(by weight ratio, r) ranging from $r = 0\%$ (non-doped) to 6 wt.%. By separating the CR and TTA processes with quantitative analysis of MEL based on a theoretical rate model, we obtain simple analytical expressions allowing the estimation of the singlet yields from CR and TTA processes in the molecular fluorescent devices, respectively.

2. Experimental

The samples used for MEL measurements were fabricated in an organic molecular beam deposition system with bass pressure of $\sim 10^{-6}$ Pa. All organic layers of the 1×2 mm^2 devices were sandwiched between indium tin oxide (ITO) anode and lithium fluoride (LiF)/Al cathode. N,N′-Di(naphthalene-1-yl)-N,N′-diphenyl-benzidine (NPB) and pure Alq_3 layers are utilized as hole transport layer and electron transport layer, respectively. The emissive layer of DCM: Alq_3 with different DCM concentrations were co-evaporated by controlling the relative deposition rate of DCM and Alq_3. The device configurations then consisted of stacked thin films of ITO/NPB (50 nm)/Alq_3: DCM (0, 2, 3, 6 wt.%, 40 nm)/Alq_3 (30 nm)/LiF (0.7 nm)/Al (100 nm).

For the transient EL measurements, we used an Agilent pulse generator (8114A) to apply rectangular pulse voltage to our devices. The pulse repetition rate was 1 kHz with the width of 60 μs. Transient EL of the devices was measured with a Hamamatsu photomultiplier (H6780-P) and a digital oscilloscope (Tektronix DPO7104). The EL spectra were measured by SpectraPro-2300i spectrum units.

The MEL measurements were performed in a close-cycle cryostat system (Janis CCS-350s) which was located between the pole pieces of an electromagnet (Lakeshore EM647). During the measurement process, the samples were mounted on the cold finger of a close-cycle cryostat and operated at temperatures from 20 to 300 K. To exclude the effects of B-field enhanced current on the MEL, the devices were driven under constant current model. Current sourcing was performed using a Keithley 2400 source-measurement unit. The silicon photodetector for EL measurement was tested to make sure there was no field dependence on its output.

3. Results and discussion

Fig. 1(a) and (b) show the room temperature (300 K) MEL at different measuring current levels for the $r = 2$ wt.% and $r = 0\%$ devices, respectively. The MEL was defined as the relative change in EL intensity as a function of B-field, i.e. $\mathrm{MEL} = [I_{EL}(B) - I_{EL}(0)]/I_{EL}(0)$, where $I_{EL}(B)$ and $I_{EL}(0)$ are the EL intensity in the presence and absence of a B-field, respectively. The MEL always increases sharply at low B-field. After reaching the maximum value at around 45 mT, the MEL in the $r = 2$ wt.% device turns to decrease or level off with increasing B-field, depending on the current levels, while the MELs in the non-doped device for $r = 0\%$ turn to saturate over the current measurement range. In our previous work [15,17], the high-field decrease in MEL were qualitatively explained by B-field mediated TTA process. In fact, the room temperature TTA process in the DCM-doped device can be further confirmed by

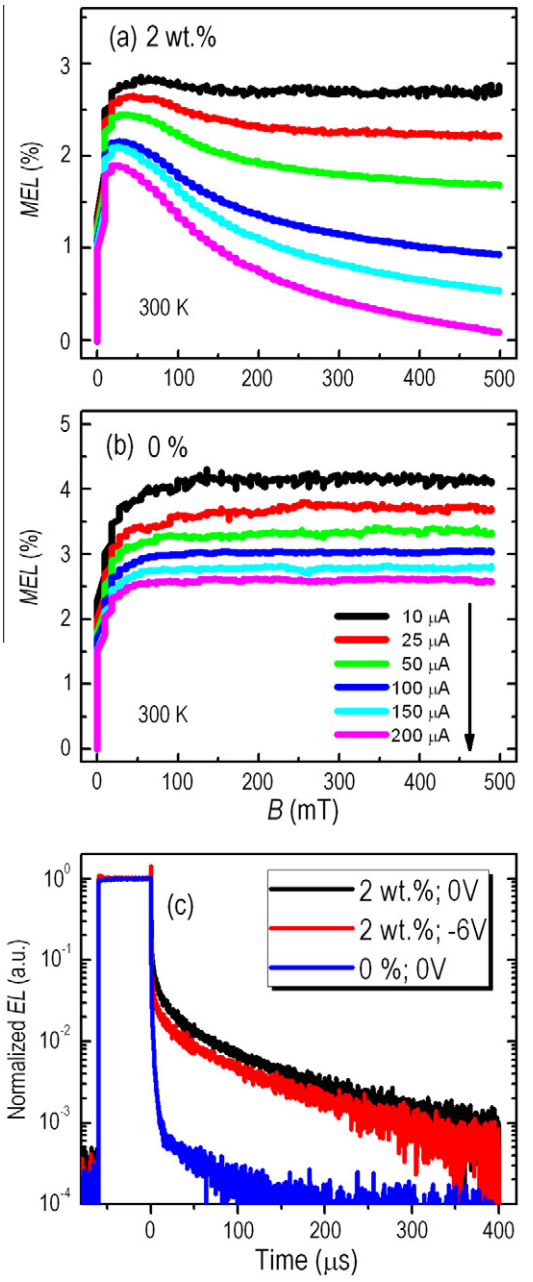

Fig. 1. MEL versus B-field in the 2 wt.% device (a) and non-doped device (b) under different driving current at 300 K. (c) Time-resolved EL intensity response of the $r = 0\%$ and $r = 2$ wt.% DCM-doped devices to 60 μs, 8 V excitation pulse, followed by 0 V or −6 V revise bias.

the transient EL measurements. Fig. 1(c) shows the time evolution of EL after a 60 μs excitation pulse was applied. It can be seen from the figure that the delayed fluorescence (DF) signal from the 2 wt.% device decays much slower than that from the non-doped device, which is consistent with the recent observation by Luo et al. [13]. In addition, nearly identical magnitudes and shapes of decay profiles in the 2 wt.% device after applying −6 V bias suggest the DF is caused by the TTA process [12,13]. Although these results

indicate that the TTA process plays an important role in the light generation in the small molecular fluorescent devices, the quantitative contribution of DF generated by TTA process to the EL intensity is still unresolved. The difficulty in distinguishing the DF from prompt fluorescence (PF) in the transient EL spectra makes the determination of the accurate relative rate of the DF very hard.

Fig. 2(a) shows the normalized current efficiencies of the $r = 2$ wt.% device measured at temperatures range from 20 to 300 K. MEL(B) curves of the $r = 2$ wt.% sample which are obtained under a large driving current of 200 μA at corresponding temperatures are compared in Fig. 2(b). It is found that higher current efficiency is corresponding with larger high-field decrease in MEL. In addition, the current efficiency is insensitive to the temperature lower than 200 K, which is similar to the situation for the high-field MEL. These results suggest some underlying correlations between the high current efficiency and TTA process since the high-field MEL is caused the B-field modulated TTA process [15,17].

In the presence of TTA, the EL intensity is the sum of the two components $I_{EL} = I_{PF} + I_{DF}$, where I_{PF} is the intensity of PF due to radiative decay of singlet excitons produced directly by CR process, and I_{DF} is intensity of DF which is generated by TTA process. Then the MEL can be expressed by

$$\mathrm{MEL} = \frac{\Delta I_{EL}}{I_{EL}} = \frac{m}{m+1}\frac{\Delta I_{PF}}{I_{PF}} + \frac{1}{m+1}\frac{\Delta I_{DF}}{I_{DF}} \quad (1)$$

with m being the ratio of PF to DF at zero field [i.e., $m = I_{PF}(0)/I_{DF}(0)$].

When electrons and holes are injected respectively from cathode and anode into the organic active layer, singlet and triplet intermolecular polaron pairs (*PP*s) are formed firstly according to spin configuration. Excitons with bound electron and hole on the same molecule are then formed after recombination of the intermolecular *PP*s [5]. Then, the direct singlet generation fraction α can be written as $\alpha = k_S/(k_S + 3k_T)$ [3], where k_S (k_T) is the recombination rate constant for singlet (triplet) exciton. In the absence of external B-field, singlet and triplet *PP*s are usually considered to be degenerate, causing a mixing between singlets and triplets through hyperfine interaction with rate k_{ISC} [18–20]. The k_{ISC} can be much faster than k_S and k_T in organic materials [21], leading to equal concentration for each level of singlet and triplet. Then the rate equation concerning the concentration of singlet *PP*s is [22]

$$\frac{d[^1\mathrm{PP}]_0}{dt} = -\frac{k_S + 3k_T}{4}[^1\mathrm{PP}]_0 + \frac{C_0}{4} \quad (2)$$

where C_0 is the formation rate constant of *PP*s and $[^1\mathrm{PP}]_0$ denotes the population of singlet *PP*s at zero field, respectively. Under the steady-state condition, we can obtain $[^1\mathrm{PP}]_0 = C_0/(k_S + 3k_T)$. When a B-field is turned on and the strength is larger than the hyperfine coupling interaction (about tens of mT), the degeneracy in triplet pairs is removed by Zeeman splitting and the hyperfine mixing remains only between ^{1}PP and $^3\mathrm{PP}_0$ (triplet *PP*s with sublevel of 0) states [18,19]. We then obtain $[^1\mathrm{PP}]_B = [^3\mathrm{PP}_0]_B = C_B/2(k_S + k_T)$ by resolving the rate equation for singlet *PP*s at external B-field [22], where C_B is the *PP* formation rate constant and $[\mathrm{PP}]_B$ is the pair populations of a species *PP* at B-field. Singlet excitons are then generated after singlet *PP*s recombined. The PF intensity is proportional to the concentration of singlet excitons from the CR process. Since the MEL measurements are made under constant current, the C_B/C_0 can be considered to be 1. Therefore, the $\Delta I_{PF}/I_{PF}$ can be written as

$$\frac{\Delta I_{PF}}{I_{PF}} = \frac{[^1\mathrm{PP}]_B}{[^1\mathrm{PP}]_0} - 1 = \frac{3}{2(2\alpha+1)} - 1 \quad (3)$$

Gärditz et al. [23] have measured the relative change of delayed EL intensity in Alq_3-based OLEDs and found that the $\Delta I_{DF}/I_{DF}$ fell to its zero-field level at about 125 mT and reached −2.5% at 200 mT. We then assume that the $\Delta I_{DF}/I_{DF}$ curves in our experiments have the same B-field dependence and take the $\Delta I_{DF}/I_{DF}|_{B=125\ \mathrm{mT}} = 0$, $\Delta I_{DF}/I_{DF}|_{B=200\ \mathrm{mT}} = -2.5\%$ as reference values. Therefore, the value of MEL at 125 mT can be regarded as the saturated magnitude of $m/(m+1)\cdot\Delta I_{PF}/I_{PF}$ [17] according to Eq. (1). In this case Eq. (1) then gives

$$\mathrm{MEL}|_{B=125\ \mathrm{mT}} = \frac{m}{m+1}\frac{\Delta I_{PF}}{I_{PF}}\bigg|_{B=125\ \mathrm{mT}} = \frac{m}{m+1}\frac{\Delta I_{PF}}{I_{PF}}\bigg|_{B=200\ \mathrm{mT}}$$

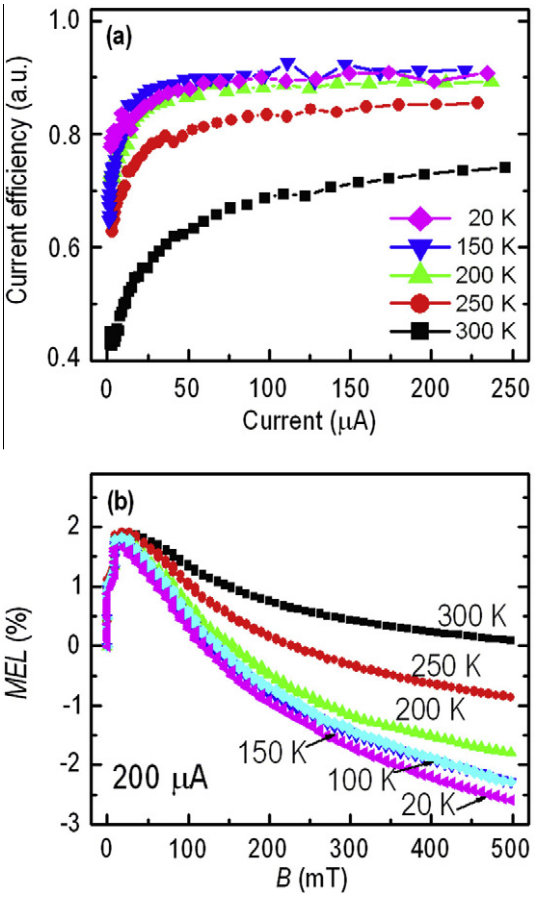

Fig. 2. (a) Normalized current efficiency for the $r = 2$ wt.% device versus current measured at temperature range from 20 to 300 K. (b) MEL versus B-field in the $r = 2$ wt.% device under different temperature at 200 μA.

$$\mathrm{MEL}|_{B=200\ \mathrm{mT}} - MEL|_{B=125\ \mathrm{mT}} = \frac{1}{m+1}\frac{\Delta I_{\mathrm{DF}}}{I_{\mathrm{DF}}}\Big|_{B=200\ \mathrm{mT}} \quad (4)$$

If the probability of radiative decay of singlet exciton is equal for PF and DF, we get $m = I_{\mathrm{PF}}(0)/I_{\mathrm{DF}}(0) = \alpha/\beta$, where the β denoting the generation fraction of extra singlet exciton via TTA process. The total singlet generation fraction is then represented by $\chi_S = \alpha + \beta$.

By using the values read out from the MEL curves which are displayed in Fig. 1 and also Fig. 2(b), m, α, β, and χ_S can be determined for each condition based on the above equations. For example, for the $r = 2$ wt.% sample at 200 μA, 300 K [see in Fig. 1(a)], by substituting $\mathrm{MEL}|_{B=125\ \mathrm{mT}} = 1.165\%$ and $\mathrm{MEL}|_{B=200\ \mathrm{mT}} = 0.743\%$ which are read out at 125 mT and 200 mT in the curve into Eq. (4), we obtain $m = 4.9$ and $\Delta I_{\mathrm{PF}}/I_{\mathrm{PF}} = 1.4\%$. These results give α of 0.240 according to Eq. (3), and then β and χ_S are determined to be 0.049 and 0.289, respectively.

It should be emphasized that these results should depend on the choosing of the reference values. The $\Delta I_{\mathrm{DF}}/I_{\mathrm{DF}}$ in organic materials under different excitation ways would show different B-field dependences. Mezyk et al. [11] have recently measured the sensitized $\Delta I_{\mathrm{DF}}/I_{\mathrm{DF}}$ in a DPA (9,10-diphenylanthracene):2% PtOEP [platinum(II) octaethylporphyrin] thin film and found that the $\Delta I_{\mathrm{DF}}/I_{\mathrm{DF}}$ fell to its zero field level at ~200 mT and reached −12% at 500 mT. To check the rationality of our method, we then take the $\Delta I_{\mathrm{DF}}/I_{\mathrm{DF}}|_{B=200\ \mathrm{mT}} = 0$ as reference value and use $\Delta I_{\mathrm{DF}}/I_{\mathrm{DF}}|_{B=500\ \mathrm{mT}} = -12\%$ to do the calculation. It gives $m = 17.2$, $\alpha = 0.244$, $\beta = 0.014$ and $\chi_S = 0.258$. Although departure is exhibited by varying the choice of the reference value, the contribution of TTA (β) can not be still ignored and the total singlet exciton yield χ_S can also exceed the classical 0.25 statistics limit. The biggest discrepancy is that the value of m calculated by using the reference values from PtOEP:DPA compound films is three times more than that calculated from Alq_3 EL device. This discrepancy can be explained by the different exciton environment in organic semiconductor between the two systems. Under laser excitation, the triplet states of PtOEP are rapidly populated due to the strong spin–orbit coupling and then the DPA triplets pile up because of energy transfer from PtOEP, leading to strong TTA in the compound [11]. The delayed EL would be much less because only a part of excitons (exciton with spin 1) are involved in TTA process in the Alq_3 EL device. Therefore, the decrease of sensitized DF with increasing B-field would be much sharper than the delayed EL, giving a large reference value at 500 mT and then the larger value of m. Given the above facts, the results which are calculated based on the reference values under electric excitation of Alq_3 device would be much more reasonable.

Fig. 3 shows the dependences of singlet generation fraction for the $r = 2$ wt.% device on measuring current and temperature. It can be seen from Fig. 3(a) that χ_S (black solid square) increases with enlarging the driving current and exceeds 0.25 spin statistics limit at current larger than 50 μA at 300 K. When the temperature decreases, the value of χ_S initially increases and then turns to saturate at temperatures lower than 150 K [see in Fig. 3(b)]. The average value of χ_S we obtain for the $r = 2$ wt.% sample driving by 200 μA at different

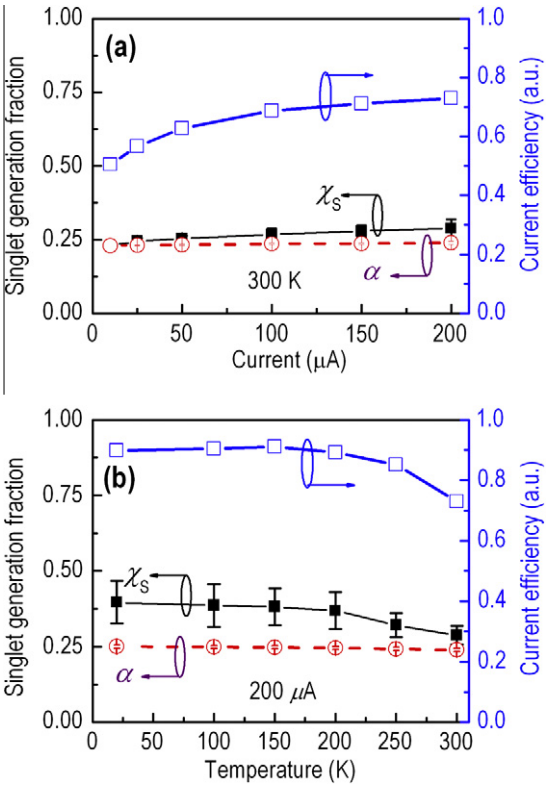

Fig. 3. The dependence of χ_S (black solid squares) and α (red open circles) on current at 300 K (a) and on temperature at 200 μA (b) for the 2 wt.% DCM-doped device. Normalized current efficiency values (blue open squares) are shown on the right y-axis of (a) and (b). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

temperature is 0.36 ± 0.05. However, there is no significant variation in α with temperature and driving current over the measurement range [red open circle], suggesting that the probability of forming either a singlet or a triplet exciton via the CR process is independent of temperature and current density. This assumption is consistent with the observation of Wilson et al. [4] in a platinum-containing monomer. The average value of α for the sample at 300 K is 0.23 ± 0.02, which is in great agreement with the value of 0.22 ± 0.03 measured by Baldo et al. [2] for small molecular Alq_3. This result also confirms that CR process in the molecular fluorescent devices is spin-independent. The dependence of χ_S on current and temperature and the large value of χ_S exceeding the statistics limit might be caused by the TTA process since TTA heavily depends on the lifetime and concentration of triplet states in the devices [24]. At large driving current and low temperature, the triplet density is enlarged and the triplet lifetime is prolonged due to the reduced phonon-assisted decay of triplets, which causes a strong TTA and then a large value of β. Normalized current efficiency for the sample [blue open square] shows the same behavior against current and temperature as χ_S, suggesting that our discussion is consistent with the experimental results since the efficiency is proportional to the singlet yields in fluorescent devices.

We note that the reference B-field selected for $\Delta I_{DF}/I_{DF} = 0$ is an important parameter for the calculation and it would be varied with temperatures and materials, so it is necessary to discuss the validity of the assumption and the related results in this work. In order to test the dependence of the calculated results on the reference field, we do the calculation by using different fields ranging from 100 to 150 mT around 125 mT as the field for $\Delta I_{DF}/I_{DF} = 0$. The variation of α and χ_S are displayed in Fig. 3 as form of error bars. The value of α is found to be nearly independent on the reference field. Although the value of χ_S exhibits its departure with changing the reference field especially at low temperatures, two important conclusions are still unchanged. The first conclusion is that the total singlet exciton yield χ_S can exceed the classical 0.25 statistics limit, and the second one is that TTA process contributes an important component ($\beta = \chi_S - \alpha$) to the singlets.

In order to elucidate the control parameters for the extra singlet generation β via TTA process, devices with different dopant concentrations are studied at different temperatures and driving currents. Fig. 4(a) shows the MEL characteristics of 0%, 2 wt.%, 3 wt.% and 6 wt.% DCM-doped samples at 20 K, 200 μA. Normalized EL spectra of the doped and pure Alq_3 devices are compared in the inset. The peak position of EL spectra around 600 nm and the complete quenching of the Alq_3 emission indicate that light emission in the doped samples comes from DCM molecule. Compared to the non-doped sample, all doped devices show a larger high-field decrease in MEL, suggesting a stronger TTA in the doped devices [15]. Fig. 4(b) displays the extra singlet generation fraction β as a function of driving current for the samples with different DCM concentration at 300 K. For the non-doped (0%) device, β are constantly equal to zero, indicating that no TTA in the pure Alq_3 device at room temperature. The value of β for the doped devices increases with driving current. The maximum β at 300 K is obtained to be about 0.05 in 2 wt.% device, suggesting that DF intensity constitutes as high as ~17% (=0.05/0.289) to the total EL intensity at room temperature in this device [the χ_S is 0.289 as shown in Fig. 3(a)]. The dependence of β on temperature for different DCM concentration devices driving at 200 μA is shown in Fig. 4(c). A rise of the β is observed with decreasing the temperature. At temperatures lower than 150 K, the β for the non-doped device is not equal to zero any longer and reaches about 0.06 at 20 K, leading to the χ_S of 0.302 [the ratio of β to χ_S is then calculated to be ~19% (=0.06/0.302)]. This phenomenon indicates strongly that TTA process plays an important role in the emission of pure Alq_3-based OLEDs at low temperature. The maximum β of 0.146 is obtained in 2 wt.% device at 20 K, pushing the χ_S to 0.397 [see in Fig. 3(b)]. The contribution of extra singlets generated by TTA process to the total singlets under this condition is then calculated to be ~34% (=0.146/0.397). When the dopant concentration r is larger than 2 wt.%, the β decreases with further increasing r at a given measuring temperature or current level. This phenomenon might be caused by the aggregation of DCM molecule in the devices [25]. The aggregation of DCM molecule can trap carriers for self-quenching and also exciton quenching [25,26], resulting in a reduced TTA process and degradation of the devices. This argument is confirmed by the red-shifts of the emission peak of EL spectra with increasing the DCM concentration [see the inset in Fig. 4(a)]. The increasing aggregation of DCM causes the enhancement of the longer wavelength emission [26].

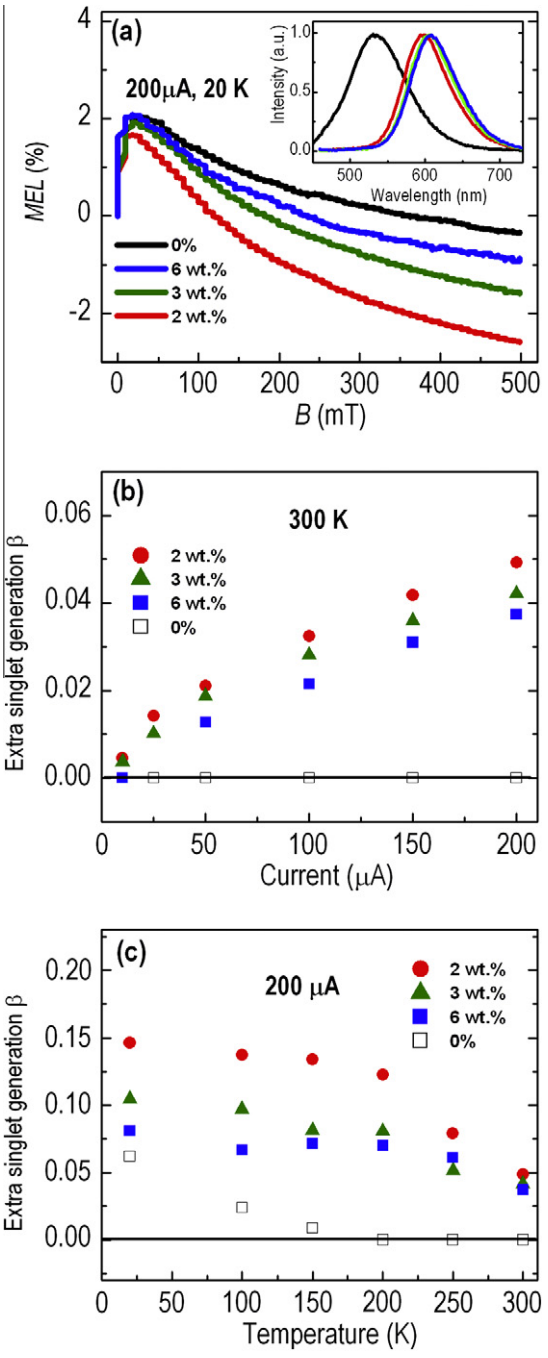

Fig. 4. (a) MEL versus B-field for 0%, 2 wt.%, 3 wt.% and 6 wt.% DCM-doped samples at 20 K, 200 μA. The normalized EL spectra for the doped and undoped devices are compared in the inset; The dependence of β on current at 300 K (b), and on temperature at 200 μA (c).

Following the above discussion, the β heavily depends on the dopant-induced exciton trapping [15,27]. Triplet excitons in the DCM-doped device are trapped in the

dopant molecules avoiding the quenching with thermal activation energy. Thus, the lifetime of triplet excitons in the DCM molecule would be long, which gives rise to a large population density of triplets and also large interaction time constant for TTA. In the non-doped devices triplets lifetime is strongly reduced due to the phonon-assisted quenching at room temperature, resulting in no TTA ($\beta = 0$) in the device even under large driving currents (high density of triplets). In the DCM-doped device with long lifetime of triplets, in contrast, TTA happens ($\beta > 0$) even at a small current level (low density of triplets). These phenomena also indicate that lifetime of triplet excitons (interaction time constant for TTA) is the primary factor for TTA, while population density of triplets is the secondary. Although the threshold value of interaction time constant for TTA is not yet exactly determined and it would depend on the triplet density, the high-field decrease in MEL can be utilized as a sensitive probe for TTA process in organic fluorescent devices.

4. Conclusions

We have demonstrated the generation fraction of singlet exciton in the small molecular based OLEDs by analyzing the MEL with a rate model. The results reveal that TTA process produces considerable extra singlets which account for as high as 19% of total singlets at 20 K in non-doped device, 34% at 20 K and 17% at room temperature in fluorescent dye doped device, causing the total singlet generation yields exceeding the classical 0.25 spin statistics limit. Of course, it should be noted that the most exact way to quantify the fraction of singlet generation in small molecular fluorescent devices should be based on quantum efficiency measurements. However, as yet, there would be still some difficulties to discern the contribution of the TTA process based on this quantum efficiency measurement. Much more research needs to be done to address this question properly. In summary, the results presented in this work can be used to understand the process of light generation in the small molecular based OLEDs, especially in the fluorescent host: guest systems with very high quantum efficiencies exceeding the classical 25% theoretical limit.

films, reaching over 1400 S/cm at 89.5% transmission with solvent post treatment [5–8].

While PEDOT:PSS is most commonly used in commercial application, some alternative forms of PEDOT synthesis have been used in electrochemical polymerization (primarily for analytical studies) or in vapor phase polymerization (VPP) where a common polymerization catalyst is the Lewis acid Fe(III) p-toluene sulfonate or $Fe(tos)_3$ [9,10]. $Fe(tos)_3$ is also the most prominent oxidant used for in situ polymerization of PEDOT, where conductivities reach over 1000 S/cm when processed with the inhibitor pyridine and water for improved film quality and to extend pot life [11,12]. Ha et al. used relatively high concentrations of imidazole in the processing solution to reduce the high reactivity of $Fe(tos)_3$ prior to processing and to "[preserve] the EDOT in monomeric form after spin-casting", where polymerization is initiated by heating the substrate [13]. They report 750 S/cm with 81% transmission at 270 Ω/sq. With the aforementioned values, PEDOT is becoming more attractive as a flexible alternative electrode to brittle transparent conductive oxides, namely preeminent and expensive indium tin oxide.

For all its applications, PEDOT:PSS has some drawbacks. The inherent low pH (less than 3) and hygroscopic nature of PSS lead to degradation of surrounding interfaces [14,15]. To overcome corrosion issues, researchers at TDA Research developed a lauryl terminated bis-poly (ethyleneglycol) PEDOT doped with perchlorate, which is processed in nitromethane and reaches conductivities of 10–60 S/cm [16]. Additionally, Kim et al. produced an organic-processable, non-acidic solution of PEDOT using a hydrophobic, imidizolium-based polyionic liquid as a counterion for use as an HTL in OLEDs [15]. They reported conductivities of 10^{-2} S/cm.

To further address some of the problems associated with PEDOT:PSS, we have attempted the synthesis of a hydrophobic, matrix-assisted PEDOT thin film using the organic electron acceptor and dehydrogentating agent 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) as both the mediator for synthesis of PEDOT and for subsequent doping during spin coating. We also attempted synthesis of PEDOT with tetrachloro-1,4-benzoquinone, which has been used successfully in the synthesis of conductive polypyrrole along with other halogenated benzoquinones and in other oxidative coupling reactions requiring dehydrogenation [17–20]. However, within the chosen environment these reagents of lower oxidative potential relative to DDQ did not initiate an observable polymerization reaction with EDOT.

In our research, we developed a versatile procedure to process PEDOT:DDQ from solution using solvents with much lower dielectric constants than MeCN, such that significant polymerization is inhibited until the solvent evaporates and the reactants reach a critical concentration which drives polymerization. It has been shown that the formation of charge transfer (CT) complexes decreases with an increase in the dielectric constant of the solvent [21]. Therefore, it was believed that in solvents with high dielectric constants, the EDOT:DDQ CT complex dissociates into a radical cation and anion which drives polymerization in solution. Conversely, the CT state is more prevalent in less polar solvents (e.g. 1,4-dioxane, THF) such that the rate of dissociation and polymerization is significantly slowed and is largely governed by concentration.

When only solutions of EDOT and DDQ were spin coated in THF, a granular, highly resistive film was produced. However, upon the addition of PVAc or a related polymer to function as a templating matrix, smooth, conductive thin films were produced. Successful films turned from a pale brown–green to a bright blue after spin coating (Fig 1), which signals the formation of reduced PEDOT chains [22]. A subsequent rinse with MeCN after drying was necessary to further polymerize and oxidize the PEDOT chains as well as to remove excess PVAc, (un)reacted DDQ, and monomer.

As stated previously, conductive polypyrrole has been synthesized in the presence of halobenzoquinones. Bruno et al. reports a two order of magnitude increase in conductivity from pressed pellets of poly(EDOT-co-pyrrole) over PEDOT as a control [23]. Thin continuous films of the copolymer may give favorable results which this procedure could offer.

Thus far, we have achieved 17 S/cm with almost 87% transmission at 550 nm, where higher conductivities were achieved at a cost of decreased transmission. When comparing in situ processing procedures employing $Fe(tos)_3$/amine inhibitor or DDQ, PEDOT:DDQ conductivity and associated values are currently lower than those achieved by PEDOT:tos. Nevertheless, the processing procedure and properties of PEDOT:DDQ are still being investigated, and potential advantages include processing in non-polar solvents with organic-processable polymers. Further, the

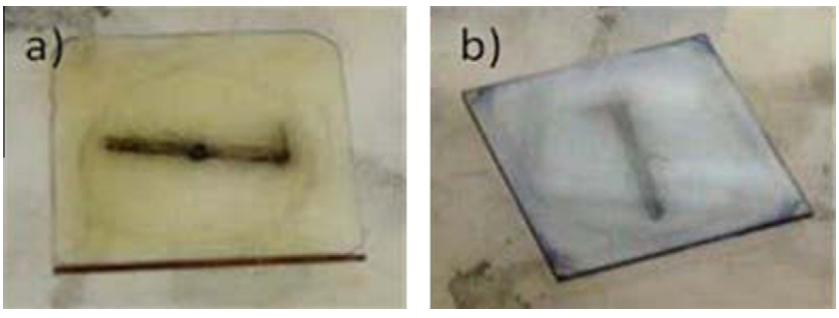

Fig. 1. THF solution of EDOT and DDQ (a) prior to spinning (b) after 2 s of spinning.

pot life of the $Fe(tos)_3$/amine inhibitor system varies. For pyridine solutions, the pot life can last up to a week whereas certain imidazole solutions are preserved indefinitely; however, in the latter, crystal formation in solution can occur and high temperatures are necessary for initiating polymerization [10]. The pyridine procedure presented by Clevios suggests processing the complete solution immediately to prevent gelling [24]. For PEDOT:DDQ, the processing solution has a relatively long pot life, and the resulting smooth, conductive film could take on a range of mechanical and optoelectronic properties dependent on the polymer additive.

2. Materials and methods

2.1. Spectroscopy

Solutions of approximately 73 μM DDQ (Aldrich 98%, stored under nitrogen) in a range of aprotic solvents (dry 1,4 dioxane, *n*-butyl acetate, dry THF, MeCN) were prepared and their spectra recorded. One molar equivalent of 3,4-ethylenedioxythiophene (EDOT, Aldrich) was added to the solutions, and the change in spectra was recorded over time.

2.2. Film formation

Multiple series of EDOT:DDQ solutions were prepared under ambient conditions in the following way: to a designated amount of PVAc (Aldrich, avg. M_w of 100,000) and DDQ was added reagent grade, dry 1,4-dioxane. After stirring for approximately 1 h to dissolve all contents, EDOT was added, and the solution was stirred for 1 h. For example, to 40.2 mg PVAc and 86.9 mg (0.38 mmol) DDQ was added 2 mL 1,4-dioxane. After 1 h of stirring, 29.9 μL EDOT (0.28 mmol) was added and stirred for another hour to give an overall concentration of 0.14 M EDOT with EDOT:DDQ in a 1:4/3 mol ratio and EDOT:PVAc in a 1:1 wt ratio. The solutions were spin coated on glass cleaned by sonication sequentially in baths of acetone and isopropanol and then oxygen plasma-treated prior to use. All films were spun at 1200 rpm for 5 s and immediately placed under a petri dish lid (9 cm diameter) for 2 h unless otherwise specified. This film recipe will be referred to as a standard film. After 2 h, films were carefully rinsed 2–3 times with MeCN and allowed to dry.

To a solution of PEDOT:PSS provided by H.C. Starck (Baytron PH 1000) was added 5% vol ethylene glycol (EG). The solution was filtered with a 0.45 μm Wattman membrane filter, spin coated at 2500 RPM for 30 s, and annealed at 120 °C for 1 h to serve as reference material – also referred to as standard.

2.3. Instrumentation

Absorption and transmission spectra were obtained by UV–vis spectroscopy (Shimadzu MPC-3100). Sheet resistance values were calculated and reported as an average of 10 values per film by 4-point probe measurements (Lucas Labs., tungsten carbide tips). X-ray photoelectron spectroscopy (XPS) and UV photoelectron spectroscopy (UPS) measurements were performed with a Poibos 100 setup (Specs) as described elsewhere [25]. Conductive AFM was performed on an AIST-NT Combiscope 1000 executed in contact mode with platinum or gold coated silicon tips at different bias voltages (PEDOT:PSS at −2.1 V, PEDOT:DDQ at 10 mV, tip radius ~50 nm).

3. Theory

In these experiments, we believe that the polymerization for conductive PEDOT with DDQ is based on the Diaz mechanism for polypyrrole [26–28]. One potential pathway to polymerization is illustrated in Scheme 1.

As benzoquinones are known to undergo one-electron reduction in aprotic solvents [29], one possible mechanism involves the initial formation of a CT complex following the collision of DDQ and EDOT. Dissociation of the complex – accelerated by solvent evaporation – and collision of the resulting radical cations could yield a cationic dimer. Once two EDOT radical cations couple, surrounding DDQ species can abstract α-hydrogen atoms. Scheme 1 represents one simplified pathway to polymer formation which shows the lifecycle of DDQ to $DDQH_2$. In this pathway a monoradical, cationic dimer is formed after hydrogen abstraction. Polymer chains grow by the addition of cationic species of EDOT.

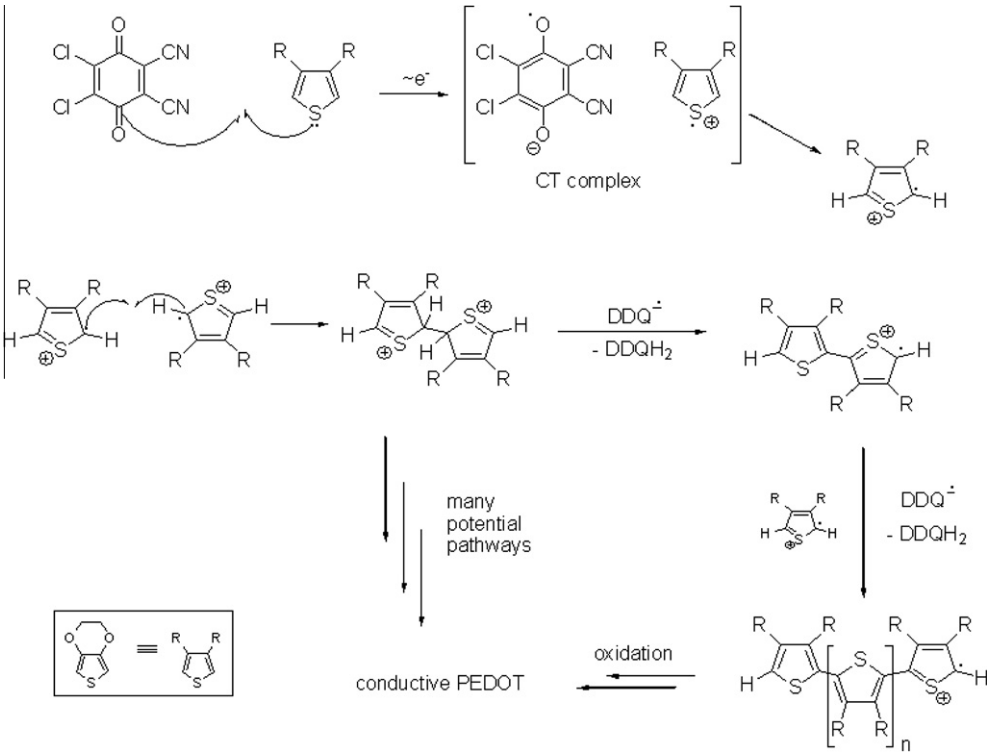
Many pathways are possible to the formation of EDOT dimers with different oxidation states, radical number, and bond order. While we do not have experimental evidence for support, we believe that the $DDQH^{\bullet}$ radical found in these processes could perform subsequent oxidation of neutral PEDOT segments or that the $DDQH^{-}$ anion can become the counterion of an already-oxidized sulfur, leading to conductive polymer chains.

4. Results and discussion

4.1. Spectroscopy

Solutions of monomer, oxidant, and different solvents exhibited characteristic colors and color changes during processing. Common ethereal solvents were selected based on their solvating ability in search of a balance between charge-screening ability and vapor pressure relative to MeCN ($\varepsilon = 36.64$, $vp_{25} = 11.9$ kPa) and include: THF ($\varepsilon = 7.52$, $vp_{25} = 21.6$ kPa), 1,4-dioxane ($\varepsilon = 2.22$, $vp_{25} = 4.95$ kPa) and *n*-butyl acetate ($\varepsilon = 5.07$, $vp_{25} = 1.66$ kPa) [30].

A slower drying process was thought to lead to longer reaction times for increased polymerization and doping, thus, improving film quality. *N*-butyl acetate did not produce conductive films after drying and rinsing with MeCN, nor was a significant blue color change observed. Even after heating to remove more solvent, the films remained highly resistive, which was attributed to steric interference from the alkyl chain during the reaction. Films employing THF turned from a pale brown-green to a bright blue within seconds of spin coating (Fig. 1) while the rate of color change for 1,4-dioxane was slower. When spin coating films with 1,4-dioxane, polymerization on the pipette tip



Scheme 1. One potential pathway for the formation of conductive PEDOT with DDQ as the oxidizing and dehydrogenating agent.

and on the substrate was slowed relative to THF due to the lower vapor pressure of the double ether. Further, THF produced films with holes after rinsing with MeCN while 1,4-dioxane did not. Thus, 1,4-dioxane was the solvent of choice in this study.

When adding EDOT to the bright yellow 1,4-dioxane DDQ solution at standard film concentrations, the solution turned dark initially and then faded to a clearer brown-green. At first, extensive polymerization was not observed in solution with the naked eye. However, in about a week, small crystals – believed to be DDQ – began to form on the bottom of the vial on which polymer grew. The addition of small amounts of toluene appeared to suppress this crystal growth which could extend the refrigerated shelf life to weeks or more.

With the same concentrations of reactants but using MeCN as the solvent, the solution turned dark immediately upon addition of EDOT and formed a significant amount of precipitate. A dark film began to coat the inside of the glass vial within a day. Thus, it is believed that such rapid polymerization was a result of the solvation of the CT-complex which initiated significant polymerization in solution.

To observe the solvent effect on DDQ and on DDQ in the presence of EDOT, UV–Vis absorption spectroscopy was performed in a polar (MeCN) and a non polar (1,4-dioxane) aprotic solvent (Fig. 2). Solutions containing only the monomer, 73 μM EDOT, show an absorption peak at around 260 nm and no other features in the observed wavelength range. Thus, the formation of a stable solution and there being little interaction of monomer and solvent were concluded. Solutions containing only 73 μM DDQ show quite different behavior depending on the solvent. For DDQ in MeCN a characteristic double peak was observed at 270 and 280 nm and for the radical anion (DDQ^{-}) at 346, 432, 457, 547, and 588 nm which are in agreement with previous reports [31,32]. This shows a strong interaction of DDQ with MeCN and supports the formation of radicals in solution. Upon addition of EDOT to the DDQ solution, the DDQ peaks reduced over time as the radical peaks increased, which indicates that MeCN supports the formation of radicals which could lead to polymerization. However, a peak around 265 nm appeared which is at the position of the sum of the original, separated EDOT and DDQ peaks.

Switching to a solvent with a much lower dielectric constant, 1,4-dioxane, the spectrum changed significantly. The combined EDOT and DDQ peak splits into separated peaks (around 264 nm and 290 nm, respectively), showing a further changing interaction with the solvent relative to MeCN. For higher wavelengths multiple peaks are visible with broad absorption bands centered around 500 and 682 nm which disappear upon the addition of EDOT. Sambhi reported the formation of charge transfer complexes of DDQ with the cyclic ethers 1,4-dioxane and THF which may account for such intense absorption peaks for this double ether [33].

For both solvents, the main peaks of EDOT and DDQ for short wavelengths were reasonably stable at this low concentration. The spectral characteristics differ between the solvents with regard to the interaction of DDQ and solvent as well as small temporal evolutions of the DDQ peaks upon the addition of EDOT. Definitive evidence for CT

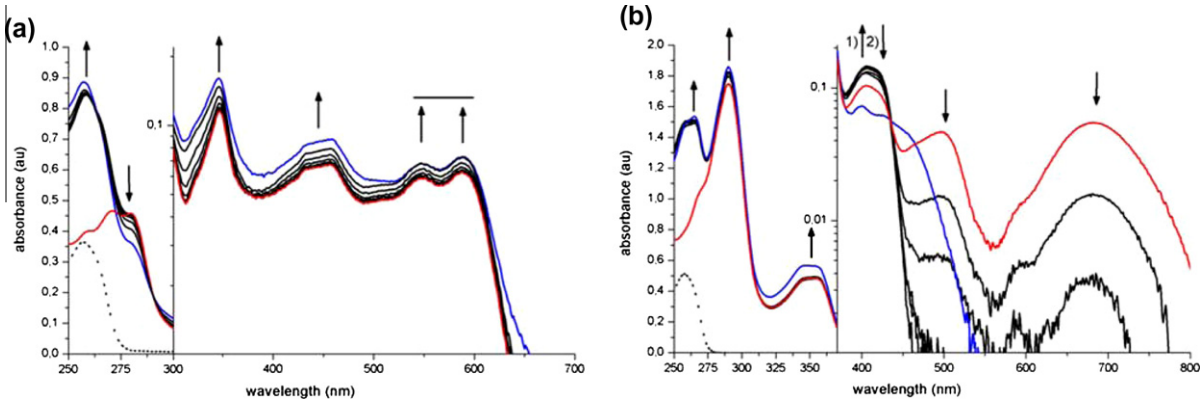


Fig. 2. UV–Vis absorption spectra, showing the temporal evolution of the solutions. Starting from 73 μM DDQ solutions (red) in aprotic solvents (a) MeCN and (b) 1,4-dioxane, the spectra begin to change upon the addition of 1 mol eq EDOT. The spectra were monitored for up to 2 h (black, several changing curves), and at 18 h post addition of EDOT (blue, last measurement). For comparison, the spectrum of 1 mol eq EDOT (dash) is given.(For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

formation in either case could not be produced from these experiments, but it is inferred that much more stable CT formation occurs in 1,4-dioxane.

4.2. Film transmission

After spin coating a standard film, it was immediately transported for transmission measurements (T_0 = 30 s after spin coating). The evolution of transmission during drying can be found in Fig. 3.

The intense blue color observed immediately after spin coating was assumed to be reduced PEDOT which absorbs around 600 nm [22]. This dip in transmission reduced over time as absorption increased in the IR which suggests the formation of oxidized PEDOT and likely, longer chains. For shorter wavelengths, the curve shows a higher transmission initially and then evolves toward the shape of the absorption spectra of EDOT:DDQ in 1,4-dioxane around 350 and 450 nm found in Fig. 2. This dip in transmission is thus attributed to DDQ, indicating that unreacted DDQ and its other forms remain in the film. Once the film is rinsed with MeCN, the sharp absorption of DDQ around 300 nm is significantly reduced (Fig. 4).

Fig. 4 depicts the change in transmission of films containing varied concentrations of EDOT while the ratio of EDOT:DDQ was held at 1:4/3 and the wt ratio of EDOT:PVAc at 1:1. Films that followed this formulation had a greenish tinge after drying and were very resistive. A dramatic shift in transmission was observed after gently rinsing the films with MeCN, where acetone produced similar results but DMSO ruined the films. The shift is attributed to further polymerization and oxidation of PEDOT monomer and oligomers, accelerated by MeCN, while rinsing away excess (un)reacted DDQ, monomer and PVAc. The difference in magnitude of transmission is attributed to different film thicknesses, formed by the varying amounts of EDOT available. The transmission curves suggest that by these concentration changes the mechanism is not altered or limited somehow, so the chemical composition and the formation mechanism is nearly uniform for all ratios.

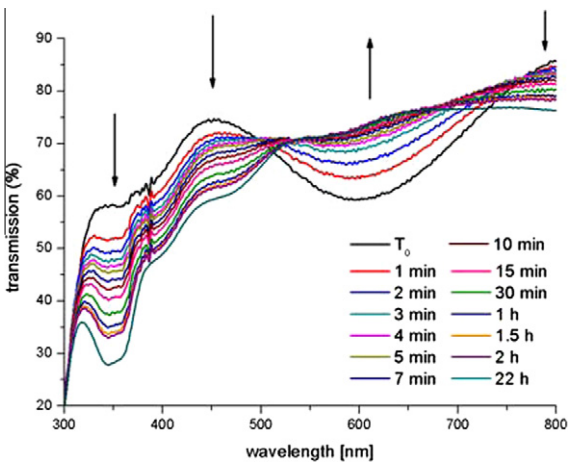

Fig. 3. Transmission measurements from the time evolution of drying a standard 0.14 M EDOT:DDQ film.

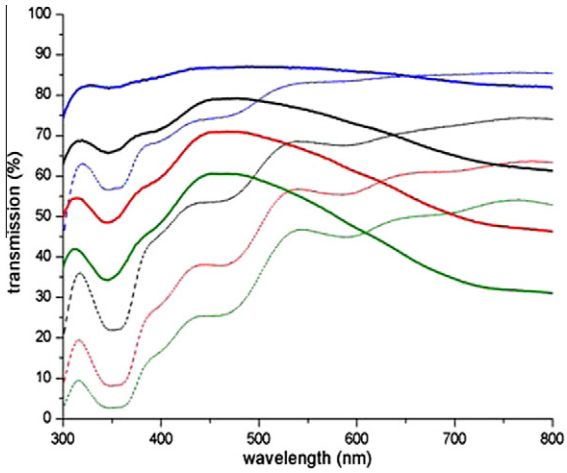

Fig. 4. Transmission spectra of EDOT:DDQ films at a ratio of 1:4/3 with an EDOT:PVAc wt ratio of 1:1. Before (dashed) and after rinsing (solid) with MeCN: 0.07 M EDOT (blue), 0.14 M EDOT (black), 0.21 M EDOT (red), 0.28 M EDOT (green) (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

This uncontrolled secondary polymerization and oxidation during rinsing is a very important step in obtaining a conductive film. For the remainder of this paper, rinsing with MeCN was considered complete when the green tinge was visibly rinsed away (2–3 rinses). It should be noted that further improvement of this step has great potential and should be investigated further. A smooth PVAc:PEDOT layer, present after rinsing, suggests that as the PEDOT forms it migrates toward the bottom of the film due to its insolubility in common solvents. Similarly, as the film dries, it appears that DDQ and $DDQH_2$ may rise to the top with the evaporating solvent.

For films that were rinsed too hard with MeCN, the film peeled off of the glass surface but did not dissolve, maintaining film structure integrity. When water was added to the film surface, droplets condensed and ran off; contact angle measurements were not taken. It appears that the film material takes on the hydrophobic nature of PVAc while simultaneously taking on the insoluble nature of PEDOT. Such properties could be attractive when engineering mechanically robust, conductive plastics like those achieved by Hansen et al. by dissolving PEDOT:tos into a PMMA substrate [12].

4.3. Concentration effects

The effects of varying the EDOT:DDQ mol ratio, EDOT concentration, and the EDOT:PVAc wt ratio on film formation and on electronic properties were investigated. As can be expected, the films were much more resistive when one molar equivalent or less of DDQ was used, where excess oxidant is needed to dope the PEDOT (Table 1). Increasing the DDQ concentration to and above stoichiometric ratios produced an increase in film thickness and eventually a wavy surface morphology. Comparing ratios of 1:5/3 and 1:2, a decrease in sheet resistance concomitant with slightly higher transparency was observed which is contrary to the trend up to that point. An EDOT:DDQ ratio of 1:4/3 was chosen as the standard film for reproducibility.

Increasing the overall concentration of a standard film produced an increase in film thickness and a decrease in transmission (Table 2). The highest conductivity in this series was achieved with the standard film recipe. It appears that the act of rinsing with MeCN both polymerizes and oxidizes PEDOT while the rigid PEDOT structure continues to lock in PVAc as observed by the increase in film thickness in Table 2. There are slight differences in the values for the two standard films (separate solutions) in Tables 1 and 2. However, considering the non-standardized rinsing of the films, these values are remarkably similar.

Varying the amount of PVAc in a standard film did not produce a trend in film thickness, where the most transparent and conductive film was at a wt ratio of 1:5/4 (Table 3). This supports the idea that the PEDOT chains migrate to the bottom of the "wet" film as they form. The supporting polymer matrix species will likely impact many aspects of the film quality for its role may include aiding in both templating chain growth as well as in providing structural stability for the film itself.

4.4. Conductive AFM

Fig. 5 compares conductive AFM images of a standard PEDOT:DDQ film and a PEDOT:PSS film with 5% vol EG deposited on glass. Both layers are not treated further before measurement, so the surface depicted is as it was after several hours of exposure to atmosphere.

For both samples, the current appears to be centered on the grains. For PEDOT:PSS, the grain size can be adjusted by changing solvent concentration, where the size depicted in Fig. 5 is representative of PEDOT:PSS at approximately 750 S/cm [8,34]. Measuring local conductivity, both samples behaved quite differently. While the PEDOT:DDQ sample showed high currents at low bias

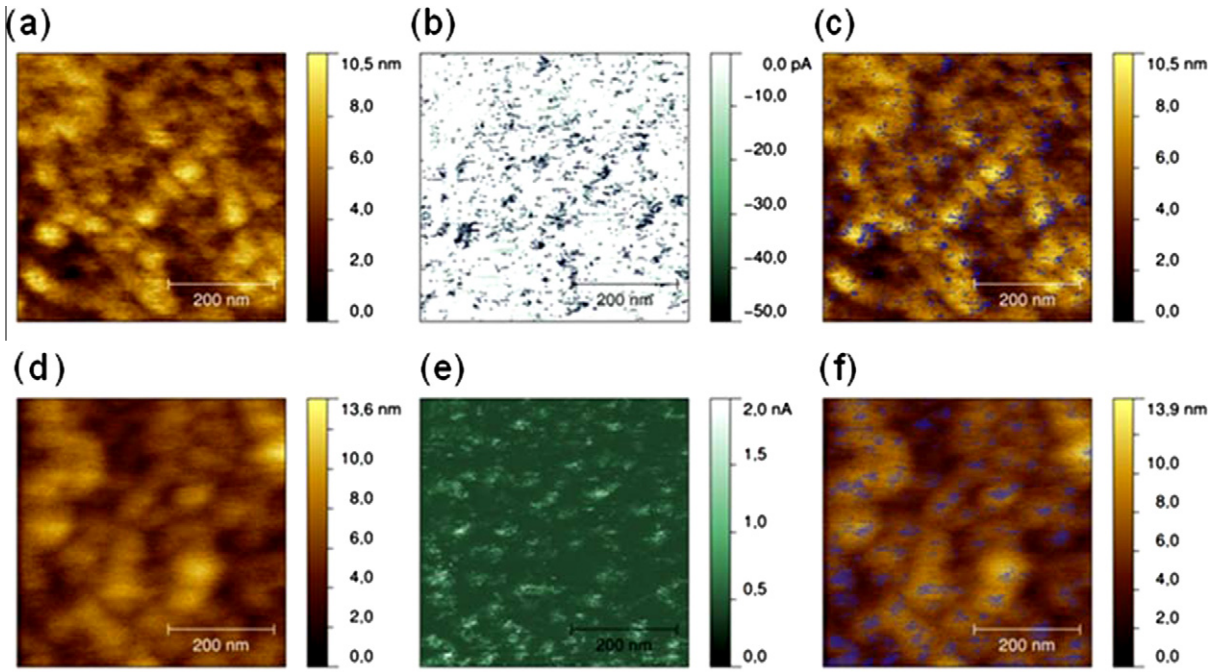

Fig. 5. Conductive AFM for standard (a–c) PEDOT:PSS and (d–f) PEDOT:DDQ. Tip bias was −2.1 V for PEDOT:PSS and 10 mV for PEDOT:DDQ. Images (c) and (f) are overlays of the subsequent images at certain current thresholds.

voltages, measuring currents on PEDOT:PSS required a relatively high bias voltage that was orders of magnitude higher than that of PEDOT:DDQ and which resulted in surface currents orders of magnitude lower. Thus, we believe there is a less conductive, PSS-rich phase present on the PEDOT:PSS surface which is in agreement with literature [35,36]. In combination with exposure to atmosphere, this results in an insulating top layer, causing poor contact properties. Such a surface layer is apparently not present on the PEDOT:DDQ film initially, resulting in significantly better contact properties. This difference in contact resistance was observed macroscopically when liquid metal was not needed to assist in sheet resistance measurements with a 4-point probe for PEDOT:DDQ while it was needed for macroscopically more conductive PEDOT:PSS.

4.5. UPS

To determine the work function (WF) and to further characterize the material, XPS and UPS measurements were performed. UP spectra of a standard PEDOT:DDQ film gave a work function of 4.62 eV. This rather low value compared to earlier measurements of 5.05 eV for PEDOT:PSS shows a significant shift of the work function due to a change of counteranion and suggests that DDQ is a weaker dopant [10,37]. However, both layers show similar intensities of occupied states near the Fermi level. Further, when comparing reported values for VPP PEDOT:tos of 4.3 ± 1 eV by UPS [38], the WF value is greater for PEDOT:DDQ. As the counterion of PSS and tosylate are identical, the surrounding chemical environment of a conductive polymer can also influence the WF which can be easily altered for PEDOT:DDQ (i.e. polymer matrix).

XPS was performed to compare PEDOT:DDQ to PEDOT:PSS. Unfortunately, our PEDOT:DDQ layers contain a rather large amount of PVAc with similar elemental and chemical structures, thus obscuring the signal. Nevertheless, some conclusions could be drawn (see Appendix A). Doping of PEDOT by DDQ was concluded, and a shift in surface chemistry toward a less PEDOT-rich top layer was observed over time.

5. Conclusion

Thin conductive films of PEDOT:DDQ were synthesized by delaying polymerization in ethereal solvents with low dielectric constants. The resulting smooth films produced by spin coating from 1,4-dioxane with PVAc as a stable, templating polymer and by rinsing with MeCN showed good structural integrity with decent conductivity and transparency. The feasibility of this approach has been proven, and a basic process has been established. Following our recipe, a film with a conductivity of 17 S/cm at 33 nm thick with 86.6% transmission at 550 nm was achieved. According to our observations, the processing solutions were sufficiently stable depending on solvent polarity, where significant polymerization is triggered by solvent evaporation in the spin-coated film. The as-coated layers still contained significant amounts of DDQ and partially reacted species, which can be reacted further by rinsing with MeCN which simultaneously removes by-products and enhances the degree of polymerization.

We are confident that the thin film properties can be improved further by optimizing many parameters such as the polymer matrix/template, solvents (and ratios), and the rinsing procedure or by changing the monomer. There is more potential for further exploration of this procedure due to its inherent versatility, where this system could rival that of the reference PEDOT:PSS. The attractive properties of this film formulation include: lower acidity relative to PSS, hydrophobic properties and structural support of the polymer additive, and a lower contact resistance relative to PEDOT:PSS. We believe PEDOT:DDQ has potential for many applications such as a hole transport layer or as a transparent electrode (e.g. in organic solar cells or other optoelectronic devices) and should be explored further.

Acknowledgments

The authors thank Olaf Hild and John Hofferberth for useful discussions and suggestions, H.C. Starck for supplying samples of Baytron PH 1000, Yong Hyun Kim and Christoph Sachse for support, and Christian May for supporting the DIZEeff. M. Machala thanks the German Federal Foreign Office for providing this experience through a Transatlantic Renewable Energy Fellowship and Dana C. Olson for suggesting this placement. This work was funded by the European Union (EFRE), the Free State of Saxony and the Fraunhofer Gesellschaft as part of the Dresdner Innovationszentrum für Energieeffizienz.

Appendix A

XPS spectra for the S(2p) signal of PEDOT:DDQ and PEDOT:PSS can be found in Fig. A1.

In both samples, the peak originating from PEDOT is at the same position within experimental error at 163.77 eV for PEDOT:DDQ and at 163.79 eV for PEDOT:PSS. For PEDOT:DDQ, a small subpeak – likely a positively charged sulfur atom – is visible. Whether this peak is present for PEDOT:PSS is unclear, since it might be hidden in the signal originating from the PSS peak. The positions of the S(2p) peak confirms the successful polymerization of EDOT and subsequent oxidation.

For a freshly prepared sample and after 2 days in ultra-high vacuum, the S(2s) signal, attributed to PEDOT and the Cl(2p) signal, attributed to DDQ, were recorded by XPS. The signal intensity for the S(2s) peak decreased by a factor of 2.4 while that of the Cl(2p) peak increases by a factor of 1.5 (Fig. A2).

From the relative peak intensities, the ratios between the different polymers/molecules in the upper few nanometers of the film can be estimated. The PEDOT:DDQ ratio was estimated by comparing Cl(2p) and S(2p) peak intensities. The values for PEDOT:PVAc and PVAc:DDQ are more error prone since the oxygen peak that is used for the calculation is present in PVAc as well as in DDQ and PEDOT. For PEDOT:PVAc, the S(2s) and O(1s) signals were

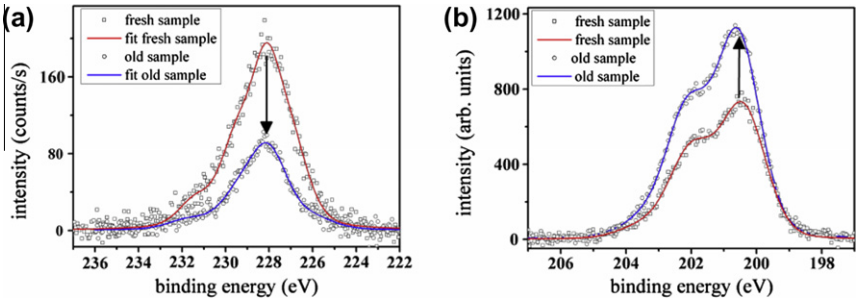

Fig. A2. XPS signals for a) S(2s) and b) Cl(2p) peaks in PEDOT:DDQ for a fresh sample and the same sample stored in ultra-high vacuum for 2 days.

Table A1
An estimation of ratios of various chemical species in PEDOT:DDQ films by XPS.

	PEDOT:DDQ	PEDOT:PVAc	PVAc:DDQ
Fresh sample	1.0	0.3	0.3
2-Day-old sample	0.3	0.1	0.3

compared whereby the O signal originating from PEDOT and DDQ was subtracted to get the fraction originating from PVAc. For PVAc:DDQ, the O(1s) and Cl(2p) signals were compared, and again the O signals from PEDOT and DDQ were subtracted Table A1.

In the older sample left in the vacuum chamber, the surface is essentially depleted of PEDOT which is not necessarily a bulk effect. This change on the surface indicates that diffusion and segregation may still be taking place, which could be controlled for improved performance. These results suggest that an investigation on long-term stability should be undertaken.

a high-k dielectric limits the insulating ability. Therefore, a metal oxide dielectric is suitable for low voltage OTFT application if the traps are passivated and the leakage current is reduced.

In this work, we demonstrated a bilayer dielectric structure consisting of random copolymer grafted room temperature sputtered metal oxide for an OTFT. The poly (styrene-co-methyl methacrylate) (PS-r-PMMA) random copolymer and hafnium oxide (HfO_x) were used as dielectrics. The PS-r-PMMA is a thoroughly studied material as a grafting layer for the template used in nanostructure patterning [17,18]. The thickness of PS-r-PMMA depends on the annealing conditions. The higher the temperature that is applied, the thicker the film that can be obtained [10,11]. For surface modification, a self-assembled monolayer (SAM) is commonly used in organic thin film transistors. The thickness of a SAM mainly depends on its chain length. Using the SAM layer usually obtains favorable device behavior. However, applying the monolayer structure in the large printing process is assumed to be difficult. Any region with few un-attached SAMs will cause the TFT to fail. Instead, long chain polymers form an "amorphous" random structure after grafting on the substrate. The substrate surface was completely covered by randomly crossover polymer chains. Consequently, the amounts of attached polymers may only affect the thickness of the dielectric with more effective process controllability. In the case of PS-r-PMMA, the film thickness of approximately several nanometers can be achieved through the temperature annealing process. The polymers that could graft on hydroxyl surface to passivate the hydroxyl surface may apply as well as PS-r-PMMA in this work. Owing to the only nanometer-thick polymer layer, the low voltage behavior of an OTFT with a high dielectric constant HfO_x could be retained.

2. Experimental

Fig. 1(a) illustrates the structure of the bottom gate and top contact OTFT used in this study. A heavily doped silicon wafer was utilized as the gate electrode. After the wafer was cleaned, an 80-nm-thick HfO_x dielectric was deposited by RF sputtering at room temperature. The HfO_x surface was then treated by O_2 plasma. The PS-r-PMMA random copolymer was dissolved in toluene with a concentration of 20 mg/ml. The PS-r-PMMA was then spin-coated on the HfO_x and heated by a hotplate in an N_2-filled glove box at 170 °C for 24 h. The chemical structure for PS-r-PMMA is shown in Fig. 1(b). High temperature annealing ensures that the PS-r-PMMA chains obtain sufficient energy to diffuse and end graft to the HfO_x surface by a condensation process [11]. After the heating process, the sample was rinsed with toluene to remove un-attached PS-r-PMMA chains, obtaining a desired thickness of PS-r-PMMA film (approximately 10 nm). The attachment of PS-r-PMMA is schematically shown in Fig. 1(c). For the organic channel layer, the pentacene was deposited by a thermal evaporator embedded in a glove box at a base pressure of 2×10^{-6} torr without substrate heating. The glove box is N_2-filled to avoid the oxygen and moisture effects on the organic semiconductor. The pentacene deposition rate was maintained at 0.1–0.2 nm/s to 40 nm thick. Finally, through a shadow mask, the gold source/drain electrodes with 30-nm-thick were deposited and defined, forming the ohmic contact between the active layer and source/drain regions. The OTFT channel length (L) and channel width (W) were 100 and 1000 μm, respectively. The pentacene for the OTFT was grown in the glove box, and the fabricated OTFTs were measured immediately after S/D formation. Additionally, the organic TFT is in a bottom gate structure, the dominant region for carrier transport is closed to the dielectric. Consequently, the additional donor-like or acceptor-like traps generated by the exposure of the OTFT to the environment are neglected.

3. Results and discussion

The transfer and output current–voltage (I–V) characteristics of the OTFT were measured by an HP 4145A

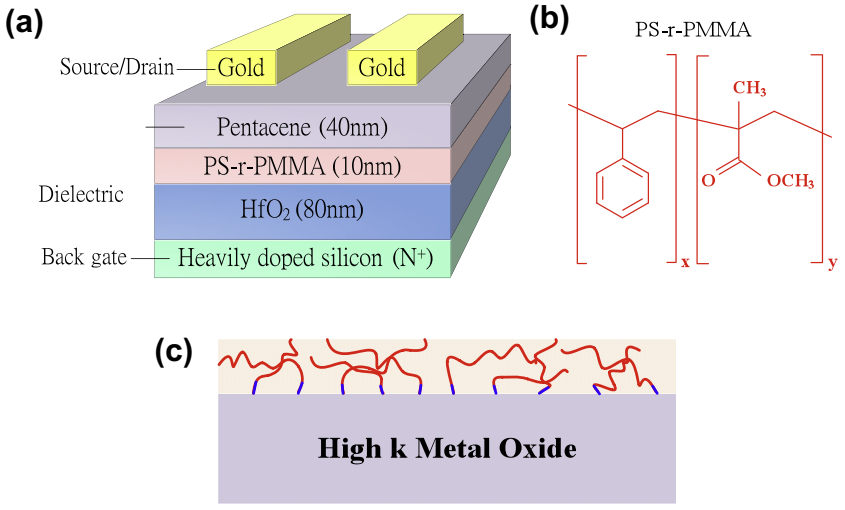

Fig. 1. (a) A schematic of the low voltage pentacene OTFT with PS-r-PMMA/HfO_x bi-layer dielectric. (b) Chemical structure of PS-r-PMMA and (c) the schematic arrangement of PS-r-PMMA on top of high k metal oxide.

semiconductor analyzer. All electrical characterizations were measured in ambient air immediately after the OTFT were made. Fig. 2(a) and (b) shows the transfer curves of pentacene-based OTFTs in which the HfO_x and PS-r-PMMA/HfO_x were each used as gate dielectrics. Details of electrical properties of a pentacene-based OTFT with PS-r-PMMA/HfO_x dielectrics and single HfO_x are listed in Table 1. The threshold voltage, subthreshold swing, and on/off current ratio (I_{on}/I_{off}) were each −1 V, 1.01 V/dec. and 10^3 for OTFT with HfO_x gate dielectrics. The equation of the drain current at the saturation regime for the Si-based MOSFET was usually used to describe the current behavior of an organic thin film transistor. The equation is expressed as follows:

$$I_d = \frac{WC_i\mu}{2L}(V_g - V_t)^2 \quad (1)$$

in which I_d is the drain current, W is the gate width, L is the gate length, C_i is the capacitance density, μ is the channel mobility, V_g is the gate voltage, and V_t is the threshold voltage. The mobility extracted from the saturation regime was 0.22 cm^2/V s. By grafting PS-r-PMMA onto the HfO_x, the off current was decreased to approximately two orders of magnitude from 10^{-9} to 10^{-11} A. Consequently, the I_{on}/I_{off} ratio was much improved to approximately 10^5 due to the leakage current reduction. In addition, the subthreshold behavior was also improved from 1.01 to 0.41 V/dec. The subthreshold swing (SS) indicates the ability of a TFT to switch from the off state to the on state. The improved SS may be due to the screening effect of PS-r-PMMA on the polarity of the HfO_x surface. The polar dielectric interface may broaden the distribution of density of states (DOS) [2]. The nonpolar PS-r-PMMA screens the dipoles of the HfO_x surface, usually leading to semiconductor/insulator interface improvement and concentrating the DOS distribution. The channel carriers can be accumulated at a small applied voltage. The improved interface may suggest higher mobility because of less interface scattering. However, the saturation mobility was not improved extensively in this work. For the TFT manufactured with different gate dielectrics, V_t might be different. Fig. 2(c) shows the output characteristics of OTFTs with the same

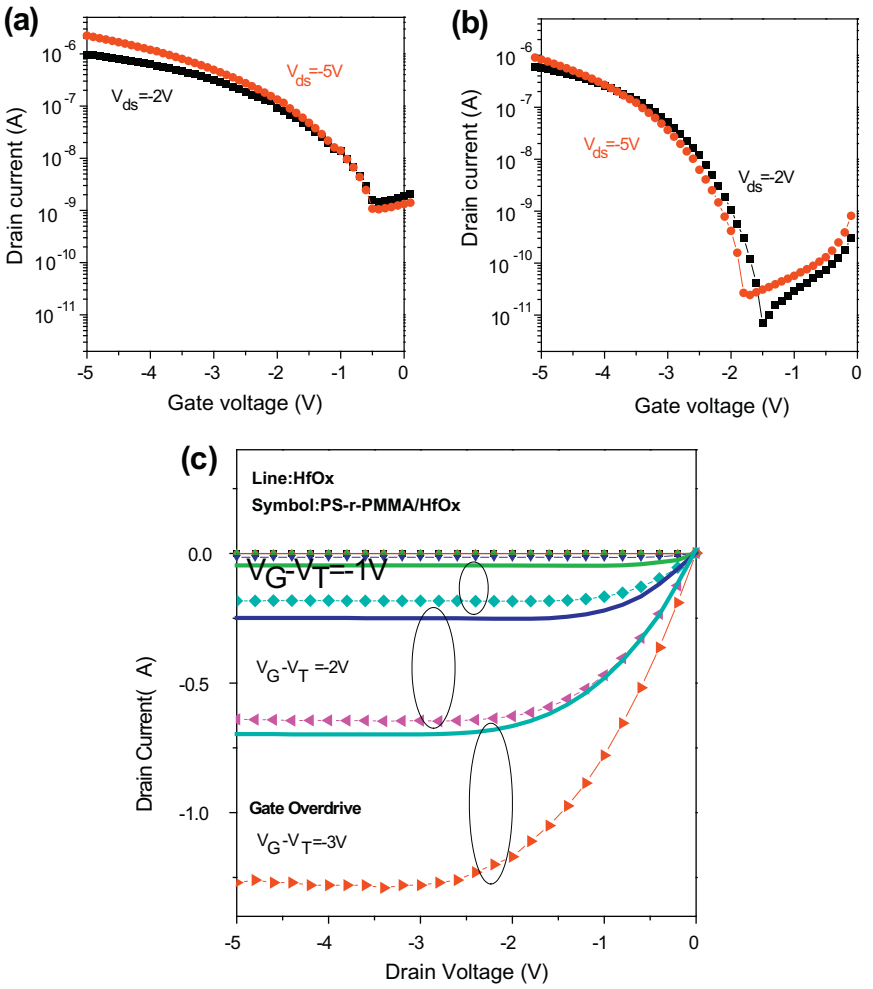

Fig. 2. Transfer curves of OTFT with (a) HfO_x and (b) PS-r-PMMA/HfO_x gate dielectrics and (c) output characteristics of OTFTs with the same gate overdrive. The gate overdrive means gate to source (V_{gs}) voltage in excess of the threshold voltage (V_t). It is the effective gate voltage applied in the TFT after threshold.

gate overdrive, V_g–V_t, to emphasize the gate controllability of the drain current for TFTs after threshold voltage. With higher mobility, higher I_{on}/I_{off}, and smaller SS, the output current for an OTFT with a PS-r-PMMA/HfO_x gate dielectric was largely increased. Furthermore, the OTFT (W/L = 500 μm/100 μm) with low PS-r-PMMA formation temperature, 130 °C, is also carried out to make sure the compatibility with the general plastic substrate. Fig. 3 shows the output curve and transfer curve based on PS-r-PMMA/HfO_x at process temperature of 130 °C for 24 h. The current–voltage characteristics are similar to the OTFT with high temperature fabricated PS-r-PMMA as gate dielectric. The OTFT has the performance with the threshold voltage of −1.5 V, the mobility of 0.19 cm^2/V s, subthreshold swing of 0.24 V/dec., and I_{on}/I_{off} of 10^5, respectively.

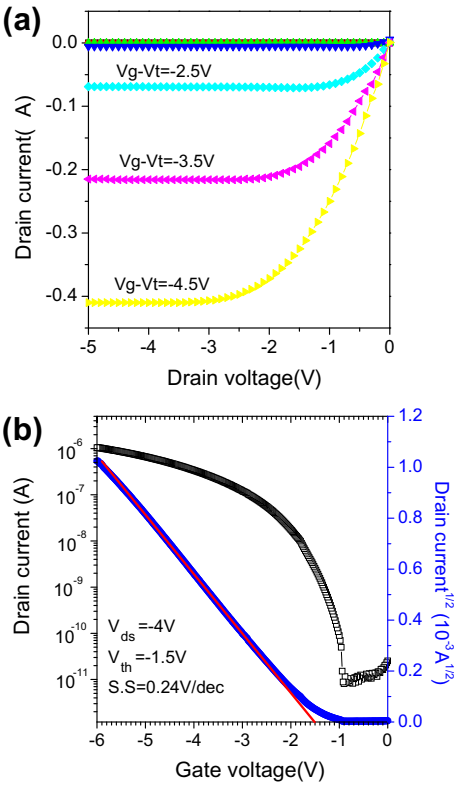

Fig. 3. Characteristics of OTFT with PS-r-PMMA/HfO_x, PS-r-PMMA layer was fabricated at 130 °C. (a) Output characteristics, (b) transfer characteristics.

To investigate the interface property, the capacitance–voltage (C–V) characteristic on an n$^+$-silicon/dielectrics/pentacene (MIS) structure was measured by an Agilent E4980A impedance analyzer at 1 MHz. The normalized capacitance for HfO_x and PS-r-PMMA/HfO_x dielectrics are shown in Fig. 4.

The transition from accumulation to depletion ranged from −2 to 1 V for the capacitor with a PS-r-PMMA/HfO_x dielectric. By contrast, the transition from accumulation to depletion for the HfO_x dielectric is much slower, ranging from −2 V to more than 5 V. The tardy transition is attributed to both the donor-like and acceptor-like states at pentacene/HfO_x interfaces that are occupied by holes in the accumulation region and electrons in the depletion region. During the voltage transition from negative to positive (accumulation to depletion), the trapped holes in the donor-like states escape gradually and contribute to the delay. Regarding the depletion behavior, electrons first fill the acceptor-like states provided by the hydroxyl groups and lead to slower transition of capacitance. Therefore, the rapid transition of an OTFT with PS-r-PMMA/HfOx dielectrics is regarded as a less interface state.The maximum interface state density, N_s, is approximated by the following equation [12]:

$$N_s = \left[\frac{SS}{\ln 10}\cdot\frac{q}{kT} - 1\right]\frac{C_i}{q} \quad (2)$$

in which the k is the Boltzmann constant, T is the absolute temperature, and C_i is the unit area capacitance. Based on this equation, the N_s for the HfO_x gate dielectric is

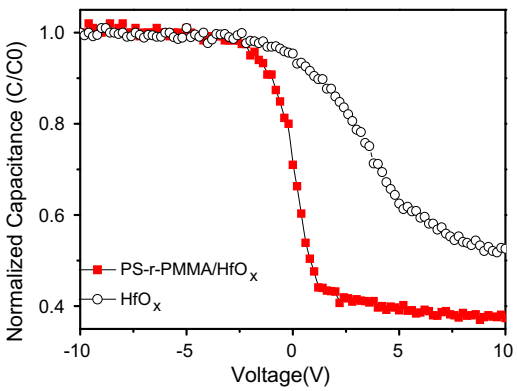

Fig. 4. Capacitance–voltage characteristics of metal/dielectrics/pentacene capacitors at 1 MHz.

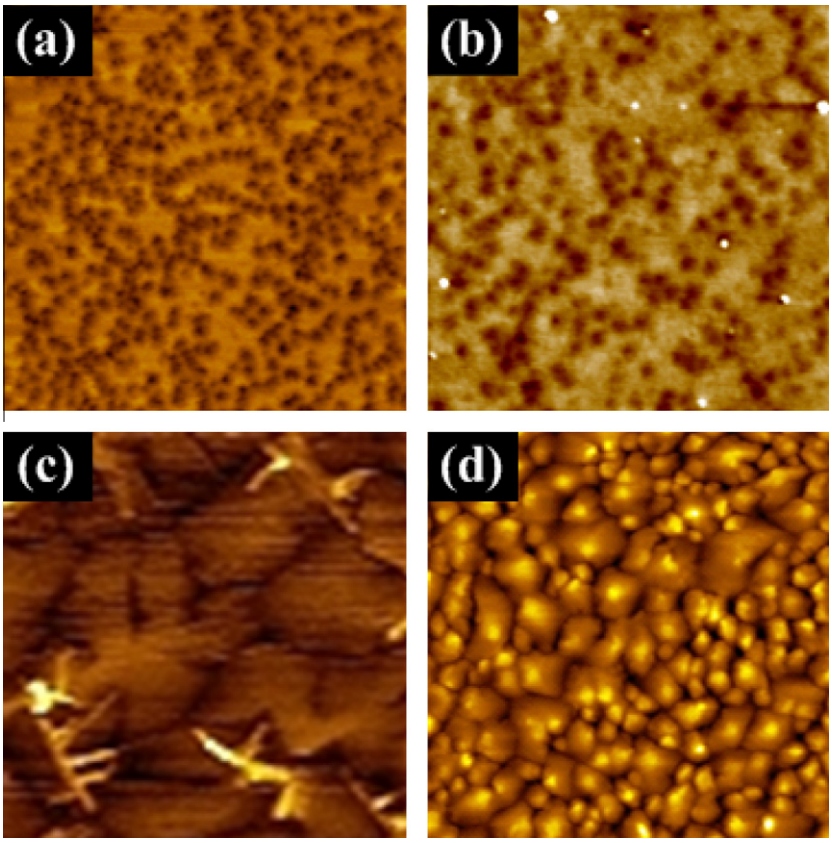

Fig. 5. AFM images of dielectrics (a) HfO_x ($2 \times 2\ \mu m^2$) (b) PS-r-PMMA/HfO_x ($2 \times 2\ \mu m^2$) and 40-nm-thick pentacene evaporated on (c) HfO_x dielectric ($3 \times 3\ \mu m^2$) (d) PS-r-PMMA/HfO_x bilayer dielectrics ($3 \times 3\ \mu m^2$).

approximately $1.65 \times 10^{13}\ cm^{-2}$. By applying a layer of PS-r-PMMA, the interface state density decreases to approximately $4.15 \times 10^{12}\ cm^{-2}$, nearly a one order magnitude of reduction.

By further investigating the leakage current reduction in the PS-r-PMMA/HfO_x dielectrics structure, the morphology of HfO_x and PS-r-PMMA/HfO_x were studied by atomic force microscopy (AFM), as shown in Fig. 5(a) and (b), respectively. For the HfO_x surface, a high density of observed pinhole-like cavities ($1.27 \times 10^6/cm^2$) caused an unsmooth dielectric surface with ~3 nm root mean square (RMS) roughness. After grafting the PS-r-PMMA layer, some pinhole-like cavities on the HfO_x surface were shielded and the density was reduced to $4.5 \times 10^5/cm^2$. The RMS roughness was decreased to ~2 nm. The application of the PS-r-PMMA layer could make the HfO_x surface smoother and partially filled the pinhole-like cavities. Therefore, the leakage current was suppressed as observed in the electrical analysis. For the organic semiconductor morphology observation, the AFM images of pentacene evaporated on the HfO_x and PS-r-PMMA/HfO_x dielectrics, as shown in Fig. 5(c) and (d), respectively. The grain size of approximately 300 nm of pentacene grown on the PS-r-PMMA is observed in Fig. 5(d). Conversely, the pentacene growth on the HfO_x results in a larger grain (~1 μm) with a dendrite structure. The grain size of pentacene on the PS-r-PMMA/HfO_x is much smaller than on the HfO_x. Due to the saturation mobility is similar for these two OTFTs. The grain size of pentacene on different dielectrics seems not strongly related to the saturation mobility in this work.

4. Conclusions

To summarize, we have demonstrated a low voltage OTFT based on PS-r-PMMA/HfO_x dielectrics. By stacking PS-r-PMMA on an HfO_x dielectric, the semiconductor/insulator interface was significantly improved. The leakage current and subthreshold swing were decreased. The OTFT with such low-*k*/high-*k* stack dielectrics can operate well below 5 V, with a sufficient on/off current ratio of 10^5, a subthreshold swing of 0.41 V/dec., and a mobility of $0.28\ cm^2/V\ s$.

selected materials for devices. For our VS-CTFT inverter for logic and photo-gating, we used a thermally-evaporated p-channel pentacene layer, sputter-deposited n-channel GaZnSn-based oxide (GZTO), and atomic layer deposited (ALD) Al_2O_3 dielectric. As a more advanced hybrid approach, we also adopted a ferroelectric poly(vinylidene fluoride/trifluoroethylene) [P(VDF–TrFE)] layer for a CTFT nonvolatile memory inverter with a pentacene memory TFT which is vertically stacked on a top-gate GZTO TFT but sharing the Al gate electrode with the n-channel TFT. Our VS-CTFT inverter nicely displays effective photo- and electrical-gating with a high voltage gain, dynamically operating in the low-voltage regime of 3, 5, and 8 V (the thin pentacene channel receives blue photons), and the ferroelectric memory inverter as an ultimate hybrid device form demonstrates promising retention properties that are triggered by ±20 V gate pulses.

2. Experimental

2.1. Vertically stacked CTFT inverter Fabrication

Vertically stacked complementary TFT (VS-CTFT) inverters were fabricated on glass substrates (Corning, Eagle 2000). Substrate was cleaned with acetone, methanol, and de-ionized water, in that order. Aluminum (Al) source/drain (S/D) electrodes were deposited by thermal evaporation. Then a 60 nm thick GaZnSnO (GZTO) channel layer was formed by co-sputtering of a Ga-doped ZnO (Ga_2O_3 5.7 wt%) and a SnO_2 target with rf power of 110 and 40 W, respectively. The sputtering was performed in a working pressure of 5 mtorr with flowing Ar and O_2 mixed (5%) gas and the deposition temperature was maintained at 100 °C (The fraction of Sn in cationic elements of the prepared GZTO film was about 32 at.%). The GZTO layer was patterned through a shadow mask for patterning ($500 \times 500\ \mu m^2$). The nominal channel length (L) was 90 μm and the width (W) was 500 μm. As a dielectric, 40 nm-thick Al_2O_3 layers were deposited by atomic layer deposition (ALD; ForAll Co., Ozone100A) at a temperature of 200 °C. Then Al top gate electrodes were then deposited by thermal evaporation. (Fig. S1a and S1b shows the dielectric properties of our ALD Al_2O_3 layer.) By now, a half of VS-CTFT inverter process was completed. As the next half, bottom-gate p-channel TFT process was proceeded. As a gate dielectric, another 40 nm-thick Al_2O_3 layer was deposited on Al gate of GZTO-TFT by ALD with the same condition taken for the first half process. The dielectric layers were patterned by photolithography and wet etching (by 50× diluted 20:1 buffered HF) to open the S/D electrodes of GZTO-TFT. Pentacene (Aldrich Chem. Co., 99% purity, no other distillation) active channel layer was then patterned on the Al_2O_3 dielectric through a shadow mask at room temperature (RT) by thermal evaporation. Deposition rate was fixed to 1 Å/s using an effusion cell (ALPHA-PLUS Co., LTE-500S) in a vacuum chamber (base pressure of $\sim 1 \times 10^{-7}$ torr). The thickness of pentacene films was 50 nm as monitored by a quartz crystal oscillator and confirmed by ellipsometry. Au pads were finally deposited as S/D electrodes by thermal evaporation in a vacuum chamber; Au source contacted Al drain of n-TFT.

2.2. Vertically stacked CTFT memory inverter Fabrication

The first half process was the same as that of the top-gate GZTO-TFT with Al_2O_3. But then, for the next half process to realize a VS-CTFT memory inverter, 200 nm-thick films of P(VDF/TrFE) 75/25 mol% copolymer were coated on the GZTO-TFT by spin casting 6 wt% cyclohexanone solutions. The P(VDF/TrFE) polymer films were cured at 160 °C for 2 h in a vacuum oven and then subsequently quenched to the RT by blowing N_2 gas (99.9% purity). In order to open the S/D Al of GZTO-TFT, we utilized lithography and O_2 plasma to sequentially etch away P(VDF–TrFE) polymer ferroelectric and Al_2O_3 dielectric. Pentacene and Au S/D evaporation were then followed as in the same way stated above in VS-CTFT inverter process.

2.3. Characterization

After confirming the electrical isolation between top and bottom TFT devices, the electrical properties of n- and p-channel TFTs were separately measured. The dielectric strength of our 40 nm thick Al_2O_3 gate dielectric and all electrical characteristics of our vertically stacked CTFT inverters, CTFT memory inverters, unit GZTO TFT and unit pentacene TFT were measured with a semiconductor parameter analyzer (HP4155C, Agilent Technologies). The capacitance–voltage (C–V) measurements at 1 MHz were performed for our dielectric with an LCR meter (HP 4284, Agilent Technologies). Dynamic gating in VS-CTFT inverter was measured using pulse generator (AFG3022B, Tektronix) and oscilloscope (TDS2014, Tektronix). Additional gating effects such as photo-gating were obtained or measured by using red (λ = 650 nm), green (540 nm), and blue (440 nm) LEDs with an optical power of ~2 mW (irradiance ~0.2 mW/cm^2). Glancing incidence XRD analysis in the 2θ mode was carried out to characterize the crystallinity of the GZTO films: the as-grown and the annealed at 200 °C for 1 h (which corresponds to the heating condition during the subsequent ALD process).

3. Results and discussion

3.1. Device schemes

Fig. 1a and b displays the schematic cross section and photographic plan views of our VS-CTFT inverter that has pentacene- and amorphous GZTO-TFTs sharing the ALD Al_2O_3 layers for bottom- and top-dielectrics, respectively, while Fig. 1c shows the photo-gating experiment using a blue light as a probe. Our GZTO film was deposited by sputtering at 100 °C and exhibited an almost amorphous phase with few crystalline peaks according to X-ray diffraction spectra as shown in Fig. S2a. Our GZTO-TFT, which went through a 200 °C ALD process for the dielectric, displayed good device performances as shown in its output and transfer curves of Fig. S2b and S2c, respectively. The ALD temperature might cause a little bit of crystallization of amorphous GZTO (Fig. S1a), but according to the transfer curves of Fig. S1c the interface between GZTO channel and Al_2O_3 dielectric is still very stable causing only minimal electrical hysteresis. The saturation mobility (μ_{sat})

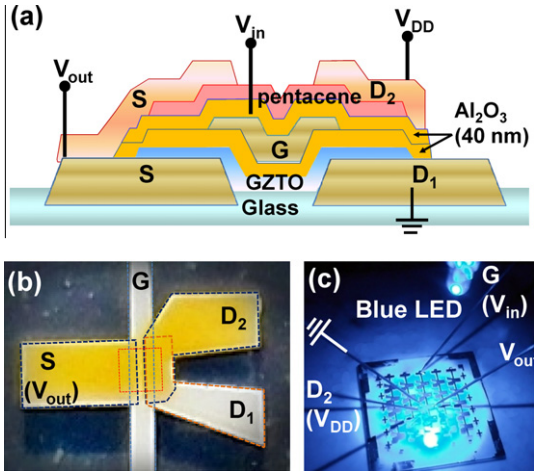

Fig. 1. (a) The schematic cross section and (b) photographic plan views of our VS-CTFT inverter that contains pentacene- and amorphous GZTO-channel TFTs using the same ALD Al_2O_3 layers for bottom- and top-dielectrics, respectively. (c) Photographic view of photo-gating experiment employing a blue light as a probe (440 nm). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

was $\sim$1.2 $cm^2\,V^{-1}\,s^{-1}$ for the top-gate TFT. (The mobility was 8.2 $cm^2\,V^{-1}\,s^{-1}$ for bottom-gate TFTs. This electron mobility difference between top- and bottom-gate configurations are addressed elsewhere, being considered to come from different channel geometries [15].)

3.2. Electrical gating of our VS-CTFT

According to the drain current–gate voltage (I_D–V_G) transfer curves of Fig. 2a, the curves from our bottom-gate pentacene- and top-gate GZTO-TFTs are quite symmetrical at their common threshold voltage (V_T) point of −0.4 V and show the maximum I_Ds of $\sim$1.5 and $\sim$4 μA at a drain voltage (V_D) of 5 V, respectively (pentacene-TFT has its saturation mobility of 0.4 $cm^2\,V^{-1}\,s^{-1}$). Pentacene-TFT showed some gate-hysteresis due to the electrons trapped by the OH groups on polar Al_2O_3 surface as the hysteresis direction indicates [16]. As a result of the symmetrical transfer curves, the voltage transfer characteristics (VTC) of our VS-CTFT inverter were nicely obtained with relatively high voltage gains of 20, 25, and 52 under respective supply voltages (V_{DD}) of 3, 5, and 8 V, as shown in Fig. 2b. (Inset shows a circuit diagram of the VS-CTFT inverter). Our CTFT inverter also dynamically operates, displaying a response time of 5–40 ms under 5 V input pulses; 5 ms rising and 40 ms falling times were recorded due to the different RC delays during p-channel and n-channel charging. (Fig. 2c and d) We actually fabricated another identical VS-CTFT inverter but with n-channel ZnO instead of amorphous GZTO, to confirm that our VS-CTFT inverter structure stably operates along with a high fabrication yield. (See Fig. S3a and S3b.) Our VS-CTFT inverter yield was over 50% either with ZnO- or with GZTO-channel, and the yield is far above that from planar CTFT inverters (less than 30%, in our experience, Ref. [8]).

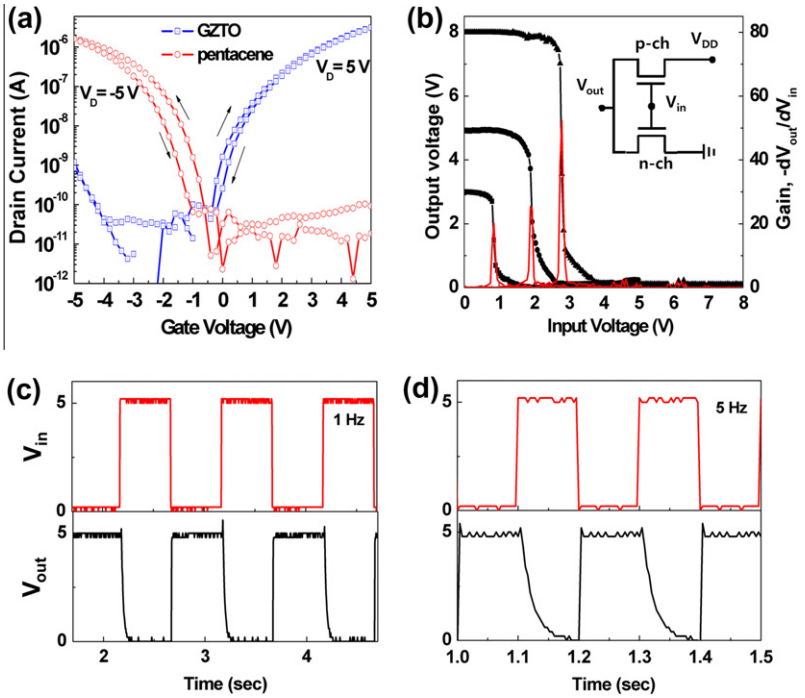

Fig. 2. (a) The drain current–gate voltage (I_D–V_G) transfer curves and b) the voltage transfer characteristics (VTC) of our VS-CTFT inverters under respective supply voltages (V_{DD}) of 3, 5, and 8 V. The curves from pentacene- and GZTO-TFTs are quite symmetrical. Inset of (b) shows a circuit diagram of the VS-CTFT inverter. Dynamic operating of our device under 5 V input pulses (c) at 1 Hz and (d) 5 Hz, respectively.

3.3. Photo-gating of VS-CTFT

Photo-gating was also implemented with our inverter since our device only exposes the pentacene-TFT on top so that the p-channel TFT may conveniently receive visible photons to collect photo-excited electrons and holes in a charge depletion state. According to the light-illuminated VTC curves of our device in Fig. 3a, the device only reacted with blue light when red, green, and blue lights were illuminated on our VS-CTFT inverter, although the highest occupied molecular orbital-lowest unoccupied molecular orbital (HOMO–LUMO) gap of solid crystalline pentacene is near 1.9 eV (which matches with red, but actual energy gap is 1.97 eV considering exciton binding energy) [17]. This photo-stability is possible with our pentacene channel layer as thin as only 50 nm. Similar results of pentacene TFT showing a weak photo-detection only on blue illumination were reported previously [8]. The dynamic photo-gating was successfully obtained near the transition voltage region (2 V) with monochromatic blue light. (For this operation our light-emitting-diode (LED) with 440 nm wavelength was pulsed at 5 V, to be periodically turned on). According to the time domain plot of Fig. 3b, the output voltage (V_{out}) in the light was clear enough to be used as an optical gating signal at the fixed input voltages (V_{in}) of 2.25 and 2.5 V but no signal was detected at exactly 2 V. In particular, the gating signal (photo-induced gain) at 2.5 V was only 0.8 V but is still regarded meaningful in that a minimum power consumption can be achievable at the V_{in} of 2.5 V, even though the photo-gain (0.8 V) was lower than that (V_{out} = 1.5 V) at 2.25 V where power consumption of the device should be quite large. The response time was around 80 ms.

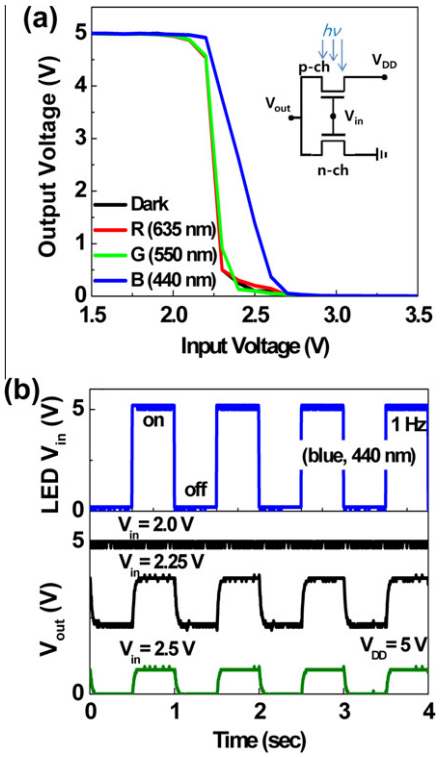

Fig. 3. (a) The light-illuminated VTC curves of our VS-CTFTs. Red (635 nm), green (550 nm), and blue (440 nm) lights were illuminated on our devices, which only reacted with blue light. (b) The dynamic photo-gating obtained near the transition voltage region (2 V) with monochromatic blue light. For this operation light-emitting-diode (LED) with 440 nm wavelength was pulsed by 5 V (LED input voltage), to be periodically turned on. The photo-induced V_{out} as an optical gating signal was obtained at the fixed V_{in} of 2, 2.25 and 2.5 V, respectively. No V_{out} signal was shown at 2 V V_{in}. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.4. Nonvolatile memory operation of ferroelectric VS-CTFT

For another hybrid device application, we deposited a ferroelectric polymer, P(VDF–TrFE) on the top-gate GZTO-TFT with ALD Al_2O_3 dielectric, so that our VS-CTFT inverter

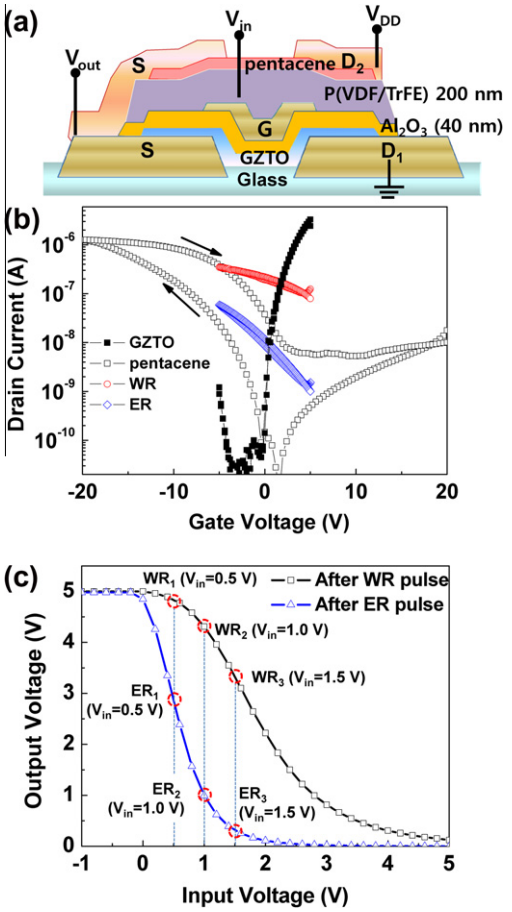

Fig. 4. (a) The schematic cross section of our CTFT memory inverter. (b) The transfer curves of top-gate GZTO-TFT and bottom-gate pentacene-TFT with ferroelectric polymer, where a large memory hysteresis is observed. As our pentacene memory TFT was pulsed with ±20 V for 1 s, write (WR, −20 V) and erase (ER, +20 V) states were clearly distinguished as red and blue I_D curves, respectively, in ±5 V V_G sweep range. (c) Inverter memory hysteresis in VTC was obtained at a V_{DD} of 5 V where we can achieve two separated V_{out} signals as WR and ER states at a fixed V_{in}. Three cases of V_{in} (0.5, 1, and 1.5 V) were marked by red circles. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

functions as a nonvolatile memory device based on the p-channel pentacene TFT with the ferroelectric polymer. Fig. 4a shows a schematic cross section of our CTFT memory inverter, which has a common gate for program pulse. Fig. 4b displays the transfer curves of our top-gate GZTO-TFT and bottom-gate pentacene-TFT with ferroelectric polymer, where a large memory hysteresis is observed. As our pentacene memory TFT was pulsed with ±20 V for 1 s (estimated coercive voltage = ~11 V for 200 nm-thick P(VDF–TrFE) according to Fig. S4a and S4b), write (WR, −20 V) and erase (ER, +20 V) states were clearly distinguished as red and blue I_D curves, respectively, in the ± 5 V V_G sweep range. Following the ±20 V pulse, inverter memory hysteresis in VTC was obtained at a V_{DD} of 5 V as shown in Fig. 4c, where we can achieve two separated V_{out} signals as WR and ER states at a fixed V_{in}. An optimum V_{in} may be selected as ~1 V, since the most clearly separated V_{out} states for WR and ER are obtained at this voltage.

Fig. 5a shows the 500 s retention properties of our nonvolatile memory inverter as measured at different V_{in} voltages of 0.5, 1, and 1.5 V after ±20 V 1 s pulse. The WR state more rapidly degrades than the ER state in general. WR and ER states were optimally maintained at a fixed V_{in} of 1 V while over time those two states became less distinguishable from each other at low V_{in} of 0.5 V or at high V_{in} of 1.5 V than at 1 V. In particular, the high V_{in} condition (1.5 V) led to the most rapid degradation of the WR state. It is because the WR state (hole accumulation in the p-TFT) obtained by −20 V pulse may not be easily retained under a (+) gate bias that would somewhat depolarize the pulse-aligned dipoles in our ferroelectric polymer. Expecting less depolarization effects, we determined 1 V as an optimum V_{in} for our memory inverter application. Therefore, 1 V was then confirmed as an optimum value according to the combined results of VTC memory hysteresis (Fig. 4c) and retention (Fig. 5a). Closer observation on the retention properties of our memory inverter was possible with the cyclic endurance test of Fig. 5b. The V_{out} as the WR signal rapidly decreases by 0.4 V for the initial 10 s after pulse although it is quite stabilized in the end, while V_{out} for the ER signal is well maintained without much increase. For the cyclic endurance test (Fig. 5b and c), sequential voltages per endurance cycle were applied on our ferroelectric memory inverter as programmed to be −20 V 1 s (WR pulse)/1 V 10 s (Reading)/+20 V 1 s (ER pulse)/1 V 10 s (Reading); V_{out} was read during the 10 s between WR and ER pulses at the optimum reading condition of 1 V-V_{in} and 5 V-V_{DD}. According to Fig. 5b and c, a very distinguished V_{out} was read as the WR and ER states, and it consistently maintained its respective values of ~4 and ~0.5 V during many cycles. We thus regard our VS-CTFT memory inverter as a unique hybrid device, to be quite useful for advanced memory applications on glass substrates.

4. Conclusion

In summary, we have fabricated organic/inorganic hybrid VS-CTFT inverters consisting of a bottom-gate

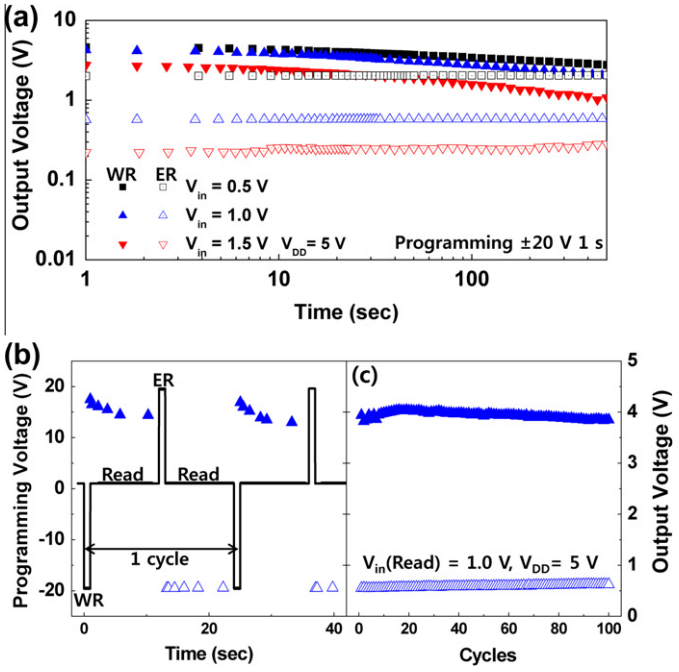

Fig. 5. (a) The 500 s retention properties of our nonvolatile memory (NVM) inverter as measured at different V_{in} voltages of 0.5, 1, and 1.5 V after ±20 V 1 s pulse. (b) Sequential programming voltages for one endurance cycle were programmed on our NVM inverters as composed of −20 V 1 s (WR)/1 V 10 s (READ)/+20 V 1 s (ER)/1 V 10 s (READ); V_{out} was read between WR and ER pulses at the optimum reading conditions of 1 V-V_{in} and 5 V-V_{DD}. (c) Results of the cyclic endurance test (100 cycles). WR and ER states were consistently maintained to be 4 and 0.5 V.

pentacene TFT and a top-gate amorphous GZTO TFT which are vertically connected with common gate. Our VS-CTFT device with Al_2O_3 dielectric well demonstrated electrical logic inverter functions and photo-gating under a blue LED, showing a maximum voltage gain of ~50, a good photo-gain of 0.8 V under 5 V-V_{DD}, and even good device yield. Our VS-CTFT device also displayed nonvolatile memory functions when we adopted P(VDF–TrFE) ferroelectric polymer for the p-channel pentacene; a more advanced organic/inorganic hybrid device form of organic ferroelectric memory TFT/oxide TFT hybrid was therefore demonstrated. We conclude that our VS-CTFT approach is quite promising in both aspects of advanced device applications and device yield.

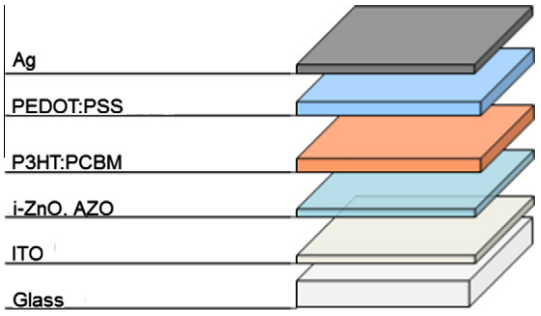

Fig. 1. Layer stack of the investigated solar cells.

using a metal oxide buffer layer between ITO and the semiconductor. One of the most intensely studied materials for this function is solution processed zinc oxide [3,8,9]. The energy levels of ZnO fit very well to the requirements for an electron injection layer. The work function is well matched to the PCBM lowest unoccupied molecular orbital (LUMO) and the valence band is deep below the highest occupied molecular orbital (HOMO) of most conjugated π-systems [10]. The wide bandgap of ZnO ensures high transmittance in the relevant spectral regime [11].

One of the few disadvantages of intrinsic ZnO (i-ZnO) is the restriction to a rather low film thickness of a few tens of nanometers due to the very low conductivity. Such a thin film imposes a major challenge for the manufacturing of polymer solar cells by high volume printing processes. On the one hand, complete coverage and a low density of pin-holes are challenging to achieve with thin film coatings. On the other hand, thin films may be less robust against mechanical stress being incurred during the subsequent printing processes. Such a robust electron injection layer is specifically important for the new generation of high performing semiconductors, which typically show the best efficiency with an active layer thickness of around or below 100 nm [12–17]. This concept is further applicable to multi-junction solar cells, where a reliable interface layer is essential to protect the lower half-cell [18].

In conclusion, we propose that thick interface layers are beneficial for enhanced device stability and increased production yield. The most straightforward way to enable thicker ZnO buffer layers is a conductivity increase via doping [11]. We are investigating aluminum (Al) as a dopant, because it is very cheap, non-toxic and resources are not limited. Vacuum processed aluminum-doped ZnO electrodes are used for various solar cell technologies like a-Si [19] or CIGS [20], and recently were also reported for organic solar cells [21].

In this work, we compare i-ZnO versus AZO, both processed from solution, as electron injection layers for organic solar cells. A dispersion of i-ZnO nanoparticles and an AZO precursor solution were prepared in organic solvents. The thin film properties of the two interface materials were characterized and the impact of their EIL thickness on the performance of the solar cells was compared. Overall, we found comparable device performance for thin i-ZnO and AZO layers. Increasing the EIL to ~100 nm results in significant performance loss in case of the i-ZnO, while cells with an AZO layer maintained their performance.

2. Materials and methods

The i-ZnO nanoparticles were prepared in methanol via hydroxylation of zinc acetate dihydrate ($ZnAc{\cdot}2H_2O$) by potassium hydroxide (KOH) adopting a method described by Harnack et al. [22] and afterwards dissolved in acetone at a concentration of 2 wt.%. The AZO solution was synthesized adopting a route described by Alam and Cameron [23] starting with a mixture of zinc acetate ($ZnAc{\cdot}2H_2O$) and aluminum hydroxide acetate ($HOAl(C_2H_3O_2)_2$) at a ratio of 1 at.%. Monoethanolamine (MEA) was added to the suspension to stabilize the Al doped ZnO complex.

The inverted photovoltaic devices were processed and characterized in ambient atmosphere. Pre-structured ITO coated glass substrates (as obtained from Osram) were subsequently cleaned in acetone and isopropyl alcohol for 10 min each. After drying, the substrates were coated with the organic precursor for AZO, respectively the i-ZnO solution, via doctor blading. Conversion of the precursor to AZO via hydrolysis was achieved by heating the samples to 260 °C for 10 min, while the i-ZnO film was dried at 150 °C for 10 min. Higher layer thicknesses were achieved via subsequent deposition steps. In case of AZO a calcination step was applied after each deposition. P3HT purchased from Merck and technical grade PCBM from Solenne were separately dissolved in chlorobenzene at a concentration of 2 wt.% and stirred for at least 1 h at 60 °C before being blended in a volume ratio of 1:1. The blended solution was stirred for at least another hour at 60 °C before use. The ca. 100 nm thick active layer was deposited via doctor blading. PEDOT:PSS (Clevios PH) from H.C. Starck was diluted in isopropyl alcohol (1:3 volume ratio) before deposition via doctor blading. The whole stack was annealed at 140 °C for 10 min on a hot plate before evaporation of a 100 nm thick Ag layer to form the top electrode. The active area of the investigated devices was 10.4 mm^2. Current density–voltage (j–V) characteristics were measured with a source measurement unit from BoTest. Illumination was provided by an Oriel Sol 1A solar simulator with AM1.5G spectra at 0.1 W/cm^2.

A UV–VIS-NIR spectrometer (Perkin Elmer – Lambda 950) was used for optical characterization of the thin films. The electrical conductivity was measured by a potentiostat (Autolab, Metrohm). Thickness of the thin films was measured by an interferometer (NanoFocus). X-ray diffraction (XRD) with CuKα radiation was done at an angle ranging from 20° to 80° by step-scanning with a step size of 0.02°.

3. Results and discussion

Table 1 compares the optical, electrical and crystalline properties of i-ZnO versus AZO. XRD spectra of AZO layers reveal a lattice stress in the 0 0 2 plane when aluminum is introduced, indicating that higher concentrations of aluminum are interstitially built into the lattice. i-ZnO particles are wurtzite type crystallites with an average crystal size of 4.2 nm while we find an average crystal size of 4.0 nm

for the converted AZO layers [24]. The optical band gap is determined by plotting $(\alpha h\nu)^2$ against $h\nu$ from UV/VIS absorption data. The optical bandgap can be found by extrapolating the linear portion of the curve to zero absorption [24]. The transmittance of the two materials is comparable. The most important difference is the increase in conductivity by about three orders of magnitude for AZO. A more detailed study of the ZnO layers will be published elsewhere [24].

Table 1
Comparison between the thin film properties of i-ZnO and AZO. The difference in the optical bandgap cannot be discussed in terms of the Moss-Burstein model due to the different synthesis, processing and conversion conditions of the i-ZnO versus the AZO film.

EIL	Crystallite size (nm)	Work function (eV)	Optical bandgap (eV)	Conductivity (S/cm)
i-ZnO	4.2	4.3	3.45	2.22×10^{-6}
AZO	4.0	4.2	3.34	2.35×10^{-3}

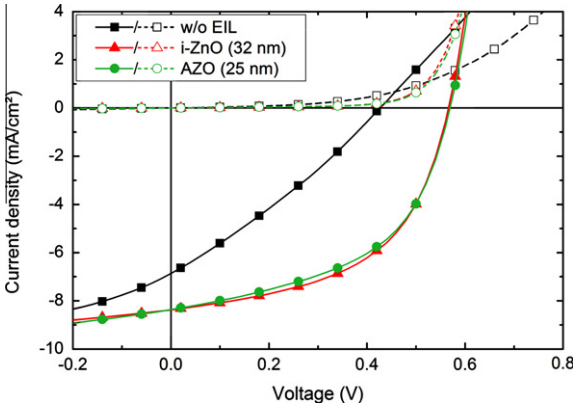

Fig. 2. j–V characteristics of solar cells without EIL, thin i-ZnO and AZO films.

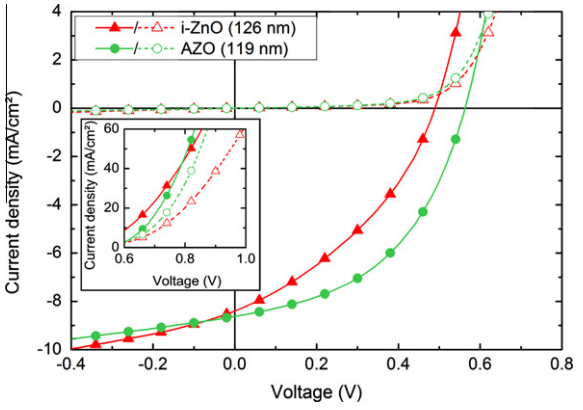

Fig. 3. j–V characteristics of solar cells with thick i-ZnO and AZO films. The inset shows the injection behavior in detail.

The layer stack of the investigated devices is shown in Fig. 1. The j–V characteristics of typical solar cells with thin i-ZnO and AZO layers (around 30 nm) are depicted in Fig. 2 and devices with thick EIL layers (above 100 nm) are shown in Fig. 3. The solar cell data for all configurations is summarized in Table 2.

A device without EIL is shown as reference in Fig. 2 as well. The j–V characteristics of the devices are dominated by a large, so-called photoshunt [25] and are further injection limited, which results in a nominal very high serial resistance of 23.6 Ω cm^2 (calculated from the slope around 1.25 V). Both loss mechanisms result from the non-selective ITO–PCBM interface. The photoshunt can be identified by the difference in slope of the illuminated versus the dark j–V curve at negative applied voltages. It originates from the several orders of magnitude higher charge carrier density of the active layer under illumination. The same mechanism is responsible for photoconductivity as well seen under forward bias as an increased injection current density. In case of the poorly charge selective ITO–PCBM interface, holes are more easily injected into the active layer at the nominal cathode. Therefore the shunt resistance scales with the conductivity of the active layer. Together with the ITO–PCBM contact resistance, this results in a decrease in the open circuit voltage (V_{OC}, 426 mV), short circuit current density (j_{SC}, −6.86 mA/cm^2), fill factor (FF, 29.2%) and consequently in a poor power conversion efficiency (PCE) of only 0.85%.

Thin layers (≈30 nm) of i-ZnO and AZO provide a much better electron selective interface and ohmic cathode contact. Losses at the cathode interface are minimized, because the electrons are extracted to i-ZnO or AZO, both at a higher work function than bare ITO. This results in increased FF, V_{OC} and j_{SC} and a significantly higher PCE of around 2.5% for both EILs. The series resistance of both device configurations is around 1.1 Ω cm^2 and well within expectations.

Increasing the layer thickness of the i-ZnO from around 30 to over 100 nm results in a severely reduced device performance from 2.5% to 1.5%. The main losses are a reduction of the FF from 53.9% to 37.7% and a reduction of the V_{OC} from 565 to 486 mV. These losses originate dominantly from three different mechanisms, which can be observed in the j–V-characteristics. First, an increase of the series resistance from 1.1 to 3.2 Ω cm^2 (see inset of Fig. 3), is

Table 2
Key parameters of the solar cells.

	V_{OC} (mV)	j_{SC} (mA/cm^2)	PCE (%)	FF (%)	R_S (Ω cm^2)	R_{Shunt} (kΩ cm^2)	$R_{Shunt/light}$ (kΩ cm^2)
w/o EIL	426	−6.86	0.85	29.2	23.6	3.0	0.29
i-ZnO (32 nm)	565	−8.41	2.56	53.9	1.1	6.2	0.59
i-ZnO (126 nm)	486	−8.40	1.54	37.7	3.2	3.1	0.33
AZO (25 nm)	569	−8.36	2.42	50.8	1.1	4.9	0.44
AZO (119 nm)	558	−8.69	2.40	49.4	1.2	3.9	0.50

caused by the thick i-ZnO layer. The higher R_S results dominantly in a FF loss. The V_{OC} loss is more subtle. The increased series resistance due to the i-ZnO layer is not expected to influence V_{OC} unless significant carrier recombination occurs in this region. Given the good charge selectivity of the ZnO layer, we exclude this loss mechanism. A contribution to the FF and V_{OC} loss originates from the already introduced photoshunt, which is much more strongly expressed in the case of thick i-ZnO layer. Photoshunts are a result of an interface-shunt, i.e. a defect shunting the electrode and the semiconductor. The photoshunt resistance is strongly dependent on the minority carrier blocking properties of the interface, the so called contact permeability of the buffer layers. This translates in our architecture to a defect, where holes become injected via the ZnO directly into the active layer [25]. We note that the photoshunt seems to emerge with increased i-ZnO layer thickness, as the shunt resistance under illumination is reduced from 0.59 kΩ cm^2 for the thin i-ZnO EIL down to 0.33 kΩ cm^2 for the thicker i-ZnO EIL (see Table 2). The dark shunt resistance also decreases from 6.0 to 3.1 kΩ cm^2. This is an indication for a reduced layer quality of the thick films. In summary, the photoshunt contributes to the losses in V_{OC} and FF. The third loss mechanism is associated with the photoconductivity of the EIL, which is much more significant for the i-ZnO based devices as compared to the AZO based devices. Illuminated i-ZnO is significantly more conductive, which leads to enhanced carrier injection under forward bias. Overall, this effect causes an increased current density under illumination (see inset of Fig. 3). This increased injected current does already compensate the photovoltaic current at lower bias, and in summary, the V_{OC} becomes reduced. This photoconductivity effect is responsible for the biggest part of the V_{OC} loss.

Solar cells with a thicker AZO EIL do not suffer from these defects. The series resistance of a device with a ~120 nm AZO layer is still as low as 1.2 Ω cm^2, which shows, that the contribution of the AZO EIL is negligible. For thicker AZO EIL the photoshunt is maintained at values larger than 0.45 kΩ cm^2, so the V_{OC} and the FF are not affected that much as for the thick i-ZnO EILs. All key parameters like FF, V_{OC}, j_{SC} and PCE remain constant for AZO layer thicknesses between 30 and 120 nm. In summary, doped ZnO opens the possibility to incorporate thick interface layers into the device architecture without sacrificing efficiency.

4. Conclusion

In this work we discussed the interface layer specifications as required from a reliable, large volume printing process for polymer solar cells. A thick electron injection layer using a solution processed aluminum-doped ZnO with high conductivity was suggested for this purpose. An increase of the intrinsic ZnO layer from 30 to ~120 nm reduced the device performance from initially 2.5% to 1.5%. The main losses are a reduction of the FF and V_{OC}, which are caused by the photoconductivity of the i-ZnO layer, the photoshunt behavior of the devices as well as its higher serial resistance. Aluminum doped ZnO could be processed as thick as 120 nm without causing losses. In the next step, the annealing temperature of the AZO films has to be reduced to around 150 °C, before these films can be processed on plastic substrates. Thick pin-hole free layers with good coverage are a prerequisite for the reliable large scale printing of organic solar cells with low shunts and high yield. In the presented concept, we incorporated thick electron injection layers into the devices. We propose that mechanically robust, thick EIL and hole injection layers (HIL) will be beneficial for the processing of thin active layers. This concept appears as an interesting strategy to optimize the lifetime and performance of single junction as well as tandem junction solar cells.

Acknowledgements

This work was funded by a German Research Foundation Project Grant (DFG; BR 4031/1-1) and the authors gratefully acknowledge the support of the Cluster of Excellence 'Engineering of Advanced Materials' at the University of Erlangen-Nuremberg, which is funded by the German Research Foundation (DFG) within the framework of its 'Excellence Initiative'. The authors would like to thank Lothar Sims, René Kogler and Jens Hauch from Konarka Technologies Inc., for the possibility to use the Kelvin Probe measurement setup.

The intermolecular bound charge pairs, or charge transfer (CT) states, which are assumed to be formed after the ultrafast splitting of the Frenkel exciton, then needs to be dissociated as well. What determines the dissociation rate of this state, and the generation rate of fully free carriers is currently debated, but it has been suggested that larger domains appears to be beneficial [27,28]. Furthermore, bi-continuous paths or continuous donor and acceptor phases are needed for successfully transporting the free electrons and holes to the corresponding electrodes, and prevent them from recombining (bimolecularly). Therefore, the optimum morphology of the active layer is actually a trade-off between charge carrier generation and transport for solution-processed PSCs. However, ideal morphology of the active layers, which strongly depends on the solubility and miscibility of two components, can rarely be spontaneously formed during solution-processing. Therefore some treatments, such as thermal treatments, mixed solvents or adding suitable additives to solvents, are usually employed to tune the morphology of the active layers to optimize performance of PSCs [23,29–32]. For instances, significant morphology and performance changes could be achieved by mixing two solvents in APFO-3:PCBM system [30]; the PCE of PSCs based on PCPDTBT:$PC_{71}BM$ was doubled by adding high boiling point alkanethiols into chlorobenzene (CB) [32,33]. Recently, considerable improvement of PCEs in PSCs by tuning the morphology of active layers with various additives has been demonstrated and becomes a more attractive method due to its simplicity and production compatibility, compared with thermal treatment [21,34,35]. DIO is a most commonly used additive, which has been proved enhancing PCE in PSCs based on several different polymers. However, beyond morphology changes, how DIO enhances performance in different polymer fullerene systems has not been fully understood, yet. To the best of our knowledge, there is also no report regarding the impacts of DIO on device stability.

Following the demonstration of a PCE of 5.4% in the PSCs based on HXS-1 and $PC_{71}BM$ processed from DCB/DIO in our previous short communication [36], in this paper, the impacts of DIO on performance of PSCs are intensively investigated with the combination of several cutting edge methods. The clear connection between the morphology of the active layer with the charge generation, recombination and transport indicates that DIO improves PCE of PSCs through tuning the morphology of the active layer with specific stoichiometry (1:2.5 w/w), to an appropriate domain size and favorable vertical bulk interpenetrating distribution, which leads to a higher photocurrent (J_{sc}) and a fill factor (FF). In addition, the stability of PSCs is essential for commercialization. Therefore, the impact of DIO on shelf-stability is also studied in this paper.

2. Experimental

The device optimization was carried out in two labs. PSCs with the structure of ITO/PEDOT:PSS/HXS-1:$PC_{71}BM$/LiF/Al for investigation on DIO effects are mostly fabricated and characterized at Linköping University using the same setup and procedure as described in reference [37]. PSCs for shelf-stability study are fabricated and characterized at Freiburg Materials Research Centre as illustrated in reference [36]. All active layers of PSCs and blend films for PL, morphology study and transport measurement are spin-coated from either DCB or DCB/DIO (97.5:2.5, v/v). Detail descriptions of mobility measurements can be found in reference [38]. PL spectra of all films are recorded with a sensitive CCD Si array detector at wavelengths throughout the visible region and near IR region to 1050 nm [39].

The topographies of the active layers are imaged with AFM, using a Dimension 3100 system (Digital Instruments/Veeco) operating in tapping mode. Silicon cantilevers (NSG10) with a force constant of 5.5–22.5 N/m, a resonance frequency of 190–325 kHz, and a tip curvature radius of 10 nm are used. TEM specimens are prepared by detaching a BHJ film from the substrate in deionized water. The film is floating on the water surface, and is picked up with a copper grid. TEM images are obtained with a LEO 912 OMEGA (Zeiss) transmission electron microscopy operated at 30 kV under proper defocus conditions. The defocus value of TEM is about 700 nm for 40,000 × magnification, which corresponds to the TEM images with 100 nm scale bar and 8 μm for 8000 × magnification, which corresponds to the TEM images with 1 μm scale bar. Films for 3-D TEM are prepared by dissolution of the PEDOT:PSS layer and transfer of the films to a copper grid, as in the TEM-measurements. 10 nm gold particles are placed on the surface of the films and used for image alignment in the reconstruction process. Tilt series are obtained using a FEI CM200 FEG microscope with a CCD with 24 μm pixel size. Images are obtained with one degree increment from −65° to 65° for the film without DIO and from −68° to 68° for the film with DIO. Magnification and postmagnification are 20,000 times and 1.531, respectively. Underfocus is set to 2 μm. Three-dimensional reconstructions are produced with filtered back projection of the images, with software produced at Karolinska Institute (Stockholm, Sweden), and visualized with bob [40].

3. Results and discussion

3.1. The effect of additive on photovoltaic device performance

The external quantum efficiency (EQEs) of the two kinds of PSCs (without or with DIO) under monochromatic light illumination and *I-V* characteristics under AM1.5 (100 mW/cm^2) are recorded and shown in Fig. 1(a) and (b), respectively. EQE of the DCB cell is similar in shape to that of the DCB/DIO cell, but somewhat lower, which maybe caused by charge recombination and/or transport indicated by field dependence of I-V curve shown in Fig. 1(b). For comparison, the device performance parameters (J_{sc}, V_{oc}, FF and PCE) of the two kinds of PSCs are summarized in Table 1. With DIO, J_{sc} is increased from 8.3 to 9.8 mA/cm^2 and FF from 0.51 to 0.69, which lead to an enhancement of PCE from 3.6% to 5.4% (a higher PCE of 5.9% can be reached in diodes with a smaller active area of about 4 mm^2), though there is a small reduction of V_{oc} from 0.85 to 0.81 V. It is well known that J_{sc} of PSCs is sensitive to many factors, but FF is mainly determined by

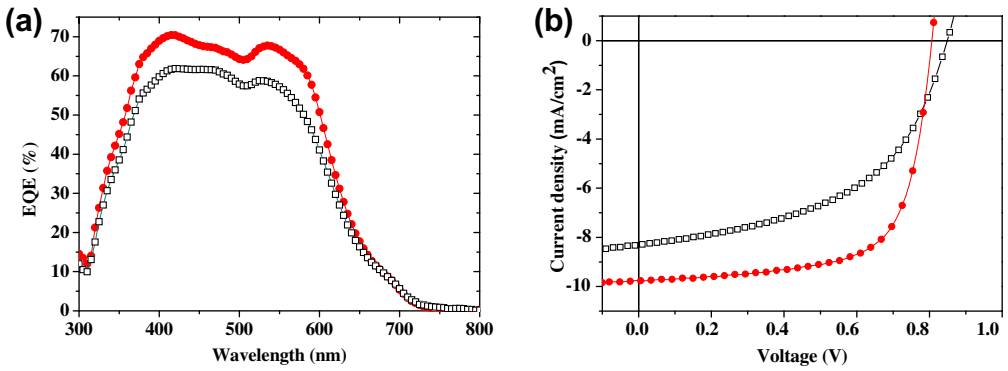

Fig. 1. (a) The EQEs and (b) I-V characteristics of PSCs spin-coated from DCB (open squares) and DCB/DIO (filled circles) under AM 1.5 illuminations.

Table 1
Parameters of HXS-1:$PC_{71}BM$ solar cell.

Solvent	J_{sc} [mA/cm^2]	V_{oc} [V]	FF	PCE	R_s [Ω cm^2]	R_{sh} [Ω cm^2]
DCB	8.3	0.85	0.51	3.6%	19	485
DCB/DIO	9.8	0.81	0.69	5.4%	7	2110

transport property of active layers and their contact with electrodes. A V_{oc} drop, in this case by 40 mV, suggests that ordering [32,41,42] of the active layer is induced by DIO, which is usually favorable for charge transport. Therefore, enlarged J_{sc} and FF combine with decreased V_{oc} imply that the following discussed morphology of the active layer in DCB/DIO cells enables more efficient charge carrier transport to the electrodes than DCB cells.

3.2. The effect of additive on the morphology of the active layers

Three kinds of microscopes are employed to examine the morphology variation between films cast from DCB and DCB/DIO. First, the topographies of pure HXS-1 films spin-coated from DCB and DCB/DIO are imaged with AFM where significantly different height images are observed (see Fig. 2(a) and (b)). The HXS-1 film from DCB/DIO exhibits much rougher surface with larger aggregations than in the film from DCB, This indicates that DIO can induce the formation of compact chain packing of HXS-1 and crystallization in aggregation form. The corresponding phase image of the HXS-1 film from DCB/DIO shown in Fig. 2(d) reveals fine fibril features contrasting with the featureless phase image of the HXS-1 film from DCB (Fig. 2(c)). This is in accordance with the finding in our previous communication [36]. HXS-1 is a planar polymer designed for facilitating polymer chain packing in solid film, which is realized by adding DIO into DCB [36]. The topographies of blends (HXS-1/$PC_{71}BM$) spin-coated from DCB and DCB/DIO are also imaged with AFM. The roughness of the blends cast from DCB/DIO increases also obviously in compare to that of the blends from DCB as shown in Fig. 2(e) and (f). As seen in the phase image, pronounced nanophase separation in the blend from DCB/DIO (Fig. 2(h)) and barely detectable phase separation of two components in the film from DCB (Fig. 2(g)) are consistent with the morphology of the pure HXS-1 due to its semi-crystalline property. This nanophase separation of HXS-1 and $PC_{71}BM$ may be a result of enhanced HXS-1 crystallization, which is again induced by DIO. The size of this feature is measured to be 10–25 nm.

