the OMLED according to the writing voltage.

Multilevel luminance test of the tandem OMLED was carried out and test result is shown in Fig. 7. The writing voltage was controlled to manage the luminance of the OMLED and the reading voltage of the OMLED was 7 V. The OMLED was not turned on at a writing voltage below 9 V and the luminance was reduced by increasing the writing voltage. Intermediate luminance level between the off and on luminance levels was obtained at the writing voltage of 10 and 12 V. Although there was some scattering of the luminance data, four different luminance levels could be achieved in the OMLED. The average luminance of the OMLED at a writing voltage of 9 V was 270 cd/m^2, while it was 48 cd/m^2 at a writing voltage of 12 V. The OMLED was turned off at a writing voltage of 15 V and the average luminance level was 0.1 cd/m^2. Therefore, it was possible to control the luminance of the OMLED at the same driving voltage by just simply changing the writing voltage of the OMLED. The luminance of the OMLED could be kept stable before changing the writing voltage of the OMLED. Therefore, nonvolatile luminance switching of the OMLED could be achieved in the OMLED with tandem structure of OBD and OLED.

The pictures of the OMLED at a reading voltage of 7 V are presented in Fig. 8. The writing voltage of the OMLED was 9 V at on state and it was 15 V at off state. Low luminance level of 1.5 cd/m^2 can be clearly seen in the figure at off state, while high luminance level of 350 cd/m^2 was obtained at on state. Therefore, it can be proved that the nonvolatile multistable luminance state can be induced in the OMLED fabricated by the stamp transfer printing process.

The stability of the nonvolatile luminance state was evaluated by measuring the photocurrent of the Si photodiode. Writing voltages of 9 and 15 V were applied alternatively and the current was measured at 7 V. Fig. 9 shows the photocurrent of the OMLED at 7 V depending on the applied voltage. The OMLED was cycled 100 times and it can be seen that the high and low luminance states were maintained stable over 100 times. This proves that the OMLED shows reproducible luminance state. The high and low current states were maintained stable before applying writing or erasing voltage.

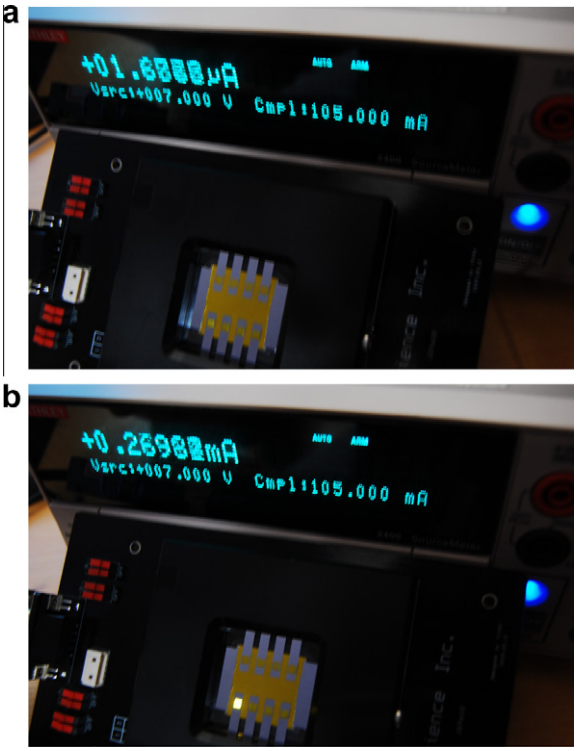

Fig. 8. Pictures of the OMLED at off (a) and on (b) state. The reading voltage was 7 V. The erasing voltage was 15 V and the writing voltage was 9 V.

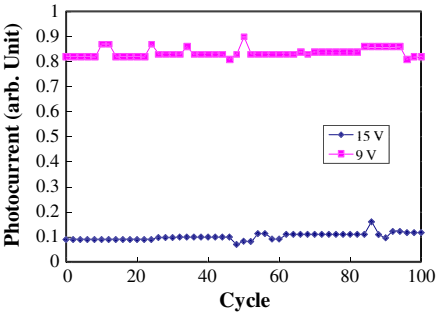

Fig. 9. Long term stability data of the OMLED through multiple cycling test.

4. Conclusions

In conclusion, solution processed tandem type OMLED with nonvolatile luminance switching over wide lumi-

nance range, four level luminance control, bipolar switching performances was successfully fabricated using a stamp transfer printing method. A high on/off ratio over 1000 was achieved in the tandem OMLED and the luminance could be managed over 300 cd/m^2 at the same voltage. The tandem structure of different device units and the stamp transfer process for the polymer film formation can be effectively used in future development of multifunctional organic electronic devices.

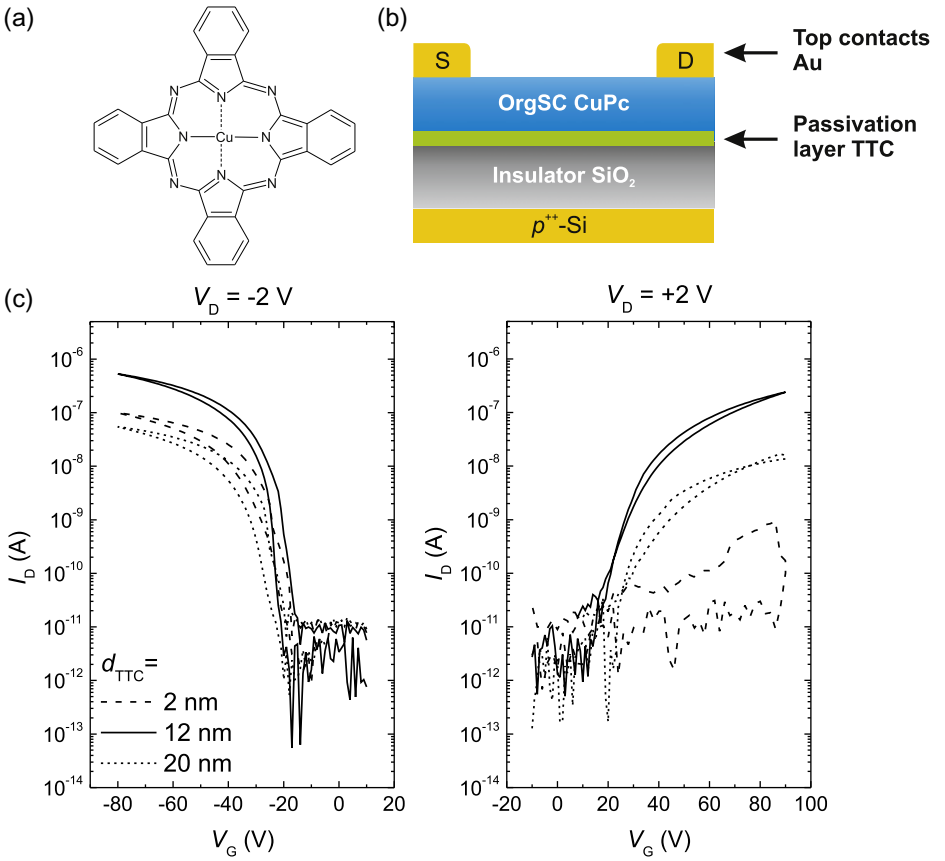

Fig. 1. (a) Chemical structure of the organic semiconductor (OrgSC) CuPc, (b) schematic layout of top-contact OFETs and (c) transfer characteristics of devices with channel length $L = 50$ μm, channel width $W = 3.0$ mm and TTC thicknesses d_{TTC} of 2 nm, 12 nm and 20 nm.

2. Experimental

We fabricated top-contact bottom-gate organic field-effect transistors with varying TTC thickness and 25 nm of CuPc on heavily *p*-doped silicon wafers with 310 nm thermally grown SiO_2 acting as gate dielectric. TTC, CuPc and the gold top contacts were fabricated by thermal evaporation. TTC layers are highly hydrophobic with a water contact angle of approximately 105°. We determined a dielectric constant of $\varepsilon_{TTC} \approx 2.5$ by capacitance measurements. A systematic sketch of the sample can be seen in Fig. 1b. On each substrate, there are six individual transistors with channel length ranging from 50 μm to 130 μm and a channel width of 3.0 mm. A detailed description of the fabrication and analysis of the OFETs is given elsewhere [9]. We found that the transistor characteristics depend strongly on the thickness and the post-deposition treatment of the TTC passivation layer. We note that the TTC thicknesses of the investigated devices are nominal thicknesses obtained from the deposited amount on the quartz monitor during evaporation, but not taking into account film roughness (see below).

3. Growth of CuPc on TTC

In Fig. 1c transfer characteristics of samples with 2, 12 and 20 nm of TTC are displayed. The sample with 2 nm TTC shows unipolar hole transport, whereas all other samples are ambipolar. The sample with 12 nm TTC reveals the best characteristics, while the 20 nm sample has a significantly reduced performance. In order to understand this behavior the TTC morphology was analyzed. As already known from previous work TTC forms crystalline terraces where the molecules are standing upright [9]. The height of one terrace (i.e. one individual TTC layer) is approximately 5 nm which agrees with the length of the molecule. For the following analysis of the charge carrier transport three thickness regimes are relevant. Fig. 2a shows atomic force microscopy (AFM) images of 2, 6 and 14 nm of TTC on SiO_2 being representative for each of these three regimes. Region I, TTC thickness lower than one monolayer, corresponds to the growth of islands of TTC on SiO_2 which are not connected to each other. On some islands even the formation of a second layer can already be seen. Region II represents TTC thicknesses between one and about three monolayers. Here, the SiO_2 is covered completely and additional TTC layers are being formed. In region III, i.e. layer thickness larger than about three monolayers, very high columns of TTC appear [10]. For a nominal thickness of 14 nm some of these columns can reach a height of 100 nm. Thus, the growth of TTC on SiO_2 can be described by a Stranski–Krastanov scenario. To determine the influence of these different growth regimes on charge carrier transport we fabricated OFETs with TTC thicknesses

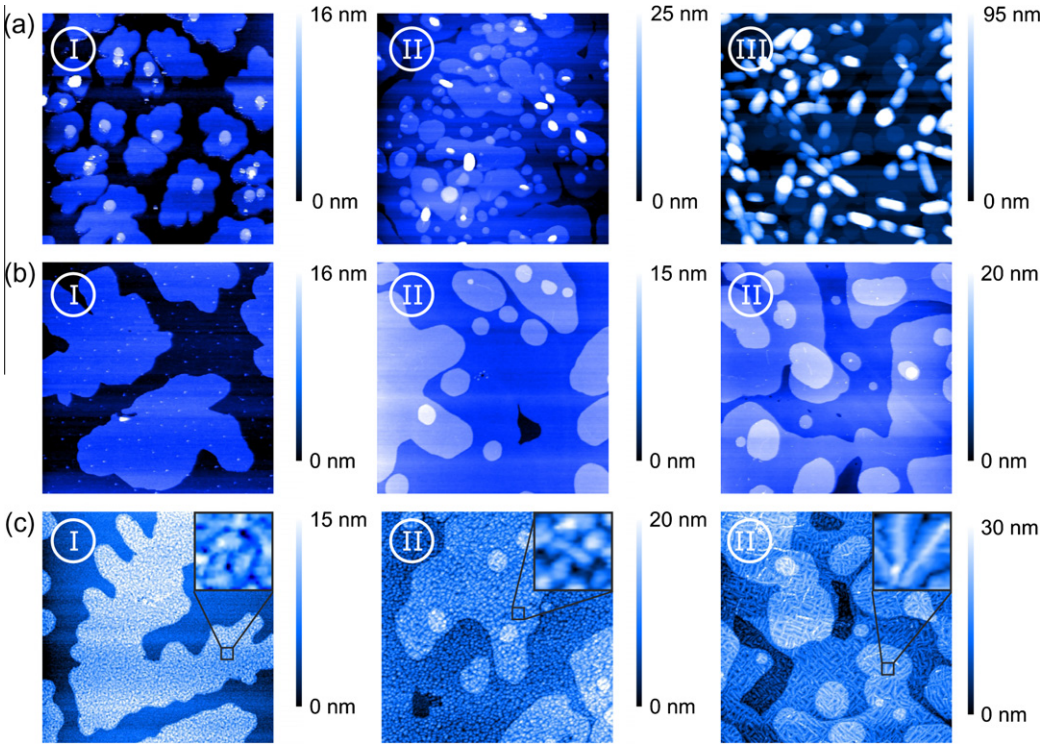

Fig. 2. (a) AFM images of nominally 2 nm (left), 6 nm (center) and 14 nm (right) TTC on SiO_2 and (b) the same as (a) but with TTC annealed at 60 °C for 2 h. Black colored areas in the 2 nm and 6 nm images of (a) and (b) symbolize bare SiO_2. (c) AFM images of 5 nm of CuPc on TTC layers prepared as in case (b) (all sizes $5 \times 5\ \mu m^2$). The numbers in circles represent the transport regimes described in the text. The insets show zoomed areas ($0.25 \times 0.25\ \mu m^2$) of the CuPc crystallites on the first TTC layer (I), on the second layer (II) and on the third layer (II*).

between 0 and 22 nm. Charge carrier mobilities were evaluated in the linear regime using the so-called transmission line method (TLM) [11]. The corresponding charge carrier mobilities are shown in Fig. 3a.

The three growth regimes can be correlated very well with three distinct transport regimes. Fig. 3c explains schematically the transport processes in the individual regimes I, II and III. In regime I the TTC layer is not fully closed. This leads to the presence of electron traps on bare SiO_2, so that there is no electron transport below roughly one complete monolayer of TTC. For 4 nm TTC there is already a percolation path for electrons, which leads to the onset of electron transport but with rather low mobility. Hole mobility is increasing with TTC thickness from around $2 \times 10^{-4}\ cm^2/Vs$ on bare SiO_2 to approximately $2 \times 10^{-2}\ cm^2/Vs$ for 8 nm TTC due to the larger grain size of CuPc on TTC as compared to SiO_2 [9]. Larger grains lead to less grain boundaries, which are a key limiting factor for charge carrier transport [12,13]. In regime II the TTC layer is fully closed and hole and electron mobilities remain relatively constant, however, the electron mobility is by a factor of 2 lower than the hole mobility. In regime III the high columns of insulating TTC begin to hinder the charge carrier transport along the interface. A larger nominal TTC thickness leads to an increase of the area occupied by these columns. Thus, electron and hole mobility decrease again with increasing TTC thickness due to a reduction of the effective area available for the transport channel at the insulator-semiconductor interface, resulting in a decrease of the current [14].

4. Effects of annealed TTC layers

From these results it can be concluded that the morphology of the TTC–CuPc interface is limiting the charge carrier transport and needs to be improved. Therefore we fabricated a series of TTC-covered SiO_2 substrates and annealed them prior to the deposition of CuPc in an oven at 60 °C for 120 min in N_2 atmosphere. Fig. 2b shows the corresponding AFM images of nominally 2, 6 and 14 nm of annealed TTC on SiO_2. For 2 nm, there are also TTC islands with a height of one monolayer, like in the non-annealed case. However, the area of the islands is larger and no second layer is formed. In the 6 nm picture, significant changes to the non-annealed samples occur: the height distribution becomes more homogeneous and the TTC terraces are enlarged. This effect is much more pronounced in the case of 14 nm and at even larger thicknesses: the previous extremely high TTC columns in the non-annealed case disappear completely and large, flat TTC terraces of constant height are being formed. We fabricated OFETs using annealed TTC passivation layers with a TTC thickness in the range from 2 to 28 nm. The rest of the fabrication was identical to the samples described above. The resulting field-effect mobilities can be seen in Fig. 3b and, again, be distinguished in

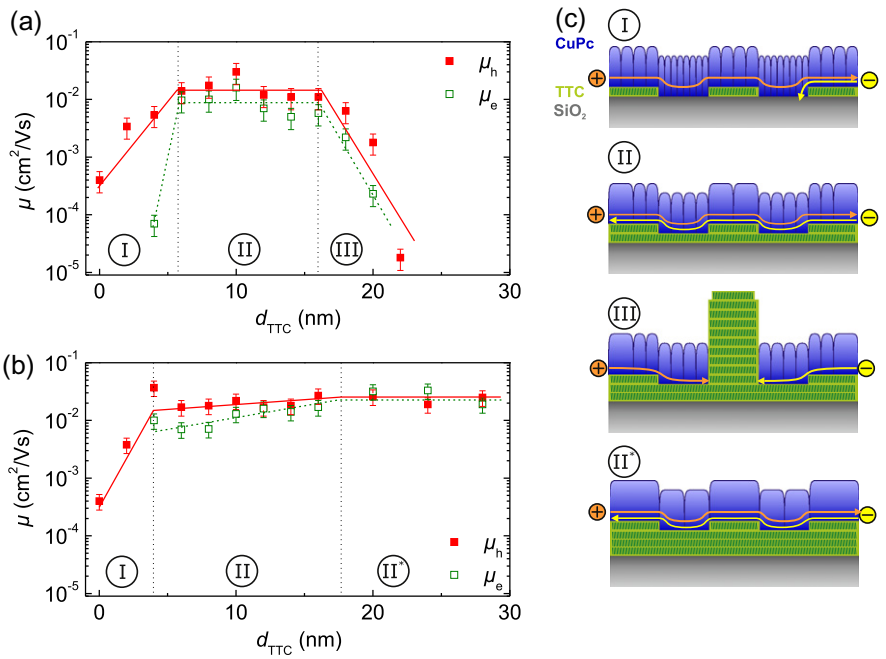

Fig. 3. (a) Field-effect mobility determined by TLM for holes (closed symbols) and electrons (open symbols) as a function of TTC thickness for as-deposited TTC layers and (b) for TTC layers annealed at 60 °C for 2 h (the lines are guides for the eye). (c) Schematic sketches of the charge carrier transport regimes.

three regimes: In regime I, 0–4 nm, there is only hole transport with increasing mobility and no electron transport. In regime II, for TTC thicknesses between 4 and 16 nm, the hole mobility increases very slowly until it reaches its maximum value ($\mu_{ho} \approx 2.0 \times 10^{-2}$ cm^2/Vs), whereas the increase of the electron mobility up to comparable values is more pronounced. In contrast to the non-annealed case there is no regime III with diminishing charge carrier transport for large TTC thicknesses. Instead, for a thickness larger than 18 nm TTC – regime II* – electron and hole mobility are equal at $\mu \approx 2.0$–3.0×10^{-2} cm^2/Vs and stay constant with increasing TTC thickness. We note that this is the highest reported value for electron mobility in CuPc and comparable to the highest reported hole mobilities in thin-film transistors with heated CuPc layers and silanization of SiO_2 surfaces [14] but still lower than the hole mobility in single-crystals ($\mu_{sc,ho} \approx 0.5 - 1$ cm^2/Vs) [15,16]. Ambipolar transport has been reported for single-crystal FETs but hole mobilities were significantly lower than other values reported for single-crystals ($\mu_{sc,ho} \approx 10^{-3}$–$10^{-1}$ cm^2/Vs) and electron mobilities were even lower than in our thin-film devices ($\mu_{sc,el} \approx 10^{-5} - 10^{-3}$ cm^2/Vs) [7]. The fact that the mobilities do not decrease for large TTC thicknesses can be explained very well with the disappearance of the high TTC columns. However, this model cannot explain why the electron mobility still increases in the range from 4 to 18 nm TTC. AFM images show that TTC forms a closed film already for 6 nm annealed TTC so that all electron traps should be passivated. Thus, the reason must be another effect on the insulator-semiconductor interface, namely in the CuPc. To investigate the effects of increasing TTC thickness on the transport channel in CuPc we performed AFM measurements with only 5 nm CuPc on nominally 2, 6 and 14 nm annealed TTC films. The results are shown in Fig. 2c. CuPc forms polycrystalline layers where the CuPc grains are very well visible and the TTC terraces can still be identified. Details about the crystalline structure of CuPc on TTC have been reported elsewhere [9]. It can clearly be seen that the CuPc grain size increases steadily with the thickness of the underlying TTC layer. On the first TTC monolayer CuPc forms round grains with an average diameter of 100 nm. On thicker TTC layers the grains become more and more elongate, e.g. on 14 nm TTC the CuPc grains have an average length of 200–230 nm. We observed a saturation of the grain size for TTC thicknesses beyond 16–18 nm with crystallite lengths up to 300 nm. This high degree of crystallinity shows that the growth of CuPc on TTC can be considered as some kind of "pseudoepitaxial" growth [9]. The reason for the increase of the crystallite size is not yet fully understood. It is imaginable that TTC grows in a slightly distorted way on SiO_2 and needs some three or four monolayers to relax to its original crystal structure, which then promotes optimum CuPc growth. Or, as indicated by preliminary X-ray diffraction measurements (not shown here), a different CuPc phase, that exhibits larger crystals, could be formed on upper TTC layers. The increase and the subsequent saturation of the CuPc grain size are coincident with the behavior of the electron mobility in the annealed devices. This effect is illustrated in Fig. 3c (II*).

The CuPc films in the presented devices are clearly polycrystalline. This limits the charge carrier transport [12,13] and explains why the mobilities in these devices are smaller than the reported values in single crystal OFETs [15,16]. Due to our simultaneous analysis of electron and hole

transport in the same device a differentiation for the two charge carrier types is possible. Levinson et al. suggested a model to analyze the grain boundary trap density in polycrystalline films which can also be applied for organic semiconductors [18,19]. In our case the temperature dependent analysis for samples with 14 nm (regime II) and 28 nm (regime II*) annealed TTC lead to electron trap densities at the grain boundaries of about 2.6×10^{12} cm^{-2} for both devices. The trap density for holes is by a factor of 1.6 lower than the trap density of electrons (see the Supplementary information for a detailed analysis). These observations can explain that there is a general difference between electron and hole transport but cannot explain the difference between regime II and II*. A difference in the mobility prefactor is observed which is related to a larger scattering rate for electrons at the grain boundaries or to a lower electron mobility inside the crystalline grains [18]. This could be an indication for a different electrostatic interaction between the charge carriers and the SiO_2 interface. Thereby, the interaction of the charge carriers in the organic semiconductor to induced polarization in the oxide insulator or to interface traps at the oxide surface, can be different for electrons and holes since the traps can be charged and thus affect electrons and holes differently. Additionally, the effective mass of the polaron can be different for negative and positive charges. Both effects will decrease with increasing distance between SiO_2 and CuPc [17]. Further investigations concerning the growth behavior and the electronic interaction are required to quantify these effects.

5. Summary

In summary, the influence of the morphology of an insulating TTC interlayer on the morphology of a semiconducting CuPc layer deposited on top and the charge carrier transport in this CuPc layer was analyzed. The insulating interlayer is free of electron traps and leads to a CuPc layer with large grain size up to 300 nm when the film thickness of the low-temperature annealed TTC film is larger than three monolayers. At room temperature the contact resistance-corrected mobilities for electrons and holes are equal and as high as the hole mobility reported for heated CuPc films. The transport is limited by the polycrystalline nature of the semiconducting film which exhibits a slight asymmetry between electrons and holes due to a difference in the grain boundary trap density for both charge carrier types. The possibility of rather high electron and hole mobilities in thin-film devices and their ambipolar nature should be considered when CuPc is used as donor in solar cells or as *p*-type semiconductor in field-effect transistors or diodes. Additionally, balanced electron and hole mobilities are also crucial for the realization of organic light-emitting field-effect transistors or complementary organic inverters based on one single active material [14,20,21].

Oxidation of the low work function cathode appears to be the main efficiency-limiting mechanism in unencapsulated OPVs in dark, similar to the case of organic light-emitting diodes (OLED), and generally, no alteration of the photoactive blend is reported in this condition [9,10,15–17]. Moisture and oxygen are demonstrated to diffuse through pinholes and edges of the cathode leading to oxidation of the metal only at the organic/metal interface; even delamination of the cathode is observed in some cases [17,18]. This degradation severely hinders charge extraction in the oxidized regions resulting in increased series resistance and reduced short-circuit current [17]. Several strategies have been proposed to overcome the rapid failure in ambient conditions, such as addition of a metal oxide layer between the active layer and the metal cathode, and/or the implementation of an inverted device architecture that avoids the need for a low work function metal entirely [19–22].

Even though PEDOT:PSS is commonly used as a hole transport layer in conventional polymer-based solar cells, its impact on device degradation remains controversial and not widely investigated [17,23–25]. Kawano et al. concluded that humidity induces formation of an insulating layer at the PEDOT:PSS/blend interface leading to device failure [23]. Norrman et al. equally observed the reaction of PSS in the presence of air, while Lloyd et al. reported that PEDOT:PSS seemed to have a negligible impact on the degradation rate of P3HT:PCBM devices with Ca/Al electrode [17,24]. In contrast, Yamanari et al. demonstrated that replacement of PEDOT:PSS by MoO_3 considerably enhances air stability of similar devices with an Al cathode, suggesting that PEDOT:PSS might accelerate the degradation [25]. Despite the fact that in these studies similar devices, aged in comparable conditions, exhibited qualitatively identical device degradation, in each case the complementary experiments led to different conclusions.

Here, we report a series of experiments to elucidate the main degradation mechanism in polymer-based solar cells in ambient atmosphere and shelf-life conditions. A combination of electrical and optical measurements allows to confirm that only charge extraction is hindered in degraded devices, whereas other steps in the photo-generation process remain unchanged. By altering device interfaces and materials, we conclude that cathode oxidation is the main degradation mechanism, and decay rate is greatly accelerated by PEDOT:PSS. To gain further insight into the mechanism, we evaluate the impact of PEDOT:PSS acidity on device degradation and show that, in fact, only its hygroscopic nature is detrimental. Consequently, ambient humidity seems to be the dominating stress factor for polymer solar cells in air, which we confirm by experiments in a controlled-humidity environment. Moreover, we evaluate device lifetime at different humidity levels at room temperature, in an effort to establish an adapted accelerated testing for OPVs subjected to these conditions. Finally, we show that humidity infiltration can also be visually observed in our devices, and this reveals further details of the degradation mechanism. While the purpose of this paper is to explain the role of PEDOT:PSS in the failure of polymer solar cells, it has broader implications since PEDOT:PSS is also used in several other organic electronics devices.

2. Experimental

2.1. Sample preparation and characterization

We prepared a variety of device architectures in this study, here we describe the preparation of standard cells and deposition of other layers which were used additionally or alternatively. We prepared standard solar cells on glass samples coated with patterned indium-tin-oxide (ITO) purchased from Kintec, with a sheet resistance of 15 Ω/□. Samples were thoroughly cleaned in a sequence of sonication in detergent, deionized water, acetone and isopropanol, and finally treated with ultraviolet-ozone. First, filtered PEDOT:PSS (HC Starck, Baytron P VPAl4083 with pH 2) was spin-coated at 3000 rpm for 60 s, giving a 35 nm thick layer. Then, samples were entered in a nitrogen filled glovebox (with H_2O and O_2 both below 1 ppm), where they were annealed at 130 °C for 10 min to remove excess water. Variation of the PEDOT:PSS thickness achieved by using spin-coating speeds between 500 and 6000 rpm. Neutral pH PEDOT:PSS purchased from Agfa (Gen5pH5 and Gen5pH7) was spin-coated and treated similar to the acidic PEDOT:PSS. Alternatively, 15 nm of molybdenum trioxide was evaporated at $\sim 10^{-7}$ mbar at a deposition rate of 2 Å/s. All further steps of processing were carried out in an inert nitrogen atmosphere. P3HT (Rieke Metals) and PCBM (Solenne bv.) were used as purchased to prepare a solution of 3 wt.% in ortho-dichlorobenzene in a 1:1 wt.% ratio. The solution was stirred inside the glovebox at 80 °C overnight and filtered with a 5 μm PTFE filter prior to use. The active layer was spin-coated at 1000 rpm for 60 s. The samples were subsequently heated at 130 °C for 10 min to achieve an optimal morphology. Standard samples were transferred to a metal evaporation chamber where 40 nm of Yb and 150 nm of Al were deposited at 10^{-7} mbar with 1.5 Å/s deposition rate, without breaking vacuum. Alternatively 40 nm Ca and 150 nm Al was evaporated in similar conditions. The metals evaporated through a shadow mask defined twelve 0.134 cm^2 on each substrate. The device area is scaled by changing the area of the metal shadow mask or even additionally decreasing the size of the ITO. On a few samples, 5 nm of C_{60} was deposited over the whole substrate prior to the metal cathode evaporation. C_{60} was sublimated at 10^{-6} mbar with a 1 Å/s deposition rate.

Photovoltaic characteristics were measured at regular intervals in ambient atmosphere with a Keithley 2602A in two-wire configuration under a Lot Oriel 1000 W Xenon arc lamp filtered by OD0.8 Newport neutral density to obtain 100 mW/cm^2 illumination intensity and AM1.5G spectrum. The lamps intensity was calibrated with an ISE Fraunhofer certified Si photodiode. Characterization of one substrate, 12 devices, requires a total illumination of ~40 s resulting in a cumulated illumination of ~5–10 min over the lifetime study. Optical microscope images are observed and recorded with Olympus AX70 at 5× magnification. Layer thicknesses were measured by a Dektak D150.

2.2. Degradation conditions

Samples were aged in ambient conditions, in dark. The ambient temperature was constantly 20 °C, while humidity varied slightly from 30% to 40% RH between experiments. Controlled atmosphere was achieved by either placing the samples in presence of (previously dried) silica gel or a saturated salt solution in a hermetically sealed chamber, which only opened for device characterization. Humidity level of 11% RH, 33% RH, 53% RH, 75% RH and 84% RH were achieved at 20 °C by using saturated solution of LiCl, $MgCl_2$, $Mg(NO_3)_2$, NaCl, and KCl, respectively [26].

2.3. Photo-induced absorption spectroscopy

Near steady-state photo-induced absorption (PIA) spectra were recorded between 2 and 1 eV by excitating with 2.54 eV photons from a mechanically modulated (275 Hz) Ar^+ laser source. The resulting change in transmission of a tungsten–halogen probe beam through the device after reflection at the back electrode (ΔR) was recorded with a phase sensitive lock-in amplifier after dispersion with a monochromator and detection using Si and InGaAs detectors. The pump power was 100 mW with a beam diameter of 2 mm. The PIA signal ($\Delta R/R$) was corrected for the photoluminescence, which was recorded in a separate experiment. The devices were held at short circuit during the measurements, at room temperature and in N_2 atmosphere, using a Oxford Optistat continuous flow cryostat.

2.4. TEM and SEM characterization

Analysis by transmission electron microscopy (TEM) is performed in a Tecnai F30 at 300 kV. Cross-sectional specimens are prepared by focused ion beam (FIB) in a Strata400S by the internal lift-out method. In case no metal is present on the surface, an Al cap layer is evaporated on the samples to protect the surface during the ion beam milling. The samples are transferred to the FIB system in nitrogen boxes and the thinned TEM specimens are analyzed as soon as possible to avoid long air exposure. Compositional analysis is done in parallel by energy dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) in scanning transmission electron microscopy (STEM) mode. STEM images are acquired in high angle annular dark field (HAADF) mode.

Characterization of the films by scanning electron microscopy (SEM) was performed with a Philips XL30 S SEM (5 kV acceleration voltage, spot size 3, and a typical working distance between 4 and 6 mm).

3. Results and discussion

3.1. Degradation of reference devices in ambient conditions

The device structure consists of indium tin oxide (ITO)/ PEDOT:PSS (35 nm)/ P3HT:PCBM (~300 nm)/Yb (40 nm)/ Al (150 nm) with an initial efficiency of 3.6 ± 0.1%, measured under 100 mW/cm^2 AM1.5G simulated solar illumination where the short-circuit current density (J_{SC}) is 9.8 ± 0.2 mA/cm^2, the open-circuit voltage (V_{OC}) is 581 ± 3 mV and the fill factor (FF) is 63 ± 0.3%. The evolution of photovoltaic device characteristics of these reference devices stored in air is shown in Fig. 1. The electrical parameters of the solar cells are normalized to their initial values to facilitate comparison. Unless stated otherwise, all samples in this study are stored at 20 °C, in dark and ambient conditions with a relative humidity (RH) level of 30–40%. Samples are briefly illuminated only during regular measurements in air. Initially, we verified that neither the illumination nor the electrical biasing induces significant additional degradation (see Fig. S1 in the Supporting information). The efficiency degradation in these devices is uniquely determined by a two-stage decrease of the J_{SC}, while the V_{OC} and FF remain constant, in agreement with previous reports [17,25]. This two-stage degradation consists of a fast, initial drop followed by a slow, almost linear degradation. Even though the series resistance increases in degraded cells, it does not follow the same kinetics as the decrease in photocurrent: it remains low during the first phase and only increases during the second stage. One could also remark that performance variation among devices increases with time. Furthermore, we found that the degradation is entirely irreversible in contrast to reports where degradation in dry air could be partially recovered [12,13].

First, we could exclude that the drop in J_{SC} stems from a loss in absorption as determined by absorption and external quantum efficiency spectrum (EQE) measurements (shown in Fig. S2a,b in the Supporting information). The EQE spectrum is evenly lowered over the whole wavelength range indicating that neither change in absorption, nor morphology reorganization occurs in the devices [27]. Furthermore, current density–voltage measurements up to high reverse bias show that the initial photocurrent density could be recovered, even in considerably aged devices by a suitably high reverse bias (Fig. 2). This indicates

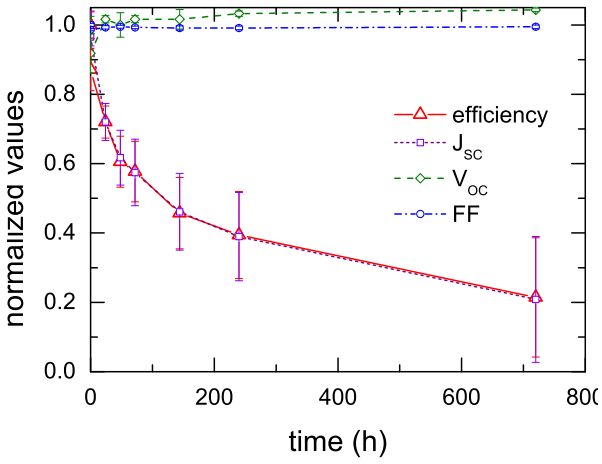

Fig. 1. Normalized solar cell parameters extracted from regular measurements under 100 mW/cm^2 AM1.5G simulated solar illumination. Devices consisting of ITO/PEDOT:PSS/P3HT:PCBM/Yb/Al were stored in shelf-life conditions, in ambient atmosphere. The values correspond to mean values and the error bars are standard deviations calculated from 12 identical devices on a single substrate.

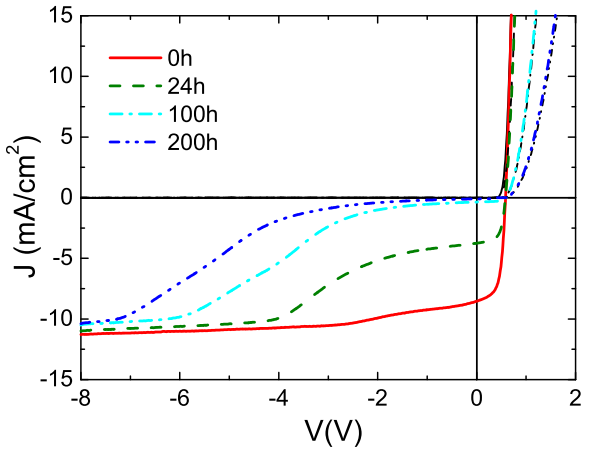

Fig. 2. Dark and illuminated current density–voltage (*JV*) measurements of reference devices stored in shelf-life conditions under ambient atmosphere.

that exciton generation is unaltered in degraded cells. Moreover, the voltage dependent photocurrent could be the signature of various loss mechanisms; the most probable ones include reduced geminate pair dissociation or hindered charge transfer at organic-electrode interfaces.

Next, we performed near-steady-state photo-induced absorption spectroscopy (PIA) measurements on fresh and degraded cells in reflection geometry to investigate the efficiency of exciton dissociation with a contactless technique. The signal that is recorded is proportional to the near-steady-state photogenerated charge carrier density. As illustrated in Fig. 3, the bands characteristic of radical cations of regio-regular P3HT, namely 1.25 and 1.7 eV, remain unchanged even after 44 h exposure to air [28]. Hence, we can conclude that charge generation also remains unaltered in devices exposed to air.

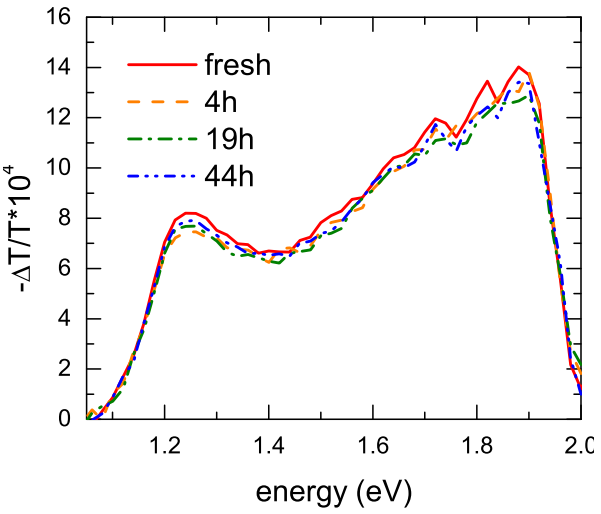

Fig. 3. Near-steady-state photo-induced absorption spectroscopy in reflection mode on devices exposed to ambient air for 0, 4, 19 and 44 h.

3.2. Impact of hole transport layers on device degradation

Further understanding of the degradation mechanism could be obtained by comparing the degradation in solar cells with the same active layer and different electrodes. In the first series we employed two different hole transport layers (HTL) in four different devices, all capped with Yb/Al cathode. We compared PEDOT:PSS, MoO_3, the stack of these two materials, as well as a sample without HTL. Except the sample without a HTL, which presents a lower initial FF (42% versus 63%), all samples yielded comparable initial efficiencies of 3.6%. Since all device parameters, except J_{SC}, remain constant during the test, we solely compared this evolution in Fig. 4. Exclusion or replacement of the PEDOT:PSS layer considerably reduced the initial degradation of J_{SC}, while the pace of the linear decay remains similar for all devices. More precisely, samples with PEDOT:PSS exhibited a lifetime of ~10 h compared to ~600 h obtained for devices employing MoO_3. Device lifetime in our study is defined as the time to reach 80% of the initial efficiency (T80). Furthermore, deposition of MoO_3 on the PEDOT:PSS layer reduced the decay rate of J_{SC} compared to only PEDOT:PSS sample. As the fast degradation is not completely impeded, the conclusion is not straightforward, but it clearly implies that direct reaction between the active layer and the PEDOT:PSS is not the cause of the degradation. It seems that MoO_3 acts as a protective layer here, either to oxygen and humidity diffusion in the PEDOT:PSS layer or diffusion from the PEDOT:PSS towards other layers/interfaces in the device.

Exchanging the Yb/Al cathode with a Ca/Al stack, which is known to be even more reactive towards atmospheric gases, led to both qualitatively and quantitatively the same J_{SC} degradation as Yb/Al (Fig. 4) [26]. Even though the degradation in current density is similar, devices with Ca/Al electrode also exhibit a linear degradation of the FF over time, unlike cells with Yb/Al (see Fig. S13 in the Supplementary information). This discrepancy might be explained by the difference in the properties of their oxide,

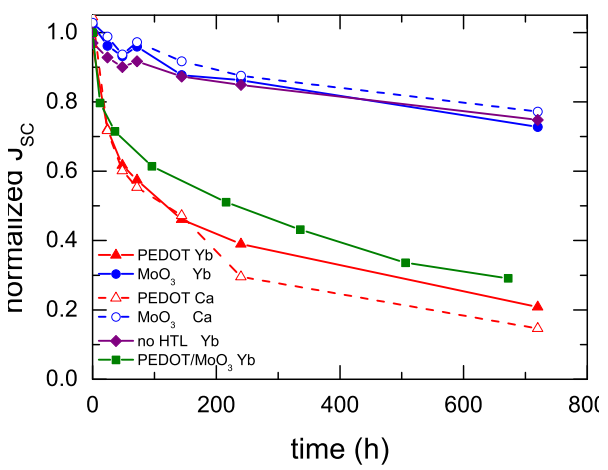

Fig. 4. Normalized current density degradation recorded on devices with identical P3HT:PCBM active layer and different hole transport layers (full lines) or metal cathodes (dashed lines) as indicated in the legend.

but further investigation of this property is out of scope of this paper.

Although these results initially suggest the degradation of the hole transport layer, low work function metals are also known to be inherently unstable in ambient conditions. Thus in an effort to elucidate the exact degradation mechanism, we continued by investigating the degradation of the metal cathode in a complete device stack by delaminating and subsequently re-depositing the electrode. Since the adhesion between the organic and metal layer proved to be strong, delamination of the electrodes with simple peeling process with tape was impossible. Therefore, we inserted a thin layer of C_{60} between the organic and the metal layer, which considerably reduces the adhesion of the metal resulting in a clean delamination process. In a control experiment we verified that the insertion of the C_{60} layer does not impact the device degradation (see Fig. S4 in the Supporting information). Then, by the re-deposition of a fresh electrode on the aged device stack, we could fully recover J_{SC} and the series resistance of the device as presented in Fig. 5. We also confirmed that the recovered performance is not due to outgasing of the aged organic layers in vacuum during the fresh electrode deposition. Therefore, this result proves that the hindered charge extraction in these devices stems from the oxidation of the low work function metal cathode and its subsequent contact with the underlying organic layers, while degradation of the hole transport layer can be excluded.

To further confirm the previous results, we exposed the ITO/PEDOT:PSS and ITO/PEDOT:PSS/P3HT:PCBM stacks to ambient conditions prior to the deposition of the subsequent layers. As the metal cathode provides a barrier to oxygen and humidity diffusion, the uncapped samples experience accelerated ageing conditions. Nevertheless, in both stacks the J_{SC} remains 8–9 mA/cm^2, even after prolonged exposure (see Fig. S5 in the Supporting information).

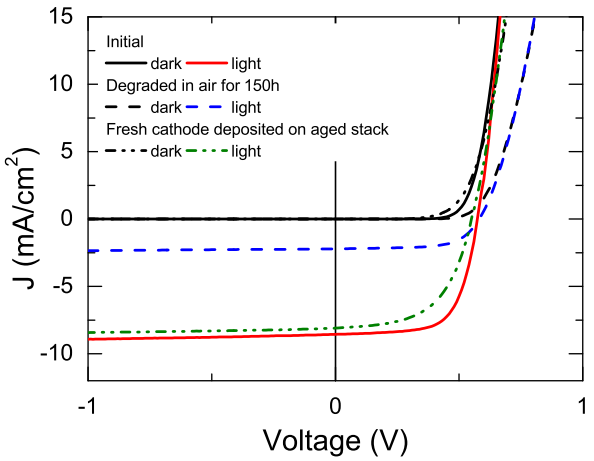

Fig. 5. Current density–voltage measurement of ITO/PEDOT:PSS/P3HT:PCBM/C_{60}/Yb/Al device stack as produced (red full), degraded in ambient conditions for 150 h with the original cathode (blue dashed) and with a fresh cathode (green dash-dot). On the degraded device stack, the cathode (Yb/Al) was delaminated and a fresh one was evaporated. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

This series of experiment confirms that the low work function metal cathode oxidation is the primary cause of degradation and, perhaps more importantly, that the hole transport layer extensively determines the pace of this degradation. Consequently, our conclusions differ from previous reports as we demonstrated that the PEDOT:PSS layer and its associated interfaces are not the main cause of degradation [23,24]. These electrical measurements are also supported by cross-sectional analysis of the device stack with transmission electron microscopy (TEM). We observed a 10–15 nm thick Yb_2O_3 layer at the metal–organic interface but clearly no sign of delamination at the interface, contrary to devices with Ca/Al cathodes [17]. This can be explained by the nature of Yb_2O_3, which forms a dense oxide layer with a comparable volume as the metal, while oxidized Ca has a significantly reduced volume resulting in void formation [26]. Furthermore, these TEM images do not show any alteration of the anode-HTL or HTL-active layer interface (see Fig. S6 in the Supporting information).

3.3. Impact of humidity on device degradation

To elucidate a detailed mechanism of the cathode oxidation accelerated by PEDOT:PSS, we pursued our investigation by focusing on different properties of PEDOT:PSS, namely the impact of its acidity and hygroscopic nature. The high acidity of the commonly used PEDOT:PSS has long been assumed to be harmful, it is surmised to etch the ITO layer resulting in Indium (In) leaching into the organic layers [29,30]. In contrast, Kok et al. reported no improvement in OLEDs lifetime with the neutralization of the PEDOT:PSS [30]. To assess the impact of PEDOT:PSS acidity, we used modified PEDOT:PSS with pH 5 and pH 7 as substitute in the reference device architecture. Devices with identical PEDOT:PSS thickness yielded similar initial efficiencies and presented comparable device degradation both for standard PEDOT:PSS and its neutral version (results shown in Fig. S7 in the Supporting information). Thus, the acidity of the PEDOT:PSS does not appear to be a contributing factor. Furthermore, energy dispersive X-ray spectroscopic (EDS) analysis on a degraded cell with the standard, acidic PEDOT:PSS only detected 2–7 at.% of Na^+ cations, while no traces of In were observed (see Fig. S6c in the Supporting information). The Na^+ cation is a residual product of the synthesis [31], and its potential impact on device degradation is unknown. This result is also in agreement with the previous experiment where we could completely recover device performance with a re-deposited cathode.

Another problem associated with PEDOT:PSS is its hygroscopic nature, meaning that in the presence of moisture it takes up water [31,32]. The impact of the hygroscopic nature of the PEDOT:PSS is investigated by ageing devices both with PEDOT:PSS and MoO_3 HTLs in dry air. The initial fast decrease of the J_{SC} of reference devices with PEDOT:PSS under ambient conditions is entirely impeded in the dry air and they exhibit identical degradation as the samples with MoO_3 shown in Fig. 6. This indicates that the hygroscopy of PEDOT:PSS clearly accelerates device degradation in the first phase of the degradation.

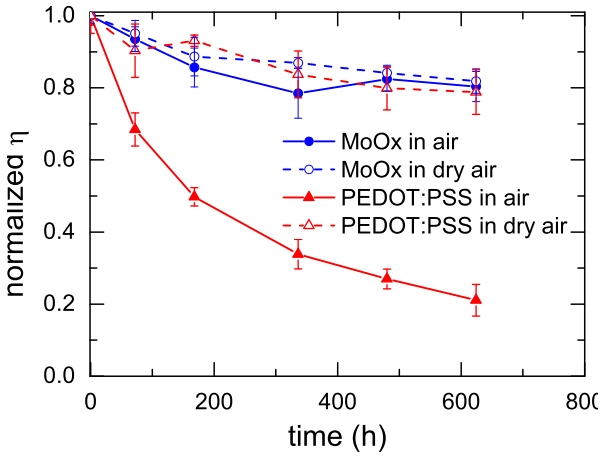

Fig. 6. Normalized efficiency degradation of devices with either PEDOT:PSS (red triangles) or MoO_3 (blue circles) as hole transport layer in ambient conditions (∼35% RH) and dry air (⩽5% RH). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Additionally, the negligible difference of the presence of humidity on the samples with MoO_3 proves the stability of the active layer and the metal cathode even in presence of moisture. Krebs et al. similarly observed that standard devices degrade faster in presence of humidity, while inverted devices interestingly behave opposite [33,34].

As a conclusion of these experiments we can extend the description of the degradation mechanism: the hygroscopic PEDOT:PSS attracts ambient humidity and enables its diffusion under the electrodes. The release of this absorbed water towards the highly reactive metal cathode leads to the rapid oxidation of the cathode. In addition, low work function metals are known to be more reactive towards humidity than oxygen. Without this additional pathway for moisture diffusion, the metal cathode oxidizes at a considerably lower pace, as the thick Al layer proves to be a good barrier.

3.4. Edge diffusion

Interestingly, humidity infiltration can be visually observed in our devices as shown in the pictures of Fig. 7a. Optical microscope images observed through the glass substrate show the intersection of the ITO lines with the Yb/Al cathodes. We distinguish a progressive color change from the edges towards the inner regions. The inner regions, with a darker color, are the electrically active zones, while the outer brighter regions do not contribute to the current, as shown by illumination masking. This visual aspect of the degradation permits to correlate the degradation in J_{SC} to the decrease in active area. As presented in Fig. 7a, the J_{SC} degradation is directly proportional to the shrinking area. In devices without PEDOT:PSS, a similar color change is observed from the edges at a considerably lower progression rate. Alteration of the device stacks color can be ascribed to different origins: oxidation of the metal cathode, change in the optical properties of the organic layers or humidity infiltration. We could exclude the first reason by detecting a similar color change in samples with Au/Al cathode. Furthermore UV–vis absorption did not allow us to detect any alteration of the transmission of the organic layers exposed to air. Another reason to this color change could be the de-doping of the PEDOT:PSS layer, but we neither observe the degradation of its electrical properties nor arousal of a characteristic absorption peak around 620 nm [35]. Direct proof of humidity infiltration from the edges was found by biasing the samples at high reverse voltage: indeed, this treatment resulted in bubble formation in the outer region of the active areas, exactly where the color change occurred (see Figs. S8 and S9 in the Supplementary information). Such bubble formation was reported in OLEDs to be due the electrolysis of water leading to gas formation, which then diffused to the organic/metal interface and formed dome-like structures [36,37].

These visual observations prove that the metal cathode is an effective barrier to humidity diffusion, with most entering via the edges. Therefore, increasing the perimeter

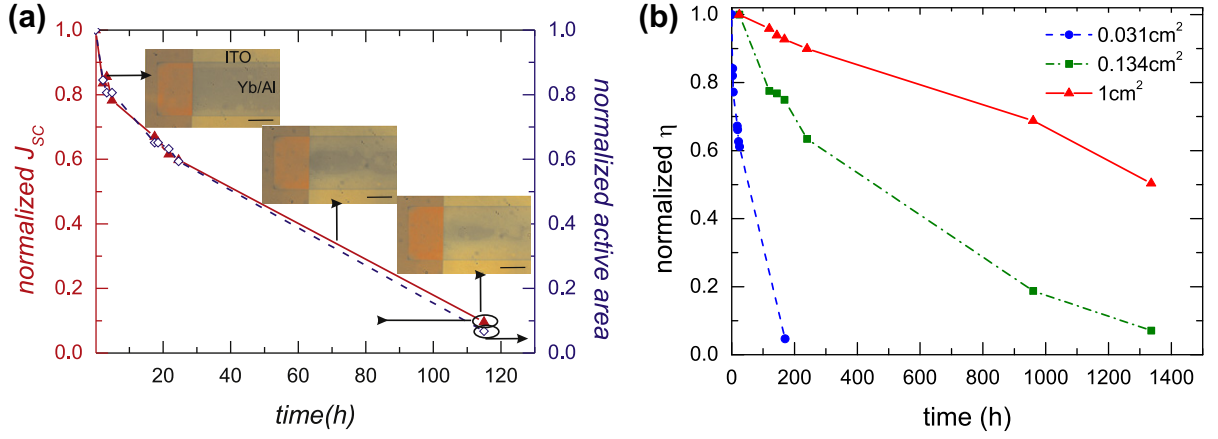

Fig. 7. (a) Normalized current density (red triangles) degradation on standard devices with 0.031 cm^2 active area, correlated with simultaneous active area degradation (blue diamonds). The scale bars correspond to 0.5 mm on the optical microscope images. The active area degradation is estimated from the microscope images, where the inner darker region is the electrically active zone. (b) Normalized efficiency degradation on standard devices with three different active areas: 0.031 cm^2 (blue circles), 0.134 cm^2 (green squares) and 1 cm^2 (red triangles) in ambient conditions. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

versus active area ratio can considerably enhance device lifetime as presented in Fig. 7b. Identical reference devices are fabricated, where the active device area is scaled by varying the size of the metal cathode and the ITO lines. Device lifetime increases from a few hours to hundreds of hours by simply scaling the device area from 0.03 to 1 cm^2. Furthermore, one should also note that infiltration through pinholes is not fully negligible; hence particle-free processing is also indispensable for reproducibly enhanced device stability. Moreover, this detailed assessment of the most relevant processing and experimental parameters on device degradation can also explain the origin of the variations in lifetime reported on similar devices by different research groups.

3.5. Accelerated shelf-life test

The in-depth understanding of the degradation mechanism in these conditions not only enables stability improvements, but also the definition of adequate accelerated testing conditions. For example, the ageing conditions applied in this study could be well-suited for separate evaluation of device encapsulation. Indeed, there is a direct correlation between the lifetime of standard samples exposed to ambient atmosphere in dark and the quality of the encapsulation against water vapor ingress. Our standard samples stored in nitrogen exhibit a lifetime of over 4000 h at room temperature [38]. As humidity proves to be the dominant stress factor, we investigated its impact on device lifetime. Standard samples were placed in a closed container in presence of saturated salt solutions imposing a precise humidity level. As presented in Fig. 8. Device lifetime decays exponentially with the humidity level at ambient temperature for both PEDOT:PSS and MoO_3 as HTLs. We assume that the water vapor ingress that explains the reduced lifetime with increasing humidity for MoO_3 HTL is to be located at the organic/metal interface

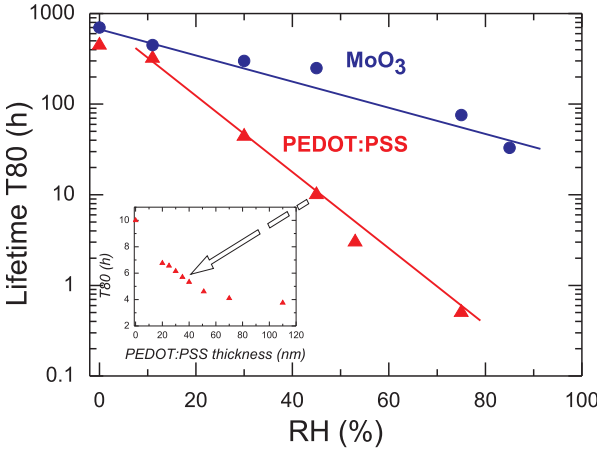

Fig. 8. Lifetime (T80) of reference samples at different humidity levels is extracted from degradation curves for devices both with PEDOT:PSS (red triangles) and MoO_3 (blue circles). The lines serve as guide to the eye. Inset: Lifetime as a function of the PEDOT:PSS layer thickness in standard devices at 42% RH. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

and to some pinholes in the metal cathode. At very low humidity levels ($\leqslant$10%), solar cells with PEDOT:PSS HTLs exhibit comparable results as MoO_3-based HTLs. At higher humidity levels, an additional diffusion mechanism seems to be activated in the case of PEDOT:PSS HTL, which is the penetration of water vapor through this HTL as shown in the previous sections. We obtained further proof of this additional pathway by scanning transmission electron microscopy (STEM) coupled with electron energy-loss spectroscopy (STEM–EELS), as an increased oxygen atom concentration was reproducibly detected only in samples that contained PEDOT:PSS and were previously exposed to air. Although the EELS data cannot distinguish between oxygen in water or other bonded state, we suppose it is a signature of the incorporation of water. To control this observation, we also analyzed samples with PEDOT:PSS and MoO_3 stored in nitrogen and in air, respectively, but none of them contained oxygen in the organic layers.

The above quantitative analysis establishes humidity as an acceleration factor for the shelf-life of devices having a low work function cathode, in our case OPV cells. Moreover, derived from the detailed understanding of the degradation mechanism, we equally identified PEDOT:PSS thickness as an acceleration factor. As presented in the inset of Fig. 8, on identical devices where only the thickness of PEDOT:PSS is varied the lifetime increases from 3 to 7 h when the thickness is scaled from 100 to 20 nm. A sample without HTL layer is represented as reference value at 0 nm. This trend obviously implies that the thickness of the PEDOT:PSS layer should be minimized, if it is not replaced by another material.

4. Conclusions

We found that the short-circuit current density degradation in devices exposed to air stems from hindered charge extraction at the cathode-organic interface. This conclusion is drawn from a set of experiments including delamination of the cathode of a degraded device and subsequent redeposition of a fresh one, in which case the initial electrical performance could be recovered. We further relate the degradation primarily to oxidation of the low work function metal cathode and we could exclude the degradation of the PEDOT:PSS layer and its associated interfaces. However, PEDOT:PSS greatly accelerates cathode oxidation due to its hygroscopic nature and it is found to promote infiltration of humidity from the device edges. Consequently this HTL layer renders conventional polymer solar cells extremely sensitive to moisture. We established an exponential relation between device lifetime and increasing humidity levels.

This detailed understanding of the degradation mechanism of OPVs in ambient atmosphere has several major implications. First, it guides further device and material optimization. Here we presented a vacuum deposited MoO_3 as an alternative HTL to enhance device stability, but recently introduced solution processed oxide layers seem also promising alternatives [39,40]. It further indicates that selection of low work function metals whose oxide is semiconducting with a conduction band close to the lowest unoccupied molecular orbital of the PCBM

may also lead to improved device stability [41,42]. Second, we propose adapted accelerated testing conditions to evaluate barrier layers and device encapsulation. The high sensitivity of the conventional device structure to moisture even at room temperature makes this ageing condition better suited than damp heat tests, where several mechanisms are activated simultaneously.

the sputter-patterned ITO edges. Such an insulating organic molecule is preferred to have low carrier (both electron and hole) mobility. It is demonstrated that the reverse current density of OLEDs based on this scheme is comparable to that of photolithography-patterned ITO-based OLEDs.

2. Results and discussion

For a comparative study, we have used two different ITO-coated glass substrates. One was purchased from Shinan SNP Co. Ltd., showing the sheet resistance of 12 Ω/□. The other one was fabricated using a sputtering deposition system (SUNICOAT-IS3000, SUNIC SYSTEM) under the DC power of 500 W and at the substrate heater temperature of 250 °C. The sputtered ITO at the rate of 2.3 Å/s exhibits the sheet resistance of 17 Ω/□. The commercial ITO was patterned using the standard photolithography process with or without a patterned polyimide insulation layer (TORAY, Photoneece™ DL-1602). In this paper, a device fabricated based on this method is referred to as a photolithography-patterned and insulator-coated (or insulator-uncoated) ITO-based OLED (PP/IC-OLED or PP/IU-OLED). Meanwhile, the sputtered ITO was patterned using a metal open mask during deposition. To make a comparison with PP/IC- and PP/IU-OLEDs, the sputter-patterned ITO edges were covered with the patterned polyimide insulation layer (Fig. 1(a)). A device fabricated based on this method is named as a sputter-patterned and insulator-coated ITO-based OLED (SP/IC-OLED), whereas a device fabricated based on this method with the insulator excluded is named as a sputter-patterned and insulator-uncoated ITO-based OLED (SP/IU-OLED) (Fig. 1(b)). In replacement of the polyimide insulation layer, thermally evaporated insulating organic molecules can be employed to cover the sputter-patterned ITO edges. A device fabricated based on this method is referred to as a sputter-patterned ITO-based and insulator-evaporated OLED (SP/IE-OLED) (Fig. 1(c)). In the SP/IE-OLED configuration, the insulating organic layer can be evaporated either right on the ITO edges or right before the cathode layer. It is noted that the insulating organic molecule evaporated right on the ITO edges should have low hole mobility (i.e., blocking hole injection), whereas it should have low electron mobility when evaporated right before the cathode (i.e., blocking electron injection).

We have fabricated phosphorescent green OLED devices that consist of a 10-nm-thick LG-101 for a hole injection layer (HIL), 25-nm-thick 4,4′-bis[*N*-(1-nathyl)-*N*-phenylamino]biphenyl (NPB) for a hole transport layer (HTL), 25-nm-thick 4,4′-*N*,*N*′-dicarbazolylbiphenyl (CBP) doped with tris(2-phenylpyridinate) iridium(III) ($Ir(ppy)_3$, 8 wt.%) for an emitting layer (EML), 10-nm-thick m-bis-(triphenylsilyl)benzene (UGH3) for a hole/exciton blocking layer (HBL), 30-nm-thick (2,9-dimethyl-4, 7-diphenyl-1, 10-phenanthroline) (Bphen) for an electron transport layer (ETL), 1-nm-thick lithium fluoride (LiF) for an electron injection layer (EIL), and 100-nm-thick aluminum (Al). In SP/IE-OLEDs, NPB is used as an insulating material, which has very low electron mobility ($\sim 1 \times 10^{-8}$ cm^2/Vs) [13]. The sheet resistance, surface roughness, and cross-sectional image of ITO were measured by aging package (Mcscience Polaronix, M6101), atomic force microscopy (AFM, XE-200 system, PSIA), and field emission scanning electron microscope (FE-SEM, Quanta 200FEG, FEI Co.), respectively.

As depicted in Fig. 1, the width of the photolithography- and sputter-patterned ITOs is 4 mm. The Al cathode has the same width as the patterned ITO anode. Insulator-coated ITO-based OLEDs (PP/IC- and SP/IC-OLEDs) have the emission area of 2×2 mm. Meanwhile, insulator-uncoated ITO-based OLEDs (PP/IU- and SP/IU-OLEDs) have the emission area of 4×4 mm. As such, the leakage

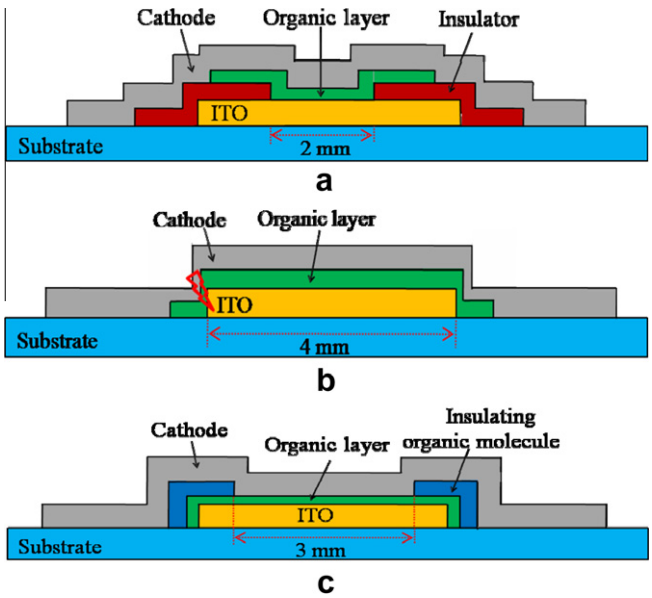

Fig. 1. Cross-sectional view of (a) SP/IC-OLED, (b) SP/IU-OLED, and (c) SP/IE-OLED structures.

current is expected to occur on the slope of the ITO edges. In SP/IE-OLEDs, the insulating NPB layer is deposited before the Al cathode, with the width of 1 mm centered at the ITO edges and with the length of 5 mm. Therefore, the emission area of SP/IE-OLEDs is as large as 3×4 mm. It is noteworthy that as the emission area of those devices is all different, a direct comparison should be made at the same current density or the current density instead of the current should be considered.

Shown in Fig. 2(a)–(c) are the images of green light emission from those devices (SP/IC-, SP/IU-, and SP/IE-OLEDs) when the current density is 10 mA/cm^2. It is clearly seen to the naked eye that the SP/IE-OLED has smaller emission area (3×4 mm) than the SP/IU-OLED (4×4 mm), indicating that the insulating organic molecule prevents the current flow effectively near the ITO edges. Fig. 2(d) shows the current efficiency of those devices as a function of the current density. Summarized in Table 1 are the luminance and current efficiency of those devices at a current density of 10 mA/cm^2. As expected, the PP/IC-OLED is shown to have the highest luminance (6114 cd/m^2) and current efficiency (54 cd/A). A small reduction (2 cd/A) in the current efficiency appears on the PP/IU-OLED due possibly to increased leak channels. Though the emission area is increased four times, yet the leakage current is little increased for photolithography-patterned ITO-based OLEDs. Meanwhile, the SP/IC-OLED shows slightly lower current efficiency (51.2 cd/A at 10 mA/cm^2) than the PP/IC-OLED. It may arise from the fact that the sheet resistance (17 Ω/□) of the sputtered ITO is higher than that (12 Ω/□) of the commercial ITO. However, the current efficiency is substantially reduced (39.6 cd/A at 10 mA/cm^2) in the SP/IU-OLED. Considering that the emission area of the SP/IU-OLED is the same as that of PP/IU-OLED, such a large

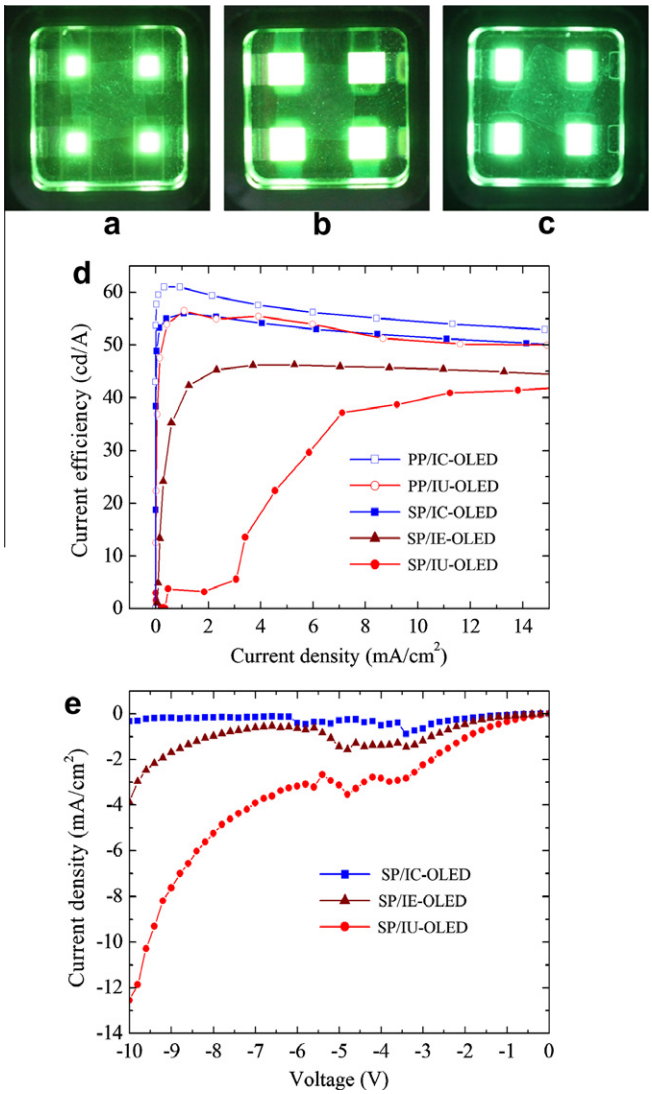

Fig. 2. Images of green light emission from (a) SP/IC-OLED, (b) SP/IU-OLED, and (c) SP/IE-OLED at 10 mA/cm^2, (d) measured current efficiency versus current density, and (e) reverse current density versus bias voltage. The insulating organic (NPB) layer of SP/IE-OLED is as thick as 50 nm.

Table 1
Measured luminance and current efficiency of those devices at a current density of 10 mA/cm^2.

@10 (mA/cm^2)	PP/IU OLED	PP/IC OLED	SP/IU OLED	SP/IC OLED	SP/IE OLED
Luminance (cd/m^2)	5837	6114	4062	5685	4983
Current efficiency (cd/A)	52	54	39.6	51.2	45.4

reduction (52 cd/A → 39.6 cd/A) in the current efficiency is due most likely to the rough surface state of the ITO edges. From the results in Fig. 2(d), we can see that the leakage current can be suppressed to a great extent by evaporation of insulating organic molecules (SP/IE-OLED), especially at low current density (<10 mA/cm^2) or below the luminance of 5000 cd/m^2.

The leakage current is further demonstrated by measuring the current density of those devices under the reverse

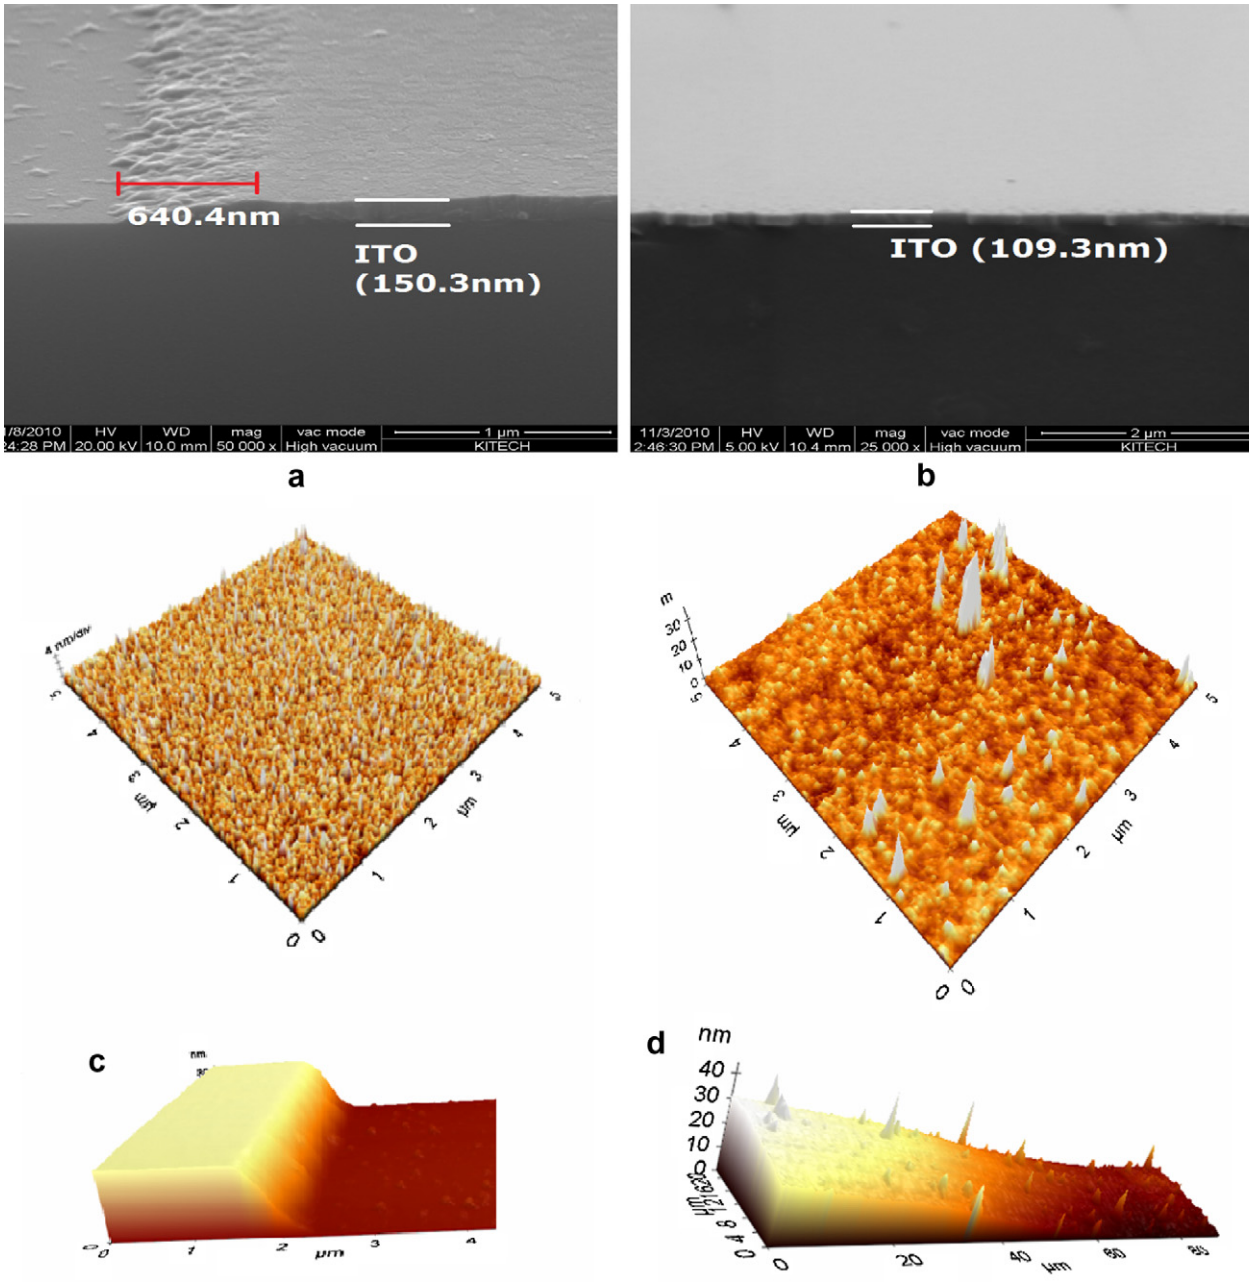

Fig. 3. FE-SEM images of (a) photolithography-patterned ITO and (b) sputter-patterned ITO and AFM images of (c) photolithography-patterned ITO and (d) sputter-patterned ITO (scanning area of 5 × 5 μm).

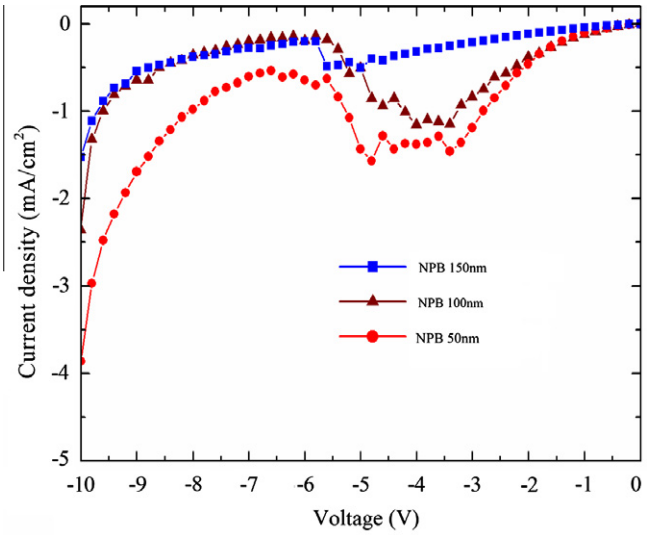

Fig. 4. Measured reverse current density of SP/IE-OLEDs for different thicknesses of insulating NPB molecule.

bias condition (from 0 V to −10 V). As shown in Fig. 2(e), significant leakage current occurs in the SP/IU-OLED device. Such leakage current is substantially suppressed in the SP/IE-OLED device. The reverse current density of SP/IC-OLED, SP/IE-OLED, and SP/IU-OLED is measured to be 118 μA/cm^2, 537 μA/cm^2, and 3.6 mA/cm^2, respectively, at the reverse bias voltage of 6.6 V. Within the range between 0 V and −7 V, the reverse current density of SP/IE-OLED is comparable to that of SP/IC-OLED, indicating that the insulating organic molecule prevents the flow of leakage current as effectively as the polyimide insulation material.

It appears that the leakage current is highly related with the surface morphology of ITO, especially on the slope of the ITO edges. To investigate it, we have measured the cross-sectional image and the surface morphology of the patterned ITOs and presented the results in Fig. 3. It was observed that the photolithography-patterned ITO has a very steep slope (the slope length is about 0.64 μm), whereas the sputter-patterned ITO has a very gentle slope (the slope length is about 400 μm). The gentle slope of the sputter-patterned ITO edges is induced by the spatial distance (5.5 cm) between the metal open mask and the substrate in the in-line sputter. The slope length could be reduced further by placing them more closely. Due to their gentle slope, we are capable of measuring the surface morphology of the sputter-patterned ITO on the slope of the ITO edges, though the whole ITO slope cannot be measured by FE-SEM. The SEM image in Fig. 3(b) was measured on the sputter-patterned ITO slope. It is likely that the ITO thickness (109.3 nm) measured on the slope is a little smaller than that (150 nm) on the flat surface. Meanwhile, we have measured the surface morphology of the photolithography-patterned ITO near the ITO edges. From Fig. 3(c) and (d), grain structure of ITO surfaces are clearly confirmed. It is evident that many rugged regions appear on the sputter-patterned ITO slope during the sputtering process. While the surface morphology of the photolithography-patterned ITO is good, with a root mean square roughness (R_{rms}) of 1.13 nm and peak to valley roughness (R_{pv}) of 10.01 nm, the surface roughness of the sputter-patterned ITO is poor, with R_{rms} of 1.837 nm and R_{pv} of 39.028 nm. A high R_{pv} indicates the existence of spikes. In Fig. 3(d), several spikes that have very large height were observed. Spike-like surface induces more injection of holes into the device, which may increase the chance of causing a short-circuit problem. It is known that R_{pv} rather than R_{rms} directly affects a leakage current under reverse bias condition [14,15]. Therefore, more leakage current appears in SP/IU-OLEDs due to high R_{pv}. In other words, non-emissive current component exists at the rugged edges of the electrode. Another cause for the occurrence of more leakage current in SP/IU-OLEDs lies in the gentle slope of the patterned ITO edges (i.e., broader spiky surface). Since the surface morphology of the photolithography-patterned ITO is relatively good, it was found that the current efficiency of the PP/IU-OLED was comparable to that of the PP/IC-OLED (Table 1).

With attempt to investigate further the effect of the insulating organic layer on the leakage current of SP/IE-OLEDs, we have varied its thickness and measured the reverse leakage current. As shown in Fig. 4, less leakage current occurs with increasing insulating organic layer thickness. It indicates that thicker insulating organic layer prevents more effectively the flow (or injection) of electrons through (into) the slope of the ITO edges. It is noteworthy that any organic molecules such as hole injecting, hole transporting, and electron transporting materials can be used as an insulating material given that their electron or hole mobility is low enough to suppress leakage current. Ideally, organic molecules that have both low electron and hole mobility are preferred. This scheme allows us to implement an in-line type organic evaporation system that does not require any photolithography process, thereby bringing in a reduction of a tact time and fabrication cost.

3. Conclusion

We have shown that, without a standard photolithography process, ITO can be patterned by a sputtering deposition and thermal evaporation of an insulating organic molecule. OLEDs based on this scheme exhibit much less leakage current, which is even comparable to that of photolithography-patterned ITO-based OLEDs. The most salient feature of this technique is that it is applicable to in-line type organic evaporation system, a reduction of fabrication cost by which is feasible.

and biological sensing has been demonstrated by an integrated semiconductor device consists of an excitation source, a photo detector (PD), and a sensing unit [8]. So far, the integrated semiconductor devices were used to detect glucose [9] and oxygen [8,10]. A sensor specific to NO has not been realized mainly because there is no sensing film for NO. In our recent work, a NO sensing hydrogel film was demonstrated possessing high selectivity, sensitivity, and stability in various pH values which could be used as the sensing unit for NO [11]. But so far no trial has been done to use the NO sensing film as the sensing unit. Besides, to miniaturize the integrated semiconductor device, a small-sized organic light-emitting diode (OLED) was used in glucose [9] and oxygen [8,10] sensor. However, the NO sensing film was characterized with a solid-state laser diode module as an excitation source, and no work has been done to show the NO sensing characteristics using OLED as an excitation source. Furthermore, unlike the laser with narrow emission spectrum, the emission spectrum of the OLED excitation light is broad, and hence the separation of reflected excitation light and the emission of the sensing unit is important in order to reduce the influence of the tail of excitation light on the emission of the sensing unit. However, optical filters based on glass substrate is conventionally used which is expensive and occupies volumes [8–10]. Light separation was never achieved in an easy way.

In this work, a NO sensor is realized for the first time by integrating a sensing hydrogel film specific to NO with a top-emitting polymer light-emitting diode (PLED), silicon (Si) PD, and two organic filters as shown in Fig. 1(a). The top-emitting PLED is used to excite the sensing hydrogel film, and the small-sized Si PD is used to detect the photoluminescence (PL) of the sensing hydrogel film. The influence of the tail of excitation light on the emission of the sensing unit is reduced by using two organic filters. Filter 1 is deposited above the transparent cathode of the top-emitting PLED to filter out the wavelength of the excitation light around the emission peak of the sensing hydrogel film. Filter 2 is placed in front of the Si PD to remove the light other than the sensing hydrogel film. The sensing film specific to NO developed in our group [11] is utilized as the sensing unit. The PL of the NO sensing hydrogel film changes after adsorbing NO, and such change in PL can be monitored by Si PD. Light signal is therefore transformed into electric signal for recording. Real-time and indicator-free detection of NO is demonstrated. All components except the NO sensing film can be sealed inside a water-proof container with electrical feedthroughs for driving PLED and monitoring photocurrent outputs from Si PD. The photocurrent response with response time within 5 min is demonstrated. In practice, after each usage, the sensing hydrogel film is the only component that needs to be replaced.

2. Experimental

Top-emitting PLED is fabricated on cleaned glass substrate. Schematic device structure and the image of the top-emitting PLED under forward bias are shown in Fig. 1(b) and (c), respectively. Aluminium (Al)/molybdenum oxide (MoO_3)/poly(3,4-ethylenedioxythiophene):

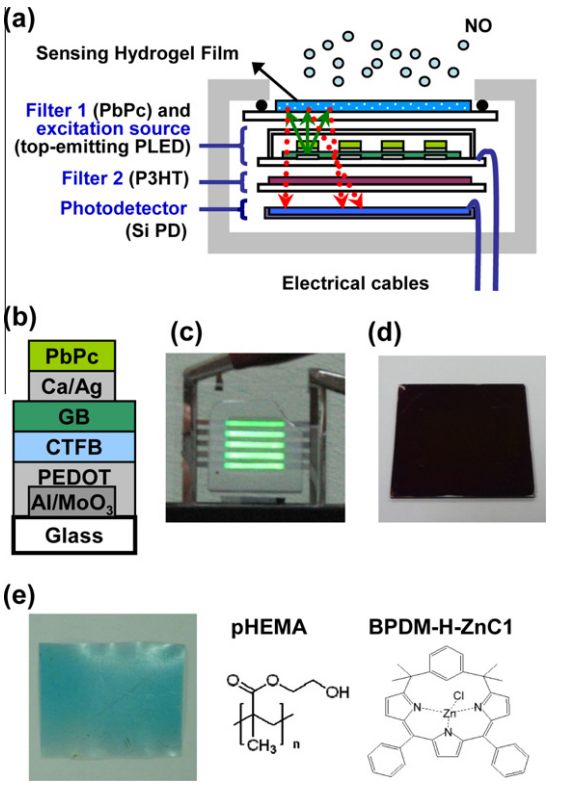

Fig. 1. (a) The schematic structure of the sensor integrated with a sensing hydrogel film, a top-emitting PLED, a Si PD, and two organic filters. (b) Device structure of the top-emitting PLED. PbPc is deposit on transparent cathode serving as filter. (c) Photograph of the top-emitting PLED. (d) Photograph of the P3HT filter. (e) Photograph of the sensing hydrogel film composed of pHEMA and BPDM–H–ZnC1. Molecule structures of pHEMA and BPDM–H–ZnC1 are also shown.

poly(styrenesulfonate) (PEDOT:PSS) is used as an opaque anode. A striped-type shadow mask is used for preparing Al (100 nm) and MoO3 (3 nm). PEDOT:PSS (CLEVIOS^{TM} P VP AI 4083) of 40 nm is then spin coated and annealed at 200 °C for 15 min. On top of the PEDOT:PSS surface, the PLED structure is cross-linkable TFB (20 nm)/Green B (65 nm)/Ca (10 nm)/Ag (15 nm)/PbPc (200 nm). The hole transport layer of cross-linkable poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(4,4′-(*N*-(p-butylphenyl))diphenylamine)] (CTFB) (in toluene) is formed by spin coating and then baked at 180 °C for 60 min. The emitting layer is also formed by spin coating polyfluorene derivative LUMATION Green B (GB) by Dow Chemical (in toluene) and then baking at 130 °C for 30 min. The transparent cathode Ca/Ag and lead phthalocyanine (PbPc) are deposited with striped-type shadow mask. Each active area is about 1 mm × 10 mm, and the width of gap between each active area is 1 mm. During the real-time detection, the luminescence of the top-emitting PLED is kept at 1600 cd/m^2. Fig. 1(d) shows 250 nm poly(3-hexylthiophene) (P3HT) Filter 2 prepared by drop casting P3HT dichlorobenzene solution on glass substrate. The sensing hydrogel film is a blend of host polymer poly(2-hydroxyethyl methacrylate) (pHEMA) and fluorescent probe 11,16-bisphenyl-6,6,21,21-tetramethyl-*m*-benzi-6,21-porphodimetheno-chloro-Zinc(II)

(BPDM–H–ZnCl). The image of the sensing hydrogel film and molecular structures of pHEMA and BPDM–H–ZnCl are shown in Fig. 1(e). BPDM–H–ZnCl (2 mg) is first dissolved in a mixture (10 ml) of 2-hydroxyethyl methacrylate (HEMA), ethylene glycol dimethacrylate (EGDMA), and azobisisobutyronitrile (AIBN), and then the blending solution is poured into a Teflon cell and annealed at 80 °C for 10 min to form a film of 180 micrometer. HEMA is used as a hydrophilic monomer, EGDMA is used as a hydrophobic cross-linker, and AIBN (1%) is used as thermal initiator. HEMA is blended with EGDMA in the weight ratio 12:1. BPDM–H–ZnCl is synthesized from *m*-benziporphodimethene based molecule.[12] The real-time detection of NO is carried out with a polydimethylsiloxane (PDMS) microfluidic system.[13] The dimension of the channel is $30 \times 15 \times 1$ mm (length × width × height). The PDMS with a sheet of sensing hydrogel film in the channel is sealed with a glass slide. Fluid inlet and outlet are located at two ends of the channel. NO bubbled water is prepared by bubbling 1000 ppm NO (in N_2 carrier gas) into DI water for 1 h. The electroluminescence (EL) spectra and current–luminance–voltage (*I–L–V*) characteristics of top-emitting PLED are measured by a Photo Research PR650 spectrophotometer integrated with Keithley 2400 multi-meter. Absorption spectra are recorded by Hewlett–Packard 845X UV–visible system. Emission spectrum of sensing hydrogel film is monitored by high resolution fiber optic spectrometer (EPP2000, StellarNet). Si PD (S2387, Hamamatsu Photonics), sensitive from visible light to infrared light, is biased at −10 V by Keithley 2400 multi-meter to monitor the photocurrent. In some experiment, 405 nm laser diode (Power Technology) is used to excite sensing hydrogel film.

3. Results and discussion

The selectivity of BPDM–H–ZnC1 is demonstrated in Fig. 2(a) and (b). Various gases are bubbled into 2×10^{-6} M BPDM–H–ZnC1 acetonitrile solution for 2 min. No dramatic difference in PL spectrum can be observed after bubbling oxygen (O_2), carbon dioxide (CO_2), and carbon monoxide (CO). A decrease in PL is observed only after bubbling NO. BPDM–H–ZnC1 is specific to NO and it does not react with O_2 and CO_2 in the atmosphere and another important signalling molecule CO. In addition, since nitrate (NO_3^-) and nitrite (NO_2^-) are end products of NO metabolism, nitrate donor (PPN(NO_2)) (PPN: bis(triphenylphosphine)iminium) and nitrite donor (PPN(NO_3)) are added into BPDM–H–ZnCl solution to test the influence of nitrate and nitrite on the PL intensity. Hydrogen peroxide (H_2O_2), another free radical in human body, is also tested. *S*-nitroso-*N*-acetylpenicillamine (SNAP) is used as NO donor. The molecule structures of SNAP, PPN(NO_2) and PPN(NO_3) are shown in Fig. 2(c). Concentrations of donors are all 10^{-3} M. Except the SNAP, no one can induce continuing decrease in PL as shown in Fig. 2(b). This demonstrates the BPDM–H–ZnCl is highly selective which makes it a reliable reagent for future applications in biological systems.

As shown in Fig. 3(a), NO sensing characteristics of the hydrogel film are first demonstrated by using a microfluidic system and 405 nm laser as excitation source. The sensing hydrogel film is initially settled in deionized (DI) water in the microfluidic channel with stable PL at 675 nm. The PL spectrum of the sensing hydrogel film is similar to the one of BPDM–H–ZnC1 solution which means BPDM–H–ZnCl probe functions well even after being trapped in pHEMA. Dramatic decrease in PL of the sensing hydrogel film can be observed when the NO bubbled water is injected into the microfluidic channel at 16th and 51st minute. The changing in PL stops after refilling the channel with DI water at 36th and 66th minutes. These characteristics show that the sensing hydrogel film is suitable for real-time and indicator-free detection.

To separate excitation light and the emission light, the first step is to filter the EL of the top-emitting PLED to form

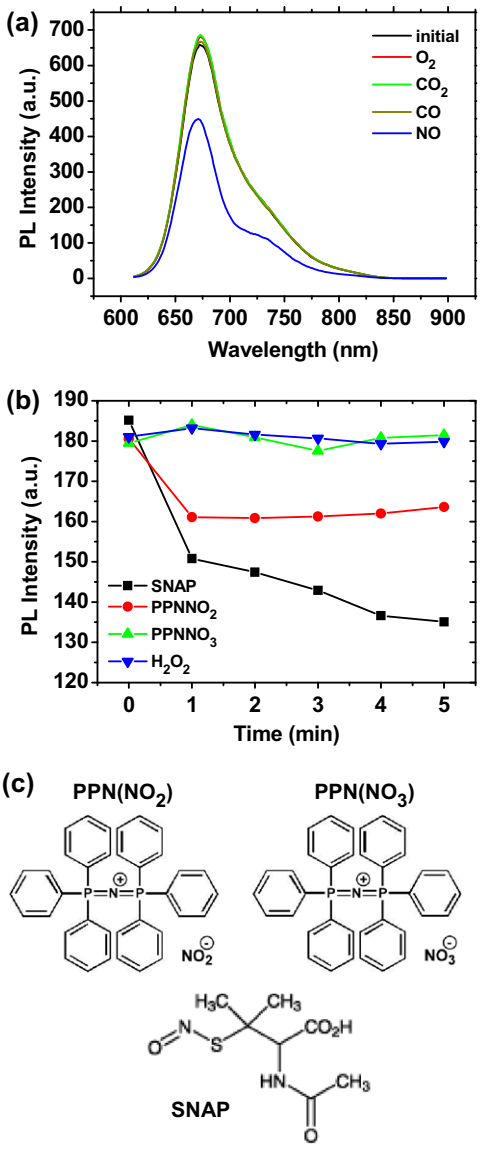

Fig. 2. (a) The PL spectra after bubbling different gases. (b) The PL intensities at 675 nm vary with time after adding different molecules. (c) The molecule structures of SNAP, PPN(NO_2) and PPN(NO_3).

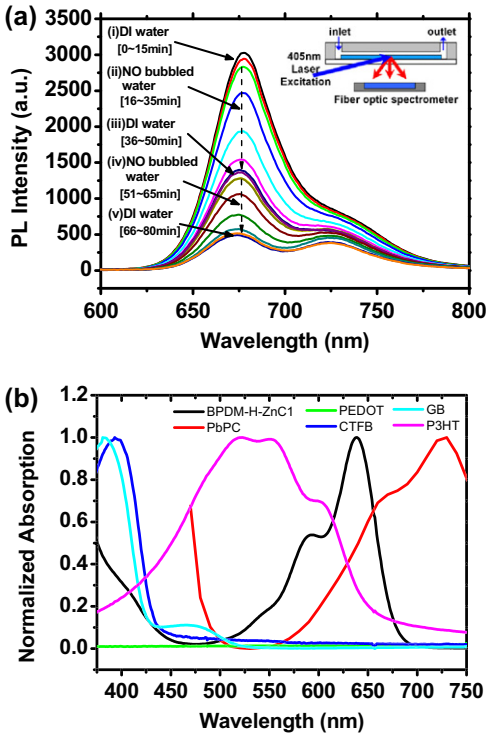

Fig. 3. (a) The PL spectra of the sensing hydrogel film placed in microfluidic channel. The inset shows the experimental setup. DI water or NO bubbled water is injected into microfluidic channel at different time. (b) Normalized absorption spectra of BPDM–H–ZnC1, PbPc, PEDOT, CTFB, GB, and P3HT.

an excitation light without the wavelength overlaps the emission of the sensing hydrogel film. Organic material PbPc is therefore deposited on top-emitting PLED as Filter 1 since it absorbs light above 600 nm with an absorption peak at 730 nm as shown in Fig. 3(b). Besides, PbPc is almost transparent for the light between 500 and 570 nm, and the emission of top-emitting PLED with PbPc on transparent cathode in that range can pass PbPc for excitation without large light intensity attenuation. Fig. 4(a) shows the EL spectra of top-emitting PLED with or without covering PbPc. The EL spectrum of the top-emitting PLED without PbPc ranges from 500 to 700 nm. Deposition of 200 nm PbPc on top-emitting PLED narrows its spectrum range and almost no emission around 675 nm can be observed. This ensures the 675 nm light that Si PD received comes mostly from the BPDM–H–ZnC1 fluorescent NO probe in the sensing hydrogel film. The luminescence and current efficiency of the top-emitting PLED with or without PbPc are shown in Fig. 4(b). Although both luminescence and current efficiency are decreased for the top-emitting PLED with PbPc filter because part of the emission is absorbed, stable current efficiency with maximum of 5.8 cd/A at 7 V can still be obtained. The luminescence at 7 V is 1600 cd/m^2 which is enough for this integrated semiconductor device.

The second step to separate excitation light and the emission light is to remove the rest of excitation light. As shown in Fig. 5(a), the spectrum shows two apparent peaks at 535 nm and 680 nm as P3HT Filter 2 is absent. Since each material used in top-emitting PLED does not have apparent absorption above 500 nm, the PL of the sensing film as well as the reflected excitation light can pass though the gaps between active areas of top-emitting PLED and received by Si PD without large light intensity attenuation. Except the PL of the sensing hydrogel film, the reflected excitation light can also be detected. In the presence of P3HT Filter 2 which absorbs most of the visible light below 650 nm, the reflected excitation light can be removed. However, the absorption of P3HT filter above 650 nm is not zero, and hence the emission from sensing hydrogel film also decreased a little but still detectable. The P3HT filter used in this work is deposited on a glass substrate and placed in front of Si PD to demonstrate its function. In practice, the P3HT filter can be deposited on Si PD or on the bottom of the PLED glass substrate for space saving.

After the separation of the excitation light and emission of the sensing hydrogel film is achieved, the change in photocurrent outputs from Si PD may represent mostly the change in PL of the sensing hydrogel film. Fig. 5(b) shows the real-time and indicator-free detection of NO by an integrated semiconductor device consisting of a sensing hydrogel film, a top-emitting PLED with PbPc filter, and a Si PD covered with P3HT filter. The photocurrent curve is smoothed by taking the average of 40 data points around each point as shown in Fig. 5(c). The photocurrent output from Si PD remains at almost the same value until the NO bubbled water is injected into the microfluidic channel. The photocurrent ceases to descend as DI water is refilled

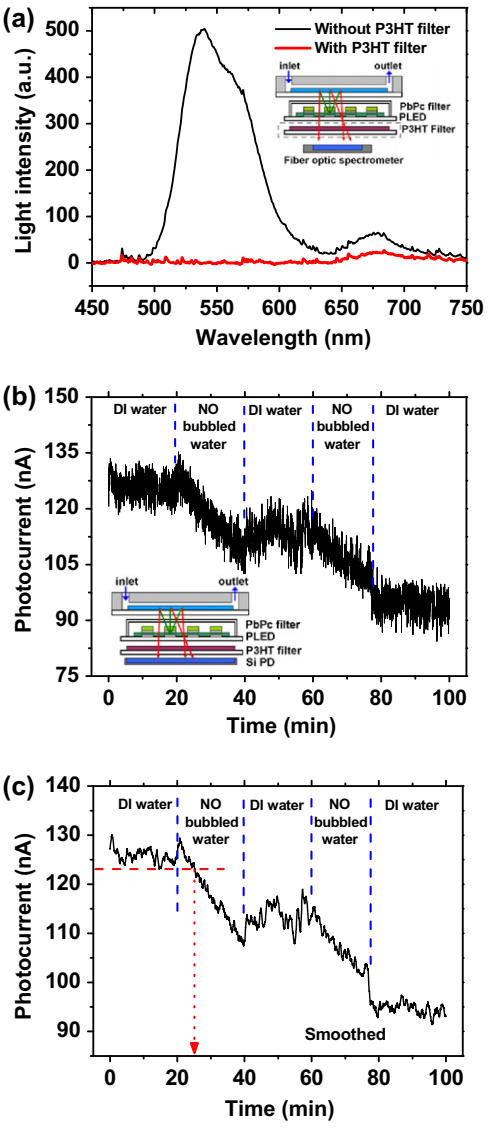

Fig. 5. (a) Spectra of the light received by Si PD with or without P3HT filter placed in front of it. (b) The photocurrent response to different environment. (c) The photocurrent response is smoothed for clarity.

into the microfluidic channel. The decrease in photocurrent corresponds to the decrease in PL intensity of the sensing hydrogel film as shown in Fig. 3(a). This is the first time that aqueous NO can be detected by an integrated solid-state optoelectronic sensor in a real-time and indicator-free manner. The NO concentration is estimated to be in the order of 10^{-3} M since it has been reported that NO solubility in oxygen-free water is 1.9 mM at 25 °C [7]. It has been demonstrated in our previous work that a higher NO concentration leads to a larger PL variation in the same time interval [11]. The slopes of the photocurrent obtained from the photocurrent vs. time plot are different for various NO concentrations. The slope of the photocurrent is therefore used to indicate the NO concentration, and the response time is the time needed for the slope of the photocurrent changes to another value and the photocurrent exceeds the noise level. Although immediate slope change is observed within few seconds after injecting NO bubbled water as shown in Fig. 4(c), the response time is still estimated to be 5 min which is determined by the time needed for the PD to output an photocurrent lower than the noise level. The response time can be improved by increasing the signal-to-noise ratio and enhancing the fluorescence of the NO probe. Increasing the surface area of the sensing film may also help. The realization of this integrated optoelectronic sensor makes the real-time and indicator-free detection of NO possible for the first time. Such a small-sized sensor is suitable for long-term and portable detection of NO, and it is a help to understand the relation between NO and physiological changes.

4. Conclusion

In conclusion, real-time and indicator-free detection of nitric oxide is achieved by an integrated semiconductor optoelectronic device consisting of a sensing film, an excitation source, and a photodetector. The influence of the excitation light on the output current of the photodetector is diminished by utilizing two organic filters. One filter is deposited above a top-emitting PLED to produce an excitation light without overlapping the emission maximum of the sensing hydrogel film. The other filter is placed in front of photodetector to prevent the excitation light get into the photodetector. The photocurrent changes as NO enters the environment and the response time is 5 min. Such integrated solid-state device is compact, small-size, and portable which can be used in fundamental research and clinical diagnosis.

need of further improvements. Hence, phosphorescent organic emitters are typically employed to efficiently utilize the triplet excitons and thus increase the radiative recombination [4]. Compared with fluorescent emitters, due to the short range of the Dexter energy transfer, phosphorescent emitters are present in much higher concentrations (~10%) in the host material, a fact which may significantly alter the carrier injection, carrier transport, and recombination process in the emitting layer (EML) [5]. With regards to the electrical properties, dopants may: (1) serve as the injection channel from the hole-transporting layer (HTL) and/or electron-transporting layer (ETL) for reducing the driving voltage [6], (2) trap carriers and decrease the carrier mobility [7–9], and (3) exhibit transport characteristics such as carrier hopping among the dopant sites, especially at high dopant concentrations [6–10]. Further, the electroluminescence (EL) mechanisms can be categorized into energy transfer from host to dopant, or carrier trapping at the dopant sites [11,12]. Due to the short carrier lifetime of the triplet excitons, triplet–triplet (TT) annihilation occurs when the charge carrier concentration is high (under high voltage driving). Hence, sometimes the phosphorescence of an OLED will reach a maximum before decreasing sharply with increasing current driving [13]. Such an efficiency roll-off sometimes hampers the use of white OLEDs in real applications. With a bipolar host, mixing host, or double emitting layer (DEML) structure, an OLED can effectively broaden its recombination zone, reduce the TT annihilation, and maintain high efficiency under reasonably high luminance levels (say, 1000 cd/m^2) [14–20]. Another popular concept is the fluorescence-interlayer-phosphorescence, which utilizes fluorescent emitters to accelerate the exciton generation, and phosphorescent emitters to convert the excitions into photons, thereby sustaining the efficiency at high injection levels [21].

Generating a broadband white light typically requires two or three types of emitters, which adds to the complications involved in material selection and device design [22,23]. In addition to considering the interplay among the host(s) and dopants materials and reducing the efficiency roll-off, two other important issues are achieving a high color rendering index (CRI) and maintaining a stable EL spectrum. In general, OLEDs with three types of emitters are preferred for high CRI applications [24]. Although it is possible to adjust the emission color by tuning the driving voltage [25], it is often preferable to achieve a white OLED emission independent of the driving conditions. To fulfill this requirement, one will need to design a device structure which can: (1) effectively confine the carriers, (2) effectively confine the excitons, and (3) maintain the energy transfer path and/or trapping conditions without saturation of the emitter sites within the driving range [26]. Typically, a blocking layer is incorporated to confine the carriers and excitons [27,28]. By sandwiching the low bandgap emitter between two high bandgap emitters, it is also possible to achieve a high level of confinement with high color stability [29]. One may also utilize a very thin EML to ensure that the recombination zone is fixed [30]. Another successful approach is the DEML. By doping emitters with different hole and electron transport properties in EML1 and EML2, respectively, carrier confinement is automatically achieved, thereby stabilizing the EL emission [31]. One potential issue for this kind of device structure is the material selection of the electron transporting host [32]. Typically, the highest occupied molecular orbital (HOMO) value of such a host is high, which results in a high driving voltage [31]. To reduce the driving voltage and manage the carriers and excitons, a hole-transporting material can be mixed into the electron-transporting host [33–35].

In this paper, we demonstrated a white OLED with a DEML configuration. The electron-transporting host was 2,2′-bis[5-phenyl-2-(1,3,4)oxadazolyl]biphenyl (OXD), which has been proven to be a suitable host for the green phosphorescent emitters, fac-tris(phenylpyridine) iridium [Ir(ppy)$_3$], in our previous study [36,37]. It was also demonstrated that the Ir(ppy)$_3$ doped OXD exhibits bipolar transport characteristics, and can be regarded as an electron-rich bipolar EML. On the other hand, the hole-transporting host was *N*,*N*-dicarbazolyl-3,5-benzene (mCP) doped with 9% iridium(III)bis[4,6-di-fluorophenyl-pyridinato-N,C2]picolinate (FIrpic). From EL spectral analysis, it was demonstrated that the recombination zone was also broad in this hole-transporting EML, because the mCP exhibited certain electron-transport characteristics. Hence, it can be regarded as a hole-transporting bipolar EML. Combining the hole- and electron-transporting EMLs with blue and green emission for the backbone of the white OLED, carrier confinement was achieved with a broad recombination zone, so that both color stability and high efficiency can be achieved with a reduction in the efficiency roll-off. Compared with single EML cases of mCP- and OXD-based OLEDs, the external quantum efficiency (EQE) improved by 33.1% and 168.6% at 2.5 mA/cm^2, respectively. Further, the color coordinates shift from 100 to 10,000 cd/m^2 was reduced from (−0.029, −0.052) and (−0.014, −0.029) to (−0.013, 0.002). Last but not least, 0.5% tris(2-phenylquinoline)iridium(III) [Ir(2-phq)$_3$] red dopants were doped in EML1 and EML2, respectively, for white light generation. Ir(2-phq)$_3$ doping resulted in almost no change in the EQE of EML2 but a boost in the EQE of EML1 to 10.49% at 2.5 mA/cm^2 due to the higher internal quantum efficiency of Ir(2-phq)$_3$ than that of FIrpic. The maximum current efficiency and power efficiency of the WOLED obtained were 35.8 cd/A and 20.5 lm/W, respectively. When the luminance increased from 100 to 10,000 cd/m^2, the variations in the Commission Internationale de l'Eclairage (CIE) coordinates were only 0.014 and 0.004.

2. Experiments

Table 1 illustrates the device structures of the OLEDs with monochromatic, bi-chromatic and white-light emissions used in this study. The hole transport layer (HTL) and electron transport layer (ETL) materials were *N*,*N*′-diphenyl-*N*,*N*′-bis(1-napthyl)-1,1′-biphenyl-4,4′-diamine (NPB) and 4,7-diphenyl-1,10-phenanthroline (BPhen), with a thickness of 50 and 40 nm, respectively. Due to the higher triplet energy of FIrpic (T_1 = 2.7 eV), we inserted a 10 nm exciton

Table 1
Device structures of OLEDs. (Unit:nm).

blocking layer (EBL) to prevent exciton diffusion from the EML to the HTL. The main host materials in the EML were *N*,*N*-dicarbazolyl-3,5-benzene (mCP) and 2,2′-bis[5-phenyl-2-(1,3,4)oxadazolyl]biphenyl (OXD), both of which exhibited bipolar characteristics. Typically, Poole-Frankel model with the form $\mu = \mu_0 \exp(\beta\sqrt{E})$ was used to describe the carrier mobility (μ) in organic thin films. μ_0 represents the zero-field carrier mobility, β describes the electric field dependence of the mobility, and E is the applied electrical field. Zero-field mobility of mCP for hole is 1.2×10^{-4} cm^2/V s, which is three times higher than that of electron (4×10^{-5} cm^2/V s) [26]. β value of the hole and electron mobility of mCP was 0.00254 and 0.00426, respectively. So, that means the hole mobility is higher than electron under low electric field. With increasing driving voltage (electric field), electron mobility increases faster than holes, which may shift recombination zone toward anode direction. For the OXD case, although we did not measure the mobility values, we have fabricated OXD with different thicknesses sandwiched by HTL and ETL materials [36]. When OXD layer was thin (40 nm), both HTL and ETL emission were both observed, which meant OXD layer can support hole and electron transport. When increasing the OXD layer to 90 nm, only HTL emission was observed. That meant the electron transport dominated. Hence, in OXD we concluded that the electron mobility is higher than that of hole one. The phosphorescent dopants for the red, green, and blue emission were tris(2-phenylquinoline)iridium(III) [$Ir(2\text{-phq})_3$], fac-tris(phenylpyridine) iridium [$Ir(ppy)_3$] and iridium(III)bis[4,6-di-fluorophenyl-pyridinato-N,C2]picolinate (FIrpic), respectively. The chemical structures and the energy diagrams of all the organic materials are shown in Fig. 1a and b, respectively.

First, we utilized the mCP/OXD (15/13 nm) DEML structure with different doping profiles for studying the carrier injection, transport, and recombination characteristics, and denoted the devices as D1 to D4, as shown in Table 1. Device D1 was a bi-chromatic OLED with 9% FIrpic doped in the mCP and 9% $Fir(pic)_3$ in the OXD. The dopants in the OXD and mCP were removed for Devices D2 and D3, which exhibited blue and green emission, respectively. In Device D4, there were no dopants in either the mCP or OXD. In the second part of the experiments, devices with the mCP, OXD, and their mixture (mCP:OXD = 1:1) as a single host of the EML were fabricated, and denoted as S1, S2, and S3, respectively, for comparison with the OLED with the DEML structure (D1). Lastly, red dopants [$Ir(2\text{-phq})_3$] were co-doped with $Ir(ppy)_3$ (Device W1) and FIrpic (Device W2) for white light generation.

3. Results and discussion

3.1. Carrier injection and transport in blue–green OLED

Fig. 2a shows the *J*–*V* characteristics of the OLEDs with different doping profiles, D1–D4, respectively, on a linear scale. One can see that the Device D1, with both green and blue dopants (denoted as B/G in Fig. 2a), exhibited the lowest driving voltage of 10.6 V at 50 mA/cm^2, as shown in Table 2. On the other hand, the driving voltage of Device D4 (denoted as U/U in Fig. 2a, where "U" means "undoped") without any dopants was the highest (12.1 V at 50 mA/cm^2), implying that the presence of the dopant helped to reduce the driving voltage. Comparing the effects of the blue and green dopants on the driving voltage, one can see that Device D2, with only the blue dopants (FIrpic), exhibited a lower driving voltage than Device D3, with only the green dopants ($Ir(ppy)_3$). To further understand the mechanism behind the dopant-induced voltage reduction in our OLEDs, we replotted the *J*–*V* characteristics on a double log scale, as shown in Fig. 2b. Here, three regions of the *J*–*V* curves can be clearly distinguished. For unipolar organic thin films, the trap-charge-limited-current equation is typically used:

$$j_{TCLC} \propto V^{l+1} \tag{1}$$

where j_{TCLC} is the current density, V is the voltage, and l is the parameter derived from the trap distribution. With a higher trap density, the l-value will be larger. If $l = 0$, we have ohmic conduction. Although our OLEDs possessed a multilayer structure with double carrier transportation, this equation can still be used for qualitative comparisons. At low voltage (Region 1), in what is typically known as the ohmic region, the current conduction is effected by the thermally activated carriers, and the l-value for the four devices, D1–D4, were quite similar, ranging from 1.17 to 1.27, as shown in Table 3. For Region 2, a typical TCLC region, Device D1, with both green and blue dopants, exhibited the highest l-value of 13.8, whereas the corresponding value for the undoped Device D4 was $l = 9.78$. The l-value of Device D2 was slightly higher than that of Device D3. These values implied that the dopants in our OLEDs served

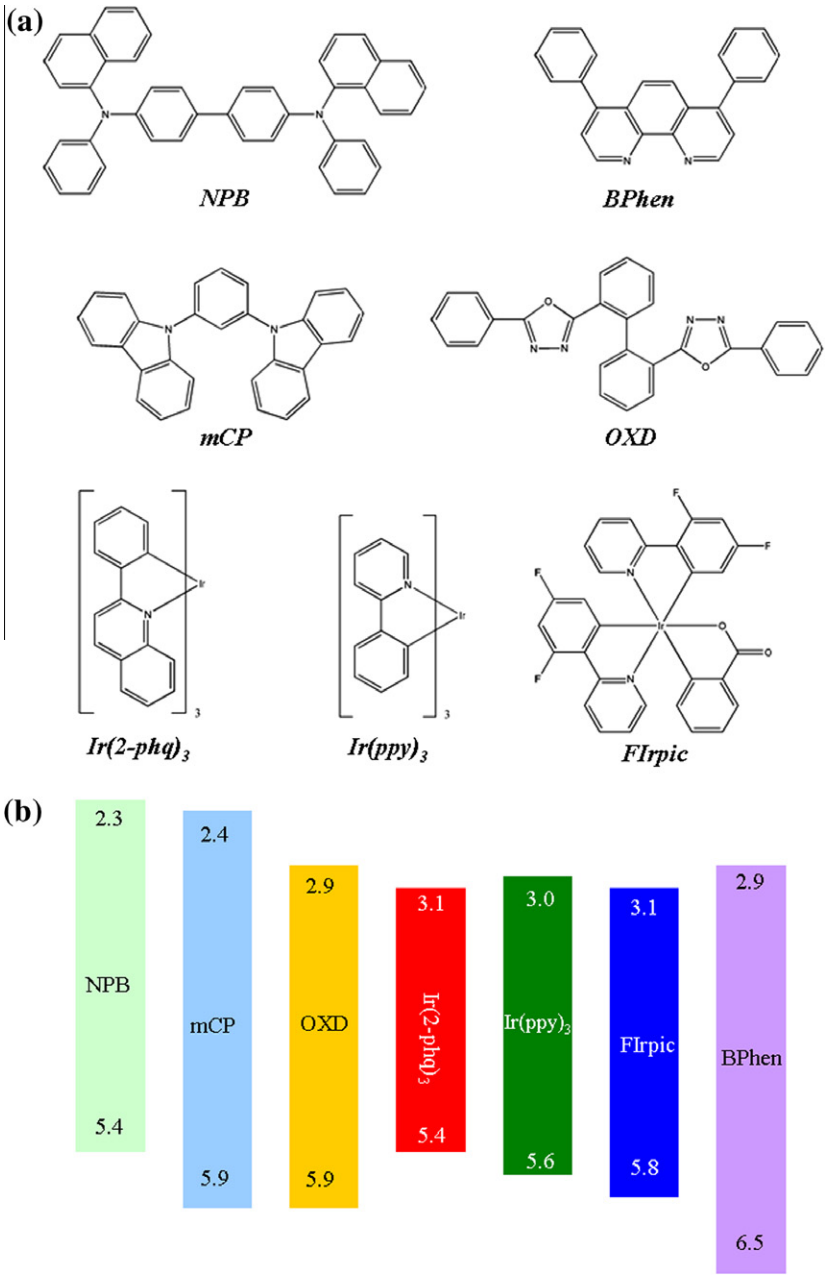

Fig. 1. (a) Chemical structures of organic materials, and (b) energy diagrams.

as trapped sites where the recombination process took place. The recombination current increased the current density, which in turn reduced the driving voltage [38]. At high injection conditions (Region 3), the traps were filled and possibly formed some space charges, provided that the recombination rate was not exceedingly high or that the electron-hole concentration was not matched in the spatial domain. This reduced the carrier mobility and also reduced the *l*-value [39]. One can also note that in Region 1 (low bias condition), the current density was the highest in the undoped device, which also implied that the dopants acted as traps, and that the free carrier concentration was the highest in the absence of dopants.

Fig. 2c shows the EL spectra of Device D1 at different driving voltages, which can be decomposed to those of Device D2 and D3, also shown as the dash lines in the figure. One can see that the EL spectral variation was quite small, with only a slight decrease in the green emission with increasing driving voltage. This suggested that the carrier confinement effected by the mCP/OXD interface was rather stable. Additionally, the recombination zone shifted slightly toward the FIrpic doped mCP layer, which resulted

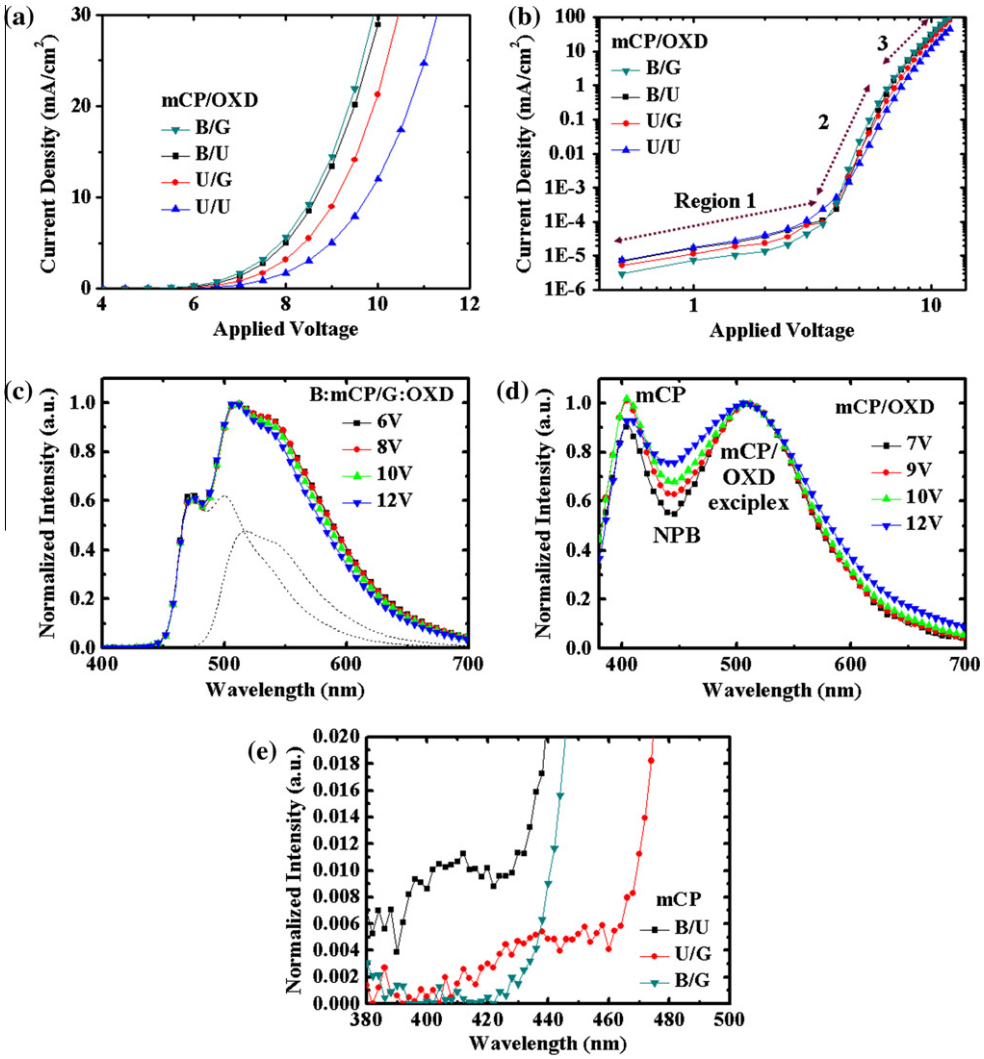

Fig. 2. *J–V* characteristics of devices D1, D2, D3, and D4 in (a) linear and (b) double log scale. B, G, and U: blue-emitter (FIrpic) doped, green $(Irppy)_3$ doped, and undoped EMLs. (c) EL spectra at different driving voltages of D1. Dashed lines shows EL spectra of D2 and D3 at 12 V. (d) EL spectra at different driving voltage of D4. (e) Zoom-in spectra at short wavelength region (<500 nm) of D1, D2, and D3 at 12 V. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

in the slight decrease in the green emission. To further investigate the emission process, we measured the EL spectrum of Device D4, as shown in Fig. 2d. There were two main peaks at 402 and 510 nm, from the exciton emission of the mCP and the exciplex emission at the mCP/OXD interface, respectively. When the driving voltage was increased from 7 to 9 V, the mCP peak increased accordingly, meaning that the recombination zone had shifted from the interface into the mCP. When the driving voltage was further increased to 10 and 12 V, the mCP peak dropped. However, the dip around 432–444 nm, from the NPB emission, increased. This suggested that the recombination zone had been extended into the NPB layer, a clue that the recombination zone in the mCP layer was rather broad. Fig. 2e shows the EL spectra in the short wavelength region of Devices D1, D2, and D3. For Device D1, there was no leakage from the EBL (mCP) or HTL (NPB). Interestingly, for Device D2, with no green dopants ($Ir(ppy)_3$) in the OXD but FIrpic in the mCP, one can detect a miniscule amount of mCP emission (400–420 nm), which came from the EBL, implying that the recombination zone had shifted toward the anode side where there were no $Ir(ppy)_3$ dopants. From our previous study, we can deduce that the $Ir(ppy)_3$ doped in the OXD served as electron traps to retard the electron transport, and also provided another hopping channel for the holes [36]. Another conclusion we may draw was that the recombination zone was truly broad in the FIrpic-doped mCP layer, making it possible to observe the emission from the EBL in Device D2. In the EL spectrum of Device D3, we can discern a low mCP emission (if any at all) and a rather obvious NPB emission, meaning that the recombination had taken place further inside the HTL. Therefore, both dopants (FIrpic and $Ir(ppy)_3$) acted as electron traps and shifted the recombination zone

Table 2
Performances of OLEDs.

Device	[a]Driving voltage (V)	Current efficiency (cd/A)	Power efficiency (lm/W)	[b]CIE coordinates shift	CIE at cd/m^2	100 [c]EQE (%)

D3	1.14	11.9	8.43
D4	1.27	9.78	8.63

towards the cathode sides, consistent with the conclusions derived from the *J–V* characteristics.

Fig. 3 shows a schematic diagram we proposed to characterize the carrier transport in the blue/green devices. Holes were injected from the anode, HTL, and EBL into EML1 (FIrpic doped mCP). It was a hole-rich EML, and holes were subsequently piled up at the mCP/OXD interface, due to the difference in the hole mobilities of the mCP and OXD. The OXD is a bipolar material with a higher electron mobility than hole mobility, and the doped Ir(ppy)3 inside the OXD opened a new hole-transporting channel. Therefore, EML2, the Ir(ppy)3 doped OXD, became an electron-rich EML. On the other hand, the electrons were injected from the cathode, ETL (HBL) into EML2. The Ir(ppy)3 captured some of the electrons and recombined with the holes. In EML2, the electrons were majority carriers. Therefore, the recombination was limited by the number of holes transported into EML2. Some of the electrons might accumulate at the mCP/OXD interface, and then become injected into EML1 and then trapped by the FIrpic. In this picture, the recombination current enhancement (driving voltage reduction) corresponded to the minor carrier concentration. As we can see from Fig. 2a, Device D2 exhibited a lower driving voltage (higher recombination current) than Device D3, which indicated that the main recombination zone was located in the EML1 and that the entire recombination zone was broad.

3.2. Comparison between OLEDs with single- and double-EML

Fig. 4a shows the *J–V* curves of Devices D1, S1, S2, and S3 for comparing the electrical characteristics between OLEDs with single- and double-EMLs. The mCP and OXD

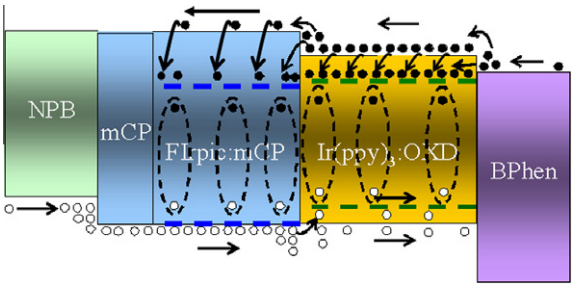

Fig. 3. Illustration of carrier injection and transport behavior in doped DEML–OLED (D1).

were hole- and electron-rich bipolar EMLs. Hence, electrons and holes were not balanced in these two cases (S1 and S2). With a DEML configuration (D1), the charge balance condition was satisfied, which reduced the driving voltage to 0.4 V at 50 mA/cm^2. By mixing mCP and OXD (1:1) as the host of the EML (S3), bipolar transport can be also achieved for the whole EML which significantly decreased the driving voltage to 8 V at 50 mA/cm^2, compared to S1 and S2.

Fig. 4b shows the EL spectra of Device S1 (with a mCP single host) at different driving voltages. One can see that the spectral variation was severe, which was due to the shift in the recombination zone. Additionally, the blue emission was rather weak, because energy was transferred from the FIrpic to Ir(ppy)$_3$. With increasing driving voltage, the blue emission increased. The insertion of an extra spacer is typically used to confine the carrier and excitons for stabilizing the color coordinates and increasing the blue emission [27]. Fig. 4c shows the EL spectra in the short wavelength regions of Devices D1 and S1. There was no leakage to the HTL side for Device S1, because the mCP was hole-rich and the main recombination zone was located near the EML/HBL interface. With increasing driving voltage, the recombination zone was shifted toward the HTL side, which increased the recombination from the FIrpic molecules with stronger blue emission.

Fig. 4d shows the EL spectra of Device S2 (with an OXD single host) at different driving voltages. Compared with the case of Device S1, the blue peak of Device S2 was

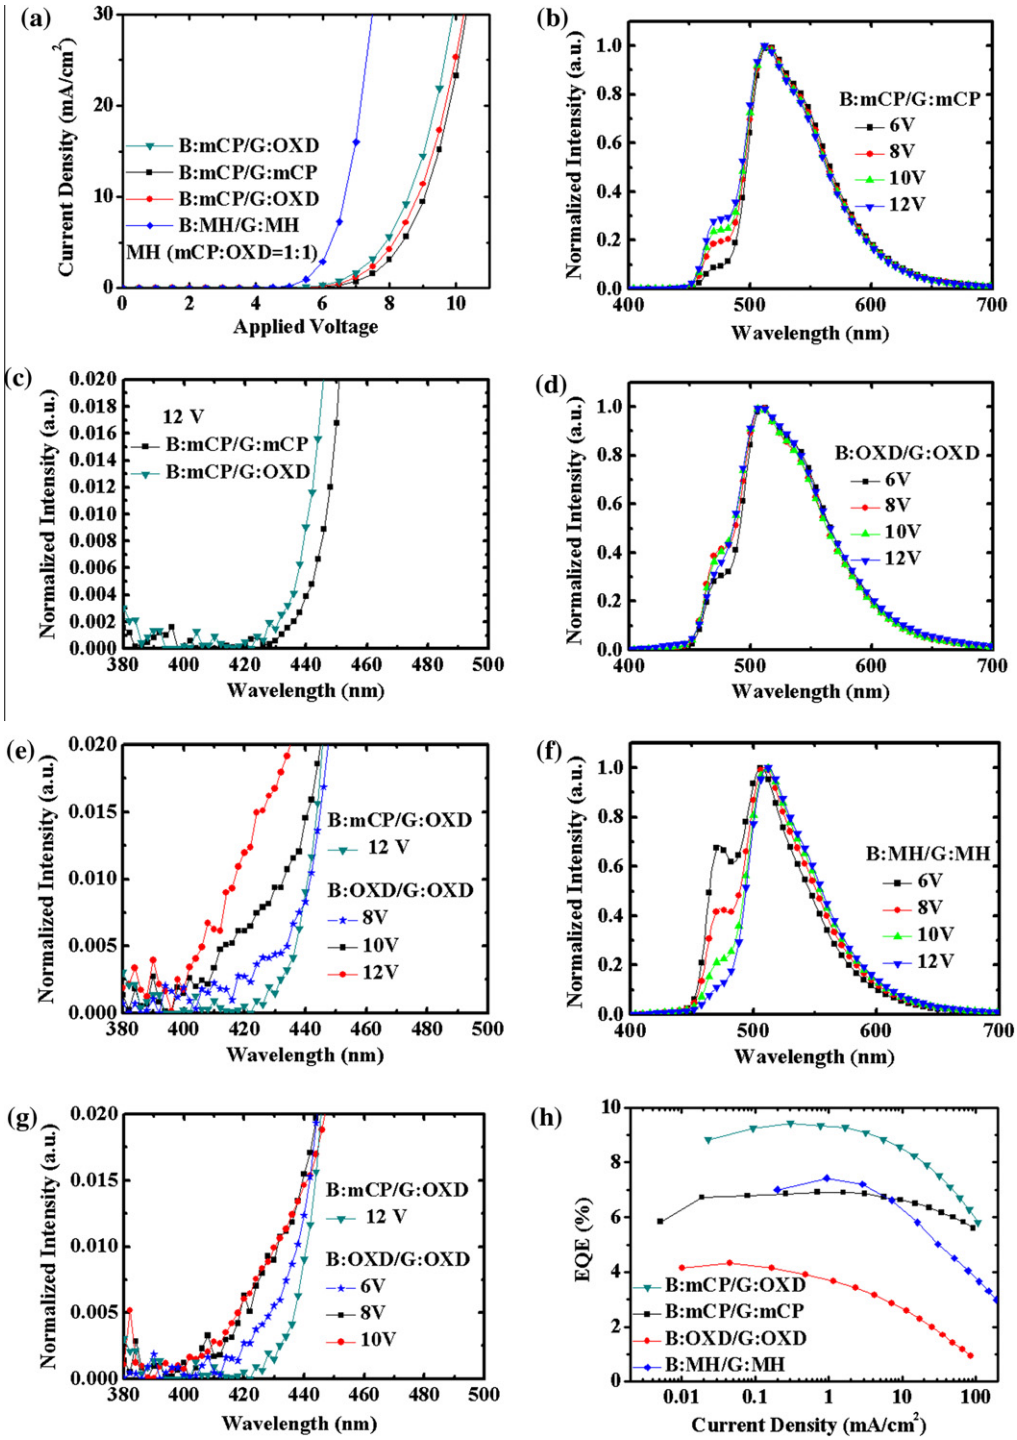

Fig. 4. (a) *J–V* characteristics of devices D1, S1, S2, and S3. (b) EL spectra at different driving voltages of S1. (c) Zoom-in spectra at short wavelength region (<500 nm) of D1 and S1 at 12 V, respectively. (d) EL spectra at different driving voltages of S2. (e) zoom-in spectra at short wavelength region (<500 nm) of D1 (at 12 V) and S2 (at 8, 10, and 12 V), respectively. (f) EL spectra at different driving voltages of S3. (g) zoom-in spectra at short wavelength region (<500 nm) of D1 (at 12 V) and S3 (at 6, 8, and 10 V), respectively. (h) EQE at different current density of D1, S1, and S2.

stronger and more stable. In this case, with the electron-rich EML, the main recombination zone was located at the EBL/EML interface, and a strong leakage from the HTL was observed, as shown in Fig. 4e. Although the main recombination zone was located in the FIrpic-doped region, the blue emission of Device S2 was still lower than

that of Device D1, because the energy transfer from the OXD to the FIrpic was less efficient than that from the mCP to the FIrpic. The blue emission increased with increasing driving voltage, which meant that the recombination zone had penetrated into the HTL. Fig. 4e shows the leakage emission in the short wavelength region. As the driving voltage was increased from 8 to 12 V, one can see that the leakage emission of the OXD-based OLED increased significantly, signifying a shift of the recombination zone toward the HTL side.

Fig. 4e and f shows the EL spectra of mixed-host OLED (Device S3) and their zoom-in spectrum at short wavelengths region, respectively. One can see that the spectral variation in mixed-host OLED was more severe than that in pure mCP (Device S1) and pure OXD (Device S2) cases. The trend of blue and green emission variation under different driving voltages for mixed-host OLED is contrary to the cases in S1 and S2. The blue emission decreased (rather than increased) rapidly with increasing driving voltage. Under low driving voltage, saying 6 V, the blue emission was even higher compared with pure mCP, pure OXD, and D EML OLEDs. To generate enough blue emission, one may need to have enough electron-hole recombination at the blue dopant region (EML close to the EBL), together with efficient host material. In our case, mCP was a better choice than OXD as the host material of FIrpic. In mixed-host case (Device S3), both electrons and mCP molecules were sufficient at the EBL/EML interface, which resulted in high blue emission under low driving voltage. As shown in Fig. 4f, there were still NPB emission (around 430 nm) due to the electron leakage into HTL. It also increased with increasing driving voltage, because the recombination peak penetrated deeper into the HTL, which was also explained previously for the pure OXD case (Device S2). In a mixed-host OLED, electrons and holes transported through their most energy favorable paths (OXD and mCP in our cases), respectively, and it was also the main reason accounting for the significant voltage reduction. So there may be some electrons accumulated at the EBL/EML interface, as shown in Fig. 4f. Similarly, holes hop through mCP molecules may transport all the way to the EML/ETL interface. And the recombination took place in the whole EML [40]. With increasing driving voltage, electrons and holes may be driven toward the EBL and ETL. Clear evidence of the electron part is the increasing NPB emission with increasing driving voltage as shown in Fig. 4f. It reduced the blue emission efficiency under high voltage driving, similar to the pure OXD cases (device S2). On the other hand, for the hole case, BPhen is a good hole-blocking layer and block the hole at the EML/HTL interface for efficient recombination with electrons supplied from cathode. With increasing driving voltage, holes were accumulated at EML/ETL interface for efficient green emission. At the same time, blue emission decreased a lot because the penetration of electrons into HBL and HTL. It may be a possible reason accounting for the severe spectral variation in mixed-host blue/green OLED. However, more evidence should be provided. Besides, optimization of mixing ratios, doping concentrations and locations should be made for boosting up efficiency and stabilizing the spectrum of the mixed-host OLED and it is out of the scope of this paper. As shown in Table 2, due to the excellent carrier confinement of the DEML structure, the CIE coordinates of Device D1 shifted only (−0.013, 0.002) in the luminance range from 100 to 10,000 cd/m^2, a drastic improvement in comparison to Devices S1 (−0.029, −0.052), S2 (−0.014, −0.029), and S3 (0.031, 0.070), respectively.

Fig. 4h shows the EQE of Devices D1, S1, S2, and S3 at different current densities. It is not surprising that the D-EML OLED exhibited a higher efficiency than the single emitting layer devices, due to better carrier confinement and charge balance. For the mCP-based OLED (S1), one can see that the efficiency was rather stable under different driving conditions, which meant that the entire recombination zone was broad and that TT annihilation was not a significant factor. On the other hand, for the OXD-OLED (S2), the efficiency dropped significantly with increasing driving current density. When the current density was 20.4 mA/cm^2, the EQE was reduced to half the maximum value (2.17%). This suggested that the OXD-EML was not as "bipolar" as the mCP device and that the recombination region was narrower. For the D-EML case, the TT annihilation was just between S1 and S2, and the EQE was reduced to half its maximum value over 100 mA/cm^2.

3.3. White OLED with red-doped B/G-DEML structure

In order to fabricate high performance WOLEDs, high efficiency dopants for red emission were doped in the EML. As shown in Table 1, the phosphorescent red emitter Ir(2-phq)$_3$ with 0.5% was co-evaporated in the Ir(ppy)$_3$:OXD and FIrpic:mCP layers, respectively for two devices, denoted as W1 and W2 [41]. Fig. 5a shows the *J–V* curves of Devices D1, W1, and W2 for comparing the electrical characteristics between dichromatic (green/blue) and white OLEDs. The addition of the low concentration red dopants increased the trap density (both for the electron and holes) and slightly increased the driving voltage by about 0.2 V at 50 mA/cm^2. Fig. 5b and c show the EL spectra at different driving current densities of Devices W1 and W2, respectively. When the red emitter was doped in the green region (W1) as shown in Fig. 5b, the relative green emission decreases for red light emission, compared with the dichromatic OLED (D1) in Fig. 2c. On the other hand, in the case of Device W2, the red emitter was doped in the blue region, and hence the blue emission decreases for red emission (by comparing Figs. 5c and 2c). For the spectral shifts, obvious drops in the red emission were observed, both in Fig. 5b and c, from the saturation or trap-filling of the low-concentration red dopant materials [42,43].

Considering the EQE shown in Fig. 5d, one can see that the efficiency of Device W1 was nearly identical to that of Device D1. When red emitters were doped in the green region, the emission efficiency of Ir(2-phq)$_3$ and Ir(ppy)$_3$ were comparable, and had little effect on the EQE. On the other hand, when Ir(2-phq)$_3$ was added into the FIrpic, the maximum EQE increased because the emission efficiency of blue emitter was lower than that of the red emitter. As shown in Fig. 6, the maximum current efficiency and power efficiency of Device W2 were 35.8 cd/A with EQE 10.73% at 6.5 V and 20.5 lm/W at 5 V, respectively.

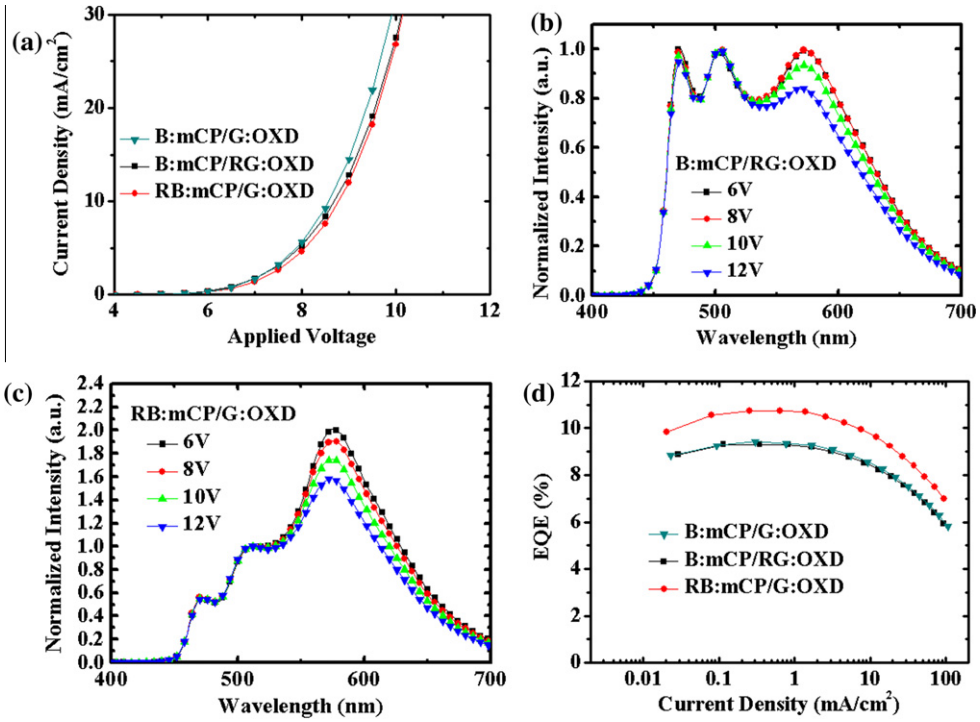

Fig. 5. (a) *J–V* characteristics of devices D1, W1, and W2. (b and c) EL spectra at different driving voltages of W1 and W2, respectively. (d) EQE at different current density of D1, W1, and W2.

The measurements of all devices were summarized in Table 2. Compared with other high efficiency white OLEDs with maximum efficiency of 19.5% and 25% in Refs. [44] and [45], respectively, our efficiency was quite low. One key point was the design of the EML. To have higher maximum quantum efficiency, one may use a thinner EML (both 10 nm in these two references), to localize the electron and hole concentrations at the same position. Although the maximum efficiency was high, however, in an OLED with thin EML, it may often result in a severe reduction in efficiency with increasing driving current due to triplet–triplet annihilation. On the other hand, our EML was 28 nm, which was much thicker, and relief the triplet–triplet annihilation effect. Besides, in fabricating our OLEDs, organic materials were purchased from the vendor and use without further purification (except that the OXD was synthesized by ourselves). Here, we purified FIrpic (only FIrpic and purify only once) and duplicate the device in D2. Amazingly, just purified once of FIpic, 50.7% improvements of cd/A was achieved. It is reasonable to expect that when all organic materials were well purified, higher maximum external quantum efficiency can be achievable. The low maximum external quantum efficiency in our device (10.73%) may come from: (1) the device configuration (thicker EML was adopted for reducing triplet–triplet annihilation), and (2) non-purification of the organic materials.

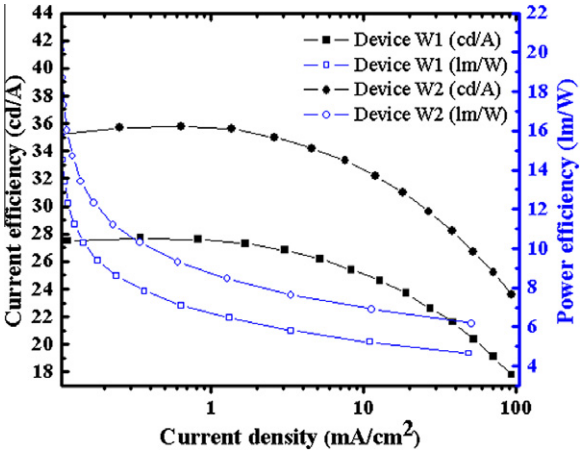

Fig. 6. Current efficiency (solid dots) and power efficiency (open dots) versus current density of W1 and W2.

We also conducted the lifetime test of Devices W2 and D3 under constant DC current driving at 50 mA/cm^2. Unfortunately, operation lifetime, which was defined as the elapsed time of luminance decreasing to its initial value, were quite short (21 and 5.3 mins for Devices W2 and D3, respectively) upon such high current stress. Interestingly, when there was no dopants in the EML1 (mCP) in Device D3 case, operation lifetime was greatly reduced compared with the white OLED (Device W2). For the EL process, input of electrical power converted to radiative light emission or heat dissipation. The latter not only had no contribution for EL, but also generated heat, which may increase temperature and deteriorate the organic material. Here, Device W2 exhibited a lower driving

voltage and higher efficiency compared with Device D3. That means lower heat was generated and the lifetime is hence elongated in Device W2 [46,47]. Checking the organic materials used in our device, one of the main bottlenecks accounting for such a short lifetime may be the use of low Tg (62 °C) organic material, BPhen, as the ETL. Here, BPhen was chosen due to its superior electron mobility, which helped to reduce voltage drop [26,48]. With replacement of other ETL materials with high Tg [49–51], elongation of operation lifetime may be possible. Comparing the normalized EL spectra of Device W2 before and after aging process (not shown here), it was found that the percentage of blue emission was reduced after aging due to its lower lifetime [52]. Because red emission was basically transferred from blue emitter, the luminance decay was more serious compared with that of green one.

4. Conclusions

In this paper, we discussed the electrical and optical characteristics of OLEDs with a DEML structure and multiple emitters. Phosphorescent green and blue dopants in the EML served as the carrier trapping and recombination centers and helped to reduce the driving voltage. Light leakage outside the EMLs was studied by EL analysis at short wavelengths, indicating that the recombination zone was broad (over the entire EML) and would become too broad (outside the EML region) without the green or blue dopants. Compared with the single EML cases (mCP and OXD), the DEML dichromatic OLED exhibited a lower driving voltage, higher EQE, and lower color shift, because the D-EML balanced the charges and confined the carriers at the mCP/OXD interface. By doping a low concentration (0.5%) red emitter in the FIrpic:mCP layer, we successfully fabricated a high efficiency WOLED with high color stability and alleviated the efficiency roll-off. The maximum current efficiency was 35.8 cd/A at 6.5 V. The EQE reached 10.49% at 2.5 mA/cm^2, and decreased to half its maximum value over 100 mA/cm^2. The CIE shifts were $(-0.014, 0.004)$ across the luminance levels from 100 to 10,000 cd/m^2.

by choosing electron-withdrawing substituents on the cyclometalated ligands to stabilize the highest occupied molecular orbital (HOMO) or electron-donating substituents on the ancillary ligands to destabilize the lowest unoccupied molecular orbital (LUMO), thus can lead to a wider HOMO–LUMO gap, as demonstrated in neutral iridium complexes [7–9]. However, for those cationic iridium complexes containing 2,2′-bipyridine(bpy)-type ancillary ligands, due to the intrinsically narrowed energy gap of bpy-type ligands [10], it is very difficult to tune the emission color into the blue region and most of the emission is still peaked at blue-green region. Therefore, the electronic properties of the ancillary ligand become the decisive factors in shifting the emission color of the cationic iridium complex toward blue region. Compared with the bpy-type ancillary ligand, the anionic N-based heterocyclic rings have attracted much research interests [5,11,12] since the electron denoting N atom of the ancillary ligand can strongly destabilize the LUMO, thus can increase the energy gap and result in a blue-shifted emission in the cationic iridium complex. Recently, Qiu and co-workers [11] demonstrated that by using ancillary ligands involving electron-donating nitrogen, 2-(1*H*-pyrazol-1-yl)pyridine (pzpy), the emission of the obtained cationic iridium complex can be successfully tuned to blue region, despite that the EQE of the LECs is only 0.28% due to the severe excited-state quenching of the complexes in the light-emitting layer.

Compared with the pzpy, triazole-pyridine ancillary ligand has even more stronger electron-donating capability to realize a blue emission from cationic iridium complex due to the strong σ-donor properties of the triazole ring [13]. Despite their successful application in neutral iridium complexes [9,14–20], however, a few about employing triazole-pyridine ancillary ligand in the cationic iridium complexes were reported. De Cola and co-workers [19,21,22] demonstrated the blue emission in LEC devices recently, in which 1,2,3-triazole as ancillary ligand was used [23]. In this paper, 1,2,4-triazole-pyridine was used as ancillary ligand in the cationic complex to tune the emission into the blue region. Moreover, it was found that cyanogen group in the alkyl chain has a significant impact on the device performances.

2. Experimental section

2.1. Materials and analytical instruments

All reactants and solvents purchased from commercial sources and used as received unless otherwise stated. All reactions were performed under an argon atmosphere. ^{1}H NMR spectra of compounds were collected on a 300 MHz spectrometer at room temperature. Photo-physical characteristics of complexes were collected at room temperature in dichloromethane (DCM) solution of 10^{-3} M, which were carefully purged with nitrogen prior to measurements. UV–vis absorption spectra were recorded on a HP 8453 spectrophotometer. PL spectra were measured with a cooled charge coupled device (CCD) coupled to a monochromator using the 325-nm line of the He-Cd laser as the excitation. Elemental analyses were performed on a Vario EL elemental analysis instrument (Elementar Co.). Thermogravimetric analyses (TGA) were performed on a Netzsch TG 209 at a heating rate of 20 °C/min. DSC measurements were performed on a Netzsch DSC 204 under N_2 flow at the heating rate of 15 °C/min. Cyclic voltammetry (CV) was performed on a CHI660A electrochemical workstation at a scan rate of 100 mV/s at room temperature under argon protection in CH_3CN solution of 10^{-3} M with tetrabutylammonium hexafluorophosphate of 0.1 mol/L as the supporting electrolyte. A platinum electrode was used as the working electrode, and a Pt wire as the counter electrode, and a calomel electrode as the reference electrode. The energy level and energy gap were calculated from the empirical formula [24]: $E_{HOMO} = -e(E_{ox} - E_{1/2,ferrocene}) + (-4.8)$ eV; $E_{LUMO} = -e(E_{red} - E_{1/2}) + (-4.8)$ eV; $E_{gap} = E_{HOMO} - E_{LUMO}$; E_{HOMO} is the energy level of the highest occupied molecular orbital; E_{LUMO} is the energy level of the lowest unoccupied molecular orbital; E_{gap} is the energy gap; E_{ox} is the oxidation potential; E_{red} is the reduction potential.

2.2. Synthesis

2.2.1. 2,2-Dimethyl-6-(3-methyl-5-(pyridin-2-yl)-4H-1,2,4-triazol-4-yl) hexanenitrile (trzpy-cn)

The compound 5-methyl-3-(pyridin-2-yl)-4*H*-1,2,4-triazole (hptz) was synthesized according to the literature [25] with a yield of 60%. The ancillary ligand 2,2-dimethyl-6-(3-methyl-5-(pyridin-2-yl)-4*H*-1,2,4-triazol-4-yl) hexanenitrile (trzpy-cn) was synthesized from hptz and 6-bromo-2,2-dimethylhexanenitrile by following procedure. Hptz (1.11 g, 7.6 mmol), 6-bromo-2,2-dimethylhexanenitrile (1.87 g, 12 mmol), and potassium carbonate (3.72 g, 11 mmol) were dissolved in acetone (40 mL). The solution was refluxed under an argon atmosphere for 48 h and then cooled to room temperature. The solvent was removed under vacuum and the residue was extracted with dichloromethane (150 mL). The product was then obtained by column chromatography on silica gel (200–300 mesh) first with petroleum ether/ethyl acetate (4:1) as the eluent, then with the ethanol to yield a white solid (1.15 g, 5.2 mmol). Yield: 68%. ^{1}H NMR ($CDCl_3$, 300 MHz), δ (ppm): 8.73 (s, 1H, ArH), 8.10 (d, 1H, J = 7.92 Hz, ArH), 7.78 (t, 1H, J = 6.27 Hz, ArH), 7.30 (d, 1H, J = 6.45 Hz, ArH), 4.18 (t, 2H, J = 6.87 Hz, –N–CH_2–), 2.55 (s, 3H), 2.0–2.1 (m, 2H), 1.52–1.58 (m, 4H), 1.33 (s, 6H).

2.2.2. [Ir(dfppy)$_2$(trzpy-cn)]PF$_6$ (**C1**)

In a round-bottomed flask, 0.200 g dichloro-bridged iridium dimer $[Ir(dfppy)_2Cl]_2$ and 2.2 equiv the ancillary ligand trzpy-cn are mixed together in 25 mL ethylene glycol. The solution was then heated to reflux (150 °C) under an inert atmosphere with constant stirring for 15 h. Upon cooling to room temperature, a 10 mL aqueous ammonium hexafluorophosphate solution (1.0 g in 10 mL deionized water) was added to the reaction mixture, producing a yellow-green powder. The precipitate was filtered and washed with deionized water, and then was dried under vacuum at 70 °C for 12 h. The crude product was purified by column chromatography on neutral alumina with CH_2Cl_2 as the eluent, yielding a light-yellow powder. Yield:

77%. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.49 (d, 1H, J = 8.04 Hz, ArH), 8.33 (d, 3H, J = 8.52 Hz, ArH), 7.81–7.93 (m, 4H, ArH), 7.49–7.56 (m, 2H, ArH), 7.21–7.24 (m, 2H, ArH), 6.50–6.60 (m, 2H, ArH), 5.64–5.68 (m, 2H, ArH), 4.72–4.89 (m, 2H), 2.10–2.15 (m, 2H), 1.78 (s, 3H), 1.44–1.48 (m, 4H), 1.34 (s, 6H). ESI: m/z 856.3 $(M-PF_6)^+$. Anal. Found (%): C 45.52, H 3.46, N 9.17. Anal. Calcd for $C_{38}H_{33}N_7$ $PF_{10}Ir$: C 45.61, H 3.30, N 9.80.

*2.2.3. [Ir(mppy)$_2$(trzpy-cn)]PF$_6$ (**C2**)*

The synthesis was similar to that of **C1** except that the dichloro-bridged diiridium complex $[Ir(dfppy)_2Cl]_2$ was replaced with $[Ir(mppy)_2Cl]_2$. Yield: 70%. ^{1}H NMR (300 M Hz, $CDCl_3$) δ (ppm): 8.31 (d, 1H, J = 7.92 Hz, ArH), 7.98–8.08 (m, 2H, ArH), 7.73–7.89 (m, 5H, ArH), 7.55 (t, 2H, J = 6.15 Hz, ArH), 7.43 (d, 1H, J = 5.79 Hz, ArH), 7.30–7.37 (m, 2H, ArH), 6.95 (t, 1H, J = 7.14 Hz, ArH), 6.83 (t, 2H, J = 7.98 Hz, ArH), 6.14 (s, 1H, ArH), 6.05 (s, 1H, ArH), 4.10–4.32 (m, 2H), 2.10 (s, 6H), 2.02–2.09 (m, 2H), 1.89 (s, 3H), 1.50–1.52 (m, 4H), 1.31 (s, 6H). ESI: m/z 812.3 $(M-PF_6)^+$. Anal. Found (%): C 50.11, H 4.35, N 9.30. Anal. Calcd for $C_{40}H_{41}N_7$ PF_6Ir: C 50.2, H 4.31, N 10.2.

*2.2.4. [Ir(dfppy)$_2$(trzpy-hx)](PF$_6$) (**C3**) and [Ir(mppy)$_2$-(trzpy-hx)](PF$_6$) (**C4**)*

Compounds **C3** and **C4** were synthesized according to the similar methods with that of **C1** and **C2**, respectively. Compound **C3**: Yield: 65%. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.33–8.35 (m, 2H, ArH), 8.27 (d, 1H, J = 9.21 Hz, ArH), 8.04–8.14 (m, 2H, ArH), 7.79–7.85 (m, 3H, ArH), 7.40–7.46 (m, 3H, ArH), 7.07 (t, 1H, J = 6.12 Hz, ArH), 6.49–6.61 (m, 2H, ArH), 5.71–5.75 (m, 1H, ArH), 5.61–5.65 (m, 1H, ArH), 4.10–4.29 (m, 2H), 1.96 (s, 3H), 1.23–1.44 (m, 12H), 0.88 (t, 3H, J = 7.08 Hz). ESI: m/z 854.3 $(M-PF_6)^+$. Anal. Found (%): C 46.21, H 3.99, N 8.18. Anal. Calcd for $C_{38}H_{36}N_6$ $PF_{10}Ir$: C 46.10, H 3.61, N 8.40.

Compound **C4**: Yield: 67%. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.29 (d, 1H, J = 7.74 Hz, ArH), 7.95–8.04 (m, 2H, ArH), 7.70–7.89 (m, 5H, ArH), 7.55 (t, 2H, J = 7.50 Hz, ArH), 7.44 (d, 1H, J = 5.73 Hz, ArH), 7.34–7.38 (m, 2H, ArH), 6.93–6.97 (m, 1H, ArH), 6.78–6.86 (m, 2H, ArH), 6.15 (s, 1H, ArH), 6.05 (s, 1H, ArH), 4.13–4.15 (m, 2H), 2.12 (s, 3H), 1.85 (s, 6H), 1.23–1.26 (m, 12H), 0.88 (t, 3H, J = 7.11 Hz). ESI: m/z 810.2 $(M-PF_6)^+$. Anal. Found (%): C 50.9, H 4.52, N 8.31. Anal. Calcd for $C_{40}H_{44}N_6PF_6Ir$: C 50.8, H 4.60, N 8.80.

2.3. Fabrication and characterization of LEC devices

LEC devices were fabricated by spin-coating the mixed solutions of complexes on indium-tin-oxide coated glass substrates to form a 100-nm thick film, followed by thermal evaporation of a 150 nm Al top contact (cathode). $BMIM^+(PF_6)^-$ was added to provide additional anions, which shortened the device response time. The electrical and emission characteristics of LECs were measured under constant bias voltages. The current density–time–luminance characteristics were collected using a Keithley 236 source measurement unit and a calibrated silicon photodiode. The luminance was calibrated by a PR-705 SpectraScan Spectrophotometer (Photo Research) with simultaneous acquisition of the EL spectra and CIE coordinates, driven by a Keithley model 2400 vague-current source, and all of the device fabrication and measurements were performed in the glove box filled with nitrogen. The alternating current (ac) impedances were measured using a HP4192A impedance analyzer in the frequency (f) range from 100 Hz to 5 MHz at room temperature, with an ac drive amplitude of 30 mV. The impedance results in the paper are expressed as: $Z = Z' - jZ''$, where Z' and Z'' are the real part and the imaginary part of the impedance, respectively.

3. Results and discussion

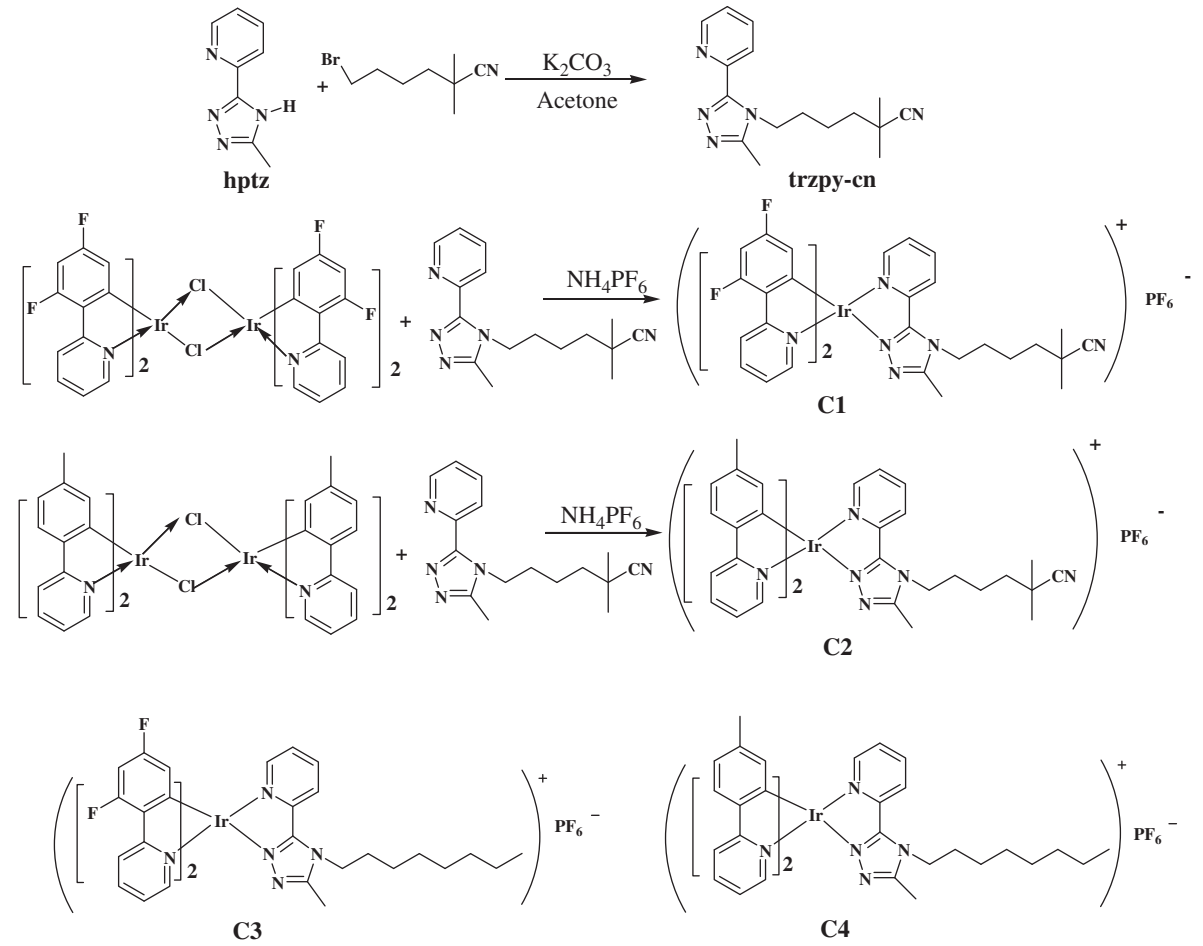
3.1. Synthesis and characterization

The synthetical routes of the ligands and complexes are shown in Scheme 1. **C1** refers to $[Ir(dfppy)_2(trzpy\text{-}cn)]^+(PF_6)^-$, and **C2** to $([Ir(mppy)_2(trzpy\text{-}cn)]^+(PF_6)^-$, where dfppy is 2-(2,4-difluorophenyl)pyridine, trzpy-cn is 2,2-dimethyl-6-(3-methyl-5 -(pyridin-2-yl)-4*H*-1,2,4-triazol-4-yl) hexanenitrile). The ancillary ligand trzpy-cn was easily synthesized from 5-methyl-3-(pyridin-2-yl)-4*H*-1,2,4-triazole (hptz) and 6-bromo-2,2-dimethylhexanenitrile by alkylation reaction. Compounds **C1** and **C2** were then synthesized by reacting dimeric iridium intermediates with trzpy-cn, following by ion exchange from Cl^- to PF_6^-. Compounds **C3** and **C4,** in which the cyanogen group is absent in the alkyl chain were synthesized with the similar methods to **C1** and **C2**, respectively, except that the 6-bromo-2,2-dimethylhexanenitrile was replaced with the 1-bromooctane.

3.2. Thermal and electrochemical properties

The thermal properties of the complexes ware investigated by the thermogravimetric (TGA) and differential scanning calorimetry (DSC). TGA curves of the complexes are shown in Fig. 1. The decomposition temperatures (T_d, corresponding to 5 wt.% loss) and the glass transition temperature (T_g) for complexes are shown in Table 1. The decomposition temperatures for **C1**, **C2**, **C3** and **C4** are as high as 370, 358, 360 and 351 °C, respectively. Compared with **C4**, the higher T_d of **C2** suggests that cyanogen group have the ability to increase the thermal stability of the complex. On the other hand, the highest T_d of **C1** could be attributed to the presence of fluorine atom and cyanogen group. The T_gs for **C2**, **C3** and **C4** are 131, 113, and 118 °C, respectively. The high T_g and T_d are important for the complexes to be used in LECs applications, which would be expected to retain stable film morphology during the device operation. The morphologies of **C1** and **C2** film were investigated by AFM (Fig. 2) spin-coated from acetonitrile solvent, which forms homogeneous film with very low average surface roughness (0.683 nm for **C1** and 0.381 nm for **C2**).

The electrochemical properties of the complexes were investigated by cyclic voltammetry (Fig. 3) and the data are summarized in Table 1. As shown in Fig. 3, the complexes exhibit reversible oxidation and reduction processes in CH_3CN solution. The redox reversibility of the complexes indicates that both holes (upon oxidation) and electrons



Scheme 1. The synthetic routes of the complexes.

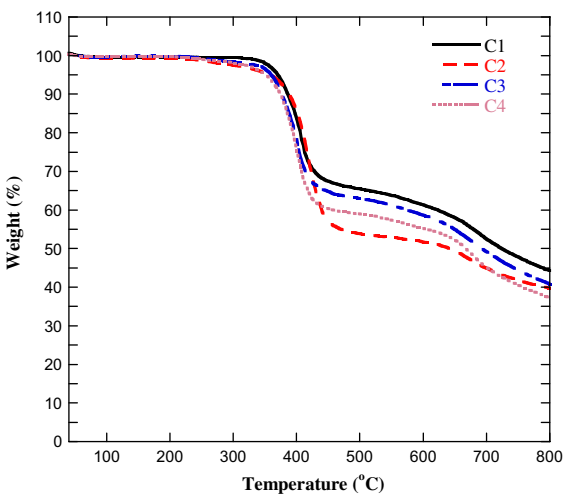


Fig. 1. TGA curves of the complexes at a heating rate of 20 °C/min in nitrogen.

(upon reduction) can be transported, therefore efficient LECs can be constructed based on these complexes. The measured oxidation potentials for **C1** and **C2** were 1.14 and 0.74 V as referred to ferrocene, respectively, which can be mainly assigned to the oxidation of Ir(**III**) cationic site to Ir(**IV**), with a minor contribution from the cyclometalated ligand. The higher oxidation potential of **C1** can be attributed to the strong electron-withdrawing fluorine substituents in the complex, which decrease the electron density in the phenylpyridines, thus make the complex more difficult to be oxidized [3,26,27].

The measured reduction potentials for **C1** and **C2** are −1.92 and −1.99 V, respectively, which are mainly assigned to the reduction of ancillary ligand. The slightly lower reduction potentials of **C1** can be attributed to the fluorine atom which also makes the complex more electrophilic and decrease the reduction potential as described in the literature [28]. The higher LUMO of **C1** (−2.88 eV) and **C2** (−2.81 eV) respect to $[Ir(ppy)_2(dtb\text{-}bpy)]PF_6$ [10] indicate that the LUMO are significantly destabilized by the ancillary ligand trzpy-cn due to the strong electron-donating triazole ring. The HOMO–LUMO gap of **C1** and **C2** are 3.05 and 2.73 eV, respectively. A wider energy gap observed in **C1** than that in **C2** thus can suggest a blue-shifted emission. The electrochemical properties of **C3** and **C4** are almost identical with that of **C1** and **C2**, respectively, as referred in Table 1.

Table 1
The physical properties of the complexes.

Complex	UV (nm)	PL (nm)	E_{ox} (V)	E_{red} (V)	HOMO (eV)	LUMO (eV)	E_{gap} (eV)	T_d[a] (°C)	T_g (°C)
C1	249, 366	454, 485	1.14	−1.92	−5.93	−2.88	3.05	370	–
C2	257, 388	480, 512	0.74	−1.99	−5.54	−2.81	2.73	358	131

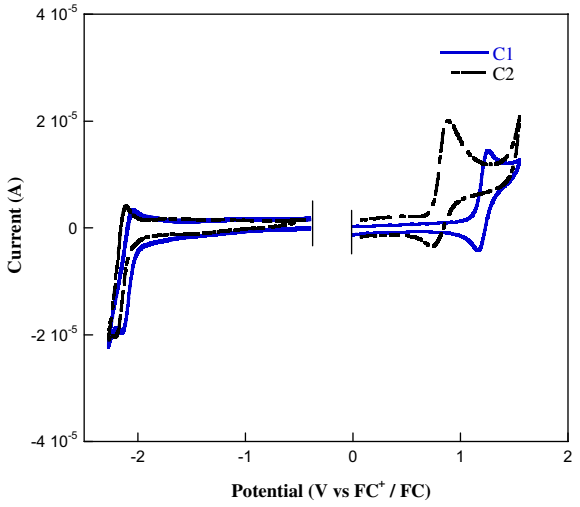

Fig. 3. Cyclic voltammograms of **C1** and **C2** in CH_3CN solution of 10^{-3} M, potentials recorded versus Fc^+/Fc (ferrocene).

3.3. Photophysical properties

The UV–vis absorption and photoluminescence (PL) spectra of the complexes in CH_2Cl_2 solution as well as in film are shown in Fig. 4. The intense absorption bands in the region of 230–350 nm can be ascribed to spin-allowed $^1\pi$–π ligand-centered (LC) transitions. The relatively weak absorption bands range between 350 nm and the visible region correspond to metal-to-ligand charge-transfer transitions (^{3}MLCT) of the complexes. As compared with **C2**, the absorption of the **C1** shows a blue-shift of 30 nm due to the electron-withdrawing fluorine atom in the ligand.

The photo-physical characteristics of the obtained complexes are summarized in Table 1. The PL spectra of **C1** and **C2** in solution are peaked at 452 nm and 479 nm, located in the blue and blue-green region, respectively. The PL spectra of **C1** are significantly blue-shifted about 80 nm with respect to the ionic iridium complexes used bpy as the ancillary ligand, such as $[Ir(dfppy)_2(dtb\text{-}bpy)](PF_6)$(534 nm) [29]. The results clearly demonstrate that the trzpy-cn ancillary ligand has a favorable capability to tune the emission color of the cationic iridium complex to blue region.

As compared with that in solution, the PL spectra of **C1** and **C2** in film are only a little broaden, implying a weak excited-state quenching of the complexes in solid-state, which is very important toward highly efficiency non-doping single-layer LECs. Of which, the emission of **C1** peaked at 454 nm in film is one of the shortest wavelength for cationic iridium complex reported up to now [26,30,31].

3.4. Electroluminescent properties

LECs with device structure of indium tin oxide (ITO)/poly(3,4-ethylenedioxy-thiophene): poly(styrene sulfonate)(PEDOT:PSS)/(complex:$BMIM^+(PF_6^-)$ 14 wt.%)/Al was fabricated, where the PEDOT:PSS layer is inserted as anode buffer layer to smoothen the anode surface and facilitate hole injection, while ionic liquid $BMIM^+(PF_6^-)$ (1-butyl-3-methylimidazolium hexafluorophosphate) is introduced into the emissive layer to reduce the response time of these devices.

Electroluminescent spectra of the complexes are shown in Fig. 5. The device based on **C1** emits sky-blue light with CIE coordinates of (0.21, 0.33), which is, to our knowledge, one of the bluest light emission for LECs from ionic complexes reported so far [4,5,8,11,26]. The device based on

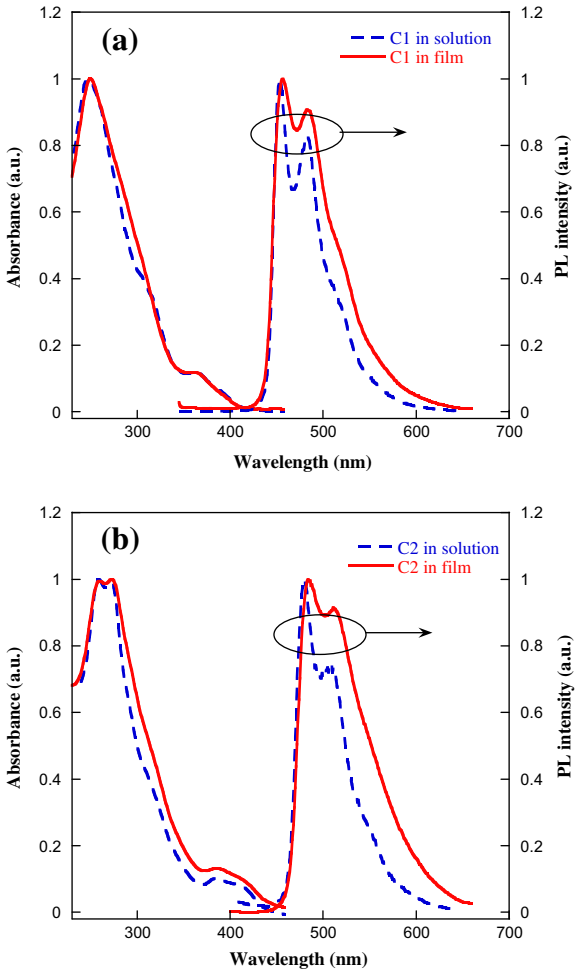

Fig. 4. Absorption spectra and fluorescence spectra of **C1** (a) and **C2** (b) in dilute CH_2Cl_2 solution and in film.

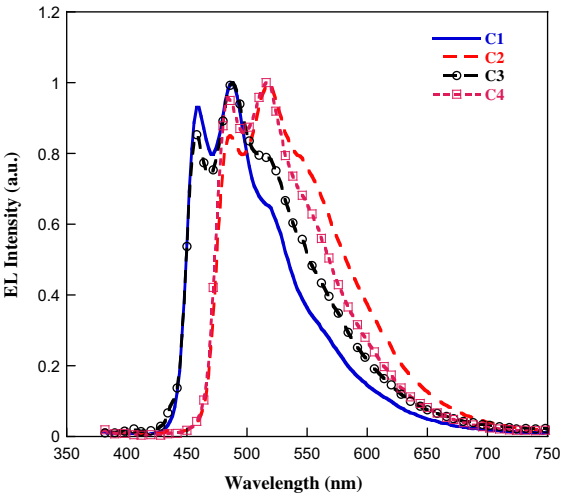

Fig. 5. Electroluminescent spectra of **C1**–**C4** with the device configuration of ITO/PEDOT:PSS/complex:$BMIMPF_6$/Al.

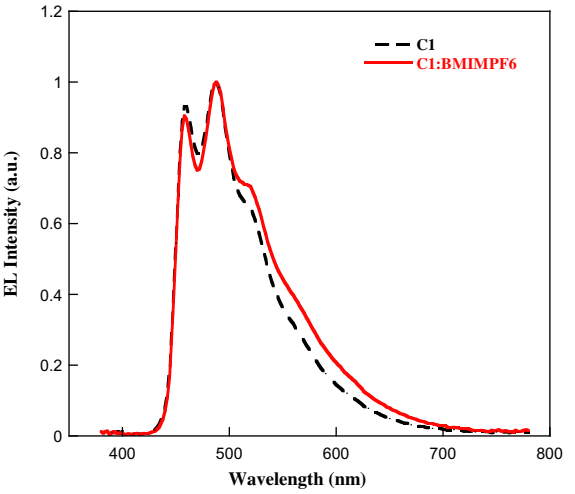

Fig. 6. Electroluminescent spectra of complex **C1** with and without $BMIMPF_6$.

C2 emits blue-green light with CIE coordinates of (0.31, 0.53). In addition, the devices from **C3** and **C4** exhibit almost the similar EL spectra with that of **C1** and **C2**, respectively. Unlike other reports [11], EL spectra of the complexes are almost identical with and without $BMIM^+(PF_6^-)$ (Fig. 6), which suggest that the emissive excited state of complexes are very stable even in the $BMIM^+(PF_6^-)$ blended film [32].

The device performances are shown in Table 2. The device from **C1** exhibit a LE of 2.6 cd/A (corresponding to an EQE of 2.7%), comparable with the best in literatures [11,26,30]. The LE of **C1** (2.6 cd/A) is 10 times of that of the **C3** (0.26 cd/A). Similarly, the LE of the **C2** device is found to be 4 times over that of **C4** device (6.8 cd/A vs. 1.7 cd/A). Fig. 7a shows the current density–luminance–time characteristics of LECs based on **C1** and **C3** under a constant bias of 5.0 V. We note that the device of **C1** exhibits much faster turn-on time (23 min vs. 45 min), higher current density, and higher brightness compared with the **C3** device. The similar results also can be found in **C2** and **C4** devices(Fig. 7b), in which **C2**/**C4** devices show faster turn-on time (4 min for **C2**, 12 min for **C4**) than **C1**/**C3** device. The results show that the cyanogen group in the alkyl chain of the complexes has a significant impact on the response time and the efficiency of LEC device.

Underlying mechanism responsible for the enhanced performances in **C1**/**C2** devices was further investigated by using alternating current (ac) impedance spectroscopy [33,34]. Fig. 8 shows Cole–Cole plots of the devices at several different bias voltages based on **C2** and **C4**. As can be clearly seen, under the same applied voltage studied, **C2** device shows much smaller electrical impedance than **C4** device, implying a higher ion mobility in the former device as expected from differential form of Ohm law. Therefore, the faster motion of the ions in the **C1**/**C2** devices can ensure the faster turn-on time and the higher current density observed in the devices as mentioned above. So

far, the observed higher ion mobilities in the **C1**/**C2** devices could be attributed to the interaction between the cyanogen group in the alkyl chain of the complexes and the electrodes, and hence lead to smaller electrical impedances and improved device efficiencies.

4. Conclusions

Four novel sky-blue and blue-green emitting cationic iridium complexes with triazole-pyridine as the ancillary ligand were prepared and characterized. The emission of these cationic iridium complexes can be tuned and blue-shifted by using triazole-pyridine ancillary ligand. Upon the cyanogen group in the side alkyl chain of the ancillary ligand, the device efficiencies were significantly improved. Single layer LECs based on **C1** and **C2** show a high luminous efficiency of 2.6 cd/A with CIE coordinate of (0.21, 0.33), and a LE of 6.8 cd/A with a CIE coordinate of (0.31, 0.53), respectively.

1. Introduction

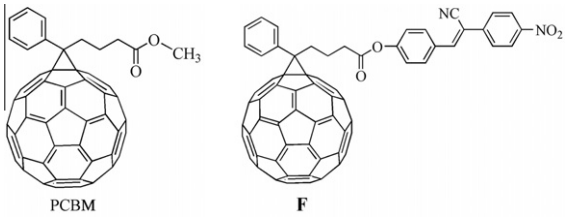
Organic semiconducting materials open the way of low-cost, flexible, and large-scale solar cells. Recently, power conversion efficiencies (PCEs) above 5% and to 6.1% have been reported for bulk-heterojunction (BHJ) solar cells [1–3]. These solar cells comprising interpenetrating networks of an organic donor (D) and a fullerene derivative acceptor (A) such as [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) constitute a promising technology because they are easy to fabricate by solution processing and are predicted theoretically to yield PCEs of up to 10–15% if a suitable low band gap donor material is discovered [4]. Although considerable research effort has been expended to develop such low band-gap donor materials [5], the highest reported efficiencies have been dominated by conjugated polymers such as poly(3-hexylthiophene) (P3HT) [6–9]. This system has been explored thoroughly for the past decade. The high efficiency of P3HT–fullerene devices can be explained by the ability of the blend to phase separate and crystallize into desirable BHJ morphologies after processing, allowing for efficient charge separation and transport [10,11]. The current effort in this area was focused on developing the low band gap polymers to harvest the near infrared light [12]. However, polymers have problems of poor reproducibility, difficulty in purification, and poor controllability in the molecular weight. Thus efforts have been laid on developing solution processable low band gap organic SM donors, because they offer advantages of easy synthesis and purification and mono-dispersion in the molecular weight, which greatly improve the reproducibility in the performance of the devices.

Most of the researchers related to BHJ solar cells have focused on polymeric donor materials, since they generally have better film-forming properties than non-polymeric materials [13]. Small-molecule (SM) donor materials can also form useable BHJ solar cells by solution processing, although it is more challenging to obtain high-quality films. The highest reported efficiencies for such devices have remained lower relative to solution processed solar cells using polymeric donor materials. SM materials, however, offer advantages over polymeric materials in terms of ease of synthesis and purification, which greatly improve fabrication reproducibility, as well as possessing a greater tendency to self assemble into ordered domains, which leads to high charge carrier mobilities [14,15]. SMs do not suffer from batch to batch variations, broad molecular-weight distributions, end-group contamination, or difficult purification methods, which can be significant problems for polymeric materials. These considerations make SMs a promising class of donor material for BHJ solar cell applications [16–24]. The PCE of solution processable SMs has steadily improved up to in the range 2.0–4.4% [25], due to considerable efforts towards the development of new SMs having low band gap and semiconducting property. Particularly, significant progress has been made in the synthesis and processing of donor–acceptor (D–A) SMs. Theoretical and experimental progresses in organic solar cells (OSCs) have demonstrated that such D–A SMs and polymers have great potential to be one class of promising materials for OSCs. D–A SMs can be considered as efficient donor materials for OSCs because of the fact that the absorption spectrum of theses molecules can be extended towards longer wavelengths by intra-molecular charge transfer (ICT) transition between donor and acceptor inside molecules [21] and the energy level can be easily controlled by introducing various electron donating or acceptor groups into the molecules.

On the other hand, a number of polyfluorenes and their derivatives have been studied as a photoactive structure in polymer light-emitting devices and solar cells on account of their large band gap, high photoluminescence, electroluminescence efficiencies, good thermal/chemical stability, and good solubility in common organic solvents. Alternating polyfluorene copolymers with various band gaps have been synthesized, and solar cells based on some of these copolymers have demonstrated PCEs of ~1% [26,27]. A literature survey revealed that certain fluorene containing copolymers have been synthesized and used for BHJ solar cells very recently [28–32]. Finally, among the various types of reported polymer semiconductors, poly(*p*-phenylenevinylenes) (PPVs) [33–35] and their derivatives are widely used in solar cell applications as p-type donor materials. Poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenlenevinylene] (MEH-PPV) is a PPV derivative which has been mainly used as electron donor for BHJ solar cells [36].

A series of low band gap SMs that contain cyanovinylene 4-nitrophenyl segments have been recently synthesized in our laboratory and used as donors with PCBM as acceptor for BHJ solar cells [37–41]. Additionally, we have very recently synthesized a modified PCBM derivative **F** (Scheme 1) carrying cyanovinylene 4-nitrophenyl segment [42]. Specifically, PCBM has been hydrolyzed to carboxylic acid and then converted to the corresponding carbonyl chloride. The latter was condensed with 4-nitro-4′-hydroxy-α-cyanostilbene to afford **F**. It showed higher solubility than PCBM in common organic solvents due to the increase of the organic moiety. Both solutions and thin films of **F** displayed stronger absorption than PCBM in the range of 250–900 nm. BHJ solar cells based on P3HT as electron donor with **F** as electron acceptor exhibited a PCE of 4.23%, while the device based on P3HT:PCBM exhibited PCE of 2.93% under the same conditions [42].

Herein, we report the synthesis of two low band gap SMs, **PH** and **FL**, based on phenylenevinylene and fluorenevinylene, respectively. They contain certain common structural characteristics, namely triphenylamine (TPA) and cyanovinylene 4-nitrophenyl segments. They are only



Scheme 1. Chemical structures of the electron acceptors (PCBM and **F**) used in this investigation.

differentiated by their central unit which is 2,5-dihexyloxy(phenylenevinylene) for **PH** and 9,9-dihexyl(fluorenevinylene) for **FL**. The aliphatic chains which are attached to the central unit enhanced the solubility of these SMs. They were successfully synthesized by a four-step reaction sequence. The last step of their synthesis included the condensation of a key-tetraaldehyde with 4-nitrobenzyl cyanide. Both SMs possess the D–A architecture. Specifically, they carry phenylenevinylene/fluorenevinylene and TPA as D units and cyanovinylene 4-nitrophenyl as A units which allow an intramolecular charge transfer (ICT), thus reducing the optical band gap (E_g^{opt}) of the SMs. Moreover, the presence of the TPA moieties is expected to increase the hole mobility of both SMs. We have used these SMs as electron donor along with PCBM or modified PCBM, i.e. **F** as electron acceptor for the fabrication of BHJ PV devices. The PCEs for the devices based on **PH**:PCBM and **FL**:PCBM cast from chloroform solvent are 1.02% and 1.46%, respectively. In addition, we investigated the effect of solvent used for the spin casting of the **FL**:PCBM blend on the PV response of the device and found that the solvent has a strong influence on the morphology of the blend films and on the PCE of the device. Finally, we have replaced the electron acceptor PCBM by the modified PCBM, i.e. **F**, which has strong absorption at lower wavelength region (below 500 nm) and fabricated BHJ devices using **FL** as electron donor. We have achieved PCE about 3.62% and 4.38% for **FL**:**F** BHJ active layer cast from o-dichlorobenzene (DCB) and 1-chloronaphthalene/o-dichlorobenzene (CN/DCB) solvent, respectively. The BHJ cast from the mixed solvents (CN/DCB) leads to an enhanced self organization and crystallinity of **FL** in active layer, which causes an increased charge transport, incident absorption and higher carrier mobility in the active layer thus contributing to the enhancement in the device performance.

2. Experimental

2.1. Reagents and solvents

4-Nitrobenzyl cyanide was synthesized from the nitration of benzyl cyanide with concentrated nitric and sulfuric acid [43]. It was recrystallized from ethanol. 1,4-Divinyl-2,5-bis(hexyloxy)-benzene was prepared by Stille coupling reaction [44] of 1,4-dibromo-2,5-bis(hexyloxy)-benzene with tributylvinyltin [45]. 9,9-Dihexyl-2,7-divinylfluorene was prepared by Stille coupling [44] of 2,7-dibromo-9,9-dihexylfluorene with tributylvinyltin [46]. *N*,*N*-dimethylformamide (DMF) and tetrahydrofuran (THF) were dried by distillation over CaH_2. Triethylamine was purified by distillation over KOH. All other reagents and solvents were commercially purchased and were used as supplied.

2.2. Preparation of small molecules

2.2.1. Compound ***3a***

A flask was charged with a mixture of **2** (0.2957 g, 0.778 mmol), 1,4-divinyl-2,5-bis(hexyloxy)-benzene (0.1285 g, 0.389 mmol), $Pd(OAc)_2$ (0.0017 g, 0.007 mmol), P(*o*-tolyl)$_3$ (0.0047 g, 0.015 mmol), DMF (10 mL), and triethylamine (3 mL). The flask was degassed and purged with N_2. The mixture was heated at 90 °C for 24 h under N_2. Then, it was filtered and the filtrate was poured into methanol. The precipitate was filtered and washed with methanol. The crude product was purified by dissolving in THF and precipitating into methanol (0.3072 g, yield 85%).

FT-IR (KBr, cm^{-1}): 2952, 2926 (C–H stretching of hexyloxy chains); 1676 (formyl); 3030, 1590, 1506 (aromatic); 1320 (C–N stretching of triphenylamine); 1286, 1272, 1214 (ether bond); 967 (*trans* vinylene bond).

^{1}H NMR ($CDCl_3$) ppm: 9.80 (s, 4H, formyl); 7.67 (m, 8H, TPA ortho to formyl); 7.30–7.2 (m, 16H, other TPA; 4H, vinylene); 6.75 (s, 2H, phenylene); 3.96 (m, 4H, $OCH_2(CH_2)_4CH_3$); 1.81 (m, 4H, $OCH_2CH_2(CH_2)_3CH_3$); 1.37 (m, 12H, $O(CH_2)_2(CH_2)_3CH_3$); 0.91 (t, 6H, $O(CH_2)_5CH_3$).

2.2.2. Compound ***3b***

Compound **3b** was similarly prepared in 80% yield (0.22 g) from the reaction of **2** (0.2106 g, 0.554 mmol), with 9,9-dihexyl-2,7-divinylfluorene (0.1071 g, 0.277 mmol) in DMF (10 mL) in the presence of triethylamine (3 mL), $Pd(OAc)_2$ (0.0012 g, 0.005 mmol) and P(*o*-tolyl)$_3$ (0.0034 g, 0.011 mmol).

FT-IR (KBr, cm^{-1}): 2950, 2925 (C–H stretching of hexyl chains); 1675 (formyl); 3029, 1592, 1504 (aromatic); 1315 (C–N stretching of TPA); 965 (*trans* vinylene bond).

^{1}H NMR ($CDCl_3$) ppm: 9.80 (s, 4H, formyl); 7.72 (m, 2H, H4 of fluorene); 7.67–7.60 (m, 4H, H1 and H3 of fluorene; 8H, TPA ortho to formyl); 7.30–7.02 (m, 16H, other TPA; 4H, vinylene); 2.06 (m, 4H, $CH_2(CH_2)_4CH_3$); 1.11 (m, 16H, $CH_2(CH_2)_4CH_3$); 0.78 (t, 6H, $(CH_2)_5CH_3$).

2.3. Small molecule ***PH***

A flask was charged with a solution of **3a** (0.3614 g, 0.389 mmol) and 4-nitrobenzyl cyanide (0.2523 g, 1.556 mmol) in DMF (15 mL). Sodium hydroxide (0.20 g, 5.00 mmol) dissolved in ethanol (5 mL) was added portionwise to the stirred solution. The mixture was stirred for 1 h at room temperature under N_2 and then was concentrated under reduced pressure. Water was added to the concentrate and the product precipitated as a dark green solid. It was filtered, washed thoroughly with water and dried to afford **PH**. It was purified by column chromatography, eluting with a mixture of dichloromethane and hexane (1:1) (0.46 g, 80%).

FT-IR (KBr, cm^{-1}): 2950, 2924 (C–H stretching of hexyloxy chains); 2158 (cyano); 1524, 1344 (nitro); 1316 (C–N stretching of TPA); 1284, 1248 (ether bond); 1584, 1504 (aromatic); 965 (*trans* vinylene bond); 1013 (cyanovinylene).

^{1}H NMR ($CDCl_3$) ppm: 8.19 (m, 8H, phenylene ortho to nitro); 7.83 (s, 4H, cyanovinylene); 7.52 (m, 8H, phenylene meta to nitro); 7.30–7.13 (m, 24H, TPA); 7.10 (m, 4H, vinylene); 6.75 (s, 2H, phenylene ortho to oxygen); 3.96 (m, 4H,

$OCH_2(CH_2)_4CH_3$); 1.81 (m, 4H, $OCH_2CH_2(CH_2)_3CH_3$); 1.37 (m, 12H, $O(CH_2)_2(CH_2)_3CH_3$); 0.91 (t, 6H, $O(CH_2)_5CH_3$).

Anal. Calcd. for $C_{94}H_{76}N_{10}O_6$: C, 74.98; H, 5.09; N, 9.30. Found: C, 74.37; H, 4.82; N, 9.13.

2.4. Small molecule *FL*

FL was similarly prepared in 83% yield (0.36 g) from the reaction of **3b** (0.2729 g, 0.277 mmol) with 4-nitrobenzyl cyanide (0.1797 g, 1.108 mmol) in DMF (15 mL) in the presence of sodium hydroxide (0.20 g, 5.00 mmol).

FT-IR (KBr, cm^{-1}): 2950, 2924 (C–H stretching of hexyl chains); 2160 (cyano); 1522, 1346 (nitro); 1314 (C–N stretching of TPA); 1584, 1506 (aromatic); 964 (*trans* vinylene bond); 1004 (cyanovinylene).

^1H NMR ($CDCl_3$) ppm: 8.19 (m, 8H, phenylene ortho to nitro); 7.83 (s, 4H, cyanovinylene); 7.72 (m, 2H, H4 of fluorene); 7.60 (m, 4H, H1 and H3 of fluorene); 7.52 (m, 8H, phenylene meta to nitro); 7.30–7.13 (m, 24H, TPA); 7.10 (m, 4H, vinylene); 2.06 (m, 4H, $CH_2(CH_2)_4CH_3$); 1.11 (m, 16H, $CH_2(CH_2)_4CH_3$); 0.78 (t, 6H, $(CH_2)_5CH_3$).

Anal. Calcd. for $C_{101}H_{80}N_{10}O_8$: C, 77.67; H, 5.16; N, 8.97. Found: C, 77.38; H, 5.21; N, 9.20.

2.5. Characterization methods

IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrometer with KBr pellets. ^1H NMR (400 MHz) spectra were obtained using a Brucker spectrometer. Chemical shifts (δ values) are given in parts per million with tetramethylsilane as an internal standard. UV–Vis spectra were recorded on a Beckman DU-640 spectrometer. Elemental analyses were carried out with a Carlo Erba model EA1108 analyzer.

The electrochemical properties of both SMs, i.e. **PH** and **FL** were examined using cyclic voltammetry (CV) (EDCA electrochemistry system). A glassy carbon electrode was used as working electrode. The SMs were coated on glassy carbon electrode from tetrahydrofuran (THF) solution and immersed in 0.1 mol/L Bu_4NPF_6 acetonitrile solution used as supporting electrolyte. Cyclic voltammograms were recorded, using Ag/Ag+ as reference electrode at a scan rate of 100 mV/s.

The crystallinity of the films was studied using the X-ray diffraction (XRD) technique (panalytical make USA) having CuKα, as radiation source of wavelength λ = 1.5405 Å with the films coated on the quartz substrates. Atomic force microscopy (AFM) images were recorded using digital instrument nanoscope in trapping mode.

2.6. Device fabrication and characterization

All the devices were fabricated on indium tin oxide (ITO) coated glass substrates. The ITO coated glass substrates were cleaned with acetone in an ultrasonic bath. A thin layer of poly(3,4-ethylene-dioxythiophene): poly(styrene sulfonate) (PEDOT:PSS) (70 nm) was spin coated on it from PEDOT:PSS aqueous solution at 2000 rpm and dried subsequently at 80 °C for 20 min in air, and then transferred into a glove box. The active layer of the blend of **PH** or **FL** with PCBM was spin coated from different solvents (chloroform, chlorobenzene, o-dichlorobenzene, and 2% additive 1-chloronaphthalene (CN) in o-dichlorobenzene), onto the PEDOT:PSS layer, and then dried in ambient conditions. The concentration of **PH** or **FL**:PCBM blend solution used in this study for spin coating was 10 mg/mL in the solvent used. The thickness of the active layers is approximately 90–95 nm. The structure of the device is ITO/PEDOT:PSS/**PH** or **FL**:PCBM/Al. The effective active area of the devices is about 20 mm^2. Current–voltage (J–V) characteristics of the devices were measured using a computer controlled Keithley 238 source meter in dark and under illumination intensity of 100 mW/cm^2 in ambient conditions. A xenon light source was used to give simulated irradiance of 100 mW/cm^2 (equivalent to and AM1.5 irradiation) at the surface of the device.

We have also fabricated BHJ devices based on **FL**:**F** using the same method. To measure the hole and electron mobilities, the devices having structure ITO/PEDOT:PSS/**FL**:**F**/Au and Al/**FL**:**F**/Al were used, respectively and the J–V characteristics in dark have been recorded.

3. Results and discussion

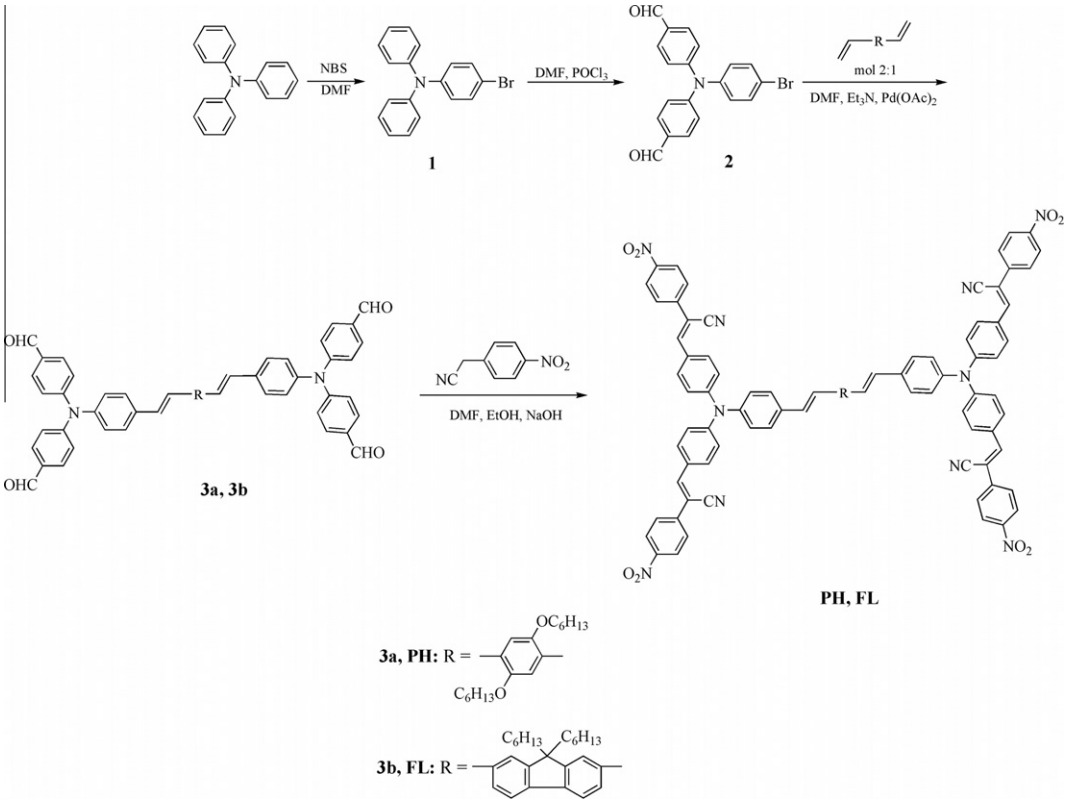
3.1. Synthesis and characterization

Scheme 2 outlines the four-step reaction for the synthesis of SMs. Compounds **1** [47] and **2** [48] have been synthesized according to reported methods. Compound **2** reacted with 1,4-divinyl-2,5-bis(hexyloxy)-benzene and 9,9-dihexyl-2,7-divinylfluorene in a mol ratio 2:1 to afford **3a** and **3b**, respectively. This reaction took place in DMF using Et_3N as acid scavenger and $Pd(OAc)_2$ as catalyst. Finally, the condensation of **3a** and **3b** with 4-nitrobenzyl cyanide in the presence of sodium hydroxide gave **PH** and **FL**, respectively. These SMs were soluble in common organic solvents such as tetrahydrofuran, chloroform and dichloromethane owing to the aliphatic chains.

The SMs were characterized by FT-IR and ^1H NMR spectroscopy. The IR spectra showed common absorption bands approximately at 2952, 2926 (C–H stretching of aliphatic chains); 2128 (cyano); 1524, 1344 (nitro); 1316 (C–N stretching of TPA); 1584, 1504 (aromatic); 965 (vinylene), and 1013 cm^{-1} (cyanovinylene). On the other hand, the ^1H NMR spectra of SMs displayed common signals at 8.19 (phenylene ortho to nitro); 7.83 (cyanovinylene); 7.52 (phenylene meta to nitro); 7.30–7.13 (TPA) and 7.10 ppm (vinylene). Finally, the aliphatic chains resonated at the range of 3.96–0.91 ppm for **PH** and 2.06–0.78 ppm for **FL**.

3.2. Photophysical and electrochemical properties

Fig. 1 depicts the UV–Vis absorption spectra of SMs in both dilute (10^{-5} M) THF solution and thin film. All photophysical and electrochemical characteristics of SMs are summarized in Table 1. The solutions showed long-wavelength absorption maximum ($\lambda_{a,max}$) or shoulder around 605 and 643 nm, while the thin films showed $\lambda_{a,max}$ at 626–632 nm. The spectra were broad and extended approximately up to 750 nm in solutions and 800 nm in



Scheme 2. Synthesis of SMs **PH** and **FL**.

thin films which is desirable for PV applications. This feature was attributed to an ICT between the electron-donating central unit (phenylenevinylene/fluorenevinylene and TPA) and the electron-accepting terminal units (cyanovinylene 4-nitrophenyl). The thin film absorption onset was located at 758 and 746 nm corresponding to an E_g^{opt} of 1.64 and 1.66 eV for **PH** and **FL**, respectively. The optical properties of SMs are similar thus supporting that their central unit did not influence significantly their photophysical characteristics.

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the organic polymers and SMs are important parameters in the design of organic photovoltaic (OPV) devices, and they can be estimated from the onset oxidation (E_{onset}^{ox}) and reduction (E_{onset}^{red}) potentials [49]. Fig. 2 shows the cyclic voltammograms of **PH** and **FL**. Similar cyclic voltammograms have been reported for other small molecules in the literature [50]. The E_{onset}^{ox} and E_{onset}^{red} potentials vs. Ag/Ag+ (Table 1) were used for calculation of the HOMO and LUMO energy levels according to the following expressions [51].

$$\mathrm{HOMO} = -q(E_{onset}^{ox} + 4.7)\ \mathrm{eV}$$

$$\mathrm{LUMO} = -q(E_{onset}^{red} + 4.7)\ \mathrm{eV}$$

The values of the HOMO and LUMO levels of the **PH** and **FL** are given in Table 1. The LUMO level of both SMs is the same but the HOMO level is −5.35 and −5.30 eV for **PH** and **FL**, respectively. This implies that the HOMO levels are mainly affected by the D unit in SM, while the LUMO levels (−3.55 eV) are primarily controlled by the acceptor moieties. Since the LUMO level of PCBM is −3.95 eV, the energy difference between the LUMOs of these SMs and PCBM is about 0.3–0.4 eV, which should be sufficient for the exciton splitting and charge dissociation [52]. In addition, the deeper HOMO level of these SMs is desirable for higher open circuit voltage (V_{oc}) of the OPVs with organic semiconductors as D materials because the V_{oc} is usually proportional to the difference between the LUMO level of the acceptor and the HOMO level of the D. The electrochemical band gaps have been estimated from the energy difference between the HOMO and LUMO levels and they are 1.80 and 1.75 eV for **PH** and **FL**, respectively.

3.3. Photovoltaic properties

Fig. 3(a) shows the *J–V* characteristics of the OPVs based on SMs (**PH** or **FL**):PCBM cast from the chloroform solvent. The PV parameters of the OPVs, including V_{oc}, short circuit current (J_{sc}), fill factor (FF) and power conversion efficiency (PCE) are summarized in Table 2. The higher value of V_{oc} for the device based on **PH**:PCBM is attributed to the lower HOMO level of **PH** as compared to **FL**. The OPV based on the **FL**:PCBM blend showed higher J_{sc} and FF than the **PH**:PCBM based device, leading to PCE of 1.46% vs. 1.02%, respectively. However, the current density is still much

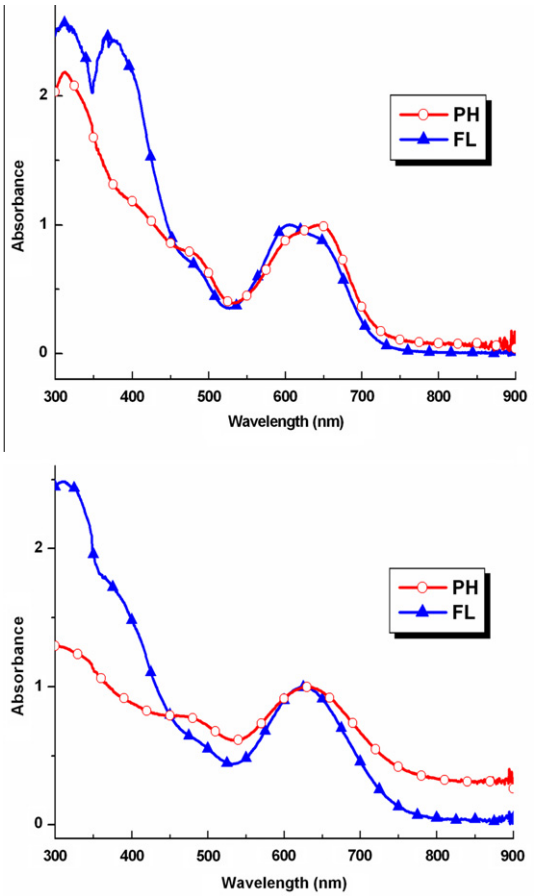


Fig. 1. UV–Vis absorption spectra of SMs in THF solution (top) and thin film (bottom).

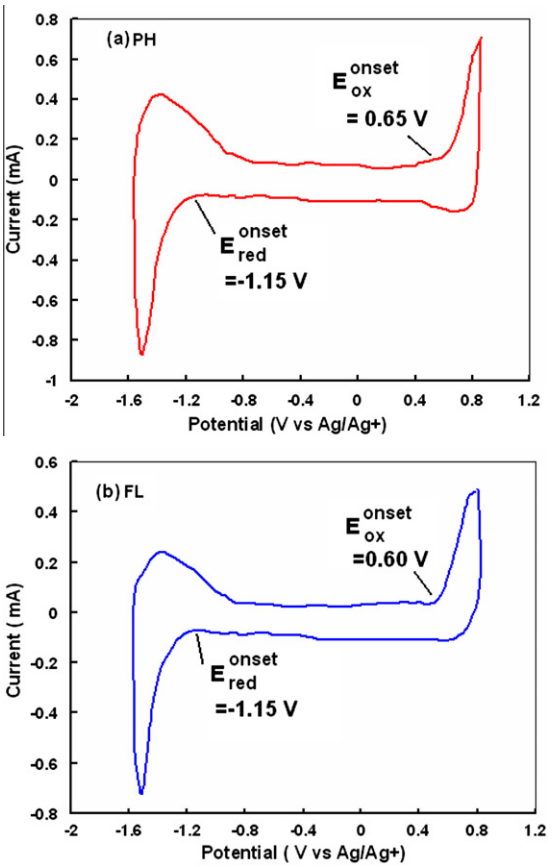

Fig. 2. Cyclic voltammograms of (a) **PH** and (b) **FL**.

lower than that for the state-of-the-art polymer/fullerene systems [13]. In order to understand the origins of the low current, we carried out the incident photon to current efficiency (IPCE) measurements. The IPCE spectra of the PV devices, as shown in Fig. 3(b), are consistent with the absorption spectra of the blend films of the active layers. The absorptions at shorter wavelength region, below 420 nm, are mainly contributed to PCBM, while those at longer wavelength region are contributed to SMs. The higher J_{sc} of the **FL**:PCBM based device compared to the **PH**:PCBM device is reflected on the higher IPCE values in the wavelength region corresponding to absorption of SMs. The higher value of the J_{sc} and PCE may also be attributed to the higher value of hole mobility for the device based on the **FL** film.

The relatively lower PCE of SM BHJ OSCs becomes the biggest hindrance to commercial application. In the case of OSCs based on polymers, some approaches have been used to improve the device efficiency including thermal annealing or utilizing additive to control the formation of interpenetrating D/A networks at nanometer scale for efficient exciton dissociation and charge transport within the BHJ devices [53]. The solvents used for the preparation of the active layer have shown a strong impact on the morphology of the blend films, which influence the performance of the devices. However, these methods are

Table 1
Optical and electrochemical properties of SMs.

SM	$\lambda_{a,max}$[a] in solution (nm)	$\lambda_{a,max}$[a] in thin film (nm)	Thin film absorption onset (nm)	E_g^{opt}[b] (eV)	E_{onset}^{ox} (V)	E_{onset}^{red} (V)	HOMO (eV)	LUMO (eV)	E_g^{el}[c] (eV)
PH	(604) 643	632	758	1.64	0.65	−1.15	−5.35	−3.55	1.80

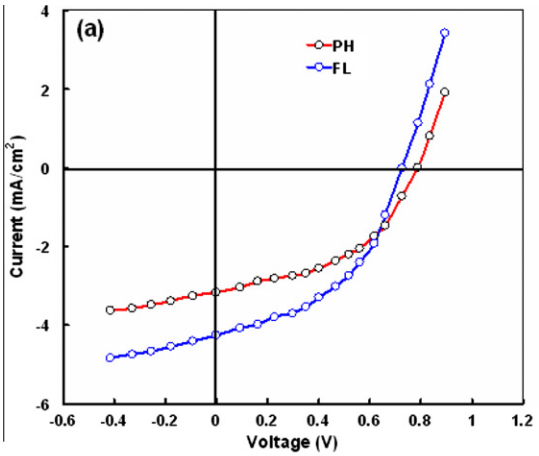
[b] E_g^{opt}: Optical band gap determined from the absorption onset in thin film.
[c] E_g^{el}: Electrochemical band gap determined from cyclic voltammetry.



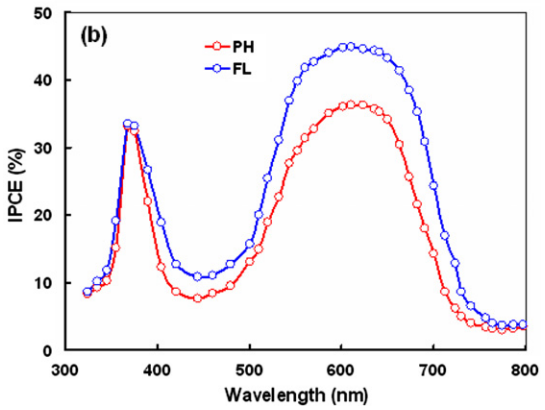


Fig. 3. (a) Current–voltage (J–V) characteristics and (b) IPCE spectra of the OSCs based on **PH**:PCBM and **FL**:PCBM cast from CF solvent under illumination of 100 mW/cm^2.

Table 2
Photovoltaic parameters of the devices based on **PH**:PCBM and **FL**:PCBM cast from chloroform (CF).

Blend	Short circuit current (J_{sc}) (mA/cm^2)	Open circuit voltage (V_{oc}) (V)	Fill factor (FF)	Power conversion efficiency (PCE) (%)
PH:PCBM	3.7	0.78	0.41	1.02
FL:PCBM	4.3	0.74	0.46	1.46

generally not applied for SM BHJ solar cells. We have studied the effect of different solvents on the performance of OPVs using the **FL**:PCBM blend.

Fig. 4 shows the UV–Vis absorption spectra of **FL**:PCBM thin films for different casting solvents. By changing the casting solvent certain differentiations appeared in the absorption spectra. For chloroform (CF) cast film the absorption spectra show two absorption bands around 360 and 626 nm. The absorption band having peak around 360 nm stems from PCBM [54], while the absorption band with peak around 626 nm represents the contribution from **FL**. For chlorobenzene (CB) cast film the peak absorption

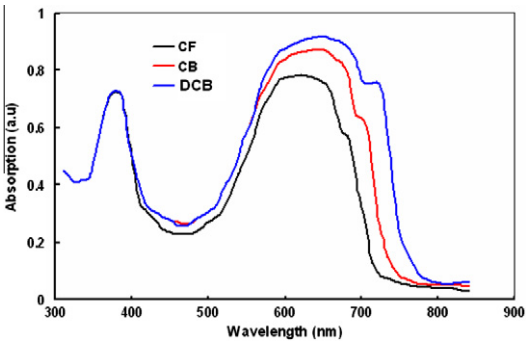

Fig. 4. Absorption spectra of **FL**:PCBM films (1:1 w:w) prepared by spin casting from different solvents.

wavelength is at 635 nm showing a 10 nm red-shift, with one shoulder peak around 670 nm. Compared to the former two films absorption spectra cast from CF and CB, the absorption spectrum of o-dichlorobenzene (DCB) cast film becomes more distinguishable and much stronger. The vibronic absorption is much more pronounced indicating strong interchain–interlayer interaction in **FL**, as well as a good ordering of blends films. Both significant red shift and pronounced shoulder appear in a more ordered film as high crystallinity order involves an enhanced conjugation length and hence a shift of the absorption spectra to lower energies.

Fig. 5 shows the XRD results from active layer **FL**:PCBM prepared by spin coating from various solvents. The XRD intensities values were obtained from peaks at $2\theta = 8.26°$ are 6.3, 10.5, 14.8, and 19.4 for the films cast from CF, CB, DCB, and CN/DCB solvents, respectively. These values correspond to the interchain spacing in **FL** associated with the degree of crystallinity. When high boiling point solvents (DCB and CB) instead of low boiling point (CF) were used for the active layer, the increased intensities were observed in the peak at $2\theta = 8.26°$. This indicates the active layers prepared from DCB and CB have higher ordered structure and more improved crystallinity than CF. In the high boiling point solvents, **FL** in the active layer may have longer time to solidify due to the slow evaporation rate of the solvents and the slow film growth rate may assist to form the high degree of self organized structure. The crystalline nature of the blend has been further improved as can be seen for the XRD pattern.

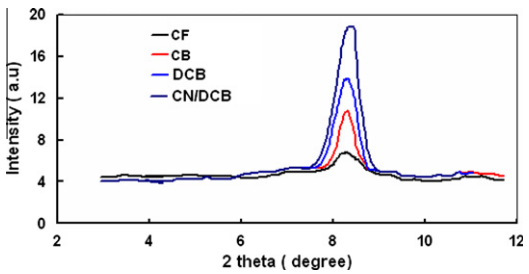

Fig. 5. X-ray diffraction spectra for **FL**:PCBM (1:1 w/w) blend thin films prepared from different solvents.

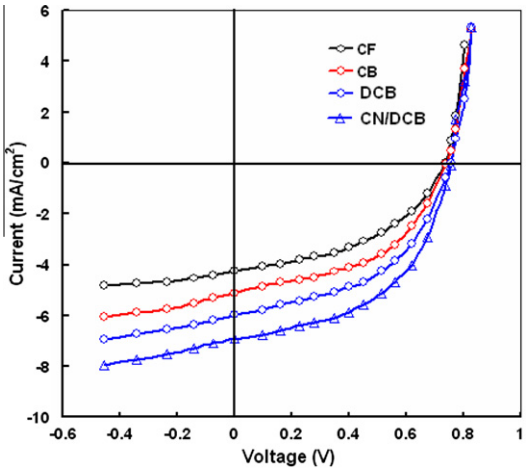

Fig. 6. Current–voltage (*J–V*) characteristics of the OSCs for **FL**:PCBM cast from different solvents under illumination intensity of 100 mW/cm^2.

Table 3
Summary of the photovoltaic parameters of the ITO/PEDOT:PSS/**FL**:PCBM/Al devices prepared from different solvents.

Solvent type	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
CF	4.3	0.74	0.46	1.46
CB	5.1	0.74	0.48	1.81
DCB	6.0	0.76	0.53	2.42
CN/DCB	7.15	0.76	0.57	3.0

The *J–V* characteristics under illumination intensity AM 1.5 (100 mW/cm^2) for the OSCs fabricated from various solvents employing **FL**:PCBM blend are shown in Fig. 6. The PV parameters of the devices are summarized in Table 3. It is seen from this table that the V_{oc} does not change under various solvent conditions but the J_{sc} and FF show a differentiation. Compared to the device made from CF solvent, the device based on CB solvent leads to an increase of PCE from 1.42% to 1.81%. Moreover, a PCE of 2.42% is observed from the device fabricated from DCB solvent, and the device fabricated from mixed CN/DCB solvents possesses PCE of 3.0%. The improvement of PCE for the devices is mainly due to the enhancement in both J_{sc} and FF values. This indicates an improved charge transport due to the expansion of the crystalline domains. The reason for this improved crystallinity in the coated films can be the different solvent evaporation speed during spin coating, since CF has a low boiling point of 60 °C, while the boiling points of CB and DCB are 130 and 180 °C, respectively. The film cast from DCB solvent is frozen very slowly owing to the high boiling point of DCB. This slow freezing of **FL** may cause a longer time for the **FL** self organization, leading to a higher degree of ordering in the material. The broadening of the absorption band and red shift in the absorption peak leads to an increase of the light harvesting by the active layer. The higher PCE for the device fabricated from mixed solvents (CN/DCB) is attributed to the increased ordering of the blend, which provides a more increased D–A interfacial area. The combined effects of the above leads to an increase in the overall PCE of the device.

3.4. Photovoltaic properties with F as electron acceptor

For the acceptor materials in OSCs, PCBM offers the advantage of good solubility in organic solvents, high electron mobility and high electron affinity. However, weak absorption in the visible region and a low LUMO energy level are the weak points of PCBM. Weak absorption in the visible region limits its contribution to light harvesting in the PV conversion. We attempted to increase the breadth of the IPCE spectrum and the overall PCE, by fabricating OSCs with a more light absorbing modified PCBM, i.e. **F** [42]. Fig. 7(a) shows the *J–V* curves of the devices based on **FL**:**F** (1:1 w/w) spin coated from DCB and CN/DCB solvents. The V_{oc}, J_{sc}, FF, and PCE of the devices are listed in Table 4. The devices based on **F** as electron acceptor show higher value of V_{oc} as compared to that for PCBM. This is attributed to the difference between the LUMO energy levels in PCBM (−3.95 eV) and **F** (−3.75 eV) [42], because the value of V_{oc} in BHJ photovoltaic device is related to the difference between the HOMO level of the donor and the LUMO level of the acceptor. The device fabricated with **FL**:**F** blend shows higher PCE (3.62%) as compared to **FL**:PCBM (2.42%) based device, cast from DCB. The overall PCE of the device based on **FL**:**F** has been further improved up to 4.38% when the blend is cast from

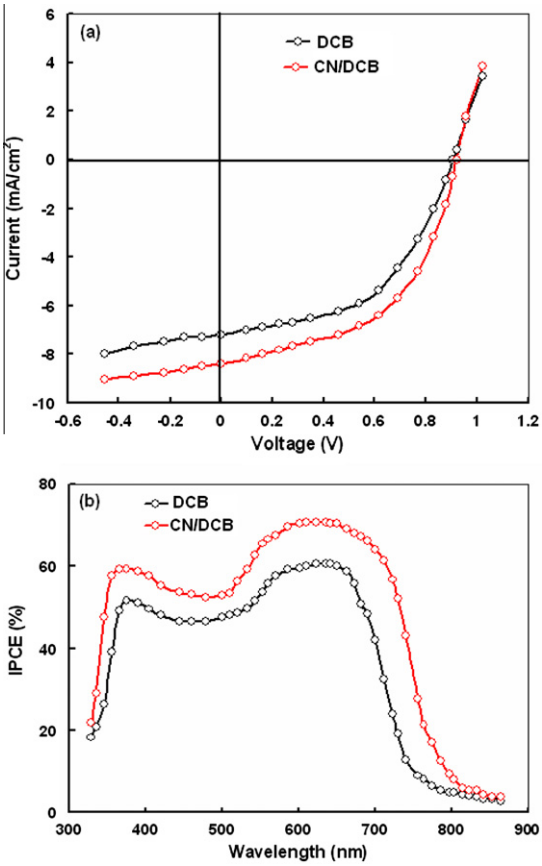

Fig. 7. (a) Current–voltage (*J–V*) characteristics and (b) of the OSCs for **FL**:**F** based on **FL**:PCBM cast from DCB and CN/DCB solvents.