To see the difference of bulk structures of two blends, the morphologies of blend films cast from two solutions are evaluated with TEM. To show both overall view and detailed information of the films, TEM images are recorded at two different scales, 1 μm (Fig. 3(a) and (c)) and 100 nm (Fig. 3(b) and (d)). Some large features bigger than 150 nm are observable. TEM images show contrast based on electron density in the thin film, so that the dark areas are assigned to the $PC_{71}BM$-rich phase. This image contrast is not caused by thickness difference because we know from AFM height image (Fig. 2e) that the film is very even and with a surface roughness being only 0.43 nm. Noticeably, the large phase separation possesses very broad and diffused interface between mixed $PC_{71}BM$-rich and HXS-1-rich phases as seen in Fig. 3(a) and (b). Such large features with indistinguishable phase interface can only be caused by inhomogeneous mixing of $PC_{71}BM$ and HXS-1 from the DCB only solution and they would not influence PSC performance. On the other hand, more homogeneously mixed blend with very fine structure from DCB/DIO can be distinguished in the overview image (Fig. 3c) and the zoomed image (Fig. 3d). This fine structure can also be seen in the film without $PC_{71}BM$ (TEM not shown), which means that the fine structure is induced by HXS-1 crystallization. This is in accordance with the AFM results. According the AFM phase images and TEM images, the thickness of the HXS-1 crystalline lamellae could be determined to be about 10–20 nm. Thereafter, $PC_{71}BM$ must be excluded from the HXS-1 crystal and reside between the lamellae, forcing a phase

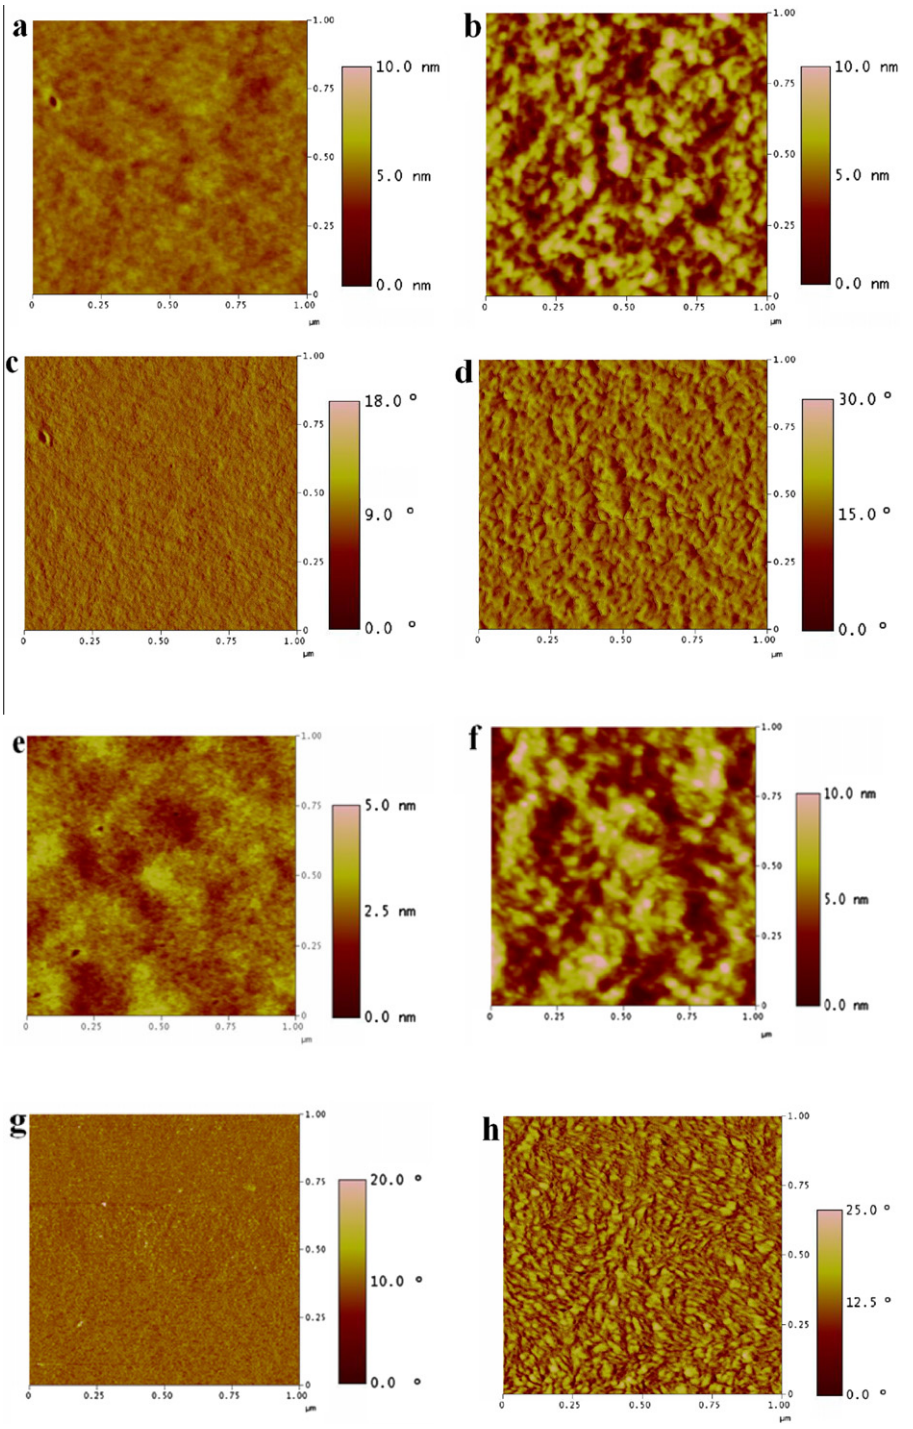

Fig. 2. (a) and (b) are the AFM height images of HXS-1 spin-coated from DCB and DCB/DIO (1 μm × 1 μm), The RMS of (a) and (b) are 0.430, 1.859 nm, respectively. (c) and (d) are the phase images corresponding to (a) and (b). (e) and (f) are AFM height images of HXS-1:$PC_{71}BM$ spin-coated from DCB and DCB/DIO. (g) and (h) are the phase images corresponding to (e) and (f). The RMS of (e) and (f) are 0.43 and 1.90 nm, respectively.

separation with the same size as the crystalline structure. To be clearly stated, the phase separation between $PC_{71}BM$ and HXS-1 is attributed to the unique crystallization of HXS-1 provoked by DIO. Another thing to be noticed, the film thickness investigated with TEM are about 150–200 nm, which means that features of 10–20 nm size seen here are stacks through the whole film. Therefore it is somewhat difficult to clearly separate the individual lamellae. Fortunately this problem can be solved with 3-D TEM investigation shown below.

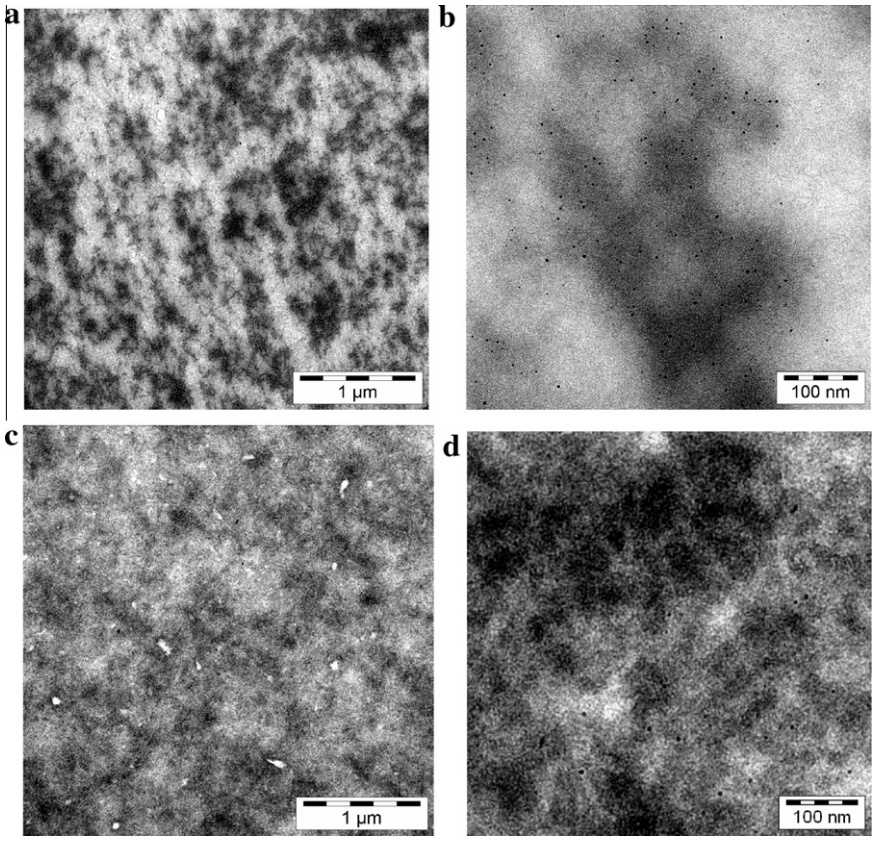

Fig. 3. The TEM images of HXS-1/$PC_{71}BM$ spin-coated from DCB (a and b) and DCB/DIO (c and d).

As the performance of PSCs depends on the vertical distribution of the two components in the active layers and free charges are transported in this direction to the collecting electrodes, it is very interesting to use a 3-D TEM to investigate the vertical distribution of HXS-1 and $PC_{71}BM$. Electron tomography reconstructions [43] are done on blend films cast from DCB and DCB/DIO (Fig. 4(a) and (b)), which show cross section overviews of the two films (ca. 310 nm wide and 60 nm deep). These reconstructions are low pass filtered at 10 nm [43]. In Fig. 4(c) and (d) the middle sections (ca 8 nm thick) in between anode and cathode interfaces of the same reconstructions are displayed, where a low pass filtering at 5 nm has been used. Light regions correspond to well scattering domains and dark regions to less scattering domains. The $PC_{71}BM$ is the more scattering material of the two [43]. Thus, the light volumes are attributed to the $PC_{71}BM$-rich domains while the dark volumes are the polymer rich domains. A coarser film structure in the film spin-coated from DCB/DIO is also found in these images shown in Fig. 4(b) and (d). The film without DIO exhibits smaller domains, which are evenly spread throughout the active layer (see Fig. 4(a) and (c)), while in the film with DIO the domains are larger and more clustered together (see Fig. 4(b) and (d)). Moreover, Fig. 4b shows more vertical continuous elongated clusters formed than that in Fig. 4a, which will facilitate charge carrier transport to collection electrodes.

3.3. The effect of additive on charge generation

Both charge generation and recombination depend strongly on the morphology of active layers. It is interesting to see how DIO influence these physical properties by comparing PL spectra under these two specific morphologies. Deteriorating charge generation is expected in DCB/DIO cells because the interface between HXS-1 and $PC_{71}BM$ is decreased due to increased domain size induced by DIO as shown in Figs. 2–4. To confirm that, the PL spectra of HXS-1:$PC_{71}BM$ films spin-coated from DCB and DCB/DIO excited by a monochromatic light with a wavelength of 405 nm is recorded (Fig. 5). Pure HXS-1 films show emission in the range of 600–900 nm, with a peak located at 685 nm (Fig. S2(B) in reference 36). The $PC_{71}BM$ film displays a relatively broad emission with a peak at 720 nm and also a shoulder at 800 nm. As expected, two morphologies result in two different PL spectra. As shown in Fig. 5, very weak emission in the region of 700 nm originated from pure HXS-1 and $PC_{71}BM$ is observed in the blend film of HXS-1:$PC_{71}BM$ from DCB indicating efficient charge transfer [36]. However, as a consequence of increasing domain size and lowering the amount of donor–acceptor interfaces by the addition of DIO, the emission peak at 710 nm dominates the PL of DCB/DIO films, which can most probably be explained by the combined emission from HXS-1 and $PC_{71}BM$ due to inefficient charge transfer

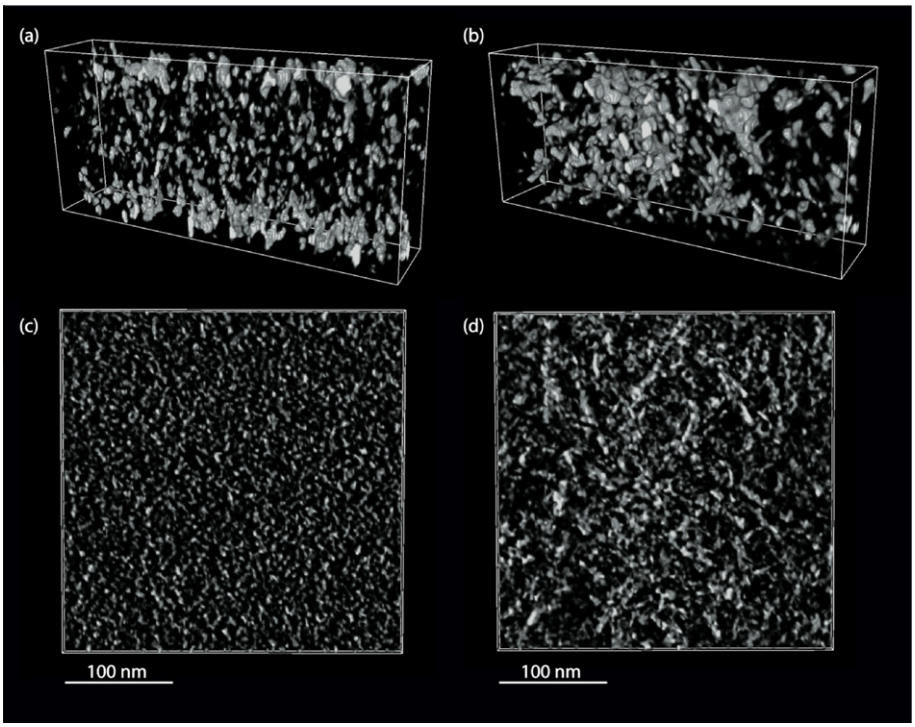

Fig. 4. The cross section overviews of the two blend films cast from DCB (a) and DCB/DIO (b). Image (c) and (d) are the middle sections (ca 8 nm thick) of the same reconstructions of (a) and (b).

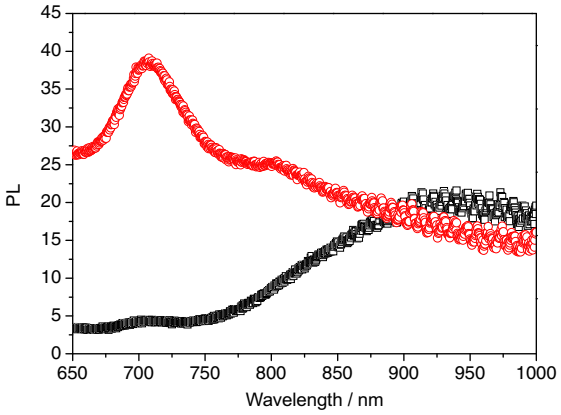

Fig. 5. The PL spectra of HXS-1/$PC_{71}BM$ film spin-coated from DCB (black squares) and DCB/DIO (red circles). The excitation wavelength is 405 nm.

since too big pure HXS-1 and $PC_{71}BM$ domains exist. So from a charge transfer point of view, DIO does not introduce a positive impact.

3.4. The effect of additive on charge carrier recombination

As shown in Fig. 5, a new broad emission with a peak located at 930 nm emerges in blend films from DCB, which is attributed to the recombination of interfacial charge transfer states (CTS) [39,44–49]. There appears to be less CTS emission from DCB/DIO films (Fig. 5), where it can only be seen as in the tail to the pure material emission. The reduced emission from the CTS in blend films from DCB/DIO compared to the blend film from DCB is interesting. Radiative recombination of CTS is a competitor to photocurrent generation in photovoltaic devices, so lower CTS emission is consistent with increased J_{sc} in DCB/DIO solar cells. Therefore, from a CTS recombination point of view, DIO introduces a positive impact, that is, decrease radiative recombination of CTS in DCB/DIO film, likely due to increasing phase separation in the active layer. Similar results have also been reported recently [47–49].

3.5. The effect of additive on transport property

The electrical properties of solar cells are very sensitive to the morphology of the active layers. To verify the different transport situations in the two kinds of PSCs, the R_s and the R_{sh} are evaluated and listed in Table 1. Upon adding DIO, the R_s of the PSC decreases significantly from 19 to 6 $\Omega\,cm^2$, which indicates that the geometry induced by DIO facilitates charge carrier transport in the active layer. Meanwhile, fourfold enhanced R_{sh} of the DCB/DIO cell implies smaller leak current or less recombination than that in DCB solar cells.

Hole and electron mobilities of the films from the two solutions are measured with FET and listed in Table 2. The hole mobility (μ_h) and electron mobility (μ_e) of DCB films are 3×10^{-5} and $1 \times 10^{-3}\,cm^2\,Vs^{-1}$, respectively. There appear to be a change in mobilities in the DCB/DIO film, where μ_h increases to $1 \times 10^{-4}\,cm^2\,Vs^{-1}$ and μ_e decreases to $6 \times 10^{-4}\,cm^2\,Vs^{-4}$, but this might be a measurement related effect. FET measurements might not be

Table 2
Hole and electron mobilities of the films from DCB and DCB/DIO.

Solvent	μ_h [cm^2 Vs^{-1}]	μ_e [cm^2 Vs^{-1}]	μ_e/μ_h
DCB	3×10^{-5}	1×10^{-3}	33.3
DCB/DIO	1×10^{-4}	6×10^{-4}	6

entirely appropriate for this material vis-à-vis solar cell performance due to the presence of ordering and spinodal decomposition [50], which may influence the correlation between FET and solar cell structures in terms of mobility. In particular, there might be an increase in PCBM concentration at the dielectric interface of the transistor in the DCB film compared to the DCB/DIO film as can be seen in Fig. 4(a) and (b), which may be responsible for the measured changes in mobility. Although an increase of the lower mobility agrees well with the increase in FF observed with additive [21], the rather small hole mobility increase and the fact that neither hole or electron mobility is particularly impressive, indicate that some other mechanism, e.g. enhanced charge separation or decreased recombination, is the main reason for the increased FF. This would also be consistent with the larger domains and the possible decrease in CTS emission seen in the films with DIO. From free charge generation and extraction perspective, a favorable morphology is thus probably more important than a high mobility in order to achieve a high FF.

3.6. The effect of DIO on the shelf-stability of the solar cells

To study the effect of additive on the shelf-stability of the solar cells, two substrates with 6 solar cells on each cast from DCB and DCB/DIO were fabricated in Freiburg Materials Research Centre. These cells are kept in a glove box filled with N_2 and their *I-V* curves are recorded for two years with different intervals in days, weeks and months after one day initial degradation. After two years, the average J_{sc}, V_{oc}, FF and PCE of 6 solar cells on the same substrate *vs* time are presented in the inset of Fig. 6 together with normalized corresponding performance parameters (Fig. 6). These 12 solar cells behave similar, V_{oc} increase, FF slightly decrease and J_{sc} clearly decrease, which result in an overall PCE decrease with time no matter if it is with or without DIO. The PCE and J_{sc} decrease by 10% for solar cells cast from DCB and 12% for those from DCB/DIO, respectively. The slightly difference (2%) in J_{sc} and PCE degradation between two groups of solar cells is in experimental error. These results indicate that DIO does not produce observable impact on the shelf-stability of solar cells. The major causes for performance degradation of these solar cells can be bleaching or/and morphology changes due to samples kept in the glove box filled with N_2. Bleaching in this case may not play a big role because the samples are only exposed to white light during I-V measurement. Therefore, the fact that degradation is only observable in the 1st year and no obvious degradation in the 2nd year indicates negligible morphology variation after one year initial relaxation.

4. Conclusions

In conclusion, the performance enhancement in the solar cells based on HXS-1:$PC_{71}BM$ by additive DIO is

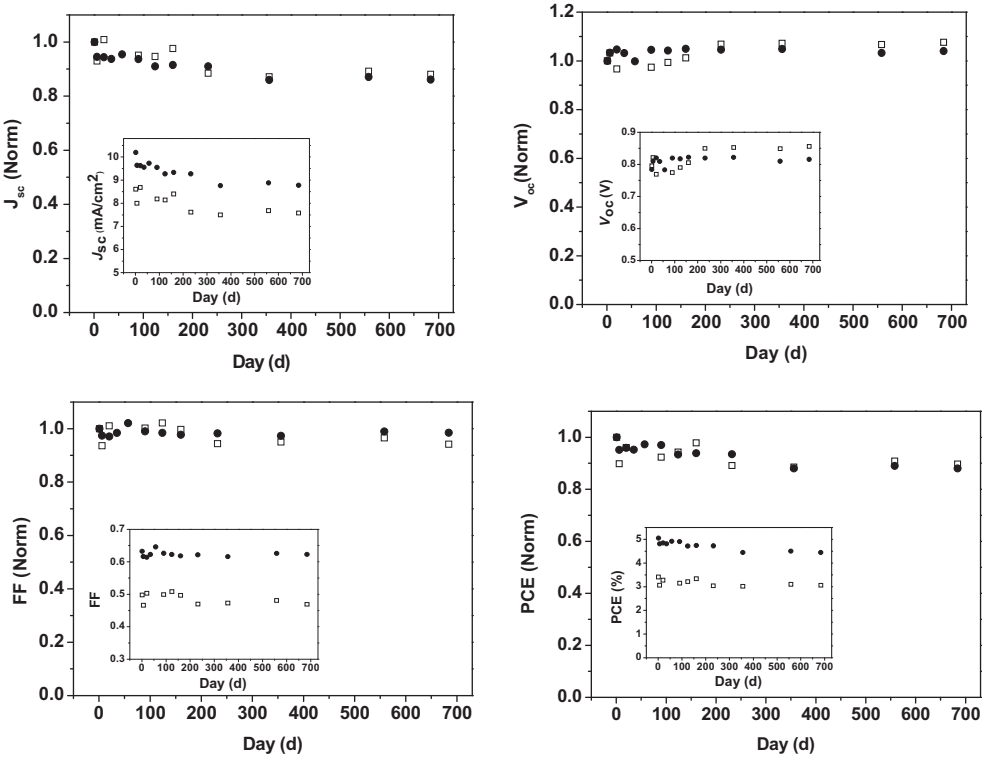

Fig. 6. Normalized and average (inset) performance parameters of HXS-1:$PC_{71}BM$ spin-coated from DCB (opened squares) and DCB/DIO (filled circles).

investigated with AFM, TEM, 3-D TEM, PL and FET. The observations from all these different techniques are well consistent with each other and make a clear connection between solar cell performance and morphology. The enhancement of J_{sc} from 8.3 to 9.8 mA/cm^2 and FF from 0.51 to 0.69 by introducing DIO into DCB is attributed to the pronounced morphology changes of the active layer induced by DIO. All of AFM, TEM and 3-D TEM images show big domains with sizes of 10–20 nm formed in the films of DCB/DIO. Specially, 3-D TEM images further demonstrate vertical continuous elongated clusters formed in DCB/DIO films. Lower PL intensity of CTS emission in the films from DCB/DIO than that from DCB, suggests that once excitons are dissociated at the interface between HXS-1 and $PC_{71}BM$ in the active layers, large domains (detected with AFM, TEM and 3-D TEM) are better at separating the holes and electrons in the two phases. All these results propose that beneficial morphology with domain size in 10–20 nm for inefficient charge recombination and vertical elongated clusters for assisting charge transport to the collecting electrodes in DCB/DIO films are the main reasons for the enhanced J_{sc} of 9.8 mA/cm^2, FF of 0.69 and PCE of 5.4%. The result of two year shelf-stability measurement indicates that DIO has no pronounced impact on the shelf-stability of the PSCs and the morphology is stable after one year initial relaxation.

Acknowledgement

Financial support by the NSF of China (20834006 and 50821062), and 863 Program (2008AA05Z425), Swedish Energy Agency, Swedish Research Council (VR) and VINNOVA are gratefully acknowledged. inorganic oxide layers separated by polymer layers. The results are promising but total thicknesses of 5–7 μm have been reported for the final device [18–20], largely exceeding the starting device thickness (a few hundred nm) and possibly modifying the final device flexibility. Another interesting approach has been recently suggested based on the introduction of a thin TiO*x* layer that acts both as a shielding and oxygen scavenging layer [21,22]; the carrier mobility of OTFTs encapsulated with TiO*x* remained stable in air for up to 500 h and degraded of one order of magnitude after 2000 h [22]. Indeed, the development of new methods for enhancing device lifetime is an important goal that must be accomplished either by developing novel packaging materials or by reducing the environment sensitivity of organic devices, without interfering with the mechanical properties and thin form factor peculiar to organic devices.

Previously obtained results on ion irradiation of polymers, showed that a controlled damage induced by the implanted ions can induce strong chemical and structural modifications of the material, altering its mechanical and electrical properties [23–25]. In particular, it was demonstrated that ion implantation not only changed the electrical conductivity of polyaniline but also significantly reduced its degradation to the moisture exposure by creating a dense, hermetic layer near the polyaniline surface through ion–polymer interactions [23]. However, the effects of ion implantation have never been investigated neither on small molecule organic semiconductors, such as pentacene, widely studied thanks to its excellent transport performance, nor on fully operating organic devices. The results here described focus on the lifetime-enhancing effects induced on pentacene OTFTs by a controlled low-energy implantation of Ne^+ and N^+ ions. These effects concern the main transport parameters of the material, such as its carrier mobility and threshold voltage, that are not only preserved after ion implantation but even stabilized on a longer time scale. Our results demonstrate that by accurately controlling the Ne^+ and N^+ ion energy and dose, it is possible to limit the ion penetration and action to the upper part of the semiconducting film, therefore preserving the device channel. Moreover, quite interestingly, the modifications induced by Ne^+ and N^+ ion implantation positively affect the stability of the electronic parameters of the device. In particular, we report on the formation of stable charged chemical species following implantation with N^+ ions that chemically react with the organic matrix and pin the device threshold voltage, thus assessing the potentiality of employing ion implantation to permanently modify the electrical transport properties of organic thin films.

2. Experimental

2.1. OTFT fabrication

Pentacene films of thickness of 50 nm and of 300 nm, were deposited on quartz slides to study by photocurrent and optical absorption spectroscopy the different relative weight of the "thin-film" and "bulk" phase (Fig. 1a). Pentacene OFETs were fabricated on highly conductive silicon substrate (acting as gate electrode) with a 500 nm thermally grown silicon dioxide layer, which acts as gate insulator. All devices have been realized using a bottom contact configuration with gold source and drain electrodes (W = 5 mm, L = 50 μm, being W and L channel width and length, respectively) patterned by means usual photolithographic process (Fig. 1b). Pentacene active layers were deposited by thermal evaporation and film thickness was monitored by a quartz crystal microbalance.

2.2. Ion implantation

Ion implantation was performed on Varian CF-3000 ion implanter at Ion Beam Materials Laboratory in Los Alamos national Laboratory. Monte Carlo SRIM code was used to estimate ion beam parameters that would produce the required damage thickness and ion profile in the pentacene. To minimize the sample exposure to the environment during the transportation, samples before and after the implantation were either packed under dry nitrogen atmosphere or sealed under vacuum. The implantation was performed under room temperature with two different ion species (N and Ne) to various fluencies. The beam flux was keep at a fixed value so that the flux effect is not a concern in these sets of experiments. The maximum ion energy was chosen so as not to completely damage the pentacene layer. According to Monte Carlo simulations by SRIM code, the thickness of the damaged layer is slightly thinner than the depth profile of the implanted ions. For example, under 25 keV (or 55 keV) N^+ ion bombardment, the damaged layer thickness in the pentacene is approximately 100 nm (or 200 nm), while the tail of the implanted N ions goes as deep as 130 nm (or 250 nm).

2.3. Photocurrent spectroscopy

Photocurrent spectroscopy analyses were carried out in the common mode planar configuration in air and at room temperature with a 150 W QTH lamp coupled to a SPEX monochromator and mechanically chopped at low frequency (<20 Hz), using a current amplifier connected to a digital lock-in amplifier (Stanford Research 850). The energy resolution was 0.01 eV at 2.40 eV. The photon flux was measured with a calibrated Si photodiode. The analyses were carried out under low-injection conditions (1×10^{13} photons/cm^2 at λ = 450 nm) and no variations were induced in the PC spectra by the incident photon beam, as assessed by comparing consecutively acquired spectra. Optical filters were used to avoid artifacts due to higher order harmonic wavelengths.

2.4. X-ray photoelectron spectroscopy

X-ray photoelectron spectroscopy (XPS) and ion sputter depth profiling analyses were done with a Physical Electronics 5600ci multi-technique surface science system. In profile mode XPS data was collected in medium energy resolution in order to increase signal intensity, and for the core level photoemission spectra shown here in high resolution (better than the intrinsic chemical linewidths) for more careful chemical analysis and assignments. Ion sputtering for the depth profile analysis was done using

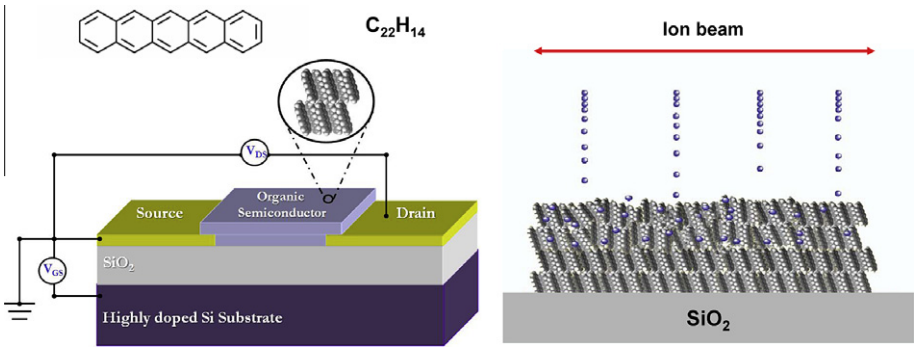

Fig. 1. Schematic layout of a pentacene organic thin film transistor.

4 keV Ar^+ ions at an approximate rate of 2 nm/minute erosion rate. XPS data acquisition was alternated with ion sputtering to obtain depth resolved information for the profile. Standard relativity sensitivity factors specific to the instrument were used to convert XPS peak area intensity to relative atomic concentration.

2.5. Electrical measurements

Drain-source current (I_D) measurements were carried out at room temperature in air and in dark. An Agilent HP 4155 Semiconductor Parameter Analyzer, provided with gold tips for contacting the electrodes, was used to control the gate voltage (V_G) and the drain-source voltage (V_D) and to measure I_D (the source being the common ground). For all devices, both mobility and threshold voltage were determined from the transfer characteristics in the saturation regime. Since the hysteresis was negligible for all devices, the device parameters are reported for the forward gate voltage sweep.

3. Results and discussion

3.1. Ion implantation effects

To achieve this goal we have implanted 300 nm thick pentacene OTFTs (the structure is shown in Fig. 1) with either Ne^+ and $^{14}N^+$ ions and we have observed by elastic recoil detection (ERD) and Fourier transform infrared (FTIR) analyses a strong modification induced in the C—H and C—C molecular bonds, forming a hydrogen-depleted carbon-rich matrix. Hydrogen loss occurs for both types of implanted ions and it increases with increasing implantation dose (more details in Supplementary Information, Figs. S1, S2).

The variations induced by ion implantation in the OTFT main electrical transport parameters, such as charge carrier mobility and threshold voltage, have been measured and Fig. 2 reports the values obtained as a function of dose for N^+ ion at 25 keV (the effects of N^+ ions as a function of increasing energy and of Ne^+ ions at 35 keV are reported in Supplementary Information, Figs. S3 and S4). The average carrier mobility and threshold voltage measured over 50 OTFTs before implantation were $\mu_0 = 0.02 \pm 0.01$ cm^2/Vs and $V_{t0} = -21 \pm 10$ V, respectively. We report in the SI section the characteristics of an investigated OTFTs (Fig. S5). Despite the large spread in μ_0 and V_{t0}, it is noteworthy that devices with very different starting μ_0 and V_{t0} values but implanted with the same dose/energy behave in a very reproducible way (as shown in more detail in the SI section, Tables T1 and T2). On the contrary, if we implant with a different (more than two orders of magnitude) ion dose two samples with an very similar initial mobility value, we record a huge difference in the mobility degradation (SI section, Fig. S6). These observations clearly indicate that the effects induced by ion implantation override the existing morphological/functional differences in the starting OTFT devices. The first value of the relative mobility of the not-implanted reference samples differs from one in Fig. 2a since it is determined using the mobility value of the reference samples re-measured after all the other samples had been exposed to ion implantation (there is a sizeable time-lag between the fabrication of the devices, their implantation and the measurement of their mobility). In this way, the mobility used to determine the first data point of Fig. 2a has been measured at the same time, both for the reference and the implanted ones. The same considerations apply to the non-zero value of the first data point for the not-implanted devices in Fig. 2b. The beam energy values have been chosen, following SRIM simulations [26], in order to limit the damage to the top portion of the active layer. The interesting result is that the OTFT performance is seriously affected only for doses higher than 5×10^{14} ions cm^{-2} for both types of ions. No particular trend can be detected in the mobility and threshold voltage variation as a function of the beam energy for N-implantation. The energy plots are not available for Ne^+ ions since for beam energies higher than 35 keV, the devices lose their field effect transistors behavior, indicating that these conditions severely damage the device active channel.

The molecular electronic density of states distribution has been investigated by photocurrent (PC) spectroscopy analyses to assess the modifications induced at the molecular level on the electronic transport properties [27–33]. PC analyses were carried out on all OTFTs except on those that have been implanted at the highest doses/energies and that, therefore, had completely lost their device behaviour (see Figs. 2, S3 and S4 in the SI section). PC spectra of OTFTs implanted with 25 keV N^+ ions at different doses are

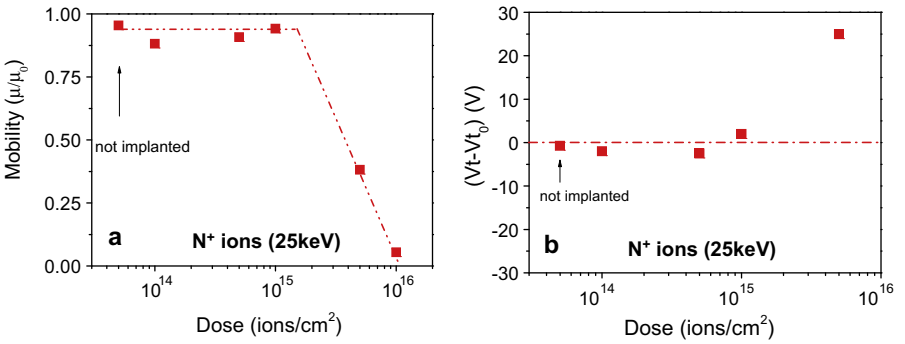

Fig. 2. Relative modification in the charge carrier mobility (μ) and threshold voltage (V_t) of OTFTs implanted with 25 keV N^+ ions as a function of the ion dose.

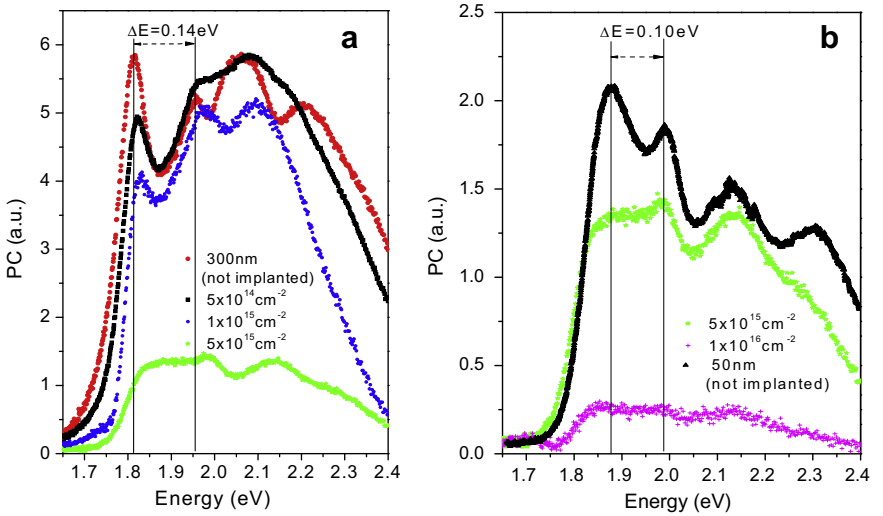

Fig. 3. Photocurrent spectra of OTFTs implanted at different N^+ ion doses. The ion energy is 25 keV. The spectrum of a not-implanted 300 nm thick reference sample is reported in (a) and the spectrum of a not-implanted 50 nm thick reference in (b). The reduction in the Davydov splitting as the pentacene layer thickness decreases is highlighted.

shown in Fig. 3 and provide a clear indication of the presence of an undamaged active pentacene film. In fact, two phases coexist in pentacene films, called the "thin-film" phase, characterized by a molecular spacing of 15.5 Å and dominant for thicknesses below 50 nm, and the "bulk" phase, characterized by a spacing of 14.5 Å and dominant for films over 150 nm thick [34,35]. The different molecular spacing derives from the different tilt angle of the molecular herringbone packing structure, which induces a different coupling of intermolecular π-electron systems. The density of states distribution obtained from PC spectra can provide information on the dominant phase of the pentacene film by assessing the Davydov splitting of the first absorption band. The Davydov splitting of the first absorption band is correlated to modifications in the film molecular structure and packing and it increases when passing from the "thin film" to the "bulk" phase [36–38]. Our measurements (Fig. 3) indicate that, as the implantation doses increase, the active layer passes from a "bulk phase" dominated (i.e. a film >150 nm thick to a "thin-film phase" dominated structure (i.e. about 50 nm thick). Fig. 3a shows the gradual decrease in the Davydov splitting with increasing implantation dose starting from the reference non-implanted sample (300 nm thick); its further evolution is highlighted in Fig. 3b, where the PC spectra of OTFTs implanted at the highest tested doses are compared with a non-implanted, 50 nm thick, reference sample. Similarly, also the mobility and threshold voltage are preserved. It is noteworthy that the PC spectrum of the highest dose implanted sample (1×10^{16} ions cm^{-2}) has an extremely poor quality and, correspondingly, the OTFT device functionality is completely lost. These PC results indicate that a thin undamaged layer of pentacene can still be preserved under the damaged top layer after ion implantation with selected doses and energies, and this layer grants the full functionality of the implanted OTFTs (see Fig. 2). Therefore, PC measurements confirm that it is possible to preserve the full functionality of the OTFT device by properly choosing ion implantation conditions. It is noteworthy that PC spectroscopy, that provides a "fingerprint" of the density of

states distribution on the pentacene film, allows identifying the actual thickness of the electrically active layer left undamaged after ion implantation, without affecting the operation of the device. Other techniques usually applied to obtain information on pentacene phases, such as X-ray diffraction, could not be easily applied to fully operational OTFTs that have also undergone ion implantation leaving their performance unaffected.

3.2. Evolution with time of OTFTs transport paramenters

We have then monitored the evolution of the transport parameters with time in ion implanted OTFTs to test the effects of the irradiation process on the aging and degradation of the device performance. The results are extremely promising since: (i) there is a clear stabilization effect induced on carrier mobility and/or in threshold voltage for at least up to 2000 h after the implantation process; (ii) implantation with $^{14}N^+$ or with Ne^+ ions induces different effects. In particular, low implantation doses (up to 3×10^{14} cm^{-2}) of 35 keV Ne^+ ions stabilize the carrier mobility (μ) (Fig. 4), while implantation with selected doses and energies of $^{14}N^+$ ions induce a stabilization of the OTFT threshold voltage (V_T) (Fig. 5). The stabilization of V_T is optimized (i.e. almost no V_T variations can be detected) for 25 keV ions and for doses up to 1×10^{15} cm^{-2}. It is noteworthy that higher doses and energies also induce a stabilization of V_T, even if it occurs at values that are largely shifted with respect to the reference, non-implanted device.

The reason for the different behavior induced by implantation with $^{14}N^+$ or with Ne^+ ions can be ascribed to the different reactivity of the two elements. In fact, Ne is not expected to chemically interact with the organic matrix, while N has a high probability of reacting with the organic matrix of pentacene once implanted within the film. We have carried out depth-resolved X-ray photoelectron spectroscopy (XPS) analyses to assess the chemical structure of both implanted species and the pentacene matrix layers by alternating XPS analyses with Ar ion sputter etching (4 keV) to form a sputter depth profile. Extensive XPS investigations were performed on both untreated and ion-implant treated specimens. This included replicate analysis, angle resolved XPS measurements in order to look for chemical differences in the near surface region (<10 nm) with depth into the material, and sputter ion XPS depth profiles to understand chemistry and elemental concentration through the thickness of the film, from the top, air exposed surface, through to the substrate where the primary electronic characteristics are active. The data shown in Fig. 6 are representative of various XPS analysis performed on the thin film pentacene system, and show unusual detail in the chemical composition of the film as a function of depth.

No Ne signal was detectable with sputter profile XPS analyses on Ne-implanted samples, indicating (as expected) that implanted Ne did not form bonds with the hydrocarbon matrix, and was thus lost into vacuum prior to, or during, XPS analyses. Fig. 6a shows the XPS depth profile for a N implanted layer (25 keV and 5×10^{16} cm^{-2} dose). The concentration of the implanted N in the pentacene is maximized at 4.5% atomic concentration (relative to carbon) at a depth of about 76 nm from the top surface in a Gaussian-like distribution as expected from the implant simulations. We have identified the presence of two main N-related chemical states, consistent with —C—N— (398.1 eV), and —C≡N (nitrile functional 399.7 eV) functional terminations on the aromatic rings (Fig. 6a inset) [39]. A minor third component at higher binding energy is indicative of the presence of $—NH_3^+$. This higher binding energy is consistent with ionic ammonium-like functionality. These observations confirm that N reacts with the hydrocarbon matrix and induces the activation/formation of both additional dipole layers (relative to virgin pentacene) and stable positive charge groups within the pentacene layer. The observed broadening of the C1s peak to higher binding energy when N is present in the organic matrix (Fig. 6b), is consistent with the activation of a C—N functionality. The only difference in the two C1s XPS traces in Fig. 6b is the presence (red trace) or absence (green trace) of implanted N in the virgin pentacene. An equivalent depth profile of the virgin pentacene does not

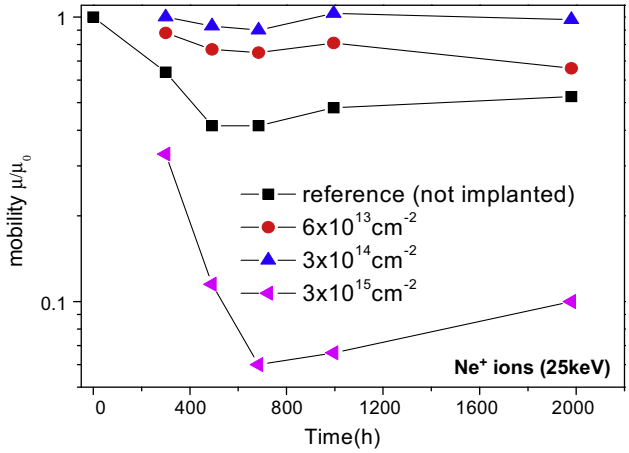

Fig. 4. Evolution with time of the relative charge carrier mobility (μ/μ_0) in Ne implanted OTFTs (ion energy 35 keV), for different ion doses.

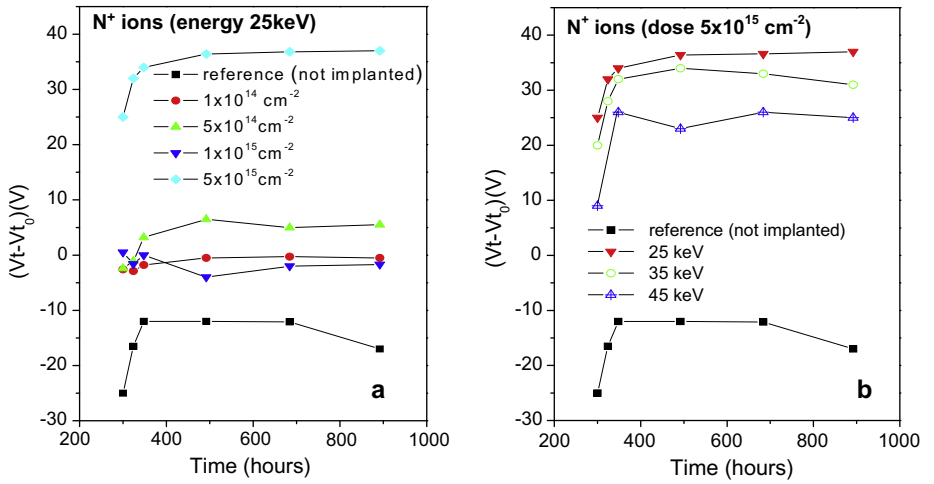

Fig. 5. Evolution with time of the relative threshold voltage ($V_t - V_{t0}$) in N^+ implanted OTFTs: (a) for different ion doses and same energy (25 keV); (b) for different ion energy and same dose (5×10^{15} cm^{-2}).

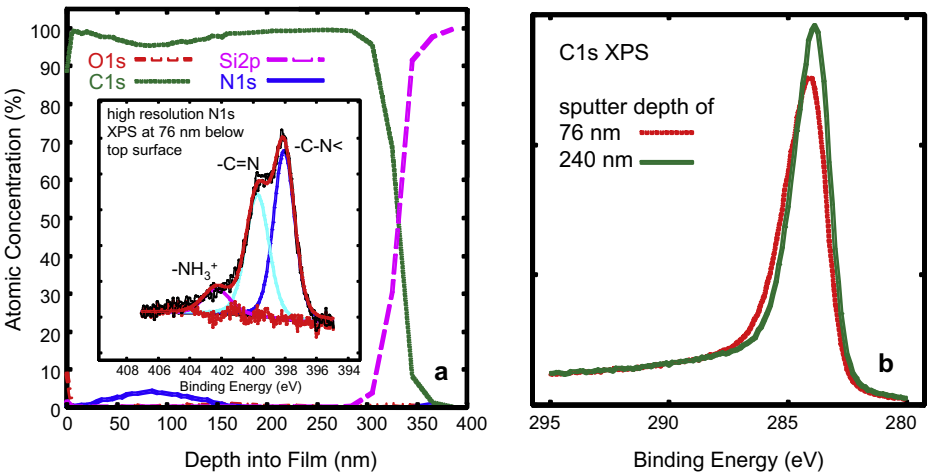

Fig. 6. Depth-resolved X-ray photoelectron spectroscopy (XPS) analyses for N^+ implanted OTFTs (ion energy 25 keV, dose 1×10^{16} cm^{-2}). The inset of (a) shows the deconvolution into the three main chemical components of the N1s peak at a film depth of 76 nm; (b) shows the modification in the chemical environment of C in the presence of N (depth of 76 nm). See text for Section 3.

show these differences, and as such, the differences are clearly due to chemical interaction (bonding) of N with C in the structure of pentacene. The N1s spectrum at the same depth (inset of 6a) also corroborates this by showing various chemical functionalities of N interacted with the C in the structure of pentacene. It is clear that the differences are due to N incorporation chemically with the pentacene matrix. These modifications lead to a different polarizability with respect to the pure pentacene that affects the material electrical behaviour.

Further interesting observations can be drawn from the V_T evolution with time; it is known that V_T in unaltered pentacene progressively degrades with time due to charge trapping effects at the semiconductor/dielectric interface. Many recent studies attribute this effect to the chemical surface structure of most dielectric layer (e.g. —OH terminations in SiO_2) [40]. In the investigated implanted devices, V_T does not significantly degrade with time (Fig. 5), indicating that these trapping effects could possibly be neutralized or masked by another effect. Since the semiconductor/dielectric interface in itself is not directly affected by the implantation process, a possible/reasonable explanation could rely on the effects induced on the OTFT active channel by the presence of charges or modification of the material polarizability, as suggested by XPS.

In particular, our XPS results indicate that N implantation gives rise to a positively charged layer that reaches different depths, controlled by the implant energy. The measured threshold voltage shift seems to be proportional to the thickness of the undamaged layer (Fig. 5b), i.e. to the difference between the film thickness and the implant depth. A simple effect can be invoked to qualitatively explain these data. The implanted charged layer induces an electric field that superposes to the gate field, thus pushing holes towards the insulating layer, i.e. into the device channel. As a consequence, it is necessary to apply a posi-

tive gate voltage in order to deplete the channel and to switch the device off. The same effect can also be obtained by keeping the energy constant (i.e. the implantation depth) and varying the dose (i.e. the density of the charges in the layer), as shown in Fig. 5a. The trend in V_t shift can be again quantified by considering the ratio between the implanted charge density and the undamaged layer capacitance. More interestingly, Fig. 5a shows how low doses ($1 \times 10^{14}\,cm^{-2}$, $5 \times 10^{14}\,cm^{-2}$, $1 \times 10^{15}\,cm^{-2}$) induce a clear stabilization effect on V_t and, on the contrary to what happens to the reference sample and to samples implanted with higher ion doses, V_t does not differ much from V_0 (the value before implantation). The stabilization effect on V_t, observed also in non V_t-shifted devices, suggests that it is this superposed electric field rather than the interface charged states that determines the effective charge carrier concentration and, as a consequence, the threshold voltage.

4. Conclusions

In summary, we have demonstrated how controlled, low energy ion implantation processes can enhance the lifetime of organic transistors, without resulting in increased thickness or modification of the electrical properties of the device. Ion implantation can be safely carried out on fully operational OTFTs, where it modifies the structure of the top portion of the organic active semiconductor layer, thus providing a barrier that reduces the sensitivity to oxygen and water vapor without affecting the functionality of the device. The air stabilization of the main electronic transport parameters of implanted OTFTs (i.e. carrier mobility and threshold voltage) has been assessed for up to 2000 h. Moreover, by selectively implanting with N^+ ions that can react with the hydrocarbon matrix, we observe effects that suggest a local modification of the charge distribution within the organic layer. These findings suggests how the effects induced by ion implantation on organic thin films extend well beyond the here reported lifetime-enhancing application and open up the way for novel and challenging developments in the realization of organic devices.

carriers, although the experimental evidence was insufficient [20]. Furthermore, Liang et al. recently demonstrated the estimation of the carrier mobility in a model OFET device by analyzing the time dependence of the current peak in DCM curves [21].

In principle, the observed current in DCM includes both capacitive and transient terms. The current in metal–insulator–semiconductor (MIS) devices with a time dependent voltage stimulus V is expressed by

$$I = \frac{dQ}{dt} = C_{\text{eff}}\frac{dV}{dt} + i_{\text{tra}}, \tag{1}$$

where C_{eff} is the effective capacitance of the device, Q is the charge, and V is the applied voltage. i_{tra} is the transient current which reflects the dynamic behavior of carrier. Thus, the observed current in DCM includes information in both the quasi-static and transient states as shown in Eq. (1). However, understanding of the second term is still limited. This is mainly because it is not easy to separate the transient contribution in a conventional DCM experiment.

In this study, we propose a new DCM scanning mode, called combined waveform DCM method, using a triangular wave with a plateau region which allows to successfully separate the quasi-static and dynamic DCM currents. By applying combined waveform DCM to pentacene (Pn) MIS devices, we demonstrate that the current peak in the DCM curve reported by Ogawa et al. actually originates from the transient contribution owing to the carrier-spreading process in this device. In addition, the decay time of the transient current in the DCM corresponds to the inverse of the relaxation frequency which is obtained from capacitance–frequency (C–f) measurement. The combined waveform DCM allows us to simultaneously collect information about the effective capacitance and the inverse of the relaxation frequency of the organic device. This advantage will be useful when investigating the device physics in organic electronics.

2. Method

As mentioned above, the current in the MIS device (Fig. 1a) is expressed by Eq. (1). We briefly explain the basics of a typical DCM curve, assuming that the device is in a quasi-static state (corresponding to conventional C–V measurements). Since the organic and insulator layers beneath the top electrode work as capacitor dielectrics without carrier injection, the observed current is governed by the serially combined capacitance of the organic and insulator layers. The current is given by

$$I = C_{\text{eff}}\frac{dV}{dt} = \frac{C_{\text{org}}C_{\text{ins}}}{C_{\text{org}} + C_{\text{ins}}}\frac{dV}{dt}. \tag{2}$$

Here, C_{org} and C_{ins} are the capacitance of the organic and insulator layers, respectively. As shown in Fig. 1b and c, the start voltage of the triangular wave is set as 0 V, and we assume that the MIS device is completely depleted at the 0 V (Fig. 1c region 1 and 2). When holes are injected from the top electrode to the organic layer at the negative voltage (Fig. 1c region 3), they accumulate at the organic/insulator interface as shown in Fig. 1a. Assuming that the current flows through the organic layer without a significant voltage drop, only the insulator layer works as a capacitor dielectric, and hence the displacement current can be expressed as

$$I = C_{\text{ins}}\frac{dV}{dt}. \tag{3}$$

Since the capacitance of the insulator layer is larger than the combined capacitance, the current increases owing to a hole injection in the backward scan ($dV/dt < 0$).

At the beginning of the forward voltage scan ($dV/dt > 0$), the holes are discharged from the organic layer to the electrode (Fig. 1c region 4); then, the organic layer is depleted and back to its initial state. As a result, I–V curves of the typical MIS structure are obtained, as shown in Fig. 1c, when the dynamic current is negligibly small.

Conventional DCM is not suited to analyze the dynamic current for devices in a transient state, because the shape of the curve is often complicated owing to the coexistence of the two terms. In order to separate the transient term, we use a voltage waveform with a ramp and plateau region as shown in Fig. 1d. In this scanning mode, first a applied voltage is kept at the start voltage (V_{str}). Then, a ramp voltage is applied and both the quasi-static and dynamic currents are observed. At the hold voltage (V_{hold}), the ramp is switched to the plateau voltage, and only the transient term is observed due to $dV/dt = 0$. By changing the V_{hold}, we can directly examine the carrier properties in various states of the device.

3. Experiment

The structure of the device under study is Au (50 nm)/Pn (100 nm)/SiO_2 (100 nm)/p-type Si (resistivity ~0.02 Ω cm). The organic layer and the Au electrode were successively fabricated using a conventional vacuum evaporation technique on a highly doped p-type Si substrate covered with SiO_2. The evaporation rate of the organic and metal layers was about 0.5 Å/s. The devices were transferred to a vacuum probe station and DCM was performed in the dark at room temperature. During the transfer of the device from the fabrication chamber to the vacuum probe station, the devices were exposed to air for a short time. We fabricated two kinds of devices, denoted as devices A

and B. The electrode area of device A is the same as the Pn area (2.4 mm^2), while that of device B (1.77 mm^2) is smaller than the Pn area (4.91 mm^2). Table 1 shows the area of Au (S_{Au}) and Pn (S_{Pn}), and the effective capacitances estimated from the device structure (dielectric constant of $\varepsilon_{Pn} = 4.0$ [22] and $\varepsilon_{SiO_2} = 3.8$). C_{dep} shows the geometrical capacitance of the device in depletion, normalized by the electrode area, and corresponds to the capacitance of Region (a) in Fig. 2. C_{inj} shows the capacitance of the device with the carrier injection from the Au electrode to the Pn layer and corresponds to the capacitance of Region (b) in Fig. 2. C_{acc} shows the capacitance of the device in which carriers accumulate over the entire Pn/SiO_2 interface and corresponds to the capacitance of Region (d) in Fig. 2.

DCM measurements were performed using the FCE-1 measurement system for ferroelectrics (Toyo Corp.) at Chiba University. The DCM curves were measured by applying biases within ±20 V to the p-type Si layer, with reference to the Au electrode. To investigate the frequency dependence of the DCM curve, the ramp rate of a triangular wave voltage was changed from 80 V/s to 800 kV/s. Impedance measurements were performed using a frequency response analyzer (Solartron SI 1260 Impedance/Gain-Phase Analyzer) combined with a dielectric interface (Solartron 1296) at University of Augsburg. The amplitude of the AC bias was set to 0.1 V for the *C–f* measurement and the DC bias was varied from −20 to 20 V.

4. Results and discussion

4.1. Analysis of DCM curves in conventional mode

Fig. 2 shows the typical DCM curves of devices A and B at a ramp rate of 80 V/s. The inset shows the comparison of the results between DCM and *C–V* measurement. Vertical axis is the current which is normalized by the electrode area divided by the ramp rate, corresponding to C_{eff} of a device with unit area. As shown in the inset (Fig. 2), the peak structure can only be observed for DCM. This is a unique feature of DCM and we will discuss its results in detail below.

In device A, the capacitance is equal to C_{dep} at voltages larger than 2 V, indicating that the device is depleted. In the backward scan, the negative current increases at 2 V owing to the hole injection from the Au electrode to the Pn layer. C_{eff} at voltages below −1 V is consistent with C_{inj} (Table 1). Then, in the forward scan, the injected carriers are discharged from the Pn to the Au electrode. Finally, the Pn layer is fully depleted and back to its initial state. In device A, the shape of the DCM curve in the forward scan is almost the same as that in the backward scan.

At voltages larger than 12 V in the backward scan, the DCM curve of device B is precisely equal to that of device A. When scanning the voltage to the negative side, the increase of the negative current owing to the hole injection appears in Region (b). The voltage of hole injection for device B is different from that for device A. This is maybe due to the effect of oxygen on Pn layer: since the Pn layer of device B is not fully covered by the top electrode, the hole injection property may be affected by the oxygen penetrated into the device. Finally, a larger capacitance about 0.8 mF/m^2 is observed in Region (d) after the current peak (Fig. 2 Region (c)). The capacitance estimated from the DCM curves indicates that the charge sheet is formed over the Pn/SiO_2 interface. After the sweep direction of the applied voltage is changed to forward at −20 V, the current gradually decreases owing to hole discharge (Fig. 2 Region (e)). The current continues to decay even in the positive bias region in device B, while the carrier discharges around the zero bias region in device A.

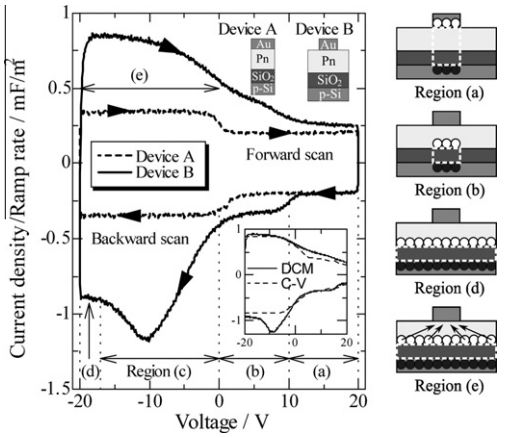

Fig. 2. Device structure dependence in DCM curves of an MIS diode (device A: dashed line, device B: solid line). Region (a): Without carrier injection. Region (b): Carrier injection from Au electrode to Pn layer. Region (c): Injected carrier spreading along the Pn/SiO_2 interface. Region (d): Carrier accumulation over the interface. Region (e): Carrier discharge from Pn layer to Au electrode. Inset: Comparison of DCM (solid line) with *C–V* curves (dashed line) for device B.

Table 1
Area and capacitance of devices A and B. The units of area and capacitance are mm^2 and mF/m^2, respectively.

	S_{Au}	S_{Pn}	C_{dep}	C_{inj}	C_{acc}
Device A	2.4	2.4	0.17	0.34	–
Device B	1.77	4.91	0.17	0.34	0.93

A peak structure is observed in Region (c), and it appears only in the DCM curve of device B. In device A, since the area of the Pn layer is the same as that of the top electrode, no carrier spreading along the Pn/SiO_2 interface can be expected after the carrier injection. Thus, we conclude that the current peak originates from the carrier-spreading effect at the Pn/SiO_2 interface. In addition, the slow discharge process in device B is also owing to its device structure because it is expected that the holes injected farther from the electrode will take longer to discharge.

Fig. 3 shows the DCM curves as a function of the frequency of the applied voltage in device A (left) and device B (right). The ramp rate of the triangular wave voltage is changed from 80 V/s to 800 kV/s. In device A, although there is no difference in the DCM curves from 80 V/s to 8 kV/s, the hole injection voltage shifts slightly to the negative voltage side at 80 and 800 kV/s with the increasing frequency (Fig. 3a). On the other hand, the peak structure in device B strongly depends on the ramp rate and finally disappears at 800 kV/s (Fig. 3c). This result implies that

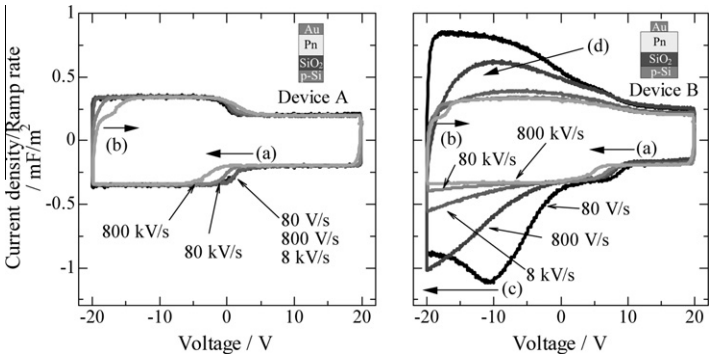

Fig. 3. DCM curves as a function of frequency of applied voltage in device A (left) and device B (right). Ramp rate is varied from 80 V/s to 800 kV/s. The curves showed characteristic changes with increasing frequency: (a) Shift of the hole injection voltage. (b) Shift of the start voltage of hole discharge. (c) Shift of the peak structure. (d) Rounded structure with hole discharge.

the relaxation time of the carrier-spreading process at the Pn/SiO_2 interface is longer than that of the carrier injection process from the electrode to the Pn layer.

In device B, we can observe the terrace structure, $-0.35\ mF/m^2$, corresponding to the C_{inj} at 80 V/s in the backward scan, that is, the injected holes first accumulate only under the electrode area and then start to spread laterally along the Pn/SiO_2 interface. This result indicates that the injected holes do not spread smoothly along the Pn/SiO_2 interface; this behavior can be explained as follows. When the voltage is applied to the sample, the electric field far from the electrode is not enough to drive the carriers laterally. Therefore, the potential difference between just under and far from the electrode prevents the injected holes from spreading at the Pn/SiO_2 interface. With increasing carrier density, the diffusion effect helps the holes to spread.

At the beginning of the forward scan in device A, the injected holes are discharged smoothly at a lower ramp rate than those discharged at 8 kV/s. In comparison, the shape of the DCM curves does not rise sharply at the apex of the triangular voltage (−20 V) for higher ramp rates, and the start voltage of the discharge shifts to the positive voltage side in Fig. 3b. This characteristic feature is also observed in device B at 800 kV/s. In addition, the rounded structure is observed only for device B when the holes which are located at the Pn/SiO_2 interface far from the electrode are discharged in the forward scan. These results indicate that the injected holes cannot follow the high frequency of the applied voltage.

4.2. Transient current characteristics during carrier spreading

Next, we discuss the results of the combined waveform DCM method. Fig. 4a and b show the combined waveform DCM curves for devices A and B, respectively. Vertical axis is the logarithm of the absolute value of current normalized by the electrode area. The measurement was performed while changing the hold voltage (V_{hold}) from 8 to −10 V in device A and from 14 to −18 V in device B, and the V_{str} of device A and B is set to 10 and 20 V, respectively. The V_{hold} is indicated by the bold number in Fig. 4a and b. The current density in the ramp region (before the voltage is held) corresponds to that measured by the traditional scanning mode in the backward scan.

In device A, while the V_{hold} is higher than 2 V, the Pn layer is completely depleted, as shown in Fig. 4a. At a V_{hold} lower than 0 V, the holes are injected from the electrode and accumulate at the Pn/SiO_2 interface. Just after the voltage is held, the current with various V_{hold} values decays immediately. If we define that t_{rel} is the time required for the current to decay less than $0.1\ mA/m^2$ from the beginning of the plateau voltage region, t_{rel} is less than 0.1 s in device A.

In Fig. 4b, the Pn layer is fully depleted around 14 V (depletion). While decreasing the V_{hold}, the current increases with a hole injection at 10 V (injection), and then, at V_{hold} = 2 V, the injected holes start to spread laterally along the Pn/SiO_2 interface. Finally, the charge sheet is completed over the interface at a V_{hold} lower than −10 V (accumulation). Note that the transient currents in the quasi-static, for example, depletion, injection, and accumulation states, decay immediately just after the voltage is held. On the other hand, it takes about 1 s for the transient current to decay at V_{hold} = 2 and −2 V in device B. This t_{rel} is much longer than that in the quasi-static state.

The above result demonstrates that we succeeded in extracting the dynamic current by using the combined waveform DCM method. The dynamic current with a large t_{rel} continues to flow during the hole-spreading at the Pn/SiO_2 interface, clearly indicating that the peak structure originates from the dynamic current. After the charge sheet is formed completely at the Pn/SiO_2 interface ($V < -10$), t_{rel} becomes much smaller. In this way, DCM is able to evaluate both quasi-static and dynamic carrier behavior in organic devices.

Fig. 4c and d show the capacitance-frequency (C–f) curves of devices A and B, respectively. The DC bias is changed from −20 to 20 V and is indicated by bold numbers. For frequencies higher than 10^3 Hz, the capacitance of device A almost agrees with the C_{dep}, because the injected holes cannot follow the frequency of the applied voltage. As the frequency slows, if the DC bias is larger than the hole injection voltage, the capacitance of the device increases and corresponds to C_{inj}. The frequency at the inflection point is called the relaxation frequency (f_{rel}). The f_{rel} at DC bias = −10 and −5 V is 129 Hz. In device A, one f_{rel} is ob-

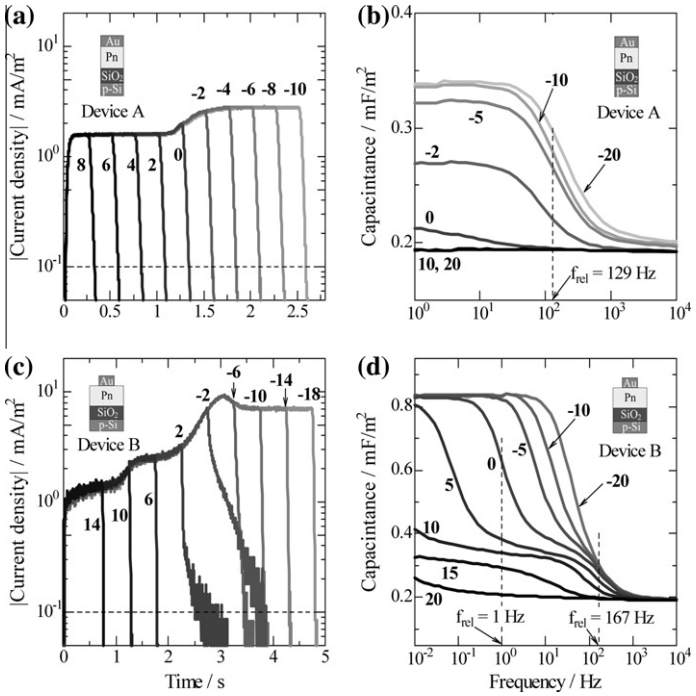

Fig. 4. Combined waveform DCM curves of device A (a) and device B (b) with the various V_{hold}. Ramp rate is 8 V/s and bold numbers show the V_{hold}. C–f curves of device A (c) and device B (d). Bold numbers show the DC bias and f_{rel} shows the relaxation frequency.

served between the depletion and injection states and reflects the hole injection speed from the electrode to the Pn layer.

In device B, the Pn layer is also depleted at frequencies higher than 10^3 Hz, as in device A. For lower frequencies, the capacitance starts to increase from a few hundred hertz; for example, f_{rel} = 167 Hz at DC bias = −5 and 0 V. This f_{rel} is comparable to that estimated for device A; this result indicates that the holes accumulated just under the electrode are following the frequency of the applied voltage. When lowering the frequency, a second increase of the capacitance can be observed at DC bias = 0 V. Since the capacitance almost corresponds to C_{acc} at the low frequency region, this second f_{rel} reflects the hole spreading speed along the Pn/SiO_2 interface. The inverse of the relaxation frequency is about 1 s, by inverting the observed f_{rel} of 1 Hz. This value corresponds well with t_{rel} of combined waveform DCM. This result demonstrates that the combined waveform DCM method is a useful tool to observe not only the effective capacitance of a device but also the relaxation time, as impedance spectroscopy.

The carrier spreading effect has been observed in some reports about inorganic FET [23,24] and organic devices [4,5,20,25–28]. By analyzing the admittance spectra, Ullah et al. suggest that the observed C–V behavior originates from a parasitic, lateral conduction effect occurring at the perimeter of the electrode [28]. In principle, the conventional C–V measurements detect the carrier behavior in static state under each step of DC voltage, which does not correspond to dynamic processes such as formation and annihilation of charge sheet under sweeping voltage. The latter is important to discuss switching properties of OFETs. On the other hand, DCM can investigate the carrier injection, accumulation and discharging processes separately. Actually, the peak structure due to transient current including information about the speed of carrier spreading (dC/dt) was observed only in the formation process (backward scan). The area of the charge sheet is changing with finite dC/dt during the formation, but almost constant in the annihilation (forward scan). From these viewpoints, DCM is a useful tool to investigate the channel behavior of OFETs, especially the switching process.

5. Conclusion

In the DCM of a Pn MIS structure, the carrier injection from the electrode to the organic layer, spreading along the Pn/SiO_2 interface, and the accumulation at the interface were clearly observed. The combined waveform DCM method was proposed and the quasi-static and dynamic currents of DCM were successfully separated in the plateau voltage region. We demonstrated that a current peak observed in the DCM curve originates from the carrier spreading along the Pn/SiO_2 interface. The transient current with a very long decay time was found during the formation of the charge sheet at the Pn/SiO_2 interface. Its decay time is consistent with t_{rel} estimated from the C–f measurement. These results indicate that DCM is a powerful tool for investigating the quasi-static and dynamic behavior of carriers in organic devices. By using various

types of combined waveforms, we can expect further extensions of DCM to investigate carrier behavior in detail.

formed on flexible substrates have been particularly attractive due to their potential applications in environment-friendly nonvolatile memory devices with low-power consumption and with flexible storage elements.

This letter reports data on the electrical bistability properties and the memory mechanisms of OBDs fabricated utilizing CIS/ZnS core–shell QDs blended with a PVK layer on indium-thin-oxide (ITO)-coated polyethylene terephthalate (PET) substrates by using a spin-coating method. Transmission electron microscopy (TEM) measurements were performed to investigate the structural properties of the colloidal CIS/ZnS core–shell QDs blended with a PVK layer. Current–voltage (I–V) measurements and data fitting were carried out to investigate the electrical bistability and the memory mechanisms of the Al/PVK + [CIS/ZnS QDs]/ITO/PET devices, and the memory mechanisms of the OBDs fabricated on flexible PET substrates are described on the basis of the I–V results.

The inorganic/organic nanocomposites consisting of colloidal CIS/ZnS QDs and a PVK conducting polymer layer used in this study were prepared on ITO-coated PET substrates by using a spin-coating technique. The PVK polymer was purchased from the Sigma–Aldrich Co., and the molar mass of the PVK was approximately 25,000 g/mol. The substrates were ultrasonically cleaned by using acetone and methanol and were thoroughly rinsed in deionized water. The chemically-cleaned substrates were then dried by using N_2 gas with a purity of 99.9999% in order to avoid interaction with air. The formation process of the CIS/ZnS QDs solution was started by using a CIS core solution. That solution consisting of 8 ml of octadecene (ODE), 0.1 mmol of indium acetate, and 0.3 mmol of miristic acid was mixed in a 25-ml three-neck flask. Then, the mixed solution was degassed at 110 °C for 2 h, and a Cu-thiol stock solution at 250 °C was added. Subsequently, the solution was heated at 200–210 °C for 2 h. Copper iodide, 0.3 mmol, was mixed with dodecanethiol, 3 ml, for the synthesis of the Cu-thiol stock solution. Then, the mixed solution, while being stirred, was slightly heated on a hot plate. When the synthesis of the CIS core solution was finished, the synthesized solution was in situ cooled to form the ZnS shell at room temperature. Zn acetate, 0.5 mmol, was added to the CIS core solution, and the solution was heated to 230 °C. Then, the solution was aged for 1.5 h at 230 °C.

To fabricate the CIS/ZnS core–shell QDs blended with a PVK layer, we added 2 mg of a $CuInS_2$/ZnS QDs solution to 50 mg of PVK dissolved in 5 ml of toluene. Then, the mixed solution was ultrasonicated for 30 min to obtain a uniform solution. After the substrate had been mounted onto a susceptor in the spin coater, the mixed solution was coated on the substrate by using a spin-coating method at 2500 rpm for 25 s. Then, the solvents existing on the samples were removed by putting the samples onto a hot plate at 90 °C for 30 min. Finally, Al top electrodes with thicknesses of 180 nm were thermally deposited through a metal mask at a system pressure of 1×10^{-6} torr. The diameter of the top Al electrode was approximately 0.3 mm, and the area of the bottom electrode was 2 cm × 2 cm. A schematic diagram of the OBDs fabricated utilizing CIS/ZnS QDs blended with a PVK layer is shown in Fig. 1(a).

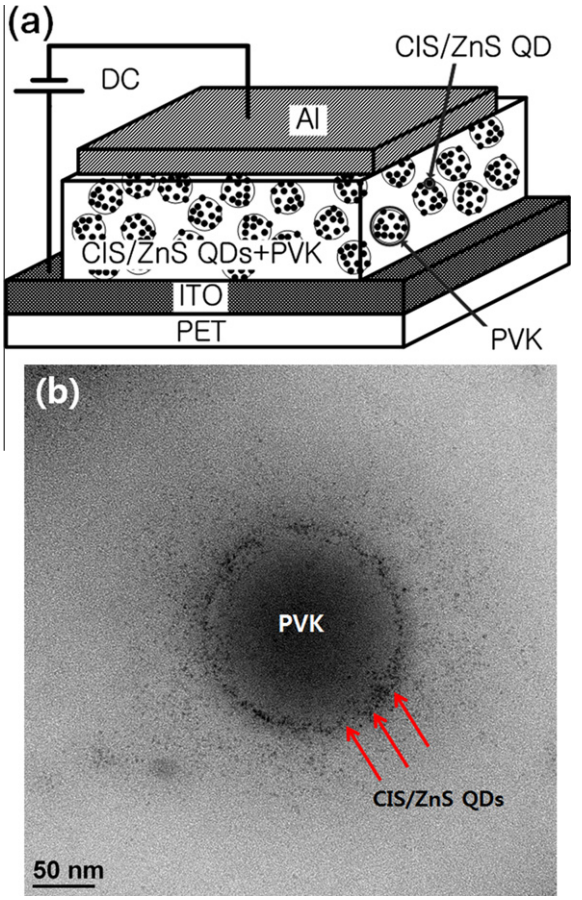

Fig. 1. (a) Schematic diagram of the OBDs based on CIS/ZnS core–shell QDs blended with a PVK polymer. (b) Plane-view bright-field transmission electron microscopy image of CIS/ZnS core–shell QDs blended with a PVK polymer.

TEM measurements (model: STEM/TEM (CM30)) were done at 200 kV. The samples for the TEM measurements were prepared by cutting and polishing with diamond paper to a thickness of approximately 30 μm and then argon-ion milling at liquid-nitrogen temperature to electron transparency. I–V measurements were performed by using a HP 4140B I–V meter at room temperature in an atmosphere.

Fig. 1(b) shows a plane-view bright-field TEM image of the CIS/ZnS QDs blended with a PVK polymer matrix. An apparent aggregation of the CIS/ZnS QDs appears around the surfaces of the PVK molecules. The TEM image indicates that the PVK has particle-like features with diameters of about 150 nm. Fig. 1(b) shows that the CIS/ZnS QDs, indicated by arrows, were attached to the surface of a PVK particle-like structure. The average diameter of the CIS/ZnS QDs is approximately 3 nm.

Fig. 2 shows the I–V curves for the Al/PVK + [CIS/ZnS QDs]/ITO/PET device. The voltage across the device was varied from −3.5 to 3.5 to −3.5 V in all cases, as shown in Fig. 2. When the bottom ITO layer is biased positive, the bias condition is forward. The I–V curves for the device clearly show current hysteresis behaviors, which are

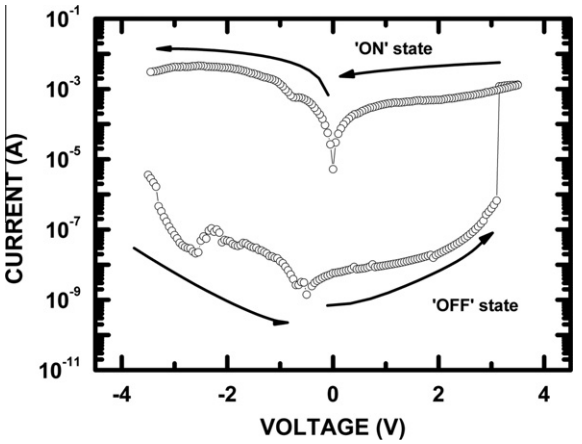

Fig. 2. Current–voltage curves for the Al/PVK + [CIS/ZnS QDs]/ITO/PET device. The scanning step of the applied voltage is 0.05 V.

essential features of bistable devices. The "ON" and the "OFF" states correspond to relatively high-conductivity and relatively low-conductivity states, respectively [21]. The maximum current ratio between the "ON" and the "OFF" states for the device at 1 V is as large as 3.9×10^4. The device without an applied voltage at an initial stage maintains an "OFF" state with a current below 10^{-6} A. The current of the device gradually increases with increasing applied voltage. The current of the device at 3.1 V abruptly increases to 10^{-3} A, indicative of a state transition to the "ON" state in the device. The transition from the "OFF" state to the "ON" state is equivalent to the "writing" process in a digital memory cell. After the transition has been achieved, the "ON" state current is maintained, with currents between 10^{-4} and 10^{-2} A, even after turning off the external power, which is evident from the *I–V* curves under a reverse bias sweep, as shown in Fig. 2. The "OFF" state can be achieved by applying a reverse bias of −3.5 V, at which the device returns to the "OFF" state from the "ON" state, indicative of the completion of the "erasing" process in a digital memory cell.

Fig. 3 shows the currents as functions of the number of cycles for the "ON" and the "OFF" states of the Al/PVK + [CIS/ZnS QDs]/ITO/PET device. A sequence of pulses lasting less than 1 ms was employed to confirm the memory endurance for the write/erase stress. An endurance larger than 5×10^3 ON/OFF switchings, together with a rewritable capability, is clearly observed. The current fluctuations in the "ON" and the "OFF" states for a large number of cycles are attributed to incomplete writing and erasing operations [6]. However, even though a state fluctuation appears, the ON/OFF ratio in the device is always larger than 10^3.

To investigate the carrier transport mechanisms in the device, we fitted the data for the *I–V* curves by using three conduction models: thermionic emission (TE), space-charge-limited current (SCLC), and Fowler–Nordheim (FN) tunneling models [22–24]. Fig. 4(a) is a log–log plot of the current as a function of the applied voltage for the entire voltage sweep range. Fig. 4(a) shows the fitting data for various current transport models in different voltage regions. The *I–V* curves exhibit three regions with different

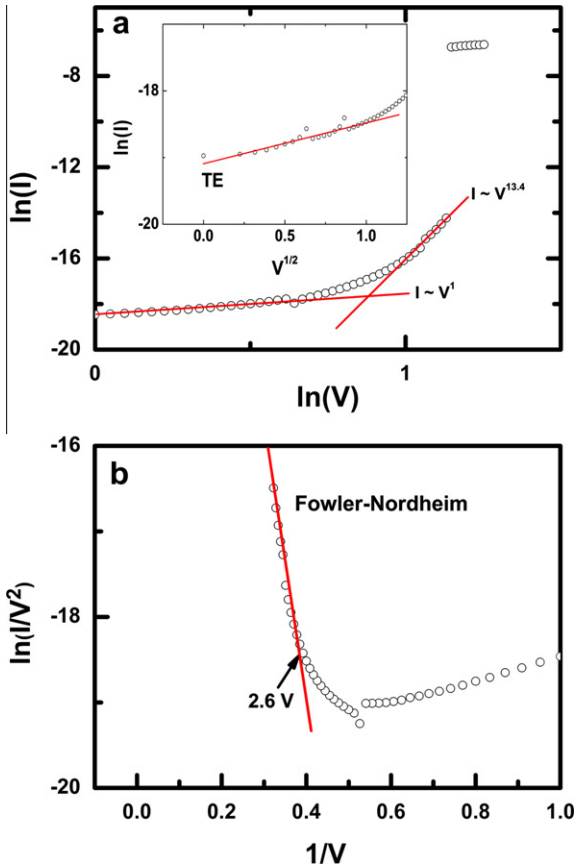

Fig. 4. (a) A log–log plot of the current as a function of the voltage for an Al/PVK + [CIS/ZnS QDs]/ITO/PET device, and the curves are fitted for the space-charge-limited current mechanism. (b) Fowler–Nordheim plot for OBDs with CIS/ZnS QD–PVK nanocomposites.

behaviors. The data at lower voltages up to 1 V can be well fitted with the TE model, as shown in the inset of Fig. 4(a), where ln(*I*) is plotted against $V^{1/2}$. The small current in the

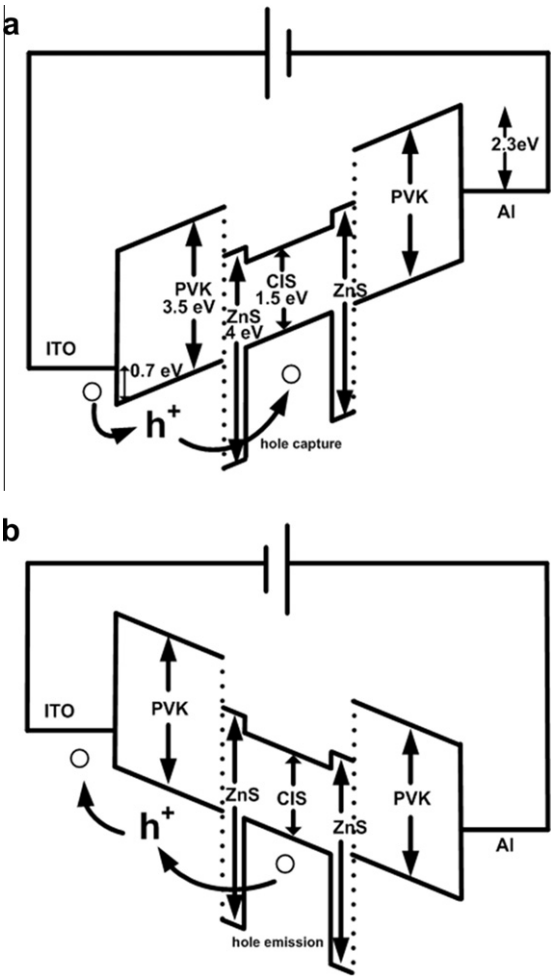

Fig. 5. Schematic diagrams of the electronic structures corresponding to the operating mechanisms of the (a) writing and (b) erasing processes for the Al/PVK + [CIS/ZnS QDs]/ITO/PET device. The energy levels for the CIS core are taken from Ref. [27], and those for the ZnS shell and the PVK layer are taken from Refs. [29,26], respectively.

region might be attributed to thermally-generated electrons from the PVK layer or from the interface between the electrode and the PVK layer [25]. Two distinct regions with different linear slopes are clearly observed at voltages above 1 V, with a changeover at 2 V. The equation $I \propto V^{\alpha}$ was used for the SCLC behavior, where α is an exponential fitting parameter. The exponential fitting parameter, α, is about 1 for the voltage range between 1 and 2 V, indicating that the electrical conduction is dominantly governed by Ohm's law in this range. The *I–V* characteristics in the applied voltage range between 2 and 3.1 V show a large linear slope of $\alpha = 13.7$, and the response follows a dominant, exponential trap SCLC ($\alpha \gg 2$). This result indicates that the traps are distributed exponentially within a forbidden gap. At voltages above 3.1 V, the magnitude of the current starts to significantly increase to higher values. Because the plot of $\ln(I/V^2)$ as a function of $1/V$ at voltages above 2.6 V is linear, as shown in Fig. 4(b), the carrier conduction in this region is dominantly attributed to FN tunneling.

Fig. 5 shows schematic diagrams of the electronic structures corresponding to the mechanisms of the writing and the erasing operations for the Al/PVK + [CIS/ZnS QDs]/ITO/PET device under (a) positive and (b) negative voltages. The LUMO and the HOMO represent the energy levels of the lowest unoccupied molecular orbital and the highest occupied molecular orbital of the PVK layer, respectively [26]. The HOMO of the PVK layer and the energy bands of the CIS core at the writing operation bend downward with increasing positive voltage, so holes injected from the ITO are tunneled through the PVK layer. The injected electron cannot tunnel through the barrier because of the relatively high barrier height at the interface between the electrode and the PVK layer. After the injection of holes via FN tunneling, the holes existing at the HOMO are transported to the CIS core along the direction of the applied voltage by hopping among the PVK molecules [27,28]. The ZnS shell around the CIS core suppresses the leakage of the captured holes due to its high energy barrier, as shown in Fig. 5(a). This results in the writing operation of the memory devices, which is transited from the OFF to the ON states. When a negative voltage is applied to the ITO electrode, the device remains in an ON state until the critical voltage of -3.5 V is reached, at which the CIS cores are discharged. The discharge of the holes captured in the CIS core about -3.5 V results in a significant decrease in the current, and the current of the device again goes to a low-current-conducting OFF state, as shown in Fig. 5(b). This results in the erasing process of the devices, which is transited from the ON to the OFF states.

In summary, OBDs based on CIS/ZnS core–shell QDs blended with a PVK layer were fabricated on flexible substrates by using a simple spin-coating method. TEM images showed that the CIS/ZnS core–shell QDs were attached to the surfaces of PVK molecules. The *I–V* curves at 300 K for the devices exhibited electrical bistabilities due to the existence of the CIS/ZnS core–shell QDs embedded in a PVK layer. The maximum ON/OFF ratio of the current bistability for the OBDs was as large as 3.9×10^4, and the cycling endurance of the ON/OFF switching for the OBDs was larger than 5×10^3. The fitting data of the *I–V* curves demonstrated that the carrier transport mechanisms related to the memory effects of the devices for the writing process were attributed to the TE and the SCLC processes while the corresponding mechanisms for the erasing process were related to the FN tunneling process.

(TBADN) are used as neat green and blue fluorescent materials, respectively. Indium-Tin-Oxide (ITO) and LiF/Al are used as the two electrodes between which the organic material is sandwiched. All samples are fabricated by the deposition of the organic materials and metals at a rate of 1.5–3 Å/s using thermal evaporation at a base pressure of $\sim 5 \times 10^{-6}$ torr on UV ozone-cleaned ITO-coated glass substrates. For photo-degradation, monochrome illumination from a 200 W Hg–Xe lamp equipped with Oriel-77200 monochromator is used. All tests are carried out in a nitrogen atmosphere.

3. Results and discussion

A group of samples of structure ITO/AlQ_3(50 nm)/LiF(x)/Al(100 nm) are fabricated and tested. In theses samples, the thickness of the LiF, x, is varied from 0 to 20 nm. Fig. 1 shows the changes in FL yield (as evident from changes in FL intensity normalized to the initial value at the same excitation power density) of these samples versus time elapsed during which the samples are either left in the dark or exposed to 365 nm illumination of power density $\sim$0.5 mW/cm^2. The temperature of the samples is kept at 22 ± 1 °C during the measurements to eliminate any thermal effects on FL yield. As the figure shows, the sample without LiF (solid triangle) shows no detectable decrease in FL yield after exposure to illumination for a period of 5 h, indicating that any photo-degradation in AlQ_3 molecules under these irradiation conditions must be insignificant in the given time frame. On the other hand, the ones containing LiF show a significant decrease in FL yield under the same conditions. More notably, the decrease in FL becomes faster as the thickness of the LiF layer increases from 1 to 20 nm. Furthermore, the decrease in FL from a sample with 100 nm AlQ_3 and 1 nm LiF (solid square) is found to be slower than that from a sample with 50 nm AlQ_3 and 1 nm LiF (hollow triangle). These observations suggest that the decrease in FL of the samples incorporating LiF may be due to the diffusion of certain species at the AlQ_3/LiF interface to bulk AlQ_3 which acts as FL quenchers, hence the less pronounced effect in samples with thicker AlQ_3 and/or thinner LiF. It should be pointed out that keeping a sample of the structure ITO/AlQ_3(50 nm)/LiF(5 nm)/Al(100 nm) in the dark (solid diamond) leads to no detectable change in FL yield, indicating that the change in FL is induced by illumination. The observations therefore suggest that the diffusing species behind the decrease in FL must be the product of some photo-induced interactions between LiF and AlQ_3.

The inset of Fig. 1 displays the percentage change in FL yield observed in these samples after 1 h of illumination versus the thickness of the LiF layer. From the figure, the faster deterioration in FL with LiF thickness appears to proceed less rapidly as thickness increases, possibly reaching saturation at a thickness of about 20 nm. This can perhaps be explained in terms of the fact that the LiF/AlQ_3 interface is not abrupt but rather diffuse possibly due to the disparate molecular sizes of AlQ_3 and LiF [15], which would allow for significant interpenetration between molecules of the two materials at the interface. Therefore, the FL loss increases quickly with LiF thickness initially (when LiF is less than 5 nm) as a result of an increasing effective AlQ_3–LiF interface, yet gradually saturates when LiF exceeds 10 nm when AlQ_3 "valleys" have been filled with LiF and no more AlQ_3–LiF interface is formed.

To further investigate the nature of the processes behind the behavior observed in Fig. 1, we study the effect of applying electric fields on the photo-induced changes in the FL yield. Fig. 2a shows the changes in FL yield of a sample of structure ITO/AlQ_3(50 nm)/LiF(1 nm)/Al(100 nm) versus time elapsed during which the samples are subjected to one of the following stress scenarios: (i) irradiation only (denoted by L), during which the sample is exposed to 405 nm illumination of power density $\sim$0.6 mW/cm^2, (ii) reverse bias only (denoted by R), during which a reverse bias of −6 V is applied across the ITO and the Al electrodes of the sample (with ITO at a more negative potential relative to Al), and (iii) irradiation and reverse bias together

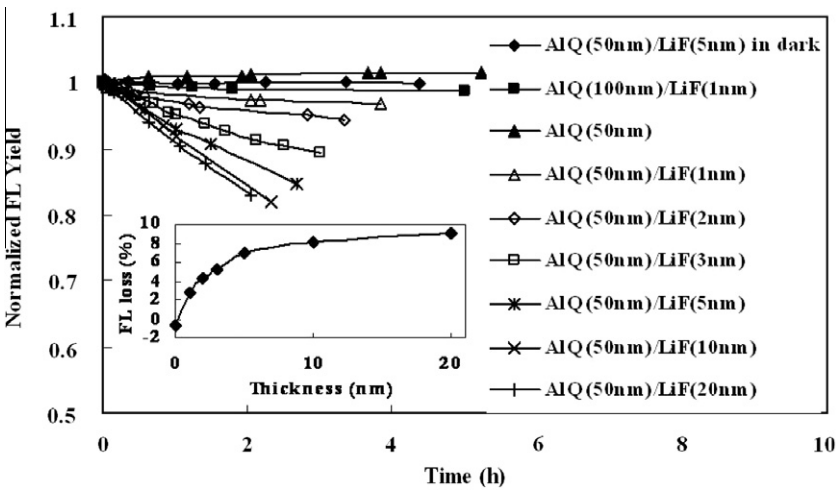

Fig. 1. The changes in FL yield versus time elapsed during which the samples are either left in the dark or exposed to 365 nm illumination of power density $\sim$0.5 mW/cm^2. Inset: the percentage change in FL yield after 1 h of illumination versus the thickness of the LiF layer.

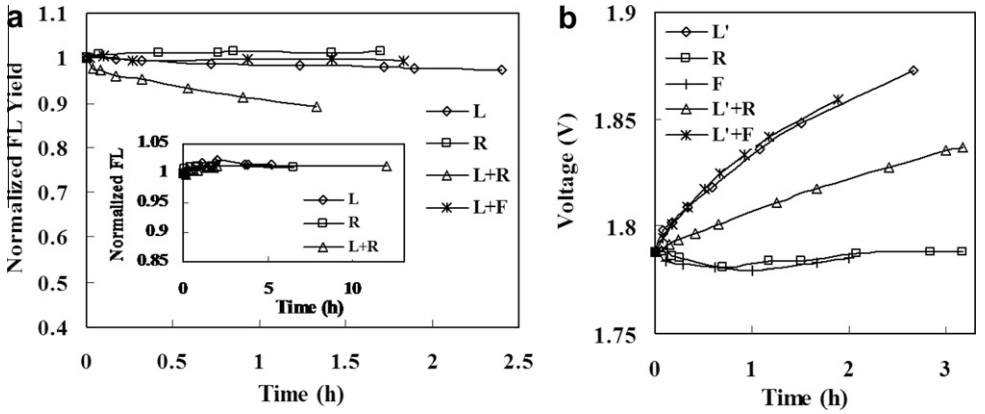

Fig. 2. (a) The changes in FL yield of samples of the structure ITO/AlQ_3(50 nm)/LiF(1 nm)/Al(100 nm) versus time elapsed during which the samples are subjected to stress scenario L, R, L + R and L + F. Inset: the changes in FL yield of samples of the structure ITO/AlQ_3(50 nm)/Al(100 nm) versus time elapsed during which the samples are subjected to stress scenario L, R and L + R. (b) The changes in V_d of the samples versus time elapsed during which the samples are subjected to scenario L' (535 nm illumination, 1 mW/cm^2), R, F, L' + R and L' + F, respectively.

(denoted by L + R), during which the sample is subjected to the conditions of (i) and (ii) simultaneously, and (iv) irradiation and forward bias together (denoted by L + F), during which the sample is subjected to the conditions of applying a forward bias of +4 V and (ii) simultaneously. A lower voltage is used in case of the forward bias in order to minimize electrical aging effects which could result from the higher current flow in this case [16]. Despite the voltage difference, the electric field across the AlQ_3/LiF interface is expected to be similar in both forward and reverse bias. This is in view of the fact that carrier concentration in the AlQ_3 will be much higher in case of forward bias (due to the good electron injection characteristics of the AlQ_3/LiF/Al contact and the much higher mobility of electrons in AlQ_3 versus that of holes [17]); hence an expectedly much lower field across the AlQ_3 layer itself in this case. As Fig. 2a depicts, exposing the sample to illumination (scenario i) leads to a gradual decrease in its FL yield, which is consistent with the results in Fig. 1, and exposing it to illumination in the presence of reverse bias (scenario iii) significantly accelerates such change. In contrast, applying a reverse bias alone (i.e. without irradiation) (scenario ii) does not bring about any detectable change in FL yield, again verifying that the underlying mechanisms are photo-induced in nature. The fact that a reverse bias can accelerate the photo-induced deterioration in FL yield suggests that the underlying processes are also electrochemical in nature. Interestingly, applying a forward bias during irradiation (scenario iv) appears to have a little bearing on the changes in FL yield, evident in the fact that the decrease in FL yield in this case is very similar to that obtained by irradiation alone without bias (i.e. similar to that obtained from scenario i). This suggests that the diffusing species, produced by some photo-induced interactions between LiF and AlQ_3 at the AlQ_3/LiF interface, may be positively charged, hence its faster migration into the AlQ_3 layer under reverse bias. In this regard, the slow decrease in FL yield observed in case of scenario i (i.e. L only) can be attributed to the diffusion of these positively charged species from the AlQ_3/LiF interface (where it is formed by photo-induced interactions) into the AlQ_3 layer, driven by concentration gradients. In scenario iii (i.e. L + R), the application of a reverse bias during illumination significantly accelerates the migration of these positively charged species into the AlQ_3 layer, hence the much faster deterioration in FL in this case. As the formation and/or release of these species from the AlQ_3/LiF interface depends on photo-induced processes, the behavior is not observed with scenario ii (R only, no illumination), and the FL yield remains essentially unchanged in this case. According to this model, we would expect the application of an opposite (i.e. forward) bias to slow down the diffusion of these species. A close examination of the FL trends in the figure indeed supports this notion, where the application of a forward bias during illumination (scenario iv, L + F) can be seen to result in a slower decrease in FL yield versus that observed under scenario i (L only). Although the difference between the two trends on the figure is small, additional work shows that using a thicker LiF layer enhances the difference.

It should be pointed out that the faster degradation in FL yield in case of scenario iii may, in principle, be alternatively attributed to an increased concentration of photogenerated carriers of AlQ_3, due to electric field-induced dissociation of AlQ_3 excitons [18], and hence to a subsequent increase in exciton–carrier interactions [19] or to a higher concentration of the unstable AlQ_3 cations [16]. In order to investigate this alternative hypothesis, we tested other samples that do not contain the LiF layer. The results are shown in the inset of Fig. 2a. As shown in the figure, subjecting the samples of the structure ITO/AlQ_3(50 nm)/Al(100 nm) to scenarios i, ii and iii leads to no detectable change in FL yield, indicating that the changes observed above are associated with LiF and are not merely due to a higher concentration of photogenerated carriers in the AlQ_3 layer. The results therefore rule out this alternative degradation mechanism.

Besides the degradation in FL yield of the bulk organic layer, the AlQ_3/LiF/Al contact also degrades as the samples

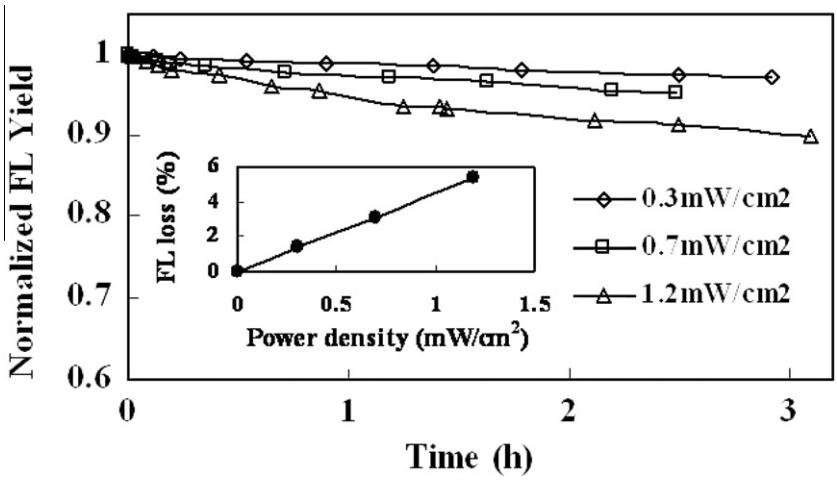

Fig. 3. Normalized FL yield of samples of structure ITO/AlQ_3(50 nm)/LiF(3 nm)/Al(100 nm) as a function of time during which the samples are exposed to 405 nm illumination at three different power densities; ~0.3, 0.7 and 1.2 mW/cm^2. Inset: the FL loss after 1 h of illumination versus the illumination power density.

are subjected to irradiation. Fig. 2b shows the changes in V_d of the samples at current density 0.3 mA/cm^2 versus time elapsed during which the samples are subjected to scenario L' (535 nm illumination, 1 mW/cm^2), R, F, L'+ R and L' + F, respectively. As the figure depicts, exposing the sample to illumination (scenario L', L' + R and L' + F) leads to a gradual increase in V_d, suggesting a deteriorated electron injection from the cathode and thus a degraded AlQ_3/LiF/Al contact.

We have also investigated the dependence of this behavior on the illumination power density and on the optical absorbance of the organic layer. Fig. 3 shows normalized FL yield of samples of structure ITO/AlQ_3(50 nm)/LiF(3 nm)/Al(100 nm) as a function of time during which the samples are exposed to 405 nm illumination at three different power densities; ~0.3, 0.7 and 1.2 mW/cm^2. As the figure shows, increasing the power density brings about a faster degradation in FL yield. The inset in Fig. 3 shows the FL loss after 1 h of illumination versus the illumination power density. Clearly, the figure shows a linear correlation, indicating that the effect depends linearly on the density of AlQ_3 excited states. Fig. 4a shows normalized FL yield versus time for a sample of structure ITO/AlQ_3(50 nm)/LiF(5 nm)/Al(100 nm) subjected to monochromatic illumination of various wavelengths in the range 365–640 nm. We note that there are small variations in the illumination power density at the different wavelengths. We therefore also normalize the data to the same illumination power density, using the linear correlation as established from Fig. 3. Fig. 4b displays the same data after being normalized to the same illumination power density. Fig. 4c displays the FL loss after 1 h of illumination according to the results in

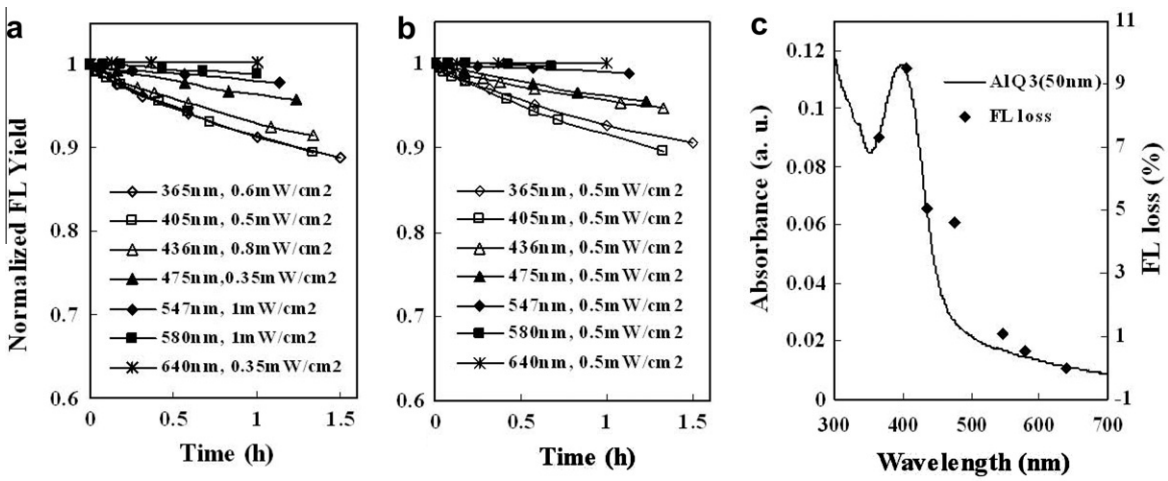

Fig. 4. (a) Normalized FL yield versus time for samples of structure ITO/AlQ_3(50 nm)/LiF(5 nm)/Al(100 nm) subjected to monochromatic illumination of various wavelengths. (b) The same data after being normalized to the same illumination power density. (c) The FL loss after 1 h of illumination according to the results in Fig. 4b and the UV–Vis absorption spectrum of neat AlQ_3.

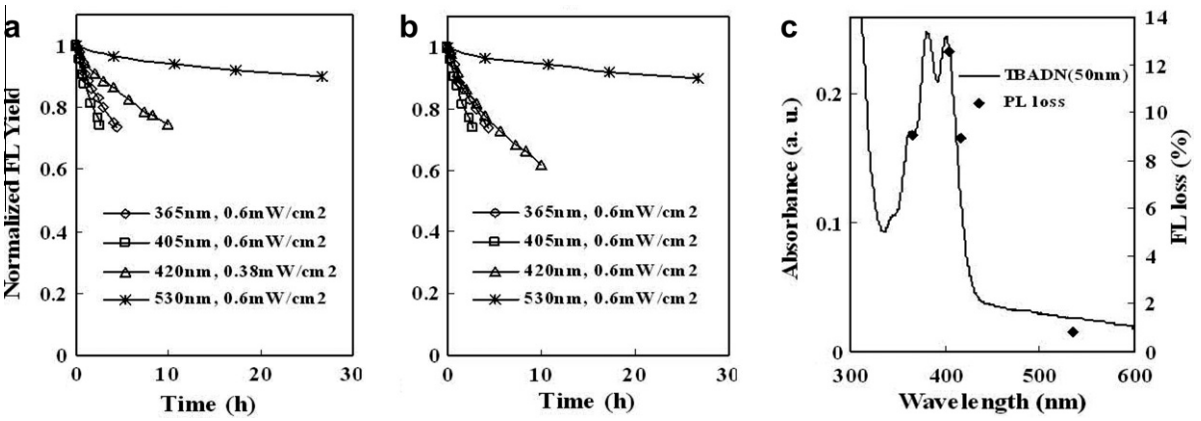

Fig. 5. (a) Normalized FL yield versus time for samples of structure ITO/TBADN(50 nm)/LiF(5 nm)/Al(100 nm) subjected to monochromatic illumination of various wavelengths. (b) The same data after being normalized to the same illumination power density. (c) The FL loss after 1 h of illumination according to the results in Fig. 4b and the UV–Vis absorption spectrum of neat TBADN.

Fig. 4b. It also shows UV–Vis absorption spectrum of neat AlQ_3. Clearly, the results show a strong correlation between the FL loss and the absorption spectrum of AlQ_3, evident in the fact that illumination at wavelengths where AlQ_3 has stronger absorption lead to a faster degradation in FL yield. The results indicate that absorption of light by the AlQ_3 layer, rather than by other species at the contact, is behind the photo-induced processes. To further confirm this conclusion, a parallel study is carried out on another set of samples that utilize another organic material TBADN. Clearly, Fig. 5c also shows a strong correlation between the FL loss and the absorption spectrum of TBADN in this case. These results convincingly indicate that the photo-induced interactions at organic/LiF/Al contact involve interactions between LiF (or some LiF species) and adjacent organic molecules that are in an excited state; possibly due to some photo-chemical reactions, and which can lead to the release of some positively charged quenchers that can diffuse into the organic layers, and, subsequently reduce the FL yield. It should be pointed out that in case of OLEDs, the effect of the diffusion of the FL quenchers could be less serious due to the applied forward bias; however, the photo-degradation of the organic/LiF/Al contacts by the device own EL leads to a deteriorated electron injection and thus poor stability [14].

4. Summary

In summary, we study the photo-stability of the organic/LiF/Al contacts widely used in organic optoelectronic and photovoltaic devices. Exposing organic/LiF/Al to illumination is found to lead to a decrease in FL yield of the organic layer. The decrease in FL is found to be due to the diffusion of certain positively charged species, possibly resulting from photochemical interactions with the LiF layer. Evidence of the correlation between the density of the excited states in the organic material and the rate of photo-degradation of the organic/LiF/Al contact is also reported. The results reveal that these widely used contacts suffer poor photo-stability.

be advantageous as a charge injecting electrode for AS since it possesses a high work function of up to >6.1 eV, but does not introduce any series impedance into the device structure. As we will show the hole mobility of N,N′-diphenyl-N,N′-bis-(1-naphthyl)-1-1′-biphenyl-4,4′-diamine (α-NPD) measured using AS with a Cl-ITO anode is found to be closer to the value measured by TOF than for an equivalent measurement with a MoO_3 charge injection layer.

2. Experimental

Single carrier devices for the AS measurements were fabricated in a Kurt J. Lesker LUMINOS® cluster tool on commercially patterned ITO coated glass with a sheet resistance less than 15 Ω/□. Substrates were ultrasonically cleaned with a standard regiment of Alconox®, acetone, and methanol followed by UV ozone treatment for 15 min. The standard device structure is as follows: anode/α-NPD (536 nm)/Ag. The anodes used in this work were bare ITO, Cl-ITO, and ITO coated with 0.75 nm of MoO_3. The active area for all devices was 2 mm^2. Cl-ITO was produced by treatment of pre-cleaned substrates with 1,2-dichlorobenzene vapor for 3 min in a sealed Pyrex Petri dish in a UV photo surface processor (SEN Lights Corporation), followed by UV ozone treatment for 3 min [10]. The thickness of the organic layer was measured using a quartz crystal microbalance calibrated using spectroscopic ellipsometry and were verified for each device using capacitance-voltage measurements. The frequency-dependent capacitance of the devices was measured using an HP4192A impedance analyzer in a vacuum cryostat [11]. Ultraviolet photoelectron spectroscopy (UPS) measurements were performed using a PHI 5500 Multi-Technique system (base pressure of $\sim 10^{-10}$ Torr) with attached organic deposition chamber using He Iα ($h\nu$ = 21.22 eV).

3. Theory

The theory behind the AS technique has been extensively discussed in the literature [1,2,4]. A very thorough summary of the technique complete with all derivations is provided in Ref. [4]. In short the AS technique is based on the measurement of the frequency-dependent capacitance of an organic thin film. The capacitance is found to exhibit a characteristic minimum as a function of frequency, which is indicative of the carrier transit time τ_{dc} across the organic film. Typically the frequency-dependent capacitance is re-plotted as the negative differential susceptance,

$$-\Delta B = -\omega(C - C_{geo}), \tag{1}$$

where $\omega = 2\pi f$ is the angular frequency, C is the capacitance and $C_{geo} = \varepsilon A/d$ is the geometric capacitance. This plot typically yields a maximum in $-\Delta B$ at a characteristic frequency $f_r = \tau_r^{-1}$. Simulation results have shown that $\tau_{dc} = 0.56\tau_r$ for non-dispersive transport [4]. The dc mobility is then given by,

$$\mu_{dc} = \frac{d^2}{\tau_{dc}(V - V_{bi})}, \tag{2}$$

where d is the device thickness, V is the applied voltage and V_{bi} is the built-in potential, which can be measured using photovoltaic measurements [12].

4. Results and discussion

Fig. 1 shows the room temperature (300 K) current-voltage (*IV*) characteristics of α-NPD single carrier devices with ITO, ITO/MoO_3, and Cl-ITO anodes. As expected the device with bare ITO anode has the lowest current density due a large injection barrier at the ITO/α-NPD interface. The current density of the devices with ITO/MoO_3 or Cl-ITO anodes is ~2 orders of magnitude higher than the device with bare ITO anode. Transition metal oxides, such as MoO_3, have been reported to lower the injection barrier into HTL molecules due to their high work function [13]. Cl-ITO also has a high work function of up to >6.1 eV (measured by the authors using photoelectron spectroscopy), which allows for a lower injection barrier into α-NPD, which has a HOMO of 5.4 eV as measured by UPS. The current density of the device with Cl-ITO anode is slightly higher than that of the device with ITO/MoO_3 anode, particularly at higher currents. This suggests that there is a series impedance introduced by the MoO_3 layer. The mobility extracted from devices with ITO/MoO_3 anode using AS might therefore be influenced by this series impedance.

To confirm that the difference in the *IV* characteristics is a result of series impedance and not due to a difference in injection barrier, we measured the energy-level alignment of α-NPD with ITO/MoO_3 and Cl-ITO using UPS. Fig. 2 shows the UPS valence band spectra of ITO/MoO_3 and Cl-ITO with and without a 3 nm thick layer of α-NPD. As expected there is no density of states at the Fermi level for ITO/MoO_3, which indicates that the MoO_3 layer is a semiconductor and hence will contribute a finite series

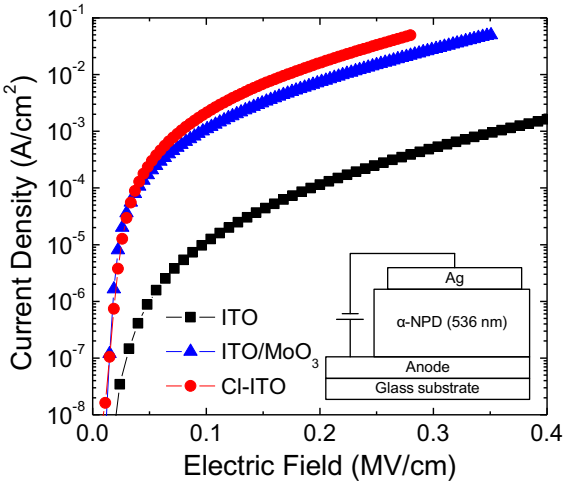

Fig. 1. Current density as a function of electric field for α-NPD single carrier devices with ITO, ITO/MoO_3, and Cl-ITO anodes. The inset shows the device structure. The electric field (F) is taken as $F = (V - V_{bi})/d$, where V is the applied voltage, V_{bi} is the built-in potential determined from photovoltaic measurements and d is the device thickness (536 nm).

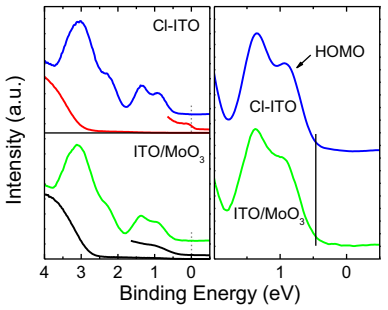

Fig. 2. Valence band spectra of ITO/MoO_3 (bottom left) and Cl-ITO (top left) with and without a 3 nm thick layer of α-NPD measured using UPS. An enlargement of the density of states near the Fermi level (indicated by the vertical dashed line) for ITO/MoO_3 and Cl-ITO is shown on the left. An enlargement of the HOMO derived peak of α-NPD on both samples is also shown on the right.

impedance to the device. The valence band of the Cl-ITO is nearly identical to that of UV ozone treated ITO (not shown). The finite density of states at the Fermi level of ITO is clearly visible in the Cl-ITO valence band spectra (ITO is a degenerate semiconductor). After deposition of α-NPD the work function of the ITO/MoO_3 and Cl-ITO decreased to 4.9 eV for both samples from 5.9 eV and 6.1 eV, respectively, indicating a large interfacial dipole at both interfaces. The HOMO derived peak of α-NPD deposited on ITO/MoO_3 and Cl-ITO are also shown in Fig. 2. The HOMO of α-NPD is found to be ~0.45 eV on both samples, which indicates that the injection barriers are the same. We have previously measured a much higher barrier of ~0.6 eV for bare UV ozone treated ITO [15], which is consistent with the *IV* characteristics shown in Fig. 1. Hence the difference in the *IV* characteristics should be the result of the series impedance introduced by the MoO_3 layer.

Fig. 3 shows the frequency-dependent capacitance and conductance of α-NPD single carrier devices with Cl-ITO anode as a function of applied bias. At zero applied bias the capacitance is nearly constant with frequency and is representative of the geometric capacitance C_{geo}. The decline in capacitance at high frequency is due to the parasitic capacitance of the test fixture and does not affect the present analysis. With increasing applied bias the characteristic minimum in the capacitance curve shifts to higher frequency, indicative of the field dependent mobility of the organic. Fig. 4 shows the negative differential susceptance $-\Delta B$ as a function of voltage for the same device. The characteristic frequency $f_r = \tau_r^{-1}$, indicated by the arrows, shifts to higher frequency with increasing applied bias. This trend indicates that the carrier transit time is shorter at higher applied bias and hence the mobility increases with electric field.

Fig. 5 shows the hole mobility as a function of electric field extracted from the negative differential susceptance of α-NPD single carrier devices with ITO, ITO/MoO_3, and Cl-ITO anodes. The mobility measured by TOF is also shown as reference [15]. As expected the mobility extracted from the device with ITO anode using AS is significantly lower than the value measured using TOF. What is

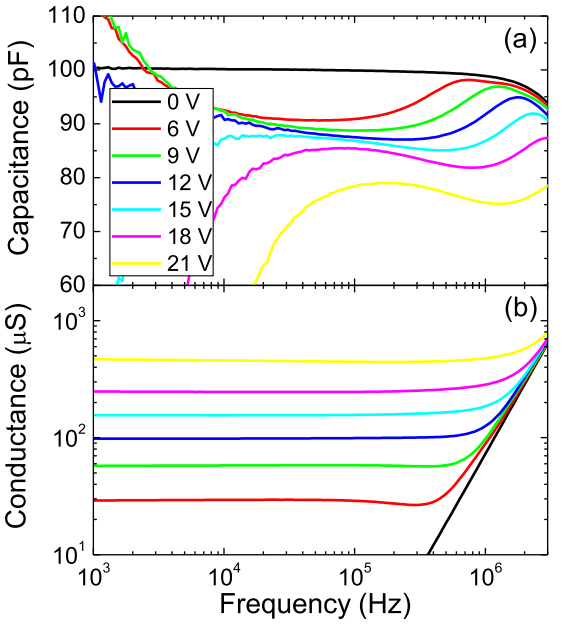

Fig. 3. Admittance spectra as a function of applied bias for α-NPD single carrier devices with Cl-ITO anode showing (a) the frequency-dependent capacitance and (b) the frequency-dependent conductance.

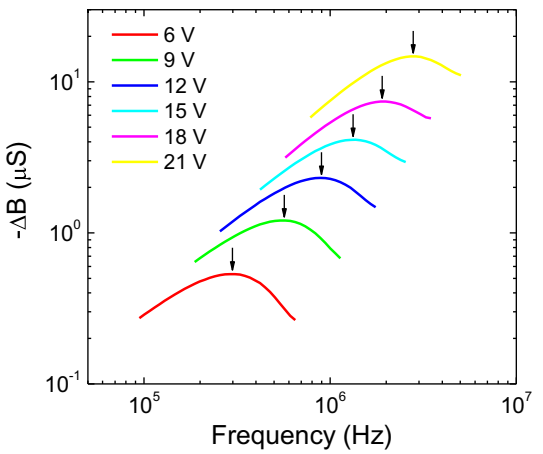

Fig. 4. Frequency-dependent negative differential susceptance as a function of applied bias for α-NPD single carrier devices with Cl-ITO anode. The arrows indicate the characteristics relaxation time $f_r = \tau_r^{-1}$.

more, the field dependence is also significantly different than the TOF results. This can be easily understood as there is a significant injection barrier of ~0.6 eV at the ITO/α-NPD interface [14]; as discussed above AS requires an Ohmic contact at the injecting electrode. The mobility extracted from the device with ITO/MoO_3 anode using AS is much closer to the value measured using TOF, but is still noticeably lower. Since MoO_3 has been reported to form an Ohmic contact with α-NPD [16] this implies that the impedance of the MoO_3 layer does indeed affect the AS measurements. On the other hand, the mobility extracted from the device with Cl-ITO anode using AS is nearly identical to the value measured using TOF, since the Cl-ITO

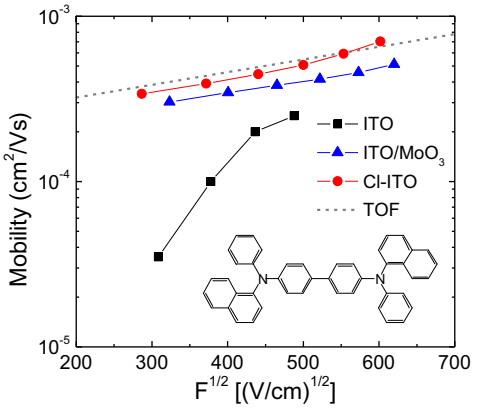

Fig. 5. The field dependent hole mobility as a function of the square root of electric field extracted from α-NPD single carrier devices with ITO, ITO/MoO_3, and Cl-ITO anodes using AS. The electric field (F) is taken as $F = (V - V_{bi})/d$, where V is the applied voltage, V_{bi} is the built-in potential determined from photovoltaic measurements and d is the device thickness (536 nm). The dashed line is the mobility measured by TOF shown as Ref. [14].

electrode does not introduce any series impedance into the device. Clearly, Cl-ITO is an advantageous charge injecting electrode for mobility measurements using AS.

5. Conclusion

In summary, we have shown that Cl-ITO can be used as a charge injecting electrode for mobility measurements using AS. The mobility extracted from devices with Cl-ITO anode using AS is found to be closer to the value measured by TOF than for devices with ITO/MoO_3 anode. The lower value of the mobility measured for the devices with ITO/MoO_3 anode is attributed to the effect of the series impedance introduced by the MoO_3 layer. Cl-ITO is therefore found to be an ideal charge injecting electrode for mobility measurements using AS since it possesses a high work function, but does not introduce any series impedance into the device structure.

Unfortunately, the fabrication of polymer thin film transistors and diodes in which both the semiconductor and the dielectric layer are solution processable polymers has been limited. This limitation is due to the inherent fabrication problem whereby an underlying dielectric layer can be damaged by spincoating the overlying semiconducting layer, in the case of bottom-gate architecture or where an underlying semiconducting layer can be damaged by spincoating the overlying dielectric layer, in the case of top-gate device architecture.

Sun et al. [10] have reported baking their PMMA dielectric film at a high temperature of 220 °C for 30 min in nitrogen gas environment in order to make the film resistant to swelling and dissolution by trichlorobenzene (TCB) used to dissolve the overlying semiconducting layer. They observed that for PMMA films baked at lower temperatures, spincoating with TCB resulted in changes in film color and increase in surface roughness. Also the difficulty in finding an orthogonal and stable solvent that does not dissolve the underlying semiconducting film when spincoated has been identified as one of the obstacles in applying crosslinkable polymer thin gate dielectrics in top-gate transistor architectures [11]. The use of solution processable semiconductor with divinyltetramethylsiloxane-bis(bisbenzocyclobutene) derivative (BCB), as a solution processable dielectric has been reported [12,13], but it turns out that BCB requires a very high curing temperature (250 °C), which is difficult to handle at times.

This work introduces matrix-assisted pulsed-laser evaporation (MAPLE) [14–16], a derivative of pulsed laser deposition (PLD), as an alternative fabrication technique that circumvents the inherent solvent selectivity problem encountered in the fabrication of organic field-effect transistors (FET) and metal–insulator–semiconductor (MIS) diodes via spincoating. It has several advantages over traditional spincoating/dipcoating techniques. Since the organic molecules arrive at the substrate free of solvent molecules, the wettability issue is eliminated. Moreover, it allows homogenous film coverage of high molecular weight organic materials for layer-by-layer growth without any laser induced damage, and provides enhanced adhesion to the substrate. Besides offering the advantage of good layer-by-layer film control, remarkable features of this technique are its solvent non-selectivity and its ability to not cause the swelling and dissolution of polymer dielectrics and semiconductors, common inherent problems associated with spincoating.

Here, an organic semiconducting material, 9,9-dioctylfluorene-co-bis-N-N-(4-butylphenyl)-bis-N,N-phenyl 1,4-phenylenediamine (PFB) was dissolved in a toluene solvent and frozen at liquid nitrogen temperature. Then the frozen target is irradiated by a pulsed laser beam (e.g. KrF excimer laser), whose energy is absorbed by the toluene and is pumped away, thereby leaving the PFB molecules to be gently evaporated and deposited without causing any swelling or dissolution of the PMMA film on the substrate. Our prior studies of MAPLE deposited polyfluorene films show that the optical and structural properties of the films remain unchanged comparable to spincoated films [17].

2. Experimental

The organic FETs and MIS diodes employed in this work are of bottom-gate with PFB as the semiconductor and PMMA as the gate dielectric. In order to fabricate the devices, glass substrates were ultrasonically cleaned in water, acetone and alcohol after which 80 nm thick aluminum electrodes were evaporated onto them inside a glove box at a rate of 3 Å/s. PMMA (molecular weight (Mw): 996,000 g/mol) purchased from Sigma–Aldrich and dissolved in three different solvents: butylacetate, toluene, and anisole, were spincoated onto the cleaned glass substrates at 2000 rpm for 1 min resulting in film thicknesses of between 500 and 550 nm as measured using a reflectometer (Mprobe). Thereafter, the samples were baked at 100 °C for 1 h in order to achieve solvent evaporation. PFB was deposited using the MAPLE technique on top of the PMMA film. Details of the MAPLE technique are reported elsewhere [17]. Briefly, a PFB/toluene solution (2 mg/ml) was filtered through a 0.22 μm pore size polytetrafluoroethylene (PTFE) membrane syringe before use. The solution was poured into a target cup and cooled to liquid nitrogen temperature. The frozen target was then installed inside a vacuum chamber evacuated to $\sim 10^{-5}$ mbar. A KrF excimer laser (Lambda Physik COMPex, $\lambda = 248$ nm; pulse duration of 20 ns) at a pulse rate of 10 Hz and an energy density of 0.9 J/cm^2 was directed at 45° angle of incidence on the cold target (2 mm × 1 mm spot size). The target was rotated with a constant speed to avoid excessive heating and erosion of a single spot on the frozen sample (target). The majority of the laser intensity was initially absorbed by the solvent molecules (toluene) causing them to vaporize; the kinetic energy of the solvent molecules is then transferred to PFB through collective collisions, resulting in the polymer to evaporate and deposit on the substrate. All the PFB films were deposited at room temperature. The growth rate was ~0.6 nm/min.

The gold source and drain electrodes, which define a channel length, $L = 50$ μm and channel width, $W = 500$ μm for FETs, and top gold contacts for MIS diodes, were deposited though metallic shadow masks. The area of the MIS diodes was determined with the aid of a scanning electron microscopy to be 7.85×10^{-3} cm^2. The electrical characterization of the FETs and MIS diodes were carried out under ambient conditions with Keithley 2400 and 236 source/measure units and HP 4284A LCR meter, respectively. The dielectric/polymer film morphologies were determined with an atomic force microscope (AFM); the measurements were carried out in tapping mode. Each of our devices contains both FET and MIS diode with Al/PMMA/PFB/Au structure and is named according to the solvent used to dissolve PMMA: butylacetate (Sample A), toluene (Sample B), and anisole (Sample C).

3. Results and discussion

3.1. Dielectric film: morphology and electrical properties

The surface morphology of the films resulting from dissolving PMMA in butylacetate, toluene, and anisole,

obtained by means of AFM (Cypher scanning probe microscope) in tapping mode are shown in Fig. 1. The films exhibited very smooth surfaces with root mean square (rms) values of 2.18, 2.35, and 2.55 Å for butylacetate, toluene, and anisole, respectively. Parallel plate capacitor structures (Al/PMMA/Al) were fabricated to investigate the dielectric properties of PMMA. The leakage current density of the films is in the low 10^{-8} A cm^{-2} for applied fields of up to 1.4 MV cm^{-1} and measurements of the dielectric constant of PMMA dissolved in the different solvents revealed a decrease of the observed dielectric constant from approximately 3.50 at 5 kHz to 2.81 at 1 MHz. This range of values is in good agreement with other published reports [18,19].

The morphology of the PFB films on PMMA in this work is similar to MAPLE-deposited PF films on SiO_2, as reported in our earlier work [17]. The average rms value of the surface roughness of PFB films is ~10 to 15 nm in an area of 2×2 μm.

3.2. MIS diode characteristics

Fig. 2(a–c) shows capacitance–voltage (*C–V*) characteristics of PFB MIS diodes with PMMA dielectric dissolved in butylacetate, toluene, and anisole measured at four different frequencies in the low kHz range. Observable is the existence of frequency dispersions in the accumulation and depletion regions. The *C–V* curves are typical of p-type organic MIS behavior characterized by an accumulation of holes at the dielectric/semiconductor interface at large negative bias, a depletion of holes from the dielectric/semiconductor interface at less negative bias, and a deep depletion of holes from the dielectric/semiconductor interfacial region at positive bias, corresponding to the accumulation, depletion, and deep depletion regimes. No inversion is observed, which is typical of organic MIS diodes. The amount of frequency dispersion in accumulation capacitance, ΔC_{OX} is approximately 0.5%, 0.8%, and 0.9% for Samples A, B, and C, respectively. These values are smaller than similar observations involving inorganic devices [20]. The dispersion in the accumulation region may arise from a difference in the response of trapped and mobile charges in the interface and the bulk.

The insets of Fig. 2(a–c) shows the hysteresis effects observed by measurement of the devices at 5 kHz by sweeping the gate bias continuously in a staircase shape with a 0.4 V step, starting from −40 V, passing through 40 V, and finally back to −40 V. The magnitude of the hysteresis, Δ, is approximately 3.47, 8.62, and 3.97 V for Samples A, B, and C, respectively. The magnitude of hysteresis observed here with PMMA as the insulator is far less than observed with the use of SiO_2 [21]. It has been noted that polar groups in PMMA result in a slow polarization of the bulk dielectric [22]. A reduced hysteresis in PMMA compared

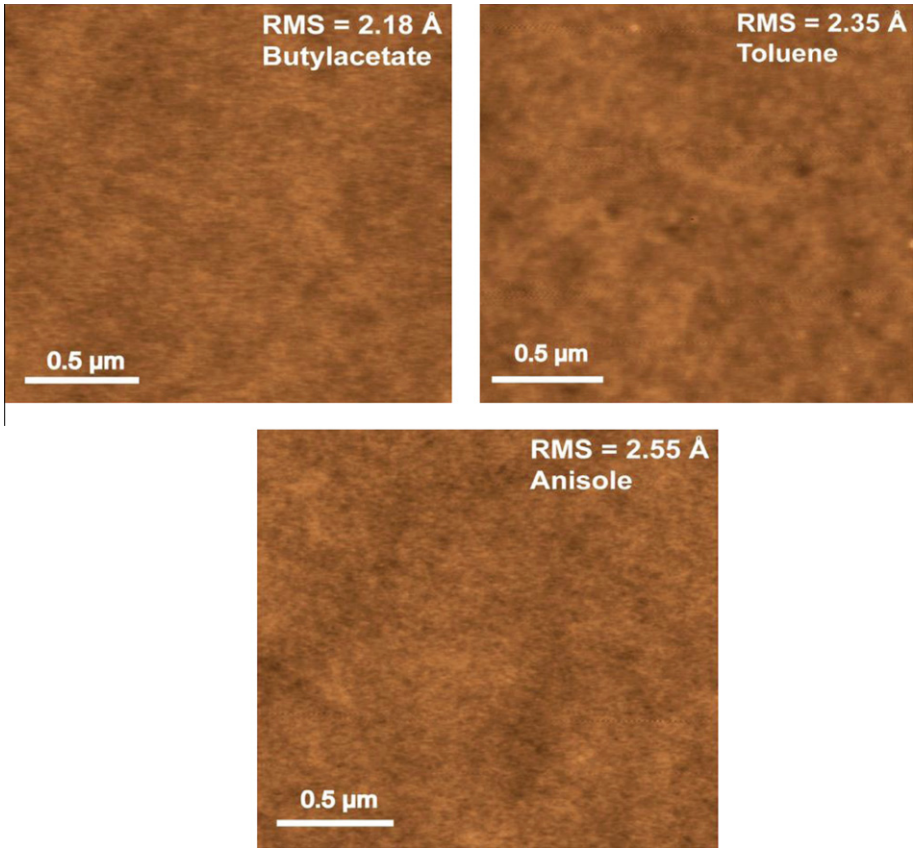

Fig. 1. Atomic force micrographs of PMMA films prepared in different solvents.