Table 4
Summary of the photovoltaic parameters of the ITO/PEDOT:PSS/**FL**:**F**/Al devices prepared from different solvents.

Solvent	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	PCE (%)
DCB	7.4	0.90	0.56	3.62
CN/DCB	8.3	0.88	0.60	4.38

mixed CN/DCB solvents. Fig. 7(b) shows the IPCE spectra of the devices fabricated from blends of **FL**:**F** cast from OCB and CN/DCB solvents. The IPCE spectra are similar with the absorption spectra of the blend. With the addition of CN in the solvent, the IPCE maximum at 630–680 nm increased from 55% to 71%, which is consistent with J_{sc} and PCE. The J_{sc} value calculated from the integration of the IPCE spectrum is 7.1 and 8.6 mA/cm^2 for the devices based on DCB and CN/DCB cast blends, respectively, which closely matches the J_{sc} values obtained from the J–V measurements under white light illumination.

The increase of J_{sc} is mainly related to more exciton and charge generation and more effective charge transport. It was found that the film cast from CN/DCB exhibits stronger absorption than that cast from DCB. The stronger absorption partially contributed to higher J_{sc} and IPCE of the device cast from CN/DCB as compared to the device cast from CB. A similar phenomenon has been observed by Yang et al. for P3HT:PCBM system [55].

Another important factor being responsible for increased J_{sc} is the charge transport in active layers. The space charge limited current (SCLC) method [56] was adopted to determine the electron and hole mobilities in blend films. Fig. 8(a) shows the dark J–V characteristics of the hole only devices having structure of ITO/PEDOT:PSS/**FL**:**F**/Au with the DCB and CN/DCB solvents casting layer films. In order to suppress the electron injection into the blend, a high work function metal gold (Au) was used as cathode. The applied voltage was corrected for the built-in voltage (V_{bi}). Compared to the device based on DCB solvent cast film, the device with CN/OCB solvent cast film shows an enhanced current density at the same driving voltage in Fig. 8(a). This indicates that the hole mobility is enhanced due to the self organization of **FL**. The J–V characteristics for the electron only devices with structure of Al/**FL**:**F**/Al are shown in Fig. 8(b). In order to suppress the hole injection into the blend, a low work function metal (Al) was used as anode. The electron and hole mobilities have been measured by fitting the dark J–V characteristics for electron and hole only devices, respectively to SCLC model at low voltages, in which the current density is given by

$$J = (9\varepsilon_o\varepsilon_r\mu V^2/8d^3)\exp[0.891\gamma(V/d)^{0.5}]$$

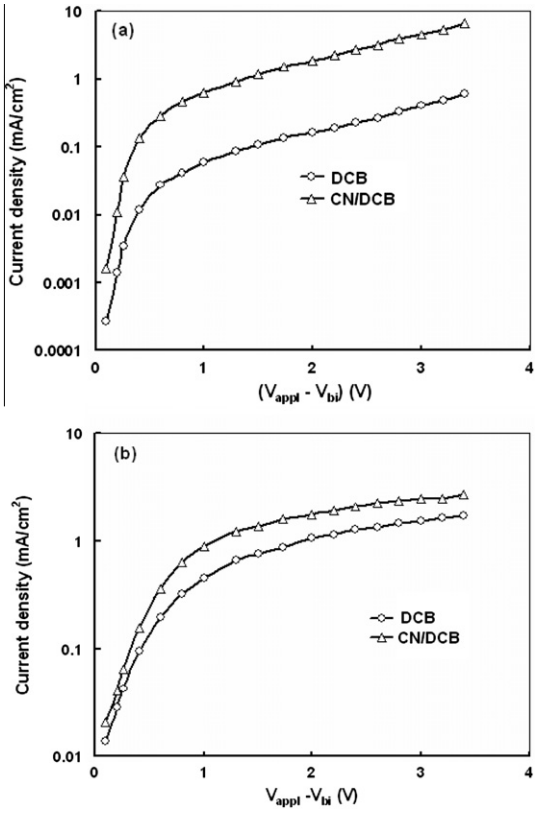

Fig. 8. Current–voltage characteristics for (a) hole only and (b) electron only devices based on **FL**:**F** blend films with DCB and CN/DCB solvents.

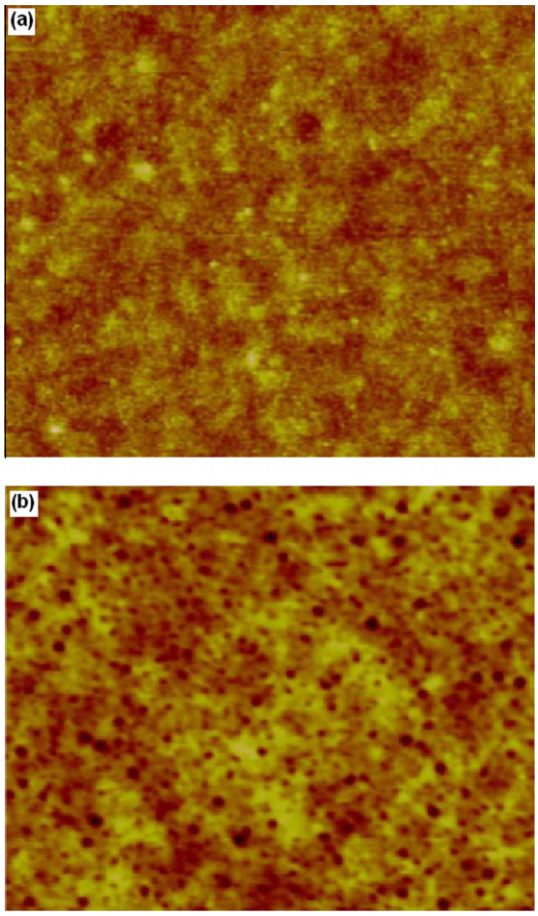

Fig. 9. AFM images of **FL**:**F** blends cast from (a) DCB and (b) CN/DCB solvents (scale 3 × 3 μm).

where $\varepsilon_o\varepsilon_r$ represent the permittivity of the material, μ is the mobility, γ is the field activation factor, and d is the thickness of the active layer and voltage $V = V_{appl} - V_{bi}$. The hole (μ_h) and electron (μ_e) mobilities of the film cast from DCB are 5.6×10^{-6} and 3.4×10^{-4} cm^2/Vs, respectively. The μ_h and μ_e for the film cast from the CN/DCB are about 1.8×10^{-5} and 2.2×10^{-4} cm^2/Vs, respectively. The smaller value of μ_e/μ_h (60.7 and 12.2 for CB and CN/DCB solvent cast film, respectively) indicates a more balanced charge transport. The more balanced charge transport contributes to the higher J_{sc} and higher PCE.

The difference in PV performance for the devices cast from DCB and CN/DCB solvents is most likely due to the change in the morphology. The effect of the solvents on the active layer morphology was also examined by the AFM technique. Fig. 9 compares the AFM images of the blend films of **FL**:**F** cast from the DCB and CN/DCB solvents. For the **FL**:**F** blend films cast from DCB solvent, its root mean square (rms) roughness is about 0.45 nm. However, when the film is cast from the CN/DCB solvent, the rms roughness is about 0.78 nm. Higher roughness of the film will give higher device efficiency. The rough surface is probably a signature of self organization of organic semiconductor, which in turn enhances ordered structure formation in thin films and increases the carrier mobility [57]. The increased roughness of the active layer enhances the D–A interfacial area leading to efficient dissociation of the excitons into free charge carriers.

4. Conclusions

Two soluble and low band gap SMs, **PH** and **FL**, were synthesized. They contained the D–A structure permitting an ICT. The absorption spectra were broad with long-wavelength absorption maximum at 605–643 nm and optical band gap of 1.64–1.66 eV, which is lower than that of P3HT. The HOMO and LUMO levels of both SMs estimated from cyclic voltammetry, suggest that they can be used as donor materials for organic BHJ PV devices. The solution processed organic BHJ PV devices using **PH**:PCBM and **FL**:PCBM cast from chloroform solvent show PCE about 1.02% and 1.42%, respectively. We have fabricated BHJ organic PV devices based on the **FL**:PCBM using various solvents such as chloroform, chlorobenzene, o-dichlorobenzene and mixed CN/DCB and investigated the influence of these solvents on the performance of the solar cells. The device with mixed CN/DCB solvents shows improved performance of PCE of 3.0%. The improved PCE is mainly attributed to the increased value of J_{sc}, which is due to the enhancement in the crystalline nature of the blend.

We have also fabricated BHJ PV devices based on **FL**:**F** blend to improve the light harvesting efficiency in the lower wavelength region and achieved PCE of about 3.62% and 4.38% with DCB and CN/DCB cast blend, respectively. The improved PCE of the device with **F** as electron acceptor is mainly attributed to both increase in J_{sc} and V_{oc}. The further improvement in the PCE, when the blend is cast from mixed CN/DCB, could be ascribed to efficient exciton dissociation at the D–A interface and a better morphological structure of the active layer.

Acknowledgment

We are thankful to Prof. Y.K. Vijay of Thin film and Membrane Science Laboratory, University of Rajasthan Jaipur (Raj.) for allowing us to undertake the device fabrication and characterization in his laboratory.

excitons to the guest molecules) [11–15]. The host materials for electrophosphorescence reported thus far are limited to a few functionalities, including carbazoles and phenylsilanes [13–16]. The carbazole derivatives, which possess sufficiently large triplet energies and carrier transport properties, are widely used as host materials in PHOLEDs [17–19]. Examples of these materials include 4,4′-bis(9-carbazolyl)-2,2′-biphenyl (CBP), 1,3-bis(9-carbazolyl)benzene (mCP) and 3,5-bis(9-carbazolyl)tetraphenylsilane (SimCP). The most commonly used host material CBP has been shown useful for green- and red-light-emitting PHOLEDs [20–26]. However, CBP has several problems such as low T_g and low triplet energy state which deteriorate efficiency and longevity of the device. It has been reported that fluorene derivatives have been important materials for OLEDs because of their high quantum yield of photoluminescence (PL), electroluminescence (EL) efficiencies and high thermal stability [27–29]. However, it has been reported that the extension of the carbazole conjugation, which decreases the triplet energy of the carbazole as in the case of CBP, can be minimized by altering the linkage group to carbazole unit, while also maximizing the thermal stability of the material [18,30]. Thus, the research directed towards the design and synthesis of new carbazole derivatives with high triplet energy and thermal stability has not been limited [31,32].

Thus, we designed highly twisted *N*-fluorenyl carbazole as a new host material. The introduction of fluorene unit, possessing high photoluminescence and electroluminescence efficiencies, to carbazole unit is to inhibit the extension of conjugation and improve the thermal stability of the material, which is suitable for host in the efficient electroluminescent devices. Moreover, the highly twisted structure due to coupling of *N*-fluorenylated carbazole would increase its glass transition temperature and molecular rigidity as well as inhibited intermolecular interaction. In the present study, we report on the synthesis and characterization of a new carbazole derivative BDFC in which fluorene-coupled at 3-position of carbazole unit. A new *N*-fluorenyl carbazole material BDFC shows the higher thermal stability ($\Delta T_{5\%}$) of 494.7 °C (CBP: 447 °C) with high glass transition temperature (T_g) of 177.8 °C (CBP: 62 °C) and a band energy gap of 3.01 eV with high triplet energy of 2.72 eV (CBP: 2.56 eV) for use as host material in the efficient organic light emitting diodes. We fabricate green-emitting phosphorescent organic light emitting diodes using the new BDFC as host and Ir(ppy) as guest emitter and report its higher device performances compared with that of the device based on widely used CBP host.

2. Experimental

2.1. Materials

All reagents and solvents were purchased from Aldrich Chemical Co. and Fluka. All the solvents were freshly distilled over appropriate drying reagents before use. The spectroscopic grade $CHCl_3$ (Aldrich) was used to measure UV–visible absorption and photoluminescence spectra of the samples. All other compounds were used as received. All the materials used in the phosphorescent organic light emitting diodes were purchased from Lumtec corp., Taiwan.

2.2. Synthesis

2.2.1. Synthesis of 9-(9′,9′-dimethyl-9H-fluoren-2-yl)-9H-carbazole (**1**)

A mixture of activated copper powder (11.4 g, 0.120 mol), K_2CO_3 (16.53 g, 0.120 mol), 9H-carbazole (20 g, 0.120 mol), 2-bromo-9′,9′-dimethyl-9H-fluorene (35.94 g, 0.132 mol) and 18-crown-6 (4.74 g, 0.0179 mol) in dichlorobenzene (200 mL) was heated to 200 °C for 30 h. After that, the reaction mixture was filtered with methylene chloride (MC). After dichlorobenzene was removed by vacuum distillation, the crude product was purified by column chromatography (using MC/hexane: 1/5 as eluent) and recrystallization with ethanol. Yield: 38.33 g (89.15%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.21–8.18 (d, 2H), 7.96–7.93 (d, 1H), 7.84–7.81 (t, 1H), 7.65–7.64 (d, 1H), 7.58–7.54 (dd, 1H), 7.51–7.39 (m, 7H), 7.35–7.30 (m, 2H), 1.58–1.55 (d, 6H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 155.16, 153.85, 141.03, 138.49, 138.45, 136.62, 127.60, 127.25, 125.96, 125.87, 123.38, 122.77, 121.46, 121.09, 120.36, 120.20, 119.89, 109.87, 47.16, 27.16. M^+: 359.

2.2.2. Synthesis of 3-bromo-9-(9′,9′-dimethyl-9H-fluoren-2-yl)-9H-carbazole (**2**)

N-Bromosuccinimide (13.37 g, 0.097 mol) was added to the solution of 9-(9′,9′-dimethyl-9H-fluoren-2-yl)-9H-carbazole (**1**) (35 g, 0.097 mol) and silica-gel (18 g) in methylene chloride (400 mL). The reaction mixture was stirred at room temperature. Before extraction with water and Methylene chloride, the reaction mixture was filtered with Methylene chloride. The mixture of reaction was purified by column chromatography (using MC/hexane: 1/5 as eluent) and recrystallization with ethanol. Yield: 40.59 g (95.10%). ^{1}H NMR (300 MHz, $CDCl_3$), δ: 8.29–8.28 (d, 1H), 8.14–8.12 (d, 1H), 7.96–7.93 (d, 1H), 7.60–7.59 (d, 1H), 7.53–7.52 (d, 1H), 7.51–7.50 (t, 3H), 7.47–7.33 (m, 6H), 1.57–1.56 (d, 6H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 155.56, 153.82, 141.36, 139.71, 138.83, 138.27, 136.08, 128.63, 127.72, 127.27, 126.68, 125.79, 125.08, 123.06, 122.77, 122.27, 121.35, 121.18, 120.52, 120.29, 120.24, 112.61, 111.37, 110.09, 47.18, 27.13. M^+: 439.

2.2.3. Synthesis of 9,9′-bis-(9,9-dimethyl-9H-fluoren-2-yl)-9H,9′H-[3,3′]bicarbazolyl (BDFC)

A mixture of bis(cyclooctadiene)nickel(0) (2.85 g, 10.37 mmol) and 2,2-bipyridyl (1.86 g, 11.92 mmol) in dimethylformamide (40 mL) and toluene (160 mL) was heated to 80 °C. After 30 min, cyclooctadiene (0.93 g, 8.64 mmol) and 3-bromo-9-(9′,9′-dimethyl-9H-fluoren-2-yl)-9H-carbazole (**2**) (4 g, 9.12 mmol) in toluene (40 mL) were added to the reaction mixture and stirred for 144 h. The reaction mixture in HCl and Dioxane was stirred for 15 min and washed with HCl. The reaction mixture was purified by column chromatography (using CH_2Cl_2/hexane: 1/10 as eluent) and recrystallization with methylene chloride and ethanol. Yield: 2.53 g (77.35%). FT-IR (KBr): 3043,

2954. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.53–8.52 (s, 1H), 8.28–8.27 (d, 1H), 8.00–7.97 (d, 1H), 7.86–7.83 (m, 2H), 7.71 (s, 1H), 7.64–7.59 (m, 2H), 7.53–7.43 (m, 6H), 1.61–1.60 (d, 6H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 155.50, 153.86, 141.50, 140.17, 138.50, 138.46, 136.70, 134.37, 127.61, 127.26, 126.10, 125.87, 125.81, 124.02, 123.62, 122.78, 121.39, 121.14, 120.48, 120.21, 120.00, 118.94, 110.15, 110.01, 47.19, 27.18. HRMS: calcd. for $C_{54}H_{40}N_2$: 716.3191, found: 716.3192.

2.3. Measurements

^{1}H nuclear magnetic resonance (NMR) spectra were recorded using DRX 300 MHz Bruker spectrometer and chemical shifts in spectra were reported in parts per million (ppm) units with tetramethylsilane as internal standard. Infrared (IR) studies of the samples were carried out using a Genesis II FT-IR spectrometer. A Jeol JMS-700 high-resolution mass spectrometer (HRMS) was used to obtain the mass spectra of the samples. Thermogravimetric analysis (TGA) was performed under nitrogen using a TA instrument 2025 thermogravimetric analyzer. The sample was heated from 50 °C to 800 °C with a heating rate of 10 °C/min. Differential scanning calorimeter (DSC) studies were carried out under nitrogen using a TA instrument 2100 differential scanning calorimeter. The sample was heated from 30 °C to 300 °C with a heating rate of 10 °C/min. UV–visible absorption and photoluminescence (PL) studies at room temperature were carried out using Perkin Elmer LAMBDA-900 UV/VIS/NIR spectrometer and LS-50B luminescence spectrophotometer, respectively and the phosphorescence spectrum was recorded from the delayed emission of BDFC at 77 K. Cyclic voltammogram (CV) of the sample was recorded using a Epsilon E3

at room temperature in a 0.1 M solution of tetrabutylammonium perchlorate (Bu_4NClO_4) in acetonitrile under nitrogen environment at a scan rate of 50 mV/s. The platinum rod was used as working and the counter electrode, and a $Ag/AgNO_3$ electrode was used as the reference electrode. The mobility of BDFC molecule was determined from the Time-of-Flight (ToF) experiment. For ToF experiment, a semitransparent aluminum (Al) layer of 20 nm thickness was deposited on the glass substrate as bottom electrode by thermal evaporation process. A thick BDFC film of 1 μm thickness was drop-casted on the bottom electrode using the BDFC solution (3 wt.% in toluene) by vacuum drying at 60 °C for 24 h. The thickness and flatness of drop-cast BDFC film were measured using an alpha-stepper (Alpha step 500, Tencor). The device for ToF experiment was completed by depositing a thin Al film of 20 nm thickness on the above prepared BDFC film for the top electrode. The ToF experiment was performed in a vacuum cryogenic chamber by illuminating the sample with N_2 laser (337 nm) pulses of duration 6 ns under a dc bias for the ToF photocurrent transients [33].

2.4. Device fabrication

The phosphorescent organic light emitting diodes were fabricated as shown in Fig. 6. The device structure was as follows: indium-tin-oxide (ITO)/1,1-bis[di-4-tolylamino]phenyl]cyclohexane (TAPC) as the hole transport layer (HTL) (30 nm)/emissive layer (EML) (30 nm)/1,3,5-tris (m-pyrid-3-yl-phenyl)benzene (TmPyPB) as the electron

transport layer (ETL) (30 nm)/LiF (1 nm)/Al (120 nm). The (4,4′-*N*, *N*′-dicarbazole)biphenyl (CBP) host for device A or 9,9′-Bis-(9,9-dimethyl-9H-fluoren-2-yl)-9H,9′H-[3,3′]bicarbazolyl (BDFC) host for the device B doped with 5% green-emitting phosphorescent dopant, fac-tris(2-phenylpyridine)iridium [Ir(ppy)$_3$] was used as emissive layer (EML). The CBP host based device was fabricated for the comparison of the device performances with that of BDFC host based device. The patterned ITO (anode) coated glass substrates were ultrasonically cleaned in acetone for 10 min followed by isopropyl alcohol, dried in each step at 90 °C for 10 min and UV treated for 10 min before loading into the deposition chamber for the device fabrication. All organic layers were deposited by thermal evaporation process under a vacuum of $\sim 5 \times 10^{-6}$ Torr and LiF as electron injection layer and Al cathode were deposited without breaking the chamber vacuum. The fabricated devices were transferred into the glove-box for the encapsulation of the devices with moisture getter using UV curable epoxy. The current density–voltage (*J*–*V*) characteristics of all devices were measured using Keithley 236 source meter. The electroluminescence and luminescence characteristics of the devices were recorded using Spectrascan PR655 spectroradiometer under ambient condition.

3. Results and discussion

The new *N*-fluorenyl carbazole material, 9,9′-bis-(9,9-dimethyl-9H-fluoren-2-yl)-9H,9′H-[3,3′]bicarbazolyl (BDFC), was prepared as depicted in Fig. 1. The BDFC was synthesized via manifold chemical reactions such as bromination, Ullmann and Yamamoto coupling reactions as described below. The compound **1** was obtained by Ullmann coupling reaction of 9H-carbazole and 2-bromo-9′,9′-dimethyl-9H-fluorene using activated copper powder, K_2CO_3 and 18-crown-6. BDFC was prepared by Yamamoto coupling reaction of compound **2** obtained from mono-bromination of compound **1**. The structure of BDFC was confirmed by ^{1}H NMR, IR and HRMS. In the IR spectrum, we confirmed the structure from disappearing of aromatic C–Br stretching at 1060 cm^{-1} (Fig. 2). The angle of 126° between carbazole and fluorene units in the highly twisted structure of BDFC molecule was determined by Spartan08 software as shown in Fig. 3.

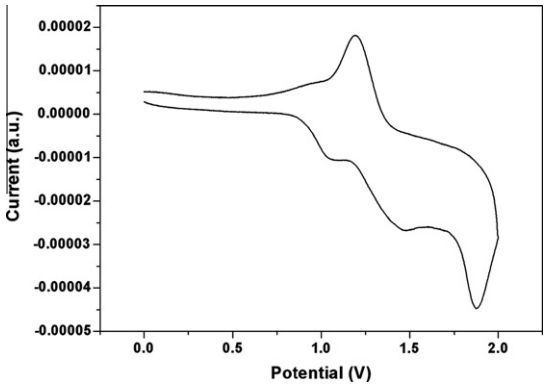

Fig. 6. Cyclic voltammogram of BDFC.

The UV–visible absorption, photoluminescence and phosphorescence (at 77 K) spectra of BDFC in toluene (1×10^{-5} M) are shown in Fig. 4. From the UV–visible absorption spectrum of BDFC, the absorption bands between 294 nm and 330 nm are assigned for S_0 to S_2 and S_0 to S_1 electronic transitions of the BDFC molecule [30]. BDFC showed the photoluminescence (PL) at 408 nm in toluene, indicating the emission from its lowest exited state. The phosphorescence spectrum of BDFC was obtained from the delayed emission of BDFC in toluene (1×10^{-5} M) at 77 K. From the phosphorescence spectrum of BDFC molecule, the triplet energy (T_1) was estimated from the highest energy peak (455 nm) to be 2.72 eV, which is higher than that (T_1: 2.56 eV) of CBP host [19,34]. The mobility of BDFC was determined from the Time-of-Flight (ToF) experiment. It was calculated using the equation $\mu = \frac{d^2}{Vt}$, where d is the thickness of the film, V is the applied dc bias voltage and t is the measured transit time [33]. The ToF mobility of BDFC host was found to be 3.4×10^{-4} cm^2/Vs at bias voltage of 28.26 mV and transit time of 10.45 μs. The thermal properties of BDFC sample were determined by differential scanning calorimeter (DSC) and thermogravimetric analysis (TGA) measurements. From the DSC data (Fig. 5b), the glass transition temperature (T_g) was observed at 177.8 °C, which is much higher than that (62 °C) of CBP, and the melting temperature (T_m) was observed at 259.62 °C as a sharp endothermic peak [19]. In TGA curve of BDFC (Fig. 5a), 5% weight loss was observed at 494.7 °C, showing the higher thermal stability compared with that (447 °C) of CBP. The higher

triplet energy and thermal stability of BDFC compared with CBP reveal the decreased conjugation of carbazole unit by fluorene unit coupled to it [18,30]. The electrochemical properties of BDFC sample was investigated by cyclic voltammetric (CV) studies. The CV curve of BDFC is shown in Fig. 6. It shows the reversible oxidation potential characterized by E_{onset} value at 0.88 V. The estimated ionization potential (IP = E_{onset} + 4.54 = HOMO level) was 5.38 eV. The higher HOMO energy level of BDFC can be useful for the efficient hole-injection and transport. The LUMO energy level of BDFC was calculated to be 2.37 eV from the edge wavelength of UV–visible absorption spectrum. BDFC having the band gap of 3.01 eV with high triplet energy of 2.72 eV could be suitable for use as host material for the efficient organic light emitting diodes. The thermal, photophysical and electrochemical properties of BDFC are listed in Table 1.

To investigate the new *N*-fluorenyl-carbazole material (BDFC) as host in organic light emitting diodes (OLEDs), the phosphorescent organic light emitting diodes (PHOLEDs) based on BDFC as host and green phosphorescent dopant, fac-tris(2-phenylpyridine)iridium [Ir(ppy)$_3$], as guest emitter were fabricated as shown in Fig. 7 and characterized. PHOLED based on widely used CBP was fabricated for the comparison. The energy level diagram and the structure of materials used in the devices are shown in Fig. 8 [19,34–38]. The PHOLEDs were fabricated using the following device structure: ITO/1,1-bis[di-4-tolylamino]phenyl]cyclohexane (TAPC) (30 nm)/host: Ir(ppy)$_3$ with optimized concentration of 5% (30 nm)/1,3,5-tris(m-pyrid-3-yl-phenyl)benzene (TmPyPB) (30 nm)/LiF/Al. The CBP was used as host in the device A and BDFC host was used in device B. TAPC with LUMO energy level of 2.0 eV (LUMO: 2.6 eV for CBP; 2.37 eV for BDFC) and higher triplet energy (T_1) of 2.9 eV (T_1: 2.56 eV for CBP; 2.72 eV for BDFC; 2.46 eV for Ir(ppy)$_3$) was used as hole transport layer (HTL), while TmPyPB with HOMO energy level of 6.68 eV (HOMO: 5.9 eV for CBP; 5.38 eV for BDFC) and higher triplet energy of 2.78 eV compared with that of host and dopants was used as electron transport layer (ETL) in the devices for the effective confinement of charge carriers and/or excitons within the emissive layer (EML). Fig. 9 shows the current density–voltage–luminescence (*J*–*V*–*L*) characteristics of devices A and B. From the *J*–*V*–*L* characteristics of device A, the drive voltages of 5 V for 100 cd/m^2 and 8 V for 1000 cd/m^2 were observed and it showed a maximum luminescence of 23,250 cd/m^2 at 16 V. Device A showed the turn-on voltage (defined as an applied voltage required for the luminescence of 1 cd/m^2) of 3 V. Fig. 10 shows the current- and external quantum-efficiency characteristics of devices A and B. Device A based on CBP host showed the maximum current efficiency of 48.0 cd/A, external quantum efficiency of 15.3% and power efficiency of 16.3 lm/W. The electroluminescence spectra of devices A and B at 10.5 V are shown in Fig. 11. The device A showed the electroluminescence (EL) emission

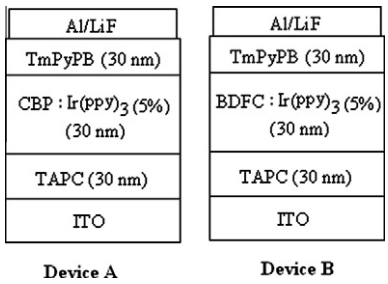

Fig. 7. The device structures of the devices A and B.

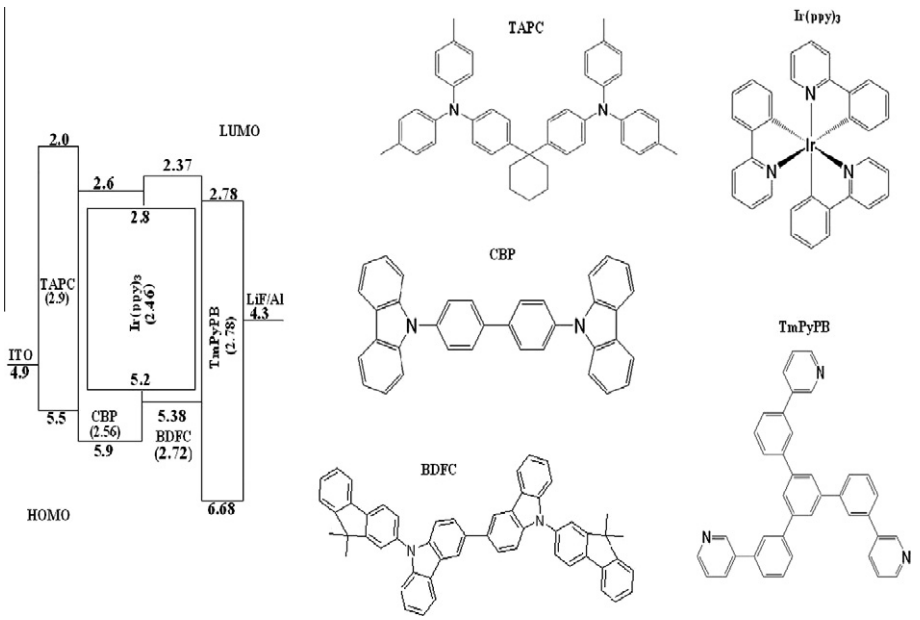

Fig. 8. The energy level diagram and molecular structures of the materials used in the devices.

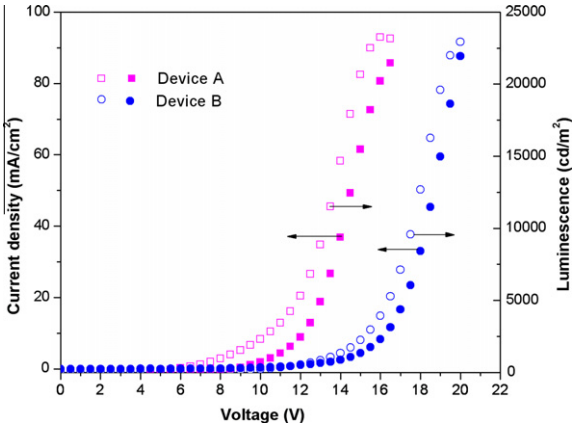

Fig. 9. The current density–voltage–luminescence (J–V–L) characteristics of devices A and B.

peak at 512 nm with shoulder peak at 539 nm with CIE color coordinates of (0.31, 0.61), originating from $Ir(ppy)_3$ dopant [36,39–41]. No emissions from the host and/or

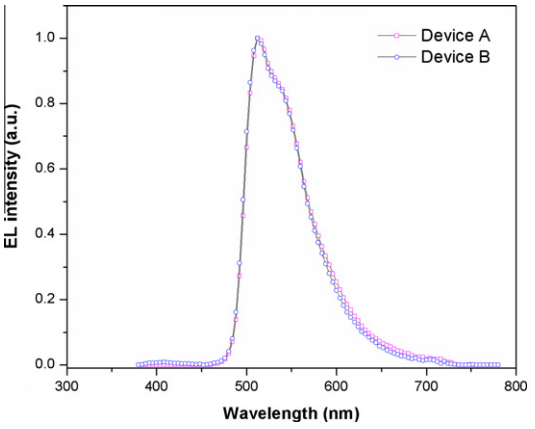

Fig. 11. The electroluminescence spectra of the devices A and B at 10.5 V.

adjacent charge transporting layers were observed, indicating the effective confinement of charge carriers and/or excitons and complete energy transfer to guest emitter in the EML of the device A.

Device B based on BDFC host showed the drive voltages of 8.5 V for 100 cd/m^2 and 13.5 V for 1000 cd/m^2, and a maximum luminescence of 22,930 cd/m^2 at 20 V as shown in Fig. 9. The turn-on voltage is increased to 3.5 V compared with that (3 V) of device A. The increased energy barrier of 0.41 eV for electron injection at BDFC/TmPyPB interface of the device B than that (0.18 eV) of device A using CBP host resulted in the higher operating voltage than that of device A. The device B using BDFC host exhibited the higher current efficiency of 56.8 cd/A, external quantum efficiency of 18.1% and power efficiency of 21.3 lm/W compared with that (48.1 cd/A, 15.3% and 16.3 lm/W) of device A using CBP host, resulting from the efficient energy transfer and the higher triplet energy (T_1: 2.72 eV) of BDFC host (T_1: 2.56 eV for CBP). The device B showed the higher quantum efficiency roll-off (17% at 8.3 mA/cm^2) for the increasing current densities compared with that (2% at 8.3 mA/cm^2) of the device A using CBP

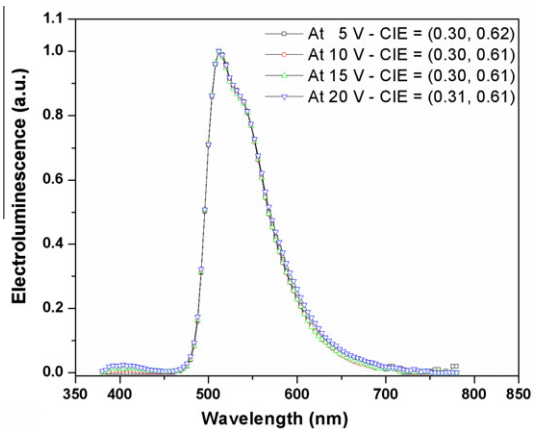

Fig. 12. The electroluminescence spectra of the device B at different voltages.

The electroluminescence characteristics of the devices.[a]

Device[b]	Turn-on voltage (V)	L (cd/m^2, V)	η_c (cd/A, V)	η_{ext} (%, V)	η_p (lm/W, V)	EL[c] (nm)	CIE (x, y)
A	3	23,250, 16.0	48.0, 10.5	15.3, 10.5	16.3, 9.0	512	(0.31, 0.61)
B	3.5	22,930, 20.0	56.8, 10.5	18.1, 10.5	21.3, 8.0	512	(0.30, 0.61)

[a] The data for brightness (L), current efficiency (η_c), external quantum efficiency (η_{ext}) and power efficiency (η_p) are the maximum values of the corresponding device. The turn-on voltage for all the devices was defined as voltage required for luminescence of 1 cd/m^2.
[b] The device structure is ITO/TAPC (30 nm)/Host: Ir(ppy)$_3$ (5%) (30 nm)/TmPyPB (30 nm)/LiF/Al with CBP host for device A and BDFC host for device B.
[c] The peak emission wavelength of the EL spectrum of corresponding device.

host. The higher efficiency roll-off of the device B can be explained by the imbalance of charge carriers in the EML due to the higher HOMO (5.38 eV) and LUMO (2.37 eV) energy levels of BDFC host than that (HOMO: 5.9 eV; LUMO: 2.6 eV) of CBP host. In other words, the higher HOMO energy level of BDFC host in the device reduces the hole injection barrier, which is much favorable for hole injection, while the higher LUMO level increases the electron injection barrier, less favor for election injection, compared with that of CBP host in device and which in turn makes the charge imbalance in the EML of the device B based on BDFC, leading to the increased efficiency roll-off compared with that of device A based on CBP. The device B showed the characteristic dopant emission at 512 nm with shoulder peak at 539 nm with CIE color coordinates of (0.30, 0.61) at 10.5 V (Fig. 11). The device B based on BDFC host exhibits the EL emission at 512 nm with CIE color coordinates of (0.30, 0.62), (0.30, 0.61), (0.30, 0.61) and (0.31, 0.61) at 5 V, 10 V, 15 V and 20 V, respectively as shown in Fig. 12. The small residual emission of device B around 408 nm at higher operating voltage is attributed to the BDFC host emission. The device based on BDFC host showed the effective confinement of triplet excitons and efficient energy transfer to the guest emitter in the EML of the device, resulted in the higher device efficiencies compared with that of CBP based device. The characteristics of the devices A and B are summarized in Table 2. The higher thermal stability (BDFC; $\Delta T_{5\%}$: 494.7 °C and T_g: 177.8 °C, CBP; $\Delta T_{5\%}$: 447 °C and T_g: 62 °C), higher triplet energy (T_1: 2.72 eV for BDFC and 2.56 eV for CBP) for the effective confinement of triplet excitons to the emitter, and the higher device performances of BDFC host could make the new *N*-fluorenyl carbazole (BDFC) host superior than widely used CBP host for the efficient organic light emitting diodes.

4. Conclusion

A new *N*-fluorenyl carbazole (BDFC) host material was synthesized and characterized. The thermal stability ($\Delta T_{5\%}$) of 494.7 °C with the high glass transition temperature (T_g) of 177.8 °C was observed from TGA and DSC studies. The physical studies of BDFC showed the emission at 408 nm and a band energy gap of 3.01 eV with high triplet energy of 2.72 eV. The highly efficient PHOLEDs employing BDFC as host have been fabricated using the structure: ITO/Di-[4-(*N*,*N*-ditolyl-amino)-phenyl]cyclohexane (TAPC)/BDFC (host): fac-tris(2-phenylpyridine)iridium [Ir(ppy)$_3$] (5%)/1,3,5-tris(m-pyrid-3-yl-phenyl)benzene (TmPyPB)/LiF/Al. The device showed the effective confinement of triplet excitons and efficient energy transfer to the guest emitter in the EML, resulted in the higher current efficiency of 56.3 cd/A, external quantum efficiency of 18.1% and power efficiency of 21.3 lm/W compared with that (48.1 cd/A, 15.3% and 16.3 lm/W) of the device based on CBP host. The results show that the new host material BDFC could be useful for the efficient organic light emitting diodes.

(J_{sc}) as high as 15 mA/cm^2, and high PCEs of greater than 5%. However, their relatively high-lying highest occupied molecular orbital (HOMO) levels limit their V_{oc} to be only around 0.6 V. Another class of poly[(9,9-dialkylfluorene)-2,7-diyl-*alt*-(4,7-bis(2-thienyl)-2,1,3-benzothiadiazole)-5,5′-diyl] (PFDTBT)-based polymers is noted for their deep HOMO levels which give high V_{oc} of ~1.0 V with corresponding PCE of 2–4% [24,25]. When the fluorene units in PFDTBT are replaced with either a carbazole [18] or a silafluorene [19] derivative, a significant enhancement of PCE (up to 6.1% PCE) could be achieved due to improved charge-transporting properties. However, these polymers have limited light harvesting capability due to their relatively large band gap (1.9 eV), which is similar to that of poly(3-hexylthiophene) (P3HT).

Indacenodithiophene (IDT)-based polymers [20,26], which show intermediate band gaps and V_{oc}s compared to the above-mentioned polymers, possess a ladder-type pentacyclic IDT moiety. It allows these polymers to function as good electron donors due to improved π electron delocalization. When this donor is copolymerized with BT, it gives a band-gap of 1.76 eV and a low-lying HOMO of ~5.23 eV. The multiple alkylphenyl side chains on IDT render polymers with better solubility and also prevent severe aggregation of the polymer chains.

Recently, a high PCE of 6.1% has been demonstrated for PSCs made from PIDTBT (Fig. 1a) containing alternating IDT and BT moieties [20]. Here, we report the photovoltaic characterizations of PIDTBT and a new polymer derivative, PIDTDTBT (Fig. 1a) in both conventional and inverted PSC device configurations. Under the AM 1.5G simulated solar illumination (100 mW/cm^2), PSCs based on PIDTBT and PIDTDTBT in a conventional architecture can reach PCE as high as 6.3% and 4.4%, respectively. Moreover, high PCEs of 4.9% and 4.2% could also be achieved for inverted architecture devices based on PIDTBT and PIDTDTBT, respectively.

2. Results and discussion

2.1. Analysis and thermal properties

PIDTBT and PIDTDTBT were synthesized using the Stille coupling reaction between the IDT monomer and 4,7-dibromo-2,1,3-benzothiadiazole or 4,7-bis(2-bromo-5-thienyl)-2,1,3-benzothiadiazole, using $Pd_2(dba)_3$ as catalyst in toluene/DMF (See Section 4.2). The number average molecular weight (M_n) of PIDTBT was 14.7 kDa with a polydispersity index (PDI) of 2.39. The M_n of PIDTDTBT was 21.4 kDa with a PDI of 1.53. Differential scanning calorimetry (DSC) thermogram with the second heating curves of the two polymers is presented in Fig. 2. No apparent thermal transitions between 30 and 350 °C were observed for PIDTBT; on the other hand, a transition around 220 °C

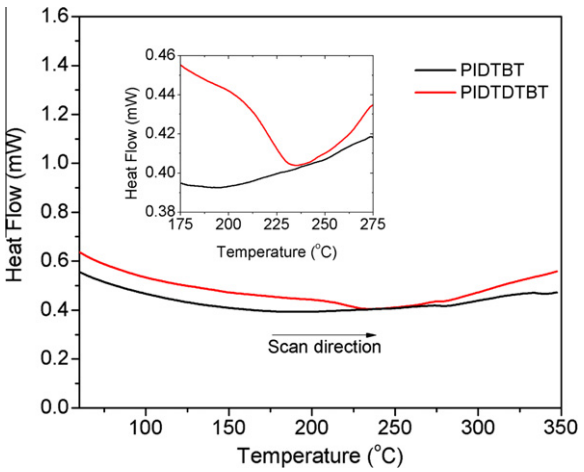

Fig. 2. DSC thermogram of PIDTBT and PIDTDTBT. Inset: enlarged image between 175 and 275 °C.

was given for PIDTDTBT, which was attributed to a glass transition.

2.2. Photophysical and electrochemical properties

The thin film absorption characteristics and the cyclic voltammogram of PIDTBT have been previously reported in Ref. [20]. The UV–Vis absorption spectra of PIDTBT and PIDTDTBT in dilute chloroform solution and in film state are shown in Fig. 1b and c, respectively. Similar to PIDTBT, PIDTDTBT shows two absorption bands due to the π–π^* transition and the intramolecular charge transfer with the absorption maxima at 445 and 590 nm, respectively. Negligible changes in the position of the peak maxima and only slight broadening of the absorption bands were observed in the cases of the cast films. From the low-energy onset of the thin film absorption, the optical bandgap of PIDTDTBT is estimated to be 1.74 eV, which is slightly smaller than 1.75 eV for PIDTBT. From the cyclic voltammograms (Fig. 3), the HOMO and LUMO levels of the PIDTDTBT were estimated to be −5.19 and −3.49 eV, respectively, using ferrocene (−4.8 eV) as the internal standard. The $E_0^{1/2}$ value of the ferrocene/ferrocinium couple vs. Ag/AgCl was 329 mV. PIDTBT has also been tested for comparison, and the HOMO and LUMO of PIDTBT were calculated to be −5.23 and −3.52 eV, respectively, giving a bandgap of 1.71 eV.

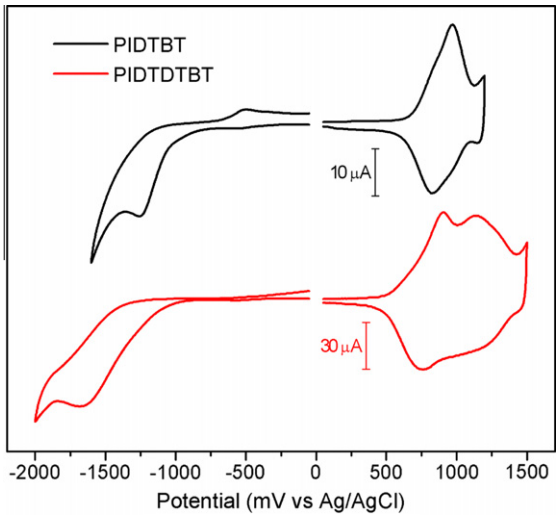

Fig. 3. Cyclic voltammograms of PIDTBT and PIDTDTBT.

2.3. Quantum mechanical calculations

The molecular geometry and the electron density of states distribution of these two polymers were calculated using density functional theory (DFT). All DFT [27,28] calculations were performed using Gaussian 09(A.02) employing the hybrid B3LYP [29,30] exchange–correlation functional with a split valence 6-31G* [31] basis set. Oligomers containing two repeating D–A pairs as illustrated in Table 1 were used for computational simplicity. The hexylphenyl side chains were also truncated to ethylphenyl groups as their replacement with shorter chains does not affect the optimized geometries of the polymers. This computational method is found to be an accurate

formalism for predicting the geometric and electronic properties of many conjugated polymers [32]. Frequency calculations were also performed on the optimized geometries of both polymers, and minima were verified through normal mode analyses which both resulted in zero imaginary modes. The ab initio simulations reveal that the conformations of the oligomer backbones of both PIDTBT and PIDTDTBT are highly coplanar (Table 1). The HOMO wave function is delocalized over the polymer backbones, and the LUMO wave function is localized on the BT acceptor group in both cases, proposing effective intramolecular charge-transfer transitions. The energy levels of the IDT-based polymers estimated from CV and DFT calculations are summarized in Table 2.

2.4. OFET characteristics

The hole-transporting properties of PIDTBT or PIDTDTBT were investigated by fabricating them into field effect transistors using a bottom-gate, top-contact configuration. The transfer and output characteristics are shown in Fig. 4. The hole mobilities extracted in the saturation regime from the linear fit of $(I_{ds})^{1/2}$ vs. V_{gs} are 0.020 and 0.013 $cm^2 V^{-1} s^{-1}$ for PIDTBT and PIDTDTBT, respectively. The more planar structure of the IDT moieties possibly reduces the degree of rotational disorder on the backbones of the polymers, leading to better charge transport. Another alternating IDTBT-based polymer with long alkyl solubilizing side chains has recently been reported to demonstrate an extraordinarily high FET mobility of 1.0 $cm^2 V^{-1} s^{-1}$ in a top-gate bottom-contact device [33], which is a further

evidence of the good charge transporting properties for the IDTBT backbone. Similarly, as we reported very recently, when the bridging carbons of PIDTBT and PIDTDTBT are substituted with silicon atoms, high mobilities could also be obtained [34].

2.5. Photovoltaic characteristics

The photovoltaic properties of PIDTBT and PIDTDTBT were investigated in both the conventional and inverted device configurations. [6,6]-Phenyl-C_{71}-butyric acid methyl ester ($PC_{71}BM$) is chosen as the n-type active material because of its stronger absorption in the visible region compared to its C_{60} counterpart. The device architectures of the conventional and the inverted devices are ITO/PEDOT:PSS/polymer:$PC_{71}BM$(1:3)/Ca/Al and ITO/ZnO/polymer:$PC_{71}BM$(1:3)/PEDOT:PSS/Ag, respectively. The photovoltaic parameters of the PSCs tested under simulated AM1.5G conditions (100 mW/cm^2) are summarized in Table 3. The *J–V* curves and the external quantum efficiency (EQE) of the best devices are shown in Fig. 5. The conventional configuration devices of PIDTBT showed a high PCE of 5.9% (6.3% for the best device), which is similar to the previously reported number for PIDTBT-based devices [20]. The PSCs based on PIDTDTBT also showed a very decent performance of 4.3%. The surface morphology of the uncovered area of the BHJ layer in the conventional structure devices was characterized by atomic force microscopy (AFM) and is shown in Fig. 6. The root-mean-square roughness of the PIDTBT:$PC_{71}BM$ and PIDTDTBT:$PC_{71}BM$ are 0.078 and 1.274 nm, respectively.

Inverted architecture PSCs feature the capability of using high work function and printable metal electrodes on top of the devices that provides better stability to the ambient atmosphere [35–37]. In addition, the unstable ITO/PEDOT:PSS interface, which is commonly observed for the conventional devices, could also be eliminated if the inverted configuration is used. Despite the advantages of inverted cells, the majority studies on inverted cells were based on polythiophene as active materials [38,39], while only few new low bandgap polymers had been tested in such configuration [15,40–42]. Therefore,

comparison of the photovoltaic properties of new materials in both conventional and inverted cells is very important to fully evaluate the performance of new polymers. For the inverted devices fabricated in this study, lower fill factor (FF) and current density (J_{sc}) were observed for PIDTBT may be due to un-optimized morphology in the BHJ layer. This leads to a slightly lower PCE of 4.7% (4.9% for the best device). The devices based on PIDTDTBT also showed a reasonable performance of 4.1%. EQEs of up to 61% and 56% were demonstrated from the conventional devices of PIDTBT and PIDTDTBT, respectively. Slightly lower EQE was observed for the inverted devices in most parts of the spectrum, resulting in lower photocurrent for the inverted devices. The EQE curves of the conventional devices deviate from the corresponding absorption curves of the active layers at wavelengths shorter than 530 nm, and in the inverted cases even greater deviations are observed between 400 and 630 nm. Since the majority of the short wavelength absorption of the active layer is mainly coming from $PC_{71}BM$, the deviations of the EQE from the absorption spectra suggest lower exciton harvesting efficiencies from $PC_{71}BM$. A similar result was also found by Burkhard et al. in the case of P3HT:$PC_{61}BM$-based BHJ cell [43].

3. Conclusions

We report the synthesis of two indacenodithiophene-containing low bandgap polymers and the characterization of highly efficient PSCs based on these polymers in their conventional and inverted device configurations. The conventional configuration device of PIDTBT shows a high PCE of around 6.3%. Its inverted device also shows a quite high efficiency (as high as 4.9%), which is among the highest reported for the inverted devices. The performance of the PSCs containing the new polymer PIDTDTBT reach PCEs of 4.4% and 4.2% for conventional and inverted structure devices, respectively. The high performance of these devices can be attributed to several of their desirable properties including low band gaps, low-lying HOMO levels, and high hole mobilities.

4. Experimental

4.1. Instruments and characterizations

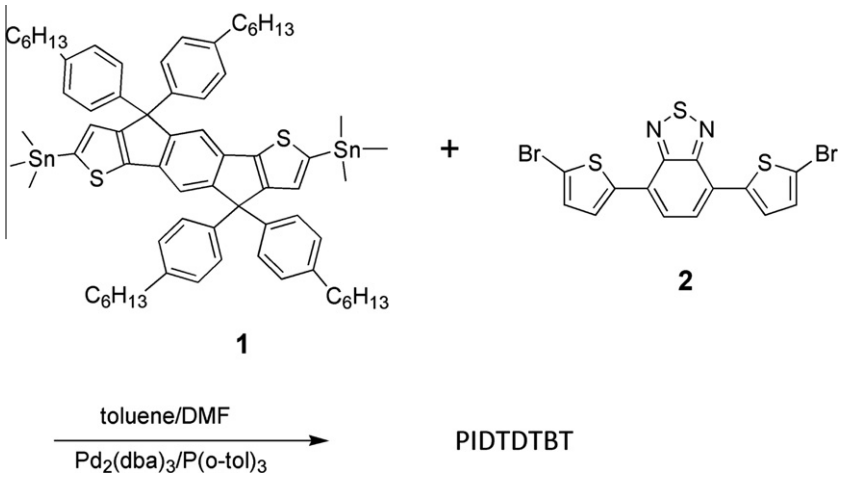
^1H and ^{13}C NMR spectra were measured on a Bruker AV-500 spectrometer operating at 125 and 500 MHz for ^{13}C and ^1H, respectively, in deuterated chloroform solution with TMS reference. Molecular weights of the polymers were determined by a waters 1515 gel permeation chromatograph (GPC) with a refractive index detector in tetrahydrofuran (THF) using a calibration curve of polystyrene standards. UV–Vis spectra were obtained on a Perkin–Elmer Lambda-9 spectrophotometer. With 2 and 2.5 mg of PIDTBT and PIDTDTBT, respectively, loaded in aluminum cups, DSC analysis was performed using DSC2010 (TA instrument) under a scanning rate of 10 °C min^{-1} and a nitrogen flow of 50 mL min^{-1}. Cyclic voltammetric data were measured on a BAS CV-50W voltammetric analyzer using tetrabutylammonium hexafluorophosphate in acetonitrile (0.1 M) (electrochemical grade, Fisher Scientific) as electrolyte and indium tin oxide (ITO) and Ag/AgCl as the working and reference electrode, respectively, at a scanning rate of 100 mV/s at room temperature under nitrogen flow. The surface morphology of the active layers was characterized under tapping mode using the Veeco multimode AFM with a Nanoscope III controller.

4.2. Materials and syntheses

[6,6]-Phenyl-C_{71}-butyric methyl ester ($PC_{71}BM$, 98%) was purchased from American Dye Source or Nano-C. Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS, Baytron P VP AI 4083) was purchase from H.C. Stark. Materials were used as received. The ZnO nanoparticles were prepared in our group using the procedure described by Beek et al. [44].

4.2.1. Synthesis of PIDTBT and PIDTDTBT

The synthetic procedure for PIDTBT can be found in Ref. [20]. Scheme 1 shows the synthetic procedures of PIDTDTBT. The donor and acceptor segments (compound



Scheme 1. Synthetic procedure of PIDTDTBT.

1–2) were synthesized according to the reported procedures [20,45]. The IDT-di-tin monomer (compound 1, 337 mg, 0.27 mmol) was charged with 4,7-bis(2-bromo-5-thienyl)-2,1,3-benzothiadiazole (compound 2, 114 mg, 0.25 mmol) in a 25 mL flask under N_2 protection. After the addition of toluene (3 mL) and DMF (0.5 mL), the mixture was degassed then $Pd_2(dba)_3$ (7 mg) and $P(o\text{-}tol)_3$ (6 mg) were added as catalyst. The mixture was heated to 120 °C and maintained at the same temperature for 24 h. After cooling to room temperature, the mixture was poured into methanol. The precipitate was collected and washed by Soxhlet extraction with methanol and acetone for 12 h, respectively. The resulting dark solid was dissolved into a small amount of chloroform and then poured into methanol again. The solid was collected and dried overnight under vacuum with the yields of 61% for PIDTDTBT. ^{1}H NMR (PIDTDTBT, $CDCl_3$, ppm): 7.85–8.02 (br, 4H), 7.11–7.44 (br, 22), 2.59 (m, 8H), 1.62 (m, 4H), 1.32 (s, 28H), 0.89 (m, 12H).

4.3. Device fabrication and characterization

4.3.1. Organic field-effect transistors

Heavily doped silicon substrates with a 300 nm thick thermally grown SiO_2 dielectric (Montco Silicon Technologies, Inc.) were cleaned sequentially by sonication in acetone and isopropyl alcohol, followed by a 5 min exposure to air plasma. The surface of the silicon substrates was treated with hexamethyldisilazane (HMDS) by vapor phase deposition in a vacuum oven (200 mTorr, 100 °C, 3 h). The water contact angle of the HMDS treated silicon substrates was around 70°. The polymer film was spin-coated from its 5 mg/ml chloroform solution at 2000 rpm under a dry nitrogen environment. No thermal treatment was performed on the polymer. Interdigitated source and drain electrodes (L = 9600 μm, W = 80 μm, W/L = 120) were defined by thermally evaporating 50 nm thick gold through a shadow mask. The transfer and output characteristics of the thin film transistors were obtained on an Agilent 4155B semiconductor parameter analyzer under nitrogen atmosphere.

4.3.2. Organic BHJ solar cells

1,2-Dichlorobenzene (DCB) solution of the polymer:$PC_{71}BM$ blends was stirred at 80 °C overnight before use. The concentration of the polymer and the $PC_{71}BM$ in DCB was 10 and 30 mg/ml, respectively. Indium tin oxide coated glass substrates (ITO, 15 Ω per square) were cleaned sequentially by sonicating in detergent, de-ionized water, acetone, and isopropyl alcohol, followed by blow-drying under nitrogen stream and exposing under oxygen plasma for 5 min. In the conventional architecture solar cells, a thin layer (ca. 40 nm) of PEDOT:PSS (filtered at 0.45 μm, Nylon) was first spin-coated onto the ITO surface and baked at 140 °C for 10 min in ambient. Subsequently, the substrates were transferred into a nitrogen-filled glovebox for further processing. The polymer:$PC_{71}BM$ BHJ layer (ca. 100 nm) was spin-coated at 1300 rpm from filtered (0.2 μm PTFE) DCB solution and the substrates were transferred into a glass petri-dish with excess DCB for 30 min of solvent vapor annealing. Ca (30 nm)/Al (100 nm) electrode was then thermally evaporated through the openings of the shadow masks with the size of 3.14 mm^2 under high vacuum (<2×10^{-6} Torr) to define the active area of the solar cells. In the case of inverted architecture devices, ZnO nanoparticles were first spin-coated onto ITO to form a 50 nm thick buffer layer. The active layer of the polymer:$PC_{71}BM$ blend was then spin-coated and vapor annealed using the same process as in the conventional architecture devices. Subsequently, a PEDOT:PSS layer (50 nm) was spin-coated on top of the active layer and again annealed for 10 min at 120 °C. Finally, Ag electrode (100 nm) was deposited under high vacuum to complete the fabrication of inverted devices. The active area of each device is also 3.14 mm^2. The current–voltage (I–V) characteristics were measured by using the Keithley 2400 source-measurement unit. An Oriel xenon lamp (450 W) coupled with an AM1.5G filter was used as the solar simulator. The light intensity was set to 1 sun (100 mW/cm^2) using a calibrated Hamamatsu silicon diode with a KG5 color filter, which can be traced to the National Renewable Energy Laboratory (NREL). The EQE system uses a lock-in amplifier (Stanford Research Systems SR830) to record the short-circuit current under chopped monochromatic light.

light-emitting materials are rare. For example, a blue light emitter with four substituents at the 2,6,9,10-positions of anthracene (2,6-bis(9,9-diethyl-9H-fluoren-2-yl)-9,10-diphenylanthracene) has been proven to exhibit an EL efficiency of 5.8 cd/A and an external quantum efficiency of 2.11% [16]. Chen et al. synthesized 9,10-diphenylanthracene (DPA)-derived copolymers emitting blue light. The OLEDs fabricated using these DPA-derived copolymers exhibited sky-blue EL (at CIE coordinates of (0.19, 0.30)) with a peak luminous efficiency of 1.26 cd/A. Still, the development of OLEDs using anthracene-derived moieties remains a challenge [17].

Herein, we report the use of an anthracene-based blue host, 9-(phenanthryl)-10-(3-(9-phenylcarbazole-9-yl)anthracene (PPCA), and a dopant 9,10-bis-biphenyl-4-yl-2,6-diphenylanthracene (BDA) which contains PAHs without amino substituents (Schemes 1 and 2). Specifically, PPCA was synthesized from 9-phenyl-9H-carbazole, which possesses good hole-transporting properties, and phenanthrene, which has good electron-transporting properties [18]. We believe that the introduction of carbazole and phenanthrene elements in the 9,10-anthracene core of PPCA is an effective method for avoiding molecular aggregation and enhancing the efficiency of transporting electrons and holes (carriers). We examined the light-emitting performance in devices fabricated using aluminum tris(8-hydroxyquinoline) (Alq_3) and 1,6-di(pyridin-3-yl)-3,8-di(naphthalene-1-yl)pyrene (N1PP) [19] as electron-transport materials. In particular, with the use of N1PP, which shows high carrier mobility, the EL efficiency of the blue OLED devices based on PAHs without amino substituents was significantly improved.

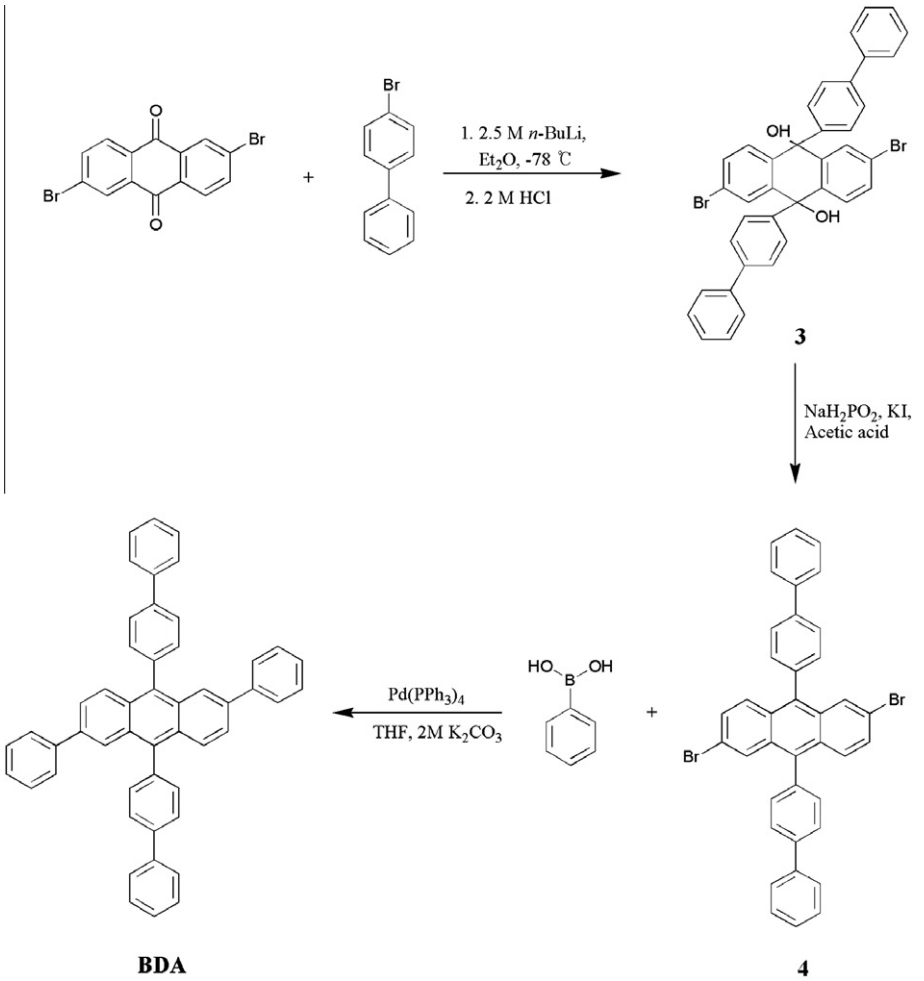

Scheme 2. Synthesis of BDA.

2. Experimental

2.1. Materials and instrument

9-Bromoanthracene, 9-phenanthreneboronic acid, 9-phenylcarbazole, and 4-bromobiphenyl were purchased from Tokyo Chemical Industry Co., Ltd., (TCI, Japan) and Aldrich Chemical Co., (USA). Compounds **1A**, **2A**, **3**, and **4** (Schemes 1 and 2) were synthesized according to literature methods as well as modified procedures [16,20]. Analytical thin-layer chromatography was performed using Kieselgel 60F-254 plates provided from Merck KGaA (Germany). Column chromatography was carried out on Merck silica gel 60 (70–230 mesh). All the solvents and reagents are commercially available and were used without further purification, unless otherwise noted. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ using a Bruker Advance 300 MHz spectrometer. Proton (^{1}H) NMR chemical shifts in $CDCl_3$ were referenced to $CHCl_3$ (7.27 ppm). Mass spectra were obtained by means of gas chromatography/high-resolution mass spectrometry. Ultraviolet and visible (UV–vis) absorption spectra were recorded with the use of a Beckman DU 650 spectrophotometer.

2.1.1. 9-Phenanthren-9-yl-anthracene (1)

A solution of 9-bromoanthracene (2 g, 7.78 mmol), 9-phenanthreneboronic acid (1.90 g, 8.56 mmol), $Pd(PPh_3)_4$ (3 mol%), and aqueous K_2CO_3 (10.8 g, 78 mmol, water 50 mL) in a toluene (10 mL)–tetrahydrofuran (THF, 50 mL) mixture was heated at a temperature of 100 °C for 10 h in a N_2 atmosphere. After the solvent was evaporated, the residue was treated with water and extracted with dichloromethane. The crude product was purified by silica gel column chromatography (10% dichloromethane (DCM) in *n*-hexane used as eluent) and further purified by recrystallization (yield: 87%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 7.18 (d, ^{1}H, J = 8.07 Hz), 7.24–7.35 (m, 3H), 7.49 (t, 2H, J = 7.4 Hz), 7.59 (d, 2H, J = 8.60 Hz), 7.75 (m, 2H), 7.80 (t, ^{1}H, J = 7.14 Hz), 7.86 (s, ^{1}H), 7.94 (d, ^{1}H, J = 7.73 Hz), 8.14 (d, 2H, 8.49 Hz), 8.78 (s, ^{1}H), 8.90 (d, 2H, J = 8.28 Hz).

2.1.2. 9-Bromo-10-phenanthren-9-yl-anthracene (2)

A solution of bromine (0.91 g, 5.70 mmol) in chloroform (20 mL) was slowly added to a solution of **1** (2 g, 5.64 mmol) in chloroform (50 mL) at room temperature. After stirring for 5 h, the mixture was poured into EtOH. The residue obtained after filtration was purified by flash chromatography using dichloromethane (yield: 89%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 7.13 (d, ^{1}H, J = 8.10 Hz), 7.26–7.34 (m, 3H), 7.56–7.73 (m, 6H), 7.68–7.81 (m, ^{1}H), 7.83 (s, ^{1}H), 7.93 (d, ^{1}H, J = 6.38 Hz), 8.70 (d, 2H, J = 8.82 Hz), 8.89 (d, 2H, J = 8.22 Hz).

2.1.3. 9-(Phenanthryl)-10-(3-(9-phenylcarbazole-9-yl)-anthracene (PPCA)

2A was allowed to react with **2** under Suzuki reaction conditions, as described in the synthesis of **1,** to afford PPCA (yield: 82%). ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 7.31–7.36 (m, 5H), 7.49–7.77 (m, 16H), 7.88–7.97 (m, 4H), 8.14–8.18 (m, ^{1}H), 8.39–8.32 (m, ^{1}H), 8.91 (d, 2H, J = 8.2 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 109.74, 109.77, 100.06, 120.21, 120.51, 122.78, 122.90, 123.19, 123.30, 12.55, 125.08, 125.30, 126.29, 126.74, 126.93, 127.0, 129.09, 127.23, 127.54, 127.65, 128.83, 129.37, 130.04, 130.45, 130.53, 130.69, 130.80, 131.82, 132.84, 134.65, 135.58, 137.78, 138.41, 140.41, 141.40; HRMS (FT MS) m/z: calcd. for $[C_{46}H_{29}N + H]^+$ 596.23, found $[M + H]^+$ 596.24; Anal. calcd. for $C_{46}H_{29}N$: C, 92.74; H, 4.91; N, 2.35. Found: C, 92.7033; H, 4.9502; N, 2.2309.

2.1.4. 9,10-Bis-biphenyl-4-yl-2,6-diphenylanthracene (BDA)

4 (2 g, 3.12 mmol) was allowed to react with phenylboronic acid (0.84 g, 6.87 mmol) under Suzuki reaction conditions, as described in the synthesis of PPCA, to afford BDA (yield: 72%); ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) 7.33–7.42 (m, 8H), 7.53–7.73 (m, 14H), 7.81–7.91 (m, 10H), 8.01 (s, 2H); HRMS (FT MS) m/z: calcd. for $[C_{46}H_{29}N + H]^+$ 635.27, found $[M + H]^+$ 635.28. Anal. calcd. for $C_{50}H_{34}$: C, 94.60; H, 5.40. Found: C, 94.6206; H, 5.4299.

2.2. Electrochemical characterization

The electrochemical properties of PPCA and BDA were characterized by means of cyclic voltammetry. The oxidation scans were carried out in a 0.1 M solution of tetraethylammonium tetrafluoroborate in anhydrous CH_2Cl_2. A platinum and Ag/AgCl disk were used as the working and reference electrodes, respectively. Specifically, the platinum disk was used as the counter electrode. Based on the highest occupied molecular orbital (HOMO) energy of the ferrocene/ferrocenium redox system (-4.8 eV), we were able to calculate the HOMO energy values of PPCA and BDA which were both equal to 5.6 eV. The band-gap energies were measured from the absorption spectra, and the lowest unoccupied molecular orbital (LUMO) energies were estimated to be equal to 2.6 eV for PPCA and 2.8 eV for BDA. The energy levels of PPCA and BDA indicate that Förster resonance energy transfer (FRET) takes place between the host (PPCA) and the dopant (BDA), because as shown in Fig. 4 the band-gap energy of PPCA is greater than that of BDA (see Supporting Information) [21,22].

2.3. OLED fabrication

OLEDs were fabricated by means of vacuum deposition onto patterned ITO glasses that had been thoroughly cleaned and subsequently, treated with oxygen plasma. Blue OLEDs were sequentially fabricated onto the ITO substrates through thermal evaporation of organic layers (evaporation rate: 2 Å/s; base pressure: 3×10^{-6} Torr). The EL spectra and CIE color coordinates were obtained using a Spectrascan PR650 photometer, while the current–voltage–luminescence (J–V–L) characteristics were measured using a Keithley 2400 source unit.

3. Results and discussion

3.1. Synthesis

Scheme 1 shows the synthetic route to PPCA. Specifically, the Pd-catalyzed Suzuki coupling reaction of 9-bromoanthracene with 9-phenanthreneboronic acid afforded **1** in 87% yield. Bromination of **1** with 1.01 equiv. of bromine in chloroform solution led to the formation of **2** in 89% yield. **2A** was synthesized through the reaction of 3-bromo-9-phenylcarbazole with 1.1 equiv. of *n*-BuLi at −78 °C and subsequent quenching of the lithiated complex with triethylborate. PPCA was synthesized through a Pd-catalyzed Suzuki coupling reaction, similarly to the case of **1**.

Scheme 2 shows the synthetic route to BDA. Specifically, **4** was synthesized according to a previously described procedure [16]. A suspension of 2,6-dibromoanthraquinone in Et_2O was slowly added to lithium-substituted biphenyl in order to obtain **3**. The latter was aromatized using NaH_2PO_2 and KI to obtain **4** in 84% yield. The next step was to obtain BDA through the Pd-catalyzed Suzuki-coupling reaction of **4** with phenylboronic acid in 2 M aqueous K_2CO_3 solution. The molecular structures of PPCA and BDA were characterized by means of ^{1}H NMR, mass spectrometry, and elemental analysis (EA).

3.2. Thermal properties and quantum yields

The thermal behavior of BDA and PPCA was evaluated by means of (a) differential scanning calorimetry (DSC) and (b) thermogravimetric analysis (TGA) under a nitrogen atmosphere. A 5% weight loss was observed at 398 and 367 °C. The melting point (T_m) of BDA and PPCA was 396 and 326 °C and the decomposition temperature (T_d) was 445 and 440 °C, respectively. These data indicate that both these materials are stable enough to endure the high temperature at which the vacuum vapor deposition is carried out (see Supporting Information).

Additionally, the fluorescence quantum yield (Φ) was measured using the standard optically diluted method in CH_2Cl_2 solution and 9,10-diphenylanthracene (Φ = 0.90, in CH_2Cl_2) as the reference standard. The fluorescence quantum yield of BDA and PPCA were 0.74 and 0.83, respectively [23,24].

3.3. Optical properties of PPCA and BDA

Fig. 1 shows the UV absorption and PL spectra of PPCA and BDA dissolved in dichloromethane as well as in the

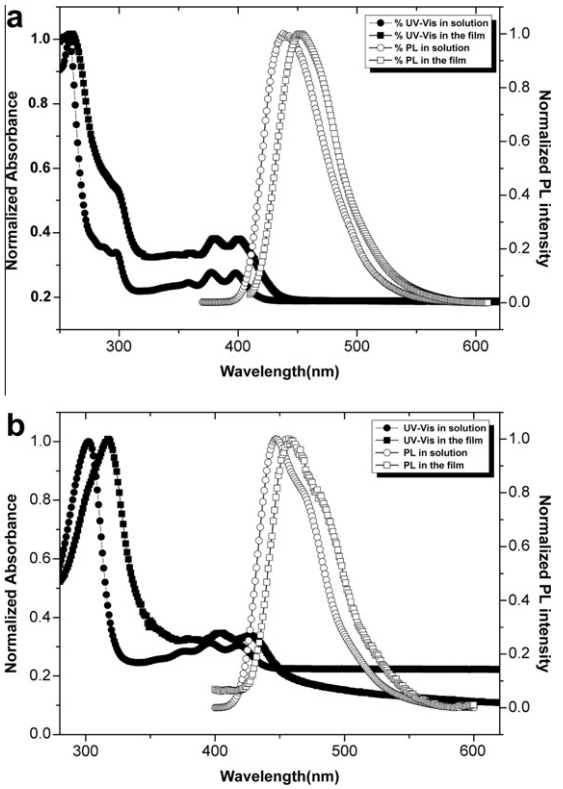

Fig. 1. UV absorption and PL spectra of PPCA and BDA dissolved in dichloromethane (CH_2Cl_2) and in the case of solid thin films deposited on a quartz substrate. (a) Normalized UV absorption and PL spectrum of PPCA. (b) Normalized absorption and PL spectrum of BDA.

form of solid thin films. Specifically, two major bands are observed in the UV absorption spectra of the material dissolved in dichloromethane and in the form of solid thin films (Fig. 1a). The first strong absorption, which is observed at a wavelength of 258 nm with a shoulder peak at 300 nm, can be attributed to the 9-phenyl-9H-carbazole moiety. The absorption peaks observed at a wavelength of 358 nm, 378 nm, and 398 nm are associated with the vibronic features of the anthracenyl core [25]. Upon photoexcitation, the PL emission of PPCA dissolved in the dichloromethane peaked at a wavelength of approximately 438 nm and at 452 nm in the case of the solid thin film. The spectral shift in solid state is due to the different dielectric constant of the surrounding medium [26].

In Fig. 1b, the absorption peaks of BDA dissolved in dichloromethane show vibrational patterns at a wavelength of 373 nm, 396 nm, and 419 nm, which are typical to aryl-substituted anthracene [16,20]. The maximum PL of BDA dissolved in dichloromethane was observed at a wavelength of 448 nm and at 456 nm in the case of the solid thin film. Additionally, in the host-dopant system, the probability of energy transfer from the excited energy donor to the energy acceptor depends on the overlap of the emission spectrum of the donor with the absorption spectrum of the acceptor. This is evident from the spectral overlap between the PL of PPCA and the UV absorption of BDA (see Supporting Information) [27–32].

3.4. EL properties and OLED characteristics

Fig. 2 shows the structures of Alq_3 and N1PP acting as electron-transporting materials and the EL spectra of the 5% doped devices driven at 10 mA/cm^2. To elucidate the energy transfer from PPCA to BDA, we fabricated two kinds of multilayer structures: ITO/DNTPD (600 Å)/α-NPB (300 Å)/

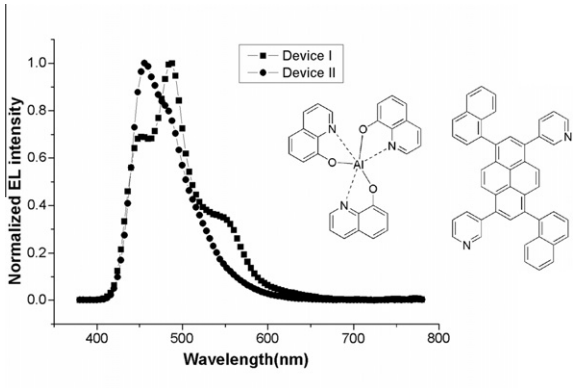

Fig. 2. EL spectra of Device I and II along with the structures of Alq_3 and N1PP.

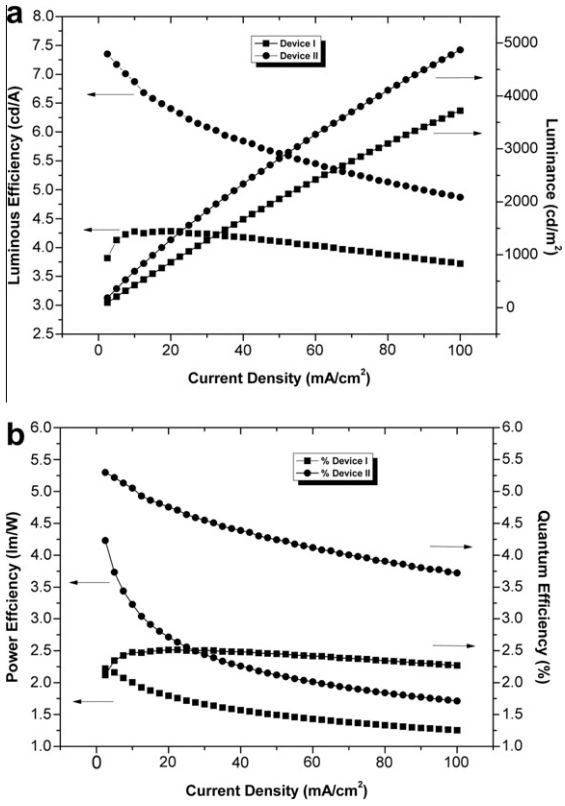

Fig. 3. EL performance of Device I and II. (a) The current–efficiency and density–luminance characteristics of Device I and II. (b) The power efficiency–current density–external quantum efficiency characteristics of Device I and II.

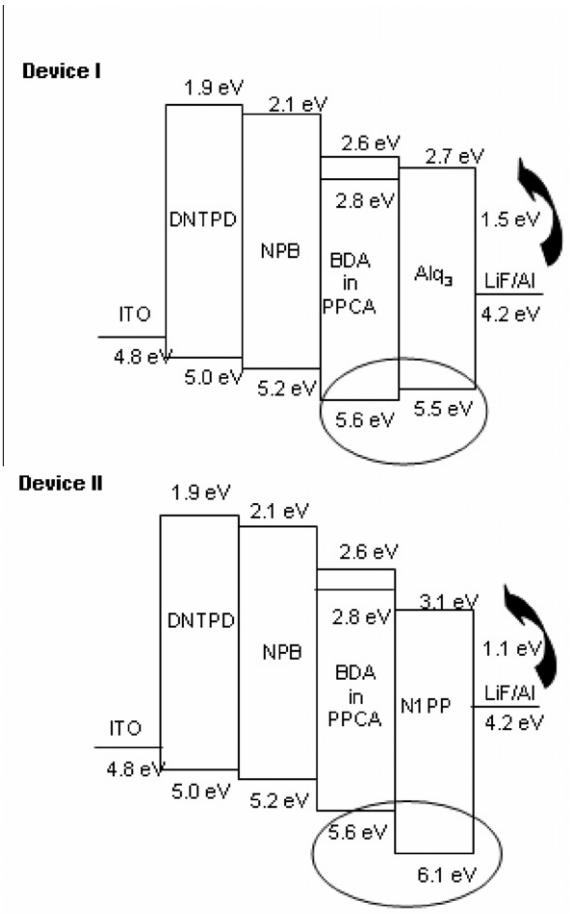

Fig. 4. HOMO and LUMO energy levels of the materials used for the fabrication of Device I and II.

PPCA:BDA 5 wt.% (250 Å)/Alq_3 (300 Å)/LiF (5 Å)/Al (1000 Å) (Device I) and ITO/DNTPD (600 Å)/α-NPB (300 Å)/PPCA:BDA 5 wt.% (250 Å)/N1PP (300 Å)/LiF (5 Å)/Al (1000 Å) (Device II). We used *N,N′*-di(4-*N,N′*-diphenylamino)phenyl)-*N,N′*-diphenylbenzidine (DNTPD) as the hole-injection layer (HIL), 4,4′-bis[*N*-(1-napthyl)-*N*-phenylamino]biphenyl (α-NPB) as the hole-transport layer (HTL), PPCA as the fluorescent blue host, BDA as the fluorescent blue dopant, N1PP and Alq_3 as the electron-transport layers (ETL) [19], and LiF as the electron-injection layer (EIL) at the LiF/Al cathode interface. The EL spectrum of Device I, in which Alq_3 was used as an ETL, was found to be different from that of Device II, which used N1PP as an ETL. In Device I, three major peaks were observed at a wavelength of 454 nm, 487 nm, and 525 nm. We believe that the two higher energy emissions are due to BDA, while the lower energy emission is due to Alq_3 [33–35].

The experimental results suggest that energy transfer takes place between the light-emitting and the electron-transporting layer. Specifically, a peak in the blue-light emission of Device II was observed at a wavelength of 456 nm, which is almost identical to that of the PL spectrum of BDA in the form of a solid thin film (Fig. 1b). This coincidence indicates that while the light emission of PPCA (host) is essentially quenched in the light emitting layer of the 5% doped device, FRET takes place between the host (PPCA) and the dopant (BDA) [35,36].

Fig. 3 shows the EL performance of Devices I and II, while their EL efficiencies are summarized in Table 1. Specifically, Device I showed a current efficiency of 4.30 cd/A, power efficiency of 2.00 lm/W, and an external quantum efficiency of 2.50% at 10 mA/cm^2 (at CIE coordinates of (0.15, 0.28)). Device II, on the other hand, delivered a better performance with a current efficiency of 6.90 cd/A, power efficiency of 3.23 lm/W, and external quantum efficiency of 5.10% at 10 mA/cm^2 (at CIE coordinates of (0.15, 0.18)).

To further verify the difference between the EL performances of Device I and II, we examined their band-gap energies. Fig. 4 show the HOMO and LUMO energy levels of the organic material, along with the work functions of their metal layers. This energy diagram reveals that the energy barrier (1.5 eV) between the EIL (4.2 eV) and ETL (Alq_3) (2.7 eV) in Device I is larger than the difference (1.1 eV) between the electrode and N1PP (3.1 eV) in Device II [19] Since Alq_3 is characterized by a higher LUMO level than N1PP, electron injection from the LiF/Al cathode into the 5% doped emission layer is rather difficult to be achieved in Device I. Furthermore, the difference between the HOMO values of the emitting layer (EML) and the ETL will cause leakage of holes from the 5% doped emitting zone into the ETL (Alq_3). In Device I, the HOMO level (5.5 eV) of Alq_3 is higher than that of PPCA (5.6 eV). This difference can explain why the electron–hole recombination may be unbalanced in the emitting zone of Device I. This unbalanced charge recombination also shifts the blue light-emitting zone to a region close to the ETL (Alq3) (Fig. 4) and therefore, Device I delivers a poor performance. On the other hand, the HOMO level of N1PP (6.1 eV) is lower than that of PPCA (5.6 eV). Because of the energy barrier (0.5 eV) between the HOMO level of PPCA (5.6 eV) and that of N1PP (6.1 eV), N1PP can act as a hole blocker preventing holes from leaking into the ETL. This behavior suggests that since N1PP has better carrier-transporting and hole-blocking characteristics, it facilitates electron–hole recombination in the 5% doped emitting zone. Consequently, the EL performance of Device II is superior to that of Device I.

Table 1
Summary of the characteristics of Devices I and II with Alq_3 and N1PP as an ETL.

Device	EL peak [nm]	Current efficiency @10 mA/cm^2 [cd/A]	Luminance @10 mA/cm^2 [cd/m^2]	Power efficiency @10 mA/cm^2 [lm/W]	External quantum efficiency [%]	CIE coordinates [*x,y*]
Device I	487	4.30	428/3720[a]	2.00	2.50	0.15, 0.28
Device II	456	6.90	687/4869[a]	3.23	5.10	0.15, 0.18

[a] Measured at 100 mA/cm^2.

4. Conclusions

In summary, we have synthesized new anthracene-based host (PPCA) and dopant (BDA) materials and used them to fabricate efficient blue OLEDs. PPCA carries an electron-transporting 9-phenanthrene moiety as well as a hole-transporting 9-phenyl-9H-carbazole moiety in the anthracene core. On the other hand, BDA consists of PAHs without amino substituents in the anthracene core. Charge balance could be achieved by using N1PP as the electron-transporting material. The device with the optimized structure, ITO/DNTPD (600 Å)/α-NPB (300 Å)/PPCA:BDA 5 wt.% (250 Å)/N1PP (300 Å)/LiF (5 Å)/Al (1000 Å) (Device II), is characterized by high blue EL performance with a current efficiency of 6.9 cd/A, a power efficiency of 3.23 lm/W, and an external quantum efficiency of 5.1% at 10 mA/cm^2 at CIE coordinates of (0.15, 0.18). This study shows that π-conjugated anthracene-functionalized PAHs without amino substituents can be used as efficient dopants for blue OLEDs.

By using phosphorescent materials that harvest both singlet and triplet excitons, the factor η_{ST} can be raised to 100% [11,12].

The factors γ, η_{ST} and q together yield the internal quantum efficiency η_{int}. By the employment of phosphorescent emitters with high radiative quantum efficiency, η_{int} can approach values close to one [13,14]. However, the most important factor still strongly limiting η_{EQE} is the outcoupling efficiency η_{out}. Due to the large difference in refractive index between air ($n = 1.0$), glass ($n \approx 1.5$) and the organic layers ($n \approx 1.7$–2.0), a large fraction of the emitted light can not leave the device due to total internal reflection and is trapped in the substrate or as waveguide modes in the thin film structure. In addition, the excitation of surface plasmons at the interface to the metallic cathode further reduces the light extraction efficiency to values typically around 20% [15]. By applying outcoupling enhancement structures like prisms, microlense arrays or microstructured substrates it is possible to extract a large fraction of substrate modes [3,16–18] and bring η_{out} up to some 30–40% at most, still representing a major limitation for high quantum efficiency.

At present, SM-OLEDs incorporating dye-doped emitting layers are superior to their polymeric counterparts concerning efficiency and lifetime, e.g. due to the straightforward implementation of doped transport layers as well as additional blocking and injection layers leading to better charge balance factor and a well-defined recombination zone. Nevertheless, polymer OLEDs often have the advantage of emitters being oriented parallel to the substrate plane [19–22]. Thus, the transition dipole moment that is usually oriented along the π-conjugated polymer chain is oriented in-plane. This considerably reduces coupling to unfavourable loss channels and can increase η_{out} by a factor of approximately 1.5 compared to a random orientation of the transition dipole moments [20]. For more than 20 years, however, it has generally been believed that evaporated amorphous films in SM-OLEDs have no preferential orientation of the molecules [19]. Though there have been reports about horizontally oriented molecules in evaporated neat films [23–25], only recently a non-isotropic dipole orientation in dye-doped films has been reported [25], opening up new possibilities for improvement of light outcoupling efficiency of OLEDs.

In this article we first explain the fundamental dependence of η_{out} on the dipole orientation by studying detailed optical simulations. Next, we investigate the orientation of the transition dipole moments in two blue fluorescent dyes, 4,4′-bis[4-(diphenylamino)styryl]biphenyl (BDASBi) [26] and 4-(2,2-diphenylethenyl)-*N*,*N*-bis(4-methylphenyl)benzenamine (PEBA) [27], doped into a 4,4′-bis(*N*-carbazole)-biphenyl (CBP) matrix. Angular dependent photoluminescence measurements yield strong evidence for a preferentially horizontal orientation for BDASBi and a random orientation for PEBA. Using BDASBi doped into CBP, horizontally oriented emitters are intentionally employed in dye-doped SM-OLEDs for the first time. By comparing to the PEBA reference device with random dipole orientation, strong evidence is found that the employment of oriented emitters can induce a substantial efficiency boost of almost 50% which is necessary for a widespread application of OLEDs in general lighting.

2. Materials, device structure and experimental methods

Organic semiconductor films generally show optical anisotropy only if the molecular shape is anisotropic as well [24,25]. Because organic solids are bound only by weak intermolecular van der Waals interaction, orientation effects can occur on any underlying substrate and even in a host matrix [25]. Fig. 1a shows the molecular structures of BDASBi and PEBA which are used as exemplary materials in this study. BDASBi is known to show a strong horizontal orientation when doped into CBP [28]. In contrast to BDASBi, which has an elongated shape, PEBA is a rather small and compact molecule. Thus, it is expected that PEBA will show much less pronounced orientation effects than BDASBi. The photoluminescence spectra of BDASBi and PEBA doped at a content of 6 wt.% into CBP are presented in Fig. 1b. Both spectra are very similar and have the same peak wavelength at around 470 nm. In addition, a comparable radiative quantum efficiency q of 0.65 and 0.55 was determined for 6 wt.%-BDASBi:CBP and PEBA:CBP films, respectively. Thus, both materials will

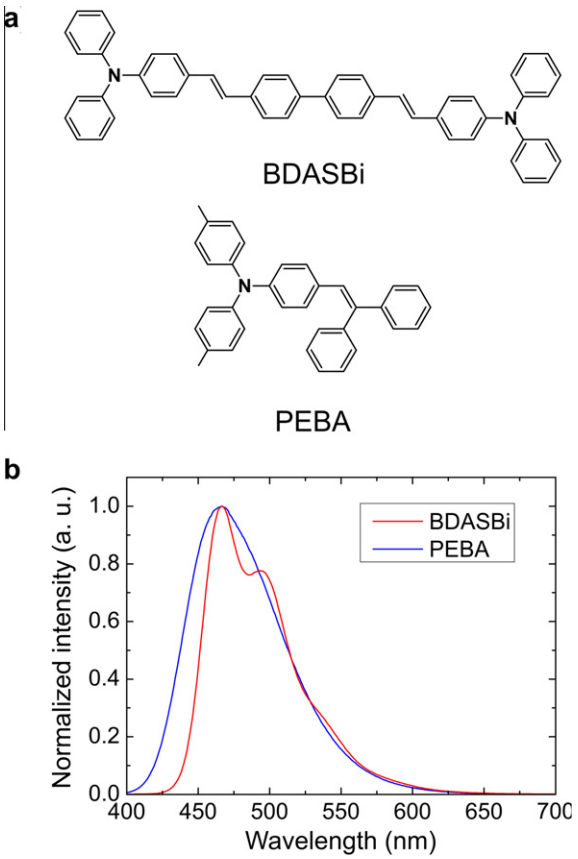

Fig. 1. (a) Molecular structures of BDASBi and PEBA. (b) Photoluminescence emission spectra of 50 nm films of BDASBi and PEBA doped into CBP (6 wt.%) measured perpendicular to the silica glass substrate.

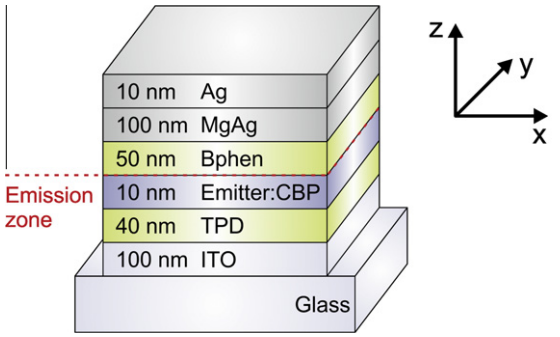

Fig. 2. Schematic diagram of the OLED structure and definition of the coordinate system and dipole orientations used in the simulation.

experience comparable cavity effects inside an OLED device.

Fig. 2 shows the basic OLED structure that is investigated in this work. The devices consist of a glass substrate covered with a patterned indium tin oxide (ITO) layer with 100 nm thickness, then 40 nm of the hole transport material *N*,*N*′-diphenyl-*N*,*N*′-bis(3-methylphenyl)-1,1′-biphenyl-4,4′-diamine (TPD), 10 nm of either BDASBi or PEBA doped into CBP (6 wt.%), 50 nm of the electron transport material 4,7-diphenyl-1,10-phenanthroline (Bphen) and a cathode consisting of 100 nm Mg:Ag (10:1) and a 10 nm thick Ag capping layer.

All organic layers were deposited in a vacuum of $<3 \times 10^{-3}$ Pa at an evaporation rate of ~0.2 nm/s except for the cathode, which was fabricated at a rate of ~0.1 nm/s. All layers of the BDASBi and PEBA OLEDs except for the doped emission layer were deposited simultaneously in order to rule out differences in layer thicknesses. In addition, the substrates were rotated at equivalent positions from the axis during deposition. The active area of the OLEDs was circularly shaped with a diameter of 1 mm.

The current density–voltage–luminance characteristics of the OLEDs were measured using a semiconductor parameter analyzer (E5273A, Agilent Co.) with an optical power meter (1930C, Newport Co.). The zero-degree spectra of the OLEDs were measured using a multichannel spectrometer (SD2000, Ocean Optics Co.) through an optical fibre whose end was located vertically towards the substrate of the working OLEDs. The silicon photodiode of the optical power meter was calibrated at a wavelength of 485 nm, corresponding to the emission peak wavelength of the OLEDs. The emission spectra of the OLEDs are sufficiently narrow to neglect the spectral dependence of the response of the silicon photodiode. The photodiode captures light within a cone of approximately 56°. For the calculation of EQE values from the measurement, a Lambertian emission was assumed which compares reasonably well with measured and simulated angular dependent spectra.

Samples for photoluminescence (PL) and quantum efficiency measurements comprised 50 nm thick doped films of 6 wt.% BDASBi or PEBA in CBP deposited on cleaned fused silica substrates. PL emission spectra were measured using a fluorescence spectrometer (FP-6500, Jasco Co.). The chosen thickness of the samples ensures that the spectra are not changed too much by waveguiding effects and that they match the emission spectra in free space. PL quantum efficiencies were determined using an absolute PL quantum yield measurement system (C9920-02, Hamamatsu Photonics K.K.).

Samples for angular dependent PL measurements consisted of 12 nm thick doped films of 6 wt.% BDASBi or PEBA in CBP deposited on cleaned glass substrates and capped with a 70 nm thick neat CBP layer. For the measurement, a fused silica half cylinder prism was attached to the substrate side of the samples by index matching fluid and the samples were mounted on a computer controlled rotation stage. A 375 nm cw laser diode incident under 45° through the encapsulated side was used as excitation source. Since CBP has only a small absorption at this wavelength, emission from the matrix is suppressed. The angular dependent PL spectrum from 0° to 90° was measured with a fibre optical spectrometer and a polarizer to distinguish between *s*- and *p*-polarized emission (for details see Ref. [28]).

3. Optical simulation of OLEDs

The effect of differently oriented transition dipole moments is most obvious by studying the results of an optical simulation which is based on a dipole model [15,29–31]. In this model, the dipoles are treated as damped forced harmonic oscillators embedded in a multilayer OLED. Without loss of generality, the substrate plane is assumed to be in the x–y-plane and the emission into the x–z-plane is considered, cf. Fig. 2. The simulation distinguishes three discrete dipole orientations p_x, p_y and p_z. According to the chosen coordinate system, the p_x- and p_y-dipoles are oriented horizontally whereas the p_z-dipoles have a vertical orientation. The p_y-dipoles emit only *s*-polarized light whereas the p_x- and p_z-dipoles are accounting for the *p*-polarized emission.

Fig. 3a shows the total dissipated optical power in a device with isotropic emitter orientation, where the emission spectrum is assumed to resemble the one of BDASBi:CBP (6 wt.%) and the radiative quantum efficiency is set to 1. Since CBP has higher hole than electron mobility [32] the emitter position is assumed to be at the interface to Bphen. Obviously, a large fraction of the dissipated power is coupled to two sharp waveguide modes (region 3) and to surface plasmons (region 4).

The contribution of each dipole orientation to the total power dissipation can be seen in Fig. 3b, which shows a cross section of Fig. 3a at 470 nm. The horizontally oriented p_x- and p_y-dipoles have their major contributions in regions (1) and (2) and couple to a *p*-polarized and an *s*-polarized waveguide mode (region 3), respectively. By contrast, the vertically oriented p_z-dipoles show almost no emission into air or substrate but couple most of their power to surface plasmons (region 4) [33]. This behaviour can be explained by taking into account that linear dipoles radiate strongest perpendicular to their direction of oscillation [31]. Thus the vertically oriented p_z-dipoles emit mainly at large angles, i.e. high in-plane wave vectors,

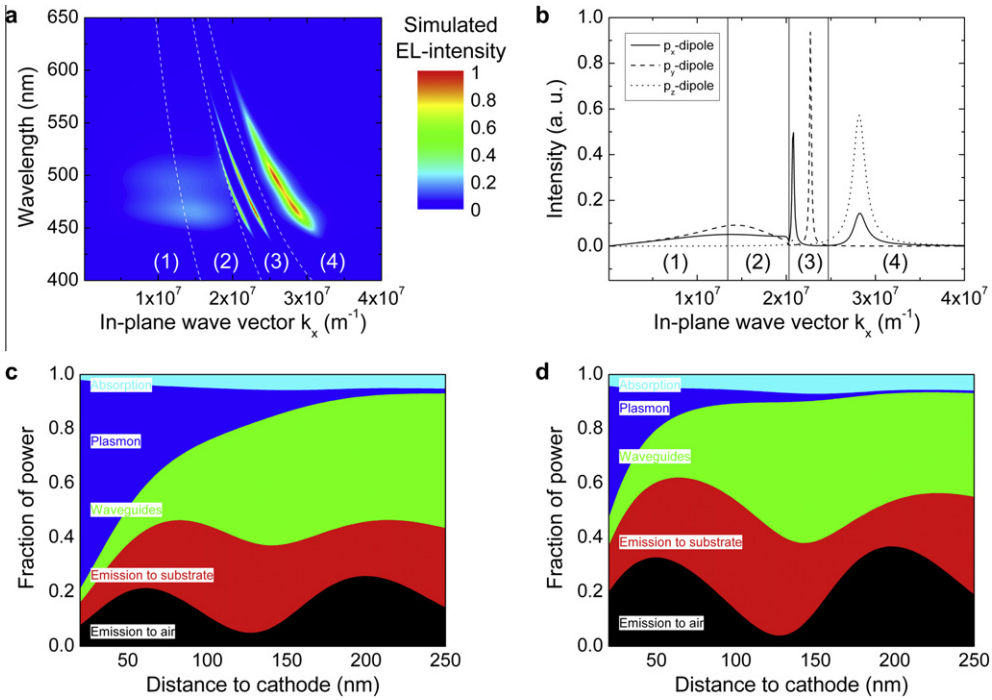

Fig. 3. (a) Simulation of the total optical power dissipation in an organic light-emitting diode as shown in Fig. 2 assuming isotropic emitter orientation with an emission spectrum resembling that of BDASBi:CBP (6 wt.%) and a radiative quantum efficiency $q = 1$. Red areas indicate high amount of dissipated power. The lines divide the graph into four regions: emission into air (1), emission into the glass substrate (2), waveguide modes (3) and coupling to surface plasmons (4). (b) Cross section of (a) at a wavelength of 470 nm. The dissipated power is split into the corresponding fractions of each dipole. The vertical lines divide the graph into four regions similar to (a). (c and d) Dissipated power in dependence of the distance to the cathode for (c) random dipole orientation and (d) horizontal dipole orientation. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Dissipated power coupled into different optical channels depending on the orientation of the transition dipole moment. Simulations are based on an OLED as shown in Fig. 2 with BDASBi:CBP (6 wt.%) as an emitting layer. The residual percentage to 100% is lost due to absorption in ITO and the organic layers and at the cathode. For the last two columns it should be noted that these numbers are not simply the average of the corresponding values of each dipole. Instead of that, a weighting according to cavity effects has to be considered.

	p_x-dipole (%)	p_y-dipole (%)	p_z-dipole (%)	Random ($p_x/p_y/p_z$) (%)	Horizontal (p_x/p_y) (%)
Direct emission to air	28.7	36.5	0.1	20.0	32.6
Substrate emission	25.1	30.2	0.9	17.3	27.6
Waveguides	11.5	27.3	3.4	13.3	19.4
Plasmons	29.8	0.7	94.3	45.7	15.3

hence dissipating their power to an unfavourable loss channel.

The fraction of power dissipated by each dipole orientation to different optical channels is displayed in Table 1. Again, the values for the p_z-dipoles clearly show that this dipole orientation does hardly contribute at all to the desired emission into air or substrate. Consequently, the outcoupling efficiency can be significantly enhanced, if only horizontally oriented dipoles are present. This is apparent from the last two columns in Table 1 which show a comparison of OLEDs consisting of a completely random and a purely horizontal dipole orientation, respectively. Both the direct emission and the substrate emission are enhanced by more than 50%, demonstrating the enormous potential of using horizontally oriented emitters in SM-OLEDs.

The main reason for the increased efficiency is a reduced coupling to surface plasmons. This is even more obvious by investigating the distance dependence of the emitter to the metallic mirror. Fig. 3(c and d) show a variation of the electron transport layer thickness for random and horizontal dipole orientation, respectively. The oscillatory behaviour results from interference effects of the emitter with its image dipole [31,34,35]. The graphs clearly display the increased outcoupling efficiency for a horizontal dipole orientation. In addition, in this case the emitter may be positioned much closer to the cathode before the coupling to surface plasmons becomes the dominant loss channel. Apparently, this is an important aspect considering stack design and OLED optimization as will be discussed later.

4. Experimental results and discussion

4.1. Determination of dipole orientation by photoluminescence measurements

For a conclusive study of orientation effects in dye-doped SM-OLEDs it is necessary to use appropriate materials that differ primarily in the orientation of their transition dipole moments. The investigation of neat films by variable angle spectroscopic ellipsometry (VASE) often yields a first indication about molecular anisotropy. In this case, the optical constants determined by VASE for neat films of BDASBi indicate a strong optical anisotropy while the result for PEBA shows almost no anisotropy; however, VASE cannot yield reliable information about dye orientation in guest–host systems.

The horizontal orientation of emitting molecules as in the neat film of BDASBi can also be observed in doped films. A first demonstration of orientation in doped films was performed by edge emission measurements [25]. A more profound conclusion about the orientation in doped films can be achieved quantitatively from an angular dependent *p*-polarized photoluminescence measurement of a thin film and comparison with optical simulations [28]. In this experiment a stack without metallic layers is used so that the emission from vertically oriented p_z-dipoles is directly measurable and information about their existence and even the exact ratio between horizontal and vertical dipoles can be obtained.

The stack under investigation comprises a 12 nm thick layer of CBP containing 6 wt.% BDASBi or PEBA, respectively, capped with a 70 nm thick neat CBP layer. Fig. 4 (a and b) display the *p*-polarized simulation results of the BDASBi sample for a completely random and a purely horizontal dipole orientation, respectively. By comparing the measured spectra shown in Fig. 4c with the simulations, it is apparent that the transition dipoles in a BDASBi:CBP layer are primarily horizontally oriented.

A precise analysis of the dipole orientation is performed by comparing the cross sections of measurement and simulations, which is displayed in Fig. 5. In addition, the cross section of a stack containing PEBA instead of BDASBi with otherwise identical structure is shown. Comparison of the measured cross section for PEBA with the simulated curves yields excellent agreement assuming a random dipole orientation. Thus, PEBA doped into CBP shows no preferred molecular orientation and the dipole orientation is completely random, i.e. on average 2/3 of the dipoles are horizontally and 1/3 vertically oriented. On the contrary, the cross section of the sample containing BDASBi shows a clear tendency towards horizontal orientation. By weighting the simulations for random and horizontal dipole orientations with 0.27 and 0.73, respectively, very good agreement between the simulated and measured curve can be obtained. These values are in excellent agreement with Ref. [28]. Consequently, it follows that the total ratio between p_z and p_x is 0.27:1. Since the horizontal p_x- and p_y-dipoles are uniformly distributed in the substrate plane, the overall fraction of vertical (p_z) dipoles is 0.27/2.27 = 12% and the fraction of horizontal (p_x, p_y) dipoles is 2/2.27 = 88%.

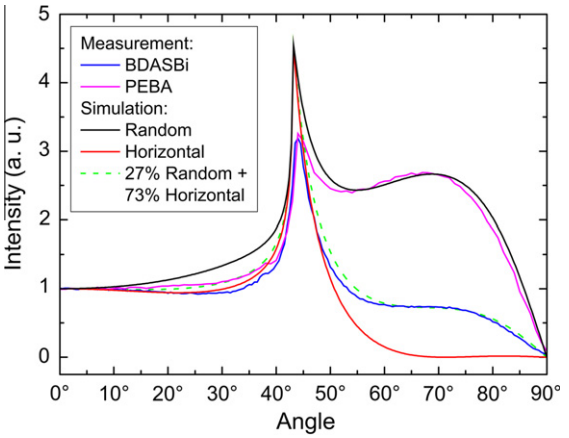

Fig. 5. Angular dependent cross section at 470 nm of the simulated and measured emission spectra shown in Fig. 4 and of a measurement with a sample containing PEBA instead of BDASBi. All cross sections are normalized to the emission at small angles because the emission in this range occurs exclusively from the horizontal p_x-dipoles. On the other hand, the emission at angles around 70° is dominated by the p_z-dipoles. The dashed line represents an average of random and horizontal dipole orientation with a relative weight of 0.27 and 0.73, respectively.

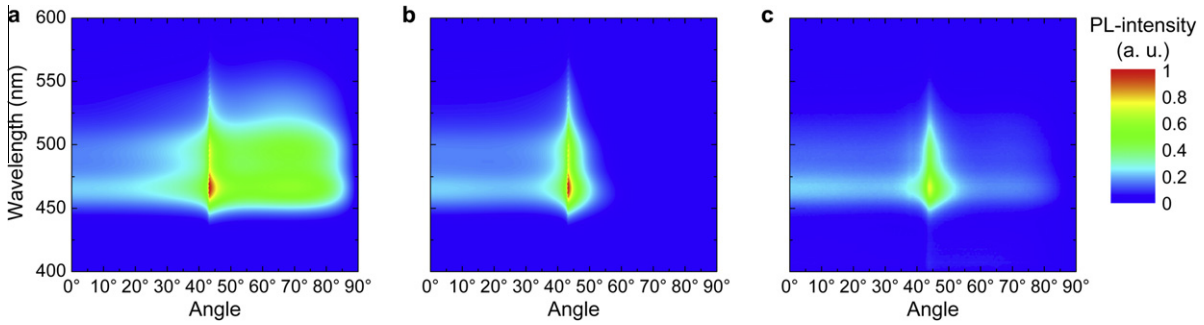

Fig. 4. Simulation and measurement of the angular dependent *p*-polarized emission spectrum of a 12 nm film of BDASBi:CBP (6 wt.%) on a glass substrate capped with 70 nm of neat CBP. Simulation assuming (a) a random dipole orientation, (b) a purely horizontal dipole orientation and (c) measured emission spectrum. The measured emission intensity is scaled so that the emission at small angles corresponds to the simulations.