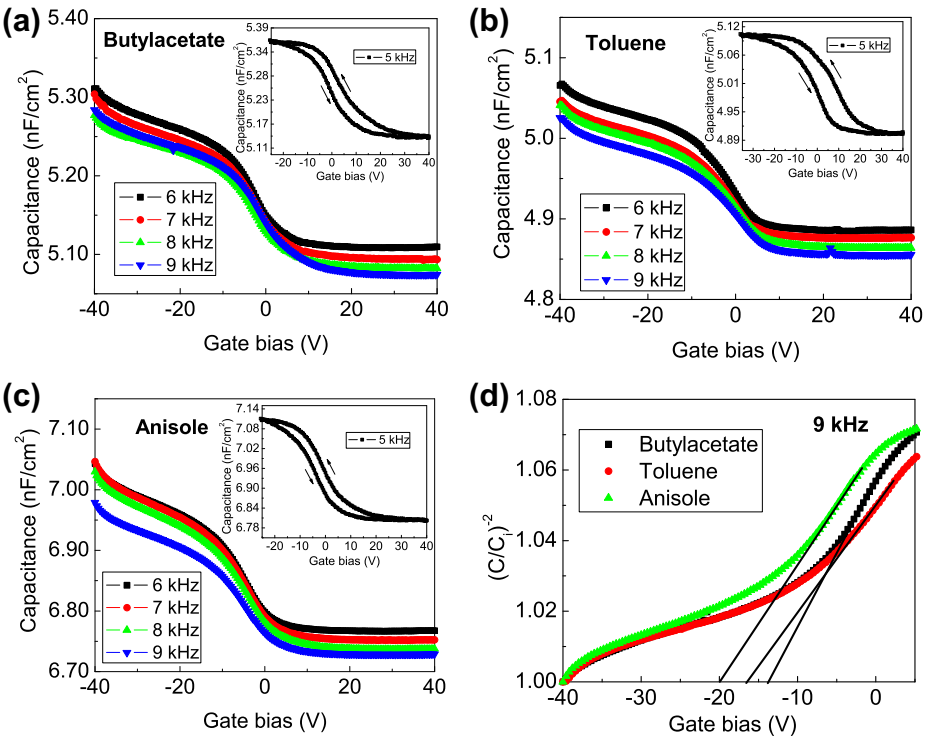

Fig. 2. *C–V* characteristics between 6 and 9 kHz for Al/PMMA/PFB/Au structure and *C–V* characteristics of Al/PMMA/PFB/Au MIS diodes at 5 kHz (insets) for (a) butylacetate (Sample A), (b) toluene (Sample B), (c) anisole (Sample C) solvents and (d) plots of $(C/C_i)^{-2}$ versus gate bias for Samples A, B, and C.

to SiO_2 may originate from a cancellation of the dipole-induced slow polarization with charge trapping; the two typically have opposite directions. The net hysteresis direction reveals the nature of charge injection. The counterclockwise loop of the hysteresis in the *C–V* curve indicates a positive carrier injection into the PFB layer with subsequent trapping [23]. The difference in the accumulation capacitance/area is due to the variations in PMMA thickness for the three MIS diodes. According to the standard Schottky–Mott analysis, the unintentional doping density can be extracted using the relation [23]

$$\frac{\partial(1/C^2)}{\partial V_G} = \frac{2}{q\varepsilon_{semi}\varepsilon_0 N_A A^2}, \tag{1}$$

where C is the capacitance in the depletion region, V_G is the gate bias, ε_{semi} is the relative permeability of the semiconductor, ε_0 is the permittivity of vacuum, A is the area of the device, and N_A is the doping density. The acceptor doping density (N_A) was estimated to be 2.6×10^{17}, 2.9×10^{17}, and 4.9×10^{17} cm^{-3} for Samples A, B, and C, respectively.

From the plot of $(C/C_i)^{-2}$ versus gate bias taken at a frequency of 9 kHz (Fig. 2(d)), flat band voltages (V_{FB}) of −14, −16.6, and −21 V were deduced for Samples A, B, and C, respectively, by extrapolating to the *x*-intercept at $(C/C_i)^{-2} = 1$. Here, C_i is the capacitance of the PMMA layer. Noticeable from this plot is the negative occurrence and the obvious shifts in V_{FB} of the three devices. While the difference in the metal and semiconductor work functions (ϕ_{ms}) and the existence of positive interface traps (Q_i) at the semiconductor–insulator interface are known to account for negative V_{FB} in non-ideal MIS capacitors as given by the relation [24]

$$V_{FB} = \phi_{ms} - \frac{Q_i}{C_i}, \tag{2}$$

our observed shifts in V_{FB} are not due to ϕ_{ms} since it is presumably similar for the three devices. Therefore, considering our calculated values for density of interface states (D_{it}) at flat band (insets of Fig. 3) for the various devices
(Sample A = 2.8×10^{12} eV^{-1} cm^{-2},
Sample B = 3.9×10^{12} eV^{-1} cm^{-2},
Sample C = 5.0×10^{12} eV^{-1} cm^{-2}),
the details of which are found below, and making use of Eq. (2), we can conclude that the shifts in V_{FB} are due to the differences in the density of holes trapped at the semiconductor–insulator interfaces of these devices. The lower the D_{it} at flat band, the less negative is the shift in flat band voltage.

Fig. 3(a–c) shows conductance–voltage (*G–V*) characteristics of the Al/PMMA/PFB/Au MIS diodes. The devices undergo a gate bias independent loss which results from the bias independence of electron and hole densities at the point where the Fermi level crosses bulk trap levels located near the mid gap [25]. This bias independent loss evidenced by the absence of conductance peaks suggests that loss in the devices is mainly dominated by generation and recombination through bulk states. Interface states usually give rise to confined energy levels at the semiconductor–insulator interface. The use of the conductance technique, as suggested by Nicollian and Brews [25] in the depletion

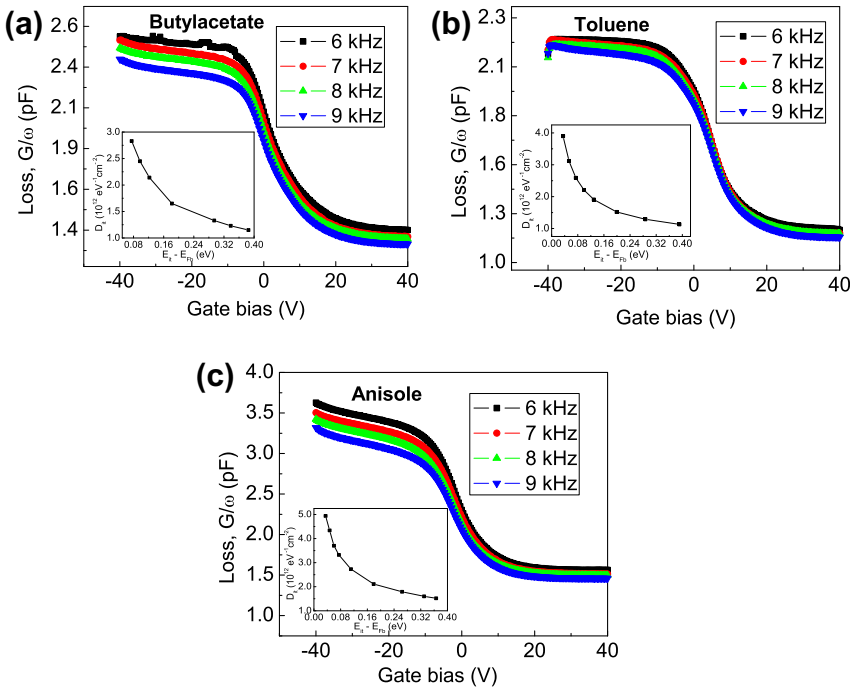

Fig. 3. Frequency dependence of loss (conductance/angular frequency) versus gate bias for PFB MIS diodes and density of interface traps, D_{it}, at the PFB/PMMA interface plotted as a function of energy above bulk Fermi level $E_{it} - E_{Fb}$ (insets) for (a) Sample A, (b) Sample B, and (c) Sample C.

region enables the extraction of interface states density, capture probability and time constant dispersion of the majority carriers (holes in this case) from the real component of the admittance.

The interface trap states change occupancy over a few k_BT/q (where k_B is the Boltzmann constant) wide centered about the Fermi level by interacting with the semiconductor bands via the emission and capture of carriers. A small ac signal applied to the gate of an MIS diode results in an alternate movement of the band edges toward or away from the Fermi level. Using the conductance technique, interface trap states are detected through the loss resulting from changes in their occupancy due to small variations in dc gate bias. Usually, a conductance peak is observed as a result of the ac loss due to capture and emissions of carriers by these interface states. An equivalent parallel conductance (G_p) extracted at different biases from the measured capacitance and conductance data is employed to estimate the density of interface traps, D_{it} using the continuum of states model given by [25]

$$\frac{G_p}{\omega} = \frac{qD_{it}}{2\omega\tau}\ln(1+\omega^2\tau^2), \tag{3}$$

where τ is interface state time constant. The capacitance and equivalent parallel conductance for a distributed or a continuum of trap states are broadened along the $\omega\tau$ axis in comparison to single-level trap states and the maximum of G_p/ω occurs at $\omega\tau = 1.98$ (while for single-level trap states, $\omega\tau = 1$). A determination of the interface trap energy states (E_{it}) can be easily carried out by calculating the degree of band bending induced by the applied bias, by solving the Poisson equation in the depletion approximation:

$$E_{it} - E_{Fb} = \frac{qN_A\varepsilon\varepsilon_0A^2}{2C_d^2}, \tag{4}$$

where q is the electronic charge, N_A is the acceptor doping density, ε is the semiconductor dielectric constant, ε_0 is the permittivity of free space, and C_d is the depletion capacitance estimated at the relevant voltage. Insets of Fig. 3(a–c) show plots of interface state density (D_{it}) versus energy for Samples A, B, and C. The results of the analyses show a non-linear decrease of the interface trap density as one moves away from the bulk Fermi level. For Sample A, D_{it} was found to decrease from approximately 2.8×10^{12} to 1.2×10^{12} eV^{-1} cm^2 over an energy range of 0.075–0.385 eV with a flat band value of 2.8×10^{12} eV^{-1} cm^2. D_{it} decreased from approximately 3.9×10^{12} to 1.1×10^{12} over an energy range of 0.035–0.395 eV in Sample B, with a calculated flat band value of 3.9×10^{12} eV^{-1} cm^{-2}. The D_{it} at flat band for Sample C was calculated to be 5.0×10^{12} eV^{-1} cm^{-2} and it decreased to approximately 1.5×10^{12} eV^{-1} cm^2 over an energy range of 0.035–0.366 eV above the bulk Fermi level. A comparison of D_{it} versus energy plots for the three samples shows that D_{it} at flat band is least in Sample A.

3.3. FET characteristics

Fig. 4(d) shows the output characteristics of the PFB-based FET prepared using butylacetate, which is typical of transistor devices. This device exhibits leakage current of the order of about 0.1 nA. Also shown in Fig. 4(a–c) are the FET transfer characteristics from all three Samples (A–C) in the saturation region ($V_D = -40$ V). The square root of the drain current is also plotted for all three.

According to theoretical prediction [23], above the threshold voltage, these transfer plots should yield a straight line whose slope is proportional to the carrier mobility (μ), as well as a threshold voltage (V_T) which is equal to the intercept. Using the standard saturation regime current–voltage FET characteristics [23],

$$\mu_{sat} = \frac{2L}{WC}\left(\frac{\partial\sqrt{I_D}}{\partial V_G}\right)^2, \tag{5}$$

where C is the capacitance per unit area of the polymer insulator, W is the channel width, L is the channel length, I_D is the drain current, and V_G is the gate voltage. The field-effect mobility in the saturation regime can be obtained by fitting the linear region of the transfer plot. Since the plots show a linear behavior at values of V_G above the threshold voltage, the calculated mobility is independent of the specific range of V_G used for the linear fit. We point out that the toluene sample shows a slight non-linear behavior at high gate voltages indicating a gate-dependent mobility; the fit region was thus restricted to V_G below -30 V. The highest average field-effect mobility of 0.2×10^{-4} cm^2 V^{-1} s^{-1} and the lowest threshold voltage of -0.2 V, respectively were obtained for Sample A. For Sample B, the average field-effect mobility was calculated to be 0.4×10^{-5} cm^2 V^{-1} s^{-1} and a threshold voltage of -3.3 V was obtained. Sample C yielded an average field-effect mobility and a threshold voltage of 0.2×10^{-5} cm^2 V^{-1} s^{-1} and -7.2 V, respectively. The FET mobilities here are higher than MAPLE deposited PFB on as-is SiO_2 as the dielectric layer [21].

The threshold voltage (V_T) is negative for all the devices, which is typical of p-channel devices and is given by the relation [24]

$$V_T = V_{FB} + \frac{Q_d}{C_i} - 2\phi_F, \tag{6}$$

where Q_d/C_i accommodates the charge in the depletion region, and ϕ_F defined as $(E_i - E_F)/q$ in the neutral substrate, is the bulk potential. From the above relation, it is understandable that an applied negative voltage higher than V_T is needed in order to achieve flat band condition. The depletion charge is proportional to the acceptor concentration (N_A), and as such, should be least for Sample A and highest for Sample C. Also looking at the obtained values for N_A, it is immediately obvious that ϕ_F is least in Sample A and highest in Sample C. Therefore, considering our aforementioned extracted values for V_{FB} (in the MIS diodes) and making use of Eq. (6), it is observable that the trend in the threshold voltage becomes easily explainable. Therefore, we can conclude that the behavior of V_T in FETs is predictable from knowledge of the doping concentration and the behavior of V_{FB} in MIS capacitors, in accordance with theory.

Considering that FETs based on polymer dielectrics typically show some hysteresis (shifts in threshold voltage depending on the sweep direction of the gate voltage) in I_D, remarkably, our FETs exhibited no hysteresis for Sample A and little hysteresis in only the off regime for Samples B and C. Hysteresis in organic thin film transistors has been linked with dielectric bulk trapping of electrons and holes injected from the gate [26,27]. It could be deduced that the absence of hysteresis in Sample A and little hysteresis in Samples B, and C are very likely due to suppressed gate injection of carriers and subsequent trapping in the PMMA bulk. The device characteristics for our FETs and MIS diodes are summarized in Table 1.

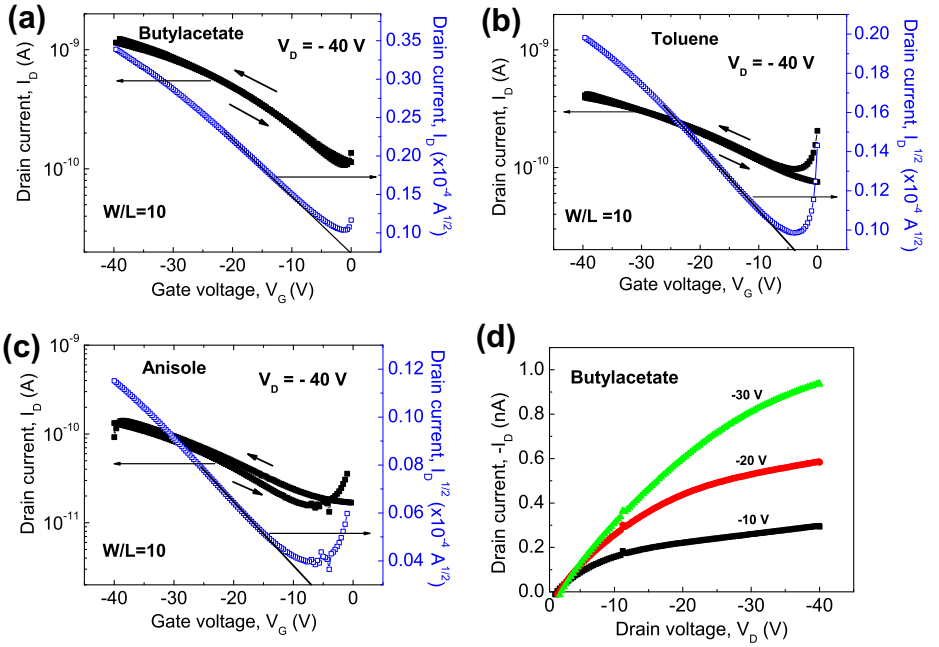

Fig. 4. Electrical transfer characteristics of the OFETs for various solvents: (a) butylacetate (Sample A), (b) toluene (Sample B), (c) anisole (Sample C), and (d) electrical output characteristics of Sample A.

Table 1
Field-effect mobilities in saturation regime, threshold voltages, root mean square values, density of interface state at flat band (D_{it}), and solubility parameters for various solvents.

	Mobility ($cm^2 V^{-1} s^{-1}$)	Threshold voltage (V)	PMMA film rms (Å)	D_{it} at flatband ($eV^{-1} cm^{-2}$)	Solubility parameters[a] $(MPa)^{1/2}$
Butylacetate	0.2×10^{-4}	−0.2	2.18	2.8×10^{12}	17.4
Toluene	0.4×10^{-5}	−3.8	2.35	3.9×10^{12}	18.1
Anisole	0.2×10^{-5}	−7.2	2.55	5.0×10^{12}	19.5

[a] Ref. [30].

As is evident from Table 1, the type of solvent used in dissolving the dielectric has quite noticeable effects on the performance of the devices. The morphology of the dielectric layer onto which the semiconducting layer is formed has been observed to play an important role in the performance of polymer devices [28]. Similarly, surface roughness of polymer dielectric films, which is very closely related to the solubility parameter, could be dependent on the type of solvent used [29]. It is well known that the less the difference between the solubility parameters of a polymer and its solvent, the more soluble the polymer is in the solvent and vice versa. Table 1 contains the solubility parameters of the various solvents used, while the solubility parameter for PMMA is 22.5 $(MPa)^{1/2}$ [30].

While the FET mobility decreased with increasing PMMA film roughness, D_{it} at flat band of the MIS diodes followed the same trend as the PMMA film roughness. Earlier reports have shown that a rougher surface leads to increase in voids and defects giving rise to increase in interface trap states at the semiconductor–dielectric interface and consequent adverse effects on field-effect mobility and molecular ordering [31–33]. Our results point in the direction that there is a trade-off between solubility and swelling of the dielectric layer in the actual device performance. Although PMMA is most soluble in anisole, the device performance is worse compared to the other two solvents. It has been observed that the degree of swelling in a polymer increases with the decrease in the difference between the solubility parameters of the polymer and the solvent [28,29]; anisole is thus most likely to leave behind the roughest PMMA film surface on evaporation, and as such, the lowest average field-effect mobility, followed by toluene, then butylacetate.

4. Conclusion

In summary, we have demonstrated the success of the MAPLE technique in overcoming the solvent selectivity and inherent swelling and dissolution problems associated with fabricating device-quality polymer FETs and MIS diodes via traditional spincoating technique especially when non-orthogonal solvents are used. It is observed that the higher the difference between the solubility parameters of the solvent and PMMA, the less rough the PMMA surface, and consequently, the better the device performance. Negative shifts of the threshold voltage in the FETs were correlated with differences in acceptor doping density and similar shifts in flat band voltage of the MIS diodes, which was found to be due to difference in the density of interface states at flat band. PFB-based FETs exhibited a hysteresis-free operation, a low threshold voltage of −0.2 V, and field-effect mobility of $0.2 \times 10^{-4} cm^2 V^{-1} s^{-1}$. The density of interface trap states in the MIS diodes was found to decrease non-linearly and is distributed over an energy range of 0.075–0.385 eV above the bulk Fermi level; the energy loss was found to be dominated by the emission and capture of carriers through bulk states. We are currently exploring other MAPLE-deposited solution processable polymers that have inherently higher charge carrier mobilities with polymer dielectrics in FET and MIS structures.

In this paper we report strong p-type surface transfer doping of C_{60}, due to formation of space charge in the C_{60} layer at the C_{60}/MoO_x interface. We investigated the interface formation of ITO, MoO_x, and C_{60} using ultraviolet photoemission spectroscopy (UPS) and inverse photoemission spectroscopy (IPES). We monitored the changes in the valence electronic structure, WF, and ionization potential of the surface as C_{60} was deposited layer by layer on a MoO_x/ITO substrate. We found that the MoO_x inter-layer substantially increased the surface WF, due to which all the energy levels of C_{60} moved up, and making C_{60} strongly p-type at the C_{60}/MoO_x interface. With further C_{60} deposition energy levels gradually relax down, resulting in an extremely thick layer of band-bending-like region. We also investigated the effect of exposing MoO_x to air and then depositing C_{60}. In this case almost no band bending was observed in C_{60}. The study therefore reveals a method of turning organic materials which on most of the metals behave as n-type, to be p-type without any intentional intermixing of materials.

2. Experimental

UPS and IPES studies were performed using a VG ESCA Lab, an ultrahigh vacuum (UHV) system equipped with a He I discharge lamp. The UHV system consists of a spectrometer chamber, an in situ oxygen plasma (OP) treatment chamber, and an evaporation chamber all interconnected. The base pressure of the spectrometer chamber is typically 8×10^{-11} torr. The base pressure of the evaporation chamber is typically 1×10^{-6} torr. The UPS spectra were recorded by using unfiltered He I (21.22 eV) excitation as the excitation source with the sample biased at −5.00 V to observe the low-energy secondary cutoff. The UV light spot size on the sample is about 1 mm in diameter. The typical instrumental resolution for UPS measurements ranges from 0.03 to 0.1 eV with the photon energy dispersion of less than 20 meV. Two substrates of size about 9 mm × 9 mm were cut from borosilicate glass sheet from Corning, coated with 250 nm thick conducting ITO, with resistivity 15 Ω per square. The substrates were treated separately in situ in oxygen ambience [11] of 600 m torr at bias voltage about −500 V for about 30 s. Both MoO_x and C_{60} were thermally evaporated layer-by-layer. Thicknesses of deposited films were monitored by quartz crystal microbalance. The 50 Å MoO_x substrate was exposed to 7.2×10^{14} Langmuir (about 10 days in atmospheric pressure) air and again inserted inside the UHV system for measurements. One Langmuir (L) exposure is equal to the 10^{-6} torr s exposure. The surface topography data were obtained with Nanoscope III (from Digital/Vecco) atomic force microscope (AFM) in tapping mode with silicon tips. All the measurements were performed at room temperature.

3. Results and discussion

In Fig. 1, the UPS spectra of C_{60} on MoO_x/ITO are presented as a function of the thickness of C_{60} over-layer. Shown in Fig. 1a and b, are the cut off and the HOMO regions of the UPS data, respectively. The WF of ITO was measured to be 5.78 eV [15,16,20–22]. Upon the deposition of 30 Å MoO_x, the surface WF became 6.8 eV. As it is clearly visible from Fig. 1a, with the C_{60} deposition the surface WF kept gradually decreasing. The WF after 1.2, 2.3, 4.7, 37.2, 74.4, 407, and 581.4 Å C_{60} deposition were measured to be 6.55, 6.49, 6.46, 6.08, 5.98, 5.64 and 5.58 eV, respectively. From Fig. 1b, we notice that there is a strong valence band peak of MoO_x at the binding energy (BE) of about 3.8 eV with respect to the Fermi level. The two occupied levels closest to the Fermi level appear right after 1.2 Å C_{60} deposition. There is a visible shift in the MoO_x valence band peak upon the deposition of C_{60} towards the higher BE. We measured this shift to be about 0.3 eV at 4.7 Å C_{60} deposition. The occupied molecular levels of C_{60} become prominent between 4.7 and 9.3 Å of C_{60} deposition. It is obvious from Fig. 1b, that all the occupied level peaks of C_{60} keep shifting towards the higher binding energy (BE). The HOMO onset BE of C_{60} after 4.7, 9.3, 37.2, 74.4, 407, and 581.4 Å C_{60} deposition were measured to be 0.21, 0.23, 0.38, 0.46, 0.81, and 0.85 eV, respectively. It is important to mention that no significant sample charging was observed during the measurements.

In Fig. 2a and b, changes in the WF and the shift in C_{60} HOMO level onset BE are presented as a function of increasing C_{60} thickness. From Fig. 2a, we observe the WF increase from 5.78 eV of the ITO to 6.8 eV upon deposition of 30 Å MoO_x, indicating an interface dipole of 1.02 eV at the MoO_x/ITO interface. With deposition of C_{60} on MoO_x/ITO we observe a slow WF change. As discussed in the previous section, if we take into account the 0.3 eV initial shift of the characteristic MoO_x peak by C_{60} deposition, there is a negligibly small surface dipole moment at the C_{60}/MoO_x interface. As C_{60} thickness increases we observe gradual WF change causing an extremely large band bending region of over 400 Å. 580Å C_{60} thickness appears to be in quasi-equilibrium state. From Fig. 2b, we observe a gradual HOMO level BE shift towards the higher BE with increasing thickness of C_{60}. Overall about 0.6 eV shift was observed in the C_{60} HOMO level onset spanning over 580 Å thickness. Both WF and HOMO level shift have similar trend of change.

The UPS data indicate that the high WF of MoO_x is causing charge transfer and surface transfer doping of C_{60}. It is further verified by reducing the WF of the MoO_x by air exposure and observed C_{60} behavior deposited on the exposed MoO_x. In Fig. 3, the UPS spectra of the C_{60} on air exposed MoO_x/ITO are presented as a function of C_{60} thickness. Fig. 3a and b, show the cut off and HOMO regions of the UPS data, respectively. Upon the deposition of 50 Å MoO_x the surface WF became 6.75 eV. After MoO_x deposition the substrate underwent an air exposure of 7.2×10^{14} L, and the substrate WF was measured to be 4.85 eV, which is 1.9 eV below the WF of an unexposed MoO_x surface. The contrast in the WF and occupied levels evolution with the C_{60} deposition is clearly visible from Fig. 3a and b, in comparison with Fig. 1a and b. The surface WF gradually increases up to 16 Å of C_{60} deposition, and saturates thereafter. From Fig. 1b, we notice that a strong valence band peak of MoO_x at the BE of ~3.75 eV. After the air exposure the valence band peak of MoO_x was ob-

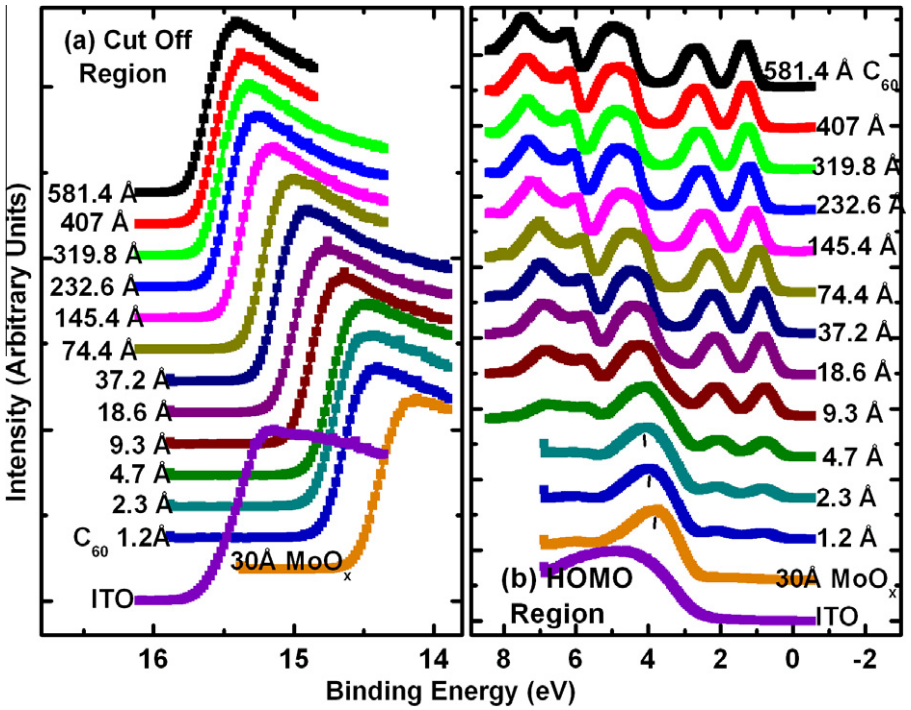

Fig. 1. UPS data for 0–581.4 Å C_{60}/30 Å MoO_x/ITO. (a) The cut-off region and (b) the HOMO region.

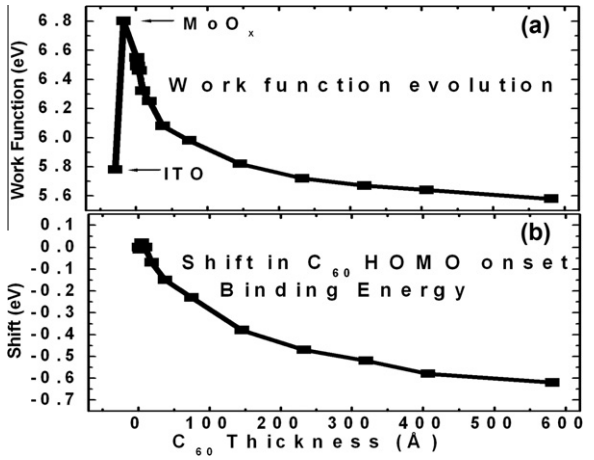

Fig. 2. Workfunction evolution (a) and HOMO onset binding energy shift (b) values for 0–581.4 Å C_{60}/30 Å MoO_x/ITO.

served at BE of ~4.3 eV, which corresponds to ~0.55 eV shift in peak position towards the higher BE than the unexposed MoO_x surface. The HOMO level peak appeared right after the 2 Å of C_{60} deposition. The occupied molecular levels feature of C_{60} became prominent between 4 and 8 Å of C_{60} deposition. It is obvious from Fig. 1b, that all the occupied level peaks of C_{60} remain almost intact with further C_{60} deposition. The HOMO onset BE of C_{60} after 4, 8, 16, 32, 64, and 128 Å C_{60} deposition were measured to be 1.25, 1.29, 1.25, 1.30, 1.37, and 1.38 eV, respectively.

In order to further demonstrate strong surface p-doping in C_{60} with pristine thermally evaporated MoO_x, we performed IPES and UPS together on an another MoO_x film and compared that with 7.2 L air exposed MoO_x substrate. Occupied and unoccupied energy levels of C_{60} near Fermi level with increasing C_{60} thickness are presented in Fig. 4. Four set of data presented in the bottom to middle of Fig. 4, are for 5, 20, 100 and 450 Å C_{60} thickness on 30 Å MoO_x/ITO substrate, 5 Å thickness one being at the bottom of Fig. 4. It is straightforward to state that the HOMO level onset is less than 0.2 eV from the Fermi level. On the unoccupied side though features are not completely develop for 5 Å coverage but the LUMO onset is about 2 eV from the Fermi level. As we increase C_{60} thickness the entire spectrum shifts towards the higher BE. At 450 Å C_{60} coverage we calculated the HOMO edge to be 0.7 eV while the LUMO peak also shifts rigidly with the HOMO one. The LUMO edge is about 1.5 eV, indicating that C_{60} is p-type even after 450 Å coverage. On top of the Fig. 4, the UPS and IPES spectrum of 128 Å C_{60} thickness are presented on 7.2 L air exposed 30 Å MoO_x/ITO substrate. The HOMO edge is measured to be 1.38 eV while the LUMO edge is about ~0.9 eV. As presented in the Fig. 4, the polaron gap (HOMO–LUMO peak to peak separation) observed to be almost fixed which further corroborates our claim. Polaron gap values are measured to be 3.93, 3.8, 3.72 and 3.79 eV for 5, 20, 100 and 450 Å C_{60} thicknesses on unexposed MoO_x substrate. It was found to be 3.78 eV for 128 Å C_{60} on the air exposed MoO_x film.

Energy level diagrams for C_{60}/30 Å MoO_x/ITO and C_{60}/(7.2×10^{14} L air exposed) 50 Å MoO_x/ITO, interfaces are depicted in Fig. 5a and b, respectively. In Fig. 5a, the interface

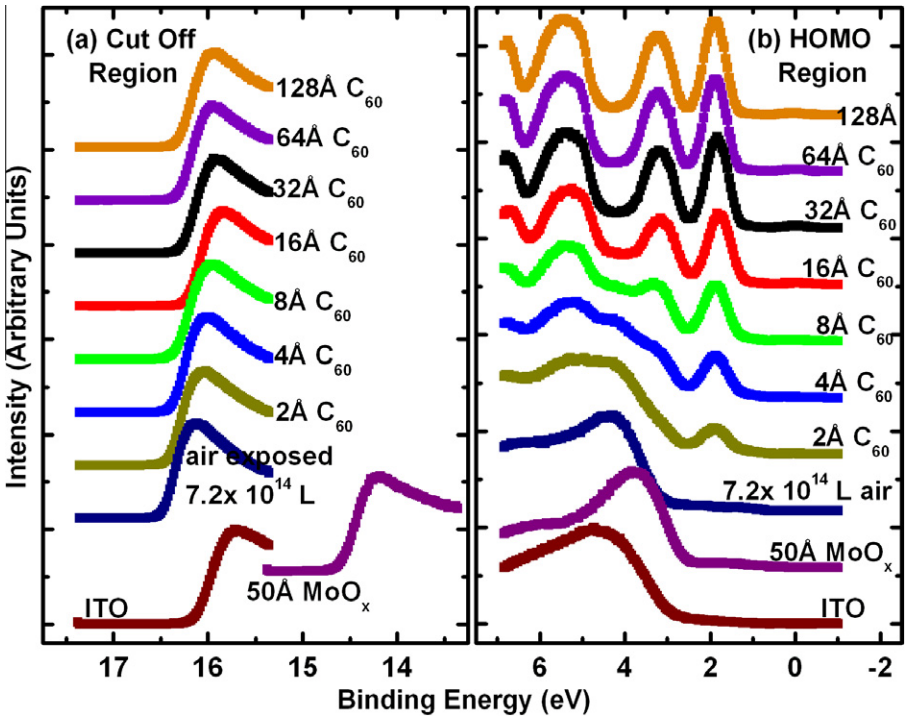

Fig. 3. UPS data for 0–128 Å C_{60}/(7.2×10^{14} L air exposed) 50 Å MoO_x/ITO. (a) The cut-off region and (b) the HOMO region.

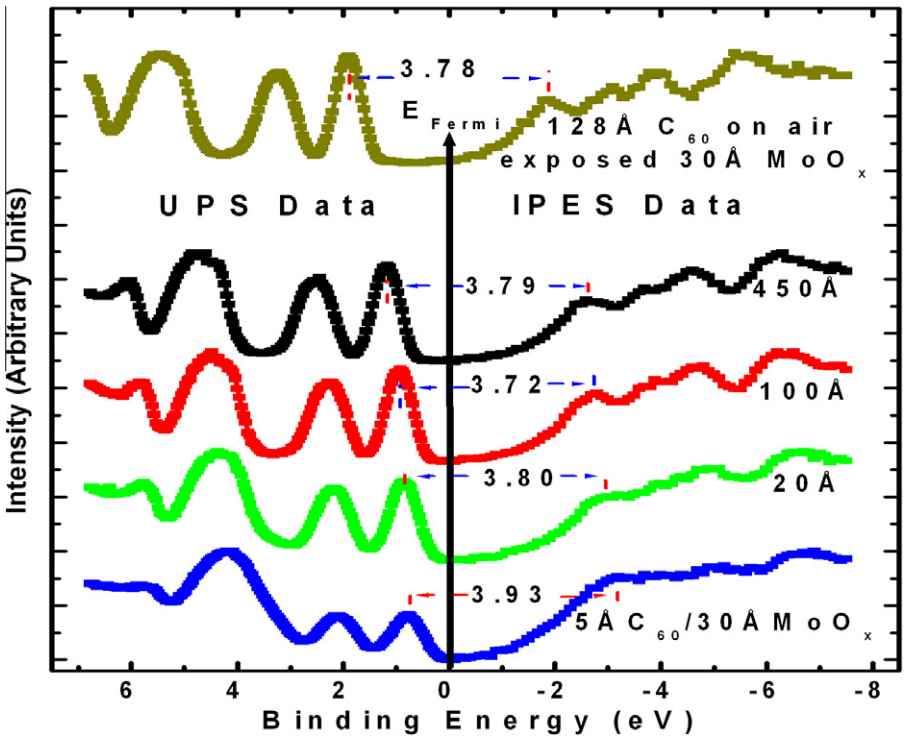

Fig. 4. UPS-IPES combined data for 5, 20, 100, 450 Å C_{60} on /30 Å MoO_x/ITO and 128 Å C_{60} on (7.2×10^{14} L air exposed) 50 Å MoO_x/ITO.

between ITO and MoO_x has an interface dipole 1.36 eV and HOMO onset BE of MoO_x was measured to be 2.63 eV. The high WF of MoO_x lifted up the C_{60} energy levels, resulting in a strong electron attraction towards the MoO_x layer from

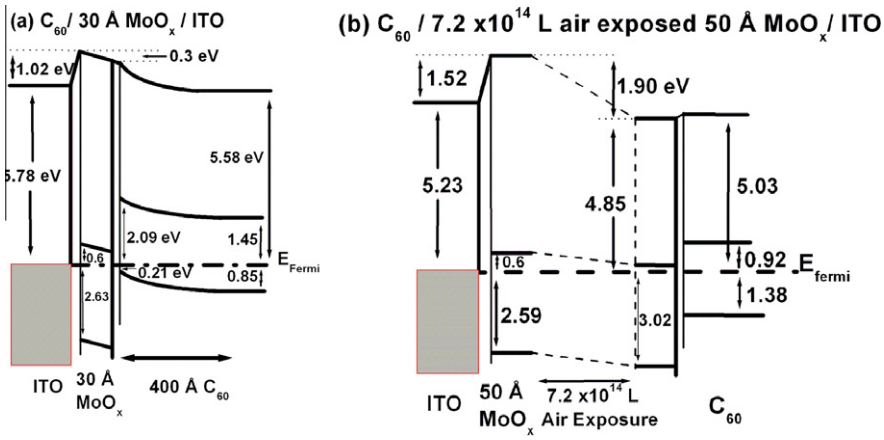

Fig. 5. Energy level alignment at, (a) C_{60}/30 Å MoO_x/ITO, and (b) C_{60}/(7.2×10^{14} L air exposed) 50 Å MoO_x/ITO.

the C_{60} side. Due to the strong attraction of electrons from the C_{60} layer to the MoO_x side, C_{60}^+ is produced, as space charge in the C_{60} layer. Close to the C_{60}/MoO_x interface the C_{60} HOMO level was observed to be almost pinned to the Fermi level, and after 4.7 Å C_{60} deposition the onset BE was measured to be 0.21 eV, indicating a strong inversion. With further C_{60} deposition a gradual relaxation was observed, resulting in a large band bending region of ~400 Å. At 581.4 Å the surface WF and the HOMO onset BE were measured to be 5.58 and 0.85 eV respectively. With the Poisson equation it is always possible in principle to calculate the charge density from the potential change, but for taking the derivative it requires fine film thickness steps, not performed in the current experiment. If we assume C_{60}^+ ions are uniformly distributed in the organic side, as reported by Ishii et. al., [23] the estimated density of C_{60}^+ ions ($N_D = (2\varepsilon_0 \cdot \varepsilon_r \cdot V_{bi})/(ed^2)$) would be 8.7×10^{16} cm^{-3}, where V_{bi} = 0.6 eV, ε_r = 4.4, and d = 580 Å.

From Fig. 5b, the ITO WF was measured to be 5.23 eV. After 50 Å of MoO_x deposition the surface FW becomes 6.75 eV. The HOMO onset BE was measured to be 2.59 eV. The difference in the ITO WF in Fig. 5a and b, is the result of variation of ITO surfaces after the O_2 plasma treatment. It is inconsequential for the subsequent experiments as the surface becomes dominated by the MoO_x overlayer with the same saturated WF. The substrate then underwent an air exposure of 7.2×10^{14} L. The exposure renders the surface WF and HOMO onset BE to be 4.85 and 3.02 eV, respectively. With C_{60} deposition almost no band bending was observed and all the energy levels remained more or less flat. Meyer et al. recently observed [24] that even after air exposure of MoO_x interlayer device performance did not suffer, as lowering of MoO_x WF only reduced the interface dipole between MoO_x and the organic hole transport layer (HTL), almost by the amount of MoO_x WF reduction due to the air exposure. The present work shows that the reported insensitivity of MoO_x to air exposure is not a general case.

Based on our previous reported device data, [17] there are noticeable differences in the open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}) that can be attributed to the variation in MoO_x inter-layer thickness. The cell with an unexposed MoO_x layer produces a V_{oc} of 1.2 V and an I_{sc} of 1.3 mA/cm^2, whereas the cell with an air exposed MoO_x layer has substantial degradation both in V_{oc} and I_{sc} with values of 0.85 V and 0.92 mA/cm^2, respectively. The cause for the variation in V_{oc} and I_{sc} in the OPV cells with different MoO_x inter-layer thickness can be understood with reference to the energy level diagram in Fig. 5. The high WF of unexposed MoO_x produces a relatively high built-in potential with an extended band bending region in the C_{60} layer. Presumably this governs photogeneration of electrons and holes in the bulk of C_{60} and the observed field dependence of photocurrent in the

MoO_x/C_{60} cells. For MoO_x/C_{60} cells with an air exposed MoO_x layer, a lower built-in potential in C_{60} is to be expected because of the lower workfunction measured for the air exposed MoO_x films. Indeed, this is consistent with the lower V_{oc} and I_{sc} obtained for OPV cells with air exposed MoO_x.

We also studied surface morphology for ITO, MoO_x and C_{60} films. In Fig. 6, atomic force microscope (AFM) data are presented for 30 s oxygen plasma (OP) treated ITO and 50 Å MoO_x film, respectively. Topography in images are from selected area of 5 μm × 5 μm from each sample. Root mean square (RMS) roughness of surfaces were measured to be 55 and 56 Å, respectively. The RMS roughness for C_{60} film was measured to be 68 Å (data not presented). These results indicate that while MoO_x grows smoothly on ITO, ~600 Å of C_{60} deposition does increase the surface roughness by about 10 Å. Given the total thickness, the small increase of the roughness should not affect the morphology and our general estimate of the layer thickness.

4. Conclusions

In conclusion, we have measured the electronic structure evolution of C_{60} on MoO_x/ITO. We observed that the high workfunction of MoO_x inter-layer strongly lift up the energy levels of C_{60} towards lower binding energy at the interface, resulting in an strong p-doping and inversion of C_{60}. The HOMO edge of C_{60} was observed at 0.21 eV below the Fermi level at the interface. We observed an exceptionally long band bending of 400 Å in the organic material, such long band bending has not been reported so far, for the organic/insulator (MoO_x) interface. With exposed MoO_x this inversion and the long band bending was not observed. This lead us to conclude that the workfunction reduction for air exposed MoO_x films does affect the energy level alignment in general. Our work suggests a method of turning organic materials which on most of the metals behave as n-type to be p-type without any intentional intermixing of materials.

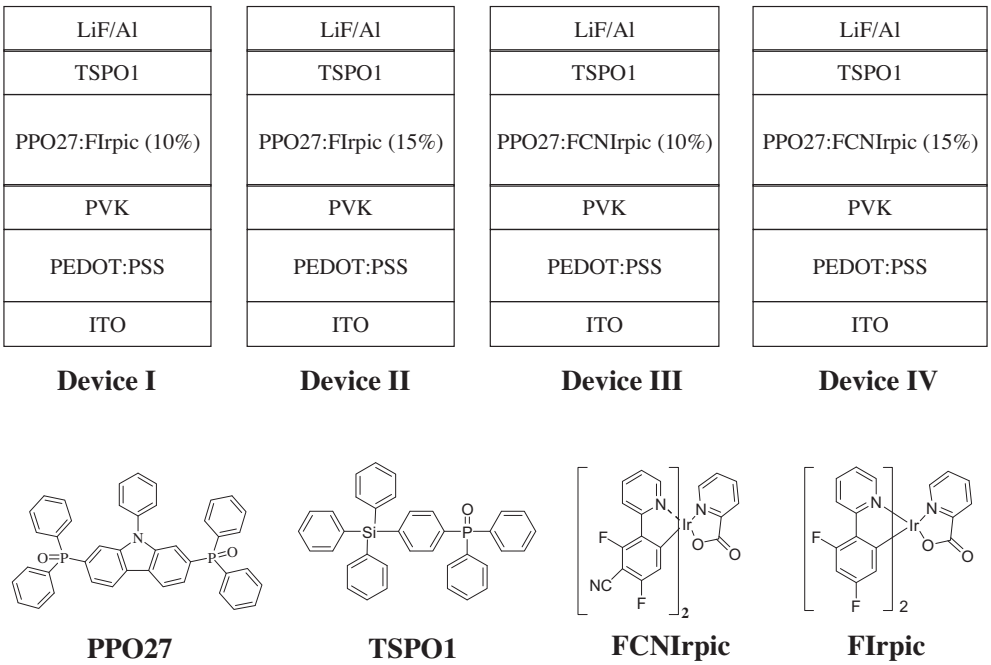

Fig. 1. Device structures of the solution processed blue PHOLEDs and chemical structures of materials used.

efficiency of 14.6% with a color coordinate of (0.15, 0.37) and high quantum efficiency of 13.4% with a color coordinate of (0.15, 0.26) were demonstrated in the solution processed PPO27:FIrpic and PPO27:FCNIrpic blue PHOLEDs.

2. Experimental

The device structure of the soluble PHOLEDs was indium thin oxide (ITO)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS, 60 nm)/PVK (15 nm)/PPO27:FIrpic or PPO27:FCNIrpic (40 nm)/diphenylphosphineoxide-4-(triphenylsilyl)phenyl (TSPO1, 35 nm)/LiF (1 nm)/Al (100 nm). The doping concentrations of the FIrpic and FCNIrpic were 10% and 15%. Device structures and chemical structures of organic materials are shown in Fig. 1. The PEDOT:PSS layer was spin coated at a thickness of 60 nm and was baked at 150 °C for 10 min to remove residual solvent. The PVK was spin coated from 0.3 wt.% chlorobenzene solution at a spin speed of 2000 rpm to make 15 nm thick hole transport layer. It was baked at 120 °C for 10 min after spin coating. The PPO27 host was dissolved in isopropanol at a concentration of 1.0 wt.% and the dopant materials were mixed in the isopropanol solution according to the doping concentration. After drying at 80 °C for 10 min, TSPO1 was deposited as the exciton blocking electron transport layer by thermal evaporation followed by LiF and Al deposition. Film morphology of the PPO27:FIrpic and PPO27:FCNIrpic was analyzed using atomic force microscope (AFM, Digital Instrument Co. Multimode Nanoscope IIIa). Current density–voltage–luminance characteristics and electroluminescence (EL) spectra of the devices were measured with Keithley 2400 source measurement unit and Minolta CS 1000A spectroradiometer.

3. Results and discussion

The synthesis of the PPO27 was reported in our previous work and the PPO27 was effective as the host material for the blue PHOLEDs doped with FIrpic and FCNIrpic [13]. It was reported that the PPO27 was suitable as the host for blue PHOLEDs because of low singlet energy of 3.25 eV and high triplet energy of 2.81 eV. In addition, it showed high glass transition temperature of 117.6 °C and stable amorphous film formation was observed in the PPO27. Therefore, the PPO27 can be used as the host material for solution processed blue PHOLEDs. In particular, the PPO27 is soluble in highly polar alcohol solvent because of highly polar diphenylphosphine oxide groups. The good solubility in alcohol solvent is advantageous because a multilayer structure can be formed using the solubility difference between the emitting layer and charge transport layers. Therefore, multilayer structure solution processed blue PHOLEDs can be fabricated using the PPO27 host material.

The PPO27 was spin coated from 2-propanol solution and the morphology of the spin coated PPO27 film was studied. Fig. 2 shows the AFM pictures of spin coated PPO27, PPO27:FIrpic and PPO27:FCNIrpic films. The surface roughnesses of the PPO27, PPO27:FIrpic and PPO27:FCNIrpic films were 0.22, 0.24 and 0.19 nm, respectively, indicating that the spin-coated films show smooth surface morphology even after spin coating from 2-propanol solution. The FIrpic and FCNIrpic were also soluble in 2-propanol and well dispersed in the PPO27 matrix. No large scale aggregation of the FIrpic and FCNIrpic was observed after spin coating. Therefore, the PPO27:FIrpic and PPO27:FCNIrpic can be used as the alcohol soluble

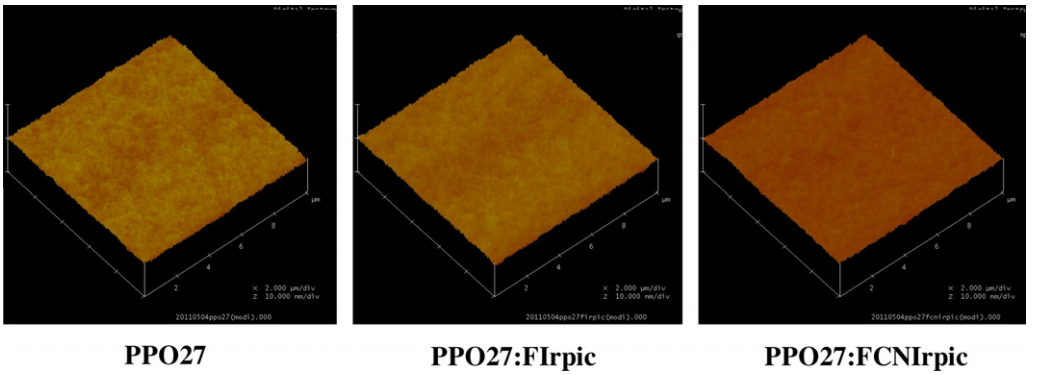

Fig. 2. Atomic force microscopic pictures of spin coated PPO27, PPO27:FIrpic and PPO27:FCNIrpic films.

phosphorescent emitting layer in solution processed blue PHOLEDs.

Fig. 3 shows the current density–voltage–luminance curves of the PPO27:FIrpic and PPO27:FCNIrpic devices. The current density was little affected by the doping concentration and similar current density was observed at 10% and 15% doping concentrations. The current density of the blue PHOLEDs was sharply increased from 4.0 V and the turn on voltage of the device was 4.0 V. The rather higher current density of the PPO27:FIrpic device than that of the PPO27:FCNIrpic device is due to good electron transport properties of FIrpic. Holes and electrons are partially transported by the dopant materials at high doping concentration, leading to high current density in the PPO27:FIrpic devices.

Quantum efficiency–current density curves of the solution processed PPO27:FIrpic and PPO27:FCNIrpic blue PHOLEDs are shown in Fig. 4. The quantum efficiency of the device II was slightly higher than that of the device I over all current density range. The maximum quantum efficiency of the device II was 14.6% at 0.71 mA/cm^2 which corresponds to the luminance of 200 cd/m^2. The device IV also showed higher quantum efficiency than the device III and the maximum quantum efficiency of the device IV was 13.4% at 0.10 mA/cm^2 which corresponds to the luminance of 21 cd/m^2. The color coordinates of the device II and device IV were (0.15, 0.36) and (0.15, 0.26). All blue PHOLEDs fabricated in this work showed high quantum efficiency compared with other solution processed blue PHOLEDs reported in the literature. In particular, the quantum efficiency of the device IV is the best efficiency value reported in the solution processed deep blue PHOLEDs with y color coordinate less than 0.30.

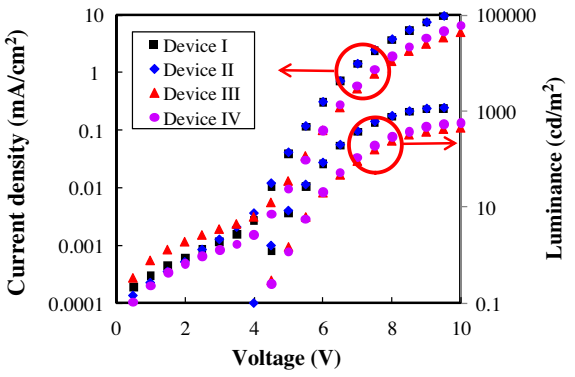

Fig. 3. Current density–voltage–luminance curves of the solution processed blue PHOLEDs with PPO27:FIrpic and PPO27:FCNIrpic emitting layers.

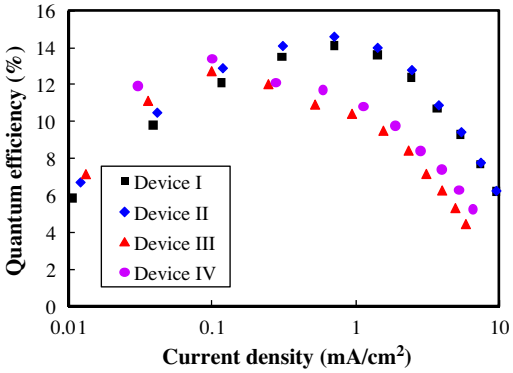

Fig. 4. Quantum efficiency–current density curves of the solution processed blue PHOLEDs with PPO27:FIrpic and PPO27:FCNIrpic emitting layers.

The high quantum efficiency of the PPO27 based blue PHOLEDs can be explained by effective charge injection and confinement, triplet exciton confinement, and stable film morphology in the emitting layer. In general, it is difficult to confine charges and triplet excitons inside the emitting layer in solution processed blue PHOLEDs because multilayer structure formation is limited by the intermixing of organic materials during solution coating process. Hole transport type exciton blocking material should be inserted between common PEDOT:PSS layer and phosphorescent emitting layer to confine charges and triplet excitons inside the emitting layer. However, most hole transport materials and phosphorescent emitting materials are soluble in organic solvents such as benzene, toluene and chlorobenzene, which limits the orthogonal film formation. However, the PPO27 host material used in this work was soluble in highly polar 2-propanol solvent and could be spin-coated on organic soluble PVK hole transport

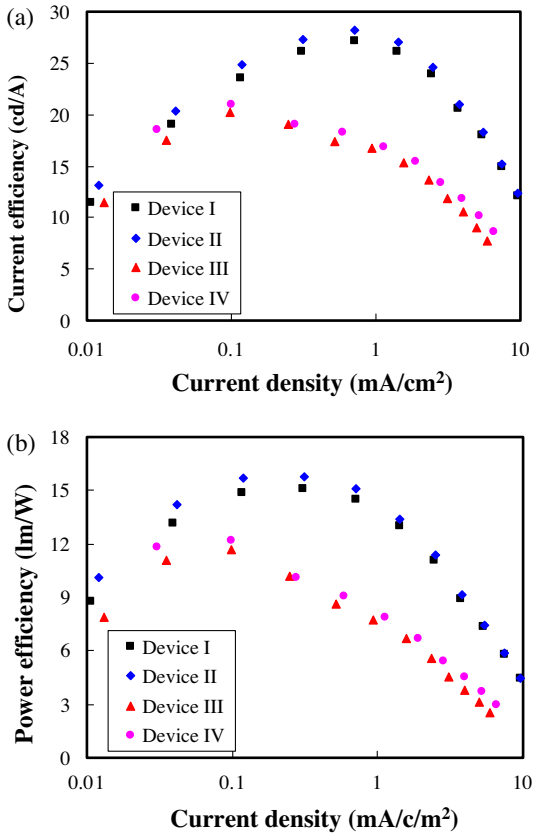

Fig. 5. (a) Current efficiency–current density and (b) power efficiency–current density curves of the solution processed blue PHOLEDs with PPO27:FIrpic and PPO27:FCNIrpic emitting layers.

layer without any intermixing. The PVK is a well-known hole transport material with the HOMO/LUMO level of 5.9/2.4 eV and a high triplet energy of 2.9 eV. The PVK injects holes into the PPO27 emitting layer and prevents the electron leakage from the emitting layer to the hole transport layer. The energy barrier for hole injection was 0.35 eV, while the energy barrier for electron leakage was 0.60 eV. Therefore, the PVK hole transport layer could effectively inject holes and block electron leakage, contributing to the improvement of recombination efficiency in the emitting layer. In addition, the high triplet energy of the PVK blocks the triplet exciton diffusion into the hole transport layer, confining triplet excitons inside the emitting layer. The triplet energy of the PVK (2.90 eV) was higher than that of FIrpic (2.65 eV) and FCNIrpic (2.74 eV), which blocked the triplet exciton leakage. Therefore, the triplet excitons of the PPO27:FIrpic and PPO27:FCNIrpic emitting layers can be confined in the emitting layer by the PVK hole transport layer. The orthogonal film formation by the spin coating of the alcohol soluble PPO27:FIrpic and PPO27:FCNIrpic emitting layers on the PVK hole transport layer improved the device performances of blue PHOLEDs.

The stable film morphology of the PPO27:FIrpic and PPO27:FCNIrpic films was also critical to the high quantum efficiency of the solution processed blue PHOLEDs. As the

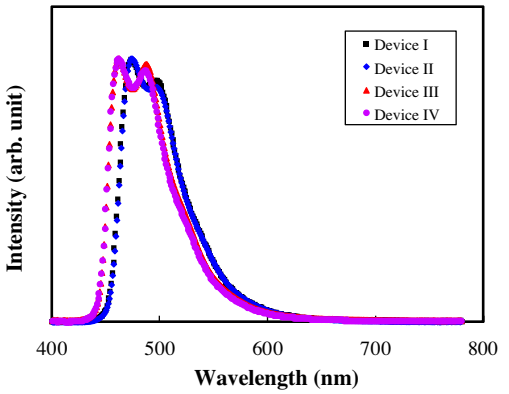

Fig. 6. Electroluminescence spectra of the solution processed blue PHOLEDs with PPO27:FIrpic and PPO27:FCNIrpic emitting layers.

FIrpic and FCNIrpic were well dispersed in the alcohol soluble PPO27 host material, little aggregation and crystallization were observed in the spin coated film, resulting in high quantum efficiency in the PPO27 based blue PHOLEDs.

Current efficiency–current density and power efficiency–current density curves of the PPO27:FIrpic and PPO27:FCNIrpic based blue PHOLEDs are shown in Fig. 5. The current efficiency and power efficiency showed similar relationship to the quantum efficiency depending on the device structure. The maximum current efficiency and power efficiency of the device II with PPO27:FIrpic emitting layer was 28.2 cd/A and 15.8 lm/W, while that of the device IV with PPO27:FCNIrpic emitting layer was 21.0 cd/A and 12.2 lm/W.

Electroluminescence (EL) spectra of the PPO27:FIrpic and PPO27:FCNIrpic devices are shown in Fig. 6. The maximum emission peak of the PPO27:FCNIrpic device was blue shifted by 12 nm compared with that of PPO27:FIrpic device because of the deep blue emission of the FCNIrpic. The color coordinate of the device IV was (0.15, 0.26) compared with (0.15, 0.36) of device II. Therefore, solution processed deep blue PHOLEDs could be effectively fabricated using the alcohol soluble PPO27:FCNIrpic emitting layer.

4. Conclusions

In conclusion, high quantum efficiency was achieved in the solution processed sky blue and deep blue PHOLEDs using alcohol soluble phosphorescent emitting layer. A multilayer device structure with an exciton blocking layer was fabricated by the spin-coating of the alcohol soluble PPO27:FIrpic and PPO27:FCNIrpic emitting layers on toluene soluble PVK exciton blocking layer. The approach to fabricate multilayer device structure using the solubility difference between the emitting layer and charge transport layers can be useful to improve the device performances of the solution processed PHOLEDs.

surface energy between the hydrophilic ITO surface and the hydrophobic HTL [5], allowing a good compatibility of the ITO surface and HTL, and hence a reduced turn-on voltage. The SAM-modified interface suppresses the crystallization of the overlaying HTL upon heating even above the glass transition temperatures of HTL materials [6]. The suppression of crystallization is an additional advantage brought about by using SAMs as a modifier.

As physically-adsorbed modifiers, chloride and acid derivatives, including phosphonic, sulfonic, and carboxylic acids, have been used [3,7–12]. For more stable SAM-ITO interfaces, chemically-bonded modifiers are considered to be preferable, because the rigid covalent bond prevents the exfoliation at the interface. Organo-alkoxysilane [4,13–19], silazane [20], and chlorosilane [21–23] have been used as modifiers, for which facile sol–gel reactions have often been used. Vapor phase reactions are also often used for the silanization [24]. However, they require high temperatures in many cases. This also limits kinds of modifiers, since the modifier should have a high thermal stability and a sufficiently high vapor pressure. In the sol−gel silanization, diluted silane molecules are immobilized on ITO surface in organic solvents, such as toluene [13–16,19], ethanol [16], and hexane [22]. The silanization includes two reaction steps [24–26]. The first step is the hydrolysis of silanes with water molecules adsorbed on a substrate surface or incorporated in a solvent to generate a silanol (Si–OH). The second step is the condensation of two silanols to form a siloxane bond on the ITO surface. The rate of hydrolysis significantly depends on the amount of water, and hence, the amount of water considerably influences on the resultant SAM structure on the ITO surface. Also, pH in a reaction solution has a significant impact on the SAM structure, because the mechanism and the kinetics of condensation reaction are completely different between under acidic and basic conditions [27,28]. When the hydrolysis and the condensation proceed via base-catalyzed mechanism, ramified silane polymers with widely-distributed molecular weights are formed, and the polymers subsequently form isolated particles. On the other hand, when the hydrolysis and the condensation proceed via acidic-catalyzed mechanism, homogeneous polymerization leads to mostly linear silane polymers with narrowly-distributed molecular weights. In addition to these factors, the rate of the condensation also depends on the amount of the silane molecule in a system. Therefore, the control of the three factors, i.e., catalytic condition, water amount, and the concentration of silane, is crucial for precise formation of SAMs and, therefore, for achieving excellent charge-injection properties of devices.

As described above, there are a number of studies targeting superior device performances by using novel modifiers. However, the systematic studies on preparation conditions for the SAM formation on ITO have not been reported. This may partly be because the amount of water and the pH are hardly controllable in hydrophobic solvents frequently used in the previous studies, such as toluene and hexane, which are immiscible with water. In this study, we investigated SAM formations of an alkylsilane, pentyltriethoxysilane (PTES), on ITO in an amphiphilic solvent, tetrahydrofuran (THF), which is miscible with water and can precisely control the amount of water and catalytic conditions. We, for the first time, systematically studied how the SAM structure and the resultant hole-injection property depend on amount of water, concentration of PTES, and catalytic condition in the reaction solution. The results obtained here would provide a benefit clue on the conditions of SAM formation for the high-performance OLEDs.

2. Experimental

2.1. Substrate preparation

We used an ITO patterned glass substrate, 55 nm ITO deposited on a soda-lime–silica glass with 0.7 mm thickness covered with 23 nm SiO_2 layer, sheet resistance of 50 Ω/sq, and an one subnanometer average roughness, as a cathode. The substrate was swabbed with acetone, followed by ultrasonic cleaning in detergent, ultrapure water, acetone, and isopropyl alcohol. The substrate was then boiled in isopropyl alcohol and placed in an ultraviolet−ozone treatment chamber (PL16-110, Sen Lights Co.). For the silane SAM formation, a freshly treated substrate was used without storage.

2.2. Silane SAM formation

Nitric acid (HNO_3: Nacalai Tesque Inc., 0.1 M) and ammonium hydroxide (NH_3: Hayashi Pure Chemical Industries, 28 wt%) were used as catalysts after being diluted with ultrapure water. Tetrahydrofuran (THF: Wako Pure Chemicals Industries, dehydrated, no stabilizer) and pentyltriethoxysilane (PTES: Tokyo Chemical Industry Co. Ltd.) were used as a solvent and a silica source, respectively.

First, THF and a given concentration of HNO_3 or NH_3 aqueous solution were mixed in a glass vessel. Under stirring in an ice water bath, PTES was added and kept stirring for 5 min. After stirring was stopped, the freshly treated ITO substrate was soaked in the solution, sealed, and kept at 40 °C for 24 h. The substrate was retrieved, rinsed with chloroform, and supersonically cleaned in chloroform for 10 min. Finally, the substrate was baked at 100 °C under vacuum to remove volatile residuals. The SAM-modified ITO substrates were used for device fabrication immediately. Hereafter, a H_2O/PTES ratio and a PTES concentration in a THF solvent are denoted as r and C_{PTES}, respectively. The value of r was controlled with the amount of catalytic aqueous solution, and thus the catalytic aqueous solutions were employed as a water source as well as a catalyst. In the present study, the sample prepared with C_{PTES} = 0 mM denoted as bare-ITO.

2.3. Silane SAM characterization

Contact angles, θ, of SAM-modified ITO substrates were measured with a contact-angle meter (Drop Mater 700, Kyowa Interface Science Co. Ltd.) using distilled water. The measurements were performed at five different points for respective substrates and the data were averaged. Surface morphology of the substrates was observed by an atomic force microscope (AFM: SPA400 + SPI3800 N, SII

Nano Technology Inc.) operating in a dynamic force mode (DFM).

2.4. Device fabrication and characterization

We used *N*, *N*′-di(1-naphthy)-*N*, *N*′-diphenylbenzidine (α-NPD) as a hole-transporting layer, tris(8-hydroxyquinoline) aluminum(III) (Alq_3) as a emissive and electron-transporting layer, lithium fluoride (LiF: Furuuchi Chemical Co. Ltd., 99.99%) as a electron-injection layer, and aluminum (Al: Kojundo Chemical Lab. Co. Ltd., 99.999%) as a cathode material. All the reagents were used as received.

Hole only devices (HODs) and OLED devices were fabricated on the SAM-modified ITO substrate by successive vapor deposition of organic layers, followed by the deposition of LiF and Al. HODs were composed of ITO-SAM/NPD 100 nm/Al 100 nm, whereas OLED devices were composed of ITO-SAM/NPD 50 nm/Alq_3 50 nm/LiF 0.6 nm/Al 100 nm. The deposition was carried out under 10^{-5} Pa. The deposition rates were 3 Å s^{-1} for the organic layers and Al, and 0.1 Å·s^{-1} for LiF. The devices thus fabricated have four active areas with 4 mm^2 each. Current density–voltage–luminance (*J*–*V*–*L*) characterization was performed using a computer-controlled source meter (Source Meter 2400, Keithley Instruments Inc.) equipped with a spectroradiometer (SR-3, TOPCON Co.). The characterization was carried out on all of the four active areas, providing information about reproducibility of the SAM formation on the ITO surfaces.

3. Results and discussion

First, we conducted a surface modification of ITO substrates with SAM and fabricated OLEDs with using the modified substrates. Fig. 1 shows the optical microscope images of the electroluminescence from the OLEDs. The images clearly indicate that in-plane uniformity of emission was considerably influenced by the catalytic condition for the SAM formation. Homogeneous emission was observed when the SAM was formed under the acidic condition (Fig. 1a), while significantly inhomogeneous emission was observed when it was formed under the basic condition (Fig. 1b). The luminance for the acidic condition (601 cd/m^2) was much larger than that for the basic condition (<100 cd/m^2) at an applied voltage of 6 V for the devices in Fig. 1. Namely, the luminescence was stronger and more homogeneous for the acidic condition than the basic condition. Fig. 2 shows the current density–voltage (*J*–*V*) and luminance–voltage (*L*–*V*) characteristics of the two OLEDs shown above (with the SAM formation under the acidic and basic conditions). For each sample, the measurements were performed on the four active areas (2 × 2 mm) and all the four data are plotted. The *J*–*V* (Fig. 2a) and *L*–*V* (Fig. 2b) plots reveal that the acidic condition led to lower turn-on voltages and higher luminance than the basic condition. Moreover, the four data for the basic condition were scattered, while those for the acidic condition were more reproducible. Thus, the in-plane uniformity of *J*–*V* and *L*–*V* characteristics highly depends on the catalytic conditions.

Fig. 3 shows the *J*–*V* plots of HODs for the 0.1, 0.01, and 0.001 M HNO_3, and 0.1 and 0.01 M NH_3 catalytic conditions. The acidic conditions exhibited higher hole-injection properties than the basic conditions, as in the case of OLEDs. In the studied case, the highest hole-injection property was achieved with 0.01 M HNO_3. The difference in the hole-injection property would be related to the surface morphologies of SAM-modified ITO substrates, as discussed below.

Fig. 4 shows the AFM images of the SAM-modified ITO substrates prepared with (a) acidic (0.01 M HNO_3) and (b) basic (0.01 M NH_3) catalysts. In the acidic condition (Fig. 4a), the roughness of the SAM was virtually the same as that of the bare ITO, indicating the coverage of a homogeneous silane layer on the ITO substrate. On the other hand, the basic condition (Fig. 4b) resulted in an inhomogeneous formation of coarse particles with the size of several micrometers in length and 30 nm in thickness. This confirms that the different luminance in Fig. 1 originates from the different homogeneity of the silane layers on the respective ITO surfaces. The contact angles of the modified surfaces were 93.6 ± 1.8° and 84.4 ± 0.5° with 0.01 M HNO_3 and 0.01 M NH_3, respectively, confirming a higher coverage of hydrophobic PTES on the ITO substrate under the acidic condition. The observation of coarse particles in Fig. 4b is explained by the fact that base-catalyzed condensation of silicate species produces ramified polymers with widely-distributed molecular weights [27,28]. The coarse particles are derived from the well-grown polymeric silicates which are formed on the ITO surface and/

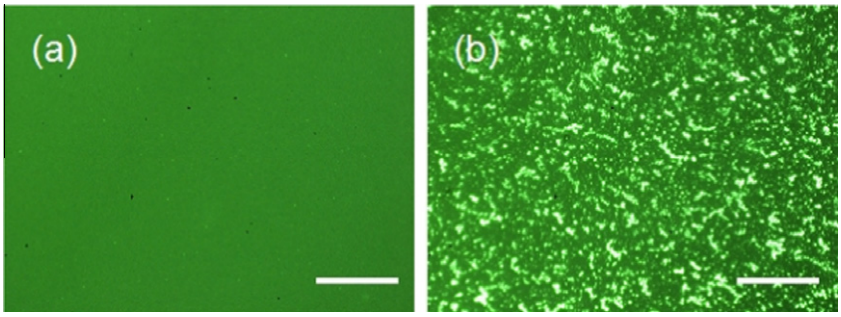

Fig. 1. Optical microscope images of the OLEDs under the applied voltage of 9 V. The SAM layers were formed with (a) acidic (0.01 M HNO_3) and (b) basic (0.01 M NH_3) catalysts under the condition of $r = 15$ and $C_{PTES} = 250$ mM. The OLEDs consist of ITO-SAM/NPD 50 nm/Alq_3 50 nm/LiF 0.6 nm/Al 100 nm. White bar = 100 μm in both the images.

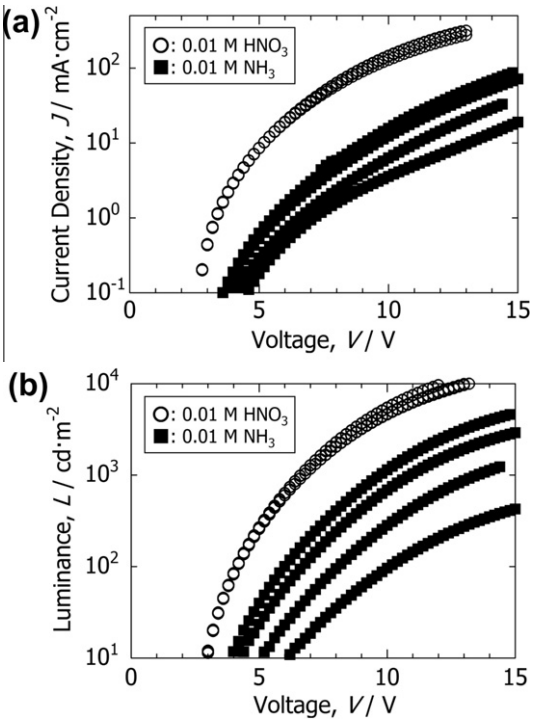

Fig. 2. (a) J–V and (b) L–V characteristics of the OLEDs composed of ITO-SAM/NPD 50 nm/Alq_3 50 nm/ LiF 0.6 nm/Al 100 nm. The SAM layers were prepared with 0.01 M HNO_3 (open circles) and 0.01 M NH_3 (closed squares) as catalysts, under the condition of $r = 15$ and $C_{PTES} = 250$ mM. The measurements were performed on the four active areas and all the data are plotted for both the devices.

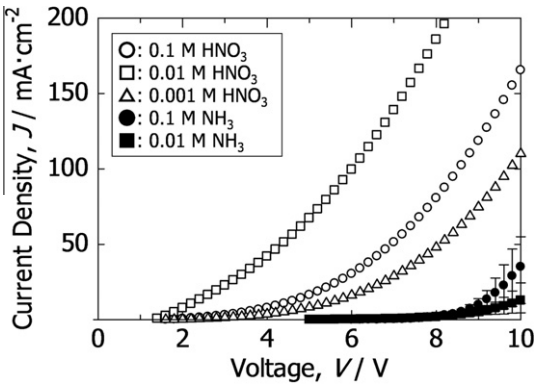

Fig. 3. J–V characteristics of HODs composed of ITO-SAM/NPD 100 nm/Al 100 nm. SAM formation was performed with the condition of $r = 10$ and $C_{PTES} = 250$ mM using various catalysts; open circles: 0.1 M HNO_3, open squares: 0.01 M HNO_3, open triangles: 0.001 M HNO_3, closed circles: 0.1 M NH_3, closed squares: 0.01 M NH_3. Error bars are depicted for HODs fabricated on the base-catalyzed SAMs, caused by the inhomogeneous characteristics among the respective four active areas.

or attached onto the surface. On the other hand, acid-catalyzed condensation of silicate species is favorable for the formation of homogenous polymer networks [27,28], which leads to the coverage of SAM on the ITO surface without segregation. Moreover, it is well-known that the rate of condensation is minimized around isoelectric point (IEP) of polymerizing silicates [29,30]. For example, the rate of condensation becomes extremely slow at pH 2.0–2.5 and 4 for silica and methylsilsesquioxane ($MeSiO_{1.5}$), respectively. In this study, the use of the condition, 0.01 M HNO_3, realized a relatively moderate condensation reaction of PTES, leading to the formation of a homogeneous silane layer.

Fig. 5 shows the J–V plots of the HODs at various r values under an acidic (0.01 M HNO_3) condition. With an increase of r, the hole-injection property was improved gradually from $r = 3$ to $r = 15$. The J increased from 11.9 mA cm^{-2} at $r = 3$ to 219 mA cm^{-2} at $r = 15$ at an applied voltage of 6 V. Further increase in r lowered the hole-injection property. For PTES, $r = 1.5$ is the stoichiometric condition for hydrolysis and condensation. However, the reactions generally take long reaction times to complete at $r = 1.5$ [27]. Thus, the excessive amount of water ($r > 1.5$) was required for the complete coverage of the ITO surface for the present reaction time, 24 h, and at the present reaction temperature, 40 °C. The best r was 15 in this case. The contact angles were 91.8 ± 0.7° at $r = 15$ and 79.9 ± 0.5 ° at $r = 30$. From the contact angles, the coverage of PTES for $r = 15$ and $r = 30$ can be roughly estimated as 88 ± 5% and 11 ± 3%, respectively. The small contact angle at $r = 30$ suggests that the condensation reaction occurred in the solvent phase rather than the ITO surface. The enhanced condensation in the solvent phase can be related to the formation of oligomers with the low connectivity to an ITO surface. A previous report [31] revealed that the oligomers with a cage structure tended to form with increasing r in a organosiloxane sol–gel system. Since the oligomers with a cage structure have no contribution to the formation of SAMs, they are isolated in a solvent. The insufficiently-modified ITO would explain the observed decrease in the hole-injection property at $r > 15$. Also, the small contact angle at $r = 30$ would be related to the increased silanols on the immobilized modifiers. An increase in r enhances the hydrolysis of PTES and produces hydrophilic silanols more effectively, leading to the small contact angle of ITO surface. Thus, the calculated coverage for $r = 30$, 11 ± 3%, would somewhat underestimate the coverage of PTES on ITO.

Fig. 6 shows the J–V plots of the HODs at various C_{PTES} values in an acidic (0.01 M HNO_3) condition at $r = 15$. The hole-injection property was improved with an increase of C_{PTES}. The J at applied voltage of 6 V increased from 3.94 to 206 mA cm^{-2}, as C_{PTES} increased from 0 to 250 mM. Fig. 7 shows the contact angle, θ, of the SAM-modified ITO surface as a function of C_{PTES}. The θ decreased from $C_{PTES} = 0$–42 mM and increased from $C_{PTES} = 42$–250 mM. The decrease in θ in the low C_{PTES} regime suggests the immobilization of hydrophilic species on ITO surface. Since the low C_{PTES} is an insufficient condition for the SAM formation, the silane layer unlikely developed on the entire surface of ITO. Thus, the immobilization of hydrolyzed PTES with hydrophilic silanols would decrease θ, as depicted in the inset of Fig. 7. In fact, the presence of silanols in silica networks was evidenced in the silica gels prepared under the acid-catalyzed condensations [27,32,33]. Whereas, in the condition of C_{PTES} from 42 to 252 mM,

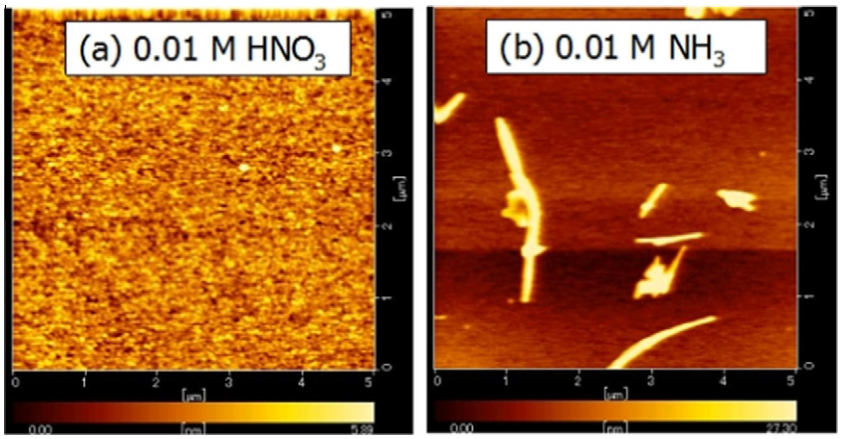

Fig. 4. AFM images of SAM-modified ITO substrates prepared under the condition of $r = 10$ and $C_{PTES} = 250$ mM with (a) acidic (0.01 M HNO_3) and (b) basic (0.01 M NH_3) catalysts. The image areas correspond to 5×5 μm.

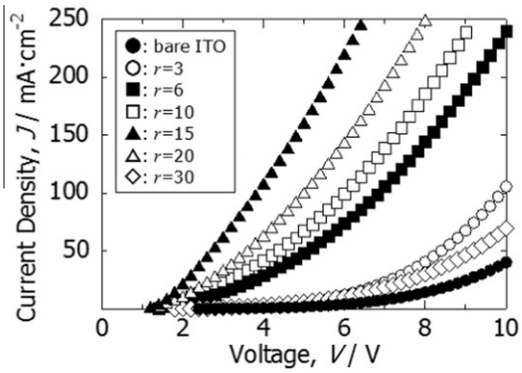

Fig. 5. The r-dependence of J–V characteristics of HODs composed of ITO-SAM/NPD 100 nm/Al 100 nm. 0.01 M HNO_3 was used as a catalyst and $C_{PTES} = 250$ mM for all the devices. closed circle: bare ITO, open circle: $r = 3$, closed square: $r = 6$, open square: $r = 10$, closed triangle: $r = 15$, open triangle: $r = 20$, open rhombus: $r = 30$.

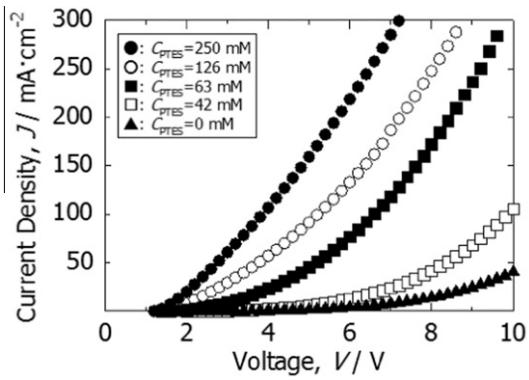

Fig. 6. Influence of C_{PTES} on J–V characteristics of HODs composed of ITO-SAM/NPD 100 nm/Al 100 nm; closed circles: 250 mM, open circles: 126 mM, closed squares: 63 mM, open squares: 42 mM, closed triangles: 0 mM. 0.01 M HNO_3 was used as a catalyst and $r = 15$ for all the devices.

θ increased due to the formation of siloxane network and the coverage of the ITO surface with the hydrophobic silane layer. At $C_{PTES} = 250$ mM, θ value virtually reached a value expected for the full coverage of PTES [4,34], meaning that 250 mM is large enough to fully cover the ITO surface.

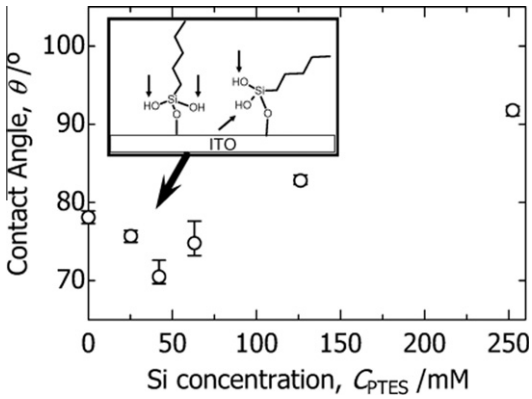

Fig. 7. Contact angles as a function of C_{PTES}.

In this way, with an appropriate pH (0.01 M HNO_3), water amount ($r = 15$), and PTES concentration ($C_{PTES} = 250$ mM), the acidic condition reproducibly provided a remarkably uniform PTES-modified ITO surface, which cannot be achieved in basic conditions. The OLEDs fabricated under this condition exhibited excellent J–V and L–V characteristics. The homogeneous PTES layer covalently-bonded to the ITO surface works as a good compatible layer with HTL, helping the hole-injection significantly. Thus, the acid-catalyzed silanization can be a very useful method for the precise modification of ITO substrates for the applications to OLED and other electronic devices. We used THF as a solvent in this work. PTES forms organosiloxane network on ITO with the formula of $RSiO_{1.5}$ through the hydrolysis and condensation reactions. Due to its hydrophobicity, oligomeric compounds of organosiloxanes easily phase separate from an aqueous solution or lower alcohols, resulting in the precipitation of amorphous compounds [35,36]. The use of THF as a solvent allows an accurate control of the

water content without the precipitation of silane compounds. Although the variation of the hole-injection property can be explained on the basis of the coverage of SAM on the ITO surface, the thickness of the silane layer should also influence on the hole-injection property; the silane layer on the ITO surface works as an insulator, and hence, the formation of a thick silane layer is undesirable. Considering the reaction mechanisms of PTES, the formation of a thick silane layer is unavoidable in the case of the base-catalyzed reactions. Therefore, the acid-catalyzed reactions would be preferable also in this sense.

4. Conclusions

By using facile sol–gel route, the conditions for SAM formation on ITO were systematically studied. The relationship between the preparation conditions of SAM and the resultant device properties was investigated by using OLEDs and HODs fabricated on SAM-modified ITO substrates. The emissions from OLEDs and the hole-injection properties of HODs revealed that the acidic conditions are favorable for the reproducible formation of SAM on the ITO surface. The SAM formation under the acidic conditions allows the homogeneous coverage of a silane layer on the ITO substrates, which leads to improved hole-injection properties from the anode. On the other hand, the use of basic conditions results in the inhomogeneous coverage of a silane layer on the ITO substrates and the decreased hole-injection from the anode. The choice of r and C_{PTES} also affect the kinetics of hydrolysis and condensation reactions of PTES, and hence the resultant SAM structures and hole-injection properties. The hole-injection property of HODs depends on the coverage of SAM on the ITO surface; the hole-injection property improved with increased coverage of SAM on the ITO surface. As a result, the highest hole-injection was achieved when SAM formation was performed under $r = 15$ and $C_{PTES} = 250$ mM, with 0.01 M HNO_3 as a catalyst. The results obtained here suggest that the device performance of OLEDs and HODs can improve drastically by choosing appropriate SAM formation conditions.

the dopant. However, most of theoretical studies only focused on the electronic property or zero bias conductance. The transport properties of the bilayer GNRs under finite bias are rarely discussed. As we know, the electronic devices always work under a finite bias voltage. For the purpose of practical applications, it is important to investigate the transport properties of bilayer GNRs under a wide range of finite bias voltages. In the present work, by applying first-principles quantum transport calculations, we investigate the electronic transport properties of a bilayer GNR device. The results show that the electronic transport properties can be modulated by changing weak interaction between two GNR molecules.

This letter is organized as follows: Section 2 gives a brief description of the model and the formulas used in calculations. The calculated results are presented in Section 3 with discussions. Finally, a summary is made in Section 4.

2. Model and formalism

In Fig. 1, we show a typical nanoelectronic device based on the bilayer GNR. Here we choose bilayer armchair GNR (AB-α stacking) [28] with the width of $N_a = 5$ as a typical system. The system is divided into three regions: the left and right electrodes and the scattering region. Each electrode is described by a supercell with two repeated carbon unit cells along the transport direction. In the scattering region, the bilayer GNR is connected to two monolayer GNR. When the intermolecular distance (D) is 5 Å, the top GNR is rotated around its main axis with 0, $\pi/4$, $\pi/3$, and $\pi/2$, which correspond to $M0$, $M1$, $M2$, and $M3$, respectively. When the D is 3 Å (3.5 Å), the top GNR is shifted along its main axis (towards the right side) with 0, 4.26, and 8.52 Å, which correspond to $M4$ ($M7$), $M5$ ($M8$), and $M6$ ($M9$), respectively. $M4$–$M6$ ($M7$–$M9$) are arranged with same stacking configure in the overlapping region of the scattering region, namely, AB-α stacking configure. Previous studies have shown that this arrangement is energetically favorable configure for bilayer GNR [28,29]. The geometrical optimizations and the electronic transport properties are all performed by the first-principles method based on the fully self-consistent *ab initio* density-functional theory [30,31]. The nonlinear current through the device is calculated using the Landauer formula [32]:

$$I(V_b) = \frac{2e}{h}\int T(E, V_b)[f_l(E-\mu_l) - f_r(E-\mu_r)]dE \quad (1)$$

where $\mu_{l(r)}$ are electrochemical potentials of the left and right electrodes and the difference of them is $\mu_l - \mu_r = eV_b$. The energy region of the transmission spectrum that contributes to the current is referred to as the bias window. The total transmission probability

$$T(E, V_b) = Tr[\Gamma_l G^R \Gamma_r G^A] \quad (2)$$

where $G^{R(A)}$ is the retarded (advanced) Green functions of the central region, $\Gamma_{l(r)}$ is the contact broadening functions associated with the left (right) electrodes. In calculation, the valence electrons are expanded in a numerical atomic-orbital basis set of double-ζ plus polarization type. The core electrons are described by norm-conserving pseudopotentials and the local-density approximation (LDA) is used to the exchange-correlation potential. The k-point sampling is 1, 1, and 100 in the x, y, z direction, respectively, and the cutoff energy is set to 150 Ry. In our model, we have assumed that the electron transport through the device is so quick that there is no time for the GNR molecules to deform [2,3,33–35].

3. Numerical results and discussion

In Fig. 2a–c, we give the current as a function of applied bias for the bilayer GNR systems. From the figure, some distinct features of calculated I–V curves can be addressed as follows: (i) For all systems, there exists a threshold voltage which can be attributed to the intrinsic semiconducting nature of armchair GNR ($N_a = 5$). (ii) When we increase the dihedral angle between two GNR molecules, the current values increase obviously with the increasing dihedral angle at same bias. Rectifying behavior can be found in $M1$, $M2$, and $M3$. From the inset of Fig. 2a, it can be found that $M2$ shows the best rectifying performance as compared with the others. The rectifying ratio in $M2$ is comparable to that in the recently reported double-silane chains system [3]. (iii) If we take the device $M5$ ($M8$) as OFF state, and $M4$ ($M7$) and $M6$ ($M9$) as ON states, the most interesting result is the appearance of the successive switch process [36] (ON–OFF–ON) when we reduce the size of overlapping region with fixed intermolecular distance. From the insets of Fig. 2b and c, the maximum value of ON–OFF ratio between $M4$ ($M7$) and $M5$ ($M8$) reaches 216 (51) at 0.45 V, and between $M6$ ($M9$) and $M5$ ($M8$) it is about 61 (25) at 0.45 V.

In Fig. 3a–d, we give the transmission spectra of $M0$–$M3$ at zero bias. From Fig. 3a, we can clearly see that the transmission coefficient is essentially zero in the energy region and a large HOMO–LUMO gap can be observed, which means very weak π–π interaction. It is known that the interaction between two molecules can lead to the splitting of the level and the magnitude of the splitting is dependent on the relative position of the interacting molecules [37]. When the dihedral angle between two GNR molecules is $\pi/4$, obvious level splitting for the frontier molecular levels can be observed. For instance, the LUMO and LUMO + 1 (splitting = 0.1 eV) in $M1$ originate from the LUMO splitting. More interestingly, we can find that the transmission coefficients and the amplitudes of the level splitting are strongly correlated, namely, the stronger the level splitting, the larger the corresponding transmission coefficient. This indicates that the molecular levels originating from large level splitting can be more effective

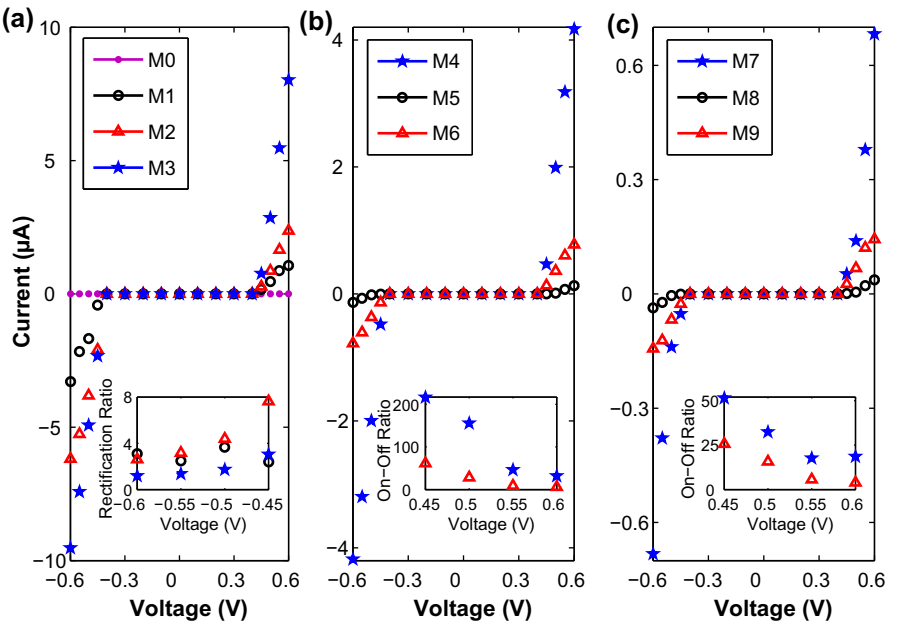

Fig. 2. (a) Calculated current as a function of the applied bias of *M*0–*M*3. The inset is the changes of rectifying ratio with the applied bias for *M*1–*M*3, respectively. (b) Calculated current as a function of the applied bias of *M*4–*M*6. The inset shows the ON/OFF ratio between *M*4 and *M*5 (blue) and between *M*6 and *M*5 (red). (c) Calculated current as a function of the applied bias of *M*7–*M*9. The inset shows the ON/OFF ratio between *M*7 and *M*8 (blue) and between *M*9 and *M*8 (red). Fig. 3. (a)–(d) The transmission coefficients (solid lines) at zero bias for systems *M*0–*M*3, respectively. The vertical dash-doted curves stand for frontier molecular levels, and the Fermi level is set to be the origin of energy. The insets of (a)–(d) give the molecularly projected self-consistent Hamiltonian (MPSH) of the LUMO for *M*0–*M*3 at zero bias, respectively.

transport channels for electron transport. From the Fig. 3b–d, we can clearly see that the level originating from the LUMO splitting is very close to the Fermi level, indicating that the electron transport at low bias is mainly

determined by the amplitudes of LUMO splitting. From *M*1–*M*3, we can find that the splitting for LUMO is monotonically increasing as the dihedral angle increases. As a result, the conductivity of the system is obviously enhanced with the increase of dihedral angle even if the size of the overlapping region between two GNR molecules is reduced in the process. To explore the possibility about the formation of bilayer molecular junction in experiment, in the insets of Fig. 3a–d, we also plot the molecular projected self-consistent Hamiltonian (MPSH) of the LUMO for *M*0–*M*3 at zero bias, respectively. From the inset of Fig. 3a, we can find that when the vertical distance between two GNR molecules is 5 Å, the electronic density for two molecules cannot overlap each other due to large spatial distance. Thus, the molecular orbit shows the character of a single molecule's orbit. However, from the insets of Fig. 3b–d, we can find that when the dihedral angle is larger than or equal to $\pi/4$, there exists obvious overlapping of electronic density between two GNR molecules and thus these orbitals show a unitary behavior related to the two GNR molecules, indicating that π–π coupling between two molecules is efficient enough to induce the formation of bilayer GNR junction [38].

In order to understand the rectifying performance in *M*1–*M*3, we take *M*2 as an example to explore the origin of this phenomenon. As we know, the frontier molecular levels can be renormalized by bias potential, which modulates the electron transport in the two probe system [39]. In Fig. 4a–d, we demonstrate the rearrangement of the LUMO respect to the bands of left and right electrodes at $V_b = \pm 0.5$ V and $V_b = \pm 0.6$ V, respectively. From the Fig. 4a–d, we can find the LUMO is the unique conducting channel in the energy region [−0.2, 0.2] eV, and it lies in different positions at same positive and negative bias. As we use the semiconductor electrodes, the transmission coefficients in the bias window cannot be observed until the conductance band minimum matches with the valence band maximum at the Fermi level. Then, further increase in bias will develop the narrow the transmission region. From previous reports [18,19,40], it is known that the match or mismatch between the molecular states and the electrode states play a vital role in the changes of the conductivity of the systems. From Fig. 4a and c, we can clearly see that when the positive bias is applied, the LUMO level overlaps with the upper part of the valence band of the right electrode, but falls into the band gap of the left electrode. Thus, the hybridization between the LUMO and electrode states can be weakened so that the electron transport ability is weak in the bands matching region [19,40]. When the corresponding negative bias is applied, the LUMO overlaps with the lower part of the conductance band of the right electrode. Meanwhile, it is interesting to find that here the LUMO level overlaps with the valence band of the left electrode, especially obvious at $V_b = -0.6$ V. This leads to the enhancement of the electron transport ability compared with the case of the positive bias. As a result, the current value at negative bias is much larger than that at corresponding positive bias and rectification appears correspondingly, as shown in Fig. 2a. From above results, we can infer that when the positive bias is applied, the bad match between the LUMO state and the bands matching region might be main origin of the rectifying behavior.

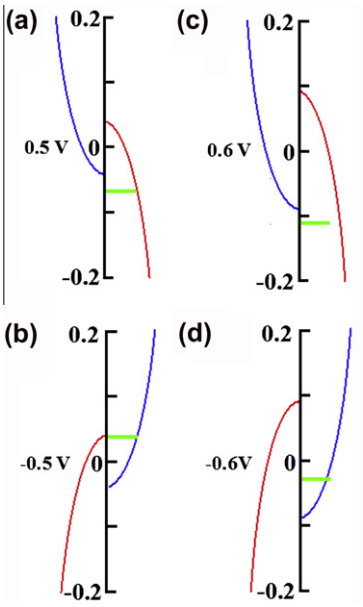

Fig. 4. The schematic diagram of the position of the LUMO in the scattering region relative to the bands of left and right electrodes at $V_b = \pm 0.5, \pm 0.6$ V. The blue and red curves indicate the conductance band and the valence band, respectively. The short lines (green) represent the position of the LUMO. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

For *M*4 (*M*7), *M*5 (*M*8), and *M*6 (*M*9), the bilayer GNR are arranged with the same intermolecular distance and stacking form in the scattering region so that the smaller the size of overlapping region, the weaker the intermolecular interaction. However, from Fig. 2b and c, we can find the currents are *M*4 (*M*7) > *M*6 (*M*9) > *M*5 (*M*8) for the same bias voltage, which means that the ON–OFF–ON process occurs when the top GNR is shifted along its main axis with fixed intermolecular distance. To understand this interesting phenomena, in Fig. 5, we present the change of the HOMO and LUMO with the bias voltage and the MPSH of the LUMO at $V_b = 0.45$ V for *M*4, *M*5, and *M*6, respectively. From Fig. 5a–c, it is found that when same bias is applied, the decrease of overlapping region can lead to the shift of the levels. Furthermore, we can clearly see that for *M*4–*M*6, the LUMO always lies inside the bias window. For the HOMO, however, a high bias voltage is necessary to drive it into the bias window. So, the electron transport through the bilayer GNR device mainly depends on the LUMO at low bias. This is similar to the cases of *M*1−*M*3. Comparing Fig. 5d and e with f, it is found that the LUMO of *M*4 and *M*5 has a high density on the overlapping region, indicating stronger coupling between two GNR molecules which plays an important role in the transport behaviors of these two systems. Comparing Fig. 5e with d, we can clearly see that the electron transport ability getting weaker in *M*5 is mainly due to the decrease of the strength of intermolecular coupling and molecule–electrode coupling. For LUMO of *M*6, although there is a low density on the overlapping region, the orbital covers

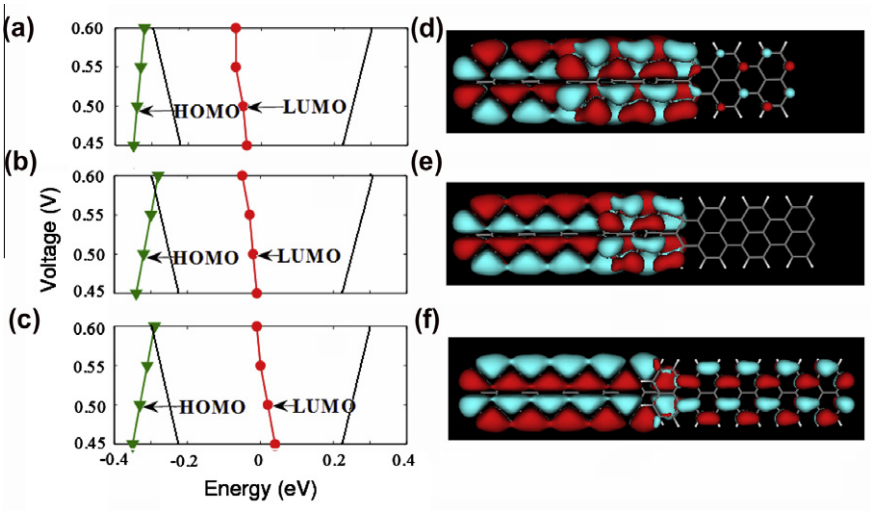

Fig. 5. (a)–(c) The shift of the HOMO and LUMO levels with the increase of bias voltage for *M*4–*M*6, respectively. (d)–(f) The molecularly projected self-consistent Hamiltonian (MPSH) of the LUMO for *M*4–*M*6 at V_b = 0.45 V, respectively.

the entire system and shows delocalized characteristic, resulting in the enhancement of the electron transport ability. As a result, the current of *M*6 is bigger than that of *M*5. However, its current is still smaller than that of *M*4. This may be due to the fact that compared with the *M*4, the slight delocalization of the LUMO in *M*6 cannot compensate for the loss of electron transport induced by the drastic decrease of the overlapping region.

4. Summary

In conclusion, we investigate the electronic transport properties of a bilayer GNR device. When we change the dihedral angle between two GNR molecules, the rectifying behavior can be observed. It is suggested that when the positive bias is applied, the bad match between the LUMO state and the bands matching region might be main origin of the rectifying behavior in *M*2. More importantly, a successive switch behavior can be realized by adjusting the overlapping region between two GNR molecules, namely by changing interaction between two GNR molecules. This can be attributed to the fact that the change of the intermolecular interaction leads to the shift of the molecular orbitals, and then leads to the change of the coupling strength between molecules and electrodes. It is suggested that we can adjust the electronic transport properties of the molecular devices by changing the weak intermolecular interaction between molecules, which provides a way for the design of molecular devices.

conductivity which at the same time substantially reduces transmissivity of the entire device [5]. As most of the organic layers are very brittle and temperature sensitive, the choice of transparent top electrode material and processing conditions are very restricted and additionally essential in all cases where an opaque substrate like foils of stainless steel for OPV is used to allow for efficient illumination of the OPV. Thin metal films like silver (Ag) allow "soft" processing conditions and exhibit a high conductivity but only a limited transmittance in the visible part of the spectrum (T_{VIS}) [6]. In contrast, transparent conductive oxides (TCOs) such as indium tin oxide (ITO) show a high T_{VIS} but relatively poor electrical properties when deposited with a gentle sputter process at room temperature [7]. In general, sputter deposition of metal-oxides on top of organic devices is related with serious issues. Recently, thin films of thermally evaporated transition metal oxides (TMO) such as tungsten oxide (WO_3) or molybdenum oxide (MoO_3) have been demonstrated as efficient buffer layers which protect the organic layers from damages induced by sputter deposition of the top electrode [3,8,9]. A severe limitation is given by the fact, that TCOs typically require some high-temperature (>300 °C) post deposition thermal treatment in order to improve their conductivity, which is not possible on top of organic devices. Therefore, the combination of the high T_{VIS} of TCOs and the excellent conductivity of metals by sandwiching a thin metal layer between two TCO layers appears to be an attractive approach. Due to their high T_{VIS} and high reflectance in the infrared region these multilayer structures are used in window glasses for thermal insulation as low-emissivity coatings [10]. Compared to a bare ITO film which achieves a low sheet resistance (R_s) of 13 Ω/sq and about T_{VIS} = 90% after annealing at 350 °C various TCO/metal/TCO structures yield similar values deposited at room temperature [11,12]. For the embedding TCO, both excellent optical and electrical properties are required. Moreover, it is favorable to use amorphous TCO materials, concerning reproducibility and homogeneity on a large active area. Additionally, amorphous film growth provides a low roughness which is essential to avoid electrical shorts in thin film technology. The requirements listed above are fulfilled by zinc tin oxide (ZTO). In recent years, ZTO has been used as the channel semiconductor in transparent thin film transistors (TFT) [2,14]. In contrast to the crystalline compound zinc-stannate (Zn_2SnO_4) which can be formed by substrate heating during deposition or thermally post deposition treatment [15], ZTO prepared at low temperatures has been shown to provide an entirely amorphous structure over a wide range of deposition parameters which is preferred in oxide TFTs to improve homogeneity on a large area [16]. ZTO layers deposited at room temperature exhibit carrier concentrations in a wide range of 10^{12}–10^{19} cm^{-3} and a Hall mobility greater than 10 $cm^2(Vs)^{-1}$ [17]. In comparison, zinc oxide (ZnO) deposited at room temperature shows significantly lower electrical conductivity and a strong tendency to form polycrystalline layers [18]. Recently, a multilayer electrode including ZTO and sputtered Ag has been shown as bottom contact for opaque OSCs especially for use on flexible substrates [19].

In this communication, we report on the origin of the high conductivity and the high transparency of a multilayer electrode, in which a thin thermally evaporated Ag layer is sandwiched by layers of ZTO, prepared by RF-sputtering. By a thorough study of structural, electrical and optical properties, we clearly evidence that the ZTO/Ag/ZTO (ZAZ) multilayer electrode is uniquely advantageous for two reasons:

The favorable interface energy of ZTO and Ag allows closed Ag layers at an Ag thickness as low as 6 nm. By comparing sputtered ZTO and evaporated MoO_3, we found that closed Ag films and therefore higher conductivity are achieved at lower Ag thickness when deposited on ZTO as on MoO_3. Thereby, conductivities in optimized ZAZ multilayers are an order of magnitude higher than that of ITO and a concomitantly high T_{VIS} can be achieved.

Furthermore, the ZTO cap on top of ultrathin Ag not only improves the overall transmissivity of the electrode but, even more importantly, enables the stabilization of electrical characteristics of the electrode by suppressing Ag diffusion. It is well known that a severe issue of many TCO/Ag/TCO electrodes is their long term stability. The tendency of thin silver layers to form agglomerates and discontinuous layers over time has been reported [13]. We show, that owing to the stabilizing effect of the sputtered ZTO cap, ZAZ is substantially more robust than ZTO/Ag (ZA).

Finally, we demonstrate the application of our novel transparent electrode as top contact for semitransparent bulk hetero junction (BHJ) OSCs with an active area in excess of 2 cm^2. For semitransparent OSCs with an ITO top electrode the efficiency drops from 2.5% to 1.5% when the active area is increased from 0.2 to 2.25 cm^2. For the 2.25 cm^2 ZAZ based devices a substantially higher efficiency of 2% is found at a concomitant high transmissivity of more than 60% for $\lambda > 650$ nm.

2. Experimental

ZAZ structures were deposited on glass substrates (17×17 mm^2, Borofloat) using a RF magnetron sputtering system and a thermal evaporation chamber under UHV conditions. The ZTO target had a size of 10 cm in diameter and existed of SnO_2/ZnO (50:50 at.%) with a purity of 99.9%. The RF process was run with a power density of 0.2 W/cm^2 in a pure argon (Ar) gas atmosphere with an Ar flow of 40 sccm at a process pressure of 12 μbar. Base pressure of the system is 10^{-8} mbar. Sputtering was performed at room temperature without any post process treatment. The distance between target and substrate was 70 mm and substrate oscillation speed was set to 17.1 min^{-1} angular velocity. Intermediate silver films were deposited from a common thermal evaporation system using molybdenum boats at a base pressure of 10^{-6} mbar. ZAZ multilayer films were fabricated without vacuum break.

R_s, carrier concentration and Hall mobility was estimated using Van-der-Pauw and Hall measurement, respectively. T_{VIS} was measured by a UV–vis spectrophotometer (Perkin-Elmer Lambda 9) in reference to glass substrates.

Film thickness was measured by a surface profilometer (Veeco Dektak 4). The surface morphology was investigated by non-contact AFM (Danish Micro Engineering). SIMS depth profiling was performed and analyzed with a 500 eV Cs^- ion beam. Cross-sectional TEM was carried out in a Philips CM 200 FEG microscope operated at 200 kV.

Details of the preparation of inverted OSCs (regioregular of poly(3-hexylthiophene):(6,6)-phenyl C61 butyric acid methyl ester) and the ITO sputter process are given in [3]. *I–V* curves were measured by a Keithley 2400 sourcemeter. Photocurrent was measured under illumination from a 300 W solar simulator with an AM1.5G filter (Newport Corp.) considering the transient characteristics of cells incorporating Titania layers [20]. Efficiencies were determined without correction for spectral mismatch.

3. Results and discussion

3.1. Transparent ZAZ multilayer structure

3.1.1. Electrical characteristics

Initially, the electrical properties of our ZAZ multilayer structures were studied by varying the thickness of the ZTO and Ag layers, respectively. ZTO layers prepared in this study exhibit a carrier concentration of 10^{17} cm^{-3} and a Hall mobility of 6 $cm^2(Vs)^{-1}$ leading to a specific resistivity of about 50 Ω cm. To determine the influence of the embedded metal film on R_s, the thickness of Ag was varied from 4 to 10 nm whereas the thickness of both ZTO layers was kept constant at 39 nm. As shown in Fig. 1, R_s of ZAZ decreases exponentially from 250 to 5 Ω/sq with increasing Ag thickness. The percolation threshold (formation of a closed and continuous film) for sputtered Ag films on top of zinc-stannate was found at a thickness of 5–6 nm [6,21]. Owing to the electronic structure of Ag and ZTO, a transfer of electrons may lead to doping of the adjacent ZTO layers [22]. As a result, for discontinuous Ag layers (<6 nm) the sheet conductivity will be governed by separated Ag islands connected via doped ZTO claddings. It is essential to note, that we did not observe any significant influence of the thickness of the ZTO cladding layers on R_s. This is in agreement with previous reports on oxide/metal/oxide multilayers [23,24].

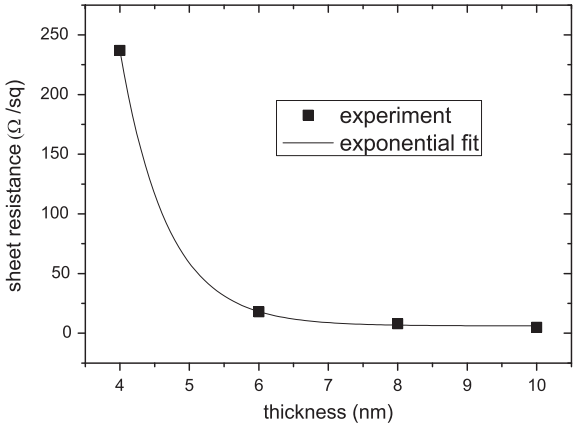

Fig. 1. Sheet resistance and exponential fit of a ZAZ multilayer structure as a function of Ag thickness. Thickness of ZTO layers sandwiching the Ag film was fixed to 39 nm each.

3.1.2. Origin of structural and morphological properties

The microstructure of Ag and ZTO films has been studied by cross sectional transmission electron microscopy (TEM). The analyzed structure consists of two ZTO layers (60 nm) and an intermediate Ag layer (6 nm) deposited on a silicon substrate (covered with 2 nm of native silicon oxide). Fig. 2(a) shows the TEM cross section of the ZAZ stack along with a magnified view of the interface. As an estimate from the TEM image, the roughness of the structure is 2–3 nm, in agreement with AFM data (not shown here). Obviously, the Ag film is continuous whereas its thickness is not homogeneous. Aside from polycrystalline growth of Ag, the inset of Fig. 2(a) confirms the completely amorphous structure of ZTO. Secondary ion mass spectroscopy (SIMS) was used to verify that there is no significant penetration or migration of Ag into the surrounding ZTO layers represented by Fig. 3. Our findings are in contrast to previous reports on Ag diffusion into an adjacent ZnO layer in case of a sputtered Ag film [25].

Fig. 2(b) shows a ZTO (60 nm)/Ag (6 nm) (ZA) structure (not capped with a second sputtered ZTO layer) after storage for 500 h in air. Strikingly, we evidence separated Ag islands in contrast to the findings for the capped Ag layer in the ZAZ stack. By carrying out conductivity measurements over several days in nitrogen atmosphere, given in Table 1(a), we found that in case of the ZAZ structure the R_s remains constant (11 Ω/sq) over 480 h whereas R_s of un-capped ZA structures increases by three orders of magnitude (20 kΩ/sq). As these experiments have been done under inert atmosphere, any oxidation of Ag due to the ambient oxygen can be ruled out. Fig. 2(c) verifies the completely amorphous growth of ZTO on top of the amorphous MoO_3 by showing the FFT images of the films in comparison to that of the crystalline Si substrate. Furthermore, it seems that there is no abrupt transition between MoO_3 and ZTO indicating an intermixing of the interface caused by highly energetic ZTO particles in the sputter process. This strikingly justifies the necessity of a buffer layer to protect the subjacent organic layers against sputter damages [3,8]. The growth of ZTO on top of MoO_3 is of paramount interest for the application as top contact on organic devices.

Taking these electrical properties and the TEM image of Fig. 2(b) into account, we conclude that island formation of silver on top of ZTO is due to a slowly proceeding surface diffusion process of Ag leading to formation of an aggregated and discontinuous Ag layer over time. Essentially, this diffusion of Ag appears to be suppressed by the second sputtered ZTO cladding layer on top of Ag. As the initial values ($t = 0$ h) of R_s of ZAZ and ZA are similar (about 10 Ω/sq), we infer that the sputter process of ZTO on top does not directly affect the Ag layer. Interestingly, if we replace both sputtered ZTO layers by thermally evaporated MoO_3 layers, we obtain significantly higher R_s of 580 Ω/sq for the MoO_3/Ag/MoO_3 (MAM) structure. Replacing the capping MoO_3 layer with ZTO (MAZ) leads to a slightly

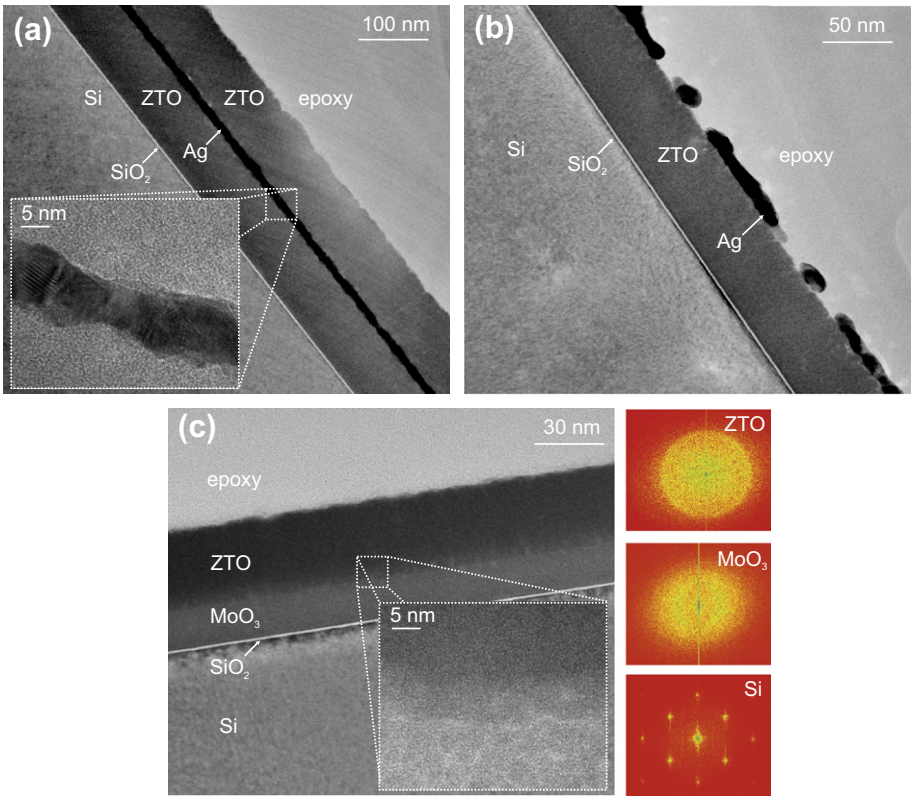

Fig. 2. (a) Cross sectional TEM image of ZAZ multilayer structure. Inset: magnified view on the constriction of Ag. (b) ZA structure deposited on silicon substrate at room temperature, showing the agglomeration of an Ag layer after storage for 500 h in air. Nominal thicknesses of the layers are 6 nm (Ag) and 60 nm (ZTO). (c) ZTO deposited on MoO_3 with FFT (fast Fourier transformation) images of Si, MoO_3 and ZTO.

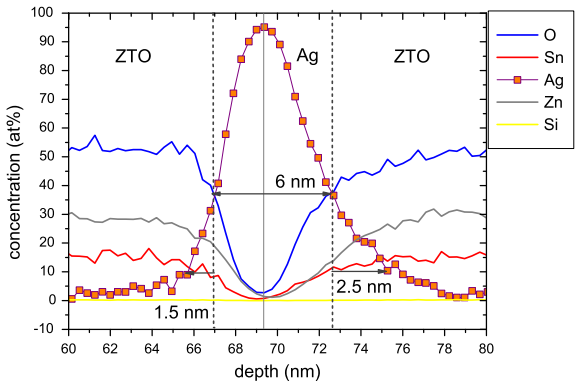

Fig. 3. Secondary ion mass spectrum (SIMS) of a ZAZ structure with a nominal layer thickness of 6 nm (Ag) and 60 nm (ZTO) deposited at room temperature on a silicon substrate.

lower R_s of 150 Ω/sq, which is still an order of magnitude higher than that of ZAZ (see Table 1(a)). The lower R_s of MAZ compared to MAM is attributed to the doping effect of ZTO as discussed above [22], which is, however, not as significant as the influence of the two metal oxides on the morphology of the subsequently grown Ag layer. In order to obtain values of R_s similar to those of ZA ($t = 0$) with 6 nm Ag interlayer, thicker Ag layers of about 10 nm are required in MA (see Table 1(b)). Thus, the deposition of silver on top of ZTO seems to be beneficial and inevitable for a low R_s and a high transparency of the multilayer electrodes.

3.1.3. Optical and overall performance

The spectral transmittance of a single ZTO layer (30 nm), a single Ag layer (12 nm) and a ZTO/Ag/ZTO sandwich structure (20/8/40 nm) is shown in Fig. 4. All layers were deposited on glass substrates. Due to high reflectivity and absorption losses, the bare Ag film shows low T_{VIS} of about 25%. By inserting Ag between two ZTO layers transmittance can be dramatically increased up to 83%. Inset of Fig. 4 demonstrates the spectral shift of the transmission maximum of ZAZ to higher wavelength by increasing the ZTO capping layer from 39 to 59 nm.

To compare the performance of several transparent conductive films on basis of optical and electrical properties, we used a figure of merit (FOM) Φ_{TC} defined by Haacke et al. [26]. The FOM is calculated by $\Phi_{TC} = T^{10}/R_s$, where T is the optical transmittance (at 550 nm in our study). A maximum of $\Phi_{TC} = 2.0 \times 10^{-2}\,\Omega^{-1}$ is reached for an optimized ZAZ structure and is an order of magnitude larger than that of an ITO film ($\Phi_{TC} = 2.4 \times 10^{-3}\,\Omega^{-1}$). The higher FOM of ZAZ is predominantly caused by its substantially lower R_s compared to ITO. Specifically, the ITO layer in this study was deposited at room temperature without any post deposition annealing according to the constraints

Table 1
(a) Time dependent measurement of R_s of various sandwich structures (ZTO/Ag (ZA), ZTO/Ag/ZTO (ZAZ), MoO_3/Ag/MoO_3 (MAM) and MoO_3/Ag/ZTO (MAZ)). Layer thicknesses are 10 nm (ZTO), 6 nm (Ag) and 20 nm (MoO_3). (b) Time dependent measurement of R_s of MoO_3 (10 nm)/Ag structures with varied Ag thickness on top.

(a) Structure	ZA		ZAZ		MAM		MAZ

given by the application as top contact of temperature sensitive organic devices [3,18]. A summary of some specific examples of ZAZ multilayers compared to bare ITO concerning R_s, Φ_{TC} and T_{VIS} is given in Table 2.

3.2. Transparent top electrode for semitransparent OSCs

To expose the outstanding performance of ZAZ we used optimized highly transparent and conductive ZAZ electrodes as top side contacts in semitransparent OSCs. Fig. 5(a) displays the spectral transmission of the entire device. Obviously, the transmission is higher at wavelengths $\lambda > 600$ nm due to the specific absorption features of P3HT:PCBM BHJ [3]. The transmission of devices with ITO as top contact is 69% at 650 nm. Compared to that, the transmission of devices with ZAZ top contact is 67% (8 nm Ag) and 60% (10 nm Ag) at 650 nm, respectively.

Table 3
Performance results of solar cell devices with different top electrodes and varied size of active area separately illuminated from both sides of the device.

Top electrode	Active area (cm^2)	Glass side				Top side			
		PCE (%)	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)	PCE (%)	V_{oc} (V)	J_{sc} (mA/cm^2)	FF (%)
ITO	0.2	2.5	0.56	7.8	58	2.1	0.55	6.2	61
	0.8	2.3	0.56	7.8	54	2	0.55	6.2	57
	2.25	1.5	0.54	7.6	37	1.3	0.54	5.8	42
ZAZ (8 nm Ag)	0.2	2.5	0.55	7.7	60	2.1	0.54	6.2	63
	0.8	2.6	0.55	7.9	61	2.2	0.55	6.4	62
	2.25	2	0.55	7.9	46	1.7	0.55	6.3	49
Al	0.2	2.5	0.55	8.5	56	–	–	–	–
	2.25	2.2	0.54	9.1	45	–	–	–	–

In Fig. 5(b) current density versus voltage (*J–V*) of devices with varied active area is shown. For devices with smaller active area of 0.2 cm^2 the difference between cells with ZAZ or ITO is small. The work function (WF) of ZTO was determined by Kelvin Probe measurements to 4.3 eV and is therefore smaller than that of ITO (WF = 4.7 eV). However, the difference in WF of the electrodes does not seem to play an important role possibly due to the subjacent high-WF molybdenum oxide layer, which is consistent to results shown by Schulze et al. [27]. The main advantage of the ZAZ top electrodes compared to ITO becomes obvious for devices with increasing active area. Obviously, cells with ZAZ top contact show higher current densities under forward bias owing to a lower series resistance compared to cells with ITO. The inset of Fig. 5(b) shows the series resistance of the cells with ITO or ZAZ top contact and an area of 2.25 cm^2 determined from the slope of the *J–V* characteristics in forward bias. As expected from the sheet resistance results of the pure electrode layers the sheet resistance of the cells with ITO top contact is higher. The series resistance plays an important role in controlling the fill factor [28]. With an optimized ZAZ top contact the semitransparent OSCs maintain a high FF even for cells with a larger device area as required for serious applications.

Table 3 summarizes the performance of devices with an active area between 0.2 and 2.25 cm^2. In general, we find higher power conversion efficiency (PCE) when devices are illuminated from glass side. This is due to a lower absorption of the bottom ITO electrode compared to optical losses in the top electrodes. Note the bottom ITO electrode is substantially more transparent due to some post deposition thermal treatment by the manufacturer. For a small active area, values for PCE, V_{oc}, J_{sc} and *FF* of cells with ITO and ZAZ top contact are similar. As a general trend, the performance of the cells decreases towards larger active area. Most strikingly, the devices with an ITO top electrode suffer from a loss in PCE for 2.25 cm^2 cells by 60% compared to PCE of devices with the smallest area used (0.2 cm^2). Opposed to that, ZAZ cells show a 30% higher PCE than ITO devices. An efficiency of 2% for semitransparent OSC states the highest efficiency with an active area larger than 2 cm^2, so far.

To figure out if the bottom ITO electrode already contributes to some limitation for the 2.25 cm^2 devices, the ZAZ top electrodes have been coated with a thick (opaque), highly conductive Ag layer. Surprisingly, the resulting cells also show lower efficiencies compared to small area devices. Furthermore opaque cells with ITO bottom and aluminum top contact show a similar decrease in FF and PCE with increasing cell area as cells with ZAZ top contact. This result hints to some limit added by R_s of the ITO bottom electrode. In further work the bottom ITO electrode could be replaced by an optimized ZAZ layer, as well.

4. Conclusion

In conclusion, we have demonstrated highly efficient transparent electrodes which are especially suitable for the use as transparent contacts on top of organic devices. An optimized (ZAZ) multilayer structure deposited at room temperature achieves a maximum transmittance of 85% at 550 nm similar to ITO under comparable process conditions. At the same time R_s is about an order of magnitude lower than that of ITO prepared at room temperature. Additionally, closed films leading to lower R_s can be achieved at lower Ag thickness when deposited on top of ZTO compared to MoO_3. We have evidenced that formation of islands and discontinuous layers due to the typically occurring surface diffusion of Ag on top of oxide materials can be effectively suppressed by using a sputtered ZTO layer on top of thin Ag films. Owing to the low R_s and a concomitantly high transmissivity, semitransparent OSCs comprising an optimized ZAZ top electrode show a 30% higher efficiency at large active device areas (>2 cm^2) compared to cells with ITO top electrode. Therefore, the presented ZAZ electrodes pave the way towards organic optoelectronic devices with substantially relaxed limitations due to resistive losses even for a larger active area, required for serious applications.

energy transfer and confinement of triplet excitons on the triplet emitters. But, if the E_g of the host is too large, deep and strong charge traps will be induced on the dopant emitters, resulting in poor conductivity of the host and a high driving voltage of the device [13]. There exists also an inherent tradeoff between E_T, E_g, and the π-conjugation length, since longer π-conjugation will lead to lower E_T and E_g but higher charge mobility for lower driving voltage and higher device efficiency [14]. The large difference in HOMO and/or LUMO level between the charge-transporting and the emitting layers will also cause energetically unfavorable charge injection and a high driving voltage. Due to the large E_g and E_T of the blue phosphorescent emitters, the search for a suitable host material is urgent and challenging. The host material used for blue PHOLEDs must have a large E_T (>2.7 eV) which results in an even wider E_g (>3.0 eV) that may act as energy barriers for the carriers transport from nearby hole or electron-transporting layer to the emitting layer, leading to high driving voltage of the FIrpic-based devices [15]. One approach to solve the problematic high driving voltage of blue PHOLEDs is to design and synthesis suitable host materials that possess both the high triplet excited state, the superior carrier-transporting property, and the appropriate energy levels (HOMO and LUMO). Up to now, researches directed toward the molecular design of host materials with high E_T, relatively narrow E_g, and good carrier-transporting properties were rather limited [8,16–17].

Heterofluorenes (HF) [18] such as nitrogafluorene (carbazole, NF) [19], sulfurafluorene (SF) [20], silafluorene (SiF) [21–23], germafluorene (GeF) [24], and phosphafluorene (PF) [25] have received a number of interests in many fields due to their particular physical and optoelectronic properties, since the breakthrough of their synthetic methods [26]. Recently, we designed and successfully prepared a serial of carbazole end-capped heterofluorenes (CzHFs) via Ullmann C—N coupling reaction in high yields [27] by mimicking the molecular structure of 4,4′-*N*,*N*′-dicarbazole-biphenyl (CBP). CBP is the most popular and famous carbazole-based host material for green and red phosphorescent emitters, but its E_T (2.56 eV) [13] is too low for blue emitters even the sky-blue phosphor, FIrpic. Our innovation is to connect the biphenyl of CBP with the bridging heteroatoms, which results in a planar heterofluorene in the centre of CBP [28]. And, this marriage of carbazole and heterofluorene in a manner as that in CBP is expected to produce interesting host materials for blue PHOLEDs with the more desirable localization and energy level of HOMOs and LUMOs and also higher E_T (∼3.0 eV) compared with those of CBP, with the aid of the great impact of the heteroatoms on the optoelectronic properties [18]. This heterofluorene-based host material benefits both from the heterofluorene which has very particular optoelectronic properties and from the carbazole which is very popular building block for host materials.

In this paper, FIrpic-based PHOLEDs using *meta*-CzHFs (*m*-CzHFs) as the host material were fabricated and the devices exhibit driving voltages lower than 3.9 V at the luminance of 1000 cd m^{-2}. With such low driving voltages, the power efficiency of the CzHF-based devices are dramatically enhanced up to 30.9 and 30.2 lm W^{-1} (with very little variation) at the practical operation brightness from 100 to 1000 cd m^{-2}. The high efficiency with the EQE of 18.4%, and the highly stable CIE (0.16, 0.31) of the *m*-CzHFs-based PHOLEDs at a wide range of brightness were also observed. This novel concept to combine carbazole and heterofluorene by structurally mimicking CBP turns out to be very effective in the molecular design of the high-performance host materials.

2. Results and discussion

2.1. Synthesis and photophysical properties of m-CzHFs

CzHFs were synthesized as reported in our previous publication [27]. An optimized Ullmann C—N cross-coupling reaction between the carbazole and dibromoheterofluorene was adopted to attach the 9-position of the carbazole moiety to the terminal ends of the heterofluorene cores in high yields (∼70%) [29]. CzHFs have good solubility in common solvents and excellent thermal properties (see Table 1) with the glass-transition temperature (T_g) above 97 °C and that of *m*-CzSF and *m*-CzOF are even higher than 110 °C, which are significantly improved in comparison with that of CBP (T_g = 62 °C) [30]. The melting point (T_m) of these materials are also high, which are all above 200 °C, and *m*-CzSF and *m*-CzOF are even nearly 300 °C. High T_g is highly desirable for host materials in OLEDs to prevent morphological changes and to suppress the formation of aggregation upon exposure to the heat produced during the device operation.

The *m*-CzHFs show two main absorption bands both in THF solution and in solid film (see Fig. S7a in S.I.), the first absorption band around 290 nm can be assigned to the carbazole-centered n-π* transition, while the other longer absorption around 320–340 nm is attributed to the π–π* transition of the entire conjugated backbone. The optical energy band gaps of the *m*-CzHFs determined from the onset of the UV–vis spectra in solid film are very similar (3.34–3.41 eV), which is very close to that of CBP (3.4 eV). The PL spectra of the host materials are between 350 and 500 nm, which are well overlapped with the metal-to-ligand charge-transfer absorption peaks of the FIrPic around 380 and 420 nm [15], indicating that efficient and rapid Förster energy transfer from the host materials to the blue phosphorescent emitter.

2.2. Triplet energy and molecular simulations

From the highest-energy 0–0 phosphorescence emissions of *m*-CzHFs (see Fig. S7b in S.I.), we estimated that their values of E_T are 2.84, 2.97, and 2.87 eV respectively, as listed in Table 1. Because *m*-CzHFs possesses significantly higher E_T than CBP resulted from the bridging of the heteroatoms, we would expect that (1) *m*-CzHFs can be good host for FIrpic (2.62 eV), (2) the energy of the triplet excitons would be transferred effectively from the host to the guest emitter, and (3) the reversing pathway (backward energy transfer) was prohibited. The HOMO and LUMO levels of *m*-CzHFs were measured using cyclic voltammetry (CV) (see Table 1 and Fig. S8 in S.I.). *m*-CzHFs

Table 1
Thermal and Electrochemical properties, triplet energy (E_T), and dipole moment of *m*-CzHFs.

Compound	Thermal analysis [°C]		Electrochemical analysis [eV]			E_T	Dipole moment

have very close HOMOs (−5.34 – −5.42 eV) and LUMOs (−2.22 ∼ −2.26 eV), and their band gaps are also quite similar (3.12–3.22 eV). Their higher band gaps than that of FIrpic (3.1 eV) ensure the exothermic energy transfer from the host to the guest. It is interesting that *m*-CzHFs have E_Ts higher than that of CBP although their bandgaps are lower, showing the great modification abilities of the heteroatom linkage. The higher HOMOs, lower LUMOs, but still higher E_Ts, compared with those of CBP, make CzHFs attractive host materials for blue triplet emitters. To gain insight into the electronic states of *m*-CzHFs, molecular simulations via ab initio density-functional theory (DFT) calculation were performed. The results show that their HOMOs are mainly determined by carbazole, whereas LUMOs are predominately localized on and are primarily determined by the central heterofluorenes (see S.I. Table S2). The separated electron density distribution between the HOMO and LUMO of CzHFs is preferable for efficient hole- and electron-transporting properties and the prevention of reverse energy transfer, enabling CzHFs the excellent host materials for PHOLEDs [31].

2.3. Device performance of the m-CzHFs as hosts for FIrpic

To evaluate the performance of the *m*-CzHFs as host materials for blue phosphorescent emitters, we fabricated the devices with the following configurations (see Fig. 1): ITO/MoO_x(2 nm)/m-MTDATA:MoO_x(15 wt.%, 30 nm)/m-MTDATA(10 nm)/Ir(ppz)$_3$(10 nm)/*m*-CzHFs:FIrpic (10 wt.%, 10 nm)/BPhen (40 nm)/LiF(1 nm)/Al (100 nm). In these devices, MoO_x acts as hole-injecting layers, 4,4′,4″-tris(3-methylphenylphenylamino)-triphenylamine (m-MTDATA) as hole-transporting layer (HTL), tris(phenylpyrazole) Iridium (Ir(ppyz)$_3$) as electron-blocking layer (EBL), and 4,7-dipheyl-1,10-phenanthroline (BPhen) as hole-blocking (HBL) and electron-transporting layer

Table 2
Performance of *m*-CzHFs-based PHOLEDs[a].