We note that quantitative information about emitter orientation can also be obtained by fluorescence lifetime measurements, as reported in Ref. [31]. This requires the preparation of a series of samples with systematically varying distance between the emission zone and a metal layer. Though being more elaborate, this method has the benefit of independently yielding the value of the radiative quantum efficiency of the emitter, too, as will be published separately for a red phosphorescent OLED [36].

4.2. Quantum efficiency of dye-doped OLEDs

As a result of the previous analysis, BDASBi and PEBA are ideal candidates for studying the effect of molecular orientation in actual OLED devices. Both materials were incorporated in a rather simple stack in order to rule out differences in device fabrication. The same stack layout as already discussed in the simulations is employed, cf. Fig. 2. Neglecting any effects of orientation, it is expected that the OLED based on BDASBi has a 1.16 times larger external quantum efficiency than the OLED with PEBA because of the difference in radiative quantum efficiency q. The simulations can also be used to predict the influence of orientation which should additionally boost the efficiency of the OLED with BDASBi. Assuming 88% horizontal orientation from the analysis above, it is expected that the OLED based on BDASBi gains an extra enhancement of outcoupling efficiency and therewith external quantum efficiency of 37%. If BDASBi were perfectly oriented horizontally, this enhancement would even amount to 59%.

For a conclusive determination of η_{out} from a measurement of η_{EQE} it is critical that all other factors in Eq. (1) are comparable. First, the spin-allowed exciton fraction η_{ST} is generally accepted to have a value of 25% in SM-OLEDs based on fluorescent emitters [6,7]. Second, the radiative quantum efficiency q was determined to be 0.65 for the 6 wt.%-BDASBi:CBP and 0.55 for PEBA:CBP layers. This difference must be included in optical simulations due to different cavity enhancement [15,37,38]. Finally, the charge balance factor γ is mainly governed by the transport layers TPD and Bphen. Since both OLEDs comprise the same structure it can be assumed that γ is rather similar in both devices. Although charge trapping effects in the doped CBP matrix can not be fully ruled out due to slightly different energy of the lowest unoccupied molecular orbitals (LUMO) of BDASBi and PEBA [39], the almost identical current–voltage characteristics (see below) give strong evidence that minor differences in charge carrier transport and recombination in both devices do not play a dominant role. In addition, it is necessary to have information concerning the emitter position and therewith the distance to the cathode as this has an important influence for the simulated outcoupling efficiency as was demonstrated in Fig. 3(c and d). Since both BDASBi and PEBA contain triphenylamine substituents it is expected that they have a higher hole than electron mobility. CBP also shows a slightly larger hole than electron mobility, therefore it is reasonable to assume that the emission takes place close to the interface between the emitting layer and Bphen. However, the assumptions concerning charge balance and emitter position are further verified by investigating the current–voltage characteristics and the spectrum at different current densities (Fig. 6).

Fig. 6a shows the current–voltage characteristics for two OLEDs based on BDASBi and PEBA as emitters, respectively. Since the OLEDs only differ in their dopant,

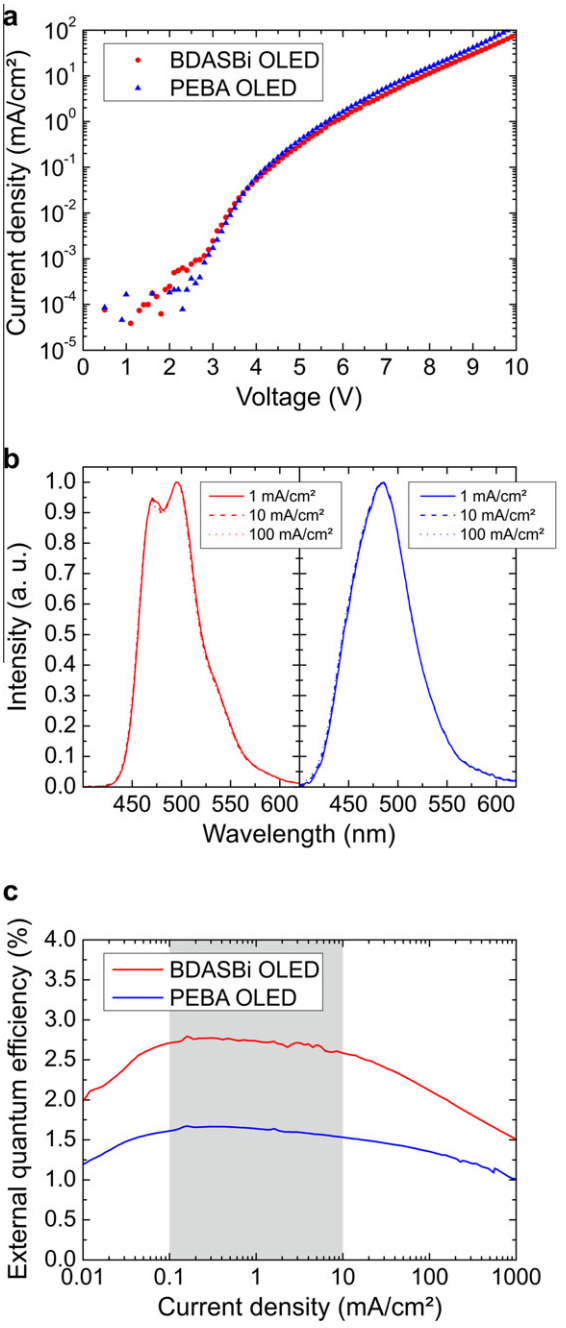

Fig. 6. (a) Measured current–voltage characteristics for OLEDs comprising either BDASBi:CBP or PEBA:CBP as an emitting layer. (b) Measured zero-degree emission spectra at different current densities. (c) Experimentally determined external EL quantum efficiencies depending on current density. The EQE values are averaged in the range between 0.1 and 10 mA/cm^2 because the measured curves show a plateau in this region. For smaller current densities there is probably no stable charge balance, while quenching processes occur for higher current densities.

the measured current density is nearly the same for both devices. This strengthens the assumption of comparable charge balance. The zero-degree spectra of both OLEDs are plotted in Fig. 6b for different current densities. The spectra are almost independent of current density, confirming that the emitter position does not depend significantly on current density as otherwise the spectra would shift due to changing cavity effects [34]. In addition, Fig. 6b illustrates again that the spectra of OLEDs fabricated with both materials are well comparable.

The external quantum efficiency is shown in Fig. 6c. Apparently, η_{EQE} of the OLED based on BDASBi is significantly larger than only a factor of 1.16 which would be expected from the difference in radiative quantum efficiency. An average in the range between 0.1 and 10 mA/cm^2 yields an η_{EQE} of 2.7% for the BDASBi-stack and 1.6% for the device based on PEBA. It should be noted that the absolute values of η_{EQE} for both devices are smaller than expected from simulations of the outcoupling efficiency yielding 3.9% for random orientation and 5.9% for perfectly parallel orientation of BDASBi molecules and 3.3% for randomly orientated PEBA molecules, respectively (see Supplementary Information S5). This is probably due to imperfect charge balance owing to the fact that no doped transport layers and selective carrier blocking layers were used in our simple OLED stack. However, since both types of OLEDs utilize identical HTL and ETL (fabricated in the same evaporation run) as well as the same matrix for the EML, we believe that both devices have quite comparable factor γ in Eq. (1). In addition we want to emphasize that we are mainly interested in the *relative* increase of outcoupling efficiency. Thus, any effects that reduce the efficiency and occur in both types of OLEDs cancel out.

Taking the difference in radiative quantum efficiency into account, it follows that the OLED based on BDASBi exhibits an increase of outcoupling efficiency by 45% due to the strongly horizontally oriented dipoles. This is even slightly higher than the value expected from the analysis of dipole orientation in both materials, but it validates the basic result of mainly horizontally oriented dipoles in BDASBi obtained by ellipsometry and the angular dependent photoluminescence measurement. Even allowing for different emitter positions in the simulation of both devices, the outcoupling and external quantum efficiency of the OLED based on BDASBi is significantly larger. Considering that the orientation of BDASBi is not yet perfectly horizontal, this manifests the enormous efficiency enhancement that can be obtained by incorporating oriented emitters into SM-OLED devices.

4.3. Discussion

The well-known concept of non-isotropic emitter orientation, presented here for the first time in dye-doped SM-OLEDs, to achieve enhanced light outcoupling, is of course not limited to fluorescent materials only, but can also be applied to phosphorescent dyes [36]. Since the latter are usually rather bulky metal–organic complexes, achieving horizontally oriented emitter molecules will be more challenging than with rod-like linear molecules used here. Nevertheless, tailoring phosphorescent materials with respect to this feature, e.g. by asymmetric organic ligands, might allow for a substantial increase in external quantum efficiency from about 20% with random emitter orientation to more than 30% in the case of flat lying dipoles – without any additional outcoupling structure.

Besides the enormous boost in outcoupling and external EL quantum efficiency, the use of oriented emitters in SM-OLEDs offers a series of additional benefits. First, the emitter position may move closer to the cathode without loosing too much energy to surface plasmons. Thus, the emitter can be placed at a position where it receives optimal interference and cavity enhancement. Additionally, with horizontally oriented emitters both the first and second cavity maxima are comparable in outcoupling efficiency, which offers more freedom in stack design. The freedom to place the emitter close to the cathode is especially important in white OLEDs and stacked OLEDs that comprise several emitting layers [40–42]. It should be noted that the advantage of horizontally oriented dipoles disappears, when high index glass substrates ($n \approx 1.8$) and thick electron transport layers are used in order to suppress coupling to waveguide modes and surface plasmons [3,4,43]. However, using substrates with such a high refractive index probably is too expensive for an application in large area OLED light sources.

Furthermore, it is essential to know the correct dipole orientation in any analysis of measured η_{EQE} values, since the outcoupling efficiency can change by more than a factor of 1.5. If the emitter orientation is not taken into account properly, this implies equivalently large errors in the determination of the internal quantum efficiency [36] and, e.g., the spin-allowed exciton fraction [21,38].

Considering material choice it must be taken into account that the effect of horizontally oriented emitter molecules can to some extend compensate for a lower radiative quantum efficiency as compared to an unoriented material. For example, the search for the longed-for stable deep-blue phosphorescent emitter could take a turn: The general difference of a factor of 4 in the external quantum efficiency between phosphorescent and fluorescent emitters reduces to only about 2.5 if the fluorescent emitter is horizontally oriented. Thus, present stability problems with blue phosphorescent emitters may be avoided without sacrificing too much in efficiency.

It is further noteworthy that oriented molecules in neat and doped films also play an important role in related disciplines. Because alignment enlarges the overlap of molecular orbitals between adjacent molecules, non-isotropic orientation can contribute to an improvement of the charge transport characteristics not only in OLEDs [44,45] but also in organic photovoltaic cells (OPVCs) and organic field-effect transistors (OFETs). Recently, small molecule OPVCs using an amorphous material with a high carrier mobility were reported [46], where the molecule has an anisotropic planar shape. We anticipate that horizontally oriented molecules with an anisotropic shape strongly improve device performance of OPVCs due to both increased absorption and enhanced charge transport. Similarly, it is well known that OFETs profit from an enhanced charge transport resulting from oriented molecules. Especially the development of electrically pumped organic lasers

based on light-emitting OFETs could benefit from oriented molecules with improved transport and light outcoupling [47].

5. Conclusions and outlook

In conclusion, an SM-OLED employing intentionally horizontally oriented emitter molecules was presented and compared to a reference device with random emitter orientation. The SM-OLED incorporating oriented emitters exhibits an increase in light-outcoupling and external quantum efficiency of about 45%. Certainly, horizontally oriented phosphorescent emitters would represent the ultimate material of choice for SM-OLEDs. Our presented technique of determining the orientation in dye-doped films by a simple angular dependent photoluminescence measurement offers a straightforward method to investigate numerous guest–host combinations and newly developed materials as well as fabrication procedures that influence molecular orientation. It should be emphasized that using horizontally oriented emitters fabricated in a common evaporation process does not change production costs at all. On the contrary, comparably efficient outcoupling enhancement techniques like scattering at Bragg gratings [48] or photonic crystal structures [49] significantly complicate the fabrication process and raise the costs accordingly.

[39] HOMO levels of BDASBi and PEBA were determined by atmospheric ultraviolet photoelectron spectroscopy (Riken Keiki, AC-3) using vacuum-deposited films. Both materials have a HOMO of 5.6 eV. In addition, a HOMO level of 6.0 eV is reported for CBP [N. Matsumoto, et al., J. Phys. Chem. C 112 (2008) 7735–7741]. LUMO levels were calculated from the HOMO levels and the low energy edges of the absorption spectra of neat BDASBi, PEBA and CBP films on fused silica. The values are 2.9 eV for BDASBi, 2.7 eV for PEBA and 2.6 eV for CBP. Hence, it cannot be ruled out completely that electron trapping plays a slightly more important role in the BDASBi devices. However, strong trapping effects would probably cause significant differences between BDASBi and PEBA OLEDs in the current–voltage characteristics, which is not observed in the measurement, cf. Fig. 6a. We therefore conclude that an increase of outcoupling efficiency due to molecular orientation is the key factor for the higher EQE of BDASBi OLEDs.

very good contestant for such applications is Cu, being a very inexpensive material with excellent electrical and optical properties already widely used in microelectronics [8]. However ultrathin (i.e. $\leqslant$10 nm) Cu films are strongly subjected to oxidation and corrosion, which alter significantly their electrical and optical properties.

In a parallel publication [9], we have shown that one can use a newly developed bilayered ultrathin-metal-film (UTMF) structure consisting of an ultrathin and continuous Cu film covered by a protective ultrathin Ni film as front electrode in organic photovoltaic (OPV) cells. The multilayer Cu–Ni UTMF exhibits significantly higher stability than single layer Cu films against temperature in ambient atmosphere. The obtained Cu–Ni bilayer UTMFs show transparency of 56% at wavelengths around 630 nm and sheet resistance of 16 Ω/sq. The Ni capping layer reduces slightly the transmission of the Cu layer while not influencing the sheet resistance. In this paper we efficiently use these multilayer transparent electrodes in OLEDs. In particular, with respect to the OPV work of Ref. [9], PEDOT:PSS instead of NiO is in contact with the transparent electrode. In terms of devices, the Cu–Ni bilayer-based OLED device shows comparable efficiency to the ITO-based OLED, which demonstrates that UTMF contacts are an effective alternative electrode to ITO because of their simple fabrication processing, mechanical flexibility [10,11] due to low thickness and ductability of metal and low cost.

2. Experimental

UTMFs were deposited by magnetron sputtering on double-side optically polished UV grade silica substrates. We prepared the following layers: Cu, Ni, and Cu with a constant 1 nm Ni capping layer, of total thickness 8 nm each. We deposited Cu and Ni by employing the same deposition conditions as mentioned in Ref. [9]. Surface roughness has to be kept below the thickness of the layer; otherwise films could be discontinuous and thus non-conductive. A Perkin–Elmer lambda 950 spectrometer was used for optical transmission measurements while Cascade Microtech 44/7 S 2749 four-point probe system with a Keithley 2001 multimeter for electrical sheet resistance measurements. The as-deposited Ni, Cu and Cu–Ni UTMFs were next used to fabricate PLED according to the following structure: Anode/PEDOT-PSS/SY/CaAg. Poly(phenylenevinylene) copolymer (SY), commercially available from Merck, was dissolved in toluene, stirred over night and filtered before being spin-coated onto the PEDOT-PSS layer for a thickness of around 80 nm. Ca and Ag were sequentially thermally evaporated ($<5 \times 10^{-6}$ mbar) onto the emitting layer using shadow mask. Additional details on the fabrication steps and corresponding characterization can be found elsewhere [6].

3. Results and discussion

Fig. 1 shows the optical transmittance spectra of as-grown Cu (8 nm), Ni (8 nm), bilayer Cu–Ni (Cu = 7 nm, Ni = 1 nm) and ITO (100 nm) commercial films. The ITO shows the highest transmittance value at 86% while the

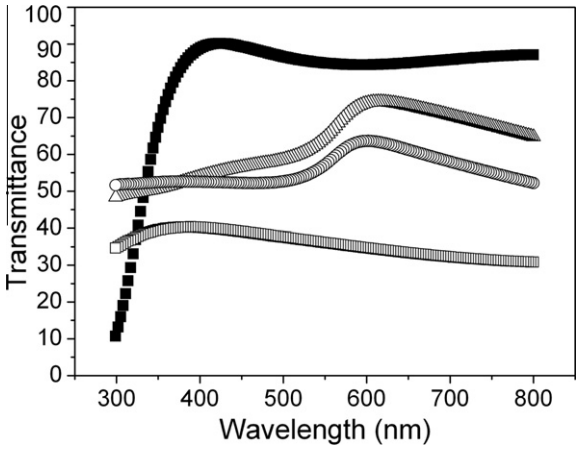

Fig. 1. Transmittance spectra over the full visible wavelength range, for all the different layers studied: ITO (■), Ni (□), Cu (△) or Cu–Ni (○).

Cu layer shows 65% and the Ni layer shows 36% (values given in Table 1). The capping of Cu by 1 nm Ni slightly suppressed the transmittance of the layer, but it is still higher than for Ni. For the sheet resistance, both ITO and Cu layers show a low value around 15–17 Ω/sq while Ni is slightly higher, around 30 Ω/sq. It is also observed that the conductivity behavior of the bilayer UTMF is mainly dominated by the underlying ultrathin Cu layer [12]. Therefore, it can be seen that the Ni capping layer slightly decreases the transparency while not affecting the sheet resistance of the Cu layer. As the sheet resistance is far more critical for device application than the transmittance (it will cause non uniformities in the emission for large area devices), such bilayer UTMF is highly promising as an electrode for optoelectronic devices. It is also well known that the reflectivity of the metallic layer, provided it to be sufficiently high, can be used to enhance the device performance via optical microcavity effect [13,14]. Furthermore, the Cu–Ni bilayer UTMF shows an improvement compared to the Ni UTMF previously studied [6].

The effect of the ozone treatment on the properties of the layer was also investigated and the details are shown in Table 1. Such treatment is a crucial step in the PLEDs fabrication process as it makes the anode material more hydrophilic, allowing for easy spin-coating of the PEDOT-PSS hole transporting layer. The 10 min ozone

Table 1
Values of transmittance, Rs and work function for the four anodes studied, before and after ozone treatment.

	ITO	Ni_8 nm	Cu_8 nm	CuNi_8 nm
Transmittance (%)				
Before ozone treatment	86	36.5	64.1	56.8
After ozone treatment	86	36.8	61.5	58.6
Rs (_/sq)				
Before ozone treatment	16.7	29.6	15.5	15.3
After ozone treatment	16.8	32.4	25.7	16.6

Roughness (nm)	0.46	0.60	0.65	0.55

[a] From literature.

treatment results in an increase of the sheet resistance of 9% for Ni, 65% for Cu, 8.5% for Cu–Ni and has almost no influence at all on the ITO layer. The effect of the ozone treatment on the transmittance is more or less negligible for all the layers studied. Cu layer shows a better transmittance and lower resistivity than Ni but as it can be seen, the effect (by ozone treatment) is quite strong on the layer. While its transmittance is only 2% decreased, its sheet resistance is increased by about 65% after 10 min treatment in ozone. Capping the Cu layer with Ni offers a better stability of the resistivity with ozone exposure, with this time only an increase of 8%. The stability improvement of the Cu layer with a Ni capping is also observed upon thermal treatment of the layers as shown in Fig. 2. The variation of the sheet resistance with thermal treatment reaches high values for temperatures as low as 100 °C for the Cu layer, while for the Cu–Ni bilayer, even up to 220 °C the variation in the sheet resistance is small. Ni also provides a larger work-function, which is beneficial for the anodic injection. Another critical factor for the use of UTMFs as electrodes in devices is the roughness of the layer deposited. It has been shown that the hole injection in PLEDs depends not only on the barrier height of the junction but also on the surface morphology and interfacial chemistry of the anode [15,16], influencing therefore the PLEDs stability and performance [17]. As-deposited UTMFs layers are all very uniform and smooth, with a low root-mean-square (RMS) roughness by contact mode AFM of less than 0.65 nm over a 1 μm^2 area, similar to the RMS roughness of ITO (see Table 1). In one word, the main drawback of the Cu layer for device application, which is its low stability to oxidation and temperature, has been solved by simply using a 1 nm Ni capping layer. Therefore, the Ni capping makes Cu–Ni UTMF very interesting for the OLEDs application as it overcomes the stability issue of the Cu layer and increases the work function, still maintaining good optical and electrical properties.

Fig. 3 compares the current–voltage (I–V) and luminance characteristics of OLEDs with a thin metal anode with respect to those of a typical ITO anode. It can be seen that the lowest performance is obtained for the Ni-based device. Slightly higher voltage threshold, lower current density and lower luminance reflect the poor transmittance and high resistivity that the 8 nm Ni layer

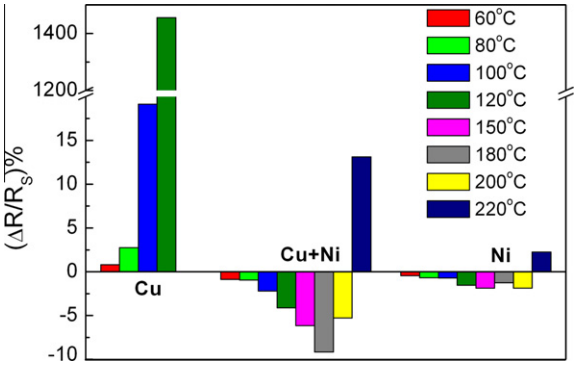

Fig. 2. Stability of the metallic layers upon temperature treatments.

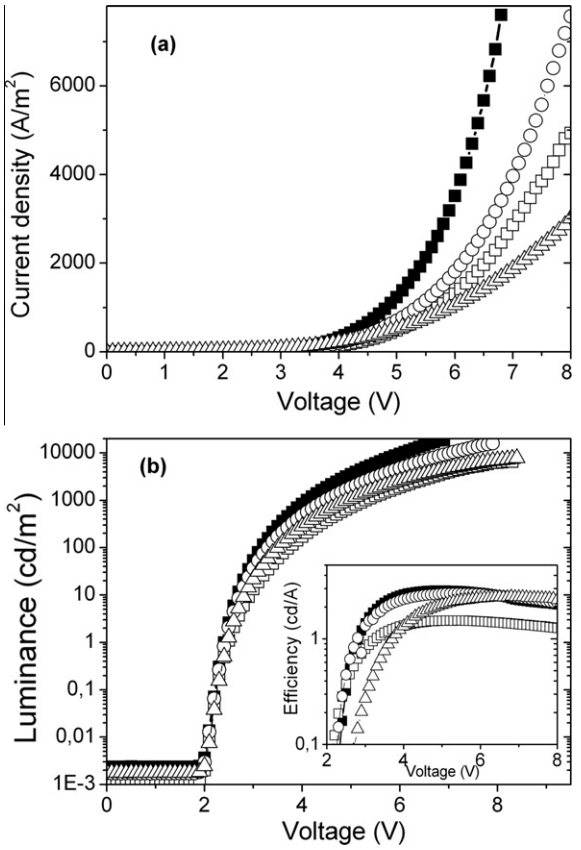

Fig. 3. I/V (a) and L/V (b) curves of SY-based OLEDs with the anode being ITO (■), Ni (□), Cu (△) or Cu–Ni (○).

exhibits. Although the work function of Ni is similar to that of ITO, the current of the Ni-based device is limited by the relatively high electrode's sheet resistance. As a consequence not enough charges enter the device to generate high efficiency as it is the case of the ITO-based device, which, on the contrary, shows a transport-limited behavior (the properties of the SY is the limiting factor here). The Cu-based device behaves very similarly to the Ni-based device, as the driving voltage at a given current density is found to be higher than that of ITO. This difference is due to the sheet resistance of Cu and Ni, which after the ozone treatment stands around 30 Ω/sq compared to 17 Ω/sq for ITO. In the case of Cu, this is evidenced for example by the difference in driving voltage increasing linearly with sheet resistance (i.e., following Ohm's law). The advantage of the Cu-based device lies in the higher transmittance of the Cu layer compared to the Ni layer and therefore it shows a higher luminance level than the Ni-based device. As a result, when looking at the device efficiency, while the Ni-based device shows a lower efficiency compared to the ITO-based device, the Cu-based device shows a similar efficiency as ITO but only at high driving voltages. Finally, the Cu–Ni-based device offers the best performance of the three UTMF anodes studied here. The current density is slightly higher than that of the ITO-based device although the sheet resistance is similar to that of ITO (around 17 Ω/

sq). The luminance level reached is similar to the ITO-based device. All in all, the efficiency of the Cu–Ni-based device is as good as the ITO-based device, as it can be seen in the inset of Fig. 3b.

An important aspect of metal based OLED is the possible presence of cavity effect, which leads to an angular dependence that is different from that of ITO-based devices. Hence, the fact that luminous efficacy is comparable in the normal direction does not necessarily guarantee that it is also in an off-normal direction. Indeed, microcavity OLED can exhibit significantly enhanced emission in the forward direction as well as a much narrower emission spectrum [18,19], making evident that possible microcavity effects of our metal-based devices have to be considered. To this end, we consider the equation of the cavity effect in OLEDs as cited in Ref. [19] to establish that a weak microcavity effect occurs associated to the low reflectivity of the Cu, Cu–Ni and ITO layers, which is about 10% at the wavelength of the emission peak (for Ni, it is about 25%). Using the same equation [19], Helander et al. [7] have shown that weak microcavity effect occurs in their OLEDs when using a thin 15 nm AuOx electrode, due to the low reflectivity of the AuOx layer (around 25%). In our case, our layers have an even lower reflectivity than for the AuOx layer of Helander et al. [7]. Furthermore, the electroluminescence (EL) spectra for all devices have been measured and are shown in Fig. 4. The full width half maximum (FWHM) of the spectrum is the same for ITO-based devices. Only the Ni-based device shows a thinner FWHM, which agrees with the value of its reflectivity – the highest among the three metal electrodes. We can thus conclude that, as in the paper by Helander et al. [7], the microcavity effect and angular dependence of our devices are quite weak.

Finally, it is important to point out again the role of the capping Ni layer which has enabled the Cu–Ni layer to retain good electrical and optical properties after the ozone treatment. This is even more visible when one studies the luminance decay as a function of operating time of the devices (shown in Fig. 5). The lifetime experiments were performed in inert atmosphere and dark condition without encapsulation, at constant voltage. For glass/ITO device, the luminance decay of the device is very slow, not reaching the half value for the 800 min of measurements. Although the luminance of the Cu–Ni anode/glass substrate device dropped initially, its decay is very smooth and reaches 50% for 800 min, at higher current as compared with the driving current for ITO anode/glass substrate. Cu anode/glass substrate devices decayed by about 50% of initial luminance after driving 20 and 25 min, respectively, whereas the glass/Cu–Ni device decayed by about 10% of initial luminance after driving the same amount of time. Actually, the ITO and Cu–Ni-based device show the same flat decay of the luminance (same slope) which really indicates the even performance of the Cu–Ni bilayer and ITO as anodes for OLEDs (Fig. 5).

4. Conclusion

In summary, we have demonstrated the use of Cu–Ni UTMF as anode in high-performance OLEDs. Previous studies have shown the potential of Ni UTMF to replace ITO for OLED applications, due to their ease of fabrication and good optical and electrical qualities. In this work, we focused on Cu UTMF which has better optical and electrical properties than Ni, although showing poor stability. In fact, we showed that a good trade-off between the Ni stability and the Cu excellent optical and electrical properties for UTMF is an ultrathin Cu layer stabilized using a capping Ni layer. Its average visible transparency is as high as 64% and its sheet resistance as low as 15 Ω/sq. The bilayer Cu–Ni UTMFs show excellent stability against temperature and oxidation. When applied to OLEDs, the devices showed high efficiency, as good as ITO-based devices with good operation stability over time. In addition, the benefits of thin films metal electrodes such as easy fabrication, mechanical flexibility [10,11], and the affordability of metal make the proposed multilayer UTMF an attractive alternative to ITO electrodes.

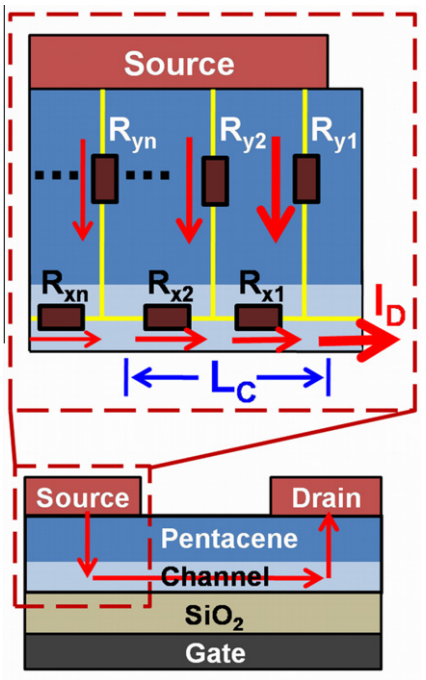

Fig. 1. Schematics of an equivalent circuit at source contact in a staggered OTFT, where charge accumulation layer is shown at vicinity above dielectric layer. Current crowding behavior and effective contact length are illustrated.

distribution in the contact region of OTFTs is not spatially uniform, and thus R_C is the total resistance of an equivalent circuit which can simulate the current flow through the contact region. Fig. 1 shows the equivalent circuit for the crowding current model in a staggered OTFT (top contact with bottom gate), where R_x and R_y are the local accumulation layer resistance in the horizontal direction and local bulk resistance in the vertical direction, respectively. The deduced expression of R_C has the same form as R_{ch}, i.e. [10,12]

$$R_C = \frac{L_C}{W\mu_{FE}C_i(V_{GS} - V_T)} \tag{2}$$

where L_C is the effective contact length referring to the equivalent extended L due to the existence of R_C. We measured ΔR_C under bias stress condition, and observed a continuous increase of both V_T and L_C with t. The observations indicate that the bias stress induced R_C instability stems from the time-dependent charge trapping, which occurs both in the charge accumulation layer and in the organic bulk in the contact region. The systematical comparison between the gold (Au) and copper (Cu) contacts suggests the charge trap distribution in the contact region having a great influence on the R_C instability.

2. Experimental

The pentacene-based OTFTs were fabricated on the heavily doped silicon (Si) substrates with 200-nm-thick thermal oxide (SiO_2) layers (University Wafer). After

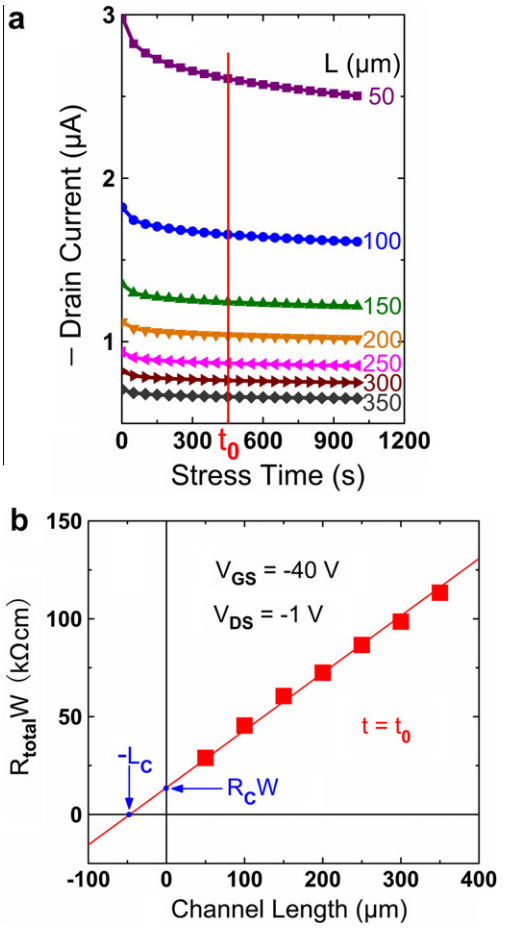

Fig. 2. (a) Drain current vs stress time in a set of pentacene-based OTFTs (Au contact) with varied channel lengths. (b) Transfer line method plot (normalized device total resistance vs channel length) of a set of pentacene-based OTFTs (Au contact) at a particular time point marked in (a), by which contact resistance and effective contact length can be precisely extracted. All TLM plots at different time points show good linearity, indicating that there is no channel length dependence of the threshold voltage shift.

standard cleaning, the substrates were precoated with a self-assembling monolayer of β-phenethyltrichlorosilane (TCI, immersed in β-phenethyltrichlorosilane solution for 6 h in a glove box). The pentacene (TCI, purified with temperature gradient sublimation) films with 40 nm thickness were subsequently deposited in high vacuum about 5×10^{-5} Pa, where the deposition rate and substrate temperature were kept at about 0.1 Å/s and 70 °C, respectively. Eventually, a set of OTFTs, having an identical W = 750 μm and varied L = 50–350 μm with 50 μm interval [8], were defined by depositing Au or Cu top electrodes (electrode length 100 μm, thermal evaporation through a shadow mask).

The bias stress measurements were carried out at room temperature in a high vacuum (about 1×10^{-4} Pa) probe station. After a quick transfer characteristics scan at t = 0 s, I_D at ON state (V_{DS} = −1 V, V_{GS} = −40 V) was continuously measured for 1000 s, followed by another quick transfer characteristics scan at t = 1000 s. As an example, the initial

and final transfer characteristics of OTFTs with Au or Cu contacts are shown in the inset in Fig. 4. The set of OTFTs with different L were measured one by one, taking a recovery time of 2 h at $V_{GS} = V_{DS} = 0$ V after each bias stress measurement. Fig. 2a shows the I_D change in the OTFTs with different L, where the transfer line method (TLM) [8] can be utilized to extract R_C and L_C at each t. For example, a plot of W-normalized total resistance (R_{total}) vs L obtained from Fig. 2a at any time point t_0 is illustrated in Fig. 2b, where W-normalized R_C and minus L_C are the y-intercept [8] and x-intercept [10] of the linear fit, respectively. Accordingly, ΔR_C with t can be experimentally recorded and analyzed. In addition, the slope of the linear fit in Fig. 2b is determined by μ_{FE} and V_T, and thus ΔV_T with t can be derived using constant μ_{FE}.

3. Results and discussion

Fig. 3 demonstrates that R_C of the Au/pentacene contact is larger than that of the Cu/pentacene contact, and in both the cases R_C is continuously increasing with t. These device behaviors are in good agreement with the reported ones [8,13], indicating R_C is not a constant parameter under bias stress condition as expressed in Eq. (1). As μ_{FE} is approximately unchanged (about 0.6 cm^2/Vs, estimated from the initial and final transfer characteristics of the long-channel OTFTs) after the bias stress measurements, the R_C increase with t may arise from an increase of V_T, L_C, or both based on Eq. (2). The t dependence of V_T and L_C can be separately measured by the TLM discussed above, and the results are discussed in the following.

In staggered OTFTs at ON state, as illustrated in Fig. 1, the charge accumulation layer is formed close to the organic/dielectric interface not only in the channel region but also in the contact region. Therefore, ΔV_T can lead to both the R_{ch} and R_C changes. Fig. 4 shows that V_T (calculated from R_{ch} using constant μ_{FE}, note that the apparent V_T extraction directly from the extrapolation of the transfer characteristics may have significant error in the case of large R_C [14]) is increasing with t as commonly observed in OTFTs [4–8], and from Eq. (2) this V_T increase contributes to the R_C increase in Fig. 3. There are two major understandings of bias stress induced ΔV_T in OTFTs (excluding the OTFTs using polarizable dielectrics): (1) Increasing charge trap sites resulting from defect generation in the channel, analogous to that in hydrogenated amorphous-Si TFTs [15]; (2) time-dependent charge trapping into a distribution of trap states in the channel [7,8]. Both the cases involve a decrease of mobile carriers with t, and the latter is more reasonable as the bias stress effect in OTFTs is to a large extent reversible corresponding to the charge trapping and release processes.

On the other hand, L_C (obtained directly from the TLM plot) is increasing with t as demonstrated in Fig. 5, and from Eq. (2) the L_C increase also contributes to the R_C increase in Fig. 3. As schematically depicted in Fig. 1, the magnitude of L_C is set by the balance of the vertical space charge limited current through the pentacene bulk (R_y) and the horizontal current through the charge accumulation layer (R_x) in the contact region [10,12]. In fact, the local current density is larger at the position closer to the contact edge next to the conducting channel, and L_C can

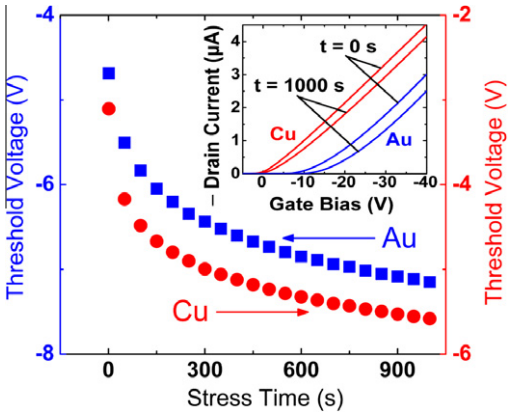

Fig. 4. Threshold voltage vs stress time of pentacene-based OTFTs with Au or Cu contacts, data calculated from experimentally derived channel resistance at different stress time. The inset shows initial and final transfer characteristics at $V_{DS} = -1$ V of OTFTs with 50 μm channel length.

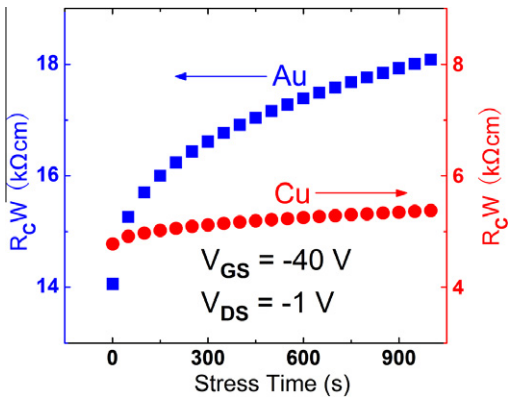

Fig. 3. Normalized contact resistance vs stress time of pentacene-based OTFTs with Au or Cu contacts, data obtained from transfer line method plots at different stress time.

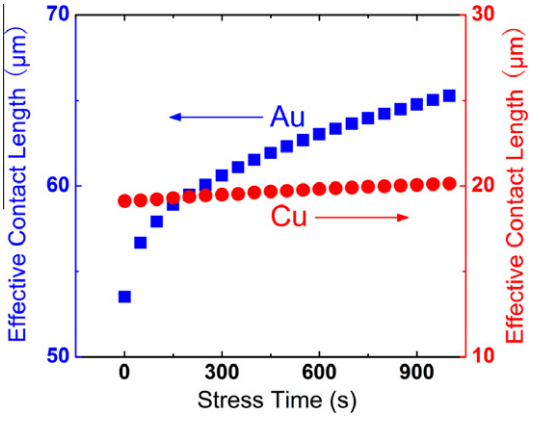

Fig. 5. Effective contact length vs stress time of pentacene-based OTFTs with Au or Cu contacts, data obtained from transfer line method plots at different stress time.

be regarded as an effective length over which the local current density is too small to contribute to the carrier injection. L_C is long when the conductivity of the charge accumulation layer is high and the bulk conductivity is relatively low, and vice versa. In the present case, the conductivity of the charge accumulation layer is decreasing with t as a result of the V_T increase demonstrated in Fig. 4, and thus L_C should be decreasing if the bulk conductivity is either increasing or unchanging with t. However, the experimental results in Fig. 5 show an opposite feature of L_C, indicating that the bulk conductivity is decreasing at the same time. Our previous works suggest that the contact region in OTFTs is a trap-rich low-mobility region, possibly arising from the metal atom diffusion and/or from the pentacene grain boundaries [13,14]. We therefore attribute the bulk conductivity decrease with t to the time-dependent charge trapping in the pentacene bulk, and the effect of this bulk trapping is stronger than that of the charge trapping in the accumulation layer. As a consequence, larger contact area is involved in the carrier injection and L_C is increasing with t. It should be noted that practically maximum L_C is the electrode length, thus Eq. (2) is no longer applicable and L_C has no more effect on ΔR_C when TLM-derived L_C exceeds the electrode length. In the present case, L_C is in the order of several tens μm as shown in Fig. 5, which is shorter than typical electrode length in OTFTs. For miniaturized devices, however, it may become an issue.

In order to further understand the R_C instability, Figs. 3–5 illustrate a comparison between the Au and Cu contacts. It is clear that the Au contact is much more unstable mainly owing to its larger L_C increase shown in Fig. 5, while ΔV_T for the both contacts are similar shown in Fig. 4. The Meyer–Neldel analysis on R_C reveals the Au contact having a wide distribution of trap states [13], described by a high characteristic temperature T_C which reflects the energy width of the trap distribution. In other words, the Au contact contains a high density of deep trap states, which is expected to enhance the charge trapping in the pentacene bulk and consequently result in a large L_C increase. In contrast, the Cu contact has a relatively narrow trap distribution [13] corresponding to a low density of deep trap states, so that the Cu contact appears more stable. Therefore, the lower R_C stability of the Au contact compared with the Cu one can be ascribed to the stronger charge trapping effect in the pentacene bulk. This consideration is consistent with the current crowding model [10], which predicts $R_C \sim T_C/T$.

The above findings indicate that both the R_{ch} and R_C instability in OTFTs may originate from a same microscopic mechanism, i.e. the time-dependent deep charge trapping. It is reasonable to consider that the deep trap states in organic thin films are spatially concentrated around particular sites, such as the grain boundaries and chemical impurities. The filling of these deep trap states can take time, e.g., the Coulomb repulsion of the pre-trapped charges build an energy barrier which impedes the further charge trapping [8]. Thus, reducing the density of the deep trap states by optimized film growth and effective interface modification is the approach to improve the operation stability of OTFTs.

4. Conclusion

The bias stress measurements combined with TLM are utilized to probe the R_C instability in pentacene-based OTFTs. R_C was observed to be increasing with t, resulting from (1) the V_T increase in the charge accumulation layer, and from (2) the L_C increase. The origin of this bias stress induced R_C instability is attributed to the charge trapping not only in the charge accumulation layer but also in the pentacene bulk. The R_C instability is strongly dependent on the extrinsic factors such as the type of electrode materials, and thus it can be suppressed by the optimization of device fabrication techniques. This work provides the hints to understand the underlying mechanism of the bias stress effect, which is considered to be correlated with the time-dependent charge trapping in OTFTs.

plasma treatment [22,23] is required to tune the surface of the active layer from hydrophobic to hydrophilic before an aqueous PEDOT:PSS can be deposited. In the literature, an amphiphilic film [18], a layer of BPhen:Li [19] deposited in vacuum, and low-conductivity PEDOT:PSS formulations [20,21] have been proposed as an interlayer. Recently, we reported on a formulation of PEDOT:PSS CPP 105D (H.C. Starck CLEVIOS) (hereafter referred to as CPP-PEDOT) as the interlayer for depositing subsequently PEDOT:PSS PH-1000 (H.C. Starck CLEVIOS) (hereafter referred to as PH-1000) as the top electrode in semitransparent solar cells [24]. The CPP-PEDOT formulation contains surfactants and additives that result in good wetting properties on top of P3HT:$PC_{60}BM$ layers [25]. However, the conductivity of CPP-PEDOT is significantly lower than that of PH-1000, which explains the need for CPP-PEDOT/PH-1000 b*i*-layers. The need for such interlayers or bi-layers of different formulations of PEDOT:PSS increases the complexity of the device fabrication.

In this work, we report on semitransparent inverted solar cells with a top electrode that is comprised of a single layer of PEDOT:PSS that combines good wetting properties and high conductivity. The single PEDOT:PSS layer is a blend consisting of a mixture of PH-1000 and CPP-PEDOT. The new PEDOT:PSS blend (hereafter referred to as CPP-PEDOT:PH-1000) showed a conductivity as high as 420 S cm^{-1} and simultaneously good wetting on the P3HT:$PC_{60}BM$ layer. The semitransparent solar cells with an inverted geometry of glass/ITO/ZnO/P3HT:$PC_{60}BM$/CPP-PEDOT:PH-1000 (1:3, volume ratio) exhibited a short-circuit current (J_{SC}) of 7.2 mA cm^{-2}, an open-circuit voltage (V_{OC}) of 0.55 V, a fill factor (FF) of 0.58, leading to a power conversion efficiency (PCE) of 2.4% estimated for 100 mW cm^{-2} AM 1.5G illumination. The devices showed transmittance of 10–70% in the wavelength range from 400 to 800 nm (Fig. 1).

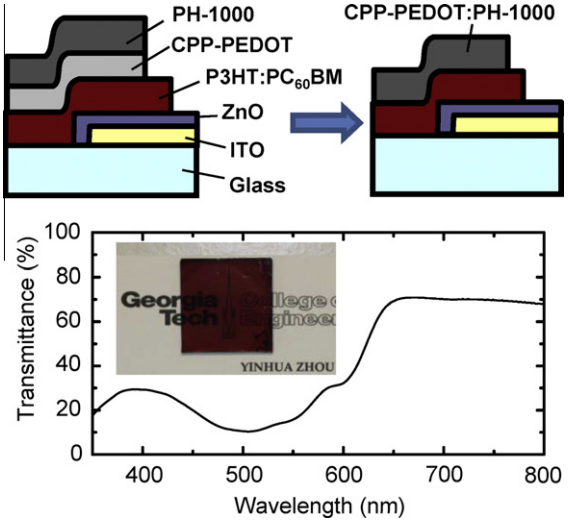

Fig. 1. (Top) Structure of a device using a bi-layer CPP-PEDOT/PH-1000 as the top electrode (left) and a simplified device using a CPP-PEDOT:PH-1000 blend as the top electrode (right). (Bottom) Transmittance spectrum of a semitransparent device using a CPP-PEDOT:PH-1000 (1:3, volume ratio) as the top electrode. The inset is a photograph of a semitransparent device with a CPP-PEDOT:PH-1000 (1:3, volume ratio) as the top electrode on a card to illustrate its level of transparency.

2. Experimental

ITO-coated glass (Colorado Concept Coatings LLC, Loveland, CO) with a sheet resistance of 15 Ω/sq was used as the substrates for the solar cells. The substrates were patterned using a kapton tape and etched by acid vapor (HNO_3: HCl, 1:3 by volume) at 60 °C for 5 min. The substrates were cleaned in an ultrasonic bath of detergent and water, rinsed with deionized water, and then cleaned in sequential ultrasonic baths of deionized water, acetone, and isopropanol. Each ultrasonic bath lasted for 20 min. Nitrogen was used to dry the substrates after each of the last three baths.

The patterned ITO substrates were transferred to an ALD system (Savannah 100, Cambridge NanoTech, Cambridge, MA) for ZnO deposition. ZnO films (200 cycles) were deposited on cleaned ITO substrates with pulses of H_2O for 15 ms and diethylzinc for 15 ms at 200 °C. The thickness of ZnO was 25 nm, measured using a profilometer (Dektak 6 M Stylus, Veeco, Plainview, NY). ZnO was patterned with a kapton tape around the ITO area and dipped into the afore mentioned dilute acid solution for 2 s at room temperature. The ITO/ZnO substrates were cleaned in sequential ultrasonic baths of acetone and isopropanol. Each ultrasonic bath lasted for 10 min and was followed by nitrogen drying. The active layer of P3HT (4002-E, Rieke Metals, Lincoln, NE): $PC_{60}BM$ (Nano-C, Westwood, MA) (1:0.7, by weight) was spin-coated on each substrate from a 34 mg/ml chlorobenzene solution and annealed at 160 °C for 10 min on a hot plate in a N_2-filled glove box. The thickness of the active layer was 200 nm.

5% dimethyl sulfoxide (DMSO) was added into PH-1000 solution and stirred overnight at 300 rpm at room temperature to increase its conductivity. Then, the PH-1000 was mixed with CPP-PEDOT in the volume ratios of 2:1, 1:1, 1:2, and 1:3 (CPP-PEDOT:PH-1000). Contact angle of these blend solutions on annealed P3HT:$PC_{60}BM$ films, was measured using a contact angle analyzer (SEO Phoenix 300, LA, CA). To evaluate the conductivity, the CPP-PEDOT:PH-1000 solutions were spin-coated onto cleaned glass substrates at a speed of 1000 rpm for 30 s and then annealed at 120 °C for 30 min in ambient air. Thicknesses of the films varied from 140 to 200 nm. The conductivities of the PH-1000 film, CPP-PEDOT film, and the CPP-PEDOT:PH-1000 films were measured using the transmission line method (TLM) with 200 nm thick Cu electrodes thermally deposited on the films.

Fig. 1, illustrates the geometries of the two different types of semitransparent solar cells considered in this study. For the devices having a bi-layer of CPP-PEDOT/PH-1000 as the top electrode (left panel in Fig. 1), a 90 nm thick layer of CPP-PEDOT was first spin-coated on the active layer at a speed of 5000 rpm for 60 s. The CPP-PEDOT layer was then patterned by contacting a polydimethylsiloxane (PDMS) layer to the unwanted area and peeling off the PDMS and CPP-PEDOT together. The samples were next annealed at 105 °C for 10 min in the N_2-filled glove box.

Then, PH-1000 (160 nm) was spin-coated on the patterned CPP-PEDOT area in ambient air. Samples were annealed at 105 °C for 10 min in the N_2-filled glove box.

For the devices with a single-layer of a CPP-PEDOT:PH-1000 blend (right panel in Fig. 1), mixtures of CPP-PEDOT:PH-1000 (1:1 and 1:3, volume ratio) were spin-coated on the active layer at a speed of 1000 rpm for 30 s in ambient air. The CPP-PEDOT:PH-1000 layers were patterned with PDMS as described above. Next, the samples were annealed at 105 °C for 10 min in the glove box. The lower panel in Fig. 1 shows the transmittance and the inset is a picture of an un-patterned solar cell with a CPP-PEDOT:PH-1000 (1:3, volume ratio) layer as the top electrode.

Before testing the device performance, Ag paste was used, outside the active area, to improve the electrical contact to the CPP-PEDOT:PH-1000 layer and to the ITO/ZnO electrodes. In order to have an accurate device area during illumination, an aperture with a well defined area of 6 mm^2 was used as a shadow mask in-front of each device. Light went through the ITO/ZnO side during the testing. Current–voltage (I–V) characteristics were measured inside a N_2-filled glove box by using a source meter (Keithley Instruments 2400, Cleveland, OH) controlled by a LabVIEW program. To test the solar cell properties under illumination, an Oriel lamp with an intensity of 100 mW cm^{-2} was used as the light source. A monochromator coupled to a 175 W Xenon lamp (ASB-XE-175EX, CVI Spectral Products, Putnam, CT) and a calibrated photodiode (S2386-44 K, Hamamatsu) were used to measure the external quantum efficiency (EQE).

3. Results and discussion

As shown in Fig. 2, PH-1000 films have a high conductivity of 560 ± 50 S cm^{-1}, but PH-1000 solutions show a high contact angle of 93 ± 4° on the P3HT:PC_{60}BM active layer. The high contact angle makes it difficult to form a uniform PH-1000 film on top of the active layer. In contrast, CPP-PEDOT solutions have a low contact angle of 31 ± 2° but films show a significantly lower conductivity of 32 ± 5 S cm^{-1} compared with PH-1000. To combine the advantages of the two PEDOT:PSS formulations, we prepared blend solutions with different volume ratios. Fig. 2 shows that the conductivity of the blend films is linearly dependent on the concentration of PH-1000, while the contact angle of the blend solutions on P3HT:PC_{60}BM remains almost unchanged for all the blend solutions, with a value that is similar to that of CPP-PEDOT solution. The combination of a high conductivity and a low contact angle allowed these blends to be used as the top electrode by solution-processing techniques, such as spin-coating.

Fig. 3 shows the I–V characteristics of devices with different top electrodes: bi-layers of CPP-PEDOT/PH-1000, CPP-PEDOT:PH1000 blends (1:1, volume ratio), and CPP-PEDOT:PH-1000 blends (1:3, volume ratio). Here, we use the current and not the current density because the photocurrent is generated only in the area defined by the aperture used during testing of the device under illumination. In contrast, the dark current flows through the whole device area which is defined by the intersection of ITO/ZnO and the top PEDOT:PSS electrode. To correct for the spectral mismatch between the lamp and AM 1.5G illumination, the values of J_{SC} under 100 mW cm^{-2} AM 1.5G illumination were estimated by convoluting the EQE with the AM 1.5G spectra [26]. Device performances with corrected values of J_{SC} and PCE are summarized in Table 1.

The devices with the bi-layer CPP-PEDOT/PH-1000 as the top electrode show a V_{OC} of 0.54 ± 0.01 V, a J_{SC} of 7.3 ± 0.4 mA cm^{-2}, a FF of 0.59 ± 0.02, and a PCE of 2.3 ± 0.1%, averaged over four devices, estimated for 100 mW cm^{-2} AM 1.5G illumination. In comparison, devices with a single layer of the CPP-PEDOT:PH-1000 (1:1, volume ratio) blend show a V_{OC} of 0.54 ± 0.01 V, a J_{SC} of 7.4 ± 0.6 mA cm^{-2}, a FF of 0.52 ± 0.01, and a PCE of 2.0 ± 0.2% averaged over four devices (Table 1). Comparing to the devices with the bi-layer CPP-PEDOT/PH1000 top electrode, the devices with CPP-PEDOT:PH1000 (1:1,

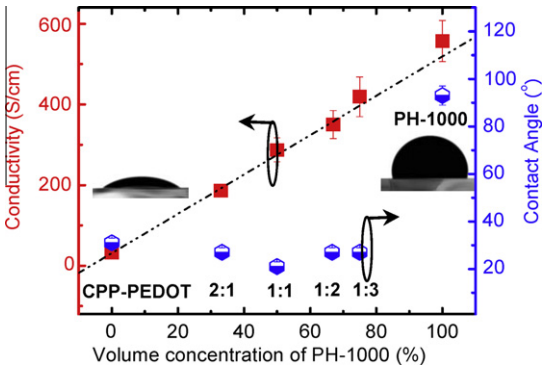

Fig. 2. Conductivity of CPP-PEDOT:PH-1000 blend films and contact angle of CPP-PEDOT:PH-1000 blend solutions on top of P3HT:PCBM layer as a function of the concentration of PH-1000 by volume. The dash-dot line is linear fit of the conductivity as a function of the concentration of PH-1000 by volume. The insets are pictures of the drops of a CPP-PEDOT solution and a PH-1000 solution on top of P3HT:PC_{60}BM layers.

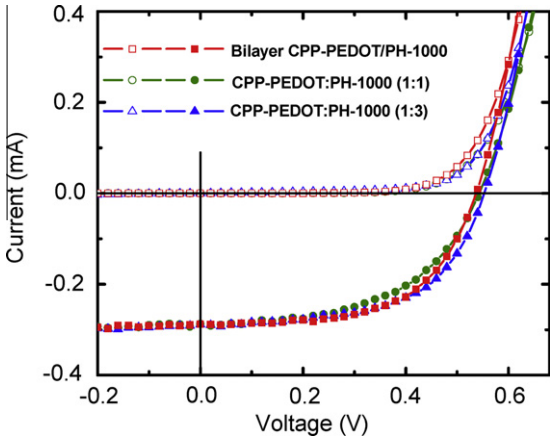

Fig. 3. I–V characteristics of devices with bi-layer CPP-PEDOT/PH-1000 (square), CPP-PEDOT:PH-1000 blend (1:1, volume ratio) (circle) and PEDOT:PH-1000 blend (1:3, volume ratio) (triangle) in the dark (open symbol) and under illumination of 100 mW cm^{-2} (filled symbol) before spectral mismatch correction. Aperture with an area of 6 mm^2 was used during the measurement.

Table 1
Photovoltaic performance of devices with different top electrodes. The data represent average values and standard deviations calculated over four devices. The values of J_{SC} were estimated by convoluting the EQE with the AM 1.5G spectra.

Device with top electrode	V_{OC} (V)	J_{SC} (mA cm^{-2})	FF	PCE (%)
CPP-PEDOT/PH-1000	0.54 ± 0.01	7.3 ± 0.4	0.59 ± 0.02	2.3 ± 0.1
CPP-PEDOT:PH-1000 (1:1)	0.54 ± 0.01	7.4 ± 0.6	0.52 ± 0.01	2.0 ± 0.2
CPP-PEDOT:PH-1000 (1:3)	0.55 ± 0.01	7.4 ± 0.3	0.58 ± 0.01	2.4 ± 0.2

volume ratio) have a lower FF. The lower FF is attributed to the higher series resistance, mainly due to the lower conductivity of CPP-PEDOT:PH-1000 (1:1, volume ratio) (186 ± 9 S cm^{-1}) than that of PH-1000 (560 ± 50 S cm^{-1}). With a blend of CPP-PEDOT:PH-1000 with a larger PH-1000 volume ratio (1:3), the higher conductivity (420 ± 5 S cm^{-1}) yielded devices with a FF of 0.58 ± 0.01, similar to that of devices with the bi-layer CPP-PEDOT/PH-1000. The PCE of the devices reached an average value of 2.4 ± 0.2%, comparable to that of devices with the bi-layer CPP-PEDOT/PH-1000 as the top electrode. For comparison, devices with a conventional structure of ITO/PEDOT:PSS AI 4083/P3HT:PC_{60}BM/Al were also fabricated [24]. These reference devices with a conventional architecture show a V_{OC} of 0.62 ± 0.01 V, a J_{SC} of 8.5 ± 0.4 mA cm^{-2}, a FF of 0.59 ± 0.01, and a PCE of 3.1 ± 0.2% (averaged over five devices). The PCE of the semitransparent solar cells with either a bi-layer CPP-PEDOT/PH-1000 top electrode, or a single layer of the blend CPP-PEDOT:PH-1000 (1:3, volume ratio) is lower than devices with a conventional structure because of the lower absorption in the active layer because of the absence of Al reflector [24]. We also note that from the CPP-PEDOT:PH-1000 blends studied, a volume ratio of 1:3 yields solar cells that are statistically almost identical to the solar cells using a bi-layer CPP-PEDOT/PH-1000. Hence, while it may be possible that blends with a higher ratio of PH-1000 could have marginally higher conductivity than the 1:3 blend, no major differences in terms of their performance in solar cell devices are expected.

We investigated the effect of changing the illuminated area through apertures, A, on the V_{OC}, FF, J_{SC} and PCE of a device using a CPP-PEDOT:PH1000 blend (1:3, by volume) as the top electrode. Fig. 4 shows the dependence of these parameters on the area illuminated through the apertures. Apertures with areas of 9.2, 4.6, 2.3, and 1.2 mm^2 were used. The maximum area considered was 22 mm^2, which corresponds to the device area, defined by the intersection of ITO/ZnO and the top PEDOT:PSS electrode. As shown in Fig. 4 the main effect of reducing A is to increase FF, because of the reduced series resistance $R_S A$, and to decrease the V_{OC}, which is a logarithmic function of area A. The logarithmic dependence of the V_{OC} on A, can be explained by considering that,

$$V_{OC} = n\frac{KT}{e}\ln\left\{1+\frac{I_{SC}}{I_0}\right\} \quad (1)$$

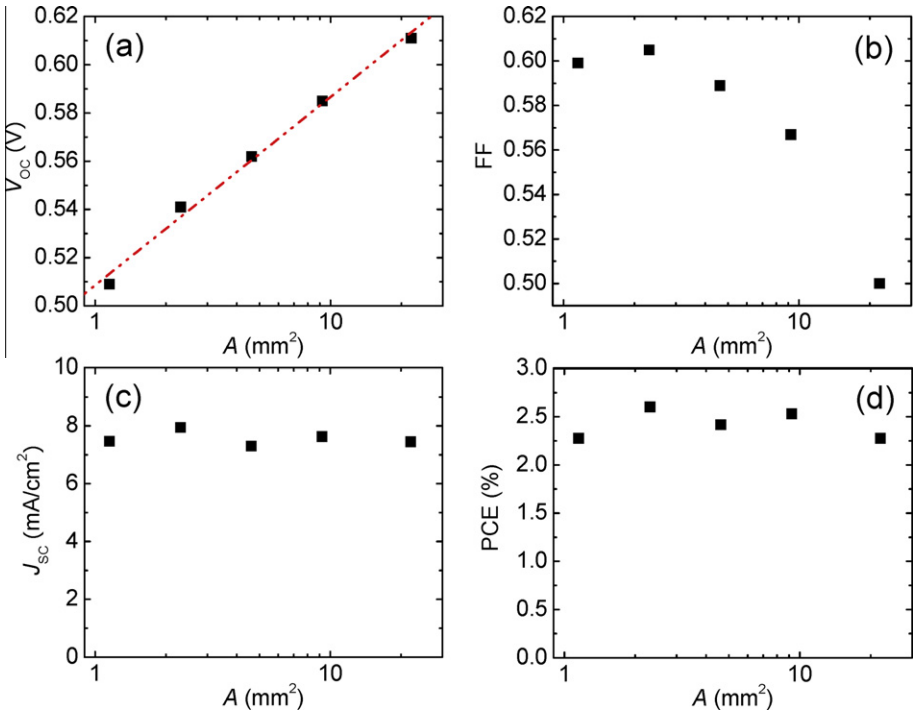

Fig. 4. The effect of the area illuminated through the apertures, A, on (a) V_{OC}, (b) FF, (c) J_{SC} and (d) PCE of a device using a CPP-PEDOT:PH1000 blend (1:3, by volume) as the top electrode. The dash-dot line in (a) is a fit of V_{OC} showing a logarithmic dependence on area A.

where n is the diode ideality factor, k is Boltzmann's constant, T is the temperature, I_0 is reverse saturation current and I_{SC} is the short circuit current, equal to $J_{SC}A$. Since $I_{SC}/I_0 \gg 1$, $V_{OC} \propto \ln(J_{SC}A)$, where J_{SC} remains constant, V_{OC} would be expected to vary logarithmically with A. However, this drop of V_{OC} is compensated with the increased FF to yield a PCE which, within the experimental error, is constant with respect to the illuminated area.

4. Conclusions

In summary, we demonstrated semitransparent organic solar cells using a single-layer of a PEDOT:PSS blend as the top electrode. Semitransparent metal-free solar cells showed an average power conversion efficiency of 2.4% estimated for 100 mW cm^{-2} AM 1.5G illumination. The single-layer PEDOT:PSS blend was prepared on top of P3HT:$PC_{60}BM$ by a one-step spin-coating process without any interlayers, which alleviates the need of vacuum deposition of a top electrode. The one-step solution-processed top electrode could be potentially applied to the fabrication of large-area devices using low-cost solution-based fabrication techniques such as by inkjet-printing or roll-to-roll processing. The higher sheet resistance of PEDOT:PSS electrodes compared with metal electrodes can be compensated by integrating these device geometries with metal grid electrodes [27,28]. These semitransparent solar cells are promising candidates for low-cost and large-area see-through power-generating windows applications.

characteristics I_D–V_{DS} of a transistor, (b) a proper model for the current–voltage characteristic in the region close to the contact, I_D–V_C, and its incorporation in the output characteristics model, and (c) an extraction method of the I_D–V_C curves at the contact and the rest of the model parameters out of the resulting combined model.

In this work, we analyze tetrasubstituted zinc phthalocyanine (ZnPc) based organic thin film transistors in which contact effects are present. Based on experimental data measured on these transistors and from other authors' measurements, we critically evaluate some of the most important previous efforts in modeling OTFTs. The results of extracting the voltage drop at the contacts from these models are compared. Some of them are mainly useful when transistors with different channel lengths are available [4–6]. Others are strictly valid for linear current–voltage (I_D–V_C) responses in the contact [7]. Others, although valid to interpret nonlinear contact effect, offer an exclusive circuit vision of the problem [8].

We incorporate a model for the I_D–V_C curves at the contact [9,10] in a recently proposed generic FET model [3]. We propose a method to extract the voltage drop at the contact (I_D–V_C curves) for single length transistors showing both linear and non-linear responses in the low drain-voltage regime of their output characteristics. From the analysis of the voltage drop at the contacts with the gate voltage, a relation of the ratio of free charge density to the total charge density with the gate voltage is deduced.

2. Material

The active semiconducting material in the OTFTs under test is as-deposited spun film of 2,9(10),16(17),23(24)-(13,17-dioxanonacosane-15-oxy)phthalocyaninato zinc(II) derivatives (ZnPc) (see Fig. 1). The compound is liquid crystalline at a relatively low temperature of 11.5 °C. The synthesis and characterization of this compound were reported in a previous publication [11]. The source and drain electrodes are gold (50 nm thick)/Ti (10 nm thick) films. The transistor configuration is bottom gated. The substrate is n-silicon (100) wafer. The gate dielectric is thermally grown SiO_2 with thickness t_{ox} = 250 nm. Transistors of 10 μm-channel-length, L, 1 mm width, W, and 150 nm organic-film thickness, t_{ox}, have been analyzed. The relative dielectric constant is assumed $\varepsilon_r = 3$ in the semiconductor film [12]; similar values are also reported for other organic materials [9,13]. The electrode work function is considered around 5.14 eV, and the HOMO and LUMO levels for the organic film are 3.34 and 5.28 eV, respectively [12].

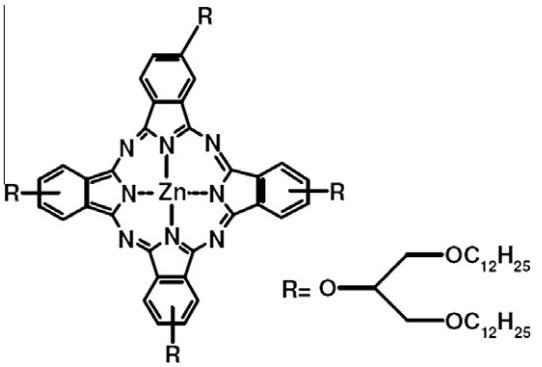

Fig. 1. Active semiconducting material analyzed in the work: as-deposited spun film of 2,9(10),16(17),23(24)-(13,17-dioxanonacosane-15-oxy)phthalocyaninato zinc(II) derivatives.

3. DC models

Fig. 2 shows experimental output characteristics measured in an Au–ZnPc bottom gated transistor at V_{GS} = 0, −10, −20, −30, and −40 V (symbols). Lines represent the fitting with the simple crystalline field-effect-transistor model (c-FET):

$$I_D = -k\left[(V_{GS} - V_T)V_{DS} - V_{DS}^2/2\right]; \quad k \equiv (\mu C_{ox} W)/L; \quad C_{ox} = \varepsilon_{ox}/t_{ox} \tag{1}$$

where εox is the dielectric constant of the gate insulator, Cox is the gate capacitance per unit area, L is the channel length and μ is the mobility. The drain current is defined as positive when entering the drain terminal (Fig. 3a). The similarity of the output characteristics of OTFTs with the I–V curves in c-FETs and amorphous thin-film transistors (a-TFTs) has been observed and explained in the past [14,15]. The fitting of experimental and theoretical curves in the saturation region produces the following parameters: k = 1.8 × 10−13 A/V2 and VT = −1.7 V. It is clear that the fitting is not good in the linear region of the curves. We can see that the experimental data are displaced around 2 V from the theoretical ones. A voltage drop at the contacts can explain this. Apart from the contact effects, there are other significant differences between organic and c-FETs, although a similarity in the current–voltage and other characteristics in these transistors exists [15]. The extraction of the mobility from the linear region produces

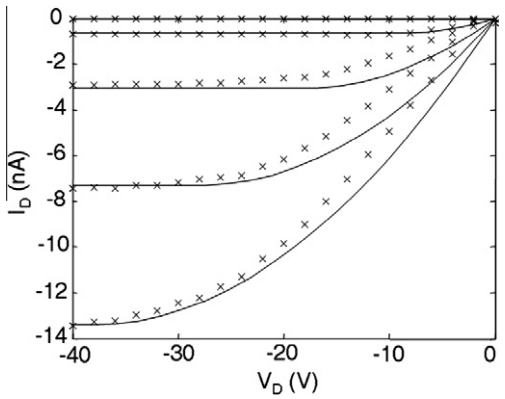

Fig. 2. Output characteristics of an Au–ZnPc bottom gated transistor at V_{GS} = 0, −10, −20, −30, and −40 V (from top to bottom). Symbols represent the experimental data. Lines represent the fitting with the simple c-FET model without contact effects ($k = 1.8 \times 10^{-13}$ A/V^2 and V_T = −1.73 V).

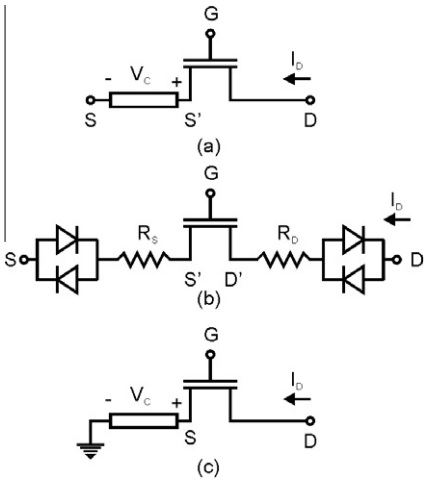

Fig. 3. (a) Equivalent circuit of a BC TFT including a voltage drop at the source contact V_C. V_{DS} is the extrinsic drain voltage. (b) Equivalent circuit of the BC TFT including nonlinear source and drain contact resistances [8]. (c) Equivalent circuit of a BC TFT including a voltage drop at the source contact V_C.

lower values than in the saturation region ($k = 1.4 \times 10-13$ A/V2). Clearly, contact effects are reducing the apparent mobility extracted in the linear region.

We can find in the literature different models that incorporate the voltage drop at the contacts, and associated methods to extract this voltage drop from the output characteristics of a transistor. This is not a trivial task because the contact effects interfere with other dependences in OTFTs [15]. The total source–drain voltage, V_{DS}, can be assumed split into a channel component, $V_{DS'}$, and a voltage drop at the contact, $V_C = V_{S'S}$ (Fig. 3a). This model takes into account that part of the external drain–source voltage is lost at the low conductivity regions near the contacts. However, this voltage drop V_C is located in the injecting contact (source). No voltage drop is considered at the extracting contact (drain). The reason is that the voltage lost at the extracting contact is much less important than the voltage lost at the injecting one, as supported by scanning potentiometry [1] and is therefore ignored.

By using the gradual channel approximation in the intrinsic channel and after integration of the potential along the channel, the current of OTFTs is obtained as [4,16]:

$$I_D = -[kL/(L-x_C)]\left[(V_{GS}-V_T)(V_{DS}-V_C) - \left(V_{DS}^2/2 - V_C^2/2\right)\right];$$
$$V_{DS} = V_{DS'} + V_C \text{ and } V_C \equiv \alpha V_{DS}, \tag{2}$$

where x_C is the width of the low conductivity region at the contact. This model is especially useful in identically processed transistors with different channel lengths (but the same channel width) [4–6]. This characterization technique, however, has two limitations. One is that a series of devices with different channel lengths, but otherwise identical, has to be available. Another is the channel transport properties in different devices might not be exactly the same. In such cases, alternative characterization techniques with variable gate biasing can be found in the literature [7,17,18]. Some of these techniques assume α as gate voltage dependant $\alpha = \alpha(V_{GS})$ but independent on V_{DS} [17–19]. That means that I_D is proportional to V_{DS}. For low values of V_{DS} the I_D–V_{DS} relation in Eq. (2) reduces to a linear one.

$$I_D = -k(V_{GS} - V_T)V_{DS}[1 - \alpha(V_{GS})]. \tag{3}$$

Other techniques model the contact effect by a series contact resistance, R_S, at source and drain [7]. The voltage drop across this series resistance modifies the I_D–V_{DS} relation. At low drain voltages this relation reduces to:

$$I_D = -k(V_{GS} - V_T)(V_{DS} - I_D R_S), \quad = -\frac{k(V_{GS}-V_T)V_{DS}}{1-kR_S(V_{GS}-V_T)}. \tag{4}$$

Non-linear I_D–V_{DS} relations such as the ones seen for low V_{DS} voltages in Fig. 2 are thus no reproducible by such linear expressions in Eqs. (3) and (4). Other approaches should be used instead [8]. These authors [8] proposed a model in which the carrier mobility depends on the gate voltage according to,

$$\mu = \mu_o[(V_G - V_T)/V_{AA}]^\gamma,\ \gamma > 0, \tag{5}$$

and highly non-linear drain and source contact series resistances are taken into account. In order to simulate non-linear I_D–V_{DS} output characteristics for organic BC TFTs, they proposed an equivalent BC TFT circuit that consists of the TFT with linear source and drain access resistances R_D and R_S, respectively, and a pair of anti-parallel leaky Schottky diodes connected to each access resistor in series, see Fig. 3b. Two diodes in parallel are needed to obtain a symmetric current–voltage characteristic. The diode non-ideality factor η, which is responsible for the steepness of the current–voltage characteristic, and the access resistances are the fitting parameters. There, $V_{DS} = (V_{D'S'} + R_S I_D + R_D I_D + 2V_{diode})$.

The idea of a gate voltage dependent mobility ($\mu \propto \{V_G - V_T\}^\gamma$, $\gamma > 0$) is based in theories such as the charge drift in the presence of tail-distributed traps (TDTs) [20] or variable range hopping (VRH) [21]. Another approach where this gate voltage dependent mobility was incorporated can be seen in [3]. In that work, the authors propose a generic analytical model for the current–voltage characteristics of organic thin-film transistors (OTFTs) [3] (Fig. 3c),

$$I_D = -k_0\left[(V_G - V_T - V_S)^{\gamma+2} - (V_G - V_T - V_D)^{\gamma+2}\right]/(\gamma+2)$$
$$k_0 = (\mu_0 C_{ox} W)/L, \tag{6}$$

where V_G and V_T are the gate bias voltage and the threshold voltage, respectively. The result is equivalent to the well-known and widely used generic FET model with a constant mobility. It is derived considering a voltage drop between the external source terminal and the internal source ($V_S \equiv V_C$) and the mobility μ is written according to the aforementioned common theoretical result [20], [21] or [22], $\mu = \mu_0(V_G - V_T - V_x)^\gamma$, where V_x is the potential in the semiconducting film of the TFT.

Assuming the values of k_0, γ, and V_T known, then a value for V_C can be found from an experimental drain current

characteristic. Thus, the complete I_D–V_C curves can be extracted from the experimental output characteristics $I_D = I_D(V_G, V_D)$. The extraction of the I_D–V_C curves requires the previous determination of k_0, γ, and V_T. The authors in [3] who proposed this generic drift model, also proposed an extraction method to determine these parameters [23]. It consists of a several step process [23] developed on identically processed transistors with different channel lengths (but the same channel width). It is similar to the model with a constant mobility in (2). By choosing the correct value for k_0, it makes all the I_D–V_C curves extracted from the different transistors to coincide. Thus, the usefulness of this extraction method is reduced to situations where several devices with different channel lengths, but otherwise identical, are available. In any case, prior to the determination of k_0, proper parameter extraction techniques are required to determine V_T and γ in (6) [23].

As mentioned in the introduction, the voltage drop at the contact region seriously affects the extraction of these (γ and V_T) and other parameters. Unless there is a method that eliminates these effects, an iterative procedure should be more convenient. Moreover, it would be very useful to find a simple and physically based model for the I_D–V_C relation at the contact in order to introduce this model in a previous generic FET model. It should employ as few parameters as possible, in order to maintain the compactness of the receiver generic FET model. In this paper, we have chosen (6) to incorporate the contact effects in, as it allows for an easy implementation and modification. Other details of the versatility of this model can be found in [3]. Our purpose is that the resulting model, after the incorporation of the contact effects, has parameters that can be characterized relatively easily, or even guessed, preventing unnecessary phenomenological fitting parameters. This is done in the following sections.

4. Contact model

For the contact region a functional model of the carrier injection $V_C = V_C(I_D)$, developed in [9,10] is initially used:

$$V_C = V_{injection}(I_D) + V_{redox}(I_D) + V_{drift}(I_D). \tag{7}$$

The model takes into account different physio-chemical mechanisms that take place at the contact: carrier injection through the barrier, $V_{injection}$, ion formation at the interface (redox reactions), V_{redox}, and charge drift in the low conductivity region of the organic material at the contact, V_{drift}. The expressions for the different components in (7) are detailed in [10]. For low values of the energy-barrier height (cases expected in well designed transistors), (7) is reduced to $V_C \approx V_{drift}(I_D)$. It is shown in [18] that the voltage drop associated with the charge drift depends on the free charge density at the interface, $p(0)$:

$$V_C = (2/3)[2J/(\varepsilon\mu\theta)]^{1/2}\left[(x_C + x_p)^{3/2} - (x_p)^{3/2}\right],$$
$$x_p \equiv J\varepsilon\theta\left[2e^2\mu(\theta p(0))^2\right], \tag{8}$$

where $J = I_D/S$ is the current density, ε is the permittivity of the organic material, μ is the mobility of the carriers, θ is the ratio of free to total charge density, x_C is the length of the contact region in the organic material, $(L–x_C)$ is the length of the intrinsic channel of the transistor, and x_p is a characteristic length defined as the point from the contact interface towards the organic film, at which the charge density $p(x_p)$ decays to $p(0)/\sqrt{2}$.

[*Note:* Please, be aware that the notations x_p and x_C have the meaning similar to those defined in [18]. In Ref. [9], L and x_C were used instead of x_C and x_p, respectively.]

Eq. (8) shows two asymptotical trends [18]. If the characteristic length x_p is a few times larger than the contact length x_C, Eq. (8) tends to Ohm's law:

$$I_D \approx eSp(0)\mu\theta V_C/x_C \equiv V_C/R. \tag{9}$$

A nonlinear relation between the current and voltage in the drift term occurs when the characteristic length x_p is much smaller than the contact length x_C and Eq. (8) reduces to the Mott–Gurney law [24,25]:

$$I_D \approx \frac{9}{8}\varepsilon\mu\theta S\frac{(V_C)^2}{(x_C)^3} \equiv M \times V_C^2. \tag{10}$$

These linear and quadratic behaviors are present in the experimental data. An example of this can be seen in poly(3-hexylthiophene) OTFTs with different source and drain electrodes, Cr and Au, (see Fig. 2 in [26]). The existence of different metallic electrodes produces different contact-voltage curves, showing these linear or non-linear responses. Transitions from linear to quadratic regimes can be seen not only by changing the electrodes, but also with the same electrode and varying the injection regime. This transition can be seen in Fig. 3 in [27], where current–voltage curves for hole injection into P3HT through Au are presented.

The inclusion of the I_D–V_C relations (9) or (10) in the generic model (6) adds a new parameter to the model. Drawing current curves $I_D = I_D(V_D, V_G)$ knowing the set of parameters (V_T, γ, k_0, M, or R) is an easy task. However, extracting these parameters from the experimental output characteristics is a major problem. There are well established parameter extraction techniques for FETs that can be used to extract the parameters in (6). An appropriate technique is proposed in [23], by the so-called H_{VG} function, which extracts the values of γ and threshold voltage V_T from the linear operation regime of the OTFT. The H_{VG} function is the ratio of the integral of the drain current over the gate bias divided by the drain current. The corresponding equation for the H_{VG} function derived from the TFT generic model (6) is:

$$H_{VG}(V_G) = \frac{\int_{<V_T}^{V_G} I_D(V_G)dV_G}{I_D(V_G)} = \frac{1}{\gamma+3} \times \frac{(V_G - V_T - V_S)^{(\gamma+3)} - (V_G - V_T - V_D)^{(\gamma+3)}}{(V_G - V_T - V_S)^{(\gamma+2)} - (V_G - V_T - V_D)^{(\gamma+2)}} \tag{11}$$

$$H_{VG}(V_G) = \begin{cases} = (V_G - V_T)/(\gamma+3), & V_D > V_G - V_T \\ \approx [(V_G - V_T)/(\gamma+2)]\{1 - R_2[V_D/(V_G - V_T)]\}, & V_D << V_G - V_T \end{cases} \tag{12}$$

where $R_2[V_D/(V_G - V_T)]$ is the remainder term, that represents the error in approximating $H_{VG}(V_G)$ by the above first order power series. In these equations, H_{VG} becomes a linear function of gate overdrive $(V_G - V_T)$ by setting $V_S = 0$, while k_0 is canceled, which is the advantage of the method. However, (12) explicitly neglects the effect of the contacts, as V_S is assumed null. That means that the values of V_T and γ may not be correct. To check this fact a hypothetical p-type transistor with the following parameters is considered: $V_T = 4.5$ V, $\gamma = 1$, $V_S = V_C = I_D R$, R varying in the range $[10^2–10^8\ \Omega]$ and k_0 in the range $[10^{-6}–10^{-12}\ A/V^2]$. The H_{VG} function, as defined in (12), is built, and parameters V_T and γ are determined in the saturation region as recommended in [23].

Fig. 4 shows the results of this method. There are ranges of R in which the extracted values for V_T and γ differ significantly from the original ones. A direct and easy-to-implement method like this one, in the absence of contact effects, is clearly altered under the presence of contact effects. Contact effects can really be a bottleneck in the extraction of the main parameter of the transistor. Despite these difficulties, we propose an extraction method in which the advantages of these methods are considered. In the next section, we propose a procedure to extract from experimental $I_D–V_{DS}$ curves, not only the values of V_T and γ,

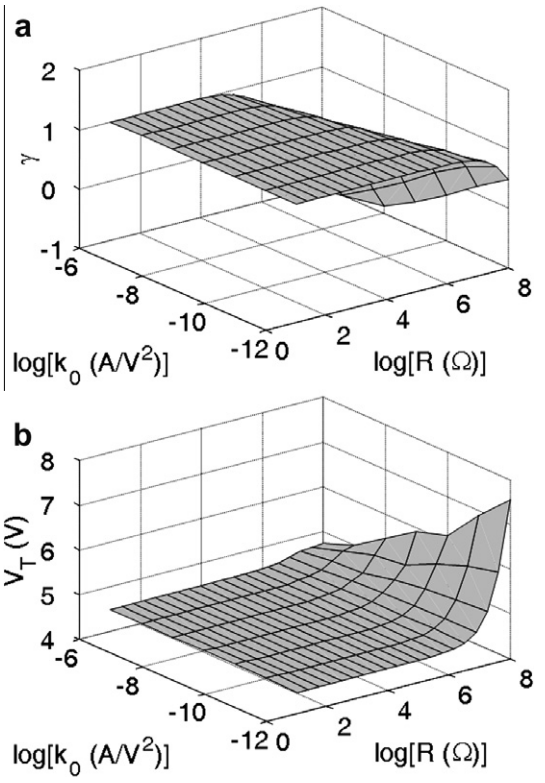

Fig. 4. (a) Extracted γ, and (b) extracted V_T from the generic drift model (6) using the H_{VG} method [22] for a transistor with initial parameters $V_T = 4.5$ V, $\gamma = 1$ and contact effects showing a linear behavior $V_S = V_C = I_D R$. The extracted γ and V_T are represented for transistors with different k_0 and R. Neglecting the voltage drop at the contact in the H_{VG} function makes the extracted values to differ from the original ones.

but also the contact voltage V_S, characterized by parameters M or R (Eqs. (9) and (10)), and the value of k_0.

5. Parameter extraction method

Upgrading a model by the introduction of new physical effects means the incorporation of additional fitting parameters that may not be possible to adjust consistently, or interfere with previous parameters of the model. The interference among parameters can be eliminated by a good initial estimation of some of them. In the case of contact effects, we provide a procedure that initially estimates the parameters associated to the contacts by slightly modifying the ideal c-MOS model. Although the ideal c-MOS model cannot accurately reproduce the complete output characteristics of an OTFT, it does provide a good initial estimation of the transistor parameters to be subsequently determined in (6), in particular those associated to the contacts. In this section, we define the steps followed to determine the complete set of parameters in (6), including the parameter associated to the contact region.

(1) Estimation of V_T and k from the ideal c-MOS model in saturation from (1).

(2) Estimation of the electric field degradation of mobility by analyzing the saturation region of the transistor. Eq. (5) is introduced in (1) and parameters defining the gate voltage dependent mobility are determined from the saturation region.

(3) Estimation of contact parameters (curves $I_D - V_C : I_D = M(V_{GS}) \times V_C^2$ or $I_D = V_C/R(V_{GS})$). The drain–source voltage is modified in (1) by the inclusion of the voltage drop at the source contact. The model is represented in Fig. 3a. For the TFT the usual analytic expression for the MOS transistor can be used:

$$I_D = -k\left((V_{GS'} - V_{T'})V_{DS'} - V_{DS'}^2/2\right), \tag{13}$$

where $V_{DS} = V_{DS'} + V_C$ and $V_{T'}$ is an internal threshold voltage defined for the intrinsic transistor in Fig. 3a. $V_{T'}$ can be evaluated as $V_{T'} = V_T - \overline{V_C(I_{Dsat})}$, where V_T is the threshold voltage extracted from the saturation region of the experimental data and $\overline{V_C(I_{Dsat})}$ is the average value of the contact voltage evaluated in saturation, $I_D = I_{Dsat}$, and different gate voltages. Note that $V_{T'}$ is not known as yet, as the contact voltage is not known at this step. In a first estimation, the modification of the gate voltage by the contact effects is neglected. It can be checked that this simplified model can reproduce the data in the linear region, where the contact effects are clearly dominant, by assuming $(V_{GS'}–V_{T'}) \sim (V_{GS}–V_T)$ in Eqs. (13), (7) and (9) (or (10)). The effect of the contact voltage on the gate voltage $V_{GS'} = V_{GS} - V_C(I_D)$ is compensated by a modification of the threshold voltage for the intrinsic TFT. The idea of the internal threshold voltage is formally introduced and physically derived in (2) (or in (6) if the gate voltage dependent mobility is considered). In this work, (13) is preferred for an initial estimation of the parameter M (or R). It avoids the mutual interference between the contact parameter M (or R) and the rest. It avoids the need of introducing an intrinsic threshold voltage, $V_{T'}$, in the OTFT model by the existence of contact effects.

(4) Estimation of an average value for the contact voltage V_S in the saturation region. Once the M (or R) parameter is extracted from the experimental data ($M = M(V_{GS})$ or $R = R(V_{GS})$), the average value of the contact voltages, evaluated at $I_D = I_{Dsat}$ for different gate voltages, can be determined, $V_S = \overline{V_C(I_{Dsat})}$.

(5) Determination of V_T and γ from the H_{VG} function. The H_{VG} function can be evaluated by introducing this average value for V_S in the saturation region: $H_{VG}(V_G) = (V_G - V_T - V_S)/(\gamma + 3)$. Once the effects of the contacts are introduced in this function, V_T and γ can be determined more accurately. The problems associated to the contact effects make the linear region no valid for the determination of such parameters. The saturation region has previously been suggested as the most appropriate region to carry on this characterization [23].

(6a) Final determination of k_0 and $M(V_{GS})$ (or $R(V_{GS})$). At this step, values for all the variables appearing in the drift generic model (6) have been derived. V_T and γ have been determined by considering the contact voltage and using a technique that eliminates the dependence with k_0 (see (11)). Thus, k_0 and M (or R) are the only parameters that require a final adjustment. In this case, Eq. (6) is used to find these values by comparing this equation with the experimental data. The parameter k_0 mainly affects the saturation region and M (or R) affects the linear region. Thus, these parameters are modified in order to fit the current voltage curves in these respective regions. Slight modifications of these two parameters found this way may be necessary to reproduce the complete set of experimental $I_D(V_D, V_G)$ curves.

(6b) Direct extraction of the I_D–V_C curves from (6). The objective of this step is twofold: (*i*) as a test to check the values of the parameters obtained in step 6a or (*ii*) as an alternative step for 6a when non reasonable values for γ are obtained in step 5.

(i) An inspection of Eq. (6) shows that with the values of the parameters k_0, V_T, γ, and M (or R) and the experimental $I_D(V_D, V_G)$ curves, one can derive I_D–V_C curves at different V_G. These I_D–V_C curves must match the ones obtained in step 6a (controlled by Eqs. (9) and (10)). Step 6b alone can be used to determine a unique I_D–V_C curve for several devices with different channel lengths, but otherwise identical [4–6], as mentioned in the previous section. All the extracted curves must converge into one. However, step 6b alone cannot be employed for the case of a set of single length transistors, as convergence is not guaranteed. Steps 1–5 provide such a procedure towards a convergence, for the physical trend given by Eqs. (9) and (10). In any case, the extraction of different I_D–V_C curves for different values of k_0, and its comparison with the value of k_0 and the curves extracted in step 6a are suggested.

(ii) The other situation where this step is necessary is when abnormal values of γ and/or V_T are obtained in previous steps, despite introducing an estimated value for the contact voltage V_S. A negative value of γ clearly indicates that the characterization needs further processing (see Fig. 4a)). In these situations, convergence between experimental data and Eq. (6) in step 6a is not achieved. An iterative procedure is suggested in this step 6b. The initial values used for γ, V_T, and k_0 in this procedure depend on the value of γ estimated in previous steps. The value of the threshold voltage is assumed initially correct. In case the value of γ extracted from step 2 is positive, this should be assumed as an initial estimation. On the contrary, the initial value for γ is assumed zero. For the selected value of γ, k_0 is varied until a physical result for the I_D–V_C curves is obtained. If it does not exist, then the value of γ is increased and k_0 is again modified. The values of γ and k_0 are alternatively modified until the I_D–V_C curves behave like (9) or (10). An arbitrary set of values for V_T, γ, and k_0, different from the actual solution, produces current voltage curves at the contact with no physical meaning (such as a change of the sign of the contact voltage or strange trends in the I_D–V_C curves).

In case, the extracted I_D–V_D curves provide a value of $V_S = \overline{V_C(I_{Dsat})}$ different from the one initially estimated in step 5, a new iteration is necessary. A new value for the threshold voltage would be determined in step 5 and 6b would be repeated.

6. Results

To check the validity of the extraction method for the contact voltage drop and the rest of the basic parameters appearing in the TFT generic model (6), we analyze data showing both linear and non-linear effects. We analyze measured I_D–V_D curves in ZnPc-based organic thin film transistors and data taken from other authors' experiments.

6.1. Non-linear contact current–voltage curves

In first place, we analyze the experimental data depicted in symbols in Fig. 2. They show a clear non-linear behavior at low drain voltages pointing out the existence of contact effects. Considering the values of the HOMO and LUMO levels for the organic film and the electrode work function given above, the energy barrier of the Au–ZnPc contact can be considered small enough to prevent current to flow through it. The current is thus dominated by the drift term. Due to the high non-linearity of the I_D–V_{DS} curves, the current–voltage relation at the contact is modeled by (10).

The extraction procedure detailed in the previous section can be followed in Fig. 5. We initially consider that the values of the mobility (assumed gate voltage dependent) and threshold voltage are extracted by fitting the experimental data in the saturation region with the ideal c-MOS model: $V_T = -1.7$ V, $\gamma = -0.03$, $V_{AA} = 24.4$ V and $\mu_{00} = 4.4 \times 10^{-6}$ cm^2/Vs. The result of this fitting (steps 1 and 2) can be seen in Fig. 2. If the contact effects are introduced in the ideal MOS model (step 3) a good agreement between the experimental data (symbols) and the combined expression resulting from (10) and (13) (solid lines) is seen in Fig. 5a. The values of M introduced in (10) to

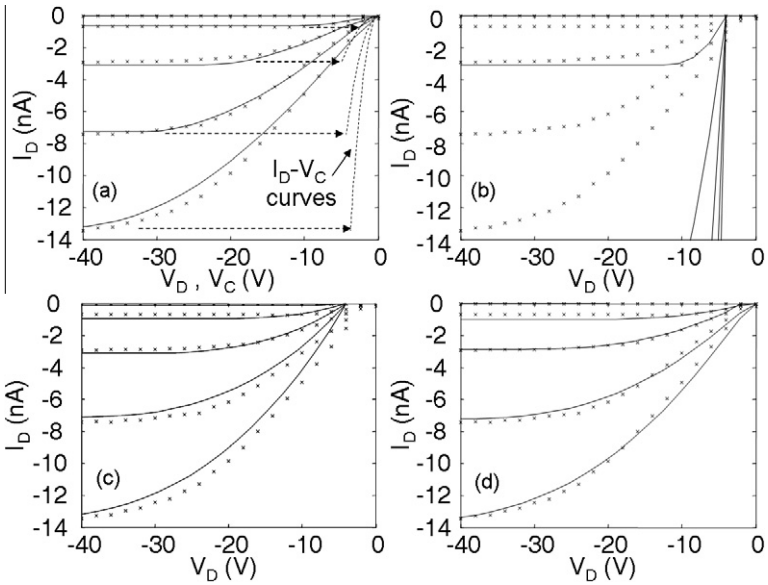

Fig. 5. Comparison of output characteristics of an Au–ZnPc bottom gated transistor measured at $V_{GS} = 0$, -10, -20, -30, and -40 V (from top to bottom in symbols) with the theoretical results obtained at different steps of our fitting procedure. (a) Fitting with the ideal MOS model corrected with the contact effects (Eq. (13)). The values of the mobility and threshold voltage are extracted from the saturation region. The mobility is considered gate voltage dependent, following expression (5). ($V_T = -1.7$ V, $\gamma = -0.03$, $V_{AA} = 24.4$ V and $\mu_{00} = 4.4 \times 10^{-6}$ cm^2/Vs). The current–voltage curves at the contact are modeled with the parameter $M(V_{GS})$. The parameter M is extracted by fitting the experimental data in the linear region ($M = 1.0 \times 10^{-10}$, 1.2×10^{-10}, 1.2×10^{-10}, 4.0×10^{-10}, and 9.5×10^{-10} A/V^2 for $V_{GS} = 0$, -10, -20, -30, and -40 V, respectively). The dashed curves on the right represent the current–voltage curves at the contact evaluated with the previous M parameter. The tips of the dashed arrows point out the value of the contact voltage evaluated in the saturation region for each gate voltage. An average value of $V_{S(average)} \approx -4$ V is obtained. (b) Fitting with the generic drift model (6). This equation is evaluated with the following parameters. Parameters V_T and γ are determined with the H_{VG} function (11) including the contact effects $V_S = V_{S(average)}$ ($\gamma = 0.8$, $V_T = 13$ V); the value of μ_0 is the one calculated from the saturation region with the ideal MOS model ($\mu_0 = 4.4 \times 10^{-6}$ cm^2/Vs); and $V_S = 0$. The last two parameters make the theoretical result to disagree with the experimental curves. (c) Fitting with the generic drift model (6) changing the parameter μ_0 to 1.7×10^{-7} cm^2/Vs; V_S is maintained null. (d) Fitting with the generic drift model (6) introducing the contact effects. μ_0 does not change. The extracted M parameter is $M = 0.3 \times 10^{-10}$, 0.7×10^{-10}, 1.2×10^{-10}, 5.0×10^{-10}, and 9.5×10^{-10} A/V^2 for $V_{GS} = 0$, -10, -20, -30, and -40 V, respectively. Despite the large modification of the values of V_T and μ_0 along the different steps of this procedure, the values of the parameter M associated to the contact voltage suffer almost no variation. That means that the use of single models, like the one propose in (13), helps finding a proper estimation of the contact I_D–V_C curves.

achieve such an agreement are $M = 1.0 \times 10^{-10}$, 1.2×10^{-10}, 1.2×10^{-10}, 4.0×10^{-10}, and 9.5×10^{-10} A/V^2 for $V_{GS} = 0$, -10, -20, -30, and -40 V, respectively. The contact I_D–V_C curves resulting from these parameters are depicted in dashed lines on the right region of Fig. 5a. Once we know these curves, the contact voltage can be evaluated in the saturation region for each gate voltage. These points are marked with the tips of the dashed arrows in Fig. 5a. An average value $V_{S(average)} \approx -4$ V is obtained from these points (step 4).

The fifth step corresponds to the determination of V_T and γ from the H_{VG} function, once a value for the contact voltage in the saturation region has been estimated. The analysis of the H_{VG} function provides the following values: $\gamma = 0.8$ and $V_T = -13$ V. A very different value for the threshold voltage is obtained in comparison to the one extracted in step 1. Fig. 5b illustrates the comparison of the experimental data with the generic drift model (6) using the values of these last two parameters, the value of μ_0 determined from the saturation region with the ideal c-MOS model ($\mu_0 = 4.4 \times 10^{-6}$ cm^2/Vs), and $V_S = 0$. It is apparent that the mixture of values of parameters extracted from different models and ignoring the contact effects produce such a disagreement. A change of the value of the mobility to 1.7×10^{-7} cm^2/Vs is necessary in order to fit the experiments in the saturation region (Fig. 5c). In this figure, V_S is maintained null in order to highlight this fact. Finally, the contact effects, by means of the parameter M in (10), are introduced in the generic drift model (6). The combined model fits the experimental data for the following set of values: $M = 0.3 \times 10^{-10}$, 0.7×10^{-10}, 1.2×10^{-10}, 5.0×10^{-10}, and 9.5×10^{-10} A/V^2 for $V_{GS} = 0$, -10, -20, -30, and -40 V, respectively (Fig. 5d). A unique value for M should be expected for a compact model. However, the compactness of this parameter is justified below by its relation with the charge density in the intrinsic channel.

The analysis of the values of the different parameters extracted in the six steps shows that the variations in V_T and γ (from the initial estimations to the final results) are very significant, while the parameter M is practically unaffected by when using either the ideal c-MOS model or the generic drift model, both in combination with our contact model. On the one hand, the generic drift model is physically well based. However, the inclusion of new parameters in it makes their extraction more difficult. On the other hand, the use of simple models like the one propose in (13), although based on approximations, are really helpful in finding a proper initial estimation of the contact

I_D–V_C curves. This is necessary to proceed with the determination of the exact values of the parameters appearing in (6).

The current–voltage curves at the contact can be directly extracted from (6) once the parameters μ_0, γ and V_T are known [23]. These curves can be seen with symbols in Fig. 6. The values of these parameters correspond to the ones extracted with our procedure in the previous paragraphs. The inset of Fig. 6 shows the comparison of the experimental data with (6) including these current voltage curves. The agreement is clearly better than the one shown in Fig. 5d. However, the current voltages curves extracted with our procedure (shown as solid lines in Fig. 6) provide a physical trend and a way to interpret the ones shown as symbols.

Experimental data measured in an Au-pentacene BC-TFT by other authors [8] are also reproduced by our model. Fig. 7 shows a comparison of the experimental data (symbols) with the generic drift model (6) in which the contact current–voltage relation (10) has been incorporated (solid lines). The transistor has the following characteristics: the SiO_2 gate-dielectric thickness is $t_{ox} = 290$ nm, the gate length is $L = 20$ μm and the gate width $W = 220$ μm.

The model parameters have been extracted using the procedure detailed in the previous section. This is a case where the value of γ extracted in step 5 shows an abnormal value despite including the contact effects, $\gamma = -0.4$. In this situation, step 6b was followed instead of step 6a. The value of γ extracted by analyzing the saturation region with the ideal c-MOS model (1) in combination with the electric field degradation of the mobility (5) was used instead, $\gamma = 0.118$. The value of the threshold voltage was determined in step 5 by means of the H_{VG} function applied to the generic drift model (6). The parameter obtained after the fitting procedure are: $k_0 = 7.78 \times 10^{-8}$ A/V^2, $\mu_0 = 0.19$ cm^2/Vs, $V_T = 17.3$ V, $\gamma = 0.118$, $M = 0.5 \times 10^{-6}$, 0.8×10^{-6}, 1.0×10^{-6}, 1.5×10^{-6}, 2.0×10^{-6}, 2.4×10^{-6}, and 2.5×10^{-6} A/V^2 for $V_{GS} = 0$, -10, -20, -30, -40, -50, and -60 V, respectively. Situations analyzed in Fig. 5 and Fig. 7 show the need to employ the advantages of simple models (although not exact ones) and to combine them in a precise sequence. The objective is to determine correct values for the transistor parameters that appear in a more compact and precise model, such as the one in (6).

Another feature of our model and its associated extraction procedure is that they allow us to determine the parameter M defined in (10). From this parameter, we can determine the evolution of the free to total charge-density ratio θ, with the gate voltage. Assuming the same value for the mobility in the transistor channel and in the low conductivity region at the contact, this ratio varies

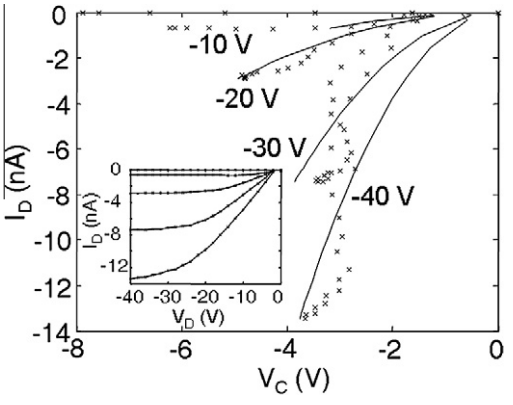

Fig. 6. Current voltage curves at the contact extracted from experimental output characteristics at different gate voltages with our procedure (solid lines) and directly from the generic drift model (6) (symbols). The parameters employed in the calculation correspond to the final ones obtained in Fig. 5. Inset: Comparison of output characteristics of an Au-ZnPc bottom gated transistor measured at $V_{GS} = 0$, -10, -20, -30, and -40 V (from top to bottom in symbols) with the theoretical results from (6) using the I_D–V_C curves shown in symbols in the main figure.

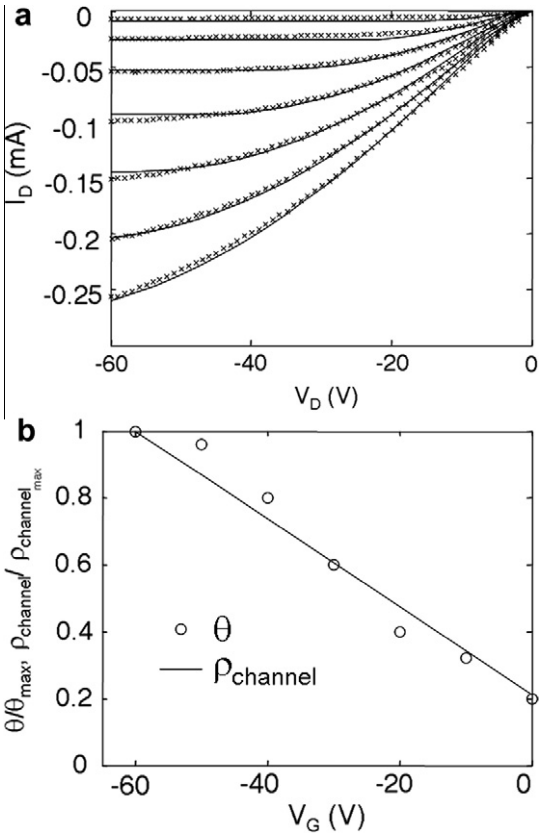

Fig. 7. (a) Comparison of output characteristics of an Au-Pentacene bottom gated transistor at $V_{GS} = 0$, -10, -20, -30, -40 V, -50 V, and -60 V from top to bottom (symbols) with the generic drift model (6) including non-linear contact effects (10) (solid lines). The dimensions of the transistor are $t_{ox} = 290 \times 10^{-7}$ cm, $W = 220 \times 10^{-4}$ cm, $L = 20 \times 10^{-4}$ cm. The parameters used in the model, determined according to the method detailed in this work, are $k_0 = 7.78 \times 10^{-8}$ A/V^2, $\mu_0 = 0.19$ cm^2/Vs, $V_T = 17.3$ V, $\gamma = 0.118$, $M = 0.5 \times 10^{-6}$, 0.8×10^{-6}, 1.0×10^{-6}, 1.5×10^{-6}, 2.0×10^{-6}, 2.4×10^{-6}, and 2.5×10^{-6} A/V^2 for $V_{GS} = 0$, -10, -20, -30, -40, -50, and -60 V, respectively. (b) Normalized values of the charge density in the channel, ρ, and free to total charge-density ratio θ in the low conductivity region near the contact. The values of θ are extracted from the previous values of M and its definition in (10). The normalization values are: $\rho_{max} = 3.4 \times 10^{18}$ cm^{-3} and $\theta_{max} = 0.06$. The charge densities in the channel and in the contact region are correlated meaning that the values of M extracted by our procedure are acceptable.

from 0.012 at $V_{GS} = 0$ V to 0.060 at $V_{GS} = -60$ V. The values of θ, necessary to fit the experimental data with our model (Fig. 7a), are represented as a function of the gate voltage in Fig. 7b (circles). In this figure, we also represent the values of the charge density in the intrinsic channel, estimated according to the equation (solid line) [28],

$$\rho_{channel} = C_{ox}\frac{1}{t_o}(V_{GS} - V_T). \quad (14)$$

The evolution of the ratio of free to total charge density with the gate voltage is in excellent agreement with the evolution of the charge density in the channel. This agreement validates the physical model we propose for the dc characteristics of organic TFTs affected by contact effects.

The non-linear behavior shown at low drain voltages in the experiments of Figs. 5 and 7 can also be reproduced by diodes in series with a resistance connected at the source and drain terminals (Fig. 3b). Good agreements between the experimental data and this model are obtained. For the experimental data in Fig. 5, the values of the model parameters in Fig. 3b that achieve the best fit are $\gamma = -0.032$, $\mu_0 = 2.65 \times 10^{-4}$ cm^2/Vs, $V_{AA} = 25.0$ V, $R_{D,S} = 10^4\ \Omega$, energy barrier at the interface $\varphi_B = 0.65$ eV and non-ideality factor of the diode $\eta = 5$. For the experimental data in Fig. 7, the values of the model parameters that achieve the best fit are $\gamma = 0.118$, $\mu_0 = 0.2$ cm^2/Vs, mobility evaluated at $V_{GS} = -60$ V, $\mu = 0.27$ cm^2/Vs, $V_{AA} = 5.70$ V, $R_{D,S} = 5$ kΩ, energy barrier at the interface $\varphi_B = 0.65$ eV and non-ideality factor of the diode $\eta = 2.5$. Although the model in Fig. 3b can reproduce the experimental data, the values of the resulting parameters should be analyzed with care, especially when high values of the non-ideality factor of the diodes and/or negative values of γ are extracted. The advantage of our model (Fig. 3c) is its physical approach to the real mechanisms affecting the low conductivity region near the contacts, [1,9].

6.2. Linear contact current–voltage curves

Current–voltage I_D–V_D curves showing linear responses at low drain voltages have also been studied in this work. Here, we apply the procedure from the previous section to extract the mobility, threshold voltage and the contact voltage drop from the output characteristics of poly(3-hexadecylthiophene)(P3HDT) transistors [17] (symbols in Fig. 8a). The solid lines correspond to the evaluation of the generic drift model (6) in which the linear contact voltage-current model in (9) has been incorporated. The values of the contact resistances $R = R(V_G)$ and the rest of the model parameters are detailed in the same figure. A good agreement is observed between the experiments and the theoretical results. The extraction procedure followed with these data does not end in step 6a, but goes through step 6b. This is another example where the parameter γ is clearly affected by the contact effects (see Fig. 4). In step 5, $\gamma = -0.3$ and $V_T = -4.5$ V are obtained assuming an average value for the contact voltage in the saturation region $V_S = \overline{V_C(I_{Dsat})} = -1.5V$. The value of γ is gradually increased and the value of k_0 is modified until the extracted I_D–V_D curves show a perfectly linear behavior, as expected by the trend of the experimental data at low drain voltages.

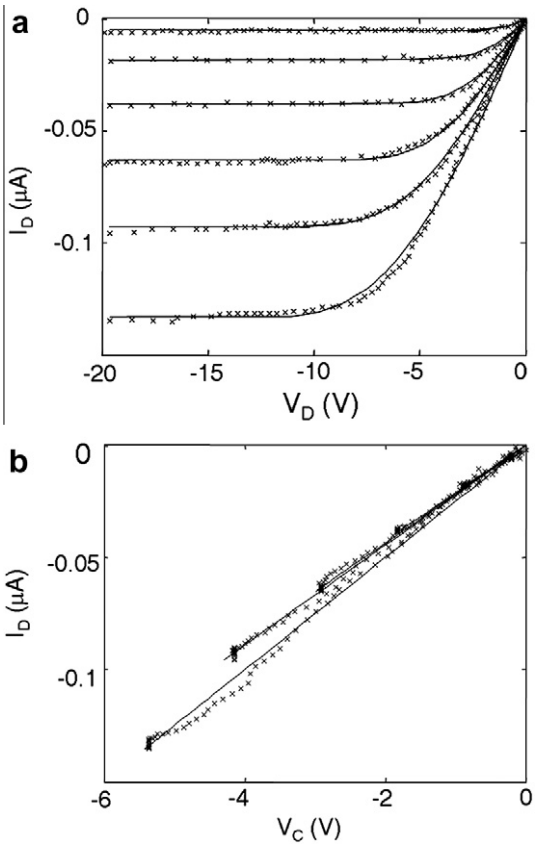

Fig. 8. (a) Output characteristics of an Au–P3HDT BC transistor at $V_G = -8$, -10, -12, -14, -16, and -18 V from the top to the bottom. Symbols represent the experimental data [17] based on material described in [29,30]. Lines represent the fitting with the generic drift model (6) including non-linear contact effects (10). The details of the samples are: thermally grown SiO_2 ($\backsim$ 200 nm), channel width $W = 0.5$ cm (multifinger configuration), and channel length $L = 10$ μm. The polymer film is 7 nm thick and was deposited by spin coating. The parameters used in the model, determined according to the method detailed in this work, are $k_0 = 3 \times 10^{-8}$ A/V^2, $\mu_0 = 1.2 \times 10^{-5}$ cm^2/Vs, $V_T = -4.5$ V, $\gamma = 1.5$, $R = 4.9 \times 10^7$, 4.8×10^7, 4.7×10^7, 4.6×10^7, 4.5×10^7, $4.0 \times 10^7\ \Omega$ for $V_G = -8$, -10, -12, -14, -16, and -18 V, respectively. (b) Current voltage curves at the contact extracted from the experimental output characteristics at different gate voltages with our procedure (solid lines). The parameters employed in the calculation correspond to the final ones obtained in Fig. 8a. The current voltage curves at the contact extracted directly from the generic drift model (6) are shown in symbols.

This occurs for $\gamma = 1.5$ (Fig. 8b). The value of the threshold voltage needs no modification.

In order to check, that this solution is unique, other pairs of values for γ and k_0 are tested. As an example, Fig. 9 shows I_D–V_D curves extracted from (6) for a lower γ, $\gamma = 0.15$, $V_T = -4.5$ V and different values of k_0, after equating I_D, V_G, and V_D to the experimental data (symbols). They are compared to the solution obtained in Fig. 8b. The set of figures shows that there is no acceptable I_D–V_D curve in any case. Fig. 9a shows positive values for V_C when negative ones are expected. Fig. 9b–d show linear responses at low values of V_C. However, the curves tend to saturate, reflecting the saturation response of the intrinsic channel,

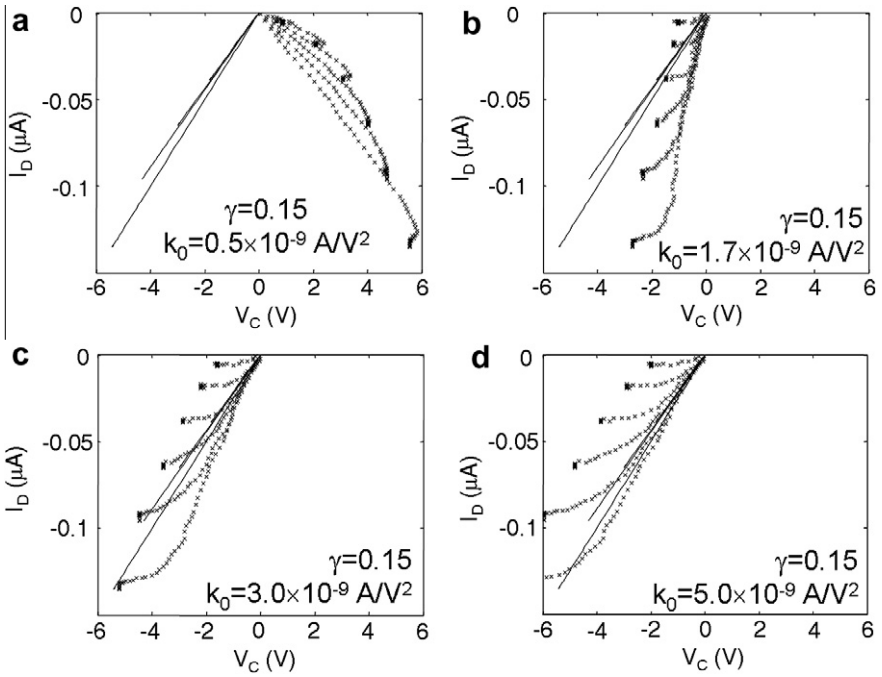

Fig. 9. Contact current–voltage curves extracted from the experimental data of Fig. 8, directly from Eq. (6) (symbols) providing this model with the parameter values $V_T = -4.5$ V and γ and k_0 given in the figures. The solid lines are used as a reference. They correspond to the final results obtained with our procedure for the I_D–V_C curves (Fig. 8). No convergence to a physical acceptable solution is seen when varying the parameter k_0 for $\gamma = 0.15$: figures (a) to (d). A similar lack of convergence towards a physical acceptable trend for the I_D–V_C curves is seen for other values of γ, except for the actual solution depicted in Fig. 8.

not the actual response of the contact region. A similar study was made with different values of γ, showing that the solution depicted in Fig. 8 is unique.

As seen in these two sub-sections, the model is able to distinguish between linear and quadratic responses for the current voltage relation at the contact region. Both responses are included under the assumption that the energy barrier at the contact imposes no restriction to the current, i.e. under the assumption of space charge limited transport $V_C \approx V_{drift}(I_D)$. Therefore, the model is limited to these situations. Outside these limits, when the energy barrier at the interface imposes a restriction to the current, non-linear I–V responses are also obtained, however not necessarily quadratic ones (thermionic emission or tunnel injection should be considered (7)). An example of this can be seen in Fig. 1 in [10], where the voltage drop at the contact of an OTFT is the sum of the voltage drop at the space charge region and the voltage necessary to surpass the barrier at the contact (a combination of injection through the barrier and space charge transport). For these cases, the quadratic model can still be used by taking into account that we are working under a second order approximation, and no connection with the physical parameters appearing in (10) is possible. In any case, properly designed transistors are expected to use contacts with low energy barriers at the interface in order to reduce the injection-voltage term. Therefore, from this practical point of view, the procedure can be considered of full applicability.

7. Conclusions

We have made use of a physical model to interpret contact effects in organic/polymeric thin film transistors, and we have incorporated it in a generic compact model that describes the output characteristics of OTFTs. The resulting model reproduces experimental data of output characteristics showing linear and highly nonlinear responses at low drain voltages. Our model is compared with previous circuit models proposed to explain these behaviors. Our model provides a way to gain physical insight about the charge density in the low conductivity region near at the contact region and mirrors the changes of charge density in the rest of the device. Actually, the evolution with the gate voltage of the free to total charge density ratio in the low conductivity region at the contact is in agreement with the estimated charge density in the channel.

In parallel to this model, a parameter extraction procedure has been proposed in order to determine the model parameters, including the additional ones associated to the contact effects. The advantages of previous procedures (although less precise) are combined in our method. Although more physically advanced model are necessary in order to take into account all the effects that appear in the OTFT, previous simple models cannot be completely disregarded. We have demonstrated their usefulness in the characterization process. The different steps of our procedure are monitored with experimental

measurements from organic thin film transistors based on zinc phthalocyanine and data from other authors' experiments.

Acknowledgments

This work was carried out within the framework of research Project No. TEC2007-66812/MIC supported by the Ministerio de Educación y Ciencia and FEDER. The authors are grateful to Professor Vefa Ahsen of Department of Chemistry, Gebze Institute of Technology, P.O. Box 141, 41400 Gebze-Kocaeli, Turkey for providing zinc phthalocyanine compounds.

voltage of the device so as to obtain high power efficiency [10]. However, there are few reports focused on homojunction OLEDs, which are only centered on fluorescent and red phosphorescent devices with quite high driving voltages [11]. In the present paper, we systematically demonstrate efficient red, green and blue homojunction phosphorescent OLEDs with various emitting dopants of tris(1-phenylisoquinolinolato-C^2,*N*)iridium(III) (Ir(piq)$_3$), *fac*-tris(2-phenylpyridine) iridium (Ir(ppy)$_3$) and iridium(III) bis(4,6-(di-fluorophenyl)pyridinato-*N*,C2′) picolinate (FIrpic) by using a series of bipolar host materials, including 2,6-bis(3-(carbazol-9-yl)phenyl) pyridine (26DCzPPy), 3,5-bis(3-(carbazol-9-yl)phenyl) pyridine (35DCzPPy) and 4,6-bis(3-(carbazol-9-yl)phenyl) pyrimidine (46DCzPPm).

2. Results and discussion

2.1. Mobility of 46DCzPPm, 26DCzPPy, 35DCzPPy and hole and electron-only devices with p/n-doped layers

In order to demonstrate the effect of *p*/*n*-doped layers, hole/electron-only devices were fabricated. Hole-only devices of indium tin oxide (ITO)/host:MoO_3 (30 nm)/host (10 nm)/*N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)-2,2′-dimethylbenzidine (NPD) (10 nm)/Al (80 nm) and electron-only devices of ITO/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) (10 nm)/host (30 nm)/host:Cs_2CO_3 (20 nm)/Al (80 nm) were fabricated to compare the injection and transport property of various doped host materials. Fig. 1 shows current density versus voltage characteristics of the devices, indicating that *p*/*n*-doped layers could get quite efficient charge carrier injection and transport in the devices. In order to obtain the best charge carrier injection and transport, here we fabricated a series of hole-only and electron-only devices with different *p*/*n*-doping concentrations to decide the optimum ones. For *p*-doped layers, 50 wt.% MoO_3 is the best one to enhance the hole injection and transport, which is shown in Fig. 1(a). For *n*-doped layers, the optimum concentrations of Cs_2CO_3 are 20 wt.% for 46DCzPPm, 50 wt.% for 26DCzPPy and 40 wt.% for 35DCzPPy, respectively, which are shown in Fig. 1(b). Here, the 46DCzPPm-based hole-only device shows the most efficient hole injection and transport. Current density versus voltage curves of hole/electron-only device show the typical shape of space charge limited current. For the electron-only device, the slopes, whose values are 1.5 for 26DCzPPy-, 0.36 for 46DCzPPm- and 0.02 for 35DCzPPy-based devices, refers to the Ohmic regime, described by $J_\Omega = q\mu nV/L$ (noted by solid lines). The regions with steep slope, trap-filling regime, correspond to the rapid change undergone by the current. The slopes, referring to the trap-free space-charge-limited-current region are 1.8 for 26DCzPPy-, 2.9 for 46DCzPPm- and 6.4 for 35DCzPPy-based devices, respectively, obeying the Mott-Gurney law $J_{SCLC} = 9\varepsilon\varepsilon_0\mu\Theta V^2/8L^3$ [13]. Three regions for hole-only devices were also marked in Fig. 1(a).

Table 1 shows hole and electron mobilities of 46DCzPPm, 35DCzPPy and 26DCzPPy neat films. Mobilities reveal that 26DCzPPy and 35DCzPPy are quite well-balanced bipolar host materials, because electron and hole mobilities are similar within one material on the order of about 10^{-5}. For 46DCzPPm, it is also a bipolar host, although its hole mobility is slightly higher than its electron mobility.

2.2. Performance of RGB homojunction devices by using 46DCzPPm, 26DCzPPy and 35DCzPPy

To evaluate 46DCzPPm, 26DCzPPy and 35DCzPPy as host materials applied in *p*–*i*–*n* homojunction devices, phosphorescent OLEDs were fabricated with commercially available phosphorescent emitters of FIrpic, Ir(ppy)$_3$ and

Table 1
Hole and electron mobilities of 46DCzPPm, 26DCzPPy and 35DCzPPy neat films prepared by vacuum vapor deposition.

Hosts	Hole mobility ($cm^2\,V^{-1}\,S^{-1}$)	Electron mobility ($cm^2\,V^{-1}\,S^{-1}$)	Electric field ($V\,cm^{-1}$)
46DCzPPm	1.3×10^{-5}	4.2×10^{-6}	8.1×10^5
26DCzPPy	2.0×10^{-5}	2.0×10^{-5}	5.6×10^5
35DCzPPy	3.7×10^{-5}	3.2×10^{-5}	5.6×10^5

Table 2
HOMO, LUMO and triplet energy levels of materials used in this study.

Material	HOMO (eV)	LUMO (eV)	T_1 (eV)
26DCzPPy	6.05	2.65	2.71
35DCzPPy	6.18	2.75	2.71
46DCzPPm	6.19	3.06	2.64
FIrpic	6.15	3.47	2.65
$Ir(ppy)_3$	5.40	2.40	2.41
$Ir(piq)_3$	5.10	3.10	2.00

$Ir(piq)_3$. Triplet energy levels (T_1) of all materials used in this study were shown in Table 2. As well known, T_1 is of great importance on the confinement of triplet exciton in a host/guest system, which is relevant with the device performance. For 26DCzPPy and 35DCzPPy, they possess a similar T_1 level of 2.71 eV, which is high enough for all triplet emitters used in this study to prevent reverse energy transfer from the guest to the host. For 46DCzPPm, its T_1 level of 2.64 eV is high enough for $Ir(ppy)_3$ (T_1 = 2.4 eV) and $Ir(piq)_3$ (T_1 = 2.0 eV) but not for FIrpic (2.65 eV), probably leading to a efficiency loss in FIrpic-based device [12].

The device with a *p–i–n* homojunction structure used in this study as shown in Fig. 2 is the following: ITO (130 nm)/host:MoO_3 (30 nm)/host (10 nm)/host:12 wt.% FIrpic or 10 wt.% $Ir(ppy)_3$ or 4 wt.% $Ir(piq)_3$ (30 nm)/host (10 nm)/host:Cs_2CO_3 (20 nm)/Al (80 nm). Fig. 3(a) and (b) shows the current density and luminance versus applied voltage characteristics and the external quantum efficiency (EQE) and power efficiency (PE) of the blue homojunction devices with various host materials. Fig. 3(a) shows that the current densities of the 46DCzPPm- and 26DCzPPy-based blue devices are almost identical, but the 46DCzPPm-based device exhibits a rather low turn-on voltage of 2.6 V (luminance of 1 cd m^{-2} was detected) and a low driving voltage of 3.1 V at 100 cd m^{-2} and 3.9 V at 1000 cd m^{-2}. Although the 35DCzPPy-based device shows a poor current density versus voltage characteristic, which could be due to inefficient charge carrier injection, a EQE of 12.9%, corresponding to a current efficiency (CE) of 27.2 cd A^{-1} with a PE of 19.6 lm W^{-1} was obtained at 100 cd m^{-2}, which is much higher than the EQE (9.1%) for the 46DCzPPm-based device with a current efficiency of 20.5 cd A^{-1} and a PE of 20.9 lm W^{-1}. High efficiencies of 10.0%, 11.6 lm W^{-1}, and 7.0%, 12.8 lm W^{-1} were realized at 1000 cd m^{-2} for the 35DCzPPy- and 46DCzPPm-based devices, respectively. Although it has been reported that 26DCzPPy is a well-known host material for FIrpic-based blue OLEDs with a heterojunction structure, efficiencies of 8.0%, 13.5 lm W^{-1} at 100 cd m^{-2} and 7.2%, 9.5 lm W^{-1} at 1000 cd m^{-2} did not show an excellent performance in a homojunction structure made during this study [14,15].

Encouraged by the results of blue *p–i–n* homojunction devices, 46DCzPPm, 26DCzPPy and 35DCzPPy were also used as host materials for fabricating $Ir(ppy)_3$-based green and $Ir(piq)_3$-based red homojunction OLEDs. Fig. 3(c) and (d) shows the current density and luminance versus applied voltage characteristics, EQE and PE of the $Ir(ppy)_3$-based green devices. Here we found out that there is an obvious difference between the *J–V* performances of the 46DCzPPm- and 26DCzPPy-based green devices. This result is quite different from the 46DCzPPm/26DCzPPy-based blue devices with almost identical *J–V* characteristic. Taking the difference in the *J–V* performance caused by using different emitting dopant into account, we could make a conclusion that the emitting dopants could have a strong influence on the charge carrier transport of the emission layer. The 46DCzPPm-based device shows high

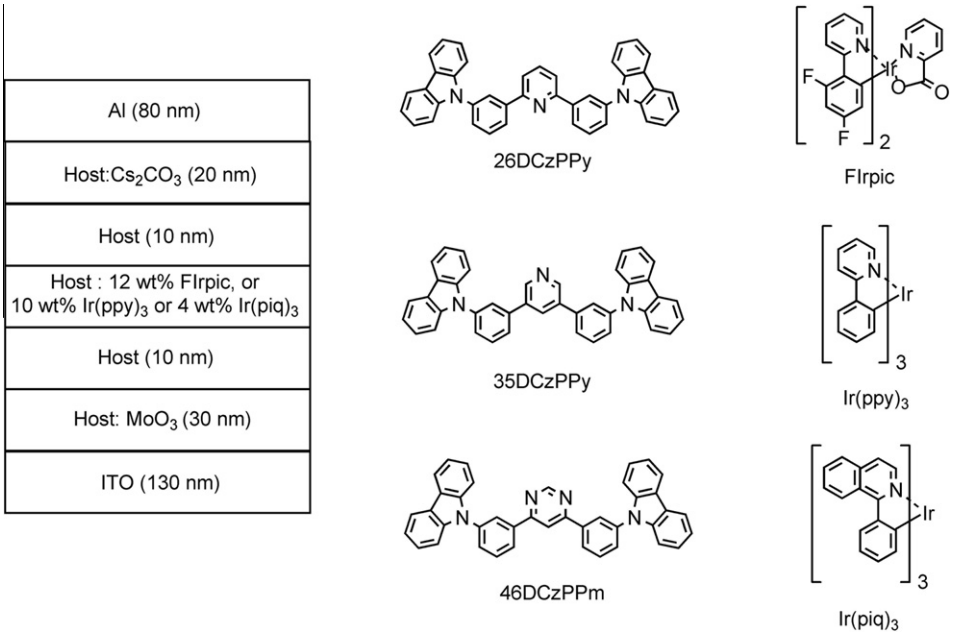

Fig. 2. Device structure of the *p–i–n* homojunction phosphorescent OLEDs. Also shown the structures for host materials 26DCzPPy, 35DCzPPy, 46DCzPPm and emitting dopants FIrpic, $Ir(ppy)_3$ and $Ir(piq)_3$.

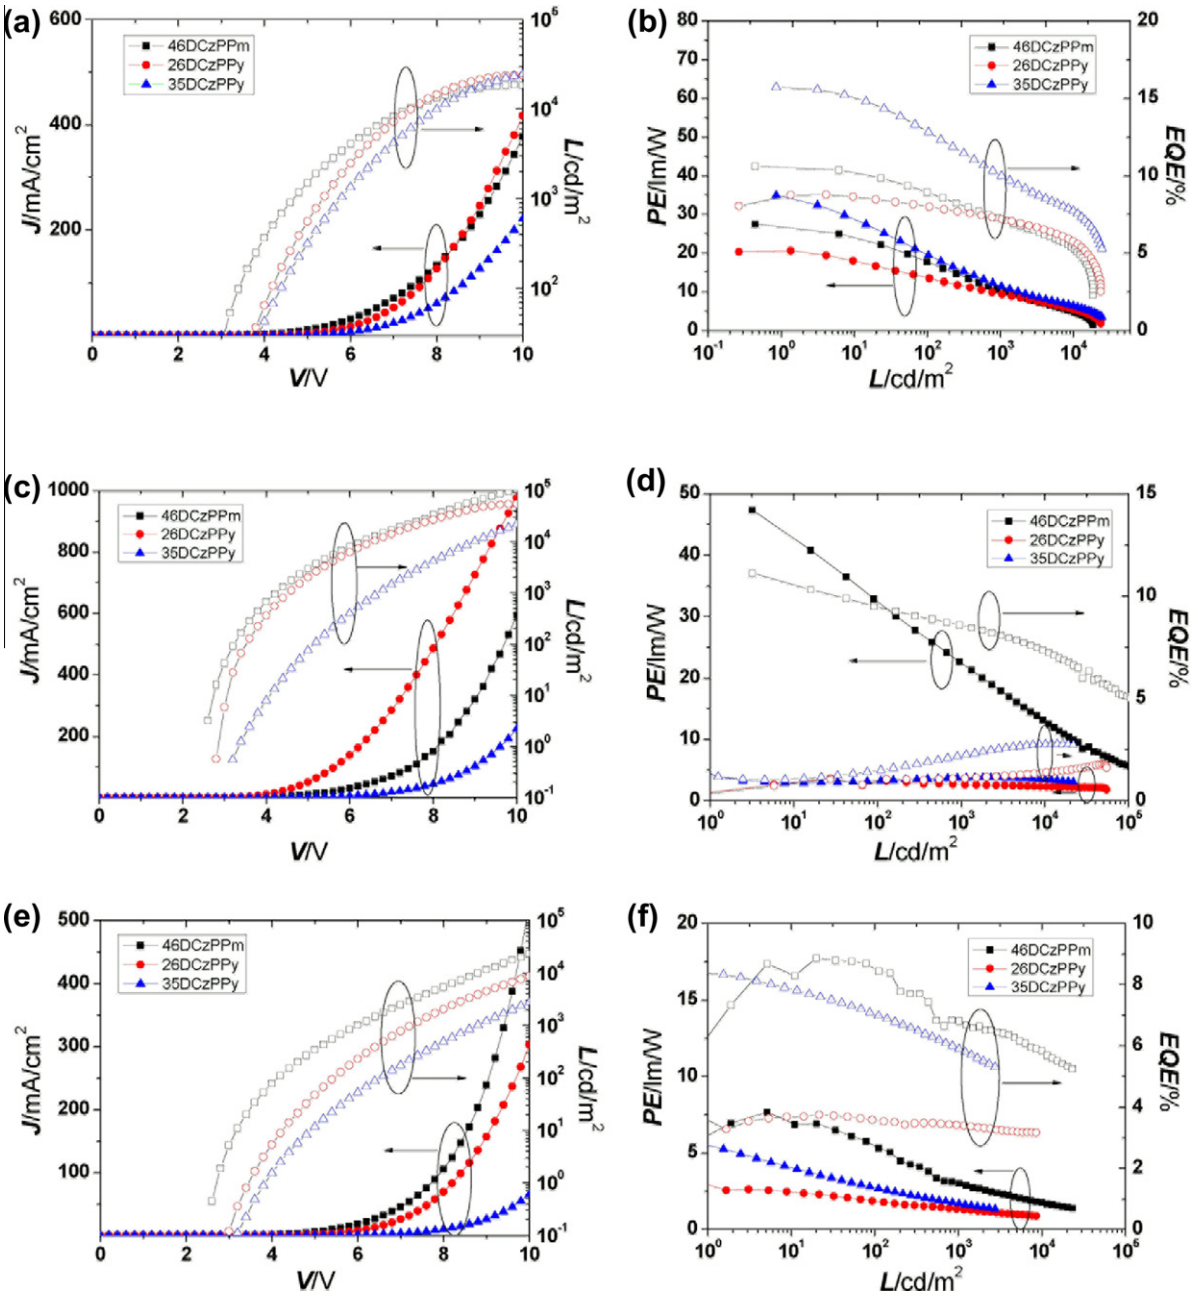

Fig. 3. *J–V–L* and power- and current efficiency characteristics of phosphorescent *p–i–n* homojunction OLEDs: ITO/host:MoO_3 (30 nm)/host (10 nm)/host:dopant (30 nm)/host (10 nm)/host:Cs_2CO_3 (20 nm)/Al by using 46DCzPPm (■□), 26DCzPPy (●○) and 35DCzPPy (▲△). (a) and (b): blue devices by using 12 wt.% FIrpic as a dopant; (c) and (d): green devices by using 8 wt.% $Ir(ppy)_3$ as a dopant; (e) and (f): red devices by using 4 wt.% $Ir(piq)_3$ as a dopant. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

efficiencies of 9.5%, 32.5 lm W^{-1} and 8.6%, 22.4 lm W^{-1} at 100 and 1000 cd m^{-2}, respectively. However, to our surprise, the 26DCzPPy- and 35DCzPPy-based devices show quite low EQE of less than 5% which is far below the typical phosphorescent efficiency.

For the $Ir(piq)_3$-based red phosphorescent homojunction devices, whose performances were shown in Fig. 3(e) and (f), the 46DCzPPm-based device shows high efficiencies of 8.5%, 5.5 lm W^{-1}, and 6.8%, 3.0 lm W^{-1} at 100 and 1000 cd m^{-2}, respectively. Although the 35DCzPPy-based device also shows high EQE of 7.0% at 100 cd m^{-2} and 5.9% at 1000 cd m^{-2}, its quite high driving voltage, which could probably be attributed to inefficient charge carrier injection from electrodes into the emission layer, leads to low power efficiency of only 2.7 and 1.7 lm W^{-1} at 100 and 1000 cd m^{-2}, respectively. For the 26DCzPPy-based device, EQE of 3.6% at 100 cd m^{-2} and 3.4% at 1000 cd m^{-2} were realized. These results are more

Table 3
Performance data of red, green and blue *p–i–n* homojunction devices by using 46DCzPPm, 26DCzPPy and 35DCzPPy.

Dopant material	Host material	Turn on voltage	Performance at 100 cd m^{-2}			Performance at 1000 cd m^{-2}		
		(V)	V (V)	EQE (%)	PE (lm W^{-1})	V (V)	EQE (%)	PE (lm W^{-1})
Flrpic	46DCzPPm	2.6	3.1	9.1	21.0	3.9	7.0	12.8
	26DCzPPy	2.9	4.2	8.0	13.5	5.4	7.2	9.5
	35DCzPPy	3.3	4.4	12.9	19.6	5.8	10.0	11.6
lr(ppy)3	46DCzPPm	2.5	3.2	9.5	32.5	4.2	8.6	22.4
	26DCzPPy	2.8	3.5	0.9	2.9	4.5	1.1	2.6
	35DCzPPy	3.3	5.1	1.5	3.2	6.7	2.2	3.7
$lr(piq)_3$	46DCzPPm	2.7	4.1	8.5	5.5	6.0	6.8	3.0
	26DCzPPy	3.4	5.4	3.6	1.8	7.2	3.4	1.3
	35DCzPPy	3.8	6.5	7.0	2.7	8.8	5.9	1.7

efficient than the previously reported $Ir(piq)_3$-based homojunction devices [11]. Regarding the *J–V* characteristics, which are shown in Fig. 3(e), the 46DCzPPm-based device showed a better performance than the 26DCzPPy-based device, proving that there is a strong relationship between the charge carrier transport and the emitting dopant. All device performance data are summarized in Table 3.

2.3. Influence of carrier balance and position of recombination zone of holes and electrons on performances of homojunction devices

Charge carrier balance is a quite important factor for the performance of an OLED, and EQE is directly related to the balance of holes and electrons in the devices [6]. For maximizing the efficiency of an OLED, we need to confine the recombination zone in the bulk of emission layer. However, for homojunction devices, partially due to the lack of hole/electron-blocking layers, the main recombination zone of holes and electrons could not be effectively confined. Instead, the recombination zone resembles to be smeared out in the 30-nm-thick emission layer. Thus, generated excitons that have long diffusion length could be quenched by *p*-type dopant MoO_3 or *n*-type dopant Cs_2CO_3. The generated excitons could also be harvested by the 10-nm-thick intrinsic bipolar host, which leads to an efficiency loss, resulting in a visible fluorescent emission of the intrinsic bipolar host [16]. This can be observed in the EL spectrum of the 26DCzPPy:$Ir(ppy)_3$-based green homojunction device (shown in Supporting Information). Thus, there exists a strong relation between the position of the recombination zone of charge carriers and the EQE of the device.

Firstly, in order to find out the main factor for the quite low efficiency in the 26DCzPPy:$Ir(ppy)_3$-based *p–i–n* homojunction device and investigate the carrier balance so as to probe the position of the recombination zone, the following control device comprising a 5-nm-thick 26DCzPPy doped with 1 wt.% 4-(dicyanomethylene)-2-tert-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran (DCJTB) layer, which is close to the cathode side, was fabricated with the structure: ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (10 nm)/26DCzPPy:$Ir(ppy)_3$ (10 wt.%, 30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm). In this device, red fluorescent material DCJTB was doped at 1 wt.% into the device to act as a sensor that aims to probe the density of charge carrier via EL spectrum of the device. The influence of DCJTB on the transport characteristic of the device could be negligible due to the quite low doping concentration of only 1 wt.%. In Fig. 4(a), for the device containing a 26DCzPPy: DCJTB layer close to the cathode side, a typical phosphorescent emission from $Ir(ppy)_3$ peaking around 520 nm was found. There also exists an obvious fluorescent emission resulted from the host near 430 nm. The EL spectrum of another control device containing a 26DCzPPy: DCJTB layer close to the anode side with the structure ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:$Ir(ppy)_3$ (10 wt.%, 30 nm)/26DCzPPy (10 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm) was shown in Fig. 4(b). As expected, this device also shows a vivid emission from $Ir(ppy)_3$, however, a clear visible emission from DCJTB around 600 nm replaces the fluorescent emission of 26DCzPPy around 430 nm that appeared in the control device containing a 26DCzPPy: DCJTB layer close to the cathode side. The possible reason for these two different EL spectra is that in the 26DCzPPy: $Ir(ppy)_3$-based device containing a 26DCzPPy:DCJTB layer close to cathode side, few holes are able to go across the 30-nm-thick 26DCzPPy:$Ir(ppy)_3$ layer and reach the 26DCzPPy:DCJTB layer so as to generate a fluorescent emission, whereas for the 26DCzPPy:$Ir(ppy)_3$-based device containing a 26DCzPPy: DCJTB layer close to the anode side, the EL spectrum including a vivid emission from DCJTB indicates that significant amount of electrons could transport through the 26DCzPPy:$Ir(ppy)_3$ layer. Thus a large number of holes are recombined in the 5-nm-thick 26DCzPPy:DCJTB layer, generating a clear visible fluorescent emission from DCJTB, indicating that the 26DCzPPy-based green *p–i–n* homojunction device is hole deficient and the recombination zone should be quite close to the anode side. The EL spectrum of the device containing a DCJTB-doped layer close to anode side varies significantly depending on the current density of the device, which increases from 0.25 to 25 mA cm^{-2}. The increasing intensity of $Ir(ppy)_3$ and decreasing intensity of DCJTB with increasing current

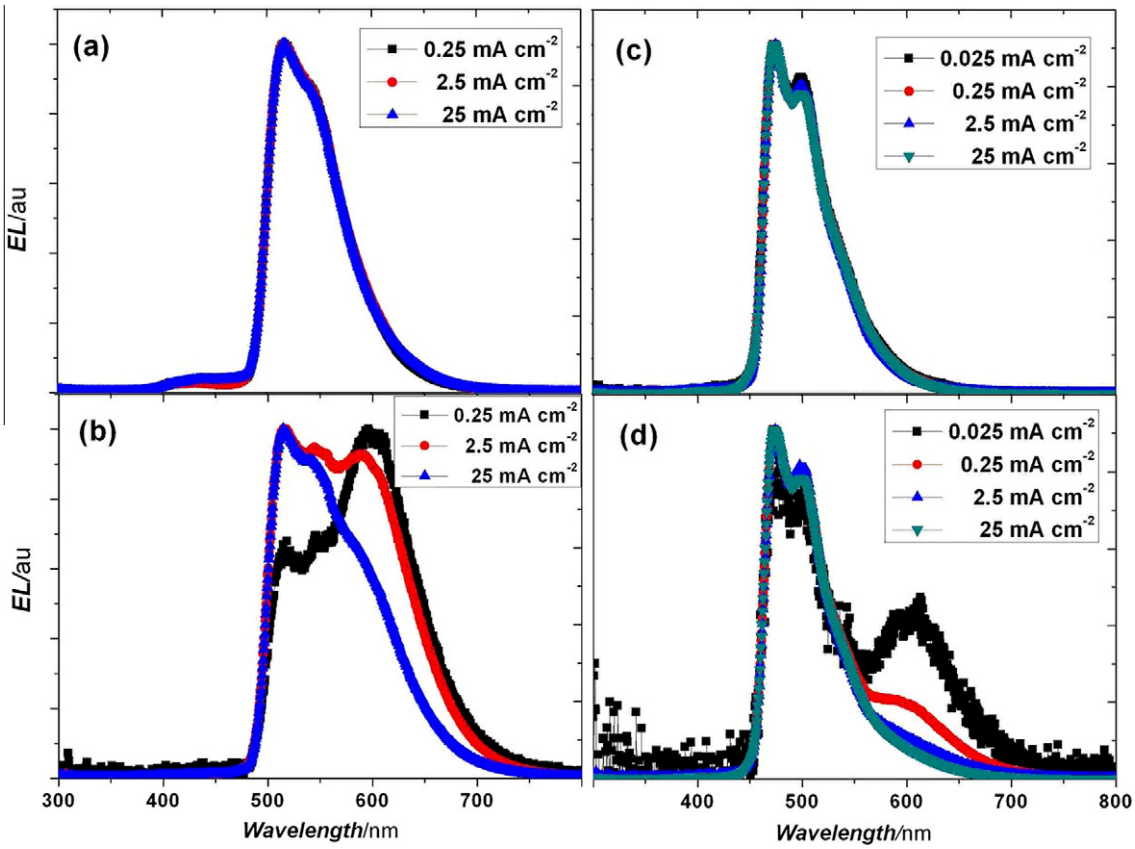

Fig. 4. EL spectra for the devices containing DCJTB. (a) ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (10 nm)/26DCzPPy:Ir(ppy)$_3$ (10 wt.%, 30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm). (b) ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:Ir(ppy)$_3$ (10 wt.%, 30 nm)/26DCzPPy (10 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm). (c) ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (10 nm)/26DCzPPy:FIrpic (12 wt.%, 30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm). (d) ITO/26DCzPPy:MoO_3 (30 nm)/26DCzPPy (2.5 nm)/26DCzPPy:DCJTB (1 wt.%, 5 nm)/26DCzPPy (2.5 nm)/26DCzPPy:FIrpic (12 wt.%, 30 nm)/26DCzPPy (10 nm)/26DCzPPy:Cs_2CO_3 (20 nm)/Al (80 nm).

density indicates the shift of the recombination zone from the anode side to the 30-nm-thick 26DCzPPy:Ir(ppy)$_3$ layer. An improved charge carrier balance attributed to the stronger hole injection when the device is under a higher external biased voltage is beneficial for the efficiency.

Considering that 26DCzPPy should be an excellent bipolar host material with well-balanced hole and electron mobilities that is shown in Table 1, the poor carrier balance is not believed to be due to low mobility of the host material, but probably due to the deficient hole injection from the anode into the emission layer. Although a 26DCzPPy:Ir(ppy)$_3$-based homojunction device was found to be hole deficient, when the blue phosphorescent material FIrpic was used as the emitting dopant, an EQE of 8.0% of the FIrpic-based blue device at 100 cd m^{-2} was obtained, which is even higher than that of the 26DCzPPy:Ir(ppy)$_3$-based device. The EL spectrum of the 26DCzPPy:FIrpic-based device (shown in Supporting Information) shows a pure emission from FIrpic without any fluorescent emission from 26DCzPPy. DCJTB was also doped at 1 wt.% into 26DCzPPy:FIrpic-based homojunction device in order to investigate its carrier balance. For the 26DCzPPy:FIrpic-based device comprising a 26DCzPPy:DCJTB layer close to cathode side, its EL spectrum shown in Fig. 4(c) does not include any emission from DCJTB. For the device comprising a 26DCzPPy:DCJTB layer close to anode side, there still exists an obvious fluorescent emission from DCJTB in the EL spectrum shown in Fig. 4(d), it can be observed that the intensity of DCJTB is far weaker than that of FIrpic, indicating a sharply decreased density of electrons in 5-nm-thick 26DCzPPy:DCJTB layer that is close to anode side. Thereby, compared with the 26DCzPPy:Ir(ppy)$_3$-based device, the improved EQE in the 26DCzPPy:FIrpic-based device should be probably due to the electron-trapping function of FIrpic that could decrease the electron current in the device and effectively improve the position of the charge carrier recombination zone throughout the device.

Carrier balances of other green and blue homojunction devices by using 46DCzPPm or 35DCzPPy as host material were also examined by observing EL spectra of DCJTB-doped devices (shown in Supporting Information). These EL spectra reveal that the 46DCzPPm/35DCzPPy-based devices are hole deficient and FIrpic functions as an electron trap, which could benefit EQE. We noticed that these devices are also hole deficient which may be attributed to

inefficient hole injection from anode to *p*-doped host layer since there should be no problem for hole transport in these hosts as they are balanced bipolar host materials.

There are obvious differences in device performances by using 26DCzPPy, 35DCzPPy, and 46DCzPPm, for example, which are the driving voltage and EQE. For the 46DCzPPm-based devices, the turn-on voltage of 2.6 V for blue, 2.5 V for green and 2.7 V for red devices are lower than that of other RGB devices by using 26DCzPPy or 35DCzPPy as a bipolar host. It seems that 46DCzPPm is the most suitable one for fabricating homojunction devices, because only it gives high efficiencies of 10.2% for blue, 11.1% for green and 8.9% for red devices under maximum EQE. This could be attributed to the fact that the poor hole supply in these homojunction devices causes the recombination zone to be close to anode side, therefore, the host with best hole injection/transport will give the best performance. From performance of hole-only devices that is shown in Fig. 1(a), we know that the 46DCzPPm-based device has the best hole injection/transport, which benefits a well-balanced system [18–20].

2.4. Electron transport characteristics of emission layers doped with FIrpic, Ir(ppy)$_3$ and Ir(piq)$_3$

From the discussion above, the 46DCzPPm-, 26DCzPPy- and 35DCzPPy-based homojunction devices were found out to be hole deficient and the recombination zones in these devices are close to ITO side. In this case, the charge trapping effect of emitting dopant will play an important role in these devices. If the emitting dopant can trap electrons, further decreasing the electron transport and improving the recombination zone of charge carriers, then the device could show a better performance.

Usually, when a guest with narrow band gap was doped into a host with a wide band gap, the energy difference of HOMO/LUMO levels between the guest and the host will be quite significant, and then the guest could become a deep trap due to this difference [17]. Energy levels HOMO (the highest occupied molecular orbital), LUMO (the lowest unoccupied molecular orbital), and triplet energy levels (T_1) of the materials used in this work were summarized in Table 2 [12]. The HOMO levels of Ir(ppy)$_3$ (5.4 eV) and Ir(piq)$_3$ (5.1 eV) are much shallower than those of the bipolar host materials (6.05 eV for 26DCzPPy, 6.18 eV for 35DCzPPy and 6.19 eV for 46DCzPPm), and the LUMO levels of Ir(piq) (3.1 eV) and FIrpic (3.47 eV) are deeper than those of the bipolar host materials (2.65 eV for 26DCzPPy, 2.75 eV for 35DCzPPy and 3.06 eV for 46DCzPPm). Thus in this host/guest system, Ir(ppy)$_3$ and Ir(piq)$_3$ could trap holes while FIrpic and Ir(piq)$_3$ could effectively trap electrons. Ir(ppy)$_3$ seems not to function as a electron-trap state probably due to its high LUMO level (2.4 eV).

To further demonstrate the influence of the emitting dopants FIrpic, Ir(ppy)$_3$ and Ir(piq)$_3$ on hole/electron transport of a 30-nm-thick emission layer, hole-only devices with a structure of ITO/NPD (20 nm)/26DCzPPy (10 nm)/26DCzPPy:12 wt.% FIrpic or 10 wt.% Ir(ppy)$_3$ or 4 wt.% Ir(piq)$_3$/26DCzPPy (10 nm)/NPD (20 nm)/Al (80 nm) and electron-only devices with a structure of ITO/1,3,5-tri (p-pyrid-3-yl-phenyl)benzene (TpPyPB) (10 nm)/26DCzPPy (10 nm)/26DCzPPy:12 wt.% FIrpic or 10 wt.% Ir(ppy)$_3$ or 4 wt.% Ir(piq)$_3$/26DCzPPy (10 nm)/TpPyPB (20 nm)/LiF (0.5 nm)/Al (80 nm) were fabricated. Fig. 5 shows the current density versus applied voltage characteristics of these devices. For the hole-only devices doped with 4 wt.% Ir(piq)$_3$ or 10 wt.% Ir(ppy)$_3$ those are shown in Fig. 5(a), they show a clearly decreased current density than that of the device with an intrinsic 30-nm-thick 26DCzPPy layer due to the hole trapping functions of Ir(ppy)$_3$ and Ir(piq)$_3$. Besides, FIrpic does not show any hole trapping effect just due to its deep HOMO level of 6.15 eV. In Fig. 5(b), compared with the electron-only device with an intrinsic 30-nm-thick 26DCzPPy layer, devices doped with 4 wt.% Ir(piq)$_3$ show a notably decreased current density which could be due to the electron-trapping function of Ir(piq)$_3$. FIrpic also shows electron-trapping function because after the turn-on voltage the current density increasing of the 26DCzPPy:FIrpic-based device is slower

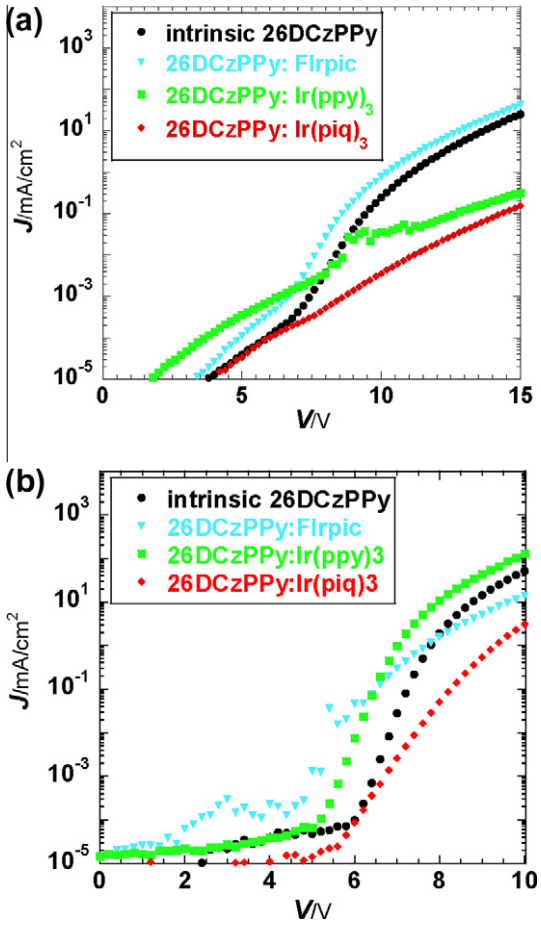

Fig. 5. Current density-driving voltage characteristics of the hole/electron-only devices for evaluating hole/electron transport of 26DCzPPy-based emission layers doped with FIrpic, Ir(ppy)$_3$ or Ir(piq)$_3$. (a) hole-only devices with a structure of ITO/NPD (20 nm)/26DCzPPy (10 nm)/26DCzPPy:12 wt.% FIrpic, or 10 wt.% Ir(ppy)$_3$ or 4 wt.% Ir(piq)$_3$ (30 nm)/26DCzPPy (10 nm)/NPD (20 nm)/Al. (b) electron-only devices with a structure of ITO/TpPyPB (10 nm)/26DCzPPy (10 nm)/26DCzPPy:12 wt.% FIrpic, or 10 wt.% Ir(ppy)$_3$ or 4 wt.% Ir(piq)$_3$ (30 nm)/26DCzPPy (10 nm)/TpPyPB (20 nm)/LiF (0.5 nm)/Al.

than that of the intrinsic 26DCzPPy-based device. Hence, the position of recombination zone in the 26DCzPPy:FIrpic/Ir(piq)$_3$-based homojunction devices could be sufficiently far away from the anode side, thereby confining charge carriers in the 30-nm-thick emission layer and eliminating the fluorescent emission from the 10-nm-thick intrinsic 26DCzPPy close to the anode. This also leads to the knowledge that most of triplet excitons are confined in the 30-nm-thick emitting layer. Current density versus voltage characteristic of the electron-only devices comprising 26DCzPPy:Ir(ppy)$_3$ layer reveals that Ir(ppy)$_3$ could keep, or slightly enhance the electron transport performance of the emission layer, making a worse carrier balance, which leads to an efficiency loss. The influence of emitting dopants doped into 35DCzPPy and 46DCzPPm on hole/electron transport were also examined (shown in Supporting Information). The results imply that Ir(ppy)$_3$ and Ir(piq)$_3$ efficiently function as hole traps and FIrpic as well as Ir(piq)$_3$ are electron traps due to their HOMO/LUMO energy level alignments when they are doped into 35DCzPPy/46DCzPPm. Ir(ppy)$_3$ can also function as an electron trap only when it is doped into 46DCzPPm, resulting in a high EQE of 9.5% at 100 cd m^{-2} in the 46DCzPPm:Ir(ppy)$_3$-based homojunction device.

3. Conclusion

In conclusion, efficient *p–i–n* homojunction OLEDs were reported that emit across the full visible color range by using a series of bipolar host materials. Several record efficiencies of 12.9% for blue, 9.5% for green, and 8.5% for red homojunction devices (at 100 cd m^{-2}) were achieved. Performance of these homojunction OLEDs is strongly dependent on the well-balanced charge carrier injection and transport of injected holes and electrons. With suitable chemical adjustment in the material structure, it is possible to obtain a more well-balanced bipolar host material. Hereby the performance of homojunction devices can be enhanced. However, for the present homojunction devices shown in this study, we did not do any further optimization and there still remains room for improvement. For example, with carefully varying the concentration of emitting dopant, we can adjust the transport performance of the organic layer. In this way, carriers can be confined in the emission layer, and a better efficiency can be expected.

4. Experimental

All devices were grown on glass substrates pre-coated with a ~130 nm thick of ITO. The substrates were cleaned with ultra purified water and organic solvents, and then dry-cleaned for 30 min by exposure to an UV-ozone ambient. All the organic layers were deposited by vacuum evaporation. The fabrication procedure of the hole-only device is described as follows: first, a bipolar host was codeposited with MoO_3 for a thickness of 30 nm, followed by an intrinsic 10-nm-thick host material. After that another 10-nm-thick NPD layer was deposited successively. Cathodes consisting of a 80-nm-thick layer Al were patterned using a shadow mask with an array of 2×2 mm^2 openings. For the electron-only devices, firstly a 10-nm-thick BCP layer was deposited, followed by an intrinsic 30-nm-thick host material. Then an *n*-doped transport layer was deposited by co-evaporation of host material and Cs_2CO_3, following a 80-nm-thick Al layer of cathode.

The fabrication procedure of homojunction devices is described as follows: first, the bipolar host with MoO_3 was deposited with a thickness of 30 nm, followed by a 10-nm-thick intrinsic host material. Subsequently, the emitting layer consisting of the host material doped with 12 wt.% FIrpic for blue, 10 wt.% Ir(ppy)$_3$ for green or 4 wt.% Ir(piq)$_3$ for red devices was deposited with a thickness of 30 nm, followed by another 10-nm-thick intrinsic host material. After that an *n*-doped transport layer was deposited by co-evaporation of host material and Cs_2CO_3. Then, a 80 nm-thick Al layer was vacuum deposited and the active area of the devices was defined as 2×2 mm^2 by using a shadow-mask. All devices were encapsulated by a glass lid with a getter attached under nitrogen atmosphere.

methods and comparing in some cases the two different contributions [3]. No direct correlation between the contributions in-dark and in-light to the electrical properties has been reported as measured on the same device.

It is known that the electrical conduction in liquid crystals and in particular in phthalocyanine-based materials is greatly affected by contaminants and environmental conditions [11,28–32]. Although a controlled doping produces a strengthening of the sensing capability, it becomes a major limitation in organic electronics applications. The amount of contaminants is less controllable when the films are deposited or cast starting from solutions, where the solvent itself or the process can provide dopants, determining unstable electrical response.

2. Experiments, results and discussion

In our work we simultaneously measured the photocurrent and the current in-dark vs. time and temperature. These measurements allow us to assess the instability of the electrical measurements and the influence of contaminants on the electrical device response.

Here we used a metal-free mesogenic phthalocyanine 2(3),9(10),16(17),23(24)-tetra(2-decyltetradecyloxy)-phthalocyanine (H_2Pc) (Fig. 1), containing very low level of ionic impurities (see Supporting information of Ref. [20]). H_2Pc is a prototype DLC compound exhibiting a columnar rectangular (Col_r) ↔ columnar hexagonal (Col_h) phase transition at T_{rh} = 333 K [33].

When a H_2Pc thin film is deposited onto a surface, in general the planar alignment of columns is spontaneously achieved regardless of the nature of the surface [33]. We performed the experiment on a thin film of H_2Pc deposited in-between two interdigitated electrodes on a test pattern with a bottom-contact layout (Fig. 2) using a sourcemeter–femtoammeter to bias the device and measure the DC current flow. Details of set-up is described in Ref. [34]. We biased the device with a voltage V = 5 V and acquired current measurements repeating thermal cycles between 303 K and 363 K at a controlled rate of 1.0 K/min. We chose this range because it is the most common condition of working temperatures without relevant effects on reorganization or on electrically induced dewetting [27];

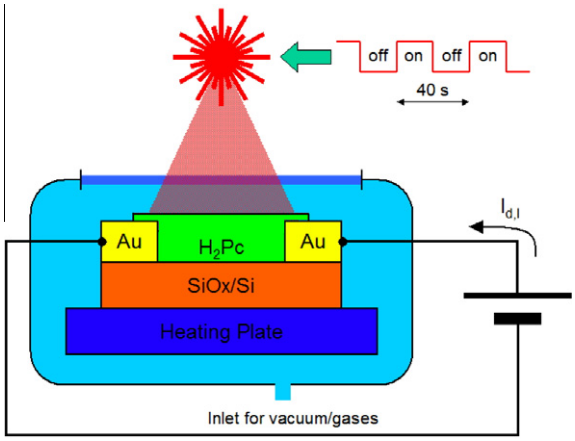

Fig. 2. Experimental setup, including the heating stage and the laser, which illuminates the sample with intermittent light during the thermal cycles.

furthermore within this range the Col_r–Col_h phase transition is expected [20]. All the measurements were performed in vacuum (P = 0.01 mbar) by illuminating the film during the thermal cycles with an intermittent light (frequency = 1/40 s) whose 680 nm wavelength is near to the maximum absorption of H_2Pc [20]. The experiment output is a set of alternating dark and light (indicated as I_d and I_l, respectively) DC current measurements.

Fig. 3a shows the I_d measurement. The triangular shape of the projection in the (t, T) plane represents the temperature sweep performed by the heating stage, assuming t_0 = 0 at 303 K as starting point and using a heating/cooling rate of 1 K/min (thus arriving to the temperature of 363 K after 1 h); the temperature is then returned to 303 K and the cycle is repeated 10.5 times. In Fig. 3b the corresponding I_l values are shown. With an interpolation routine (see methods) we generated the I_d (t, T) and the I_l (t, T) surfaces presented in Fig. 3a and b. By subtracting I_d from the corresponding I_l values we extracted the photocurrent contribution (I_p), which is due to excited H_2Pc states generated by light absorption (Fig. 3c) [35]. The noise level in the I_l and I_d measurements was less than 6pA rms, making the calculated values of I_p at least 11 times bigger than its

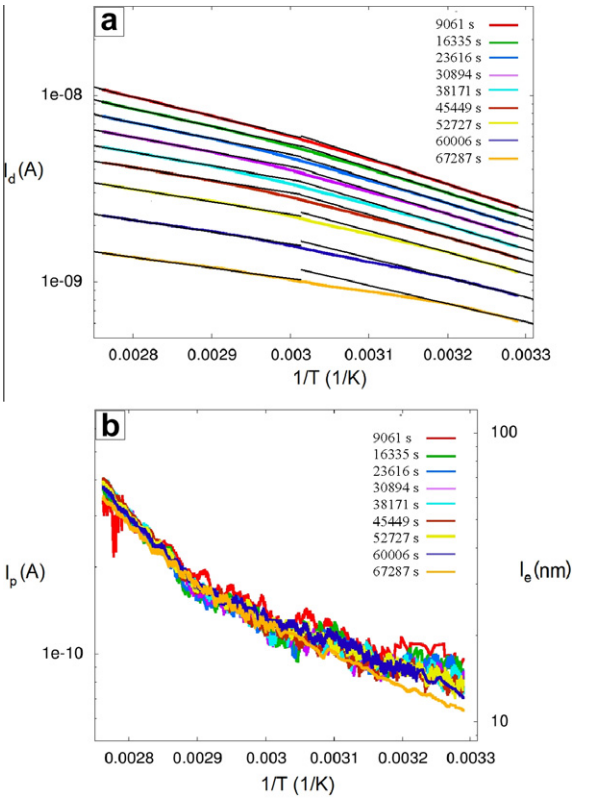

Fig. 4. Dependence of current in-dark (I_d) (a), photocurrent contribution (I_p) (b, left axis) and photogenerated charge carriers diffusion length (l_e) (b, right axis) from the absolute temperature for fixed times (A = 9061 s, B = 16,335 s, C = 23,616 s, D = 30,894 s, E = 38,171 s, F = 45,449 s, G = 52,727 s, H = 60,006 s, I = 67,287 s).

indetermination $\sigma_{Ip} = \sqrt{2} \cdot \sigma_{Id}$ (see details of error analysis in Section 4.5).

We find that I_p is almost independent on time, in contrast with I_d (t, T) and I_l (t, T).

Fig. 4a shows sections of the surface I_d (t, T) performed at intervals of 2 h in an Arrhenius plot.

We identified two different activated regimes corresponding to each liquid crystalline phase:

$$I_d = \begin{cases} A_r \cdot \exp(-\frac{E_r}{k_B T}) & T < T_{rh}; \\ A_h \cdot \exp(-\frac{E_h}{k_B T}) & T > T_{rh}. \end{cases} \quad (1)$$

The prefactor A_r and the activation energy E_r belong to the Col_r phase, while A_h and E_h to the Col_h phase. T_{rh} is the temperature of the Col_r–Col_h phase transition. We identified the two regimes and we extracted the prefactors and the activation energies without fixing a priori T_{rh}. Then we calculated the temperature where the two lines in the Arrhenius plot corresponding to the two regimes of Eq. (1) intersect each other. This temperature (328.40 ± 5.07) K is in good agreement with the DSC results (331.45 K) [36].

Both A_r and A_h decrease in time with a decay constant of respectively 6420 (±590) s and 5451 (±146) s. From the fit according to Eq. (1) we extracted E_r = (0.245 ± 0.024) eV and E_h = (0.153 ± 0.030) eV. Assuming the Drude model, the in-dark current is given by:

$$I_d = q \cdot p(t, T) \cdot \mu_p \cdot V \cdot d \cdot W \cdot L^{-1} \quad (2)$$

where q is the elementary charge, $p(t, T)$ the number density of holes, μ_p their mobility, V is the electrical potential and d, W, L, the channel height, width and length, respectively.

By performing experiments in different atmospheric conditions (air, N_2, H_2O_2 vapours), thus in very different doping conditions, we obtained similar value of E_r and E_h.

Since in our range of T, μ_p is almost constant or weakly dependent on temperature [5] and time [20,21], the change of I_d with time and temperature can be ascribed to the change (decrease) of doping levels and possibly to the reorganization of ionic impurities inside the H_2Pc thin film [32].

The holes responsible for the electrical p-conduction are induced in the HOMO level by the presence an acceptor level introduced by doping [37]. This acceptor level is distant from the HOMO by E_r and E_h, depending on temperature. The change of activation energy at the Col_r–Col_h transition can be assigned to the stacking of H_2Pc molecules. In the Col_r mesophase, the normal to the disk-like molecules is

tilted by $\alpha = 15–18°$ vs. the column axis, whereas in Col_h mesophase is parallel [20]. The two supramolecular arrangements impose different overlaps between stacked molecules that finally impact on the energy of the HOMO level and consequently on its distance in energy with respect to the acceptor level.

The prefactors A_r and A_c are proportional to the doping level (number of acceptor states) in the film [38,39]. The fact that they decay in time can be interpreted as after the fabrication process relatively a high level of doping remains in the film. This is consistent with oxygen doping from air. By keeping the film in vacuum during the thermal cycles, the contaminants are progressively removed (evaporated).

By exciting the H_2Pc molecules in the film with the laser electron–holes pairs are generated [20,35] and their contribution to the current is independent from the doping level introduced during the film growth. The following equation for the photocurrent flowing between the electrodes in the case of intrinsic semiconductors applies [40]:

$$I_p = q \cdot \eta \cdot \frac{P_{opt}}{h\nu} \cdot \frac{(\mu_n + \mu_p) \cdot \tau \cdot V}{L^2} \tag{3}$$

where η is the quantum efficiency (i.e.; number of carriers generated per photon absorbed), P_{opt} the optical power, h the Planck constant, ν the frequency of the incident photons, τ the carriers lifetime, μ_{n-p}, respectively the electrons and holes mobility and L the channel length, viz. the distance between the electrodes. $q \cdot \eta \cdot P_{opt} \cdot (h \cdot \nu)^{-1}$ is the primary photocurrent.

Considering that the photogenerated charge carriers diffusion length l_e is the distance travelled by the carriers with a drift velocity $\langle v_n \rangle + \langle v_p \rangle = (\mu_n + \mu_p) \cdot V \cdot L^{-1}$ during their lifetime τ, the relationship between the diffusion length and the channel length is equal to the ratio between the measured photocurrent and the primary photocurrent:

$$\frac{\langle l_e \rangle}{L} = \frac{I_p}{q \cdot \eta \cdot \frac{P_{opt}}{h\nu}} \tag{4}$$

Fig. 4b shows the plot of I_p and l_e vs. temperature. l_e is obtained upon re-scaling the time-sections of the surface $I_p(t, T)$ by the constant factor $L \cdot q^{-1} \cdot \eta^{-1} \cdot P_{opt}^{-1} \cdot h\nu$, assuming a quantum efficiency $\eta = 0.5\%$, which is the value reported in Ref. [16] for phthalocyanines. The diffusion length increases with temperature, varying from 10 to 70 nm. This value, of the order of few hundreds molecular cores, is consistent with the reported excitons migration length [41] and intra column coherence length (150 nm) obtained by XRD [42] on DLCs.

We systematically observed two activated regimes in the I_p vs. temperature plot, but we did not find a significant correlation with the temperature of the Col_r–Col_h phase transition. Applying the same analysis as the one reported for I_d, we extracted a temperature of 344 ± 3 K for the example of Fig. 4b, and a mean value of 339 ± 10 K among different experiments performed in vacuum. Noticeably, in contrast with the measurements in-dark, we systematically observed that the average activation energy at low temperatures $E_{LT}^{p} = 0.125 \pm 0.047$ eV is smaller than the activation energy at high temperatures $E_{HT}^{p} = 0.509 \pm 0.067$ eV.

Furthermore, also in the case of the I_p curves, tiny fluctuations in the transport properties are present that seem to be correlated with the elapsed time. In Fig. 4b a small change in the local slope at the lowest temperatures is observed, suggesting slow reorganization dynamics affecting the photocurrent at these temperatures. From the linear fits in the range 0.0031–0.0033 K^{-1} the slopes increase of about three times, from −737.4 K at 9061 s to −2387.1 K at 67,287 s. This behaviour is not systematic, either for the direction of the slope change or for the temperature range in which it occurs; it is still under investigation.

3. Conclusions

In conclusion we observed that the two measurements of DC current in-dark and photocurrent exhibit a very different behaviour with respect to the functional form and the stability over time and temperature.

The measurement in-dark is characterized by two activation energies that depend on the liquid crystalline phase, indicating a different relative position between the HOMO and the acceptor levels for each phase. The acceptor level can be introduced by doping during the fabrication process. Doping levels are mainly responsible for the conductivity of the film in-dark conditions, causing instabilities in the electrical measurements because during the experiment the contaminants are partially removed by evaporation or they reorganize [32]. This instability is particularly influent when the timescale for reorganization of dopants is comparable with the time scale of the temperature sweep. For this reason it is crucial to perform a procedure of interpolation, which leads to a time correction of the current vs. temperature curves in order to extract instantaneous $I_d(T)$ curves, as indicated here.

On the other hand, the functional form of the measurements at light reflects the photogenerated charge carriers diffusion length, which seems to be not much correlated with the film phase [20]. The amount of carriers in the photocurrent measurements is generated with the laser and is constant with temperature, in contrast to the measure in-dark, where the carriers are promoted by thermal excitation from acceptor states. The electric field separates the photo-generated carriers and the behaviour of I_p vs. temperature reflects the variation in the distance that carriers travel unperturbed until they find a structural defect or a trap. This distance can be indeed considered as the coherence (correlation) length of a column; we did not find any significant change of regime in the diffusion length of the photogenerated charge carriers that could be correlated with the phase transition. The observation that the current in-dark decreases in time (Fig. 3a), while the photocurrent contribution remains stable (Fig. 3c), suggests that the decay of I_d in time is not due to degradation of the material during the experiment. Here we used H_2Pc as representative material; however our approach is general and can be extended to other liquid crystals and more in general to other classes of organic materials such as molecular [43,44] or polymeric [45,46] semiconductors.

4. Experimental details

4.1. Substrate cleaning and film preparation

The test pattern is made up of a highly doped Si layer of 0.5 mm, with a 1 μm thick layer of thermal SiO*x*. The Au interdigitated electrodes are fabricated by photolithography and have a thickness of 150 nm. This test pattern was provided by Philips Research Laboratory, Eindhoven, The Netherlands. It features four devices with channel length equal to 10 μm and channel width equal to 10 mm.

We washed the test pattern with Heptane (HPLC grade) and we dry it with pure Nitrogen; then we washed it with Acetone (HPLC grade), drying with pure Nitrogen. We finally dip the test pattern in HF 4% for 20 s, washed it with electronic grade water and then dried it with pure Nitrogen. We put the substrate in an air plasma chamber (PELCO easiGlow 91000) for 10 min, setting $I = 30$ mA and $P = 0.4$ mbar.

After the cleaning procedure we deposited the H_2Pc film by spin coating from a 20 mg/mL solution in heptane (HPLC grade), setting the angular velocity to 2000 rpm. With these conditions we obtained a film 130 nm thick. We attached the film to the sample holder of the heating stage and made the electrical connections with silver paint. We baked the film at 313 K in vacuum ($P = 0.01$ mbar) for 30 min, then we heated it up to 456 K in order to induce the columnar organization, that we verified by optical microscopy using cross polarizers filters. We performed the same experiment described in the text on H_2Pc films in different ambient conditions, verifying the film stability during the experiment by using an optical microscope.

4.2. Determination of optical power transferred to the film (P_{opt}) and sample overheating by laser irradiation

To excite the sample we used a standard 680 nm laser diode with a nominal optical power of 1 mW coupled to a variable focus optic system. We determined the power deposited in the film P_{opt} using the formula:

$$P_{opt} = P_{laser} \cdot Ads \cdot L \cdot W \cdot s_{spot}^{-1} = 2.1 \cdot 10^{-5} W \quad (5)$$

where P_{laser} is the total power emitted by the laser in a spot of surface s_{spot}, $L{\cdot}W$ is the sensitive area of the device and Ads is the relation between the power transferred to the film and the power that arrives to the surface, i.e. excludes the power that is transferred to the substrate or reflected out of the sample. We measured the actual $P_{laser} = 0.4$ mW using a photodiode Thorlabs, Inc. model DET36A. We regulated the area of the spot to cover all the sensitive area of the device; then we measure $s_{spot} = 0.7 \times 10^{-6}$ m^2 from an image taken using the optical microscope. Also we took periodically images with the microscope to verify that the position of the laser remains unchanged during the experiment. To determine Ads we made a Monte Carlo simulation of the photons trajectory. It considers 10^7 photons arriving to a system which is made up of four layers: (1) air with an absorption coefficient $\alpha = 0$ and refractive index $n = 1$; (2) a 130 nm thick H_2Pc layer with $\alpha = 4.2 \cdot \times 10^4$ cm^{-1} and $n = 2.66$ [47]; (3) a 1 μm thick SiO*x* layer with $\alpha = 10$ cm^{-1} and $n = 1.46$; and (4) a 0.5 mm thick Si layer with $\alpha = 3 \times 10^3$ cm^{-1} and $n = 3.5$.

This simulation considers reflections at the interfaces and light attenuation in the different layers. The percentage of the laser power is distributed as follows: 37.1(6)% remains in the H_2Pc film, 0.0476(2)% in the SiO*x* layer, and 38.7(3)% in the Si layer. The remaining 24.1(5)% is reflected out of the sample.

Using these results we estimated that the increase of temperature between the bottom of the Si substrate and the H_2Pc top interface is less than 1 mK using a 1-D heat transmission model.

4.3. Experimental setup

The measurement system is based on a heating stage (Linkham TMHS600). We replaced one of the gas inlets of the heating stage with a feed through that allows the electrical connections from the sample to the sourcemeter. We used the stage input for vacuum/gases to control the atmosphere in the chamber. The stage is connected to a TP94 controller, a Keithley 6430 sourcemeter–femtammeter and a laser connected to a Keithley 3930A function generator. We substituted the optics of the laser diode with a 3.3 Macro Zoom lens (Edmund Optics) to regulate the focal distance between the laser and the sample, illuminating completely the active area of the device.

The TP94 controller is connected to the computer through a RS232 interface. The Keithley 6430 and the Keithley 3930A are connected to the computer through an IEEE-488 Bus. In this configuration we are able to set from the computer a temperature ramp, to set the voltage, to take at pre-set intervals an electrical measurement of current and to control the laser intensity on the sample, alternating dark–light cycles.

4.4. Generation of I_d, I_l and I_p surfaces

The measurement cycles give alternating I_d and I_l data at intervals of 0.3 K. Performing a 2D interpolation of the data points in Fig. 3a and b in the heating part of the cycles we obtained the three surfaces shown in Fig. 3a–c.

We first performed the interpolation of I_d and I_l in T with a linear function because the variation on I_d (T) and I_l (T) is very smooth. At this point we subtracted the I_p curve from the I_l to obtain I_p. The use of a linear interpolation avoids artefacts in the subtraction. We then performed exponential interpolation in time (a linear interpolation on the logarithm of the current) to obtain the three surfaces.

4.5. Error analysis

The error propagation of I_l and I_d into I_p was calculated by the equation:

$$\sigma_{I_p}^2 = \sigma_{I_l}^2 + \sigma_{I_d}^2 - 2 \cdot \mathrm{cov}[I_l, I_d] \quad (6)$$

As the sourcemeter measures consecutive I_d and I_l values, which are in the same range, we consider $\sigma_{I_l} = \sigma_{I_d}$. For uncorrelated noise (i.e. thermal/shot noise) $\mathrm{cov}[I_l, I_d] = 0$, thus the error in I_p calculation is: $\sigma_{I_p} = \sqrt{2} \cdot \sigma_{I_d}$ (Table 1).

Table 1
Summarizes the relevant values for the calculation of the signal to noise ratio (SNR).

Time→	9061 (s)	67287 (s)	Note
Range I_d	2–12 nA	0.6–1.4 nA	Data of Fig. 4
Range I_p	0.1–0.4 nA	0.06–0.35 nA	Data of Fig. 4
$(I_l - I_d)/I_d$	5–3.3%	10–25%	
σ_{I_d}	<6pA rms	<2pA rms	Measured current noise in the same range and same conditions than the I_d
SNR (I_p)	>11	>21	Calculated as $\frac{I_p}{\sqrt{2}\cdot\sigma_{I_d}}$

The electrical transport through SAMs of alkanemonothiols with a methyl end group (–CH_3), and alkanedithiols with a thiol end group (–SH), has been reported previously [4,6]. Alkanedithiols with a length of *N* carbon atoms (HS–C_NH_{2N}–SH) are abbreviated as *CN*DT and alkanemonothiols (C_NH_{2N+1}–SH) as *CN*MT. The transport mechanism is nonresonant tunneling. The transmission of a junction can be modeled with a multi-barrier tunnel [7] model yielding for the resistance of a single molecule, *R*, at low bias:

$$R = \frac{h}{2e^2}T^{-1} = 12.9\ k\Omega T_{\mathrm{Au-S}}^{-1}T_{mol}^{-1}T_{SAM\ PEDOT}^{-1} \quad (1)$$

where *h* is Planck constant, *e* is the elementary charge, *T* is the overall transmission probability and where $T_{\mathrm{Au-S}}$, T_{mol} and $T_{SAM\ PEDOT}$ are the transmission probabilities for the gold–sulfur bottom contact, the molecule itself and the SAM/PEDOT:PSS top contact, respectively. Rewriting in practical terms yields:

$$R = 12.9\ k\Omega r_{\mathrm{Au-S}}r_{mol}r_{SAM\ PEDOT} \quad (2)$$

where $r_{\mathrm{Au-S}}$, r_{mol} and $r_{SAM\ PEDOT}$ are dimensionless resistance contribution factors accounting for the resistance contribution of the bottom contact, the molecule and the top contact, respectively. The molecule contribution is given by $r_{mol} \sim exp(\beta n)$, where β is the decay coefficient and *n* the number of carbon atoms in the backbone. Note that the resistance behavior of the PEDOT:PSS layer itself in a junction is nontrivial [8], and this can hold for the $r_{SAM\ PEDOT}$ contribution. Nevertheless, for a *monocomponent* SAM junction the $r_{SAM\ PEDOT}$ factor is constant and the dependence of the resistance on molecular length is found exponential [4,6,9]. This dependence derives from the r_{mol} *single-molecule* term, as long as the overall resistance is dominated by the molecule. The SAM junction resistance is then given by the single molecule resistance divided by the grafting density, under the plausible assumption that cooperative effects can be disregarded.

What about *mixed* SAMs? To investigate the contribution of both the length of the molecule and the nature of the end group we systematically studied the electric resistance of binary mixed monolayers of alkanemonothiols and alkanedithiols. First we kept the end group constant in the series of mixed monothiols and mixed dithiols, varying only the length of the molecule. Subsequently we investigated mixed SAMs of an alkanemonothiol and an alkanedithiol. In this case, both the length of the molecule as well as the interfacial composition are varied.

2. Results and discussion

2.1. "Walking along the lines"

The simplest binary SAM in terms of molecular interactions is a mixture of alkanemonothiols, in which the chemical composition of the end group is similar to that of the main chain. Let us focus on the mixed monolayers of C12MT and C18MT. In Fig. 1 the normalized resistance, *RS*, is presented on a semi-logarithmic scale as a function of the mole fraction of C18MT in the SAM solution. Each data point represents the average value of about 40 junctions. The data can be fitted with a straight line in semi-logarithmic coordinates that might indicate an exponential dependence of the normalized resistance on the composition in the SAM solution. Note that the segregation coefficient was verified to be unity, meaning that the composition of the SAM is the same as that of the solution (see Section 4). The chemical structures of the end points are schematically depicted in Fig. 1. A variation in composition translates as a linear variation in average layer thickness. Fig. 1 shows that the resistance increases with layer thickness exponentially.

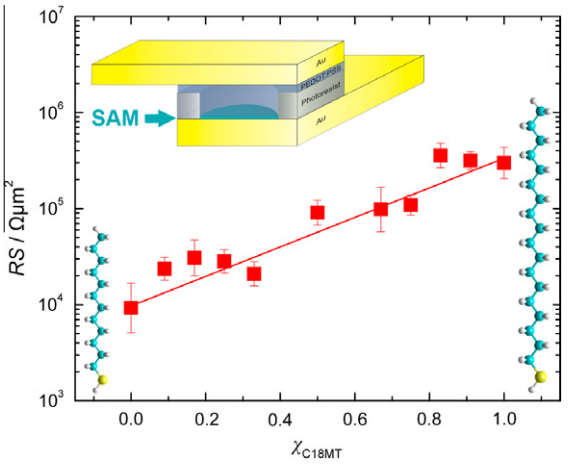

Fig. 1. Normalized resistance, *RS*, of binary mixed SAMs of C12 and C18 monothiols (C12MT and C18MT), as a function of mole fraction of C18MT in solution, χ_{C18MT}. The solid red line represents an exponential fit to the data. The inset shows a schematic cross section of the junction. The chemical structures of the end points are included to illustrate that the resistance increases with increasing layer thickness. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Next we turn to the resistance of a series of mixed monothiol–dithiol monolayers, namely C17MT with the dithiol C12DT. In this series both the average thickness and the interfacial composition are varied simultaneously. The normalized resistance is presented in Fig. 2 on a semi-logarithmic scale as a function of the mole fraction of C17MT in solution. Each data point represents the average value over about 20 junctions. As in the case of the mixed monothiols we observe that the normalized resistance appears to depend exponentially on composition. However, the dithiol, which is the shortest of the two molecules, has a higher resistance in monocomponent SAM than the monothiol, which is longer (their chemical structures are schematically depicted in Fig. 2). Therefore, Fig. 2 unambiguously shows that the resistance of the mixed C12DT–C17MT SAM decreases with increasing average layer thickness.

To complete this study, we fabricated all the binary monolayers of four components, *viz.* two alkanemonothiols C17MT and C20MT and two alkanedithiols C12DT and C16DT, except for the C12DT–C20MT mixed SAM. In this latter system, the big difference in the number of carbons is expected to lead to a non-unity segregation factor due to preferential adsorption [10,11]. The normalized resistances are presented in Fig. 3 on a semi-logarithmic scale

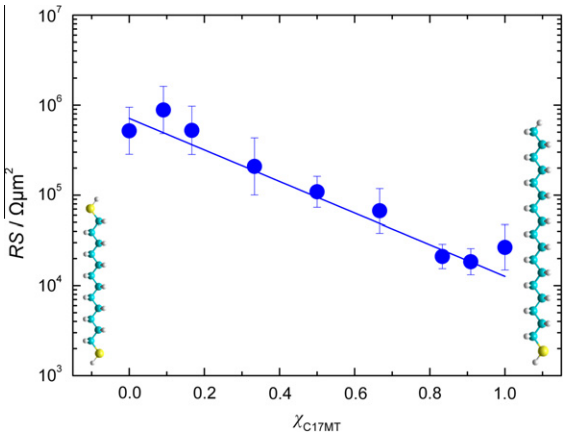

Fig. 2. Normalized resistance, *RS*, of binary mixed SAMs of C12 dithiol and C17 monothiol (C12DT and C17MT), as a function of mole fraction of C17MT in solution, χ_{C17MT}. The solid blue line represents an exponential fit to the data. The chemical structures of the end points are included to illustrate that the resistance *decreases* with *increasing* layer thickness. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

as a function of average number of atoms, as calculated from the mole fraction in solution assuming a segregation coefficient of unity. The resistances of all binary SAMs can be fitted with straight lines that might indicate an exponential dependence on the average number of atoms.

The constructed resistance diagram of Fig. 3 shows a trapezoidal correlation. The mixed monothiol C17MT–C20MT SAM and the mixed dithiol C12DT–C16DT SAM exhibit the same slope, yielding parallel lines. Throughout each of these two series, the contributions to the resistance from the top and bottom contacts are constant. The resistance changes only due to a different number of carbon atoms. The contribution of the top contact is reflected in

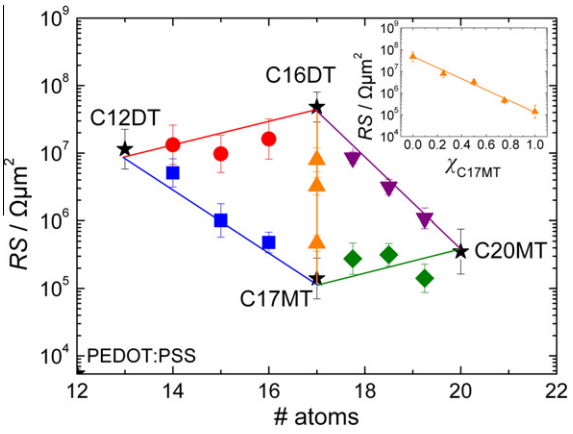

Fig. 3. Geometric resistance diagram showing a trapezoidal correlation. Normalized resistance, *RS*, of all binary mixed SAMs based on the end points C12DT, C16DT, C17MT and C20MT, as a function of average number of atoms. The fully drawn curves are a guide to the eye. The inset shows the normalized resistance of the C16DT–C17MT mixed SAMs as a function of the mole fraction of C17MT in solution. The vertical axis starts at $5 \times 10^3\ \Omega\,\mu m^2$, the value for the corresponding PEDOT:PSS only junction.

the series C16DT–C17MT. The average number of atoms in the mixed SAM is constant, while the interfacial composition is varied. The resistance systematically varies with composition over more than two orders of magnitude. The simultaneous effect of molecular length and nature of the end group is observed along the C12DT–C17MT and C16DT–C20MT lines. For both these series an apparently exponential dependence on the average number of atoms is found. The slope, however, is different because the change in the number of atoms at the end points is different; hence the corresponding lines in the trapezoid are not parallel.

2.2. Discussion

As a matter of fact, the experimental results leading to the diagram in Fig. 3 are quite puzzling. The first hypothesis to consider is that in a mixed SAM the overall resistance is given by the resistance of all its constituent individual molecules connected in parallel, i.e. as in a monocomponent SAM. It is easy to show that the behavior this hypothesis predicts contradicts experiment. Indeed, addition of significantly more conductive molecules would quickly reduce the resistance of a mixed SAM already when their fraction is low, because they would act as "shorts". On the other hand, a low share of less conductive molecules has no spectacular effect. The dependence of resistance on composition simulated in Figs. 4 and 5 is far from both the experimental points and from the straight line in semilogarithmic coordinates. We are forced to conclude that not every molecule in the mixed SAM carries current fully and independently.

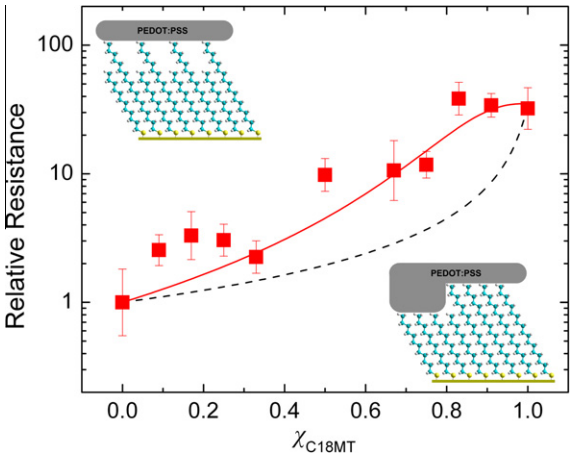

Fig. 4. Relative resistance of binary mixed SAMs of C12 and C18 monothiols (C12MT and C18MT), as a function of mole fraction of C18MT in solution, χ_{C18MT}, taken from Fig. 1 and normalized to the end point C12MT. The insets show the two cases of the mixed SAM microstructure. The top left depicts intermixing and the bottom right inset depicts phase separation. The dashed black line is calculated assuming that all the molecules of each component have the same resistance equal to their resistance in their respective monocomponent SAMs and are connected in parallel in the mixed SAMs. The solid red line is calculated by parameterization of the microstructure using Eq. (3). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

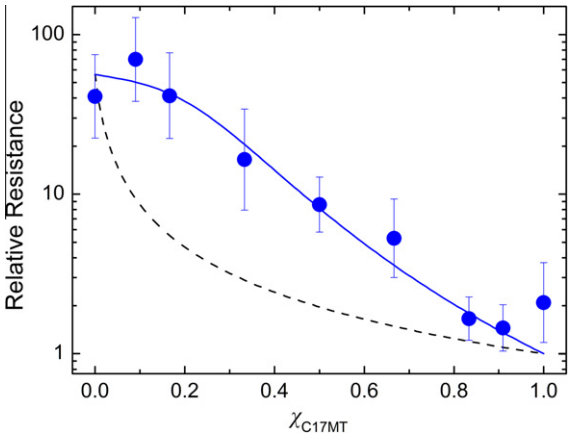

Fig. 5. Relative resistance of binary mixed SAMs of C12 dithiol and C17 monothiol (C12DT and C17MT), as a function of mole fraction of C17MT in solution, χ_{C17MT}, as taken from Fig. 2 and normalized to the end point C17MT. The dashed black line is calculated assuming that all the molecules of each component have the same resistance equal to their resistance in their respective monocomponent SAMs and are connected in parallel in the mixed SAMs. The blue line is calculated by parameterization of the microstructure using Eq. (3). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Another extreme hypothesis would be that molecular composition of the SAM is irrelevant, it just serves as an effective medium (spacer) that only modifies the average width of the tunneling barrier between the contacts. Such a model seems compatible with the exponential dependence on average thickness found. We note that for MT–MT and DT–DT mixed SAMs the slope obtained amounts to 3.54 per fraction. The difference between the end points is six carbon atoms, yielding a slope of 0.6 per carbon atom. Apparently, both systems exhibit the same length dependence with a decay coefficient of about 0.6 per carbon atom. This value corresponds to the one derived in Fig. 1 and to published decay constants for alkane based molecules of 0.5–1.2 [4,6,9]. The resistance changes only due to a different number of carbon atoms, according to Eq. (2), where molecular contribution is given by $r_{mol} \sim exp(\beta n)$, where β is the constant decay coefficient and n in this case is the *average* number of carbon atoms.

Whatever the possible physical justification of this model, not all the observed facts are compatible with it. Note that the absolute value for the resistances of the mixed monothiols is different from that of the mixed dithiols. According to Eq. (2), this offset originates from the different end groups, $-CH_3$ versus –SH, yielding a different top contact contribution, $r_{SAM\ PEDOT}$ [5,6,9,12–14]. The numbers imply a more transparent contact barrier, i.e. a higher transmission coefficient, for the methyl/PEDOT:PSS interface as for the thiol/PEDOT:PSS interface. We note that this behavior is counterintuitive: the water-based suspension PEDOT:PSS is expected to be repelled by the hydrophobic methyl end group of the alkanemonothiols, yielding a less intimate physical contact. Therefore the absolute resistance of a dithiol SAM is expected to be lower than that of a monothiol SAM, contrary to what is experimentally observed; at the moment, we have no explanation for this fact. This difference is significant enough to make certain monocomponent SAMs of longer MT less resistive than those of DT with shorter molecules. Consequently, a systematic resistance *decrease* with *increasing* average layer thickness for certain monothiol–dithiol mixed SAMs (Fig. 3) was observed, which contradicts the effective medium model and stresses the importance of microscopic structure of the junction.

2.3. A phenomenological model for the mixed SAM resistance

The consideration in the previous section demonstrates that a viable model for mixed SAMs should take into account their microstructure in a realistic way, assuming that the resistance can be calculated as for an equivalent circuit of a parallel resistor network. With this in mind, we propose a microdomain model that by parameterization of the microstructure explains the resistance data.

A mixed monolayer is a dynamic system formed at room temperature at relatively low concentrations. Though full phase segregation is thermodynamically favorable, the SAM will nevertheless contain phases with kinetically-formed compositions [15] where domains of different sizes coexist probably even with single molecules. For the purpose of an equivalent circuit of a mixed SAM composed of molecules A and B, we limit the model to four parallel resistances, per molecule: (i) A-domain, (ii) A-single, (iii) B-domain and (iv) B-single. The difference in effective resistance of the same molecule as single or a domain member is supposed to reflect contact and conformational issues, rather than mutual influence of the molecules that we consider irrelevant. Indeed, the longer molecules likely act as pillars and only they are fully contacted by PEDOT:PSS, preventing all short molecules from being equally well contacted and fully contribute to the current. On the other hand, the longer molecules trapped into the shorter molecule domains can hardly stand straight but rather adopt bent conformations. Consequently, "domain" in this context signifies an ensemble of molecules vast enough to be fully contacted (i.e. the fraction of molecules at its boundaries being relatively small), while "singles" might as well apply to groups of a few molecules. Therefore, the resistance of the A and B in domains corresponds to that of the monocomponent SAMs of A and B, respectively, while the resistances of A and B singles have to be parameterized.

We need now a model for the composition of a mixed SAM in terms of domains and singles for both components. It has been known that alkanethiol SAM formation is a two-stage process, the initial fast step being diffusion-limited adsorption and the second slow step reorganization of the primary monolayer described as surface crystallization [16]. For a *mixed* monolayer, we suppose that only a part of the molecules of each type will assemble into domains, while the rest will be in the form of singles. It is reasonable to assume that the shares of the domains and singles depends on the composition of the SAM. Let the molecular composition of the monolayer be characterized by the mole fraction of A denoted by χ; the fraction of B is then $1 - \chi$, $\chi = 0$ corresponds to pure B and $\chi = 1$ corresponds to pure A. When $\chi \to 0$, all molecules B are expected to be organized in domains, while for $\chi \to 1$ practically all

molecules B are single: a view supported by previously reported STM data [17]. We suppose further that a certain number of molecules, n, must meet to form a critical nucleus leading to the formation of a domain, which is more likely to occur when there are more molecules of a given component in the mixed monolayer, hence at a higher mole fraction of this component. Within such a probabilistic approach, the population, of A and B arranged in domains is, χ^n and $(1-\chi)^n$, respectively. The population of singles is then $\chi-\chi^n$ for A and $(1-\chi)$–$(1-\chi)^n$ for B. The resistance of the mixed SAM as a function of composition is then given by:

$$\frac{1}{R}=\frac{\chi^n}{R_{\text{A-domain}}}+\frac{(1-\chi^{n-1})\chi}{R_{\text{A-single}}}+\frac{(1-\chi)^n}{R_{\text{B-domain}}}+\frac{(1-\chi)\left[1-(1-\chi)^{n-1}\right]}{R_{\text{B-single}}} \quad (3)$$

For the mixed SAMs of Fig. 4, the molecule A is C18 monothiol and the molecule B is C12 monothiol. The resistances of the domains, $R_{\text{A-domain}}$ and $R_{\text{B-domain}}$, are taken equal to that of the corresponding end points, *viz.* the pure single component SAMs. As in the case of a perfectly mixed monolayer, the top inset of Fig. 4, we assume that the single molecules C12 monothiol embedded in domains of C18 monothiols, are not contacted by the PEDOT:PSS top contact. Therefore they do not contribute to the overall resistance. Only when organized in sufficiently large domains the short molecules contribute to the overall resistance, as schematically depicted in the lower inset of Fig. 4. The only parameters left are the exponent n and the resistance of a single molecule C18 monothiol in domains of C12 monothiol, $R_{\text{A-single}}$. Fitting the experimental data with Eq. (3) (fully drawn red curve in Fig. 4) yields $n = 2.3$ and $R_{\text{A-single}} = 43$. The resistance of single C18MT molecules in domains of C12MT, $R_{\text{A-single}}$, is in the same order of magnitude as the C18MT domains.

Parameterization of the microstructure can also explain the observed resistance behavior of the mixed C12DT–C17MT system of Fig. 2, where the resistance actually *decreases* with *increasing* average layer thickness. The resistances are replotted in Fig. 5 where the values are normalized to the pure C17MT SAM. Similarly as above, we take the resistances of the domains equal to that of the corresponding end points, the pure monocomponent SAMs. The contribution of the short single molecules is again disregarded. The only parameters left in Eq. (3) are the exponent n and the resistance of a single molecule C17 monothiol in domains of C12 dithiol, $R_{\text{A-single}}$. The dashed black curve in Fig. 4 is calculated assuming that the resistance for single C17MT molecules is the same as that in domains. Contrary to Fig. 4, this assumption does not lead to a fit to the data. This is because C17MT molecules are highly conductive in comparison with C12DT molecules and constitute electric shorts in a C12DT domain. A fitting of both n and $R_{\text{A-single}}$ yields a good agreement, however, with $n = 3.3$ and the relative resistance of the single C17MT molecule equal to 27, an order of magnitude higher than when organized in domains.

This approximately 20-fold increase in the resistance of single long monothiols can be related to their molecular conformation. It has been shown that the resistance of an alkane molecule increases an order of magnitude when gauche defects are introduced [18]. The emergence of defects can be due to conformational disorder, whose origin in a mixed SAM has been described previously [11,15]. Close to the gold surface, the mixed SAM is ordered. The free volume introduced into the outer part of the longer molecules in the monolayer by the presence of the shorter chains makes it disordered and liquid-like. The loss of lateral and orientational order implies the existence of gauche defects.

We note that the degree of conformational disorder in the longer molecules depends on their share in the mixed SAM. At low fraction the gauche densities per molecule are higher [15], meaning that most of the longer molecules exist as singles, in agreement with the assumption that the domain fraction depends on the monolayer composition.

Conformational changes, or gauche defects, affect the charge transport through a molecule directly [18,19], by reducing the periodicity. Indirectly, the resistance can be affected by the presence of bent molecules via altered interface energy of a methyl- to a methylene terminated interface [15,20], as well as by diminishing the electronic coupling of the shorter SAM domains to the top contact [21].

For the monothiol-dithiol SAMs, the presence of gauche defects can be inferred from analysis. On the other hand, conformational disorder in mixed monothiols does not manifest in our electric measurements as the single long molecules already have a higher resistance.

Relatively small values for n support the hypothesis that the dependence of the normalized resistance on the fraction is non-exponential, but follows a power law. Moreover, as simple as our model might be, it embodies some tracts of nucleation and growth phenomena. The assumption of a critical nucleus size of 1–2 molecules might be reasonable [22], although weaker intermolecular interactions can lead to critical nucleus sizes larger than two [23]. The different interactions between the components in the two systems, owing to their different chemical structures, could explain the variation in the value of n. A more rigorous treatment, which would account for the dynamics of the binary SAM in order to relate the trend to the critical nucleus size is beyond the scope of the present work.

3. Synopsis

We have investigated the electrical transport through mixed self-assembled monolayers in large-area molecular junctions. The SAM is formed on a gold bottom electrode inside a photolithographically defined interconnect in photoresist. The conducting polymer PEDOT:PSS is used as top contact. To investigate the contribution of both the length of the molecule and the nature of the end group on the resistance, we systematically studied the charge transport through mixed monolayers of alkanemonothiols and alkanedithiols. We verified by ellipsometry measurements that the segregation coefficient is unity for all investigated binary SAMs. To disentangle the role of the length of the molecule and the interfacial composition we prepared mixed monolayers of all different binary combinations of

two monothiols and two dithiols. The end group is fixed in a series of mixed monothiols and in a series of mixed dithiols.

A trapezoidal correlation in semi-logarithmic resistance-composition coordinates has been obtained (Fig. 3). The straight lines seem to indicate an exponential dependence on composition, or on the average molecular length, also in the case of mono- and dithiol mixed SAMs where resistance can decrease with increasing layer thickness, as the longer component is more conductive in monocomponent SAM. However mathematically simple, exponential dependence is difficult to justify physically for mixed monolayers, unlike the case of monocomponent SAMs where this dependence has a single-molecule tunneling origin.

We search for the origin of the resistance-composition dependence in mixed SAMs in an equivalent circuit model based on their microdomain structure for which we suggest a simple model. In essence, we suppose that the effective resistance of a molecule can differ depending on whether it is isolated (that is, trapped within an alien molecular domain) or belongs to a domain of the same molecules, due to contact and conformational issues. The simulated dependence is non-exponential and leads to a good agreement between calculated and measured resistances with only two fit parameters.

4. Experimental section

A 4-in. silicon wafer with a 500 nm thermally grown oxide was passivated using hexamethyldisilazane (HMDS). A 1 nm layer of chromium was thermally evaporated through a shadow mask, followed by 60 nm of gold. The rms roughness of the bottom contact is about 0.7 nm over an area of 0.25 μm^2.

The two terminal junctions were photolithographically defined in an insulating matrix of photoresist, ma-N 1410 (Micro Resist Technology GmbH). The negative photoresist was spincoated on the wafer resulting in a layer of 570 nm. After a pre-bake step to remove any remaining solvents, the layer was exposed to UV light with a Karl Süss MA1006 mask aligner, to define the vertical interconnects, ranging from 5 to 100 μm in diameter. After development, the film was hard baked at 200 °C for at least 1 h to render the photoresist insoluble in ethanol, the solvent used in the SAM formation. The wafer was subsequently cut in several pieces using a diamond tip pen. This allowed the simultaneous processing of different mixed SAMs on a single wafer, thereby eliminating processing variations that can affect device performance. A last step before self-assembly was cleaning of the bottom gold contacts with a PDC plasma cleaner (Harrick plasma) to remove any photoresist residuals.

The self-assembled monolayers were formed from molecules dissolved in ethanol. The series of molecules used in this work include 1-dodecanethiol (C12MT), 1-heptadecanethiol (C17MT), 1-octadecanethiol (C18MT), 1-eicosanethiol (C20MT), 1,12-dodecanedithiol (C12DT) and 1,16-hexadecanedithiol (C16DT). All solvents and molecules except C17MT, C20MT, C12DT and C16DT were purchased from Sigma–Aldrich. The synthesis of the other molecules was performed starting from the carboxylic acid, hydroxyl or bromide precursor, depending on the commercially available compounds.

Mixed solutions of various molar ratios between the two components were prepared by mixing stock solutions of each component at the appropriate volume ratio. The wafer pieces were immersed in the solutions for at least 36 h, under nitrogen. The concentration in ethanol was 3×10^{-3} M for the C12DT–C17MT system, 6×10^{-3} M for the C12MT–C18MT systems and 1×10^{-2} M for the mixed SAMs of Fig. 3. The higher concentration is required to prevent formation of a looped phase when using longer alkanedithiols (C16DT) [24]. After the self-assembly, the wafer pieces were thoroughly rinsed with ethanol, toluene and *iso*-propanol to remove any remaining alkanethiol molecules.

Subsequently, the interlayer of PEDOT:PSS, a water-based suspension of poly(3,4-ethylenedioxythiophene) and poly(4-styrenesulphonic acid), was spin coated. PEDOT:PSS acts as a highly conductive buffer layer that protects the SAM during subsequent evaporation of the top gold contact. Two blends were used. (a) Baytron® PH500, H.C. Starck GmbH & Co., filtered over a 1 μm Whatman® glass filter. Dimethylsulfoxide (5% v/v) was added to increase the conductivity [25] and (b) AGFA® ICP new type filtered over a 5 μm Whatman® glass filter. Blend (a) was used for the C12MT–C18MT system, while blend (b) was used for all other experiments. The PEDOT:PSS solution was spincoated, resulting in a layer thickness of about 90 nm. The wafer was then immediately transferred to a vacuum oven for at least 1 h to dry the film.

To facilitate contacting the top electrode, 100 nm of gold was evaporated through a shadow mask. This gold layer, apart from ensuring a better contact with the measurement probes, also serves as a self aligned mask for the removal of redundant PEDOT:PSS by reactive ion etching (O_2 plasma). This step eliminates any parasitic currents from top to bottom electrode.

Current–voltage (*I–V*) measurements were performed in two home-built probe stations using a Keithley 4200 Semiconductor Analyzer Characterization System. The probe stations were pressurized at 10^{-6}–10^{-7} mbar for at least 6 h before the measurements, to remove any water absorbed in the PEDOT:PSS layer. Devices were swept in the voltage range of 0 to 1 to −1 V and back to 0 V and the recorded current densities were averaged for all devices with different diameter. The normalized resistance (*RS*, resistance × area, $\Omega\,\mu m^2$) was then calculated at 0.1 V bias. The resistance scales linearly with device area for junctions of 5–100 μm in diameter, resulting in identical *RS* values.

Ellipsometric measurements, to verify that the segregation coefficient is unity and that the layer thickness linearly increases with composition, were performed using a V-VASE® ellipsometer (J.A. Woolam Co., Inc.) equipped with an HS-190 high speed monochromatic system and controlled with a VB-400 module. All measurements were performed at the reflection geometry in the spectral range from 350 to 500 nm with a step of 3 nm, at an angle of incidence of 65–75° with a step of 5° and 10 revisions/measurement. Acquired data were analyzed using WVASE32® software. The index of refraction for monothiols and

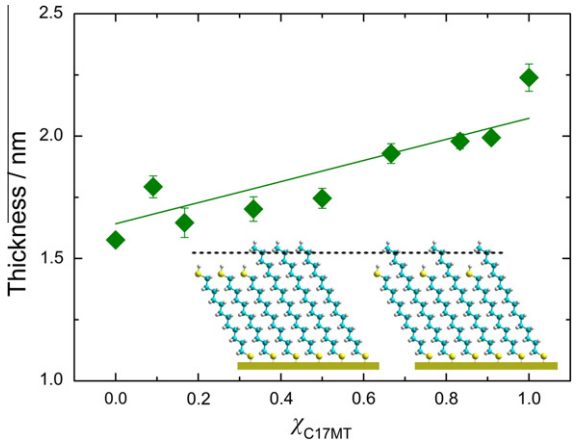

Fig. 6. The thickness obtained from ellipsometry measurements on binary mixed SAMs of C12 dithiol and C17 monothiol (C12DT and C17MT), as a function of the fraction C17MT in solution, χ_{C17MT}. The fully drawn curve is a linear extrapolation between the end points, which have been calculated using Hyperchem 7.5.

dithiols was taken equal as 1.45. The layer thickness derived as a function of composition in solution for the C12DT–C17MT mixed SAMs is presented in Fig. 6. A linear dependence is found indicating that within experimental error the segregation coefficient is unity, as has been reported previously [26]. This conclusion is substantiated by the calculated layer thicknesses indicated by the fully drawn curve. The end points follow from the length of the molecule, calculated with Hyperchem 7.5, adding 2.3 Å for the S–Au bonds and taking an off-normal tilt angle of 30°. The fully drawn curve is obtained by a linear extrapolation between the end points and fits the data well. This analysis applies for all binary SAMs here investigated.

For the sample preparation, a silicon wafer with 500 nm thermally grown oxide was rinsed with *iso*-propanol, dried in a dry spinner and coated with 1 nm Cr adhesion layer and 60 nm of Au, according to the procedure described above. The wafer was cut to pieces, which were transferred in nitrogen filled bottles for the ellipsometry measurements (one reference point per piece). Subsequently, the pieces were treated in a plasma cleaner and immersed in the respective solutions to self-assemble the monolayers. Ellipsometry samples and molecular junctions were prepared simultaneously from the same solutions. The thickness of the SAMs was determined by averaging at least three different measurements on each piece.

The phosphorescent white EML is fabricated with solution-process. The fluorescent white EML is prepared with solution-premixed method and deposited with thermal deposition method [13]. The hole-modulation layer (TPBi), electron transporting layer (TPBi), electron injection layer (LiF), and aluminum cathode were also deposited with thermal deposition method.

2.2. Device characterization

The luminance of the resultant white OLEDs were measured by using a Minolta CS-100 luminance-meter. The CIE chromatic coordinates and EL spectrum were measured by using a Photo Research PR-655 spectrascan spectroradiometer. A Keithley 2400 electrometer was used to measure the current–voltage (I–V) characteristics. The emission area of all the resultant devices was 25 mm^2 and only the luminance in the forward direction was measured.

3. Results and discussion

Fig. 1 compares the CRI and power-efficiency results of the studied white OLED device, against previously reported ones [4–6,8–12,14–23]. The most efficient white OLED, showed power-efficiency of 44 lm/W, while exhibiting a medium CRI of 68. The high-CRI white OLEDs showed an efficiency ranging between 5 and 36 lm/W. The highest reported CRI was 97, but the device showed a relatively low efficiency of 0.6 lm/W. By employing five emitters, in two white EMLs separated by an HML, we achieved a record-breaking CRI of 98 was with a comparatively high power-efficiency, 8.3 lm/W, at 100 cd/m^2, or 96 with 5.2 lm/W at 1000 cd/m^2.

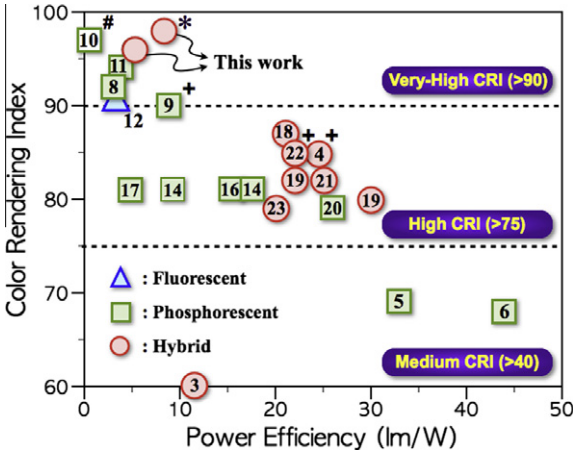

Fig. 1. Color rendering index (CRI) results with respect to efficacy of the studied OLED with double white emissive layers, compared with those reported previously. All the data, unless otherwise specified, are compared at 1000 cd/m^2 on devices without the use of light outcoupling methods (∗: 100 cd/m^2, +: 500 cd/m^2, #: maximum brightness), The OLEDs with fluorescent, phosphorescent, and hybrid material systems are presented with symbols of blue triangle (△), green square (□) and red circle (○), respectively. Except the device in Ref. [10], all the others are composed of multiple emissive layers. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 2 shows the energy diagrams of Devices I–V. Devices I and II consisted of only one EML, while Devices III–V had two EMLs. Device III did not contain an HML, and Devices IV and V were comprised of an HML with 4 and 2.5 nm, respectively. All these devices used 125 nm indium tin oxide as the anode, a 25 nm poly(3,4-ethylene-dioxythiophene)-poly-(styrenesulfonate) (PEDOT:PSS) the HTL, a 32 nm 1,3,5-trisN-phenylbenzimidazol-2-ylbenzene (TPBi) the ETL, a 0.7 nm lithium fluoride the EIL and 150 nm aluminum for the cathode.

In Device I, three phosphorescent emitters were employed in the white EML with a host of 4,4′-Tris(carbazol-9-yl)triphenylamine (TCTA). The respective doping concentrations were 14, 0.5, and 1.0 wt.% for the blue dye of bis(3,5-difluoro-2-(2-pyridyl)-phenyl-(2-carboxypyridyl)) iridium (III) (FIrpic), green dye tris(2-phenylpyridine)iridium (III) [Ir(ppy)$_3$] and red dye bis(1-phenylisoquinoline)(acetylacetonate) iridium (III) [Ir(piq)$_2$(acac)].

The white EML in Device II comprised a fluorescent deep-blue light emitting host 2,7-bis{2[phenyl(m-tolyl)amino]-9,9-dimethyl-fluorene-7-yl}-9,9-dimethyl-fluorene (MDP3FL) doped with 1% fluorescent yellow dye 5,6,11,12-tetra-phenylnaphthacene (Rubrene). Devices III–V comprised both the aforementioned phosphorescent white and fluorescent white EMLs, with respective thicknesses of 20 and 8 nm.

Fig. 3 shows the EL spectra and CRI values of the studied devices. Device I exhibited a three-wavelength white emission with 78 CRI at 1000 cd/m^2. Device II exhibited a white emission composed of two complementary colors, but had only 72 CRI. To improve the CRI, we attempted to stack the two white EMLs to integrate their EL spectra and fabricated

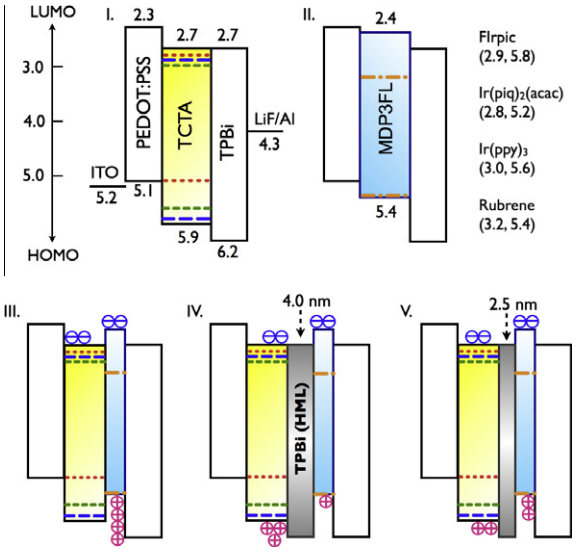

Fig. 2. Schematic illustrations of the three-wavelength phosphorescent white OLED (Device I) and the two-wavelength fluorescent white OLED (Device II). Devices III–V are five-wavelength white OLEDs with the three-wavelength phosphorescent and two-wavelength fluorescent white emissive layers, where Device III contains no hole modulation layer (HML), Device IV 4 nm HML, and Device V 2.5 nm HML. With the use of an HML with a proper thickness (Device V), the entering holes and electrons can be well distributed into the two white emissive zones.