Host compoud	EL [nm]	η_{ext} [%]	V_{on}[b] [V]	η_c [cd/A]	η_p [lm/W]	L[c] (cd/m^2)	CIE, (x,y)[d]
m-CzNF	468	9.0	3.0	17.3	17.0	4186	(0.157,0.301)
m-CzOF	472	17.8	3.0	36.4	31.2	9504	(0.160,0.316)
m-CzSF	468	18.4	3.2	34.8	29.6	9884	(0.159,0.306)

[a] Maximum external quantum efficiency (η_{ext}), current efficiency (η_c), and power efficiency (η_p).
[b] The applied voltage (Von) required for brightness of 10 cd m^{-2}.
[c] The luminescence (L) at 5 V.
[d] CIE (*x*,*y*) at the brightness of 1000 cd m^{-2}.

(ETL). From Fig. 2, holes can be effectively injected into the host with small barrier (<0.3 eV) and be blocked by BPhen with the energy barrier about 0.9 eV; whilst the electron is injected into the host with the similar barrier as that of hole (0.3–0.4 eV) and is blocked by Ir(ppz)$_3$ with the barrier over 0.5 eV. In such a device construction, the holes and electrons can be effectively confined in the host layer to form host excitons, which subsequently transfer exothermicly to FIrpic for the blue phosphorescence. The device performance, as summarized in Table 2, is extraordinary with low turn-on voltages (<3.0 V), and high maximum external quantum efficiency, current efficiency, and power efficiency, up to 18.4%, 36.4 cd A^{-1}, and 31.2 lm W^{-1}, respectively. At a brightness level of 1000 and 5000 cd m^{-2}, the driving voltages are still lower than 4.5 V with the external quantum efficiencies retain as high as 18.1% and 16.8%. The performance is comparable with the previously reported highest values for FIrpic-based devices [10,11].

From Fig. 2a, the electroluminescence (EL) spectra of the *m*-CzHFs-based devices show identical FIrpic emission without any residue emission from the host and/or adjacent layer, even at high current densities, indicating complete energy transfer from the host to the guest upon electrical excitation and excellent confinement of charge carriers and excitons in the emitting layer. FIrpic is a greenish-blue emitter with a typical emission peak around 472 nm and a shoulder at 500 nm with CIE (*x*, *y*) around (0.17, 0.34), depending on the emission band profile [15]. One advantage of the EL spectra of our devices is that they all displayed bluer emission with an emission peak at 468 (*m*-CzNF and *m*-CzSF) and 472 nm (*m*-CzOF) and a vibrational peak around 495–498 nm with a narrow full-width at half maximum (FWHM) of 55 nm and a CIE (*x*, *y*) around (0.16, 0.30). The bluer emission and improved color purity are probably attributed to the excellent miscibility and morphological stability of CzHFs, which effectively separated and clamped the doped FIrpic, depressing the ground-state association and leaving single molecule emission of the dopant in the solid solution (host) [15].

Fig. 2b displays the current density–voltage-luminance characteristics of these devices and obvious advantages of our devices lie in the very low turn-on and driving voltages. Remarkably, the driving voltages required for brightness of 10, 100, and 1000 cd m^{-2} are 3.0–3.2, 3.4–3.5, and 3.8–4.0 V with corresponding current density of 1.1–1.2, 1.3–1.4, 1.9–3.3 mA cm^{-2}, respectively. And at 5 V, our devices show high luminance from 4186 to 9884 cd/m^2. With such low driving voltages and current densities, the efficiency of the CzHFs-based PHOLEDs is dramatically enhanced. In Fig. 2(c and d), the highest current efficiency of 36.4 cd A^{-1} is reached at 4.0 V, with the corresponding brightness of 1613 cd m^{-2} and current density of 2.24 mA cm^{-2}, while the highest power efficiency of 31.2 lm W^{-1} is observed at 3.6 V, with brightness of 360 cd m^{-2} and current density of 1.02 mA cm^{-2}. The efficiency roll-off of the devices is greatly reduced in the blue PHOLEDs with *m*-CzHFs as the host material (see Fig. 2a). For example, the external quantum efficiency of the *m*-CzSF-based device is 15.8%, 18.4% (maximum), 18.2%, and 15.3% at 100, 791, 1000, and 5000 cd m^{-2}, respectively, suggesting the balanced charge transporting in our devices. Color stability of PHOLEDs with different host materials were monitored according to luminance, as shown in Fig. 2e. The color coordinate of (0.16, 0.30) was little affected within the luminance range, indicating good color stability of the devices. And, their normalized EL spectra are identical over the range of the current density from 10 to 50 mA cm^{-2}, which further assures the stability of our devices. The low driving voltage, high efficiency, and high stability of the *m*-CzHFs-based devices at practical brightness are mainly resulted from the low charge injection barrier, the balanced charge transport, and the reduced triplet–triplet annihilation of the CzHFs-based devices due to the proper device structural design (see Fig. 1).

The *m*-CzNF-based device shows lower brightness, efficiency, and color stability due to two main reasons. One is its high dipole moment (see Table 1) which results in low carrier mobilityand increased triplet–triplet annihilation [32]. The other is the alkyl linked to the N atom, which influences the molecular packing of the thin film, resulting in low charge mobility. The relatively lower T_g of *m*-CzNF (97 °C) is also an important reason for its lower device performance. *m*-CzOF and *m*-CzSF have comparable device performances due to their similar photophysical and electrochemical properties. Considering the higher triplet energy of *m*-CzOF, it may find further applications in deep blue PHOLEDs. In comparison with the device results of Seidler [33] and Wu [34] based on the host materials that are very similar to *m*-CzNF (with only different substituents on the carbazole core), which showed efficiencies up to 15%, 31 cd A^{-1}, and 28 lm W^{-1} under a different device structure, the performance of our *m*-CzNF based device is a little lower, suggesting that our devices based on *m*-CzOF and *m*-CzSF can be further improved by optimizing device structures. The high performance of the FIrpic-based blue PHOLEDs using *m*-CzHFs as the host material in this research proves the validity of our approach to design host materials by connecting the biphenyl of CBP with heteroatoms.

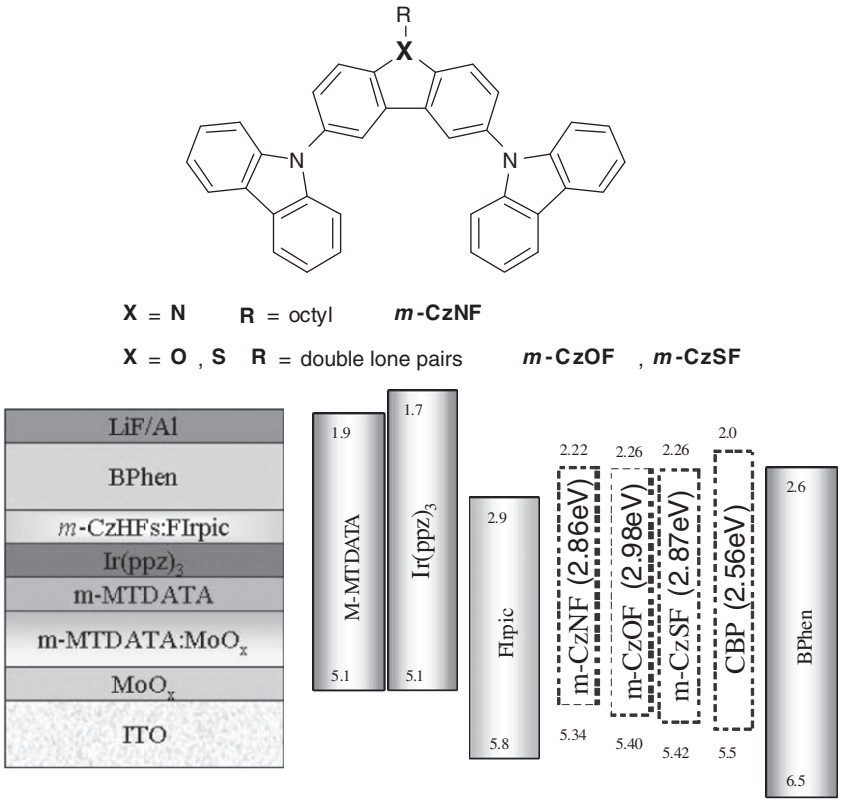

Fig. 1. Device structure and energy level diagrams of the *m*-CzHFs-based PHOLEDs.SYNOPSIS TOC.

3. Conclusions

In summary, *m*-CzHFs of *m*-CzNF, *m*-CzOF, and *m*-CzSF, which possess superior localization and energy level of HOMOs and LUMOs and also higher E_T (~3.0 eV) compared with CBP, were reported for use as blue phosphorescent hosts. Their superiorities in high-efficiency and low-voltage blue PHOLEDs have been demonstrated. The extraordinary device performance of *m*-CzOF was observed with low turn-on voltages (<3.0 V), and high maximum external quantum, current, and power efficiencies, up to 18.4%, 36.4 cd A^{-1}, and 31.2 lm W^{-1}, respectively. At the brightness level of 5000 cd m^{-2}, the driving voltages are still lower than 4.5 V with the external quantum efficiencies retain as high as 16.8%. The important concept of combining carbazole and heterofluorene via structurally mimicking CBP has proven to be successful in the rational molecular design of the high-performance host materials for PHOLEDs. *m*-CzHFs that can be prepared easily in high yields, are ideal host materials for blue PHOLEDs and their excellent device performance enables them to be good choice in the next-generation flat-panel displays and lighting technologies.

4. Experimental

The OLEDs were fabricated using a vacuum thermal evaporation chamber with high-vacuum (~10^{-4} Pa) at a rate of 0.1–0.2 nm/s. The devices without encapsulation were measured in ambient atmosphere at room temperature. Electroluminescent (EL) spectra and CIE corrdinates of the devices were measured by a PR650 spectroscan spectrometer, as well as the luminance-voltage and current–voltage characteristics were measured simultaneously with a programmable Keithley 2400 voltage-current source. The cyclic voltammetry (CV) measurements were performed at room temperature on a CHI660E system in a typical three-electrode cell. The phosphorescence spectra of the compounds were measured using an Edinburgh LFS920 fluorescence spectrophotometer at 77 K, with a 5 ms delay time. All computations were done with Gaussian03 program package with B3LYP/6–31G(d) for structure optimizations and vibrational analysis.

to tune the electrochemical and the optical properties of π-conjugated polymers. The first is the increasing the conjugation length. An increase in the conjugation length results in decreasing the band gap (E_g), limited by Peierls distortion [18]. A second strategy is to change the electron density via incorporation of electron donating or withdrawing groups onto the polymer. The third method is to modify the steric interaction between repeat units within the polymer backbone, using more planar systems result in better orbital overlap, thereby lowering the band gap. The fused-ring units allow fine-tuning of the polymer band gap due to the enhanced π–π stacking between the polymeric chains. Following this strategy, we previously reported the synthesis of thienyl and ethylenedioxybenzene functionalized thieno[3,4-b]pyrazines [19] as precursors to investigate the effect of changes in π-conjugated terthienyls on the electronic and optoelectronic properties of the resulting polymers.

In an earlier work, a series of polymers with a conjugated core building block containing dibenzo[*a,c*]phenazine moiety as the acceptor unit and thiophene based donor units were synthesized [20]. In the present study, three new donor–acceptor–donor polymers with 10,11, 12,13-tetrahydrodibenzo[*a,c*]phenazine moiety as the acceptor unit and thiophene, 3-hexyl thiophene and 3,4-ethylenedioxythiophene as the donor units were synthesized. The effect of replacing the 10,11,12,13-tetrahydrodibenzo[*a,c*]phenazine moiety with dibenzo[*a,c*]phenazine as the acceptor unit on the electrochemical and spectroelectrochemical properties of the resulting polymers were analyzed.

2. Experimental

2.1. Materials

Dichloromethane (DCM), chloroform ($CHCl_3$), hexane, ethanol, *N*-bromosuccinimide (NBS), cyclohexane-1,2-diamine, dichlorobis(triphenyl phosphine)palladium(II) ($Pd(PPh_3)_2Cl_2$), *p*-toluene sulfonic acid (PTSA) were purchased from Sigma–Aldrich. Silica gel was purchased from Merck and tetrahydrofuran (THF) was purchased from Fisher Scienific UK Limited. Tributylstannane compounds [21–23] and 2,7-dibromophenanthrene-9,10-dione [24] were prepared according to literature method. THF was dried and distilled over benzophenone–sodium under nitrogen before use.

2.2. Instrument

^{1}H-NMR and ^{13}C-NMR spectra of compounds were recorded in $CDCl_3$ using Bruker Spectrospin Avance DPX-400 Spectrometer and chemical shifts were given relative to tetramethylsilane. Voltalab 50 potentiostat was used for the investigation of the redox behavior of monomers. Electropolymerizations were carried out in a three-electrode cell consisting of indium tin oxide (ITO, Delta technologies, 8–12 Ω/cm^2) coated glass as the working electrode, platinum wire as the counter electrode, and Ag wire as the pseudo-reference electrode (0.3 V vs Fc/Fc^+). UV–Vis-NIR spectra of the polymers were recorded on a Varian Cary 5000 spectrophotometer. Minolta CS-100 spectrophotometer was used for colorimetry measurements.

2.3. Synthesis

2.3.1. 2,7-Dibromo-10,11,12,13-tetrahydrodibenzo[a,c]phenazine (3)

2,7-Dibromophenanthrene-9,10-dione (300 mg, 0.82 mmol), ethanol (50 mL), catalytic amount PTSA and cyclohexane-1,2-diamine (0.82 mmol) were placed in a round-bottomed flask fitted with a condenser. The mixture was heated under reflux. At the end of the reaction, cloudy mixture was observed. Upon cooling, filtration of the reaction mixture followed by washing with ethanol afforded the desired product, 2,7-dibromo-10,11,12,13-tetrahydrodibenzo[*a,c*]phenazine. To purify the dibrominated compound, column chromatography was performed over silica gel, eluting with 1:5 ($CHCl_3$:Hexane).

White solid (180 mg, 49%) IR υ = 3074, 2931, 1878, 1598, 1479, 1427, 1371, 1323, 1263, 1197, 1074, 955, 898, 797, 733, 655, 526 cm^{-1}. ^{1}H-NMR (400 MHz $CDCl_3$): δ (ppm) 9.04 (d, 2H, J = 2.2 Hz), 8.12 (d, 2H, J = 8.7 Hz), 7.64 (dd, 2H, J = 8.7, 2.2 Hz), 3.08–3.10 (m, 4H), 1.99–2.02 (m, 4H) ^{13}C-NMR (100 MHz, $CDCl_3$): δ (ppm) 153.3, 137.4, 131.7, 131.4, 128.7, 127.6, 124.1, 122.1, 32.7, 22.8.

2.3.2. General procedure for the synthesis of 4, 5, 6 via Stille coupling

2,7-Dibromo-10,11,12,13-tetrahydrodibenzo[*a,c*]phenazine (100 mg, 0.23 mmol), and tributylstannane compound (0.92 mmol) were dissolved in anhydrous THF (80 ml), the solution was purged with argon for 30 min and $Pd(PPh_3)_2Cl_2$ (40 mg, 0.057 mmol) was added at room temperature. The mixture was refluxed over night under argon atmosphere. The crude products were purified by column chromatography using DCM – Hexane as the eluent.

2.3.2.1. 2,7-Bis(4-hexylthiophen-2-yl)-10,11,12,13-tetrahydro dibenzo[a,c] phenazine (4, HTBP). The crude product was purified by column chromatography (DCM:Hexane 1:3) to give 4, HTBP (82 mg, 58%) as pale yellow solid. IR υ = 3055, 2925, 2852, 1611, 1460, 1371, 1323, 903, 810, 724, 580 cm^{-1}. ^{1}H-NMR (400 MHz $CDCl_3$): δ (ppm) 9.21 (s, 2H), 8.33 (d, 2H, J = 8.5 Hz), 7.79 (d, 2H, J = 8.5 Hz), 7.34 (s, 2H), 6.88 (s, 2H), 3.10–3.18 (m, 4H), 2.60 (t, 4H, J = 7.6 Hz), 1.88–2.03 (m, 4H), 1.63 (p, 4H), 1.26–1.35 (m, 12H), 0.84 (t, 6H, J = 7.0 Hz) ^{13}C-NMR (100 MHz, $CDCl_3$): δ (ppm) 152.8, 144.8, 144.1, 138.9, 133.8, 130.4, 129.9, 126.6, 125.5, 123.4, 121.6, 120.2, 33.0, 32.0, 31.0, 30.8, 29.3, 23.2, 22.9, 14.4. HRMS *m/z* calcd for $C_{40}H_{44}N_2S_2$ 617.3024 found 617.3046 $[M+H]^+$.

2.3.2.2. 2,7-Bis(2,3-dihydrothieno[3,4-b][1,4]dioxin-5-yl)-10, 11,12,13-tetrahydrodibenzo [a,c]phenazine (5, DTBP). The crude product was purified by column chromatography (DCM:Hexane 3:1) to give 5, DTBP (86 mg, 66%) as a yellow solid. IR υ = 3112, 2932, 1610, 1503, 1437, 1365, 1168, 1071, 897, 810, 755, 605 cm^{-1}. ^{1}H-NMR (400 MHz $CDCl_3$): δ (ppm) 9.31 (d, 2H, J = 1.8 Hz), 8.37 (d, 2H, J = 8.7 Hz), 7.99 (dd, 2H, J = 8.7, 1.8 Hz), 6.30 (s, 2H), 4.32–4.33 (m, 4H),

4.22–4.24 (m, 4H), 3.10–3.16 (m, 4H), 1.97–1.99 (m, 4H). ^{13}C-NMR (100 MHz, $CDCl_3$): δ (ppm) 151.3, 141.3, 137.7, 137.6, 131.1, 129.1, 128.1, 125.5, 121.8, 120.5, 116.6, 97.0, 63.8, 63.4, 31.8, 21.9. HRMS *m/z* calcd for $C_{32}H_{24}N_2O_4S_2$ 565.1256 found 565.1250 $[M+H]^+$.

2.3.2.3. 2,7-Di(thiophen-2-yl)-10,11,12,13-tetrahydrodibenzo [a,c]phenazine (6, TTBP). The crude product was purified by column chromatography (DCM:Hexane 5:1) to give 6, TTBP (68 mg, 66%) as yellow solid. IR υ = 3067, 2934, 1898, 1610, 1446, 1371, 1193, 1075, 903, 811, 696, 592 cm^{-1}. ^{1}H-NMR (400 MHz $CDCl_3$): δ (ppm) 9.35 (d, 2H, J = 1.9 Hz), 8.49 (d, 2H, *J* = 8.5 Hz), 7.91 (dd, 2H, *J* = 8.5, 1.9 Hz), 7.53 (dd, 2H, *J* = 3.5, 1.0 Hz), 7.30 (dd, 2H, *J* = 5.1, 1.0 Hz), 7.10 (dd, 2H, *J* = 5.1, 3.5 Hz), 3.18–3.21 (m,4H), 2.02–2.05 (m, 4H). HRMS *m/z* calcd for $C_{28}H_{20}N_2S_2$ 449.1146 found 449.1139 $[M+H]^+$.

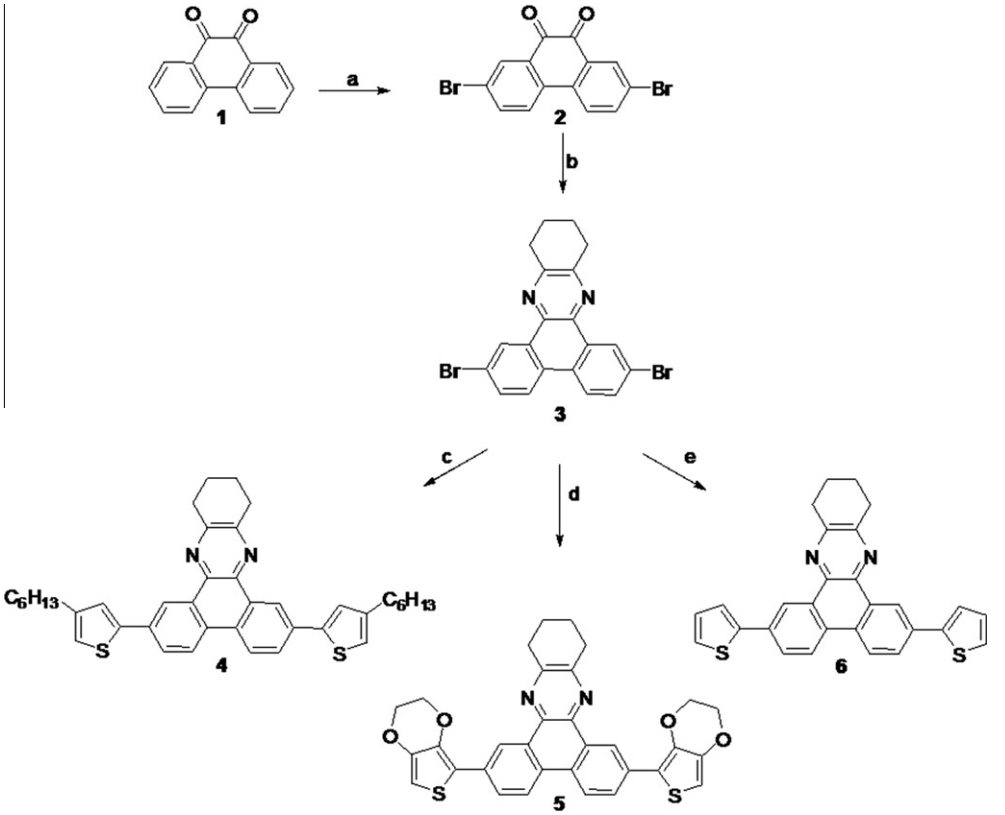
3. Results and discussion

3.1. Synthesis of monomers

Syntheses of the monomers are depicted Scheme 1. In literature, there are a number of methods [25–28] for the synthesis of 2,7-dibromophenanthrene-9,10-dione 2 starting from phenanthrene-9,10-dione or 2,7-dibromophenanthrene. With the help of one of them [24], it was synthesized starting from phenanthrene-9,10-dione 1 in the presence of NBS and concentrated H_2SO_4. Condensation reaction of 2 with cyclohexane-1,2-diamine afforded 3 in 49% yield, to obtain which reflux in EtOH for 5 h. To increase the reaction yields, *p*-toluene sulfonic acid was utilized as the catalyst. If the reaction medium is kept at room temperature without catalyst, there is no aromatization in the phenazine ring. However, this product is highly unstable and undergoes rearrangement with heat or light [25]. Finally, condensation product 3 was reacted with related stannane compounds in the presence of $Pd(PPh_3)_2Cl_2$ to obtain target monomers 4 (HTBP), 5 (DTBP) and 6 (TTBP) in moderate yields (58–66%).

3.2. Electropolymerization

The electrochemical behavior of HTBP, DTBP and TTBP were investigated by cyclic voltammetry technique. Cyclic voltammetry (CV) is a very useful method that reveals the electroactivity of the compounds in concern. It also gives evidence on the reversibility of the electron transfer reactions during the electropolymerization. Electrochemical polymerizations of the monomers were studied via CV in a solution of 10^{-2} M monomer on an ITO working electrode.



Scheme 1. The synthetic route of the monomers. (a) NBS, conc. H_2SO_4, rt, 3h (b) Cyclohexane-1,2-diamine, PTSA, EtOH, reflux, 5h (c–e) $Pd(PPh_3)_2Cl_2$, stannanes(tributyl(4-hexylthiophen-2-yl)stannane)(c), tributyl(2,3-dihydrothieno[3,4-*b*][1,4]dioxin-5-yl)stannane(d) and tributyl(thiophen-2-yl)stannane(e), dry THF, overnight reflux.

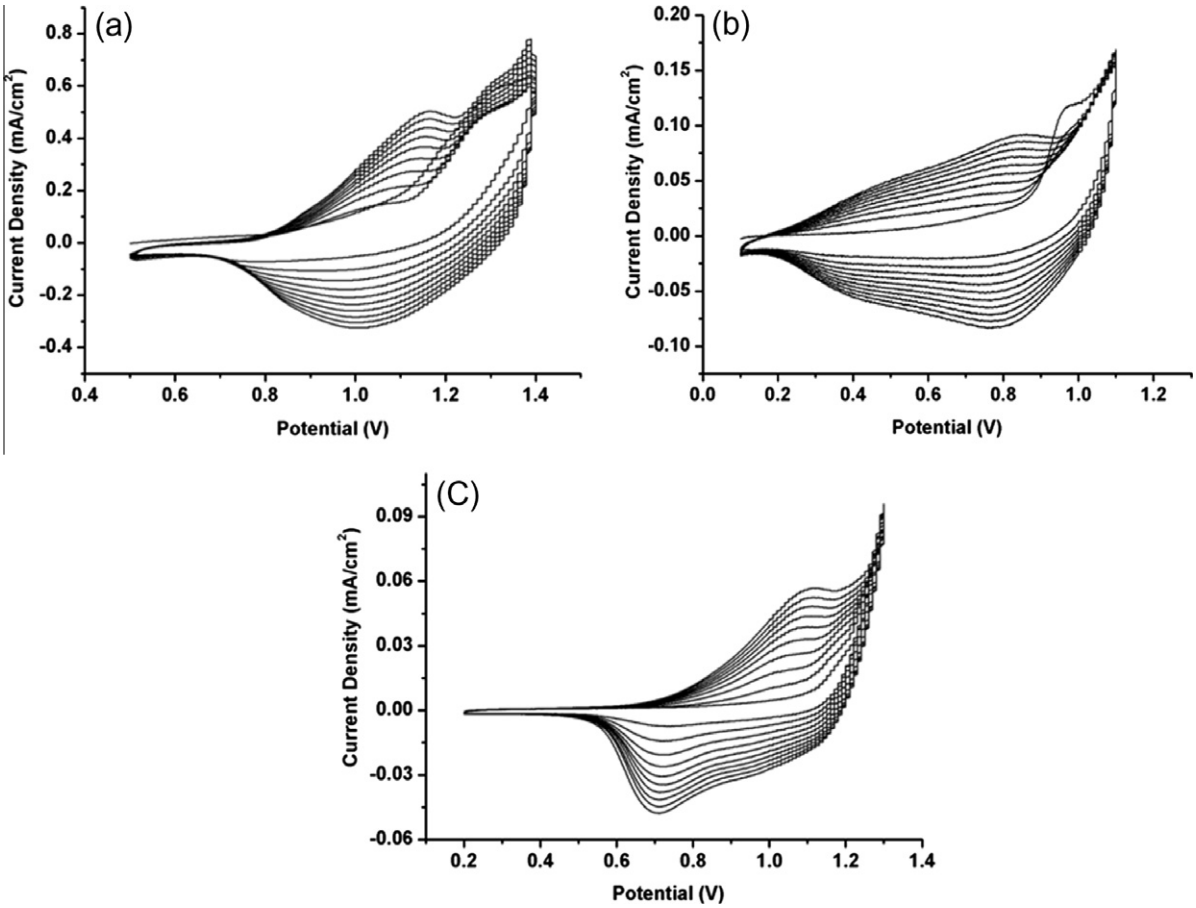


Fig. 1. Cyclic voltammogram of (a) PHTBP (b) PDTBP (c) PTTBP in DCM (for PDTBP, DCM/ACN(5/95)) solution containing 0.1 M $TBAPF_6$, scan rate 100 mV s^{-1}.

Cyclic voltammograms showed both an irreversible oxidation wave corresponding to the oxidation of the monomers and the reversible redox couple for the polymers (Fig. 1). While the monomer oxidation potential of DTBP was observed at 0.97 V, they were at 1.28 V for HTBP and >1.3 V for TTBP. Comparing the onsets of monomer oxidation, DTBP was much more easily oxidized than both HTBP and TTBP. The presence of electron-donating ethylene-dioxy bridge on EDOT units lowers the oxidation potential compared to those of thiophene and 3-hexyl thiophene substituted monomers. The oxidation peak potentials of polymers vary from 0.83 to 1.16 V vs Ag wire pseudo reference electrode, whereas the reduction peak potentials were in a range of 0.70–1.00 V. As the cyclic scan proceeded, intensities of anodic and cathodic currents of the polymer films gradually increased, indicating the presence of a conductive polymer on the electrode.

Our previous work where dibenzo[*a,c*]phenazine moiety was used as the acceptor unit, 2,7-di(thiophen-2-yl)dibenzo[a,c]phenazine (TTP) did not produce an adherent thin polymer film on ITO-coated electrode surface [19]. Introduction of alkyl bridge on the backbone of π-conjugated system leads to obtain a polymer film on the surface of working electrode. It seems like that the presence of alkyl bridge enhanced the solubility of the resulting oligomer, thereby the polymer film grows on the surface of electrode.

3.3. Spectroelectrochemistry

Polymers were prepared by repetitive potential-sweep anodic oxidation of the corresponding monomers HTBP and TTBP on ITO coated glass slides in DCM. For DTBP, a DCM/ACN mixture (5:95) was utilized with 0.1 M $TBAPF_6$ at a scan rate 100 mV s^{-1}. After electropolymerization, the polymer coated electrode was washed with acetonitrile to remove unreacted monomer. To investigate spectroscopic changes, UV–Vis-NIR spectrophotometer was used in a monomer free system. The spectra of polymers were recorded continuously versus time while applying a constant potential. Fig. 2 illustrates the optoelectrochemistry of PHTBP, PDTBP and PTTBP. Stepwise oxidation of the PHTBP shows the fading of absorbance at 395 nm which belongs to π–π* transition. As polymer film gets oxidized, typical evolution of peaks at 620 nm and 1500 nm occurred corresponding to polaronic and bipolaronic bands, respectively. The band gap of PHTBP, onset of the π–π* transition for the neutral polymer was calculated as 2.5 eV using the absorption band centered at 395 nm. The absorbance assigned to π–π* transition for PDTBP is at

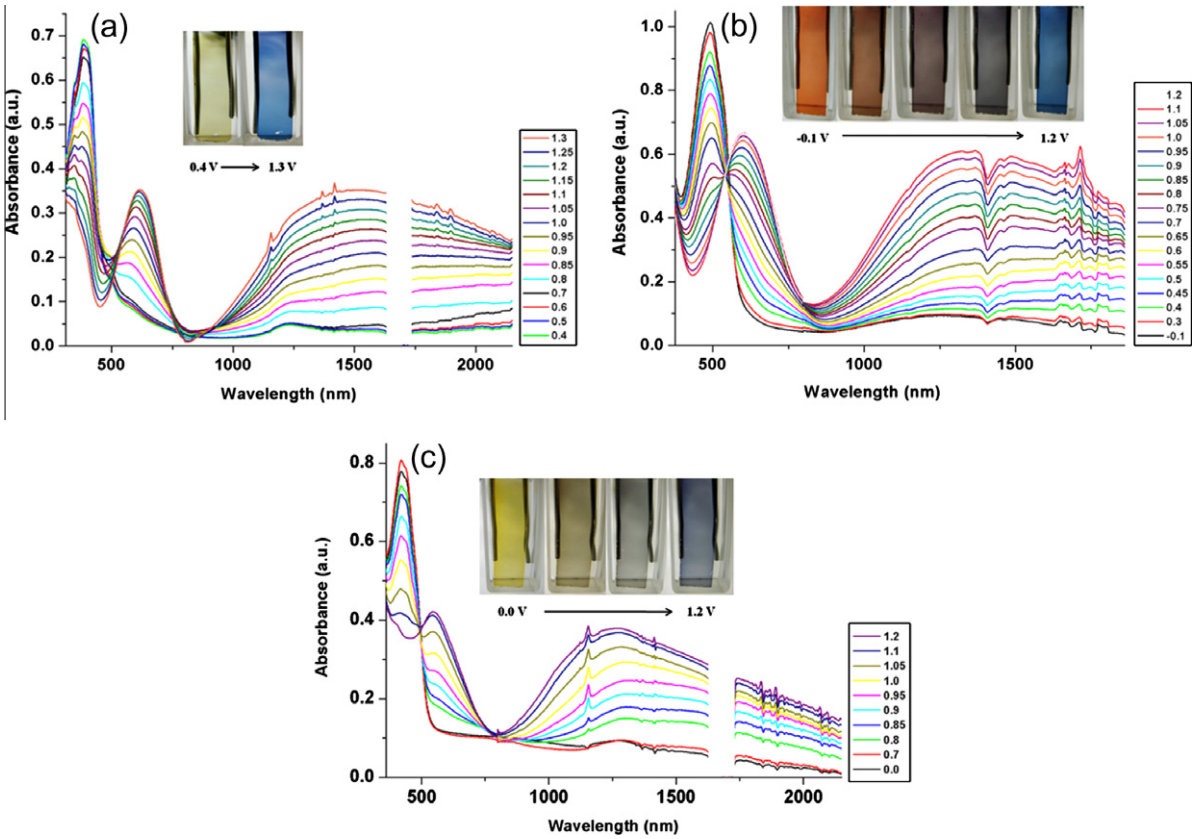

Fig. 2. Spectroelectrochemical spectra of (a) PHTBP with applied potential between +0.4 and +1.3 V in DCM/$TBAPF_6$ (b) PDTBP with applied potential between −0.1 and +1.2 V in ACN/DCM/$TBAPF_6$ (c) PTTBP with applied potential between 0.0 and +1.2 V in DCM/$TBAPF_6$.

490 nm and this transition was observed at 430 for PTTBP. The band gap of PDTBP was calculated as 2.0 eV and that of PTTBP was calculated as 2.2 eV using the wavelength value at the onset of the π–π^* transition. The difference in band gap, 0.5 eV, between PHTBP and PDTBP can be explained by distortion of backbone planarity. Presence of alkyl chains at the β-position of thiophene ring causes steric interactions between repeat units within the polymer backbone, resulting in decreasing π orbital overlap.

The π–π^* transition for 10,11,12,13-tetrahydrodibenzo[*a,c*]phenazine containing polymers takes place at an higher energy than those of the dibenzo[*a,c*]phenazine derivatives [20]. Introduction of alkyl bridge on the backbone of π-conjugated system instead of aromatic unit leads to deviation from the planarity, resulting in decreasing π-orbital overlap, thereby the absorption band of π–π^* transition shifts to shorter wavelength.

3.4. Colorimetry

Color and luminance (L) changes were monitored as the potential was increased. According to the CIE (Commission Internationale de I'Eclairage) system of colorimetry, the color is made up of three attributes; luminance (Y), hue (x), and saturation (y).

Polymers of PDTBP and PTTBP reveal several distinct colors since the polaron bands of the polymers are still in the visible region (Table 1, colors refer to polymer thicknesses between 0.5 and 1 microns). Polymers of PDTBP and PTTBP have the ability to achieve multi-colors with small structural modifications. Multicolored electrochromism observed in a polymer is a promising property since these types of materials can be utilized as active layers in many device applications especially in the information technologies. On the other hand, PHTBP film changes from a yellow neutral state to a blue oxidized state.

PDTBP is orange in its neutral state. Upon oxidation, the orange color of the polymer turns into brown. Further oxidation results in purple. A gray color was observed when +0.7 V potential was applied. When the potential is further increased the polymer turns into a blue color.

The color of the PTTBP film is yellow in its neutral state. Its color switches from yellow to greenish brown due to further oxidation. When +0.9 V potential is applied, the polymer turns into gray. Further oxidation causes blue color.

3.5. Electrochemical switching

Electrochromic switching studies were carried out to obtain changes in the transmittance (optical contrast). A square-wave potential step method coupled with optical spectroscopy is used to obtain the switching times and the contrast for these polymers. For that matter, polymer

Table 2
Switching properties of polymers.

Polymer	PHTBP			PDTBP			PTTBP		
λ_{max} (nm)	395	620	1500	490	610	1320	430	550	1270
Switching time (s)	1.7	1 5	1.8	0.8	0.7	06	2.3	0.5	0.5

films were switched between their neutral and oxidized states with a time interval of 5 s to monitor their stability, optical contrasts and switching times both in visible and NIR regions. The results were displayed in Fig. 3 where transmittance–time profiles of the polymers were recorded during double step spectrochronoamperometry.

In Near-IR region, PTTBP film has the maximum contrast ratio (% ΔT) as 64% at 1270 nm. The corresponding data are given in Fig. 3.

The switching time from oxidized state to reduced state of an electrochromic polymer is yet another important parameter to determine its potential application in electrochromic windows. The time required for full oxidized state from full reduced state is defined as the response time. The switching time data for polymers are given in Table 2.

4. Conclusion

A series of π-conjugated monomers based on 10,11, 12,13-tetrahydrodibenzo[*a,c*]phenazine as the acceptor unit was synthesized to understand the effects of donor strength on the optoelectronic and redox properties of the electropolymerized materials. Multicolored polymers from PDTBP and PTTBP were successfully synthesized via electrochemical methods. Spectroelectrochemical studies and electrochromic characterization demonstrated that the polymer containing EDOT unit in the polymer backbone not only decreased the band gap (E_g) but also enhanced the electrochromic properties such as optical contrast, switching time and multicolor properties. The polymer films with their electrochromic property, comparatively fast switching time and high optical contrast, are expected to be useful for practical use in smart windows.

and the high-conductivity state, with the difference in the conductivity on several orders of magnitude. These two conductivity states can thus be used to represent and memorize the logic "1" and logic "0" states.

In our previous work, we reported ONBM devices adopting polymer-chain-stabilized gold (Au) nanoparticles dispersed in the host polymer as the active memory layer. Being stabilized with polymer chains, the Au nanoparticles were well dispersed in the host polymer and the ONBM devices exhibited promising memory characteristics and endurance [4]. We also suggested the trap-filling space-charge-limited current (SCLC) as the transport mechanism for the bistable operation of the Au nanoparticle ONBM devices [5]. In such a mechanism, with a large enough voltage applied, a large number of injected carriers can completely fill the traps existing in the nanoparticle-dispersed host layer, and the device enters the higher-conductivity trap-filled conduction state [6]. On the other hand, if the traps are not completely filled, the current conduction is limited by the traps and the device is in the trap-limited SCLC (low-conductivity) state [6]. In addition, we noticed that the device current is not proportional to the device area. In our and other nanoparticle-based or nanomaterial-based ONBM devices, the bistable operation is all highly related to the distributed nanoparticles. Since the dispersion of nanoparticles in a host to some degree is random, it is therefore reasonable to speculate that the current conduction in such nanoparticle-based ONBM devices might not be uniform over the whole device area. Yet, such an issue had not been thoroughly investigated and possible localized current transport paths had not been clearly visualized before. In this work, we report that the spatial distribution of the current transport paths in Au nanoparticle ONBM devices can be investigated by the so-called the optical beam induced resistance change (OBIRCH) method [23], in which the thermal energy transferred by a scanning laser beam was used to resolve the spatial distribution of electric conduction in the memory devices. Through adoption of the OBIRCH technique, the localized current transport paths in ONBM devices can be clearly visualized for the first time, demonstrating that the OBIRCH technique might be an useful method to characterize localized current transport paths in organic devices.

2. Experiment

2.1. Device preparation and characterization

The active layer of the memory device consists of the host polymer material and the polymer-stabilized Au nanoparticles [4]. Fig. 1 shows the schematic structure of the polymer-stabilized Au nanoparticle. The polymer chains are attached with a sulfur atom at one end, which stabilizes the Au clusters with an S–Au bond to form the Au nanoparticles. The polymer used to prepare polymer-stabilized Au nanoparticles was [4-Cyano-2,4,4-trimethyl-2-methylsulfanylthiocarbonylsulfanyl-poly (butyric acid 1-adamantan-1-yl-1-methyl-ethyl ester)] or the so-called PCm. The chemical structure of the PCm is also shown in Fig. 1. The polymer-stabilized Au nanoparticles are considered immobile in the same host polymer material (i.e. PCm) during fabrication and electrical operation of devices, thus beneficial to the stability and endurance of the memory devices [4]. The properties of the polymer-stabilized Au nanoparticles and films had been discussed in details previously [4].

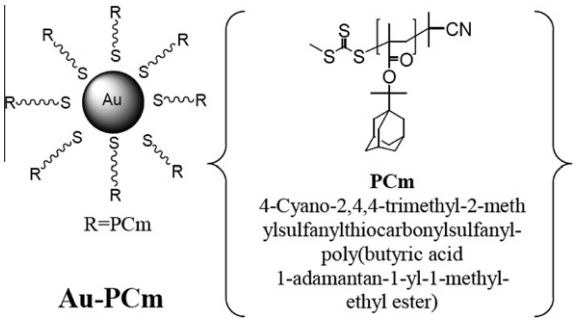

Fig. 1. The schematic structure of the polymer-stabilized Au nanoparticle and the host polymer PCm.

The memory devices were fabricated using the following procedures. First, glass substrates were cleaned by detergent solution, de-ionized water, acetone, and isopropanol (IPA) sequentially in the ultrasonic cleaner and then were dried in a vacuum oven at 100 °C. A 75-nm-thick aluminum (Al) was then deposited by a thermal evaporator with a base pressure of 2×10^{-6} Torr, using a shadow mask to pattern the bottom electrodes. Subsequently, the ultraviolet (UV)-ozone treatment was applied to treat the Al surface to enhance the adhesion of the subsequent polymer layer onto the electrode. The solution containing the active-layer materials was spin-coated onto the bottom electrode in a glove box filled with N_2. The solution was prepared by dissolving the polymer-stabilized Au nanoparticles (Au-NP) (0.05 wt.%) and the host polymer PCm (2.4 wt.%) in 1,2-dichlorobenzene [4]. The particle sizes of Au nanoparticles were 3–5 nm. The thickness of the dried active layer had been determined by transmission electron microscopy (TEM) to be about 50 nm. Finally, the Al top electrode was deposited by thermal evaporation using the shadow mask. The completed memory cell had a device structure of Al/PCm + Au-NP/Al, as shown in Fig. 2. The area of the memory cell was 2×2 mm^2. The current–voltage (I–V) characteristics of the ONBM devices were measured by an HP 4156C semiconductor analyzer under the ambient condition.

2.2. OBIRCH measurement

The distribution of current transport paths in ONBM was investigated by using a scanning laser beam as a source of thermal energy transfer to induce local changes of the temperature and the electronic/conduction properties. This method is usually called the optical beam induced resistance change (OBIRCH) method [23], which is often used in semiconductor devices and integrated circuits to detect localization of current paths and abnormal current paths. Fig. 3 shows the schematic setup of the OBIRCH measurement. An OBIRCH system μAMOS-200 of

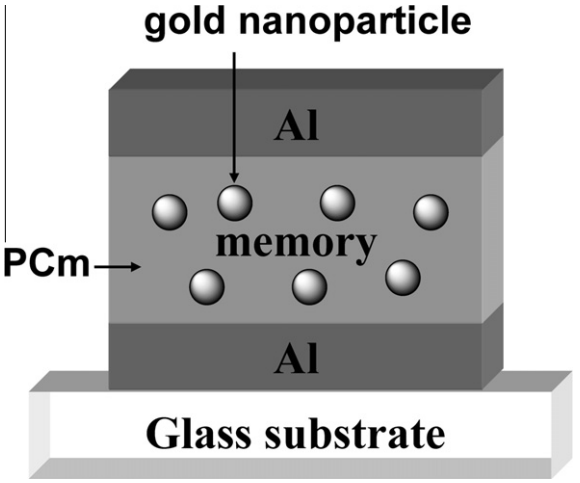

Fig. 2. The schematic structure of the device.

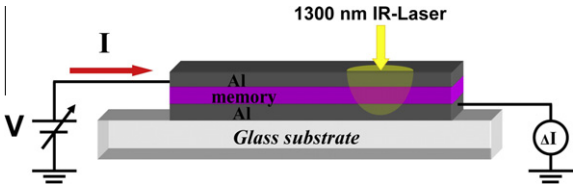

Fig. 3. The schematic setup of the OBIRCH measurement.

Hamamatsu Photonics was used in this study. In the measurement, a constant voltage (e.g. 1 V) was applied to the memory device under test (which was pre-set in either the "1" state or the "0" state) and a laser beam was scanned over the top surface of the device. An IR laser (1.3 μm, 370 mW) was utilized and the spot size of the laser beam was ~6 μm. Because the spot size of the laser beam is much smaller than the device area, the device thickness is very small (50 nm) compared to both the device area and the laser beam, and the laser beam stays at each location only for a short time, the heating and thermal diffusion in the vertical direction (to the active layer) can be considered effective but meanwhile localized in the lateral direction. In scanning the IR laser beam, simultaneously the current (I) and the current change (ΔI) of the device (under the constant bias voltage) at each scanning step were measured and recorded. The recorded current change (ΔI) along with the laser scanning can then be displayed as a two-dimensional image over the device area to visualize the distribution of electronic properties/conduction. The OBIRCH method has the particular advantage that it is a non-destructive characterization method.

3. Results and discussions

3.1. I–V characteristics of the ONBM devices

The current–voltage (I–V) characteristics of the Al/PCm + Au–NP/Al device are shown in Fig. 4. Two distinct conducting states were observed in the I–V characteristics.

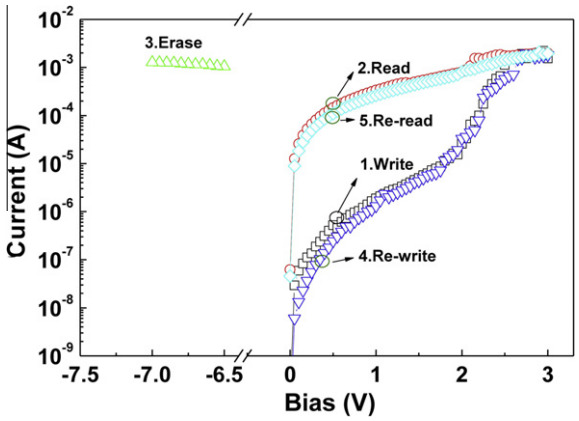

Fig. 4. The current–voltage (I–V) characteristics of the Al/PCm + Au-NP/Al device.

A low-conductivity state with a low current of approximately 10^{-7}–10^{-6} A was recorded in the voltage range of 0–1 V for the first voltage sweep. It corresponds to the "0" state of the bistable memory. When the applied voltage approached 2.3 V (the writing voltage), a remarkably abrupt current increase from 10^{-5} to 10^{-3} A was observed. Once the writing voltage was applied, the device remained in the high-conductivity state (with a current being several orders of magnitude higher than that before writing) even when the writing voltage was removed and a lower bias voltage (e.g. 1 V, i.e. the reading voltage) was subsequently applied. Such behaviors clearly manifested the nonvolatile memory characteristics. This high-conductivity state corresponds to the "1" state of the memory device. In addition, the device can be switched from the high-conductivity state back to the low-conductivity state by applying a high enough negative bias voltage of −6.5–−7 V (i.e. the erasing voltage). After the device was restored to its low-conductivity state, once again, it could be switched to the high-conductivity state by applying a positive voltage sweep again, exhibiting I–V characteristics similar to the first voltage sweep (i.e. the "rewrite" curve in Fig. 4). Similarly, the reading and erasing actions could be repeated, also showing similar I–V characteristics (e.g. the "re-read" curve in Fig. 4). Thus, this device clearly shows the characteristics of a rewritable nonvolatile bistable memory. For the purpose of this present work, only the basic I–V characteristics of the device are discussed here. More information on the endurance and retention characteristics of the device could be fund in our previous work [4].

3.2. OBIRCH analysis of the ONBM devices

The distribution of current transport paths in ONBM was investigated by using a scanning laser beam as a source of thermal energy transfer to induce local changes of the temperature and the electronic/conduction properties. This method is usually called the optical beam induced resistance change (OBIRCH) method [23]. In OBIRCH measurements as shown in Fig. 3, when a spot in the device is illuminated by the laser beam, part of the

laser energy is absorbed and is converted into heat, rendering the local temperature change (rise) in the illuminated area. The local temperature change could affect the local electronic properties/conduction. When there is a spatial non-uniformity in local electronic properties/conduction, the local temperature change at different locations would induce different changes in local electronic properties/conduction. If a constant bias is applied to the device, different changes in local electronic properties/conduction in turn would result in a spatial distribution of the current change ΔI (or resistance change) in scanning the laser beam. In principle, $\Delta I(x) \propto [\Delta R(x)/R(x)]J(x) \propto [\Delta R(x)/V]J(x)^2$, where $\Delta I(x)$ is the current change induced by a laser beam at the position x, $J(x)$ is the current density at x, $R(x)$ is the local resistance (i.e. $V/J(x)$) at x, $\Delta R(x)$ is the change of local resistance at x induced by the laser beam at x, and V is the applied constant voltage. The two-dimensional image of ΔI thus visualizes the distribution of electronic properties/conduction over the device area. This mapping would be particularly sensitive when the device current paths are highly localized to some spots, since ΔI would be more significant when the laser beam is scanned over these spots (note $\Delta I(x)$ is proportional to $J(x)^2$ under a constant bias voltage). In this study, the property of interest is the distribution of the current conduction paths for the "on" state (high-conductivity state) of the ONBM device. The OBIRCH method has the particular advantage that it is a non-destructive characterization method.

Fig. 5(a) shows the OBIRCH ΔI image of the ONBM device (which is superimposed with the optical microscopic image of the device taken simultaneously) recorded upon applying a writing voltage of nearly 3 V. At this writing voltage, a relatively high current (1.05 mA) was recorded, which corresponded to the logic "1" state. Several green[1] points in Fig. 5(a) indicate the locations of large ΔI in scanning the IR laser. Such an image indicates that upon applying a writing voltage (i.e. in the writing mode), the current conduction was localized. After the writing process, a smaller reading voltage (1 V) was applied to read the ONBM. In this reading mode, still a relatively large current of 0.126 mA was recorded, indicating the ONBM remained in the logic "1" (or "on") state. Furthermore, upon applying the reading voltage (i.e. in the reading mode) subequently, the OBIRCH ΔI image of the device was also recorded and is shown in Fig. 5(b). Again, some green points (locations of large ΔI) occur in the image, indicating also localized current conduction in the reading mode. Interestingly, one notices that locations of large ΔI in the reading mode almost coincide with locations of large ΔI in the writing mode. Overall, these results suggest that in the ONBM devices using polymer-stabilized Au nanoparticles, the current transport paths for the "on" state during the writing mode or the reading mode are localized and that once the localized current transport paths are established in the writing mode, the current transport in the subsequent reading mode would basically follow the same paths. Such localized current transport paths resemble "filament formation" suggested by some previous works [4–22], which may be associated with thermal evaporation of the metal electrode or with points where the film thickness is less or there are more nanoparticles. Yet, in a reference device with the structure of Al/PCm/Al, the current was low and it did not show conductance switching. It thus suggests that the memory effect and localized current transport paths in the present device are highly associated with Au nanoparticles.

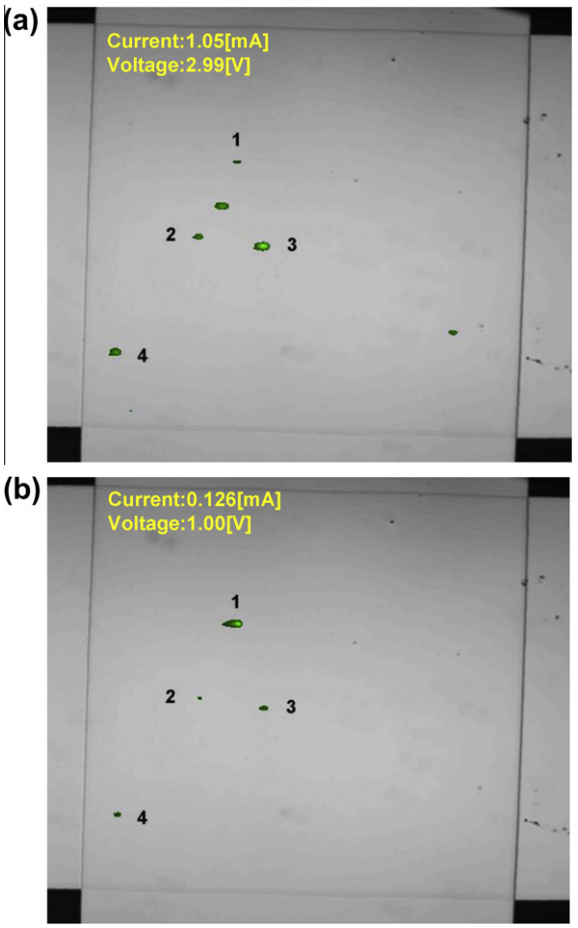

Fig. 5. OBIRCH ΔI images of the ONBM device (which is superimposed with the optical microscopic image of the device taken simultaneously): (a) recorded upon applying a writing voltage of nearly 3 V, and (b) recorded upon applying the 1-V reading voltage (i.e. in the reading mode) after the writing process.

To further investigate how the current transport paths would vary in repeated write–read–erase–write processes, a voltage of −6.5–−7 V was further applied to erase the ONBM device of Fig. 5. After erasing, a 1-V reading voltage was again applied to read the ONBM and a very small current of 1.3 μA was recorded, indicating the ONBM be switched back to the logic "0" (or "off") state. Upon applying the reading voltage, the OBIRCH ΔI image of the device under the "0" state was also recorded and is shown in Fig. 6(a). In contrast to the OBIRCH image in the "1" state, the "0" state image is homogeneous and no singular points (i.e. locations of relatively significant thermally induced

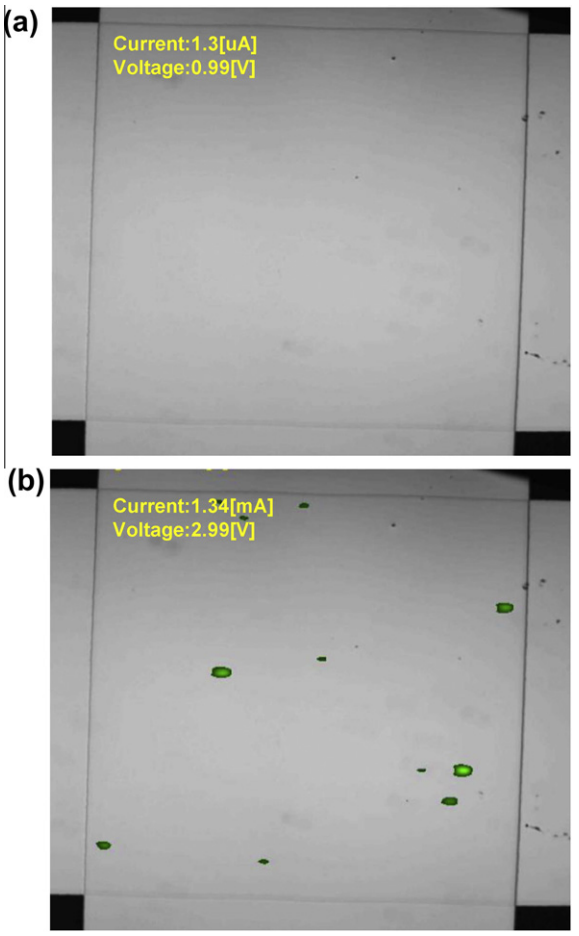

Fig. 6. OBIRCH ΔI images of the ONBM device in Fig. 5: (a) recorded upon applying the 1-V reading voltage (i.e. in the reading mode) after the erasing process, and (b) recorded upon subsequently applying a writing voltage of nearly 3 V again.

ΔI) occur in the image. When a writing voltage of nearly 3 V was applied again, in addition to the relatively large current (1.34 mA), localized current paths (marked as green[2] points in the OBIRCH ΔI image Fig. 6(b) recorded simultaneously) were found again. Similar localized current transport paths were also observed in the subsequent reading mode (e.g. with applying a smaller bias voltage of 1 V after writing). However, locations of the current paths in Fig. 6(b) are different from the previous current paths found in Fig. 5(a) and (b). Such results indicate that although the localized current transport paths established in each writing process would remain for the ONBM device to sustain the "1" state till the subsequent erasing operation, yet the localized current transport paths established vary from writing to writing. According to the previous model we established for the Au nanoparticle ONBM, the current conduction state is associated with the filling status of the trap levels of Au nanoparticles. During each erasing process, filled trap levels would be evacuated. The established conduction paths would be eliminated and the device would return to the low-conductivity state. In the subsequent writing process, some trap-filled high -conductivity paths would be established again, somehow randomly and varied from writing to writing, with filling trap levels of Au nanoparticles along the conduction paths. Such phenomena might have significant implications to operation or applications of such or similar devices. For instance, it may have impacts on how much one can shrink the device size. When the device area is largely reduced, such phenomena may affect the device-to-device variation in a memory array, the writing to writing variation of a device, or the long-term operation of devices. It may be worthy of further studies.

4. Conclusions

In summary, the so-called optical beam induced resistance change (OBIRCH) method, which is a non-destructive characterization method, was adopted to investigate the spatial distribution of current transport paths in Au nanoparticle nonvolatile bistable memory devices. With using a scanning laser beam as a thermal source to induce local changes of the temperature and the electronic/conduction properties, simultaneously the current change of the device (under the constant bias voltage) at each scanning step was recorded to visualize the distribution of the current conduction paths in devices. The results reveal that in the bistable memory devices using polymer-stabilized Au nanoparticles, the current transport paths during the writing mode or the subsequent reading mode (of the "on" state) are localized, and that once the localized current transport paths are established in the writing mode, the current transport in the subsequent reading mode (of the "on" state) would basically follow the same paths. The established conduction paths would be eliminated in the erasing process and re-established in the next writing process. Yet, the current conduction paths established for the "on" state are somehow random and vary from writing to writing. Results of this work might have significant implications to operation or applications of such memory devices. This work demonstrates that the OBIRCH technique might be an useful method to characterize localized current transport paths in organic devices.

tum efficiency due to charge balance in the emitting layer. The highly efficient deep-blue OLEDs can surely be realized by using bipolar host materials without employing a DEL structure, and thus, one of the key methods of simplifying the device structure of deep-blue POLEDs is the development of a suitable host material. It has been difficult to synthesize a bipolar host material with high E_T to confine the triplets of deep-blue dopant in the guest. The only molecular architecture that combines high E_T and bipolar carrier transport properties has been realized by combining a hole-transporting carbazole substituent and an electron-transporting phosphine oxide (phosphine sulfide) substituent [19–23]. The novel molecular architecture should be proposed to discuss more about the effect of such a bipolar host material on the efficiency of simplified deep-blue POLEDs.

In this paper, we report on a new bipolar host material for use in simply structured, deep-blue POLEDs, 2-[(4-carbazolyl-9-yl)phenyl]-2-[(4-pyridoindolyl-9-yl)phenyl]adamantane (Ad-CzPd). The simplified POLED consists of only three layers, namely, a hole-transporting layer, an emitting layer, and an electron-transporting layer, yet the η_{EQE} of the FIr6-based POLED is 13% at a current density (J) of 0.1 mA/cm^2. This efficiency is three times higher than the previously reported value for the same device structure [14]. The new host has both a hole-transporting carbazole substituent [16] and an electron-transporting pyridoindole substituent [18]. By combining these two substituents, an ideal host for a blue POLED, which exhibits both high E_T and bipolar transportability, can be realized. We have found that this novel molecular architecture is useful for simplifying and fabricating highly efficient, deep-blue POLED devices, since it distributes the carrier recombination region within the emitting layer.

2. Experimental

2.1. Preparation of Ad-CzPd

Ad-CzPd was synthesized by the reactions outlined in Scheme 1. 2,2-Bis(4-aminophenyl)damantane **1** was synthesized by adapting the dehydration method [24]. The reaction of 2-adamantanone with aniline and aniline hydrogen chloride in refluxing produced bis-aminophenyl product 1. Bis-iodophenyl product 2 was synthesized by the Sandmeyer reaction, in which aromatic amino compounds were converted into halogeno benzene derivatives. The nucleophilic aromatic substitution of 2 with 5H-pyrido[4,3-b]indole in the presence of Cu furnished monoiodophenyl intermediate 3. Furthermore, nucleophilic aromatic substitution of 3 with carbazole in the presence of Cu furnished the desired product Ad-CzPd.

The structure of Ad-CzPd was identified using NMR. The following 37 hydrogen signals were detected by ^{1}H NMR ($CDCl_3$, 600 MHz): δ 9.4 (1H, s), 8.5 (1H, d, J = 5.5 Hz), 8.2 (1H, d, J = 7.6 Hz), 8.1 (2H, d, J = 7.6 Hz), 7.7 (4H, dd, J = 19.2, 7.8 Hz), 7.5–7.4 (6H, m), 7.4–7.3 (4H, m), 7.3 (4H, dd, J = 19.2, 7.8 Hz), 3.4 (2H, s), 2.2 (4H, t, J = 13.7 Hz), 2.0 (2H, s), 1.9 (4H, d, J = 12.4 Hz), 1.8 (2H, d).

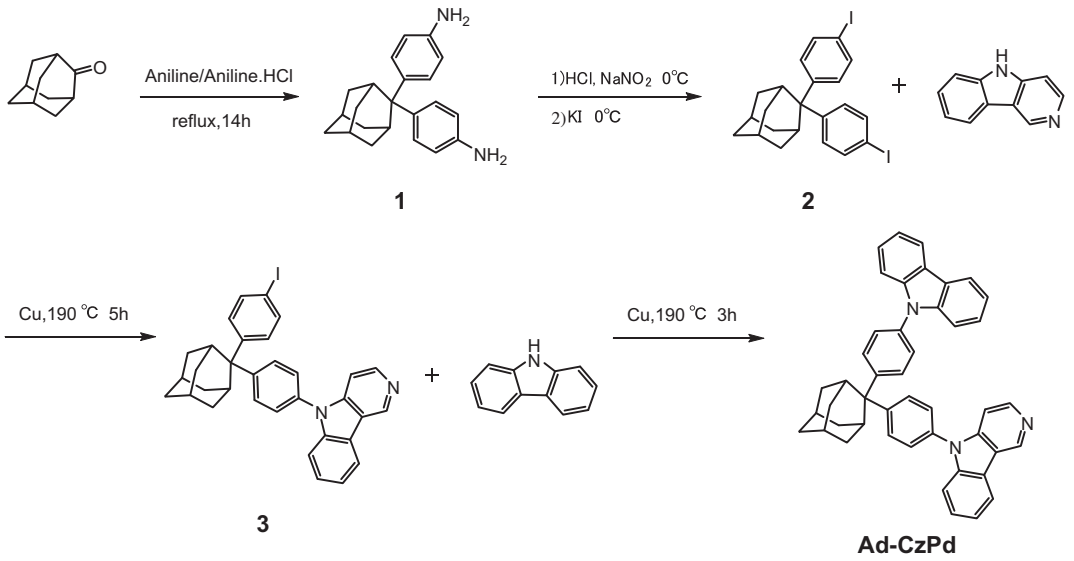
Ad-CzPd showed excellent thermal properties with a glass transition temperature (T_g) of 165 °C and a melting point of 345 °C, both of which are determined by differential scanning calorimetry. The purity of Ad-CzPd confirmed to be over 99% from high performance liquid chromatography.

2.2. Device fabrication

To clarify the carrier transportability of Ad-CzPd, we compared the hole and electron transport properties of Ad-CzPd, Ad-Cz and Ad-Pd thin films in the hole-only and electron-only devices, as shown in Fig. 1a and b. Furthermore, we compared the carrier transport properties of Ad-CzPd and 4,4′-bis(*N*-carbazolyl)-1,1′-biphenyl (CBP), which is a well-known bipolar host material [19]. The structure of the hole-only device is ITO/PEDOT:PSS (35 nm)/α-NPD (8 nm)/Ad-CzPd or Ad-Cz or Ad-Pd or CBP (60 nm)/α-NPD (8 nm)/Al (100 nm) (ITO: indium-tin oxide; PEDOT:PSS: poly(3,4-ethylenedioxythiophene)/poly(styrene sulfonic acid); α-NPD: 4,4′-bis[*N*-(1-naphthyl)-*N*-phenyl-amino]biphenyl). The structure of the electron-only device is ITO/PEDOT:PSS (35 nm)/UGH2 (10 nm)/Ad-CzPd or Ad-Cz or Ad-Pd or CBP (40 nm)/TmPyPB (20 nm)/LiF (1 nm)/Al (100 nm) (UGH2: *p*-bis(triphenylsilyly) benzene; TmPyPB: 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene) [11,13]. Then, we developed three types of FIr6-based OLEDs as shown in Fig. 1c. The device structure is ITO/PEDOT:PSS (35 nm)/TAPC (40 nm)/3 wt.% FIr6 in Ad-Cz or Ad-Pd or Ad-CzPd (35 nm)/TmPyPB (40 nm)/LiF (1 nm)/Al (100 nm) (TAPC: 1,1-bis[(di-4-tolylamino)phenyl] cyclohexane). Since TmPyPB has a relatively high E_T in a commercially available electron-transporting material, we selected it as the electron-transporting/hole-blocking layer [11]. The hole-only and electron-only devices, and POLEDs were developed on a glass substrate coated with a 150-nm-thick indium-tin oxide (ITO) layer. Prior to the fabrication of the organic layers, the substrate was cleaned with ultra-purified water and organic solvents, and treated with a UV-ozone ambient. To reduce the possibility of electrical shorts within the device, PEDOT:PSS, diluted in water, was spun onto the substrate to form a 35-nm-thick PEDOT:PSS layer after being baked for 1 h at 180 °C. The other organic layers were sequentially deposited onto the substrate without breaking the vacuum at a pressure of about 10^{-5} Pa. After cathode formation, the devices were encapsulated using a UV-epoxy resin and a glass cover within a nitrogen atmosphere. The electroluminescent (EL) spectra and luminance were measured with a spectroradiometer (Minolta CS-1000). A digital source meter (Keithley 2400) and a desktop computer used to operate the devices were connected. We assumed that the emission from the OLED device was isotropic, such that the luminance was Lambertian, and calculated the η_{EQE} from the luminance (L), J, and EL spectra.

3. Results and discussion

Fig. 2 shows the molecular structure and absorption spectrum of Ad-CzPd. The optical band gap (E_g) of Ad-CzPd was estimated to be 3.5 eV from the cutoff wavelength of the absorption peak (354 nm). The ionization potential (IP) of Ad-CzPd was estimated to be 5.9 eV (close to that



Scheme 1. Synthesis of Ad-CzPd.

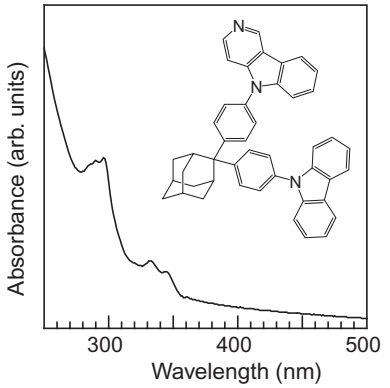

Fig. 2. UV–vis absorption spectrum of Ad-CzPd.

of 2,2-bis(4-carbazolyl-9-ylphenyl)adamantane (AdCz)) from spectroscopic measurements of the photoemission in air (AC-3, Rikenkeiki) [16]. We estimated the electron affinity of Ad-CzPd to be 2.4 eV (close to that of 2,2-bis(4-pyridoindolyl-9-ylphenyl)adamantane (Ad-Pd)) by subtracting E_g from IP [18]. The photoluminescence (PL) efficiency (Φ_{PL}) of the FIr6-doped Ad-CzPd film was measured using an absolute PL quantum yield measurement system (C9920, Hamamatsu), and it was found that the Φ_{PL} of the 6 wt.% film (82%) is higher than that of the FIr6-doped Ad-Cz film [16]. From this observation, we confirmed that the triplet energy transfer from FIr6 to Ad-CzPd is completely suppressed and the energy is confined in FIr6.

Fig. 3 shows the current density-applied voltage (J–V) characteristics of (a) a hole-only device and (b) an electron-only device. The Ad-Cz-based device shows the highest current density in the hole-only device, while the corresponding electron-only device shows the lowest current density. In contrast, the Ad-Pd-based device shows the highest current density at a low electric field in the electron-only device, while the corresponding hole-only device shows the lowest current density. These results clearly demonstrate that the carbazole substituent transports holes and the pyridoindole substituent transports electrons [16,18]. It is evident that the Ad-CzPd-based device has a similar current density to the CBP-based device, indicating the bipolar carrier transportability of Ad-CzPd [25]. Thus, Ad-CzPd is likely to be a suitable host for a simply structured blue POLED because of its high E_T and bipolar transportability.

The J–V–L characteristics of three types of FIr6-based OLED device are shown in Fig. 4a. The Ad-Cz-based device appears to have a higher current density than the Ad-Pd-based device. This difference is expected to be caused by the differences in carrier injection/transport properties. Not only is the carrier injection barrier at the anode/organic layer interface smaller than that at the cathode/organic

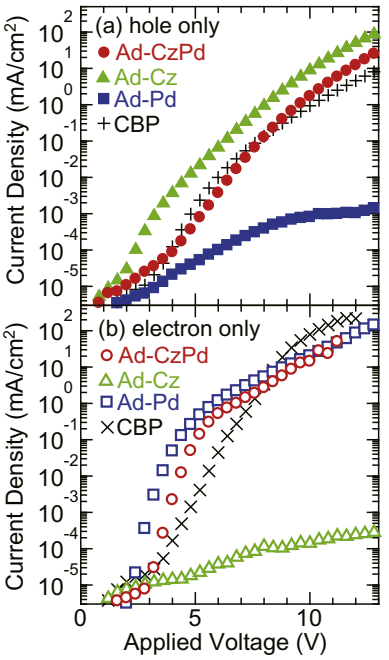

Fig. 3. Current density–voltage characteristics of (a) hole-only and (b) electron-only devices.

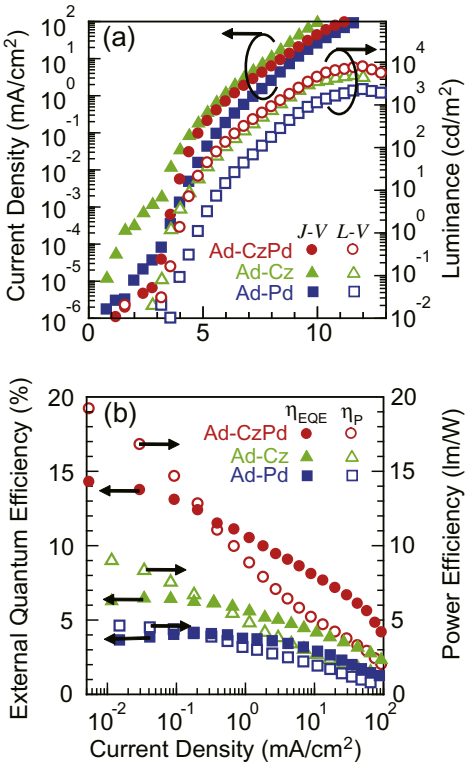

Fig. 4. (a) Current–density (J, left) and luminance (L, right) voltage characteristics of three devices. (b) External quantum efficiency (η_{EQE}, left) and power efficiency (η_P, right) current density characteristics of three devices.

layer interface, but also the hole mobility of TAPC is higher than the electron mobility of TmPyPB [11,26]. Thus, it is reasonable to suppose that the Ad-Cz-based device, the host material of which can transport holes, has an advantage in carrier recombination. The current density of the Ad-CzPd-based device is between those of the other two devices. Fig. 4b shows the η_{EQE} and power efficiency (η_P) of each device. The Ad-CzPd-based device has the largest maximum η_{EQE} of 14%. This efficiency can be explained by the distribution of the carrier recombination region within the emitting layer [16].

Fig. 5 shows the EL spectra of the Ad-Pd and Ad-CzPd-based devices driven at 1 mA/cm^2. In both OLEDs, the shape of the EL spectrum is almost independent of current density. The EL spectrum of the Ad-Pd-based device shows a residual emission at around 570 nm. Although the vibrational peak was intensified in the Ad-Pd-based device because of the difference in recombination zone [20,27], the small change in the intensity of the vibrational peak at 570 nm is expected [14,20]. Thus, the emission can be attributed to the emission from the electromer of TAPC, since the carrier recombination region is localized at the TAPC/emission layer interface because of the electron transportability of Ad-Pd [28]. In fact, the Ad-Pd-based device shows η_{EQE} of about 10% by inserting the thin Ad-Cz layer (10 nm) between TAPC and the emitting layer, where the residual emission is not observed (not shown). As we have reported on the Ad-Cz-based device, residual emissions not from the guest material reduce the efficiency of POLEDs [16]. Unlike the EL spectrum of the Ad-Pd-based device, the EL spectrum of the Ad-CzPd-based device does not show any residual emissions from the host and/or adjacent layer, indicating an almost complete energy and/or charge transfer from the host exciton to the guest upon the electrical excitation and excellent confinement of charge carriers and excitons in the emitting layer. By employing a bipolar host material with high E_T, the carrier recombination region is distributed over the emitting layer. Such a distribution of the recombination region was previously achieved by employing a DEL structure [15–18] and/or bipolar host materials that consist of carbazole and phosphine oxide (phosphine sulfide) substituents

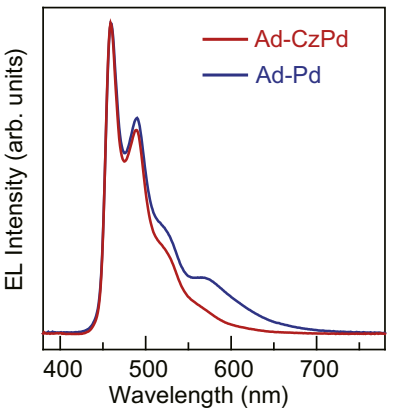

Fig. 5. EL spectra for two types of FIr6-based OLED devices. The host of one device is Ad-CzPd, and that of the other is Ad-Pd.

Table 1

[19–23]. Here, we have demonstrated that the distribution of the carrier recombination region in deep-blue POLEDs can be achieved by employing a bipolar host material that consists of carbazole and pyridoindole substituents. An efficient FIr6 emission is obtained in the simply structured POLED by using a bipolar host material with a novel molecular architecture.

Table 1 shows the device structures (organic layer configurations), turn-on voltages, efficiencies, and Commission Internationale de L'Eclairage (CIE) coordinates of an Ad-CzPd-based POLED and other FIr6-doped POLEDs. Turn-on voltage is defined as the voltage corresponding to a luminance of 0.1 cd/m^2. The efficiencies of the Ad-CzPd-based device are approximately three times higher than those of a similarly structured device [14]. Although its η_{EQE} is slightly lower than that of the four-layer device, its η_P is slightly higher [14]. This difference in η_P is caused by the difference in turn-on voltage (driving voltage). The turn-on voltage of the conventional device is higher because of the use of the poor electron-transporting material UGH2 [18]. The bipolar host material with high E_T not only is very efficient, but also reduces the driving voltage by not using a low conductivity material.

Finally, we discuss the efficiency of the Ad-CzPd-based POLED in the high-current–density region. Although the Ad-CzPd exhibits bipolar carrier transportability, a roll-off of efficiency is observed, as shown in Fig. 4b. Such a roll-off of efficiency is observed not only in our Ad-CzPd-based POLED but also in other bipolar-host-based deep-blue POLEDs [19–22]. On the other hand, Jeon et al. have realized a deep-blue POLED with high quantum efficiency and low efficiency roll-off [23]. They proposed that the important parameters for realizing high efficiency and low efficiency roll-off are bipolar charge transport properties of the host, balanced charge injection, triplet exciton confinement in the emitting layer and triplet exciton confinement by carrier-transporting layers. If we take these parameters into consideration, the triplet exciton should be confined by the carrier-transporting layer in our Ad-CzPd-based OLED to suppress the roll-off of efficiency. Although the E_T of TAPC is sufficiently high to confine the triplet excitons of FIr6, the E_T of TmPyPB is similar to that of FIr6, which leads to triplet exciton quenching [11,14,23,29,30]. Unlike the DEL-structured device, the carrier recombination region is directly located in the carrier-transporting layer in simply structured device. Thus, the development of the carrier transporting layer with high E_T is another problem in the simplification of the device structure of efficient blue POLEDs.

4. Summary

We succeeded in developing a simply structured, deep-blue POLED by using a bipolar host material with high E_T. The novel molecular architecture that combines high E_T and bipolar carrier transport properties was realized by combining a hole-transporting carbazole substituent with an electron-transporting pyridoindole substituent. The simplified device consists of three organic layers, and it had a maximum η_{EQE} of about 13% and η_P of about 15 lm/W at a current density of 0.1 mA/cm^2. Residual emissions were prevented by distributing the carrier recombination region within the emitting layer. The efficiency of the three-layer POLED was found to be comparable to that of a conventional four-layer POLED. We believe that the bipolar host material with high E_T will be useful for fabricating simple, highly efficient, deep-blue POLEDs.

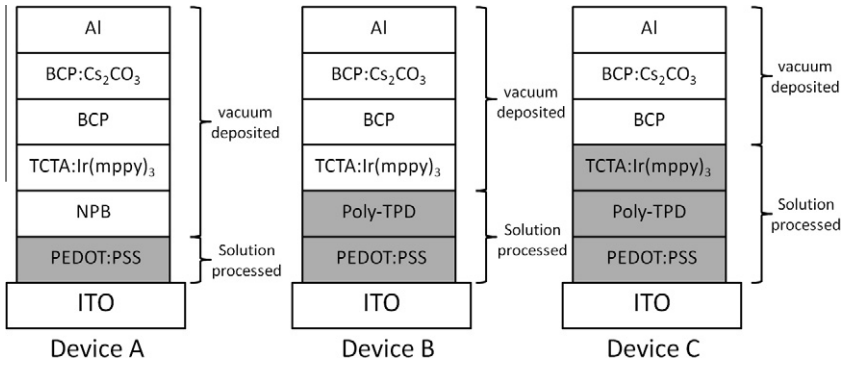

Fig. 1. The device architectures of the OLEDs fabricated in these experiments. The reference device A consists of a spincoated PEDOT:PSS hole injection layer (HIL) and evaporated small molecules. For device B the NPB hole transport (HTL) layer is replaced with a spincoated poly-TPD HTL and device C in which the first three layers including the emissive layer (EML) are solution processed.

ethylenedioxythiophene):poly(styrenesulfonic acid) (PEDOT:PSS) was used as hole injection layer (HIL). The main purpose of using a solution processed PEDOT:PSS HIL is the planarizing of the patterned ITO, while improving the injection into the subsequently deposited layers due to its relatively high work function (5.2 eV) [9]. In addition, the use of a heavily doped HIL eliminates the need for high work function anode materials, which allows the replacement of ITO by less expensive materials. For the reference device 10 nm of *N*,*N*′-bis(1-naphtalenyl)-*N*-*N*′-bis(phenylbenzidine) (NPB) was deposited on top of the PEDOT:PSS layer by thermal evaporation. For the hybrid devices a thin layer of a polyarylamine poly(*N*,*N*,(diphenyl)-*N*′,*N*′di-(4-hexylphenyl)-4,4′-biphenyldiamine (pTPD) was used as the hole transporting and electron blocking layer. It was spincoated on top of the PEDOT:PSS layer, annealed and rinsed twice with its solvent. After this treatment a thin insoluble layer of pPTD remains on which the light emitting layer can be deposited by spincoating from the same solvent. For the monochrome devices the emissive layer consisted either of a combination of a 2,2′,7,7′-tetrakis-(*N*,*N*-diphenylamino)-9,9′-spirobifluoren (s-TAD) host doped with 10 wt.% of Iridium(III)bis(2-methyldibenzo-[f,h]quinoxaline)(acetylacetonate) (ADS076) red phosphorescent emitter or a 4,4′,4″-tris(carbazol-9-yl)triphenylamine (TCTA) host doped with 10 wt.% Iridium(III)tris(2-(4-tolyl)pyridinato-N,C) (Ir(mppy)$_3$) green phosphorescent emitter. ADS076 and Ir(mppy)$_3$ were chosen as emitter for their high luminescence and commercial availability. [10,11]. S-TAD and TCTA were chosen as the matrix molecules for their amorphous behavior after spincoating, ensuring good film forming properties [4]. For the monochrome devices, following the deposition of the emissive layer 10 nm layer of 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (Bathocuproine, BCP) was thermally evaporated on top, which serves as a hole blocking layer. Subsequently, Cs_2CO_3 was co-evaporated with BCP in a 1 to 5 ratio (by wt.), forming a 30 nm doped electron injection/transport layer. An aluminum cathode was evaporated in a separate vacuum chamber to finish the devices, serving as both a top electrode and an optical mirror to increase the luminance through the transparent bottom contact. In the case of the white light emitting devices, prior to the hole blocking layer additional (green and blue) light emitting layers were deposited using thermal vacuum deposition techniques.

The organic layers were evaporated using thermal vacuum deposition at a base pressure of 10^{-6} mbar in a high-vacuum chamber integrated in an inert-atmosphere (<0.1 ppm O_2 and H_2O) glove box. The aluminum cathode was thermally evaporated at a pressure of 10^{-6} mbar in a separate chamber in the same glove box. Current density and luminance versus voltage characteristics were measured using a Keithley 2400 source meter and a photodiode coupled to a Keithley 6485 pico-amperometer using a Minolta LS100 for calibration of the photodiode. The EL spectrum was measured using an Avantes luminance spectrometer. The thicknesses of the solution processed layers were determined using an Ambios XP1 profilometer. The thicknesses of the evaporated layers were monitored by calibrated quartz-crystal sensors.

3. Results and discussion

3.1. Replacement of hole transport layer

The current density *(J)* and luminance *(L)* versus voltage *(V)* characteristics of the reference device are shown in Figs. 2 and 3. Low turn-on voltages were obtained while the luminous efficiencies of 40 cd/A (see Fig. 4) and 40 lm/W are in the range of what can be expected using an Ir(mppy)$_3$ emitter. As a first step to investigate the influence of replacing thermally evaporated layers by solution processed layers, the NPB hole transport layer (HTL) was replaced by a spincoated poly[*N*,*N*′-bis(4-butylphenyl)-*N*,*N*′-bis(phenyl)benzidine] (poly-TPD) layer. The chemical structures and energy levels of poly-TPD and NPB resemble each other closely, making poly-TPD an appropriate substituent. An important benefit of using poly-TPD as a solution processed HTL is that it forms an insoluble interlayer of a few nm when spincoated on PEDOT:PSS and annealed subsequently, a feature also observed in similar polymers [12–14]. This allows solution processing on top of the HTL, which is not possible using a HTL consisting of NPB. Furthermore, the thickness of the insoluble interlayer depends only on the annealing time and temperature, and

is independent on the initial thickness of the as-cast layer. This is advantageous for practical considerations, since the preparation of defect free layers at these thicknesses is challenging. Poly-TPD was spincoated on top of PEDOT:PSS from a chlorobenzene solution to give layers of approximately 20 nm. The layers were annealed at 150 °C for 30 min immediately after deposition. Subsequently, the soluble part of the poly-TPD layer was removed with a double chlorobenzene wash, leaving only the insoluble interlayer to remain. The subsequent layers were thermally evaporated following the procedure of the reference device. The *J–L–V* characteristics of the device with a poly-TPD HTL in comparison with the reference device are depicted in Figs. 2 and 3. The current density and luminance are in close resemblance. Moreover, there seems to be no loss in current efficiency when the NPB HTL is replaced by the poly-TPD HTL. Omission of a HTL does lead to a slight decrease in current efficiency whereas both the current density and luminance are higher (not shown).

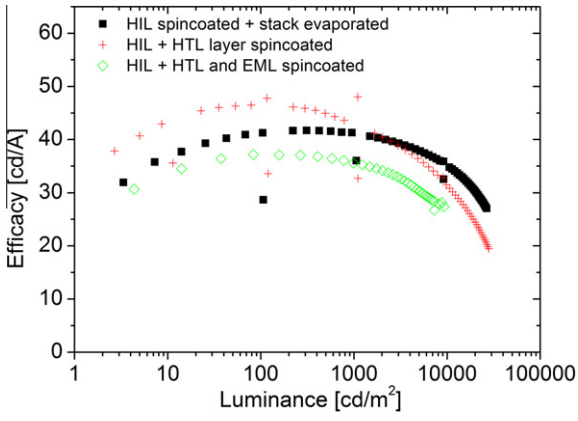

Fig. 4. Efficacy versus luminance of the fabricated green OLEDs. Filled squares: the reference device A. Crosses: device B where the hole transport (HTL) layer is replaced with a spincoated poly-TPD HTL and finally device C (open diamonds) in which the first three layers including the emissive layer (EML) are solution processed. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.).

3.2. Replacement of emitting layer

As the obtained poly-TPD interlayer is insoluble, the emitting layer (EML) can be solution processed on top of the HTL. For green emitting devices, a 20 nm layer of TCTA doped with $Ir(mppy)_3$ (16 wt.%) was spincoated from toluene solution on top of the HTL, followed by the evaporation of the subsequent layers. The obtained light emission is uniform for the whole device area, indicating that the thin emissive layer is defect-free. The feasibility of solution processing very thin and homogenous layers is indispensable to reduce the voltage drop and hence allow for high power efficiencies of wet-processed multilayer OLEDs, which is shown to be achieved using the small molecular TCTA host. From the *J–L–V* characteristics for this device and the reference device, as shown in Figs. 2 and 3, it can be observed that both the current densities as well as the luminance are in close resemblance. The similarity in performance can also be seen in the efficacy (Fig. 4), reaching maximum values close to 40 cd/A for all three described devices at a luminescence of 1000 cd/m^2.

To verify if these partially solution processed OLEDs can also yield competitive white light emitting diodes, a hybrid white light emitting device was prepared. First, in a similar approach to the green emitting device, a red emitting device was fabricated in which the first three layers are processed by spincoating. Here, a 20 nm layer of s-TAD doped with ADS076 (10 wt.%) was spincoated from a toluene solution on top of the HTL and HIL. Again, devices were completed by the evaporation of the hole blocking, electron injecting layers and the cathode resulting in similar

performances as obtained for a fully evaporated reference devices. Next, the emissive layer was complimented by subsequent thermal evaporation of green and blue emitter layers yielding a white OLED. Fig. 5 shows the *J–L–V* characteristics of the combined evaporated and solution processed device together with the fully evaporated reference device. The turn-on voltage for the two devices is identical. Also the luminance and current density versus voltage curves are very similar for the two devices, with the only difference the slightly lower current density and luminance values at higher voltages obtained for the partially solution processed device. This slightly lower luminance is reflected in the lower current efficiency values, reaching 8 cd/A versus 10 cd/A for the reference device. In both cases the current efficiency values remains practically the same up to high luminance values (2000 cd/m^2), which is an indication that in both devices the hole and electron current are quite well balanced. The electro-emission spectra for the partially solution processed device is practically the same as that of the reference device (Fig. 6, inset). For these white light emitting devices the effect of the different processing methods on the lifetime has been investigated. In Fig. 7 the luminance versus time characteristics are depicted with an initial luminance level of 700 cd/m^2. A similar stability for the devices with one layer and two layers out of solution is observed. For the device in which the first three layers are solution processed a stable long-term trend is observed as well. However, in contrast to the first two hybrid devices, where a negative burn-in effect is apparent, here a positive burn-in effect is evident followed by a more rapid degradation. Such an increase of the luminance with time was also reported in [15] but less pronounced. We ascribe the observed increase to morphology changes of the solution processed emitting layer, i.e. to some reorientations of the small molecules in the red emissive layer which are favored due to a rise in temperature during operation mode and potential out gassing of residual solvent. The inset of Fig. 6 shows the

electroluminescence spectrum for the three layer from solution device after a luminance decay of more than 50%. What can be observed is that the red emission has decreased slightly more than the blue and green emission, indicating that the solution processed red layer is the least stable part. And although not studied in detail this implies that device C (Fig. 1) most likely has a similar or higher lifetime. We would like to point out that even the three layer approach shows stable and promising lifetime results. Lifetimes (time to reach 50% of initial luminance) can be extrapolated to more than 1000 h for the OLED containing three layers processed from solution and approximately 2000 h for both references. To the best of our knowledge these are the best lifetime values found for white hybrid architectures based on solution processed polymers and small molecules so far. Considering these results, a partly

solution processed device can be a competitive alternative to completely evaporated OLEDs.

4. Conclusions

In conclusion, we have shown the fabrication of highly efficient, partly solution processed phosphorescent OLEDs with small molecular host materials. Evaporated layers in an optimized reference device were stepwise replaced by solution processed layers. Replacing the evaporated NPB HTL by a solution processed poly-TPD interlayer did not affect the performance and allows spincoating of the emissive layer after annealing. Comparable results for a solution processed and evaporated EML were obtained for a red and green emitting device and for the red emitting layer of a white OLED with lifetime in excess of 1000 h. This shows that solution processing can be a promising alternative to thermal evaporation, in order to reduce production costs.

expected in the direction parallel to the aligned grains [11]. The higher mobility was interpreted as better connectivity due to the existence of elongated polymer chains connecting two neighboring grains. These observations indicate that in addition to the appearance of crystalline grains, the connectivity between the grains is an important factor for charge transport.

Various microstructures have been realized by modifying chemical designs (e.g., regioregularity [12,13] and MW [10,14]), by applying different processing methods (e.g., using various boiling-point solvents [15,16] and changing deposition conditions [5,17]), or by employing different post-treatments [18,19]. Within liquid crystalline polymers in particular, thermal annealing – a typical example of post-treatment – plays an important role in self-healing, that is, in reducing the grain boundaries and increasing the average grain size. For instance, annealing of poly(2,5-bis(3-alkylthiophen-2-yl)thieno[3,2-b]thiophene) (PBTTT) thin films induces an extraordinary three-dimensional (3D) terrace structure that is composed of lamellar sheets stacked by interdigitated side chains in between [18,20].

The annealed film is then cooled down in order to form the solid thin film from the liquid crystalline phase. The recrystallization is a non-isothermal process, and accordingly, the cooling rate through the transition may affect the recrystallization process and the resultant microstructures of the thin films. This non-isothermal process is, however, not extensively studied; therefore, the correlation between the cooling rate and the microstructure is not yet known.

In this paper, we report that the cooling rate in the recrystallization from the liquid crystalline mesophase to the solid phase strongly influences on the microstructural morphology of PBTTT thin films and charge transport characteristics. Non-isothermal behavior in the recrystallization process is monitored by differential scanning calorimetry (DSC) measurements at various cooling rates. Microstructures of the films with different cooling rates are examined using AFM and two-dimensional grazing incidence wide-angle X-ray scattering (2D GIWAXS) experiments. Thin-film transistors (TFTs) with each resulting film as an active layer are fabricated. The transport characteristics show the dependence of charge transport on cooling rate from room temperature down to low temperatures.

2. Material and methods

Commercially available PBTTT-C14 (Merck Chemical Co.) was used as is. Thermal analysis of PBTTT was implemented using a differential scanning calorimeter (DSC 204 F1, NETZSCH). Powder PBTTT (3.69 mg) was used; it was heated at a rate of 10 °C/min and cooled at various rates under N_2 gas flow. Thin-film fabrication was performed in a glove box filled with N_2 gas. A heavily n-doped silicon (Si) wafer with a thermally grown 200 nm silicon dioxide (SiO_2) layer was used as a substrate. Before fabrication, substrates were completely dried at 120 °C on a hot plate in the glove box after sonication with acetone followed by ethanol. The substrates were treated with octatrichlorosilane (OTS) to make the surface hydrophobic. PBTTT solution was prepared at 0.5 wt% concentration in chlorobenzene. The heated solution (125 °C) was spin cast onto the substrate at 3000 rpm resulting in approximately 30 nm-thick films.

For an accurate measurement of sample annealing/cooling temperature at its equilibrium, a thermometer was attached to a large-mass metal plate which was placed on a conventional hot plate. Samples were placed on the metal plate and annealed at 150 °C above the liquid crystalline phase transition temperature for 10 min. Average cooling rates over the exothermic region were determined by monitoring temperature of the metal plate. AFM images were taken with Dimension 3100 (Veeco Instruments) operating in the tapping mode.

2D GIWAXS measurements were conducted at the 4C2 beamline of the Pohang Accelerator Laboratory at Pohang University of Science & Technology [21]. A monochromatized X-ray radiation source of 8.979 keV (wavelength $\lambda = 0.138$ nm) with a size of 0.5 mm (height) × 0.8 mm (width) was used. A 2D charge-coupled device (CCD) detector (MAR USA) producing 2D data of 2084 × 2084 pixel was used (where each pixel size is 57.6 × 57.6 μm^2). Samples were loaded on a homemade z-axis goniometer in a vacuum chamber. The exposure time for the measurements was 60 s.

TFT devices were fabricated with conventional top-contact geometry. The heavily n-doped substrate worked as a gate electrode. Source and drain electrodes were formed on the spin-coated polymer layer by thermal evaporation of 70 nm Au using a patterned shadow mask. The channel length (L) and channel width (W) were 50 μm and 2000 μm, respectively, with W/L = 40. All electrical measurements were performed with the Keithley 2636 Dual-Channel System SourceMeter. For temperature dependent transport measurements, samples were mounted on the cold head of a GM refrigerator (130GM, Leybold Cryogenics) where a Si thermometer (LakeShore Cryotronics) was attached. Every measurement was conducted after full thermal equilibrium was reached.

10	97.5	26.48
3.5	112.9	26.02

3. Results and discussion

3.1. Non-isothermal recrystallization behavior

When a PBTTT film is formed on the substrate by deposition, innate defects hinder the construction of ordered microstructure. Annealing these films above the liquid crystalline phase transition temperature (T_H) induces side-chain melting and freely moving polymer backbones. Subsequent cooling of the films induces the well-ordered structures because defects in the films are removed, resulting in a 3D terrace structure with domains of typically several hundred nanometers in lateral size. This is the basic mechanism of self-healing via thermal treatment in the liquid crystalline polymers. Upon cooling below the recrystallization temperature (T_C), most of the high-quality structural order formed in the liquid crystalline phase is preserved by side chain interdigitation, which is attributed to the origin of the exceptional 3D registry between the layers in PBTTT. Simultaneous X-ray diffraction (XRD) measurements along the thermal cycle show that a reorganized structure is maintained throughout the recrystallization process [22].

We systematically studied the recrystallization process by measuring the thermal properties of PBTTT powder by DSC. The samples were first heated at a fixed rate of 10 °C/min and subsequently cooled at various cooling rates from 3.5 to 40 °C/min. The exothermic heat flow curves for various cooling rates are shown in Fig. 1. The exothermic behavior at a cooling rate of 10 °C/min is consistent with previously reported results [18,22]. When the sample is cooled from the liquid crystalline phase, the DSC curve shows a peak owing to the recrystallization transition, which is strongly dependent on the cooling rate. The key parameters of the recrystallization transition are listed in Table 1. Fast cooling through the recrystallization

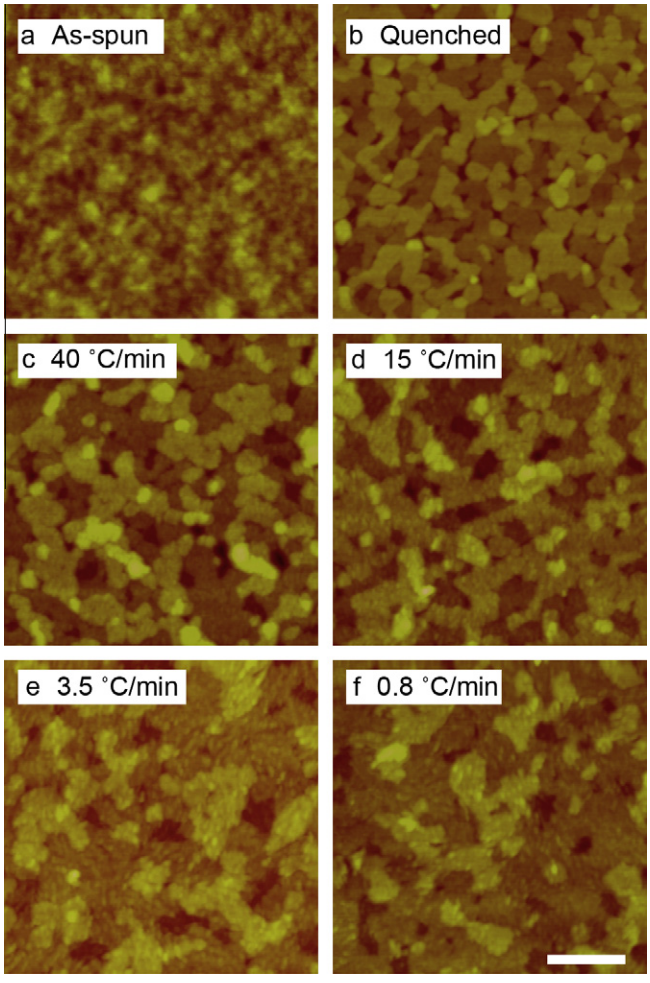

Fig. 2. AFM images of PBTTT films with various cooling rates. Scale bar denotes 500 nm.

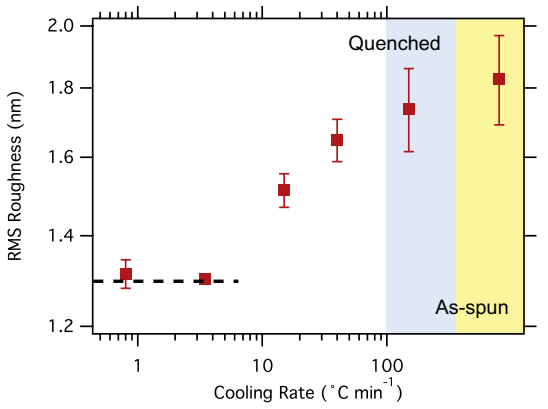

Fig. 3. RMS roughness values obtained from the AFM surface images for the films with various cooling rates.

temperature prohibits the release of sufficient heat for the recrystallization and homogenous interdigitation of the polymers. Thus, as the cooling rate increases, the exothermal peak shifts to lower temperatures, which is the typical characteristic of the meta-stability in the first-order phase transition. The enthalpy change (ΔH) of the recrystallization for the fast-cooled sample does not reach the value obtained from the slow-cooled sample. The insufficient recrystallization time probably leads to poor interdigitation and inhomogeneous recrystallization (see Supplementary data). We performed the measurements with powdered PBTTTs and presumed that the recrystallization process in the polymer thin films is not unusually different from that of powdered polymers.

3.2. Effect of cooling rate on PBTTT microstructure

In order to directly study the effect of recrystallization rate on the microstructure of PBTTT thin films, the topography images were obtained using AFM (Fig. 2). All the samples were annealed at 150 °C for 10 min and cooled at various rates. Small (50–100 nm) water-droplet-like domains were observed in the fast-cooled sample in Fig. 2b. In the slow-cooled samples, on the other hand, relatively large (several hundred nanometers) and flat domains were observed, as shown in Fig. 2e and f. Recent TEM studies showed that the large lateral domains in the terrace structure are composed of crystalline subunits (~10 nm in size) [7]. Thus the large domains are not directly characterizing the size of grains but reflecting possibly enhanced connectivity between the grains with relatively small angles. A variety of domain sizes displayed in Fig. 2 can be

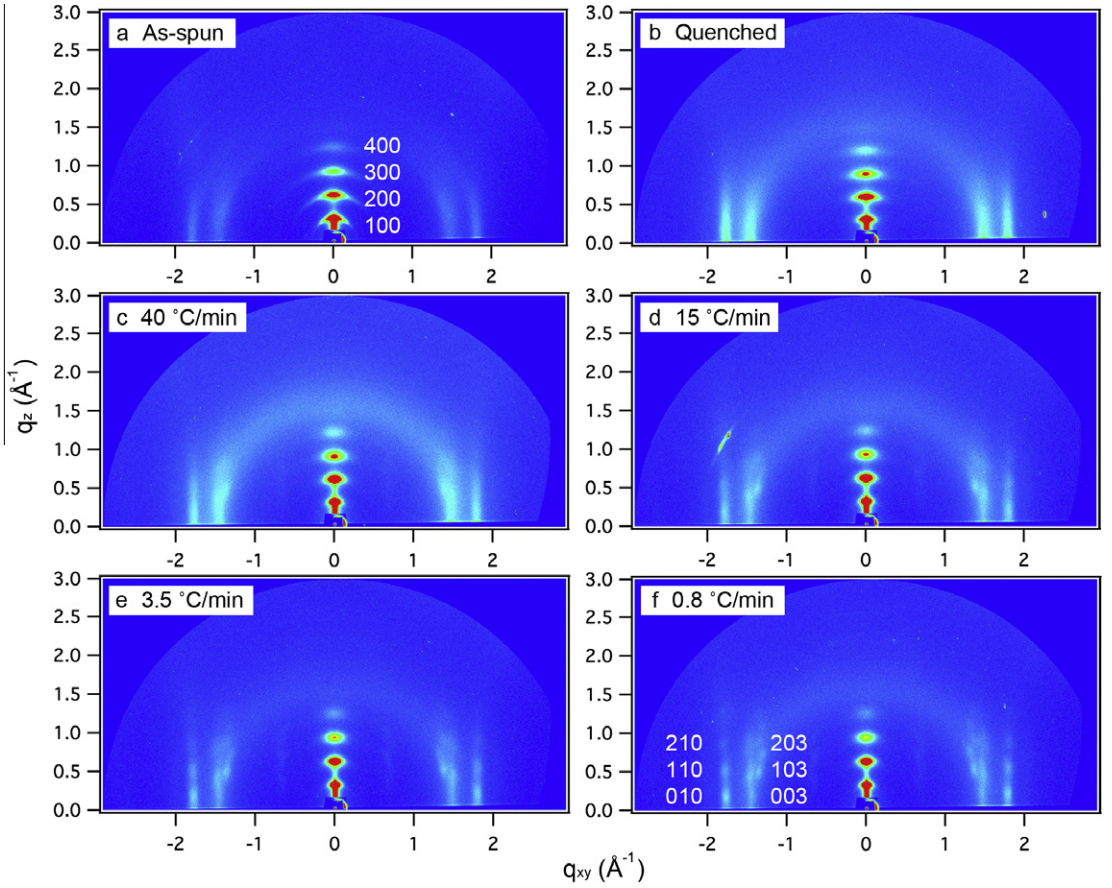

Fig. 4. 2D X-ray scattering at the grazing incidence of PBTTT films with various cooling rates. (a) (h 0 0) peaks and (f) mixed index peaks (e.g., (h 1 0) and (h 0 3)) are labeled.

interpreted by the indication that slow recrystallization leads to better connectivity among PBTTT molecules and consequently larger ordered domains, as is proposed in the previous section. Samples cooled at intermediate cooling rates show progressive improvement in morphology.

Another noticeable effect of slow cooling on the terrace structure is the flattening of surface layers to smoother surface morphologies. While the quenched sample exhibits rough surface morphology with small domains distributed over five or more layers, slow-cooled samples show smoother morphology with mostly one or two layers appearing on the surface. The root-mean-square (RMS) roughness of the films, shown in Fig. 3, quantitatively indicates the improvement of the surface morphology as the cooling rate decreases. Finally, RMS roughness saturates to about 1.3 nm with a cooling rate less than 15 °C/min. The substrate roughness was found to reduce the lateral domain size and the extent of long-range order, prevent the terrace formation, and suppress the field-effect mobility [17]. From this perspective, formation of large and smooth domains in the 3D terrace structure is likely to be an essential component for realization of high-performance polymer thin films.

The effect of the cooling rate on the long-range order in the polymer was determined by 2D GIWAXS measurements. The 2D diffraction patterns for the various samples shown in Fig. 4 exhibit several noticeable differences. One is the *d*-spacing in the normal direction to the substrate.

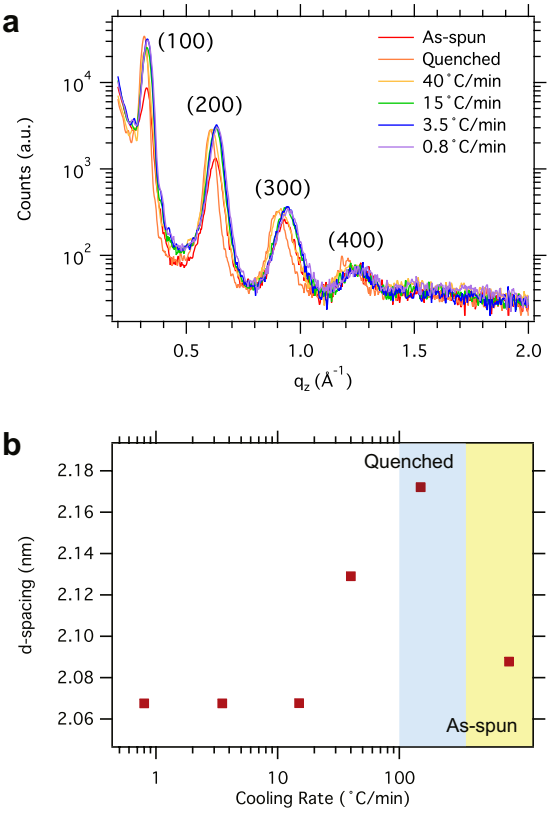

Fig. 5. (a) Out-of-plane X-ray scattering from PBTTT films for various cooling rates and (b) corresponding lamellar spacing distances.

The *d*-spacing can be obtained from the out-of-plane diffraction peak position, i.e., the q_z direction slice at $q_{xy} = 0$, as shown in Fig. 5. The *d*-spacing of the diffraction peak in the fastest cooled film was 21.7 Å. As the cooling rate decreased, the *d*-spacing decreased and saturated to 20.7 Å for samples cooled slower than 15 °C/min, which is consistent with the results of the previously reported XRD analysis showing that the layer spacing changes with the thermal cycle [22]. The cooling rate dependence of the *d*-spacing can be explained by the different recrystallization times of melted side-chains. Above T_H, side-chain melting expands the vertical layer spacing, and subsequent cooling down through T_C leads to the formation of interdigitated side-chains, reducing the layer-to-layer distance. It can be inferred that if melted side-chains have insufficient time to recrystallize, layer packing does not occur sufficiently; in contrast, sufficient recrystallization time guarantees relatively close-packing of the layers. It is worthwhile to mention that in-plane diffraction patterns show negligible cooling rate dependence (not shown here), which is consistent with the previous literatures [19]. This suggests that annealing modifies only the lamellar stacking and not the π-stacking.

Another prominent feature found in the 2D GIWAXS measurements is the shape and the intensity of Bragg peaks, from which the extent of layer ordering and tilting orientations can be compared. Figs. 6a–c show the 2D patterns of the (2 0 0) Bragg peaks of polymer films for different cooling rates. A perfectly aligned structure would exhibit an elliptical pattern in the Bragg peak, whereas a misaligned structure would exhibit an arc-shaped pattern [17,23]. The elliptical shape of the Bragg peak in the slow-cooled sample clearly demonstrates the lack of tilted layers in this sample in comparison to the as-spun sample or the quench-cooled sample. We also examined at the horizontal (q_{xy}-direction) slice of the (2 0 0) peak intensity, as shown in Fig. 6d. The width of the peak is related to the lateral length of the ordered structure along the surface, in other words, the lateral domain size. The tilting of domains broadens the width of the horizontal peak intensity. The sharp and narrow peak of the slow-cooled sample indicates the highly oriented large in-plane domains. Since each layer is mutually supported by adjacent layers during recrystallization, side-chain interdigitation also enhances the lateral ordering, resulting in formation of large-size domains [22].

In addition, the higher-order mixed-index Bragg peaks, which are an index of 3D ordering, exhibit strong dependence on the cooling rate in the direct comparison of the (h 1 0) peaks, as depicted in Fig. 7. The intensity data were collected from the slice of the 2D diffraction patterns at the (0 1 0) peak point along the q_z direction. Although higher-order mixed-index peaks are indistinguishable in the as-spun sample and the fast-cooled samples, they become discernable in the slow-cooled samples, as (h 1 0) and (h 0 3) peak series labeled in Fig. 4f.

We did not study the microstructures of TFT at the dielectric interface which dominates the 2D transport in TFT. However, it is not unnatural to think that the cooling rate influences overall film structure of about 30 nm thickness including the dielectric interface.

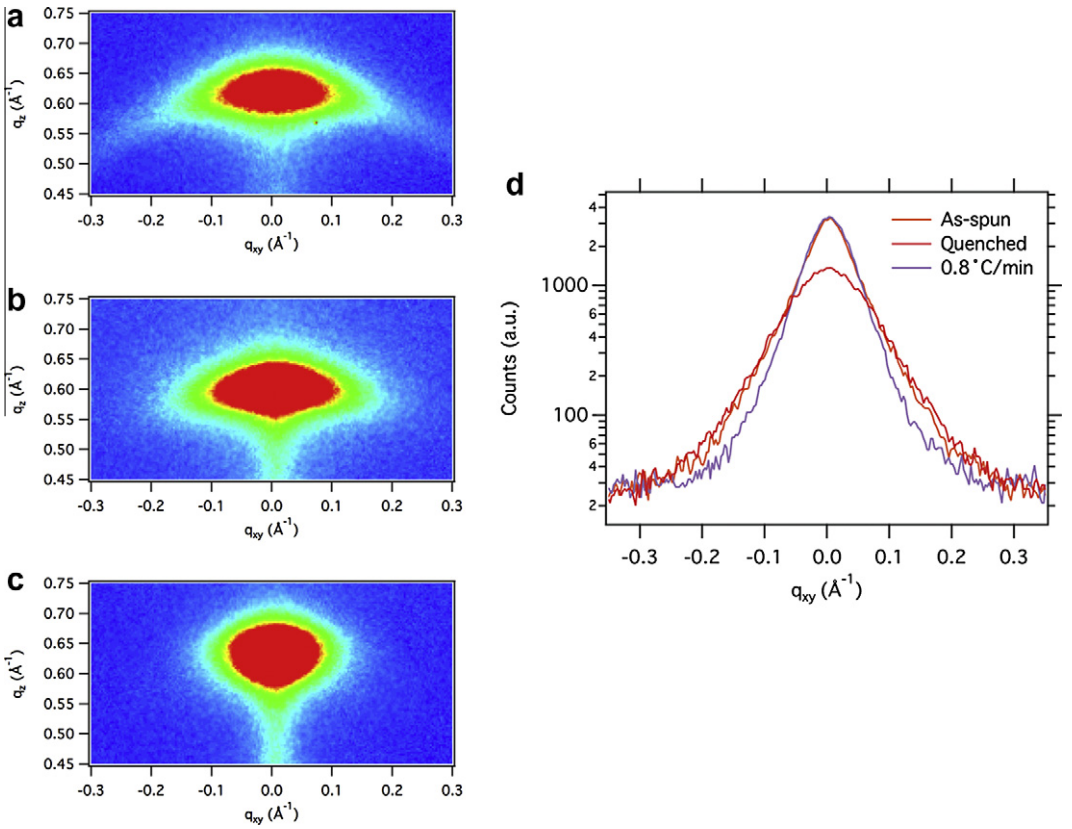

Fig. 6. 2D X-ray scattering near the (2 0 0) Bragg peak of a film of PBTTT (a) as-spun, (b) quenched and (c) slowly cooled at 0.8 °C/min. The peak patterns were plotted on the same intensity scale. (d) q_{xy} scan of the (2 0 0) peak for the corresponding films.

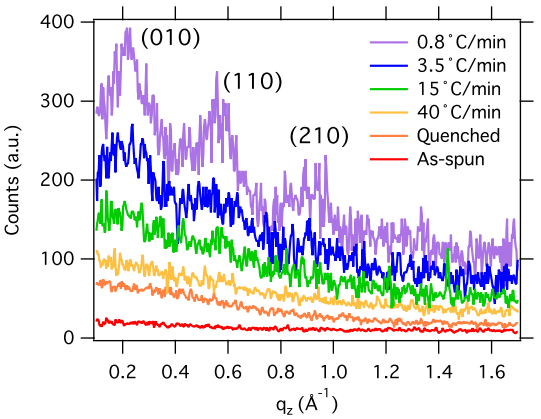

Fig. 7. q_z Scan along the (h 1 0) peak series for various cooling rates.

3.3. Effect of cooling rate on charge transport in TFT device

In order to study the effect of different morphologies on charge transport, the transfer characteristics of PBTTT TFTs with a top-contact configuration were investigated (Fig. 8a). All the devices exhibited high performance p-type TFT characteristics operating in the accumulation mode. The cooling-rate-dependent charge carrier mobility measured in the saturation region is shown in Fig. 8b. The mobility tends to increase as the cooling rate decreases. When the cooling rate is sufficiently low (lower than 15 °C/min), the mobility saturates at a certain value and becomes unaffected by further decrease in the cooling rate. The saturated mobility obtained from the slow-cooled samples is few times higher than the mobility from the quench-cooled sample.

To investigate the relationship between the recrystallization rate and the charge transport further, transport measurement was carried out at various temperatures. All the mobilities were measured in the saturation region at fixed effective gate bias, i.e., $V_g - V_t = -20$ V. The mobility monotonically decreases as temperature decreases. This temperature dependence becomes stronger with increasing cooling rate, as shown in Fig. 8b. The activation energy, i.e., the slope of mobility as a function of temperature, is calculated and plotted in Fig. 8c, showing a clear increase with increasing cooling rate. All the activation energy values are in reasonable agreement with those in previous work [7]. The activation energy also saturates for a sufficiently slow cooled sample, which is consistent with the behavior of raw mobility as a function of the cooling rate.

The relatively small mobility in the fast-cooled PBTTT film is closely related to its higher activation energy, which can be treated as an effective energy barrier that obstructs

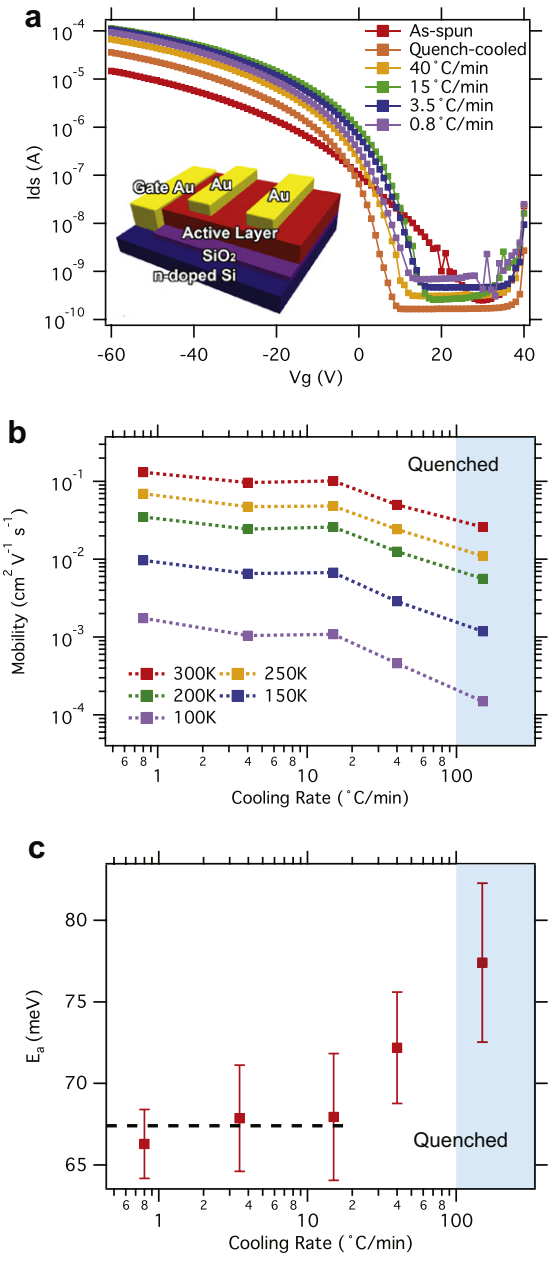

Fig. 8. (a) Cooling rate dependent transfer characteristics of PBTTT TFTs. The inset depicts the TFT configuration used in this study. (b) Cooling-rate-dependent mobility measured at various temperatures. (c) Activation energies are obtained for various cooling rates.

the charge transport. The dominant source of charge transport obstruction is grain boundaries, which is proliferated upon faster cooling. In other words, smaller mobility with higher activation energy can be attributed to its microstructure, which contains small and rough domains with worse connectivity induced by fast recrystallization. Sufficiently slow cooling results in well-connected, smooth, and large-size domains; the critical value of the cooling rate is found to be around 15 °C/min.

4. Conclusions

We have demonstrated the effect of recrystallization rate on the morphology and charge transport properties of a PBTTT thin film. DSC measurements at various cooling rates confirmed that the cooling rate plays an essential role in the recrystallization process. The connectivity between domains increases through recrystallization, resulting in larger domains. The microstructures obtained at various cooling rates were extensively studied by AFM and 2D GI-WAXS. Slower cooling leads to well-connected large domains with 3D ordering, whereas faster cooling induces misaligned small domains. The charge carrier mobility increases with decreasing cooling rate and saturates for a cooling rate slower than the critical value of 15 °C/min. The activation energy obtained from the temperature dependent transport measurement showed that the charge transport obstruction tends to reduce as the cooling rate reaches the critical value. The smaller activation energy observed in the sufficiently slow cooled sample is attributed to the improved microstructure of the thin film.

P3HT degrade rapidly [10–13]. A number of studies report that this is related to formation of a charge transfer complex between O_2 and the polymer (CTC-P/O_2). This charge transfer complex can act as a precursor for formation of a charge pair consisting of a positively charged radical cation (or polaron) on the polymer chain (P^+) in combination with O_2^- [12]. It has also been found that electronic excitation of the charge transfer complex by light strongly enhances the charge formation [12–15]. This provides a possible explanation for the rapid degradation of P3HT in the presence of both light and O_2 [12–18]. Presently it is not fully clear, which wavelengths promote charge generation from the charge transfer complex. Furthermore, one might expect rapid recombination of the photogenerated P^+ and O_2^- to reform the ground state charge transfer complex CTC-P/O_2. Finally it is not clear whether the generated O_2^- directly initiates a radical chain reaction leading to large scale degradation. One study has indicated that photoinduced degradation as probed by fluorescence quenching is still partly reversible in the initial stage [14].

In this study we focus on the initial stages of photoinduced changes in films of π-conjugated polymers. We investigate P3HT and also a poly(cyclopentadithiophene-alt-benzothiadiazole) derivative, PCPDTBT, which shows higher power conversion efficiencies in bulk heterojunctions with PCBM than P3HT. The highest reported efficiency for PCPDTBT:PCBM is 5.5% [19]. By combining results from several spectroscopic techniques (infrared and visible optical spectroscopy and electron paramagnetic resonance (EPR) we find unambiguous evidence that in the first stage of the photoinduced degradation persistent charge pairs P^+ O_2^- are generated. These are stable in the dark for hours but disappear again upon removal of O_2 by applying a vacuum. This charge formation also occurs in the presence of PCBM. The fact that no other photochemical reaction products could be identified in this early stage of photodegradation, combined with the stability of the photoinduced charges, indicates that the P^+ and O_2^- charge pair is stabilized by chemical interactions and needs to be reactivated to initiate chemical degradation of the polymer.

2. Experimental

P3HT was obtained from Rieke Metals (Sepiolid P200) and was regioregular; PCBM was obtained from Solenne BV; poly[2,6-(4,4-bis(2-ethylhexyl)-4H-cyclopenta[2,1-*b*;3,4-*b*′] dithiophene)-alt-4,7-(2,1,3-benzothiadiazole) (PCPDTBT) was obtained from Konarka.

Absorption spectra of spin coated (from chloroform solutions) films on quartz substrates were recorded with a Perkin Elmer Lambda 40 UV–vis Spectrometer. Controlled exposure to oxygen of the samples was achieved using a bath cryostat (Oxford Instruments) at room temperature that controlled the atmosphere around the sample. The illumination was performed in situ with a 365 nm UV lamp (Spectroline, model CM-10, Spectronics Corporation). The optical data were corrected by subtraction of the absorption spectrum of the P3HT film in the dark. Data points in Fig. 2c were calculated subtracting the optical density at 700 nm from the optical density at the mentioned wavelength.

Electron paramagnetic resonance (EPR) at 9.44 GHz (X-band) was measured with a Bruker ESP 300E spectrometer using a cavity with a 50% transmission grid for illumination. The films for EPR experiments in the solid state were drop cast on glass substrates, dried in an oxygen free atmosphere, peeled off the substrates and inserted in the EPR sample tubes. The illumination in the EPR experiments was done by focusing the filtered ($\lambda > 510$ nm for vis experiments and $250 < \lambda < 450$ nm for UV illumination) white light from a 500 W Xe light source. Samples were irradiated for a known period of time, ranging from 5 s to several hours. The evolution of the peak-to-peak EPR intensity was monitored as a function of illumination time and oxygen exposure. In all the measurements the microwave power used was 10 mW. A time constant of 326 ms and conversion time of 162 ms were used. The field was modulated with an amplitude of 1 G at a frequency of 100 kHz. The microwave frequency and magnetic field were measured using a HP 5350B microwave frequency counter and a ER 035 M NMR gauss meter. Single scans were sufficient to obtain an acceptable signal-to-noise ratio.

FT-IR measurements were performed in drop cast films from chlorobenzene solutions (thicknesses in the range of μm). Infrared spectra were measured on a Perkin Elmer Spectrum One UATR FT-IR spectrophotometer. Illumination of the samples was performed with a desktop lamp and a cutoff ($\lambda > 510$ nm) filter. Chemical doping of P3HT

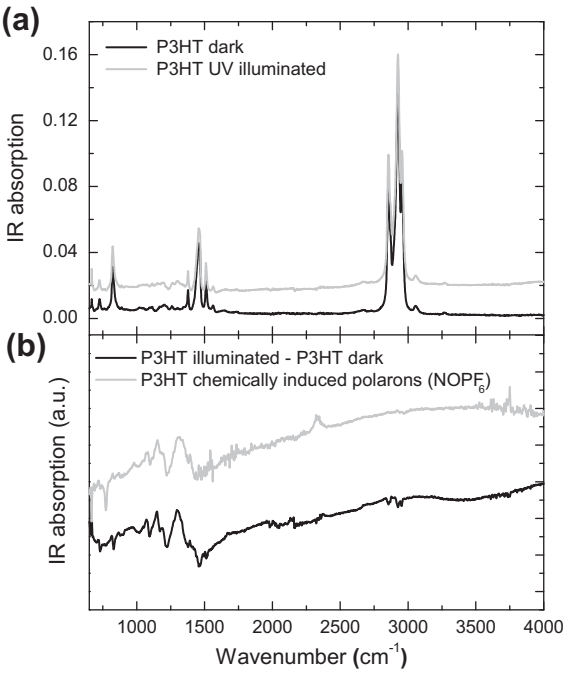

Fig. 1. (a) FT-IR absorption spectra of a P3HT film prior to and after illumination with UV light in ambient air for several minutes. (b) Corresponding difference spectrum for P3HT before and after illumination (black line). For comparison also the difference spectrum upon chemical oxidation of P3HT with $NOPF_6$ is shown (grey line).

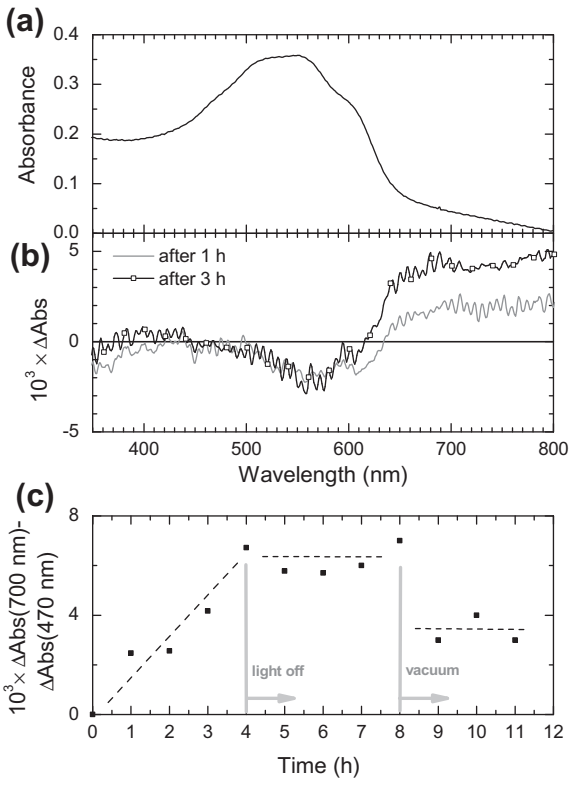

Fig. 2. (a) Optical absorption of a P3HT film. (b) Differential absorption (ΔAbs) after UV illumination for 1 and 3 h in air with respect to the initial 'dark' absorption. (c) Difference of ΔAbs at 700 nm and at 470 nm as function of illumination time. The illumination was ended after 4 h and the sample chamber was evacuated after 8 h.

in film was achieved by adding nitrosyl hexafluorophosphate ($NOPF_6$) to a P3HT solution followed by drop casting.

3. Results and discussion

In Fig. 1a we show the FT-IR spectra of a P3HT film before and after illumination in ambient air. As can be seen, illumination induces a new broad absorption band with a maximum near or above 4000 cm^{-1}. This feature is clearly visible in the difference spectrum, obtained by subtracting the spectrum taken before illumination from the spectrum after illumination, as shown in Fig. 1b. Besides the broad 4000 cm^{-1} band, a few narrower features are induced in the range below 1500 cm^{-1}. Surprisingly, no new infrared bands appear due to photochemical degradation products such as e.g. carbonyl moieties in the range of 1800–1650 cm^{-1} [20] or sulfonyl groups (between 1400 to 1300 and 1100 to 1000 cm^{-1}). The photoinduced species in the P3HT film can be identified unambiguously by comparing with the differential absorption induced by oxidative doping of the polymer with the strong electron acceptor $NOPF_6$. Oxidative doping of P3HT induces a low-energy electronic absorption (P_1 band) with a maximum around 4000 cm^{-1} corresponding to the $D_1 \leftarrow D_0$ transition of the radical cation on the polymer chain [21]. Associated with this transition are characteristic infrared active vibrational (IRAV) modes occurring below 1500 cm^{-1} as a consequence of symmetry breaking in the charged state [22,23]. The close match between doping and photoinduced spectra show that illumination results in formation of radical cations in the film. We stress that the photoinduced changes appear gradually during the long illumination period and persist for hours after turning off the illumination. Hence, we conclude that in the first stage of photodegradation, stable radical cations on P3HT are formed before any photochemical degradation products become detectable via IR.

The photoinduced radical cations in the P3HT film can also be detected via optical spectroscopy in the visible and near infrared spectral range. In Fig. 2 we show the UV–vis absorption spectrum of a film of P3HT before illumination, together with the differential absorbance induced by irradiation with UV light for 1 and 3 h of illumination in ambient air. As can be seen, the ground state absorption of the polymer in the 450-650 nm range, corresponding to the S_0–S_1 optical transition, is bleached upon illumination. A new absorption band appears in the 650–800 nm wavelength range that can be interpreted as the high energy electronic absorption (P_2 band) of P3HT corresponding to the $D_2 \leftarrow D_0$ transition of the radical cation on the polymer [21]. The time evolution of the number density of radical cations can be visualized by plotting the difference of the photoinduced absorption probed at 700 and 470 nm (Fig. 2c). This procedure minimizes the influence of small shifts in the baseline of the spectral measurement. During illumination the density of radical cations increases slowly over the course of hours and after terminating the illumination, the charges persist. However, upon evacuation of the sample chamber, the photoinduced changes can to a large extent be reversed. This indicates that the persistent charges owe their stability to the presence of molecular oxygen and that upon removal of O_2, they recombine.

To investigate the recombination of charges upon removal of O_2 in detail, we have used EPR spectroscopy. This technique allows us to probe the radical cations directly without interference of the EPR silent neutral polymer. As can be seen in Fig. 3, illumination of a P3HT sample in air at temperature $T = 293$ K induces an EPR signal with a g-value of 2.00158. This g-value is slightly different from the free electron g-value (2.0023), indicating delocalization of electrons along the polymer backbone. The intensity of this EPR signal rises steadily with the illumination time. In the dark the signal persists for at least 4 h (Fig. 3).

By varying the experimental conditions it can be proven that the formation of radicals on the polymer chains is a light induced process associated with the presence of molecular oxygen. This is illustrated in Fig. 4. Here we show changes in the peak-to-peak intensity with time for the EPR signal centered on $g = 2.00158$, for different experimental conditions. Generally, the g-value and line width of this signal remain unaltered during the experiment.

We find that both UV and visible illumination induce radicals. Furthermore illumination of films of P3HT cast, dried, mounted, and illuminated in absence of oxygen (sample type A, Fig. 4 squares) does not result in the formation of radicals. Merely exposing these pristine films

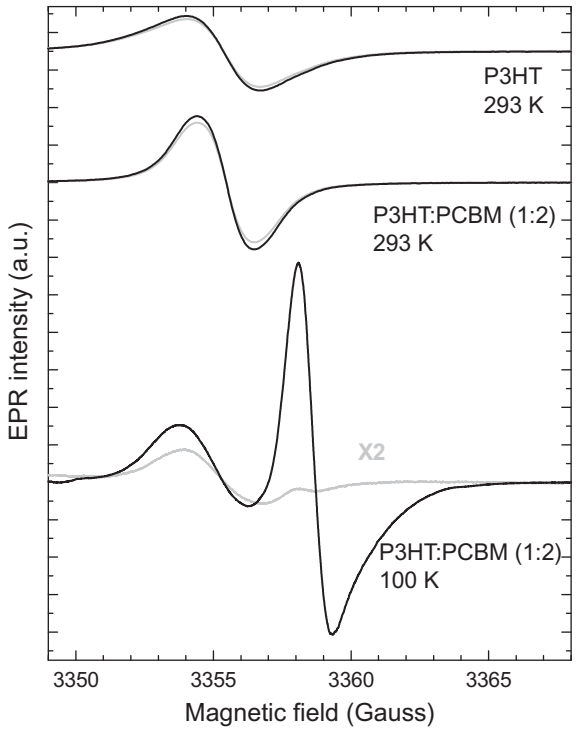

Fig. 3. (Top) Black line: EPR spectrum of P3HT at room temperature during UV illumination, with the film having been illuminated continuously in the 4 h prior to the measurement. Grey line: EPR spectrum of the same film after having been in the dark for 4 h after recording the spectrum shown as the black line. (Middle) Black and grey line: Same measurements as above but now for a P3HT:PCBM (1:2) mixed film at room temperature. (Bottom): Black and grey line same but now for a P3HT:PCBM (1:2) mixed film at $T = 100$ K. The 'light off' spectrum of P3HT:PCBM at 100 K has been multiplied by 2 for a better comparison.

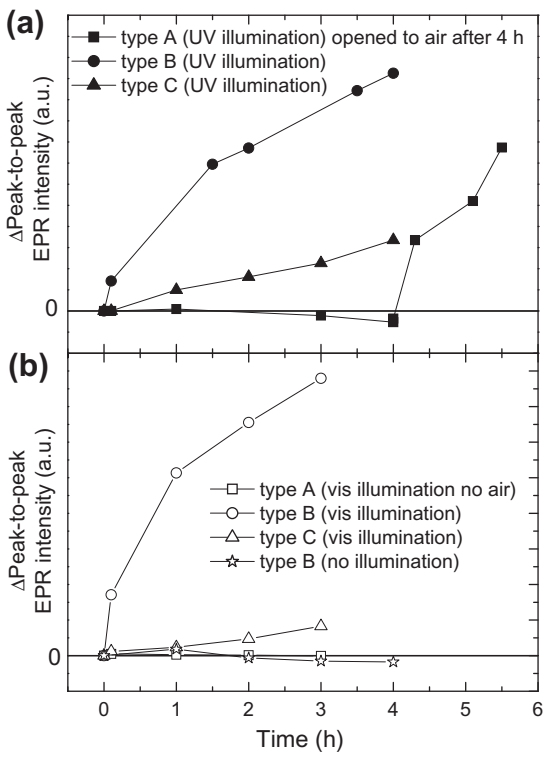

Fig. 4. Peak-to-peak EPR intensity vs. illumination time for P3HT films at 298 K. (a) UV ($\lambda < 420$ nm) illumination. (b) Visible ($\lambda > 510$ nm) illumination. Sample type A: film dried and mounted in absence of oxygen. Type B: dried in absence of oxygen and mounted in oxygen. Type C: dried and mounted in oxygen (type C). All samples were measured in air except sample type A that was kept oxygen free in a sealed tube. In the top graph the effect of opening the sealed tube containing A to air after 4 h of illumination is shown.

to oxygen at the start of the measurements series does also not result in formation of radical as long as no oxygen is present during illumination. On the other hand samples cast and dried in the absence of oxygen – but mounted and measured in air – (type B, Fig. 4 circles) do show formation of P3HT radical cations in EPR when illuminated, but not in the absence of light (type B, Fig. 4 stars). This proves that radical formation is the result of photoinduced electron transfer from P3HT to O_2. Unfortunately, the EPR signal from the superoxide radical anion (O_2^-) is too broad to be detectable at atmospheric pressures [23]. An indirect indication for the formation of O_2^- upon illumination of P3HT could be obtained from EPR experiments on solutions using a spin trap that reacts with O_2^- (experimental results not shown).

Surprisingly, samples of type B show significantly larger changes in the peak-to-peak intensity upon illumination than samples cast, dried, mounted and measured in air (type C, Fig. 4 triangles). We explain this influence of sample preparation as follows. Due to inadvertent exposure to light during sample preparation, films prepared and mounted in air contain already a larger density of radical cations at the start of the EPR experiment. As the density of radical cations seems to have an asymptotic maximal limit, samples mounted in presence of oxygen show a smaller increase in signal intensity than samples prepared under oxygen free conditions.

The EPR measurements confirm the observation that the persistent radical cations on P3HT recombine upon removal of O_2 from the sample. This is illustrated in Fig. 5. Upon evacuation of the EPR tube, the signal intensity due the P3HT radical cations drops dramatically.

Formation of persistent radical cations on the P3HT also occurs in the presence of the electron acceptor PCBM. In these mixtures illumination primarily results in the formation of $P3HT^+/PCBM^-$ charge pairs. At low temperature, during illumination, negative radical EPR signal of PCBM with a g-value of 1.9996 can be clearly resolved (Fig. 3). The $P3HT^+/PCBM^-$ charge pairs are known to be metastable and after terminating the illumination, the intensity of the PCBM radical anion signal decreases rapidly. After 4 h in the dark at low temperature, the PCBM signal has almost completely vanished from the EPR spectrum. A signal of P3HT radical cations however remains under these conditions. We attribute this signal to $P3HT^+/O_2^-$ charge pairs. At room temperature due to rapid spin relaxation and charge recombination the PCBM radical anion signal is hardly visible in the EPR spectra. Under these conditions, the persistent radical cations on P3HT formed via interaction with O_2 can easily be identified from the EPR spectra.

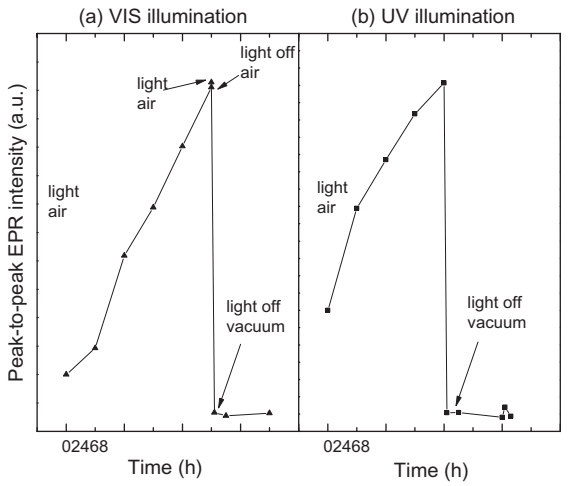

Fig. 5. Peak-to-peak EPR ($T = 298$ K) intensity vs. illumination time for P3HT film samples (type B) in oxygen atmosphere under illumination. (a) Visible illumination($\lambda > 510$ nm). (b) UV illumination ($\lambda < 420$ nm). After 5 and 4 h, respectively, the illumination was switched off and the sample was evacuated to 3×10^{-5} mbar.

The time evolution of the P3HT radical cation signal in mixed films containing also PCBM is further illustrated in Fig. 6.

The experiments described here involve the influence of air on photoinduced processes. Experiments focusing on

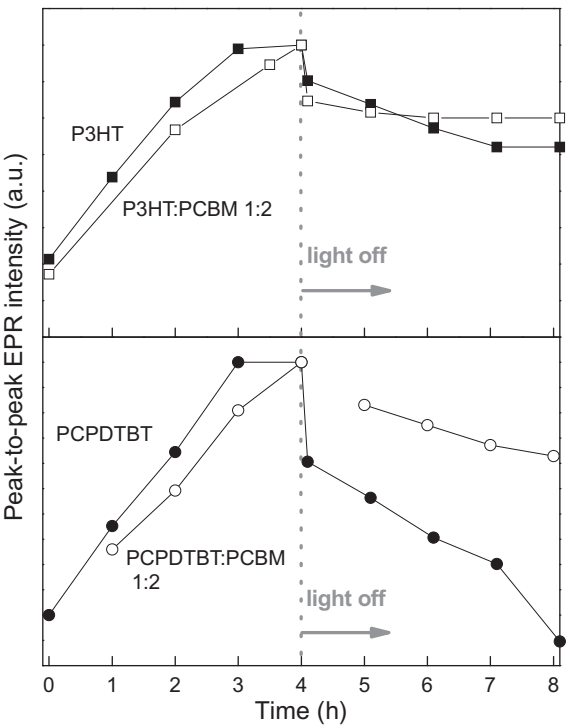

Fig. 6. Normalized peak-to-peak EPR ($T = 298$ K) intensity vs. UV illumination time for P3HT, PCPDTBT, P3HT:PCBM, and PCPDTBT:PCBM film samples (prepared as type B) in oxygen atmosphere. $t = 0$ h corresponds to the first moment of illumination and oxygen exposure of the samples.

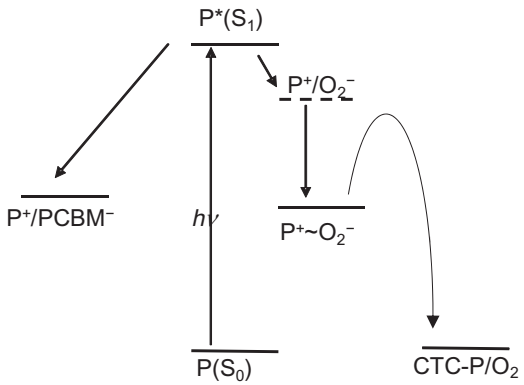

Fig. 7. Diagram illustrating the energy levels and transitions after photoexcitation of the polymer (P) in presence of PCBM or O_2 as electron acceptors. P* is the excited singlet state; P^+/O_2^- represents the initial excited charge transfer state of polymer with oxygen; $P^+ \sim O_2^-$ a relaxed excited charge transfer state; CTC-P/O_2 is the ground state charge transfer complex of P and O_2.

the influence of moisture contained in the air on the photoinduced changes, have shown that water without molecular oxygen does not give rise to formation of metastable photoinduced charges as observed in presence of O_2. Furthermore photoinduced charges are also observed in absence of H_2O [17].

Formation of persistent radical cations in the presence of light and oxygen is a property that is not restricted to films of P3HT. Also for PCPDTBT, EPR experiments indicate the formation of persistent radical cations in the presence of air (Fig. 6).

4. Conclusions

In summary, we find that illumination of the π-conjugated polymers P3HT and PCPDTBT in the presence of air leads to formation of persistent radical cations on the polymer chain. Charge formation is interpreted as the result of a photoinduced electron transfer from photoexcited polymer (P^*) to O_2 to form an excited charge transfer state (P^+/O_2^-). For P3HT the energy of the excited charge transfer state with O_2 is estimated at 1.9 eV ± 0.1 above the ground state [24]. In order to explain the persistent nature of the photoinduced charges, we postulate an energy barrier separating the excited charge transfer state (P^+/O_2) from the ground state charge transfer complex (CTC) between O_2 and polymer (CTC-P/O_2) (Fig. 7). This barrier may arise from stabilization of the excited charge transfer state and may be the result of chemical interactions between the O_2 and the polymer, leading to a 'relaxed' charge transfer state ($P^+ \sim O_2$). Because merely lowering the atmospheric pressure in the sample tube is enough to break up the charge pair, it seems unlikely that a completely covalent bond is formed between these two species in the relaxed charge transfer state. Given the acidity of alkylaromatic cation radicals [25], the basicity of the superoxide radical [26] and the reversible nature of the interaction, an acid-base reaction between cationic polymer and superoxide radical (e.g. coupled photoinduced electron and proton

transfer) seems a possibility. Formation of persistent charges also takes place in the presence of PCBM.

the cavity ($q \rightarrow q_{eff}$). Finally, only a fraction of the internally generated photons can leave the structure, as described by the outcoupling factor η_{out}.

The emissive process is considered as a dipole transition with the transition dipole moment having a certain orientation ϑ with respect to the normal of the surrounding layered system [7]. The emission of any arbitrarily oriented emitter can be decomposed into contributions of three orthogonal dipoles (||TE, ||TM, ⊥TM), as illustrated in Fig. 1a. These orthogonal dipoles are specified according to their orientation with respect to the interfaces of the layered system (parallel "||" with $\vartheta = \pi/2$, perpendicular "⊥" with $\vartheta = 0$) and the corresponding polarization of the emitted radiation (transverse-electric "TE", transverse-magnetic "TM"). Note that q_{eff} and η_{out} severely depend on the emitter position within the active layer as well as on the emitter orientation [14]. The OLED emission originates from an ensemble of emissive sites with an angular distribution $g(\vartheta)$ of their transition dipole moments. Then, only the relative contributions of parallel and perpendicular dipoles $p_{||}$:$p_{\perp}$ according to the integral quantities

$$p_{||} = \int_0^{\pi/2} g(\vartheta) \cdot \sin^2(\vartheta) \cdot \sin(\vartheta) d\vartheta \quad (2)$$

$$p_{\perp} = \int_0^{\pi/2} g(\vartheta) \cdot \cos^2(\vartheta) \cdot \sin(\vartheta) d\vartheta \quad (3)$$

enter the calculation [7] and will be determined experimentally in this paper.

In order to optimize the efficiency of OLEDs, the material specific electrical (γ) and optical ($\eta_{S/T}$ and q) properties as well as the layered system specific parameters (q_{eff} and η_{out}) need to be maximized. In state-of-the-art OLEDs the recombination zone is confined within a narrow layer by applying appropriate blocking materials and thus, recombination of all charge carriers is achieved ($\gamma = 1$) [15]. Utilizing phosphorescent emissive materials allows for both, singlet and triplet excitons, to decay radiatively into the ground state, yielding $\eta_{S/T} = 1$ [5]. Furthermore, emitter systems with short triplet-lifetimes and with reduced phonon mediated non-radiative relaxation processes promise the possibility of $q = 1$ [16]. However, the energy of an excited emitter can be radiated into different optical channels and only a small part of the light is finally emitted to the outside medium air, thus fundamentally limiting η_{out}. Optimizing an OLED stack enhances the emission of dipoles lying parallel to the plane of the OLED layers as this global optimum allows for extracting most power into air. Unfortunately, this optimized stack architecture tends to trap almost all light generated by perpendicularly oriented dipoles inside the layered system or the substrate glass, since perpendicular emitters undergo opposite interference conditions compared to the parallel ones [7,14]. As a result, analyzing and optimizing OLED systems require the knowledge of the emitter orientation distribution, that is generally assumed to be predominantly parallel for polymers and perfectly isotropic (a superposition of parallel and perpendicular dipoles with a ratio of $p_{||}$:$p_{\perp}$ = 2:1) for

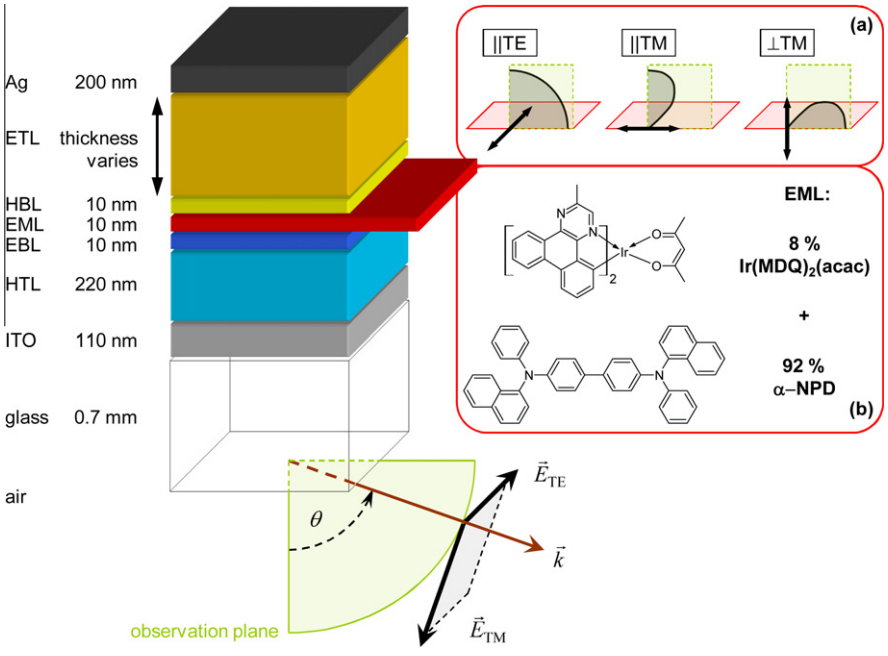

Fig. 1. Sketch of the thin film stack consisting of indium-tin oxide (ITO) as transparent anode on a glass substrate, covered by a thermally evaporated stack of hole transport (HTL), electron blocking (EBL), emitting (EML), hole blocking (HBL), and electron transport layer (ETL), contacted by a silver (Ag) cathode. The EML is prepared by co-evaporating the α-NPD matrix material with 8 wt.% of the red emitting phosphorescent dye $Ir(MDQ)_2(acac)$ as indicated in the inset. (b). An OLED series with varying ETL thicknesses from about 40 nm up to almost 400 nm has been analyzed. For angular resolved experiments, emission pattern in air has been scanned in one dimension (angle θ). The observation direction k and the orientations of the two perpendicular electric field polarization components TE and TM are drawn for convenience. The inset (a) illustrates the three basic dipoles and corresponding emission patterns assuming an infinite emitting medium. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

small molecule guest–host systems [6,7,17–23]. The simple fact that the optical outcoupling efficiency for exclusively parallel oriented emitters is about 50% larger than for emitters with isotropic orientation [6,7], suggests a highly promising OLED optimization approach.

2. Material and methods

In this paper the emitter orientation of the well-known red triplet-emitting material Iridium(III)bis(2-methyldibenzo-[f,h]quinoxaline)(acetylacetonate) [$Ir(MDQ)_2$(acac), 8 wt.%] in a *N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)-benzidine [α-NPD] matrix is studied. The chemical structures of $Ir(MDQ)_2$(acac) and α-NPD as well as the architecture of the OLED stack are shown in Fig. 1.

2.1. OLED fabrication

OLED samples, comprising several individually addressable circular pixels of 4 mm^2 area, have been prepared by thermal evaporation of organic materials onto commercial ITO coated substrates. The layered structure (Fig. 1) was fabricated using standard evaporation techniques at a base pressure of 10^{-7} mbar and an evaporation rate of 0.05 nm/s. Doped ETL and HTL were used in order to improve electron and hole transport, respectively, introducing the dopant by co-evaporation. This technique was also used for incorporating red emitters into the EML matrix. After cathode evaporation all devices were encapsulated with a glass lid containing a getter. Analogous structures, but without getter and without cathode, have been prepared for photoluminescence experiments.

2.2. Electroluminescence (EL) emission pattern measurement

In order to access the optical far-field of the OLED, polarized angular radiation patterns have been recorded utilizing a rotational stage (CR1/M-Z7E, Thorlabs) where the OLED was mounted, and an optical detection system consisting of a wire grid linear polarizer (NT47-101, Edmund Optics) with attached achromatic waveplate (AQWP05M-630, Thorlabs), combined with a fiber coupled calibrated spectrometer (SD2000, Ocean Optics). The resulting experimental intensity data $I(\theta,\lambda)$ possess a wavelength resolution of $\Delta\lambda < 5$ nm and an angular resolution of $\Delta\theta < 0.5^\circ$, as well as an intensity uncertainty below 2%. The OLED was driven at a current density of $j = 50$ mA/cm^2 using a constant current source (GS610, Yokogawa). Radiation patterns recorded at $j = 1$ mA/cm^2 and $j = 100$ mA/cm^2 show identical relative characteristics.

2.3. Photoluminescence (PL) radiation pattern measurement

An OLED stack without cathode and comprising 31 nm and 65 nm thick HTL and ETL layers, respectively, has been encapsulated without getter in order to enable for optically excited luminescence experiments using an almost linearly polarized continuous wave laser ($\lambda = 375$ nm). Polarized emission patterns inside the substrate have been measured by mounting the sample with an immersion coupled fused silica half cylinder on a computer controlled rotational stage. The angular dependent PL spectrum was measured with a calibrated fiber optical spectrometer and a polarizer to distinguish between TE and TM polarized emission. The measured cross sections are normalized to the values at small angles because the emission in this range occurs exclusively from parallel dipoles. Emission patterns have been shown to be independent of both, the incident angle and the polarization of the illuminating laser beam.

2.4. Radiation pattern analysis

Prior to any analysis, the wavelength-dependent, complex dispersion data ($n + i\kappa$) of all materials involved have been measured utilizing dispersion-model-free reflection–transmission-spectroscopy, a method published previously [24]. Subsequent spectral reflectivity analysis enables for exact determination of layer thicknesses. Device emission has been simulated by means of a self-developed software tool, based upon the theory of Chance, Prock, and Silbey [25–27]. By analyzing TE polarized emission following approaches presented previously [7,14], we determined the emitter's internal EL spectrum to be identical to the PL spectrum and the emission zone to be constant.

3. Results

Varying the distance between the emissive sites and the cathode by adjusting the electron transport layer (ETL) thickness imposes the most pronounced effects onto the optical device properties because of interference effects arising due to the reflection at the mirror like metal cathode. As previously demonstrated [7,14], the presence of perpendicularly oriented emitters can be visualized by adapting the ETL thickness. For the system under study, a 160 nm thick ETL induces destructive interference for emitters aligned parallel to the layers, while enhancing the emission of perpendicularly oriented emitters into the air half space, thus being a particularly sensitive probe for studying the presence of perpendicular dipoles. Fig. 2a shows the experimentally observed radiation pattern for TM polarized emission. Knowing the optical constants and layer thicknesses of all materials, the radiation pattern $I(\theta,\lambda)$ of the device is calculated according to classical theory [25], where further details can be found in previous publications [14,21,26,27]. Obviously, the experimental emission pattern is well described assuming a ratio of $p_{||}:p_{\perp} = 2:(0.63 \pm 0.07)$ for parallel vs. perpendicularly oriented emitters. Thus, the amount of perpendicularly oriented active sites is significantly lower compared to the common isotropic assumption ($p_{||}:p_{\perp} = 2:1$). Note that this result is obtained in an operating OLED differing from an optimized stack only in the increased ETL thickness.

In order to prove this surprising result, the emitter orientation has been determined independently using optically excited luminescence from an essentially identical stack without the metal cathode, following the approach presented in Ref. [6]. Again, the quantitative analysis in Fig. 3 yields a fraction of $p_{||}:p_{\perp} = 2:(0.67 \pm 0.05)$ for parallel vs. perpendicular emitters well within the confidence

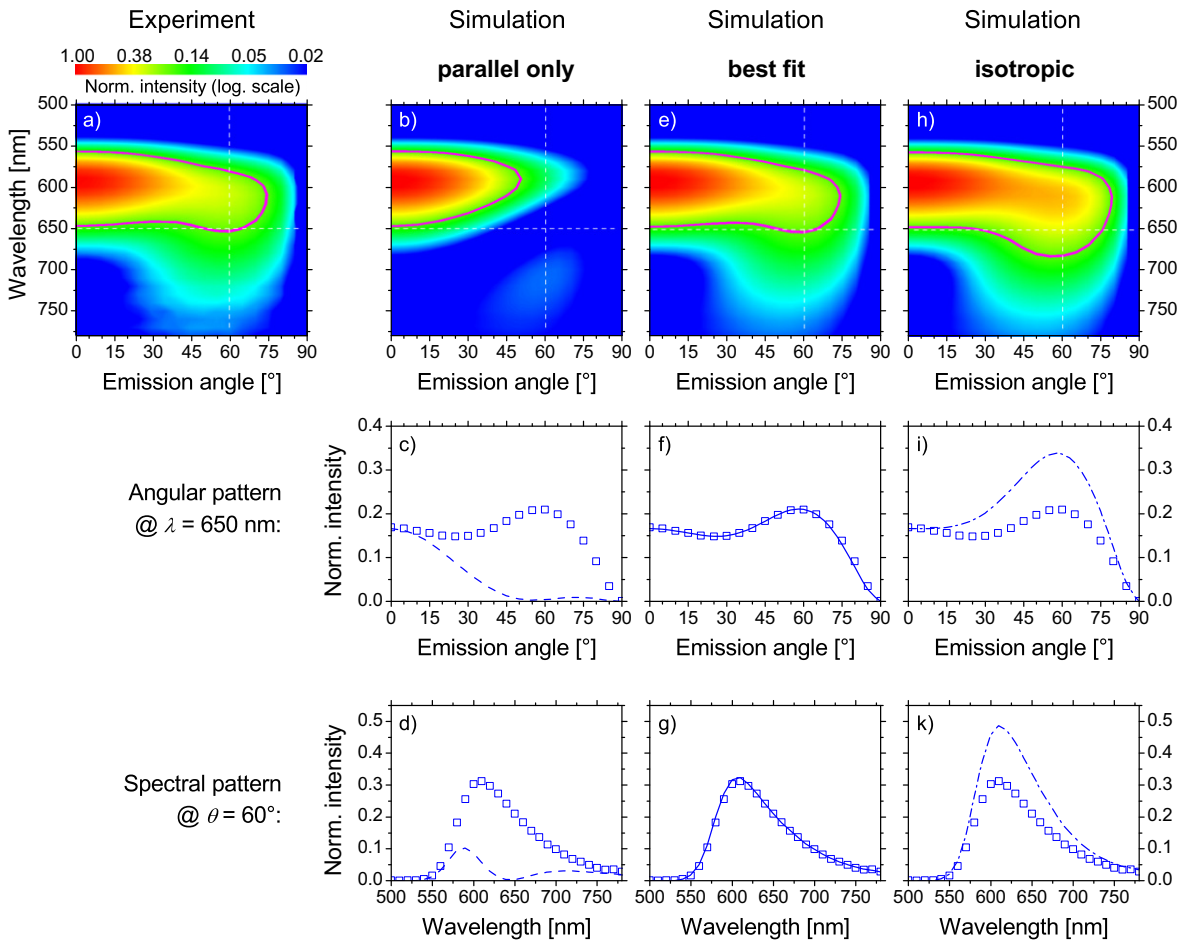

Fig. 2. Experimental and theoretical results obtained for the TM-polarized, spectral and angular resolved emission pattern $I(\theta,\lambda)$ in air of the adapted OLED comprising 160 nm ETL thickness. False color plots containing the entire spectral and angular pattern (top row; a, b, e, h) exhibit a logarithmic intensity scale to better visualize low intensity data. The value 0.2 is accentuated by a magenta line, the cross sections at angle $\theta = 60°$ and wavelength $\lambda = 650$ nm are indicated by white dashed lines. Cross section data for one fixed wavelength ($\lambda = 650$ nm; middle row; c, f, i) and one fixed angle ($\theta = 60°$; bottom row; d, g, k) are plotted with experimental results (squares) as well as the theoretical predictions (lines). Simulation results for three different emitter orientations are shown: An emitter alignment strictly parallel to the interfaces is assumed for the left "parallel" column (b, c, d); and an isotropic distribution for the right "isotropic" column (h, i, k). These two assumptions fail to yield a match to the experimental data, resulting in a "best fit" (middle column; e, f, g) assuming a fraction of 2:(0.63 ± 0.07) for parallel and perpendicular emitter contributions.

interval of the result in electrical operation, and clearly demonstrating a significant difference to the commonly assumed isotropic case.

So far, the discussion is based on a single device comprising the adapted ETL thickness of 160 nm. Additionally, quantitative radiation pattern analysis as well as emission lifetime measurements have been performed with a series of similar devices with varying ETL thickness in the 40–400 nm range (results not shown). The relative amount of perpendicular emitters could be confirmed with a device comprising a 333 nm thick ETL layer that is the second optimum for coupling of perpendicular emitters into air. Thus, the preferred parallel orientation is valid for all reasonable emitter–cathode distances, including devices which are optimized for maximum efficiency. Furthermore, no effect of pump current density on the determined orientation distribution was apparent up to 100 mA/cm^2 current density. Additionally, the internal luminescence quantum efficiency extrapolated to zero current was measured to be $q_0 = (74 \pm 4)\%$ utilizing previously published methods [22,23]. In result, we conclude that this particular emissive system is precisely described by quantitative optical simulation.

4. Discussion

The orientation distribution of Ir(MDQ)$_2$(acac) in α-NPD has been determined by two different optical methods with and without electrical excitation, both yielding identical results. The presence of non-isotropically distributed emitter ensembles in this phosphorescent guest–host system is concluded. We attribute this truly surprising result to the morphology of the α-NPD matrix blended with

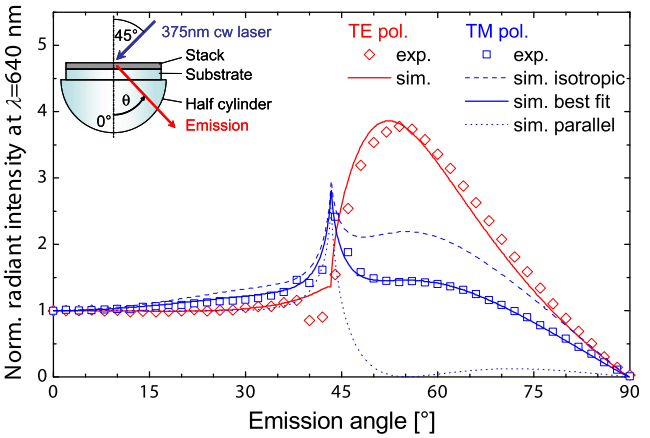

Fig. 3. Angular and polarization resolved photoluminescence emission pattern $I(\theta,640\,\text{nm})$ obtained by optical excitation at 375 nm and detection at 640 nm wavelength. An OLED stack according to Fig. 1 with HTL thickness of 31 nm and ETL thickness of 65 nm, but without the Ag cathode was used. The experimental geometry is illustrated in the inset. Data are normalized to perpendicular emission ($\theta = 0°$). Obviously, TM polarized emission is overestimated when assuming an isotropic emitter ensemble. The fit reveals a relative contribution of 2:(0.67 ± 0.05) parallel vs. perpendicular emitters.

the $Ir(MDQ)_2(acac)$ chromophore. The interaction of the asymmetric molecules during co-evaporation and the resulting predominantly parallel orientation of the dipole transition moments are not fully understood yet. We consider additional investigations potentially utilizing more sophisticated spectroscopic techniques in order to understand and to further exploit this effect.

It is worth to note that a slight birefringence of the α-NPD matrix has been observed [28] previously. Taking this effect into account yields an even more pronounced parallel emitter contribution but still within the confidence limits given.

The emitter orientation distribution obtained for the investigated small-molecular OLED emitter system reveals: the active sites in phosphorescent small molecule guest–host systems are not necessarily distributed isotropically. While the common assumption of isotropy yields a $p_{||}:p_{\perp} = 2:1$ ratio of parallel vs. perpendicularly aligned emitters, our result corresponds to a ratio of $p_{||}:p_{\perp} = 2:0.63$, i.e., a predominantly parallel orientation. Consequently, one generally accepted argument applied to discussions of triplet emitting OLED devices must be revised. Beyond doubt, there are triplet emitters with isotropic orientation, but this attribute cannot be assumed generally. By contrast, emitter orientation based optimization of OLED devices seems to be within reach, since parallel emitters preferably emit into air and, therefore, reduce the effect of surface plasmon polariton excitation at the cathode as optical loss channel. This optimization potential is illustrated by the calculations shown in Fig. 4. Assuming an optimized stack with the emitter properties obtained in this work yields 22.5% *EQE* (green curve in Fig. 4). A further emitter based optimization towards high quantum efficiency ($q = 0.95$) and an improved, predominantly parallel emitter orientation (with a ratio of $p_{||}:p_{\perp} = 2:0.14$ according to a realistic angular distribution with ±22° total width) could boost this efficiency by a factor of 1.5 to reach *EQE* = 35% (red curve in Fig. 4). Note that these efficiency values are given for the planar OLED system according to

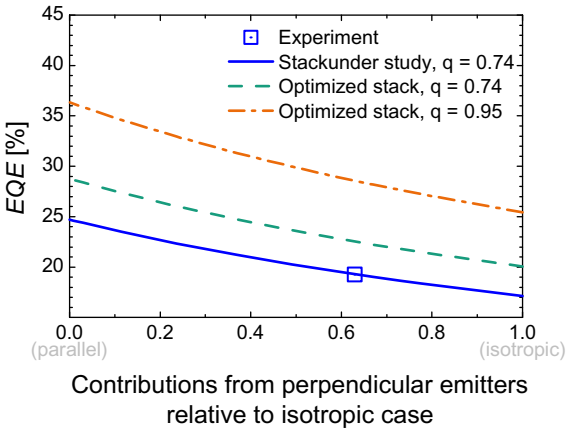

Fig. 4. OLED external quantum efficiencies vs. the relative amount x of perpendicular emitters as given in the text ($p_{||}:p_{\perp} = 2:x$). The square indicates the best value reached within this study at an ETL thickness of 250 nm. Plotting *EQE*-values simulated for this system with different amounts of perpendicular emitters yields the blue curve. Optimizing the OLED stack by varying ETL (~250 nm), HTL (~90 nm), and ITO (~90 nm) thicknesses yields the green curve with potential device efficiencies of 20–30%. Extending the simulation towards nearly ideal emitters ($q = 0.95$, red curve) provides planar devices with the highest possible efficiencies, potentially exceeding 30% *EQE*. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 1, avoiding more or less expensive internal or external outcoupling structures.

Interestingly, *EQE*-values in excess of 30% – definitely impossible with isotropic emitters (see Fig. 4) – have been reported recently [29], but without giving a sound explanation for this unexpected high number. Our results clearly demonstrate that an *EQE*-value in this range is feasible without any outcoupling enhancement structures by using phosphorescent emitters with their transition dipole moments being preferentially oriented in the substrate plane. This opens up novel approaches for OLED efficiency improvement by using smart emissive materials with

advantageous molecular orientation. Materials design, the influence of the matrix material, and the substrate as well as film deposition conditions are just a few parameters that need to be studied further to exploit the huge potential of the dipole emitter orientation in OLEDs.

In recent years, PEDOT:PSS sheet resistance could be decreased to around 100 Ω/sq and even less and consequently also grid free organic solar cells with a transparent polymer electrode [5,7–10] were fabricated, including large scale deposition techniques like spray-coating [10,11]. Since the increased sheet resistance of the polymer electrode compared to ITO (10–30 Ω/sq) affects the solar cell fill factor, these kinds of devices are usually less efficient than ITO reference samples. So far, the impact of a polymer electrode on organic photodetector performance, significant at reverse bias voltage, is not reported in literature. In this work we show the applicability of a highly conductive and transparent PEDOT:PSS layer as top electrode for a top-absorbing organic photodetector and we report on the device performance with varying anode sheet resistance.

2. Experimental

All devices were fabricated in a nitrogen-filled glovebox. The layer sequence of an inverted photodiode is shown in Fig. 1. The aluminum bottom electrode with an area size of 7 mm^2 and a thickness of around 100 nm was thermally evaporated through a shadow mask on a glass substrate. The photoactive material PCBM:P3HT (ratio 0.75:1 by weight) was solved in 1,2-dichlorobenzene (46 mg/ml) and spin-coated on the substrates with a thickness of about 300 nm. To overcome the problem of spin-coating the water-based electron-blocking layer PEDOT:PSS (Clevios™ P VP CH 8000) on top of the hydrophobic blend layer, a sensible oxygen plasma treatment was performed creating polar oxygen species on the blend as described in [2]. The thickness of this low-conductive PEDOT:PSS layer is around 170 nm.

The conductive top electrode was prepared by adding ethylene glycol to PEDOT:PSS Clevios™ PH 1000 with a mixing ratio of 10:100 (by weight) which we determined as optimal ratio for high conductive films. Since the wetting ability of this PEDOT:PSS mix is significantly reduced compared to pure PEDOT:PSS films, about 0.3% of the wetting agent Dynol™ 604 was added to the mix to improve adhesion. After stirring for several hours, the formulation was spin-coated on top of the first PEDOT:PSS layer. Without Dynol™ we obtained similar results for the sheet resistance of spin-coated PEDOT:PSS layers but reproducibility suffered due to layer inhomogeneities. The annealing of the PEDOT:PSS layer was performed at 140 °C for 10 min on a hot plate.

Before characterization the devices were encapsulated with thin glass sheets and an epoxy resin.

Electrical characterization was performed by using a Keithley 2600 sourcemeter. The samples were illuminated with an halogen lamp with a power density of 100 mW/cm^2. The spectral resolved external quantum efficiency (EQE) and the transmission spectra were measured by lock-in-technique (Merlin Digital Lock-in Radiometry System), using a solar simulator with 300 W power and an Oriel Cornerstone 260 monochromator. The sheet resistance of the conductive PEDOT:PSS formulation was determined by 4-point-probe measurements of spin-coated films on glass substrates, using a Keithley 4200-SC System.

For determination of the cut-off frequency the organic photodiode were illuminated with square light pulses which were generated by a waveform generator Keithley 2602. The photocurrent of the diode was then amplified by a FEMTO Current Amplifier DHPCA-100 and the decrease of transient voltage by increasing pulse frequency was measured by a 1.5 GHz digital sampling oscilloscope (LeCroy Wavepro 715zi).

3. Results

3.1. Top-electrode transmission and sheet resistance

In Fig. 2 the transmission spectra of conductive PEDOT:PSS layers with different layer thicknesses are shown. For comparison, two alternative anode materials, commercially available indium-tin-oxide (ITO) and a

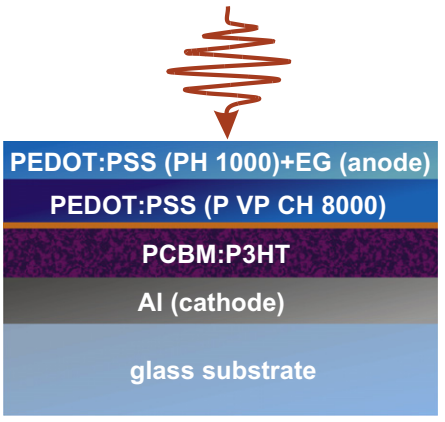

Fig. 1. Layer structure of a top-absorbing inverted photodiode with a polymeric top-contact layer. The thin layer between the photoactive layer (PCBM:P3HT) and PEDOT:PSS indicates the introduced oxide layer due to plasma treatment.

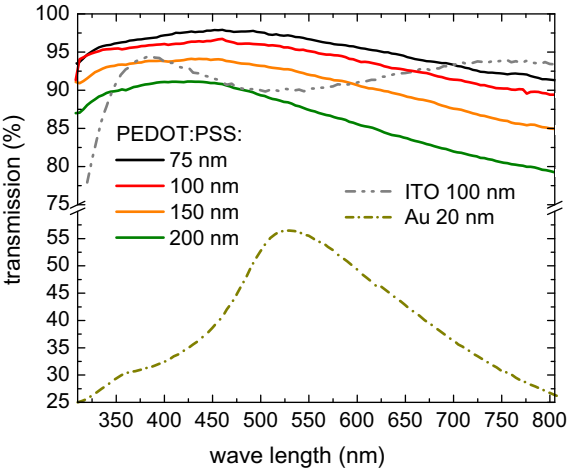

Fig. 2. Transmission spectra of PEDOT:PSS layers (with different thicknesses), commercially available ITO and a 20 nm thick gold layer electrode.

20 nm thick gold layer, are added to Fig. 2. Whereas ITO is a standard anode material used for non-inverted diodes, deposition on organic layers can decrease the inverted device performance because of the high temperatures and kinetic energies involved [12]. Instead a thin semi-transparent gold layer (work function: 5.1 eV) can be thermally evaporated on top of an inverted structure [2] but with poor transmission properties. Compared to these materials, the modified PEDOT:PSS exhibits a very high transmission even for thick layers. In Fig. 3 the increase of PEDOT:PSS transmission at a wave length of 450 nm is measured as a function of the sheet resistance and the layer thickness d which are related by $R_{sheet} \propto 1/d$. The wave length of 450 nm corresponds to the PEDOT:PSS maximum transmission and is also near to the absorption maximum of the PCBM:P3HT blend in the visible region. Even for the thickest investigated layers (up to 260 nm) shown in Fig. 3 the transmission is still >90%.

Compared with ITO, the transmission properties of the modified PEDOT:PSS layers up to a thickness of about 150 nm (see Fig. 2) are superior for a device with a PCBM:P3HT blend in the visible region of the spectrum, minor losses appear for the red region near the absorption edge of PCBM:P3HT at about 650 nm.

3.2. I–V curves

In Fig. 4 *I–V* characteristics of two inverted photodetectors with different anode materials are shown. The device structure with a gold layer as top electrode material was first proposed in [2] and improved here by using 1,2-dichlorobenzene (1,2-DCB) as solvent for the photoactive layer. 1,2-DCB, featuring a high boiling point, enables spin-coating of thick photoactive layers reducing the dark current to state-of-the-art values [13,14]. Furthermore, compared to the results in [2], 1,2-DCB improves the space charge limited current transport through the plasma-treated blend, comprising interfacial oxide states, to the

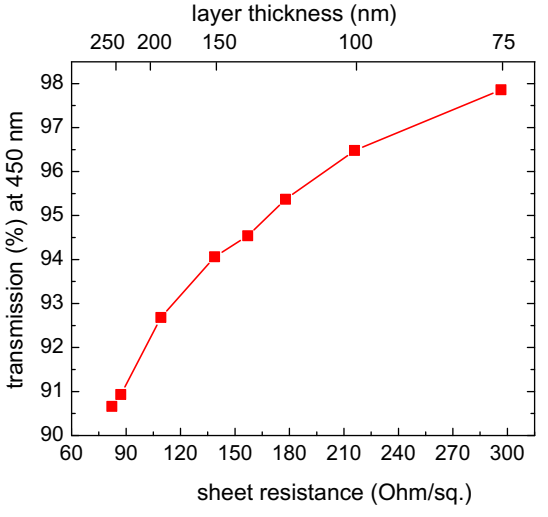

Fig. 3. Transmission change at a wave length of 450 nm (max. transmission) of PEDOT:PSS layers as a function of their sheet resistance and layer thickness.

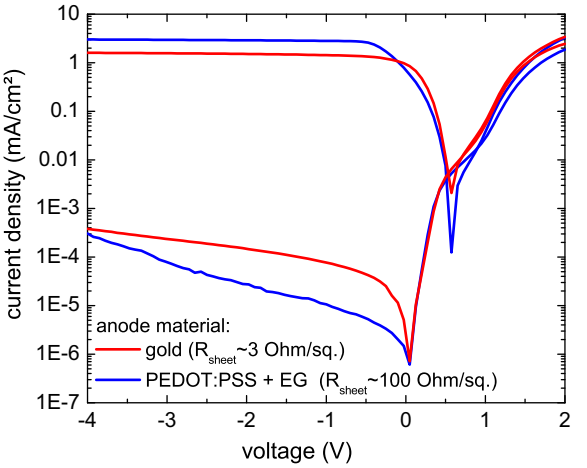

Fig. 4. Typical *I–V* curves of inverted diodes with a gold respective polymer electrode under dark and illuminated conditions. The applied light intensity was 100 mW/cm^2.

PEDOT:PSS layer. Going from forward to reverse bias, the photocurrent plateau value is reached at about −0.5 V as shown in Fig. 4, compared to −1 V for using toluene as solvent [2]. This solvent dependence of the space charge limited current is still not clear but might be related to an increased number of hopping paths since the overall P3HT concentration on the blend surface can be increased by the slow evaporation of 1,2-DCB [15].

The second *I–V* characteristic shown in Fig. 4 results when replacing the semi-transparent gold anode with a polymer electrode comprising a sheet resistance of 100 Ω/sq. The device sustains a similar low dark current for high reverse bias (2×10^{-4} mA/cm^2 at −4 V), but even one order of magnitude lower current for smaller reverse bias (1×10^{-5} mA/cm^2 at −1 V). The current density under illumination increases about 50% due to the enhanced transparency of the polymer layer thus improving the photocurrent on/off-ratio at −4 V to four orders of magnitudes. The forward current density, strongly influenced by deep traps introduced by the plasma treatment as described in [2], is slightly reduced due to the higher resistance of the polymer electrode (100 Ω/sq) compared to the gold electrode (3 Ω/sq).

Comparing the impact of different layer thicknesses and according sheet resistances of the anode on the *I–V* characteristics, we found that by increasing R_{sheet} from 100 to 300 Ω/sq neither the for a photodetector relevant dark nor light backward current are influenced within accuracy of fabrication and characterization, whereas the forward current density slightly decreases. Since a photodetector is operated in reverse bias, the increased serial resistance introduced by the polymer electrode, even if deposited as a thin layer with lower conductance, does not limit the electrical detector performance.

3.3. EQE

The improved light transmittance of the inverted diode with PEDOT:PSS anode instead of gold manifests itself by

remarkable values of the external quantum efficiency (EQE). In Fig. 5 the EQEs of inverted photodetectors with gold (20 nm thick) respective polymer anode (200 nm thick) are shown. Whereas the narrow transmission spectrum of a 20 nm thick gold layer with a transmission maximum of about 55% showed in Fig. 2 is responsible for an EQE inhibiting a maximum of only about 45% at 530 nm (−4 V) and efficiency losses at the short wave length range, the replacement with PEDOT:PSS increases the short wave length part of the EQE and shifts the maximum over 70% (−4 V). This value is comparable to the EQE of state-of-the-art non-inverted ITO photodetectors [13,14].

The dependence of the EQE on the sheet resistance is shown in the inset of Fig. 5. With increasing R_{sheet} (decreasing layer thickness) from 100 to 300 Ω/sq the EQE decreases about 7.5%. This is interesting since the transmission at the same wavelength (see Fig. 3) increases by 6.5% when increasing R_{sheet} from 100 to 300 Ω/sq. Consequently, decreasing the sheet resistance has bigger impact on device performance than increasing the transmission. An optimal layer thickness for the inverted photodetector could not be determined since lowering of the spin-coating speed results in the formation of inhomogenous PEDOT:PSS films and consequently large EQE variations.

3.4. Cut-off frequency

The cut-off frequency is a measure of the photodiode response to time-modulated incident light. Commonly, it is defined as the frequency at which the photocurrent pulse height is attenuated by a factor of $\frac{1}{\sqrt{2}}$, the so called −3 dB cut-off frequency f_c. It is influenced by the transit time t_{tr} of the light generated carriers traveling through blend and PEDOT:PSS to the electrodes. The transit time is given by $t_{tr} = d^2/\mu V$ with layer thicknesses d, carrier mobility μ and voltage drop V. For inverted photodetectors with different conductive electrodes but with the same layer structure in between, the transit time towards the electrodes is constant. The serial resistance of the electrodes, proportional to the sheet resistance R_{sheet}, plus additional load resistances sum up to a total resistance R. The time constant $t_{rc} = RC$ takes this resistance into account, together with the photodiode capacitance $C \propto A/d$ (with diode area A).

The overall device time constant t is the root-sum-square value of the individual time constants [16]:

$$t = \sqrt{t_{tr}^2 + t_{rc}^2} \quad (1)$$

It is related to the cut-off frequency $f_c \propto 1/2\pi t$.

Since the sheet resistance of a polymer electrode can be about two orders of magnitude higher than that of a metal electrode, also t_{rc} can increase remarkably. To investigate the impact of the sheet resistance on the dynamic behavior of photodiodes with a polymer top electrode, the cut-off frequencies were measured.

In Fig. 6 the frequency response of an inverted diode with a polymer electrode (100 Ω/sq) on illuminating it with square light pulses (light intensity 0.8 mW/cm², duty cycle 50%) is shown. At about 420 kHz the −3 dB attenuation is reached. This is a state-of-the-art −3 dB cut-off frequency for organic photodiodes [2,14,17]. Increasing R_{sheet} from 100 to 300 Ω/sq results in a cut-off frequency decrease to about 260 kHz.

Considering this experimentally determined dependence between sheet resistance and cut-off frequency in the inset of Fig. 6 and assuming that C is equal for each diode, it is possible to determine a proportional factor $x = t_{tr}/t_{rc}$ for different t_{rc} respective R_{sheet} with Eq. (1). Assuming $R \propto R_{sheet}$, a change of R_{sheet} also causes a proportional change of t_{rc}. For the device with the lowest sheet resistance, R_{sheet} = 100 Ω/sq, $x = 2$ follows, which means that t_{tr} contributes about four times more (see Eq. (1)) to the overall time constant than t_{rc}. In addition, also an upper limit of the cut-off frequency of the photodetectors with polymer electrodes can be estimated with Eq. (1) and the data of the inset of Fig. 6. With $RC = 0$ only the transit time determines the overall time constant t, resulting in an

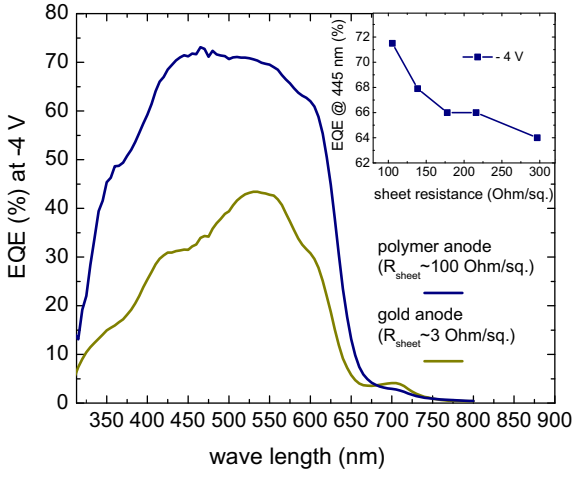

Fig. 5. External quantum efficiency (EQE) of devices with gold respective polymer electrodes. The inset shows the EQE decrease with increasing anode sheet resistance.

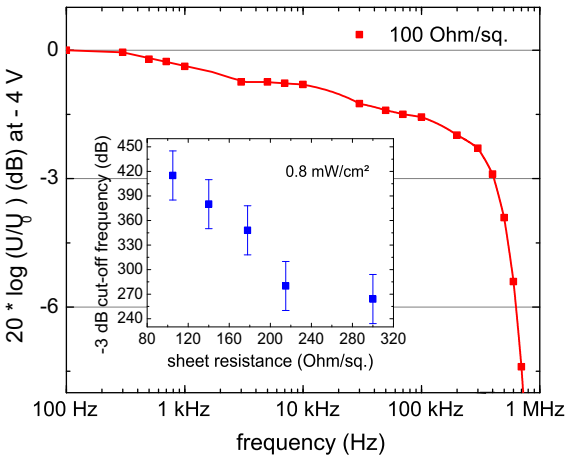

Fig. 6. Frequency response of an photodiode with electrode sheet resistance of 100 Ω/sq at −4 V. The inset shows the dependence of the −3 dB cut-off frequency on the electrode sheet resistance.

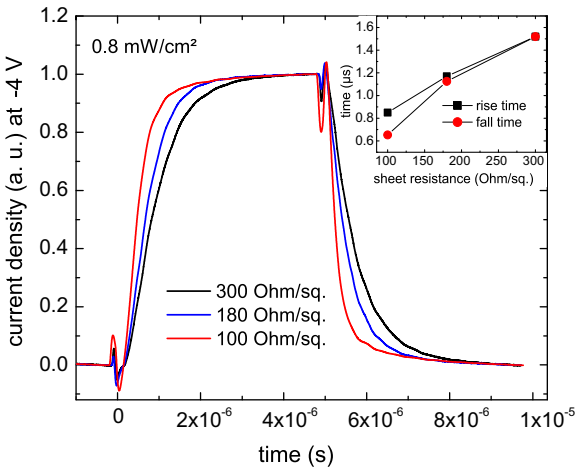

Fig. 7. Dynamic photocurrent response for diodes with different sheet resistances. The applied light pulse length was 5 µs and the frequency 100 kHz. The inset shows the decrease of rise and fall time with decreasing sheet resistance. Overshoots are dedicated to capacitive effects arising from cables.

upper cut-off frequency limit of about 470 kHz which is barely higher as the highest cut-off frequency measured in Fig. 6.

In Fig. 7 typical light pulse responses of the photodetectors with different anode sheet resistances are shown for a light pulse frequency of 100 kHz. The shape of the response changes for the different resistances, meaning that also rise and fall time (the fall time is defined as time required for a pulse to decrease from 90% to 10% of the peak value) change accordingly. This is shown in the inset of Fig. 7 where the response times double for increasing R_{sheet} from 100 to 300 Ω/sq. The behavior is consistent with the trend shown before in Fig. 6 where the cut-off frequency reduces approximately by half.

4. Conclusion

In conclusion, we have demonstrated the fabrication of an ITO-free inverted organic photodetector with state-of-the-art performance regarding the low dark current, the high on/off-ratio (four orders of magnitude at −4 V) and the high EQE of 70% (at 500 nm, at −4 V). The higher sheet resistance of the transparent polymer electrode, containing ethylene glycol as conductivity enhancer, does not significantly affect the photodetector performance. Comparing photodetectors with different electrode sheet resistances between 100 and 300 Ω/sq, we found out that the thickest and most conductive electrode lead to the highest EQE in spite of higher transmission losses compared with the lower conductive electrodes. This implies that a further conductivity enhancement could even increase the EQE to higher values. The highest cut-off frequency we measured was around 400 kHz, which is in spite of the high anode sheet resistance of 100 Ω/sq a state-of-the-art value.

The solution-processability of all layers except for the cathode makes this organic photodiode suitable for an easy deposition and integration on top of inorganic read-out-electronics such as CMOS-circuits.

because of the crystallization occurring upon annealing. In 2010, Anthopoulos et al. continued this work and demonstrated the suitability of squarylium dyes as ambipolar semiconductors [20].

Although to date the mobility of squarine based transistor is not as high as ordinary semiconductors, the enhancement via simple and cheap post-process such as annealing is a potential advantage. In this paper, we fabricated p-type transistors based on a series of indolium squarine dyes, ISQ1, ISQ2 and ISQ3 (Fig. 1), and compared the effect of structural factors, such as intramolecular H-bondings and steric hindrance, on the phase transition and electrical properties enhancement of the semiconducting layer. The mobility of solution processed device came up to 4.8×10^{-3} cm^2/Vs and the highest mobility of 0.2 cm^2/Vs was achieved in single crystal device.

2. Experimental

2.1. General description

All commercial available materials were used as received without further purification unless otherwise stated. All reactions were heated in refluxing under Ar atmosphere with anhydrous solvents. ^1H NMR data were collected on JEOL JNM-ECA 600 MHz spectrometer with chemical shifts reference to tetramethylsilane in $CDCl_3$. Mass spectrometry was performed with Thermo Fisher LTQ LCMS spectrometer. Material purity was analyzed with Agilent 1100 High Performance Liquid Chromatograph (HPLC). Thermal gravimetric analysis was performed in nitrogen with TA Instrument TGA Q5000 (heating rate of 10 °C/min). Optical images were taken via Olympus BX51M microscope. The dynamic atomic force microscopy (DFM) of the ISQ film was taken by Seiko SPI 3800 Series SPA-400 scanning probe microscope.

2.2. Material synthesis

The octadecyltrichlorosilane (OTS) and 3,4-dihydroxy-3-cyclobutene-1,2-dione was purchased from Acros. 2,3,3-trimethyl-4,5-benzo-3H-indole was purchased from Alfa Aesar. The remaining chemicals and solvents were purchased from Sigma–Aldrich. 2,4-bis(3,3-dimethyl-2-benzoindolinylidenemethyl)cyclobutenediylium-1,3-diolate (ISQ3) was synthesized by a modified procedure accordi ng to previously published methods [21]. 3,4-dihydroxy-3-cyclobutene-1,2-dione and 2,3,3-trimethyl-4,5-benzo-3H-indole in molar ratio 1:2 were heated in toluene:*n*-butanol for 6 h and then heated azeotropically using a Dean–Stark trap for 2 h. The extra solvents were removed by vacuum distillation. The precipitate was isolated and purified by column chromatography and recrystallization to get dark green crystals with a yield of 84%. The purity was assessed by NMR and HPLC and found to be higher than 99.5%. ^1H NMR ($CDCl_3$): δ 13.13 (s, 2H, NH), 7.39–7.96 (d or t, 12H, benzoindole), 5.60 (s, 2H, CH), 1.74 (s, 12H, CH_3). MS-ESI (CH_2Cl_2) *m/z*: 495.45 (M–H); calcd for $C_{34}H_{28}N_2O_2$: 496.22. Anal. found: C 81.75, H 5.66, N 5.58; Anal. calcd: C 82.23, H 5.68, N 5.64. The other ISQ compounds were synthesized and purified by similar procedures.

2.3. X-ray diffraction

The purple prism crystal of ISQ2 and dark green platelet crystal of ISQ3 were grown by slow evaporation from the ISQ/dichloromethane solution at room temperature. X-ray crystallography was performed on a Bruker CCD diffractometer for ISQ2 at 293 K and on a Rigaku CrystalClear CCD diffractometer for ISQ3 at 153 K. Computations were performed using the Shelxtl NT ver. 5.10 program package [22] on an IBM PC 586 computer [22]. Analytic expressions of atomic scattering factors were employed, and anomalous dispersion corrections were incorporated [23]. Crystal drawings were produced with XP [22].

The film samples were prepared by vacuum deposition of 50 nm ISQ on silicon wafers. X-ray diffraction patterns were collected by Rigaku-2500 diffractometer equipped with a Cu target. 2θ scan ranged from 3° to 100° at a speed of 6°/min.

The film samples were prepared by vacuum deposition of 50 nm ISQ on silicon wafers. X-ray diffraction patterns were collected by Rigaku-2500 diffractometer equipped with a Cu target. 2θ scan ranged from 3° to 100° at a speed of 6°/min.

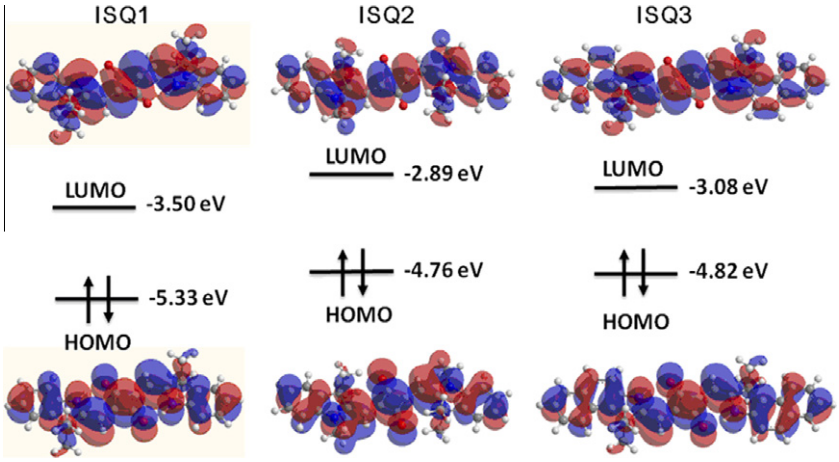

Fig. 2. HOMO and LUMO of the singlet ground-state ISQ.

2.4. Energy band

Absorption spectra of 10^{-3} M ISQ/CH_2Cl_2 solution in a quartz cuvette were recorded with Aglient 8453 UV–Vis spectrophotometer. The maximum absorption edges were observed at 664 nm for ISQ2 and 713 nm for ISQ3, from which the band gaps of ISQ2 and ISQ3 were estimated to be 1.87 and 1.74 eV respectively. The electrochemical properties were investigated by cyclic voltammetry. The measurement was performed on a Princeton Applied Research Potentiostat/Galvanostat model 283 voltammetric analyzer in dichloromethane at a scan rate of 100 mV/s and a range from −2 to 2 V. Ferrocene was added as an internal reference. From the oxidation with peaks for ISQ and ferrocene, the highest occupied molecular orbital (HOMO) level of ISQ2 and ISQ3 was estimated to be −4.76 and −4.80 eV. According to the spectrum data, the lowest unoccupied molecular orbital (LUMO) level of ISQ2 and ISQ3 was deduced to be −2.89 and −3.08 eV.

2.5. Device fabrication and characterization

Bottom gate top contact field-effect transistors were fabricated on heavily n^+ doped silicon wafer with a 300 nm thermally grown SiO_2 gate dielectric. The wafers were subsequently cleaned by sonication in toluene, acetone and isopropynol. SiO_2 surface was treated by piranha solution and then modified with OTS. Forty-five nanometers ISQ were thermally deposited at a rate of 1 Å/s under a pressure of 10^{-4} Pa. For solution processed devices, 0.4 wt% ISQ/$C_2H_4Cl_2$ solution was spin coated onto the substrate in glove box. Forty-five nanometers films were obtained and then baked at 40 °C for 10 min. For single crystal devices, the ISQ crystal strips were in situ assembled on the OTS modified substrates by immersing the substrates into 10^{-3} M ISQ/CH_2Cl_2 solution and then slowly evaporating the solvent in a saturated hexane atmosphere for two weeks. Finally 50 nm Au was vacuum deposited through a shadow mask as drain and source electrodes. Electrical characteristics of the transistors were measured with Keithley 4200 in air and without encapsulation.

3. Results and discussion

3.1. π–π packing mode on intermolecular electrostatic interaction

Due to the recomposition effect of squaric acid, 1,3-sysmetrically substituted squarines hold separate charge centers. Through rapid configuration resonance, positive charges are averagely dispersed on both side groups (Fig. 1) [24]. ISQ1 was studied as a basic structure. ISQ2 and ISQ3 were employed as comparison. For ISQ1 and ISQ3, the intramolecular H-bondings between squaric ring and the indole ring help constructing a quasi-heptatomic ring and benefitted the flat structure. For ISQ2, as the hindrance of attached methyls on nitrogens, no H-bondings formed between the indole ring and the squaric ring. There is also a 180° reversal in the plane of the side groups [25]. For ISQ3, the conjugated area was enlarged by extending aromatic rings on indole groups, which also increased rigidity and the hindrance of molecular motion. Geometrical configurations were explored by theoretical calculation at B3LYP/6-311+G(d,p) level and verified by crystal structural diffraction. Fig. 2 shows the profiles and the relative energy levels of HOMO and LUMO. As the frontier orbital was delocalized among the whole molecular plane, a close face to face packing would benefit the π–π carrier transport between neighboring molecules.

The crystal packing of ISQs was shown in Fig. 3. Face to face packing was found in the cell. The closest interplanar distance of ISQ1 is 3.6 Å. For ISQ2 this value is 3.9 Å, larger than 3.6 Å, the upper limit of general π–π interaction. For ISQ3 it is only 3.3 Å, indicating better conjugated transport efficiency. Twenty-five- and eighteen degree torsions of side groups were observed in ISQ2 and ISQ3 respectively, which is different with the near planar structure of ISQ1.

To characterize the distribution of electron-rich and electron-deficient parts, net charge calculation was

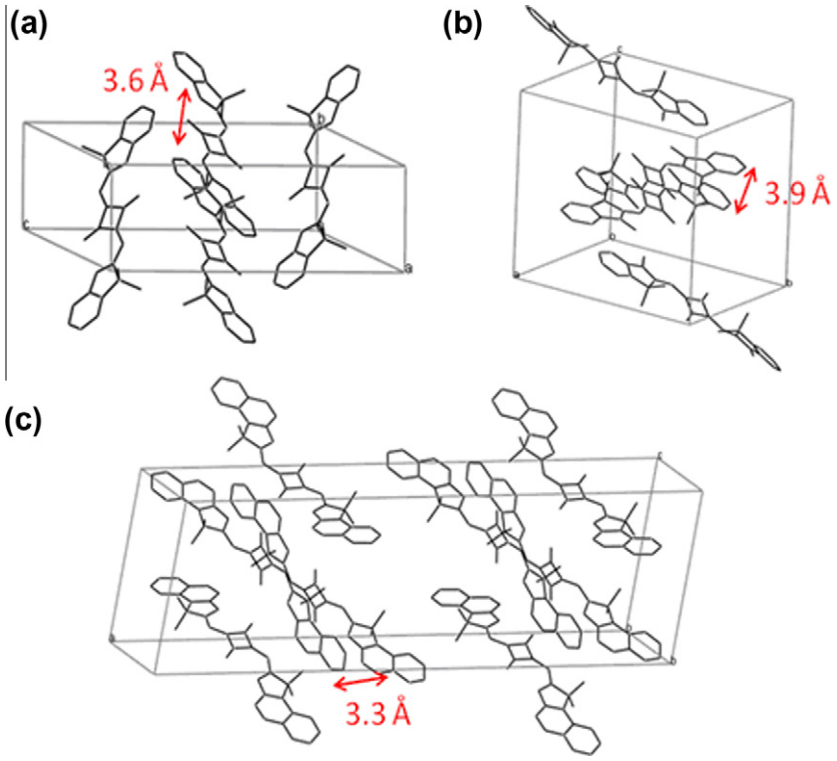

Fig. 3. Crystal packing of ISQ1 (a), ISQ2 (b) and ISQ3 (c) in a single cell (hydrogens omited).

performed by natural bond orbital population at PBE1PBE/6–311+G(d, p) level. It was found the central squaric ring with two oxygen atoms carried more negative charges and the two side groups carried more positive charges. Remarkably, the staggered packing of squaric rings and side groups for adjacent molecules accorded with this result. The electrostatic interaction, marked by double arrows in Fig. 4, also indicated that the torsion originated from the mismatch of the charge centers.

In ISQ1, the positive centers face well against the negative centers. Besides the intramolecular H-bondings, the electrostatic attraction of opposite charge centers helps keeping planar packing. However, for ISQ2, no H-bondings assist in limiting the rotation of indole groups and the hindrance of N-methyls prevents fine packing between inverse centers. The shift of the relative positions causes partly overlapped positive areas. The direction of the electrostatic repulsion is consistent with the observed torsion. Though ISQ3 is structurally similar to ISQ1, the extended benzene rings of side groups intruded into the positive region where repulsion took place.

To investigate whether the contrary charge centers could enable ambipolar transport, inner reorganization energy (λ_h and λ_e) was calculated based on the result of energy and geometrical optimization for ISQ ions at B3LYP/6-311+G(d,p) level: $\lambda_h = E^+/E - E + E/E^+ - E^+$, $\lambda_e = E^-/E - E + E/E^- - E^-$, where E, E^+ and E^- are the optimized energy of neutral, positive and negative molecules, E^+/E means the static energy of positive molecule based on the geometrically optimized configuration of neutral molecule; E/E^+, E^-/E and E/E^- are defined correspondingly. For ISQ1, $\lambda_h = 0.168$ eV, $\lambda_e = 0.271$ eV; for ISQ2, $\lambda_h = 0.208$ eV, $\lambda_e = 0.266$ eV; for ISQ3, $\lambda_h = 0.134$ eV, $\lambda_e = 0.264$ eV. The

results predicted ISQs are mainly hole-transporters and ISQ3 might have higher mobility than ISQ1.

3.2. ISQ field-effect transistors

The processability of three ISQ compounds is similar. The decomposition temperatures were estimated to 265 °C for ISQ2 and 288 °C for ISQ3, and both have good solubility in halohyrocarbons. The film quality via vacuum thermal deposition and solution process was investigated by DFM (Fig. 5). The root mean square (RMS) roughness is generally less than 1 nm, except ISQ2 spin-coated film because crystallization during spin coating caused rather coarse surface.

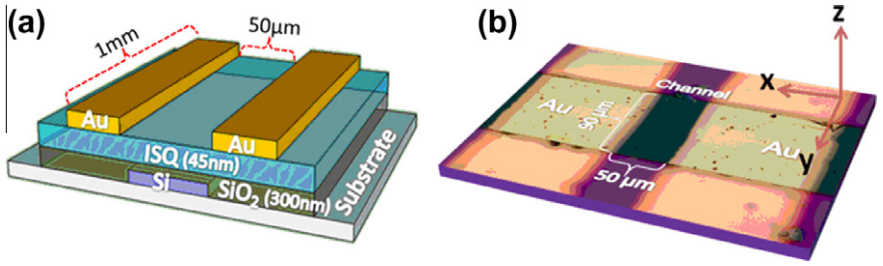

Fig. 6. (a) Architecture of ISQ field-effect transistor and (b) optical image of ISQ3 single crystal transistor.

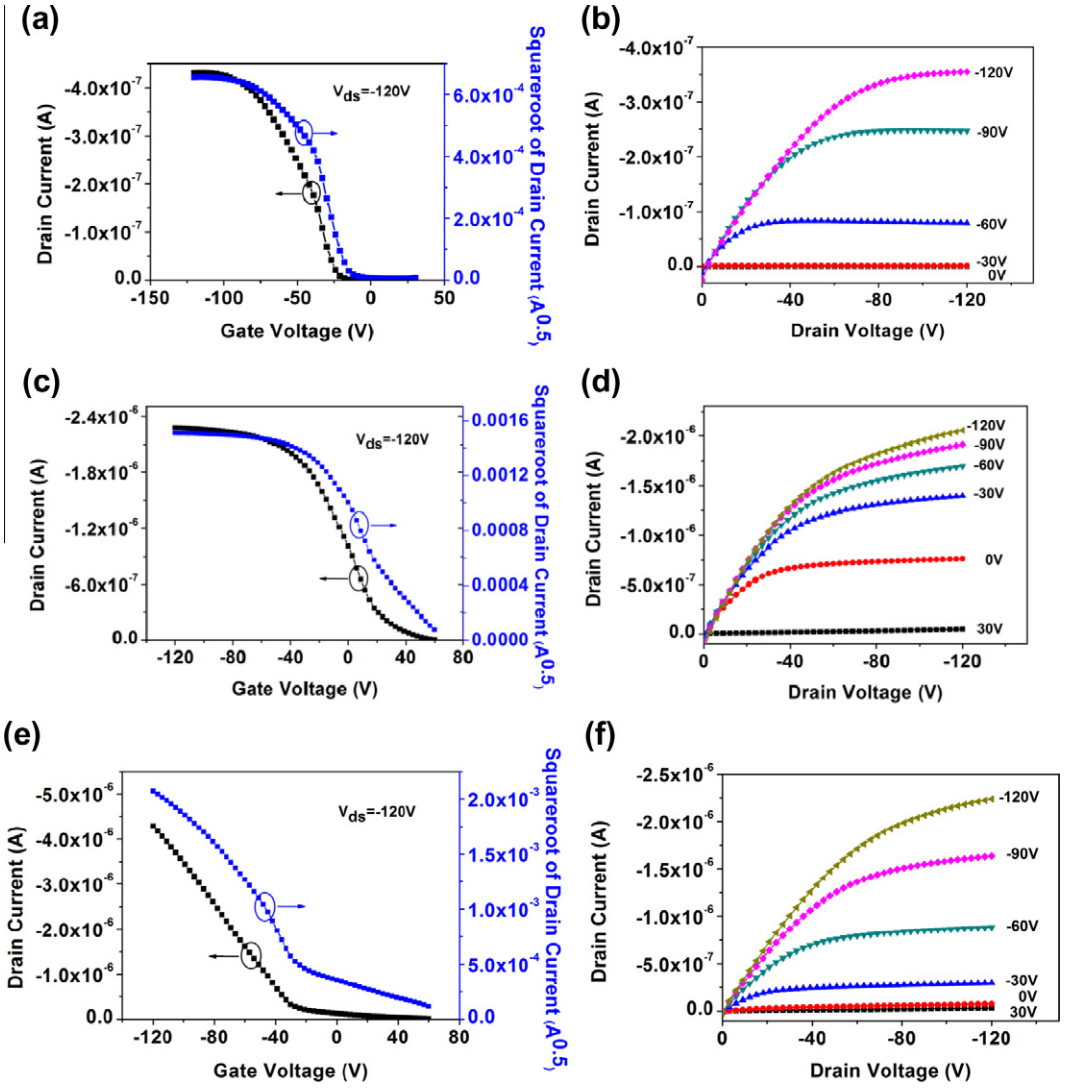

Fig. 7. Transistor characteristic curves: (a, b) ISQ1 by thermal evaporation; (c, d) ISQ3 by spin coating, with *W*/*L* of 20; (e, f) ISQ3 single crystal with *W*/*L* of 1.8.

Top-contact bottom-gate transistors based on thermally deposited and spin coated films of ISQ2 and ISQ3 were fabricated on Si/SiO_2 wafers (Fig. 6a). In addition, single crystal device of ISQ1 and ISQ3 was also obtained by solution growth (Fig. 6b). Except spin coated device of ISQ2, all ISQ transistors exhibited typical p-type field effect characteristics with saturated output. Post annealing in the N_2-filled glove box at 80 °C for 8 h accelerated the crystallization of the ISQ films, and consequently enhanced the device performance. The highest mobility for thermal

[a] The listed values are derived from the devices with the best mobility.

evaporated devices was achieved by ISQ1. The best spin-coated device and single crystal device were achieved by ISQ3. Representative transfer and output curves of these devices were displayed in Fig. 7. The best electrical parameters for all kinds of devices were summarized in Table 1.

3.3. Mobility dependence on crystallization and morphology of the channel

As estimated by inner reorganization energy, the performance of ISQ2 devices is lower than the ISQ1 and ISQ2. This could be explained by the large π–π interplanar distance and the hindrance from N-methyls. ISQ3 was expected to have better performance than ISQ1. Its evaporated device has mobility of 5.4×10^{-4} cm^2/Vs and on/off ratio of 10^4, which is the highest among all samples before annealing. However, no visible crystalline regions formed after annealing, and thus little performance improvement was detected. To compare the speed of crystallization, 50 nm ISQs were thermally deposited on silicon wafers and characterized by XRD. Initially all samples had same diffraction pattern as pure silicon wafers (Fig. 8a). In the test 24 h later, diffractional peaks appeared only in ISQ1 and ISQ2 films, which indicated a trend from amorphous state to polycrystalline state (Fig. 8b). The difficulty for evaporated ISQ3 films to reorder its micro structure into crystal phase could be explained by the large hindrance from the structural rigidity.

For solution processed ISQ3 device, solvent in the films counteracted the effect of the steric hindrance and made the films' polycrystallization possible. From the optical image (Fig. 9b), we can find that the annealed channels contained the light blue area (region 1) and the dark blue area (region 2). The magnified images show that, in region 1, the polycrystalline film is continuous (Fig. 9c), while region 2 was filled with large and separate crystal particles (Fig. 9d). As the two regions are parallely connected between the electrodes, assuming that the threshold voltages of the two regions are uniform, the total saturated drain current could be expressed as

$$I = I_1 + I_2 = \frac{\mu_1 W_1 C_0 (V_G - V_T)^2}{2L} + \frac{\mu_2 W_2 C_0 (V_G - V_T)^2}{2L} \quad (1)$$

where μ_1, W_1 and μ_2, W_2 are the mobilities and the channel widths of region 1 and 2, respectively. Assuming φ_1 and φ_1

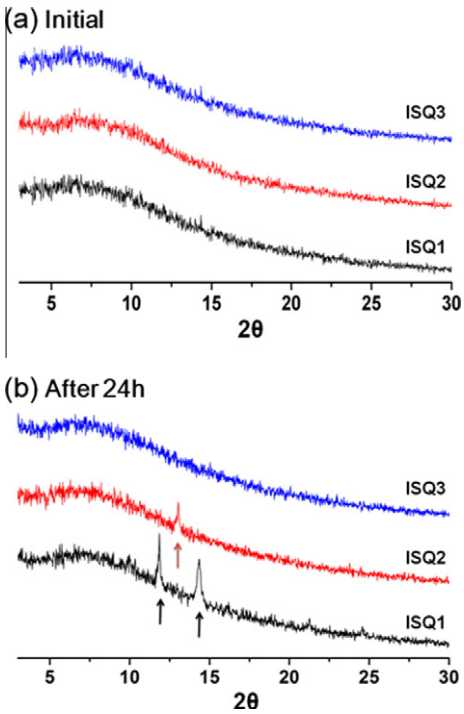

Fig. 8. XRD patterns of 50 nm ISQ films on silicon. (a) Initial; (b) 24 h later.

were the fractions of region 1 and region 2 in the whole channel width, respectively, then

$$W_1 = W \cdot \varphi_1 \quad (2)$$

$$W_2 = W \cdot \varphi_2 \quad (3)$$

From Eqs. (1)–(3), we can get Eq. (4):

$$I = \frac{WC_0 (V_G - V_T)^2}{2L} (\mu_1 \varphi_1 + \mu_2 \varphi_2) \quad (4)$$

Therefore the effective mobility (μ_e) of the whole channel could be written as

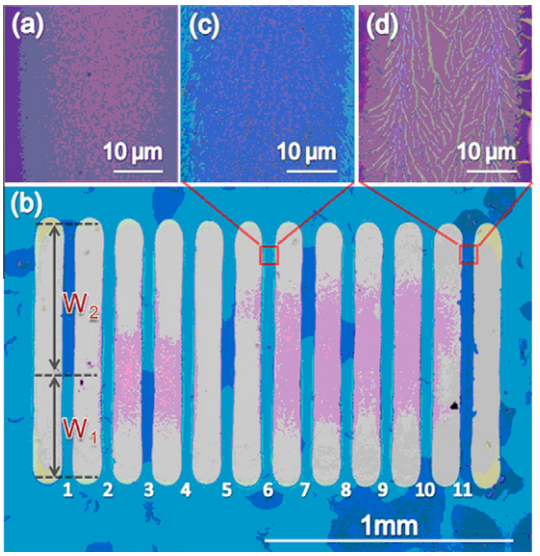

Fig. 9. Optical images of the spin coated ISQ3 device: (a) the channel before annealing; (b) the total 11 channels after annealing; the morphology of (c) region 1 and (d) region 2.

$$\mu_e = \mu_1\varphi_1 + \mu_2\varphi_2 \tag{5}$$

Since $\varphi_1 + \varphi_2 = 1$, supposing the mobility of region 1 in all channels is uniform and the mobility of region 2 in all channels is uniform, Eq. (5) could be changed into Eq. (6).

$$\mu_e = (\mu_1 - \mu_2)\varphi_1 + \mu_2 \tag{6}$$

According to Eq. (6), we know the effective channel mobility is linearly dependent on the percentage of each region.

The data of all the 11 channels on one substrate were listed in Table 2. It was found the linear fitting of Eq. (6) conformed well to the experimental values (Fig. 10). The average mobilities of region 1 and 2 in this device were thus determined as 2.8×10^{-3} and 4.6×10^{-5} cm^2/Vs respectively from the fitting parameters. We think the higher mobility of region 1 resulted from the better transport in polycrystalline phase and fine continuity. In region 2, excessive crystallization caused discontinuity and large grain boundaries, which prohibited the transport of the carriers and resulted in the low mobility. Therefore, the channel status of the best mobility (4.8×10^{-3} cm^2/Vs) in our experiments should consist of region 1. Our analysis indicated that annealing condition and structural property of semiconductors are important factors of the channel structure, and should be carefully controlled to improve the device performance.

In single crystal device of ISQ3, the highest mobility of 0.2 cm^2/Vs was obtained with an on/off ratio of 3×10^2, better than ISQ1 (0.078 cm^2/Vs and 10^2). One possible reason for this improvement is the enlargement of side conjugated groups. However, according to the stacking modes and the interplanar distances of ISQ1 and ISQ3 crystals (shown in Fig. 3), the anisotropies of the transport efficiency should exist. At present, mobilities of ISQ1 and ISQ2 crystals were measured only in *x*–*y* plane as shown in Fig. 6b and the molecular orientation along the channel is not clear yet. Therefore, more research works on the anisotropic transport are necessary in our follow-up works for understanding the mechanisms of charge transport in ISQ crystals. Meanwhile, it was noticed that large thickness of crystal (50 μm for ISQ3 and 30 μm for ISQ1) weakened field induction and the top contact structures increased the off current. The potentiality of ISQ dyes has not been adequately exploited yet.

Table 2
The effective channel mobilities of spin coated ISQ3 transistors after annealing.

Channel No.	φ_1(%)	φ_2(%)	μ[cm^2/(Vs)]
1	42	58	1.14×10^{-3}
2	100	0	2.96×10^{-3}
3	65	35	1.83×10^{-3}
4	100	0	2.75×10^{-3}
5	75	25	1.97×10^{-3}
6	100	0	2.85×10^{-3}
7	67	27	1.87×10^{-3}
8	83	17	2.53×10^{-3}
9	100	0	2.74×10^{-3}
10	89	11	2.55×10^{-3}
11	0	100	1.11×10^{-4}

3.4. Stability

All the annealed devices were kept in air without encapsulation. The mobility in a period of 4 months was shown in Fig. 11. Generally there was no break down and severe aging for these devices. The mobility of thermal vacuum deposition device of ISQ1 decayed fast in the first few months. Ambient H_2O and O_2 were thought to be the predominant physical reasons. The sudden degradation of ISQ3 single crystal device from the 3rd month may result from the natural airslake and the wear of Au electrodes in repeating measurements. As the compact structure of crystal phase is effective in carrier transport and preventing the infiltration of ambient impurity, the rising mobility in ISQ2 thermal evaporated and ISQ3 spin-coated devices could be related with the gradual completion of spontaneous crystallization process.

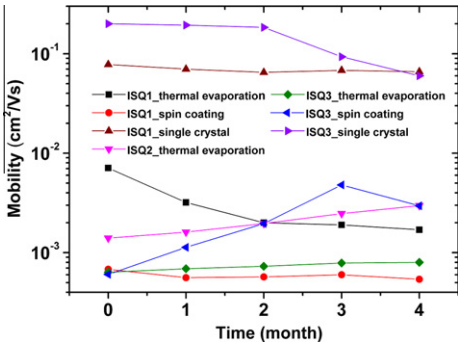

Fig. 11. The stability of ISQ transistors in air.

4. Conclusion

In summary, a series of ISQ compounds were systematically investigated as semiconductors in OFETs. The comparison between structure and performance clarified the relation of the intermolecular electrostatic interaction to the packing configuration in crystal phase. The crystallization speed and morphology of polycrystalline film could be controlled by adjusted the structural rigidity. Highest mobility of 0.2 cm^2/Vs was obtained, which could be improved by further optimization. Moreover, the application of ISQ compounds broadens the scale for stable semiconductors in OFETs.

Acknowledgments

The authors greatly appreciate the help from Prof. Ruji Wang, Prof. Yongge Wei and Prof. Huizhong Kou in the analysis of crystal structure. This work was financially supported by the National Natural Science Foundation of China (60877026 and 50990062), the National Key Basic Research and Development Program of China under Grant (2009CB930602).

Light-Emitting Diodes (PhOLEDs). Specificity of LEDs compared to LECs is that light emission is instantly observed upon application of a sufficient voltage. PhOLEDs have been without contest the most widely investigated devices [12] even if use of neutral metal complexes limits the possibilities offered by coordination chemistry. As drawbacks, PhOLEDs are highly sensitive to the doping concentration and devices suffer from reduced emission efficiency while increasing the concentration of phosphorescent emitters, thus rendering their elaboration more difficult than LECs [13]. Recently, new devices involving the use of iridium soft salts based on an equimolar mixture of cationic and anionic iridium complexes have been reported [14]. Even if charged iridium complexes are included in the active layer, size of iridium (III) ions prevents their motions and resulting devices thus behave like a conventional diode.

Herein, we report on the synthesis of a new iridium (III) soft salt combining a cationic heteroleptic iridium complex prepared with a bipyridine as the ancillary ligand and an anionic iridium complex bearing thiocyanate anions as ligands. Soft salt was investigated as emitter in PhOLEDs and device characteristics of the corresponding device are reported. Cationic complex was also used as single emitter in LEC device and relevant data are summarized. Electrochemical, UV–visible absorption and photoluminescence properties were also investigated. DFT results obtained for soft salt **C·A** and cationic complex **C·PF$_6$** allowed us to rationalize the effect of the substituent on the optical properties and to assign the nature of the relevant excited states involved in the electroluminescence process.

2. Experimental

2.1. General informations

Electrochemical measurements were performed in a three electrode cell equipped with a 1 mm diameter carbon disk as the working electrode, platinum wire as the counter electrode and $Hg_2Cl_{2(s)}/Hg_{(l)}$ (saturated calomel electrode SCE) as the reference electrode. The supporting electrolyte was tetrabutylammonium perchlorate (TBAP) 0.1 M (Fluka, puriss.) and the solutions were deaerated by argon bubbling prior each experiment. Cyclic voltammograms (CVs) were recorded with a 600 CH Instruments potentiostat connected to a PC. Mass spectroscopy was performed by the Spectropole of the Université Paul Cézanne (Marseille). ESI mass spectral analyses were recorded with a 3200 QTRAP (Applied Biosystems SCIEX) mass spectrometer. The HRMS mass spectral analysis was performed with a QStar Elite (Applied Biosystems SCIEX) mass spectrometer. UV–visible spectra were recorded using a CARY 500 UV–visible–NIR spectrophotometer (Varian). Each sample was analyzed in a similar way: about 10 μL of a 1 mM solution of the chromophore were introduced into the cell (1 cm optical path) and diluted with an appropriate volume of solvent (spectroscopic grade), in order to obtain absorbance values lower than 1. Measurements of the molar absorption coefficient were made by recording the spectra corresponding to several aliquots of 10 μL of the chromophore solution in 2 mL of solvent, and then drawing a Beer–Lambert plot. Fluorescence spectral analyses were carried out with a Cary Eclipse spectrofluorimeter (Varian). Optical density was adjusted below 0.1 to avoid reabsorption artifacts. The fluorescence decay curves were obtained with a time-correlated single-photon-counting method using a titanium/sapphire laser (82 MHz, fundamental wave: 695–1000 nm, repetition rate lowered to 4 MHz by a pulse-peaker, 1 ps pulse width) pumped by an argon ion laser. A doubling crystal was used to reach 495 nm excitation. Solid state spectroscopic data were obtained on thin films of material deposited by sublimation under secondary vacuum (10^{-6} mbar) from organic-designed temperature-controlled thermal oven with alumina beds. Thickness of approx. 50 nm was controlled using built-in piezoelectric sensor assuming a material density of 1.25. Solid state absorption and emission spectra were recorded with a UV MC2 spectrophotometer from the SAFAS Monaco society and a Photon Technology International spectrofluorimeter. ^{1}H and ^{13}C NMR spectra were determined on a Bruker Advance DPX 300 MHz spectrometer: ^{1}H (300 MHz) and ^{13}C (75.5 MHz). The ^{1}H chemical shifts were referenced to the solvent peak: $CDCl_3$ (7.26 ppm), and the ^{13}C chemical shifts were referenced to the solvent peak: $CDCl_3$ (77.0 ppm). ^{1}H and ^{13}C NMR spectra were also obtained at room temperature in 5 mm o.d. tubes on a Bruker Avance 300 spectrometer equipped with a QNP probe head at the University of Versailles. All calculations were performed with the Gaussian03 program [15] in vacuo on a Nec TX7 with 32 processors Itanium 2 of the MESO center of the ENS Cachan. Orbitals were generated with the cubgen module of Gaussian and visualized with GaussView 3.0 of Gaussian Inc. GaussSum 2.1 [16,17] was used for the electronic spectrum simulation. The equation employed by the program to calculate the theoretical spectrum and the extinction coefficients is based on Gaussian convolution and is reported in the open source code of the program (available at http://gausssum.svn.sf.net/viewvc/gausssum/Trunk/src/gausssum/).

All starting materials and solvents were purchased from Aldrich and used as supplied commercially. Dimers Ir_2(ppy)$_4$μ-Cl$_2$ [18,19] (ppy = 2-phenylpyridine) and Ir_2(dfppy)$_4$ μ-Cl$_2$ [20,21] (dfppy = 2-(2′,4′-difluorophenylpyridine) were synthesized in a inert atmosphere according to the Nonoyama route by refluxing $IrCl_3 \cdot 3H_2O$ with 2–2.5 equivalents of cyclometalating ligand in a 3:1 mixture of 2-ethoxyethanol and water. Heteroleptic complexes $NBu_4 \cdot [Ir(dfppy)_2(SCN)_2]$ [22,23] (**NBu$_4$·A**) was synthesized from procedures adapted from the literature with tetrabutylammonium thiocyanate. Ir(ppy)$_2$(4,4′-dinonyl-2,2′-bipyridine)·PF$_6$ (**C·PF$_6$**) [24] was synthesized from a procedure reported in the literature without modification and with similar yield.

2.2. General procedure for the synthesis of the anionic complex *NBu$_4$·A*

A mixture of dichlorobridged iridium (III) dimer Ir_2(dfppy)$_4$μ-Cl$_2$ (1 eq.) was stirred with tetra *n*-butylammonium thiocyanate (10 eq.) in a mixture MeOH/$CHCl_3$ (50/50) with a few drops of DMF. The reaction mixture was stirred at reflux overnight. The solvent was removed under reduced pressure and addition of ether precipitated a solid which was filtered off and dried. Anionic complex **NBu$_4$·A** was obtained in 72% yield. Noticeably, significant

2.3. General procedure for the synthesis of soft salt C·A

A mixture of **C·PF$_6$** (50 mg, 0.0474 mmol, 1.07 eq.), **NBu$_4$·A** (33 mg, 0.0439 mmol) were stirred at room temperature for one hour in a mixture of water/THF/$CHCl_3$: 10/7/5. Organic solvents were removed under reduced pressure and the residue was extracted several times with DCM. The organic phases were combined, dried over magnesium sulfate and the solvent removed under reduced pressure. Yellow solid was used without any further purification.

2.4. OLED fabrication and measurements

PhOLEDs were fabricated onto cleaned indium tin oxide (ITO) glass substrates with sheet resistance of 10–12 Ω/cm^2. Prior to organic layer deposition, the ITO substrates were successively washed with acetone, ethanol and isopropanol under ultrasonic for 15 min, and finally exposed to UV-ozone 20 min. A poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) layer was spin-coated in ambient atmosphere at a rate of 3000 rpm for 90 s and then dried by baking in air at 120 °C for 1 h. A filtered solution of poly(vinylcarbazole) (PVK, average M_n = 25,000–50 000, 20 mg/mL in 1,2-dichlorobenzene) was spin-coated at a rate of 3000 rpm for 40 s on top of the PEDOT:PSS layer. The light-emitting layers (soft salts) were then spin-coated from the 1,2-dichlorobenzene solution (30 or 60 mg/mL). The assembly was transferred into a deposition chamber where the calcium cathode was deposited by thermal evaporation under secondary vacuum, followed by the deposition of aluminum. The Ca (300 nm)/Al (60 nm) bilayer cathode of the device was formed with a shadow mask. Current density–voltage–luminescence (J–V–L) characteristics of the PhOLEDs and LECs were measured with a Keithley 4200 Semiconductor analyzer coupled with a Hamamatsu

Light sensor calibrated with a Minolta CS-100 luminancemeter. The EL spectra were collected with an Ocean Optics HR2000 Spectrometer. Chromatic Coordinates were calculated from the EL spectra and reported following the CIE-1964 chromaticity diagram. From the electrode deposition step, devices are stored and characterized in nitrogen filled gloveboxes (0_2 and H_2O < 0.1 ppm) without encapsulation.

3. Results and discussion

3.1. Synthesis and characterization

Syntheses of cationic iridium (III) complex **C·PF$_6$**, anionic iridium (III) complex **NBu$_4$·A** and corresponding soft salt **C·A** are schematically presented in the Scheme 1 and described in detail in the experimental section. Anion **NBu$_4$·A** was conveniently synthesized by reaction of the corresponding dichloro-bridged iridium (III) dimer [Ir(dfppy)$_2$(Cl)]$_2$ with 2 equivalents of tetra *n*-butylammonium thiocyanate in refluxing dichloromethane. Precipitation in ether provided **NBu$_4$·A** in 72% yield. Preparation of the mononuclear cationic complex **C·PF$_6$** was carried out under inert atmosphere through reaction of the dimer [Ir(ppy)$_2$(Cl)]$_2$ with 2 equivalents of bipyridine ligand in 75% yield. Choice of this bipyridine (4,4′-dinonyl-2,2′-bipyridine) as the ancillary ligand for **C·PF$_6$** was motivated by previous results published on light-emitting devices highlighting that addition of alkyl substituents on the bipiridyl ligand efficiently inhibited self-quenching of the excited states in charged complexes [25].

3.2. UV–visible absorptions and photoluminescence properties

The absorption and photoluminescence (PL) spectra of complexes **C·PF$_6$** and **NBu$_4$·A**, soft salt **CA**, recorded in the solid state and in solution, are shown in Figs. 1 and 2 for absorption, Figs. 3 and 4 for emission, respectively. Absorption spectra displayed the typical intense bands observed for iridium complexes in the Ultraviolet part of the spectrum between 200 and 300 nm, assigned to spin-allowed $^1\pi$–π^* ligand-centered transitions in both the 4,4′-dinonyl-2,2′-bipyridine and the 2′,4′-difluorophenylpyridine ligands. The less-intense, lower-energy absorption features extending from 300 to 450 nm were attributed to both spin-allowed and spin-forbidden metal-to-ligand charge transfer (MLCT) transitions [26,27]. Interestingly, charged complexes **C·PF$_6$**, **NBu$_4$·A**, and soft salt **C·A** exhibited similar absorption spectra in solution and in the solid state.

Fig. 3 shows a comparison of the emission spectra of complexes **C·PF$_6$**, **NBu$_4$·A** and soft salt **C·A** measured in the solid state at 298 K. When excited within the π–π^* and MLCT absorption band, solid films of all complexes **C·PF$_6$**, **NBu$_4$·A** and **C·A** exhibited a main peak with emission maxima centered at 558, 555 and 564 nm, respectively, followed by a shoulder at 597 nm for **NBu$_4$·A** (see Table 1). In contrast, the same experiments performed in deaerated solutions evidenced a slight blue shift of the emission maximum for **C·A** with maximum centered at 552 nm whereas maximum remained unchanged for **C·PF$_6$** (559 nm). On the opposite, emission maximum of anionic complex **A** strongly blue shifted in solution with maximum detected at 466 nm ($\Delta\lambda$ = 89 nm). Hypsochromic shift of the photoluminescence in solution for **NBu$_4$·A** compared to **C·PF$_6$** originates from the presence of electron-withdrawing fluorine on the ligands, therefore raising the Lowest Unoccupied Molecular Orbitals (LUMO) levels and increasing the band gap. Spectral blue shifts observed for the solution spectra of **NBu$_4$·A** and **C·A** relative to their solid-state photoluminescence can be attributed to aggregation-induced emissions and was notably previously reported for anionic iridium complexes by Graetzel and co-workers [28]. With reference to previous work on mixed-ligand cationic iridium complexes, nature of the emissive excited states in solution can be assigned

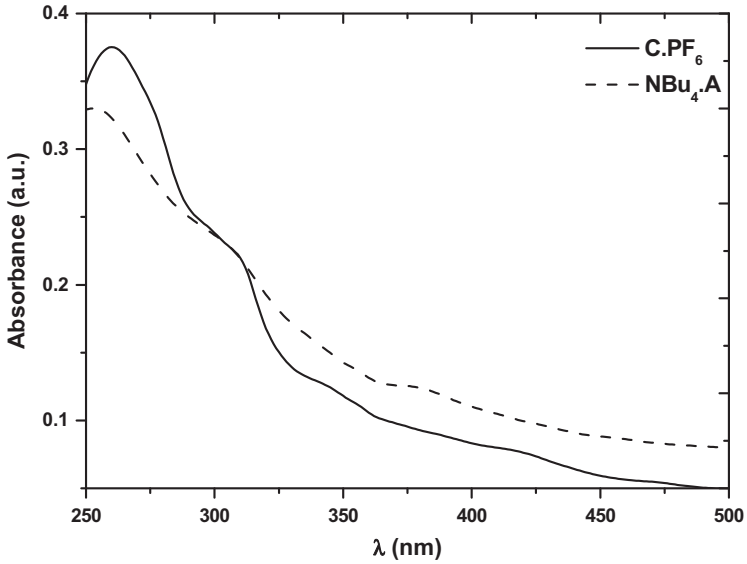

Fig. 1. UV–visible absorption spectra of complexes **C·PF$_6$** (solid line) and **NBu$_4$·A** (dashed line) in the solid state.

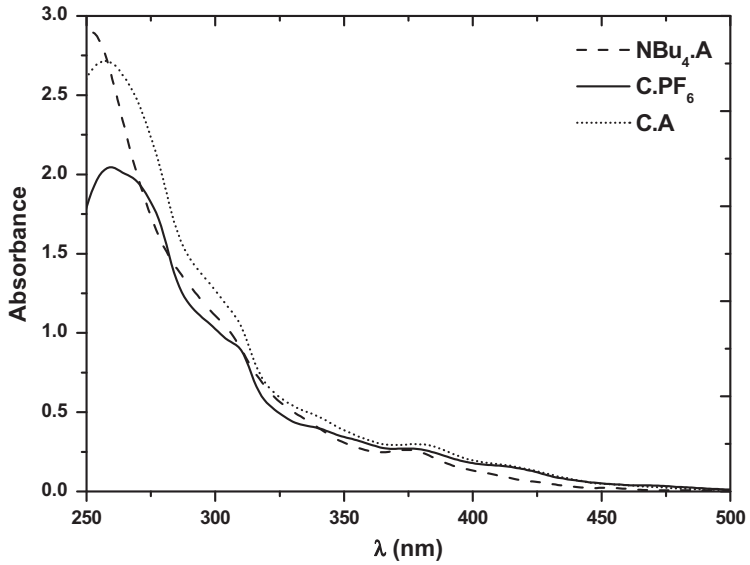

Fig. 2. UV–visible absorption spectra of complexes **C·PF$_6$**, **NBu$_4$·A** and **C·A** in CH_2Cl_2.

for **C·PF$_6$** to both metal-to-ligand and ligand-to-ligand charge transfer characters (^{3}MLCT and ^{3}LLCT, respectively) mixed with a ^{3}LC π–π^* character [19,29–32]. Concerning **NBu$_4$·A**, luminescence was assigned to the emission state of ^{3}MLCT. Interestingly, a lower photoluminescence is observed for anionic complex **NBu$_4$·A** compared to **C·PF$_6$**, as clearly demonstrated on the spectrum of **C·A** in solution by the intensity of the shoulder related to the anionic contribution at 466 nm. Noticeably, a strong red shift of the solid state emission wavelength for **NBu$_4$·A** was evidenced compared to that previously reported in the literature for the same complex without fluorines. (λ_{em}(NBu_4[Ir(ppy)$_2$(NCS)$_2$]) = 500 nm, $\Delta\lambda_{em}$ = 55 nm) [27].

3.3. Electrochemical properties

In order to investigate the frontier orbitals of the two complexes, their electrochemical behavior was investigated by cyclic voltammetry (CV) in acetonitrile on a carbon electrode. The results are presented in Fig. 5 and their respective redox data gathered in the Table 2. Highest Occupied Molecular Orbital (HOMO) and Lowest Unoccupied Molecular Orbitals (LUMO) levels of each complex were determined by using the correspondence between the electrode potentials values measured vs. Standard Hydrogen Electrode (SHE) and the redox Fermi energy values measured vs. electron energy in vacuum (see equation) [33]:

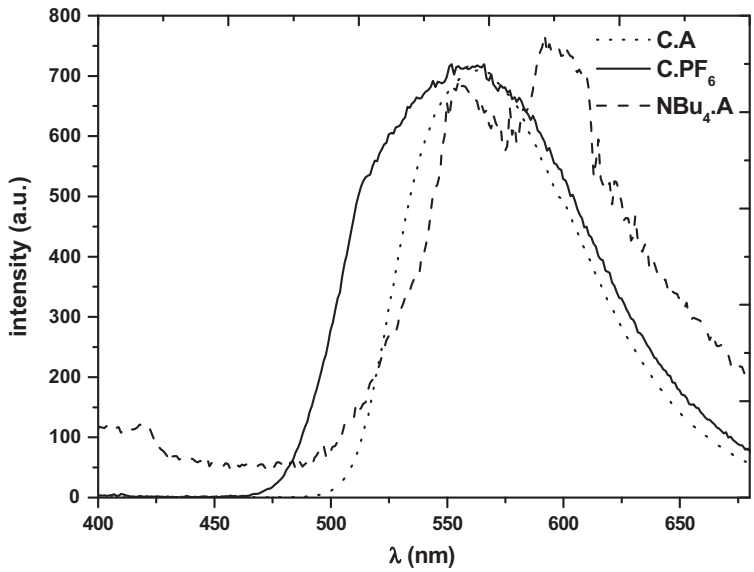

Fig. 3. Normalized photoluminescence spectra of complexes **C·PF$_6$**, **NBu$_4$·A** and **C·A** in thin films (λ_{ex} = 350 nm) at 298 K.

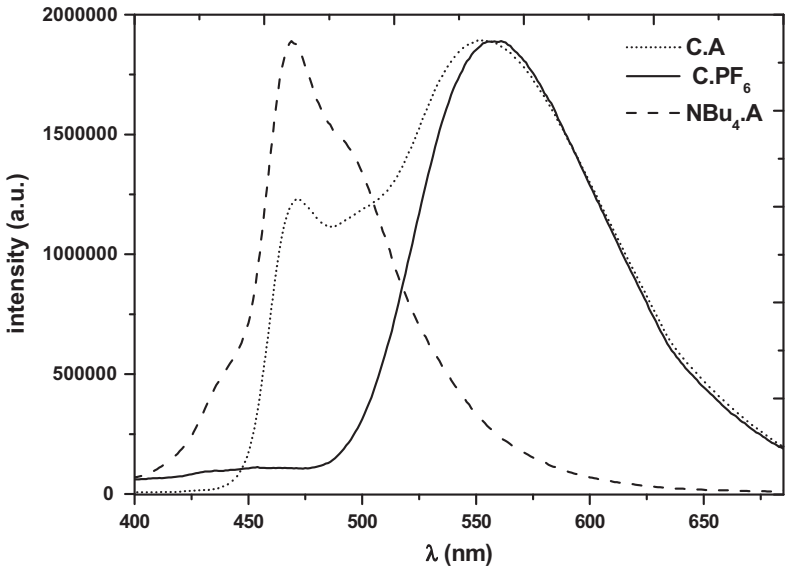

Fig. 4. Normalized photoluminescence spectra of complexes **C·PF$_6$**, **NBu$_4$·A** and **C·A** in argon-degassed CH_2Cl_2 (λ_{ex} = 350 nm) at 298 K.

$$E^{redox}_{F,0}\ (eV) = -E\ (V) - 4.4$$

The HOMO and the LUMO energy of the soft salts were then determined by the lowest energy potential of the pair of iridium complexes.

All complexes showed oxidation processes in the range of +1.01 to +1.28 V corresponding to the metal centered $Ir^{III/IV}$ process. The one-electron oxidation process was assigned to the removal of an electron from the metal-centered HOMO and complex **C·PF$_6$** only showed reversible oxidation. As expected, **NBu$_4$·A** was the easiest complex to oxidize, as a result of the negative charge on the complex. Concerning reduction processes, **C·PF$_6$** displayed one reversible reduction wave at −1.41 V. This reduction process can be attributed to ligand-based $bpy^{0/-}$ process and consisted in the addition of one electron on bpy-centered LUMO. Reduction process was more difficult for **NBu$_4$·A** due to the negative electric charge of the anionic complex and the phenylpyridine instead of bpy involved ligand (see DFT calculations). When combined in the soft salt, cyclic voltammogram of **C·A** displayed an overlap of the voltammograms of both individual components. As a result, **C·A** soft salt exhibited the lowest energy oxidation originating from the HOMO of the anion and the reduction process was issued from the LUMO of the cation, respectively.

Determination of the HOMOs and LUMOs of each iridium partner by electrochemistry confirmed the origin of the yellow photoluminescence observed for the soft salt **C·A** (see Fig. 7). Introduction of the negatively charged thiocyanate ligands on **Bu$_4$N·A** destabilized its HOMO (−5.2 eV) by releasing electron density from the ligand to the metal and also increased the energy of the LUMO (−2.7 eV). On the opposite, positive charge of the cationic complex stabilizes its HOMO (−5.6 eV) by removing electron density from the metal and also lowers its LUMO (−3.1 eV). Therefore, as the MLCT state of the cationic complex is stabilized compared to the MLCT state of the anionic one, yellow emission for the soft salt is thus observed in agreement with the measured HOMO–LUMO gap (2.2 eV).

3.4. Electroluminescent properties of PhOLEDs

In the only previous report concerning the incorporation of soft salt in light-emitting devices [14], iridium soft salts were tested both as emitters in single layered LECs and in multilayered OLED devices. Careful study of the resulting devices evidenced that soft salts behave as neutral complexes and that OLEDs were obtained as no delay between turn-on time and emission was observed. In our case, poly(*N*-vinylcarbazole) (PVK) was used as a hole-injection layer because of its good solubility in common organic solvents, excellent film-forming properties, high glass-transition-temperature (200 °C) and high triplet energy (3.0 eV) [34]. As previously mentioned by Thompson and co-workers, PVK layer was also introduced to lower the hole-injection barrier while preventing the agglomeration or the crystallization of the soft salt layer [14]. Structure of the investigated device was the following: ITO/PEDOT:PSS (40 nm)/PVK (20 nm)/iridium complexes/Ca (300 nm)/Al (60 nm) (Scheme 2). In particular, best performances of the PhOLED devices were obtained in our case when the iridium-containing layer was spin-coated onto the surface of PVK rather than blended with PVK, thus traducing that PVK was more efficiently acting as a hole-injection layer than as a host in a host–guest strategy. Thickness of the emissive layer was also optimized to improve the device performances. Fig. 6 shows the current–voltage–luminance curves obtained for the optimized PhOLED. Noticeably, in our case and contrarily to the previously reported deposition process, soft salt layer was deposited in a 1,2-dichlorobenzene solution to avoid the dissolution of the PVK underlayer, this polymer being highly soluble in acetonitrile.

[b] $E^{\circ}_{ox}(½)$.

Detailed performances of OLEDs and LECs are summarized in Table 3. Double-layered active devices exhibited a peak current efficiency of 0.66 cd A^{-1} and a maximum brightness of 1114 cd m^{-2} for an optimal active layer thickness of 73 nm. Dramatic decrease of the device efficiency was evidenced with increasing the thickness of the active layer. Thickness of the emissive layer was controlled by mean of the concentration of the deposited solution. The corresponding CIE chromaticity coordinates were $x = 0.43$, $y = 0.54$, indicating that the device showed nearly saturated yellow emission. The EL spectrum of the PhOLED displayed an emission peak centered at 553 nm (see inset in Fig. 6) almost identical to that observed in the photoluminescent spectrum (λ_{em} = 552 nm). Compared to results previously reported for devices with the similar soft salt **C′·A′** (see the Scheme 2), our devices displayed higher turn-on voltage but higher brightness at low voltage. However, whatever the thickness of the emissive layer was, all devices displayed current efficiencies significantly lower to what expected. Low performance of our devices originates

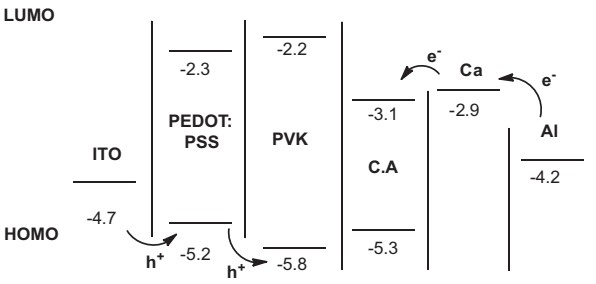

Fig. 7. Energy level diagram of the materials and Fermi levels of the electrodes used in OLEDs. The Highest and Lowest Occupied Molecular Orbitals (HOMO and LUMO) levels of **C·A** were calculated from its oxidation potentials.

from the poor matching existing between the two HOMOs and LUMOs of the soft salt. By the quite high energy barrier existing between the two HOMOs and LUMOs (0.4 eV), carriers exchange was impeded and exciton formation hindered.

3.5. Electroluminescent properties of LECs

Cationic iridium complex was also investigated as emitter in LEC devices. LEC devices were prepared with **C·PF$_6$** using the following configuration: ITO/PEDOT:PSS (40 nm)/PVK (20 nm)/cationic iridium complex/Ca (300 nm)/Al (60 nm). All solutions were spin-coated in 1,2-dichlorobenzene as solvent. In LEC devices, size of the counterions is reported to strongly impact the turn-on time by the production rate of the electric field at the electrodes due to ion motion. Therefore, we expected that the small anion PF_6^- could produce the electric field faster than larger counter anions. As first experiments, the light output vs. voltage was investigated for each fabricated devices. By applying voltage, **C·PF$_6$** emitted light above a turn-on voltage determined as being over 3.8 V (see inset in Fig. 8). The turn-on voltage was significantly higher than the electrochemical gap (ΔE = 2.29 eV). As expected, as the thickness of the functional layer increased, the turn-on voltage increased as well and was assigned to an enhanced resistivity of the emissive layer. Above this turn-on voltage, the emission intensity increased with increasing the applied voltage as evidenced in the Fig. 8. Another specificity of LECs is that they can be operated at a bias voltage higher than their electrochemical bandgap. As the band-gap for **C·PF$_6$** was electrochemically determined to be 2.29 eV and to investigate its time-dependent brightness, devices were tested under the applied bias of 7 V. Under application of this voltage, light emission was observed within a few minutes. Brightness reached a maximum luminance of 128 cd m^{-2} after 33 min. Then, a slow decay of the brightness was evidenced as a result of the low operational stability of LECs arising from various detrimental side-reaction processes [35,36]. Half-life of the device, defined as the time for the brightness of the device to decay half-maximum under a constant bias was determined to be 167 min. Surprisingly, investigation of the electroluminescence spectrum of the device evidenced a modification of the emission color over time under a constant applied voltage (see Fig. 10). When the device was switched on at 5 V, the emission color profoundly changed from green to yellow within a few minutes (see Fig. 9). Variation of the color emission over time was ascribed to a temperature-induced modification of the molecular packing or to the degradation of the active layer. Under application of the bias, temperature dissipation induced a temperature rise of the active layer and the micro and/or nanostructures of the light emissive layer changed. As a result, the emitted color was modified. This color tunability of OLEDs has notably previously been reported by acting on various parameters

such as the driving voltage, current [37–39] and temperature [40,41].

3.6. DFT calculations

Density functional theory (DFT) calculations at the B3LYP level of the hybrid functional theory were performed with a mixed basis set (double ξ quality LANL2 and the corresponding pseudo-potential for the metal and 6−31+G(d) for all other atoms) to optimize the geometry of both complexes and generate orbitals. The contour plots depicted in Fig. 11 clearly show that the HOMO of **C·PF$_6$** mainly comprises a contribution of the d_π orbitals of the Ir^{III} center and some π-orbital contributions of the two phenylpyridine ligands. In contrast, the LUMO is mainly localized on the ancillary bipyridine unit and consists of pyridyl π^* orbitals. Similarly, the HOMO of **NBu$_4$·A** is a mixture of Ir^{III} d_π orbitals and π orbitals of the two thiocyanate units. However, contrarily to **C·PF$_6$**, the LUMO distribution of **NBu$_4$·A** primarily resides on the phenylpyridine units of the complex and not on the ancillary ligand, as observed for **C·PF$_6$**. Therefore, introduction of the electron-releasing anionic thiocyanate ligand and the fluorine atoms on the phenylpyridine ligands in **NBu$_4$·A** inverted the contribution of both the cyclometallating ligands and the ancillary ligand in the HOMO and LUMO orbitals compared to **C·PF$_6$**. From Fig. 11, it was also possible to determine that the alkyl chain on the bipyridine ligand was essentially not contributing to the HOMO of **C·PF$_6$**, thus

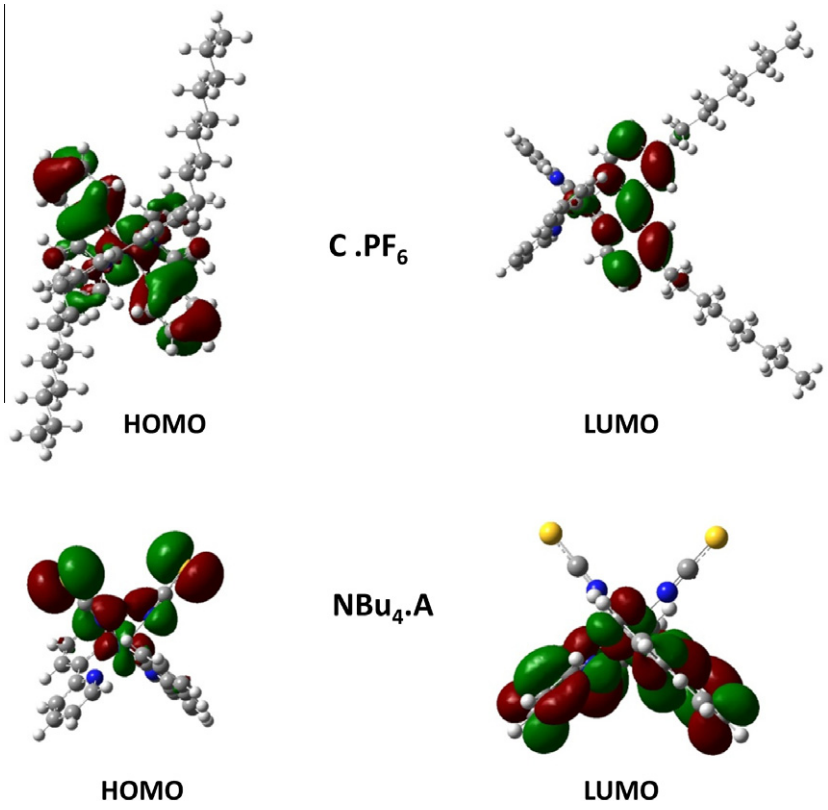

Fig. 11. Contour plots of the frontier orbitals of **C·PF$_6$** and **NBu$_4$·A** in the ground state as determined by the DFT calculations. Counteranion or countercation were not taken into consideration during geometry optimization.

suggesting the little dependence of the HOMO and LUMO level of **C·PF$_6$** to the variation of the alkyl chain length. Alkyl chains on the complex mostly contribute to render the complex more soluble in common organic solvents while limiting its crystallization within the active layer.

4. Conclusions

In conclusion, efficient electrophosphorescent devices were fabricated using the cationic complex **C·PF$_6$** as a single emitter in LECs or mixed with an anionic complex (**C·A**) in soft salt-based PhOLEDs. Interestingly, LECs demonstrated a color-variability attributed to a modification of the emissive layer with the temperature, i.e. molecular packing and/or degradation. Electroluminescent PhOLED fabricated by the spin-coating technique showed higher-performances compared to that previously reported in the literature by a higher luminance at low voltages, thus demonstrating that soft salt-based PhOLEDs constitute a promising alternative to conventional PhOLEDs based on neutral complexes.

realized as a nanoscale electronic power source [8]. Recently, single NW photovoltaic devices using coaxial NWs consisting of ZnO and P3HT exhibited a η value of 0.036% [9]. The nanoscale photovoltaic cells using the coaxial NWs, composite NWs, or various nanostructures must be studied to fabricate high-efficiency future energy harvesting systems.

In this study, we report on the nanoscale optical and photoresponsive electrical characteristics of composite NWs of *p*-type P3HT and *n*-type PCBM materials. The P3HT:PCBM composite NWs were fabricated through a wetting process based on an alumina (Al_2O_3) nanoporous template. The nanoscale phase separation of the P3HT and PCBM materials in the composite NWs was observed by optical absorption spectra and laser confocal microscope Raman and photoluminescence (PL) spectra. For the photoresponsive electrical properties of an isolated single strand of the P3HT:PCBM composite NWs, the Au–Al electrodes were patterned using an electron beam (E-beam) lithography technique, and the current–voltage (I–V) characteristic curves with and without light illumination were measured and analyzed. The current levels of the single NW at a high bias ($\geqslant$10 V) were enhanced by light illumination because of the contribution of the photogenerated charges in the *p*-type P3HT materials. The photovoltaic effect was observed for the cells using P3HT:PCBM composite NWs.

2. Experimental

The P3HT:PCBM composite NWs were fabricated through a wetting method by using Al_2O_3 nanoporous templates (Whatman International Ltd.) with a pore size of 100 nm [10]. Regio-regular P3HT and PCBM powders were purchased from Sigma–Aldrich Co. and Nanobest Co., respectively, and they were used without further purification. The molecular weight and regio-regularity of the P3HT materials were 50 kDa and 90–93%, respectively. The P3HT and PCBM were simultaneously dissolved in dichlorobenzene ($C_6H_4Cl_2$) with stirring for 12 h at 100 °C. The relative concentration (wt.%) of the P3HT and PCBM materials varied from 1:1 to 1:2 and 1:4 wt.%. The composite solution was dropped onto the Al_2O_3 nanoporous templates placed on a hotplate at 60 °C in an air atmosphere. The composite solution with the Al_2O_3 template was annealed in a vacuum oven at 150 °C for 1 h. The Al_2O_3 nanoporous template was removed only by using 2.0 M NaOH solvent. Fig. 1(a) shows the schematic illustration of the fabrication process of the P3HT:PCBM composite NWs. The P3HT and PCBM NWs themselves were also fabricated through the same wetting method using Al_2O_3 nanoporous templates.

The formation of the P3HT:PCBM composite NWs was visualized using SEM images (Hitachi S-4300). The ultraviolet and visible (UV/Vis) absorption spectra (Agilent 8453) of the NWs were measured for optical properties. The nanoscale PL and Raman spectra for an isolated single strand of the NW were measured by using a laser confocal microscope (LCM) (NanoFocus Inc., Albatross SPM). For LCM PL spectra, the incident laser power with an excitation wavelength of 488 nm and the acquisition time were fixed at about 10 μW and 0.5 s, respectively. For the LCM Raman

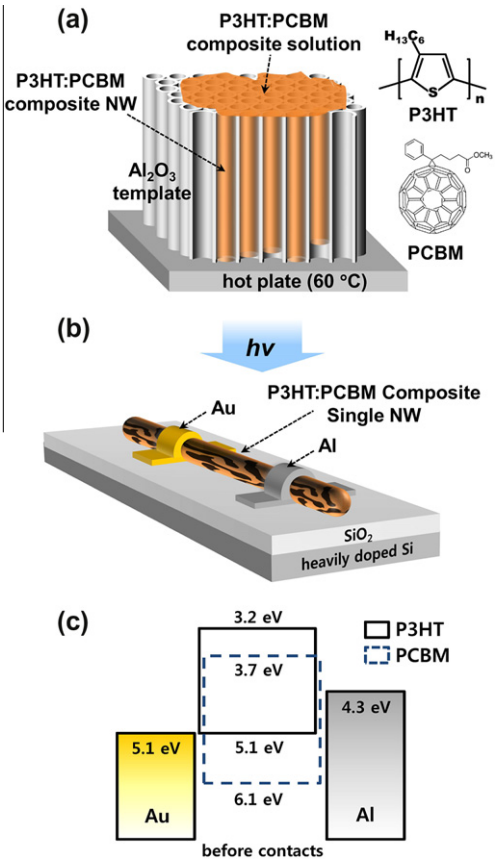

Fig. 1. Schematic illustrations of (a) the fabrication process of the P3HT:PCBM composite NWs and (b) the nanodevice with Au and Al electrodes using the P3HT:PCBM single NW. (c) Energy band diagram of the P3HT and PCBM materials and the Fermi levels of Au and Al electrodes.

spectrum of the single NW, the incident laser power with an excitation wavelength of 488 nm and the acquisition time were at about 20–40 μW and 60 s, respectively. The detailed method of the LCM experiment was reported earlier [11].

To investigate the photoresponsive electrical characteristics of the P3HT:PCBM single NW, an E-beam lithography technique was employed to fabricate two-probe electrodes of Au and Al. Fig. 1(b) shows a schematic illustration of the nanodevice using the P3HT:PCBM single NW. The distance between the Au and Al electrodes was about 1 μm. The SiO_2 dielectric layer with a thickness of 250 nm was grown by the chemical vapor deposition method onto the heavily doped Si substrate. Fig. 1(c) shows the energy band diagram of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) levels of the P3HT and PCBM materials and the Fermi levels of the electrodes for the nanodevice [12]. Before measurements were performed, the single NW device was annealed one more time in a vacuum oven at 150 °C for 1 h. The current–voltage (I–V) characteristic curves of the single NW were measured under a vacuum condition at 10^{-3} Torr, using a Keithley 237 SMU and Keithley 487 picoammeter. The incident light (λ = 455 nm) power from

a correlated LED (Thorlabs) was 8.5 mW at the sample location and the distance between the device and the light source was about 5 cm. The leakage current was negligible due to the relatively low current level ($\leqslant$1 nA) both with and without light illumination.

Photovoltaic cells were fabricated by using the P3HT:PCBM composite NWs with the concentration of 1:1 wt.%. The poly (3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) layer was spin-coated onto the ITO glass. The P3HT:PCBM composite NWs dispersed in methanol solvent were deposited onto the PEDOT:PSS layer through the spin coating. The P3HT:PCBM composite NW layer was covered by an insulating poly (methyl methacrylate) (PMMA) before the deposition of the Al electrode.

3. Results and discussion

Fig. 2(a) shows the SEM image of the P3HT:PCBM composite NWs, in which the formation of the NWs was confirmed and the diameter and length of the NWs was about 200 nm and 50 μm, respectively. To study the structural properties of the NWs, the LCM Raman spectra were measured for a single strand of the P3HT NWs, the PCBM NWs, and the P3HT:PCBM composite NWs, as shown in Fig. 2(b). For the P3HT single NW, LCM Raman characteristic peaks of P3HT material corresponding to the $C_\alpha = C_\beta, C_\beta{-}C_{\beta'}$, and $C_{\alpha'} = C_{\beta'}$ stretching modes in the thiophene ring were observed at 1429, 1359, and 1492 cm^{-1}, respectively [13]. For the PCBM single NW, two broad Raman peaks with a relatively low intensity were observed at 1424 and 1600 cm^{-1}. The Raman mode of the C_{60} molecules at 1465 cm^{-1} corresponding to the tangential stretching mode of the PCBM material was downshifted to 1424 cm^{-1}. The broad and weak LCM Raman peaks for the PCBM single NW may originate from the polymerization of the C_{60} due to exposure of the focused laser beam during the LCM Raman measurement [14,15]. For the P3HT:PCBM composite single NW, the Raman characteristic peaks corresponding to P3HT and PCBM materials were simultaneously observed at 1429, 1359, 1492, and 1600 cm^{-1}, as shown in Fig. 2(b). From the results of the LCM Raman spectra, both P3HT and PCBM phases existed in the P3HT:PCBM composite single NW.

Fig. 2(c) shows normalized UV/Vis absorption spectra for the P3HT NWs, the PCBM NWs, and the P3HT:PCBM composite NWs dispersed in methanol. For the P3HT NWs, the UV/Vis absorption characteristic peaks of the regio-regular P3HT material were observed at 525, 570, and 620 nm. The relatively strong absorption band at the longer wavelengths of 570 and 620 nm implies a longer π-conjugation length [16], because of the enhanced interchain interactions and ring planarity during the formation of NWs in the limited nanopore space [17–19]. For the PCBM NWs, the maximum absorption peak was observed at 327 nm with broad absorption in the visible range [20]. For the P3HT:PCBM composite NWs, the absorption peaks corresponding to the P3HT and PCBM materials were simultaneously observed at 327, 525, 570, and 620 nm. The UV/Vis absorption spectra for the P3HT:PCBM composite NWs with various weight ratios of the P3HT and PCBM materials were measured, as shown in Fig. 2(c). Below 500 nm, the relative intensity of the UV/Vis absorption for the composite NWs increased as the concentration of the PCBM material increased. The intensity of the absorption at 620 nm due to the P3HT material increased as the concentration of the PCBM material decreased. These results are attributed to the reduction of the interchain interaction of the P3HT main chains through the blending of the PCBM molecules, which are consistent with previous reports of the P3HT:PCBM composite nanoparticles (NPs) [21–23].

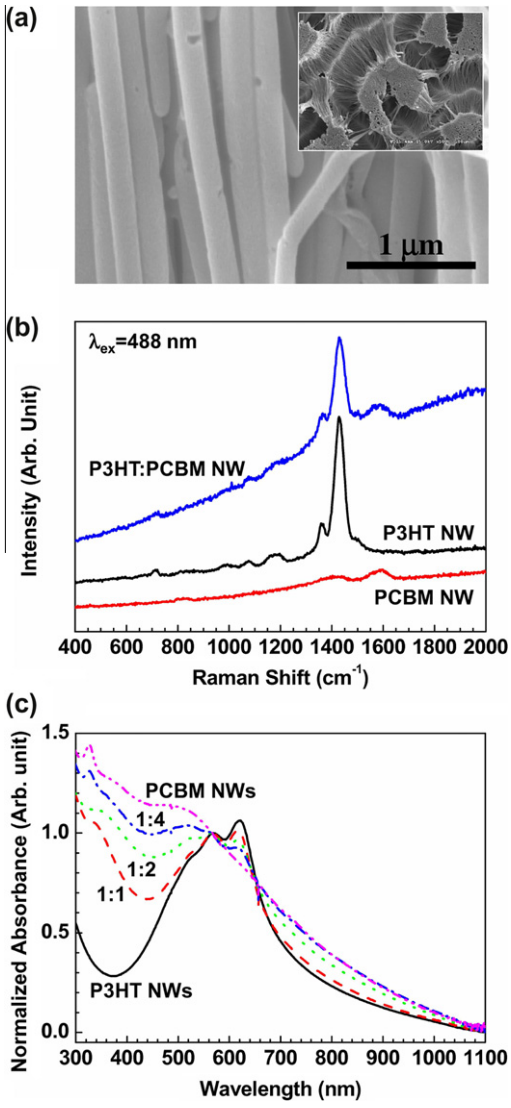

Fig. 2. (a) SEM image of the P3HT:PCBM composite NWs. Inset: SEM image of the bundle of P3HT:PCBM NWs. (b) LCM Raman spectra for the single NW of the P3HT and PCBM materials, and of the P3HT:PCBM composites. (c) Normalized UV/Vis absorption spectra for the P3HT NWs, the PCBM NWs, and the P3HT:PCBM composite NWs (with various concentrations of 1:1, 1:2, and 1:4 wt.%) dispersed in methanol.

To investigate the nanoscale luminescence and phase separation, the LCM PL spectra of single NWs were measured. Fig. 3(a) shows normalized LCM PL spectra (λ_{ex} = 488 nm) for the single NW of the P3HT, PCBM, and

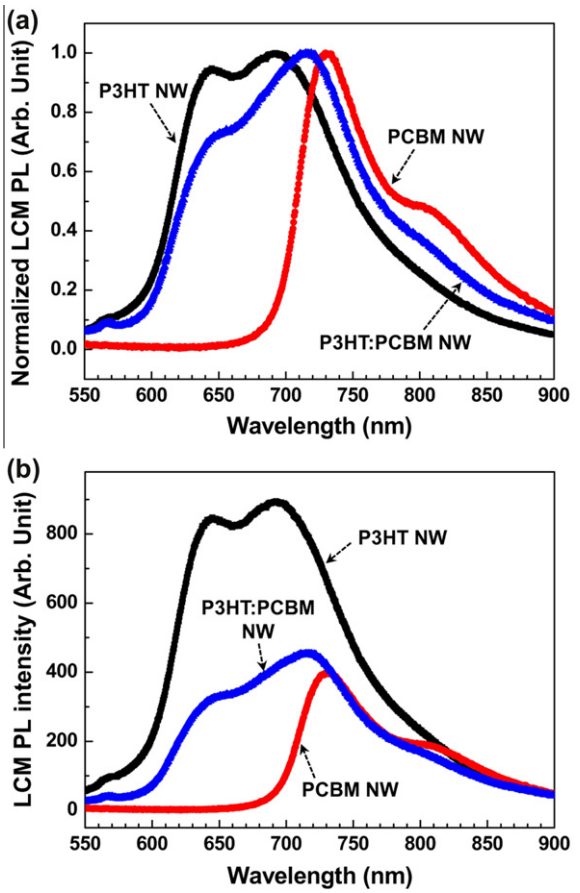

Fig. 3. (a) Normalized LCM PL spectra (λ_{ex} = 488 nm) for the single NWs of the P3HT, PCBM, and P3HT:PCBM composite. (b) LCM PL spectra with an absolute intensity for the single NWs of the P3HT, PCBM, and P3HT:PCBM composite.

P3HT:PCBM composite (1:1 wt.%). The LCM PL spectra were measured at 30 different positions in the same NW, and then, the averaged LCM PL spectrum was obtained for each single NW. For the P3HT single NW, the LCM PL peaks corresponding to the 0–0 and 0–1 transitions of the P3HT material were observed at 650 and 700 nm, respectively, which was due to two crystalline regions of the interdigitated alkyl side chains and the tilted alkyl side chains between neighboring π-stacks, respectively [22,23]. The two observed LCM PL peaks due to the two crystalline configurations for the P3HT NWs were qualitatively consistent with the UV/Vis absorption peaks with the strong interchain interaction. The LCM PL peak of the PCBM single NW was observed at 730 nm with a shoulder peak at 810 nm. For the P3HT:PCBM composite single NW, the maximum LCM PL peak at 725 nm with shoulder peaks at 650 and 810 nm were observed, indicating the coexistence of P3HT and PCBM phases in the single NW. It is noted that the main LCM PL peak at 725 nm for the composite NW was relatively red-shifted as compared with that (700 nm) of the P3HT NW. The results of the LCM PL spectra for the P3HT:PCBM composite single NW are consistent with the previous results for the P3HT:PCBM single NP [22,23].

The absolute intensities of LCM PL spectra for the single NWs of the P3HT, PCBM, and P3HT:PCBM composite were measured under the same experimental conditions, as shown in Fig. 3(b). The LCM PL characteristic peaks of the P3HT and PCBM materials were observed in the composite single NW. The LCM PL intensity of the P3HT:PCBM single NW relatively decreased compared with that of the P3HT single NW, because of the charge transfer from the P3HT to the PCBM (i.e., PL quenching). The results of the LCM Raman and PL spectra and UV/Vis absorption spectra suggest that, for the P3HT:PCBM composite single NW, the P3HT and PCBM materials were well phase-separated on the nanoscale.