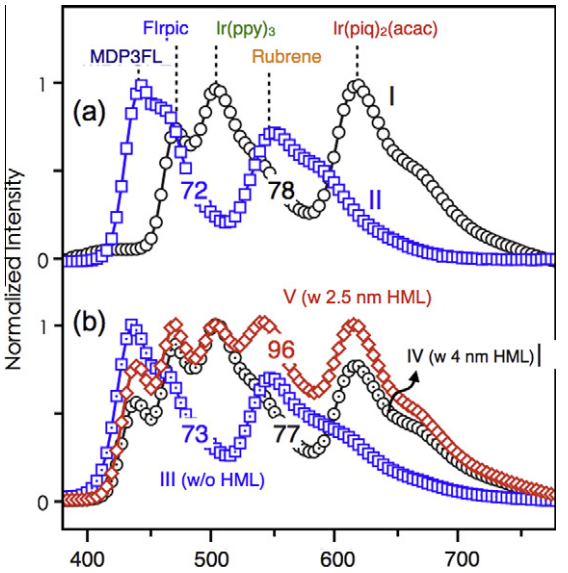

Fig. 3. The resultant EL-spectra of (a) the single white emissive layer containing OLEDs, Devices I and II, and (b) the double white emissive layers containing OLEDs, Devices III–V. A five-wavelength emission with 96 CRI at 1000 nits is observed as a 2.5 nm HML is employed, or 77 CRI if the HML is 4 nm. Whilst, only two-wavelength emission with 73 CRI is observed in the absence of the HML.

a five-wavelength very-high CRI OLED. However, the resulting device (Device III) showed an EL spectrum similar to that of Device II, with a CRI of only 73. This could be attributed to the fact that the transport of the holes was faster than that of electrons in Device III, leading to holes and electrons recombining in the MDP3FL-composing EML. This was the same in Device II, which emitted a two-wavelength spectrum [24,25].

In order to achieve a five-wavelength spectrum OLED, we had to increase the emitting strength of TCTA-composed EML. Therefore, we incorporated a 4 nm hole-modulation layer TPBi between the two EMLs to block some holes in the TCTA-composed EML. However, the resulting primary emission of Device IV was contributed by the Blue FIiric, green Ir(ppy)$_3$, and red Ir(piq)$_2$(acac), with relatively weaker intensities of deep-blue MDP3FL and yellow Rubrene, exhibiting a 77 CRI. This implied that TPBi layer had provided a 0.3 eV hole-injection barrier at the interface of TCTA and TPBi, blocking most of the holes in the TCTA-composed EML, leading to the major recombination zone formed within it.

Surprisingly, as we decreased the thickness of the TPBi layer to 2.5 nm, the CRI markedly improved to 96 (Device V). This was attributed to the fact that an appropriate layer thickness of TPBi could distribute the holes into two white EMLs and control the recombination zones, resulting in a balance intensity of all emitters, thereby producing a full-wavelength spectrum with a very-high CRI.

Fig. 4 showed the hole-modulation layer effects on the resultant current densities. For the double EMLs devices, the current density deceased as the thickness of TPBi hole-modulation layer increased. This effect could be attributed to the 0.3 eV hole-injection barrier at the interface of TCTA and TPBi as well as that the thicker

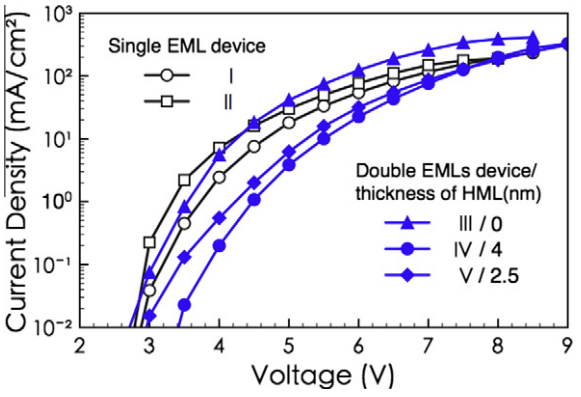

Fig. 4. The resultant current density of the five devices studied. The addition of the HML (TPBi) indeed effectively decreases the current density of the device, proving TPBi to be an effective hole modulating layer in these devices.

HML would form stronger barrier and block more holes, resulting in lower current density.

Fig. 5 shows the electroluminescence (EL) spectra with corresponding Commission International de l'Eclairage (CIE) 1931 coordinates of Device V at different luminance. The increased intensity of the blue- and green-emissions (relative to the red emission), with respect to the luminance explains why the CIE coordinates were blue shifted. This shift showed that a greater degree of recombination had to have been taking place in the blue- and green-emission dyes under high luminance. This was due to fact that the hole-injection barriers from PEDOT to dyes were 0.1 eV to Ir(piq)$_2$(acac), 0.5 eV to Ir(ppy)$_3$ and 0.7 eV to FIrpic, as shown in Fig. 2. Therefore, the holes preferred to inject red Ir(piq)$_2$(acac) at low applied voltage, due to the comparatively low hole-injection barrier. The holes would

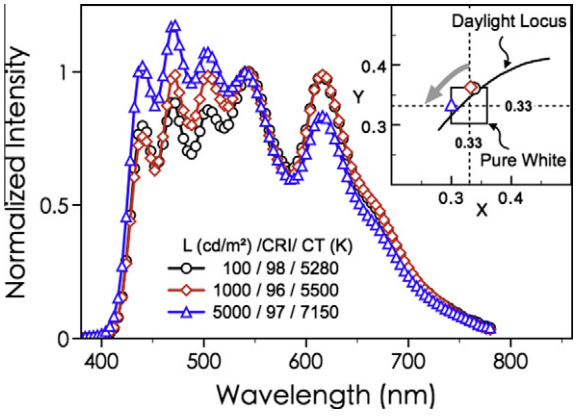

Fig. 5. The EL spectra of the double white emissive layers containing OLED (Device V) at varying luminance. The corresponding CRI varies slightly between 96 and 98 and color temperature increases from 5280 to 7150 K for brightness changing from 100 to 5000 cd/m^2. The inset shows the corresponding 1931 CIE coordinates that fall within the pure-white region and are very close to the daylight (Planckian) locus, indicating Device V to be an ideal candidate for high-quality illumination.

Table 1
Effects of the absence and presence of a hole-modulation layer on the resultant color rendering index, efficacy, and color-temperature of the five-wavelength white OLEDs with double white emissive layers.

Device	HML thickness (nm)	CRI	Power efficiency (lm/W)	Color temperature (K)	1931 CIE coordinates
		At 100/1000 cd/m^2			
I	–	71/78	7.8/4.1	4000/4380	(0.39, 0.42)/(0.37, 0.40)
II	–	67/72	11.3/8.4	7530/8840	(0.30, 0.31)/(0.29, 0.30)
III	–	69/73	6.4/3.6	7350/9570	(0.30, 0.32)/(0.29, 0.29)
IV	4	78/77	8.2/4.9	5580/6600	(0.33, 0.36)/(0.31, 0.34)
V	2.5	98/96	8.3/5.2	5280/5500	(0.34, 0.36)/(0.33, 0.36)

have enough energy to overcome higher barriers and inject green Ir(ppy)$_3$ and blue FIrpic at high applied voltage, leading to an increase in the generation of exciton and observable blue- and green-emissions. It is worth mentioning that the CRI remained around 96–98 throughout the brightness range over which we investigated. As seen in the inset (Fig. 5), the CIE coordinates of Device V indeed fall within the pure-white region and are very close to daylight (Planckian) locus, indicating Device V to possess the characteristics required for high-quality illumination [26].

Table 1 summarizes the electroluminescence (EL) characteristics of the studied devices. As shown, the single white EML devices (Devices I and II) exhibited 78 and 72 CRI at 1000 cd/m^2. By combining two white EMLs, Device III exhibited only 73 CRI and the lowest power efficiency of 3.6 lm/W. With the use of 4 nm HML, the CRI and power efficiency of the device (Device IV) were slightly improved to 77 and 4.9 lm/W. After decreasing the thickness of HTL to 2.5 nm, the resulting device (Device V) showed a very-high CRI of 96 and a comparatively high power efficiency of 5.2 lm/W at 1000 cd/m^2. Device V also yielded a pure-white emission and a color temperature of approximately 5500 K, which would be a suitable source of daylight equivalent illumination, enabling people to remain awake and active.

In conclusion, we demonstrate a very-high CRI white OLED by using double white emitting layers and incorporating a 2.5 nm hole-modulation layer to regulate the intensities of the emitters. The resultant device showed a very-high CRI of 98 with a power efficiency of 8.3 lm/W at 100 cd/m^2.

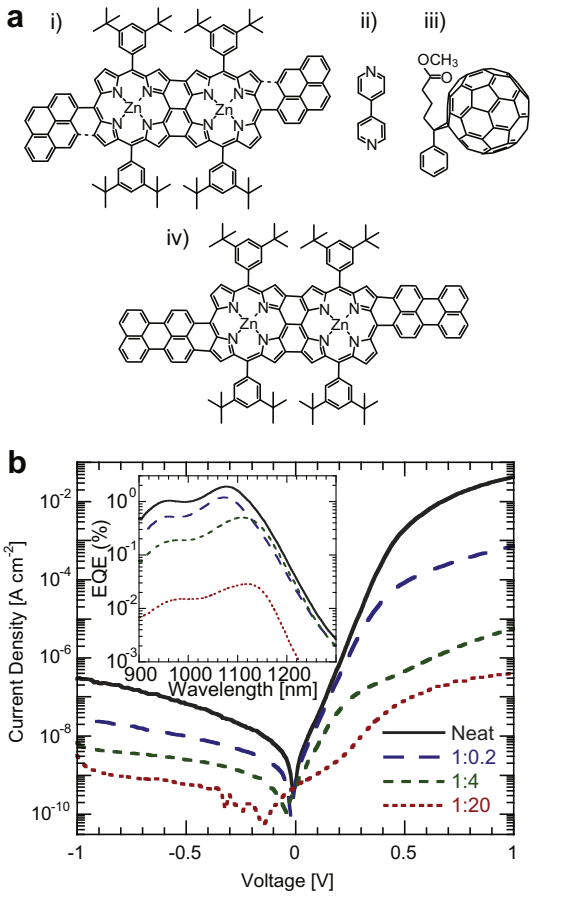

Fig. 1. (a) (i) Molecular structure of zinc pophyrin tape dimer with pyrene end groups where the dashed lines represent hydrogen positions for Psub and a carbon–carbon bond for Pfused, (ii) 4,4'-Bipyridyl, (iii) phenyl-C_{61}-butyric acid methyl ester (PCBM), and (iv) perylene-fused Zn porphyrin dimer. (b) Current density–voltage characteristics and spectrally resolved *EQE* (inset) for varying molar ratios of Psub in PCBM.

and, hence, modify their energetics, exciton diffusion lengths, and electrical conductivities [6]. Specifically, fullerenes, such as PCBM, interact strongly with porphyrin molecules because of strong π–π interactions between the porphyrin center and the curved fullerene surface [6a]. Thus, PCBM tends to evenly disperse among porphyrin molecules to form supramolecular complexes rather than phase-separate into a bulk heterojunction, as observed in polymer–PCBM photovoltaic cells [7].

We have examined other additives based on pyridine compounds. Here, the lone electron pair on the nitrogen atom forms a coordination bond with the Zn atom in the porphyrin core. In fact, small quantities (1–5 vol%) of pyridine are commonly added to organic solvents to increase porphyrin solubility by disrupting intermolecular π-stacking. In particular, complexes involving Bipy coordination to Zn porphyrins are well documented [6d–f], and may form 2:1 or 3:2 complexes, depending on the constituent concentrations [6d]. Here, Bipy stabalizes the porphyrins in a co-facial configuration, increasing short-range ordering and electronic coupling between the π-systems, red shifts the Zn–porphyrin absorption spectrum, and may modify the excited state relaxation dynamics [6d,6f].

In this work, we use Bipy and other pyridines to understand the effects of coordination complexation on device performance. We show that addition of both PCBM and Bipy to the donor layer can increase the zero-bias specific detectivity of porphyrin dimer photodetectors to $D^* = 8.8 \pm 0.2 \times 10^{11}$ Jones ($EQE = 3.6 \pm 0.1\%$) at $\lambda = 1150$ nm, and $D^* = 8.2 \pm 0.2 \times 10^{10}$ Jones ($EQE = 10.5 \pm 0.2\%$) at $\lambda = 1400$ nm. When only Bipy is added, an $EQE = 13.5 \pm 0.3\%$ is achieved. These efficiencies are roughly double and specific detectivities roughly 4-fold higher than previous reports of detectors employing porphyrin tapes [4b], and the specific detectivities are similar to those of commercially available, room temperature Ge photodetectors ($\sim 2 \times 10^{11}$ Jones).

The fabrication and measurement procedures follow previous work [4b], except that the porphyrin–dimer solutions (10 mg/ml in chlorobenzene with 5 vol% pyridine) were first passed through activated alumina to remove oxidized impurities. Additives, dissolved in chlorobenzene, were introduced and the solutions were further diluted to 5 mg/ml of porphyrin in chlorobenzene with 5 vol% pyridine. Devices were fabricated on detergent- and solvent-cleaned indium tin oxide (150 nm thick, ~5 Ω/square) on glass, coated with a 45 nm-thick planarizing layer of poly(3,4-ethlenedioxythiophene)-poly(styrenesulfonate). Donor materials were deposited on a heated substrate ($T = 100$ °C) with a film-casting knife, resulting in film thicknesses of 60 ± 12 nm. The 125 nm-thick C_{60} electron acceptor layer, 10 nm-thick bathocuproine exciton blocking layer, and 150 nm-thick 1 mm-diameter Ag cathodes were sequentially deposited by vacuum thermal evaporation at a base pressure of $\sim 10^{-7}$ torr. The neat C_{60} acceptor layer was required to dissociate excitons generated in the porphyrin layer, prevent shorts, and maximize NIR absorption [4b].

Current–voltage characteristics were measured using a semiconductor parameter analyzer, and the *EQE* was measured using a lock-in amplifier with devices illuminated with monochromatic, chopped light at ~200 Hz. The effect that additives have on the energies of the porphyrin dimer films was studied by ultraviolet photoelectron spectroscopy (UPS).

Donor layers with molar ratios of Psub:PCBM ranging from 1:0 to 1:20 were used to investigate the effects of fullerene incorporation. As the PCBM concentration was increased, the *EQE* decreased from $1.9 \pm 0.1\%$ for neat Psub to below 0.1% for a Psub:PCBM ratio of 1:20 (Fig. 1). This behavior is distinctly different than when PCBM is used as an electron acceptor for polymers [7] or some small molecules [8], in which case the donor and PCBM phases separate into an interpenetrating network with an increased exciton dissociation efficiency, and thus *EQE* [7] Although the *EQE* of the porphyrin detectors decreases upon addition of PCBM, the dark current decreases, and thus the diode differential resistance increases from $1.4 \pm 0.1 \times 10^9\ \Omega\,cm^2$ for a neat film to $2.9 \pm 0.4 \times 10^{10}\ \Omega\,cm^2$ at a 1:20 M ratio of Psub:PCBM. At that same time, the Q-band absorption peak undergoes a bathochromic shift from $\lambda = 1090$ nm to $\lambda = 1120$ nm with increasing

PCBM concentration, consistent with previous observations [4c,6b].

In this series, the highest specific detectivity ($D^* = 4.0 \pm 0.3 \times 10^{11}$ Jones) was obtained for a Psub:PCBM ratio of 1:0.2. Here, $D^* = \mathscr{R}A^{1/2}S_N^{-1}$, where $\mathscr{R}$ is the responsivity, A is the detector active area, and S_N is the spectral noise density. At zero bias where our detectors are characterized, S_N is dominated by thermal noise with $S_N = (4k_BT/R_D)^{1/2}$, where k_B is the Boltzmann constant, T is the temperature, and R_D is the zero-bias differential resistance [9]. The decrease in *EQE* and increase in R_D have opposite effects on specific detectivity; however, at low PCBM concentrations the increase in differential resistance significantly outweighs the reduction in *EQE*, thereby increasing D^*.

We also investigated a variety of modified pyridines and found that donor-like pyridines (e.g. pyridine, pyrazine, isoquinoline, 4-dimethylaminopyridine) red shift the Psub absorption peak from $\lambda = 1090$ nm to $\lambda = 1100$–1120 nm, disrupt molecular packing and decrease *EQE*, while acceptor-like compounds (e.g. 4-trifluoromethylpyridine or 4-pyridinecarbonitrile) decrease the *EQE* without affecting wavelength response. However, Bipy, a bidentate pyridine molecule, both red shifts the Psub absorption to $\lambda = 1150$ nm, as commonly observed [10] and doubles the NIR *EQE*.

The effects of Bipy additives were explored by varying Pfused:Bipy molar ratios from 1:0.5 to 1:4. Current density (J)-voltage (V) characteristics and spectrally resolved *EQE* are shown in Fig. 2. The specific detectivity is the highest for a neat film (*EQE* = 10.2 ± 0.2% and $D^* = 3.4 \pm 0.2 \times 10^{10}$ Jones at $\lambda = 1330$ nm), although the photoresponse was highest at a ratio of Pfused:Bipy = 1:3 (where *EQE* = 13.5 ± 0.3% and $D^* = 2.1 \pm 0.1 \times 10^{10}$ Jones at $\lambda = 1385$ nm). For the Psub:Bipy = 1:1 device, similar improvements were observed; the *EQE* increased from 1.9 ± 0.1% to 4.0 ± 0.1% accompanied by a decrease in differential resistance from $1.4 \pm 0.1 \times 10^9\ \Omega\,cm^2$ to $7.7 \pm 0.1 \times 10^8\ \Omega\,cm^2$, leading to an increase in detectivity from $D^* = 4.2 \pm 0.2 \times 10^{11}$ Jones to $7.1 \pm 0.2 \times 10^{11}$ Jones. The increase in *EQE* with Bipy additives suggests an increase in the exciton diffusion length in the porphyrin film due to the increased molecular coupling associated with the Bipy linkage.

To maximize D^*, varying amounts of PCBM were added to films with a dimer:Bipy ratio of 1:1. For Psub:PCBM:Bipy = 1:0.1:1, a maximum detectivity of $D^* = 8.8 \pm 0.2 \times 10^{11}$ Jones and *EQE* = 3.6 ± 0.1% at $\lambda = 1150$ nm was observed, and a Pfused:PCBM:Bipy ratio of 1:0.75:1 was found to have a maximum detectivity of $D^* = 8.2 \pm 0.2 \times 10^{10}$ Jones and *EQE* = 10.5 ± 0.2% at $\lambda = 1400$ nm. The J–V characteristics, spectrally resolved *EQEs*, and specific detectivities for Psub:PCBM:Bipy and Pfused:PCBM:Bipy devices are shown in Fig. 3.

Ultraviolet photoelectron spectroscopy was used to investigate the source of the changes in the J–V characteristics. From the measurements, we infer a highest occupied molecular orbital (HOMO) energy of −4.6 ± 0.1 eV for the neat Psub film, −4.7 ± 0.1 eV for a Psub:PCBM ratio of 1:0.2, and −4.5 ± 0.1 eV for a Psub:Bipy ratio of 1:1. For organic heterojunction devices, the saturation dark current density due to generation and recombination at the donor–acceptor heterointerface is: $J_s = J_{S0}exp(-\Delta E_{DA}/k_BT)$, where ΔE_{DA} is the difference between the HOMO energy of the donor and the lowest unoccupied molecular orbital energy of the acceptor, and $J_{S0} = J_S(T = \infty)$ [11]. Using the saturation current for neat Psub ($J_S = 1.1 \pm 0.1 \times 10^{-9}$ A cm^{-2}), Psub:PCBM = 1:0.2 ($J_S = 5.0 \pm 2.0 \times 10^{-10}$ A cm^{-2}) and Psub:Bipy = 1:1 ($J_S = 5.8 \pm 0.2 \times 10^{-9}$ A cm^{-2}), the change in ΔE_{DA} and thus changes in the HOMO energy

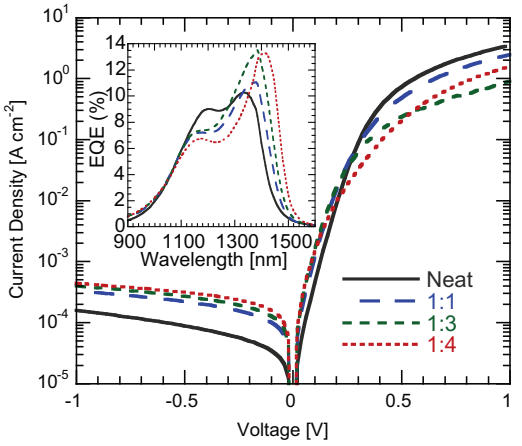

Fig. 2. Current density–voltage characteristics and spectrally resolved EQE (inset) for varying molar ratios of Pfused in Bipy.

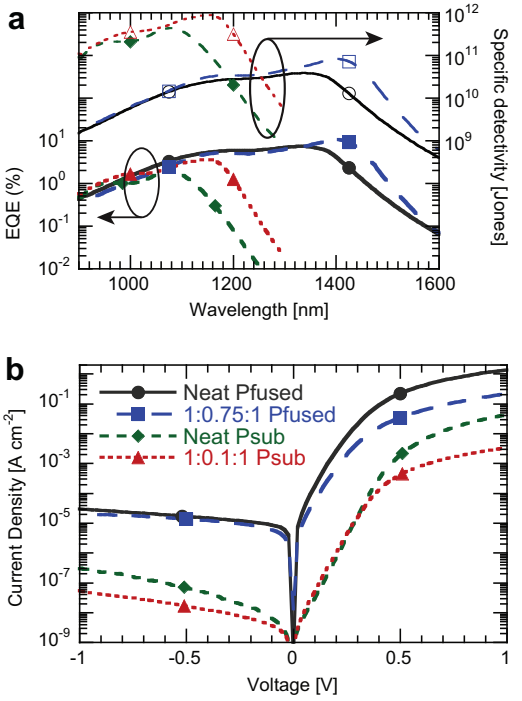

Fig. 3. (a) Spectrally resolved external quantum efficiency (*EQE*-closed symbols) and specific detectivity (solid symbols), and (b) current density–voltage characteristics and for neat Psub (diamonds) and 1:0.1:1 ratio of Psub:PCBM:Bipy (triangles) and for neat Pfused (circles) and 1:0.75:1 ratio of Pfused:PCBM:Bipy (squares).

can be calculated. Relative to neat Psub (HOMO = −4.6 ± 0.1 eV), it was found that PCBM reduced the calculated HOMO energy by 0.02 ± 0.01 eV and Bipy increased the calculated HOMO energy by 0.06 ± 0.01 eV. The agreement between the measured saturation current and the HOMO energy for Psub is within the error of the UPS measurements.

The addition of PCBM to the Psub films optimized for D^* results in insignificant changes to the root-mean square (RMS) roughness of 0.7 ± 0.1 nm (as determined by atomic force microscopy) and the intensity of the (0 0 1) X-ray diffraction peak. The addition of Bipy to Psub (1:1) reduced the intensity of the (0 0 1) diffraction peak by ~90% indicating a reduced crystallinity, and also had an insignificant effect on the film RMS roughness (0.7 ± 0.1 nm and 0.8 ± 0.1 nm for a neat film, and one containing Bipy, respectively), while the addition of Bipy to the less soluble Pfused increases the RMS roughness from 1.3 ± 0.1 nm to 2.3 ± 0.1 nm. The addition of Bipy to the porphyrin solution reduces the solubility of the dimers, resulting in eventual precipitation of the Pfused. The decreased solubility limited the use of Bipy to a dimer similar to Pfused, but having the meso- and beta-positions bonded to the 3- and 4-positions of perylene, as shown in Fig. 1a. Devices using films of neat perylene-fused porphyrin dimers achieved an $EQE = 9.1 \pm 0.2\%$ at $\lambda = 1485$ nm while devices with molar ratios ranging from pyrene-fused:Bipy = 1:0.5 to 1:3 resulted in devices with reduced efficiency.

As noted above, the PCBM and Bipy additives resulted in a red shift in the porphyrin Q-band absorption with increasing concentration. The spacing between Zn-cores in adjacent molecules of our porphyrin tapes is characterized by large distances of 9.5–10 Å [4b], while complexes of fullerenes and metalloporphyrins are characterized by distances of only 2.6–3 Å [4b,6b]. For porphyrin fullerene complexes, an absorption red shift is commonly observed and attributed to favorable van der Waals attraction with a contribution of weak charge transfer between the porphyrin and the fullerene, decreasing the energy of the porphyrin π–π^* transition and the HOMO and LUMO energies [4c,6b]. For the axial metaloprophyrin–imine complexes, the red shift is a well documented phenomenon and typically interpreted as combination of several factors [12]. The first is a decrease in the energy of the π–π^* transition in the metalloporphyrin-additive complex, resulting from the metal becoming more electropositive on coordination of the π-acidic imine ligand, leading to an increase in HOMO energy and stabilization of the LUMO [12a,b]. Metal to pyridine charge transfer on imine coordination to the metalloporphyrin as well as geometry changes in the complex as a result of imine coordination also contribute to the red shift [6f,12c]. Lastly, coordination of two porphyrins through the bidentate Bipy molecule in related systems is thought to provide enhanced coupling between the π-orbitals of linked porphyrin molecules, significantly increasing mobility of positive charges along olygoporphyrin wires [19b]. The substantial increase in exciton diffusion length with the addition of Bipy additives observed here can also be explained by the increased coupling between π-orbitals of diporphyrin cores mediated by the Bipy ligands.

In conclusion, we have demonstrated that adding PCBM to both Psub and Pfused donors reduces *EQE* and increases differential resistance, while adding Bipy increases *EQE* and decreases differential resistance. Both additives cause the NIR photoresponse to red shift with increasing concentration. Psub:PCBM:Bipy = 1:0.1:1 devices have $EQE = 3.6\%$ and $D^* = 8.8 \pm 0.2 \times 10^{11}$ Jones at $\lambda = 1150$ nm, whereas Pfused:PCBM:Bipy = 1:0.75:1 detectors have $EQE = 10.5\%$ and $D^* = 8.2 \pm 0.2 \times 10^{10}$ Jones at $\lambda = 1400$ nm. An $EQE = 13.5\%$ and $D^* = 2.1 \pm 0.1 \times 10^{10}$ Jones at $\lambda = 1385$ nm, was achieved for Pfused:Bipy = 1:3. The decrease in dark current with the addition of PCBM, the increase in *EQE* with addition of Bipy, and the absorption red shift with the addition of Bipy or PCBM are direct consequences of the resulting changes in the frontier orbital energies, and may apply to other porphyrin-based detectors or photovoltaics.

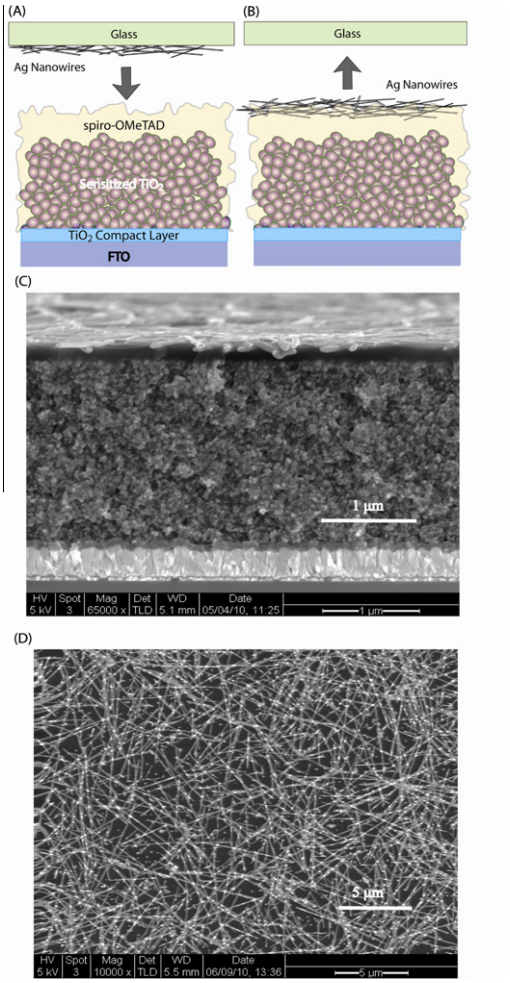

Fig. 1. Device schematic of dye sensitized solar cell (A) before and (B) after Ag NW lamination. (C) SEM side view image (65,000× magnification, 1 μm scale bar) and (D) SEM top view image (10,000× magnification, 5 μm scale bar) of solid-state DSC after Ag NW lamination.

Ag NWs show high transparency in the solar spectrum, have low sheet resistance, and can be processed with high throughput. As the nanowire concentration of the film increases, the transmission decreases and the films become more reflective. In this letter, we show that thick Ag NW meshes can be deposited on top of ss-DSCs as the reflective counter electrode without an annealing step producing comparable power conversion efficiencies versus the evaporated Ag control devices.

ss-DSCs have an empirically optimized titania film thickness of ~2.2 μm (versus >10 μm for liquid DSCs); which is likely due to higher rates of recombination [12,13]. Despite the thinner device architecture, which lowers overall light absorption, ss-DSCs have recently achieved maximum power conversion efficiencies of 6.1% [14]. ss-DSCs have the potential to match or exceed liquid based DSC performance by developing higher molar extinction coefficient dyes for increased light absorption [15–17], hole conductors with lower HOMO levels, new architectures to increase light harvesting [18–23], and tandem devices.

2. Experimental

2.1. Solid-state dye-sensitized solar cell device fabrication

Solid-state DSCs are shown schematically in Fig. 1A. ss-DSCs consist of Flourine doped SnO_2 conducting glass (Hartford Glass TEC 15) which was partially etched using zinc powder and HCl (12%) then cleaned by sonication sequentially in 10% extran, acetone, isopropanol, and water. A 50 nm compact TiO_2 layer was deposited via aerosol spray pyrolysis using air as the carrier gas [24]. Mesoporous titania films were deposited via doctor blading of commercially available paste (Dyesol 18NR-T) and slowly heated to 500 °C for 30 min in air. It should be noted, that TiO_2 paste deposition was performed in a laminar flow hood to minimize dust contamination that can affect the Ag NW transfer. Films were subsequently treated in 0.02 M $TiCl_4$ aqueous solution overnight at room temperature [25]. Samples were then heated to 450 °C for 10 min cooled to approximately 80 °C and immersed in 0.3 mM of Z907 (Solaronix SA) in a 1:1 mixture of acetonitrile and tert-butyl alcohol for 12–18 h. The organic hole conductor solution was made by dissolving 72 mg of 2,2′,7,7′tetrakis-(*N*,*N*-di-*p*-methoxyphenylamine)-9,9′-spirobifluorene (spiro-OMeTAD) in 400 μl of chlorobenzene and then adding 7 μl of tert-butylpyridine and 15 μl of 0.6 M bis(trifluoromethane)sulfonamide lithium salt (Fluka) in acetonitrile. The doped spiro-OMeTAD solution was deposited on the substrate and allowed to infiltrate the TiO_2 for 30 s prior to spin coating (2000 RPM for 40 s) and dried in a dessicator for several hours. Ag counter electrodes (200 nm) for the control devices were evaporated at 2×10^{-6} torr on half of the substrate.

2.2. Silver nanowire synthesis and lamination onto DSC

Silver nanowires were synthesized by reducing Ag nitrate in the presence of poly(vinyl pyrrolidione) in ethylene glycol which resulted in Ag NWs that were on average 8.7 μm long and have 103 nm diameters [11,26]. To create films on the host substrate, Ag NWs were deposited from methanol onto coverslip glass and annealed at 180 °C to fuse the junctions between the wires and enhance conductivity [10,11,27]. The Ag NW films were then pressed onto the spiro-OMeTAD at a pressure of 1.6×10^4 psi for approximately 30 s, as illustrated in Fig. 1A and B. Care should be taken during lamination to remove any debris on the press and align the press to consistently apply pressure across the glass surface; inconsistent pressure can cause substrate cracking. Laminated Ag NW films were roughly 2–4 nanowires thick (100–200 nm) as shown in the SEM image in Fig. 1C. During lamination >95% of the Ag NWs are transferred to the ss-DSC substrate. The overall surface coverage is relatively sparse as shown in Fig. 1D. ImageJ software was used to analyze the SEM image and determined that approximately 59% of the spiro-OMeTAD surface is covered by AgNWs. A four-point probe measurement was used to determine a sheet resistance of 4.5 Ω/□ for AgNWs counter electrode versus 1.3 Ω/□ for 200 nm of evaporated silver on inert

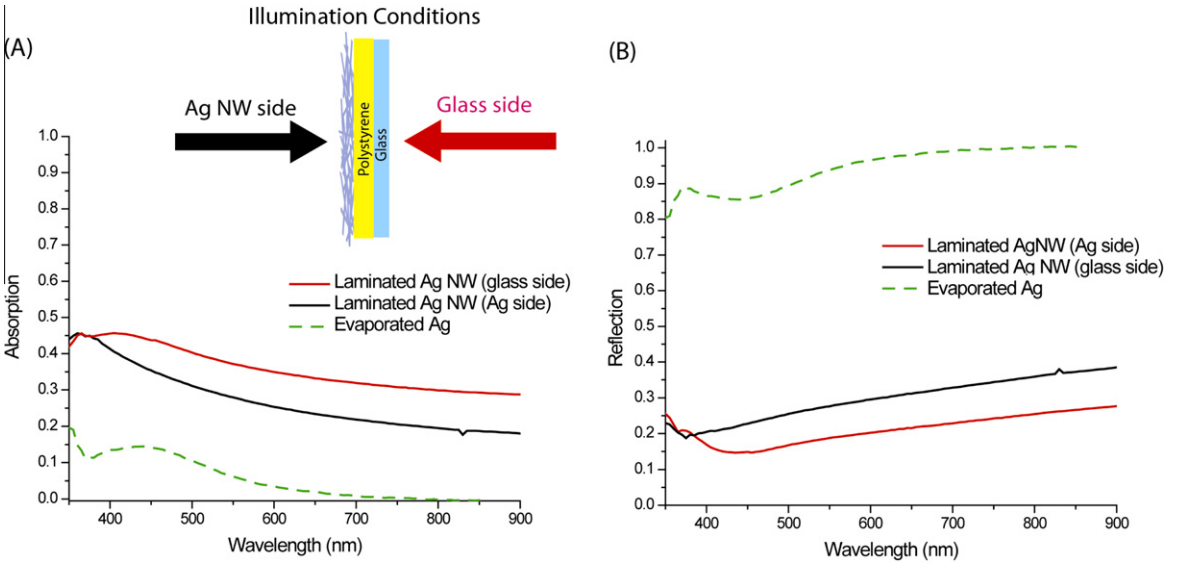

Fig. 2. Specular and diffuse (A) Absorption and (B) reflection of evaporated Ag versus laminated Ag NW electrodes on polystyrene/glass substrate under various illumination conditions described in the inset.

polystyrene films. The counter electrode makes a relatively small contribution to the series resistance which is dominated by the FTO (15 Ω/□) and the internal resistance of the doped spiro-OMeTAD. It should be noted, that Ag NWs were laminated on the same substrate as evaporated Ag to ensure the most accurate comparison.

3. Results and discussion

For measurements to determine the optical properties of the counter electrodes, Ag was evaporated and Ag NWs were pressed into a thin layer (<100 nm) of polystyrene on a glass slide as shown in the inset of Fig. 2. Polystyrene is a wide band gap polymer with negligible absorption in the visible and near-infrared portion of the spectrum. Absolute (i.e. specular and diffuse) light absorption (Fig. 2A) and transmission were measured with an integrating sphere (Labsphere) with methods previously described [28]. The absolute reflection (Fig. 2B) was calculated from the absorption and transmission values (i.e. $R = 1 - T - A$). The absorption of Ag NWs is dependent upon the illumination condition; Ag NWs absorb more light when illuminated from the glass/polystyrene side (red solid)[1] versus the Ag NW side (black solid) as shown in Fig. 2A. The increase in absorption may be caused by increased light scattering due to changes in the Ag NW morphology during lamination and via total internal reflections inside the polystyrene/glass. During lamination, the cylindrically shaped silver nanowires penetrate into the soft polymer surface creating a rough, scattering interface on the polystyrene side. However, the portion of the Ag NW touching the host substrate is flattened and becomes relatively smooth (Fig. 1C) reducing light scattering. Secondly, light scattered in the polystyrene, which has an index of refraction of approximately 1.55, can undergo total internal reflection increasing the optical path length and increasing overall light absorption by Ag NWs. Evaporated Ag (green dash) is only slightly absorptive and is highly reflective throughout the spectrum for both illumination directions. The variation in reflection between Ag NWs and evaporated Ag films is primarily related to higher light absorption by the Ag NWs and the low surface density of Ag NWs compared to the unity surface coverage of evaporated Ag.

Fig. 3A displays the total light absorption of all layers in ss-DSC devices using Ag NWs and evaporated Ag contacts illuminated through the FTO side. Spiro-OMeTAD dominates light absorption inside the ss-DSC from 350 to 425 nm. Both the evaporated Ag and Ag NW ss-DSCs have similar absorption profiles in the region where the sensitizing dye absorbs most strongly (425–550 nm). At the peak absorption of the Z907 (525 nm), roughly 80% of the light is absorbed by the control versus 71% for the Ag NW ss-DSCs. Most of the loss in absorption is due to transmission through the device; specular transmission measurements (not shown) reveal that 15% of the light at 525 nm is transmitted through the Ag NW ss-DSC. In the red/near-infrared portion of the spectrum, the Ag NW ss-DSCs have overall higher absorption due to Ag NW absorption that does not contribute to the photocurrent. It should be noted that the Ag NW ss-DSC absorption profile is smoother and does not contain the interference effects typically seen with evaporated electrodes. Because these measurements were taken on the same substrate, the smooth profile further strengthens our hypothesis that pressing nanowires into the spiro-OMeTAD overlayer roughens the rear interface, increasing scattering off of the back contact and reducing interference effects.

External quantum efficiency (EQE) measurements were performed at a chopping frequency of 45 Hz using a Stanford Research System lock-in amplifier (Model SR830) under white light bias equivalent to 10% sun. The

Electrode	Device Area	Jsc [mA/cm^2]	Voc [mV]	FF	PCE (%)
Evaporated Ag	0.09 cm^2	6.2	765	0.60	2.8
Laminated Ag NW	0.07 cm^2	5.2	755	0.69	2.7

Fig. 3. (A) Total light absorption and external quantum efficiency plots of solid-state dye-sensitized solar cells made with evaporated Ag and laminated Ag NW counter electrodes. (B) Photocurrent density versus voltage (JV) plot of ss-DSCs with Ag NW counter electrode (red line) versus evaporated Ag control (dashed black line). PV device characteristics are shown in the figure inset.

EQE, shown in Fig. 3A, scales with light absorption and explains the correspondingly lower photocurrent of Ag NW ss-DSCs versus the control shown in Fig. 3B. Ag NW devices have comparable power conversion efficiency (2.7%) versus the control ss-DSC (2.8%). Ag NW devices have lower short-circuit current density (Jsc), due to a lower reflectivity, but consistently displayed higher fill factors (FF) and behaved differently during light soaking. Evaporated Ag devices initially had very low fill factors (0.4–0.45) and required >15 min of light soaking (100% sun) under +1 V bias to dramatically increase the fill factor (0.55–0.60). Ag NW based devices had significantly higher initial fill factors (0.57–0.65) that increased slightly over <5 min of light soaking to (0.62–0.69). It should be noted that FF ranges were based on five devices that contained an equal number of evaporated Ag and Ag NW electrodes. Despite the slightly higher sheet resistance of Ag NW electrodes, the overall series resistance, which can be approximated as the slope of the JV curves at far forward bias, is nominally the same for both devices. The spiro-OMeTAD overlayer is known to increase the series resistance and decrease the fill factor of ss-DSCs [29]. Pressed Ag NWs penetrate into the 150–200 nm spiro-OMeTAD overlayer, which we believe helps lower the effective series resistance within the spiro-OMeTAD layer, compensating for the higher sheet resistance of the Ag NWs. In addition, Ag NWs films are fabricated and stored in air, which creates a thin silver oxide layer on the surface that increases the work function and may improve charge collection. The work function of Ag, at 4.4 eV, is significantly higher than the HOMO level of spiro-OMeTAD (5.2 eV), which requires large band bending or Fermi-level pinning [30] at the spiro-OMeTAD/Ag interface for good electrical contact. However, silver oxide (Ag_2O) has a work function of 5.1 eV and often exhibits p-type conductivity [31], which would act as an ideal charge collector with minimal recombination losses at this interface [5]. Evaporated Ag electrodes, however, are deposited in vacuum and may require time to allow for oxygen to diffuse and oxidize Ag at the metal/spiro-OMeTAD interface, possibly explaining the requirement of longer light soaking times to achieve a higher FF. A complete explanation of the effects of light soaking on solid-state DSCs is beyond the scope of this work and will be discussed in a future study.

4. Discussion and conclusion

Reflectivity, and thus overall power conversion efficiency of metal nanowire based electrodes, can be improved by developing new procedures to deposit more nanowires on the ss-DSC. Laminated Ag NWs are limited due to the pressing procedure, as each wire must come into contact with the soft hole conductor to be transferred. Wire meshes that are too thick cannot be completely transferred to another substrate. Directly spray coating or doctor blading NWs onto the cell could increase the overall surface concentration. These techniques would require solvents that do not dissolve the spiro-OMeTAD and a low temperature sintering step to prevent degradation of the ss-DSC. Laminating Ag nanoparticle films, which can be made into more densely packed films, may also result in more reflective films [9,32].

To the best of our knowledge, reflective silver nanowire meshes represent the first replacement of evaporated metal counter electrodes used in solid-state DSCs. This work demonstrates the general feasibility of laminating Ag NWs on ss-DSCs and achieves comparable device performance with standard thermally deposited Ag electrodes but with the potential for high throughput processing and unity material usage. This work may be extended to

semi-transparent Ag NW electrodes for ss-DSCs. Semi-transparent Ag NW meshes could be used as the front contact on glass-free, flexible ss-DSCs which use titania nanoparticles on metal foil [33] and also as an intermediary electrode in a tandem ss-DSC architecture. Finally, it should be noted that Ag NWs are dissolved by iodide based electrolytes, but may be implemented in liquid DSCs that use organic electrolytes [34,35].

In the current work, we focus on investigating the S-shape effect in bilayer heterojunction photovoltaic devices induced by the exciton blocking layer (EBL) which has shown to be an essential layer for high performance bilayer OPV devices [8]. Previously, the effect of different kinds of materials working as EBL on the performance of OPV have been researched by Yu et al. [19] and demonstrated the J_{SC} of the device would decrease exponentially with the thicknesses of the buffer layer thicknesses and they attributed this effect to the decrease of conductivity. Particularly for the bathocuproine (BCP), Peumans et al. have shown that favorable hopping states were induced by the thermalization of the hot metal atoms on the BCP layer and they found the optimum BCP thickness is around 15 nm. Here, instead of just comparing the *J–V* curves of the devices with various BCP thicknesses, we tried to understand the physics origin of the EBL thickness effect by using *C–V* measurements to study the charge accumulation effect due to the presence of thick exciton blocking layer in the bilayer heterojunction photovoltaic devices. We demonstrated the occurrence of the S-shape effect in the *J–V* curves and charge accumulation in the device can be controlled by modulating the BCP layer thickness from 5 to 20 nm. We also applied a numerical model to simulate the *J–V* curve of the devices and the model suggests that the interfacial recombination near the C_{60}/BCP interface and BCP layer cause S-shape effect in *J–V* curves. Our finding indicates the importance of the charge accumulation effect and a careful control of the exciton blocking layer in bilayer heterojunction OPV devices.

2. Experimental

In our bilayer heterojunction OPV devices, MoO_3 (99.5%, Aldrich), CuPc (99%, Aldrich), C_{60} (99.5%, Aldrich), BCP (98%, Aldrich), were used as received. Indium-tin-oxide (ITO) coated glass substrates with sheet resistance of 13 Ω/□ were cleaned using DI water and chemical solvents [8,20]. After cleaning, the substrates were dried by 99.995% pure nitrogen and treated by O_2 plasma for 15 min prior to loading into vacuum chamber. All the materials were deposited using thermal evaporation under a pressure of $<1 \times 10^{-6}$ Torr at a deposition rate of 0.1 nm/s for organic layers and Ag cathode. Fig. 1 shows the schematic structure of bilayer heterojunction small molecule organic solar cells, ITO/MoO_3(10 nm)/CuPc(20 nm)/C_{60}(45 nm)/BCP(5–20 nm)/Ag(100 nm). In the work, all the processing factors were kept identical except the thicknesses of the BCP layers and a quartz crystal monitor was used to determine film thickness and deposition rate. The Ag cathodes were evaporated through a metal shadow mask with 2 mm diameter openings. The *J–V* characteristics were measured by a Keithley 2400 under illumination of AM1.5G 95 mW/cm^2 simulated solar spectrum from a solar simulator (Newport 69911). The power density of the solar simulator was calibrated by a silicon reference cell (NIST) and monitored by a power meter throughout the measurement. The *C–V* curve was measured by Agilent B1500A Semiconductor Device Analyzer.

3. Numerical model

Although the S-shape effect in the bilayer heterojunction photovoltaic has not been intensively investigated, the S-shape effect in bulk heterojunction OPV has been recently studied by numerical simulation and it has been observed that surface recombination rate as a boundary condition governs the S-shape properties in the *J–V* curves of the bulk heterojunction OPV [21]. Similar to the numerical model in Ref. [21], the one-dimensional carrier transport model for the device is based on the Poisson equation and continuity equation under steady state,

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{q}{\varepsilon_0 \varepsilon_r}(p - n) \tag{1}$$

$$\nabla \cdot J - R + G = 0 \tag{2}$$

The current density can be further substituted by the charge transport equations,

$$J_p = -KT\mu_p \partial p/\partial x + qp\mu_p F \tag{3}$$

$$J_n = KT\mu_n \partial n/\partial x + qn\mu_n F \tag{4}$$

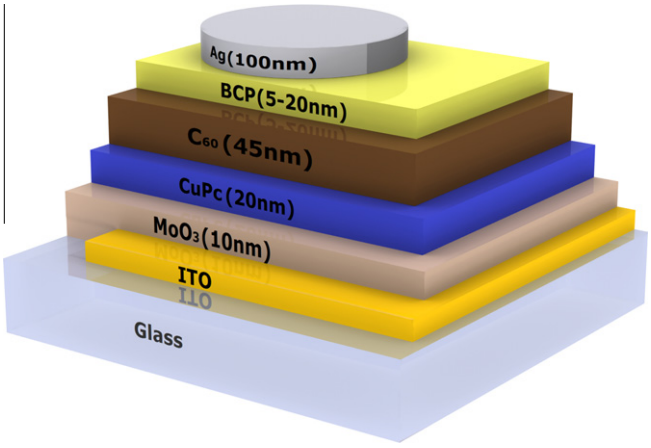

Fig. 1. The schematic of bilayer heterojunction small molecule organic solar cell.

In the above equations, μ_n and μ_p are the charge carrier mobility for electrons and holes, q is the elementary charge, T is the temperature, n and p are the electron and hole density and ε_r is the material effective dielectric permeability, F denotes the electrical field, R and G describe the recombination and generation rate of the charge carriers. According to the thermionic emission theory [22], the boundary conditions can be written as,

$$n(0) = N_c \exp\left[-\frac{(E_{g1} - \phi_1)}{KT}\right] \quad (5)$$

$$p(0) = N_v \exp\left(-\frac{\phi_1}{KT}\right) \quad (6)$$

$$n(L) = N_c \exp\left(-\frac{\phi_2}{KT}\right) \quad (7)$$

$$p(L) = N_v \exp\left[-\frac{(E_{g2} - \phi_2)}{KT}\right] \quad (8)$$

Eqs. (5)–(8) state the hole and electron concentrations at the interfaces between anode/donor and cathode/acceptor, respectively, and the band diagram of the simulation model is shown in Fig. 2. N_c and N_v are the corresponding effective charge carrier density. The electron and hole concentrations at the anode/donor interface are calculated by the energy difference between the anode work function and hole conducting highest occupied molecular orbital (HOMO), i.e. ϕ_1 in Fig. 2. In analogy, ϕ_2 is used to evaluate the carrier concentration at the buffer layer and cathode interface. The set of equations are solved by numerical approach AMPS-1D [23].

In bilayer heterojunction OPV devices, excitons are generated by the irradiated photon and diffuse to the interface of donor/acceptor where the excitons will then be split up. Due to the favor in energy, the holes remain on donor's HOMO whereas the electrons are transferred to acceptor's LUMO [20,24]. In the current model, the generation process is represented by inserting a 5 nm generation layer with a bandgap (E_g) between the donor and acceptor layers (as shown in Fig. 2) and the free carriers are generated from this layer [25]. Furthermore, we considered BCP layer effect by introducing the buffer layer with thickness varying from 5 to 20 nm as shown in Fig. 2. It is important to noticed that using the buffer layer with a smaller bandgap to replace BCP layer is due to (i) preventing the numerical instability in the simulation model which is based on inorganic semiconductor theories; (ii) the buffer layer consists of two opposite effects; one is the charge hopping states induced by silver deposition for carrier transfer and the other is the gap states for recombination. When the buffer layer is thin, the hopping states would be dominant and when the buffer layer is thick, as the generated charges cannot hop to the electrode effectively, they will recombine near the C_{60}/BCP interface hence the gap states for recombination would be dominant. For simplicity, we adapted the buffer layer for qualitatively study of the S-shape effect in the J–V curves. The parameters used in the simulation are given in Table 1.

Table 1
The parameters used in simulation.

Parameter	Symbol	Numerical value
Bandgap [9,23]	E_{gA}, E_{gD}	1.7 eV, 1.7 eV
	E_g	1.4 eV
Electron mobility	μ_n	10^{-1} cm^2/Vs
Hole mobility	μ_p	10^{-2} cm^2/Vs
Eff. density of states	N_c, N_v	1.7×10^{21} cm^{-3}
Dielectric constant[a] CuPc, C_{60}	ε_r	3, 4
Injection barrier	ϕ_1, ϕ_2	0 eV, 0.1 eV
Temperature	T	300 K
Thickness of organic semiconductor	L_1, L_2, L_3	20, 5 and 45 nm
Contact recombination rate	S_{NO}, S_{PO}	10^{10} cm/s, 10^{10} cm/s
	S_{NL}, S_{PL}	10^{10} cm/s, 10^{10} cm/s
Discrete donor-like gap state concentration	ND[b]	10^{18} cm^{-3}
Capture cross section	σ[c]	10^{-10} cm^2

4. Results and discussion

The J–V curves of the experimental and simulated devices are shown in Fig. 3(a) and (b), respectively. In Fig. 3(a), it can be noticed that when the thickness of BCP is below 15 nm, normal exponential J–V curves are

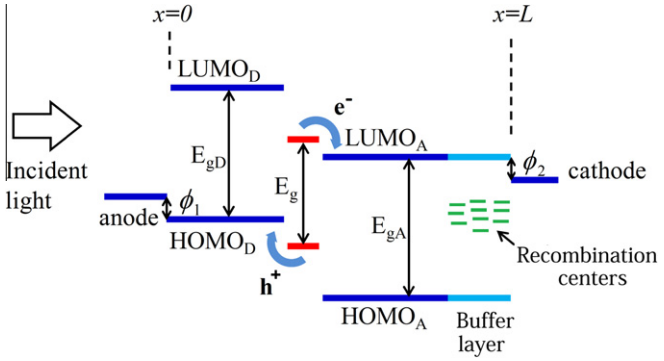

Fig. 2. Band diagram used in simulation with insert of a thin generation layer.

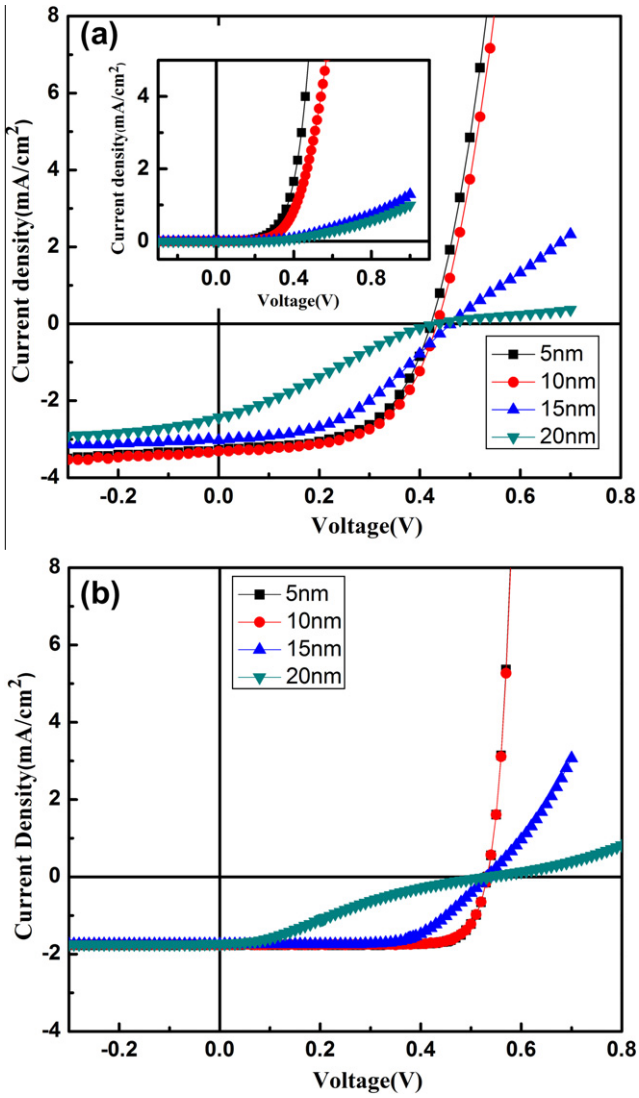

Fig. 3. The *J–V* characteristic varies with the thickness of BCP layer; (a) ITO/MoO_3(10 nm)/CuPc(20 nm)/nmC_{60}(45 nm)/BCP(x)/Ag, inset shows the *J–V* curves of the devices under dark. (b) The numerically simulated *J–V* curves with different buffer layer thicknesses.

observed. When the thickness of the BCP equals to 15 nm, an S-shape characteristic appears and the exponential diode curve degrades remarkably, leading to a significant drop in the FF. When increasing the BCP thickness up to 20 nm, the S-shape is further reinforced. It is worthy to mention that the *J–V* curves of the device under dark does not show the kinks (inset of Fig. 3(a)) which implies the kink observed in the *J–V* curves under illumination is related to the photo-generated carriers. The current observation about the critical thickness of the BCP layer agrees with the previous work [8], where the permeated depth of the hot metal atoms in BCP layer during evaporating of electrode is around 15 nm. We argue the BCP layer consists of two regions (sub-layers): an unaffected BCP layer and the metal permeated BCP layer. The unaffected region is a barrier for electron transport, and cause charge accumulation at the contact with C_{60} layer, while the metal permeated region has favorable hopping site for the electrons to hop through. If the BCP layer thickness is thin and the metal permeated layer is dominant, the S-shape effect would be vanished. On the other hand, when the BCP layer is 15 nm or thicker, the unaffected BCP region will dominate the electron transport process in the device and S-shape *J–V* curves would be observed. The simulation results shown in Fig. 3(b) agree with the experimental results when the buffer layer is thin, the charge carriers will be extracted by cathode effectively and resulting an exponential *J–V* curve. While the buffer layer is thick, the charge extraction will be hindered; the photo-generated charges would be recombined in the buffer layer and induce the S-shape *J–V* curve.

The thickness effect of the BCP exciton blocking layer is further illustrated by the band diagram as shown in Fig. 4(a) and (b). The extracted current density (J_E) presents at *J–V* curve is related to the recombination current (J_R) and the photo-generated current (J_G) by

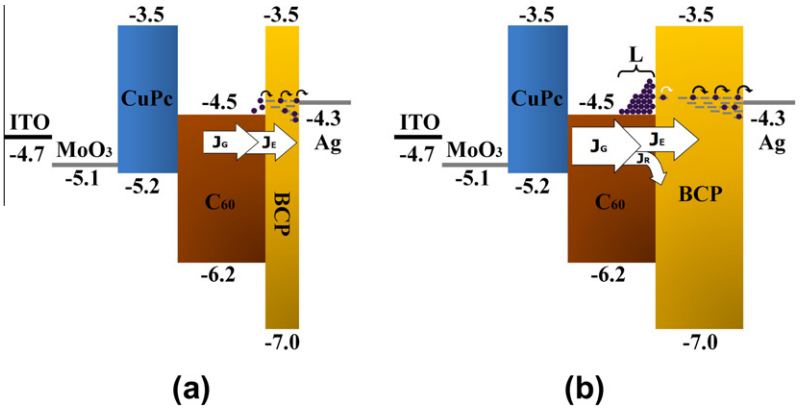

Fig. 4. The energy diagram of the bilayer heterojunction solar cell, including a distribution of trap density in BCP layer. The units are in eV and the inserted arrows show the interfacial electrical process before extracted by cathode, (a) device with 5nmBCP, (b) device with 20nmBCP. The curved arrows represent the hopping mechanism across the BCP layer.

$$J_E = J_G - J_R \tag{9}$$

Similar to the surface recombination boundary condition in the bulk heterojunction OPV [21], the space charge recombination current density at the charge accumulation region can be written as [26],

$$J_R = q \cdot R \cdot L = q \cdot \frac{\Delta n}{\tau} \cdot L \tag{10}$$

where Δn refers to the accumulated charge density at the interface between acceptor and cathode, τ is the lifetime for electron in acceptor, L is the charge accumulation layer thickness and R is recombination rate. According to the experimental results, when the BCP thickness is equal to 5 or 10 nm (Fig. 4(a)), the charge accumulation carrier density (Δn) is small and the charge accumulation layer region L cannot be formed hence the recombination current can be neglected. When the thickness of BCP layer increases (Fig. 4(b)), the blocking effect induces the charge accumulation and the gap states recombination current (J_R) makes a significant influence on the J_E and induces the shape change in the J–V curves as shown in both experimental and simulation results.

To further confirm the charge accumulation effect in the devices with thick BCP layer, we performed C–V measurements (Fig. 5) in the 5 and 20 nm BCP devices both under dark and illumination with AM 1.5 filter [27]. One can deviate the C–V bias range into two different regions, smaller than the V_{oc} (around 0.43 V) and larger than V_{oc}. In the dark environment, the capacitances of both devices remain nearly constant until the applied bias is close to V_{oc}. The constant capacitances of both devices under dark are considered as the geometric capacitance of the device and it is around 3 nF. When the applied bias is larger than V_{oc}, the capacitances begin to be uptrend, where charges are injected from the electrode and the 5 nm BCP device has larger capacitance than that with the 20 nm BCP which implies more effective charge injection in the former. While under illumination, the 5 nm BCP devices does not show a significant increase in the capacitance at the voltage range between negative bias to V_{oc}, it indicates that the photo-generated charges can be effectively collected

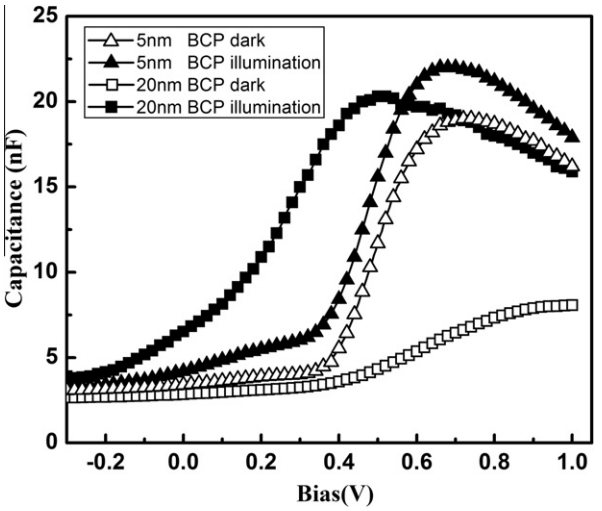

Fig. 5. Capacitance–voltage curve of devices with 5 and 20 nm BCP under dark and AM1.5 filer, the frequency used is 1 kHz, OSC is 20 meV.

by the electrode and no charge accumulation occurs; however, for the 20 nm BCP device, a significant increase is observed in the same bias range, which implies the photo-generated carriers are accumulated within the device and cannot be collected by the electrode effectively. The charge accumulation effect can also be used to explain the S-shape effect in the J–V curves; by considering the case of zero applied electric field ($V = 0$), the 20 nm BCP device has the larger capacitance value than the 5 nm BCP device which implies not all photo-generated charges are collected and measured externally at the electrode hence the short circuit current (J_{SC}) of the 20 nm device is smaller as shown in Fig. 3(a). By comparing the J–V and C–V measurement results, we attribute the increases of BCP thickness would cause charge accumulation within the device and resulting in the S-shape effect in the J–V curves. Accompany with the S-shape effect in the J–V curves of the device, the fill factors and the power conversion efficiencies would also decrease when the BCP layer increases as shown in Table 2. It can be

Table 2
The parameters of device performance.

BCP	S-shape	FF	J_{SC} (mA/cm^2)	V_{oc} (V)	η (%)	R_s (Ω cm^2)	R_p (Ω cm^2)
5 nm	–	0.57	3.28	0.43	0.84	4.397	1212
10 nm	–	0.58	3.31	0.43	0.87	4.700	1329
15 nm	√	0.44	3.03	0.47	0.66	–	–
20 nm	√	0.26	2.44	0.44	0.29	–	–

seen that there is an undesirable drop on the FF of the devices caused by increasing the thickness of BCP from 10 to 20 nm. The more than 2-fold degradation of FF from 0.58 to 0.26 is induced by the S-shape *J–V* curves. It is also worthy to mention that the open circuit voltage V_{oc} of the bilayer heterojunction devices does not show a general variation trend when the BCP thickness increases. It may be due to the band bending at the interfaces between the organic layers could partly compensate for band bending at the metal–organic interface hence no significant change in V_{oc} is observed as in the bilayer heterojunction devices where V_{oc} drops when S-shape *J–V* curves occur [28].

5. Conclusion

In conclude, we study the thickness effect of exciton blocking layer in bilayer heterojunction organic solar cells. We demonstrated charge accumulation would occur in thick BCP layer which causes S-shape effect in the *J–V* curves and significantly degrades the device performance. A numerical method is developed to reproduce the *J–V* curves by inserting a buffer layer with a gap state recombination site. The simulation results indicate when the BCP layer is thicker than 15 nm, the interfacial recombination will modulate the extracted current and induce an S-shape characteristic in the *J–V* curves. The charge accumulation hypothesis is further confirmed experimentally by the *C–V* measurement of the devices under dark and under solar simulator illumination. Our work demonstrated the thickness of exciton blocking layer plays an important role in the performance and provides insights into the origin of the S-shape phenomenon in planar bilayer heterojunction organic photovoltaics.

the absorption enhancement due to scattering [16–20]. Moreover, the backside structures do not increase the optical transmission at oblique angles of incidence (AOIs).

Herein, we present a quasi-periodic structure (QPS) on the indium tin oxide (ITO) anode, fabricated by scalable colloidal lithography. The ITO-QPS effectively couples the incident light to the photo-active layer via antireflection and light trapping mechanisms to boost the conversion efficiency of organic solar cells. Moreover, angle-resolved absorption spectroscopy reveals outstanding light coupling via ITO-QPS at large AOIs, promising omnidirectional and broadband light harvesting.

2. Experimental

The schematic illustration of the fabrication process is shown in Fig. 1. The ITO-QPS was fabricated with scalable colloidal lithography utilizing polystyrene (PS) nanospheres with a diameter of 600 nm as sacrificial masks. First, the PS spheres were spun-coated onto 260 nm thick ITO glass which self-assembled into a monolayer of closely-packed beads. A metal etcher (ILD-4100) was then employed to fabricate the ITO nanorod structure with BCl_3 = 100 sccm injection, pressure of 5 mtorr and an etching time of 170 s, which resulted in an ITO nanorod with a height of 100 nm. Removal of leftover PS was performed by dipping the ITO glass into acetone with sonification for 5 min. The scanning electron images (SEM) of the ITO-QPS before depositing the active layers are shown in Fig. 2a and b.

The glass substrate with ITO-QPS was then cleaned by ultrasonic treatment in detergents, including methanol, acetone and isopropyl alcohol, and finally dried overnight in an oven. Then, 12 nm PEDOT:PSS (Baytron P VP A1 4083) was spun-cast on the ultraviolet ozone-treated ITO. After annealing the PEDOT:PSS film at 120 °C for 30 min in the air, the sample was transferred to a glove box. The active material consisted of 2 wt.% RR-P3HT (Mw 3.7×10^4 g mol^{-1}) and 2 wt.% PCBM in a dichlorobenzene solution, obtained from Rieke Metals and Nano-C Inc., respectively.

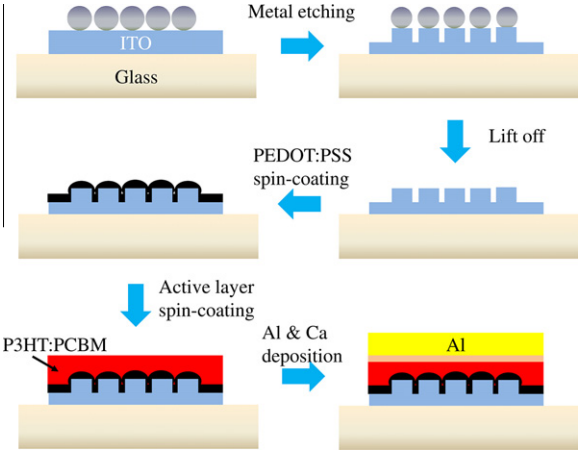

Fig. 1. The fabrication process of an organic solar cell with a patterned frontal electrode using colloidal lithography.

The solution blend was then spun-cast onto the PEDOT:PSS layer at a speed of 600 rpm for 60 s and then dried in covered Petri glass dishes for 30 min at room temperature. The thickness of P3HT:PCBM is 170 nm. Next, the semi-finished samples were baked on a hotplate for 30 min at 120 °C. Finally, 30 nm thick calcium followed by 60 nm thick aluminum was thermally coated onto the active material at a pressure of 6×10^{-6} torr through a 0.1 cm^2 shadow mask. The samples are prepared with a size of 20 × 50 mm and the results shown here are the averages of three samples.

Efficiency measurements were performed under simulated AM1.5G irradiation (100 mW/cm^2) using a Xenon lamp-based Thermal Oriel 1000 W solar simulator. The spectrum of the solar simulator was calibrated by a PV-measurement (PVM-154) mono-Si solar cell (NREL calibrated), and a Si photo diode with KG-5 color filter (Hamamatsu, Inc.) was used to check the irradiation of the exposed area (100 mW/cm^2). The PVM-154 combined with a KG-5 filter (350–700 nm passed, Newport) was used to simulate a reference solar cell with a spectral response from 350 to 700 nm, where the calibration was based on the IEC-69094-1 spectrum. *I–V* curves were measured with a semiconductor source measure unit (Keithley 2400) using a four wire connection and the measurements were corrected for the external series resistance. Stability in time is continuously monitored by routinely repeating the measurements on c-Si solar cells. The temperature of the cells was actively controlled during the measurements at 25 ± 1 °C.

The external quantum efficiency (EQE) system is equipped with a 450 W Xenon lamp (Oriel Instrument, model 6266) light source, a water-based IR filter (Oriel Instrument, model 6123 NS) and a monochromator (Oriel Instrument, model 74,100). The beam spot on the sample is rectangular, measuring roughly 1 × 3 mm. A calibrated silicon photodetector (Newport 818-UV) was used to calibrate the EQE system before measurements. A lock-in amplifier (Standard Research System, SR830) and an optical chopper controller (SR540), set in the voltage mode, were also equipped to lock the output signal and the photocurrent was converted to the voltage using a 1 ohm resistor, which was parallel to the sample. The temperature of cells was again actively controlled during the measurements at 25 ± 1 °C.

3. Results and discussion

Fig. 3 depicts the measured absorption and external quantum efficiency (EQE) spectra of organic solar cells with the ITO-QPS and with a flat ITO layer at normal incidence. The absorption measurement was carried out using an integrating sphere system to collect the scattered reflected photons. The superior absorption in the entire spectrum for the ITO-QPS cell is shown, especially in the wavelength range between 520 and 670 nm. The enhanced absorption results from the light coupling by the ITO-QPS, which serves both functions as the antireflection and forward scattering for light trapping. Inspection of the absorption and EQE spectra confirms that the enhanced carrier generation is contributed from the superior photon absorption.

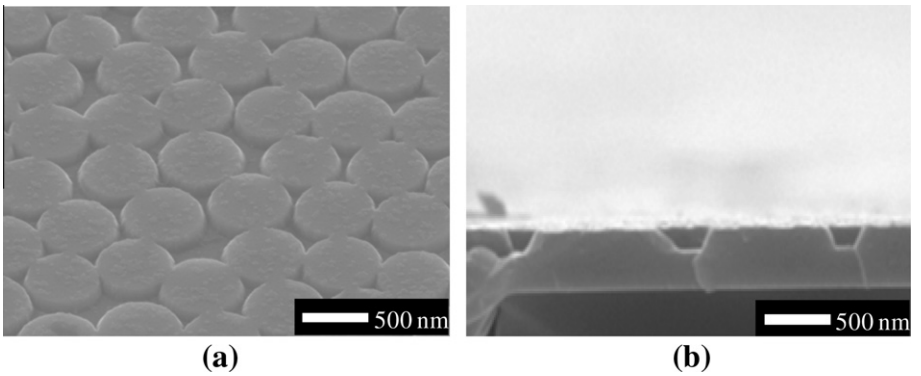

Fig. 2. The (a) top view and (b) cross-section SEM images of the ITO-QPS before the deposition of organic materials.

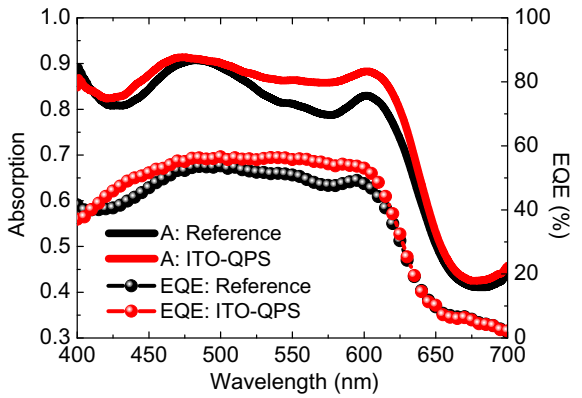

Fig. 3. Measured absorption and external quantum efficiency (EQE) spectra for the flat cell and the cell with an ITO-QPS.

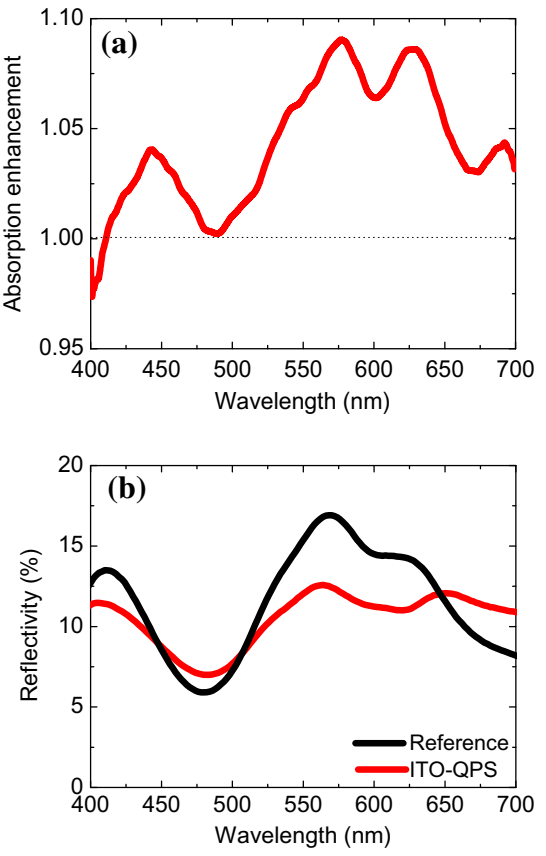

Fig. 4. (a) Absorption enhancement of the ITO-QPS cell to the reference. (b) Measured reflectivity of the devices without an Al back reflector.

The absorption enhancement by taking the ratio of absorption in Fig. 3 is plotted in Fig. 4a, which demonstrates a broadband improvement from 500 to 700 nm due to sufficient photon coupling by the frontal pattern. A required absorption length for different wavelengths can be calculated by $L = 1/\alpha$, where α is the measured absorption coefficient of P3HT:PCBM. The round-trip light propagation length is twice the thickness of P3HT:PCBM, approximately 340 nm, which corresponds to the absorption length for the 620 nm wavelength. The absorption enhancement in the spectrum region below $\lambda = 620$ nm, where the incident photons can be completely absorbed within a round-trip path length in the P3HT:PCBM layer, shows the antireflective property of the frontal ITO nanostructure. Forward scattering by the frontal ITO-QPS contributes to the absorption enhancement in P3HT:PCBM layer after $\lambda = 620$ nm. The measured reflectivity of the devices without Al back reflector is shown in Fig. 4b. In the wavelength range of $640 < \lambda < 700$ nm, the ITO-QPS device has higher reflection than the reference device before the Al back reflector deposition. However, after the deposition of Al back reflector, the absorption for the ITO-QPS cell was enhanced, which indicates the absorption enhancement (see in Fig. 4a) was contributed by light trapping. The enhanced absorption of the ITO-QPS cell reflects the boosting of the power conversion efficiency. The current density–voltage (J–V) characteristics for the reference and ITO-QPS cells under AM 1.5 conditions are shown in Fig. 5. The conversion efficiencies for the reference and ITO-QPS cells are measured at 2.91% and 3.26%, respectively. Compared to the reference cell, the ITO-QPS cell shows a 12% enhancement. This efficiency enhancement is contributed from the optical absorption, which results in an increase in the short-circuit current density,

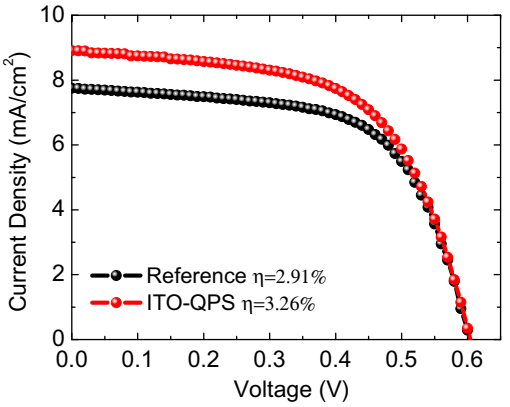

Fig. 5. Measured current–voltage curve of cells.

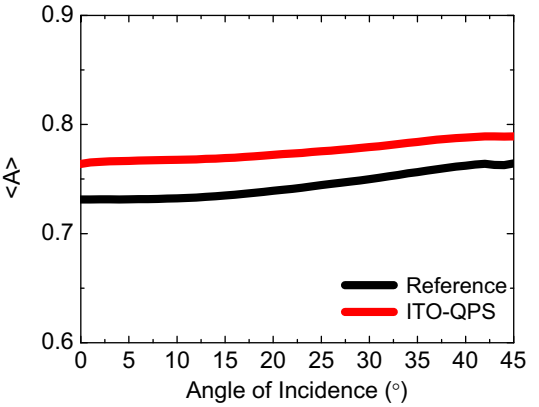

Fig. 7. Averaged absorption of the reference film and the ITO-QPS cell.

J_{sc} = 8.91 mA/cm^2 compared to the reference cell with J_{sc} = 7.75 mA/cm^2. The open circuit voltage V_{oc} of the ITO-QPS cell remains the same (0.6 V) and the deterioration of fill factors (from 63.6% to 61%) could result from the damaged ITO after metal etching.

The light harvesting at large angles of incidence is another key issue for thin film solar cells. The large-angle light harvesting of the cell benefits sufficient power generation in the daytime. Fig. 6a and b show the measured angle-resolved absorption spectroscopy of the reference cell and the ITO-QPS cell, respectively. Angle-resolved absorption spectroscopy is performed within the wavelength of 400 and 700 nm. However, only the wavelength range between 400 and 650 nm is shown, to reveal a clear contrast in the color maps. The measuring systems utilize a custom-built 15 cm radius integrating sphere with a motor-controlled rotational sample stage in the center and a randomly polarized broadband Xenon lamp to simulate the polarization state of sun light. The collection of reflected photons is then analyzed by a spectrometer (QE65000, Ocean Optics) to obtain the absorption spectrum with respect to different angles of incidence, of up to 45°. The system is calibrated by the reflective spectrum of a NIST-standard, intrinsic Si at normal incidence. Evidently, the angular absorption is enhanced by the ITO-QPS, especially in the range of $540 < \lambda < 620$ nm. The optical coupling at oblique AOI is tailed by the ITO-QPS, which modified the guiding conditions of the thin film layers. The coupling only takes place when the optical momentum of incident photons satisfies the guided modes of the ITO-QPS patterned films. We define a parameter, averaged absorption <A>, to express the capability of solar power harvesting by each cell:

$$< A >= \frac{\int_{400\,nm}^{700\,nm} A(\lambda,\theta) I_{AM1.5G}(\lambda) d\lambda}{\int_{400\,nm}^{700\,nm} I_{AM1.5G}(\lambda) d\lambda} \quad (1)$$

Where A(λ, θ) is the measured angular absorption spectrum, θ is the incident angle with respect to the normal surface, and $I_{AM1.5G}$ is the photon flux density of the solar spectrum [21]. We neglect taking the normal component of incident solar photon flux (i.e. $I_{AM1.5G}\cos\theta$) as varying the incident angle, to have a better understanding of the angular absorption of the patterned cells. Fig. 7 shows <A> with respect to the AOIs up to 45° for the reference cell and the ITO-QPS cell. The results illustrate that the ITO-QPS cell sufficiently absorbs the incident solar power at large AOIs. As seen in Fig. 7, the averaged absorption of the ITO-QPS cell does not rise as fast as the reference, indicating the insensitivity to the angles of incidence.

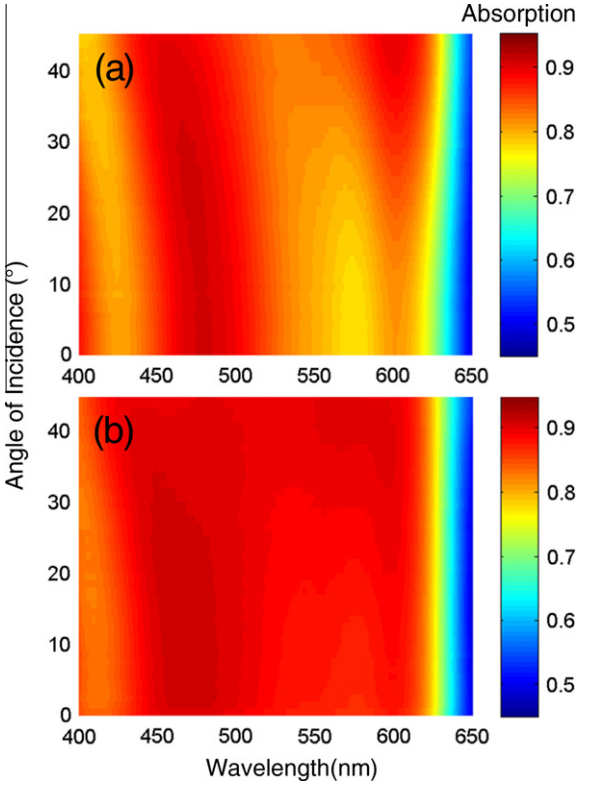

Fig. 6. Angular absorption spectra of (a) the reference cell, and (b) the ITO-QPS cell.

4. Conclusion

In conclusion, we have demonstrated thin-film organic solar cells with a frontal ITO quasi-periodic structure. The

ITO-QPS is fabricated by colloidal lithography, which is applicable for large scale production. The measured cell absorption spectra closely matches the external quantum efficiencies and results in power conversion efficiencies of 3.26% for the ITO-QPS cell, compared to a conversion efficiency of 2.91% for the reference cell. Angle-resolved absorption spectroscopy measurements also show enhanced light coupling at the cells at an oblique angle of incidence. This new design is not strictly relevant to organic based devices, but may be broadly applicable to other common thin-film solar cell materials systems such as a-Si:H, CdTe, and CIGS. This result can directly impact the attainment of the scalable green energy from thin-film solar cells.

Acknowledgment

The authors would like to thank Dr. Chung-Hsiang Lin for his technical support and helpful suggestions.

strategies have been proposed, including the confinement of the emissive zone [9] and the synthesis of white light polymers for voltage-independency [10] or the utilization of a phosphorescent moiety in the polymer chain [11] for high efficiency. However, the simplest and most effective way to solve these problems would be to make a miscible polymer blend. Recently, some researches that improved miscibility by blending the copolymer with the compound, both of which have the same moiety, have been reported [12,13].

In this work, we fabricated voltage-independent white-light-emitting diodes thanks to the homogeneity of the blue and green miscible polymers, due to their having the same moiety. Fluorene-based polymers including copolymers are well blended with each other without phase separation and the polymer chains, which contribute to the blue and green emissions, are mixed with each other at the molecular level. Moreover, these polymers have good chemical compatibility with $Ir(PIQ)_3$ which is the red phosphorescent dye that is used. Therefore, each component interacts with the others in a single active layer without phase separation. The energy transfer from the conjugated polymers to the Ir complex can be controlled by means of the homogeneous blend film. The phosphorescent dye ($Ir(PIQ)_3$) enhances the luminous efficiency by enabling both the singlet and triplet excitons to contribute to the electrophosphorescent emission through radiative decay, and is miscible with the polymer blends, which leads to a highly efficient Förster energy transfer from these fluorene-based polymers to $Ir(PIQ)_3$. This results in voltage-independent and highly efficient white light-emitting diodes.

2. Experimental

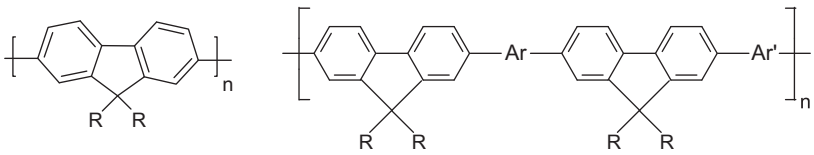
Herein, we fabricated a miscible polymer blend for use as the emissive layer by using copolymer to improve the chemical miscibility. The emissive layer consists of three components, polyfluorene-type blue LEP (Lumation BlueJ light-emitting polymers, Trademark of Dow Chemical Company, BlueJ) [blue emitter], Lumation Green 1304 (Dow Chemical Company) [green emitter], and Tris(1-phenylisoquinoline) iridium (III) ($Ir(PIQ)_3$) [red emitter] for color tuning as well as for enhancing the efficiency. Unlike the other polymer blend, BlueJ and Green 1304 form a homogeneous film, because Green 1304 has the same fluorene moiety as the one in BlueJ [14–17]. The structures of these components are shown in Scheme 1. Due to this homogeneity, we were able to obtain highly efficient voltage-independent white-light emitting devices.

Poly(3,4-ethylenedioxithiophene)/poly(styrene sulfonate) (PEDOT:PSS) was purchased from Baytron PH, H. C. Starck (Germany) and 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (Bathocuproine BCP) was purchased from American Dye Sources, Inc. The heavy metal phosphorescent material for the red emission, tris(1-phenylisoquinoline) iridium (III) ($Ir(PIQ)_3$), was purchased from Sigma–Aldrich Co. The polymers were used as received. Indium tin oxide (ITO)-coated glass substrates were cleaned by sonication in chloroform for 30 min and then in acetone/isopropyl alcohol (1:1) solution for 30 min and treated with an oxygen plasma before use. A layer of PSS:PEDOT with a thickness of 20 nm was first spin-coated on the treated substrate, and annealed at 120 °C for 1 h in a vacuum. Then, blends of BlueJ, Green 1304, and $Ir(PIQ)_3$ in chlorobenzene (10 mg/mL) were spin coated on top of the substrate precoated with the PSS:PEDOT layer. For device fabrication, we employed a single-active-layer architecture (ITO/PEDOT/BlueJ:Green 1304:$Ir(PIQ)_3$ blend/BCP/Li:Al with a 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) layer as the hole blocking layer. The BCP layer (10 nm) was thermally evaporated onto the blend layer at a pressure below 1×10^{-6} Torr before the deposition of the electrodes and, then, a cathode layer consisting of 150-nm-thick Li:Al alloy was vacuum deposited at a pressure of 1×10^{-6} Torr.

All measurements of the EL properties were performed on the devices encapsulated with a cover glass using epoxy adhesive. The emission light of the devices was measured by a luminance meter (Minolta, LS-100). The electrical and luminescent characteristics of the devices were analyzed by means of a current and voltage source measurement unit (Keithley 236) and a luminance meter (LS-100), respectively. The photoluminescent (PL) and electroluminescent (EL) spectra were measured using fluorospectroscopy (ISS PC1 Photon Counter Meter). The CIE coordinate was quantitatively evaluated from the EL spectra (using the previously reported numerical formulas) [18,19]. Lastly, the morphology of the top surface of the polymer blend was investigated by scanning probe microscopy (SPM, DI NanoScope IIIa). SPM measurements were performed in air with an etched silicon probe with a length of 125 μm and spring constants ranging from 20 to 100 N/m. Scanning was carried out in Tapping™ mode and the frequency was about 0.5 Hz.

3. Results and discussion

Fig. 1a shows the absorption (Abs) and photoluminescence (PL) spectra of the BlueJ and Green 1304 polymers and of $Ir(PIQ)_3$. The emission of BlueJ ($\lambda_{max} = 457$) is broadly overlapped with the absorption of Green 1304 ($\lambda_{max} = 390$), and the absorptions of $Ir(PIQ)_3$ at 430 and 475 nm, which correspond to the transitions from the ground state to the singlet MLCT and triplet MLCT excited



BlueJ Green 1304

(a) Normalized absorption (Abs) and photoluminescence (PL) spectra of BlueJ, Green, and Ir(PIQ)$_3$ (a): PL of BlueJ, (b): PL of Green, (c): PL of to Ir(PIQ)$_3$, (d): Abs of BlueJ, (e): Abs of Green, (f): Abs of Ir(PIQ)$_3$). (b) Normalized photoluminescence spectra of thin blend films of BlueJ:-Green: Ir(PIQ)$_3$ (a): blend film at a ratio of 87.9:10.9:1.2, (b): blend film at a ratio of 91.8:7.6:0.6).

states, respectively, are well overlapped with the emissions of BlueJ and Green 1304 (λ_{max} = 530) [20]. These spectra overlapping meet the necessary condition of Förster-type dipole–dipole energy transfer. Based on this, we would expect energy transfer to occur not only from BlueJ to Green 1304 and Ir(PIQ)$_3$, but also from Green 1304 to Ir(PIQ)$_3$. The energy of the singlet excitons from the host conjugated polymers is transferred to Ir(PIQ)$_3$, in spite of the absence of a medium for energy transfer, because the triplet energy state of the red-emissive Ir complex is relatively lower than that of the blue or green phosphorescent materials, which results in a partial energy transfer from the polymers to Ir(PIQ)$_3$.

Fig. 1b shows the normalized PL spectra of the blended films of the three materials. A pure white emission was observed at a blending ratio of 87.9(BlueJ): 10.9(Green 1304): 1.2(Ir(PIQ)$_3$). However, the optimal ratio required to obtain pure white electroluminescence was slightly different from that of the white photoluminescent spectrum, because direct charge injection and charge trapping occur in Ir(PIQ)$_3$, due to the relatively small bandgap, and partial energy transfer from the conjugated polymers to Ir(PIQ)$_3$ also contributes to the charge trapping mechanism. Therefore, we gradually decreased the intensity of the PL spectrum from blue to red by controlling the composition of the emissive layer, as can be seen in Fig. 1b. We varied the blending ratios of BlueJ and Green 1304, while fixing the ratio of Ir(PIQ)$_3$ at 0.6 wt.%. We found that the optimal blending ratio for the pure white electroluminescent emission is 91.8(BlueJ): 7.6(Green 1304): 0.6(Ir(PIQ)$_3$). At this ratio, most of the singlet excitons generated from BlueJ can contribute to the blue EL emission, due to the small amount of green and red guests, resulting in its having a similar EL intensity to those from Green 1304 and Ir(PIQ)$_3$. Each component emits three individual colors simultaneously due to the partial energy transfer from these conjugated polymers to the phosphorescent dye. Therefore, a pure white emission is obtained.

The atomic force microscopic (AFM) images of the blended film with the optimal ratio (BlueJ: Green: Ir(PIQ)$_3$ = 91.8:7.6:0.6) are shown in Fig. 2. In these images, the film does not show any significant phase-separated morphology (root mean square value is 2.1 nm) even at the nano scale. Based on this, we could confirm that a miscible blend was obtained for the light-emitting layer by employing polymers having the same moiety. Due to this homogeneous morphology, the blue, green and red emitters cannot emit individually, resulting in a stable white light emission without any variation of the color with increasing voltage.

The EL spectra of the ITO/PEDOT/BlueJ: Green 1304: Ir(PIQ)$_3$ blend/BCP/Li:Al device measured at various voltages are shown in Fig. 3. The spectra contain three main peaks at 457, 530 and 618 nm, respectively, which are generated by BlueJ, Green 1304, Ir(PIQ)$_3$, respectively. The EL spectra covered the whole visible range from 400 to 800 nm and, thus, the device emits white light. In previously reported WLEDs based on immiscible polymer blends, the composition is not so homogeneous normal to the surface, due to the different wettability of each component to the surface. This can induce changes of the emissive zone as a function of the bias voltage, resulting in a non-pure white emission [21,22]. However in this study, the compositional change in the miscible polymer blend is negligible and, hence, our WLED is insensitive to the applied voltage. The Commission Internationale de L'Eclariage (CIE) coordinates of the WLEDs are shown in Fig. 4 and their performances are summarized in Table 1. The CIE coordinate is near to "pure" white light (0.33, 0.33) at a wide range of voltages from 10 to 16 V.

It is very interesting to observe the difference between the EL and PL spectra. In the EL spectra, the intensity of BlueJ is smaller and that of Ir(PIQ)$_3$ is larger, as compared to the PL spectra. The first difference is caused by the similar absorption spectra of BlueJ and Green 1304. When the blended film is excited at 380 nm, which corresponds to the maximum absorption peak of the host BlueJ, to obtain its PL spectra, the emission of Green 1304 is triggered simultaneously, because it has the same maximum absorption peak as BlueJ. Thus, the intensity of Green 1304 in the PL spectra includes the absorption at 380 nm as well as the excitation energy transfer from BlueJ. In

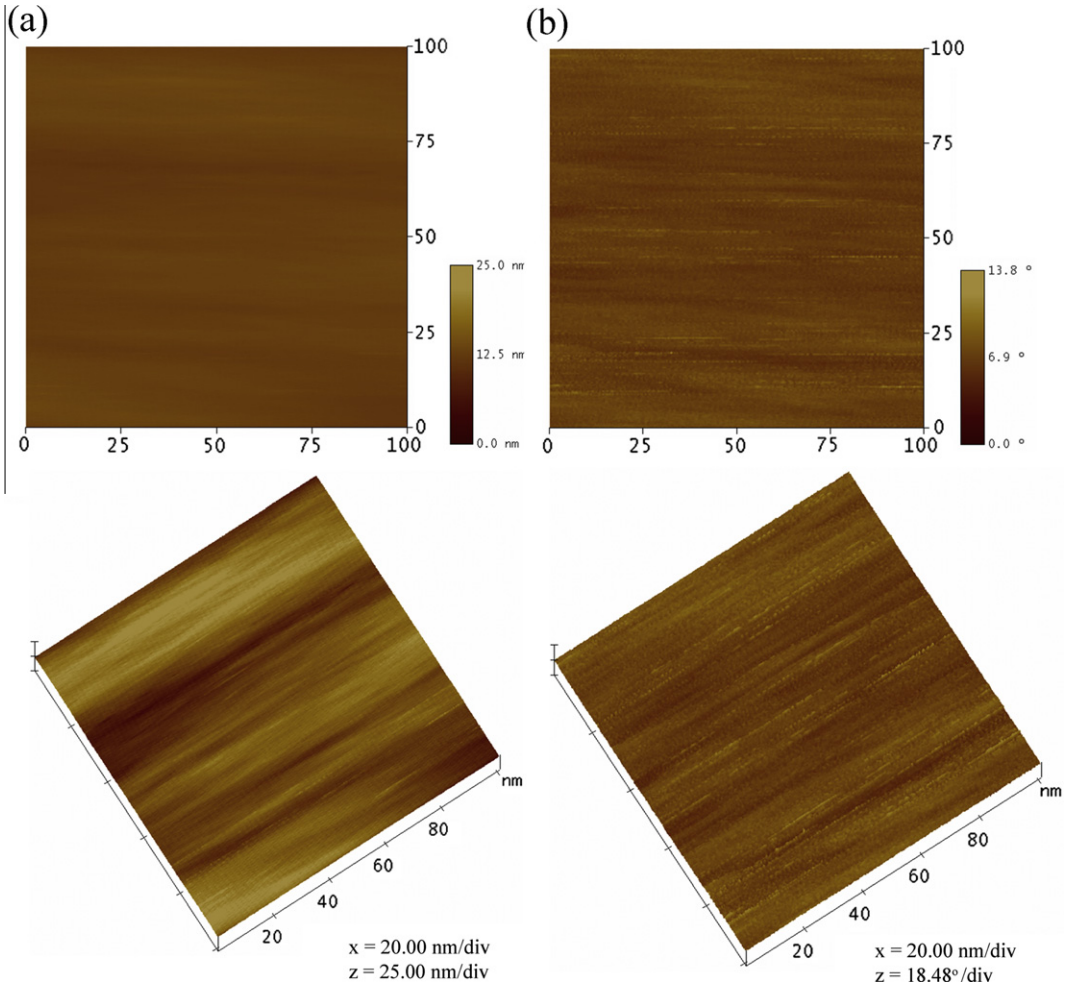

Fig. 2. AFM images of the surfaces of the blend film of BlueJ:Green:Ir(PIQ)$_3$ at a ratio of 91.8:7.6:0.6. The size of each image is 0.1 μm × 0.1 μm. (a) height and (b) phase.

the PL spectra, the energy transfer from the host molecules to the dopants is dominant for the white light emission. However, in the EL spectra, a charge-trapping mechanism, in which the dopant serves as a charge trap and provides a recombination site, can occur. In the PL studies, the red and green emissions are mostly generated by energy transfer from the host material. In the EL studies, however, the charge-trapping mechanism can contribute to the green and red emissions.

The current–density vs. voltage and brightness vs. voltage characteristics of the ITO/PEDOT/BlueJ 91.8: Green 1304 7.6: Ir(PIQ)$_3$ 0.6 (wt.%) blend/BCP/Li:Al device are shown in Fig. 5a and b, respectively. The device achieved a maximum brightness of 10295 cd/m^2 at 16.4 V and a current density of 174 mA/m^2. The luminous efficiencies (LE) of the various light-emitting devices are shown as a function of the current density in Fig. 6. The maximum LE values of the reference devices, B: ITO/PEDOT/BlueJ/BCP/Li:Al and G: ITO/PEDOT/Green 1304/BCP/Li:A are 2.61 cd/A at 38.1 mA/cm^2 and 14.4 cd/A at 63.4 mA/cm^2, respectively. Green 1304 is a copolymer which contains an energy donor and electron transport material in its

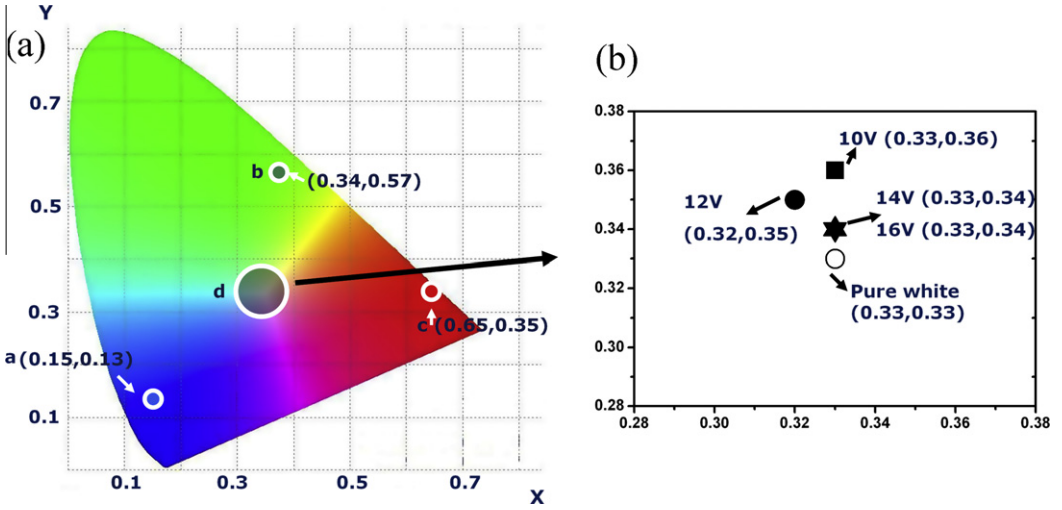

Fig. 4. The CIE coordinate of the devices. (a) a: BlueJ, b: Green c: $Ir(PIQ)_3$ d: ITO/PEDOT/BlueJ:Green:$Ir(PIQ)_3$ blend/BCP/Li:Al device measured at various voltages (10–16 V) and (b) the CIE coordinate of d is enlarged and indicated.

Table 1
The performance of the white light-emitting device is summarized. The luminance, current density, external quantum efficiency (EQE), luminance efficiency, and CIE coordinates are the results corresponding to each voltage.

Voltage (V)	Current density (mA/cm^2)	Efficiency		Luminance	CIE
		EQE (%)	(cd/A)		
10	2.6	2.6	7.77	208	(0.33, 0.36)
12	10.8	2.8	8.22	918	(0.32, 0.35)
14	39.9	2.7	7.89	3248	(0.33, 0.34)
16	145	2.4	6.57	9885	(0.33, 0.34)

structure, so it shows a much better LE than BlueJ. When we blend these two materials at the optimized ratio, the maximum LE of B + G: ITO/PEDOT/BlueJ: Green 1304 blend/BCP/Li:Al is slightly higher than that of BlueJ, 3.59 cd/A at 25.6 mA/cm^2. However, after we doped this blend with the phosphorescent dye, $Ir(PIQ)_3$, the maximum LE was enormously increased from 3.59 to 8.34 cd/A at 5.99 mA/cm^2 (a voltage of 11.2 V and a brightness of 516 cd/m^2). Even at a luminance of 3500 cd/m^2, the luminance efficiency remained high (around 8 cd/A) due to the efficient energy transfer and charge trapping. These efficiencies are very high compared to the reported values for other white light-emitting devices, in spite of the poor balance of the charge carriers. It is known that excitons are separated into electrons and holes at the interfaces of phase-separated morphologies and this lowers the efficiency of WLEDs based on immiscible polymer blends. However, in this work, this effect was diminished by preparing miscible blends. A gradual decrease of the luminance efficiency was observed as the current density increased, which is probably due to triplet–triplet annihilation [23].

4. Conclusions

We demonstrated color-invariant and highly efficient white light-emitting diodes with a homogeneous single emissive layer. By utilizing a miscible polymer blend system which uses the polymers with same fluorene moiety, typical problems of immiscible polymer systems such as their voltage-dependence and low efficiency were solved. High luminous efficiency was also obtained via efficient energy transfer from these polymers to the phosphorescent dye. A near pure white-light emission was observed over a wide range of voltage from 10 to 16 V, with a maximum brightness of 10295 cd/m^2, luminous efficiency of 8.34 cd/A and external quantum efficiency of 2.86%. These white-light emitting diodes were single-active-layer devices fabricated by spin-casting from a solution. The simple device structure and the promise of low-cost manufacturing make this approach attractive for large-area solid-state-lighting applications.

current crowding [3,7,8] and charge accumulation [7] effects, in the framework of a physically based analytical theory.

2.1. Current crowding mechanism

As shown in Fig. 1, the current crowding mechanism approximates the total access resistance by a simplified network of distributed resistances [3,8,9]. In this approach, the total contact resistance can be expressed as:

$$R_c = \sqrt{\rho_B r_{ch}}\coth\left(d\sqrt{\frac{r_{ch}}{\rho_B}}\right) \quad (1)$$

where d represents the electrode length. r_{ch} ($\Omega\,m^{-1}$) is equal to $R_{ch}/\Delta y$ where R_{ch} (Ω) is the infinitesimal channel resistance (see Fig. 1), supposed to be uniform [3], and Δy (m) is an infinitesimal length. ρ_B (Ω m) is equal to $R_b.\Delta y$ where R_b is the bulk infinitesimal resistance (Ω) between the source and the channel as illustrated in Fig. 1. In strong accumulation, i.e. well above threshold voltage V_T, one has:

$$r_{ch} = \frac{1}{W\mu C_i(V_G - V_T)} \quad (2)$$

where μ is the channel mobility, C_i is the gate dielectric capacitance per unit area ($F\,m^{-2}$), V_g is the gate voltage and W (m) is the transistor width. In order to calculate the total contact resistance given by Eq. (1), the resistivity ρ_B need also to be evaluated.

2.2. Equation of ρ_B

The calculation of the vertical bulk resistivity needs to include the impact of accumulation layers created by the action of both the gate voltage (at the top) and the ohmic metal contact (at the back). In the following, to derive ρ_B, the 1D Metal Insulator Semiconductor Metal (MISM) stack has been considered (inset of Fig. 2). This architecture represents the stack above the source (or drain) electrode

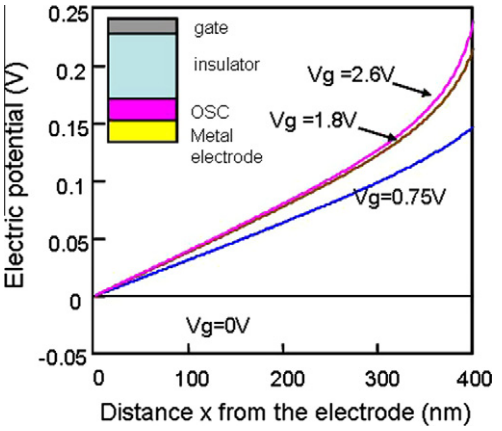

Fig. 2. Numerical simulation of the electric potential in the organic semiconductor of a Metal Insulator Semiconductor Metal capacitance, shown in the inset ($n_0 = 10^{13}$ cm^{-3}, $V_m = 0$ V, $th_{ins} = 1$ μm).

contact in OTFT's. In the drift diffusion model, the current density j in the vertical direction x is given by:

$$j = -e\frac{kT}{e}\mu_{vt}\frac{dn}{dx} - en\mu_{vt}\frac{dV}{dx} \quad (3)$$

where μ_{vt} represents the vertical mobility, n the electron concentration, V is the electric potential, e the elementary charge, T the temperature and k the Boltzmann constant. The current density can be expressed as a function of the applied voltages, integrating Eq. (3), as follow:

$$j\cdot\int_0^{th}\frac{dx}{en\mu_{vt}} = (V_m - V_i - \Delta V) + \frac{kT}{e}[\ln(n(x = th)) - \ln(n(x = 0))] \quad (4)$$

where V_m is the potential at the metal/OSC back interface (which corresponds to an "effective" work function difference between the OSC and the metal electrode [15]), V_i is

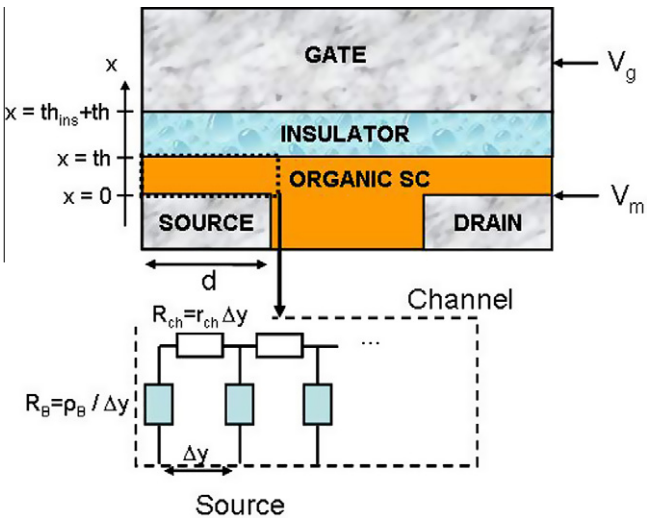

Fig. 1. Schematic device architecture, illustrating the current crowding mechanism between source and channel, and the resistance network used to model it.

the potential at the insulator OSC interface, ΔV the potential drop between the back electrode and the channel, *th* represents the OSC thickness.

Assuming that the current flow is low enough such that it does not alter the carrier distribution from its equilibrium ($j = 0$) value, the carrier concentration n may be approximated by:

$$n(x) \approx n_0 \exp\left(\frac{eV(x)}{kT}\right) \tag{5}$$

where n_0 represents the free thermal charge carriers. Inserting Eq. (5) into Eq. (4) leads to:

$$j \cdot \int_0^{th} \frac{dx}{en\mu_{tr}} \approx (V_m - V_i - \Delta V) + \frac{kT}{e}\left[\ln\left(n_0 \exp\left(\frac{eV_i}{kT}\right)\right) - \ln\left(n_0 \exp\left(\frac{eV_m}{kT}\right)\right)\right] = -\Delta V \tag{6}$$

As a consequence, the vertical bulk resistivity may be expressed as:

$$\rho_B = \frac{-\Delta V}{jW} = \frac{1}{W}\int_0^{th} \frac{dx}{e\mu_{vt} n(x)} \tag{7}$$

2.3. Calculation of the electric potential V(x) and carrier profile n(x)

From Eq. (7), it appears that the calculation of ρ_B requires to derive the carrier concentration profile $n(x)$, and thus, according to Eq. (5), the electric potential $V(x)$. To this aim, the potential is calculated solving Poisson equation in the 1D MISM capacitance at different gate voltages:

$$\frac{d^2V}{dx^2} = -\frac{\rho(V)}{\varepsilon_{OSC}} \tag{8}$$

$$\text{where } \rho(V) = -e\left[n_0 \exp\left[\frac{eV}{kT}\right] - n_0\right] \tag{9}$$

The boundary conditions are given by the following equations:

$$V(0) = V_m \text{ and } -\varepsilon_{OSC}\frac{dV}{dx}(x = th) = \varepsilon_{ins}E_{ins} \tag{10}$$

where V_m represents the effective work function difference between the OSC and the metal electrode, E_{ins} the electric field in the insulator. $\varepsilon_{ins/OSC}$ represents respectively the dielectric constant of the insulator and the organic semiconductor OSC. In all calculations, in agreement with the materials used in experiments, ε_{ins} has been taken equal to $2 \cdot \varepsilon_0$ [16] and ε_{OSC} to $3 \cdot \varepsilon_0$ (value often used for organic semiconductors [17]).