Fig. 4(a) represents the SEM image of the nanodevice using the P3HT:PCBM composite single NW with Au and Al electrodes. The I–V characteristic curve of the P3HT:PCBM single NW with the P3HT:PCBM concentration of 1:2 wt.% in the dark condition shows diode-like behavior, as shown in Fig. 4(b). In the case of the reverse bias, energy barriers of 1.4 eV existed for electron injection between the Fermi energy level (E_F) of Au and the LUMO level of PCBM and barriers of 0.8 eV existed for hole injection between the E_F of Al and the HOMO level of P3HT. However, in the case of the forward bias, there was no energy barrier for the hole injection from the Au electrode, and a relatively lower barrier of 0.6 eV existed for the electron injection from the Al electrode. These induce the diode-like behavior of the nanodevice using the P3HT:PCBM composite single NW in the dark condition. Under light illumination, the current levels of the P3HT:PCBM single NW were clearly enhanced at a relatively high bias ($V \geqslant 10$ V), as shown in Fig. 4(b). Excitons were created in the major P3HT and minor PCBM materials, and they dissociated to electrons and holes due to the applied electric field near the interface of the P3HT and PCBM [24]. The increased ratios of the currents with the light illumination were estimated to be ~3.5 at −50 V and ~3.2 at 50 V, as shown in Fig. 4(b) and its inset. To study photocurrent (I_{ph}) behavior of the single P3HT:PCBM NWs with different concentrations of P3HT and PCBM such as 1:1, 1:2, and 1:4 wt.%, the I_{ph} was obtained from difference between currents with and without light illumination (i.e., $I_{ph} = I_{light} - I_{dark}$) [24]. It is noted that these NWs are new batch samples compared to those in Fig. 4(b). The I_{ph}'s were plotted as a function of applied bias, as shown in Fig. 4(c). The I_{ph} values of the single composite NW decreased as the concentration of PCBM increased, which is due to the reduction of the interchain interaction of the P3HT main chains through the blending of the PCBM molecules. These results were supported by the UV/Vis absorption spectra of the composite NWs (Fig. 2(c)). The decay of the photocurrent (after the light was turned off; I) for the P3HT:PCBM single composite NW exhibited a slow relaxation (i.e., relatively long relaxation time), which was fitted to a double exponential decay of the photocurrent after the light was turned off, as shown in the inset of Fig. 4(c). The fitted curves have a form of $I(t) = I_1 \exp(-t/\tau_1) + I_2 \exp(-t/\tau_2) + I_0$. Here, I_1 and I_2 are the amplitudes of the processes and τ_1 and τ_2 are the time constants. With the applying bias of 50 V, the fitting parameters of the P3HT:PCBM single NW with the concentration of 1:1 wt.% were estimated to be I_1 ~3.52×10^{-10} A, τ_1 ~0.92 s, I_2

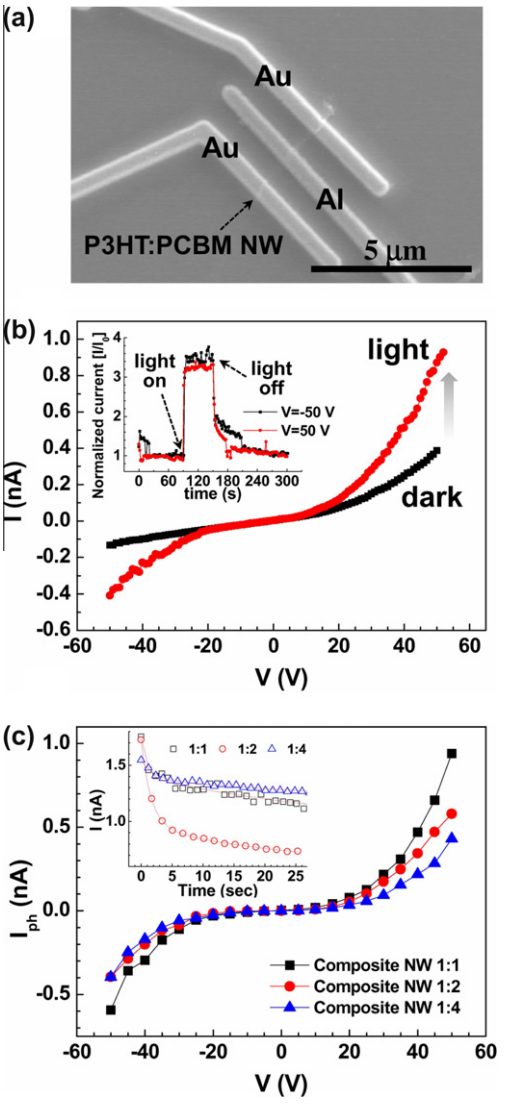

Fig. 4. (a) SEM image of the nanodevice using a single NW with Au and Al electrodes. (b) I–V characteristic curves for the P3HT:PCBM single NW with a P3HT:PCBM concentration of 1:2 wt.% with and without light irradiation. Inset: Normalized currents of the composite NW with and without light illumination, as a function of time. (c) The I_{ph}–V characteristic curves for the P3HT:PCBM single NWs with different concentrations of 1:1, 1:2, and 1:4 wt.%. Inset: Decay curves of photocurrent (at V = 50 V) for the P3HT:PCBM single NWs with different concentrations of 1:1, 1:2, and 1:4 wt.%, based on double exponential decay.

$\sim 4.76 \times 10^{-10}$ A, τ_2 ~37.46 s, and I_0 $\sim 9.23 \times 10^{-10}$ A. For the NW with 1:2 wt.%, I_1 $\sim 7.59 \times 10^{-10}$ A, τ_1 ~1.58 s, I_2 $\sim 3.61 \times 10^{-10}$ A, τ_2 ~23.18 s, and I_0 $\sim 6.08 \times 10^{-10}$ A were estimated. For the NW with 1:4 wt.%, I_1 $\sim 1.71 \times 10^{-10}$ A, τ_1 ~1.93 s, I_2 $\sim 2.64 \times 10^{-10}$ A, τ_2 ~50.39 s, and I_0 $\sim 1.11 \times 10^{-9}$ A were estimated. The relaxation time τ_2 was considerably longer than τ_1 for all NWs. The relaxation time τ_1 of the single composite NW increased as the concentration of PCBM increased. The observed double exponential decay of the photocurrent suggests a bipolar transport mechanism of the photogenerated electrons and holes through two photoactive traps [25]. Therefore, the photocurrent of the P3HT:PCBM composite NW can be caused by two photoactive traps and distinct charge carriers at the interface. The use of high crystalline organic semiconductors with low trap density can improve the switching speed of the photocurrent [26]. It is noted that the photovoltaic effect of the nanodevices using the composite single NW was measured at a low bias region (⩽0.5 V) for 2 nanodevices among 25 different ones, in which the power conversion efficiencies (η's) were 0.016% and 2.03%. The average value of the η's was estimated to be 1.62 (±1.42)%.

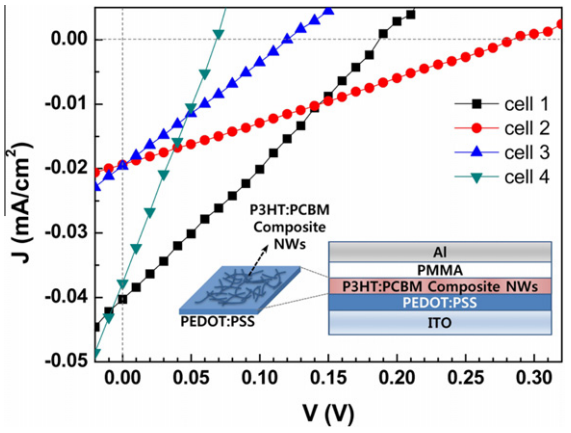

Fig. 5. J–V characteristic curves of the OPVCs using P3HT:PCBM composite NWs.

The OPVCs were fabricated by using the P3HT:PCBM composite NWs with a concentration of 1:1 wt.%, as shown in the inset of Fig. 5. The photovoltaic (current density)–V characteristic curves of the cells were consistently observed, as shown in Fig. 5. The power conversion efficiency [$\eta = FF \cdot (J_{sc}V_{oc}/P_{in})$] of the cells was 0.04–0.14% with a 100 mW/cm^2 simulated solar spectrum (1 SUN AM 1.5G). The average value of the η's was estimated to be 0.068 (±0.051)%. The various η's and J–V characteristics of the OPVCs using the composite NWs might be due to the different distributions of the composite NWs. For the OPVC with a maximum η = 0.14%, the J_{sc} and V_{oc} were measured to be about 1.94×10^{-2} mA/cm^2 and 0.28 V, respectively. The fill factor ($FF = J_{max}V_{max}/J_{sc}V_{oc}$) of the cell was 0.27. The pristine area overlapped by the ITO and Al electrodes was used to estimate the current density. When the effective area contributed by the composite NWs only is used for the current density, the J_{sc} and η of OPVCs using the P3HT:PCBM composite NWs can be expected to be higher. Therefore, the results suggest that the p-type P3HT and n-type PCBM materials of the composite NW were phase separated on the nanoscale, which contributed to the photovoltaic effect.

4. Conclusion

Composite NWs with heterojunctions of P3HT and PCBM materials were fabricated using a wetting method. From the UV/Vis absorption spectra, the coexistence of the P3HT and PCBM materials in the P3HT:PCBM composite NWs was observed. From the LCM Raman and PL spectra of the P3HT:PCBM single NW, the nanoscale phase

separation of P3HT and PCBM materials was observed. The LCM PL intensity of the P3HT:PCBM composite NWs decreased due to the efficient charge transfer. The $I-V$ characteristics of the nanodevices using the P3HT:PCBM single NW exhibited diode-like behaviors in the dark. With light illumination, the current level of the composite NW was clearly enhanced at a high bias. The photovoltaic effect was observed for the OPVCs using the P3HT:PCBM composite NWs.

have been reported [13]. These attachments, based on the electronic properties of the neutral semiconducting form of conjugated systems, have had a great effect on the chemistry of these systems. This new formation has created a strong change in point of view regarding the molecular engineering of the electronic properties of materials derived from conjugated systems and hence on the structural control of their band gap [10].

In particular, thiophene and carbazole containing polymers have been of recent attraction due to their interesting electrochemical and optical behavior, and electrochromic properties [14]. Using these materials in electrochromic applications that possess the ability to reversibly color change by altering redox state has emerged [15]. Besides, polycarbazole is well-known as a good hole transport and photonic material for optoelectronic devices [16]. Polycarbazoles are known as not only an efficient short wavelength emitter but also as a strong electro-donating (p-type) chromophore [17]. Another advantage of carbazole is that it can be easily functionalized at its (3,6-) [18], (2,7-) [19] or *N*-positions [20] and then covalently linked into polymeric systems, both in the main chain [21] as building blocks and in a side chain as pendant unit [22]. Furthermore, poly(3,6-carbazole)s show interesting electrochromic properties because of the conjugation breaks that are present due to the inclusion of a 3,6-linkage. These broken conjugation lengths generate radical cations, which are separated from one another and do not combine. Therefore, the ability of poly(3,6-carbazole) derivatives to form two distinct oxidation states further ability to exhibit many colors on the ITO/glass surface upon applied positive potentials [15a,23].

Since 2,7-carbazoles were theoretically found to have smaller energy gaps than the 3,6-carbazoles, the small energy gaps of these monomers are expected to contribute to a lowering of the band gaps in the resulting polymers [17b–e]. Due to easily synthesized, there are many reports about poly(3,6-carbazole)s [24]. For instance, direct oxidative polymerization or electropolymerization of carbazoles resulted in just oligomeric materials linked at the 3,6- positions [23,25]. On the other hand, the synthesis of poly(2,7-carbazole)s was not straightforward due to unreactive the 2 and 7 positions of carbazole. Several approaches have been developed to overcome the barrier to obtaining various poly(2,7-carbazole) derivatives [19].

Herein, we synthesized a new poly(2,7-carbazole) derivative bearing electro-withdrawing $-NO_2$ substituent that could easily be polymerized electrochemically to give stable, electroactive and electrochromic materials (Scheme 1). When compared to the poly-9-phenyl-2,7-di-2-thienyl-9H-carbazole (poly(TCT)) standard molecule, as a result of the attachment of $-NO_2$ moiety to the structure, it gain many useful properties such as multi-electrochromic behavior, high redox stability, and high coloration efficiency.

2. Experimental

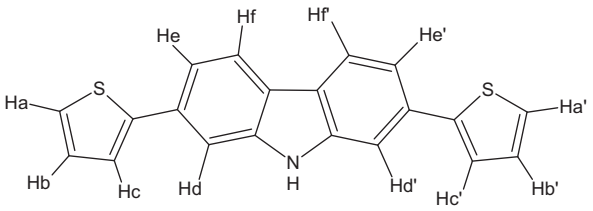
2.1. Materials

All chemicals purchased from Aldrich, Merck and Fluka and used without further purification. 2-Azido-4,4′-dinitrobiphenyl (1), 2,7-dinitro-9*H*-carbazole (2), 2,7-diamino-9*H*-carbazole (3), 2,7-diiodo-9*H*-carbazole (4) were prepared from previously published procedures [19].

2.2. Synthesis of 2,7-di-2-thienyl-9H-carbazole (**5**)

Compound **4** (0.5 g, 0.95 mmol) was dissolved in acetic anhydride (20 mL) and added boron trifluoride diethyl etherate (0.15 mL) with refluxing for 1 h to yield 9-acetyl-2,7-diiodocarbazole as a residue. A mixture of 9-acetyl-2,7-diiodocarbazole (0.44 g, 1 mmol) 2-thiopheneboronic-acid (0.27 g, 2 mmol), 20 mL THF and 3 M 5 mL of Na_2CO_3 solution was stirred at room temperature for 2 h under argon atmosphere. Then $Pd(PPh_3)_4$ (0.02 g) was added to this solution as catalyst and the reaction was refluxed for 24 h. The mixture was cooled to room temperature and then poured into a large amount of methanol (500 mL), and the mixture of 9-acetyl-2,7-di-2-thienylcarbazole was obtained by filtration. Finally the residue was dissolved in THF (50 mL), DMSO (10 mL), H_2O (5 mL), and then KOH (9.72 g, 0.173 mol) was added, and the mixture was refluxed for 24 h. The reaction mixture was cooled to room temperature, neutralized by HCl, and then poured into water to give the final product. Remaining solid was crystallized in methanol two times. The solid was dried at 50 °C under vacuum. *Yield: 0.34 g, 87%, brown color product.*

FT-IR (cm^{-1}): 3397 (–NH); 3063, (C–H aromatic); 1605, (C=C aromatic), 685 (thienyl C–H) (^{1}H NMR, $CHCl_3$-d, ppm): δ, 11.96, (s, 1H, N–H); 7.94 (d, 2H, Ar-$H_{ff'}$); 7.62 (d, 2H, Ar-$H_{cc'}$); 7.55, (s, 2H, Ar-$H_{dd'}$); 7.39, (d, 2H, Ar-$H_{aa'}$); 7.14, (m, 4H, Ar-$H_{ff'}$, Ar-$H_{bb'}$).

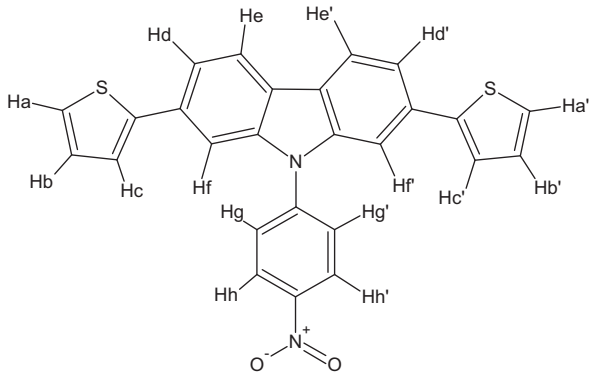


2.3. Synthesis of 9-(4-nitrophenyl)-2,7-di-2-thienyl -9H-carbazole (TCT-N)

Compound **5** (0.18 g, 0.54 mmol), K_2CO_3 (0.15 g, 1.0 mmol), Cu powder (0.05 g) and 1-iodo-4-nitrobenzene (0.135 g, 0.54 mmol) were added to 30 mL nitrobenzene and heated to reflux temperature for 48 h under argon atmosphere. Then the reaction mixture was cooled, filtered through a pad of celite and nitrobenzene was removed under vacuum. Remaining solid was dissolved in DMF and poured into cold water. The precipitated product was filtered, recrystallized from a mixture of chloroform/hexane (1/3; v/v) dried at 60 °C under vacuum. *Yield: 0.1 g, 41%, yellow color product.*

FT-IR (cm^{-1}): 3093, 3068, (C–H aromatic); 1594 (C=C aromatic); 1522, 1340 ($-NO_2$), (^{1}H NMR, $CHCl_3$-d, ppm): δ, 8.18, (d, 2H, $H_{hh'}$); 7.89 (d, 2H, Ar-$H_{ee'}$); 7.57 (d, 2H, Ar-

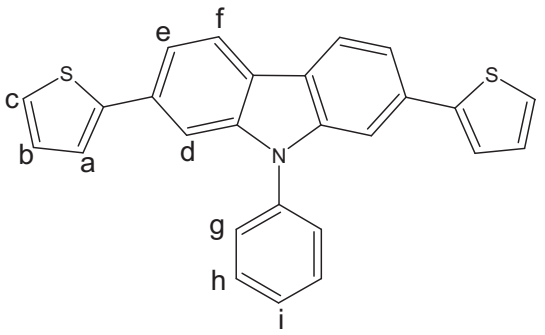
$H_{cc'}$); 7.37, (d, 2H, Ar-$H_{gg'}$); 7.35, (d, 2H, Ar-$H_{aa'}$); 7.28, (d, 2H, Ar-$H_{ff'}$); 7.22, (s, 2H, Ar-$H_{dd'}$); 7.13, (dd, 2H, Ar-$H_{bb'}$).



2.4. Synthesis of 9-phenyl-2,7-di-2-thienyl -9H-carbazole standard molecule (TCT)

2,7-Di-2-thienyl-9*H*-carbazole (0.09 g, 0.27 mmol), K_2CO_3 (0.075 g, 0.05 mmol), Cu powder (0.05 g) and iodobenzene (0.2 g, 0.49 mmol) were added to 20 mL nitrobenzene and heated to reflux temperature for 48 h under argon atmosphere. Then the reaction mixture was cooled, filtered through a pad of celite and nitrobenzene was removed under vacuum. Remaining solid was dissolved in DMF and poured into cold water. The precipitated product was filtered, recrystallized from a mixture of chloroform/hexane (1/2; v/v) dried at 60 °C under vacuum. *Yield: 0.08 g, 70%, light yellow color product.*

FT-IR (cm^{-1}): 3088, 3045, (C–H aromatic); 1592, 1450 (C=C aromatic); (^{1}H NMR, DMSO-d_6, ppm): δ, 7.98, (d, 2H, $H_{ff'}$); 7.52 (d, 2H, Ar-$H_{aa'}$); 7.41 (t, 2H, Ar-$H_{hh'}$); 7.37, (d, 2H, Ar-$H_{gg'}$); 7.24, (d, 2H, Ar-$H_{cc'}$); 7.16, (d, 2H, Ar-$H_{ii'}$); 7.13, (s, 2H, Ar-$H_{dd'}$); 6.97, (d, 2H, Ar-$H_{bb'}$); 6.77, (d, 2H, Ar-$H_{bb'}$).



2.5. Electrochemical polymerization

Electrochemical polymerization of TCT-N and TCT were carried out in a dichloromethane solution of 2.0×10^{-3} M monomers and 0.1 M $TBAPF_6$ by repetitive cycling at a scan rate of 100 mV/s. A platinum wire was used as a counter electrode and Ag wire as a pseudo reference. The polymer was directly coated onto platinum disk (0.02 cm^2) or indium–tin oxide (ITO, 8–12 Ω, 0.8 cm × 5 cm) and then the film was rinsed with acetonitrile to remove from electrolyte salt.

2.6. Instrumentation

FT-IR spectra were recorded by a Perkin Elmer FT-IR Spectrum One by using ATR system (4000–650 cm^{-1}). ^{1}H NMR (Bruker Avance DPX-400) spectra were recorded at 25 °C in deuterated chloroform and TMS as internal standard.

Cyclic voltammetry (CV) technique used for electrochemical measurements was performed using Biologic SP50 potentiostat–galvanostat system. The electrochemical cell includes an Ag/AgCl as reference electrode (RE), Pt wire as counter electrode (CE) and glassy carbon as working electrode (WE) immersed in 0.1 M $TBAPF_6$/acetonitrile as the supporting electrolyte. CV measurements were carried under argon atmosphere. HOMO and LUMO energy levels of polymer were calculated according to the inner reference ferrocene redox couple E (Fc/Fc+) = +0.41 V (*vs.* Ag/AgCl) in acetonitrile by using the formula EHOMO = $-e(E_{ox}-E_{Fc})$ + (−4.8 eV) [26]. Onset values of oxidation potentials were taken into account while calculating HOMO energy levels. LUMO energy levels of TCT and poly-TCT were calculated by subtracting the optical band gap from HOMO level.

UV–Vis spectra were recorded by Analytic Jena-Speedcord S600 spectrophotometer. The absorption spectra of monomer and polymer were recorded in dichloromethane. The optical band gap (E_g) of products were calculated from their low energy absorption edges (λ_{onset}) ($E_g = 1241/\lambda_{onset}$) [27].

Spectro-electrochemical measurements were carried out to consider absorption spectra of this polymer film under applied potential [28]. The spectroelectrochemical cell consisted of a quartz cell, an Ag wire (RE), Pt wire counter electrode (CE) and ITO/glass as transparent working electrode (WE). Measurements were carried out in the 0.1 M $TBAPF_6$ as supporting electrolyte in acetonitrile.

Colorimetric measurements were performed by using Konica Minolta CS-200 chromameter with viewing geometry as recommended by CIE. According the CIE system, the color is made up of three attributes; luminance (L), hue (a), and saturation (b) [29]. These parameters were measured at neural and oxidized state of the poly-TCT-N and poly-TCT on the ITO/glass surface.

3. Results and discussion

3.1. Synthesis and characterization

The new 2,7-carbazole derivative bearing –NO_2 pendant was synthesized in six steps. Starting from 2-amino-4,4′-dinitrobiphenyl, 2,7-dinitro functionalized carbazoles typically obtained from the Cadogan ring-closure reactions were firstly synthesized by Morin and Leclerc [19]. Reduction of nitro group of this intermediate product was performed by using Pd/C and hydrazine monohydrate, a different reducing conditions used by Morin and Leclerc

Scheme 1. [19]. 2,7-Diiodo-*9H*-carbazole (**4**) was synthesized in two steps. In the first step, 2,7-diamino-9*H*-carbazole (**3**) was converted to diaazonium salt and then to give **4** adding KI to this solution [19]. After that, the diiodo compound coupled with thiophene was carried out by using Suzuki type coupling reaction to get 2,7-dithienyl-*9H*-carbazole (**5**). Consequently, the electroactive monomers (TCT-N and TCT) were synthesized by Ullman type condensation of 5 and iodophenyl derivatives in nitrobenzene in the presence of CuI as catalyst and K_2CO_3. The reaction yields of TCT-N and TCT were found to be 41% and 70%, respectively.

After completion of the synthetic works, chemical structure of TCT-N was identified by FT-IR, and ^{1}H NMR. Significant changes were observed in the spectral properties of the initial compounds and the products. In FT-IR spectrum of **1**, characteristic triple bond vibration exerted by azide ($-N_3$) groups was observed at 2123 cm^{-1} and also characteristic $-NH_2$ vibrations at about 3200–3400 cm^{-1} were disappeared. In the next step, as a result of the ring closure reaction, characteristic N–H vibration band for secondary amines of obtained carbazole derivative was observed at 3339 cm^{-1}. Then, **3** obtained from reduction of **2** was identified from its characteristic $-NH_2$ bond vibration at 3306 and 3205 cm^{-1}. In the FT-IR spectra of **4** characteristic $-NH_2$ vibration attributed to **3** disappeared. The FT-IR spectrum of 5 obtained with the attached thienyl moiety on the structure exhibits characteristic strong peak at 685 cm^{-1} (for α-hydrogens of thiophene rings). Finally, TCT-N synthesized from Ullmann condensation of **F10** with 1-iodo-4-nitrobenzene, their characteristic unsymmetric and symmetric $-NO_2$ vibrations were observed at 1522 and 1340 cm^{-1}, respectively. Also characteristic –NH vibration for secondary amines was removed in this spectrum (see Electronic Supplementary information).

In the ^{1}H NMR spectrum of TCT-N monomer, the phenylene proton signals neighboring $-NO_2$ moiety were observed at higher ppm (8.09 ppm) than that of other proton signals due to electro-withdrawing effect of $-NO_2$ substituent. Besides characteristic thienyl β-H doublet signal was observed at 7.12 ppm. Furthermore, other signals attributed to thiophene and carbazole moieties were observed as expected. Finally, FT-IR and ^{1}H NMR spectroscopy results proved that all chemical reactions were completed successfully (Fig. 1).

Electrochemical polymerization was carried out in a reaction medium containing 2.0×10^{-3} M TCT-N or TCT monomer and 0.1 M TBAPF6/dichloromethane via repetitive cycling at a scan rate of 100 mV s^{-1}. The electroactive

polymers were directly coated onto the working electrode (platinum disk or ITO/glass surface). Potentiodynamic electrochemical polymerization of TCT-N was carried out repetitive cycling at a potential between 0 and 1.45 V exhibited a new redox couple at 0.89–1.31 V ($E^{ox}_{p,1/2}$ = 1.12) (Fig. 2a). Due to presence of $-NO_2$ moiety, electrochemical polymerization of TCT-N requires to reach higher potentials compared with TCT standard molecule. Because of this reason, the electrochemical polymerization of TCT was carried out by repetitive cycling at a potential between 0 and 1.40 V exhibited two new redox couples at 0.85–0.95 V ($E^{ox1}_{p,1/2}$ = 0.90 V), and 1.08–1.22 V ($E^{ox2}_{p,1/2}$ = 1.15 V) (Fig. 2b). These two redox couple may be attributed to polaronic and bipolaronic formation of the occurred polymer chain by the electrochemical process [30]. Due to electro-withdrawing effect of the $-NO_2$ substituent on the poly(TCT-N), the two redox states could not be observed at this potential of 1.40 V. In addition, all peaks were increased current density after each successive cycle clearly indicated the formation of poly(TCT-N) and/or poly(TCT) deposited onto the surface of the working electrode. Prepared polymer films on ITO/glass surface was dedoped electrochemically in monomer free-electrolyte solution to equilibrate the redox behavior after washing with an acetonitrile to remove the unreacted monomers and/or oligomeric species. Then, the polymers on ITO/glass surface partly dissolved in dichloromethane by using ultrasonic bath for UV–Vis absorption measurements.

3.2. Optical and electrochemical properties

The UV–Vis absorption spectra of TCT-N and TCT monomers and polymers were recorded in dichloromethane (Fig. 3). The lowest energy bands of TCT-N and TCT standard molecule at about λ_{max} = 350 nm attributed to thiophene-carbazole-thiophene (TCT) π-conjugated system. Although λ_{max} of TCT-N and TCT are the same, the absorption band of TCT-N is broadened than that of TCT. Thus, TCT-N has an onset value of 472 nm corresponding to a 76 nm red shift with respect to that of the TCT. This significant bathochromic shift is attributed to the $-NO_2$ electro-withdrawing effect. According to these results, the optical band gap values of TCT and TCT-N were found to be 3.13 and 2.63 eV. On the other hand, the lowest energy transition band (λ_{max}) of poly(TCT-N) was observed at about 415 nm. This significant bathochromic shift is attributed to resulting the polymer with extended π-system. Due to TCT-N consist of $-NO_2$ moiety, the molecule require for higher potential than that of TCT and thus reduced both the length of chain and degree of conjugation with respect to that of the TCT. Because of this effect, 20 nm red shift of λ_{max} was observed in the λ_{max} of TCT. Finally, for poly(TCT-N), the onset absorption is 580 nm corresponding to an energy band gap of 2.13 eV. Besides, the poly-TCT has an onset value of 615 nm (equal to a band gap of 2.01 eV) corresponding to a 35 nm red shift with respect to that of the poly(TCT-N).

The electrochemical properties of TCT-N and TCT monomer and their polymers were investigated by cyclic voltammetry (CV). An explicit difference in redox behavior of the TCT-N and TCT can be deduced from the CV which was depicted in Fig. 4. During CV scan in the anodic regime of TCT-N and TCT monomer, TCT-N exhibited an irreversible oxidation peak at $E^{ox}_{m,a}$ = 1.46 V *vs.* Ag/AgCl during an anodic scan, and this oxidation potential is higher than that of TCT (semi reversible; $E^{ox}_{m,a}$ = 1.25 and $E^{ox}_{m,c}$ = 1.11 V; $E^{ox}_{m,1/2}$ = 1.19 V *vs.* Ag/AgCl). As expected, this result indicated that TCT has a more electron rich nature than TCT-N when attaching the $-NO_2$ moiety in a similar system. On the other hand, to record the cyclic voltammogram of poly(TCT-N) and poly(TCT), the polymer films prepared by repetitive potential cycling were rinsed in a monomer-free-electrolyte solution. Due to the extended conjugation in the polymers backbone, the oxidation potentials were observed as reversible and at lower potential with compared to corresponding monomers. On the other hand, in the cathodic regime, cyclic voltammogram of TCT-N exhibits characteristic reversible reduction couple with potentials of $E^{red}_{m,c}$ = −0.93 V $-E^{red}_{m,a}$ = −0.85 V and $E^{red}_{m,1/2}$ = −0.89 V which reflects the reduction process of $-NO_2$

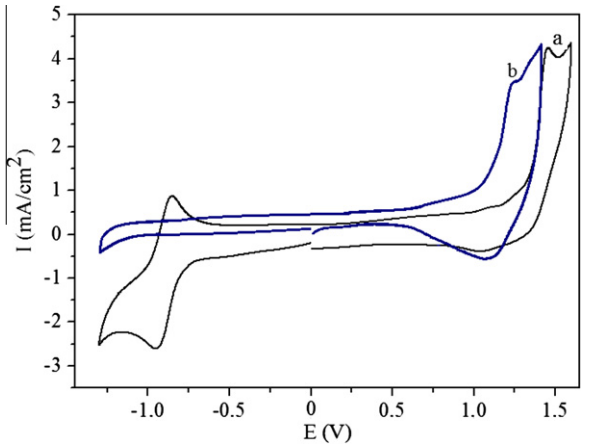

Fig. 4. Cyclic voltammogram of TCT-N (a) TCT (b) in the 0.1 M $TBAPF_6$/dichloromethane, scan rate 100 mV/s, *vs.* Ag/AgCl.

moiety. In comparison to the monomer, the reduction couple of poly(TCT-N) broadened and slightly shifted positively ($E^{red}_{p,c} = -0.91$ V – $E^{red}_{p,a} = -0.77$ V and $E^{red}_{m,1/2} = -0.84$ V) and the conjugated backbone is still sufficiently conducting to allow electron transfer at potentials. Besides, HOMO–LUMO energy levels of TCT-N and poly(TCT-N) were calculated according to the onset values of their oxidation and reduction potentials. The LUMO energy levels of TCT and poly(TCT) were calculated by adding the optical band gap from their HOMO levels (Table 1). As a result of the data in Table 1, optical and electrochemical properties of the molecules were greatly influenced by the addition of electro-withdrawing $–NO_2$ as subunit in the structure.

The spectro-electrochemical properties of the poly(TCT-N) film were determined upon doping process (Fig. 5) and compared to poly-TCT (Fig. 6) in order to get further support for the effect of $–NO_2$ electro-withdrawing moiety. In the neutral state, the poly(TCT-N) had one maximum absorption at 418 nm (λ_{max}, π–π^* transition). The optical band gap (E_g) of poly(TCT-N) was found to be 2.18 eV from the onset of absorption, which is somewhat higher than the E_g of poly-TCT (2.06 eV). Upon oxidation, the intensity of the λ_{max} was simultaneously decreased up to a certain first and second broad bands intensified at about 762 (0–1.0 V) and 1000 nm (1.0–1.6 V) indicated the formation of polarons and bipolarons on poly(TCT-N) film, respectively (Fig. 5). Thus, NIR region, above 700 nm, was strongly absorbed at the fully oxidized state. Based on foregoing results, the orange color of the film with Commision Internationale de l'Eclairage (CIE) color parameters (Luminance $L = 60$, hue $a = 7$, and saturation $b = 57$) turned into green (L: 54; a: −20; b: 43), turquoise (L: 42; a: −16; b: 2), and dark blue (L: 38; a: −2; b: −10), respectively, upon oxidation (Fig. 5). On the other hand, when the intensity of the π–$\pi*$ transition band of poly(TCT) film ($\lambda_{max} = 422$ nm) decreased, a new broad absorption band at about 790 nm started to intensify due to the polaron formation (0–0.8 V). Upon further oxidation, a broad band between 400 and 1000 nm also intensified (1–1.4 V). Thus all visible and near-IR regions were absorbed by the poly(TCT) film at fully oxidized state. The yellow color of the film with CIE color parameters (L: 75; a: −11; b: 64) turned into dark gray (L: 39; a: −6; b: 13), upon oxidation (Fig. 6).

Double step chronoamperometry technique was used to monitor the changes in the electro-optical responses during switching. Electrochromic parameters of the polymer

films were analyzed by changes that occurred in the transmittance (increments and decrements of the absorption band at 420 and 1000 nm with respect to time) while switching the potential step wisely between neutral and oxidized states with a residence time of 10 s [28a]. The percentage transmittance changes (%ΔT) of poly(TCT-N) between the neutral (at 0 V) and oxidized states (at 1.6 V) were found to be 22% for 420 nm and 57% for 1000 nm (Fig. 5). For poly(TCT), these values were found as 8% for 420 nm and 55% for 1000 nm (Fig. 6). Besides, the oxidation and reduction response times were measured to be 4.3 and 1.3 s for poly(TCT-N) and 0.8 and 1.8 s for poly(TCT) (Fig. 7). Optical activities of the poly(TCT-N) and poly(TCT) polymer film were retained by 92% and 77% even after 1000 cycles of operation, respectively (Fig. 7). Although the response times were relatively slow, the polymer film of TCT-N was more stable than that of TCT upon repetitive cycles.

On the other hand, the coloration efficiency (CE) was calculated by using $CE = \Delta OD/Q_d$ and $\Delta OD = \log (T_{colored}/T_{bleached})$, where Q_d is the injected/ejected charge between neutral and oxidized states, $T_{colored}$ and $T_{bleached}$ are the transmittance in the oxidized and neutral states, respectively. Using this equation, CE of poly(TCT-N) and poly(TCT) was measured to be 264 and 126 $cm^2\,C^{-1}$ by chronoamperometry, while switching the polymer films between oxidized and reduced states. The results clearly show that the coloration efficiency of poly(TCT-N) is two times greater than that of poly(TCT). Toppare et al. reported the multi-electrochromic polymer of thiophene-pyrrole-thiophene (SNS) analogue containing electro-withdrawing $-NO_2$ substituent [31]. Based on previous results, it can be easily seen that the prepared polymer film of TCT-N has much better electrochromic performance than that of its SNS analogue and poly(TCT) standard.

4. Conclusion

Herein, we have reported the synthesis of a new multi-electrochromic 2,7 linked thiophene-carbazole-thiophene (TCT) derivative containing an electro-withdrawing $-NO_2$ substituent. It has been determined that the optical and the electrochemical properties of the monomer were

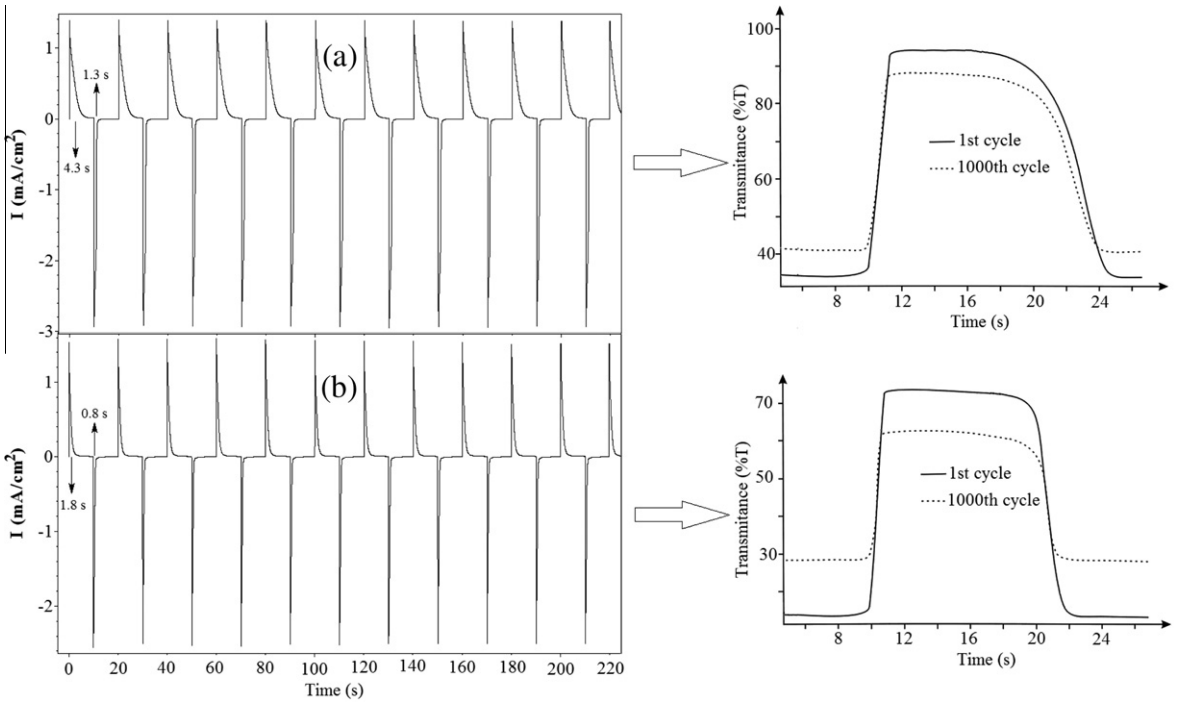

Fig. 7. Electrochemical switching, optical absorbance monitored at 1000 nm for poly-TCT-N (a) and poly-TCT (b) film between 0 and 1.6 V.

greatly influenced the presence of the electro-withdrawing $-NO_2$ as subunit in the structure. TCT-N monomer was electrochemically polymerized onto transparent ITO/glass surface to give a quite stable multi-electrochromic polymer with a high contrast ratio in the NIR region (ΔT = 57% at 1000 nm). In comparison to TCT standard reference, polymer film of TCT-N has much better electrochromic performance in terms of multielectrochromic behavior, high resistance to over oxidation and high contrast ratio at near-IR region. With a high contrast ratio and an impressive electrochemical stability, TCT-N is a possible good candidate for electrochromic applications.

the soluble blue PHOLEDs is not suitable for display application. Deep blue color with *y* color coordinate below 0.20 is required for display application, but no solution processed deep blue PHOLED has been fabricated. High triplet energy host materials with a triplet energy over 2.90 eV and morphological stability after solution film coating are required to develop deep blue PHOLEDs. In addition, soluble deep blue emitting phosphorescent dopant materials are needed to obtain deep blue color. However, there has been no report fabricating soluble deep blue PHOLEDs because no soluble host and dopant material was available for application in deep blue PHOLEDs. Therefore, it is important to develop solution processed deep blue PHOLEDs using soluble host and dopant materials.

Phosphine oxide type compounds can be a candidate as a high triplet energy soluble host materials. Our group reported high external quantum efficiency in deep blue PHOLEDs using phosphine oxide type host materials [19–21]. In particular, *N*,*N*′-Dicarbazolyl-3,5-benzene based phosphine oxide compound showed above 20% external quantum efficiency in deep blue PHOLEDs [19]. Therefore, the phosphine oxide type host materials can be useful as the host materials for soluble deep blue PHOLEDs.

In this work, solution processed deep blue PHOLEDs were developed using a soluble high triplet energy host material and a deep blue emitting phosphorescent dopant. High quantum efficiency of 22.1% and a deep blue color coordinate of (0.14, 0.19) were demonstrated from solution processed deep blue PHOLEDs. The quantum efficiency is one of the best efficiency values reported in solution processed blue PHOLEDs and this work is the first paper reporting deep blue PHOLEDs fabricated by solution process.

2. Experimental

The synthesis of the mCPPO1 was described in our previous work [19]. The device structure of the blue PHOLED was indium thin oxide (ITO)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS) (60 nm)/PVK (10 nm)/(9-(3-(9H-carbazol-9-yl)phenyl)-9H-carbazol-3-yl)-diphenylphosphine oxide (mCPPO1):bis((3,5-difluoro-4-cyanophenyl)pyridine) iridium picolinate (FCNIrpic) (20 nm, 3%)/4-(triphenylsilyl)phenyldiphenylphosphine oxide (TSPO1) (35 nm)/LiF(1 nm)/Al(200 nm). The soluble deep blue PHOLED with PVK host instead of mCPPO1 was also fabricated for comparison. The mCPPO1:FCNIrpic emitting layer was spin coated from toluene solution and the concentration of the mCPPO1 solution was 1.0 wt.%. The mCPPO1:FCNIrpic film was baked at 80 °C for 10 min to remove residual solvent after spin coating. PVK hole transport layer was formed by spin coating from 0.3 wt.% chlorobenzene solution at a spin speed of 1000 rpm. The PVK layer was baked at 110 °C for 10 min after spin coating. TSPO1 was vacuum deposited at a vacuum pressure of 8.0×10^{-7} torr at a deposition rate of 0.1 nm/s. All devices were encapsulated with a CaO getter and a glass lid after device fabrication. Current density–voltage–luminance performances of the soluble blue PHOLEDs were measured with a Keithley 2400 source measurement unit and a CS 1000 spectroradiometer. Surface morphology of the spin coated mCPPO1:FCNIrpic film was analyzed using atomic force microscope.

3. Results and discussion

There are several requirements for the soluble host materials for solution processed high efficiency deep blue PHOLEDs. The host material should form uniform film with low surface roughness less than 1 nm, which is comparable to that of vacuum deposited film. The solution coated film should also be stable and form amorphous film. In addition to the smooth surface morphology after coating, high triplet energy and bipolar charge transport properties are important to obtain high efficiency in soluble deep blue PHOLEDs. Other than these, good solubility in common aromatic solvents such as toluene, chlorobenzene and dichlorobenzene is also required for good mixing with blue phosphorescent dopant.

A high triplet energy host material, mCPPO1, was reported to be effective as the host material for vacuum deposited blue PHOLEDs [19]. It has a high triplet energy of 3.00 eV and bipolar charge transport properties. In addition, the asymmetric molecular structure of the mCPPO1 is suitable for amorphous film formation. Therefore, the mCPPO1 is suitable as the host material for solution processed deep blue PHOLEDs. A deep blue emitting phosphorescent dopant, FCNIrpic, was reported in other works and gave high efficiency [19]. It has highly polar substituents and picolinic acid as the ancillary ligand. Although the dopant with three main ligands without any ancillary ligand was not soluble in aromatic solvent, the FCNIrpic was soluble in chlorobenzene and dichlorobenzene. Therefore, the FNCIrpic can be used as the soluble deep blue emitting dopant in solution processed deep blue PHOLEDs. Chemical structures of host and dopant materials are shown in Fig. 1.

The mCPPO1 and FNCIrpic were mixed in toluene solvent and was spin coated on Si substrate and PVK film to study the morphology of the mCPPO1:FNCIrpic film. Atomic force microscope pictures of spin coated mCPPO1:FCNIrpic and PVK/mCPPO1:FCNIrpic films are shown in Fig. 1. The mCPPO1:FCNIrpic and PVK/mCPPO1:FCNIrpic films showed smooth morphology with a surface roughness of 0.47 and 0.48 nm, respectively. The mCPPO1:FCNIrpic film could be stably coated on the PVK layer with little intermixing because the high molecular weight PVK layer shows poor solubility in toluene. There was little aggregation of the FCNIrpic dopant and uniform morphology was observed in spin coated mCPPO1:FCNIrpic film. The surface roughness of the mCPPO1:FCNIrpic film was comparable to that of the vacuum deposited mCPPO1:FCNIrpic film. This indicates that the mCPPO1:FCNIrpic film forms stable morphology after spin coating from toluene solution. The low surface roughness of the mCPPO1:FCNIrpic film was maintained even after thermal annealing at 110 °C for 10 min, indicating morphological stability of the mCPPO1:FCNIrpic film. The high temperature morphological stability of the mCPPO1:FCNIrpic film is due to the thermal and morpho-

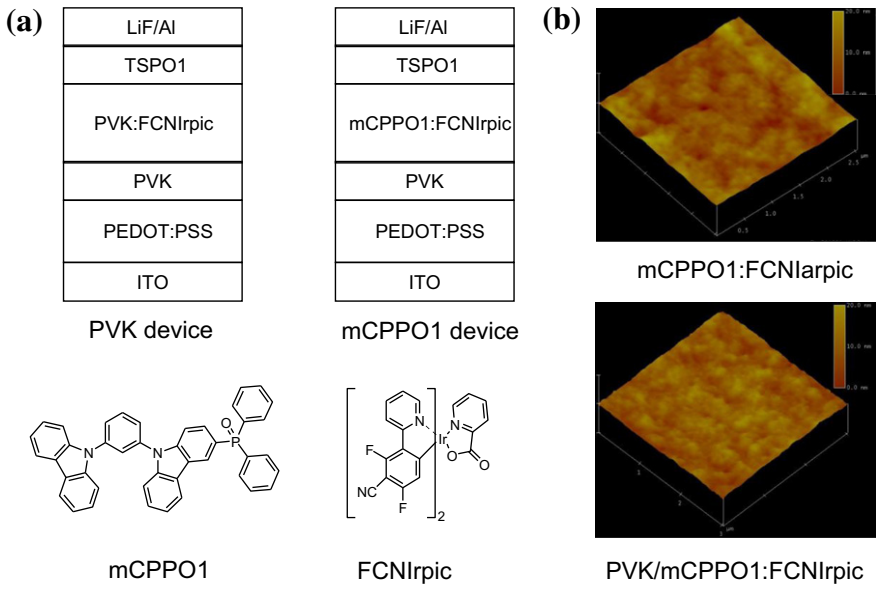

Fig. 1. Device structures and chemical structures of mCPPO1 and FCNIrpic (a) and atomic force microscope image of the spin coated mCPPO1:FCNIrpic and PVK/mCPPO1:FCNIrpic films (b).

logical stability of the mCPPO1. The mCPPO1 has a high glass transition temperature of 115 °C, which contributed to the morphological stability at high temperature.

Deep blue PHOLEDs with a basic device structure of ITO/PEDOT:PSS/PVK/mCPPO1:FCNIrpic/TSPO1/LiF/Al was fabricated. Annealing temperature to remove residual solvent was changed from 80 to 140 °C to optimize the process. Fig. 2 shows the device performances of the deep blue PHOLEDs according to the annealing temperature of the emitting layer. The current density and luminance of the deep blue PHOLEDs were not greatly affected by the annealing temperature up to 110 °C, but they were significantly reduced at 140 °C. This indicates that the spin coated mCPPO1:FCNIrpic emitting layer is degraded at 140 °C. The emitting layer was stable up to 110 °C in the morphology study of the mCPPO1:FCNIrpic film, resulting in stable device performances at 110 °C. The quantum efficiency was also very low after 140 °C thermal treatment. The quantum efficiency of the 80 and 110 °C treated deep blue PHOLEDs was similar. The maximum quantum efficiency of the two devices was 19.5%. However, the quantum efficiency at high luminance was better in the device thermally annealed at 80 °C than the device annealed at 110 °C. The efficiency was dropped at high luminance after thermal annealing at 110 °C, which may be due to slight aggregation of the FCNIrpic dopant. Therefore, the thermal annealing of the emitting layer was performed at 80 °C.

The device performances of the deep blue PHOLEDs with the mCPPO1:FCNIrpic emitting layer were further optimized by changing the thickness of the emitting layer from 30 to 20 nm. A deep blue PHOLED with PVK host instead of mCPPO1 was also fabricated for comparison. Device performances of the solution processed deep blue PHOLEDs are shown in Fig. 3. It can be shown that the current density of the mCPPO1 device is higher than that of the PVK device. PVK has the highest occupied molecular orbital (HOMO) of 5.9 eV and the lowest unoccupied molecular orbital (LUMO) of 2.4 eV. Although the PVK

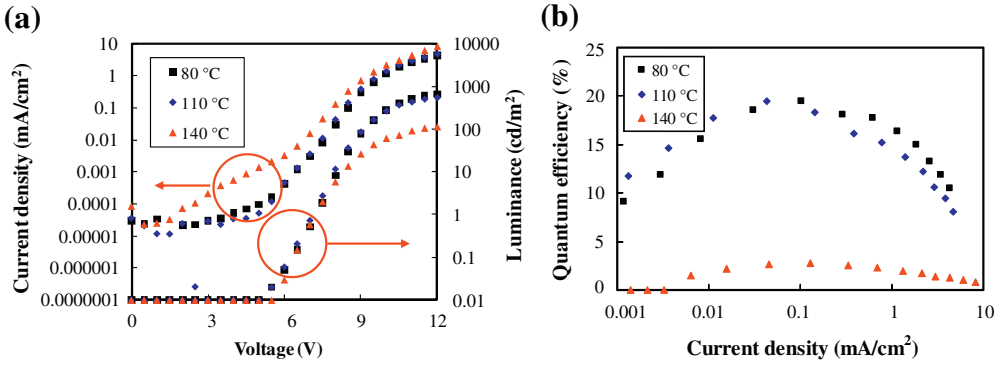

Fig. 2. Current density–voltage–luminance curves (a) and quantum efficiency–current density curves of spin coated mCPPO1:FCNIrpic devices according to annealing temperature (b).

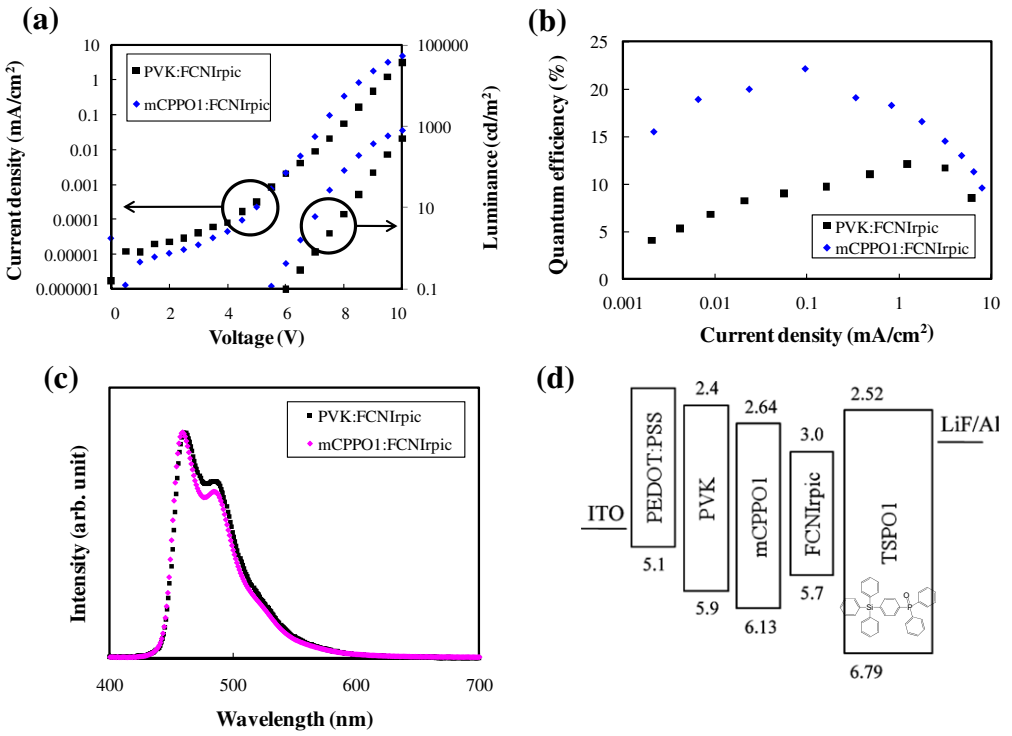

Fig. 3. Current density–voltage–luminance (a), quantum efficiency–current density (b), and electroluminescence (c) curves of mCPPO1and PVK based blue phosphorescent organic light-emitting diodes in addition to the energy level diagram of the device and chemical structure of TSPO1 (d).

shows good hole injection and transport properties, poor electron injection and transport properties of PVK reduced the current density of the PVK device. The mCPPO1 has hole transport carbazole unit and electron transport diphenylphosphine oxide unit in the molecular structure. Therefore, it shows good hole transport and electron transport properties, which resulted in high current density in the mCPPO1 device. In addition, the HOMO level of mCPPO1 was 6.13 eV for good hole injection from PVK and the LUMO level was 2.64 eV for electron injection from TSPO1 with the LUMO level of 2.52 eV for efficient electron injection into the mCPPO1. Energy level diagram and chemical structure of TSPO1 are shown in Fig. 3(d). The luminance of the mCPPO1 device was also high in the mCPPO1 device, which is due to high current density and high recombination efficiency of the mCPPO1 device.

The quantum efficiency–current density curves of the solution processed deep blue PHOLEDs are shown in Fig. 3(b). The quantum efficiency of the mCPPO1 device was much higher than that of the PVK device over all current density range. The maximum quantum efficiency of the mCPPO1 device was 22.1% and the quantum efficiencies at 0.42 mA/cm^2 (100 cd/m^2) and 2.61 mA/cm^2 (500 cd/m^2) were 18.9% and 15.1%, respectively. This quantum efficiency is one of the best efficiency values reported in soluble blue PHOLEDs. The maximum quantum efficiency of the PVK:FCNIrpic device was only 12.1%. The high quantum efficiency of the mCPPO1:FCNIrpic device can be explained by the high triplet energy and bipolar charge transport properties of the mCPPO1. The FCNIrpic dopant has a triplet energy of 2.74 eV and the host should have higher triplet energy than the dopant material. The mCPPO1 has higher triplet energy than FCNIrpic dopant and the triplet energy can be effectively transferred from mCPPO1 host to FCNIrpic dopant. As mentioned above, bipolar charge transport properties of the mCPPO1 balanced holes and electrons in the emitting layer, inducing high recombination efficiency in the emitting layer. In the case of the PVK, poor electron transport properties of the PVK limited the quantum efficiency. Maximum current efficiency and current efficiency at 100 cd/m^2 of the mCPPO1:FCNIrpic device were 28.4 and 23.9 cd/A.

Electroluminescence (EL) spectra of mCPPO1:FCNIrpic and PVK:FCNIrpic devices are shown in Fig. 3(c). Maximum emission peak of the blue PHOLEDs was observed at 457 nm and a color coordinate of (0.14, 0.19) was obtained in the soluble deep blue PHOLEDs. Within our knowledge, this is the first work reporting deep blue color in solution processed blue PHOLEDs. No emission other than FCNIrpic emission was detected in the EL spectra, indicating effective exciton confinement and energy transfer to FCNIrpic in the emitting layer.

4. Conclusions

In conclusion, a high efficiency solution processed deep blue PHOLED with a deep blue color coordinate of (0.14, 0.19) was developed using a soluble emitting layer of mCPPO1 and FCNIrpic. A maximum quantum efficiency of 22.1% and a quantum efficiency of 18.9% at 100 cd/m^2 were achieved in the soluble deep blue PHOLEDs. High effi-

ciency soluble deep blue PHOLEDs were realized using the mCPPO1:FCNIrpic emitting layer for the first time and further development of soluble host and dopant materials may enhance the quantum efficiency of soluble blue PHOLEDs further.

Among the blue-emitting materials, anthracene derivatives are particularly attractive due to their excellent photoluminescence and electroluminescence properties [12–16]. Such as, triarylamines [17,18], or the other moieties [19–21] have been incorporated into anthracene unit to improve hole injection and charge carrier transport properties. Although a number of vacuum-deposited anthrance-based molecules have been reported as efficient blue electroluminescent materials [22,23], solution-processed analogs remain rare and largely unexplored in OLEDs for its poor solubility and aggregating properties. In our previous work [24], we have demonstrated that 1,3,5-tri (9-anthracene) benzene is a good core emitter, and its centered starburst oligofluorenes show robust blue light emission in an OLED device. Although these materials exhibit deep blue emission, and the current efficiency is up to 1.8 cd/A, but the values of T_g are only about 110 °C for the oligofluorenes possessing long alkyl chains.

Here, we report the design and synthesis of four symmetric dendrimer molecules based on the following two principles. Firstly, the propeller-like, and highly rigid 1,3,5-tri (9-anthracene) benzene group was used as the core, which can reduce strong intermolecular interactions and suppress fluorescence quenching. Secondly, using stilbenzene as a conjugated bridge, the different electron donor dendrons (naphthalene, diphenylbenzene, carbazole, and diphenylamine) were introduced at the peripheries of the core to improve solubility in common organic solvents, influence the charge transporting properties, enhance the morphological stability and the thermal stability and improve color purity. As we expected, all of these materials possess high glass transition temperatures (T_g) and good morphological properties, and exhibit good EL performance with low driving voltages in solution-processed double-layer OLED devices. These materials are a promising class of solution-processable blue emitters for practical applications.

2. Experimental section

2.1. Material and methods

All reagents and solvents were used as purchased from Aldrich and were used without further purification. ^{1}H NMR spectra were recorded using a Bruker-AF301 AT 400 MHz. High resolution mass spectrometric measurements were carried out using a Bruker autoflex MALDI-TOF mass spectrometer. Fluorescence spectra were obtained on a Perkin Elmer LS55 Luminescence spectrometer and UV–Vis spectra were measured using a Shimadzu-3150 UV–Vis–NIR spectrophotometer. The differential scanning calorimetry (DSC) analysis was performed under a nitrogen atmosphere at a heating rate of 10 °C/min using a PE Instruments DSC 2920. Thermogravimetric analysis (TGA) was undertaken using a SEIKO EXSTAR 6000 TG/DTA 6200 unit under nitrogen atmosphere at a heating rate of 10 °C/min. To measure the PL quantum yields (Φ_f), degassed solutions of the compounds in CH_2Cl_2 were prepared. The concentration was adjusted so that the absorbance of the solution would be lower than 0.1. The excitation was performed at 360 nm and 9,10-diphenylanthracene(DPA) in CH_2Cl_2 (Φ_f = 0.9 in CH_2Cl_2) or solid film(η_{DPA} = 1) was used as a standard [25,26]. Cyclic voltammetry measurements were carried out in a conventional three electrode cell using a Pt button working electrode of 2 mm in diameter, a platinum wire counter electrode, and a Ag/AgCl (0.1 M) reference electrode on a computer-controlled EG&G Potentiostat/Galvanostat model 283 at room temperature. Reductions CV of all compounds were performed in dichloromethane containing 0.1 M tetrabutylammoniumhexafluorophosphate (Bu_4NPF_6) as the supporting electrolyte.

2.2. Synthesis

The structures and synthetic routes of the four well-defined compounds are shown in Scheme 1. 1,3,5-tri(anthracen-9-yl)benzene (**1**) and 1,3,5-tris(10-bromo anthracen-9-yl)benzene (**2**) were synthesized according to the literature [24].

2.2.1. Synthesis of compound (**3**)

A 100 ml round-bottomed flask was charged with compound **2** (422 mg, 0.5 mmol), toluene (20 ml), and ethanol (10 ml) under nitrogen atmosphere. Subsequently, 4-formylphenylboronic acid (375 mg, 2.5 mmol), tetrabutylammonium bromide (0.96 g, 2.98 mmol) and aqueous potassium carbonate (15.0 ml, 30 mmol) were added slowly to the solution. 10 min later, tetrakis (triphenylphosphine) palladium (0) (173 mg, 0.15 mmol) was added and the reaction mixture was stirred under reflux for 24 h in the absence of light. After cooling to room temperature, the precipitate was filtrated and washed with distilled water and methanol, a yellow powder was obtained. Yield 0.34 g (74%). ^{1}H NMR: ($CDCl_3$, 400 MHz): δ (ppm) 10.21 (s, 3H), 8.30–8.28 (d, J = 8.8 Hz, 6H), 8.15–8.13 (d, J = 8.0 Hz, 6H), 7.90 (s, 3H), 7.68–7.56 (m, 18H), 7.43–7.40 (t, J = 7.6 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 191.98, 145.92, 139.21, 136.94, 135.86, 135.77, 133.98, 132.18, 129.93, 129.87, 129.60, 126.85, 126.64, 125.72, 125.63. 2.2.2. Synthesis of compound (**4**)

A 500 ml three-neck round-bottomed flask was charged with 4-bromobenzylphosphonium bromide (5.21 g, 10.0 mmol), sodium hydride (0.75 g, 30.0 mmol) and THF (200 ml) under nitrogen atmosphere. After stirring for 1 h, at 40 °C, compound **3** (2.3 g, 2.5 mmol) was added. The solution was continuously stirred for 4 h at room temperature and the product was precipitated by the addition of methanol (200 ml). The precipitated solid was filtrated and washed with methanol, a light yellow solid powder was obtained. Yield 3.2 g (93%). ^{1}H NMR: ($CDCl_3$, 400 MHz): δ (ppm) 8.30–8.28 (d, J = 8.0 Hz, 6H), 7.89 (s, 3H), 7.78–7.75 (m, 12H), 7.56–7.39 (m, 33H), 7.26–7.21 (m, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 136.34, 132.20, 132.10, 131.98, 131.89, 131.82, 131.51, 131.41, 130.81, 130.59, 130.01, 128.58, 128.47, 128.07, 127.85, 127.13, 126.82, 126.62, 125.55, 125.16. 2.2.3. Synthesis of compound (*5a*)

A 500 ml three-neck round-bottomed flask was added compound **4** (137.8 mg, 0.1 mmol), 1-naphthaleneboronic acid (111 mg, 0.5 mmol), toluene (20 ml), ethanol (10 ml), 2 M K_2CO_3 (15 ml, 30 mmol) aqueous solution and tetrakis-(triphenylphosphine) palladium (0) (173 mg, 0.15 mmol) in turn, then the reaction mixture was refluxed under nitrogen for 24 h in the absence of light. After cooling to the room temperature, the precipitate was collected by filtration and washed with distilled water and methanol. The crude product was purified by column chromatography and dried under vacuum to yield a yellowish solid. Yield: 92%. ^{1}H NMR: ($CDCl_3$, 400 MHz): δ (ppm) compound **5a**: 8.30–8.28 (d, J = 8.0 Hz, 6H), 8.00–7.81 (m, 26H), 7.74–7.72 (m, 6H), 7.58–7.26 (m, 40H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 140.24, 139.87, 139.32, 138.46, 137.20, 136.67, 136.41, 134.05, 133.88, 131.79, 131.58, 130.50, 130.05, 128.75, 128.60, 128.24, 128.13, 127.87, 127.74, 127.21, 126.88, 126.61, 126.51, 126.09, 125.99, 125.96, 125.82, 125.56, 125.41, 125.17. MS (MALDI-TOF): 1519.6144 (m/z), calcd for $C_{120}H_{78}$: 1519.6132. Anal. Calcd. For $C_{120}H_{78}$: C 94.83, H 5.17; found: C 94.58, H 5.42.

2.2.4. Synthesis of compound (*5b*)

The compound was synthesized using a similar procedure as for compound **5a**, yield: 85%. ^{1}H NMR: ($CDCl_3$, 400 MHz): δ (ppm) 8.32–8.30 (d, J = 8.8 Hz, 6H), 7.91–7.72 (m, 50H), 7.57–7.35 (m, 40H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 142.45, 141.79, 141.15, 140.36, 139.28, 138.47, 137.17, 136.71, 136.59, 136.41, 131.78, 130.01, 129.17, 128.87, 128.79, 128.60, 128.55, 127.64, 127.59, 127.38, 127.25, 127.18, 127.11, 126.81, 126.60, 126.12, 125.54, 125.32, 125.17, 124.94 MS (MALDI-TOF): 1825.7515 (m/z), calcd for $C_{144}H_{96}$: 1825.7546. Anal. Calcd. For $C_{144}H_{96}$: C 94.70, H 5.30; found: C 94.85, H 5.15.

2.2.5. Synthesis of compound (*5c*)

A mixture of compound **4** (689 mg, 0.5 mmol), carbazole (376 mg, 2.25 mmol), CuI (14.25 mg, 0.075 mmol), 18-crown-6 (19 mg, 0.25 mmol), K_2CO_3 (310.5 mg, 2.25 mmol) and 1,3-di-methyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone (DMPU, 2.0 ml) was heated to 190 °C for 24 h under a nitrogen atmosphere. After cooling down to room temperature, the mixture was quenched with 1 N hydrochloric acid, then extracted with dichloromethane, washed with $NH_3{\cdot}H_2O$ and water. The combined organic phases were dried ($MgSO_4$) and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel using hexane as the eluent to give compound **5c** as a yellow solid. Yield: 80%. ^{1}H NMR: ($CDCl_3$, 400 MHz): δ (ppm) 8.33–8.31 (d, J = 9.2 Hz, 6H), 8.17–8.15 (d, J = 7.6 Hz, 6H), 7.92 (s, 3H), 7.83–7.80 (m, 18H), 7.63–7.38 (m, 42H), 7.33–7.29 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 140.80, 140.70, 139.30, 138.69, 137.12, 137.00, 136.51, 136.44, 136.42, 134.04, 131.84, 130.42, 130.03, 129.25, 128.08, 127.90, 127.27, 127.18, 126.84, 126.68, 125.98, 125.57, 125.20, 123.46, 120.35, 120.02. MS (MALDI-TOF): 1636.6458 (m/z), calcd for $C_{126}H_{81}N_3$: 1636.6461. Anal. Calcd. For $C_{126}H_{81}N_3$: C 92.45, H 4.99, N 2.57; found: C 92.31, H 5.17, N 2.52.

*2.2.6. Synthesis of compound (**5d**)*

The compound was synthesized using a similar procedure as for compound **5c**. Yield: 74%. 8.30–8.28 (d, J = 8.8 Hz, 6H), 8.17–8.15 (d, J = 7.6 Hz, 6H), 7.89–7.88 (s, 3H), 7.78–7.72 (m, 18H), 7.60–7.37 (m, 48H), 7.27–7.21 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 139.25, 138.68, 137.19, 136.62, 136.36, 136.29, 134.01, 131.86, 131.79, 131.72, 131.49, 130.57, 129.99, 129.30, 129.10, 128.87, 128.75, 127.81, 127.44, 126.80, 126.54, 126.31, 125.53, 125.17, 124.55, 121.45. MS (MALDI-TOF): 1641.6924 (m/z), calcd for $C_{126}H_{87}N_3$: 1641.6900. Anal. Calcd. For $C_{126}H_{87}N_3$: C 92.11, H 5.34, N 2.56; found: C 92.10, H 5.39, N 2.51.

2.3. Device fabrication

To investigate the electroluminescent (EL) properties of the symmetric starburst compounds containing different surface groups, double layer OLEDs were fabricated via solution processing according to the previous literature.[27] The device structures of the OLEDs were as follows: ITO/PEDOT:PSS/**5a–5d** or (doping **DPAVBi**) /TPBI/LiF/Al. Polyethylene dioxythiophene-polystyrene sulfate (PEDOT-PSS) and 2,2′,2″-(1,3,5-benzenetriyl)tris[1-phenyl-1H-benzimidazole] (TPBI) were used as hole injection and hole-blocking/electron-transporting layer, respectively. The active layer was spin-coated from toluene solution, and TPBI layer was deposited by means of conventional vacuum deposition onto the ITO-coated glass substrates. The *J–V–L* characteristics of the EL devices were measured using a Keithley 2400 source meter and a Keithley 2000 source multimeter equipped with a calibrated silicon photodiode. The EL spectra were measured using a JY SPEX CCD3000 spectrometer. The thicknesses of the films were measured using the instrument of Profiler DEKTAK150. All of the measurements were carried out at room temperature under ambient conditions.

3. Results and discussion

3.1. Synthesis, Thermal, Film-forming, Optical and Electrochemical properties

Four target compounds, **5a, 5b, 5c** and **5d,** were prepared as shown in Scheme 1. Detailed synthesis of the 1,3,5-tris(10-bromoanthracen-9-yl)benzene (**2**) has been described in previous work [24]. The intermediate **3** was synthesized by the Pd-catalyzed Suzuki cross-coupling of formylated benzene boric acid with compound **2** with excellent yields, and were easily purified by a simple filtration and washed with distilled water and methanol. Then Wittig reaction of 4-bromobenzyl-phosphonium bromide and compound **3** gave the compound **4** in 93% yield at 40 °C. The target compounds **5a** and **5b** were obtained in 92% and 85% of isolated yield, by an easy Suzuki coupling reaction, respectively. The target compound **5c** and 5**d** were obtained in 80% and 74% of isolated yield by the CuI-catalyzed Ullman reaction, respectively. All the four target compounds were soluble in common organic solvents (CH_2Cl_2, toluene), and characterized fully by ^{1}H and ^{13}C NMR, MALDI-TOF, and elemental analysis.

Thermal properties of these compounds were studied using DSC and TGA. The thermal properties were measured under N_2 gas condition at heating rates of 10 °C/min, and the related data are listed in Table 1. As shown in Fig. 1a, compounds **5a–5d** exhibit a high glass transition temperature (T_g) at 166, 189, 260, and 231 °C, respectively. The high T_g are attributed to the rigid core and the star shaped dendrons can effectively suppress the crystallization (or arm aggregation). High decomposition temperatures (T_d, 5% weight loss) of these compounds were also observed at 484, 504, 497, and 427 °C (Fig. 1b), respectively, which may be due to the highly stability of the 1,3,5-tri (9-anthracene) benzene core and the side groups. The stable aromatic side group can supply electron to the styryl group and enhance the thermal stability of material.[28] The relatively high T_g and T_d of these star shaped compounds is very desirable for high performance OLED applications.

Efficient film-forming properties of light emitting materials used in OLEDs are crucial for the performance of the devices, so the surface morphologies of thin films of the four compounds (**5a**, **5b**, **5c** and **5d**) were examined. As showed in Fig. 2, the AFM images show smooth and amorphous thin films formed by spin-coating the compounds (**5a**, **5b**, **5c** and **5d**) from toluene solution. The deposited films were annealed under N_2 gas condition at 150 °C for 0.5 h. The annealed film exhibits a fairly smooth surface morphology with a root-mean-square (rms) roughness of 0.5539, 0.6211, 0.5202 and 0.6565 nm for **5a, 5b, 5c** and **5d**, respectively. This suggests that all of the compounds possess excellent thermal and amorphous stability, which indicates that the rigid propeller core influences the arrangement of the molecules in the thin films, and 1,3,5-tri(9-anthracene)benzene is a good core emitter for star-shaped fluorophore.

Fig. 3 shows the normalized UV–Vis and fluorescence spectra of compounds **5a, 5b, 5c** and **5d** in a CH_2Cl_2 solution and in the thin film. The related photophysical properties were listed in Table 1. All of these compounds have similarly structured absorption spectra (range: 330–440 nm) and emission spectra (range: 400–550 nm) in solution. This indicates that the photophysical properties are mainly determined by the core 1, 3, 5-tri(9-anthracene)benzene. The absorption in the range 330–440 nm is assigned to the $S_1 \leftarrow S_0$ transition of the anthracene moiety. In the solid state, all of them show strong pure-blue emission with a main peak at 448, 453, 451 and 460 nm, respectively, which shows that the introduction of dipenylamine results in a notable red-shift in PL spectra and peripheral dendrons can affect the molecular interaction. The quantum yields of compound **4a**-**4d** in CH_2Cl_2 were 0.68, 0.66, 0.67 and 0.64, respectively, which is even higher than the typical blue material m-ADN [25]. The quantum yield in solid state was also measured, the relative high values indicated that no obviously aggregating or quenching phenomena appeared. In order to further investigate the morphological stability of these materials, the Abs and PL spectra before/after annealing state (see Figure S4.) was also researched, the absorbance and PL emission have no clearly change after annealing (150 °C for 1 h), which showed that the morphological stability of material is excellent. The optical energy bandgaps of the compound

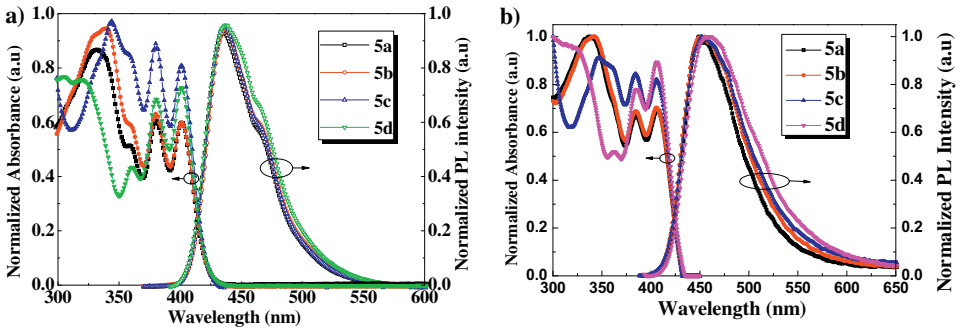

Fig. 3. (a) Absorption and photoluminescence spectra of compound **5a, 5b, 5c** and **5d** in CH_2Cl_2; (b) Absorption and PL spectrum of the compounds **5a, 5b, 5c** and **5d** in thin film (ca. 40 nm).

5a, **5b**, **5c**, and **5d** are 2.92, 2.95, 2.94, and 2.93 eV, respectively, which is calculated from the threshold of the optical absorption.

In addition to the photophysical properties, the electrochemical properties are also very important in evaluating a material usefulness for optoelectronic applications. The electrochemical behaviors of the compounds **5a**, **5b**, **5c** and **5d** were examined by cyclic voltammetry using a standard three-electrode electrochemical cell in an electrolyte solution of 0.1 M tetrabutylammoniumhexafluorophosphate ($TBPAPF_6$) dissolved in dichloromethane [29]. The onset oxidation peaks (E_{ox}) for **5a–5d** were 1.26, 1.23,

1.21 and 1.19 eV, respectively (see Figure S3). Thus, the HOMO levels were determined to be −5.57, −5.54, −5.52 and −5.50 eV by the method $-(E_{ox} + 4.31)$ eV reported by Li et al. [25] (Table 1). The values were very close to that of 9,10-diphenylanthracene (5.54 eV), which indicates the HOMO level of these compounds were mainly decided by 1,3,5-tri(9-anthracene)-benzene center and the side groups were only finely tune the energy gap and the HOMO level. Generally speaking, the electrochemical properties and photophysical properties of compound **5a**–**5d** in dilute solution are very similar, mirroring the anthracene unit's characteristics. It shows every individual arm's electrochemical properties are remained unperturbed for the propeller topology serving as a spacer to effectively block conjugation.

3.2. Device performance

To study the EL properties of these compounds, double-layered devices with the configuration ITO/PEDOT:PSS (40 nm)/**5a–5d** (40 nm)/TPBI (40 nm)/LiF (1 nm) /Al (100 nm) (emitter: **5a**, Device 1; **5b**, Device 2; **5c**, Device 3; **5d**, Device 4) were fabricated by spin-coating from a toluene solution (ca. 7 mg/ml). The EL performances of these compounds are listed in Table 2. Double-layer devices utilizing compounds **5a** and **5b** exhibit a maximum brightness of 3366, 2740 cd/m^2, luminous efficiency of 1.7, 1.6 cd/A, with CIE coordinates **5a** (0.15, 0.17), **5b** (0.15, 0.14). For compounds **5c** and **5d**, the double-layer devices showed a maximum brightness of 4754, 1562 cd/m^2, luminous efficiency of 2.0, 2.4 cd/A, with CIE coordinates **5c**

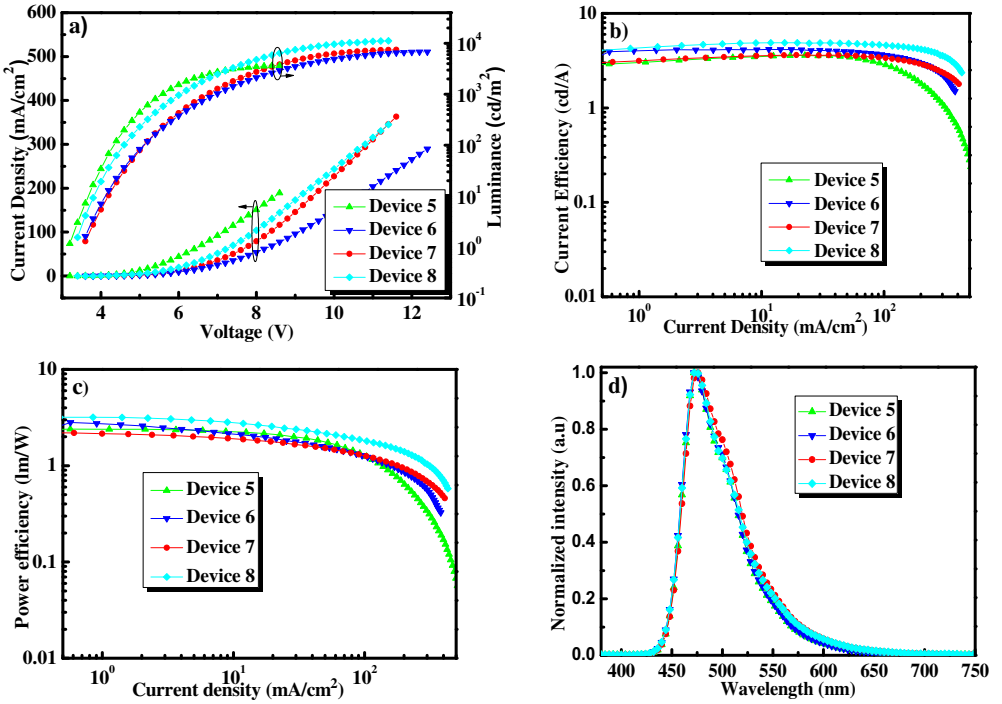

Fig. 5. (a) J–V–L curve of the four doped devices; (b) current efficiency-current density characteristics; (c) powder efficiency-current density characteristics; (d) EL spectra of the four doped devices.

(0.16, 0.19), **5d** (0.18, 0.28). Fig. 4 shows the EL spectra, the current density–voltage-brightness and the current density-efficiency characteristics of the devices (**1**, **2**, **3**, **4**). EL spectra of the devices based on the emitters **5c** and **5d** have obviously red-shift compared to the compounds **5a** and **5b**, it is induced by the carbazole and diphenylamine group's electronic-donating properties. Especialy, the EL spectrum of the device 4 has a red shift about 20 nm compared to that of device four. Additionally, the electroluminescence (EL) of all devices remained quite stable under different driving voltages (see Figure S1).

In order to further improve the device efficiency, we adopted a host-dopant system using these materials as the host and a highly fluorescent blue dye, DPAVBi, as dopant at a concentration of 5%. Table 2 summarizes the key EL performance of doped devices (**5**, **6**, **7**, **8**), all of them show a strong blue emission with current efficiency of 3.6–4.9 cd/A. Fig. 5. shows the EL spectra, the current density–voltage-brightness and the current density-efficiency characteristics of devices (**5**, **6**, **7**, **8**). The device **8** exhibits a maximum brightness of 11204 cd/m^2 at 11.4 V, and a maximum current efficiency of 4.9 cd/A with CIE coordinates of (0.17, 0.31). We ascribe the higher efficiency to the more efficient Förster energy transfer because there is more overlap between the emission of compound **5d** and the absorption of DPAVBi. As shown in Fig. 5d, the EL spectra of all DPAVBi doped devices (**5**, **6**, **7**, **8**) exhibit bright blue emissions at 472 nm with a shoulder at around 496 nm, which is the intrinsic characteristic of the emissions from the dopant DPAVBi. This result indicates completed energy transfer from the host to dopant. From the Fig. 6, it is obviously that the quantum efficiency of the doped device has been improved, which indicated that the better device performance in the doped device is not due to the change of emission colors. More interestingly, the driving voltage of all the devices is low (ca. 3.6 eV), in which device **5** exhibits the lowest driving voltage of 3.2 V. This indicates that the energy levels of the host materials and the dopant DPAVBi are well matched. Additionally, the dopant DPAVBi can also act as the hole trapper in all of doped devices, so the turn on voltage of the most of doped devices are lower than the undoped devices(see Table 2) [30]. Excellent EL stability (see Figure S2) and the efficient color purity render these materials promising candidates for display applications. We believe that optimization could further improve the device

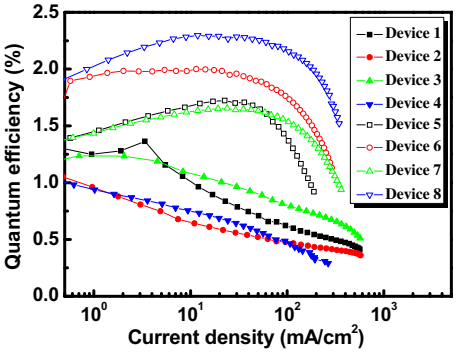

Fig. 6. Quantum efficiency-current density characteristics of devices **1–8**.

performance and fully explore the potential of these starburst materials.

4. Conclusion

In summary, we present a series of novel blue star-shaped molecules, in which the propeller core 1,3,5-tri(9-anthracene)benzene and the different dendrons were bridged by the stilbenzene. These materials exhibit high thermal stability (high glass transition temperature in the range 166–231 °C) with good film forming properties. Meanwhile, their optical and electronic properties can be tuned by adjusting the appropriated surface groups. The nondoped OLED devices fabricated using compound **5c** exhibits a maximum brightness of 4754 cd/m^2 and maximum current efficiency of 2.0 cd/A (corresponding to a power efficiency of 1.71 lm/W) with CIE$_{x,y}$ color coordinates of (x = 0.16, y = 0.19) and the devices' threshold voltage are only 3.4 eV. Compound **5d** shows an even higher efficiency of up to 4.90 cd/A with CIE$_{x,y}$ color coordinates of (x = 0.17, y = 0.31). These results will be beneficial for the molecular design of blue dendritic materials.

In this work, we provide new insight into the light generation mechanism of an AC-driven light-emitting device in a transistor configuration. The semiconductor para-hexaphenylene (p6P) with a wide band-gap (3 eV) acts as the active material. By combining time-resolved EL experiments with a study of the influence of the biasing parameters (gate voltage amplitude and DC potential of the drain voltage) on the light emission intensity, we reveal a device operating mechanism that combines hole injection and SCF assisted electron tunneling from an individual metal electrode. A theoretical calculation on the basis of Arkhipov's charge injection model [16] predicts an increasing hole injection probability with increasing temperature, which is qualitatively in agreement with our low temperature experiments. Our proposed device operating mechanism can explain well the light emission from a unipolar transistor platform driven by AC gate voltage. This operating approach has implication for the development of nano-scale light-emitting devices [15] and can assist in the design of facile fabricated OLED architectures, which constitute a promising component of novel full color displays [17].

2. Experimental

2.1. Device fabrication

300 nm thermally grown SiO_2 formed the gate dielectric while the underlying highly *n*-doped silicon ($\rho = 0.025$ Ω cm) served as back gate electrode. Titanium/gold (2 nm/30 nm) source and drain electrodes were fabricated on the SiO_2 by optical lithography, electron-beam deposition and lift-off. The total channel width was 2.66 cm and the channel length *L* was either 2.5, 10, or 25 μm. After substrate fabrication and cleaning, a 50 nm thick p6P film was deposited (rate approx. 0.2 Å s^{-1}) with the substrate at room temperature under high-vacuum conditions ($\sim 10^{-7}$ mbar). Fig. 1a illustrates the device configuration and the operating circuit used for light emission experiments together with the p6P molecular structure. Although each metal contact is actually acting sequentially as electron "drain" and electron "source" during AC-driven operation, we have used the conventional terms "drain" and "source" as labels in order to distinguish between the metal contacts on the transistor platform.

2.2. Characterization methods

Electrical DC measurements (not shown here) were conducted under ambient conditions to confirm that the p6P transistor acts as a *p*-type device. The leakage current was found to be negligible compared with the injection current, which is assumed to be the situation as well for AC biasing. The light emission experiments were performed under vacuum conditions ($\sim 10^{-4}$ mbar) by symmetrically biasing the source and drain electrodes relative to ground, while an AC voltage was applied to the gate electrode. The spatial distribution of the emission (Fig. 1b and c) was recorded by a camera mounted on a microscope while the spectrum (Fig. 1d) was recorded with an ARC SpectraPro-150 spectrometer. A He-Cd laser with wavelength of 325 nm was used as the excitation source to record photoluminescence (PL) spectra. Time-resolved data were recorded by a photomultiplier tube (Hamamatsu R943–02) connected to a digital storage oscilloscope (Instek GDS-2102) via a DC preamplifier (Hamamatsu C7319). Low temperature measurements (down to 30 K) were made under vacuum conditions ($\sim 10^{-5}$ mbar) in a cryocooler (Sumitomo CNA-11 Helium Compressor Unit).

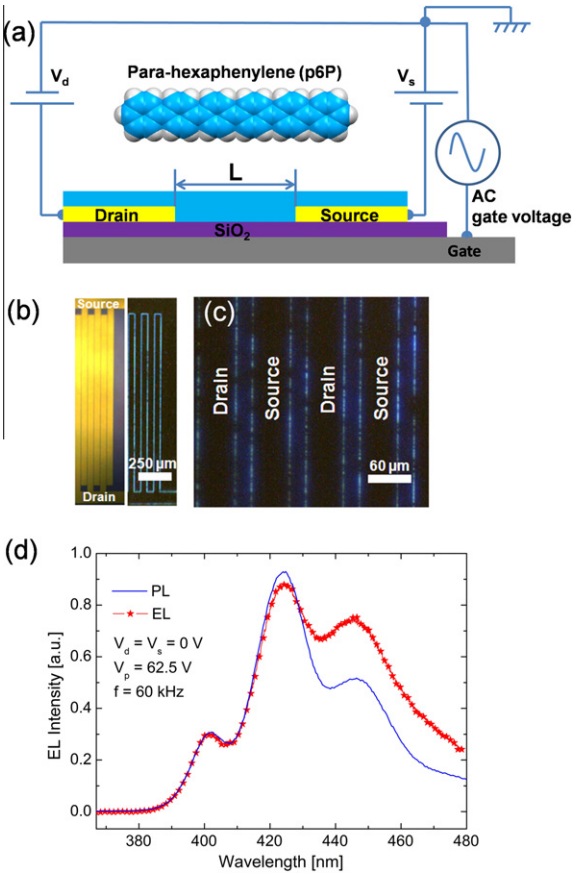

Fig. 1. (a) Schematic diagram of the operating circuit for light emission experiments along with the device configuration. Inset: molecular structure of p6P. (b) Optical microscope image of AC-driven light emission when only the drain electrode is biased while the source electrode is floating. (c) AC-driven light emission when both the drain and source electrodes are biased (channel length is 25 μm). (d) EL spectrum from a p6P OLET under gate voltage amplitude of 62.5 V. A scaled PL spectrum is shown for comparison.

3. Results and discussion

Fig. 1b and c show AC-driven light emission from a p6P film. In Fig. 1b, only the drain electrode was biased while the source electrode was floating. This gives rise to light emission close to the interface between the drain electrode and the p6P film. When both the drain and the source electrodes were biased, light emission from both sides of the channel (i.e., from both electrode-p6P interfaces) can be observed as seen from Fig. 1c. No light emission was observed when the gate terminal was biased by a DC voltage.

This must be due to high electron injection barrier in our p6P-based device under DC biasing. Fig. 1d shows the electroluminescence spectrum obtained with an amplitude of the sinusoidal gate voltage (V_p) of 62.5 V (frequency was 60 kHz and drain and source electrodes were grounded). A scaled PL spectrum is provided for comparison. The similarity of EL and PL spectra with three main peaks at 401, 422, and 448 nm corresponding to the $(0 \rightarrow 0)$, $(0 \rightarrow 1)$, and $(0 \rightarrow 2)$ vibronic transitions [18], respectively, indicates that identical excitonic transitions take place in both cases although with different relative intensities.

Since the light emission in our devices occurs from the circumference of a single biased electrode and from both sides of the device channel when both electrodes are biased, this indicates that charge transport across the channel does not play a role in the light generation process. Instead, the emitted photons must be caused by the radiative recombination of holes and electrons injected from the same metal electrode. However, the work function of gold used for the electrode is 5.1 eV while the electron affinity of p6P is 3 eV; this leads to an estimated electron barrier height of more than 2 eV (neglecting a possible interface dipole). This suggests the hole injection probability is much higher than the electron injection probability. This is in accordance with the previously reported transistor output characteristics, in which no *n*-type behavior was observed [15]. Our transistor therefore constitutes a unipolar device, however without any charge transport across the channel during AC operation.

The time-resolved EL intensity measurements in Fig. 2a and b show how the light emission is correlated to the instantaneous gate voltage. The gate voltage waveforms in Fig. 2a and b are square wave and sinusoidal, respectively, and the amplitude in both cases is 50 V with a frequency of 20 kHz. Two distinct peaks can be observed within one period both for square wave and sinusoidal gate voltage. The larger EL peak appears when the gate voltage shifts from a negative to a positive value. In contrast, the smaller EL peak appears when the gate voltage shifts from a positive to a negative value. Using a light source with a known intensity, we calibrated our photomultiplier setup in order to quantify the emission intensity. The ratio of collected to emitted light was estimated by assuming a Lambertian emitter, while the emission area was found as the full width at half maximum of the emission zone multiplied by the emission zone length. This provides an estimate of the averaged intensity of 8×10^{-8} (estimated uncertainty: -3×10^{-8},$+7 \times 10^{-8}$) W cm^{-2} for the data presented in Fig. 2b. To compare the averaged EL intensity generated from square wave and sinusoidal gate voltage, the amplitude of the gate voltage V_p was varied from 40 to 60 V in steps of 5 V, while the drain electrode was grounded and the source electrode was floating. Fig. 2c shows how the EL intensity increases as V_p increases both for square wave and sinusoidal gate voltages. The EL intensity has been determined by summing up from 380 to 480 nm of the corresponding spectrum. The inset shows the ratio of the EL intensities for square wave to sinusoidal gate voltages. A constant ratio of 1.73 is obtained. Since the effective value of a square wave is 1.41 times higher than the effective value of a sine wave with the same amplitude,

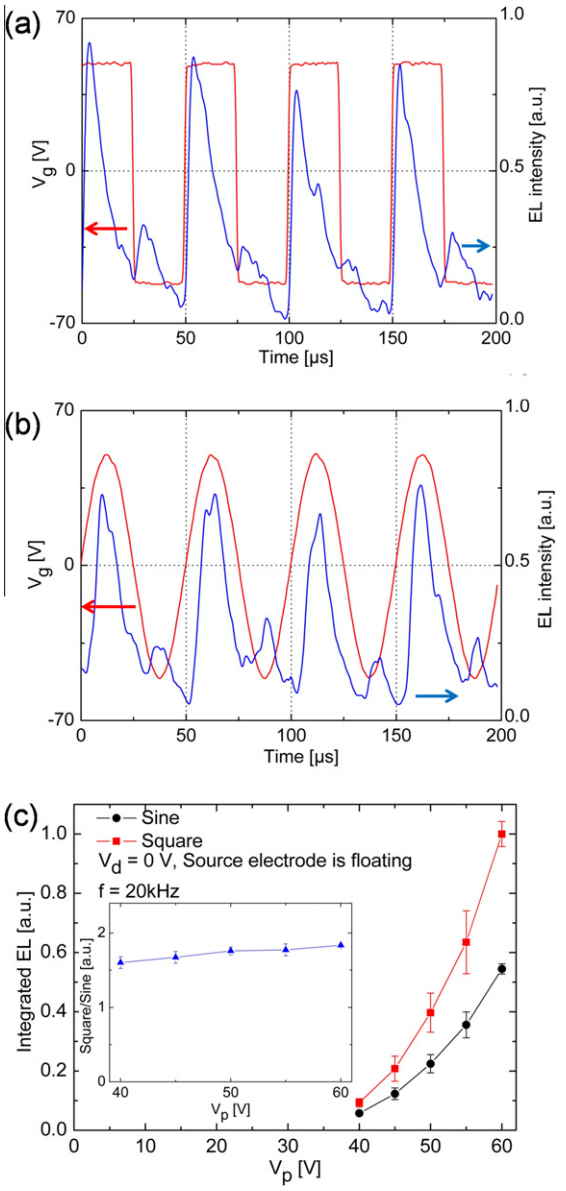

Fig. 2. Time dependence of EL emission intensity (blue curve) as a function of (a) square wave gate voltage (red curve) and (b) sinusoidal gate voltage. (c) Integrated EL emission intensity as a function of (square wave and sinusoidal) gate voltage amplitude V_p. Inset: ratio of EL intensity obtained from square wave gate voltage to the intensity from sinusoidal gate voltage.

a ratio higher than 1 is expected, however, this simplistic view cannot account for non-linear processes involved in charge injection across an energy barrier. A more appropriate analysis would be to study the effects of the gate voltage waveform using a theoretical model based on thermally assisted tunneling. We will elaborate on this aspect below.

In order to investigate the influence of the drain voltage V_d on the emission intensity, a series of measurements were conducted, in which V_d was varied while the amplitude and frequency of the square wave gate voltage were

fixed and the source electrode was floating. As shown in Fig. 3, the integrated EL intensity increases when the drain electrode is positively biased while a negative drain potential causes a reduced EL intensity. Two measurement sequences were made in either direction: one from negative V_d to positive V_d and one in the other direction. This shows that the observed EL variations are indeed caused by the drain potential and are not due to a possible degradation effect. In our previous work, we have investigated the frequency dependence of the light emission intensity under AC biasing [14,15]. The emission intensity generally increased with increasing frequency until saturation or even a small reduction was observed around a few hundred kHz.

On the basis of these results, we propose the following device operating mechanism: As mentioned above, charge transport across the channel is not part of the light generation process. Rather, the two types of charge-carriers are sequentially injected from the same contact. This must mean that one type of charge is piled up in the organic film close to the electrode interface during one half-period of the gate voltage effectively forming a space-charge region at this position. During the subsequent half-period of the gate voltage, the opposite charge-carrier is injected, recombines with the first type of carrier, and thereby causes light emission. Since the injection of holes is much more probable than the injection of electrons in our device, the space-charge region must be formed by holes piling up either due to deep hole traps or short hole transport distance under high frequency operation. The positive space-charge region is therefore formed during the negative half-period of the gate voltage, as illustrated in Fig. 4a. In the next (positive) half-period, electrons are injected into the organic material to recombine with the previously injected holes. Since the injection barrier of electrons between Au and p6P is very high, the electrons are most likely to tunnel into the p6P. The electron tunneling process is primarily influenced by the positive space-charge region rather than the positive gate voltage (Fig. 4b). This can be argued as follows: During the negative half-period of the gate voltage, holes are injected. If the DC potential of the drain electrode is increased (positive V_d), this leads to an increased hole injection and therefore a larger space-charge. In the following, positive half-period of the gate voltage, electrons are tunneling into the organic material. The positive value of V_d means that the drain to gate voltage difference is effectively reduced. If the main factor driving the electron tunneling would be the gate voltage, then the electron tunneling and thus also the emission intensity should be less than at zero V_d. On the contrary, if the main driving mechanism for electron injection is tunneling assisted by the positive SCF, then the additionally injected holes caused by the positive V_d should enhance electron tunneling and thereby emission intensity. Since positive V_d causes increased EL intensity as shown in Fig. 3, the second explanation must be correct.

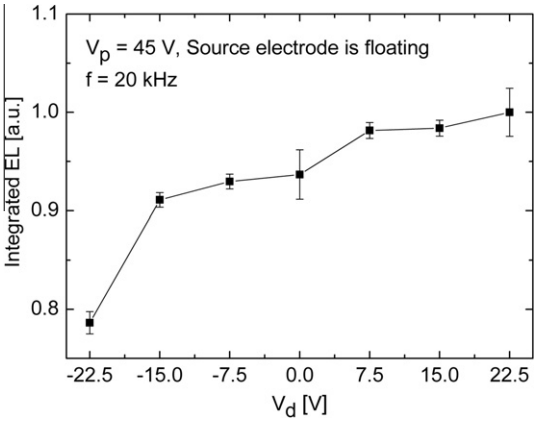

Fig. 3. Integrated EL intensity as a function of drain electrode voltage V_d (source electrode was floating). The gate voltage amplitude was $V_p = 45$ V and the frequency was $f = 20$ kHz.

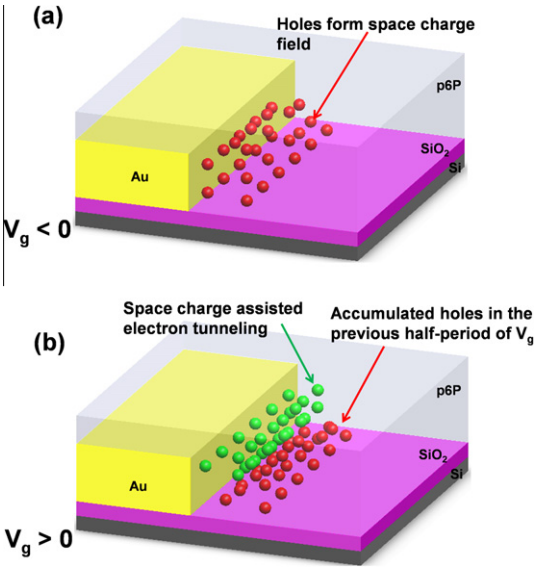

Fig. 4. Schematic illustration of the device operating mechanism (red indicates holes; green indicates electrons). (a) Holes are injected from Au into semiconductor to form positive SCF. (b) In the next half-period of AC gate biasing, electrons tunnel into the semiconductor assisted by the previously formed positive SCF.

The time-resolved EL intensity illustrated in Fig. 2a and b can be explained by this model. The majority of the light emission occurs when the gate voltage shifts from a negative to a positive value, corresponding to the shift from hole to electron injection. This means the electron injection is significantly enhanced due to the positive SCF, which is formed by holes injected in the previous half-period of the AC gate voltage. The decay of the emission intensity after reaching its maximum must be caused by the recombination process that reduces the hole intensity. Upon elimination of the SCF by electron–hole recombination, electron injection continues at a lower rate caused only by the positive gate voltage. When the AC gate voltage shifts polarity, a smaller EL peak can be observed, which is caused by the recombination of the electrons injected in the previous positive gate regime and the holes injected during this negative gate bias.

Since the electron tunneling is enhanced by the positive SCF formed by previously injected holes, the hole injection

is an important factor to determine the overall light emission of the p6P device. We therefore focus on the hole injection aspects in the following discussion and assume the EL intensity to be proportional to the magnitude of the hole injection. Our previous work showed that the relationship between the EL intensity and the gate voltage amplitude corresponds to a straight line in a Fowler–Nordheim (F–N)-type plot [14]. However, F–N theory describes charge-carrier tunneling through an energy barrier into a delocalized state, which is typically not the case in organic materials, in which the charge-carriers form localized polarons. F–N theory is therefore not applicable for the present system [19]. Instead, we have applied a model based on thermally assisted tunneling developed by Arkhipov et al. [16] in order to study hole injection into the hopping state distribution of the p6P semiconductor. In this model, the hole injection occurs over/through a potential barrier $U(x)$ given by

$$U(x) = \phi - \frac{q^2}{16\pi\varepsilon_0\varepsilon_r x} - qFx \tag{1}$$

where x is distance from the metal electrode, ϕ is the energy difference between the work function of gold and the HOMO (highest occupied molecular orbital) level of p6P, $\varepsilon_0\varepsilon_r$ is the dielectric constant, q is the elementary charge, and F is the external field strength. The hole injection is considered including either the return of the charge-carrier to the metal electrode or the diffusive escape from the image potential to the semiconductor bulk. Therefore, the injected current I_{inj} can be described in terms of the tunneling probability $\exp(-2\overline{\Gamma}x_0)$ (x_0 is the distance from the contact the charge-carrier made the first jump) and the escape probability $w_{\text{esc}}(x_0)$

$$I_{\text{inj}} \propto \int_a^\infty dx_0 \exp(-2\overline{\Gamma}x_0)\cdot w_{\text{esc}}(x_0)\cdot \int_{-\infty}^{\infty} dE Bol(E) g[U(x_0) - E] \tag{2}$$

where $\overline{\Gamma}$ is the inverse localization radius and a is the nearest neighbor distance. $Bol(E)$ is a Boltzmann factor defined as

$$Bol(E) = \begin{cases} \exp(-\frac{E}{k_B T}) & E > 0; \\ 1 & E < 0. \end{cases} \tag{3}$$

The Gaussian energy distribution with an energy width σ is given by

$$g(E) = \frac{N_0}{\sqrt{2\pi}\cdot\sigma}\cdot\exp\left(-\frac{E^2}{2\cdot\sigma^2}\right) \tag{4}$$

where N_0 is the density of p6P molecules.

Applying this model, we calculated the hole injection from a gold electrode to p6P with the external electric field generated either by a square wave or a sinusoidal gate voltage (with parameters ϕ = 0.9 eV, σ = 0.27 eV, T = 295 K, ε_r = 1.9, a = 5.57 Å, $\overline{\Gamma}$ = (3Å)$^{-1}$, and $N_0 = 1.71\times10^{21}$ cm^{-3} [20]). Only one half-period of gate voltage is considered in the calculation due to the waveform repetition of the gate voltage. For simplicity, the external electric field near the vicinity of the injecting gold electrode was estimated simply as the gate voltage divided by the thickness of SiO_2 gate dielectric. We have performed finite element analysis calculations to verify that this assumption is reasonable. The amplitude of the gate voltage was varied from 40 to 60 V, with steps of 5 V. The resulting ratio of hole injection generated by square wave gate voltage to that generated by sinusoidal gate voltage is approximately 2.2, which is 27% larger than the experimental value shown in Fig. 2c. This difference could be due to the neglect of the suppressing effect of the positive SCF on the further hole injection during the negative half-cycle of the AC gate voltage. This suppressing effect is larger for the square wave case resulting in an overestimation of the EL ratio.

In order to better understand the underlying operating mechanism, we characterized the temperature dependence of the PL and EL output. As illustrated in Fig. 5a, both the PL and EL intensity increase as the temperature decreases from 295 to 30 K. With increasing temperature, the probability for coupling to phonon modes and thus in general for non-radiative decay process increases, as observed by an increase of the Huang–Rhys factor for p6P nanofiber films [21]. In addition, it can be seen that the PL increases more than the EL. The ratio of the normalized EL intensity to the normalized PL intensity $W_{\text{EL}}(T)/W_{\text{PL}}(T)$ is also shown in Fig. 5a. The temperature dependence of this ratio can be correlated with the temperature dependence of the hole injection as follows: The detected EL intensity $W_{\text{EL}}(T)$ is given by:

$$W_{EL}(T) = k_1\cdot\eta_{\text{ext}}(T)\cdot I_{\text{inj}}(T) \tag{5}$$

where $I_{\text{inj}}(T)$ is the injected current, $\eta_{\text{ext}}(T)$ is the temperature-dependent external quantum efficiency, and the temperature-independent proportionality constant k_1 includes the unit charge, the photon energy and collection efficiency of the detector. From [22] we describe $\eta_{\text{ext}}(T)$ by:

$$\eta_{\text{ext}}(T) = R_{\text{st}}\cdot\gamma\cdot\Phi_{\text{outc}}\cdot\Phi_{\text{PL}}(T) \tag{6}$$

where $\Phi_{\text{PL}}(T)$ is the efficiency of radiative decay, R_{st} is the singlet to triplet ratio (typically 0.25), γ is the charge balance factor, Φ_{outc} is the outcoupling efficiency. The detected PL intensity $W_{\text{PL}}(T)$ is given by:

$$W_{\text{PL}}(T) = k_2\cdot\Phi_{\text{outc}}\cdot\alpha(T)\cdot\Phi_{\text{PL}}(T) \tag{7}$$

where the proportionality constant k_2 includes the intensity of the stimulating light, the photon energy, and the collection efficiency of the detector. Since the temperature dependence of the absorption cross section $\alpha(T)$ is very weak for p6P films [23], we neglect its temperature dependence here, i.e., $\alpha(T) = \alpha$. By combining Eq. (5-7), the ratio of the EL and PL intensities is found to be

$$\frac{W_{\text{EL}}(T)}{W_{\text{PL}}(T)} = \frac{k_1}{k_2\cdot\alpha}\cdot R_{\text{st}}\cdot\gamma\cdot I_{\text{inj}}(T). \tag{8}$$

Since all factors in Eq. (8) except the injected current have negligible temperature dependence, the ratio $W_{\text{EL}}(T)/W_{\text{PL}}(T)$ should therefore have the same temperature dependence as the injected current.

Fig. 5b shows the temperature dependence of the current injection calculated using the approach based on Arkhipov's model, and the ratio derived from experiment is again illustrated for comparison. The calculated current

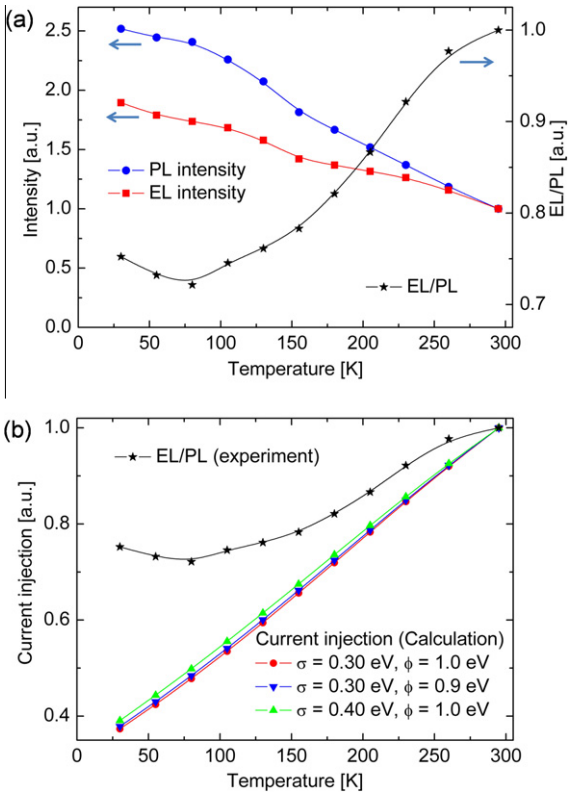

Fig. 5. (a) Temperature dependence of PL and EL intensity (data have been normalized at $T = 295$ K) of a p6P light-emitting device. The square wave gate voltage amplitude was 37.5 V; the biasing frequency was 15 kHz. (b) Theoretical calculation of current injection compared with experiment.

injection varies only slightly if the hole injection barrier ϕ or the energy width σ is varied. Also, it can be seen that the theory predicts a stronger temperature dependence than what is observed experimentally. This large deviation could be due to the inadequacy of the Gaussian energy distribution of the hopping state [24]. Nevertheless, the calculation based on Arkhipov's model reproduces qualitatively the trend observed experimentally, which is not captured by the F–N formalism.

We have focused on the hole injection between gold and p6P because the hole injection barrier in this case (typically 0.9 eV) is much lower than the electron injection barrier (2.1 eV). In contrast, electron injection should be mainly studied for the organic materials which possesses lower electron injection barrier with respect to the injecting electrodes.

To rule out the possibility that impact ionization could be involved in the light generation process, similar substrates but with aluminum rather than gold electrodes were fabricated. Since aluminum electrodes oxidize under ambient conditions, there will be an insulating layer of aluminum oxide between the electrode and the p6P, and light emission would under such circumstances only be possible via impact ionization [25]. Based on the sensitivity of our detection system, we estimate that the light emission from aluminum electrode devices is at least two orders of magnitude lower than that from gold electrode devices under similar biasing parameters, indicating that impact ionization plays an insignificant role for the light generation.

4. Conclusions

In this study, we have investigated the operating mechanism of organic light-emitting devices based on a transistor platform driven by an AC gate voltage. The holes and electrons are sequentially injected from the same metal electrode under the AC gate biasing. Positive SCF is dominant if the hole injection barrier is much lower than the electron injection barrier, and this positive SCF assists in the subsequent electron injection. Therefore, electrically driven light emission can be obtained in a *p*-type unipolar organic field-effect transistor platform, from which light emission is difficult to derive under traditional DC gate voltage. We assume this charge-carrier injection assisted by SCF is also valid for *n*-type organic transistors and that a similar model would therefore be applicable.

Further appropriate metal/semiconductor interface modification could help enhance the light emission output from the light-emitting devices by changing the interface dipole and morphology [26], thus leading to possible improvement towards the realization of electrically driven organic laser diodes. Besides, the better understanding of the operating mechanism can assist in the design of future light-emitting devices when attempting to localize the light emission.

and b). The devices were obtained with the following three steps: (i) the Si substrates (with 300 nm SiO_2) were modified by the octadecyltrimethoxysilane (OTMS) monolayer through spin-casting method [20], which was used to passivate the traps at the semiconductor/insulator interface; (ii) rubrene single crystals were grown onto the surface via physical vapor transport (PVT) technique; (iii) the electrodes were fabricated by gluing Au-films onto the single crystals directly from pre-deposited Au film [3,21] with channel formed simultaneously (a pre-deposited Au-film (about 100 nm thick on another substrate) was firstly cut into small pieces (usually about tens of micrometers in width and hundreds of micrometers in length) and secondly a small piece of Au-film was glued by a probe of a micromanipulator station and then was placed onto the single crystals). As shown in Fig. 1b, the channel length was about 20 μm and the channel width was dependent on the size of single crystals, ranging from several to tens of micrometers. The "gluing Au-films" technique is used as it is free from lithography and thermal radiation during metal deposition which has been shown to result in better contact between the semiconductor and the electrodes [21]. The current–voltage curve was measured using only the two gold electrodes, and the silicon substrate was disconnected from the measurement electrical circuit. It is important to point out that the reason that we select silicon substrate is due to its commercial availability, smooth surface and convenience to be modified by self assembled monolayers (SAMs). Therefore, the silicon substrate is not used as gate electrode as in other conventional OFET structure. That is, the device is characterized under a two-terminal condition.

The current–voltage characteristics of a typical device are shown in Fig. 1c. Interestingly, the current-curves displays rectifying properties with rectification ratio as high as 10^5–10^6 at ±5 V in most devices, and exchanging electrodes results in the same rectifying characteristics (Fig. 1c). Although formation of Schottky contact between organic semiconductor and the electrodes could lead to a rectifying behavior, several evidences reveal that it is not the dominant mechanism for the observed *I*–*V* characteristics. Firstly, the highest occupied molecular orbital (HOMO) energy level (−5.1 to −5.36 eV) matches well with the Fermi level of Au electrodes (∼−5.1 eV) [18,22], and therefore a low injection barrier of holes is expected. Secondly, when we measured the device in a FET mode, we did not observe any suppression of drain current at low drain voltages, suggesting that the contact between the semiconductor and the electrodes is Ohmic one instead of the Schottky contact (see Supplementary data). Thirdly, the measured *I*–*V* curves do not obey the exponential law that is commonly used to describe the *I*–*V* relation for Schottky diodes (see Fig. 1c inset and descriptions below). To further investigate the mechanism of the rectifying behavior, we varied the intrinsic carrier density in the rubrene crystals via two methods: (1) to modify the substrate surface with (tridecafluoro-1,1,2,2-tetrahydrooctyl)trichlorosilane (FTS) (through chemical vapor deposition (CVD) method [23]), which has been used previously to dope organic semiconductors via charge transfer mechanism [23,24]; and (2) to measure the device under illumination [17,25]. (Note that a gate-voltage is required in this case to dissociate the photo-induced electron-hole pairs [26].) In both cases, the rectifying behavior disappeared and the devices showed almost symmetric *I*–*V* relations at low voltages (Fig. 2a and b, inset). The fact that the increasing of carrier density could eliminate the rectifying properties suggests again that the rectifying property is unlikely originated from the Schottky contact.

Instead of the metal-semiconductor Schottky barrier, we propose that the rectifying effect is a consequence of the simultaneously formed vertical and lateral distributed electric fields throughout the organic semiconductor:

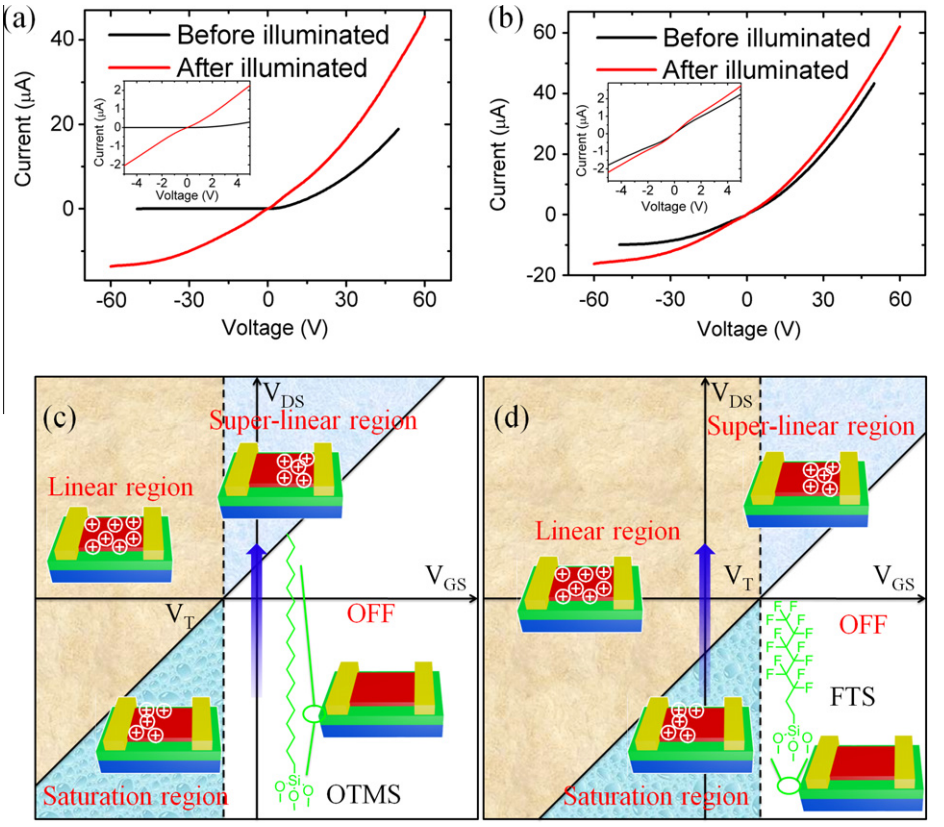

Fig. 2. Current–voltage curves of rubrene devices (a) on OTMS and (b) FTS modified substrates, (inset, amplification curves around low voltage). Four operation regimes of p-channel FET: off-state, saturation, linear and super-linear regimes in the situation for (c) OTMS and (d) FTS modified substrates. The blue arrows indicate the measurement condition of our devices (note that $V_{GS} = 0$ is assumed for two-terminal devices). Adapted with permission from Ref. [27]. Copyright© 2010 Elsevier B.V. applying a bias voltage between two gold electrodes not only varies the lateral electrostatic potential linearly along the channel but also creates a vertical potential drop between the top and bottom surfaces of the semiconductor, which is similar to applying a gate voltage. Once this potential drop exceeds the threshold voltage V_T, an accumulation layer is formed in the semiconductor and the device is turned on. Different from the regular on-state of an FET where the channel potential is modulated by the gate voltage, in our devices, the channel potential is modulated by the laterally applied voltages. The channel is always "pinched-off" at the grounded electrode, since the potential in this region is close to zero. As a consequence, the device is operated in a "saturation region". This operation mode is also known as super-linear region as shown in Fig. 2c and d, which is often observed in ambipolar OFETs [27,28]. In our two-terminal devices, the "gate voltage V_{GS}" can be considered as fixed at zero and the rectifying property is strongly dependent on the threshold voltage. For the OTMS modified substrates, the density of trap states at the rubrene/OTMS interface is low and therefore V_T is close to 0 V (see Supplementary data); applying a relatively small positive voltage across the lateral electrodes (equivalent to "V_{DS}") can turn the device from "off" to the super-linear region. For the FTS modified devices, on the other hand, due to the presence of the electron-withdrawing groups, a layer of fixed charges is formed at the rubrene/FTS interface [24] which shifts the V_T towards positive voltage. In this case, when "V_{DS}" is changed from negative to positive voltage, the device is switched from the saturation region to the linear region. At last, when the devices are illuminated, the concentration of charges [17,25] in the semiconductor is further increased, and the V_T is shifted to a much more positive voltage value. As a result, only linear operation mode can be observed for "V_{DS}" in the range of −5 to +5 V.

In order to verify the above model, we fit the experimental data to the equations that describe the super-linear and linear models, respectively. For the OTMS modified devices, when a positive voltage bias is applied, the devices are considered to be operated in the super-linear region. Fig. 3a plots the fitting results of measured I–V curves using the equation $I_{DS} = I_s(V_{DS} - V_T)^2(1 - \lambda V_{DS})$, where λ is the channel-length modulation parameter according to Shichman–Hodges model. Good fitting results are obtained as shown in the figure. We also tried to fit the data with the models for other operation modes, but the fittings are poorly coincident and require using physically irrational fitting parameters. Different from the OTMS modified devices, the FTS treated ones have I–V curves that are best

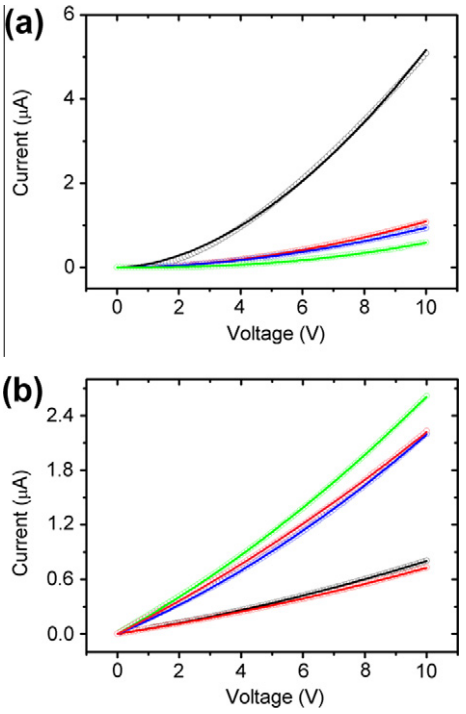

Fig. 3. Open circles: experimental data of different devices (a) on OTMS modified substrates and (b) on FTS modified substrates at positive voltage. Solid lines: fitting curves by using equation of (a) super-linear and (b) linear regimes.

fitted with the linear region model $I_{DS} = I_s[V_T V_{DS} - (V_{DS})^2/2]$, as plotted in Fig. 3b. In summary, the current–voltage characteristics of the two terminal devices can be well described by one of the operation models of field-effect transistors, and the position of V_T, which is dependent on the intrinsic carrier density at the rubrene/substrate interface, determines the cross point of the different operation modes.

3. Conclusions

In conclusion, we observed a rectifying behavior in lateral, symmetrical two-terminal device based on rubrene single crystals. We have showed that the rectifying property of the device was originated from a mechanism that is similar to the super-linear operation of field-effect transistors. We have also demonstrated that we can turn on or off this rectifying behavior by changing the density of space charge in the organic semiconductor/substrate interface, which essentially affects the threshold voltage V_T. These results demonstrated a simple approach that could potentially be used to fabricate organic rectifiers, oscillator, etc. without application of multi-layer device structure such as MOSFET diode.

4. Experimental

All solvents and reagents were obtained from commercial source and used as received unless ultra noted. The substrates (Si with 300 nm-thick SiO_2 layer, 11 nF cm^{-2}) were first rinsed with water, acetone and isopropanol, respectively. Then they were cleaned by oxygen plasma for 10 min. The FTS monolayer modified substrates were obtained by CVD method (self-assembled in vacuum at 100 °C for 1 h) according to literature [23]. And then the FTS modified substrates were rinsed by acetone and isopropanol respectively. The OTMS modified substrates were obtained via spin-coating method according to literature [20]. And then the OTMS modified substrates were washed by toluene and isopropanol respectively. Single crystals of rubrene were grown onto the OTMS or FTS-modified SiO_2/Si substrate by PVT method at sublimation temperature of 245 °C (Ar, 100 sccm). Then devices were fabricated by attaching Au-films onto single crystals as two-terminal electrodes [21]. Device fabrication and characteristics were obtained with a Keithley 4200 SCS and Wentworth Labs probe station in a clean and shielded box at room temperature in air. SEM was performed on a FEI field-emission scanning electron microscope.

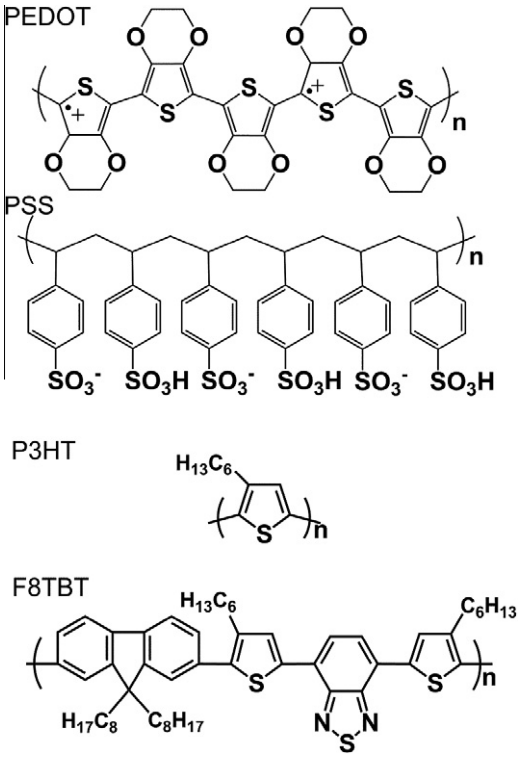

Fig. 1. Chemical structures of polymers used.

Generally these colloidal particles are described as entanglements of PSS chains with PEDOT oligomer units adsorbed to them. When in aqueous solution, the hydrophobicity of the adsorbed PEDOT causes preferential orientation of the hydrophilic sulfate groups to the outside and the PEDOT-rich parts of the chain to the inside of the entangled polymer chain, causing a micelle-like formation. From the macroscopic point of view this results in a particle with a PEDOT-rich conductive core and an insulating PSS-rich shell, which has been verified in numerous investigations on dried films, e.g. via XPS [5,13,14]. While the particles are in a swollen state when in aqueous solution, they shrink drastically during drying (water content up to ~95%) [12]. The PSS content in these solutions may be altered to tune the electric properties of PEDOT:PSS films. Up to a certain concentration, the PSS dopant enhances PEDOT:PSS film conductivity (up to ~10 S/cm). It decreases again for higher PSS content, due to the formation of PSS insulating cover layers or lamellae [15,16].

In this work we study the influence of thermal treatment on the PEDOT:PSS solution and resulting effects on the device performance of solar cells made from P3 HT (poly(3-hexylthiophene)) and F8TBT (poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthiophen-5-yl)2,1,3-benzothiadiazole]-2′,2″-diyl)) (Fig. 1) [17]. Besides electrical characterization of photovoltaic cells we employ photoelectron spectroscopy (both X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron yield spectroscopy (PEYS)), atomic force microscopy (AFM) and electrical conductivity measurements to characterize solid PEDOT:PSS thin films, and ion activity measurement (pH) and photon correlation spectroscopy (Dynamic Light Scattering (DLS)) on solutions to reveal the interplay between thermal treatment of PEDOT:PSS, resulting thin film properties and photovoltaic performance.

2. Experimental details

2.1. Materials

All substrates used (Spectrosil quartz glass, indium-tin oxide (ITO) coated sodium silicate glass) were cleaned by sonication in acetone and isopropanol (20 min. each), followed by oxygen plasma etching (250 W, 10 min). The aqueous colloidal PEDOT:PSS solution used has a PEDOT-to-PSS ratio of 1:16 (Clevios P VP AI 4083, H.C. Starck GmbH, subsequently enriched with PSS). Its nominal solid content is 2.2% and the particle size in the swollen state (in solution) is characterized by d_{50} of 80 nm and d_{90} of 100 nm (d_n implies that n wt.% of the particles are below the given size). The molecular weight of PSS in *Clevios P* is M_W = 313,000 and M_n = 134,000. The aqueous PSS solution (Scientific Polymer Products Inc.) has a solid content of 20 wt.% and the PSS a molecular weight of M_W = 70,000. Powdered In_2O_3 (99.99 % Sigma–Aldrich) was added to PEDOT:PSS solution for some pH measurements at a concentration of 1.21 mg/mL.

For the solar cell active layers a binary all-polymer blend was used, consisting of poly((9,9-dioctylfluorene)-2,7-diyl-alt-[4,7-bis(3-hexylthien-5-yl)-2,1,3-benzothiadiazole]-2′,2″-diyl) (F8TBT) supplied by Cambridge Display Technology Ltd. with a molecular weight (M_W) of 55,000 and poly(3-hexylthiophene) (P3HT) supplied by Rieke Metals Inc. with a molecular weight (M_W) of 46,000 and a regioregularity of 93% (electronic grade). The photoactive polymers were used without further purification. The P3HT:F8TBT system has been intensively studied previously in photodetector or photovoltaic applications [18,19] and in solar cells gave external quantum efficiencies up to 26% and power conversion efficiencies of 1.8% under solar simulator conditions [2].

2.2. Preparation

The PEDOT:PSS solutions were sonicated (10 min) before use. The solution heating was carried out in a metal hot block to ensure homogeneous heat distribution and the heated solutions were filtered with a preheated 0.25 μm filter (Whatman PP w/GMF polypropylene membrane syringe filter with glass microfiber prefilter) before film deposition or solution characterization. Sonicated PEDOT:PSS solutions were modified by heating at temperatures between 20 °C and 90 °C for at least 10 min before further processing. The warm solutions were filtered and characterized either undiluted (pH value determination) or diluted (to a ratio of 1:50 for PEDOT:PSS) with water of the same temperature (dynamic light scattering). Undiluted, heated, filtered PEDOT:PSS solutions were deposited as thin films for further characterization (photovoltaic studies, conductivity, photoelectron spectroscopy, AFM, profilometer). This was done via spin-coating in ambient

air to yield a final thickness of about 70 nm. Note that the spin-coating chuck and substrate were at room temperature, so that the polymer solution cooled during spin-coating. The spin-cast samples were annealed at 230 °C while purged with dry N_2 gas (<1 ppm H_2O) for 30 min to remove residual water. This temperature was found to be optimum for device performance in our previous study [11]. Samples were then cooled to room temperature in dry N_2 atmosphere and immediately sealed in separate small containers (additionally to glovebox storage) until further processing or measurement to avoid water or oxygen uptake. For conductivity determination gold channels with 80 μm channel width (sets of two parallel 3 mm-long gold stripes with a spacing of 80 μm) were evaporated (thickness: 50 nm) onto clean glass substrates, followed by deposition of PEDOT:PSS on top. For photoelectron spectroscopy studies (PEYS and XPS), the heated PEDOT:PSS solution was spun on fully covered ITO glass substrates. Profilometer and AFM imaging samples were prepared on Spectrosil quartz glass substrates. Photovoltaic devices were fabricated spinning a continuous layer of PEDOT:PSS on patterned ITO glass substrates. These were transferred to a nitrogen-filled glovebox for subsequent device fabrication steps. Firstly, the photoactive polymer layer was deposited on top by spin-coating from a 70 °C *o*-xylene solution of a 1:1 blend of P3HT:F8TBT (20 mg/mL) to give an active layer thickness of 70 nm. Then a 100 nm aluminum cathode was evaporated, followed by annealing of the device at 140 °C for 10 min. Finally devices were encapsulated with an epoxy-glass combination, prior to any air exposure and testing. All devices had an active area of 4.5 mm^2.

2.3. Methods

Surface imaging was performed using atomic force microscopy (Veeco Dimension 3100 AFM) operated in tapping mode and with a probe tip of radius of curvature R_C < 10 nm. Film thickness was measured using a stylus profilometer (Veeco Dektak 6 M). Monitoring of the pH values in solution was performed using a Jenway 370 pH meter, high-temperature-stable quartz-glass-bodied combination electrode and connected thermo element. The pH measurement was performed with automatic temperature compensation after two-point calibration. For device characterization, external quantum efficiency (EQE) was measured as a function of wavelength, using a monochromatic light source (250 W tungsten filament lamp, passed through a monochromator), with a final spot size smaller then the device active area. The short-circuit current was recorded with a Keithley 2635 source measure unit (SMU). Incident light intensity was continuously monitored during measurement and calibrated by a Thorlabs SM5PD1A photodiode. Current–voltage characteristics were recorded in the dark and under the same illumination as used for EQE measurements using the Keithley 2635 SMU. Current–voltage characteristics were also acquired under simulated solar conditions (intensity equivalent to 100 mW/cm^2, AM 1.5 G, after correction for spectral mismatch) using a solar simulator light source (Oriel 81160-1000) calibrated to a silicon reference cell. The hydrodynamic diameter of particles was determined by dynamic light scattering measurements using a Malvern Zetasizer. Measurements were performed on aqueous PEDOT:PSS solutions in the diluted regime (below overlap concentration). Two different concentrations, namely of 50 or 100 μg/ml were used to ensure independence of the data from solution concentration. Three independently prepared solutions were measured for each temperature with at least 20 runs each (number of runs was setted by the Zetasizer software, dependent on the signal quality). The statistical particle size distribution for each measurement was calculated by the Malvern Zetasizer software. The program also takes temperature dependent parameters (e.g. solvent viscosity) into account. Resistance of the PEDOT:PSS films was measured under a N_2 atmosphere, using a two-point-probe setup on a Karl Suss probe station connected to an HP 4155B semiconductor parameter analyzer. The measurement was performed in-plane, across the PEDOT:PSS-covered evaporated 80 μm gold channel, by penetrating the polymer to make contact with the gold electrodes. XPS measurements were performed in an ultra-high-vacuum system with a Kratos Axis Ultra DLD XPS with a monochromated Al K_α X-ray gun ($h\nu$ = 1486.69 eV) and a delay line detector. XPS data were analysed with *CasaXPS* (spectral data processing and analysis software). The core-level spectra were fitted with a combination of Gaussian and Lorentzian peaks after Shirley-background subtraction. Work functions were determined with photoelectron yield spectroscopy (PEYS) in air using a Riken-Keiki AC-2 surface analyzer (Riken Keiki Co., Ltd.). Full details of the AC-2 measurement can be found in the literature [20]. Briefly, film work function is determined by detecting the photoelectrons emitted from the film while the energy of incident UV light from a deuterium lamp (here operating at 250 nW) is varied between 4.5 and 6.2 eV with a monochromator. The work function is equal to the onset of photoelectron emission. For organic solids it is extracted from the linear fit of $Y^{1/3}$ on a plot of $Y^{1/3}$ versus $h\nu$ since $Y \sim (h\nu - W_f)^3$, where Y is the photoelectron yield, $h\nu$ the incident photon energy and W_f the material work function [21]. PEYS is advantageous compared to common UPS, because no vacuum is required and no charging of the sample occurs. Since also slower electrons are detected, the probing depth is 20–30 nm, much larger than for UPS (~10 nm), so surface effects have less impact on the measurement. This latter feature is useful to draw conclusions about the existence and thickness of thin dielectric surface layers on top of the samples from analysis of the yield slope [22]. If the photoelectron emission is retarded by such a damping surface layer, the slope will be smaller.

3. Results

For the investigation of heating effects on PEDOT:PSS solution and the consequences on solar cell performance we follow two different approaches. On the one hand physicochemical modifications occuring within the solution upon heating can be expected. On the other hand solution characteristics will affect the morphology and properties of solid thin films produced from such solutions via spin-coating. By examining in-depth the temperature

dependent properties of both solution and film, insight into the impact on photovoltaic device performance may be derived.

3.1. Effects on solution

One observation from PEDOT:PSS solution heating is the considerable change of particle size in solution, as determined by dynamic light scattering (DLS). Fig. 2a shows the distributions of hydrodynamic diameters in colloidal PEDOT:PSS solutions at various solution temperatures. We note that repeated measurements (as described in Section 2) yielded very similar distributions. It can be seen that the average particle size (Fig. 2b) remains stable at values of about 230 nm up to a solution temperature of 50 °C. With further heating from 60 °C up to 90 °C the particle size decreases rapidly to a new lower plateau at around ~40 nm, representing a size reduction of 83%. In thickness measurements on spun films for different solution temperatures we achieved similar values for all films of 71 ± 4 nm, confirming the absence of significant alterations of the solid content of the filtered solutions [23,24]. We further found that the size alterations are reversible, with larger particles reforming in solution upon cooling. Associated effects occurring under spin-coating conditions will be discussed later.

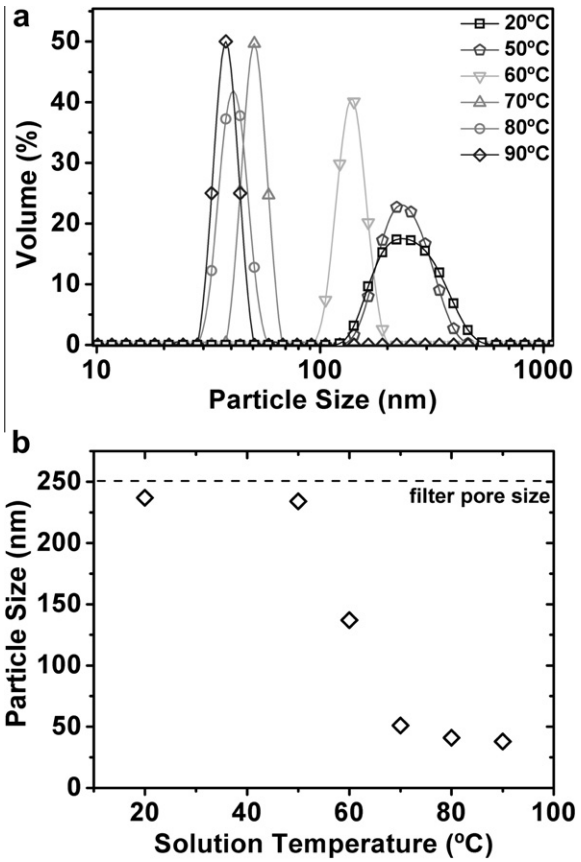

Fig. 2. Size distribution (a) and average particle diameters (b) in colloidal PEDOT:PSS solutions as a function of solution temperature as determined via dynamic light scattering.

Physicochemical processes in solution, especially in the presence of electrolytes like PSS, can be accompanied by changes in pH, since the concentration of hydrogen ions is affected. We found, however, no change in solution pH with heating, with a value of 1.23 ± 0.05 measured independent of solution temperature (between 20 °C and 90 °C) and in agreement with specifications provided by the supplier of 1.2–1.8. Thus we can discount any temperature-induced ion exchanges involving hydrogen. We note that since solution deposition involves contact with the ITO electrode, there may be a corrosive interaction during the brief spin-coating period before the film dries. To exclude any ITO-induced change in pH we have also measured the pH of PEDOT:PSS solutions with In_2O_3 powder added. A concentration of 1.21 mg/mL was used to simulate the maximum likely concentration of dissolved In_2O_3 in a 60 μl solution that is dispensed onto an ITO electrode (dimensions of ITO stripe: 12 mm × 7 mm × 120 nm) during spin-coating. However, we saw no change in pH with In_2O_3 added, remaining at pH 1.23 ± 0.05 independent of temperature. We note that this is contrast to the results of Chang and Chen [25], who observed an increase in pH value by adding In_2O_3 to PEDOT:PSS solution at room temperature, however the reaction was observed to take several hours, much longer than the time window of a few minutes used here to mimic spin-coating conditions. These observations show that whatever reactions may take place between PEDOT:PSS and ITO (such as the release of indium into the PEDOT:PSS solution), they do not significantly affect the concentration of the hydrogen ions.

3.2. Effects on films

We firstly look for possible chemical modifications of films spin-coated at different solution temperatures with X-ray photoelectron spectroscopy. Having a probing depth of less than 10 nm, XPS is used to quantify the elemental surface composition and provides information about the chemical environment. Survey scans covering binding energies of 0–1400 eV were first performed to identify elements in the film, with significant amounts of sodium (1070 eV), oxygen (532 eV), indium (446 eV), carbon (284 eV) and sulfur (170 eV) found. As discussed above, the presence of indium is most likely caused by diffusion of indium ions induced by the high acidity of the PEDOT:PSS solution [26]. Sodium is a trace component in PEDOT:PSS solutions (here less than 400 ppm after ion-exchange purification, as stated by the supplier), caused by the preparation process, involving Na^+PSS^-. The nominal concentrations of the elements detected near the surface of a standard room temperature spun PEDOT:PSS film were: 1.1% sodium (Na 1s), 19.3% oxygen (O 1s), 1.8% indium (In 3d), 70.6% carbon (C 1s) and 7.2% sulfur (S 2p). A comparison between sample films spun from differently heated solutions showed slightly varying compositions (changes <2%), but no obvious trends. High-resolution scans of oxygen (O 1s) and sulfur (S 2p) peaks were recorded to check for any changes in chemical environment of these two elements, which are of specific interest for PEDOT:PSS, such as changes in chemical bonds [8,27]. According to the work of Greczynski et al. [5] the sulfur

and oxygen peaks of PEDOT:PSS may have multiple components originating from PEDOT, PSSH and $PSS^{-}Na^{+}$ species that all have slightly shifted characteristic energies. The sulfur and oxygen core-level spectra for our PEDOT:PSS films spun from solutions heated between 20 °C and 90 °C are shown in Fig. 3.

The sulfur spectra obtained (Fig. 3a) are all consistent with one chemical species, namely the PSSH doublet located at 169.9 eV (S $2p_{1/2}$) and 168.7 eV (S $2p_{3/2}$). No indications of $PSS^{-}Na^{+}$ or PEDOT were found. We note that the effective energy values slightly differ from those reported in literature [5], which may result from the calibration of the spectrometer. We did not observe any change in the sulfur core-level spectra with heating of the PEDOT:PSS solutions. Analysis of the oxygen core-level spectra (Fig. 3b) showed only two contributions; one is attributed to oxygen—sulfur double bonds (O═S) in the sulfonate group in PSSH at 532.2 eV and the other to hydroxyl groups (O—H) at 533.4 eV from PSSH and residual water [5]. The hydroxyl peak appears to be rather broad, possibly caused by hydroxyl groups participating in hydrogen bonds [5]. A peak intensity ratio between O—H bonds and O═S bonds of 1:9 was observed (measured composition 10.5% O—H and 89.5% O═S). We suggest that the comparatively low amount of O—H bonds is mainly caused by our post-deposition film annealing at 230 °C, which firstly might have removed most inter- and intra-particle water and additionally condensated (dehydrolysed) a large quantity of the existing hydroxyl groups in the solid film. No further contributions of either $PSS^{-}Na^{+}$ or PEDOT were found. Just as for the sulfur, no significant changes between the films spun from solution at different temperatures were observed in the oxygen core-level spectra. It should be mentioned that our 230 °C film annealing step is below the temperature at which the rupture of the sulfonate group from PSS takes place [5,11]. This has been supported by further XPS studies which we have performed on PEDOT:PSS films annealed at temperatures between 140 °C and 300 °C in N_2 (graphs not shown). Only for films annealed above 260 °C we could observe additional contributions due to the presence of PEDOT at the surface (at 165.4 eV (S $2p_{1/2}$), 164.2 eV (S $2p_{3/2}$) and 533.6 eV (O 1s)) and an energy-shift in the PSS sulfur doublet, indicating the predominance of $PSS^{-}Na^{+}$ due to PSSH degradation. Both effects were already reported in the literature [5].

For most optoelectronic applications, as in organic photovoltaic devices, the work function of the electrode is crucial and can be one of the factors limiting performance. We have therefore determined the work function changes of films spun from PEDOT:PSS solutions heated at different temperatures via (ultraviolet) photoelectron yield spectroscopy (PEYS). Additionally the yield slopes have been analyzed which can indicate an increase or decrease in the thickness of dielectric surface layers such as excess PSS. Fig. 4a shows the baseline-corrected plots of the photoelectron yield $Y^{1/3}$ plotted against photon energy for different solution temperatures.

At first sight the absence of obvious onset shifts or changes of slope implies that there are only subtle differences upon variation of solution temperature. The work function values and slopes, obtained from linear fits to $Y^{1/3}$, are displayed in Fig. 4b. Despite the comparatively high experimental uncertainty of the measurement ($\Delta W_f = \pm 0.05$ eV), there appears to be a trend in the work function development with solution temperature. Up to 70 °C the work function W_f remains at a stable value of around 5.38 eV; with higher solution temperatures it increases up to 5.50 eV for the 90 °C sample. The slopes of the photoemission yield curves, which represent a measure of the photoelectron emission rates, do not follow the same trend. The highest emission rate within the studied temperature range was found for films spun from room-temperature solution. With increasing solution temperature the emission rate drops, with a minimum for the 70 °C sample. Temperatures above 70 °C cause rising emission rates (higher slopes) from the films. This could be an indication for a variation in thickness of the excess PSS surface layer with solution temperature or changing film density. It should be noted that the short exposure to air during the measurement might have slightly influenced the data due to the strongly hygroscopic nature of PSS. However, apart from a control sample that had been exposed to air for several hours, none of the films shows signs of strong water uptake, which is typically reflected by a strongly lowered work function of around 5.05 eV [6,7,28].

Conductivity is likely to be one of the most important characteristics of an electrode material in a solar cell. PEDOT:PSS films were spun from solutions at different temperatures and subsequently annealed for conductivity measurement. The corresponding development of in-plane conductivity with solution temperature is shown in Fig. 5.

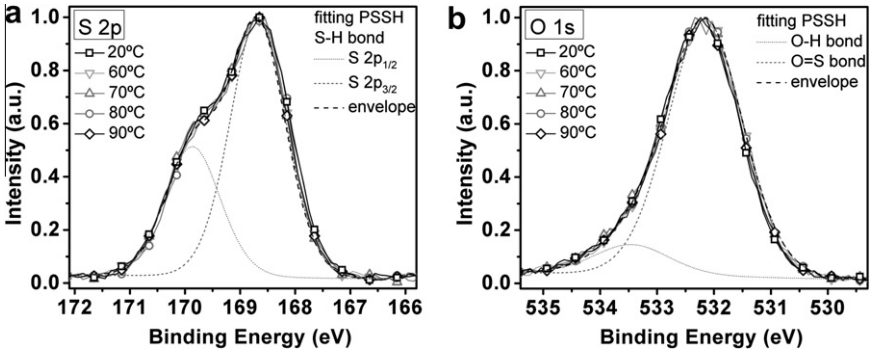

Fig. 3. (a) Sulfur (S 2p) and (b) oxygen (O 1s) XPS core-level spectra of PEDOT:PSS films spun from differently heated solutions.

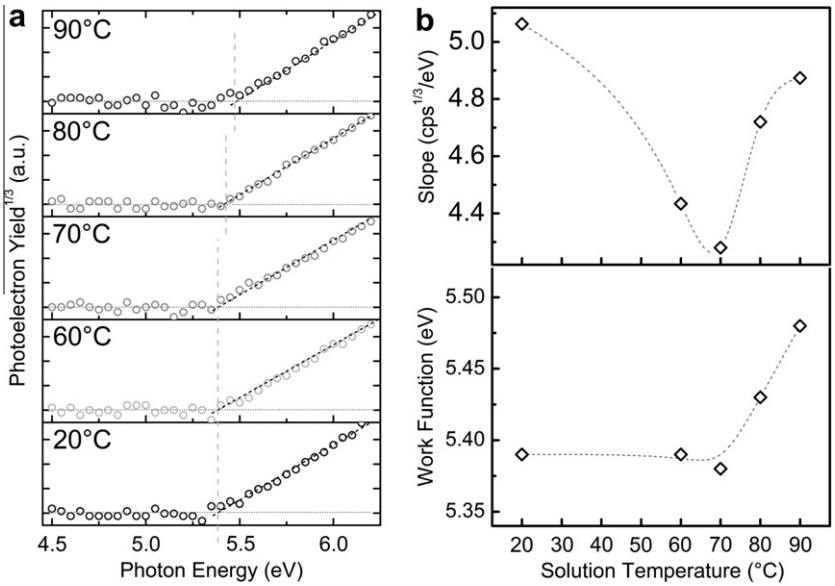

Fig. 4. (a) Cube root plot of the photoelectron yield from PEDOT:PSS films prepared from heated solution. (b) Slope extracted from linear fit to yield (top) and measured work function (bottom) as a function of PEDOT:PSS solution temperature (the dashed lines are a guide to the eye).

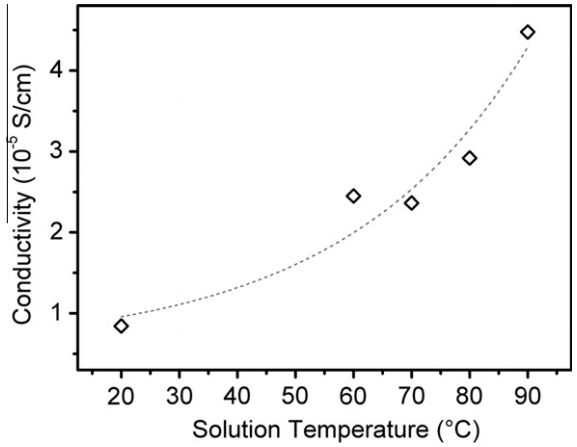

Fig. 5. In-plane conductivity of equally annealed PEDOT:PSS films spun from differently heated aqueous colloidal PEDOT:PSS solutions (the dashed line is meant as guide to the eye).

We found that the in-plane bulk conductivity is enhanced by a factor of five with increasing solution temperature from 20 °C to 90 °C. This is in good agreement with results reported by Tsai et al. [29], who found 2–3 times higher conductivity in films spun from PEDOT:PSS solutions heated from 20 to 160 °C.

The morphology of PEDOT:PSS solid films, spun from solution at different temperatures has been investigated with AFM. Fig. 6a shows the height images for PEDOT:PSS films spun from heated solutions between 20 °C and 90 °C, after subsequent annealing.

It is apparent that although the macroscopic roughness of all films is very similar, there is a refinement in the microscopic structure for films spun at 60 °C and higher. There are obviously considerable changes in particle dimension depending on the PEDOT:PSS solution temperature. The average particle size (Fig. 6b), as acquired from statistical feature size analysis of AFM cross-sectional line scans of the different films, reveals a trend similar to that one seen from DLS on PEDOT:PSS solutions (Fig. 2b). The feature size remains stable at about 55 nm for films up to 50 °C solution temperature and then drops quickly for higher temperatures to a new plateau at around 20 nm. It should be mentioned that a further size decrease might not be detectable as AFM resolution is limited by the tip size (R_C < 10 nm).

3.3. Effects on solar cells

Finally the effect of PEDOT:PSS solution temperature on the performance of P3HT:F8TBT solar cells has been studied. Fig. 7 plots external quantum efficiency *EQE* (Fig. 7a), current–voltage characteristics under solar simulator conditions (AM1.5G) (Fig. 7b) and specific key solar cell parameters (Fig. 7c) (namely short-circuit current density, J_{sc}, open-circuit voltage, V_{oc}, fill factor, *FF*, and power conversion efficiency, η) as a function of PEDOT:PSS solution temperature. As expected, the *EQE* curves (Fig. 7a) do not show any significant spectral change since the active layer is kept constant. However, there are variations in the magnitude of *EQE* with maximum *EQE* increasing with increasing PEDOT:PSS solution temperature to a maximum at 70 °C, then falling again as temperature is increased to 90 °C. A similar trend is seen in the current–voltage characteristics. Fig. 7c shows that all key parameters are optimized with a solution temperature of 70 °C, which is most apparent for J_{sc} and η, while V_{oc} and *FF* only change slightly.

4. Discussion

Among the numerous publications addressing the optimization of PEDOT:PSS films for use in organic

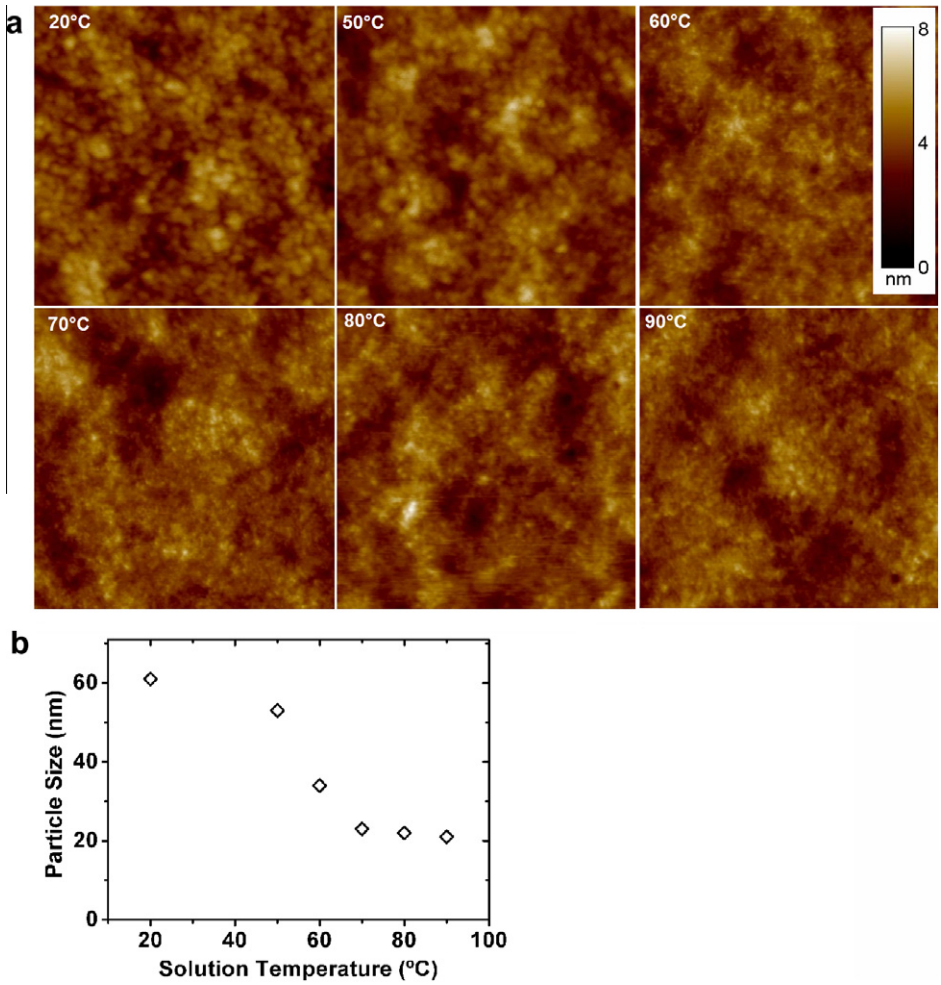

Fig. 6. (a) AFM height images (2 μm × 2 μm) of the surface morphology for PEDOT:PSS films spun from heated solutions. (b) Temperature dependent development of average feature size in these films.

optoelectronic devices, changes in particle/grain size by addition of dopants or co-solvents, have occasionally been addressed. Usually these have been attributed to agglomerate formation [30–32], e.g. due to dominating Van-der-Waals forces facilitated by partial removal of the repulsive negatively charged surface PSS layer (e.g. by solvent additives) [33]. We found in our experiments that the size variations could be detected within a few minutes in highly diluted solutions. This makes agglomeration as a cause for a size increase unlikely, since the required diffusion processes for interparticle contacts take place on a much longer time scale (days or weeks). Furthermore the particles could not be broken down by ultrasonication, which also speaks against agglomeration effects. We suggest that the observed solution-temperature-induced size effects are rather associated with the phase behavior of PEDOT:PSS, which has not been reported in this context so far.

The solubility of PEDOT:PSS in aqueous solution is mainly determined by the presence of the charged sulfonate groups on the polystyrene backbone, since PEDOT and polystyrene are both hydrophobic on their own. Experimental and theoretical approaches reported in literature have shown that phase behavior of PSS crucially depends on the degree of sulfonation, the distribution of the sulfonate groups along the backbone, the presence and strength of counter ions or the presence of salts in solution [34–37], information which was not fully available, either for commercial PSS solution or for the PSS used in PEDOT:PSS, making it difficult to compare the two systems. Although some values could have been determined experimentally, that is beyond the scope of this publication.

The size dependence of NaPSS with temperature has been the subject of only few earlier studies, finding an increase of hydrodynamic size of the chains with increasing solution temperature from 5 nm up to 18 nm and demixing with an upper critical solution temperature (UCST) [38,34]. Fig. 2 shows an opposite trend, with a decrease in size of PEDOT:PSS particles with increasing solution temperature. This indicates phase separation of the polymer solution at high solution temperatures. Microscopically this means that the polymer chains are most extended at low temperatures and contract/collapse towards higher temperatures. A phase behavior of this kind is typical for a lower critical

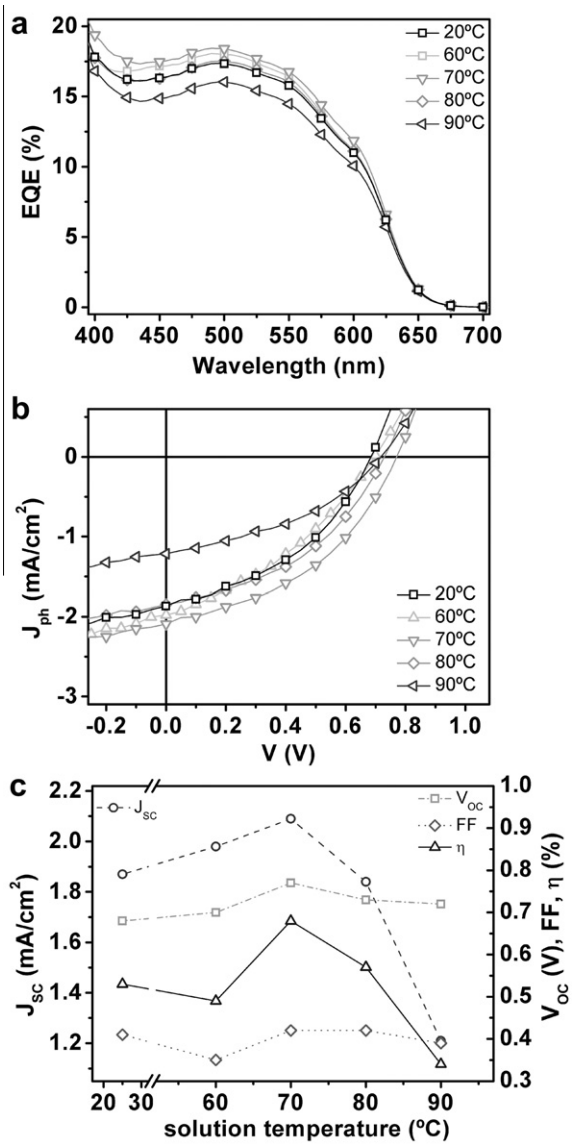

Fig. 7. Characteristics of solar cell devices with PEDOT:PSS films spun from differently heated PEDOT:PSS solutions, (a) external quantum efficiency, (b) photocurrent density (AM1.5G) and (c) key photovoltaic parameters.

solution temperature (LCST), similar to the phase behavior of other polymer solutions [39a]. The variation of particle size in the dry PEDOT:PSS films shows an very similar behavior. Although this trend could also arise from the change of other solution parameters during spin-coating, the similarity of Figs. 2b and 6b suggests the dominance of an LCST behavior of PEDOT:PSS on the particle size in the film. Fig. 8 summarizes the two data sets and schematically indicates the trajectories in phase space of the two experiments. Heating a solution at fixed concentration is indicated by the red dashed (vertical) arrow. Phase separation occurs when the trajectory crosses the binodal line (boundary between polymer–solvent miscibility and immiscibility). In a dilute solution this is accompanied by a step decrease in the hydrodynamic diameter, as observed in the DLS experiments (Fig. 8, right), caused by a collapse of the polymer chains. This process is fully reversible. Spin-coating, on the other hand ideally occurs at constant temperature. Solvent evaporation increases the solution concentration, indicated by the blue dashed (horizontal) arrow in the phase diagram. Horizontally crossing the binodal gives rise to a similar step in particle size, as observed in the as-cast films (Fig. 8, left). In practice, the trajectory for spin-coating from heated solutions is slightly more complex. In addition to a rapid concentration change, the temperature also changes, by casting the solution onto a cold substrate and through evaporative cooling. While this implies a diagonal trajectory in the phase diagram (indicated by the purple (diagonal) arrows), the description for the ideal spin-coating process remains qualitatively valid. Both trends for the hydrodynamic and solid diameter agree well with this scenario. Preheating the substrates, while feasible, substantially changes the evaporation rate of the solution, possibly causing additional changes in the films. The very similar cross-over temperatures of the two data sets in Fig. 8 suggest, however, that film formation occurs much more quickly than a change in particle size. This is in agreement with recent results showing a very slow change in the conformation of polymer brushes upon crossing a LCST [39b].

A further interesting observation arises from the comparison of Figs. 2b and 6b. The particle diameter decreased from 230 nm in solution to 55 nm in the film (i.e. by a factor of 4) when the casting from a 20 °C solution, compared to a size change from 40 nm to 20 nm (by a factor of 2) when the spin coating was above 70 °C. This observation indicates that the coils were less swollen in solution at the high temperatures compared to room temperature, in good agreement with the LCST assumption mentioned above. This result also matches well recent non-equilibrium effects in spin-cast polystyrene films reported by Thomas et al. [40], showing that that solution coil conformations are substantially preserved in the film after spin-coating [41].

In the case of the PEDOT:PSS micellar solution, the signature of an LCST behavior is as follows: Because most PSS chains are localized around PEDOT cores, the phase transition leads to a change in micellar size, which leads to the observations in Fig. 8. Secondly macroscopic phase separation of the suspension into polymer-rich and polymer poor phases should set in at high temperatures. This second process, which is much slower (on the time scale of many hours), was not investigated in detail.

LCST phase behavior of polymer solutions is less common than the UCST type, but often occurs for polymers that can form hydrogen bonds with the solvent [42]. In the case of PEDOT:PSS the presence of hydrogen bridges between sulfonate groups has been reported [31], which could be responsible for the observed LCST phase behavior. It is worth mentioning that hydrated PSS-chains are to some degree extended into the aqueous medium, while they are fully collapsed in the dry film. Macroscopically this is observed when swollen particles in solution shrink during drying, leading to the reported dried PEDOT:PSS grains with PEDOT-rich core, covered by a thin insulating PSS layer [37,38].

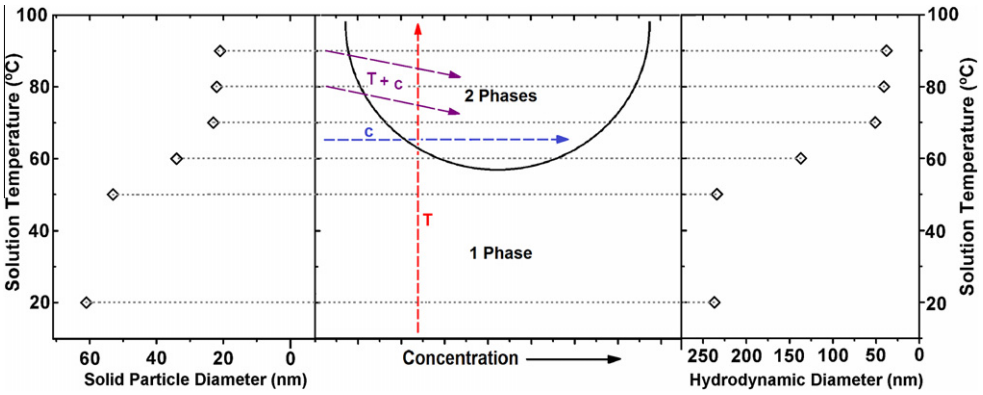

Fig. 8. Schematic LCST-phase diagram illustrating trajectories of solution heating and spin-coating, associated with the obtained trends of average particle diameters as determined from DLS from PEDOT:PSS colloidal solutions (right) and in solid films (left) as a function of solution temperature.

We did not observe any variation in pH value of the PEDOT:PSS solution during heating, neither in pure solution nor involving indium oxide. This is not indicative of PEDOT:PSS-induced ITO corrosion during film formation, which is suspected to cause damage of the organic active layer by indium diffusion already during device fabrication.

The temperature-induced shrinkage of the PEDOT:PSS particles was accompanied by a considerable effect on the film conductivity which was quadrupled by solution heating. It has been reported that smaller PEDOT:PSS particles actually cause lower film conductivity [12], since PEDOT:PSS conductivity is determined by the extension of the conducting PEDOT-rich domains and the hopping distance/frequency across the insulating PSS phases. We found that the interface properties are characterized by an increasingly refined structure and densification of the PEDOT:PSS film, leading to shorter hopping distance between the conductive PEDOT-rich units, the consequence of which is a lower bulk resistance and enhanced interlayer contact.

However, the fact that even for small particles the PSS-shell is at least 10 nm thick, explains why no PEDOT was detected from the films via XPS within the nominal probing depth of 10 nm, independent of the solution temperature. Nor was any other evidence for chemical changes found near the surface.

The observed increase in film work function for solutions exceeding 70 °C is probably caused by the densification of the film causing considerable changes in the interface properties. Even more significant is the behavior of the photoelectron emission rates, represented by the yield slope. The rate starts at a high level, because for low solution temperatures the films are porous and in spite of the thicker damping PSS shell surrounding the particles, more electrons can be detected. When the film density grows towards 70 °C, the rates go down, due to increasingly hindered signal from the depth of the film. Exceeding 70 °C, the emission rates raise again, because the dimensions of the PSS shell of the particles are significantly reduced.

When films from solution-heated PEDOT:PSS are incorporated into a P3HT:F8TBT solar cell, we find that actually most of the key characteristics peak at a PEDOT:PSS solution temperature of 70 °C. It seems obvious that the largest improvement is caused by the enhanced conductivity of the PEDOT:PSS films. However, it is still questionable why the PV performance does not improve beyond 70 °C while the conductivity is still rising. Possible reasons include changes in work function or other interface properties, and changes in vertical charge transport (as opposed to the lateral conductivity measured here). Although the observed work function shift is not large ($\Delta W_f = 0.1$ eV), it could be just sufficient to form a barrier for hole extraction from P3HT. Accordingly the performance would go down for higher solution temperatures. It has been reported earlier [43], that vertical charge transport in PEDOT:PSS can be up to three orders of magnitude lower than in-plane, due to layers of segregated excess PSS. Though we cannot prove this by our spectroscopic or imaging data, it is possible that the phase transitions seen in PEDOT:PSS are accompanied by alterations of the amount of electrostatically bound excess PSS. In that case the release or withdrawal of free PSS into/from solution could certainly change the presence and extension of insulating horizontal PSS interlayers in the resulting films.

5. Conclusions

In this work, the influence of heating on PEDOT:PSS colloidal solutions and its consequence on the performance of polymer–polymer photovoltaic devices has been investigated. We found reversible heat-induced reduction in size of PEDOT:PSS particles by solution heating between 20 °C and 70 °C. We associated this transition with LCST-type phase behavior of PEDOT:PSS. This transition from large particles with a thicker (expanded) insulating PSS-shell to smaller particles covered with a thin (contracted chains) PSS layer causes property alterations in resulting films. In particular, increasing the solution temperature results in films with finer structure, higher density, increased conductivity and work function. Solar cell performance was found to improve, but only up to 70 °C. Above 70 °C, device performance deteriorated alongside an increase in PEDOT:PSS work function, suggesting the formation of a hole

extraction barrier. Based on our observations, we conclude that PEDOT:PSS solutions heated at 70 °C deliver the most beneficial film properties for P3HT:F8TBT solar cells. These results may have implications in the roll-to-roll manufacture of organic photovoltaics, where the liquid film deposited by printing is heated to aid drying [44,45]. Changes in PEDOT:PSS particle size during this process may have a direct impact on device performance.

cathode) and hole (at the anode) transport level in the organic semiconductor. From then on, electrons and holes are injected in the active layer. The ions react by (electrostatically) compensating the injected charge, in other words the anions and cations respectively stabilize the oxidation and reduction of the polymer. This process is called electrochemical doping [4].

In wide-gap planar LECs, this electrochemical doping can be visualized by monitoring the PL of the active layer under UV illumination; [16] in the presence of doping, PL is quenched in the active layer [17]. Particularly interesting is the way in which this doping occurs. Starting from the electrodes, doped regions expand towards each other. During this expansion, doping fronts are visible as sharp transitions between the undoped region and the n- and p-doped regions. These fronts have been observed to accelerate. Fig. 1a (blue symbols) shows a typical measurement [18] of the front position versus time.

Several experimental studies [19–21] have been performed on these fronts as well as analytical [22,23] and numerical modeling [24]. Robinson and co-workers developed an analytical model that predicts the position of the doping fronts and the resultant switch-on time. They assumed that both the potential over the shrinking undoped region and the conductivity through this region remain equal. The first assumption is however not necessarily true in LECs. Recent measurements of the electrostatic potential have shown that the potential does not strongly evolve during doping front progression [25]. Results presented in the present work confirm these findings.

Here we demonstrate by numerical modeling [4] that a doping dependent mobility [26] is required to generate the accelerating doping fronts observed experimentally (Fig. 1b, blue symbols). In addition the ion mobility with respect to the electron/hole mobility is critical for front formation as well as for other transient properties like the formation of electric double layers (EDLs) [27] and a light-emitting p–n junction. For formation of accelerating doping fronts, the ion mobility needs to be approximately equal to the electron/hole mobility in the undoped polymer. In simulations that obey these criteria, the doping front propagation shows an excellent agreement with experimentally observed doping fronts as shown in Fig. 1a (black solid line) [18]. As opposed to the t^2 dependency of the front position obtained by Robinson et al. [22] (Fig. 1a, red solid line) our model shows a less strong time dependence of the front position. Next to this fundamental understanding of the formation of doping fronts, also the transient behavior and the switch-on time in LECs are rationalized by means of numerical modeling. The simulations indicate that the switch on time is mostly related to the time an ion needs to cross approximately half the device.

2. Material and methods

2.1. Computational details

A 1-dimensional model was used in which an active layer with a length of 2 μm was divided in discrete, equidistant grid points [4,25]. The numerical model solves the drift–diffusion equations for electrons, holes, anions and cations and Poisson's equation on this grid by forward integration in time. Devices with a bandgap $E_g = 2$ eV were simulated during operation at a bias voltage $V_{bias} = 5$ V. A detailed description of the numerical model can be found in the Supplementary Information sections A and B. Simulations were ran for devices with an initial homogeneous ion concentration $c_0 = 1 \times 10^{-1}$ nm^{-3}. No binding energy was assumed between anions and cations. The electrodes were ionically-blocking and electrons and holes were injected from the contacts according to a dedicated injection model that gives rise to field dependent injection [4]. The injection model is described in detail in the Supplementary Information and has the advantage that injection is not affected by grid-point spacing. At the start of the simulations, no electrons and holes are present in the device. The hole and electron injection barriers were set at 0.5 and 1.5 eV respectively to simulate an asymmetric device. Such an asymmetry is realistic for actual planar LECs, in which both the anode and the cathode are made from a single material, e.g. Au. Bimolecular electron–hole

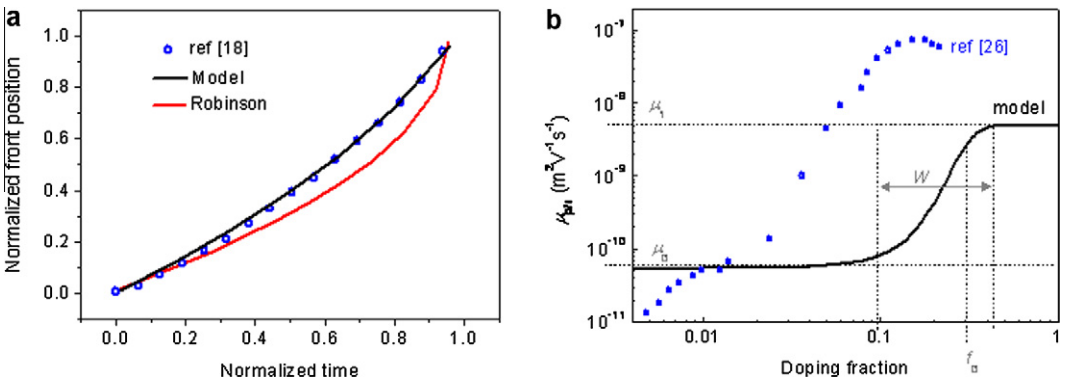

Fig. 1. (a) Front position during switch-on in an LEC as obtained experimentally (blue markers) [18], analytically (red line) [22] and by numerical modeling (black line). The model curve follows from modeling of a planar LEC with a doping dependent $\mu_{p/n}$ according to Eq. (1) for $\mu_0 = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1}, $\mu_1 = 5 \times 10^{-8}$ m^2 V^{-1} s^{-1}, $f_0 = 0.13$ and $W = 0.015$. (b) The electron/hole mobility as a function of the doping fraction. The blue graph was experimentally determined by Shimotani et al. [26] in regioregular P3HT (here the mobility values are divided by 10^2) and the black graph follows from Eq. (1) for $\mu_0 = 5{\cdot}10^{-11}$ m^2 V^{-1} s^{-1}, $\mu_1 = 5 \times 10^{-9}$ m^2 V^{-1} s^{-1}, $f_0 = 0.3$ and $W = 0.04$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

recombination was described by a Langevin process and the electrostatic potential was determined by Poisson's equation. Furthermore, energetic and spatial disorder, as present in real polymers, were omitted for convenience, as were charge traps. In addition, we set the relative dielectric constant $\varepsilon = 3$ and the temperature $T = 300$ K.

To implement a doping density dependency of the electron/hole mobility ($\mu_{p/n}$) the following expression was used:

$$\mu_{p/n}(f) = \frac{\mu_{p/n.1} - \mu_{p/n,0}}{1 + \exp\left(\frac{f_0 - f}{W}\right)} + \mu_{p/n,0}. \quad (1)$$

Here f is the doping fraction which is equal to the carrier density divided by the density of states (=0.3 nm^{-3}). This approximation of the doping fraction is justified by the observation (see Supplementary Information Fig. C.1) that the net ion density always equals the net electronic charge density in the doped regions. Regarding the other parameters, $\mu_{p/n,1}$ is the mobility at maximal doping ($f = 1$), $\mu_{p/n,0}$ is the mobility in the absence of doping ($f = 0$), and f_0 and W are two parameters that set the transition from μ_0 and μ_1:f_0 determines at which doping fraction the mobility increases and W determines the range of doping fractions over which this increase occurs. Fig. 1b shows a typical plot of the doping dependent mobility that follows from Eq. (1) for $f_0 = 0.3$, $W = 0.04$, $\mu_0 = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1} and $\mu_1 = 5 \times 10^{-9}$ m^2 V^{-1} s^{-1}. The anion and cation mobilities were chosen to be equal to each other and doping independent. Ion mobilities ranged from 5×10^{-12} to 5×10^{-9} m^2 V^{-1} s^{-1}.

Since our interest is the transient behavior of LECs, calculations started with the application of a bias voltage on a homogeneous device and were continued until steady state was reached. At $t = 0$ the electron and hole density equals zero and the anion and cation density equals c_0. It was checked that the inter-electrode gap and meshing did not affect the outcome of the calculations in any non-trivial manner (see Supplementary Information A).

3. Results and discussion

Multiple simulations were performed to analyze the effect of the electronic and ionic mobilities on the transient behavior in LECs. The time-evolution of the electron and hole density profiles that follow from these simulations are shown in Fig. 2. The absence (Fig. 2a–d) and presence (Fig. 2e–f) of a doping dependent mobility was studied as well as the effect of the ion mobility. The doping dependent mobility that is shown in Fig. 1b (model) was used in these simulations. It will be shown below that the qualitative behavior in these simulations only depends on the relative values of the mobilities of the electronic and ionic species.

Starting from $t = 0$, the processes in these devices are similar: anions and cations move towards the anode and cathode respectively forming EDLs (see Supplementary Information Fig. S4). When the resultant potential drop at the interfaces has become similar in size to the injection barriers, charge carriers start being injected. During EDL formation, the anion and cation concentrations in the bulk remain equal to maintain charge neutrality. Only at the electrodes this neutrality is broken because of depletion of one type of ion and accumulation of the other. During the subsequent injection of either electrons or holes, a third type of charge carrier comes into play. To maintain charge neutrality in the bulk, the anion and cation densities start to differ. At this stage, where injection of carriers is initiated, differences in the transient processes arise when ion or carrier mobilities are altered.

When interpreting the results shown in Fig. 2, the discussion focuses on two characteristics: (1) the collision of the p- and n-doped regions and (2) the saturation of doping at each grid-point after the doping front has passed. Here, doping is saturated when a doping fraction of approximately 0.2–0.3 is reached, i.e. at a charge density of $2–3 \times 10^{-1} \times 0.3$ nm^{-3} in Fig. 2. Note that in experiments, strong PL quenching is observed when the doping density reaches a threshold level; PL quenching is not necessarily linear with doping fraction [16].

As a first example, we show in Fig. 2b, the time evolution of the doping of the active layer assuming a doping-independent mobility of $\mu_{ion} = \mu_{p/n} = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1}. No sharp transitions are observed from doped to undoped regions: the doped regions already connect to each other while the doping density in roughly half the cell is far from saturated. However, in case of a doping dependent mobility $\mu_{p/n}$ (Fig. 2f), the transition between the doped and undoped regions becomes sharper; the increased mobility of electrons and holes injected behind the front results in a faster saturation of doping compared to the progression of the doped region through the intrinsic region. The enhanced mobility behind the front also ensures a sufficient supply of carriers towards the fronts to prevent a decrease of the doping rate at the front. In contrast to the situation for a doping-independent mobility (panel b), the time needed to completely dope the active layer in panel f is limited by the front progression and not by the process of saturating the doping behind the fronts.

When the ion mobility is decreased by a factor 10 ($\mu_{ion} = 5 \times 10^{-12}$ m^2 V^{-1} s^{-1}, panels a and e) both doping regions come into contact even before doping has saturated at any position in the cell. No sharp transitions are observed from doped to undoped regions. These observations are the result of the relative immobility of the ions compared to the electrons and holes, which mainly hampers the actual doping of the active layer. Since $\mu_{p/n,0} > \mu_{ion}$ progression of the electronic charges through the device is fast relative to the actual doping at any fixed position in the device. Consequently there is a small doping density difference between the front and the doped regions just behind it, which results in only a minor carrier mobility enhancement behind the front. Therefore, the carriers behind the front are not propelled towards the front as was observed in Fig. 2f. For that reason, the two doping fronts have already moved across the active layer while the doping process is far from finished. After the doped regions have met, doping saturates more or less evenly throughout the LEC. This result indicates that if $\mu_{ion} < \mu_{p/n,0}$ homogeneous doping of the active layer is found rather than doping by doping fronts.

On the other hand, when the ion mobility is increased by a factor 10 ($\mu_{ion} = 5 \times 10^{-10}$ m^2 V^{-1} s^{-1}, panels c and g),

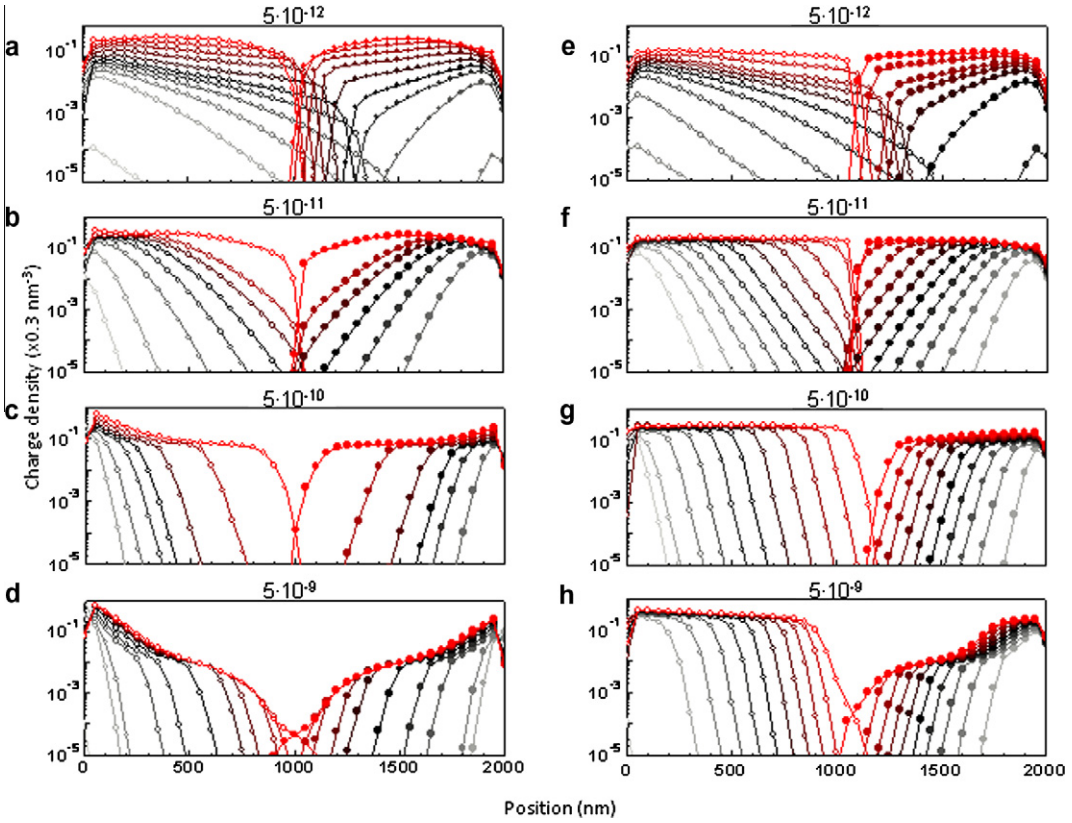

Fig. 2. Transient carrier concentration profiles in LECs for (a)–(d) a constant $\mu_{p/n}$ equal to 5×10^{-11} $m^2 V^{-1} s^{-1}$ and (e)–(h) a doping dependent $\mu_{p/n}$ (see Fig. 1b, model). Holes (open circles) are injected from the left and electrons (closed circles) from the right. The corresponding values of μ_{ion} are shown at the top of each graph expressed in $m^2 V^{-1} s^{-1}$. The movement in time is expressed by the color change of the graphs from light gray to black followed by red. The final red graphs are not the steady state distributions but represent the moment the p–n junction has formed. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

sharp doping fronts are formed for both a density dependent and a density independent $\mu_{p/n}$. The origin of the formation of these sharp fronts is however different as compared to the fronts formed in Fig. 2f. In case a constant $\mu_{p/n}$ is chosen (panel c) anions and cations always move faster than the injected carriers. As a result, the available anions and cations are able to electrostatically compensate the injected carriers relatively fast. As shown in our previous publication, [4] in the absence of injected carriers, because of e.g. relatively poor carrier injection, the ions tend to screen the bulk from the electric field. Here this tendency is observed during doping of the active layer: the electric field E_i in the intrinsic region, that drives the doping front, is reduced by ion screening (see Supplementary Information Fig. D.1). Accordingly the carriers at the fronts are slowed down, while newly injected carriers in the already doped regions are accelerated because of a locally enhanced field. (see Supplementary Information Fig. D.2c for the potential evolution). This combination results in a sharp doping front. For a doping dependent mobility (panel g), the same behavior of the ions is observed; ions accumulate at the front to screen the intrinsic region from the applied field. In addition, in this case the doping-enhanced mobility of injected carriers is larger than the ion mobility. Hence, these carriers can more easily approach the carriers at the front, which further sharpens the doping front in panel g as compared to panel c. (see Supplementary Information Fig. D.3 for an evaluation of the sharpness of the n-type doping front during propagation).

In case the ion mobility is increased even more, i.e. 5×10^{-9} $m^2 V^{-1} s^{-1}$, the effects of a reduction of E_i become more pronounced, as shown by relatively large doping density close to the electrodes in panels d and h. Furthermore, the strong depletion of ions from the intrinsic region becomes a limiting factor. The regions close to the electrodes absorb most of the ions and hence they are not directly available for electrochemical doping. Consequently, the doping fronts slow down as no more ions are available in the intrinsic region. After that, ions from the already doped regions are transported backwards to the front to complete the doping (the ion density profiles are shown in Supplementary Information Fig. D.4). This backward ion transport is driven by the inward movement of electrons and holes.

It is important to point out that the steady state carrier distributions and potential profiles are the same for each ion mobility as the ion mobility only affects the transient characteristics in LECs, not the steady state characteristics [4]. The graphs in Fig. 2 are plotted until the p–n junction

has formed, hence the red curves do not represent complete equilibrium.

The positions of the sharp doping fronts observed in Fig. 2 are plotted vs. time in Fig. 3a. For each doping profile in Fig. 2 the position at which the doping density equaled a constant, arbitrarily chosen value of 3×10^{-3} nm^{-3} was taken to produce Fig. 3a. A different choice of this value hardly affects the doping front propagation profiles in Fig. 3a, because the shape of the doping density profile is more or less constant during doping front propagation (see e.g. Fig. 2g). The observed acceleration (superlinear behavior in Fig. 3a and c) or deceleration (sublinear behavior) of the sharp doping fronts can be related to the origins of sharp front formation as discussed above. A reduction of the electric field and/or ion density in the intrinsic region was found to underlay the fronts observed in panels c, d, g, and h of Fig. 2. Both these effects directly lead to a deceleration of the doping front. Consequently, newly injected carriers have time enough to dope the region behind the front and thus maintain a constant doping density from the electrodes towards the fronts, which is perceived as a sharp doping front. In case sharp doping fronts are formed because the mobility of newly injected carriers is enhanced (Fig. 2f), the doping front velocity is observed to slightly increase with time because of the large supply of injected carriers. These effects or combinations of these effects can be observed in the front position vs. time plots in Fig. 3a. Consider the front position vs. time graphs for a doping-dependent mobility (gray–black lines). For $\mu_{ion} = 5 \times 10^{-9}$ m^2 V^{-1} s^{-1} (light gray line) the front speed declines because of a reduction of both E_i and ion density in the intrinsic region. For $\mu_{ion} = 5 \times 10^{-10}$ m^2 V^{-1} s^{-1} (dark gray line) the front speed is constant, being the sum of opposite effects: a reduction of E_i and an enhancement of $\mu_{p/n}$ in the doped regions. For $\mu_{ion} = \mu_{p/n,0} = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1} (black line), the front speed increases, because $\mu_{p/n}$ is enhanced. The latter, an increasing front speed, is in agreement with published experimental data, see Fig. 1a [22]. In case $\mu_{p/n}$ is doping-independent (red lines), the front speed mainly declines because of the reduction of E_i and ion density in the intrinsic regions.

To study the effect of a sharper mobility increase as a function of doping, simulations were performed in which parameters W and f_0 in Eq. (1) were decreased. The used mobility curves are shown in Fig. 3b. Simulations of the front propagation were performed for all these curves while $\mu_{ion} = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1}. The results are shown in Fig. 3c. If the mobility increase becomes sharper with respect to an increased doping density, the time needed for both fronts to meet each other clearly decreases. Further-

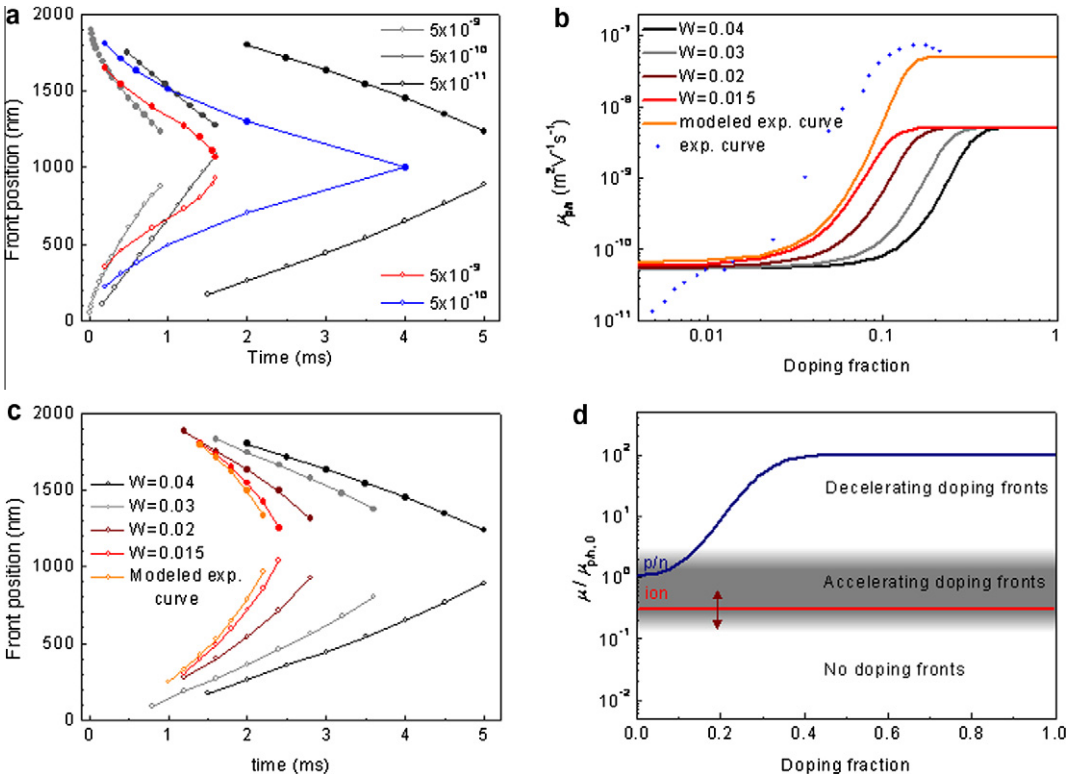

Fig. 3. Calculated doping front position vs. time plots in LECs for different carrier mobility functions. The p- and n-type doping fronts are denoted by the open and closed circles respectively. (a) The doping front propagation for different values of μ_{ion} as indicated in the legend in m^2 V^{-1} s^{-1}. The gray–black lines and red lines correspond to a density dependent and independent $\mu_{p/n}$ respectively. (b) Different doping dependent mobility functions for which $\mu_0 = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1}, $\mu_1 = 5 \times 10^{-9}$ m^2 V^{-1} s^{-1}, $W = 0.04/0.03/0.02/0.015$ and $f_0 = 0.3/0.22/0.14/0.10$. For the orange line, $W = 0.015$, $f_0 = 0.13$ and $\mu_1 = 5 \times 10^{-8}$ m^2 V^{-1} s^{-1}. (c) The doping front propagation for the different doping dependent mobility functions shown in (b). (d) Schematic of the ion mobility criteria with respect to the doping dependent electron and hole mobility (blue line) that result in the formation of accelerating doping fronts in LECs during switch-on. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

more, also a larger acceleration of the fronts is observed. These observations are related to the enhanced carrier mobility at progressively lower doping levels: the higher carrier mobility behind the front results in an increased supply of carriers for doping at the fronts, enabling the front to move faster through the active layer. Also a simulation was performed with a doping dependency of the mobility that mimics the experimental mobility curve in Fig. 1b (see orange line in Fig. 3b). The resultant front position vs. time curve is shown in Fig. 3c. This result was normalized and plotted in Fig. 1a to enable comparison with the experiment [22]. A striking similarity is observed, constituting the validity of the model. Furthermore, it shows that the chosen mobility dependency seems qualitatively correct in describing front propagation in LECs. More comparisons of the experimental and modeled front position vs. time plots are shown in the Supplementary Information (Fig. E.1b, d and e). To ensure the device length did not qualitatively influence the results, simulations of a longer device were performed that showed qualitatively similar behavior (see Supplementary Information Fig. E.1c). Furthermore, the results are qualitatively not strongly dependent on the ion concentration c_0. Quantitatively, an increase of c_0 results in faster movement of the fronts through the device (see Supplementary Information Fig. E.1a). This effect originates from the availability of more ions to dope the organic semiconductor, thereby increasing the rate of doping behind the fronts. The consequently increased doping density results in an increased supply rate of carriers towards the fronts that effectively increases the doping front propagation.

The phase diagram shown in Fig. 3d summarizes the results shown in Figs. 2 and 3a–c. In the diagram the doping dependent $\mu_{p/n}$ is shown relative to $\mu_{p/n,0}$. Dependent on the ratio between μ_{ion} and $\mu_{p/n,0}$, three regions can be identified: (1) if $\mu_{ion} \ll \mu_{p/n,0}$ no doping fronts are formed; (2) if $\mu_{ion} \approx \mu_{p/n,0}$ accelerating doping fronts are formed; and (3) if $\mu_{ion} \ll \mu_{p/n,0}$ decelerating doping fronts are formed. For a constant $\mu_{p/n}$ the central region disappears so either no or decelerating doping fronts are formed. As already mentioned, experiments on planar LECs have indicated the formation of doping fronts during turn-on that accelerate when closing in on each other [18]. Combination of these experimental results with our numerical modeling strongly indicates that $\mu_{p/n}$ depends similarly on doping and that μ_{ion} is of the same order as $\mu_{p/n,0}$.

From the simulations presented in Fig. 2e–h current vs. time plots were made to study the transient behavior in LECs with a doping dependent mobility for different ion mobilities. A typical plot is shown in Fig. 4a. The ionic and electronic contributions to the current are plotted separately as well to make the total current transient more comprehensive. At $t = 0$, the current is completely carried by the ions. These ions first form the EDLs at the electrodes, resulting in injection of holes (marked with arrow 1 in Fig. 4a) and electrons (arrow 2). Electron injection is delayed compared to hole injection because of the larger injection barrier that needs to be overcome by formation of a larger EDL. This injection results in an increased electronic current. Following this injection, the active layer is doped, during which the ionic current is observed to slowly decrease and the electronic current to increase. The initiation of recombination (orange line in Fig. 4a) indicates that the doping fronts have met (arrow 3). After this, both recombination and the electronic current increase [28]. This indicates the further doping of the active layer until at some time the current as well as the recombination suddenly drop (arrow 4). This is related to a change in the electric field distribution after which the externally applied electric field becomes concentrated in the recombination region rather than being distributed over the entire active layer: The p–n junction has formed. Hence, meeting of the doping front does not coincide with but precedes the formation of a p–n junction. The appearance of a sharp potential drop in the p–n junction arises from the anions and cations being completely removed from the junction region [4]. These ions have been used to maximize doping in the surrounding regions. Because of the relatively small density of carriers in the recombination region, the conductivity is relatively low compared to the doped regions. Therefore, in order to fulfill current conservation, a larger field in the junction region is needed then in the doped regions.

The time between the application of a bias and the injection of holes, the injection of electrons, the doping front meeting and the p–n junction formation is plotted in Fig. 4b as a function of μ_{ion} relative to $\mu_{p/n,0}$. The time is normalized by the time an ion needs to travel across the device in the presence of an (average) field equal to $((V_{bias} - E_g))/L$. A horizontal line in this graph indicates that the time needed for the corresponding process depends linearly on μ_{ion} and bias. Accordingly, the graph shows that the time needed for the initiation of electron and hole injection linearly depends on μ_{ion}. This can also be easily deduced from the fact that injection of carriers is directly related to the formation of EDLs, which results from a reorganization of the ion density across the device. The meeting of the doping fronts that follows after injection of carriers is however not linearly related to μ_{ion}. Doping of the active layer is related to both $\mu_{p/n}$ and μ_{ion}. This is unlike the conclusion drawn by Robinson et al. that mainly ionic movement in the intrinsic region determines the time needed to dope the active layer [22]. Rather, the doping front propagation is determined on one hand by the electron/hole transport in the doped regions and at the doping front, and on the other hand by the ion transport in the intrinsic region. Formation of a light-emitting p–n junction is observed to be linearly dependent on μ_{ion} at small values of $\mu_{ion}/\mu_{p/n,0}$, for the used parameters <10. As discussed above this time is related to ion depletion from the recombination zone. This, in turn, can only occur when the transfer of mobile anions (cations) from the n (p)-doped region to the p (n)-doped region is completed. For this to complete, the largest distance ions need to travel in a mostly symmetric device is a bit more than half the device length. A value of ~0.6 is found in the modeling shown in Fig. 4b (orange graph). For large $\mu_{ion}/\mu_{p/n,0}$, i.e. slow electronic carriers, the formation of a light-emitting p–n junction becomes limited by the meeting of the doping fronts. In this case, the ions are already depleted from the recombination region before the fronts have met, which is determined by the slow electronic charge carriers.

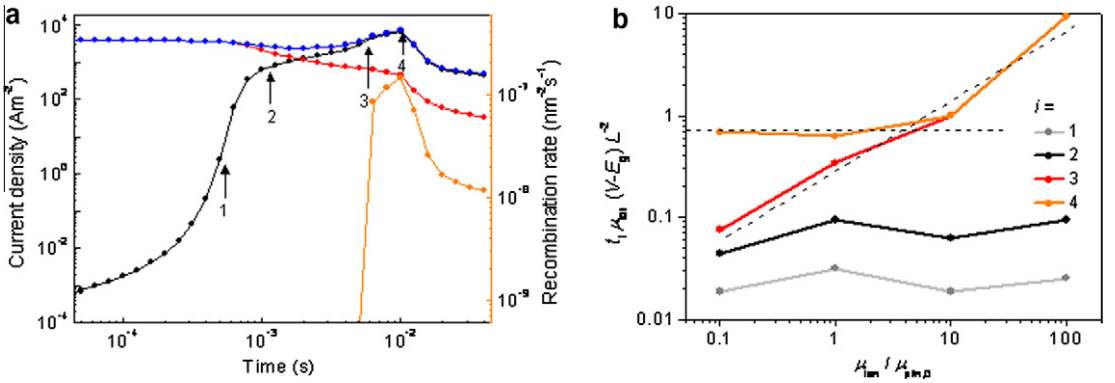

Fig. 4. Calculated transient behavior in LECs in case a doping dependent $\mu_{p/n}$ is chosen (c.f. Fig. 1b). (a) Calculated J, t and R, t characteristics in an LEC for $\mu_{ion} = 5 \times 10^{-11}$ m^2 V^{-1} s^{-1} (c.f. Fig. 2f). The blue, red, black and orange graphs represent the total current density J_{total}, the ion current density J_{ion}, the electron and hole current density $J_{p/n}$ and the recombination rate R respectively. (b) Time scale comparison for four characteristic processes in LECs for different values of $\mu_{ion}/\mu_{p/n,0}$. One, two, three, and four refer to initiation of hole injection, initiation of electron injection, front meeting and formation of a light-emitting p–n junction respectively. In (b) the dashed lines highlight the transition in behavior of the time needed for junction formation (4) around $\mu_{ion}/\mu_{p/n,0} \approx 5$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The transition point (in this case at $\mu_{ion}/\mu_{p/n,0} \approx 10$) at which the switch-on time in LECs becomes dependent on the doping front propagation is related to the choice of the doping dependency of $\mu_{p/n}$. In the simulations from which Fig. 4b is constructed, the doping fractions in case doping is nearly saturated lies in between 0.2 and 0.3, which can be translated to $\mu_{p/n} \approx 10 \cdot \mu_{p/n,0}$. This effective mobility in the doped regions determines the transition point. In case of a doping independent $\mu_{p/n}$, the effective mobility is equal to $\mu_{p/n}$ and the transition point is thus expected at $\mu_{ion}/\mu_{p/n,0} = 1$. This is indeed the case in our model (see Fig. F.1 in Supplementary Information).

In our previous publication [25] results on a planar ion rich LEC were published in which a significant amount of time was observed between initiation of light emission (10 s), i.e. meeting of the doping fronts, and the formation of a p–n junction (~20 s). Comparison of those results with the modeling presented here in Fig. 4b indicates that $\mu_{ion}/\mu_{p/n,0} < 10$, as the 10 s time difference proves that p–n junction formation was not limited by doping front propagation. Therefore, the switch-on time of this LEC can be used to estimate the ion mobility, as $t_{switch\text{-}on}\mu_{ion}(V_{bias} - E_g)L^{-2} \approx 0.6$ must hold. For $L = 100$ μm and $V_{bias} = 8$ V and $E_g \approx 2$ eV, the ion mobility is then estimated to be 5×10^{-11} m^2 V^{-1} s^{-1} at a temperature of 323 K. The conclusion that $\mu_{ion}/\mu_{p/n,0} < 10$ is also consistent with the discussion of Fig. 3b since in these devices accelerating doping fronts are typically observed. More particularly, from the parameter window for accelerating doping fronts it can, with some caution, be estimated that the electronic charge carrier mobility in PPV-based LECs is also of the order of 5×10^{-11} m^2 V^{-1} s^{-1}, which is surprisingly close to typical values for pure PPV derivatives [29,30]. A further comparison can be done between the experimental results on the planar ion rich LEC in Ref. [25] and the simulation results shown in Figs. 2f and 4a and Supplementary Information Fig. B.2f. First of all the potential profile evolution is similar: The potential distribution (see Supplementary Information Fig. B.2f) hardly changes during doping front propagation. Also the current response to an applied bias voltage (see Fig. 4a) is the same in both experiment and model. These results further prove that the experiment is adequately modeled.

One deviating experiment in literature is reported in which the doping fronts were found to have a constant speed [31]. Gao et al. did measurements on such an LEC, which has an inter-electrode distance of 2 mm and is biased at 200 V. Our modeling shows that in case a constant front speed is encountered, μ_{ion} must be large relative to $\mu_{p/n,0}$ (see Figs. 2g and 3a). Inspection of Fig. 4b furthermore shows that the doping process in such an LEC is not limited by the ion redistribution, but by the electronic carrier mobility.

A side-note on the mobility discussion above is that rather than a single, constant ion mobility, a range of ion mobilities is expected in actual LECs, which further may differ for anions and cations. The determined ion mobility therefore applies to the most mobile fraction of ions. This hypothesis is in agreement with the finding in Ref. [25] that the actual amount of *mobile* ions is far less than the amount of ions put into the active layer.

4. Conclusions

Numerical modeling has shown that the time needed for LECs to electrochemically dope the active layer and switch-on is dependent on a combination of the ion mobility, the electron/hole mobility, the applied bias voltage and the thickness of the active layer.

Regarding the doping process three regimes were identified, related to the mobilities of all present charge carriers. If $\mu_{ion} > \mu_{p/n}$, the active layer is doped by decelerating doping fronts sweeping the active layer, whereas if $\mu_{ion} < \mu_{p/n}$ the active layer is doped homogeneously across the complete device. Only in case a doping dependent $\mu_{p/n}$ is chosen in addition to μ_{ion} being approximately equal to $\mu_{p/n}$ in the undoped state ($\mu_{p/n,0}$), accelerating doping fronts are formed.

The switch-on time in LECs is shown to become independent of $\mu_{p/n}$ when the ratio between $\mu_{ion}/\mu_{p/n}$ becomes

small enough. For a doping independent $\mu_{p/n}$ this critical ratio is unity, whereas in case of a doping dependent $\mu_{p/n}$, $\mu_{ion} < \sim 10\ \mu_{p/n,0}$. Generally the latter occurs in planar LECs where accelerating doping fronts are often observed. This enables the extraction of the ion mobility from the switch-on time of LECs. Further experiments are required to check whether the extracted ion mobility is indeed correct.

for device optimization. More importantly many researches have been reported that the film morphology and carrier mobility are significantly affected by the MW of poly(3-hexylthiophene) (P3HT) [31–33]. For example, Heeger et al. found that the optimum annealing temperature for bulk heterojunction material is related to the MW of P3HT [31]. The devices made of higher MW P3HT exhibits higher performance because of the persistence conjugation length of polymer chain and the proper interconnections within bicontinuous network. However, P3HT is not the ideal polymer due to its relatively large bandgap. It is essential to obtain low band gap material so light-harvesting abilities of polymers can be enhanced to improve BHJ device efficiencies. One successful approach to low bandgap materials involved donor–acceptor (D–A) copolymers, in which electron-rich units and electron-deficient moieties are integrated into a single conjugated polymeric system. Furthermore, replacing the bridge carbon atom in cyclopentadithiophene (CPDT)-based copolymers with a silicon atom has been shown to be an efficient way to improve solar cell performance [34–36]. The silole-based polymer is found to feature better crystallinity, lower bimolecular recombination, favorable morphology and higher carrier mobility compared with its carbon counterpart. While D–A copolymers have been developed for efficient BHJ solar cells, the differences in their MW and their impact on the film morphology and the opto-electronic properties have not been thoroughly addressed. In this article, we investigated the influence of MW on various optical and physico-chemical properties of Si-PCPDTTBT:PCBM films. We have also correlated the morphology and exciton lifetime distribution for the Si-PCPDTTBT:PCBM films with various MWs. Finally, the photovoltaic performances of the devices based on the hybrids with different MWs are also presented.

2. Experimental

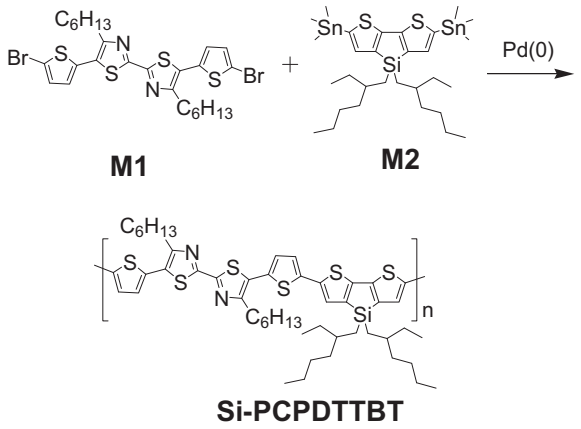
2.1. Material

Monomers M1 and M2 were synthesized according to a reported procedure [36], and the characterization is described as follows. The synthetic route of copolymer Si-PCPDTTBT is shown in Schemes 1, and the procedure is described as follows:

M1. Yield: 65%. ^{1}H NMR: δ 7.03 (d, 2H), 6.92 (d, 2H), 2.86 (t, 4H), 1.72 (m, 4H), 1.40–1.15 (m, 12H), 0.86 (t, 6H). EI-MS: m/z 656. M2. Yield: 92%. ^{1}H NMR: δ 7.06 (s, 2H), 1.68 (m, 2H), 1.4–1.13 (m, 16H), 0.90 (t, 6H), 0.83 (t, 6H), 0.74 (m, 4H), 0.32 (s, 18H).

2.2. General procedure of polymerzation

A solution of M1 (2.00 g, 2.68 mmol) and M2 (1.70 g, 2.68 mmol) in toluene (40 mL) was purged with Ar for 10 min and then $Pd(PPh_3)_4$ (0.150 g, 0.134 mmol) and triphenylphosphine (0.21 g, 0.80 mmol) were added. After purging with Ar for 20 min, the mixture was heated under reflux in an oil bath set at 110 °C under an Ar atmosphere. The mixture was cooled to room temperature, MeOH (100 mL) was added, and the precipitated polymer was filtered out. After Soxhlet extraction with MeOH, hexane, and $CHCl_3$, the polymer was recovered from the $CHCl_3$ phase through reprecipitation with MeOH and then dried under vacuum for 1 day. The MW of polymer was controlled by changing the reaction time, which was monitored by GPC. In this study, Si-PCPDTTBT with four different MWs was synthesized. The reaction times were 6, 10, 24, and 48 h, respectively. The detail information of the MWs for the as-prepared polymers are shown in Table 1.



Scheme 1. Synthetic Route of Si-PCPDTTBT Copolymer.

2.3. Device fabrication

The polymer solar cells are consisted of a layer of the Si-PCPDTTBT/PCBM blend thin film sandwiched between a transparent anode (ITO) and a metal cathode. Prior to device fabrication, the ITO glasses (1.5×1.5 cm^2) were cleaned ultrasonically in detergent, deionized water, acetone, and isopropyl alcohol. After routine solvent cleaning, the substrates were treated with UV ozone for 15 min. The modified ITO surface was then obtained by spin-coating a layer of PEDOT:PSS (ca. 30 nm). Subsequently, the active layer, Si-PCPDTTBT/PCBM (1:2 w/w), was spin-coated from DCB onto the PEDOT:PSS-modified ITO surface. Finally, layers of Ca (30 nm) and Al (100 nm) were thermally evaporated under vacuum (pressure: $<6 \times 10^{-6}$ torr) through a shadow mask. The active area of the device was 0.12 cm^2. In the hole-only devices, Ca was replaced with MoO_3

Table 1
Summary of the MWs, polydispersities (PDI) and yields of Si-PCPDTTBT samples in this study.

Sample of Si-PCPDTTBT	Reaction Time (hours)	M_n[a] (kg/mol)	M_w[a] (kg/mol)	PDI	Yield (%)
Low MW	6	6.3	12.2	1.93	61
Medium MW	10	12.7	15.7	1.23	55
	24	22.9	27.3	1.19	57
High MW	48	33.6	38.9	1.15	56

[a] Molecular weights and polydispersity were measured by GPC, using THF as an eluent, polystyrene as a standard. *M*n, number average molecular weight. *M*w, weight average molecular weight.

Table 2
Summary of the transition temperature of Si-PCPDTTBT with various MWs.

Sample of Si-PCPDTTBT	T_g[a] (°C)	T_m[a] (°C)	T_c[a] (°C)	T_d[b] (°C)
Low MW	163	239	n.d.[c]	375
Medium MW	167	245	n.d.[c]	390
	165	251	227	429
High MW	166	253	234	430

[a] The T_g, T_m and T_c were measured by DSC at a heating rate of 10 °C/min.
[b] Temperature (°C) at 5% weight loss measured by TGA at a heating rate of 10 °C/min under nitrogen.
[c] No noticeable transition temperature was observed.

because its higher work function (Φ = 5.3 eV) provided a better hole injection contact for Si-PCPDTTBT/PCBM. A layer of 20 nm thick MoO_3 was thermally evaporated and then it was capped with a layer of Al (50 nm). For the electron-only devices, the PEDOT:PSS layer was replaced with $CsCO_3$ (Φ = 2.9 eV), which is an efficient electron injection layer. This layer of Cs_2CO_3 was thermally evaporated to a thickness of 2 nm. The active layers were then annealed at 130 °C for 20 min to provide the final hole- and electron-only devices.

2.4. Characteriaztion

The cell performance was tested under simulated AM 1.5 G irradiation at 100 mW cm^{-2} using a Xe lamp-based solar simulator (Thermal Oriel 1000 W). The light intensity was calibrated using a mono-silicon photodiode equipped with a Hamamatsu KG-5 color filter. The whole measurement process was performed at room temperature in a glove box filled with N_2. The absorption spectra were obtained from Jasco-V-670 UV-visible spectrophotometer. X-ray diffraction (XRD) studies were performed by Philips X'Pert/MPD. For the fluorescence measurements, the samples were excited with light (wavelength: 470 nm) from a picosecond laser (LDH-P-C-470, PicoQuant); the fluorescence lifetime signal was measured using time-correlated single photon counting (TCSPC). To map the lifetime images, the samples were scanned using an Olympus FV300 confocal optical microscope equipped with a PicoQuant PDM single photon avalanche diode detector and a PicoQuant PicoHarp 300 USB interface for TCSPC. The fluorescence signal was improved using an edge filter (REF-473.0-25, CVI). The acquisition time for each lifetime image (pixel size: 512 × 512) was 20 min. The surface morphologies of the polymer films were investigated using an atomic force microscope (Digital Instrument NS 3a controller equipped with a D3100 stage). The EQE action spectra were obtained under short-circuit conditions. The light source was a 450-W Xe lamp (Oriel Instrument, model 6266) equipped with a water-based IR filter (Oriel Instrument, model 6123NS). The light output from the monochromator (Oriel Instrument, model 74100) was focused onto the photovoltaic cell under test.

3. Results and discussion

Scheme 1 shows the chemical structure and the synthetic route of Si-PCPDTTBT. On the basis of the electron donor–acceptor concept, the strong electron–accepting

Table 3
List of electron and hole mobility of devices based on Si-PCPDTTBT:PCBM with various MWs.

Sample	Low MW	Medium MW		High MW
	6.3	12.7	22.9	33.6
μ_e (m^2 V^{-1} s^{-1})	9.7×10^{-8}	1.1×10^{-7}	1.5×10^{-7}	2.7×10^{-7}

(2D) sheets can be significantly enhanced by means of interchain stacking leading to an enhancement in device efficiency.

Table 1 summarizes the MWs, polydispersities (PDI) and yield of the pristine Si-PCPDTTBT samples used in this study. It should be mentioned that the solubility of Si-PCPDTTBT becomes very poor with MW larger than 33.6 kg/mol (M_n). The thermal stabilities and phase transition temperatures of Si-PCPDTTBT, including 5% weight loss temperatures (T_d), glass transition temperatures (T_g), melting temperatures (T_m), and crystallization temperatures (T_c) characterized by Thermogravimetric analyses (TGA) and differential scanning calorimetry (DSC) are summarized in Table 2. All copolymers are thermally stable up to 375–430 °C upon heating and show T_g values over 163 °C. The T_d and T_g for Si-PCPDTTBT are found to increase with increasing MWs. The increase of thermal stability with higher MW is attributed from stronger π−π interaction and polymer chain entanglement as observed in many polymer systems. In addition, the detectable melting temperatures (T_m) and crystallization temperatures (T_c) of Si-PCPDTTBT suggested that it has great potential in organic solar cells application since their high ordering capabilities can enhance the formation of phase-separated ordered nanostructures in the photovoltaic layer desirable for charge transport and separation.

As shown in the absorption spectra (Fig. 1), with the increase of Si-PCPDTTBT MW, a significant red shift of the absorption for the edge of Si-PCPDTTBT from solution (10^{-6} M in chlorobenzene), together with more pronounced vibronic absorption shoulders is observed. The result indicates that charge carriers and excitons in the higher MW Si-PCPDTTBT can delocalize over a larger extent as a result of π–π stacking and a stronger wave function overlap, and the absorbance band extend from 500 to 525 nm is attributed to a fully delocalized excitonic π–π* transition. The corresponding images for the polymer solution with various MWs are shown in the inset of Fig. 1a. On the other hand, the solid film exhibited an absorption pattern similar to that recorded in solution, except that a slight red-shift occurred in the solid state as a result of interchain association and aggregation. It is worthy to mention that the polymer with higher MWs reveal a pronounced vibronic peak. This indicates that aggregation already occurs for the high MW Si-PCPDTTBT due to the strong π–π interaction in the solution state.

Since morphology has been shown to affect mobility, efforts were made in this study to conduct a comprehensive

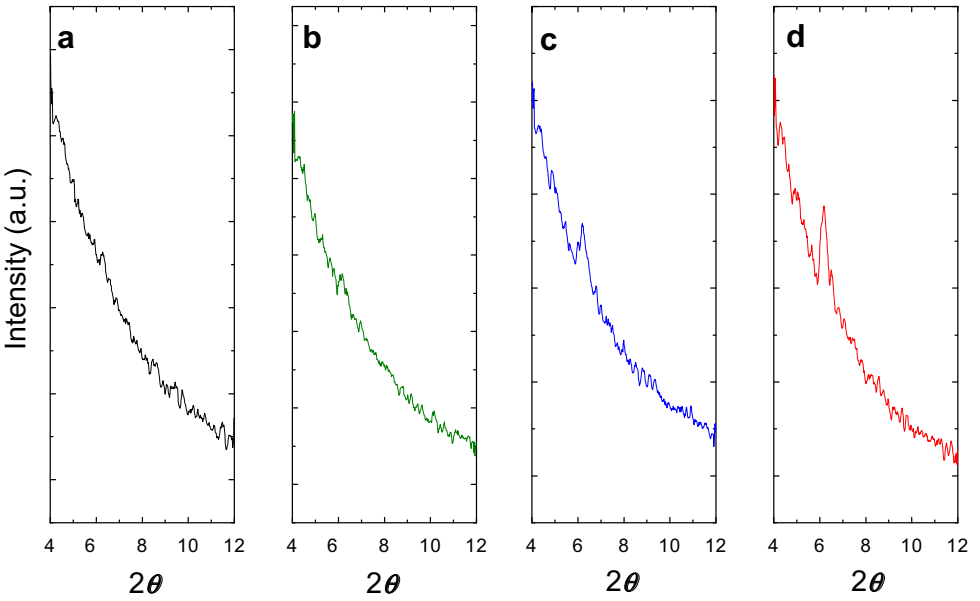

Fig. 4. XRD spectra of Si-PCPDTTBT:PCBM films with various MWs. (a) 6.3 kg/mol, (b) 12.7 kg/mol, (c) 22.9 kg/mol, (d) 33.6 kg/mol.

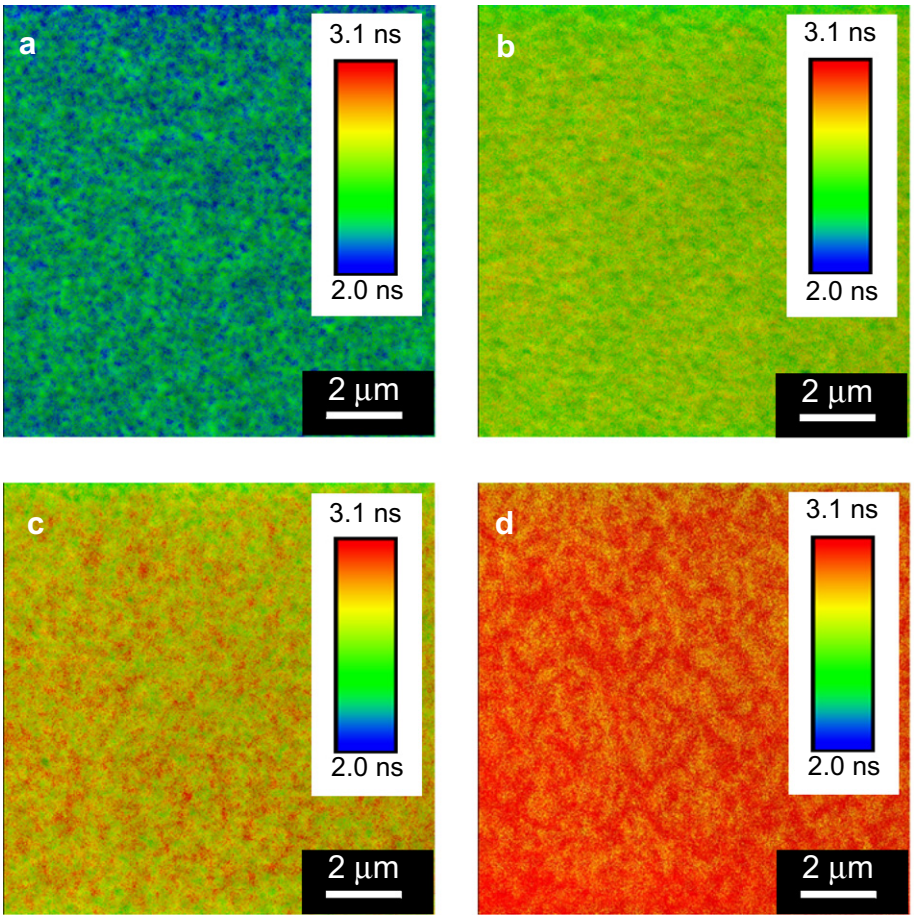

Fig. 5. Exciton lifetime images of the Si-PCPDTTBT:PCBM film with various MWs, (a) 6.3 kg/mol, (b) 12.7 kg/mol, (c) 22.9 kg/mol, (d) 33.6 kg/mol. measured after excitation at 470 nm using a picosecond laser microscope (512 × 512 pixels).

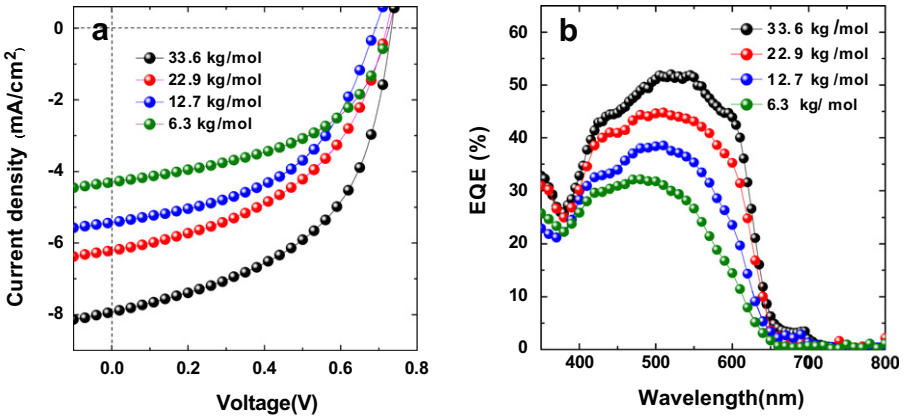

Fig. 6. (a) *J–V* curves and (b) EQE spectra of Si-PCPDTTBT:PCBM-based BHJ solar cells with various MWs.

characterization in terms of MW dependency by AFM and TEM analysis. It has been reported that P3HT with lower MW polymer chains are more able to pack into crystals forming a rod-like morphology [32]. It is interesting; however, the low MW Si-PCPDTTBT reveals very smooth morphology. This can be explained by a much more complicated structure such as Si-PCPDTTBT instead of P3HT, which prevent the polymer chains from stacking. With increasing polymer MW, Si-PCPDTTBT:PCBM films reveal rougher surface morphology with stronger crystallinity. For the 33.6 kg/mol Si-PCPDTTBT/PCBM film, the morphology exhibits coarse, chainlike features, having an average size of 30 nm, running across the surface as shown in Fig. 2d. The corresponding phase images in Fig. 2h also features many channels with a diameter of 20 nm distributed throughout the film originated from the separation between the Si-PCPDTTBT and PCBM. Because the exciton diffusion length in organic materials typically ranges from 10 to 30 nm depending on the mobility, the feature size can offer a certain degree of segregation for the two components to maintain suitable mixing for charge transport and exciton dissociation.

The MW impact on nanoscale morphology is also confirmed by TEM as shown in Fig. 3. In the TEM images, polymer nanofibers look bright and PCBM-rich regions appear dark because of the lower density of polymer crystals compared to PCBM. The TEM images are consistent with the AFM results. For the 6.3 kg/mol Si-PCPDTTBT, hardly any polymer fibers can be discerned. The TEM image of the blending films processed with higher MWs shows phase separation clearly with the appearance of interconnected fibers which are surrounded by darker fullerene-rich regions. With the increase of the polymer MWs, the amount and diameter of Si-PCPDTTBT fibers become larger and coarser. Since the J_{SC} and FF are strongly dependent on the transport properties of the networks in the BHJ film, it can be expected that, at least in part, the formation of the larger domains with wider connective cross sections within the high MW Si-PCPDTTBT network can leads to an improved device performance.

Further investigation of the crystalline nature of Si-PCPDTTBT is accomplished using XRD of polymer films as shown in Fig. 4. The low MW Si-PCPDTTBT exhibits an amorphous pattern indicating the disorder structure. Increased intensity is observed with increasing MW for the peak at $2\theta = 6.17°$, which corresponds to the layering distance, $d_{100} = 14.3$ Å, between the sheets of Si-PCPDTTBT chains associated with the plane perpendicular to their longitudinal axes. The features are in good agreement with the results of AFM and TEM images. It is known that long polymer chains are more prone to entanglement [37]. Hiorns has suggested the entanglement of P3HT may cause the alignment of conjugated segments to be more difficult to achieve, leading to disorder structure [38]. This proposal does not obviously agree with the results displayed here. For the high MW Si-PCPDTTBT, the polymer chains tend to stack and aggregate forming a preferential orientation of the polymer domains. This can be further supported by the charge mobility as shown in Table 3. The charge mobility calculated by space-charge limited current reveals that the holes mobility increases with increasing MW leading to more balanced charge mobility. It is likely that mobility could increase with MW because the closer organization of the polymer chains. Moreover, the charge carriers can travel farther along longer chains before they have to hop to another chain. The net reduction in hopping events could result in an increased mobility. In order to further investigate the optophysical properties of Si-PCPDTTBT/PCBM film with various MWs, we performed the exciton lifetime mapping using time-resolved PL measurement system combining with a confocal laser scanning microscopy [39,40]. This technique enabled us to examine the distribution of the exciton lifetimes within a wide range. Fig. 5 shows the exciton lifetime images (10×10 μm) with the corresponding statistical histograms for these samples. All the samples reveal a uniform exciton lifetime distribution throughout the films. This behavior suggests that good mixing exists between the polymer and the fullerene, leading to a more-efficient energy transfer. The average value of exciton lifetime increases from 2.3 to 3.2 ns with respect to the increase in polymer MW. The slight increase in exciton lifetime can be explained by the better crystallinity of the high MW Si-PCPDTTBT. The enhanced stacking of Si-PCPDTTBT

expels some PCBM molecules from the polymer domain, leading to demixing between the two components which impedes the efficiency of exciton dissociation. Therefore, the average value of exciton lifetime increases with high MW Si-PCPDTTBT.

Fig. 6 presents the current–voltage (J–V) curves and external quantum efficiencies (EQEs) of solar cells incorporating Si-PCPDTTBT blended with PCBM. The V_{OC} remains unchanged at about 0.71 ± 0.02 V even with different MWs of Si-PCPDTTBT. However, the J_{SC} and PCE of the devices vary significantly with polymer MWs as seen from Fig. 6a. The J_{SC} varies from as low as 4.29 mA/cm^2 (for 6.3 kg/mol Si-PCPDTTBT) to as high as 8.7 mA/cm^2 (for 33.6 kg/mol Si-PCPDTTBT). Consistent with the trend in J_{SC}, the EQE magnitude generally increases from 29.3% (6.3 kg/mol Si-PCPDTTBT) to 51.6% (33.6 kg/mol Si-PCPDTTBT). Combining 0.73 V of V_{OC} and 51.9% FF, an efficiency of 3.33% is achieved for the device based on 33.6 kg/mol Si-PCPDTTBT. The correlation between the solar cell performance and the MW of the Si-PCPDTTBT is similar to that of P3HT:PCBM system. The main difference in PCE arises from the better charge mobility and more favorable morphology. For high MW Si-PCPDTTBT, the long polymer chains tend to form the appropriate aggregation in the solution. With such partially aggregated solution, the blending of Si-PCPDTTBT and PCBM can easily produce phase separation during spin coating process to create continuous percolation pathways for charge transport.

4. Conclusion

In conclusion, we have shown the effect of MW on the performance of photovoltaic devices based on Si-PCPDTTBT:PCBM. Morphological analysis indicates that higher MW Si-PCPDTTBT tends to form stacked aggregation and produce better interconnections within the bicontinuous network which can enhance the charge transport. Based on our device performance, the aggregation of Si-PCPDTTBT is an essential process to guarantee high solar cell performance. The PCE can be enhanced from 1.54% to 3.33% for the 6.3 and 33.6 kg/mol Si-PCPDTTBT, respectively. However, the MW of Si-PCPDTTBT cannot be further increased due to the solubility problems. Thus, considering carrier mobility, materials solubility, crystallinity and morphology, the cell performance can be further improved by using mixture of Si-PCPDTTBT with different molecular weights.

between the electrode and an organic layer [2,6–14], although other interfaces are also important in the inverted device structure [15].

In this paper, we demonstrate, based on the energy levels and the current density–voltage (*J–V*) characteristics of electron only devices, that the interface between an n-doped ETL (n-ETL) and an ETL is as important as the interface between the cathode and the n-ETL for efficient electron injection to an emitting layer. By properly selecting an ETM to have no energy barrier for electron injection between the n-ETL and the ETL, we could realize a high performance IBOLED with the maximum EQE of 20% and the maximum power efficiency of 80 lm/W.

2. Experimental

The inverted bottom emission OLEDs we fabricated have the structure of ITO/n-doped ETL (20 nm)/undoped ETL (30 nm)/8 wt.% Ir(ppy)$_3$ doped 4,4′-*N*,*N*′-dicarbazole-biphenyl (CBP) (15 nm)/undoped 1,1′-bis-(4-bis(4-methyl-phenyl)-amino-phenyl)-cyclohexane (TAPC) (30 nm)/8 wt.% ReO_3 doped TAPC (20 nm)/Al. The organic layers and the metal anode were successively deposited on pre-cleaned 150 nm-thick-indium tin oxide (ITO) patterned glass substrates. Three different *ETMs* of bis-4,6-(3,5-di-3-pyridylphenyl)-2-methylpyrimi-dine (B3PYMPM), 4,7-diphenyl-1,10-phenanthroline (Bphen), and 2,2′,2″-(1,3,5-benzenetriyl)tris-[1-phenyl-1H-benzimidazole] (TPBi) were selected to investigate their effects on the performance of the inverted OLEDs. Rb_2CO_3 was used as the n-dopant in the n-doped ETLs with a doping concentration of 15% for all the devices [16,17]. ReO_3 was used as the p-dopant in the devices [18–20]. The current density–voltage–luminance (*J–V–L*) characteristics of the devices were measured using a Keithley 237 semiconductor parameter analyzer and a Photo Research spectrophotometer (PR-650).

3. Results and discussion

Fig. 1 shows the *J–V–L* characteristics of the inverted OLEDs. Among the three ETMs, B3PYMPM resulted in the lowest charge injection and turn-on voltages of 1.9 V and 2.4 V, respectively. The injection voltage was defined as the voltage where the charge injection begins to rise, and the turn-on voltage was defined as the voltage at the luminance of 1 cd/m^2. The driving voltage at 1000 cd/m^2 is only 4.3 V for the device with the B3PYMPM ETL followed by 5.4 V for the BPhen ETL and 7.4 V for TPBi ETL. These facts indicate that electrons are more easily injected and transported from the bottom cathode to the light emitting layer in the B3PYMPM device than the others because the hole injection layer and the hole transport layer are the same in the three devices. It is interesting to note that the difference between the injection voltage and the turn-on voltage is very small (0.5 V) for the B3PYMPM device but it is large, i.e. about 1.5 V, for the other devices, indicating a more balanced injection of electrons and holes in the B3PYMPM device than the other devices.

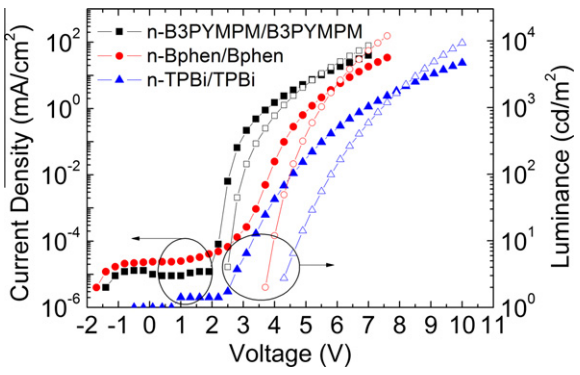

Fig. 1. The current density–voltage–luminance (*J–V–L*) characteristics of the three different inverted OLEDs.

The electron injection and transport characteristics of the devices were interpreted using two different electron only devices: (a) ITO/n-ETL (50 nm)/Al; and (b) ITO/n-ETL (20 nm)/undoped ETL (30 nm)/Al. The three different ETMs were used as the ETLs and the doping concentration was 15% in all the devices. Negative bias was applied on the ITO electrode for the electron injection from ITO to the ETLs. Fig. 2 shows the *J–V* characteristics of the devices. It is very interesting to note that the *J–V characteristics* of the electron only devices with the structure (a) are not consistent with the *J–V* characteristics of the IBOLEDs. In the electron only devices, the BPhen device shows the highest current among the three devices followed by the B3PYMPM and the TPBi devices. In the OLEDs, however, the B3PYMPM device showed the higher current and *luminance* in the low voltage region than the BPhen device.

The difference can be understood using the electron only devices with the structure (b). Insertion of the intrinsic ETL between the n-*ETL* and the Al electrode in the electron only devices modified the *J–V* characteristics significantly as shown in Fig. 2. It lowers the current density by orders of magnitude in low voltage (Ohmic current) region. Also, all the *J–V* curves showed a transition from the Ohmic current where *J* is linearly proportional to applied voltage to the trap charge limited current (TCLC).

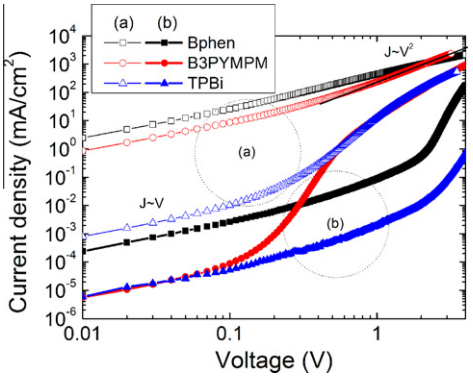

Fig. 2. Current density–voltage characteristics of electron-only devices with the inverted structures of (a) ITO/Rb_2CO_3 doped ETL (50 m, 15 wt.%)/Al (open symbol) or (b) ITO/Rb_2CO_3 doped ETL (20 m, 15 wt.%)/undoped ETL (30 nm)/Al (solid symbol).

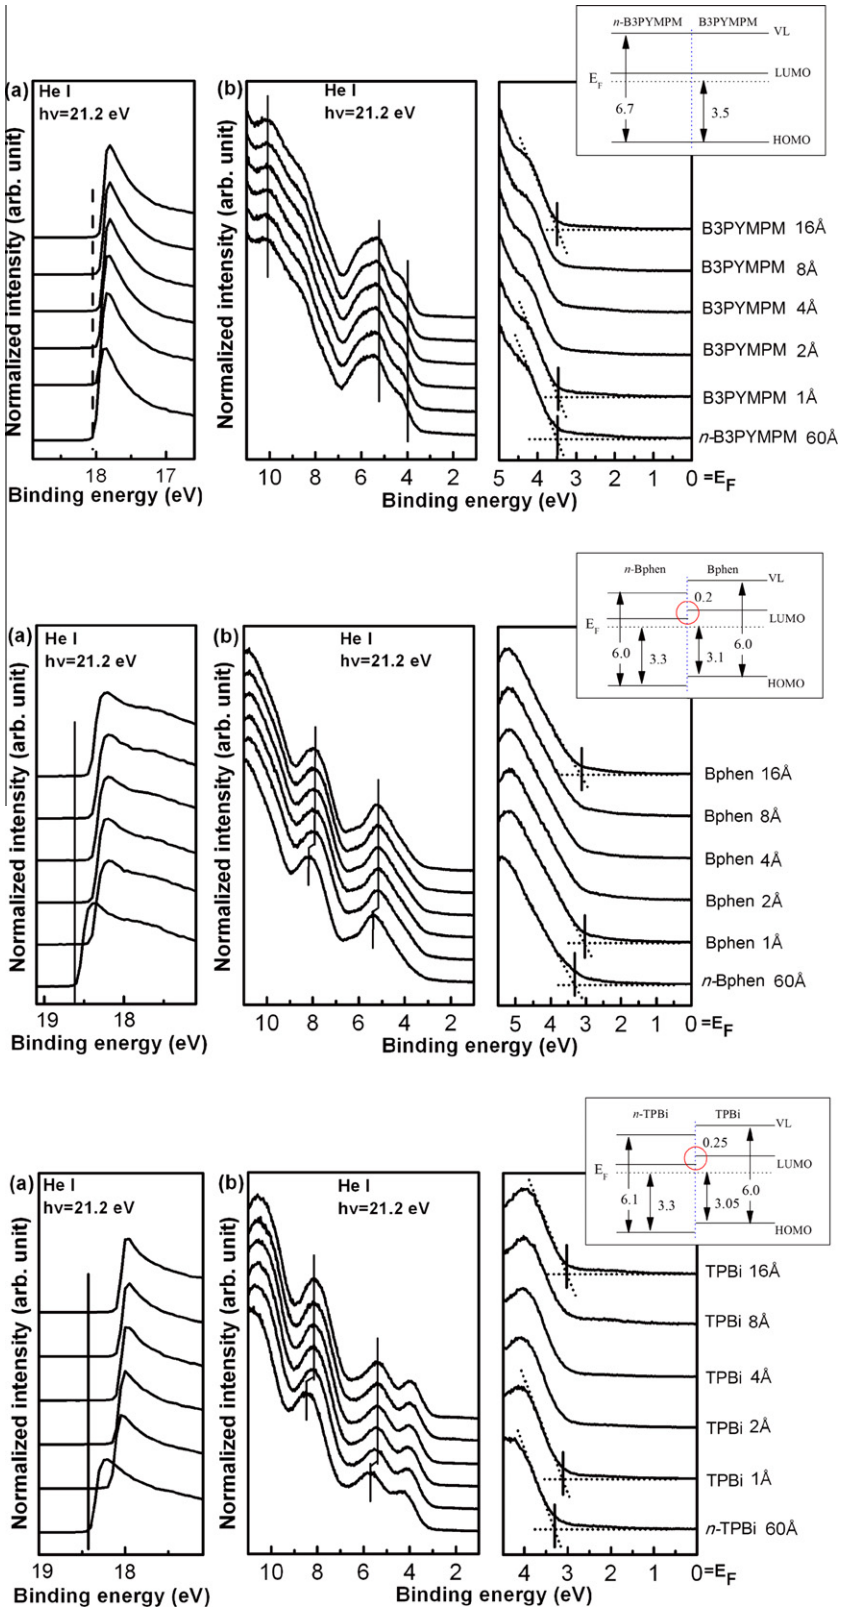

Fig. 3. UPS spectra near (a) the onset and (b) the valence band region of (1) ITO/n-B3PYMPM/B3PYMPM, (2) ITO/n-Bphen/Bphen, and (3) ITO/n-TPBi/TPBi structures. The insets show the resulting energy level diagrams and all binding energies are referenced to the Fermi level (E_F) of ITO. Vertical lines address the position of featured states. n-Doped ETL is gradually deposited on ITO followed by the deposition of an undoped ETM on the n-doped ETL.

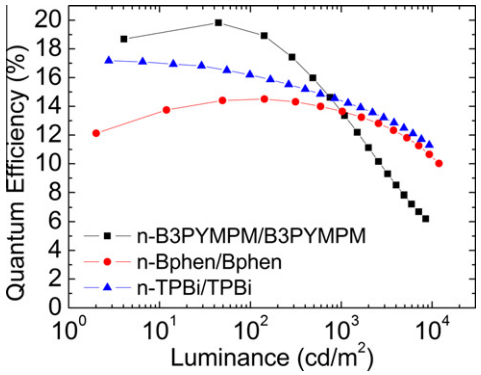

Fig. 4. External quantum efficiencies (EQEs) vs. luminance of three-different inverted OLEDs.

Interestingly enough, the B3PYMPM layer exhibited the transition at a much lower voltage than the other two materials. The current density in the B3PYMPM based electron only device dramatically increases as the voltage increases over 0.1 V. This fact suggests that the barrier height for electron injection from the n-B3PYMPM layer to the undoped B3PYMPM layer is lower than for other materials.

The injection characteristics and the energy band alignment at the interfaces of the devices were further investigated by ultraviolet photoelectron spectroscopy (UPS). UPS measurements were carried out with He I (21.2 eV) and He II (40.8 eV) as excitation sources at a base pressure at 10^{-10} Torr. The detailed experimental procedures were described in the previous reports [21,22]. Fig. 3-1–3 shows the evolutions of UPS spectra near (a) the onset and (b) the valence band region during junction formation between undoped ETLs and n-doped ETLs. All binding energies are referenced to the Fermi level (E_F) of ITO. The vacuum level (VL) shift and highest occupied molecular orbital (HOMO) level position can be analyzed with increment of thickness of the organic materials from the figures, and they are indicated by vertical lines, respectively. The position of HOMO is determined by interpolating the shoulder of HOMO signal and background of the spectra. Fig. 3-1 shows little change in the onset spectra (a) and the valence band spectra (b) when pristine B3PYMPM is deposited on n-doped B3PYMPM, indicating that there is no interface dipole and HOMO offset between n-doped B3PYMPM and pristine B3PYMPM. In contrast, however, Bphen and TPBi exhibit the shift of 0.2 and 0.25 eV toward the lower binding energy, respectively, both in the vacuum level and the HOMO level between the n-doped and the undoped layers as shown in Fig. 3-2 and 3. It is interesting to note that the shifts are abrupt at the junctions, implying the existence of interface dipole.

The energy level diagrams of the ITO/n-ETL/ETL structure extracted from the UPS spectra for the three ETMs are displayed in the insets of Fig. 3-1–3. Lowest unoccupied molecular orbital (LUMO) energy levels are included in the diagrams by adding the optical band gap of the materials obtained from the lowest energy absorption edge of the UV–Vis absorption spectra to the HOMO levels. Since the optical band gap of a doped organic film is similar to that of the pristine film [23], the complete energy level diagrams were constructed in both n-doped ETL and undoped ETL regions using the optical band gap of 3.6 eV for B3PYMPM [24], 3.4 eV for Bphen [25], and 3.5 eV for TPBi [26]. The energy barriers for electron injection between ITO and the n-ETLs are 0.1 eV for B3PYMPM and Bphen, and 0.2 eV for TPBi, respectively. All the devices have relatively low energy barriers because of the doping effect of Rb_2CO_3 [16,17]. However, the energy barriers between the n-ETL and the ETL are significantly different from each other. B3PYMPM showed no energy barrier while the energy barrier in Bphen was 0.2 eV, and that in TPBi was 0.25 eV. These results are consistent with the *J–V* characteristics of the IBOLEDs and the electron only devices where the lowest injection and turn on voltage (Fig. 1) and the lowest transition voltage (Fig. 2) were observed in the devices with B3PYMPM ETL. The current density of the electron only device with the homo-junction of n-B3PYMPM and B3PYMPM dramatically increases at the lowest voltage about 0.1 V as shown in Fig. 2, resulting from the lowest electron injection barrier at the interface of the homo-junction among three different systems.

The energy barrier between n-ETL and ETL significantly influences the performance of the inverted OLEDs as shown in Fig. 4. The B3PYMPM based device exhibited the maximum external quantum efficiency of 19.8% (at 45 cd/m^2) which is the highest efficiency reported up to now in the IBOLEDs to the best of our knowledge. It is more than a 30% increase from the previous best efficiency of 15% [14]. The maximum power efficiency (η_{power}) of the device with the B3PYMPM ETL is very high with the value of 79.8 lm/W, and it is 1.8 times higher than that of 42.7 lm/W for TPBi ETL and 37.3 lm/W for Bphen ETL as summarized in Table 1. However, the η_{power} of the device with the B3PYMPM rapidly decreases after 100 cd/m^2, and finally reached 33.3 lm/W at 1000 cd/m^2. It is just 1.2 times higher than that of 27.2 lm/W for the device with Bphen ETL, indicating that roll off in the device with B3PYMPM is much larger than the other devices due to the formation of an exciplex observed in the emission spectrum of the device at high luminance (not shown).

Table 1
Characteristics of the IBOLEDs with three different ETMs.

ETM	$V_{Injection}$	V_{1cd/m^2}	EQE (%)			η_{power} (lm/W)	
			Max.	@ 100 cd/m^2	@ 1000 cd/m^2	Max.	@ 1000 cd/m^2
B3PYMPM	1.9 V	2.4 V	19.8	19.2	13.5	79.8	33.3
Bphen	2.2 V	3.6 V	14.2	14.5	13.6	37.3	27.2
TPBi	2.4 V	4.0 V	17.1	16.1	14.3	42.7	21.2

4. Conclusion

In summary, we developed a high performance inverted OLED and investigated the effect of the n-ETL/ETL interface on the performance of inverted OLEDs. Among the three ETMs, B3PYMPM resulted in the lowest injection and turn-on voltages of 1.9, and 2.4 V, respectively, and the highest maximum EQE of 19.8% at low voltage. UPS measurements showed that there is no energy barrier for electron injection between n-B3PYMPM and B3PYMPM, while Bphen and TPBi have energy barriers of 0.2 and 0.25 eV, respectively. As a result, the electron only device exhibited a large increase in current at a much lower voltage than the other two materials. The energy barrier between n-ETL and ETL is one of the most important factors for high performance inverted OLEDs.

polythiophene OFETs annealed in solvent vapors exhibit higher μ_{FET} compared to virgin samples [13].

Obtaining polycrystalline or amorphous molecular films is possible with a variety of deposition methods described in the literature. Spin coating, drop casting and vacuum evaporation are chosen most often [17] but one should also turn attention to spray coating – a method very convenient for cost-efficient large scale production and appropriate for a great number of materials [18–21]. The spray deposition has been applied in fabrication of organic OFETs [19–21], solar cells [18,22], light emitting diodes [23], and for electrode deposition [24]. Being a fast and simple technique for large-area application, the spray coating technique has nevertheless an important drawback: the homogeneity of the layers so obtained is inferior to that of layers fabricated by spin coating.

Three regimes of spray coating can be distinguished: wet, intermediate and dry [19,25]. In the wet regime, the solution flow is high and nozzle-substrate distance is short enough to avoid drying of solution droplets before reaching the substrate. This results in formation of a wet layer of polymer on the substrate. In the dry regime, when the nozzle-substrate distance is long, the solvent evaporates before reaching the sample and a polymer powder is cast on the substrate. The intermediate regime seems to be most suitable for the deposition of organic thin films. In this case wet droplets reach the substrate surface but they get dry before a next droplet accesses the film. The thickness can be easily controlled in this regime by adjusting the spraying time. Deposition parameters: temperature, solvent volatility, geometry of spraying system, nozzle speed and diameter, flow of solution may be adjusted to obtain required type of spraying.

In this work, we present results of a comparative study of spray and spin coated P3HT films deposited from fresh and aged solutions, acting as active layers of OFETs. Our main interest was the effect of the deposition technique and of the solution used on the morphology, and optical and electrical properties of the films.

2. Experimental

Regioregular P3HT was purchased from Ossila Ltd. (electronic grade, M_W = 65.5 kDa, regioregularity 96.6%). Chloroform solutions of P3HT (10 mg/ml), either freshly made or aged for 2 months, were used for thin film deposition. During the aging period, the solutions were kept in tightly closed vessels at ambient temperature. The films of P3HT were deposited by spin coating or by spray coating in ambient air. The spin coated samples were deposited at 900 rpm. For the spray coating, we used the Badger airbrush spray gun, the nozzle – substrate distance being controlled manually. We exploited the intermediate regime of spraying (a wet droplet comes to the substrate surface, getting dry before the next droplet reaches the film), claimed to be optimum for homogeneity of the films [19,25]. The following working parameters were employed: the nozzle – substrate distance amounted to (12 ± 2) cm, the total spraying time was equal to (5 ± 1) s, the deposition was carried out at ambient atmosphere, at room temperature ((23 ± 2) °C). The substrate was also kept at room temperature.

Four groups of samples (spin coated from fresh solution, spin coated from aged solution, spray coated from fresh solution, spray coated from aged solution) were compared.

The surface morphology of P3HT films was investigated using an atomic force microscope (AFM, NanoScope V, Veeco). AFM was also used for determination of film thicknesses. Absorption spectra of the films deposited on quartz substrates as well as of the solutions were measured with Perkin Elmer Lambda 20 UV–Vis spectrophotometer.

Silicon(n+)/SiO_2 wafers with deposited gold interdigital electrodes (purchased from Fraunhofer Institute for Photonic Microsystems, Dresden, Germany) were used as substrates for OFETs (Fig.1). The SiO_2 layer was 230 nm thick, the thicknesses of gold electrodes amounted to 30 nm (with additional 10 nm of ITO underneath). The length, L, and width of the FET channel, W, amounted to 10 μm and 1 cm, respectively. The surface capacitance of the insulator, C, was equal to 15 nF/cm^2.

The electrical characteristics were measured using a PC controlled system consisting of two Keithley 6517 electrometers, both capable of sourcing a dc voltage to source and gate electrodes. The experiments were performed in vacuum (p < 3 Pa).

The mobilities of charge carriers, μ_{FET}, have been determined from current–voltage characteristics measured in OFETs with active P3HT layers, fabricated according to each of the four procedures mentioned above (spin and spray casting, fresh and aged solutions). Over 15 transistors of each type of samples were employed in order to obtain more reliable data minimizing accidental errors. The FET mobilities have been calculated from the transfer current–voltage characteristics in the saturation regime employing the equation [26]:

$$I_{SD} = \mu_{FET}\frac{WC}{2L}(U_G - U_T)^2, \quad (1)$$

I_{SD} standing for the source–drain current, and U_G and U_T being gate and threshold voltages, respectively.

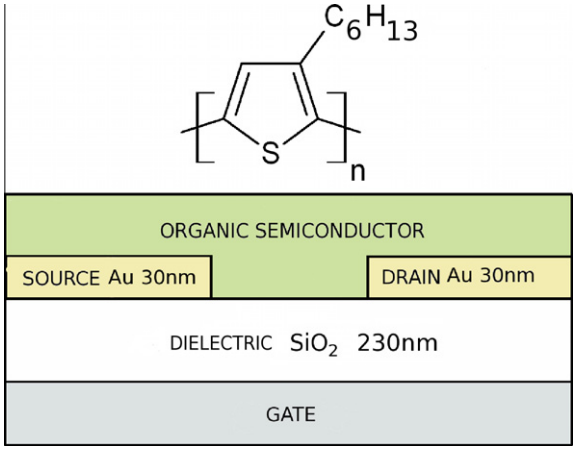

Fig. 1. Schematic representation of the structures under study. The chemical formula of P3HT is given on the top of the scheme.

3. Results and discussion

P3HT solutions, stored for a sufficiently long time, undergo aging, the process manifesting itself in changes of color and consistence. Freshly made chloroform solutions were clear orange-reddish liquids of low viscosity; after 2 months of aging the solutions became opaque, gel-like and dark brown. It should be mentioned that the rate of the process depends on solvent used: aging of the chloroform solution of P3HT occurs much slower than of solutions in other solvents (e.g., toluene or xylene). The difference can be rationalized taking into account a better solubility of P3HT in chloroform compared to that in other solvents. The difference in solubilities can be expressed by respective differences in their solubility parameters [9,27] ($\delta_{P3HT} = 19.27\ J^{0.5}\ cm^{-1.5}$; $\delta_{P3HT} - \delta_{chloroform} = 0.31\ J^{0.5}\ cm^{-1.5}$) compared to the solubility parameters of toluene ($\delta_{P3HT} - \delta_{toluene} = 1.00\ J^{0.5}\ cm^{-1.5}$) or xylene ($\delta_{P3HT} - \delta_{xylene} = 1.32\ J^{0.5}\ cm^{-1.5}$). Admixture of a solvent which does not dissolve P3HT (for example, anisole [3,28]) speeds up the aging of the solution to a few days instead of months. In this work, however, neat chloroform solutions of P3HT were used because of the high values of μ_{FET} observed in OFETs deposited from chloroform [8].

Surfaces of spin coated films were reasonably smooth; their thicknesses, measured by AFM, amounted to (130 ± 10) nm. The surfaces of the spray coated films appeared quite rough, the thicknesses of individual samples varying locally between 70 and 200 nm. It is believed, however, that the surface roughness of the sprayed films affects the quality of the organic films near the semiconductor–insulator interface to a lesser degree [20] since the channel thickness in OFETs is limited to a few nm close to the interface. Thus any inhomogeneity above this limit is not expected to matter in performance of bottom contact FETs.

AFM images of surfaces of the studied P3HT films are presented in Fig. 2. The surfaces of sprayed films appear highly nonuniform, with small areas but also with abundance of regions containing pinholes, lumps and craters. Similar irregularities were also observed earlier in sprayed films of P3HT [19].

The morphology of films fabricated using freshly made chloroform solutions of P3HT was found dramatically different from those fabricated from aged solutions. The difference is demonstrated on AFM images (Fig. 2) showing nanofeatures on the surface of the films. The films fabricated from fresh solution did not exhibit any specific features on the surfaces (Fig.2, top images) whereas nanofibers are clearly visible in the films deposited from aged solutions (Fig.2, bottom images). A particularly high concentration of the nanofibers can be observed in the spin coated films, their length reaching a few μm (Fig. 2, left bottom image). The nanofibers on the surfaces of the spray coated films (Fig. 2, right bottom image) appear less discernible compared to the spin coated ones. The nanofiber width amounts to ca. 40 nm regardless the deposition technique applied.

The difference between the lengths of nanofibers in spin- and spray-coated films may be explained by analyzing technological aspects of the film formation. In the spin coated films, the nanofibers are extended, nearly parallel to the sample surfaces and oriented to some degree by the centrifugal force acting on them during the deposition (*vide infra*) whereas one cannot notice any privileged orientation in the spray coated films.

A further insight into the process of formation of the nanofibers can be obtained from the analysis of spectra of the solutions and thin films in the visible region. The spectra shown in Figs. 3a and 4 exhibit distinct differences between freshly made and aged solutions, as well as between films fabricated from these solutions. The absorption spectra of fresh chloroform solution of P3HT (concentration amounting to 0.5 mg/ml) exhibit a maximum at 457 nm (Fig. 3a, curve 1), typical of solutions of non-aggregated polythiophene [3,9]. Increasing concentration of the polymer results in appearance of a new band peaking at 610 nm (Fig. 3a, curves 2 and 3). The latter band appears more pronounced in the spectra of the aged solution (curves 4–6); one can also identify another band peaking at 553 nm as well as a small spectral feature around 510 nm (Fig. 3a, curve 4). These bands have been assigned to an electronic transition and its vibrational satellites in the ordered P3HT [9].

The process of aggregation of P3HT in chloroform solutions was followed by monitoring the temporal evolution of the 610 nm peak in the solutions of the lowest and the highest concentrations used in our experiments (0.5 and 10 mg/cm^3, respectively). Within the time span of the experiment (6 days), we noticed a continuous increase of the intensity, its rate depending on the concentration of the solution. The results are shown in Fig. 3b. The rates of the process (processes) responsible for the build-up of the peak strongly depend on the concentration of the solution; in order to place the temporal dependencies for both concentrations on a common diagram, we adopted an auxiliary variable z, linearly dependent on the absorbance at 610 nm (A) and defined as

$$z = \frac{A(t) - A(t_o)}{c^2}, \tag{2}$$

where t_o is the time of the start of the experiment, and c is the concentration of the solution. It should be stressed, however, that the linear courses of the increase of the peak height do not mean that the kinetic process responsible for the changes be of the order 0; it rather shows that our measurements cover the initial period only. The process (processes) occurring in the solutions should result in an equilibrium established beyond the time scale of the present experiment. The slopes of the lines displayed in Fig. 3b ($(1/c^2)(dA/dt)$) do not differ much thus suggesting that the process may be governed by the second order kinetics. Hence, the rate of formation of the fibers should rapidly increase with the concentration as was indeed found in our experiments. The time necessary to attain the equilibrium in the experiments reported in this paper (P3HT in chloroform solutions) is of the order of weeks/months. It is worth noting that the aged solutions, stored over the period of 9 months are quite stable: their spectra were found essentially identical with those taken after 2 months of aging. Finally, it should be stressed that the rate of nanofiber

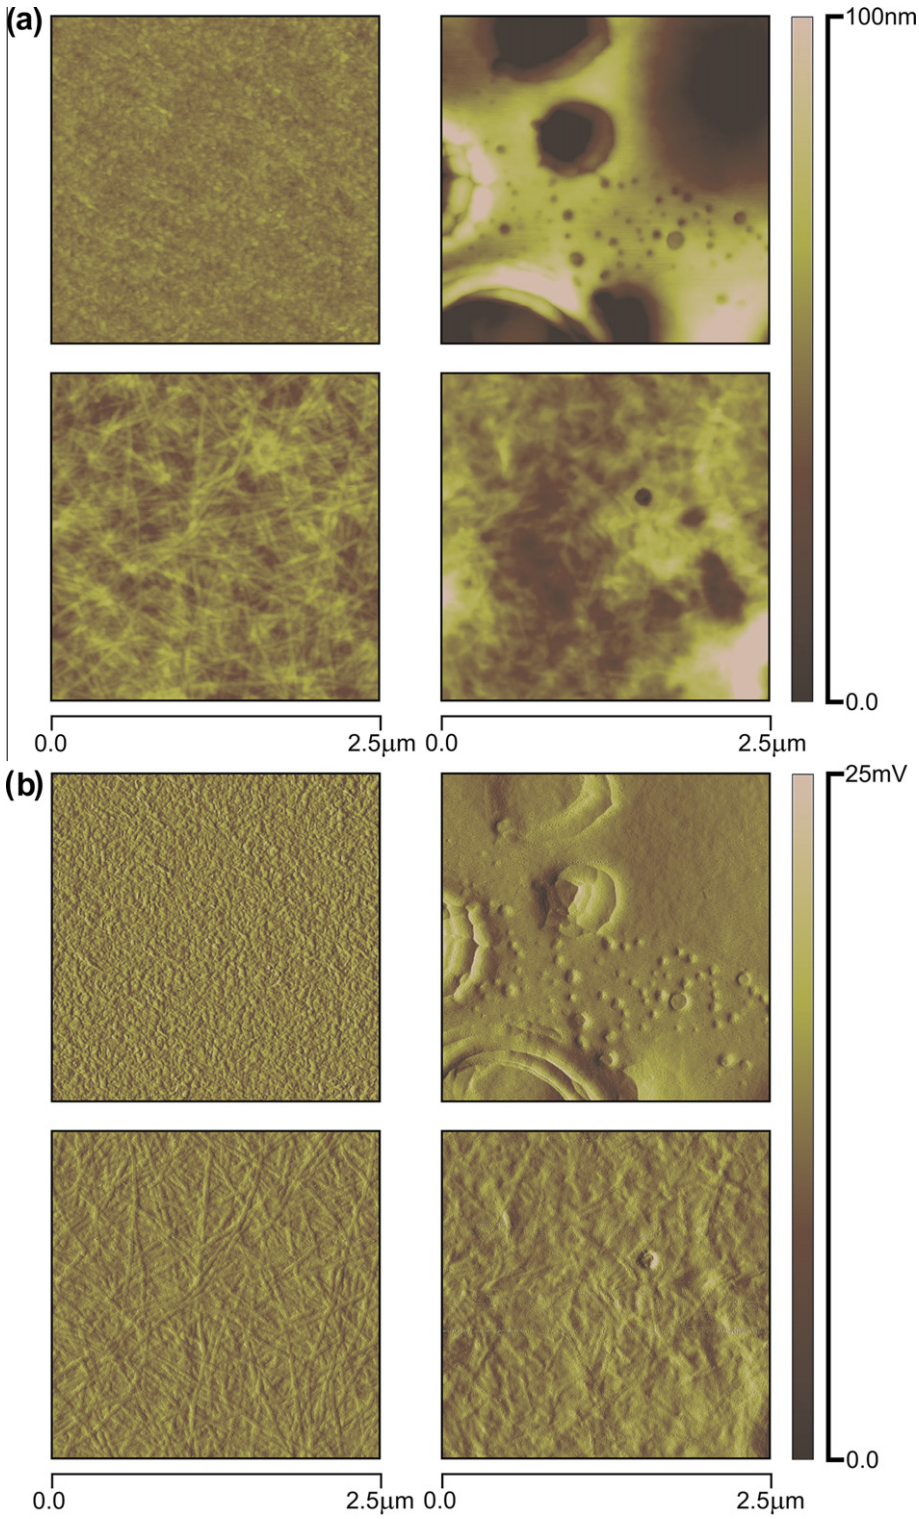

Fig. 2. AFM images of surface morphologies of spin coated (left side) and spray coated (right side) P3HT films deposited from fresh (top) and aged (bottom) solutions: (a) heights (amplitude signals); (b) amplitude error signals.

formation can be substantially increased by using another solvent or a suitable mixture of solvents [9,10].

The peaks characteristic of nanofibers are dominating features in the spectra of P3HT films shown in Fig. 4a.

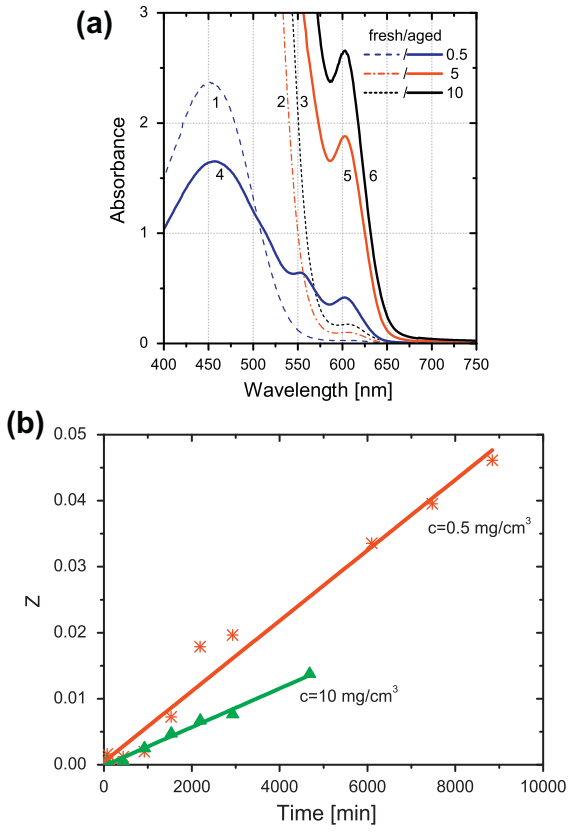

Fig. 3. (a) Absorption spectra of fresh (curves 1–3) and aged (curves 4–6) solutions of P3HT. The concentrations amount to 0.5 mg/ml (curves 1 and 4), 5 mg/ml (curves 2 and 5), and 10 mg/ml (curves 3 and 6). (b) Temporal evolution of the 610 nm peak. The concentration of the solution amounted to 0.5 mg/cm^3 (asterisks) and 10 mg/cm^3 (triangles). The parameter z, linearly dependent on the absorbance, has been defined in the text.

The spectra of the films fabricated in various conditions are similar in their general appearance but different in details; for example, the absorbance at the 610 nm peak in films deposited from fresh solutions is lower than that in spectra of the films made of aged solutions. For a more detailed analysis, the spectra were deconvoluted into 6 Gaussian peaks (cf. Fig. 4b and Table 1). The first five peaks, with narrow halfwidths (0.056–0.085 eV), can be attributed to electronic transitions in ordered (π-stacked) P3HT aggregates, whereas the broad component with the halfwidth amounting to 0.36–0.44 eV, is due to absorption in non-aggregated P3HT. It should be noted that the energies of the deconvoluted peaks come reasonably close to the values reported by Morfa et al. [29] (see Table 1).

An interesting conclusion can be drawn from a comparison of the heights of the deconvoluted peaks (cf. Table 1). The heights of the peaks associated with the P3HT aggregates are apparently more pronounced in the spectra of the films deposited from aged solutions. On average, the amplitudes of the five narrow peaks are 8% higher in the spray coated films and as much as 16% higher in spin coated ones. One may relate this result to the presence of nanoaggregates of P3HT in the samples, their concentration being higher in samples deposited from the aged solutions, and particularly high in spin-coated ones.

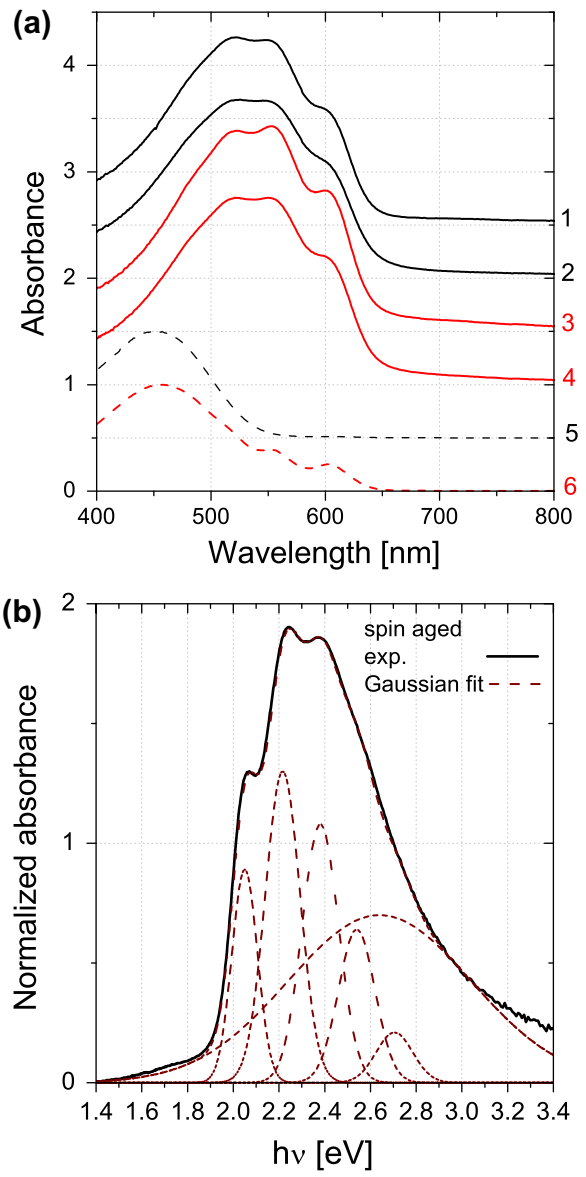

Fig. 4. (a) Absorption spectra of spin coated (curves 1 and 3) and spray coated (curves 2 and 4) films fabricated from fresh (curves 1 and 2) and aged (curves 3 and 4) solutions. Thicknesses of the films ranged from 120 to 140 nm. Curves 5 and 6 are spectra of the fresh and aged solutions, respectively. All spectra have been normalized at 457 nm and vertically displaced. (b) Absorption spectrum of a spin coated film deposited from the aged solution, fitted with 6 Gaussian curves. Solid line – experimental curve; dashed lines – deconvoluted Gaussian bands.

Aiming at elucidating a possible effect of presence and orientation of nanofibers on transport of charge carriers, we determined the carrier mobilities in OFETs fabricated using the four methods of deposition mentioned in the preceding section. Examples of output and transfer current–voltage characteristics of the studied OFETs are shown in Fig. 5a and b, respectively. The characteristics were measured for gate and source-drain voltages ranging

from −50 to 0 V. The threshold voltages in studied OFETs ranged between −15 and −25 V.