Numerical solutions of Eq. (8) have been plotted in Fig. 2. These results reveal that the electric potential in the volume of the OSC varies almost linearly. Indeed, for gate voltage higher than the threshold voltage, due to the channel screening, the potential does not depend anymore on the applied gate bias (except, of course, at the insulator/OSC interface) (Fig. 2). This maximum surface potential is called V_i and corresponds to the surface potential at threshold conditions. As a result, the potential profile in the OSC volume can be approximated by:

$$V(x) \approx (V_i - V_m)\frac{x}{th} + V_m \tag{11}$$

Here we assume that the source to drain bias is very low (which is the case in the regime of extraction of the contact resistances in [10] and [11]: $V_d = 1$ V). Thus the potential $V(x)$ is assumed independent of the position along the source electrode. This would be exact if the source to drain bias was equal to zero.

Noticing that the surface potential at threshold V_i corresponds to the value of the surface potential where the bending due to electron charge concentration ($-e\,n(x)$) can no longer be neglected, this potential can be numerically deduced solving the following equation (see Appendix):

$$V_i = \frac{2en_0}{\varepsilon_{OSC}}\left(\frac{kTth}{e(V_i - V_m)}\right)^2\left(\exp\left(\frac{eV_i}{kT}\right) - \exp\left(\frac{eV_m}{kT}\right)\right) \tag{12}$$

Finally, the surface potential at threshold V_i corresponds to a particular value of the gate voltage, which is in fact the MIS capacitor threshold voltage, and is given by:

$$V_T = V_i\left(1 + \frac{\varepsilon_{OSC}}{\varepsilon_{ins}}\frac{th_{ins}}{th}\right) - V_m\left(\frac{\varepsilon_{OSC}}{\varepsilon_{ins}}\frac{th_{ins}}{th}\right) \tag{13}$$

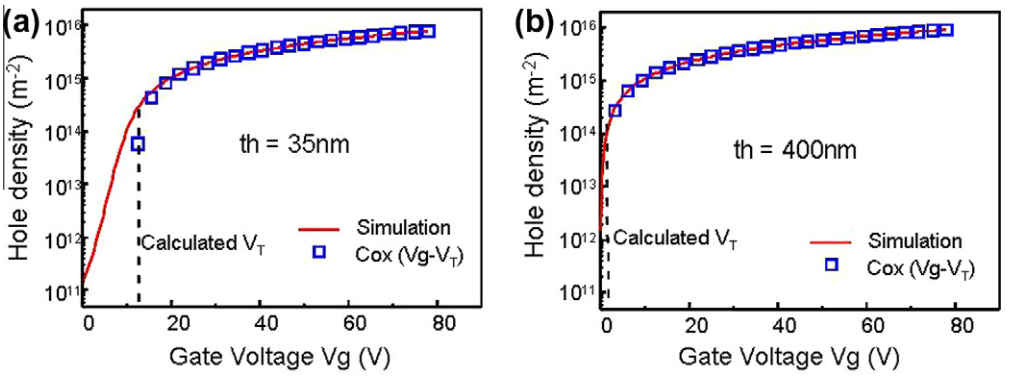

Fig. 3. Hole density calculated by numerical (line) and analytical (symbol) calculations for an organic semiconductor thickness of (a) 35 nm and (b) 400 nm ($n_0 = 3.6\ 10^{12}$ cm^{-3}, $V_m = 0$ V, $th_{ins} = 1$ μm).

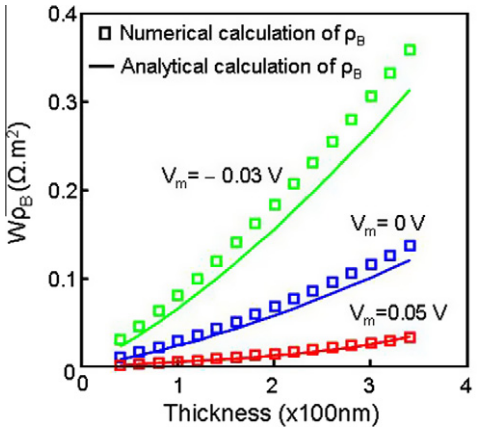

Fig. 4. Vertical bulk resistivity versus organic semiconductor thickness calculated using the analytical model Eq. (14) (lines) and a numerical integration of Eqs. (7) and (8) (symbols), for several effective work function differences at the back electrode ($n_0 = 5.5\ 10^{12}$ cm^{-3}, $\mu_{vt} = 0.0045$ cm^2 V^{-1} s^{-1}, $th_{ins} = 1.2$ μm).

This expression of V_T has been found in good agreement with the threshold voltage extracted from numerical calculations of the charge, as shown in Fig. 3. Using Eq. (11), the vertical bulk resistivity (ρ_B) can be derived as follows:

$$W\rho_B = \int_0^{th} \frac{1}{e\mu_{vt}n_0 \exp(eV(x)/kT)}\,dx = \frac{th}{e\mu_{vt}n_0}\frac{kT}{e(V_i - V_m)}\left[\exp\left(\frac{-eV_m}{kT}\right) - \exp\left(\frac{-eV_i}{kT}\right)\right] \quad (14)$$

Combining Eqs. (1), (2), (12), and (14), the series resistance can thus be analytically calculated.

Comparison between Eq. (14) and numerical calculations of Eq. (7) are shown in Fig. 4. It appears that simulations and model are in good agreement. In particular, as shown in Fig. 4, the back electrode effective work function difference dependency of the vertical resistivity is well captured by the analytical model. In the next section, models for threshold voltage (Eq. (13)) and series resistance (Eq. (14)) are compared with experiments.

3. Device fabrication and discussion

The model presented in the last section has been compared with experiments, first performed in Metal Insulator Semiconductor Metal (MISM) capacitors, to validate the $n(x)$ calculation, and then carried out on transistor, to validate the overall contact resistance model.

3.1. MISM fabrication

The 1D model can be partly validated by comparing threshold voltages calculated using (Eq. (13)) with measurements extracted from MISM capacitance measurements. MISM capacitance was fabricated using the following process. Polyethylene naphthalate (PEN) films were used as flexible substrates. Thirty nanometers of thick Au bottom electrode was deposited by plasma vapor deposition. A *N*,*N*-dialkylsubstituted-(1,7&1,6)-dicyanoperylene-3,4:9, 10-bis(dicarboximide) derivative (Polyera ActivInk™ N1400) bought from Polyera Corporation was diluted in 1,2-dichloro-benzene at a concentration of 4 mg mL^{-1} and spin-coated at 4 different rotation speed to get different thickness. Then the semiconductor films were cured at a temperature of 115 °C for 5 min to eliminate the solvent. For all the spin-coating steps of the process, the plastic substrates were mounted on a silicon wafer using a drop of ethanol. The thickness of the OSC layer was measured with a profilometer. Samples with thicknesses varying from 50 to 140 nm have been processed. Cytop™ dielectric was then spin-coated on top of the semiconductor and cured at 100 °C for 20 min. The thickness of the layer was measured with a profilometer around 1 μm. To promote adhesion of the gate electrode on the highly hydrophobic insulating layer, solution of Nafion diluted at 30 mg mL^{-1} in isopropanol was spin-coated at 1000 rpm. Finally an Ag ink gate electrode was printed by ink-jet using a Dimatix set up.

3.2. Threshold voltage dependency versus OSC thickness

Capacitance measurements of MISM device were performed on a Agilent 4980A at low frequencies i.e. below 10 kHz. Threshold voltages were then extracted using the maximum of the first derivative of *C*–*V* curves (a similar procedure to the one used in transistors [18]). Experimental values and modeling results obtained using Eq. (13) are both represented in Fig 5. As can be seen, the same trend was found between simulations and experiments, showing the consistency of our model.

3.3. Contact resistance simulations

Modeling results have been compared with experimental contact resistances taken from [11] featuring different OSC thicknesses and gate voltages (Fig 6). Again, using the same set of parameters, the model can satisfactory capture both thickness and bias dependencies.

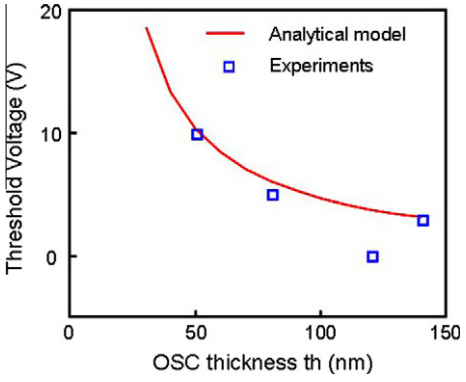

Fig. 5. Experimental (square) and theoretical (line, Eq. (3)) threshold voltage (V_T) of a capacitor versus organic semiconductor thickness *th*. Experimental V_T have been extracted on CV measurements performed on capacitor featuring different thicknesses ($n_0 = 10^{13}$ cm^{-3}, $V_m = -0.02$ V, $th_{ins} = 1$ μm).

Finally, the impact of the back electrode work function difference has been investigated both in modeling and experiments taken from [10] (Fig. 7), where the gold work function was modified by treatment with self assembled monolayers (SAM) on its surface before semiconductor deposition. From simulation, the work function difference between gold treated with 4-(methylsulfanyl)-thiophenol (MeSTP) and with 4-nitrothiophenol (NOTP) was found equal to 0.065–0.01 = 0.055 eV. This value is much lower than the 0.7 eV that can be found in [10] from UPS measurements performed on metal only treated with SAMs (before semiconductor deposition). This difference can be explained by the modification of the surface's work function of the system metal including SAMs, once organic semiconductors are deposited. This might originate from the formation of a dipole at the interface metal/semiconductor [19].

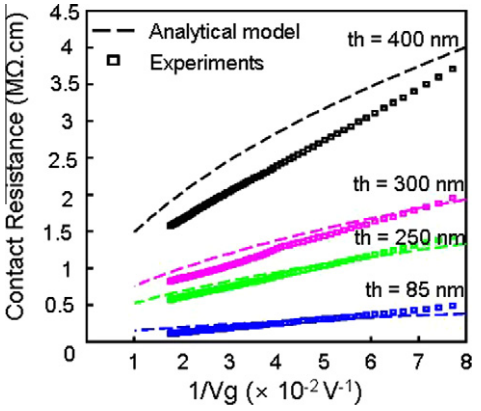

Fig. 6. Comparison of the analytical and experimental contact resistance versus $1/V_g$, featuring different OSC thicknesses ($n_0 = 5.5\ 10^{12}$ cm^{-3}, $\mu_{vt} = 0.007$ cm^2 V^{-1} s^{-1}, channel mobility μ from experiments [9], $V_m = 0$ V, $d = 20$ μm, $th_{ins} = 1.2$ μm).

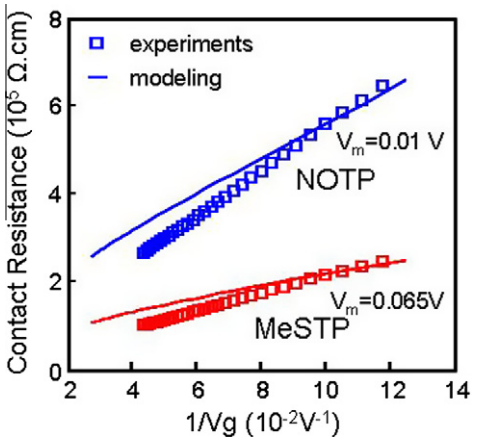

Fig. 7. Comparison between the theoretical and experimental contact resistance versus $1/V_g$, for two different effective work functions V_m (obtained using two different Self Assembled Monolayer – MST and NT) ($th = 130$ nm, $n_0 = 5.5\ 10^{12}$ cm^{-3}, $\mu_{vt} = 0.007$ cm^2 V^{-1} s^{-1}, channel mobility μ from experiments $\mu = 0.05$ cm^2 V^{-1} s^{-1} [8], $d = 20$ μm, $th_{ins} = 1.2$ μm).

4. Conclusion

In this work, an analytical model of the contact resistance in top gate/bottom contacts organic thin film transistors has been proposed. It combines both the current crowding mechanism and an original modelling of the vertical accumulation of charges between channel and back electrode.

The modelling of the charge versus gate voltage in vertical stacks has been validated by comparing theoretical and experimental threshold voltages in simple capacitance structure.

In addition, the gate voltage dependency of the contact resistance has been found to be nicely reproduced by this model, much better than in a pure current crowding approach, without requiring any numerical simulations or empirical vertical resistivity formulas. Finally, this model well captures the semiconductor thickness and metal work function dependencies of the contact resistance, in agreement with previously reported experimental data. It should be noted that it has not been necessary to invoke any traps or specific injection/transport mechanisms.

Appendix A

In the following appendix, the derivation of (Eq. (12)), i.e. the determination of the surface potential at threshold condition, is detailed. The solution of the Poisson equation in 1D is simply:

$$V(x) = \int_0^x \left(\int_0^y -\frac{\rho(z)}{\varepsilon_{OSC}} dz \right) dy + bx + c$$

where b and c represent two constants to determine. Given that:

$$\rho(x) = -e\left[n_0 \exp\left[\frac{eV(x)}{kT}\right] - n_0 \right] \approx -en_0 \exp\left[\frac{eV(x)}{kT}\right]$$

and considering that the potential varies linearly with position (which is the case before the channel formation), we get:

$$\int_0^x \left(\int_0^y -\frac{\rho(z)}{\varepsilon_{OSC}} dz \right) dy = \frac{en_0}{\varepsilon_{OSC}} \left[\left(\frac{kTth}{e(V_i - V_m)} \right)^2 \exp\left(\frac{eV_m}{kT}\right) \times \left(\exp\left(\frac{e(V - V_m)}{kT} \frac{x}{th} \right) - 1 \right) - x \left(\frac{kTth}{e(V_i - V_m)} \right) \exp\left(\frac{eV_m}{kT}\right) \right.$$

Using the first boundary condition $V(0) = V_m$,

$$V(x) = \frac{en_0}{\varepsilon_{OSC}} \left(\frac{kTth}{e(V_i - V_m)} \right)^2 \times \exp\left(\frac{eV_m}{kT}\right) \left(\exp\left(\frac{e(V - V_m)}{kT} \frac{x}{th} \right) - 1 \right) + cx + V_m$$

And applying the second boundary condition $V(th) = V_i$ leads to:

$$c \cdot th + V_m = V_i - e \times \frac{n_0}{\varepsilon_{OSC}} \left(\frac{kTth}{e(V_i - V_m)} \right)^2 \left(\exp\left(\frac{eV_i}{kT}\right) - \exp\left(\frac{eV_m}{kT}\right) \right)$$

The electron charge starts to significantly impact the potential shape (moving away from its linear dependency at the interface), when,

$$c \cdot x + V_m < \int_0^x \left(\int_0^y -\frac{\rho(z)}{\varepsilon_{OSC}} dz \right) dy$$

which means when,

$$V_i = \frac{2en_0}{\varepsilon_{OSC}} \left(\frac{kTth}{e(V_i - V_m)} \right)^2 \left(\exp\left(\frac{eV_i}{kT} \right) - \exp\left(\frac{eV_m}{kT} \right) \right)$$

This equation can be used to find the surface potential V_i at threshold condition. Above threshold, the potential increases mostly inside the channel, while the rest of the $V(x)$ curve remains unchanged.

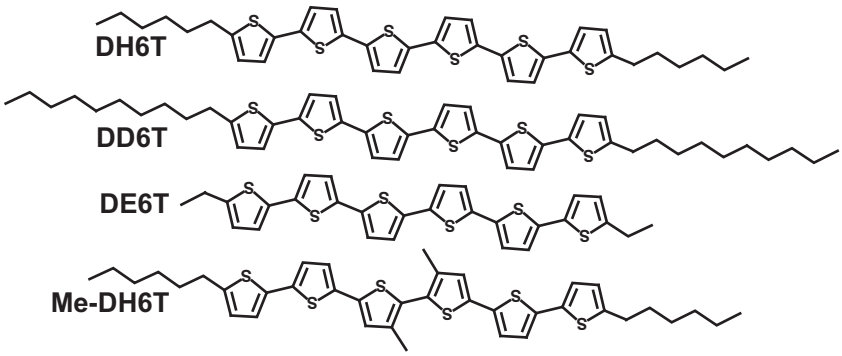

Fig. 1. Chemical structure of the alkylated sexithiophene derivatives.

increases not only solubility and thus processability of 6T, but also device performance by changing the microstructure of the thin films. In such a way, vacuum-sublimed COMs like 6T on metal substrates often grow in a flat lying orientation in ultra-thin films (a few molecular layers), which gradually changes to a vertically inclined or even standing orientation for thicker (several ten nm) films [12,30,31]. Hexylated sexithiophene (α,ω-dihexylsexithiophene, DH6T) on metal substrates, however, undergoes a defined orientational transition from flat lying molecules in monolayers to nearly upright standing molecules starting from the second molecular layer onwards [3,32,33]. The IE/EA of a layer of standing DH6T are lower than those of flat lying DH6T, and a highest occupied molecular orbital (HOMO)-level offset of 0.6 eV was reported for this organic/organic homointerface [3,32,33]. For DH6T on Ag(1 1 1) pre-covered with a monolayer of the molecular acceptor tetrafluoro-tetracyanoquinodimethane (F4-TCNQ), which undergoes a charge transfer reaction with metals and therewith significantly increases the substrate work function [34–36], the HOMO-level of the lying monolayer is just below the Fermi-level (E_F) of the substrate [37]. The HOMO-level of the standing second layer with reduced IE is, however, not found above the Fermi-level, instead the HOMO is pinned below the substrate E_F, accompanied by an interface dipole [37]. Thus, hexyl chains are not long enough to form a layer that is capable to electronically decouple the layers of standing and lying DH6T, and the question arises whether longer alkyl chains are able to do so. Furthermore, the mechanism of *Fermi-level pinning* [38–41] attracts interest, since the proposed integer or fractional "charge transfer" across the nominally insulating hexyl layers of standing DH6T in the DH6T/F4-TCNQ/Ag(1 1 1) system [37] seems implausible. A slight shift of the center-of-mass of the electron density of the conjugated moieties of the molecules with respect to the atomic nuclei might be an alternative scenario, which was recently suggested to explain Fermi-level pinning at metal/self-assembled monolayers (SAMs)/COM interfaces [42]. Such a charge rearrangement, or polarization, might be related to induced density of states at the interface caused by either charge neutrality levels [43–45] or disorder of the adsorbate [46,47]. Even though polarization is widely discussed as origin for vacuum-level shifts at organic/metal and organic/organic interfaces [2,48] it is not commonly used to describe Fermi-level pinning at such interfaces [37–40].

To elucidate the impact of alkyl chains on the growth mode and electronic structure of COMs on metal substrates, we performed thickness dependent ultraviolet photoelectron spectroscopy (UPS) experiments on the 6T-derivatives α,ω-didecylsexithiophene (DD6T) [49], α,ω-diethylsexithiophene (DE6T) and 3′,4′-dimethyl-α,ω-dihexylsexithiophene (Me-DH6T) (chemical structures shown in Fig. 1) on Ag(1 1 1) substrates. Furthermore, to freeze out thermal motion and to thus increase the impact of a possible molecular fastener effect of long alkyl chains [19–21], we also investigated the samples' electronic structure at low temperatures (∼35 K). The charge rearrangement in the context of Fermi-level pinning was examined using DD6T on the high work function substrate Ag(1 1 1) pre-covered with F4-TCNQ.

2. Experimental details

Organic molecular thin films (6T derivatives from Heraeus Clevios GmbH, F4-TCNQ from Sigma–Aldrich) were prepared by vacuum sublimation on clean Ag(1 1 1) surfaces (repeated Ar-ion sputtering and annealing cycles (up to 550 °C)) using resistively heated quartz crucibles with deposition rates of about 0.25 Å/min. The film mass thickness was monitored with a quartz crystal microbalance. Hence, the values for the coverage correspond to values of nominal film thickness. UPS experiments were performed using a custom built apparatus [50] equipped with a HeI UV-light-source and a hemispherical electron energy analyzer (Scienta R3000). The interconnected sample preparation chambers (base pressure 2×10^{-10} mbar) and analysis chamber (base pressure 4×10^{-10} mbar) allowed sample transfer without breaking ultrahigh vacuum conditions. The angle between the incident beam and the sample was fixed to 65°. The spectra were measured at photoelectron emission angles (θ_e) of 0° (normal emission) and 45° (off-normal emission) with an acceptance angle of ±10°. The energy resolution at room temperature was set to 80 meV. The error of UPS binding energy (BE) values is estimated to be ± 0.05 eV. For the measurement of the secondary electron cutoff (SECO) the sample was biased at −3.00 V. All preparation steps were performed at room

temperature. UPS measurements were carried out at room temperature and additionally at low temperatures (~35 K) for multilayer films.

3. Impact of alkyl chains at sexithiophene thin film growth

Deposition of 2 Å DD6T on a clean Ag(1 1 1) substrate attenuated the Ag(1 1 1) photoemission features (d-bands around 4–7 eV BE, Shockley surface state and Fermi-edge) and several new features appeared, most notable a peak centered at 1.60 eV BE, which is assigned to emission from the HOMO of DD6T (Fig. 2). The HOMO peak showed enhanced intensity measured at a photoelectron emission angle of 45 ° compared to normal emission, which is commonly observed for flat lying COMs [51–53]. The vacuum level decreased by 0.49 eV (as derived from the shift of the SECO), which is mainly ascribed to the push-back effect [2,54,55] due to the weak interaction between 6T moieties and Ag. Increasing the coverage up to 6 Å decreased the vacuum level further, resulting in a total vacuum-level shift of 0.80 eV. In the valence electron region the molecular derived features gained intensity without a notable change of binding energy. Our nominal coverage of ~6 Å may thus correspond to an essentially flat lying monolayer of DD6T on Ag(1 1 1) because further increase of the coverage up to the final value of 30 Å did not change the vacuum level significantly. Starting from a nominal coverage of 10 Å a new peak (centered at 0.98 eV BE) arose at the low BE side of the monolayer HOMO (Fig. 2, best visible in the normal emission spectra). In addition, a peak centered around 11 eV BE, which is assigned to stem mainly from nonbonding S-orbitals [56], lost intensity with increasing coverage and got masked by emission dominated by the alkyl chains [33,56] in the energy range from 4 to 12 eV BE.

The spectra of DD6T/Ag(1 1 1) are virtually identical with the UPS spectra of DH6T/Ag(1 1 1) [3,32,33], where the emission at the low BE side of the monolayer HOMO was ascribed to emission from the multilayer HOMO of standing molecules. In both cases, the IE (defined as difference from the low BE HOMO onset to the vacuum level) is decreased from monolayer to multilayer coverage (for DH6T from 4.85 eV to 4.35 eV [32] and for DD6T from 4.95 eV to 4.48 eV). For DH6T/Ag(1 1 1) the lying monolayer/standing multilayer growth mode was confirmed by X-ray diffraction, metastable atom electron spectroscopy [33] and atomic force microscopy [32], thus it is straightforward to conclude on the same growth mode prevailing also for DD6T. This growth model (Fig. 3a) is further supported by the decrease of the S-derived peak around 11 eV BE (Fig. 2), which is hardly accessible (due to the limited photoelectron mean free path) by UPS through a layer of standing decyl chains. Note that the terms "lying" and "standing" are used to describe the basic orientation of the conjugated backbone of the 6T derivatives and the actual orientation might differ slightly from being totally parallel (perpendicular) to the substrate surface. Moreover, alkylated oligothiophenes are well known to exhibit rich conformational freedom in thin films [14,15,25,29], e.g., the hexyl chains of the standing layers of DH6T on Ag(1 1 1) are twisted by 28° with respect to the conjugated backbone [33].

Nominal 30 Å DD6T might be somewhat less than one closed layer of standing molecules on an almost closed layer of lying molecules. However, the 30 Å DD6T spectra already exhibited signs of slight charging during photoemission, which led to a rigid shift of all photoemission features of 0.08 eV to lower kinetic energy after ~1 h of

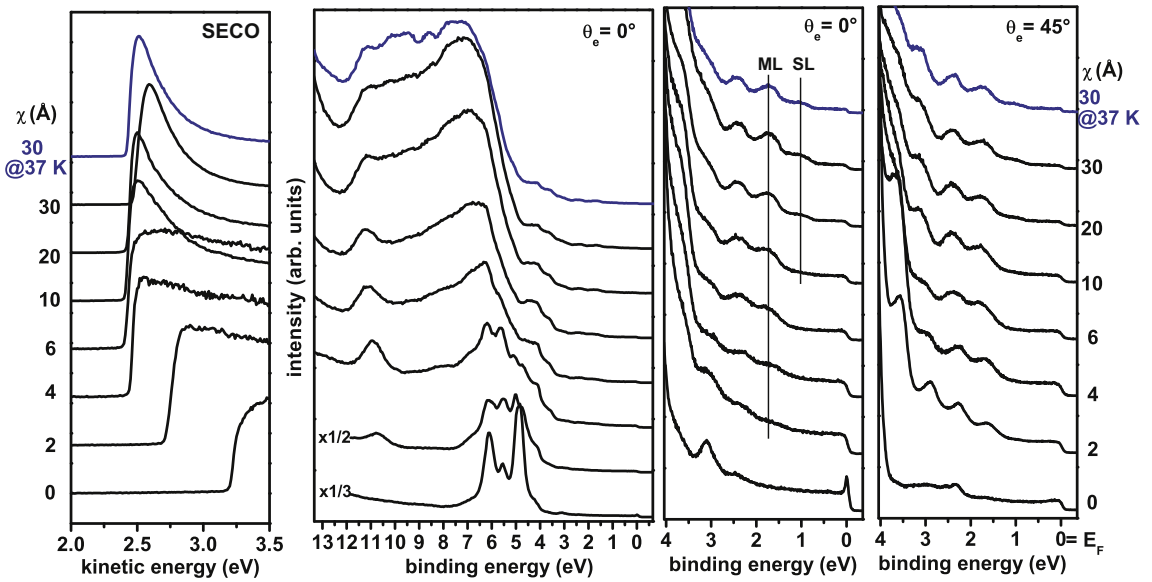

Fig. 2. Thickness dependent UPS spectra of DD6T on Ag(1 1 1). From left to right the secondary cut-off (SECO) region, a wide range spectra in normal emission and a close up of the region near to the Fermi-level (E_F) for photoelectron emission angles (θ_e) of 0° and 45° are displayed. χ denotes the nominal film thickness. The emission from the monolayer HOMO (ML) and second layer HOMO (SL) is marked by lines.

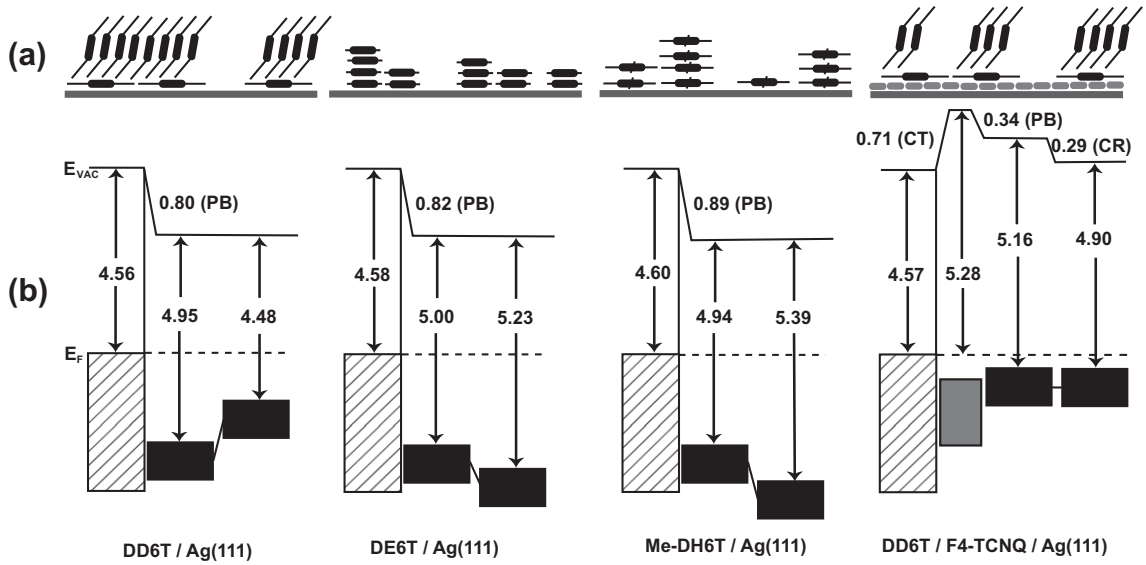

Fig. 3. (a) Schematic growth modes of the 6T-derivatives on Ag(1 1 1) as deduced from UPS measurements. The conformation of standing DD6T layers is adopted from the DH6T/Ag(1 1 1) system [33], however, the actual tilt angle between decyl chains and 6T-backbone might be different. (b) Schematic energy-level diagrams of substrate, monolayer and multilayer of the respective molecule. For the substrates the work functions and for the 6T-derivative thin films the ionization energies (defined as difference from the HOMO onset to the vacuum level (E_{VAC})) are given in eV. The main origin of vacuum-level shifts is indicated by PB (push-back effect), CT (charge transfer between metal substrate and F4-TCNQ) and CR (charge rearrangement), respectively. E_F corresponds to the Fermi-level of the substrate.

exposure to the UV-light and thus prohibited reliable UPS measurements on samples with higher nominal coverage. The multilayer spectra measured at low temperature (Fig. 2) were essentially the same as room temperature spectra (slight shifts in BE position are probably due to enhanced charging at this low temperature), however the alkyl emission part of the spectra changed, most notably a new clear peak centered at 8.57 eV BE appeared, which is probably because thermal excitations of the alkyl chains are frozen.

In contrast to DD6T, for DE6T *no* new emission features at the low BE side of the monolayer HOMO could be observed (Fig. 4a, full set of spectra in the Supporting Information) for coverages beyond the nominal monolayer. The DE6T multilayer IE (5.23 eV) is larger than the monolayer IE (5.00 eV), resembling the experimental findings for 6T on Ag(1 1 1) [57]. The shift of COM energy levels to higher BE in the second layer of organic thin films at metal surfaces is commonly observed and can be mainly attributed to a final-state effect, i.e., a decreased photohole screening efficiency of the molecular monolayer compared to the metal substrate [55,57,58]. Thus, the growth mode of DE6T on Ag(1 1 1) is similar to 6T on Ag(1 1 1) [57] with flat lying molecules also in the multilayer (Fig. 3a).

For DE6T multilayers (20 Å and 100 Å), the maxima of a peak that is derived from six nearly degenerate localized S-orbitals [33,56,59] have different BE for θ_e of 0° (4.59 eV) and of 45° (4.23 eV). For crystalline 6T on p(2 × 1) oxygen reconstructed Cu(1 1 0) a similar behavior was observed and ascribed to an intermolecular band dispersion [59]. As the 6T bandwidth (~0.5 eV) is similar to the shift of the DE6T peak center (0.37 eV) also for DE6T a reasonable crystalline quality can thus be expected. Note that the actual bandwidth of this feature for DE6T/Ag(1 1 1) was not determined in detail as only spectra at θ_e of 0° and of 45° were acquired. Moreover, also other factors like different angular dependent photoemission cross sections [9] of the six orbitals giving rise to the peak might contribute to the peak shift. Another S-derived peak (~11.50 eV) and the peaks derived from the delocalized HOMO, HOMO-1 and HOMO-2 (centered at 1.99, 2.63 and 3.25 eV BE, respectively) did not show any dispersion, which is consistent with the absence of intramolecular band dispersion of crystalline 6T [59]. Cooling the sample to 32 K increased the assumed dispersion width of the localized peak to 0.46 eV.

The spectra of Me-DH6T (Fig. 4b and Supporting Information) resemble the DE6T spectra, with an increase of the IE from 4.94 eV (4 Å coverage) to 5.39 eV (80 Å coverage). This increase in IE and the absence of charging during photoemission of multilayer films (in contrast to DD6T multilayers but in accordance with DE6T multilayers) points to essentially flat lying molecules also in the multilayer. The growth mode of Me-DH6T (Fig. 3a) is thus similar to DE6T and 6T with no orientational transition and in contrast to the unmethylated parent molecule DH6T on Ag(1 1 1) [3,32,33]. However, the unusually large BE shift of the valence electron region between mono- and multilayer of 0.45 eV may not be explained by screening alone, also the microstructure of the different layers might be different and thus impacting the electronic structure by intermolecular interactions [60] and/or slightly different – but still essentially lying – orientations [7,10,61]. In addition, the steric effect of the methyl groups at the third and fourth thiophene unit in Me-DH6T may cause a non-planar molecular conformation in the bulk, while the molecule

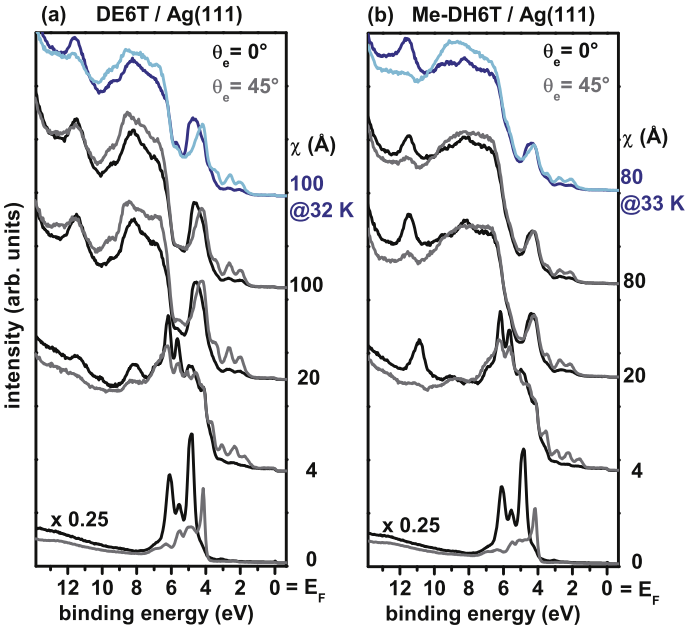

Fig. 4. UPS spectra of (a) DE6T and (b) Me-DH6T on Ag(1 1 1) for increasing nominal film thickness (χ). Wide range spectra for photoelectron emission angles (θ_e) of 0° (black, dark blue) and 45° (gray, light blue) are displayed. The 45°-emission spectra are slightly scaled in order to match the intensity of the S-derived peak around 4.50 eV BE of the 0°-spectra. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

may be forced in a more planar conformation in the monolayer, which increases conjugation along the backbone and consequently lowers the IE [57]. In contrast to DE6T, the θ_e-dependence of the S-derived peak at ~4.40 eV BE is smaller for Me-DH6T (0.09 eV), which points to more disorder and/or a slightly different average orientation of Me-DH6T/Ag(1 1 1) compared to DE6T/Ag(1 1 1). Upon cooling the BE shift increased to 0.15 eV.

The growth models and associated interface energy level diagrams (Fig. 3) allow a discussion of the rules of molecular self-assembly at metal surfaces (without strong molecule–metal interactions) with particular attention on the influence of the saturated alkyl-chain length and position on the conjugated backbone. In the case of the straight molecules DE6T, DH6T [3,32,33] and DD6T, it is obvious that the critical length of alkyl side chains, which leads to sufficient hydrophobic interaction between themselves and triggers the lying/standing orientation–transition is between three and six repeat units. Increasing the alkyl length further, e.g., to ten units in the present case for DD6T, does not change the growth mode significantly. An interesting case is Me-DH6T, where the addition of two methyl groups (compared to DH6T) at the two central thiophene units leads to a completely different growth mode. The structure of standing DH6T on lying DH6T on Ag(1 1 1) [33] is similar to the known bulk crystal phase [24,28,62,63]. For Me-DH6T this structure is suppressed by the methylation of DH6T and Me-DH6T assembles in a markedly different way. In comparison, also β,β'-DH6T vacuum sublimed at Au substrates did not adopt a standing orientation already in the second layer, but exhibited a 6T-like growth mode [64]. Furthermore, DH6T deposited on Ag(1 1 1) pre-covered with a monolayer of tetratetracontane – a simple long alkyl chain – did not adopt an almost standing orientation [33]. Thus, the balanced interplay of favored mutual alkyl interaction (molecular fastener effect) and attractive π-system–substrate interaction leads to the specific orientation and structure of the organic thin film.

Notably, the valence spectra measured at low temperature did not exhibit significant changes compared to the room temperature spectra, with exception of DD6T/Ag(1 1 1). Here, the emission from the alkyl chains gained features by cooling the sample, most pronounced a new peak emerging at 8.57 eV BE (Fig. 2). This may be a hint for increased ordering of the alkyl chains by the molecular fastener effect, which is prevented at room temperature by thermal motion. However, the denser packing of the alkyl chains does not affect the conjugated backbone of the molecule significantly, as no unusual sharpening of the HOMO-peak could be observed at low temperature compared to room temperature. For the other 6T-derivatives the packing structure and/or the smaller alkyl chains hinder a pronounced alkyl–alkyl interaction. DE6T, with the shortest alkyl chains within the investigated molecule series, shows the largest bandwidth of the S-derived localized peak, which might be interpreted as the system with the best intermolecular order of the conjugated molecular moieties.

4. Charge rearrangement across alkyl layers

To realize a high work function substrate for deposition of DD6T, F4-TCNQ was deposited stepwise onto Ag(1 1 1) until the increase of the vacuum level (in total 0.71 eV) (Fig. 5) saturated, resulting in an effective substrate work

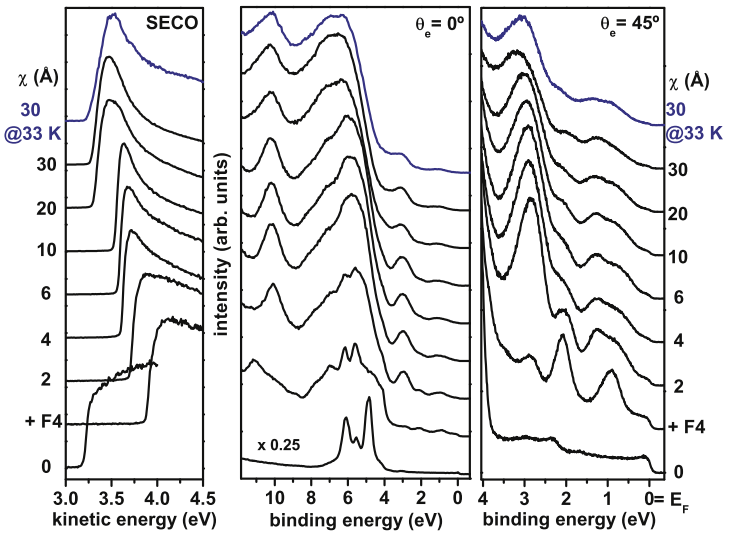

Fig. 5. UPS spectra of DD6T on F4-TCNQ (F4) pre-covered Ag(1 1 1). The secondary electron cut-off (SECO) region, a wide range spectra in normal emission and a close up of the region near to the Fermi-level (E_F) for a photoelectron emission angle (θ_e) of 45° are displayed.

function of 5.28 eV. Depositing up to 6 Å DD6T on the F4-TCNQ/Ag(1 1 1) substrate attenuated the F4-TCNQ features [36,37] and led to a dominant photoemission peak centered at 2.90 eV BE, which is assigned to the localized S-derived states of DD6T. The features at lower BE were comparably smeared out, the low BE onset of photoemission was at 0.22 eV. The vacuum level decreased by 0.34 eV. Deposition of DD6T up to the final coverage of 30 Å decreased the vacuum-level further by 0.29 eV and did not change the valence electron spectral signature. Thus, also in this case the IE of the multilayer is reduced compared to the monolayer, i.e., the orientation is changing from lying to standing (Fig. 3). The absolute IE values for monolayer (5.16 eV) and multilayer (4.90 eV) DD6T on F4-TCNQ/Ag(1 1 1) do not correspond exactly to the values of DD6T on pristine Ag(1 1 1). However, the IE is difficult to interpret for organic heterostructures without exact knowledge of thin film morphology [65]. Also for molecules that form amorphous films, where collective electrostatic orientation effects can be excluded, a change in the IE on F4-TCNQ pre-covered metals has been observed [66]. Moreover, standing DD6T exhibits pronounced island growth, because the two peaks due to localized S-derived states (~2.90 eV BE and ~10.20 eV BE) were not attenuated sufficiently even for a nominal coverage of 30 Å as for DD6T on pristine Ag(1 1 1). The IE change from lying to standing DD6T is only 0.26 eV for DD6T on F4-TCNQ pre-covered Ag(1 1 1) compared to 0.47 eV for DD6T on pristine Ag(1 1 1). For (on a molecular level) inhomogeneously covered surfaces the SECO quantifies the area averaged arithmetic mean of the vacuum levels of covered and uncovered substrate patches, whereas the valence electron photoemission spectrum is the superposition of the spectral features of the respective sample patches [67,68]. This makes the correct assignment of ionization energies at such interfaces very difficult if a shift of the vacuum-level occurs at the interface. Thus, the 0.47 eV IE difference at the organic homointerface of DD6T on pristine Ag(1 1 1) might reflect the more realistic difference in the IE of lying and standing DD6T. Consequently, most probably half of the lying DD6T on F4-TCNQ/Ag(1 1 1) was covered with standing DD6T for nominal 30 Å coverage. However, also this 30 Å DD6T/F4-TCNQ/Ag(1 1 1) film showed charging during UPS measurements which is expected for photoemission across standing alkyl layers [32].

Without the vacuum-level shift between lying and standing DD6T the HOMO onset of standing DD6T would be *above* the substrate Fermi-level (Fig. 3). Thus, the situation at this organic/organic homointerface is reminiscent to Fermi-level pinning [38–41]. The results reveal that decyl chains are *not* long enough to electronically decouple two semiconducting layers (lying DD6T and the 6T core of standing DD6T). Fermi-level alignment at the DH6T/F4-TCNQ/Ag(1 1 1) system, which shows an analogous behavior to DD6T/F4-TCNQ/Ag(1 1 1), was explained to be facilitated by a charge transfer from standing DH6T to the substrate [37]. However, in this case the calculated average charge transfer per molecule was only ~0.03 q, which could also be interpreted in terms of one transferred charge per 33 molecules. Recently, it was shown by means of two photon photoemission that the alkyl layers at the DH6T/Ag(1 1 1) interface lead to charge localization in standing DH6T layers [69]. In the case of integer charge transfer the small fraction of charged molecules would thus lead to laterally isolated dipoles at the organic/metal interface (Fig. 6a). Since the electron potential energy around such a dipole rapidly converges to a common value [7], the energy-level alignment of neighboring molecules is not (or only negligible) affected by an isolated dipole [70]. Consequently, an integer charge transfer would not lead to thermodynamic equilibrium at this interface. Thus, a static charge transfer from standing DD6T to the metal substrate is quite improbable. In addition, the charging of the 30 Å DD6T layers (on both, pristine Ag(1 1 1) as F4-TCNQ pre-covered substrate) demonstrates that even the charge density gradient originating from the photoholes cannot

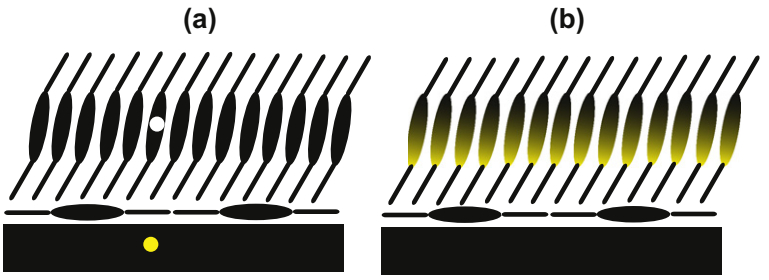

Fig. 6. Sketch of two different mechanisms for explaining the interface dipole between lying and standing DD6T: (a) integer charge transfer, (b) polarization of the conjugated parts of DD6T.

trigger sufficient dynamic charge transfer across the decyl layers.

In a recent density functional theory study [42] on interfaces between metal/SAM and COM a directly related issue was addressed. It was found that in the case of Fermi-level pinning no charge transfer from the COM to the metal substrate occurs but a charge rearrangement at the COM/SAM interface. Thus, the interface dipole has its origin in a slight shift of the adsorbate's electron density center-of-mass with respect to the atomic nuclei, corresponding to a localized polarization. For DD6T and DH6T thin films such a screening would make the unlikely static charge transfer across the alkyl chains obsolete and thus offers a new view on the insulating properties of alkyl chains. The basic mechanism is sketched in Fig. 6b. As the polarizability of the saturated alkyl chains is much smaller compared to the conjugated backbone, the polarization of the 6T backbone could be dominating. Furthermore, the polarization might yield structural changes of standing DD6T and thus lead to a density of disorder induced gap-states [46,47], which might additionally impact the energy-level alignment. The basic principle of polarization instead of charge transfer may not be restricted to the special case of alkylated COMs but may also prevail for other cases of Fermi-level pinning of organic thin films.

5. Conclusions

We could demonstrate that both, the substitution-position and the length of alkyl chains of 6T derivatives play an important role in the self-assembly of these molecules on Ag(1 1 1) surfaces. If the alkyl chains are long enough and attached only at the α,ω position of 6T, the molecules exhibit a growth mode with flat lying monolayer and standing second layer. This orientational transition can be prevented by adding additional methyl groups at the 6T backbone. Since the orientation to a substrate is crucial for energy-level alignment and thus the charge transport efficiency in an organic film, these findings offer an approach for engineering organic thin film structures for enhanced performance of organic devices. Moreover, decyl chains are not long enough to electronically decouple two semiconducting layers. A previously proposed charge transfer across long alkyl chains is, however, unlikely and thermodynamic equilibrium in the context of Fermi-level pinning might also be achieved by a small shift of the center-of-mass of the molecule's electron density.

Acknowledgments

The authors thank Shunsuke Hosoumi for assistance during UPS measurements, Ingo Salzmann for fruitful discussions and Heraeus Clevios GmbH for providing the 6T derivatives. Fig. 1. (a) Evaporation rate vs. the crucible temperatures for $Ir(ppy)_3$, $Ir(MDQ)_2(acac)$, and an (10:1) $Ir(ppy)_3$ to $Ir(MDQ)_2(acac)$ mixture; geometry of (b) a co-evaporation from three individual sources and (c) a co-evaporation from only two sources using premixed dyes. In (b) and (c), thickness of arrows indicates evaporation rate.

from the same crucible. Obviously, the combined rate is mainly influenced by the one of the higher concentrated $Ir(ppy)_3$. This makes co-doped EMLs possible with this kind of approach.

To fabricate OLEDs with mixed EMLs and a balanced emission spectrum, the dye with the lower triplet level has to have a very low doping concentration [9]. The other emitter can have typical concentrations between 1% and 15%. At a certain temperature (e.g. 210 °C) the two dyes $Ir(ppy)_3$ and $Ir(MDQ)_2(acac)$ evaporate at a rate of roughly 0.25 Å/s and less than 0.01 Å/s, respectively. Since the sublimation curve for $Ir(MDQ)_2(acac)$ in Fig. 1 always lies below the one of $Ir(ppy)_3$, we assume that the evaporation rate of $Ir(MDQ)_2(acac)$ in the mixture is also lower than the one of $Ir(ppy)_3$. Therefore, a co-evaporation of a premix of $Ir(ppy)_3$ and $Ir(MDQ)_2(acac)$ results in a strongly different rate for green and red which can lead to mixed EMLs with very low red concentrations and a nearly balanced emission. The two different evaporation curves are the key to generate this doping difference. For example, for a weight ratio of (10:1) in the crucible, the ratio of $Ir(ppy)_3$ to $Ir(MDQ)_2(acac)$ in the final layer should be even larger as the ratio of the evaporation rates is >25:1. But the difference in the evaporation curves of the materials will have consequences on the long term stability of the mixture's molecular composition. A detailed discussion on this will be shown in the next section.

To prepare the dye mixture, appropriate amounts of both materials are weighed and stirred in Argon atmosphere. Special care has to be taken to reach a homogeneous blend as the $Ir(ppy)_3$ molecules tend to stick together easily. Thus, the mixture is pestled in an agate mortar to guarantee a proper intermixing of the dyes before it is filled into the evaporation crucible.

2. PL pretests

In order to characterize co-doped EMLs fabricated by co-evaporation of premixed dyes from one crucible, we prepare layers on float glass substrates for Photoluminescence (PL) characterization. These consist of the matrix 4,4′,4″-tris(carbazol-9-yl)triphenylamine (TCTA) and the two dyes $Ir(ppy)_3$ and $Ir(MDQ)_2(acac)$ from the same evaporation source. The geometry of the evaporation can be seen in Fig. 1(c). All layers are thermally evaporated at a background pressure of 5×10^{-6} Pa, are 40 nm thick and encapsulated afterwards in Argon atmosphere. For PL measurements they are excited at a wavelength of λ_{exc} = 385 nm so that excitons are only formed on the dyes, not on the matrix TCTA. Since all PL samples have identical thickness and are excited with the same wavelength and optical power, PL spectra show the relative changes caused by different film compositions.

Fig. 2 shows the PL signal of these layers with the dyes evaporated from the same source. The different PL spectra belong to samples with an increasing number of evaporations from the mixed crucible. The ratio of $Ir(ppy)_3$ to $Ir(MDQ)_2(acac)$ in the crucible was set to (10:1), the doping ratio between TCTA and the dyes is [89:11]. After several evaporation cycles a substantial change in the emission color of the layers is detected. The more evaporations from the crucible the stronger is the color shift towards a purely red emission. Having in mind the high sensitivity of the color of mixed EMLs on the concentration of the dye with the lowest triplet level ($Ir(MDQ)_2(acac)$) [3,9], the spectral shift over several processed samples indicates that the change in the molecular ratio is of the order of 3 (cf. classical evaporation in Fig. 4). Even the last evaporation (14th sample), just before the crucible was empty, still shows a green emission from $Ir(ppy)_3$. As the change of the dye ratio probably takes place at the surface of the

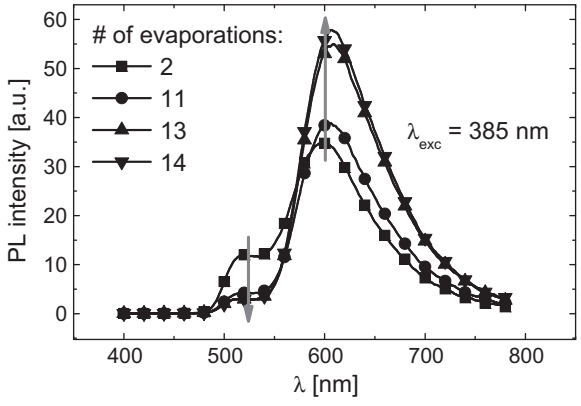

Fig. 2. PL spectra of layers of TCTA doped with $Ir(ppy)_3$ and $Ir(MDQ)_2(acac)$ (TCTA:dyes [89:11]). The emitters were evaporated from the same source with a mixing ratio of (10:1). After several evaporations the spectral composition has changed significantly.

mixture, the color change could possibly be reduced by continuously stirring the mixture during the evaporation.

The depletion of Ir(ppy)$_3$ molecules over time can also be used from the start to reach different emission spectra. As various crucible compositions can lead to different molecular ratios in the layers they also affect the relative strength of green and red emission. Fig. 3 shows PL signals of layers which used different mixtures of Ir(ppy)$_3$ and Ir(MDQ)$_2$(acac) with a doping ratio of [89:11] for TCTA:-dyes. The higher the percentage of Ir(ppy)$_3$ is in the crucible, the lower is the emission of Ir(MDQ)$_2$(acac) in the layer. The rate detection during evaporation only monitors the rate of the entire mixed crucible. If the green to red ratio in the source is high, the overall rate is mainly given by Ir(ppy)$_3$ molecules. If it is decreased, more Ir(MDQ)$_2$(acac) needs to be evaporated to reach the same combined rate. This results in different molecular ratios in the final layer which lead to shifts in the emission spectra.

How do these results compare to PL spectra of layers realized by classical co-evaporation from individual sources (Fig. 1(b))? For this, three different layers were fabricated using the same materials by co-doping from single sources. The concentration of Ir(ppy)$_3$ was kept constant at 10% while the one of Ir(MDQ)$_2$(acac) was varied from 0.3% to 1%. The remaining percentage up to 100% is given by the matrix TCTA. Fig. 4 shows the PL spectra of these three layers as well as the one of the first mixture with the (10:1) composition in the crucible. They all show the typical behavior of mixed EMLs containing two dyes with different emissive levels.

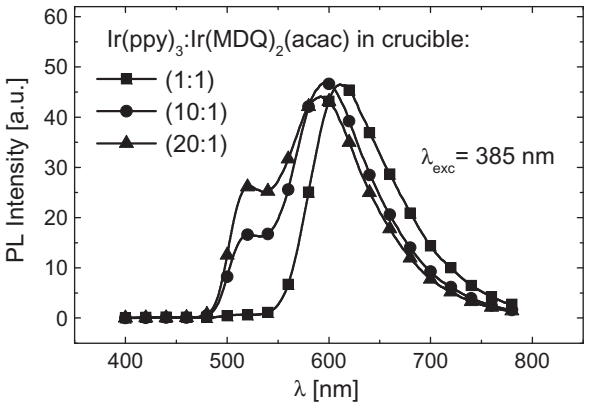

Fig. 3. PL spectra of layers of TCTA doped with Ir(ppy)$_3$ and Ir(MDQ)$_2$(acac) (TCTA:dyes [89:11]). The emitters were evaporated from the same source with different mixing ratios leading to different spectra.

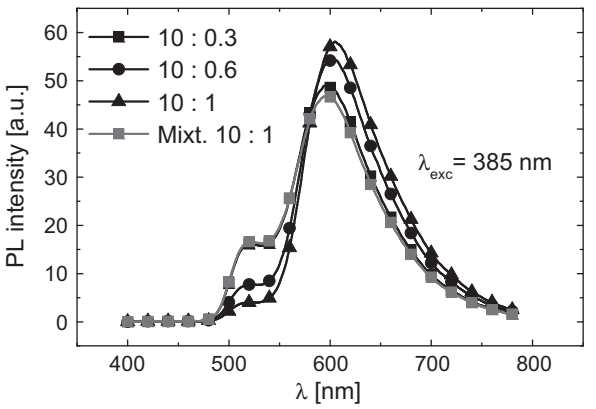

Fig. 4. PL spectra of layers of TCTA doped with Ir(ppy)$_3$ and Ir(MDQ)$_2$(acac). Black curves represent classically evaporated layers from three individual sources with 10% Ir(ppy)$_3$ and 0.3% to 1% Ir(MDQ)$_2$(acac). Gray curve represents a co-evaporated layer using a premixed crucible of (10:1) Ir(ppy)$_3$ to Ir(MDQ)$_2$(acac).

Already a small addition of Ir(MDQ)$_2$(acac), co-doped into the same layer as the Ir(ppy)$_3$, causes a significant change in the emission color of the otherwise green OLED. The strong orange-red peak ($\lambda_{Ir(MDQ)_2(acac)} \approx 600$ nm) generated by relatively few molecules is due to an exciton transfer from the lowest triplet level $T_1 = 2.4$ eV of Ir(ppy)$_3$ to the one of Ir(MDQ)$_2$(acac) with $T_1 = 2.1$ eV which reduces green emission ($\lambda_{Ir(ppy)_3} \approx 515$ nm) [3]. Even at red concentrations much smaller than the 10% of Ir(ppy)$_3$, the majority of excitons decays on Ir(MDQ)$_2$(acac) molecules. These characteristic spectra can also be achieved with a co-evaporation using a premix of dyes which confirms the purpose of this technique. The sensitivity of the spectrum with respect to the exact concentration of Ir(MDQ)$_2$(acac) allows us to detect even small changes in the red concentration with simple PL measurements. Additionally, there is no decrease in the PL efficiency of the layers by the co-evaporation from the same crucible.

The classical sample with [89.7:10:0.3] contains the lowest red doping concentration which can be reproducibly fabricated with our evaporation tool, therefore, representing the most greenish classical spectrum possible. Fig. 3 shows that even greener spectra are possible using the co-evaporation from the same crucible which means that it allows us to cross this procedural barrier.

3. Yellow OLEDs

Yellow OLEDs with mixed EMLs from classical evaporation and co-evaporation of a premix are prepared to show the feasability of this process. For this, we choose a yellow test device which can be easily combined with a blue fluorescent or phosphorescent emitter, e.g. 2,2′,7,7′-tetrakis(2,2-diphenylvinyl)spiro-9,9′-bifluorene (Spiro-DPVBi) or iridium(III)bis(4,6-difluorophenylpyridinato-N,C20)picolinate (FIrpic) to create a warm white light-emitting diode [6,7].

The device structure of the OLED which can be seen in Fig. 5 is the following: 120 nm indium tin oxide (ITO) anode/40 nm di-[4-(*N*,*N*-ditolyl-amino)-phenyl]cyclohexane (TAPC)/7 nm TCTA co-doped with Ir(ppy)$_3$ and Ir(MDQ)$_2$(acac)/10 nm 4,7-diphenyl-1,10-phenanthroline (BPhen)/40 nm tris(8-hydroxy-quinolinato)aluminum (Alq$_3$)/0.7 nm lithium fluoride (LiF)/200 nm aluminum cathode. The EML consisting of the matrix material TCTA and the two dyes is either classically co-doped from two separate evaporation sources for Ir(ppy)$_3$ and Ir(MDQ)$_2$(acac) or the one source containing the dye mixture. The classically co-doped devices are the references to assess the performance of the OLEDs realized by the dye mixture.

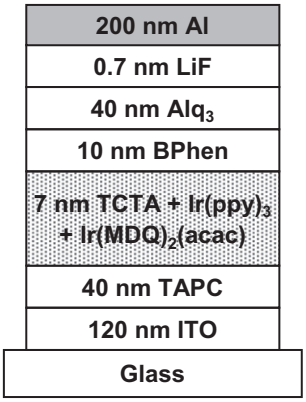

Fig. 5. Stack layout of yellow OLED with mixed EML.

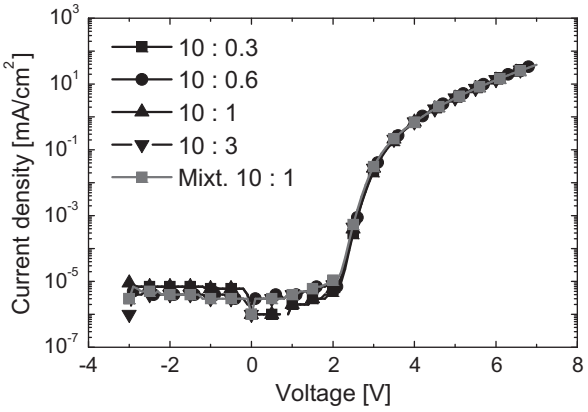

Fig. 6. IV characteristics of the different OLEDs.

The first four curves in Fig. 6 show the IV characteristics of the reference diodes with concentrations of 10% $Ir(ppy)_3$ and a variation of 0.3%, 0.6%, 1%, and 3% $Ir(MDQ)_2(acac)$ in 89.7%, 89.4%, 89%, and 87% TCTA, respectively. The $Ir(ppy)_3$ concentration was chosen to be 10% since devices with $Ir(ppy)_3$ concentrations around this value have shown high external quantum efficiencies (EQE) [10]. The gray curve is the one of the OLED which used the premix during fabrication. As can be seen, the evaporation from the same crucible has no effects on the IV characteristics of the devices. All samples seem to have the same injection barriers as well as identical charge carrier mobilities.

Fig. 7 shows the corresponding spectra of the five diodes. These results are similar to the ones for the PL pretests and other publications which show how sensitive co-doped EMLs are to the concentration of the dye with the lowest triplet level [3,9,11]. Again, the nearly balanced spectrum of the classically evaporated reference of [89.7:10:0.3] is closely met by the one of the premix co-evaporation given by the gray curve. It is confirmed that the red concentration within the layer is significantly lower than the nominal value of (10:1). In fact, it would be very close to a device with 10% $Ir(ppy)_3$ and 0.4% $Ir(MDQ)_2(acac)$. The external quantum efficiency of the diode

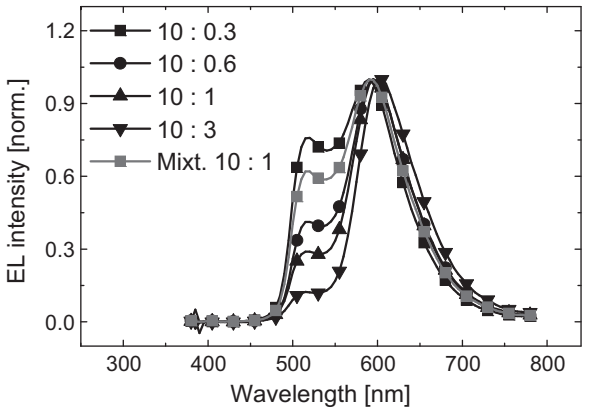

Fig. 7. Normalized electroluminescence spectra of OLEDs with classically co-evaporated EML with TCTA:$Ir(ppy)_3$:$Ir(MDQ)_2(acac)$ doping ratios of [89.7:10:0.3], [89.4:10:0.6], [89:10:1], [87:10:3], and the one with the EML from the (10:1) mixture and a matrix to mixture ratio of [89:11]. Only the emitter ratios are shown to describe the curves in the graph.

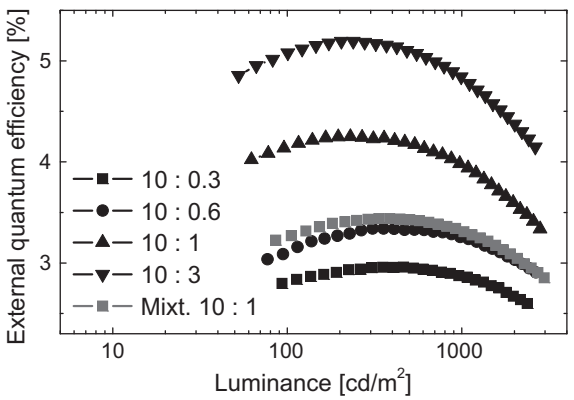

Fig. 8. External quantum efficiency of OLEDs with classically co-evaporated EML with TCTA:$Ir(ppy)_3$:$Ir(MDQ)_2(acac)$ doping ratios of [89.7:10:0.3], [89.4:10:0.6], [89:10:1], [87:10:3], and the one with the EML from the (10:1) mixture and a matrix to mixture ratio of [89:11]. Only the emitter ratios are shown to describe the curves in the graph.

from the mixture is even better than expected for a device with 10% $Ir(ppy)_3$ and 0.4% $Ir(MDQ)_2(acac)$ (cf. Fig. 8).

Nevertheless, the efficiency increases if more red molecules are added to the co-doped layer. Possible reasons for this effect can be: (i) $Ir(MDQ)_2(acac)$ is a more efficient emitter than $Ir(ppy)_3$; (ii) exciton transfer to $Ir(MDQ)_2(acac)$ reduces quenching effects in the device; (iii) $Ir(MDQ)_2(acac)$ molecules act as traps for charge carriers which improves the charge balance; (iv) the microcavity of the device allows for better extraction of red light. The IV characteristics do not indicate a trap behavior of the $Ir(MDQ)_2(acac)$ molecules and optical simulations show that the microcavity is even better for green light, ruling out the last two reasons. Also, $Ir(ppy)_3$ is a very efficient emitter so that device efficiencies cannot be increased that strongly by a higher internal quantum efficiency of $Ir(MDQ)_2(acac)$ [12]. Therefore, the reduction of triplet–triplet annihilation (TTA) in the EML is the most reasonable explanation. Excitons which have been transferred to the few

Table 1
Characteristics of the five fabricated OLEDs at a luminance of 1000 cd/m^2.

OLED	V (V)	EQE (%)	Lum. eff. (lm/W)	CIE x/y

10:0.6	5.9	2.93	4.2	0.51/0.47
10:1	5.8	3.97	5.0	0.53/0.45
10:3	5.8	4.84	5.0	0.58/0.41
Mixt. 10:1	5.9	3.32	4.7	0.47/0.50

$Ir(MDQ)_2(acac)$ molecules are located on the lowest triplet level in the EML. Since the red concentration is so low, the diffusion of these excitons is hindered compared to the ones still remaining on $Ir(ppy)_3$. The more excitons are transferred to $Ir(MDQ)_2(acac)$ the less they diffuse and encounter each other thus, reducing TTA. Table 1 gives an overview of the OLEDs' characteristics at a luminance of 1000 cd/m^2.

However, the biggest advantage of this combined evaporation of both dyes is the rate control. In the case of classical co-evaporation the rate of the dye with the lowest triplet level has to be very small compared to the second emitter and especially the matrix material. Only then a spectrum can be reached in which both dye peaks are nearly balanced. This can be seen in Fig. 7 where already a concentration of 1% $Ir(MDQ)_2(acac)$ results in a dominating orange-red emission. This asymmetry in the detection of evaporation rates and the subsequent temperature control of the evaporation sources can be difficult, expensive and potentially lowering the overall yield. A doping concentration of 0.3% is already close to the limit of reliable processability in an evaporation machine with a rate detection by oscillating crystals and a simple geometry. In case of the mixed evaporation, the rate of the dye source is significantly higher since the difference in the dyes' concentrations does not need to be monitored but is determined by the weight ratio within the crucible. This allows for simpler machine layouts and an easier process control for the production of organic light-emitting diodes which would result in higher yield and lower cost.

4. Conclusion

In summary, we have compared two different production techniques leading to co-doped emission layers on glass as well as in OLEDs. The alternative approach of evaporating a mixture of two dyes from one source gives results similar to the classical one which uses an individual source for each dye. Using this technique, the ratio between the two emitters in the layer is determined by the relative concentration within the evaporation crucible which makes it easier to control a high mixing ratio. The resulting spectra show that both dye moieties are present and work efficiently in an emission layer, even though the evaporation temperatures of the dyes are very different. This holds several advantages for production as the evaporation can be simpler and cheaper compared to the classical method. On the other hand, the composition of the mixture in the crucible changes constantly due to the different evaporation temperatures of the two dyes. This results in the reproducibility of the layers still being an issue.

single more flexible polymers such as polystyrenesulfonate, nanostructured surfaces were applied [10], since flexible polymers, including alkylated polythiophenes, tend to collapse or aggregate [11], causing significant heterogeneities in sub-monolayer films. Due to the notorious difficulty to fabricate ultrathin (sub-monolayer range) semiconducting polymer films, detailed investigations on the coverage dependent evolution of electrode Φ and valence electronic energy levels for such polymers are rare [12]. On the other hand, spin coating is a well suited method for preparing polymer films of 10 nm thickness and beyond. In principle, one could use thicker conjugated polymer films for evaluating the energy level alignment under the assumption that the energy levels throughout the semiconductor layer are constant as function film thickness, i.e., no band bending occurs. Nonetheless, clearly discriminating between these two competing effects is complicated if actual polymer film thickness and homogeneity are not well established [13]. It is thus still uncertain to what extent an interface dipole determines polymer/electrode energetics and whether it can clearly be delineated from band bending.

In the present study, we investigate the energy level alignment at a prototypical semiconductor polymer/polymer electrode interface of direct relevance for organic photovoltaics with the polymeric donor poly(3-hexylthiophene) (P3HT) and the intrinsically conductive polymer poly(ethylenedioxythiophene):poly(styrenesulfonate) (PEDT:PSS) as electrode. We focus on the initial stage of interface formation by measuring Φ and the valence electronic structure with ultraviolet photoelectron spectroscopy for defined P3HT coverage from the submonolayer regime to thick films. Clear evidence for the formation of an abrupt interface dipole between the P3HT monolayer and PEDT:PSS is found.

2. Experimental details

Indium-tin-oxide (ITO) coated glass (sheet resistance 15–30 Ω) was used as substrate. ITO coupons were cleaned by sonication in acetone and isopropanol, followed by 20 min UV/ozone exposure in ambient. PEDT:PSS (Al4083, H.C. Stark GmbH & Co. KG) was spin coated from aqueous dispersion at 1500 rpm and dried at 200 °C for 5 min in ambient atmosphere. P3HT (Aldrich, M_n ~64,000 g/mol) was spin coated (3000 and 1500 rpm) in inert atmosphere from chloroform solution with concentrations of 0.5, 1 and 2 mg/ml to vary film thickness. The chemical structures of the polymers are shown in Fig. 1. Ultraviolet photoelectron spectroscopy (UPS) and X-ray photoelectron spectroscopy (XPS) measurements were performed at the end station SurICat (beamline PM4) at the synchrotron light source BESSY II (Berlin, Germany). Spectra were collected with a hemispherical electron energy analyzer (Scienta SES 100) using an excitation photon energy of 30 eV for UPS and 620 eV for XPS. The secondary electron cutoff (SECO) spectra were recorded with a sample bias of −10 V to clear the analyzer work function. The error of binding energy and work function values reported below is estimated to be smaller than ±0.05 eV. After UPS

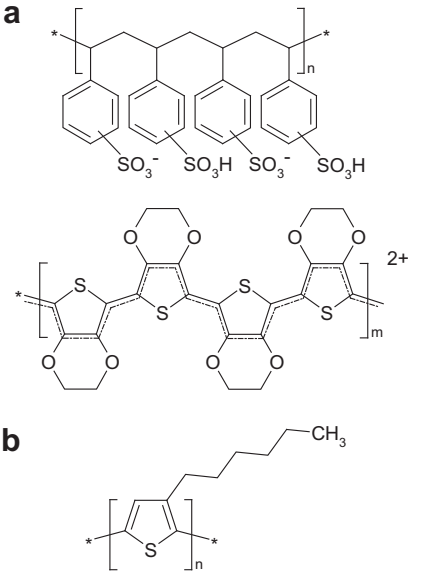

Fig. 1. Chemical structure of (a) PEDT:PSS and (b) P3HT.

and XPS measurements samples were washed in 25 ml chloroform for 10 s at ambient atmosphere to reduce the thickness of the P3HT layer to the monolayer regime. A second series of samples were annealed *in situ* at ~120 °C for 30 min. Annealed samples were also washed subsequently in order to reduce the film thickness.

To determine the thickness of P3HT films the optical absorption at 550 nm wavelength was used in conjunction with atomic force microscopy (AFM) thickness measurements. For this purpose, P3HT films were spin coated on fused silica with various thicknesses and the absorbance was measured using standard UV–vis spectroscopy (Perkin Elmer, Lambda 650). The film thickness was determined by measuring the step height across a mechanical scratch within the film with an AFM (Veeco Multimode). The slope of a linear fit of absorbance *versus* film thickness yielded a P3HT absorption coefficient at 550 nm of 0.009(4) nm^{-1}. The thickness of P3HT films used for UPS was estimated measuring the absorbance at 550 nm of control samples prepared under identical preparation conditions. The absorbance of control the samples was measured right after preparation to avoid bleaching in ambient conditions. The absorbance of the ITO/PEDT:PSS substrates was measured before spin coating P3HT for every individual sample to establish reliable background spectra for each P3HT film. The thickness of washed ultrathin films was additionally confirmed by evaluating the intensity of the S2p core level signal of the PEDT:PSS substrate in XPS. The P3HT film thickness was calculated assuming an exponential decrease of the substrate signal with increasing P3HT coverage and an elastic mean free path for photoelectrons of 2 nm [14]. The results on P3HT thickness were in good agreement with the values obtained from the absorbance measurements within a maximum error of 25% for ultrathin P3HT films. The main error cause is most likely an inhomogeneous P3HT coverage on top of PEDT:PSS in the

ultrathin (ca. monolayer) regime. Overall, P3HT films were homogeneous, with surface roughness values below 1.4 nm at all thicknesses as determined by AFM (see Supplementary information). Comparable surface roughness was measured for pristine PEDT:PSS films.

3. Results and discussion

The presentation of data and their discussion is organized as follows. First, we discuss the pristine PEDT:PSS surface properties and revisit the overall electronic structure of a thick (20 nm) P3HT film. Subsequently, we turn towards thinner and ultrathin P3HT films and their electronic structure on PEDT:PSS.

The work function (Φ) of pristine PEDT:PSS was 4.70 eV (Fig. 2a). To quantify the influence of the P3HT solvent alone on the conductive polymer Φ a pristine PEDT:PSS film was exposed to chloroform by mimicking a spin-coating process. This yielded an increase of Φ to 4.90 eV (Fig. 2b), which is most likely the result of changes in the surface morphology of PEDT and PSS, which is known to strongly affect Φ [15]. In addition, chloroform treatment may aid the removal of residual water from PEDT:PSS, which also increases Φ [15]. In the following, we thus refer all Φ changes due to P3HT deposition to this higher value of 4.90 eV because it includes the effect of the P3HT solvent on the results.

Representative UPS SECO and valence spectra of a 20 nm P3HT film on PEDT:PSS are shown in Fig. 2c and d. The intense peak centered at ca. 3 eV binding energy in the valence region is dominated by emission from a localized π-band. The comparably flat feature between 0.25 and 2.5 eV is due to emission from the delocalized frontier π-band of P3HT [16]. The low binding energy onset of this band at 0.25 eV below the Fermi-level (E_F) defines the valence band maximum. The sample Φ is reduced to 4.35 eV upon P3HT film deposition, and the P3HT ionization energy (IE) is 4.60 eV, obtained by adding the energy difference between the valence band onset and E_F (i.e., the hole injection barrier) to Φ. Because the IE of P3HT is smaller than Φ of the substrate, hypothetical vacuum level alignment at the interface would position part of the filled valence band states above E_F, corresponding to a non-equilibrium situation. Consequently, electrons from P3HT are transferred to PEDT:PSS and an "interface dipole" (ID; equivalent to a change of sample Φ) develops. This interfacial charge transfer induces an electric field that moves the electronic states of P3HT below E_F, thus limiting further charge transfer and pinning of the P3HT levels relative to E_F. In a simple approximation, the ID might be estimated as the difference between Φ of PEDT:PSS (4.9 eV) and IE of P3HT (4.6 eV), yielding 0.3 eV in the present case. In contrast, the measured ID for the 20 nm thick P3HT film is 0.55 eV (*cf.* Fig. 2b and c). The discrepancy of 0.25 eV can be explained by the model that suggests that pinning does not occur directly at the valence band onset of the semiconducting polymer but at the positive polaron levels that result on P3HT due to electron transfer to PEDT:PSS [17,18]. Thus pinning should occur at the positive polaron level, which was proposed to be in the gap of the organic semiconductor due to relaxation of the conjugated system upon charging, typically a few 100 meV above the valence band onset of the neutral polymer [19–22]. The interfacial charge transfer between P3HT and PEDT:PSS might be written, in analogy to the ID mechanism proposed for pentacene and PEDT:PSS [13]:

$$PEDT^+ + PSS^- + P3HT^0 \rightarrow PEDT^0 + PSS^- + P3HT^+ \qquad (1)$$

where the PSS^- moieties counterbalance the charge of the PEDT and P3HT positive polarons. An alternative model to pinning at defined polaron levels takes into account that real polymer films contain conformational and structural defects, which lead to a broadening of the effective density of states compared to an idealized defect-free single crystal. This gives rise to intra-gap states between the valence band maximum and E_F, whose density may be well below the sensitivity of the present experimental setup [23,24]. Consequently, pinning may occur at these states and will as well involve electron transfer from P3HT to PEDT:PSS.

However, the above discussion is only relevant if all energy levels in P3HT are flat across the entire film thickness and the valence band binding energy and vacuum level position measured at the surface of the 20 nm thick film represent those at the interface. For instance, any effects due to band bending cannot be captured in such an experiment. The above assumption is not readily justified as numerous reports suggest that band bending in organic semiconductor films exits [7,25–29]. Because UPS measurements are very surface sensitive (~1 nm information depth) no information about the position of the energy levels neither in the bulk nor at the interface of the P3HT film with PEDT:PSS are available without decreasing the film thickness significantly below 20 nm. While preparing defined thin films with small molecular materials *via* sublimation is straight forward, the controlled formation of ultrathin polymer films *via* spin coating is highly challenging. For our further investigations of the intimate

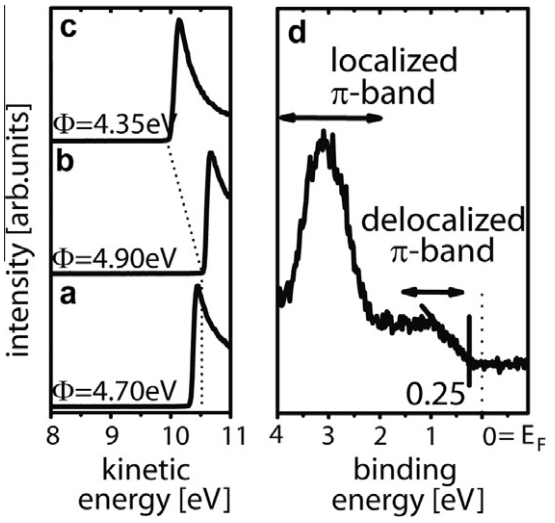

Fig. 2. Secondary electron cutoff of (a) pristine PEDT:PSS, (b) PEDT:PSS washed with chloroform, and (c) 20 nm P3HT on PEDT:PSS. (d) Valence band UPS spectrum of 20 nm P3HT on PEDT:PSS.

P3HT/PEDT:PSS interface with UPS we prepared samples by spin coating highly diluted solutions and also by employing additional solvent-washing for realizing ultrathin P3HT films with ca. 1 nm thickness, i.e., in the monolayer range. We investigated such samples with and without annealing in UHV at 120 °C for 30 min to (i) eliminate residual solvents and (ii) to investigate possible influences of annealing-induced polymer conformation changes. Fig. 3 shows UPS spectra of annealed P3HT films on PEDT:PSS with various thickness, and apparently the energy level positions vary as a function of film thickness. This observation already justifies the critical assessment of the reliability to derive interface energetic from just measuring rather thick polymer films from above. For instance, the vacuum level (and therefore Φ) and the position of the valence band onset remained constant for P3HT films in the thickness range 20–3.6 nm, but a significant decrease of Φ by ~0.20 eV and a shift of the valence band onset by ~0.15 eV to lower binding energy were observed for ultrathin films. Note that the peak maximum of the localized π-band shifted to lower binding energy by almost the same amount as the valence band onset (Fig. 3b). To check whether the annealing step impacted the crystallinity and/or morphology in our P3HT films, possibly influencing the electronic properties [30], we measured analogous samples without annealing. These spectra exhibited fully analogous shifts of the vacuum level and of the valence band, with marginally different absolute values (typically within 0.05 eV) for the individual samples (Fig. 4). Therefore, significant morphological changes that would compromise our results can be ruled out.

Fig. 5 summarizes the evolution of sample Φ and the valence band onset position of P3HT films as function of film thickness. As can be seen in Fig. 5a the qualitative trend of Φ and the valence band onset are different. While Φ exhibits a gradual decrease for increasing P3HT thickness (up to 2 nm where saturation sets in), the valence band onset position exhibits an abrupt shift by 0.15 eV above film thicknesses of 2 nm. Considering that the distance between two P3HT chains perpendicular to the π–π stacking direction is ~1.6 nm [16], our ultrathin films (<2 nm) are in the monolayer or even sub-monolayer regime. Therefore, pinholes in the P3HT layers or even extended uncovered PEDT:PSS areas may exist. Because UPS measures Φ area-averaged as long as the inhomogeneous surface patches are not extending over several 100 nm, the measured Φ is an average of that of pristine PEDT:PSS and that of P3HT covered areas, leading in the present case to a gradual decrease of Φ with increasing coverage. Once full monolayer coverage is reached, sample Φ should remain constant for higher film thickness in this scenario, which we indeed observe beyond 2 nm P3HT thickness (Fig. 5a). This kind of behavior was observed so far only for small molecules evaporated on PEDT:PSS or clean metal surfaces [3,15,23,31], whereas band bending was evoked for polymers when vacuum level shifts were observed after deposition on electrode materials [7,29]. Note that the concept of band bending within a monolayer of a polymer cannot be applied meaningfully. The absence of band bending in the thickness region below 2 nm can be ruled out formally because of the abrupt shift of the valence band onset position while Φ decreases continuously. If band bending were occurring, all energy levels, thus also the valence band and Φ should shift in parallel.

The charge transfer area-density at the interface, needed to create typically occurring vacuum level shifts, is in general relatively low. For this reason the positive polaron pinning level that is created in P3HT because of the predicted charge transfer contributes only very little to the UPS spectra and could not be directly detected yet. To estimate the transferred charge at the interface per area for our work function change $\Delta\Phi$ of 0.55 eV between pristine PEDT:PSS and at least a full P3HT monolayer, we calculate the dipole density using the Helmholtz equation:

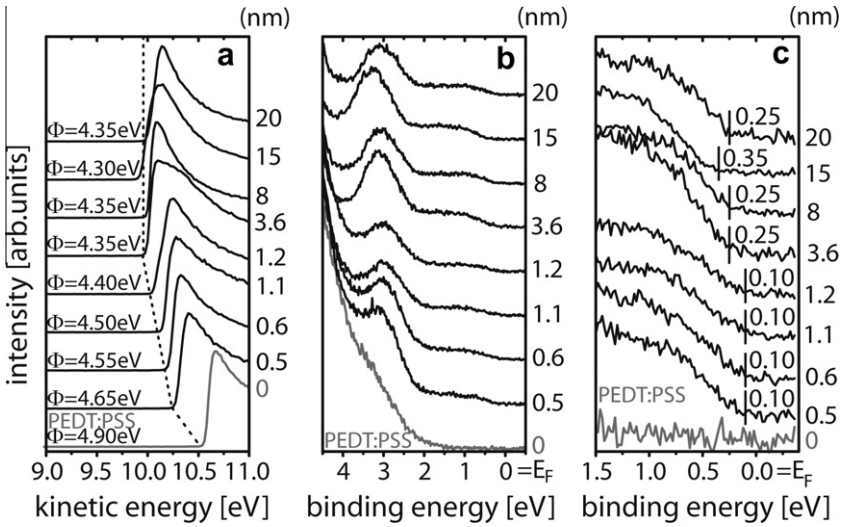

Fig. 3. UPS spectra of P3HT films with varying thickness (given at the right side of axes) on PEDT:PSS after *in situ* annealing at 120 °C for 30 min: (a) SECO, (b) valence region and (c) zoom on the valence band onset.

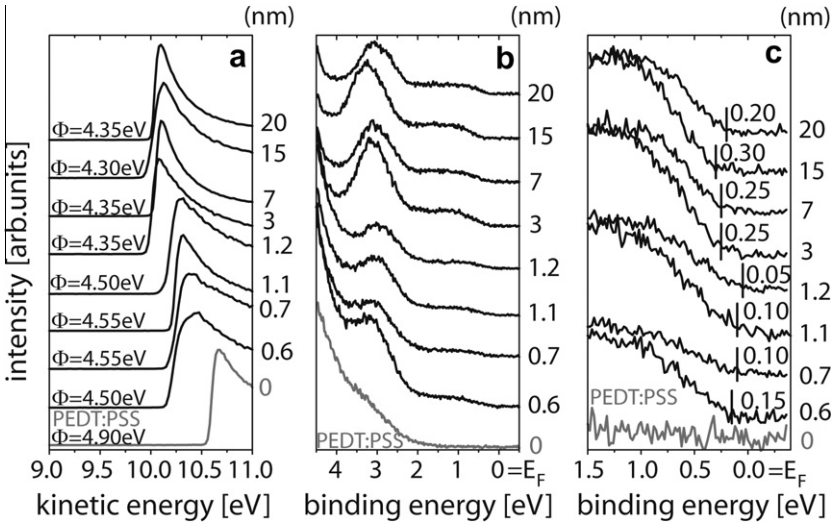

Fig. 4. UPS spectra of not-annealed P3HT films with varying thickness (given at the right side of axes) on PEDT:PSS: (a) SECO, (b) valence region and (c) zoom on the valence band onset.

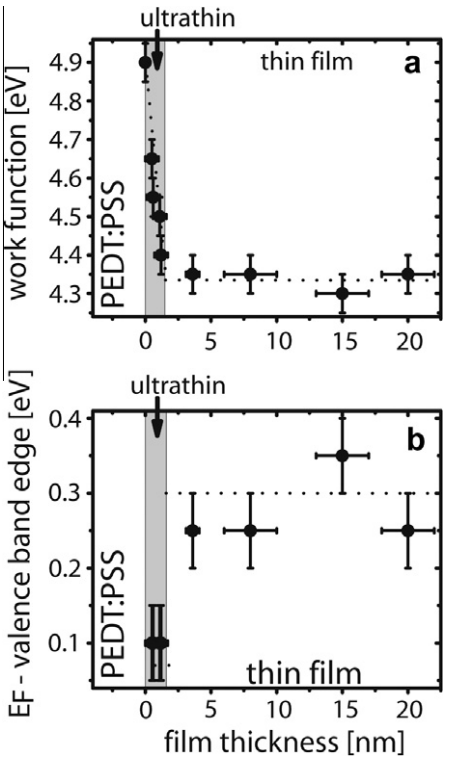

Fig. 5. Work function (a) and position of the low binding energy valence band onset (b) as a function of P3HT thickness on PEDT:PSS (data for annealed samples from Fig. 3).

$$\Delta\Phi = \frac{e \cdot n \cdot |\vec{\mu}|}{\varepsilon_0 \varepsilon_r} \tag{2}$$

with e the elementary charge, n the surface dipole density, $|\vec{\mu}|$ the dipole moment perpendicular to the surface, ε_0 the vacuum permittivity, and ε_r the relative dielectric constant. With $|\vec{\mu}| = 1.6 \times 10^{-28}$ Cm (charge separation of one electron over a distance of 1 nm) and setting ε_r at 3, which is a commonly accepted value for P3HT, one obtains $n = 0.1\ \mathrm{nm}^{-2}$. If we assume a crystalline P3HT film with the π–π stacking direction parallel to the substrate surface the density of thiophene units amounts to $n_{th} = 11\ \mathrm{nm}^{-2}$ [16,31,32]. Taking additionally into account that the polaron state is approximately delocalized over 4–10 thiophene units [33,34], roughly 3–10% of the thiophene units are involved in polaron state formation, which should be detectable with UPS if they indeed form intra-gap states. In fact, UPS spectra of ultrathin films in the sub-monolayer regime exhibit spectral changes of the valence band that might correspond to such additional intensity in the nominally empty energy gap. Fig. 6 compares the valence spectra of 20 and 0.5 nm thick P3HT films. In this plot, the valence band onsets are aligned to 0 eV binding energy and the intensity at 1.5 eV binding energy is normalized to 1. In direct

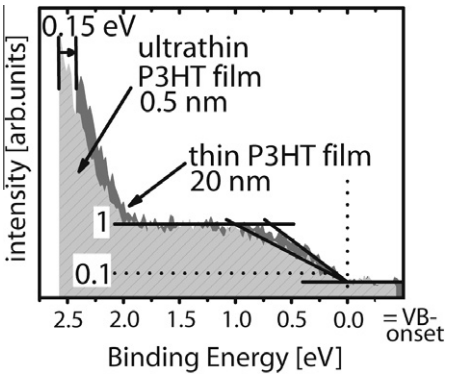

Fig. 6. Comparison of valence band UPS spectra of P3HT films on PEDT:PSS with 20 nm and ca. 0.5 nm film thickness. The intensity at 1.5 eV was normalized to one and the low binding energy valence band onset was set to 0 eV binding energy.

comparison, the 0.5 nm film appears to have a wider delocalized π-band and a smaller slope at its low binding energy onset. This observation, together with the smaller absolute binding energy of ultrathin film valence bands with respect to E_F (by ca. 0.15 eV, *cf*. Fig. 5b) might indicate the existence of polarons formed by the charge transfer reaction between the PEDT:PSS substrate and P3HT.

4. Conclusions

Ultraviolet photoelectron spectroscopy was used to investigate the energy level alignment at the P3HT/PEDT:PSS interface from sub-monolayer to multilayer coverage, using solution processing. Sample Φ decreased monotonically from 4.90 (pristine PEDT:PSS) to 4.35 eV for a monolayer-equivalent of P3HT (ca. 2 nm) and remained constant for larger semiconducting polymer thickness. In contrast, a sudden binding energy increase by ca. 0.15 eV of the valence band onset at the monolayer-multilayer transition was observed. This is interpreted by a P3HT/PEDT:PSS charge exchange reaction that lowers Φ as a function of P3HT coverage up to a full monolayer. This is in accordance with the changes of the valence spectral signatures that occur upon monolayer completion. Consequently, these observations are in full analogy to the established behavior of evaporated small organic molecule/electrode interfaces with an interface dipole, where the first molecular layer determines Φ while the valence level position is determined by interfacial chemistry. The thorough use of ultrathin polymer films allow us to rule out that effects in relation to band bending play a role upon intimate interface formation between a conductive polymer electrode and semiconducting polymers. Band bending may occur at polymer thicknesses well beyond the monolayer, but the initial Φ change of electrodes upon polymer monolayer formation should not be evaluated as classical doping-related space charge effects.

systemically. We discuss two types of TEWOLEDs according to the anode: (1) metal and (2) 1D metallic–dielectric photonic crystal. Our results indicated that TEWOLEDs could be used as lighting devices with high CRI and stable angular color uniformity or displays with wide color gamut by carefully designing the structure of the devices.

2. Review of current developments in TEWOLEDs

Extensive efforts have focused on eliminating the microcavity effects in TEWOLEDs. Transparent conductive oxide like ITO and semitransparent metals with or without light outcoupling layer are commonly used in TEWOLEDs. In 2005, Kanno et al. [23] fabricated a TEWOLED with Ni anode and ITO cathode. The power efficiency and the CIE coordinates of the device are 9.8 lm/W ± 1.0 lm/W and (0.42, 0.39), respectively. There is only weak angular dependence in the spectra, and the CIE coordinates shifted by (0.02, −0.01) from 0° to 60°.

However, the ITO sputtering technology is hard to control and more researchers would like to use metal films as cathodes. In 2005, Hsu et al. [17] reported a TEWOLED employing a SnO_2 index-matching layer on the Ca (5 nm)/Ag (15 nm) cathode. A near-white light emission (0.31, 0.47) with an efficiency of 22.2 cd/A is obtained and the emission shows less angular dependence. In 2007, Zhu et al. [18] reported a TEWOLED with Ca (6 nm)/Au (15 nm)/Alq_3 (50 nm) cathode. The device shows a maximum power efficiency of 12.8 lm/W. There is less angular dependence in the spectra, and the CIE shifted by (0.01, −0.03) from 0° to 60°. In 2008, Lee and Tseng [24] reported a nearly Lambertian TEWOLED with low-reflectivity molybdenum (Mo) anode and Al (1.5 nm)/Ag (17.5 nm)/N,N′-bis-(1-naphthyl)-N, N′diphenyl-1,1-biphenyl-4,4′diamine (NPB, 30 nm) as cathode. A white emission with efficiency of 3.7 cd/A and CIE coordinates of (0.33, 0.39) is obtained, and the emission shows less angular dependence. In 2010, Freitag et al. [12] demonstrated a TEWOLED with Al (60 nm) as anode and Al (1 nm)/Ag (15 nm)/NPB (50 nm) as cathode. The emission shows CIE coordinates of (0.420, 0.407) at approximately 1000 cd/m^2, the power efficiency and color rendering indices (CRI) are 8.0 lm/W and 75.6, respectively. However, the light emission from the device exhibits a rather strong directionality, rather than a Lambertian behavior. Currently, Xie et al. [11] reported a TEWOLED with Cu anode and Al (2 nm)/Ag (18 nm)/4,4′,4″-tris-(3-methylphenyl-phenylamino)-tripheny-lamine (m-MTDATA, 50 nm) cathode. The device reaches high efficiencies of 17.6 lm/W at a current density of 10 mA/cm^2, and low voltage of 4.4 V at 1000 cd/m^2. And the emission shows less angular dependence.

TEWOLEDs utilizing microcavity effect also have been reported. In 2008, Kim et al. [25] reported the TEWOLED with Ag/ITO anode and Al (2.0 nm)/Ag (20 nm)/ITO (63 nm)/SiO_2 (42 nm) cathode. By varying the microcavity length of TEOLEDs through the variation of the anode ITO thickness and, by optimizing the dopant DCJTB concentration and the thickness of the emissive 4,4′-bis(2,2′-diphenylvinyl)-1,1′-biphenyl (DPVBi) layer, an EL spectrum composed of two complementary wavelengths close to white light could be obtained. But the light-emitting efficiency was merely about 1.4 lm/W and there is no report on the angular dependence characteristics in the EL spectra.

In 2009 and 2010, we reported the microcavity TEWOLED with 1D metallic–dielectric photonic crystal anode and Al (1 nm)/Ag (20 nm)/MoO_x (35 nm) cathode [13,26]. By simply adjusting the thickness of the dielectric layer, multiple-peak TEWOLEDs with EL peaks at desired wavelengths were achieved. However, the emission is obvious angular dependence, for example, the CIE coordinates shifted by (0.06, 0.01) from 0° to 60° in a two-peak TEWOLED.

In 2010, Wang et al. [27] reported a microcavity inverted TEWOLED with Al (100 nm) anode and Ag (24 nm)/NPB (80 nm) cathode. The device showed an efficiency of 5.6 cd/A and the CRI is 68. However, the emission is severe angular dependence, and the CIE coordinates shifted by (0.06, 0.1) from 0° to 60°.

3. Results and discussion

The approximate theoretical spectrum for emission in the microcavity device can be calculated following the approach of Deppe et al. [28]. The emission properties of TEWOLEDs are investigated using the optical module of the OLED simulation software SimOLED [29].

In our simulation, two kinds of devices with the following configurations were prepared: Blue–yellow (BY) device: anode/MoO_x (1.5 nm)/m-MTDATA (28 nm)/NPB (10 nm)/DPVBi (15 nm)/4,4-N,N-dicarbazole-biphenyl (CBP, 5 nm)/CBP:bis(2-(2-fluorphenyl)-1,3-benzothiozolato-N,C2′) iridium (acetylacetonate) [$(F–BT)_2Ir(acac)$] (7 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen, 30 nm)/cathode; Red–green–blue (RGB) device: anode/MoO_x (1.5 nm)/m-MTDATA (25 nm)/NPB (10 nm)/DPVBi (15 nm)/CBP (2 nm)/CBP:$Ir(ppy)_3$ (5 nm)/CBP:$Ir(piq)_2(acac)$ (5 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen, 35 nm)/cathode. According to the energy levels of the materials, we assume that the excitons will form at the interfaces of NPB/DPVBi and CBP:$(F–BT)_2Ir(acac)$/Bphen in BY device, and at the interfaces of NPB/DPVBi, CBP/CBP:$Ir(ppy)_3$, and CBP:CBP:$Ir(piq)_2(acac)$/Bphen in RGB device. The refractive index data for metals were taken from the literature [30]. The optical constants of the organic materials and light outcoupling layers were measured using a variable angle spectroscopic ellipsometer [31].

3.1. Metal–metal microcavity TEWOLED

3.1.1. Influence of different metals on the performance of TEWOLED

The calculations have been performed for six metals (Ag, Au, Al, Mo, Cu and Sm) in BY devices. Ag, Au, Al, Mo and Cu were considered for the bottom anode, and LiF/Al (1 nm)/Ag (15 nm), LiF/Al (1 nm)/Au (15 nm) and Sm (30 nm) were considered for the top cathode. Fig. 1 shows the calculated spectra of the BY devices with different anodes and LiF/Al/Ag cathode in a forward direction.

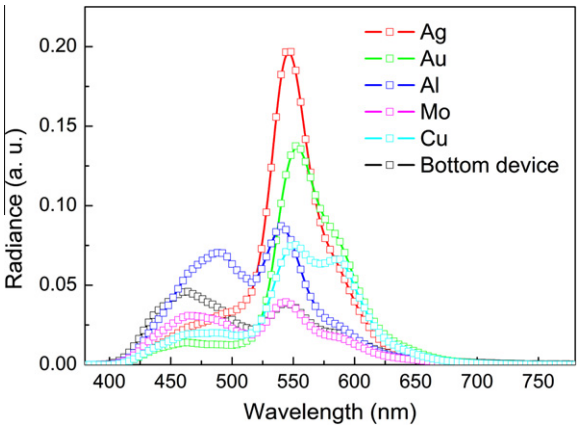

Fig. 1. The calculated spectra of the BY devices with different anodes and LiF/Al/Ag cathode in forward direction.

The spectra of the TEWOLEDs reveal dependence on the anode metals. Only the Mo device shows similar EL spectra with the bottom one. The Ag and Au devices present strongly enhanced yellow emission and suppressed blue emission, while Al device presents enhanced green emission and Cu device presents enhanced red emission. It can be explained by the forward directed cavity emission and the reflection of their anode as shown in Fig. 2. The cavity emission was obtained by considering wavelength-independent intrinsic luminescence spectra of the emitters [12]. The calculated resonant wavelength of Ag, Au, Al, Mo, and Cu devices are 548, 560, 504, 504 and 584 nm, respectively. And Ag, Au, Al, and Cu devices showed strong cavity emission intensity due to the high reflection in the resonant wavelength. The different resonant wavelengths of the devices could be attributed to the different phase changes on the reflection of the metal anodes. Thus, the Ag and Au devices show enhanced yellow emission, Cu device shows enhanced red emission and Al device shows enhanced green emission. Although the resonant wavelength of Mo device is 504 nm, the relatively low reflection of Mo makes a relatively weak cavity emission in this device, thus, the Mo device shows similar EL spectra with the bottom one in the forward direction.

The angular emission characteristics of the TEWOLED with LiF/Al/Ag cathode and Ag anode are shown in Fig. 3. The device shows a strong change in EL spectra with a varying observation angle. The enhanced blue emission and suppressed yellow emission were observed with the increase of the observation angle. And the CIE coordinates shifted by $(0.036, 0.017)$ from 0° to 30° and shifted by $(0.157, 0.366)$ from 0° to 80°. The devices with Au, Al, Mo and Cu anodes also present severe angular dependence. Although the Mo device shows relatively weak microcavity effect, the CIE coordinates also shifted by $(0.017, 0.039)$ from 0° to 30° and shifted by $(0.047, 0.170)$ from 0° to 80°. Besides, the performance of the LiF/Al/Au-cathode TEWOLEDs with different metal anodes is similar to that of the LiF/Al/Au-cathode devices.

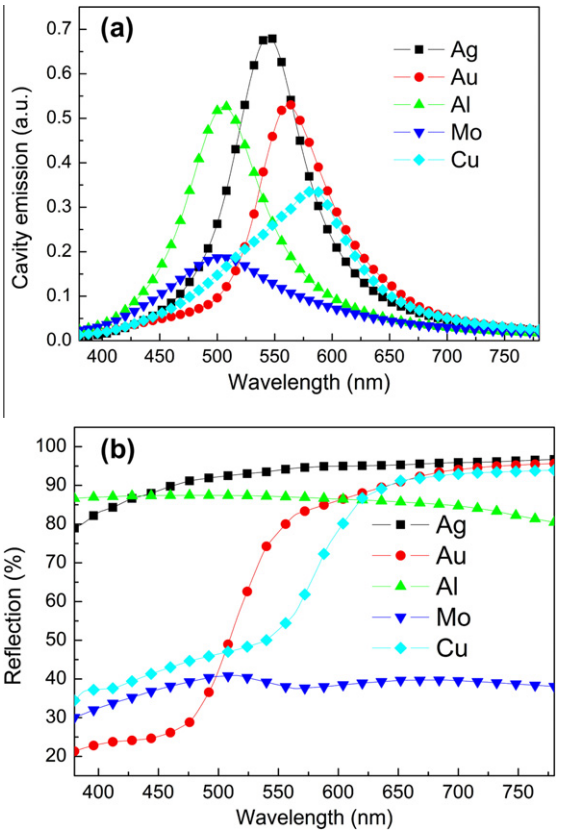

Fig. 2. (a) Forward directed cavity emission of the device, and (b) reflection of the anode materials.

The severe angular dependence characteristics of the above device can be attributed to the high reflection of the cathode as shown in Fig. 4. If using a low reflection metal such as Sm, the angular dependence characteristics of the devices could be meliorated. Fig. 5 shows the calculated EL spectra of the device with Ag anode and Sm cathode. There is no obvious changing on the spectra with a varying observation angle. And the CIE coordinates only shifted by $(0.008, 0.009)$ from 0° to 30° and shifted by $(0.044, 0.024)$ from 0° to 80°. The improvement of the angular dependence characteristics of the device can be attributed to the low reflection and high transmission of the Sm cathode (about 5% and 45% in the visible region).

3.1.2. Influence of light outcoupling layer on the performance of TEWOLED

The angular color uniformity of the TEWOLEDs could be improved by introducing a light outcoupling layer on the top of the cathode. Thomschke et al. [19] had described a numerical simulation of the effect of the light outcoupling layer on the angular emission characteristics of the TEWOLEDs. Here, we present a detailed optical simulation of the light outcoupling layer on the performance of the TEWOLEDs.

Firstly, the influence of different light outcoupling layers according to their reflective index (n) on the performance of the TEWOLEDs was discussed. Low-n material

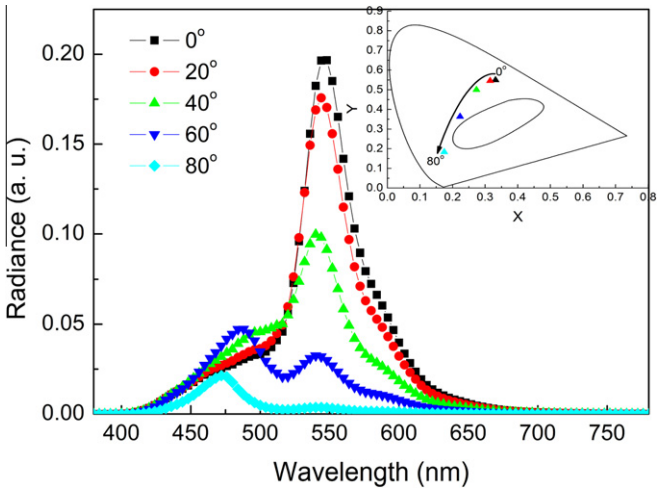

Fig. 3. The angular characteristics of the TEWOLED with LiF/Al/Ag cathode and Ag anode.

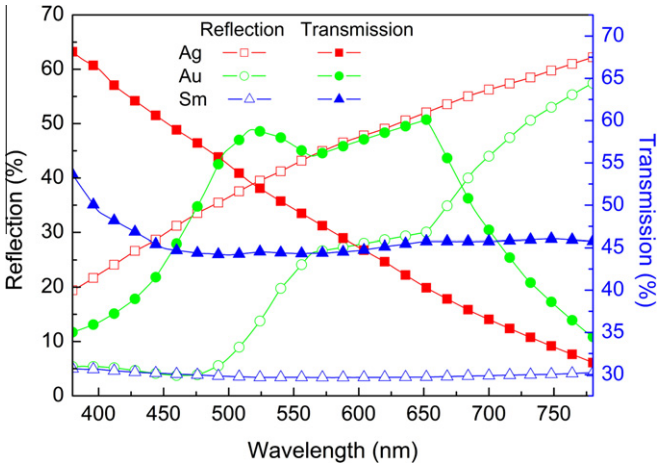

Fig. 4. Reflection and transmission of the cathode materials.

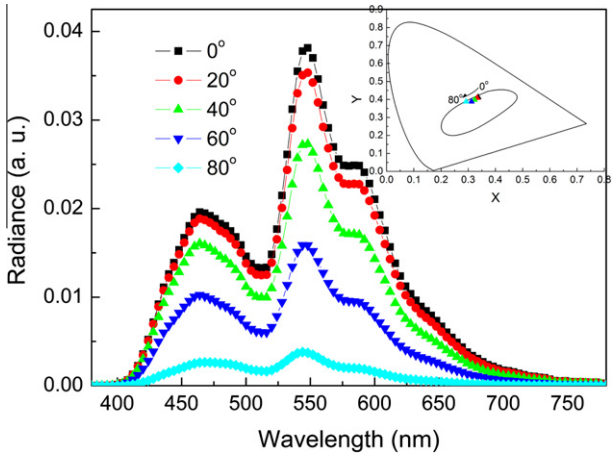

Fig. 5. The calculated EL spectra of the device with Ag anode and Sm cathode.

MgF_2 (~1.37), moderate-*n* material Alq_3 (~1.7–1.85) and high-*n* material MoO_x (~2–2.4) are used as the light outcoupling layers. As an example, the BY device using Ag as cathode and anode is presented. And the thickness of the light outcoupling layer has been optimized. Fig. 6 shows the calculated EL spectra of the BY devices with different light outcoupling layers. The introduction of the light outcoupling layers improved the angular color uniformity, but the improvement level is dependent on the reflective index of the layer. A low-*n* light outcoupling layer shows slight improvement in the angular color uniformity. The color shifted by (0.065, 0.086) for MgF_2 light outcoupling layer, by (0.03, 0.05) for Alq_3 light outcoupling layer, and only by (0.014, 0.018) for MoO_x light outcoupling layer

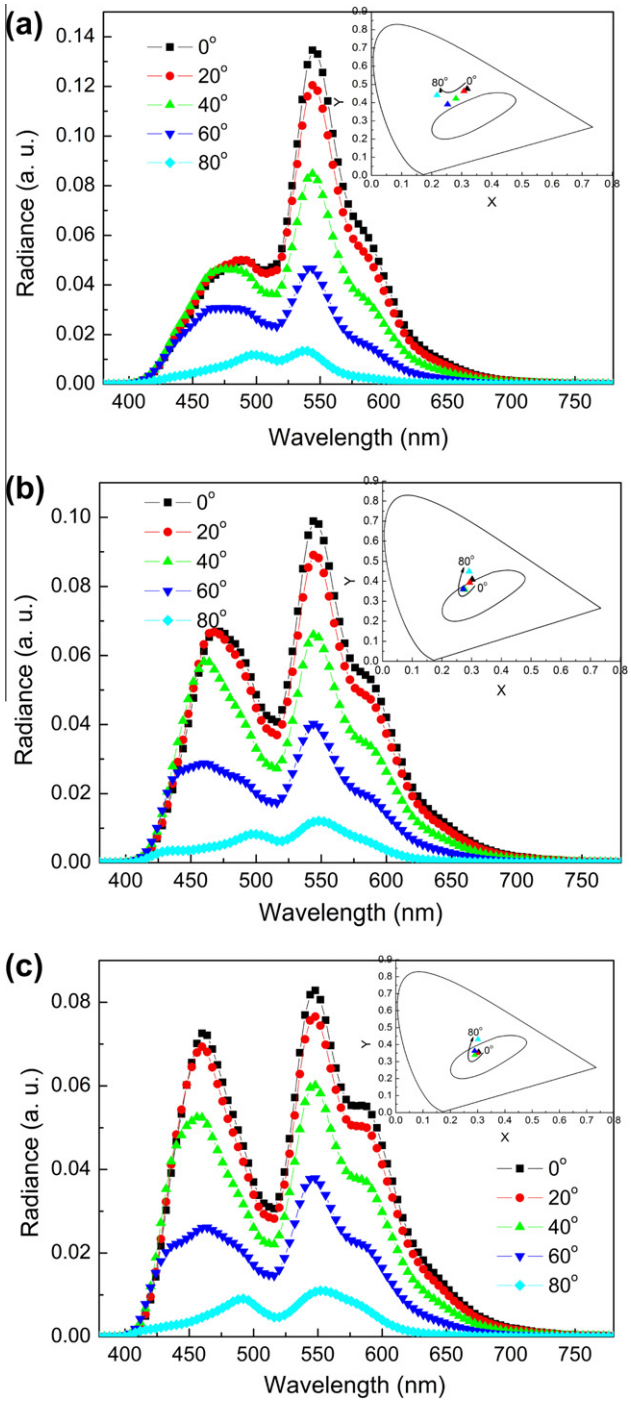

Fig. 6. Calculated EL spectra of the BY devices with (a) MgF_2, (b) Alq_3, and (c) MoO_x light outcoupling layer.

from 0° to 60°. It can be explained by the cavity emission of the devices as a function of the viewing angle as shown in Fig. 7. We can see that the higher the reflective index, the wider the cavity emission spectra are. The wide and flat cavity emission spectra indicated that the microcavity effect in the devices is similar at any wavelength, especially at the peak wavelengths of the device. Beside, the normalized cavity emission spectra of the high-n light outcoupling layer device are relatively angle independent at the viewing angle less than 60°. However, for devices without or with low-n light outcoupling layer, the cavity emission spectra are narrow and a blue shift in resonance wavelength λ_R of 52 nm and 20 nm can be observed. Hence, a high-n light outcoupling layer shows obvious

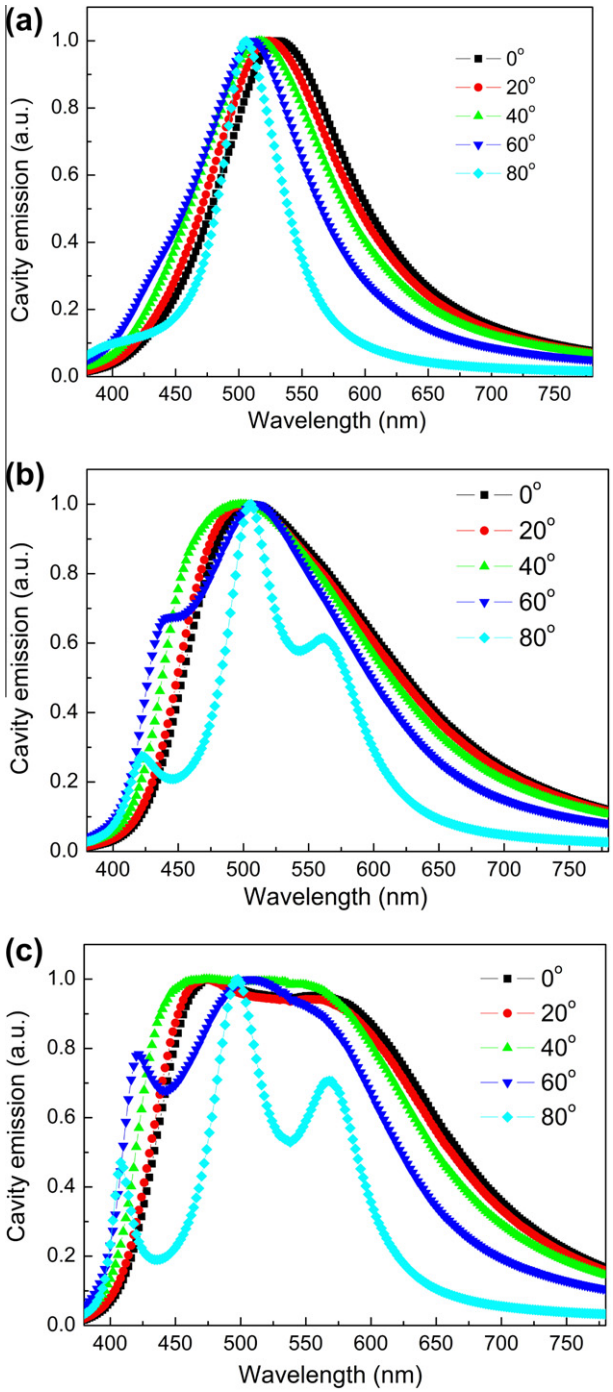

Fig. 7. Cavity emission of the devices as a function of the viewing angle with (a) MgF_2, (b) Alq_3, and (c) MoO_x light outcoupling layer.

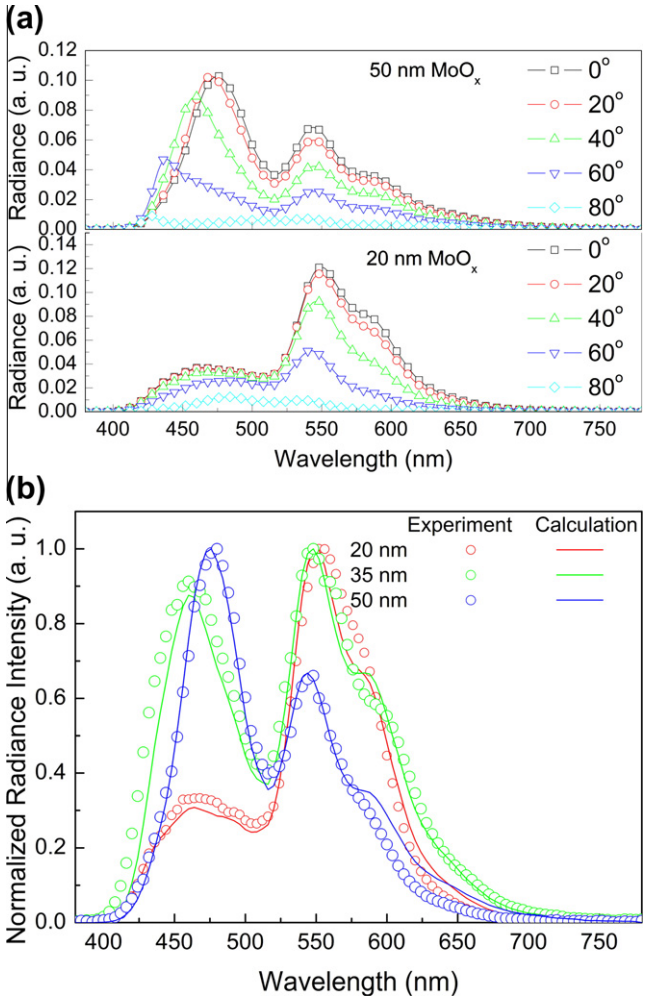

Fig. 8. (a) Calculated EL spectra of the devices with 20- or 50-nm MoO_x light outcoupling layer, and (b) calculated and experimental results of the normalized radiance intensity in forward direction of the TEWOLED.

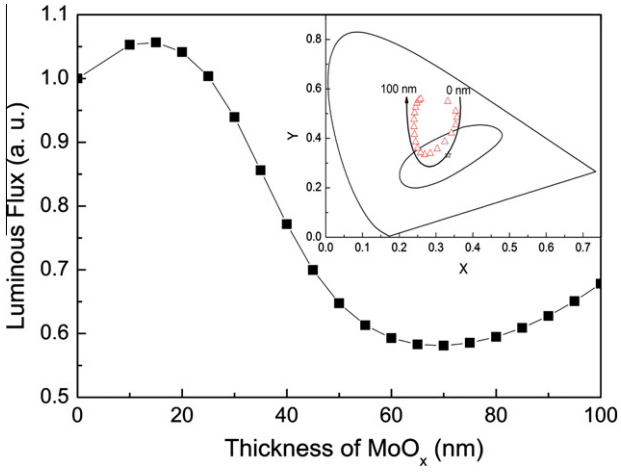

Fig. 9. Normalized luminous flux of the TEWOLED as a function of the thickness of MoO_x layer.

improvement in the angular color uniformity and the corresponding color coordinates of the device are stable with increasing viewing angle.

The thickness of the light outcoupling layer also plays an important role in the angular color uniformity. Fig. 8(a) shows the calculated EL spectra of the BY devices with 20- and 50-nm MoO_x light outcoupling layers at different viewing angle. The blue shift of blue emission in device with 50 nm MoO_x light outcoupling layer and blue shift of yellow emission in device with 20 nm MoO_x light outcoupling layer are observed with increasing viewing angles. The CIE coordinates shift by (0.06, 0.08) for 20-nm MoO_x light outcoupling layer and by (0.09, 0.03) for 50-nm MoO_x light outcoupling layer from 0° to 60°. It also can be explained by the cavity emission of the devices. The cavity emission spectra of the devices with 20 and 50 nm MoO_x light outcoupling layers are narrow. For a device with 20 nm MoO_x light outcoupling layers, λ_R is 564 nm in forward direction and with increasing viewing angle, a blue shift in λ_R of 34 nm from 0° to 60° is observed. In comparison, for a device with 50 nm MoO_x light outcoupling layers, λ_R is 484 nm in the forward direction and with an increasing viewing angle, a blue shift in λ_R of 48 nm from 0° to 60° is observed. Fig. 8(b) shows the calculated and experimental results of the normalized radiance intensity in the forward direction of the TEWOLED. We can see that the calculated results agree well with the experimental results.

The light outcoupling layer also plays an important role in the luminance of the TEWOLED. Fig. 9 shows the normalized luminous flux (obtained from luminous intensity by integration with respect to the solid angle θ in the forward hemisphere) of the TEWOLED as a function of the thickness of MoO_x layer. The luminous flux of the device is dependent on the thickness of the light outcoupling layer. Generally speaking, the light outcoupling layer will not affect the electrical characteristic of the device. Then, the change of luminous flux could respond to the changing of efficiency of the device. Although the efficiency of the device with a 15-nm-thick MoO_x is the highest, the emission of the device is not a white light emission. Thus, the optical optimization of the TEWOLED must depend on the synthetic consideration of angular color uniformity, CIE coordinates and efficiency (luminous flux).

3.1.3. Optimization of the TEWOLED for lighting

Based on the above analysis, the BY TEWOLED with a 35-nm MoO_x light outcoupling layer has stable angular color uniformity and relatively strong radiated power. However, a high CRI is important for a lighting device. The CRI of this device is 64. The CRI in the greyish red and reddish purple regions is not good because of the relatively low intensity of the red emission. If a red emission is enhanced in the device, the CRI of the device can be improved. Thus, we optimized the RGB TEWOLED using Ag anode and LiF/Al/Ag (15 nm) cathode considering the angular color uniformity and the radiated power. A 35-nm MoO_x was used as the light outcoupling layer. Fig. 10 shows the calculated EL spectra of the device. The device had relatively stable angular color uniformity and the CIE coordinates shifted by (0.027, 0.019) from 0° to 60°. The CRI and the correlated color temperature (CCT) in the forward direction of the device are 90 and 6750 K, respectively. And the CRI of this device is also less angular dependent. The CRI can reach 83 at a viewing angle of 60°. The results indicated that a color-stable and high-CRI TEWOLED could be obtained by carefully designing the structure, and such a device could be used as a white lighting device.

We passed emission of this device through the color filters whose transmission spectra are shown in Fig. 11 and we assume the transmission of the color filters is unchanged with the increasing of the incident angle. The CIE coordinates of the filtered R, G, B emission are (0.668, 0.327), (0.208, 0.637), and (0.131, 0.118) in the forward direction, which change to (0.659, 0.333), (0.201, 0.649), (0.133, 0.119) at 60°. The R, G, and B colors shifted by (0.009, −0.006), (0.007, −0.008), and (−0.002, −0.001) from 0° to 60° and the device gives a color gamut [relative to the NTSC (National Television Standards Committee) standard] of 82.9% at 0°, to 83.5% at 30° and to

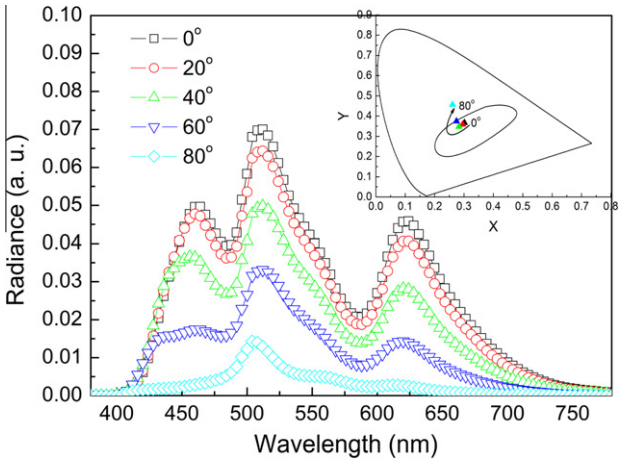

Fig. 10. Calculated EL spectra of RGB device with optimized structure.

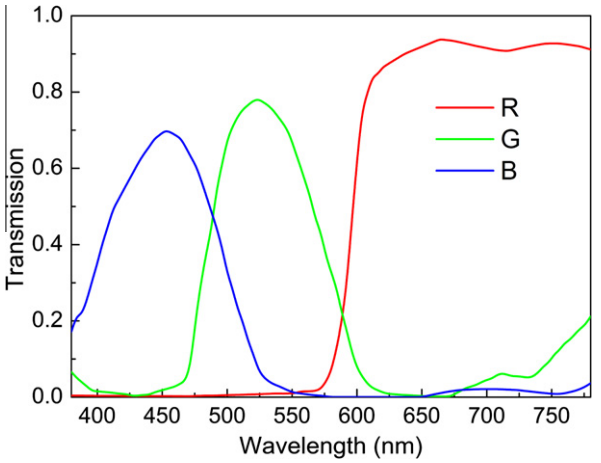

Fig. 11. Transmission spectra of the R, G, and B color filters. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

84% at 60°, which is same as 84% of the corresponding bottom device.

3.2. Microcavity TEWOLED Based on MDPC anode

We have reported the microcavity TEWOLED with MDPC anode in our previous work. In principle, a multiple-peak TEWOLED with EL peaks at desired wavelengths can be achieved by adjusting the thickness of the dielectric layer or the period of the MDPC. If we carefully design the structure of this device, the emission spectra of the device could well match the transmission spectra of RGB color filters to achieve a wide color gamut display.

3.2.1. Influence of dielectric layer thickness on the performance of TEWOLED

Firstly, the influence of the dielectric layer thickness on the performance of the TEWOLED is demonstrated. The LiF/Al (1 nm)/Ag (20 nm)/MoO_x (35 nm) was used as the cathode, and the MDPC has a structure of Ag (150 nm)/Alq_3 (x nm)/Ag(20 nm)/Alq_3 (y nm)/Ag (20 nm).

Fig. 12 shows the EL spectra of the TEWOLED with the MDPC anode (x = 50 nm and y change from 20 to 100 nm) in the forward direction. The spectra of the device are sensitive to the y. With the increasing of y, the red shift in cavity emission was observed. Besides, a new resonance peak appeared in the blue region and the resonance intensity increased with the increasing of y. Therefore, the EL spectra of the device are red shifted and present enhanced short-wavelength emission and suppressed long-wavelength emission. If y is increased further, no more resonance peak could be occurred except that we changed the value of x.

Fig. 13 shows the EL spectra of the TEWOLED with the MDPC anode (y = 80 nm and x change from 50 to 130 nm) in the forward direction. The spectra of the TEWOLEDs also reveal a dependence on x. With the increasing of x, the red shift in cavity emission was also observed. And when x > 90 nm, the cavity emission shows a three-peak resonance. Hence, the three-peak resonance TEWOLED was obtained.

In order to validate the accuracy of the simulation, the calculated results are compared to the experimental results. A two-peak TEWOLED with LiF/Al (1 nm)/Ag (20 nm)/MoO_x (35 nm) as the cathode and Ag (150 nm)/Alq_3 (75 nm)/Ag (20 nm)/Alq_3 (45 nm)/Ag (20 nm) as anode were performed. From Fig. 14, we can see that the calculated EL spectra and CIE coordinates agree very well with the experimental results. In the calculation, the layer thicknesses were adjusted on the order of a few percent, which is well within the experimental uncertainties.

3.2.2. Influence of metal in the MDPC on the performance of TEWOLED

A two-peak or three-peak TEWOLED could be obtained by simply adjusting the thickness of the dielectric layers in the MDPC based on the above simulation and our experiment. However, the emission is obvious angular dependence in the above device. It could be slightly improved

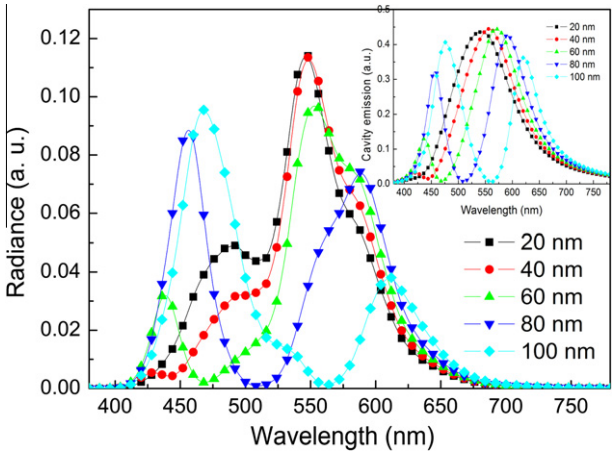

Fig. 12. The EL spectra of the TEWOLED with Ag (150 nm)/Alq_3 (50 nm)/Ag (20 nm)/Alq_3 (y nm)/Ag (20 nm) anode (y change from 20 to 100 nm, inset is the cavity emission of the devices).

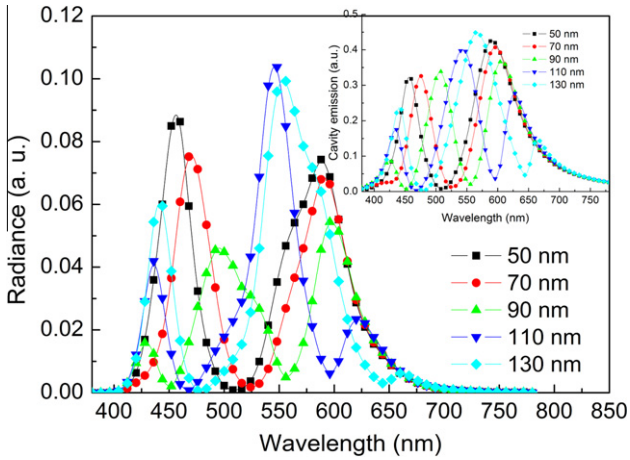

Fig. 13. The EL spectra of the TEWOLED with Ag (150 nm)/Alq_3 (x nm)/Ag(20 nm)/Alq_3 (80 nm)/Ag (20 nm) anode (x change from 50 to 130 nm, inset is the cavity emission of the devices).

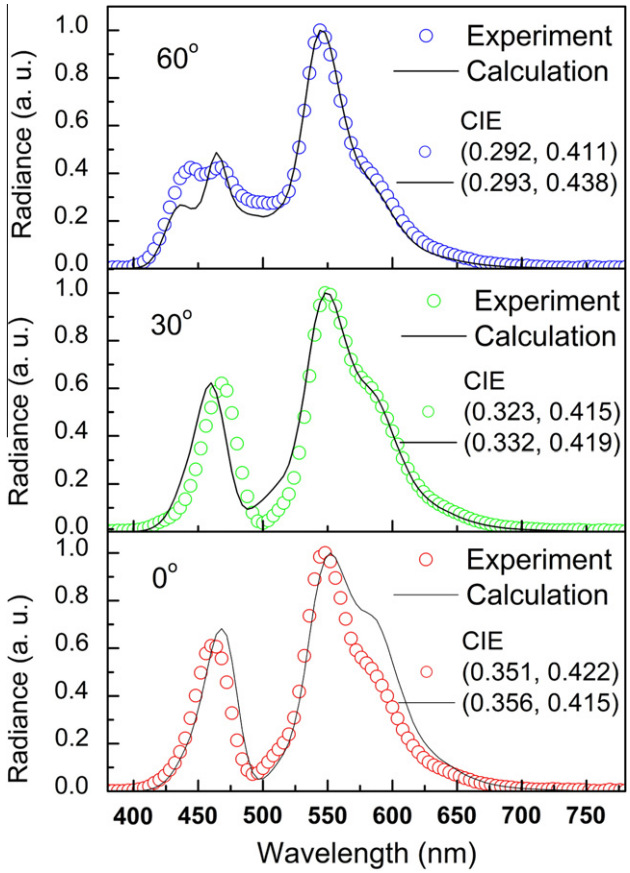

Fig. 14. Calculated and experimental EL spectra of the two-peak TEWOLEDs.

by optimized light outcoupling layer on the top of the cathode. The color shifted by $(0.035, -0.029)$ and $(-0.026, 0.042)$ from 0° to 60° for the two-peak and three-peak TEWOLEDs with the optimized light outcoupling layer.

The angular dependence characteristics of such devices could be improved by using a low reflective metal in the MDPC. For example, the device with Au (150 nm)/Alq_3 (75 nm)/Au (20 nm)/Alq_3 (65 nm)/Au (20 nm) anode and LiF/Al (1 nm)/Ag (20 nm)/MoO_x (55 nm) cathode shows

angular dependence in the EL spectra [Fig. 15(a)]. However, as we all know, two different light spectra that have the same effect on the three color receptors in the human eye will be perceived as the same color. Thus, the CIE coordinates of this device only shift by (±0.013, 0.013) from 0° to 80°. But, the CRI of device [Fig. 15(b)] depended on the viewing angle which is undesirable for lighting applications.

3.2.3. Optimization of the TEWOLED for display

Based on the above analysis, we can find that there is a strong microcavity effect in the TEWOLED based on MDPC anode. Although the CIE of the device can keep stable, the CRI and the CCT of the device are angular dependent which is undesirable for lighting applications. However, a wide color gamut display could be obtained by using TEWOLED based on MDPC anode.

Fig. 16 shows the EL spectra of the RGB device with Au (150 nm)/Alq_3 (100 nm)/Ag (20 nm)/Alq_3 (105 nm)/Ag (20 nm) anode and LiF/Al (1 nm)/Ag (20 nm)/MoO_x (65 nm) cathode. A narrow-three-peak TEWOLED was obtained. And we can see that the blue shifts were observed in the EL spectra of the device with the increasing of the viewing angle. However, the CIE coordinates of this device only shift by (−0.018, 0.009) from 0° to 30°. And the spectra of the TEWOLED well match the transmission spectra of RGB color filters as shown in Fig. 17. If we passed emission

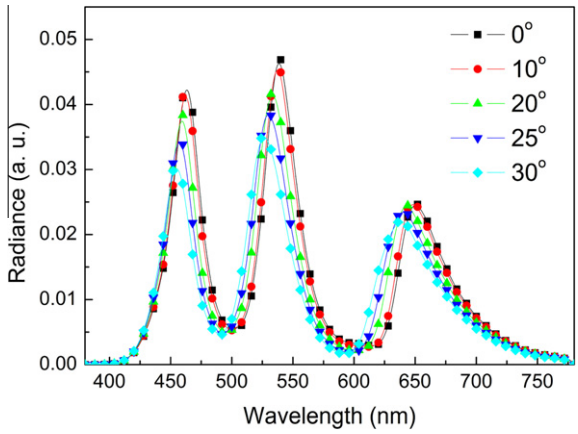

Fig. 16. EL spectra of the RGB device with a Au/Alq_3/Ag/Alq_3/Ag anode and LiF/Al (1 nm)/Ag (20 nm)/MoO_x (65 nm) cathode.

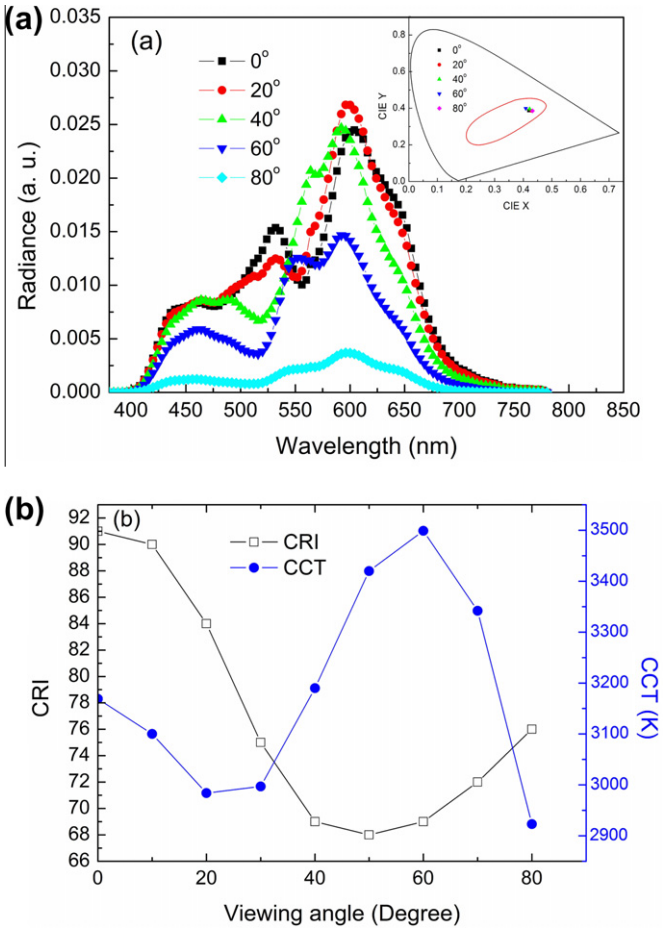

Fig. 15. (a) The angular characteristics, and (b) CRI and CCT of the TEWOLED with a Au/Alq_3/Au/Alq_3/Au anode and LiF/Al (1 nm)/Ag (20 nm)/MoO_x (55 nm) cathode.

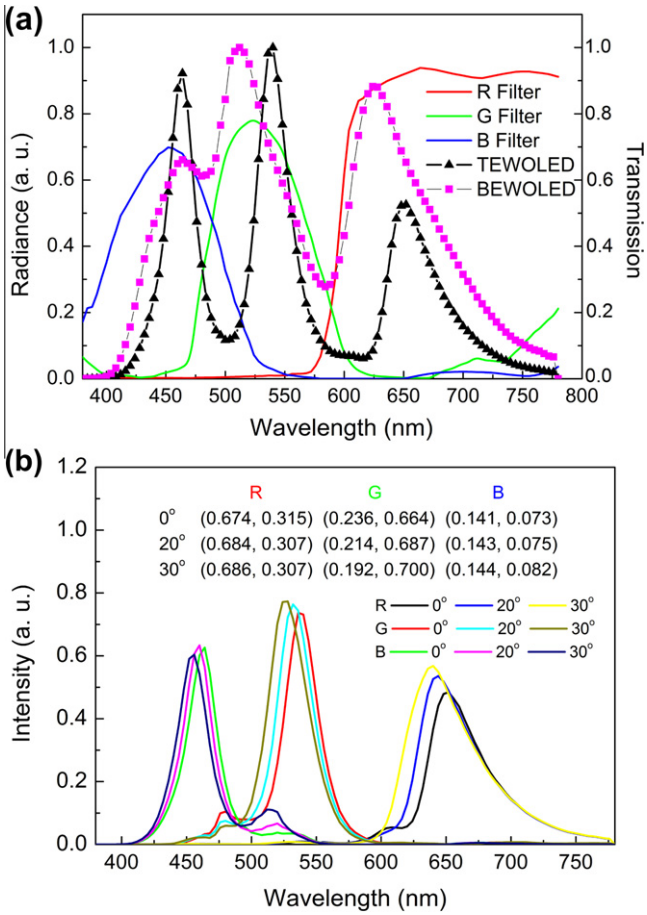

Fig. 17. (a) White OLED and color filter spectra, and (b) filtered R, G, and B spectra obtained by passing emission of TEWOLEDs through the RGB color filters. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

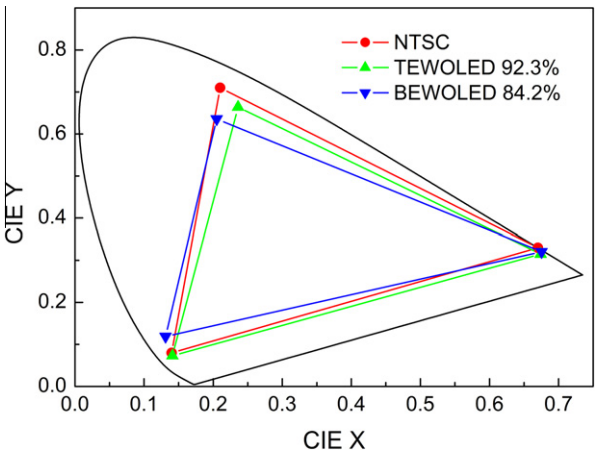

Fig. 18. CIE coordinates of filtered RGB colors for TEWOLED and BEWOLED in comparison with the NTSC standard.

of this device through the color filters, the CIE coordinates of the filtered R, G, B emissions are (0.674, 0.315), (0.236, 0.664), (0.141, 0.073) in the forward direction, which change to (0.684, 0.307), (0.214, 0.687), (0.143, 0.075) at 20° and (0.686, 0.307), (0.192, 0.700), (0.144, 0.082) at 30° [Fig. 17(b)]. The R, G, and B colors shifted by (−0.010, 0.008), (0.022, −0.023), and (−0.002, −0.002) from 0° to 20°. And the device gives a color gamut of 92.3% at 0° and to 99.4% at 20°. CIE coordinates of filtered RGB colors for TEWOLED and BEWOLED in the forward direction are shown in Fig. 18 for comparison. TEWOLED gives a greatly enhanced color gamut of 92.3% versus 84.2% of BEWOLED. The results indicated that the TEWOLED with an MDPC anode could be a selective light source for a near-to-eye display, such as headset microdisplay.

4. Conclusion

Optical properties of ITO-free top-emitting white organic light-emitting devices are simulated and optimized. The main conclusions supported by simulation are as follows.

- Metal–metal microcavity TEWOLED could be used as lighting with high CRI by a carefully designed structure of the devices. The angular characteristics of such devices can be improved by using low reflective electrodes or by introducing a light outcoupling layer with a high reflective index.

- Microcavity TEWOLED based on MDPC anode could realize a near-to-eye display with a wide color gamut. An over 90% NTSC color gamut and viewing angle of 20° could be obtained by a carefully designed structure of the device. And a white device with relative stable CIE coordinates also can be obtained by a carefully designed structure of the MDPC.
- Recent advances in conductive doping of organic semiconductors gave us more choices in electrodes and in structure of the device. The efficiency of the TEWOLED could be compared with that of the bottom one. For example, the top-emitting OLEDs reported by Xie et al. [11] and Freitag et al. [12] exhibit a performance superior to similar devices in the bottom-emission configuration.

2. Unit-area fringing capacitance at the "back" of the thin film

The TFT is a planar structure with semiconducting thin film for the transistor's channel, and conducting (metal) thin films for the drain and source contacts, as depicted in the bottom of Fig. 1. The films are stacked together with thin films for a gate insulator and a gate terminal conductor. There are several possible arrangements for the stack, but we will assume that the aspect ratio of film thicknesses to planar sizes is very small, and the semiconducting film and the metal electrodes are in the same plane, as shown at the top of Fig. 1. With this assumption, there are formulas for the fringing capacitance C_W per unit width of planar capacitors. We utilize these formulas to obtain the fringing capacitance C_B per unit area of channel, because the unit-area capacitances are significant quantities in the expressions for field-effect transistors. For example, one uses the gate insulator (oxide) capacitance per unit area, C_{ox}, to write the equation for the channel current $I_D = (W/L)\mu C_{ox}(V_G - V_T)^2/2$ in the saturation regime of an ideal field-effect transistor. The notations will be introduced later, along with the derivations.

It is shown in [3,4] by conformal mapping, that the capacitance C_W (per unit width) of a planar capacitor with infinite width (W), and a separation (s) between the neighbouring edges of the capacitor plates is given as ratio of the complete elliptic integrals of first kind $K(m)$

$$C_W = \varepsilon_0 \frac{K(m')}{K(m)},$$
$$\text{with } m = k^2 \text{ and } m' = 1 - m = 1 - k^2 = (k')^2, \tag{1}$$

where $\varepsilon_0 = 8.85 \times 10^{-14}$ F/cm is the permittivity of free space taken as an approximation for the actual permittivity of the air or other media in the "back" of the TFT semiconducting film. The complete elliptic integral of first kind $K(m)$ is

$$K(m) = \int_0^1 \frac{dt}{\sqrt{1-t^2}\sqrt{1-mt^2}}, \tag{2}$$

where (m) is called "parameter", $k = m^{1/2}$ is called "elliptic modulus", and the corresponding complementary quantities m', k' and $K'(m) = K(m')$ are in relations as indicated in Eq. (1).

The elliptic integrals do not have closed-form analytical solutions, but there are power series expansions for the complete elliptic integral of first kind, and numerical calculations are implemented in many computer programs such as MatLab, Mathematica or Maple. In addition, there is a very useful analytical approximation for the ratio $K(m')/K(m)$, given by [3]

$$\frac{C_W}{\varepsilon_0} = \frac{K(m')}{K(m)} \approx \begin{cases} \frac{1}{\pi}\ln\left(2\frac{1+(1-m)^{1/4}}{1-(1-m)^{1/4}}\right), \text{if } m \leqslant 1/2 \\ \pi/\ln\left(2\frac{1+m^{1/4}}{1-m^{1/4}}\right), \text{if } m \geqslant 1/2 \end{cases}, \tag{3}$$

which we have verified to be accurate at least for 5 significant digits, as compared with the numerical calculation using MatLab. As per the first derivative, the approximation is also reasonably accurate, with a small spurious glitch at $m = 1/2$, and except for the first and last 2–3 points when $0 \leftarrow m \rightarrow 1$, but this is easily avoidable by choosing sufficiently small step for m.

It is shown in [3,4] that Eq. (1) is general. It is based on conformal Christoffel–Schwarz transformation of a complex half-plane to a polygon, and is applicable for many geometries of capacitor plates and dielectric layers. The different geometries cause differences in the functions used in the conformal mapping toward parallel-plate capacitor, from which different expressions follow for the "parameter" m, or equivalently for the elliptic modulus k. As follows from Eq. (41) in [4], for the geometry shown at the top in Fig. 1, the "parameter" m is

$$m = \frac{(L + 2L_1)s}{(L + L_1)(s + L_1)}. \tag{4}$$

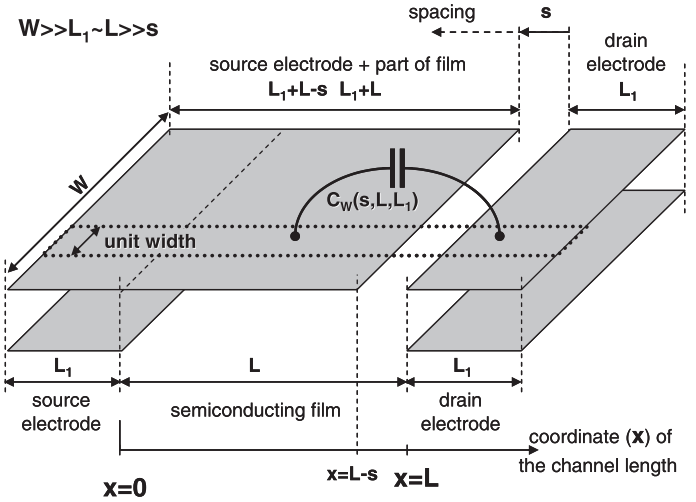

Fig. 1. TFT planar layout (in the bottom) and idealized zero-thickness geometry (on the top) with artificial separation (s) used to obtain fringing capacitance $C_W(s)$ per unit width between drain and semiconducting film. The derivative $C_{BD} = \partial C_W/\partial s$ will represent the geometrical fringing capacitance per unit area of the channel between the "back" of the semiconducting film and drain electrode at position $x = (L - s)$ along the channel axis (x).

Two details are worth mentioning. First, Eq. (1) is after half-plane conformal mapping, and therefore, it is for the fringing capacitance C_W only on one side of the planar capacitor, as depicted in Fig. 1. If the planar capacitor was with free-standing plates, then the actual capacitance would be $2C_W$. However, via the large gate capacitance at the "front" of the TFT semiconducting film, the conductive gate electrode screens the electric field on one side of the TFT film, so, the fringing capacitance between the semiconducting film and drain or source electrode is only in the "back" of the semiconducting film, and is given with C_W by Eq. (1) without the need to double it.

The second detail is that C_W is per unit width W of the TFT channel, as indicated in Fig. 1, whereas one desires an expression for fringing capacitance C_{BD} per unit area of the TFT channel in order to derive equations for the current in the TFT. The channel-drain unit-area fringing capacitance C_{BD} can be obtained as a derivative of C_W in respect with the coordinate (x) along the TFT channel length

$$C_{BD} = \frac{\partial C_W}{\partial x} = -\frac{\partial C_W}{\partial s} \approx \frac{\varepsilon_0}{\pi s} = \frac{\varepsilon_0}{\pi(L-x)} \tag{5}$$

Eq. (5) is a "1/distance" approximation. This equation is valid for a TFT with a wide and not very short channel. Also, the sizes of the drain and source film electrodes are assumed to be similar to the channel sizes, and the layers are sufficiently thin, that is, $W \gg L_1 \sim L \gg s > t_s \sim t_{ox}$, where t_{ox} is the thickness of the gate insulator and t_s is the thickness of semiconducting film. The analytical validation of Eq. (5) at these conditions is given in Appendix A.

The accuracy of the "1/distance" approximation for C_{BD} is illustrated in Fig. 2 for two cases: narrow drain electrode (L_1 = 3 μm) and normal length of the drain electrode (L_1 = 30 μm). One may observe some deviation from the "1/distance" approximation in the left-hand figure only when both of the following conditions are encountered: $L > 10L_1$ and $s > L_1$. These conditions are rarely occurring in practical devices, since one uses normally wide contact electrodes for drain and source with $L_1 \geqslant L$. Also, even if $L > 10L_1$, the loss of accuracy is for large distances $s > L_1$, at which the fringing capacitance is several orders of magnitude smaller as compared with the values corresponding to the proximity of electrode. Thus, the "1/distance" approximation of Eq. (5) for C_{BD} can be used to analyze the effects related to "back" of the semiconducting film.

3. "Extra" biasing through the fringing capacitance at the "back" of the film

Consider the cross-section of the TFT depicted in Fig. 3a on left and take the approximation from Eq. (5) for the fringing capacitance C_{BD} (per unit area of the channel) between the drain terminal and the "back" of the TFT film at position (x) along the channel length. The approximation is given by

$$C_{BD} \approx \frac{\varepsilon_0 \varepsilon_B}{\pi(L-x)}, \text{capacitance from film's "}back\text{" to drain,}$$
$$\text{with source} = 0 \leqslant x \leqslant L = \text{drain,} \tag{6}$$

where ε_B is the relative permittivity of the media at the "back" of the semiconducting film in the TFT, C_{BD} is biased by the drain bias voltage $V = V_D$, and the insulator "thickness" of C_{BD} is $\pi(L-x)$ and varies with the position (x) along the channel length. Similarly, the fringing capacitance C_{BS} (per the same unit area of the channel) between the source terminal and the "back" of the TFT film at position (x) along the channel length is

$$C_{BS} \approx \frac{\varepsilon_0 \varepsilon_B}{\pi x}, \text{capacitance from film's "}back\text{" to source,}$$
$$\text{with source} = 0 \leqslant x \leqslant L = \text{drain,} \tag{7}$$

the insulator "thickness" of C_{BS} is πx, and C_{BS} is shown in Fig. 3 in a gray color, since the source bias voltage is V_S = 0.

Consider the equivalent circuit of the TFT depicted in Fig. 3b. The mobile charge Q_s induced in the thin film provides the conduction (current) in the TFT. Normally, at gate bias V_G above the threshold voltage V_T of the TFT, Q_s is

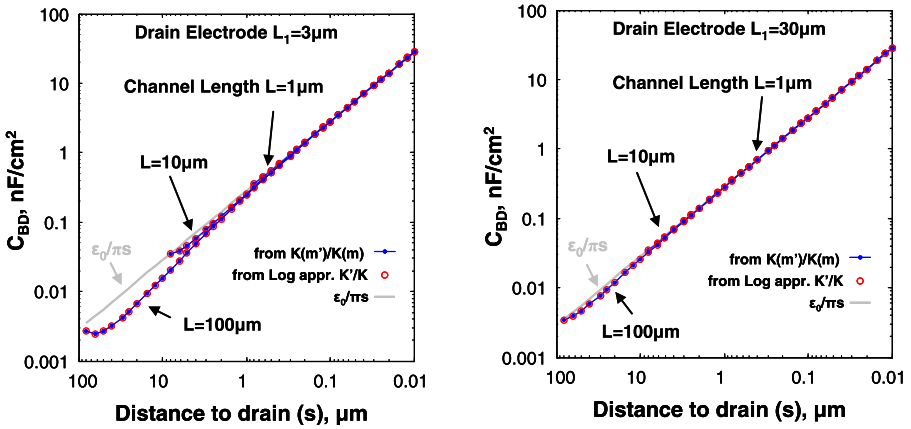

Fig. 2. Accuracy of the "1/distance" approximation (gray lines without symbols) of Eq. (5) for the unit-area fringing capacitance C_{BD} between the "back" of the thin film and drain electrode in TFTs of different channel lengths (L = 1, 10 and 100 μm) with narrow (left-hand figure, L_1 = 3 μm) and normal (right-hand figure, L_1 = 30 μm) drain electrodes. The thin lines with dots are when the ratio $K(m')/K(m)$ in Eq. (1) is obtained from numerically evaluated elliptic integrals, and the larger open circles are when $K(m')/K(m)$ is obtained from the analytical approximation of Eq. (3), showing very accurate approximation. The horizontal axes are reversed to correspond to other figures, in which the drain electrode is drawn on the right-hand side.

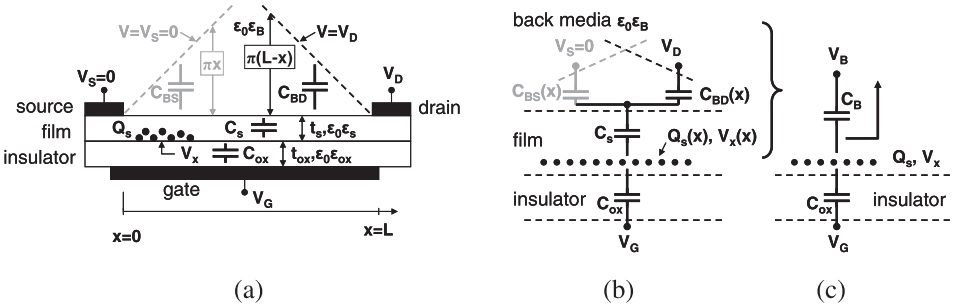

Fig. 3. Schematic representation of the TFT cross-section (a) and equivalent circuits (b) and (c) with capacitances, voltages and other notations.

induced mainly by the bias V_G through the gate insulator (oxide) capacitance C_{ox} and additionally by the drain bias voltage V_D via the capacitive divider C_{BD}–C_{BS}–C_s, where C_s is the unit-area capacitance of the thin film. The expressions for the unit-area oxide and semiconducting film capacitances are

$$C_{ox} \equiv C_I = \frac{\varepsilon_0 \varepsilon_{ox}}{t_{ox}}, \text{gate insulator capacitance at the "}\textit{front}\text{" of semiconducting film,} \quad (8)$$

$$C_s = \frac{\varepsilon_0 \varepsilon_s}{t_s}, \text{semiconducting film capacitance toward the "}\textit{back}\text{" of the film,} \quad (9)$$

with relative permittivity ε_{ox} and ε_s, respectively, usually $\varepsilon_{ox} \approx \varepsilon_s \sim 3$–4 for OTFTs, and corresponding thicknesses t_{ox} and t_s.

The charge due the gate bias voltage V_G is a linear function of the potential V_x (x) of the film along the channel coordinate (x), since C_{ox} is a constant in the TFT. In contrast, C_{BD} and C_{BS} depend reciprocally on the channel coordinate, and one needs to rationalize the capacitive divider C_{BD}–C_{BS}–C_s associated with the "back" of the semiconducting film, in order to obtain an expression for the "extra" bias through the fringing capacitances. An equivalent capacitance C_B and an equivalent voltage V_B that describe the "extra" bias, which the TFT encounters from the "back" of the semiconducting film, seen at point in Fig. 3c, can be obtained by means of Thevenin's theorem. Considering that $V_S = 0$, then only V_D contributes to the "extra" bias, and the expressions are

$$C_B = \frac{1}{\frac{1}{C_s} + \frac{1}{C_{BD}+C_{BS}}} = \frac{C_L}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)} > 0, \text{ film's "}\textit{back}\text{" capacitance per unit area,} \quad (10)$$

$$V_B = \frac{V_D C_{BD}}{C_{BD} + C_{BS}} = V_D \frac{x}{L}, \text{ equivalent bias voltage at the "}\textit{back}\text{" of the TFT,} \quad (11)$$

where C_L is the characteristic fringing capacitance (per unit area) of the TFT with channel length L, and for the planar arrangement discussed in the previous section, C_L is

$$C_L = \frac{\varepsilon_0 \varepsilon_B}{\pi L}. \quad (12)$$

Note that the channel coordinate ($0 \leqslant x \leqslant L$) is between zero and the channel length L, but this does not cause division by zero in Eq. (10), since $C_L/C_s \approx (\varepsilon_B/\varepsilon_s)(t_s/L)/\pi > 0$ is a positive and non-zero number, although it can be very small. Thus, a multiplication of equalities and non-equalities by the expression in the denominator of Eq. (10) is allowable in the following derivations.

4. "Extra" current due to the fringing capacitance at the "back" of the film in TFT

As shown in Fig. 3, the drain bias voltage V_D will cause an "extra" charge ΔQ_s and consequently an "extra" current ΔI_D in the TFT. This is in comparison to the ideal case when the charge Q_{so} and the corresponding current I_o are determined only by the gate bias voltage V_G, since the DC current I_D in the TFT is proportional to the induced charge $Q_s = Q_{so} + \Delta Q_s$ (per unit channel area). At a given position (x) along the TFT channel, the current is

$$\frac{I_D}{\mu W} = Q_s \frac{\partial V_x}{\partial x} = (Q_{so} + \Delta Q_s)\frac{\partial V_x}{\partial x} = \frac{I_o + \Delta I_D}{\mu W}, \quad (13)$$

where W is the width of the TFT channel, μ is the carrier mobility, and V_x is the potential in the semiconductor film ($0 = V_S \leqslant V_x(x) \leqslant V_D$). Here, the potential V_S of the TFT's source terminal is taken as a zero reference potential and the effective value of the gate bias dependent mobility μ is assumed approximately independent of the channel position, considering a much lower impact of V_D on μ. Note also that the electric field and electric potential have opposite polarities by the sign convention in principle, but we omit the minus sign since we give explicitly the direction of the current from the drain terminal to the source terminal, and we use the equation only to determine the magnitudes.

The general solution of Eq. (13) is not a trivial explicit analytical expression, because the potential V_x and the lateral electric field $\partial V_x/\partial x$ in the semiconducting film are not known *a priori*. Furthermore, Q_{so} and ΔQ_s are functions of V_x, and, ΔQ_s also depends on the position (x) along the channel length L, owing to the product of the position-dependent capacitance C_B, Eq. (10), and the equivalent voltage V_B, Eq. (11). Nevertheless, it is possible to obtain partial solutions of Eq. (13) for several distinct cases, namely, at gate bias V_G above the TFT threshold voltage V_T, and for off-state of the TFT when $V_G \ll V_T$. The two cases, respectively assume either dominant or negligible

contribution of the gate-induced charge Q_{so} in the total charge Q_s.

In this section, we address the case of the TFT operating at the above threshold condition, $V_G \gg V_T$. For this bias condition, the drain bias voltage V_D causes an "extra" current that is observable as an increase of the drain current in the saturation regime, when $V_D > (V_G - V_T)$. In the next section, we will discuss the other distinct case, $V_G \ll V_T$, which is usually termed as operation deep in sub-threshold regime, or off-state of the TFT. In this case, the high drain bias voltage independently induces the charge ΔQ_s in the semiconducting film via the fringing capacitance at the "back" of the semiconducting film in the TFT.

For the operation of the TFT at above-threshold conditions, the total induced charge Q_s is taken as $Q_s \approx Q_{so}$, assuming that the charge Q_{so} due to the gate bias voltage V_G is dominant and the charge ΔQ_s due to the fringing capacitance and drain bias is small. Therefore, the gate-induced charge is

$$Q_{so} = (V_G - V_T - V_x)C_{ox}, \tag{14}$$

and Q_{so} is proportional to the product of the gate insulator capacitance C_{ox} and the gate overdrive voltage $V_{GT} = (V_G - V_T)$ reduced with the potential V_x in the semiconducting film. In addition to Q_{so}, and with the condition that the potential in the film is weakly or not affected by V_D via C_B and V_B, that is $\Delta Q_s \ll Q_{so}$, then the drain bias will induce a charge

$$\Delta Q_s = V_B \times C_B = V_D \frac{x}{L} \times \frac{C_L}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)}. \tag{15}$$

The threshold voltage and gate bias voltage are not present in Eq. (15) for the additional minor charge ΔQ_s. This is because V_T is already overcome by V_G in the voltage term for the dominant charge Q_{so}, as given with Eq. (14). Also, the relatively large-magnitude of Q_s screens the film's "front" (gate) and "back" biases from each other. Since the gate-induced charge Q_{so} is dominant, then the pinch-off condition $(V_{GT} - V_{xo}) = 0$ for zero induced charge at $V_x > V_{xo}$ is determined from $Q_{so}(V_{xo}) = 0$. Thus, the two components I_o and ΔI_D in Eq. (13) for the DC current I_D are

$$\frac{I_o}{\mu W} = Q_{so}\frac{\partial V_x}{\partial x} = C_{ox}(V_G - V_T - V_x)\frac{\partial V_x}{\partial x}, \text{and} \tag{16}$$

$$\frac{\Delta I_D}{\mu W} = \Delta Q_s \frac{\partial V_x}{\partial x} = \frac{V_D C_L \frac{x}{L}}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)}\frac{\partial V_x}{\partial x} \leqslant \frac{V_D C_L}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)}\frac{\partial V_x}{\partial x} \tag{17}$$

with $0 = V_S \leqslant V_x \leqslant V_m = \min(V_D, V_G - V_T)$, where one has to take V_x spanning from the zero potential of the source terminal $V_S = 0$ to a maximum value V_m in the calculations of the induced unipolar charge Q_s, with V_m being the lesser of the drain bias voltage V_D and gate overdrive voltage $V_{GT} = (V_G - V_T)$. As noted after Eq. (12), the factor in the denominator of Eq. (17) is finite and positive, and therefore, one can multiply the equation by this factor to arrange it as

$$\frac{\Delta I_D}{\mu W}\left[\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)\right] = V_D C_L \frac{x}{L}\frac{\partial V_x}{\partial x} \leqslant V_D C_L \frac{\partial V_x}{\partial x}. \tag{18}$$

It can be shown that the area under $V_D V_L (x/L)\partial V_x/\partial x$ and $V_D V_L \partial V_x/\partial x$ disagree with a maximum error of 50% for the linear regime, for which $\partial V_x/\partial x \approx$ constant. However, the error is much lower for the saturation regime, since the magnitude $\partial V_x/\partial x$ of the lateral electric field is a peaking function at $x \to L$, so $x/L \to 1$. Thus, the approximation $x/L \approx 1$ in the numerators of Eqs. (17) and (18) capture the order of magnitude of the effects associated with the fringing capacitances at the "back" of the semiconducting film in the TFT with reasonable accuracy, when the TFT operates in the above-threshold regimes.

Performing the integrations in Appendix B, the current I_o driven by the gate bias V_G–C_{ox} in TFT is

$$\frac{I_o L}{\mu W} = C_{ox}\frac{(V_G - V_T)^2 - (V_G - V_T - V_m)^2}{2} = C_{ox} \times \begin{cases} (V_G - V_T - 0.5V_D)V_D, & \text{when } V_m = V_D \\ & \text{in the linear regime,} \\ 0.5(V_G - V_T)^2, & \text{when } V_m = (V_G - V_T) \\ & \text{in the saturation regime,} \end{cases} \tag{19}$$

as expected for an ideal TFT without effects from fringing capacitances. The "extra" current ΔI_D driven by the drain bias V_D through the fringing capacitances at the "back" of the semiconducting film in the TFT at gate bias above threshold, $V_G > V_T$, is

$$\frac{\Delta I_D L}{\mu W} \approx \frac{C_L V_D V_m}{\frac{1}{6} + \frac{C_L}{C_s}} \approx 6 C_L V_D V_m \approx 6\frac{\varepsilon_0 \varepsilon_B}{L} \times \begin{cases} V_D^2, & \text{in the linear regime,} \\ V_D(V_G - V_T), & \text{in the saturation regime,} \end{cases} \tag{20}$$

considering that the ratio $C_L/C_s \ll 1$, as mentioned earlier by Eq. (l2). Thus, combining Eqs. (19) and (20), the impact of the fringing capacitance at biasing of TFT above threshold $(V_G > V_T)$ can be summarised by the ratio $\delta = \Delta I_D/I_o$, as

$$\delta = \frac{\Delta I_D}{I_o}\bigg|_{V_G > V_T} \approx \frac{\frac{6 C_L V_D V_m}{1 + 6C_L/C_s}}{C_{ox}\frac{(V_G - V_T)^2 - (V_G - V_T - V_m)^2}{2}} \approx 12\frac{C_L}{C_{ox}} \times \begin{cases} \frac{V_D}{2(V_G - V_T) - V_D}, & \text{when } V_m = V_D \leqslant (V_G - V_T) \text{ in the linear regime,} \\ \frac{V_D}{V_G - V_T}, & \text{when } V_m = (V_G - V_T) \leqslant V_D \text{ in the saturation regime.} \end{cases} \tag{21}$$

Note that this result is approximate since we have used an inequality to derive it and have made assumptions for a dominant Q_{so}, so that the integration limits for V_x are set by $V_{xo} = (V_G - V_T)$, as stated after Eq. (15). Furthermore, for simplicity of the derived equations, we have not included the bias dependence of the mobility, which is a typical effect in amorphous and organic TFTs that can be included as explained in details in [6–8]. As estimated in Appendix B, the exclusion of the mobility enhancement factor is not critical, both for the behaviours and magnitudes related to C_L. We have also omitted other charge transport phenomena, such as contact effects [6,7,9,10] and space-charge limited conduction (SCLC) [5,11], which are not negligible in the TFTs, since the charge carrier mobility in

these transistors is low compared to the crystalline transistors. Nevertheless, we will demonstrate below that Eq. (21) captures the order of magnitude for effects that are usually attributed to the so-called channel length modulation by an empirical analogy with crystalline field-effect transistors.

4.1. Channel length modulation and fringing capacitance effects

One can make several qualitative observations from Eq. (21) for the dependences that are typical for the channel length modulation caused by an increased drain bias $V_D > V_{Dsat} \approx (V_G - V_T)$ in crystalline field-effect transistors, e.g., MOS transistors operating in the saturation regime [1]. The origin of the channel length modulation is the small depleted region ΔL near the drain of the MOS transistor with potential $V_x > V_{Dsat}$, which reduces the integration limit for the current from L to $(L-\Delta L)$ by the integration on the left-hand side of Eq. (16), c.f., Eq. (34) in Appendix B. Consequently, as detailed in Appendix C, the actual current I_{MOS} becomes larger than the saturation current I_{SAT} of the ideal MOS transistor, and as a first-order of approximation, the relative increase of the channel current due to channel modulation is

$$\delta_{MOS} = \frac{I_{MOS} - I_{SAT}}{I_{SAT}} \approx \frac{\Delta L}{L} \approx \lambda[V_D - (V_G - V_T)], \text{ when } V_D > (V_G - V_T) \quad (22)$$

implying that δ_{MOS} and λ are reciprocal functions of the channel length L. The channel length modulation parameter λ has a dimension $1/V$, its reciprocal value $1/\lambda = V_A \propto L$ is known as the Early voltage, and it does not vary much with the bias of the MOS transistor. Several other expressions can be found in [1], but the comparison of the above expression for δ_{MOS} with Eq. (21) for the corresponding δ in TFT clearly demonstrates the analogy that can be made for similar impacts from channel length modulation and fringing capacitances in TFTs. Namely, by Eqs. (21) and (22), the "extra" drain current ΔI_D in the TFT operating in the saturation regime at above-threshold gate biasing is proportional to the drain bias voltage V_D, and it is a reciprocal function of the channel length, since $C_L \propto L^{-1}$, as previously given in Eq. (12). The difference between the models is in the place for the expression of the gate overdrive voltage $V_{GT} = (V_G - V_T)$. V_{GT} is subtracted from V_D in the first-order equations for channel length modulation, whereas V_{GT} is in the denominator of the equation derived from fringing capacitance in TFT. Nevertheless, both models suggest reduction of the ratio $\delta = \Delta I/I$ when the gate bias increases. Perhaps is worth mentioning that the correspondence between channel length modulation parameter λ, the Early voltage V_A and the ratio C_L/C_{ox} of fringing to gate dielectric capacitances in the TFT is given generally by the following chain of relations

$$\lambda \sim \frac{1}{V_A} \sim 12\frac{C_L}{C_{ox}}\frac{1}{(V_G - V_T)} \approx \frac{12\varepsilon_0\varepsilon_B}{C_{ox}\pi L(V_G - V_T)}. \quad (23)$$

The terms in this chain are inversely proportional to the gate length L of field-effect transistors, but the values vary, since the models differ in physical origin and arrangement of equations, while the behaviour and the prediction of these models are similar.

4.2. Characterization of TFT by means of fringing capacitance at the "back" of the film

From the above discussion, the impact of channel length modulation and effects from fringing capacitance might be not distinguished qualitatively in practice. Instead, we propose a quantitative analysis of experimental data for TFTs based on the model in Eqs. (19) and (21). In this analysis, we consider ε_B as a fitting parameter. Its value will distinguish the fringing capacitance from other effects, such as channel length modulation or space charge limited conduction and contact effects. One expects $\varepsilon_B \sim 1$, if the fringing capacitance is in the origin of the "extra" current, and higher values for ε_B, when the other effects contribute to the "extra" current. The quantitative analysis uses the characterization procedure detailed in Appendix D. The procedure has two main steps. In the first step, we evaluate the ratio C_L/C_{ox} from the saturation I_D–V_D characteristic at given gate bias voltage $V_G > V_T$. In the second step, the mobility corresponding to the same V_G and from the same I_D–V_D characteristic is evaluated, assuming that the mobility variation is weak as function of the drain bias in the saturation regime, following the arguments given after Eq. (21) earlier. An intermediate averaging between the steps is helpful to remedy unavoidable scattering of data for C_L. Such averaging is usually possible, since one normally measures a family of I_D–V_D characteristic at several gate bias voltages.

To obtain the ratio C_L/C_{ox} in the first step, one uses data only for the saturation region in the output characteristics ($I_D = f(V_D > V_G - V_T)$ at constant V_G) of the TFT at a given gate bias voltage $V_G > V_T$. Thus, Eqs. (24) and (25) are only for the saturation regime of operation of the TFT. One data point in the saturation region is chosen as a reference current $I_{Dref} = I_D(V_{Dref} > V_G - V_T)$ at a reference drain bias voltage V_{Dref}. If the TFT is a normally-off field-effect transistor (the threshold voltage V_T has the same polarity as the gate V_G and drain V_D bias voltages), then a convenient choice for I_{Dref} and V_{Dref} is the biasing condition that corresponds to the diode connection of the TFT. In this case, the drain and gate bias voltages are equal, $V_{Dref} = V_G$, thus, I_{Dref} is easily measured during experiments, and therefore, we provide the expressions for the case of I_{Dref} chosen at the diode connection, $V_{Dref} = V_G > V_{GT} = (V_G - V_T)$. This case is denoted by "for normally-off TFT" in Eq. (24). One uses the larger general expression for normally-on TFTs, or if data for diode connection is not available.

Since I_D and I_{Dref} are measured in the saturation regime at predetermined bias voltages V_G, V_D, V_{Dref}, and also knowing the threshold voltage V_T of the TFT, then one experimentally characterizes the ratio C_L/C_{ox} from

$$\frac{C_L}{C_{ox}} = \frac{(V_G - V_T)\delta_{ref}}{12[V_D - V_{Dref}(1+\delta_{ref})]} = \frac{\varepsilon_0\varepsilon_B}{C_{ox}\pi L} = \frac{t_{ox}}{\varepsilon_{ox}}\frac{\varepsilon_B}{\pi L}, = \frac{(V_G - V_T)\delta_{ref}}{12[V_D - V_G(1+\delta_{ref})]} \text{ for normally-off TFT}, \quad (24)$$

where the supplementary relative difference between I_{Dref} and $I_D(V_D \neq V_{Dref})$ is $\delta_{ref} = (I_D - I_{Dref})/I_{Dref}$. Knowing the values of V_T, L and C_{ox}, one calculates the characteristic fringing capacitance C_L by using Eq. (24). The effective values for the relative permittivity ε_B of the media at the "back" of the film can also be obtained. It is expected that the calculated effective values for ε_B will be larger than the actual relative permittivity of the media in the "back" of the TFT. This is because Eq. (12) is for an ideal planar structure, while in the real TFT, there are edges, corners and other geometric features, e.g., encapsulation and protection layers. Also, the characterization technique attributes the "extra" current ΔI_D solely to the fringing capacitance, which is not the only transport phenomenon that contributes to ΔI_D. Therefore, one should be careful by the interpretation of the values, especially for ε_B. We have observed, in the application of this characterization procedure to experimental data, that there is some scattering in the values for the ratio C_L/C_{ox} and ε_B. This scattering is a result of the neglected space-charge limited conduction in amorphous films, contact effects and variation of mobility with bias, or other uncertainties in the information for layout sizes, V_T and C_{ox}. Therefore, one should implement data post-processing, such as averaging, and optimization of values by fitting to the measured data. It is recommended, in the post-processing step, to consider several gate bias conditions and to estimate a single value for C_L/C_{ox} or ε_B, before proceeding to the second step for characterization of the mobility.

The second step for evaluation the mobility uses the ratio C_L/C_{ox} obtained from the first step in the following equation

$$\mu(V_G, V_D) = \frac{2L}{WC_{ox}} \frac{I_o}{(V_G - V_T)^2}, \text{ at } V_D > (V_G - V_T), \\ = \frac{2L}{WC_{ox}(V_G - V_T)} \frac{I_D}{(V_G - V_T + V_D 12C_L/C_{ox})}. \quad (25)$$

The values for the ratio C_L/C_{ox} in this formula can be adopted point-by-point, as calculated by Eq. (24) for the various biasing voltages V_D and V_G in the saturation regime. However, the better choice is to use a single representative value, in order to avoid unnecessary scattering, and also, to obtain a value for a model parameter, e.g., the effective value for relative permittivity ε_B of the media at the "back" of the film. Despite these precautions, there is still scattering in the values for the effective mobility, as calculated from the formula. This scattering is for the same reasons described above for the values of the ratio C_L/C_{ox}. Nevertheless, one obtains data for the mobility, which can be used further for compact modeling of the mobility [8], and then modeling of the characteristics of the TFT with generic and more sophisticated compact models such as described in [6,7,12].

4.3. Verification with pentacene thin film transistors

By performing all the steps in the above characterization techniques, we present in Fig. 4 the results from the quantitative study of experimental data for organic TFTs against the hypothesis for impact from fringing capacitance. The black lines in the figure are the experimentally gathered data, as reported in the literature. The gray lines represent the "ideal" current I_o of the TFT, which is driven by the gate bias voltage V_G via the gate insulator capacitance C_{ox} and I_o is according to Eq. (19). Obviously, I_o saturates to constant values at $V_D > (V_G - V_T)$. We show only several curves for I_o in the figure, since the plots became too crowded when drawing all lines.

The symbols in Fig. 4 represent the recalculated total current $I_D = I_o + \Delta I_D = I_o(1 + \delta)$, where $\delta = \Delta I_D/I_o$ is according to Eq. (21), with $C_L = \varepsilon_0\varepsilon_B/\pi L$ given by Eq. (12). The drain current I_D is the sum of I_o and the "extra" current ΔI_D, the latter driven by the drain bias voltage V_D through the fringing capacitance. Since $\varepsilon_B \sim 1$ is expected for the fringing capacitance, then the value of ε_B becomes an indicator whether the deviation from the flat I_o–V_D characteristic in the saturation regime is consistent with the hypothesis for an impact from fringing at the "back" of the film in the TFT. Each sub-figure shows the data in linear and logarithmic plots to provide better perspective on problems encountered during the analysis. When problems were encountered, then the affected data points are shown in Fig. 4 with symbols in gray color. Thus, the black symbols in the figure are representing the results from the reliable fitting to the experimental data.

Fig. 4a shows the data reported in [13] for a TFT with pentacene semiconducting film and channel length $L = 10$ μm. The "extra" current ΔI_D is relatively small. Fig. 4b shows the data reported in the same publication for another pentacene TFT with a short channel of length $L = 1$ μm, but otherwise identical and simultaneously fabricated with the 10 μm long-channel TFT in Fig 4a. The saturation of I_D is weak in the 1 μm short-channel TFT, and the "extra" current ΔI_D becomes large in this TFT, as depicted with several arrows in Fig 4b. Importantly, the single value of $\varepsilon_B = 1.12$ used to fit the experimental data in Fig. 4a and b confirms the derived model for the impact of the fringing capacitance at the "back" of the semiconducting film in the TFT, because the value of ε_B is very close to the expected value of unity. This result builds a confidence that the fringing takes place in TFTs, and also verifies the characterization technique, although several data points in Fig. 4b do not match the experimental data, owing to the increased contribution of contact effects at low drain bias and higher currents [6,7,11].

4.4. Verification with rubrene single crystal organic transistors

The result from the second quantitative study for the impact of fringing capacitance in TFTs is shown in Fig. 4c for data reported in [14] for a rubrene single-crystal organic transistor. This transistor is fabricated by a very different approach, as compared to the typical fabrication approaches for TFTs. The semiconductor is a small freestanding faceted plate of rubrene with planar sizes 2–3 mm and thickness of about 0.5 mm. The rubrene plate is mechanically contacted by laminating to an elastomeric stamp with drain, source and gate embedded in the stamp. Rubrene has a relatively high mobility, effective value of about 3 cm^2/Vs in this transistor, and the transistor conducts

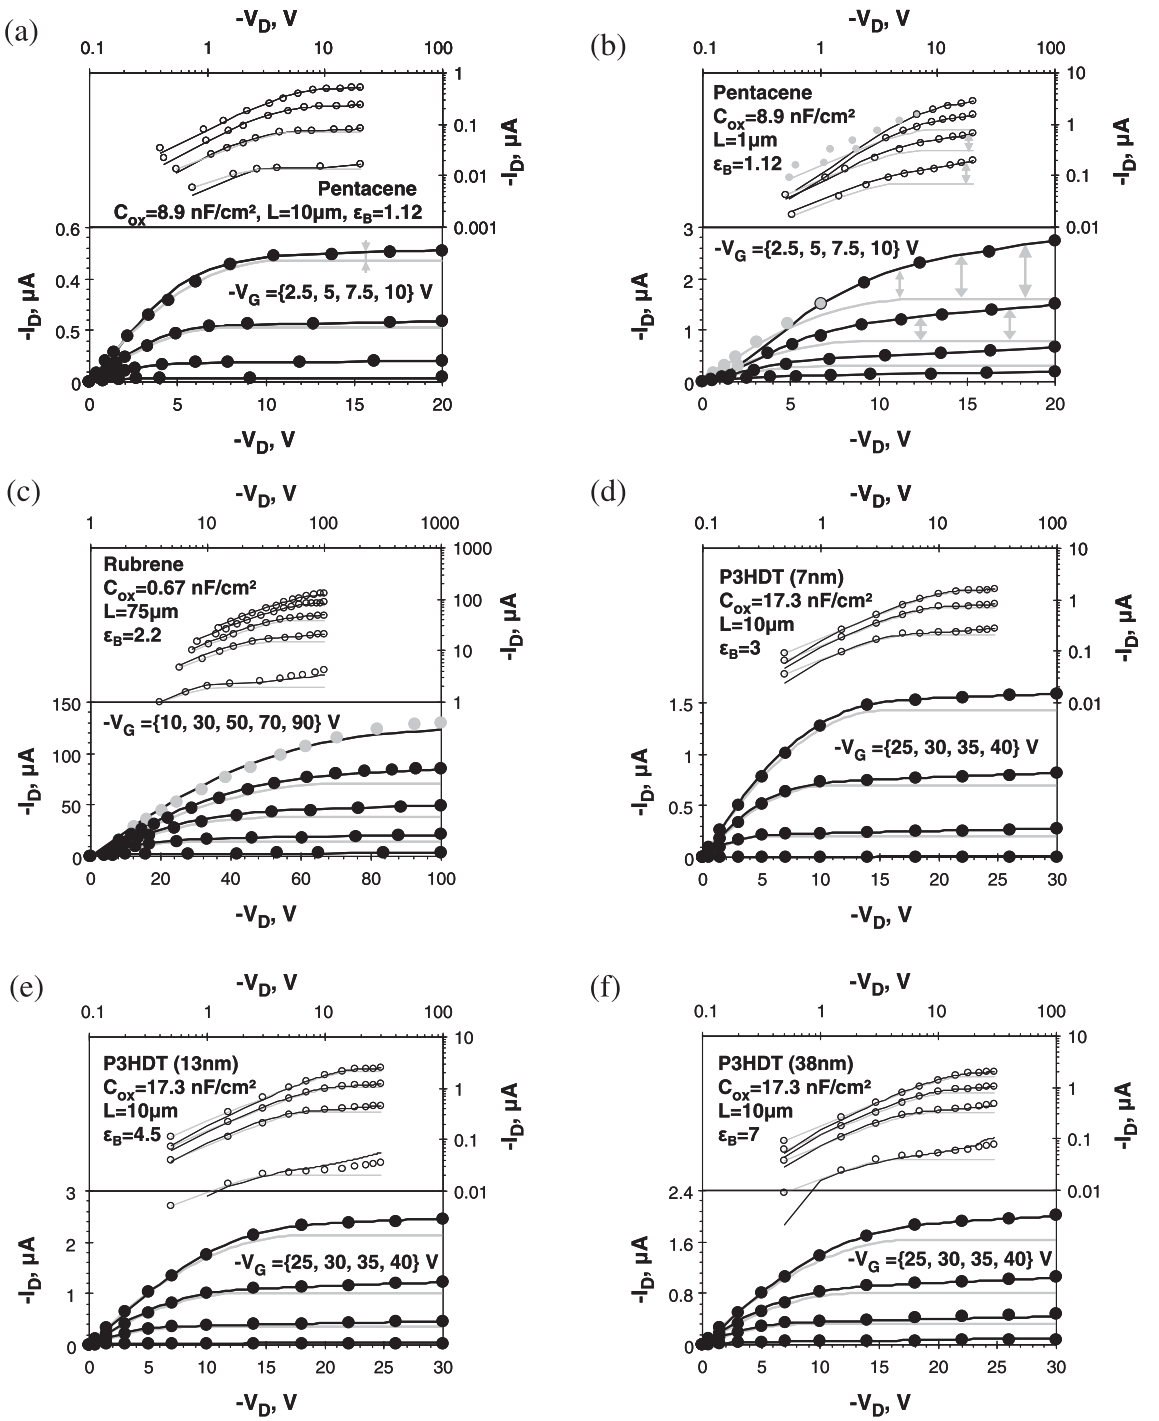

Fig. 4. Quantitative study of the "extra" current due to fringing capacitance in organic TFTs in terms of the effective relative permittivity ε_B of the media in the film's "back" (a) and (b) are pentacene TFTs with different channel lengths [13] (c) is a rubrene single-crystal TFT, mechanically contacted to elastomeric stamp with drain, source and gate embedded in the stamp [14] (d), (e) and (f) are poly(3-hexadecylthiophene), P3HDT, bottom-contact TFTs with different thicknesses of the semiconducting film [15]. Each data set is shown in linear and logarithmic plots. Black lines are measured data. Gray lines represent the ideal current I_o, driven by V_G. The symbols represent the sum of Io and the "extra" current ΔI_D driven by V_D. Gray symbols denote questionable fitting, owing to other effects in TFTs.

currents in the range of 0.1 mA at high gate and drain bias voltages, which caused problem to fit the data when neglecting the weak electrical contact between the stamp and the crystal, as indicated with the gray-color symbols in the figure. Nevertheless, at lower $V_G < 80$ V, the fitting was good and the symbols in Fig. 4c are obtained by

calculation with $\varepsilon_B = 2.2$. The value of ε_B is slightly higher than unity, and we attribute this to the arrangement of the transistor. The transistor is not exactly a thin-film transistor, because the thickness of the rubrene crystal is larger than the transistor's channel length, and the fringing fields in the "back" are actually inside the relatively thick plate of rubrene. Since rubrene has a relative permittivity in the range of 4, then one expects a value larger than unity for the effective relative permittivity ε_B of the planar fringing capacitance in this sample. Thus, $\varepsilon_B = 2.2$ is justified to be reasonable and the good fit to experimental data verifies the applicability of the derived equations for the "extra" current from fringing capacitance even for not-very thin-film transistors.

4.5. Verification with thin film transistors with varying semiconducting polymer thicknesses

Looking back at the derivations, we have made the assumption by Eq. (20) that the thickness t_s of the semiconducting film has a negligible effect in the TFTs, since the corresponding capacitance $C_s = \varepsilon_0\varepsilon_s/t_s \gg C_L$. In an attempt to evaluate the effect of the film thickness, we have analyzed the data reported in [15] for TFTs with different thicknesses t_s of the poly(3-hexadecylthiophene), P3HDT, semiconducting films. The results shown in Fig. 4d for $t_s = 7$ nm, in Fig. 4e for $t_s = 13$ nm and in Fig. 4f for $t_s = 38$ nm indicate a very good fit between the fringing capacitance model and the experimental data, both at low and high drain voltages and currents. This observation implies that the model is sustainable, and the place of the gate overdrive voltage (V_G–V_T) in a product with V_D in Eq. (20) and in a ratio in Eq. (21) is correct, although different from the format of the equations usually used to model the "extra" current in the saturation regime of operation of the TFT in terms of channel length modulation, compare again to Eq. (22).

For the data in Fig. 4d–f, the effective values of the relative permittivity ε_B gradually increase from 3 to 7, when increasing the film thickness from $t_s = 7$ nm to 38 nm. These TFTs have planar bottom-contact structure with comb-shaped drain and source electrodes (10 μm finger width) separated by the channel meander at distance $L = 10$ μm, the latter being the channel length of the TFT. One may expect some increase of ε_B, either owing to corners or cross-capacitance between fingers and meander, but the values $\varepsilon_B = 3$–7 for relative permittivity are too large to be realistic consequence from the TFT layout, since only the room atmosphere was on the top of the semiconducting film, and the room air has relative permittivity close to unity. Thus, while the derived model is suitable for compact modeling, one should be careful with the physical interpretation of the values of the model parameters, especially, with the value for ε_B. Values of ε_B above 2.5 indicate that the fringing effects, although existing, are only a portion of the many charge transport phenomena in the TFTs [10]. Indeed, the analyses of the experimental data in [15] were in terms of space charge limited conduction (SCLC); the analyses in this publication clearly distinguished SCLC in the leakage currents of these TFTs at low gate biasing and off-state.

In the next section, we examine the contribution of fringing capacitance at the condition of low gate bias, which is the other distinct case, when the charge ΔQ_s induced by the drain bias voltage V_D in the semiconducting film can dominate over the charge Q_{so} weakly induced by the gate bias voltage V_G, or generated by other means, e.g., thermally or optically.

5. "Extra" FET due to the fringing capacitance at the "back" of the film in TFT

Consider the cross-section of the TFT schematically depicted in Fig. 5 for the semi-insulating "off" state with some small amount of induced charges $Q_s = Q_{so} + \Delta Q_s$ (per unit channel area, as defined by Eq. (13) earlier). In this case, the gate bias voltage V_G is low, and the charge Q_{so}, induced by V_G, cannot be taken as the dominant charge in the semiconducting film. Apart from this detail, the cross-section in Fig. 5 is identical to Fig. 3. The detail, however, leads to several consequences. First, since Q_s is low, then the structure is semi-insulating. Second, the low Q_s cannot screen the "back" and the "front" interfaces of the semiconducting film each from other, and Gauss' law has to be applied from the top to the bottom of the structure, as depicted in the equivalent circuit in Fig. 5. Third, the induced charges Q_{so} and ΔQ_s are separated, while they are induced in the same manner in the capacitive divider C_{ox}–C_B by the "front" bias voltage V_G and "back" bias voltage V_B, with the later given by Eq. (11). The expressions for

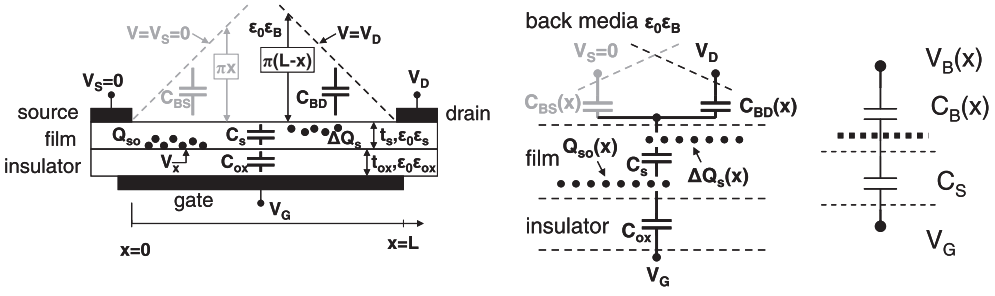

Fig. 5. Schematic representation of the cross-section and equivalent circuit of the TFT in semi-insulating state.

C_{ox} and C_B are the same as in Eqs. (8) and (10), respectively, and C_B includes C_{BD}, C_{BS} and C_s shown in the equivalent circuit of Fig. 5.

So, without the screening due to Q_s, one can place the threshold voltage V_T in series with the capacitive divider for the calculation of the induced charge Q_s, or equivalently, V_T can be added to the potential V_x in the semiconducting film. Consequently, from Gauss' law in the C_{ox}–C_B divider, one gets

$$\frac{V_G C_{ox} + V_B C_B}{C_{ox} + C_B} - V_x - V_T = V_{EODR} = \frac{Q_s}{C_{ox} + C_B}. \quad (26)$$

The left-hand side of this equation is an equivalent overdrive voltage V_{EODR}, caused by the simultaneously applied "front" V_G and "back" V_B bias voltages. Substituting the "back" bias voltage V_B with the expression given by Eq. (11), and after multiplication with the non-zero quantity $(C_{ox} + C_B)$, one easily obtains that

$$Q_s = C_{ox}(V_G - V_T - V_x) + C_B(V_D - V_T - V_x). \quad (27)$$

This result indicates the superposition of the "front" and "back" biases due to V_G and V_D, respectively. Similar to Eqs. (14) and (15), Q_s can be separated into two parts:

$$Q_{so} = (V_G - V_T - V_x)C_{ox}, \text{ for } V_x \leqslant (V_G - V_T), \text{ and } Q_{so} = 0 \text{ otherwise; and} \quad (28)$$

$$\Delta Q_s = (V_D - V_T - V_x)C_B, \text{ for } V_x \leqslant (V_D - V_T), \text{ and } \Delta Q_s = 0 \text{ otherwise}, \quad (29)$$

which indicate independence of the gate and drain bias voltages biases, as expected for the semi-insulating case of the TFT, and different integration limits when considering that Q_{so} and ΔQ_s are unipolar charges.

Since Eq. (28) is identical to Eq. (14), including the limits for V_x, then the current I_o driven by V_G is given by Eq. (19). In contrast, the expression for the "extra" current ΔI_L driven by V_D will be different from Eq. (20), because the expressions in Eqs. (15) and (29) are different, along with the different integration limits. Consequently, one performs the integrations of Eq. (29), as shown in Appendix E, and obtains the "extra" current ΔI_L driven by V_D in the semi-insulating "off" state of the TFT as

$$\frac{\Delta I_L L}{\mu W} \approx \frac{C_L}{\frac{1}{6}+\frac{C_L}{C_s}} \frac{[\max(0, V_D - V_T)]^2 - [\max(0, -V_T)]^2}{2} \approx 6\frac{\varepsilon_0 \varepsilon_B}{\pi L} \times \begin{cases} 0, \text{ if } V_D < V_T, \text{ possible only for normally-off TFT} \\ \frac{(V_D - V_T)^2}{2}, \text{ if } V_D \geqslant V_T \text{ for normally-off TFT} \\ \frac{(V_D - V_T)^2 - V_T^2}{2} = \frac{V_D(V_D - 2V_T)}{2}, \text{ if } V_T < 0 \text{ for normally-on TFT} \end{cases} \quad (30)$$

Observe that the gate bias voltage V_G does not participate in the expressions for ΔI_L, thus, ΔI_L is a leakage-like current in the off-state of the TFT, driven only by V_D. Therefore, the "extra" current ΔI_L driven by V_D in the semi-insulating "off" state of the TFT can be viewed as a current from an "extra" transistor in parallel to the main transistor with the ideal current I_o, the latter driven by the gate bias voltage V_G. A close examination of Eq. (30) indicates that V_D substitutes V_G in the expressions for ΔI_L, that is a virtual $V_G = V_D$, and corresponds to a diode connection of the "extra" FET with a virtual "back"-gate capacitance $6C_L = 6\varepsilon_0\varepsilon_B/\pi L$. This "extra" FET is shown with gray color in Fig. 6, because it affects normally only the leakage of the TFT (see the log–log plots at the lowest V_G in Fig. 4e and Fig. 4f), which is not of significant concern for a good quality TFT. While the "back"-gate capacitance of the "extra" FET is different, the remaining parameters, e.g., channel sizes W and L, threshold voltage V_T, mobility μ, etc., are identical to the corresponding parameters of the main gate-controlled FET, driven by V_G via C_{ox}. Note that if the TFT is a normally-off device (V_T and V_D are of the same polarity), then the "extra" FET operates in the saturation regime. On the other hand, it operates in the linear regime, if the TFT is normally-on device (V_T and V_D are of different polarities). The current source in Fig. 6 corresponds to the "extra" current ΔI_D given by Eq. (20), and its significance was discussed in the previous section. The multiplying term $\mu W/L$ for ΔI_D is omitted in the figure for clarity, and to observe that the effects of fringing capacitance at the "back" of the TFT film result in a capacitance $6C_L$ for both "extra" currents ΔI_L and ΔI_D.

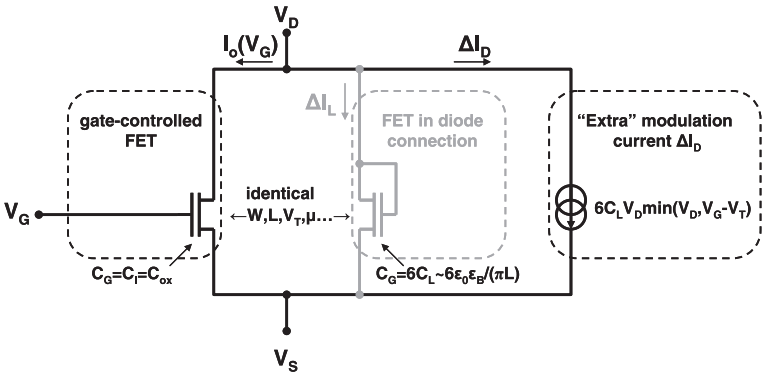

Fig. 6. Equivalent circuit suitable for TFT compact modeling with the impact of the fringing film-"back" capacitance included as "gate" capacitance C_L in an "extra" FET in diode connection (in gray color) according to Eq. (30), and the "extra" current ΔI_D, the latter according to Eq. (20) with $\mu W/L$ omitted in the figure for clarity. Normally, $C_L \ll C_{ox}$.

6. Discussions

The analysis of results from the conformal mapping of the TFT planar structure implies that the unit-area capacitances at the "back" of the semiconducting film have reciprocal dependences on the distances between the electrodes and the position along the channel (see Eqs. (5)–(7)). Consequently, the drain terminal bias voltage is forwarded to the channel by the "back"-film fringing capacitance with a characteristic value C_L, as given by Eq. (12). Therefore, the TFT is additionally driven by the drain bias voltage V_D, causing "extra" currents ΔI_D (Eq. (20)), and ΔI_L (Eq. (30)), in addition to the "ideal" current I_o (Eq. (19)), driven by the gate bias voltage V_G.

The "extra" current ΔI_D corresponds to the case of high gate bias voltage $V_G \gg V_T$, when the gate bias induces large areal density of charge carriers Q_s. The effect of ΔI_D is similar in behaviour to channel length modulation in field-effect transistors operating in the saturation regime. We provide a characterization technique that evaluates the characteristic value C_L of the "back"-film fringing capacitance from this regime and, consequently, the effective value of the relative permittivity ε_B of the media in the "back" of the TFT film. One should be careful in the interpretation of the values for ε_B, since $\varepsilon_B \sim 1\ldots2$ are reasonable, considering the assumptions by the derivation of the relations, while values $\varepsilon_B > 2$ indicate that the fringing capacitance is contributing, but might be not the dominant cause for modulation of the output I_D–V_D characteristics in the saturation regime of the operation of the TFT. Nevertheless, the derived Eq. (21) provides the format in which the modulation can be implemented in compact models for TFT, having also the correspondence to other empirical models for channel length modulation, as indicated by Eq. (23).

The "extra" current ΔI_L corresponds to the case of low gate bias voltage $V_G \sim V_T$, when the areal density Q_s of charge carriers is negligible, and ΔI_L depends only on the drain bias voltage V_D. The dependence is equivalent to consider an "extra" TFT in a diode connection with a "back"-gate capacitance $6C_L$, instead of C_{ox}, but otherwise identical and in parallel to the main TFT. Consequently, ΔI_L has a quadratic dependence on the ratio V_D/L, which is qualitatively similar to a leakage from space-charge limited conduction (SCLC) in the semiconducting film of the TFT, since SCLC current in thin films is given by [5]

$$\frac{I_{SCLC}L}{\mu W} = 2\frac{\varepsilon_0\varepsilon_s}{\pi L}V_D^2. \tag{31}$$

A simple comparison between Eqs. (30) and (31) implies that SCLC uses the doubled permittivity of the semiconducting film, $2\varepsilon_s$, whereas ΔI_L uses the tripled permittivity of the media in the "back" of the film, $3\varepsilon_B$. Since $\varepsilon_B \sim 1$ and $\varepsilon_s \sim 3$ for organic materials, then I_{SCLC} and ΔI_L have very similar magnitudes; and the two effects might be difficult to distinguish even quantitatively in the leakage current of the organic TFT.

Several other observations can be made in the results from the above derivations. The "extra" currents ΔI_D and ΔI_L caused by the drain bias via the film-"back" fringing capacitance are reciprocal functions of the channel length $\Delta I_D \propto L^{-2}$, Eq. (20), and $\Delta I_L \propto L^{-2}$, Eq. (30), which is normally observed as inverse proportionality $\Delta L/L \propto 1/L$ for the channel length modulation $\Delta L/L$, see Eqs. (22) and (23). Second, $\Delta L/L$ is proportional to the ratio t_{ox}/L of the gate insulator thickness t_{ox} and channel length L. Third, the "leakage" ΔI_L is a quadratic function of the drain bias voltage V_D in short-channel organic transistors [15,16], whereas the modulating current ΔI_D is a nearly linear function of V_D, when the TFT is operating at high gate and drain biases in the saturation regime.

7. Conclusions

The analysis of the fringing capacitance at the "back" surface of the film of TFT indicates that this capacitance contributes to the enhancement of the channel current, which at present is usually attributed to channel length modulation in the TFT operating in the saturation regime at high drain bias voltages V_D, and space-charge limited conduction in the leakage current of the TFT at low gate bias. A method to derive the capacitance models and simple analytical expressions are provided for the impact of the fringing capacitance at the "back" of the film of the TFT. These expressions are in agreement with dependences routinely observed in experiments, which, however, implies that the impact from the fringing capacitance behaviourally is very similar to effects due to channel length modulation and leakage effects, and these effects can be distinguished only quantitatively. It should be mentioned that the simple expressions presented here may need to be refined, since they are derived from non-equalities and with approximations. Therefore, they can be considered as a step towards a more elaborate study of the effects related to fringing capacitances in TFTs. From a detailed literature search up to 2010, we did not find any publication describing the effects related to the fringing capacitance at the "back" of the semiconducting film, to perform a comparison. Therefore, we state that the effects described in this work are possible, and that they need to be verified in detail with specific experiments.

Appendix A

Eq. (5) can be validated by considering $L \approx L_1 \gg s$ in Eq. (4) and substituting the small values of the "parameter" $m \sim 1.5\ s/L_1 \ll 1/2$ in the upper line of Eq. (3). The substitutions yield

$$\frac{C_W}{\varepsilon_0} = \frac{K(m')}{K(m)} \approx \frac{1}{\pi}\ln\left(2\frac{1+(1-m)^{1/4}}{1-(1-m)^{1/4}}\right) \approx \frac{1}{\pi}\ln\left(2\frac{1+1-m/4}{1-1+m/4}\right) \approx \frac{1}{\pi}\ln\left(\frac{16}{m}\right) \approx \frac{\ln(10L_1)-\ln(s)}{\pi}, \tag{32}$$

taking also a binomial expansion $(1-m)^{1/4} \approx 1 - m/4$ for $m \ll 1$. Consequently, the derivative is

$$\frac{\partial C_W/\partial s}{\varepsilon_0} = \frac{\partial}{\partial s}\left[\frac{K(m')}{K(m)}\right] \approx \frac{\partial}{\partial s}\left[\frac{\ln(10L_1) - \ln(s)}{\pi}\right] = -\frac{1}{\pi}\frac{\partial \ln(s)}{\partial s} = -\frac{1}{\pi s}, \quad (33)$$

from which the "1/distance" approximate result in Eq. (5) follows.

Appendix B

Rewriting Eqs. (16) and (18) in integral form with separated variables, we get

$$\int_0^L \frac{I_o}{\mu W} dx = \int_{V_s=0}^{\min(V_D,V_{GT})} C_{ox}(V_G - V_T - V_x) dV_x, \text{ and} \quad (34)$$

$$\int_0^L \frac{\Delta I_D}{\mu W}\left[\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)\right] dx \leqslant \int_{V_{S=0}}^{\min(V_D,V_{GT})} V_D C_L dV_x. \quad (35)$$

These integrals are easily solved, taking into account that the currents I_o and ΔI_D have unchanged magnitudes along the channel length coordinate (x). The remaining parameters are constants set either by the materials and the layout of the TFT, or by the biasing conditions. The integrations in Eqs. (34) and (35) yield the results given in Eqs. (19) and (20).

Including the bias enhancement of the mobility, $\mu = \mu_o(V_G - V_T - V_x)^\gamma$, where μ_o is constant mobility prefactor at gate overdrive $(V_G - V_T) = 1$ V and γ is mobility enhancement factor, Eqs. (34) and (35) are rewritten as

$$\int_0^L \frac{I_o}{\mu_{oW}} dx = \int_{V_s=0}^{\min(V_D,V_{GT})} C_{ox}(V_G - V_T - V_x)^{1+\gamma} dV_x, \text{ and} \quad (36)$$

$$\int_0^L \frac{\Delta I_D}{\mu_{oW}}\left[\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)\right] dx \leqslant \int_{V_{S=0}}^{\min(V_D,V_{GT})} V_D C_L (V_G - V_T - V_x)^\gamma dV_x. \quad (37)$$

The integration of Eq. (36) yields the TFT generic DC model [6]

$$\frac{I_o L}{\mu_o W} = C_{ox}\frac{(V_G - V_T)^{2+\gamma} - [\max(0, V_G - V_T - V_D)]^{2+\gamma}}{2+\gamma} \approx C_{ox} \times \begin{cases} (V_G - V_T))^{1+\gamma} V_D (1 - \text{err}_o), \text{ when} \\ \quad V_D \ll (V_G - V_T) \text{in the linear regime,} \\ \frac{(V_G - V_T))^{2+\gamma}}{2+\gamma}, \text{ when } (V_G - V_T) \leqslant V_D \\ \quad \text{in the saturation regime} \end{cases} \quad (38)$$

The error term for the linear regime is in the order of $\text{err}_o = O[1/2(1+\gamma)(V_D/V_{GT})^2]$, where $V_{GT} = (V_G - V_T)$ is the gate overdrive.

The integration of Eq. (37) yields the "extra" current due to fringing capacitance

$$\frac{\Delta I_D L}{\mu_o W} \leqslant \frac{C_L V_D}{\frac{1}{6} + \frac{C_L}{C_s}} \frac{(V_G - V_T)^{1+\gamma} - [\max(0, (V_G - V_T - V_D))]^{1+\gamma}}{1+\gamma} \approx 6\frac{\varepsilon_0 \varepsilon_B}{\pi L} \times \begin{cases} V_D^2 (V_G - V_T)^\gamma (1 - err_\Delta), \text{ when} \\ \quad V_D \ll (V_G - V_T) \text{ in the linear regime,} \\ V_D \frac{(V_G - V_T))^{1+\gamma}}{1+\gamma}, \text{ when } (V_G - V_T) \leqslant V_D \\ \quad \text{in the saturation regime,} \end{cases} \quad (39)$$

which is similar to Eq. (20) for the case without bias enhancement of mobility. The error term for the linear regime is in the order of $\text{err}_\Delta = O[1/2\gamma(V_D/V_{GT})^2]$.

Consequently, the bias enhancement term $(V_G - V_T)^\gamma$ is cancelled in the ratio $\delta = \Delta I_D/I_o$, as

$$\delta = \frac{\Delta I_D}{I_o}\Big|_{V_G > V_T, \gamma > 0} \approx 12\frac{C_L}{C_{ox}} \times \begin{cases} \frac{V_D}{2(V_G - V_T) - V_D(1 - err)}, \text{ when } V_D \ll (V_G - V_T) \\ \quad \text{in the linear regime,} \\ \frac{V_D}{V_G - V_T}\frac{1+\gamma/2}{1+\gamma}, \text{ when } (V_G - V_T) \leqslant V_D \\ \quad \text{in the saturation regime,} \end{cases} \quad (40)$$

The comparison between Eqs. (21) and (40) indicates identical bias dependences. The error term for the linear regime is in the order of $\text{err} = O[\gamma/(2+\gamma)]$, and is in the denominator, because $\text{err}_\Delta < \text{err}_o$. When the mobility enhancement factor γ is included, then the full expression for δ is tedious and inappropriate for manual analyses. Provided that $\gamma < 1$ in TFTs with good electrical performance, then $\text{err} < 50\%$ and the omission of γ will not cause deviations larger than 25% between the values of δ calculated by Eqs. (21) and (40). These deviations are lower than the uncertainty for the values of the fringing capacitance C_L. Therefore, we pursued the analyses with the simpler equations without including the mobility enhancement factor γ.

Appendix C

The shortening of the channel with the small depleted region Δ L near the drain of the MOS transistor with potential $V_x > V_{Dast}$ reduces the integration limit for the current from L to $(L - \Delta L)$ by the integration on the left-hand side of Eq. (34). Consequently,

$$\int_0^{L-\Delta L} \frac{I_{MOS}}{\mu W} d = \int_{V_S=0}^{V_G - V_T} C_{ox}(V_G - V_T - V_x) dV_x \Rightarrow \frac{I_{MOS} L}{\mu W}\left(1 - \frac{\Delta L}{L}\right) = C_{ox}\frac{(V_G - V_T)^2}{2} = \frac{I_{SAT} L}{\mu W} \quad (41)$$

Comparing the relative increase of the current with the free of channel modulation current I_{SAT}, then

$$\delta_{MOS} = \frac{I_{MOS} - I_{SAT}}{I_{SAT}} = \frac{1}{1 - \Delta L/L} - 1 \approx \frac{\Delta L}{L} \propto \frac{V_D - (V_G - V_T)}{L}, \quad (42)$$

Since $\Delta L/L \ll 1$, then one usually takes the first order approximation $\Delta L/L = \lambda(V_D - V_{Dsat})$, as follows from above, and given by Eq. (22).

Appendix D

By analogy with MOS transistors, one usually takes the drain current at biasing condition $V_D = V_{GT} = (V_G - V_T)$ as the saturation current I_{SAT} in the TFT and uses Eq. (19) to evaluate mobility from the equality $I_{SAT}L = W\mu C_{ox}(V_G - V_T)^2/2$. However, we see in Eq. (20) that the "extra" current ΔI_D is not zero at this condition, and also $\delta = \Delta I_D/I_o > 0$ in Eq. (21). Therefore, at a given gate bias voltage V_G, we choose a reference current $I_{Dref} = I_D(V_{Dref} > V_G - V_T)$ in the saturation region of the output characteristic ($I_D = f(V_D)$ at constant V_G) of the TFT. If the TFT is normally-off field-effect transistor (the threshold voltage V_T has the same polarity as the gate V_G and drain V_D bias voltages), then a convenient choice is the biasing condition $V_{Dref} = V_G$ that corresponds to the diode connection of the TFT, because I_{Dref} is easily measured during experiments. In this case, the equations are simpler, therefore, when possible, we provide the corresponding expressions, labelled with "for normally-off TFT". The equations in this appendix are only for the saturation regime of operation of the TFT above threshold $V_G > V_T$, so these expressions should not be applied to data from other regions of operation.

From eq. (21) we have

$$I_{Dref} = I_o(1+\delta) = I_o\left(1 + \frac{V_{Dref}}{V_G - V_T}12\frac{C_L}{C_{ox}}\right), \\ = I_o\left(1 + \frac{V_G}{V_G - V_T}12\frac{C_L}{C_{ox}}\right) \text{ for normally-off TFT.} \tag{43}$$

For the same V_G, and at any other $V_D > (V_G - V_T)$ in the saturation regime

$$I_D = I_o\left(1 + \frac{V_D}{V_G - V_T}12\frac{C_L}{C_{ox}}\right), \text{ with } V_D \neq V_{Dref}. \tag{44}$$

Therefore, the ratio I_D/I_{Dref} and the relative difference δ_{ref} between I_D and I_{Dref} are

$$\frac{I_D}{I_{Dref}} = \frac{V_G - V_T + V_D 12C_L/C_{ox}}{V_G - V_T + V_{Dref}12C_L/C_{ox}} = \delta_{ref} + 1, \\ = \frac{V_G - V_T + V_D 12C_L/C_{ox}}{V_G(1 + 12C_L/C_{ox}) - V_T} \text{ for normally-off TFT,} \tag{45}$$

and

$$\delta_{ref} = \frac{I_D}{I_{Dref}} - 1 = \frac{(V_D - V_{Dref})12C_L/C_{ox}}{V_G - V_T + V_{Dref}12C_L/C_{ox}}, \\ = \frac{(V_D - V_G)12C_L/C_{ox}}{V_G(1 + 12C_L/C_{ox}) - V_T} \text{ for normally-off TFT.} \tag{46}$$

Since I_D and I_{Dref} are measured at predetermined bias voltages V_G, V_D, V_{Dref}, and also knowing the threshold voltage V_T of the TFT, then one rearranges the terms, and experimentally characterizes the ratio C_L/C_{ox} from

$$\frac{C_L}{C_{ox}} = \frac{(V_G - V_T)\delta_{ref}}{12[V_D - V_{Dref}(1+\delta_{ref})]} = \frac{\varepsilon_0\varepsilon_B}{C_{ox}\pi L} = \frac{t_{ox}}{\varepsilon_{ox}}\frac{\varepsilon_B}{\pi L}, \\ = \frac{(V_G - V_T)\delta_{ref}}{12[V_D - V_G(1+\delta_{ref})]} \text{ for normally-off TFT.} \tag{47}$$

The calculation of $\delta_{ref} = I_D/I_{Dref} - 1$ by Eq. (46) from measured data and the consequent substitution of the values of δ_{ref} in Eq. (47) comprise the experimental characterization of the characteristic fringing capacitance C_L (see Eq. (12)) at the "back" of the film in the TFT from operation of the TFT in the saturation regime, because knowing the value of C_{ox}, one calculates C_L and can also obtain the effective value for the relative permittivity ε_B of the media at the "back" of the film, since the channel length L is also known. Therefore, Eqs. (46) and (47) are given also in the text by Eq. (24), and their use is discussed there. From the discussion, one should consider in practice data post-processing for determination of a single value for C_L/C_{ox} or ε_B.

Once the ratio C_L/C_{ox} is obtained, then one can reduce the measured current I_D with the "extra" current ΔI_D due to fringing capacitance at the "back" of the semiconducting film in the TFT, and can also obtain the ideal current I_o due to the gate bias and C_{ox} at the "front" of the film. The ideal current I_o is given by Eq. (19) and the reduction is based on Eq. (21) for the ratio $\delta = \Delta I_D/I_o$ of currents driven by the drain bias V_D through the fringing capacitances and by the gate bias V_G through C_{ox}. Consider as in Eq. (43) that $I_D = (1+\delta)I_o$. Then, $I_o = I_D/(1+\delta)$, and in the saturation regime

$$I_o = \frac{W}{L}\mu C_{ox}\frac{(V_G - V_T)^2}{2} = \frac{I_D}{1 + \frac{V_D}{V_G - V_T}12\frac{C_L}{C_{ox}}}, \text{ at } V_D > (V_G - V_T). \tag{48}$$

Generally, the channel width W, channel length L, the threshold voltage V_T and gate insulator capacitance C_{ox} (per unit area) of the TFT are known. Also, V_G, V_D and I_D are known from the measured I–V curves of the TFT in the saturation regime. Therefore, the last equation above is rearranged as a formula for calculation of the charge carrier mobility at various biasing conditions, as given by Eq. (25) in the text.

Appendix E

One obtains the "extra" current ΔI_L in the semi-insulating state of the TFT, from a derivation that is similar with the derivation of the "extra" current ΔI_D for the above-threshold regime, but using a different equation for the charge ΔQ_s. Using Eq. (29) for ΔQ_s, we write the transport equation for ΔI_L as

$$\frac{\Delta I_L}{\mu W} = \Delta Q_s\frac{\partial V_x}{\partial x} = \frac{(V_D - V_T - V_x)C_L\frac{x}{L}}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)}\frac{\partial V_x}{\partial x} \\ \leqslant \frac{(V_D - V_T - V_x)C_L}{\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)}\frac{\partial V_x}{\partial x}, \tag{49}$$

with $0 = V_s \leqslant V_x \leqslant V_{mD} = \min(V_D, V_D - V_T)$. Observe that $V_{mD} \neq V_m = \min(V_D, V_G - V_T)$, since V_D induces charge independently of V_G. As noted after Eq. (12), the factor in the denominator of Eq. (49) is finite and positive. Therefore, one can multiply the equation by this factor, in order to obtain an integral with separated variables

$$\int_0^L \frac{\Delta I_L}{\mu W}\left[\frac{C_L}{C_s} + \frac{x}{L}\left(1 - \frac{x}{L}\right)\right]dx \\ \leqslant \int_{\min(V_S=0,\ V_D - V_T)}^{\min(V_D,\ V_D - V_T)} (V_D - V_T - V_x)C_L dV_x. \tag{50}$$

The lower boundary of the last integral is modified so that spurious negative currents are avoided when writing the solution of the integrals, given by

$$\frac{\Delta I_L}{\mu W}\left(\frac{C_L}{C_s}+\frac{L}{2L}-\frac{L^2}{3L^2}\right) \leqslant C_L\frac{[\max(0,V_D-V_T)]^2-[\max(0,V_D-V_T-V_D)]^2}{2}. \quad (51)$$

Cancelling the channel length L in the left-hand brackets, followed by division of the equation on the resulting positive term $(C_L/C_s + 1/6)$, one obtains the final expression, given by Eq. (30) in the text. The three possible cases stated there explain the purpose of the function max(0,x), which generates expressions for TFT with virtual "back"-gate capacitance $6C_L$ in the diode connection.

that charge generation efficiencies of metal oxide dopants are predominantly controlled by the dispersion characteristics of the dopant in an organic semiconductor. This finding opens a way toward the development of efficient dopants for organic semiconductors by improving the dispersion characteristics.

2. Experimental

The films were deposited on a copper TEM grid covered with formvar and carbon films for the TEM analysis. TEM (Jeol, JEM-3000F) with an accelerating voltage of 300 kV was used for the imaging of a doped sample, respectively. Doped organic layers were formed by coevaporation of each dopant and host by thermal evaporation in a high vacuum. The doping concentration was controlled by the evaporation rates of the dopant and host in the range 0.02–2 Å/s. "Image J" was used for the image treatment and the particle analysis of the TEM image.

The hole-only devices are consisting of indium tin oxide (ITO)/MoO_3- or ReO_3-doped 1,4-bis[*N*-(1-naphthyl)-*N*′-phenylamino]-4,4′ diamine (NPB) (50 nm)/Ag (50 nm). Glass substrates with patterned ITO (150 nm thick) were used to fabricate hole-only devices after they were cleaned with acetone and isopropyl alcohol. The fabricated devices were encapsulated with a getter in a dry nitrogen glove box prior to testing. *J*–*V* characteristics were measured with a Keithley 2400 semiconductor parameter analyzer.

3. Results and discussion