A histogram demonstrating the statistics of values of μ_{FET} determined from our experiments, shown in Fig. 6, points to an important effect of the character of the used solution and method of deposition (see also Table 2). Average mobilities in P3HT OFETs obtained from the fresh solution were practically the same for spin coated and spray coated samples ((0.5 ± 0.1) and $(0.4 \pm 0.2) \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$, respectively). Spray coating using the aged solution yielded devices exhibiting significantly higher mobilities ($(1.5 \pm 0.5) \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$). Even higher hole mobilities were determined in spin coated samples deposited from the aged solution: the average value amounted to $(7 \pm 5) \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$. The high average mobility was accompanied by an exceptionally large

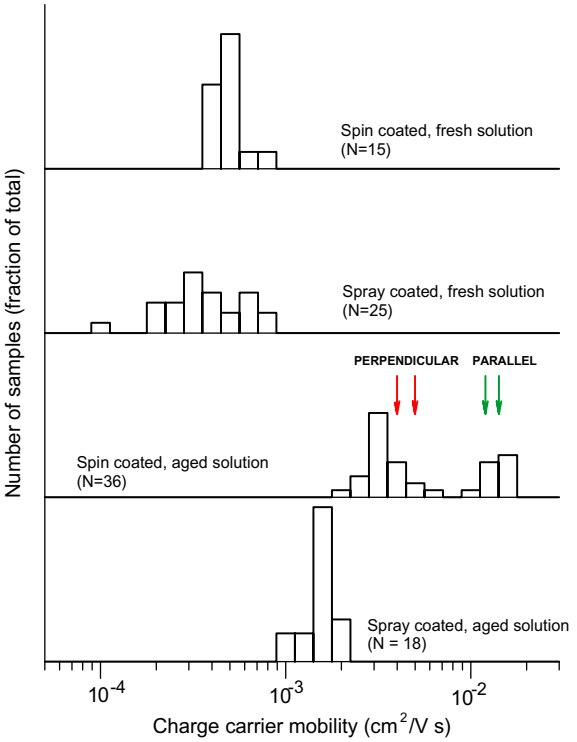

Fig. 6. Statistics of mobilities for the four groups of samples. Total numbers of measured samples of each group are given in the figure. The arrows indicate the mobilities determined in OFETs fabricated with the channels oriented parallel or perpendicular to the direction of the centrifugal force. Note the logarithmic scale of mobilities.

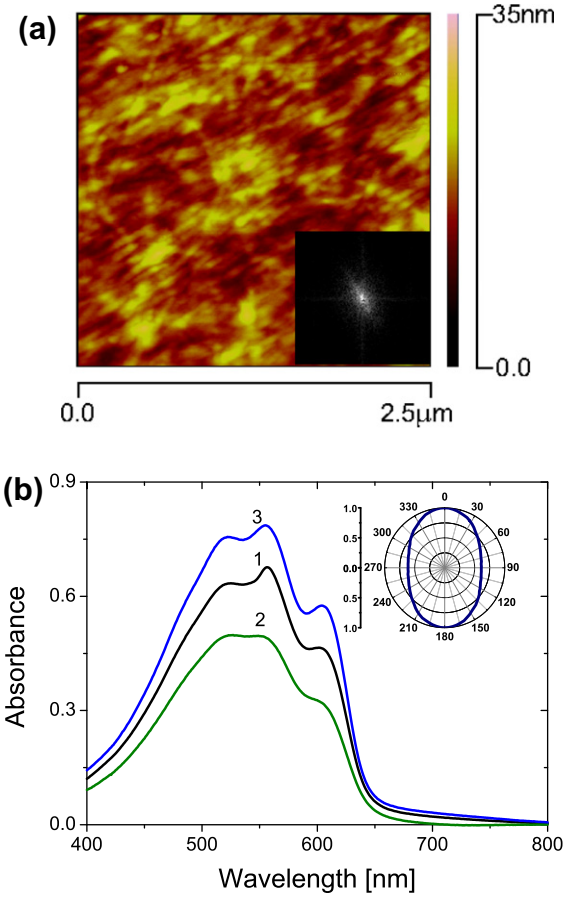

Fig. 7. (a) AFM image of surface morphology of a spin coated P3HT film deposited from an aged chloroform solution. The direction of the centrifugal force was from left to right. Inset: Fourier transform of the main image. The long axis of the shape shown in the insert is perpendicular to the preferred orientation of the nanofibers. (b) Absorption spectra of a P3HT film deposited by the spin coating of an aged solution. (1) Spectrum taken with unpolarized light; (2) light polarized along the preferential orientation of the fibers; (3) light polarized perpendicular to the fibers. Inset: angular dependence of the transmittance at 514.5 nm. The polarization angle was changed every 4° between 0° and 180° (the zero point was set in the direction of minimum absorbance).

spread of the results: the highest mobilities exceeded in some samples 10^{-2} cm^2 V^{-1} s^{-1} being over 1 order of magnitude higher than typical mobilities in FETs fabricated from the fresh solution.

The large scatter of the mobilities in OFETs fabricated by spin coating of the aged solution needs a comment. The results shown in Fig. 6 point to an interesting difference between the samples spin coated using the aged solution and those belonging to the three remaining groups: while the results obtained for the latter three groups of samples are spread around single maxima, spin coating of the aged solution yields results grouped around two maxima. It is tempting to associate this feature with the morphology of the spin coated samples; indeed, a closer inspection of the AFM pictures reveals a certain degree of orientation of the nanofibers along the direction of the centrifugal force acting on the samples during the spin coating. In order to verify this hypothesis, we prepared additional two pairs of samples,

Table 2
Average and maximum values of field effect mobilities of charge carriers, μ_{FET}.

	Average μ_{FET}[a] (10^{-3} cm^2 V^{-1} s^{-1})	The highest μ_{FET} (10^{-3} cm^2 V^{-1} s^{-1})	Nanofibers on the surface (AFM)
Spin coating			
Fresh solution	0.5 ± 0.1	0.73	No
Aged solution	7 ± 5	15.6	High concentration, partly oriented
Spray coating			
Fresh solution	0.4 ± 0.2	0.76	No
Aged solution	1.5 ± 0.5	1.92	High concentration, no preferred orientation

with the channels in each pair oriented parallel or perpendicular to the direction of the centrifugal force. The resulting mobilities are indicated by the arrows in Fig. 6.

Moreover, additional samples were fabricated for AFM inspection and spectroscopic measurements using polarized light, with a determined orientation with respect to the centrifugal force, using the same aged solution and employing identical conditions of deposition. The surface morphology is shown in Fig. 7a, the spectra taken with the polarized light – in Fig. 7b. In both cases, the results point to an anisotropy of the samples, thus confirming validity of our hypothesis about the ordering of P3HT nanofibers by the centrifugal force and its influence on the carrier mobility.

4. Conclusions

We carried out a comparative study of OFETs fabricated of P3HT, relating their performance to their morphology dependent on the consistency of solutions used and deposition technique. Mobilities of charge carriers in samples fabricated using fresh solutions have been found of the order of $10^{-4}\,cm^2\,V^{-1}\,s^{-1}$, irrespective of the deposition technique. Use of aged solutions results in an increase of the carrier mobilities in the devices by ca. one order of magnitude or more. The mobilities in spray coated OFETs have been found of the order of $10^{-3}\,cm^2\,V^{-1}\,s^{-1}$, on the same level as the values reported by Abdellah et al. [19] and one order of magnitude lower than those in P3HT FETs fabricated with an optimized fabrication technique by Chan et al. [20]. Spin coated P3HT films deposited using aged solutions exhibit even higher mobilities, particularly high in samples with some degree of orientation of the nanofibers parallel to the channel length.

Our results confirm that the presence of nanofibers, their length and their orientation are decisive factors for achieving high carrier mobilities in OFETs. We have also demonstrated that use of the spray coating technique, albeit simple and technologically convenient, has its price: lack of orientation of nanofibers, and their shorter lengths result in lower mobilities.

The organic/polymer rectifiers may be formed with the vertical Schottky diodes or the diode-configured thin-film transistors (TFTs) [11]. The appealing property of a transistor-based rectifier is its ease of integration with the logic gates [12,13]. Yet, its response frequency may be limited by the longer carrier transport path (i.e. the channel length) [11,14]. On the other hand, the active layer thickness of the vertical Schottky diode can be easily reduced, thereby having a larger potential to achieve much higher operating frequencies [15]. The requirements for implementing high-speed organic rectifying diode in general include high current density under the forward bias for faster charging of the load circuits, low current density under the reverse bias to reduce charge leakage of the load capacitor during the reverse-bias half cycle, and low turn-on voltage to reduce voltage drop on the diode and to produce higher voltage output. In recent years, there have been reports on progresses in operation frequencies of organic/polymer rectifiers [11,15–20]. Yet except for few cases of vacuum-deposited small-molecule organic rectifying devices showing operation frequencies around or exceeding 13.56 MHz [15,20], in general there is still difficulty for solution-processed polymer devices to achieve such high operating frequencies.

In this work, we report the implementation of flexible high-frequency rectifying diodes using the polythiophene-based semiconducting polymers and the polycarbonate substrates. We show how the intermediate hole-injection layer between the anode and the semiconducting polymer and the semiconducting polymer itself affect the characteristics/performances of the rectifying diodes. Furthermore, we integrate the polymer-based vertical Schottky diode rectifier, antenna and capacitors to demonstrate a flexible wireless power-transmission sheet that can convert a 13.56 MHz electromagnetic wave into the dc power.

2. Experiment

2.1. Fabrication and characterization of polymer diodes

Two types of device structures on polycarbonate (PC) substrates, as shown in Fig. 1, were studied in this work. The device structure for type-I devices is: PC/IZO/semiconducting polymer/Al, while the device structure for type-II devices is: PC/IZO/PEDOT:PSS/semiconducting polymer/Al. In both devices, transparent and conducting indium zinc oxide (IZO) was used as the anode and Al was used as the cathode. IZO was reported to provide good optical/electrical performances even by low-temperature deposition and exhibit low internal stress and etching stability when deposited on plastic substrates [21], making it attractive for applications in flexible electronics. PC/IZO substrates used in this work were purchased from Teijin Ltd. and had a sheet resistance of 30 Ω/square and light transmittance of 87%.

The chemical structures of semiconducting polymers and conducting polymers used in this work are shown in Fig. 2. Two types of semiconducting polymers, poly(3-hexylthiophene) (P3HT) and poly(3,3‴didodecylquaterthiophene) (PQT-12) shown in Fig. 2, were used in devices. P3HT is a widely used semiconducting polymer for polymer devices [22], while PQT-12 is a polythiophene-based polymer that had been reported to exhibit higher carrier mobilities than P3HT in polymer devices [22–26]. P3HT was purchased from Rieke Metals, Inc. and was used as received. PQT-12 was purchased from American Dye Source, Inc. and was used either as received or after in-house purification. The polydispersity index (PDI) of PQT-12 decreased from 1.6 (Mw = 19 kg/mol) to 1.4 (Mw = 26 kg/mol) after purification by gel-permeation chromatography (GPC). In type-II devices, the conducting polymer (3,4-ethylenedioxy thiophene)poly(styrene sulfonate) (PEDOT:PSS) as shown in Fig. 2 was inserted between the IZO anode and the semiconducting polymer as the hole-injection layer [27]. Two models of PEDOT:PSS, one having a higher conductivity (Baytron P HCV4, resistivity = 10^3 Ω cm) and one having a lower conductivity (Baytron P VP AI 4083, resistivity = 10^4 Ω cm), were purchased from H.C. Stark and were used in this study. Fig. 2(d) shows the energy levels of PEDOT, P3HT, and PQT-12 used in this work [28–30].

In fabrication of devices, polycarbonates coated with IZO was first cleaned by sonification in de-ionized water, acetone and isopropyl alcohol sequentially, and then dried in an oven at 100 °C for 30 min. After the wet cleaning, the substrate was further subjected to a dry cleaning in UV ozone for 25 min. For type-I devices, a semiconducting polymer (e.g. P3HT) was then directly spin-coated onto IZO. For type-II devices, prior to deposition of the semiconducting polymer (P3HT or PQT-12), a hole-injection layer of PEDOT:PSS was spin-coated onto the PC/IZO substrate at 4000 rpm to form a 50-nm-thick film. The PEDOT:PSS coated substrate was then baked on a hotplate at 110 °C for 20 min. The 160-nm-thick semiconducting polymer, P3HT or PQT-12, were coated onto IZO or PEDOT:PSS by spin-coating. P3HT was spin-coated under the N_2 environment, followed by annealing at 110 °C. PQT-12 was spin-coated under the ambient environment, followed by annealing at 145 °C. Finally, the aluminum electrode was deposited by thermal evaporation. The area of each Schottky diode was 0.07 mm^2, as defined by the shadow mask. We found the small device area is one of the important

factors to achieve high-frequency operation of the device. After device fabrication, the current–voltage characteristics of the diodes were measured using an Agilent 4156C Semiconductor Parameter Analyzer.

2.2. Frequency response measurements

Fig. 3 shows the schematic circuit configuration for measuring the frequency response of the diode rectifier. It consisted of a function generator (to provide the ac input signal V_{supply} of various frequencies), the polymer diode, a load capacitance (C_L), a load resistance (R_L), and an oscilloscope (to measure the dc output signal $V_{D.C.}$). The function generator Agilent 3120A was used to feed the input ac signal into the rectifier circuit. The output of the diode rectifier was recorded by a Tektronix TDS3052B oscilloscope with the input impedance set to 1 MΩ. A 0.1 μF capacitor was used as the load capacitor.

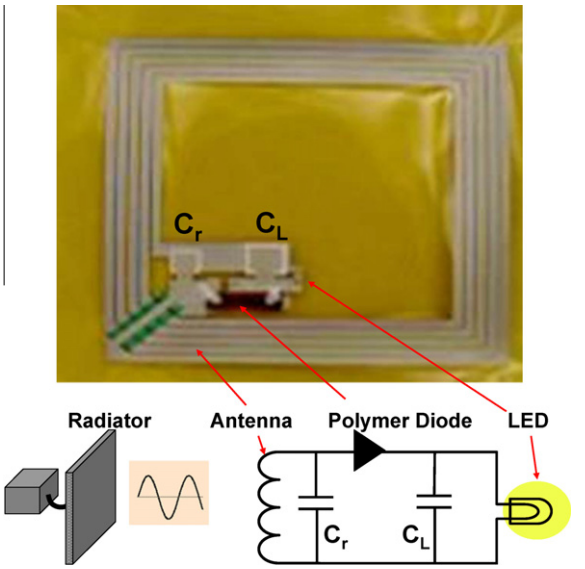

Fig. 4. The schematic configuration of the flexible wireless power-transmission sheet/system and a photo of the power-transmission sheet.

2.3. Flexible wireless power-transmission sheet

To demonstrate the use of the high-speed polymer rectifying diode in wireless power transmission, the polymer rectifying diode developed in this work was integrated into a flexible wireless power-transmission sheet and system. Fig. 4 shows the schematic configuration of the flexible wireless power-transmission sheet and system. The flexible wireless power-transmission sheet on plastics consisted of a printed metal-coil antenna (4.6 × 4.6 cm, L = 2.281 μH), a resonant capacitance (C_r = 60.4 pF), a polymer diode, a load capacitance (C_L = 201 pF), and a commercial inorganic light emitting diode (LED) as the load. The antenna and bottom electrodes of capacitors were screen-printed on polyimide substrates. Then, the polymer dielectrics (for capacitors) and the top electrodes of capacitors were coated by screen printing in sequence. Finally, the polymer Schottky diode and commercial inorganic LED were mounted on the sheet having patterned antenna and capacitors. The darker area in Fig. 4 represents the color of the PQT-12 film, but the actual active area of the polymer diode used was 0.07 mm^2, as determined by the overlap of the bottom IZO electrode and the top Al electrode.

3. Results and discussion

3.1. Effects of PEDOT:PSS intermediate layer

First, the effects of the intermediate layer (i.e. PEDOT:PSS) between the IZO anode and the semiconducting

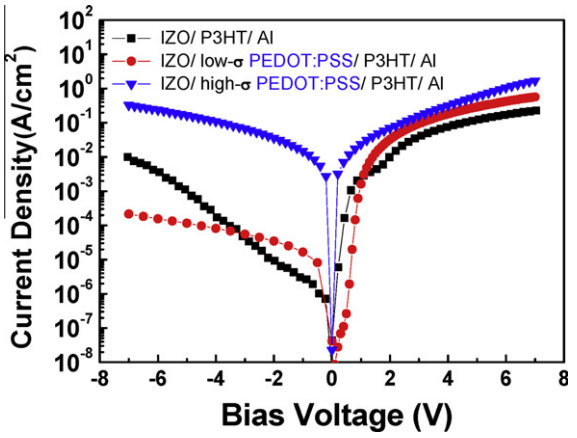

Fig. 5. *I–V* characteristics of P3HT diodes having the structures of: IZO/P3HT/Al, IZO/lower-conductivity (low-σ) PEDOT:PSS/P3HT/Al, and IZO/higher-conductivity (high-σ) PEDOT:PSS/P3HT/Al.

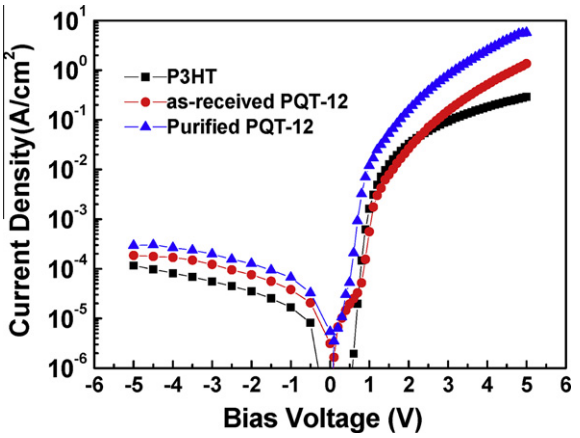

Fig. 6. *I–V* characteristics of the IZO/low-σ PEDOT:PSS/semiconducting polymer/Al diodes using P3HT, as-received PQT-12, and in-house purified PQT-12.

layer was studied. Fig. 5 shows the *I–V* characteristics of P3HT diodes having no PEDOT:PSS intermediate layer, having the lower-conductivity (low-σ) PEDOT:PSS intermediate layer, and having the higher-conductivity (high-σ) PEDOT:PSS intermediate layer. Diodes with either high-conductivity or low-conductivity PEDOT:PSS exhibit higher forward current densities than the diode without PEDOT:PSS, indicating that the adoption of PEDOT:PSS is effective in providing a better contact and enhancing hole injection to the semiconducting polymer in consideration of energy levels of materials shown in the Fig. 2(d). The diode using the higher-conductivity PEDOT:PSS, however, exhibits much higher reverse leakage current than the other two diodes. Such much larger reverse leakage current may due to fringing and lateral conductivity associated with the higher PEDOT:PSS conductivity. Therefore, the conductivity of the PEDOT:PSS hole-injection layer should be judiciously tuned to obtain both enhanced forward current and yet also low reverse leakage current, thus achieving high rectification desired for high-performance diode rectifiers. In the three devices shown in Fig. 1, indeed the diode adopting the lower-conductivity PEDOT:PSS shows both enhanced forward current and yet also low reverse leakage current, consequently giving the enhanced diode rectification ratio.

3.2. Effects of different semiconductor polymers

After investigating effects of the anode intermediate layers, we then studied characteristics of diodes using different semiconducting polymers. Due to the effectiveness of the low-σ PEDOT:PSS in both enhancing the forward current and suppressing the reverse leakage current, the same device structure of IZO/low-σ PEDOT:PSS/semiconducting polymer/Al was extended to test different semiconducting polymers (i.e. both P3HT and PQT-12). Fig. 6 shows the *I–V* characteristics of the diode using P3HT, the diode using the as-received PQT-12, and the diode using the in-house purified PQT-12. It is seen that with adopting the PQT-12, the forward current of the diode is increased. The diode current is further enhanced when using the purified PQT-12. The current enhancement (at 5 V) is more than one order of magnitude, when compared to the P3HT diode. Simultaneously, the rectification ratio of the diode is also enhanced. It is supposed that the better performance of the PQT-12 diodes is owing to the higher mobility of PQT-12, which in general can show a mobility (0.1–0.7 cm^2/Vs) about one order higher than that of P3HT (0.01–0.1 $cm^2/V\,s$) [22–26]. Overall, a forward current density up to ~6 A/cm^2 at 5 V and a rectification ratio up to 2×10^4 at ±5 V were achieved with the rectifying diodes using purified PQT-12. The high current density observed for the PQT-12 diode is comparable to those of high-performance organic diodes using vacuum-deposited organic semiconductors [15,20,31].

In addition to better electrical characteristics, PQT-12 diodes also exhibit better environmental stability in comparison with P3HT diodes. Fig. 7(a) shows the *I–V* characteristics of a same P3HT diode measured when freshly made and after being stored in the air for 120 h. Clearly the diode characteristics had degraded dramatically after extended exposure to the ambient. On the other hand, after a same storage test, the characteristics of the PQT-12 diode only varied slightly, as shown in Fig. 7(b). It had been reported that the HOMO energy level of PQT-12 is higher than that of P3HT due to the difference in conjugation structures, thus making it less susceptible to oxidative doping associated with ambient gases (e.g. humidity, etc.) and more environmentally stable [32,33].

3.3. Frequency response of the polymer diode rectifier

The frequency response of the diode rectifier was measured using the basic rectifier circuit configuration shown in Fig. 3, which consists of the polymer diode, a load capacitance (C_L), and a load resistance (R_L). The load resistance of 1 MΩ and load capacitance of 0.1 μF were used in this study, which were chosen to make $R_L \times C_L$ much larger than the period of the input ac voltage to avoid/reduce the output voltage ripples [34]. Fig. 8 shows the frequency

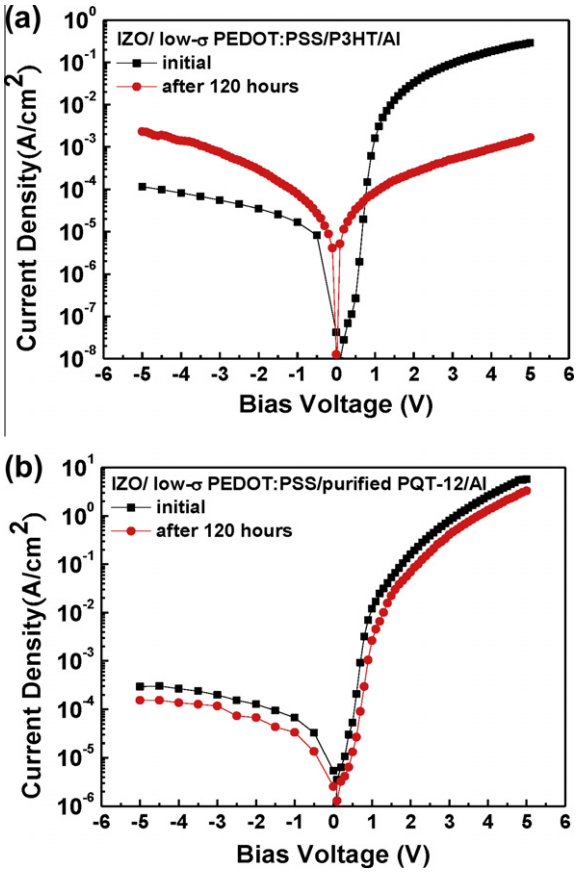

Fig. 7. *I–V* characteristics of IZO/low-σ PEDOT:PSS/semiconducting polymer/Al diodes measured when freshly made and after being stored in the air for 120 h: (a) P3HT diode, (b) purified PQT-12 diodes.

response, i.e. the dc output voltage vs. the frequency of the input ac signal (with an amplitude of 10 V), of the diode rectifiers using the three polymer diodes of IZO/low-σ PEDOT:PSS/P3HT/Al, IZO/low-σ PEDOT:PSS/as-received PQT-12/Al, and IZO/low-σ PEDOT:PSS/purified PQT-12/Al. The rectifier using the purified PQT-12 exhibits the highest operation frequency. The 3-dB frequency of the rectifier using the purified PQT-12 is higher than 14 MHz (which is beyond the upper frequency limit of our instrument). Indeed, the output voltage remains rather constant up to 14 MHz. The maximum operation frequency (f_{MAX}) of the rectifying diode is determined by the transition time (t_t) of carriers traveling through the polymer diode during the forward-bias half cycle, i.e. roughly speaking $f_{MAX} \approx \mu(V_A - V_{dc})/L^2$, where V_A is the amplitude of the input ac voltage, V_{dc} the output dc voltage at the load capacitance, μ the bulk material mobility, and L the diode thickness [15]. With the same active-layer thickness and the same applied ac voltage, the purified PQT-12 diode gives the highest operation frequency, presumably due to its higher carrier mobility. Fig. 9 shows the output voltage waveform of the purified PQT-12 diode rectifier along with the 13.56 MHz/10 V input ac signal. When operated at 13.56 MHz/10 V, the purified PQT-12 diode rectifier outputs a dc voltage of ~4 V.

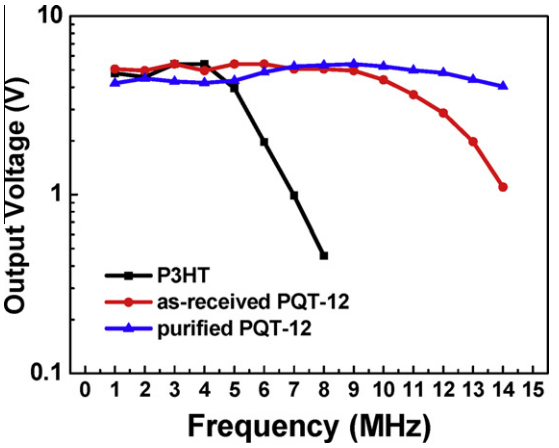

Fig. 8. The frequency response, i.e. the dc output voltage vs. the frequency of the input ac signal (with an amplitude of 10 V), of the diode rectifiers using the three polymer diodes of: IZO/low-σ PEDOT:PSS/P3HT/Al, IZO/low-σ PEDOT:PSS/as-received PQT-12/Al, and IZO/low-σ PEDOT:PSS/purified PQT-12/Al.

3.4. Use of the polymer diode rectifier in flexible wireless power-transmission sheet

To demonstrate the use of the high-speed polymer rectifying diode in wireless power transmission, the polymer rectifying diode developed in this work was integrated into a flexible wireless power-transmission sheet and system, whose configuration and photo are shown in Fig. 4. The wireless power-transmission sheet consists of a resonant circuit and a rectifier circuit. The resonant circuit receives the energy from the radiator and the rectifier circuit converts the ac signal from the resonant circuit to dc voltage. The resonant circuit is composed of a resonant capacitor (C_r) and the inductor coil (L) of the antenna. The resonant frequency of the resonant circuit has been tuned at the carrier frequency of the radiator (13.56 MHz in the present case) to obtain the best performance. The rectifier circuit is composed of a polymer diode and a filter capacitor (C_L). A commercial inorganic LED was mounted onto the sheet to demonstrate the function of the power-transmission sheet. The photograph in Fig. 10 shows that a flexible

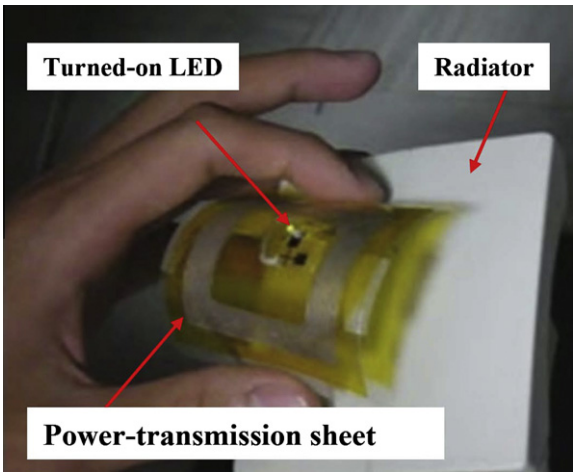

Fig. 10. A photograph showing that a flexible wireless power-transmission sheet (under the bending status) was receiving 13.56 MHz RF power from the radiator and converting it into dc voltage to drive the LED (the bright spot in the photo).

wireless power-transmission sheet was receiving 13.56 MHz RF power from the radiator and converting it into dc voltage to drive the LED. In Fig. 10, it is seen that even under the bending state, the wireless power-transmission sheet remained normally functional, clearly demonstrating the flexibility and the functionality of wireless power transmission.

4. Conclusions

In summary, we successfully implemented flexible high-frequency rectifying diodes on polycarbonate substrates using the polythiophene-based semiconducting polymers. We show that the appropriate conductivity of the intermediate hole-injection layer PEDOT:PSS between the anode and the semiconducting polymer is critical to simultaneously achieve enhanced forward currents and rectification ratios. Among the semiconducting polymers studied (P3HT and PQT-12), the diodes based on carefully purified PQT-12 exhibited higher forward currents, higher rectification ratios, much better environmental stability, and much higher operation frequencies. A forward current density up to $\sim$6 A/cm^2 at 5 V, a rectification ratio up to 2×10^4 at ±5 V, and an operation frequency of the diode rectifier over 14 MHz were achieved with the PQT-12 rectifying diodes. Finally, to demonstrate the use of the high-speed polymer rectifying diode in wireless power transmission, we integrate the polymer-based vertical Schottky diode rectifier, printed antenna and capacitors on plastic substrates to demonstrate a flexible wireless power-transmission sheet that can convert a 13.56 MHz electromagnetic wave into the dc power to drive load devices.

organic metal–chelate complexes such as tris(8-hydroxyquinoline) aluminum (Alq_3) and its beryllium derivatives, e.g., $Bebq_2$ and Beq_2 [9]. Organic metal–chelate complexes have been widely used as electron-transporting and host emitting materials in OLEDs because they are thermally and morphologically stable that can be evaporated into thin films, they are easily synthesized and purified, and their molecular geometry can be designed to avoid exciplex formation, e.g. with 4,4′-bis(*N*-(1-naphthyl)-*N*-phenylamino)biphenyl (NPB) at the interface. For example, utilizing Alq_3 as the electron-transporting host material, phosphorescent dyes were for the first time successfully incorporated in OLEDs, achieving high electro-luminescence (EL) efficiencies by utilizing both the singlet and triplet state energies [1b]. Recently, several efficient PHOLEDs have been reported that use bis(2-(2-hydroxyphenyl)-pyridine)beryllium ($Bepp_2$) as an electron-transporting host material and either combine it with another layer of hole-transporting host layer in a double layer structure or use a *p-i-n* structure with multiple-doped-layer system [10], due to the excellent charge transport ability of this beryllium complex [11]. Here, we present a simple and highly efficient single-emitting-layer PHOLED that uses $Bepp_2$ as the electron-transporting host material and bis(7,8-benzoquinolinato) iridium(III) (*N*,*N*′-diisopropyl-benzamidine) ($(bzq)_2Ir(dipba)$) [12] as the phosphorescent dye to enhance the electro-luminescence performance. This PHOLED device exhibits substantially lower driving voltage (2.8 V) and higher EL efficiencies than those based on the CBP host. It shows dramatically enhanced peak values of more than 70 cd A^{-1} for luminous efficiency, 55 lm W^{-1} for power efficiency, and 23% for external quantum efficiency. The high EL performance is attributed to the well-matched energy levels of $Bepp_2$ with the hole-/electron- transporting (HT/ET) materials as well as the highly efficient and complete energy transfer between the host and the guest.

2. Experimental section

2.1. Materials

NPB, CBP and 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBI) were commercially available. $Bepp_2$ and $(bzq)_2Ir(dipba)$ were prepared according to literature procedures [11,12], and their structures are shown in Fig. 1. Hexane was distilled over sodium benzophenone ketyl under a nitrogen atmosphere and degassed by three freeze–pump–thaw cycles. All glassware, syringes, magnetic stirring bars and needles were dried in a convection oven for at least 4 h before use. Reactions were monitored with thin layer chromatography (TLC) using commercial TLC plates (Silica gel 60 F254, Merck Co.) under either 254 or 365 nm UV light. Silica column chromatography was done with silica gel 60 G (particle size 5–40 μm, Merck Co.). ^{1}H NMR spectra were recorded on a Bruker AVANVE 300 MHz spectrometer with tetramethylsilane as an internal standard. Mass spectra were measured on a GC/MS mass spectrometer. Elemental analyses were performed on a flash EA 1112 elemental analyzer.

2.1.2. Bis(7,8-benzoquinolinato) iridium(III) (*N*,*N*′-diisopropyl-benzamidine) ($(bzq)_2Ir(dipba)$)

MS: m/z 753 (M^+). Anal. Calcd for $C_{39}H_{35}IrN_4$: C, 62.29; H, 4.69; N, 7.45. Found: C, 62.12; H, 4.78; N, 7.55. ^{1}H NMR (300 MHz, $CDCl_3$) δ 9.63 (d, *J* = 5.10, 2H), 8.19 (d, *J* = 8.1 Hz, 2H), 7.74 (d, *J* = 9.0 Hz, 2H), 7.62 (t, *J* = 7.2, 2H), 7.60 (d, *J* = 9.0 Hz, 2H), 7.44 – 7.33 (m, 5H), 7.30 (d, *J* = 8.1 Hz, 2H), 6.91 (t, *J* = 7.2 Hz, 2H), 6.38 (d, *J* = 7.2 Hz, 2H), 3.23–3.16 (m, 2H), 0.65 (d, *J* = 6.0 Hz, 6H), −0.47 (d, *J* = 6.0 Hz, 6H).

2.2. Absorption, PL and electrochemical measurements

Absorption spectra were obtained using a Shimadzu UV-2550 UV–vis spectrometer. The PL spectra were recorded by a Perkin–Elmer LS-55 fluorescence spectrometer with a Xe arc lamp excitation source. All solvents were degassed via three freeze–pump–thaw cycles before use.

Electrochemical measurements were performed on a BAS 100 W Bioanalytical electrochemical work station, using Pt as the working electrode, platinum wire as the auxiliary electrode, and a porous glass wick Ag/Ag^+ as the reference electrode, standardized against ferrocene/ferrocenium couple, scan rate 100 mV s^{-1}. Due to the limitation [13] in measuring reduction potentials in the range of −2.7 to −3.5 V in CH_2Cl_2, only the oxidation potentials for $Bepp_2$ and $(bzq)_2Ir(dipba)$ were obtained, and no reduction wave was detected within the electrochemical window of CH_2Cl_2. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels of both complexes were calculated from the cyclic voltammetry (CV) data as well as their absorption spectra. The proposed energy diagram of the materials used in OLEDs is shown in Fig. 1, where the values for NPB, CBP and TPBI are taken from the literature [14].

2.3. Fabrication of the OLEDs and EL measurements

The devices were grown on a glass slide precoated with indium tin oxide (ITO) that has a sheet resistance equal to 20 Ω cm^{-2}. The ITO glass was routinely cleaned by sonicating in detergent solutions, rinsing with acetone, boiling in isopropanol, rinsing with methanol, and then de-ionized water. The glass was dried in vacuum oven between each cleaning step above. To reduce the possibility of electrical shorts on the ITO anode and increase the value of its work function, the ITO substrate was treated using a Plasma Cleaner (PDC-32G-2, 100 W) with the oxygen ambient. Prior to the deposition, all the organic materials were purified by sublimation. The organic layers were sequentially deposited onto the substrate without breaking vacuum at a pressure of about 10^{-4} Pa. A very thin layer of LiF was used to enhance electron injection from aluminum cathode. A shadows mask with 2×3 mm^2 openings was used to define the cathode. The EL spectra, brightness, CIE coordinates and the current–brightness–voltage characteristics of the devices were measured with a rapid scan system using a spectrophotometer (PR-650, Photo Research) and a computer-controlled, programmable, direct-current (DC) source (Keithley 2400). Luminance–voltage and current–voltage characteristics of the EL devices were measured at room temperature under an ambient atmosphere.

3. Results and discussion

3.1. Absorption and photoluminescent (PL) properties

To investigate the energy-transfer properties of the host–guest system, a series of evaporated-film and solution samples of $Bepp_2$ and $(bzq)_2Ir(dipba)$ were prepared, and their UV–vis absorption and PL emission spectra are shown in Fig. 2. The $(bzq)_2Ir(dipba)$ neat film exhibits a typical metal-to-ligand charge transfer (MLCT) absorption band centered at 520 nm and a strong orange emission at 600 nm. The PL spectrum of the $Bepp_2$ neat film shows an emission peak at 445 nm at room temperature and this peak blue shifts to 430 nm at 77 K (the glass state) with a phosphorescence shoulder at 470 nm [15]. From these spectroscopic data, the corresponding triplet energy (T_1) of $Bepp_2$ was estimated to be 2.6 eV, higher than the value (2.2 eV) estimated for $(bzq)_2Ir(dipba)$. The fact that the phosphorescence spectrum of $Bepp_2$ and the MLCT absorption band of $(bzq)_2Ir(dipba)$ significant overlaps together with a triplet energy alignment suggest that an efficient triplet energy transfer from $Bepp_2$ to $(bzq)_2Ir(dipba)$ is possible. Indeed, this efficient triplet energy transfer has been demonstrated by the unique emission observed in the PL spectrum of the $Bepp_2$: $(bzq)_2Ir(dipba)$ thin film with the doping concentration of 8 wt%.

3.2. EL properties

To examine the EL properties of $Bepp_2$ as an electron-transporting host material, a series of PHOLEDs (devices I–III) were fabricated with a device configuration of ITO/NPB (40 nm)/doping EML (8 wt%, 15 nm)/ETL and HBL (35 nm)/LiF (1 nm)/Al. In devices I and III, 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBI) was used as the electron-transporting layer (ETL) and hole-blocking layer (HBL) [16], whereas in device II a neat film of $Bepp_2$ was used as the ETL. To test the EML property of $Bepp_2$, in devices I and II, a film of $Bepp_2$ doped with $(bzq)_2Ir(dipba)$ was used as the emitting layer. For comparison, device III using CBP instead of $Bepp_2$ as the host was fabricated.

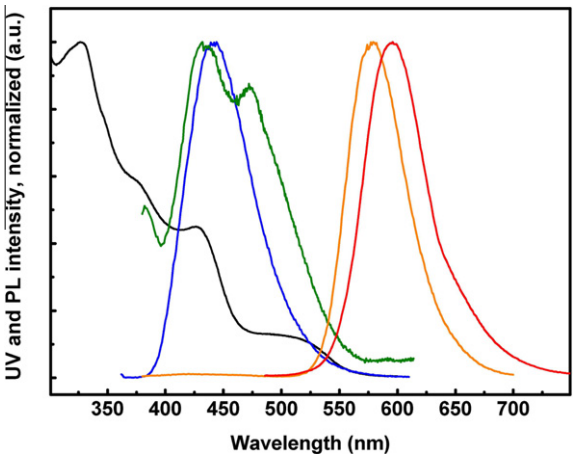

Fig. 2. UV absorption spectrum (black line) and PL spectrum (red line) of neat $(bzq)_2Ir(dipba)$ film, PL spectrum of neat $Bepp_2$ film (blue line), PL spectrum in solution (THF, 77 K) (green line) and PL spectrum of $(bzq)_2Ir(dipba)$ doped in $Bepp_2$ film (8 wt%) (orange line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

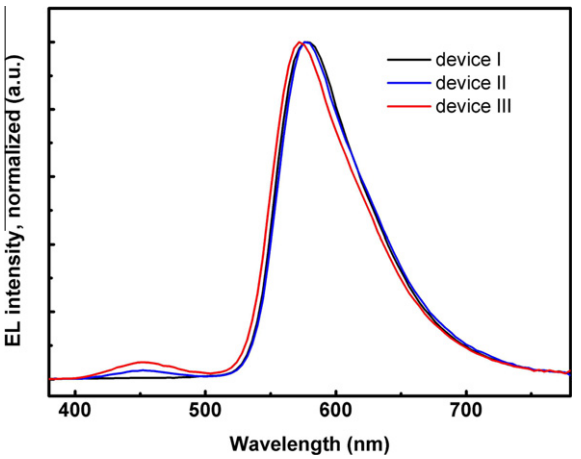

Fig. 3. EL spectra of device I, II and III at the brightness of 10,000 cd m^{-2}.

As shown in Fig. 3, the normalized EL spectra of device I, II, and III at high brightness of 10,000 cd m^{-2} all have similar emission peaks at around 575 nm. The lack of a host emission in the EL spectrum of device I indicates a complete energy transfer from $Bepp_2$ to $(bzq)_2Ir(dipba)$. This is as expected under the doping concentration of 8 wt% and is consistent with the characteristic PL spectra of the doped film shown in Fig. 2. In device II, where neat $Bepp_2$ film is utilized as the ETL, a slight shoulder emission at

around 450 nm is observed as the brightness gradually increased above 5000 cd m^{-2}. Because devices I and II use the same host:dopant combination as well as the doping concentration and thickness, the slight change of their EL spectra at high brightness, i.e., high driving voltages, indicates that the recombination zone in device II is extended to the ETL region made of neat $Bepp_2$. This extension of the recombination zone in device II is consistent with the fact that a HBL such as a TPBI film is not present in device II but is present in device I. In device III, a weak emission at 450 nm was also observed that can be attributed to the emission from CBP that originates from incomplete energy transfer and/or charge transfer from the host to the guest [17]. The presence of this weak emission from CBP suggests that it is not a favorable host for this specific phosphorescent guest emitter, i.e., $(bzq)_2Ir(dipba)$.

As shown in the current density–brightness–voltage plots (Fig. 4), devices I and II exhibited similar and very low turn-on voltage of 2.8 and 2.7 V, respectively, much lower than the 3.5 V value of the CBP-based device III. Moreover, devices I and II show a fast rise of the EL intensity and the current density as the voltage increases. The driving voltages of the $Bepp_2$-based devices I and II at a brightness of 100 cd m^{-2} and a current density of 100 mA cm^{-2} are ~3.7 and 7–8 V, respectively. These values are much lower than those of the CBP-based device, i.e., 5.0 and 11.0 V, respectively. At a driving voltage of 9.5 V, devices I and II reached their peak radiance at 36,110 and 31,170 cd m^{-2}, respectively, whereas devices III needed a higher voltages of 13.5 V to achieve the same brightness levels (37,110 cd m^{-2}). The relatively low driving voltages and the linear response of brightness with current density for devices I and II indicate that they are highly efficient PHOLEDs that have a suitable host–guest system. Since both devices I and II use $Bepp_2$ as the host material, this high efficiency can be attributed to the higher HOMO levels of the beryllium complex than that of CBP (See Fig. 1 for the energy-level diagrams). The low driving voltages of devices I and II may also result from the well-matched energy levels of $Bepp_2$ with HTL that enhances the holes injection from the HTL to the EML. When compared with device I, device II shows a slightly faster rise in the current density and a slower rise in the EL intensity as the driving voltage increases. This trend becomes more obvious as the driving voltage increases further and further (Fig. 4). This phenomenon supports our previous hypothesis that the holes or excitons may have leaked into the ETL in device II. As a result, the triplet excitons could have been quenched in the neat $Bepp_2$ ETL of device II, leading to lower EL performance.

The LE (luminous efficiency)–EQE (external quantum efficiency)–PE (power efficiency)–brightness characteristics for devices I, II and III are shown in Fig. 5. As expected, both devices based on $Bepp_2$ show much higher EL efficiencies than those of CBP-based device III. Devices I and II exhibit the exciting peak LE of 70.9 cd A^{-1} (23.4% for EQE, 4.4 V) and 62.8 cd A^{-1} (21.4% for EQE, 4.0 V) at the reliable brightness of 605 and 270 cd m^{-2}, respectively. In comparison, device III exhibit a much lower peak value of 38.1 cd A^{-1} (12.4% for EQE) at the brightness of 245 cd m^{-2} (5.5 V). In addition, as a result of the low driving voltages, the PE of $Bepp_2$-based devices are dramatically enhanced. The maximum PE and the corresponding values at the practical brightness of 100 and 1000 cd m^{-2} are 56.3, 56.1 and 46.8 lm W^{-1} for device I and 51.9, 51.5 and 36.5 lm W^{-1} for device II, respectively. These PE values are significantly better than those of device III, i.e., 23.0, 23.0 and 17.6 lm W^{-1}, respectively.

These data showed that there are at least three properties of $Bepp_2$ make it to construct an OLED with high EL efficiency and relatively low driving voltages. First, the HOMO levels of $Bepp_2$ in ETL and NPB in HTL match very well. Second, the relatively high energy of the triplet state of $Bepp_2$ together with a well overlap of the phosphorescence spectrum of $Bepp_2$ and the MLCT absorption band of $(bzq)_2Ir(dipba)$ ensure that an exothermic energy transfer from the host to the guest can occur. Third, the similar LUMO energy levels of $Bepp_2$, TPBI and $(bzq)_2Ir(dipba)$ (shown in Fig. 1) can facilitate a smooth injection of electrons from TPBI to $Bepp_2$ and also possibly a direct electron injection and exciton formation from TPBI onto

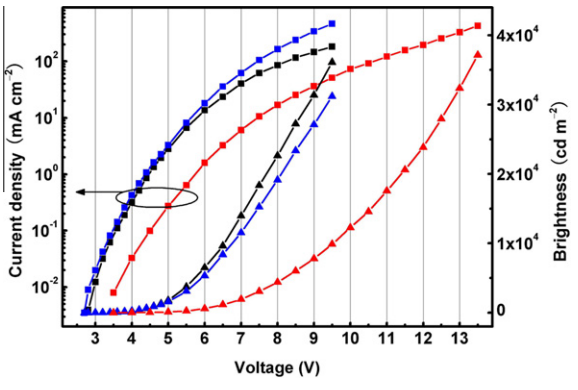

Fig. 4. Current density–brightness–driving voltage curves of device I (black), II (blue) and III (red). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

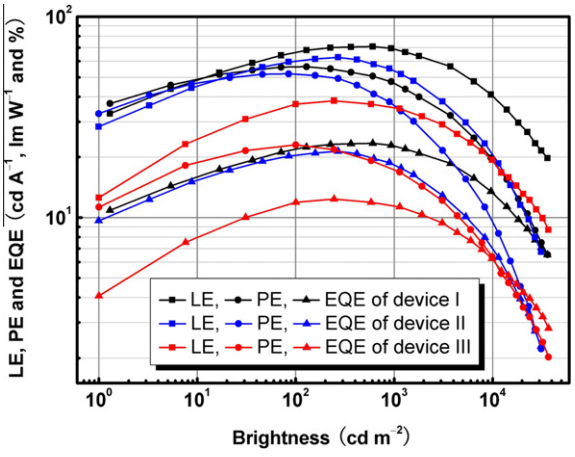

Fig. 5. LE (luminous efficiency)–, EQE (external quantum efficiency)– and PE (power efficiency)–brightness characteristics for the device I, II and III.

$(bzq)_2Ir(dipba)$ [18]. We have previously demonstrated the direct electron injection and exciton formation mechanism can improve EL efficiencies [12,15b]. In comparison with $Bepp_2$, CBP used in device III has a much lower LUMO level that can act as trapping sites for electrons. This electron trapping could reduce the EL performance of the corresponding devices also.

4. Conclusions

In summary, highly efficient PHOLEDs employing a classical beryllium metal–chelate complex $Bepp_2$ as a host material have been successfully developed. The $Bepp_2$-based devices exhibit significantly enhanced EL performance with low driving voltages and high EL efficiencies compared with the device that uses CBP as the host as well as those PHOLEDs reported in the literature that use fluorescent metal–chelate complexes at electron-transporting-type host material [1b,9]. The excellent EL performance of the $Bepp_2$-based devices is attributed to the well-matched energy levels of $Bepp_2$ with HT and ET (or HB) materials together with the efficient triplet energy transfer from $Bepp_2$ to the $(bzq)_2Ir(dipba)$ guest. This efficient transfer of triplet energy between $Bepp_2$/$(bzq)_2Ir(dipba)$ is especially important because our host/guest system of $Bepp_2$/$(bzq)_2Ir(dipba)$ show a much better EL performance than the systems based on $Bepp_2$ and other phosphorescence guests such as $Ir(ppy)_3$ [10]. These findings demonstrate that $Bepp_2$ is a promising host material to replace the commonly used CBP because of its higher EL efficiency and its relative high triplet energy (~2.6 eV). This high triplet energy should facilitate the development highly efficient PHOLEDs based on green-, orange- and red-phosphorescent guest emitters.

morphology for organic BHJ solar cells is where the lateral dimensions of the donor and acceptor domains correspond to roughly twice the exciton diffusion lengths while the domains form continuous pathways for electrons and holes along the current direction.

Various parameters such as: solvents [7,11,12], drying time of the active layer [13,14], techniques used for deposition [14], ratio between electron donor and electron acceptor materials [15] and the post-annealing [6] affect extensively the morphology and the performance of polymer BHJ solar cells. Due to large variation in material properties, an optimized processing recipe for one polymer:fullerene system cannot be extrapolated directly to another polymer:fullerene system. Generally, if the polymer:fullerene system is changed, the optimum processing conditions have to be determined again.

However, it has been shown that regardless of the polymer:fullerene system used, a nano-scale interpenetrating network of electron-donor and electron-acceptor is unquestionably a common feature that is required for an efficient BHJ cells [16].

Besides optimizing the aforementioned processing parameters to gain control of the nano-scale structure of polymer solar cells, several other approaches have also been used to fine tune the phase morphology of BHJ films with some success. These include the addition of processing additives to the blend of polymer:fullerene to enhance the phase separation between the two materials [17], and the vertical modulation of the nano-scale morphology by modifying the distribution of donors and acceptors to make the BHJ layers richer in donors and acceptors near the anode and the cathode respectively [18].

Recently, poly(2,7-carbazole) derivatives have gained momentum as a class of promising alternative materials to poly(3-hexylthiophene) (P3HT) in organic solar cell applications. Among them, poly[N-9″-hepta-decanyl-2,7-carbazole-alt-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)] (PCDTBT) has a relatively deeper highest occupied molecular orbital (HOMO) of 5.45 eV compared to the HOMO of 5.1 eV of the P3HT. As a result, a high open circuit voltage (V_{oc}) of 0.9 V was reached in PCDTBT:fullerene devices [5]. In addition, the HOMO level of the PCDTBT is below the air oxidation threshold of 5.27 eV, which ensures better air-stability [19]. Park et al. reported a power conversion efficiency (PCE) of 6.1% on devices with an active area of 0.127 cm^2 prepared by spin-coating a dichlorobenzene solution of PCDTBT:$PC_{70}BM$ (1:4) as the active layer, and a thin TiOx layer as an optical spacer [7]. We demonstrated the importance of optical interference in PCDTBT/$PC_{70}BM$ device optimization and the need to consider the whole layer stack as a system in optical design, and obtained a PCE of 5.7% on cells with an active area of 1.0 cm^2. However, efforts to further improve the device efficiency were hampered by the fact that PCDTBT is an amorphous polymer, and responds poorly to thermal or solvent annealing, and to the use of common additives.

In this paper, we report the effect of processing conditions on the performance of PCDTBT:$PC_{70}BM$ based cells, and the fine tuning of the nano-scale morphology of PCDTBT:$PC_{70}BM$ BHJ active layers by using a mixed solvent. In the first part of the experiment, the active layers with different PCDTBT:$PC_{70}BM$ ratios were spin cast using two solvents: chloroform (CF) and 1,2-dichlorobenzene (ODCB). These solvents were chosen primarily due to the good solubility of PCDTBT and $PC_{70}BM$ in them. However, as chloroform and 1,2-dichlorobenzene have respectively a low (60 °C) and a high (178 °C) boiling point, the PCDTBT:$PC_{70}BM$ films prepared using CF or ODCB exhibit very different morphologies, possibly due to the slow and fast evaporation rate of solvents. These observations are correlated to the organic field effect transistor (OFET) transport measurements to explain the variations in photovoltaic (PV) performance. The electron mobility in the BHJ films prepared with ODCB is very close to that in pure $PC_{70}BM$ film, and the hole mobility is close to that in pure PCDTBT film, indicating the formation of a more or less continuous donor and acceptor network. As a result, the devices prepared using ODCB show better overall photovoltaic performance than the ones prepared using CF.

For the second part of the experiment, the nano-scale morphology of the PCDTBT:$PC_{70}BM$ BHJ film was further tuned by using a mixed solvent of chloroform and 1,2-dichlorbenzene. At a CF:ODCB ratio of 50%:50%, a high PCE of 6.1% was achieved on PCDTBT:$PC_{70}BM$ (1:3) devices with an active area of 1 cm^2, under AM 1.5 G irradiation of 100 mW/cm^2, where an optimal phase separation led to low exciton recombination rate and the highest short-circuit current density. This PCE, obtained without using an optical spacer and antireflective coating on the glass, approaches the theoretical limit of 6.5% as estimated from the Scharber diagram [20,21].

2. Experimental

Pre-patterned indium tin oxide (ITO)-coated glass slides, purchased from Luminescence Technology Corp., were used as substrates. The sheet resistance and thickness of the ITO are 12 Ω/sq and 150 nm, respectively. The ITO substrates were first cleaned with detergent, ultrasonicated in acetone and isopropyl alcohol for 15 min, and dried in an oven at 120 °C. UV-ozone treatment was then performed for 15 min. A film of poly(ethylene dioxythiophene) (PEDOT:PSS-Baytron® P) was spin cast on top of the ITO substrates and was dried for 15 min at 140 °C. Afterwards, chloroform and 1,2-dichlorobenzene solutions of PCDTBT:$PC_{70}BM$ with different weight ratios (1:2, 1:3, 1:4) were spin cast in a nitrogen-filled glove-box, onto the PEDOT:PSS film to form the active layer. The thickness of the PEDOT:PSS layer (30 nm) and the active layer (80 nm) were optimized in our previous work [5]. Finally, a bilayer cathode consisting of 100 nm Al on top of 2 nm LiF was thermally evaporated through a shadow mask on the active layer to form cells with an active area of 1 cm^2. More than 70 devices cast from CF, ODCB and a mixture of CF and ODCB in different ratios were fabricated and characterized.

The photovoltaic parameters were extracted from the current–voltage (J–V) characteristics measured in air with a Keithley 2400 Digital SourceMeter and the photocurrent was generated under AM 1.5 G irradiation of 100 mW/cm^2 from a ScienceTech SS 500 W solar simulator. The light intensity was adjusted using a calibrated Si photodiode with a KG-5 filter purchased from PV Measurements, Inc.

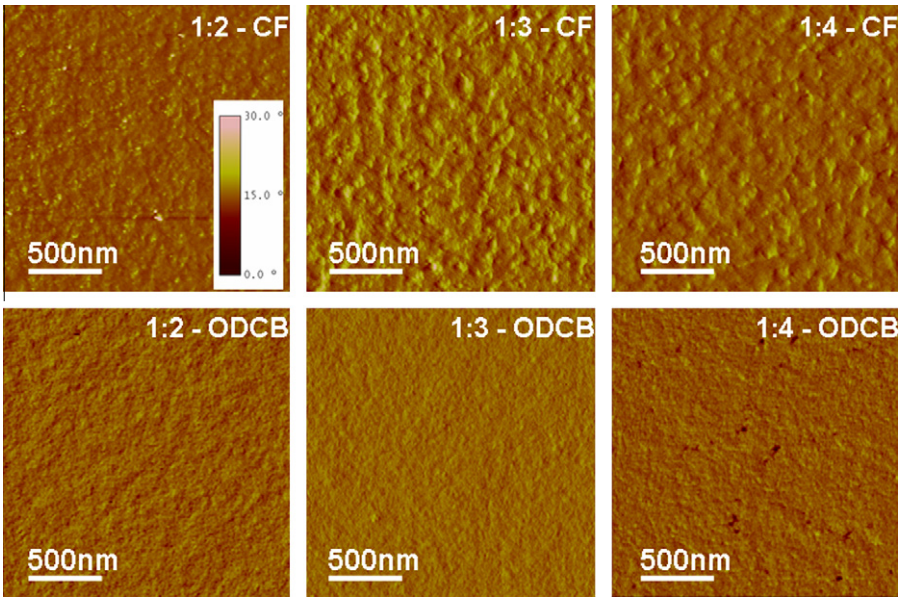

Fig. 1. Tapping-mode atomic force microscopy images of PCDTBT:$PC_{70}BM$ films cast from chloroform and 1,2-dichlorobenzene with different PCDTBT:$PC_{70}BM$ weight ratios on PEDOT:PSS layer.

The thickness of the polymer films were measured by a Dektak profilometer.

For OFET measurement, a heavily doped n-Si wafer with an overlayer of SiO_2 (230 nm, Ci = 15nF/cm^2) was used as a substrate. With bottom contact configuration, sputtered gold films were used as Source and Drain electrodes. An interdigitated layout was used for the OFET where channel length and width are 20 μm and 10 mm, respectively. PCDTBT:$PC_{70}BM$ solutions, like the PV devices, were spin cast to cover the Source and Drain electrodes.

The hole and the electron mobilities were deduced from the saturation regime of the *J–V* characteristics, which were performed with a computer-controlled semiconductor parameter analyzer (HP4145A).

3. Results and discussion

Fig. 1 displays the surface topography, investigated by the atomic force microscopy (AFM), of PCDTBT:$PC_{70}BM$ films with various weight ratios, cast from CF and ODCB solutions on the PEDOT:PSS layer. The PV parameters of corresponding devices are shown in Table 1.

The ODCB-films exhibit a smooth surface and small domains, while the CF-films exhibit a structured surface with large domains. Surface roughness values measured for 1:2, 1:3 and 1:4 PCDBTB:$PC_{70}BM$ weight ratios were: ~1.17, 1.21 and 1.22 nm for CF-films; ~0.89, 0.90 and 0.86 nm for ODCB-films, respectively. The increase of domains size with increasing ratio of $PC_{70}BM$ in the CF-films is presumably the reason for the decrease of the short circuit current density in CF-devices (see Table 1); as large domains in BHJ layer not only increase the distance for excitons to reach an heterojunction, but also reduce the interfaces between the polymer and the fullerene, leading to a low exciton dissociation efficiency. The short-circuit current density (J_{sc}) of ODCB-devices remains constant (around 10.7 mA/cm^2) for different PCDBTB:$PC_{70}BM$ ratios. This trend has also been observed with the J_{sc} values calculated from the external quantum efficiency (EQE) data (Fig. 2). The J_{sc} values calculated from the EQE data of CF-devices with 1:2, 1:3 and 1:4 ratios are 10.3, 9.8, and 8.9 mA/cm^2, respectively. For ODCB-devices, the values are 10.2, 10.3, and 10.2 mA/cm^2. These values are about 3.7–5.5% lower than those obtained from *J–V* characteristics, indicating a possible spectral mismatch within this error range.

Table 1
Photovoltaic parameters and OFET mobility of devices based on PCDTBT:$PC_{70}BM$ active layer cast from chloroform and 1,2-dichlorobenzene with different PCDTBT:$PC_{70}BM$ weight ratios.

Active layer spun-cast from	Ratio *D*:*A*	J_{sc} (mA/cm^2)	V_{oc} (V)	FF (%)	η (%)	μ_H	μ_E	μ_E/μ_H
						(*10^{-4} cm^2/V s)		
Chloroform	1:2	10.7	0.91	59	5.7	5.84	1.75	0.30
	1:3	10.3	0.89	61	5.6	5.51	3.70	0.67
	1:4	9.3	0.88	61	5.0	6.11	5.44	0.89
1,2-Dichlorobenzene	1:2	10.7	0.91	58	5.6	1.98	9.27	4.68
	1:3	10.8	0.89	62	6.0	1.92	20.1	10.5
	1:4	10.8	0.88	63	6.0	1.99	29.1	14.6

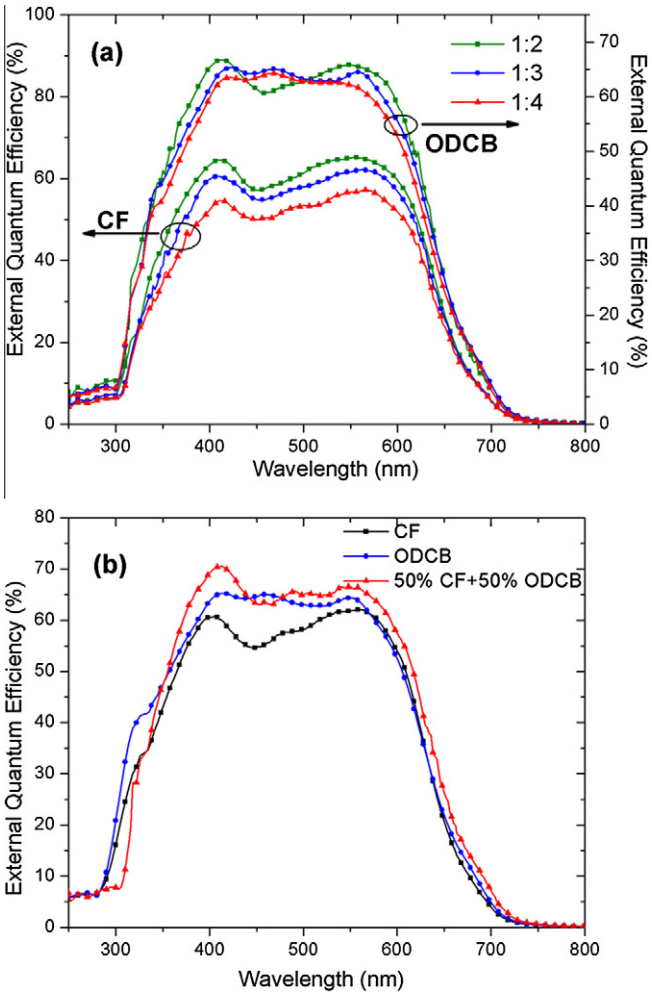

Fig. 2. Comparison of external quantum efficiencies of PCDTBT:$PC_{70}BM$ devices cast from chloroform and 1,2-dichlorobenzene with different weight ratios (a) and mixed CF:ODCB solvent for a PCDTBT:$PC_{70}BM$ weight ratio of 1:3 (b).

It is worth noting that at the same PCDTBT:$PC_{70}BM$ ratio there is no difference in the total light absorption by the devices prepared by CF or ODCB, as revealed by small angle reflectance (data not shown) measurement. Therefore the difference in their J_{sc} at the same PCDTBT:$PC_{70}BM$ ratio for the CF and ODCB-devices is not caused by light absorption.

A small reduction in V_{oc} was observed with the increase of $PC_{70}BM$ concentration in both CF and ODCB-devices. This trend was previously observed in other polymer:fullerene system devices [22,23]. The exact reason for the reduction in V_{oc} is not clear. It might be caused by the increase in leakage current with increasing $PC_{70}BM$ concentration [24]; or by the energetic losses of the dissociated charges due to the band bending at the electrodes [25], which is probably affected by $PC_{70}BM$ concentration. Another possibility is that at higher PCBM concentration the charge transfer state may shift to a lower energy as a result of increased permittivity, causing a reduction in V_{oc}, as shown in polyfluorene copolymer/fullerene devices [23].

We attempt to correlate the nano-scale morphology of the active layers and the PV parameters of the devices to the charge carrier mobility data measured from OFET mobility tests, shown in Table 1. The electron and hole mobilities are assigned to the electron acceptor ($PC_{70}BM$) and electron donor (PCDTBT) materials respectively.

Three observations ensue from OFET data. Firstly the electron mobility increases with the ratio of $PC_{70}BM$ for both CF- and ODCB-films. This illustrates an enhanced electron transport in the BHJ films due to improved connections between $PC_{70}BM$ molecules, leading to a higher fill factor in PV devices. But the ODCB-films exhibit much finer domain structure and relatively higher electron mobility, and at PCDTBT:$PC_{70}BM$ ratio of 1:4, the electron mobility approaches the value in pure $PC_{70}BM$ film (3.5×10^{-3} cm^2/V s), demonstrating a much better connection between $PC_{70}BM$ molecules and domains, as compared with the CF-films. Secondly, the hole mobility remains approximately constant at different ratios of PCDTBT:$PC_{70}BM$, proving that even with high concentration of $PC_{70}BM$, a continuous network of PCDTBT is maintained. Thirdly, the domain size plays a critical role in determining the exciton dissociation efficiency, and thus the short circuit current. As shown by the device prepared from CF solution at a PCDTBT:$PC_{70}BM$ weight ratio of 1:4, although the electron mobility is much

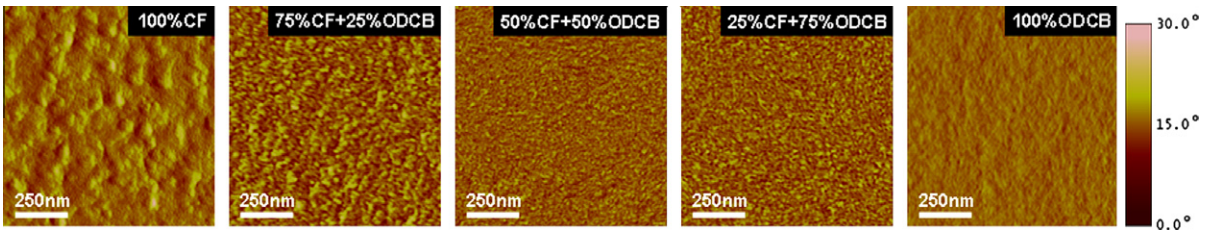

Fig. 3. Comparison of atomic force microscopy images of PCDTBT:$PC_{70}BM$ (weight ratio 1:3) spin cast from various CF:ODCB ratios on PEDOT:PSS layer.

Table 2
Photovoltaic parameters of devices based on PCDTBT:$PC_{70}BM$ (1:3) active layer cast from chloroform, 1,2-dichlorobenzene, and a mixture of chloroform and 1,2-dichlorobenzene with different ratios.

Active layer spun-cast from	J_{sc} (from EQE) (mA/cm^2)	V_{oc} (V)	FF (%)	η (%)
CF	10.3 (9.8)	0.89	61	5.6
75% CF + 25% ODCB	10.5 (10.3)	0.90	59	5.6
50% CF + 50% ODCB	11.0 (10.7)	0.91	61	6.1
25% CF + 75% ODCB	11.0 (10.8)	0.89	59	5.8
ODCB	10.7 (10.3)	0.89	62	5.9

higher as compared to the devices prepared at 1:2 and 1:3 ratios, the device has the lowest J_{sc} (~9.3 m mA/cm^2) and overall low performance due to the large $PC_{70}BM$ domains. This demonstrates the need of maintaining proper domain size when trying to improve the charge carrier mobilities in BHJ films for high performance.

Fig. 3 shows the AFM images of PCDTBT:$PC_{70}BM$ films (weight ratio 1:3) prepared using mixed CF and ODCB of different ratios (100%:0%, 75%:25%, 50%:50%, 25%:75%, 0%:100%). The domains size becomes progressively finer with increasing ODCB ratio. The corresponding short circuit current densities are 10.3, 10.5, 11.0, 11.0 and 10.7 mA/cm^2 respectively (see Table 2). This trend has also been observed for the short-circuit current densities calculated from the EQE data. Fig. 2b shows the EQE spectra of devices cast from CF, ODCB, and mixed CF and ODCB at 50%:50% ratio.

The J_{sc} is higher for devices cast from 50%:50% and 25%:75% solutions, corresponding presumably to the optimal domain sizes. Larger domains, as in the case of devices cast from 100%:0%, 75%:25% solutions, lead to a larger exciton recombination rate. The domain sizes in films cast from pure ODCB are probably smaller than the exciton diffusion length. Although a small domain structure is very efficient for exciton dissociation, it is not very effective in separating the charge transfer complex and transporting free charge carriers. The highest PCE of 6.1% was obtained from PCDTBT:$PC_{70}BM$ (1:3) devices prepared using a CF:ODCB mixing ratio of 50%:50%, with J_{sc} of 11.0 mA/cm^2, V_{oc} of 0.91 V, and a fill factor of 61% (Table 2). This improvement is attributed to the optimized nano-scale morphology for efficient exciton dissociation and charge transport.

The films prepared using different CF:ODCB ratios were also investigated by using transmission electron microscopy (TEM). The images are shown in Fig. 4. The films cast from mixed CF:ODCB solvent at ratios of 50%:50%, 25%:75% present similar morphology to the film cast from pure ODCB, with fine and indistinguishable domain structure. But domains are clearly discerned in films cast from pure CF solution and they probably correspond to the domains in the AFM images. From the energy dispersive X-ray (EDX) measurement, no sulfur signal was detected from these domains, indicating these are $PC_{70}BM$-rich domains, because PCDTBT contains sulfur and $PC_{70}BM$ does not. This clarifies the AFM results (Fig. 1), where the domain size becomes larger with increasing $PC_{70}BM$ ratio in the blend film.

We believe that the domains are discernable in 100%:0%, 75%:25% films because of their size (>100 nm) is larger than the thickness of the film (~80 nm). When the size becomes smaller than the film thickness (probably the case in 50%:50%, 25%:75%, 0%:100% films), the domains vertically overlap and are hardly distinguishable by transmission electron microscopy.

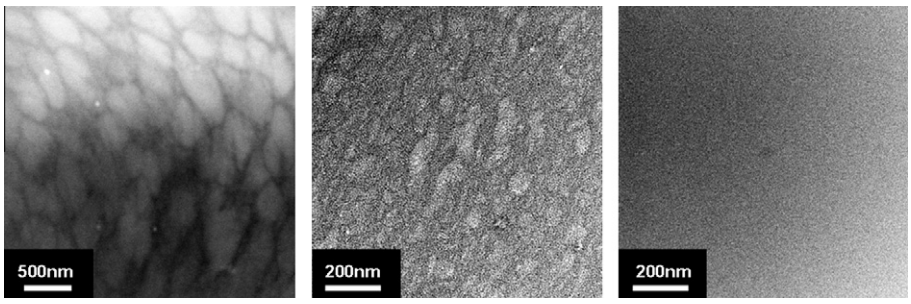

Fig. 4. Transmission electron microscopy images of PCDTBT:$PC_{70}BM$ (weight ratio 1:3) spin cast from 100% CF (left), 75% CF:25% ODCB (center), 100% ODCB (right) on carbon-coated copper TEM grids.

4. Conclusion

In conclusion, PCDTBT:$PC_{70}BM$ active layer spin cast from chloroform solution shows a structured surface with large domains as compared to the films spin cast from 1,2-dichlorobenzene solution. The high values of electron mobility in 1,2-dichlorobenzene devices prove that the 1,2-dichlorobenzene films ensure a better connection between $PC_{70}BM$ domains. The domain size in PCDTBT:$PC_{70}BM$ films can be further tuned by using a mixture of chloroform and 1,2-dichlorobenzene with different ratios. At a CF:ODCB mixing ratio of 50%:50%, a PCE of 6.1% was obtained from PCDTBT:$PC_{70}BM$ (1:3) devices with an active area of 1 cm^2.

Like the 'standard' OFET, the device current – and therefore light emission – can be controlled through suitable application of gate and drain voltages, i.e. addressing on a 2D plane. The combination of addressability and efficient light emission into a single device could be advantageous in a display application, but despite such technological potential, the LH-FEBT remains relatively unexplored and much can be done to better understand them. In particular, their current–voltage curves (which are closely tied to light emission) have a distinctive shape that clearly depends on device dimensions and the properties of its constituent semiconductors, and so we explore how these parameters relate to the curves and see if simple rules could be found.

2. Device fabrication

Organic semiconductors combining high mobility with light emission are few and far between. In this study on the current–voltage characteristics of LH-FEBTs, high mobilities took precedence over light emission, and an LH-FEBT based on pentacene (p-type) and zinc oxide (n-type) was studied. The device was fabricated on n^+-Si/SiO_2 (200 nm) substrates by first depositing ZnO by thermal decomposition of zinc acetate precursor [13], which resulted in a roughly 10 nm film. This process was repeated another five times to ensure good ZnO coverage. One half of the ZnO film was then protected with adhesive tape while the exposed half was etched away in dilute acetic acid. The tape was then removed and pentacene was deposited on the bare half of the substrate by thermal evaporation through a shadow mask, which resulted in a slight overlap of pentacene on top of the ZnO. Another shadow mask was aligned onto the sample for deposition of the gold source and drain contacts via evaporation. Fig. 1 (top) shows the schematic device structure.

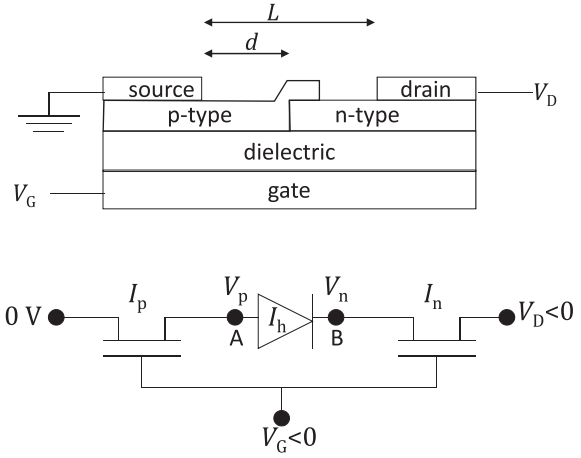

Fig. 1. (Top) Schematic diagram of a pentacene/ZnO LH-FEBT, showing the heterojunction within the transistor channel. L is the total transistor length, and d defines the location of the heterojunction. (Below) An equivalent circuit model of an LH-FEBT consisting of a diode sandwiched between a p-type transistor and an n-type transistor. Points A and B represent virtual contacts between the transistors and the diode, which are at voltages V_p and V_n, respectively. The p-type transistor current depends on V_p and V_G, the diode current depends on $(V_p - V_n)$, and the n-type transistor current depends on V_n, V_D and V_G.

3. Experimental current–voltage curves

Fig. 2A shows the current–drain voltage I_D–V_D curves of the pentacene/ZnO LH-FEBT, as measured by a Keithley 4200 semiconductor analyser, at gate voltages ranging from −10 to −70 V in 10 V steps. Using the curve with a gate voltage of −20 V as an example, the current was low at low drain voltages due to a discontinuous hole accumulation layer. As the drain voltage increased, the hole accumulation layer became continuous and conductivity rose, but the current eventually saturated when the electron accumulation layer was 'pinched off'. Fig. 2B shows the current–gate voltage I_D–V_G curves of the device at drain voltages of −10 to −70 V. These curves all exhibit remarkably similar asymmetric bell-shaped profiles: starting at a low current near 0 V, the current 'turns on' at a gate voltage of roughly −10 V, then increases rapidly to a maximum before attenuating more gradually to zero at a 'turn-off' voltage that depends on the drain voltage. As the drain voltage V_D increases (in magnitude), the peaks increase while also shifting gradually to the right. The I_D–V_G curves are visually more distinctive than the I_D–V_D curves, and the following analysis will therefore address the key features of the I_D–V_G curves: the 'turn-on' and 'turn-off' voltages, the slope before and after the peak, and the peak itself.

4. Equivalent circuit model

Analysis of the current–gate voltage curves of the pentacene/ZnO LH-FEBT is based on an equivalent circuit model, shown in Fig. 1 (bottom). The source contact of the LH-FEBT is grounded, and the drain contact held at a negative drain voltage V_D. The model treats the heterojunction as a diode with 'virtual' contacts at points A and B, with voltages of V_p and V_n, respectively. The diode is thus forward-biased by $\Delta V = (V_p - V_n)$. The virtual contact A also acts as the virtual drain electrode for the p-type transistor on the left of the heterojunction, while virtual contact B acts as the virtual source electrode for the n-type transistor on the right. Since the p- and n-type semiconductors are deposited on a single gate/dielectric substrate, the two transistors must share a gate voltage V_G.

4.1. Mathematical representation

A well-established model (based on the gradual channel approximation) for the current–voltage behaviour of thin film transistors such as OFETs is:

$$I_D = \frac{CW\mu}{L}\left(V_G - V_T - \frac{V_D}{2}\right)V_D \quad (1)$$

in the linear, or non-saturation, regime, where I_D is the current flowing from source to drain, C is the capacitance per unit area of the gate dielectric layer, W is the channel width, μ is the carrier mobility, L is channel length from source to drain, and V_T is the threshold voltage. When the drain voltage increases to $(V_G - V_T)$ and beyond, the vertical field arising from the gate ceases to support a

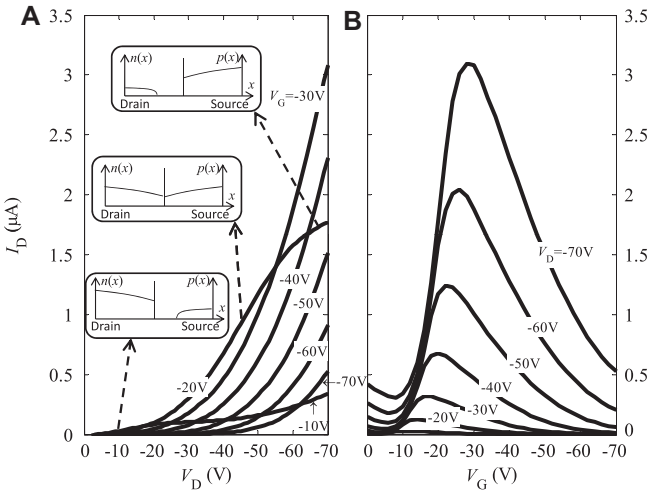

Fig. 2. (A) Current–drain voltage characteristics of a pentacene/ZnO LH-FEBT with gate voltages of −10 to −70 V in 10 V steps. At V_G = −20 V, the output curve began at a low current due to a discontinuous p-channel even though the n-channel is complete. As V_D increased, the p-channel grew to reach the interface so that a complete conduction channel formed and conductivity rose. When V_D increased further, the n-channel became pinched-off and conductivity fell, leading to current saturation. (B) Current–gate voltage characteristics of the same device with drain voltages of −10 to −70 V in 10 V steps. The curves all possess the same asymmetric bell-shaped profile.

continuous conduction channel, and the transistor operates in the saturation regime:

$$I_D = \frac{CW\mu}{2L}(V_G - V_T)^2 \tag{2}$$

We now apply Eqs. (1) and (2) to the model LH-FEBT. Referring to Fig. 1, the source contact of the left-hand-side p-type transistor is at 0 V, while the virtual negative contact is at V_p. Substituting into Eqs. (1) and (2) yields the current I_p in the p-type virtual transistor:

$$I_p = \begin{cases} \frac{CW\mu_p}{d}\left(V_G - V_{Tp} - \frac{V_p}{2}\right)V_p, & V_G - V_{Tp} < V_p \leqslant 0 \\ \frac{CW\mu_p}{2d}(V_G - V_{Tp})^2, & V_p \leqslant V_G - V_{Tp} \leqslant 0 \\ 0, & 0 < V_G - V_{Tp} \end{cases} \tag{3}$$

where μ_p is the hole mobility, V_{Tp} is the threshold voltage for the p-type virtual transistor and d is its channel length, taken to be the length between the positive contact and the heterojunction. Here we have assumed the length of the heterojunction diode to be negligibly small relative to the channel length. For now, we defer discussion of the diode to a later part of the manuscript. From top to bottom, the inequality conditions correspond to the linear regime, the saturation regime and when the transistor is in an 'off' state, respectively.

In the case of the virtual n-type transistor on the right of the heterojunction (see Fig. 1), both the gate voltage V_G and the voltage V_n at the virtual positive contact must be shifted relative to the drain voltage V_D before substitution into Eqs. (1) and (2). This yields the current in the n-type virtual transistor:

$$I_n = \begin{cases} \frac{CW\mu_n}{L-d}\left(V_G - V_D - V_{Tn} - \frac{V_n - V_D}{2}\right)(V_n - V_D), & V_D \leqslant V_n < V_G - V_{Tn} \\ \frac{CW\mu_n}{2(L-d)}(V_G - V_D - V_{Tn})^2, & V_D \leqslant V_G - V_{Tn} \leqslant V_n \\ 0, & V_G - V_{Tn} < V_D \end{cases} \tag{4}$$

where μ_n is the electron mobility and V_{Tn} is the threshold voltage of the n-type virtual transistor.

Illustrative plots of Eqs. (3) and (4) are shown in Fig. 3 for a fixed drain voltage V_D, with Fig. 3A–C each corresponding to a different gate voltage V_G. Fig. 3A corresponds to a regime when V_G is low (close to zero). The I_p and I_n curves are functions of the floating voltages V_p and V_n respectively, and the currents flowing through the two transistors, $I_p(V_p)$ and $I_n(V_n)$, must also equal the diode current $I_h(V_p–V_n)$. Without detailed knowledge of the current–voltage characteristics of the heterojunction diode, a possible operating point of the device can be represented by the dotted tie-line in Fig. 3A, which specifies the current as well as both floating voltages V_p and V_n (crosses).

4.2. Analysis of peak voltage and other key features

Due to saturation behaviour of the p-type transistor, the length of the tie-line, which is also the diode voltage drop, does not affect its vertical position (i.e. device current) appreciably. One can then infer that in the low V_G regime, the LH-FEBT current is effectively the p-type transistor saturation current. Therefore from Eq. (3), the 'turn-on' voltage in the current–gate voltage curves must be the p-type threshold voltage V_{Tp}, while the slope in the low V_G regime is proportional to μ_p/d (see Supplementary information, for more detail).

Fig. 3B shows device operation at an increased V_G while keeping V_D constant. If we make the reasonable assumption that the diode voltage drop (i.e. length of the tie-line) changes negligibly over small current changes, then it becomes clear that Fig. 3B represents device operation at the peak, since deviation from this particular gate voltage in either direction leads to the tie-line moving downwards. At this point, the saturation currents of both virtual transistors equate, but the actual LH-FEBT current still depends

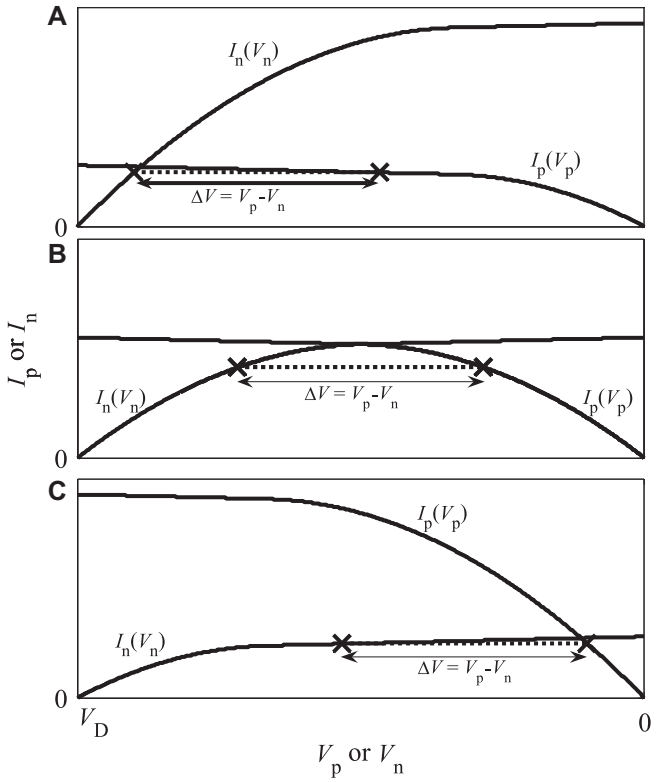

Fig. 3. (A) A graphical representation of Eqs. (3) and (4), showing the current $I_p(V_p)$ and $I_n(V_n)$ in each virtual transistor when V_G is small. The operating point can be represented by the dotted tie-line, which specifies the floating voltages V_p and V_n as well as the common current value. As V_G increases, $I_p(V_p)$ will increase in magnitude, leading to current increase. (B) When the device is operating at peak current, V_G must be at a value where both virtual transistors have equal saturation currents, regardless of ΔV. (C) A representation of $I_p(V_p)$ and $I_n(V_n)$ when V_G is large. As V_G increases further, $I_n(V_n)$ will decrease in magnitude, leading to attenuation in current.

on V_p–V_n, and so the peak current cannot be calculated without knowledge of the diode characteristics. We can still, however, calculate the *voltage* position of the peak $V_{G,peak}$ by equating the saturation currents from Eqs. (3) and (4):

$$\frac{CW\mu_p}{2d}\left(V_{G,peak} - V_{Tp}\right)^2 = \frac{CW\mu_n}{2(L-d)}\left(V_{G,peak} - V_D - V_{Tn}\right)^2 \tag{5}$$

Solving for $V_{G,peak}$ gives:

$$V_{G,peak} = \frac{\sqrt{\frac{\mu_p}{d}}V_{Tp} + \sqrt{\frac{\mu_n}{L-d}}(V_{Tn} + V_D)}{\sqrt{\frac{\mu_p}{d}} + \sqrt{\frac{\mu_n}{L-d}}} \tag{6}$$

In Fig. 3C, the gate voltage has been increased further still. Following an argument similar to that accompanying Fig. 3A, the LH-FEBT current in the high V_G regime is effectively the n-type transistor saturation current. This leads us to deduce that, in the high V_G regime of the I_D–V_G curves, the 'turn-off' voltage is $V_D + V_{Tn}$, and the slope of the curve is proportional to $\mu_n/(L-d)$.

4.3. Comparison with experiment

To verify our analysis, unipolar pentacene OFETs and ZnO FETs were used to estimate the hole and electron mobility of each material (see Supplementary information). The pentacene films have a hole mobility of about 0.16 cm^2/V s with a threshold voltage of −17 V, and the ZnO film has an electron mobility of about 0.051 cm^2/V s with a threshold voltage of −23 V. The heterojunction of the LH-FEBT is closer to the source contact such that d = 25 μm, with L = 200 μm. Substituting these values into Eq. (6), the predicted peak voltage when V_D = −70 V is $V_{G,peak}$ = −29 V, which is remarkably close to the corresponding experimental value of −28 V (see Fig. 2B).

The 'turn-on' voltage is predicted to be −17 V, which is an overestimate of the actual, which appears to be around −10 V. The 'turn-on' voltage has been partially obscured by a background current, which is likely due to current flowing to the gate. Possible explanations for this current include the presence of pinholes in the dielectric film, and a lateral field extending outside the channel between the source and drain, leading to spreading of current. Because the n-type transistor has a *negative* threshold voltage (i.e. depletion mode), the 'turn-off' voltages for V_D = −70, −60 and −50 V lie beyond the V-axis of Fig. 2B. However, for V_D = −40 V, the 'turn-off' voltage is calculated as $V_D + V_{Tn} = -63$ V, which again agrees well with the data.

Lastly, by comparing the values μ_p/d = 6.4 cm/V s and $\mu_p/(L-d)$ = 0.29 cm/V s, we expect the I_D–V_G curves to be

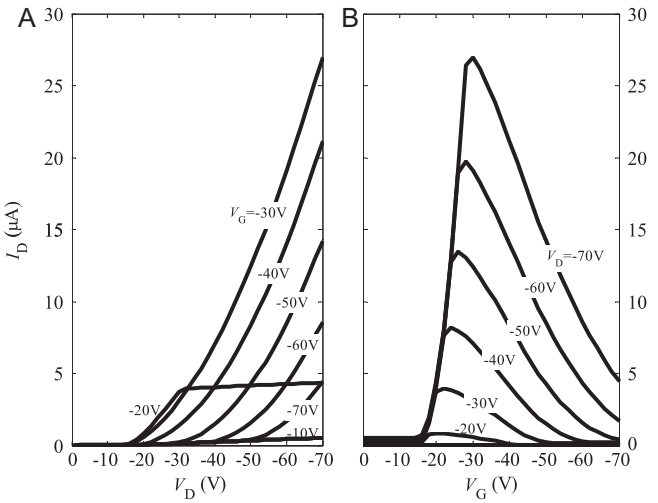

Fig. 4. (A) Simulated current–drain voltage curves for a pentacene/ZnO LH-FEBT based on Eqs. (3), (4) and (7), with gate voltages of −10 to −70 V in 10 V steps. (B) Simulated current–gate voltage curves with drain voltages of −10 to −70 V in 10 V steps. The curves in both subfigures clearly reproduce the general features seen in the experimental data (Figs. 2A and B).

steep at low gate voltages but gentle at high gate voltages, which is indeed the case observed in Fig. 2B.

5. Numerical solution

The arrangement of energy levels and band-bending effects for organic–inorganic interfaces – and by extension, heterojunction charge transport – are in general unclear. A possible mechanism for the injection of carriers across the LH-FEBT heterojunction is Schottky emission [14,15], which has a current density given by:

$$J_s = \frac{4\pi m_e e}{h^3}(kT)^2 \exp\left[\frac{1}{kT}\left(-\phi + \sqrt{\frac{e^3E}{4\pi\epsilon_0}}\right)\right] \quad (7)$$

where m_e is the electronic mass, h is Planck's constant, k is Boltzmann's constant, T is the temperature, ϵ_0 is the vacuum permittivity and E is the electric field strength. ϕ is the offset between the appropriate energy levels of the two semiconductors when injecting carriers from one to the other. Each semiconductor pair has two energy level offsets, but because of the exponential nature of Eq. (7), the larger of the two offsets can be considered negligible, i.e. we assume, in this case, that electrons are injected from ZnO into pentacene (conduction band-LUMO offset is roughly 1.4 eV), whereas hole injection from pentacene into ZnO occurs at a comparatively negligible rate (HOMO-valence band offset is roughly 2.6 eV).

Eqs. (3), (4) and (7) form a system of equations which can be solved to obtain full current–voltage characteristics. However, Eq. (7) requires a conduction channel cross-sectional area, and the electric field strength E at the heterojunction. The conducting channel in FETs is a very thin layer at the semiconductor/dielectric interface; we therefore assumed its thickness as 1 nm. For simplicity, we also made the approximation $E = (V_p - V_n)/l$, where l is a constant length over which the potential drops, which assumes a constant field at the heterojunction over a region of length l. Recent surface potential measurements on a P3HT:NTCDI LH-FEBT [2] showed the region of potential drop at the heterojunction to be smaller than the 100 nm resolution of the instrument. Therefore in our calculations, we used a value of l = 10 nm.

The numerical solution to the system of Eqs. (3), (4) and (7) was computed for the pentacene/ZnO LH-FEBT, using a simple self-written iterative procedure. The calculated curves are shown in Fig. 4A and B, and they clearly reproduce the features seen in experimental data (Fig. 2A and B). In particular, the calculated I_D–V_G curves bear close resemblance to the skewed bell-shaped profile seen in Fig. 2B. De Vusser et al. used the Silvaco Atlas software to model an LH-FEBT. Their model was two-dimensional and allowed for slightly ambipolar transport in the constituent semiconductors; however, they did not consider energy level offsets at the heterojunction. Despite these differences, the simulated I_D–V_D curves from their group appear similar to those reported here.

To validate the applicability of our analysis, we have simulated LH-FEBTs based on other semiconductor combinations such as pentacene/PTCDI, DH-BTZ-4T/NTCDA, etc., and found similar levels of agreement between experimental and simulated curves. However, we found that overestimation of device peak current (by up to a factor of about 10, as is the case of pentacene/ZnO) was a common discrepancy. To address this discrepancy, mobility values were obtained from the low-current region (reflective of the LH-FEBT peak current) of the unipolar FET I_D–V_G curves, which are lower than those reported under Section 4.3. However, these lower mobilities only account for less than half of the discrepancy. Increasing the length of the diode region over which the potential drops resulted in reduction of the simulated current, but before it could

reach experimental levels, the I_D–V_G curves took on a semi-circular appearance and lost resemblance to the experimental curves. The simulated curves were also found to be virtually independent of the conducting channel thickness, even when a value of 100 nm was used.

6. Conclusion

Lateral heterostructure field-effect bipolar transistors (LH-FEBTs) are still relatively new to the field of organic electronics, and their properties remain largely unexplored. Using a simple equivalent circuit model of an LH-FEBT, we have shown the origins of key features in the current–voltage curves: the 'turn-on' and 'turn-off' voltages, the slopes, and the peak. We recognise that there are limitations in the model, but despite these, we have found simple rules relating these features to the mobilities and threshold voltages of the constituent semiconductors – rules that will surely be useful in the design of LH-FEBTs in potential applications. A summary of these rules and their applications are as follows:

1. The turn-on voltage of an LH-FEBT is determined solely by the threshold voltage of the p-type semiconductor. To operate the device at the lowest voltages possible, we therefore need to reduce the p-type threshold voltage.
2. The slope of the I_D–V_G curve between its turn-on and peak voltages depends mostly on the mobility of the p-type semiconductor. In an application requiring good control of the current using the gate voltage, such as for displays, a gentle slope is sought. In this case, μ_h has to be lower than μ_e such that the peak voltage is pushed further away from the turn-on voltage.
3. For a pair of p- and n-type semiconductors whose mobilities and threshold voltages are known, we can then use the peak voltage Eq. (6) to determine the necessary operating range (to switch from 'off' to peak) of the LH-FEBT.

of mechanical flexibility, device reliability and control of the degradation processes. In addition it also offers original potentials to regenerate or to renew the active parts of the devices without disposing of the whole device simply by injecting a fresh batch of liquid electronic materials, an aspect which is impossible to achieve with polymer and small molecules thin films obtained by solution or evaporation processing. The demonstration of an organic rewritable nonvolatile bistable memory based on a liquid carbazole host is an important step towards the development of organic liquid optoelectronic devices.

2. Experimental

The silver nPs presented in Fig. 1b were synthesized at room temperature and in toluene by chemical reduction by hydrazine monohydrate of silver acetate mixed with dodecyl amine and decanoic acid [15]. After 15 min, the as-formed nPs were mixed with hexane thiol and extracted from the reaction media by centrifugation and redissolution in a blend of ethanol and chloroform. After repeating the extraction step several times, the resulting nPs of about 10 nm diameter were finally redispersed in pure chloroform. The absorption spectra of the EHCz layer and the silver nPs solution are shown in Fig. 1c and were measured using a UV–visible-near infrared scanning absorption spectro-photometer (Shimadzu UV-3100PC). Liquid carbazole is fully transparent in the visible and presents strong absorption features in the UV. The two peaks between 310 and 360 nm are characteristic of the carbazole monomer unit. The spectrum of the silver nPs shows an absorption peak centered at about 430 nm resulting from the surface plasmon excitation moderated by the Ag-thiol bonding. The concentration of silver nPs in chloroform solutions was determined based on the absorbance of the nPs solution and their molar extinction coefficient at 410 nm. Appropriate volumes of these stock solutions were then mixed with known volumes of EHCz. By neglecting the volumes of the coated nPs, once the chloroform had been evaporated the concentration of nPs in EHCz was calculated from the concentration of the stock solution and a straightforward volume ratio. Once blended, the low concentration of the silver nPs in the devices and the low absorption coefficients of the EHCz and indium tin oxide (ITO) in the visible, make the organic bistable liquid memory devices fabricated in this study nearly transparent, which can be of strong interest for practical electronic applications.

The schematic structure of the organic liquid bistable memory devices is shown in Fig. 2a. ITO glass substrates ($10\ \Omega/cm^2$) were patterned through standard etching techniques followed by ultrasound cleaning in pure water, 2-propanol, acetone and chloroform baths finalized by an UV-ozone treatment. Empty cells were prepared by clipping tightly the two ITO glass substrates together. The thickness of the sample was controlled using silica spheres with a diameter of 5 μm (Sekisui Chemical Ltd) and dispersed into

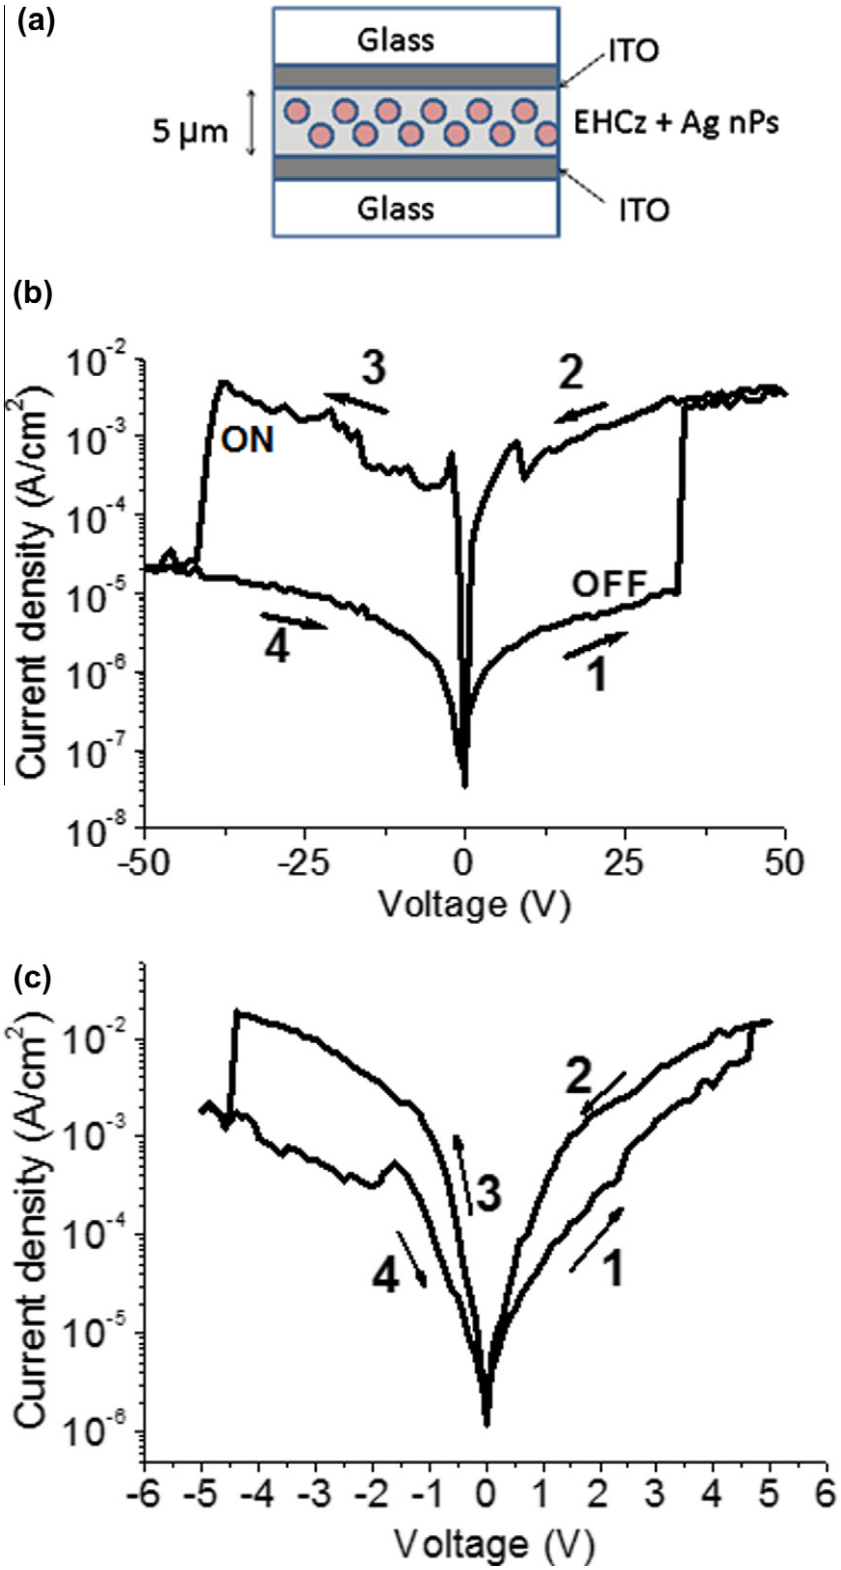

Fig. 2. (a) Schematic of the hybrid memory devices, (b) current density–voltage curve of the ITO/EHCz + Ag-nPs/ITO device fabricated with [Ag-nP] = 8.5×10^{-10} M. (c) current density–voltage curve of a device using [Ag-nP] = 8.5×10^{-9} M. The arrows indicate the voltage-scanning direction.

a silicon paste (Dow Corning). The top and bottom ITO electrodes were aligned perpendicularly to define an active area of 3×3 mm^2. Solution of silver nPs coated with hexanethiol ligands was prepared in chloroform at specific concentrations (8.5×10^{-10} and 8.5×10^{-9} M) and then mixed into 10 mg of the liquid carbazole host. Note that these concentrations lead to a mass ratio between the nPs and the organic host comparable to those used in a recent work on bistable memories based on a PVK/Ag-nPs colloidal film [16]. After evaporation of the residual solvent, the empty cells were filled with the liquid carbazole/nPs blends by capillarity. The current–voltage characteristics of the organic liquid bistable memories were measured using a picoammeter/voltage source unit (Keithley 6487) interfaced and controlled by a computer. A typical sweep speed of 3.5 V/s was used for all the measurements of the *I–V* characteristics to reduce the influence of this parameter on the hysteresis behavior and to allow meaningful comparison between devices. Noticeably the device fabrication and all the characterization were performed in air.

3. Results and discussion

A typical current density–voltage curve of the organic liquid bistable memory device is shown in Fig. 2b. The response shows a strong electrical hysteresis behavior which is essential for the operation of a bistable memory device. It can also be seen that the bistable behavior is nearly symmetric which is consistent with the symmetric structure of our devices. A very low current can be measured during the forward bias scan from 0 to 35 V where a very sharp increase in the current is observed. When the bias voltage is further increased above 38 ± 3 V, the sample exhibits a very high current density. The abrupt transition between the low and high conductance levels corresponds to the switching from the OFF state to the ON state of the memory device. The ratio of the conductivities associated with these two states in our liquid memory devices was found to be of the order of 2×10^2. The device shows a good stability in the ON state during the subsequent voltage scan from 50 to −40 V. At a reverse applied external bias of −40 V, the current suddenly drops and the high conductivity of the ON state is changed back to the low conductivity of the OFF state. The device is then stable in the OFF state during the scan from −50 to 0 V. No hysteresis is observed in samples which do not contain silver nPs, which indicates that the nPs play a key role on the bistability mechanism observed in this memory device. The nP concentration in the liquid EHCz has a strong impact on the hysteresis and the values of the current densities in both the ON and OFF states. The comparison of the current density–voltage curves displayed in Fig. 2b and c shows that an increase in the nP concentration leads to higher conductivity in both ON and OFF states, lower switching threshold voltage and lower ON/OFF ratio. This result suggests that the performance of these liquid memory devices could be further optimized. It is also worth noticing that the maximum applied electric field across our devices is on the order of 1×10^5 V/cm, which is lower than the fields previously used to measure the charge carrier mobilities in EHCz by the time-of-flight technique [11]. Thus, any heating effects generated when applying voltage up to 50 V on the charge transport properties and the characteristics of the devices can be neglected. In addition, whereas the present work used voltage values when compared with the literature, it should be mentioned that the applied electric field required for the transition between the OFF and ON states is nonetheless comparable with those reported in bistable thin film memories based on metallic nanoparticles blended into a polymer host all of which are of the order of 10^5 V/cm [6,16].

As shown in Fig. 3, the device exhibits an ohmic behavior in the OFF state and a space-charge limited current (SCLC) behavior in the ON state. The [Ag-nP] = 8.5×10^{-10} M device presents a current density, *J*, associated with the OFF state proportional to the applied voltage *V*, as expected when the current is injection limited and results from thermally generated free carriers [17]. The slope was found to be about $2.5 \pm 0.5 \times 10^{-7}$ Ω/cm. In the ON-state, the *J* and *V* average relationship is different, non-linear and can be better described by a $J \propto V^{1.8}$ law. This is consistent with a trap-free space charge limited conduction where trapping sites in the active layer are filled as the voltage is increased. This result strongly suggests that the memory effect in our devices is related to charge storage within the hexanethiol capped silver nPs which act as charge carrier trap centers [17,18]. The observation of different conduction mechanisms in the two states of the organic memory indicates that the electronic structure of the device is modified through the electrical transition [19]. The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital LUMO levels of EHCz have been measured to be around 5.8 and 2.3 eV, respectively [14], while silver has a work function of about 4.7 eV. Thus, the silver nPs can act as charge traps in the EHCz host. Similarly to what has been reported in devices based on gold nPs doping at similar concentrations a semiconducting polymer host, including PVK, the bistability can be attributed to electric-field-induced charge transfer between silver nPs and EHCz involving charges tunneling through the insulating coating of the nPs [6,16,20]. When blending the nPs into the EHCz host, the liquid carbazole plays the role of electron donor and the nPs act as electron acceptor. When applying a high electric field across the device, an electric-field-induced charge transfer can occur between the liquid carbazole and the nPs, resulting in EHCz being positively charged and the nPs being negatively charged. As previously demonstrated [6,16], this effect leads to a decrease of the bandgap and a significant improvement of the conductivity of the hybrid material, which is associated to the ON-state of the memory devices. For the transition from the ON- to the OFF-state, a reverse bias is then required to make the electric-field-induced charge transfer complexes return back to their initial state. Note that the stability of the negative charges trapped on the silver nPs in the ON state is certainly associated with the insulating hexanethiol ligands surrounding the nPs, which eliminate the possibility for the charges to recombine in the absence of an applied electric field.

Other key characteristics of organic bistable memory devices are evidently their stability characteristics in both ON and OFF state under a constant applied voltage stress as

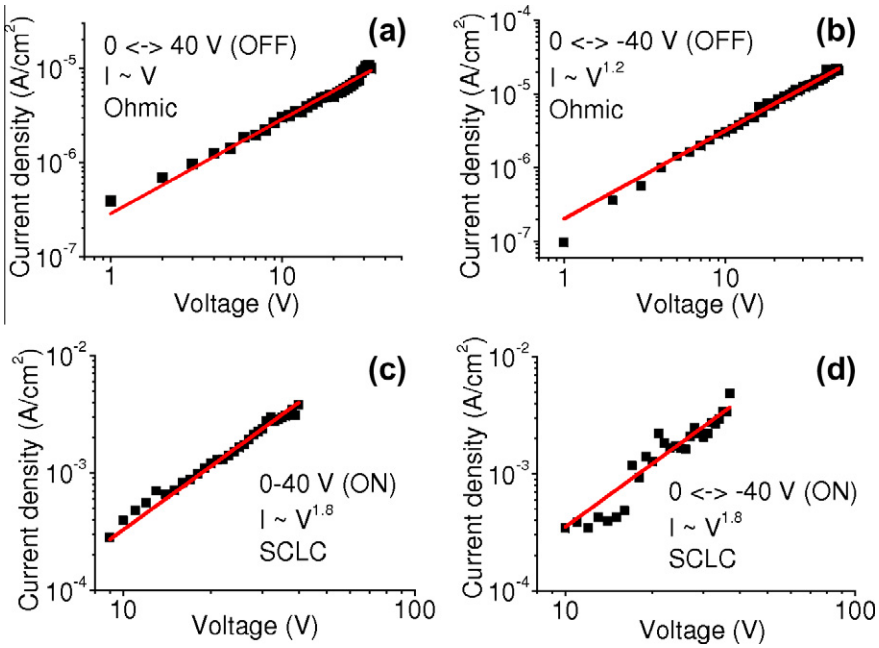

Fig. 3. Fitting results of the current density–voltage curves of the memory device with [Ag-nP] = 8.5×10^{-10} M in log–log scale and deduced mechanisms: ohmic [(a) and (b)], SCLC [(c) and (d)].

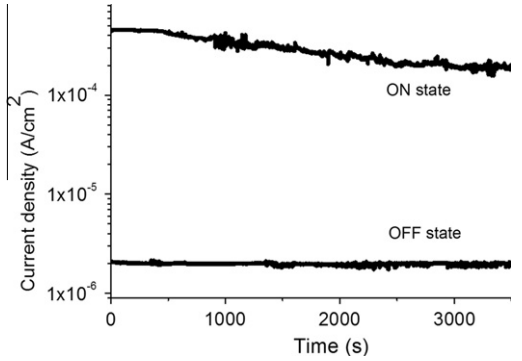

Fig. 4. Stability of an organic liquid bistable memory device in the ON and OFF states under a constant bias of 10 V, [Ag-nP] = 8.5×10^{-10} M.

well as their ability to read, write and erase data. Fig. 4 shows the stability of the device in both the ON and OFF states under a continuous constant voltage of 10 V for 1 h. A slow decrease of the ON state current is observed but overall the device shows little degradation over time.

Write–read–erase cycle tests were also performed on the device. As shown in Fig. 5a, different bias voltages were used for the writing to the ON state (+50 V), the reading (+10 V) and the erasing (−50 V) processes. The corresponding absolute value of the current response is plotted in Fig. 5b and is found to follow the applied write–read–erase–read cycles. Consequently, the results provide clear evidences that hybrid organic–inorganic liquid bistable devices can be electrically programmed for rewritable non-volatile memory applications. For further development of the organic liquid memories, it is evident that the switching threshold voltage and the ON/OFF ratio of the devices

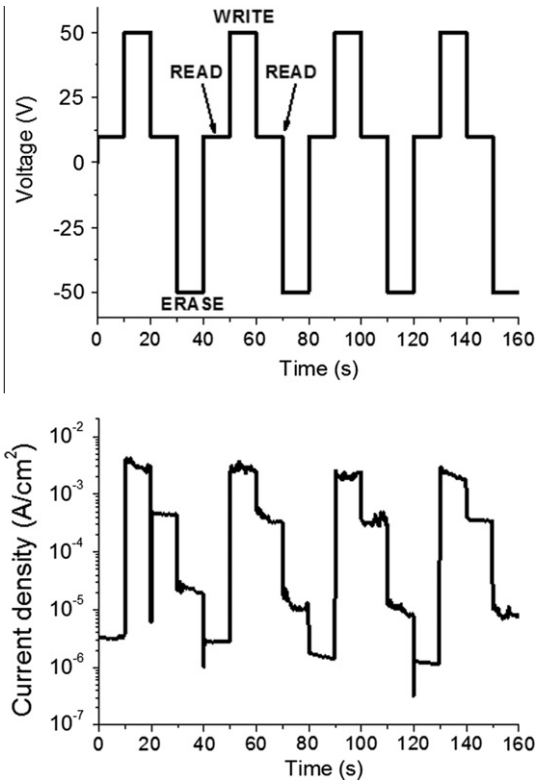

Fig. 5. Write–read–erase–read voltage cycles measured in an hybrid liquid bistable memory: (a) input applied voltages and (b) output currents as a function of time. [Ag-nP] = 8.5×10^{-10} M.

need to be improved for practical applications. For this purpose, devices with much thinner hybrid active layers could be envisaged along with efforts towards materials design and optimization.

4. Conclusion

In conclusion, a liquid hybrid organic-inorganic bistable memory device based on a blend of hexanethiol capped silver nPs and liquid carbazole EHCz was demonstrated. The device can be electrically switched between two states which conductivities are more than two orders of magnitude apart of one another. The repeatable and nonvolatile electrically bistable properties observed in our liquid memories are attributed to an electric-field-induced charge transfer between the liquid carbazole and the silver nPs. This study opens a very promising way for organic electronic memory devices and supports the concepts that liquid carbazole and that blending organic and inorganic materials to complement each other electronic properties have strong potentials for the development of soft optoelectronic.

Perylene bisimides (PBIs) have been demonstrated n-type semiconductors which have large conjugated structures and strong electron affinities [18–21]. Because of the representative geometric, electronic and transport properties, PBIs show the promising applications in optical and electronic devices [22–24]. Attaching substituents, such as perfluoroalkyl, fluorine, chlorine, cyanide, etc. to the conjugated perylene bisimide core could stabilize molecular orbitals and facilitate electron transport successfully [25–28]. This kind of functionalization of material will improve device performance and increase lifetime of the device. The similar substituents have been investigated and demonstrated practical for device design [18,29,30]. Two kinds of substituents referred in our theoretical work: substituents at imide nitrogen positions with fluorinated groups and substituents at bay positions with different electron-withdrawing atoms. The compounds with substituents of fluoroalkyl and fluorophenyl groups, such as $-CH_2C_3F_7$ and $-C_6F_5$ at imide nitrogen position of perylene bisimide have been demonstrated to perform the air-stable electron mobilities with the improved solubility [30,31]. The molecular models in the present work – a series of n-type electron-withdrawing derivatives based on perylene bisimide are shown in Scheme 1. Mobility is the intrinsic property of organic crystal and it is the most important characteristic when evaluate the material performance. Some groups have investigated this kind of functionalization of PBI, Chen et al. have measured the highest mobility $0.068\ cm^2\ V^{-1}\ s^{-1}$ of fluorine substituents [30] and $0.35\ cm^2\ V^{-1}\ s^{-1}$ have been reported by Schmidt et al. of the derivatives with both bay and imide nitrogen substituents of PBI [27]. Delgado et al. have investigated considerable PBI derivatives and found that the important impact of the intermolecular packing on the charge transport properties [18]. Here we provide the theoretical study of detailed influences of these electron-withdrawing substituents on geometric structures, electronic properties, especially the carrier mobilities. We developed a method to simulate the angular-resolution mobility and investigated the anisotropic behaviors of organic material [32].

In the present work, both hole and electron hopping motions are considered and the related electronic and transport properties of the two kinds of hoppings are discussed. Density functional theory (DFT) calculations have been performed to investigate the geometries, molecular orbitals, electron affinities and reorganization energies of PBI monomers. The absorption spectra of all the derivatives in the tetrahydrofuran solution have been simulated with time-dependent density functional theory (TDDFT) method. The intermolecular electronic couplings and charge transport mobilities at room temperature have been deduced with the available single crystal structures. The anisotropic mobility is simulated with our angular-resolution expression. The functionalized derivatives of perylene bisimides have been compared systematically in terms of these charge transport properties. The theoretical analysis is helpful to understand the influence of the structure variations on the transport properties of these organic conjugated molecules and direct the high-performance material design.

2. Theoretical methodology

Density functional theory (DFT) has been employed to calculate the structural, electronic and transport properties of these organic semiconductors. It has been demonstrated reliable to study the organic conjugated molecules [4,10,33]. In the solid state the reorganization energy is mostly from the internal energy relaxation when charge transport and the contribution from the environment to the reorganization energy could be neglected [34–36]. Thus the reorganization energy could be expressed as:

$$\lambda_{hole} = \lambda_0^+ + \lambda_+ = (E_0^* - E_0) + (E_+^* - E_+) \quad (1)$$

$$\lambda_{electron} = \lambda_0^- + \lambda_- = (E_0^* - E_0) + (E_-^* - E_-) \quad (2)$$

where E_0 and E_+/E_- denote the energies of the neutral and cation/anion molecules in their lowest energy geometries, E_0^* and E_+^* E_-^* are the energies of the neutral and cation/anion monomers with the cation/anion and neutral geometries, respectively. The calculations of reorganization

Scheme 1. Schematic of the structures of investigated PBI derivatives.

energy are performed with B3LYP functional with 6-311G** basis set. Time-dependent density functional theory (TDDFT) is also employed to simulate the absorption spectra of investigated semiconductors. These calculations are carried out with Gaussian 09 program package [37].

The evolution of electronic coupling t is based on the molecular orbitals of the conjugated molecules. The coupling matrix element could be deduced as Eq. (3).

$$t = \frac{J_{12} - S_{12}(E_1 + E_2)/2}{1 - S_{12}^2} \tag{3}$$

The electronic coupling t could be written with charge transfer integral J, overlap matrix S and site energy of monomer E, as described in the reference [38]. The monomer orbitals with proper orthogonalization are used as basis sets for the Hamiltonian of this dimer system. Assuming h is the Kohn–Sham Hamiltonian of a dimer pair system and $\varphi_1^{H/L}$, $\varphi_2^{H/L}$ are the localized molecular orbitals of adjacent monomers. For hole transport the highest occupied molecular orbitals (HOMOs) of monomers are used as the basis function while for electron transport the lowest unoccupied molecular orbitals (LUMOs) are used correspondingly, and then S, J and E could be expressed as:

$$\begin{aligned} J_{12} &= \langle \varphi_1^{H/L} | h | \varphi_2^{H/L} \rangle \\ S_{12} &= \langle \varphi_1^{H/L} | \varphi_2^{H/L} \rangle \\ E_1 &= \langle \varphi_1^{H/L} | h | \varphi_1^{H/L} \rangle \\ E_2 &= \langle \varphi_2^{H/L} | h | \varphi_2^{H/L} \rangle \end{aligned} \tag{4}$$

In the calculation of electronic coupling, the fragment orbital approach is applied with Amsterdam density functional (ADF) software [39]. The local density functional VWN combined with PW91 gradient corrections and TZ2P basis set are selected as the calculation method.

There are two widely used models to describe the charge transport in organic semiconductors: the band-like model and the hopping model [40]. The former is usually applied at very low temperature. At room temperature the charge carriers in organic single crystals are localized and the charge transport in a sequential hopping mode between neighboring molecules which could be described by Marcus theory. Hutchison and Bromley et al. have demonstrated that for organic oligomers the thermally assisted polaron hopping mechanism is reasonable [41–43]. Here we mainly investigate the electron and hole transport behaviors of PBI derivatives at room temperature and employ the hopping mechanism. According to Marcus–Hush theory the hopping rate k could expressed as [44–46]:

$$k = \frac{t^2}{\hbar}\left(\frac{\pi}{\lambda k_B T}\right)^{1/2} \exp\left(-\frac{\lambda}{4k_B T}\right) \tag{5}$$

where k_B is the Boltzmann constant and T is the temperature which is 298 K in our calculation. The reorganization energy λ and electronic coupling t between two adjacent molecules are key parameters for the charge hopping rate.

The hopping mobility μ could be evaluated from the Einstein relation:

$$\mu = \frac{eD}{k_B T} \tag{6}$$

where D is the diffusion efficient. Assuming the hopping motion is an isolated random walk and there is no correlation between charge hopping motions, the diffusion coefficient D could be evaluated from the hopping rate:$D = \frac{1}{2n}\sum_i r_i^2 k_i P_i$, n is the spatial dimensionality, k_i denotes the hopping rate along the specific hopping path i, r_i is the intermolecular center-of-mass distance between two neighboring molecules and P_i is the hopping probability for the specific path i which can be calculated by: $P_i = k_i/\sum_i k_i$.

The mobility orientation function is deduced to simulate the angular-resolution anisotropic mobility, see details in reference [32].

$$\mu_\Phi = \frac{e}{2k_B T}\sum_i k_i r_i^2 P_i \cos^2\gamma_i \cos^2(\theta_i - \Phi) \tag{7}$$

here γ_i is the angle of hopping path relative to the plane of interest, ϕ is the orientation angle of the transistor channel relative to the specific crystallographic axis and θ_i is the angle of the projected hopping path relative to the specific axis. These calculations are based on the detailed analysis of the molecular packing of organic single crystals.

3. Results and discussion

3.1. Geometry and molecular orbital

Some selected optimized geometric parameters, including bond lengths, bond angles and dihedral angles of A1, A2, B1, C1 and C3 molecules both in neutral and anion states are listed in Table A. 1 in the Supporting Information. From the calculated results, we could tell that most bond lengths have visible change between neutral and anion states. The modification of C–C bond lengths in anion state are very big except for the ones located in two conjugated cores, e.g. the bond length difference of C_1–C_2 is 0.023 Å while the one of C_2–C_3 is only 0.002 Å for compound A1. The C–N bonds lengthen 0.006 Å in the anion state. The strengths of C–O bonds are weaker in the anion states and the bond lengths are all increased by about 0.012 Å. The electron transport also induces the bond angle change, e.g. the bond angle C_2–C_3–C_7 of investigated molecules decrease by about 0.2° in anion state. For different PBI derivatives we could detect the geometric conformation change induced by attaching electron-withdrawing groups. When substituents are attached to nitrogen atom of perylene bisimide core, the C–N bond is lengthened by 0.01 Å and other bonds are almost changeless. However, substituents at the bay positions of perylene bisimide core bring the obvious geometric differences. The bonds have stretching vibration and the angles C_5–C_6–C_8 increases by more than 2°. With the calculated geometries we could find that the conformation change of these compounds when electrons transport are considerable which directly induce the large reorganization energies. Compound A1 and A2 keep a relatively planar conjugated core with the dihedral angles less than 1°. The compounds with substituents at the bay positions have the visible twist, and also the planarity of the conjugated structure for this kind of derivatives is influenced by electron transport. For B1, it

is more planar in anion state than in neutral state. However, for compound C1, the dihedral angles of conjugated structure are increased significantly in the radial-anion state and the torsion is enhanced. The geometric structure of the isolated molecule plays an important role in determining the molecular arrangement of the single crystal.

Fig. 1 shows the calculated molecular orbital levels of all the investigated PBI compounds. General n-type organic semiconductor materials are air sensitive and the electrons are easily trapped by the ambient oxidants. Because of instability of these materials, the device lifetime and performance have been limited. Attaching electron-withdrawing substituents to conjugated semiconductor could lower the molecular orbitals and improve the stability of materials. In the figure we could find both HOMOs and LUMOs have been stabilized by at least 0.3 eV for these PBI derivatives. The energy gaps, which mean the energy difference between HOMO and LUMO, are very close for these compounds. The HOMO and LUMO plots of all the investigated monomers at B3LYP/6-311G** calculation level are shown in Fig. A.1–A.10 in the Supporting Information. The charges are strongly located in the conjugated perylene bisimide center for all the compounds. All these derivatives are practical to produce semiconductors with improved stability. It is an effective strategy to decrease the electrons trapping by the ambient oxygen and moisture and obtain the air-stable materials. When realizing the application of organic material in electronic devices, solution process is an important operation. However, most organic conjugated semiconductors have poor solubility, thus increasing the solubility is also an object in molecular design. The added electron-withdrawing substituents in our investigated system would improve the solubility efficiently because the polarity has been increased with the introduced polar atoms.

3.2. Ionization potential, electron affinity and reorganization energy

Adiabatic ionization potentials and electron affinities of all considered compounds are calculated with DFT method at the level of B3LYP/6-311G**, as shown in Fig. 2. The ionization potential and electron affinity relate to the ability of holes and electrons coming across the energy barrier and injecting the metal electrodes or empty orbitals. The introduction of electron-withdrawing substituents increases the ionization potential and electron affinity obviously. According to Newman, a practical requirement for n-type material is that organic conjugated semiconductor have electron affinity between 3 eV and 4 eV [47]. These substituents are favorable for n-type semiconductors in respect of the electron affinity. An increase of electron affinity (cal. 0.3–0.9 eV) has been observed from our calculation. The enhanced electron affinity facilitates the electrons injecting into LUMOs of semiconductors effectively.

Reorganization energy is the relaxation of site energy by vibrations [38]. The calculations of reorganization energies of hole and electron transport are based on the idea of adiabatic potential energy surface at the level of B3LYP/6-311G** as well, shown in Table 1. When the substituented groups are attached to compound A1, the obvious increases of reorganization energies are observed. These increases are not helpful for charge carriers transport and the hopping rate will be decreased according to Marcus theory. The electron transport will induce larger structural relaxation than hole transport. A main reason why the mobility of n-type semiconductor is usually lower than

p-type one is the difference of the reorganization energy when electron and hole transport.

The variation of the substituents at the bay positions has obvious influence on the charge transport reorganization energy. Fig. 3 shows the evolution of electron transport reorganization energy with electronegativity of the substituented atoms at the bay positions. A2, B1, B2 and B3 have the similar geometries only the different subsituented atoms at the bay positions. According to Pauling definition the electronegativity of H, F, Cl and Br are 2.10, 4.00, 3.16 and 2.96, respectively. The evolution of reorganization energy has been analyzed which follows a straight line expression. As the electronegativity increase the electron transport reorganization energy increase, correspondingly. When PBI molecule is substituted with F which has the largest electronegativity, the electron transport reorganization energy could come to 0.333 eV. With the fitting line we could deduce the reorganization energy substituted with other atoms. These electron-withdrawing groups could improve the stability and electron injection effectively though they would introduce the obvious increase of reorganization energy which is not expected by device design.

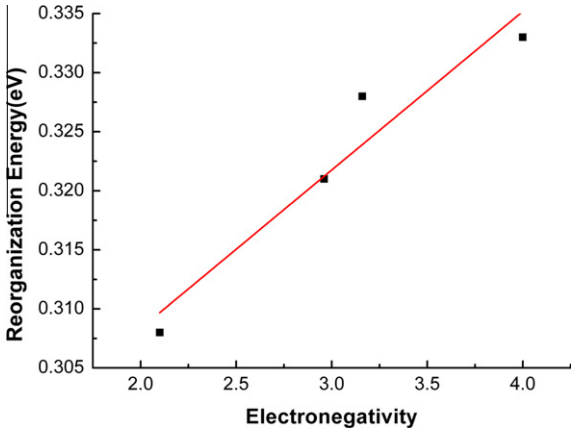

Fig. 3. Correlation of reorganization energy of electron transport with electronegativity of substituented atom at the bay positions.

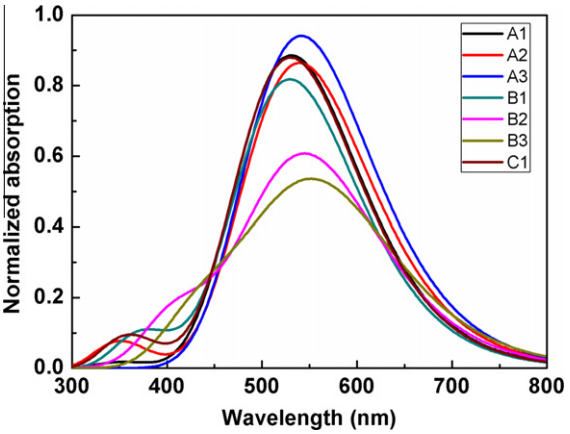

Fig. 4. UV-Vis absorption spectra of A2, B1, B2, B3 and C1 in tetrahydrofuran (THF) solution.

3.3. Absorption spectra

Time-dependent DFT calculations at B3LYP/6-311G** level are performed to simulate the absorption spectra of these PBI derivatives. The theoretical simulations of absorption spectra are performed in tetrahydrofuran solution with SCM model. From the simulated spectra in Fig. 4, we find that the PBI derivatives have broad and strong absorption in the UV-Visible region especially from 400 to 700 nm. The perylene cores are the chromophore centers for these compounds and all the derivatives have the maximum absorption peak almost in the same area near 530 nm which assigns to the π–π^* transition. It reflects that these derivatives need almost the same optical transition energy. Attaching the strong electron-withdrawing fluorine atoms on the core positions will induce the blue shift of the absorption spectra which means the energy increase needed for the optical transition. Relative to the absorption maximum of B1, the red shift of 9 nm for B2 and the red shift of 18 nm for B3 have been observed. Though the structures of B1 and C1 have evident differences from Table A.1, the absorption spectra of the two compounds show almost the same shape and distribution only a tiny difference in the absorption strength. The calculated results are in good agreement with the corresponding experimental ones by Chen et al. [30] and Jones et al. [48]. These results indicate that the organic conjugated PBI compounds have advantages in terms of absorption spectra and they have potential to realize the application in organic solar cell.

3.4. Electronic coupling and anisotropic mobility

Fig. 5 shows the molecular packings of compound A2, B3 and C1 as well as the torsion angles of perylene bisimide plane. The dimers of molecule D with adjacent molecules in single crystal are marked as D_1, D_2, D_3, D_p (D_p denotes the dimer in two neighboring packing layers) ..., and the center-of-mass distance of the two closest conjugated molecules is presented. The theoretical analysis are based on the single crystals from Schmidt et al. [49]. If

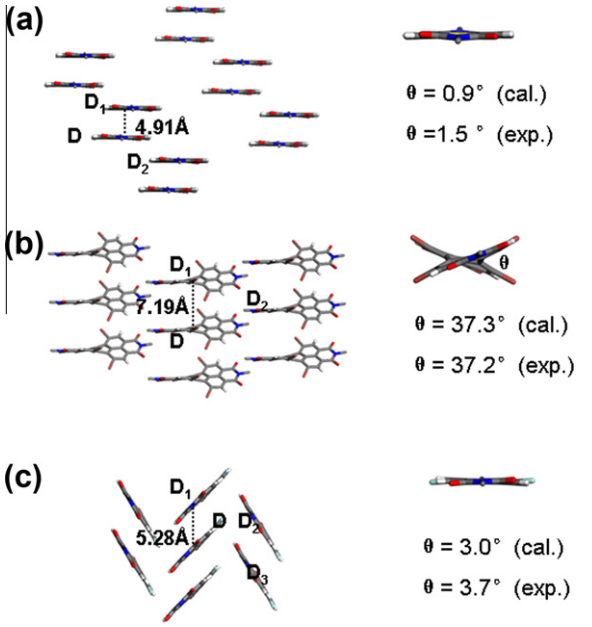

Fig. 5. Molecular packings of compounds (a) A2, (b) B3 and (c) C1 [49] with the center-of-mass distance between the conjugated centers and the torsion angles of the perylene bisimide plane by DFT calculation (cal.) as well as the experimental results (exp.). Fluoroalkyl groups have been removed for clarity.

there is no substituent at the bay position, the conjugated perylene bisimide part is almost planar, like A1, A2 and A3. The torsion angle from calculation by DFT method (0.9°) and experiment measurement (1.5°) [49] of compound A2 indicate the good planarity of this kind of molecule. The electron-withdrawing substituents at 1, 6, 7, and 12 positions can make a twisting angle as large as 35° and the conjugated PBI skeletons have been largely distorted. The calculated torsion angle of B3 molecule is 37.3 ° which is in good agreement with 37.2 ° from experiment [49].

The molecular arrangement in crystal structure is mostly determined by molecular conformation and intermolecular interactions. From the comparison of B1 and C1, we find that the addition of fluorine atoms at the bay positions enlarge the torsion of perylene backbone out of planarity which would not facilitate the dense packing and hence the intermolecular electronic coupling. The packing modes are mainly affected by the molecular conformation. The face-to-face stacking with a short distance with the large coupling area could contribute to the high mobility. The molecular packing of A2 crystal keeps a slipped stack while C1 crystal changes to a herringbone one with an increased intermolecular center-to-center distance. The charge mobility is partly dependent on the molecular distance of the conjugated compounds. The centroid distance is 4.91 Å of the closest conjugated molecules for A2 while it is 7.19 Å for B3 and 5.28 Å for C1. The planar torsion hinders the approach of the molecules and obstructs the molecule packing densely.

With the known crystal structures, the electronic couplings of neighboring molecules of compounds A2, B2, B3, B4 and C1 are calculated, listed in Table A.2 in the Supporting Information. For the most organic single crystals the electronic couplings between the molecules in the same organic packing layer are much stronger than that between the molecules in two neighboring layers. For A2 crystal, the electronic couplings for dimer D_p is far less than the ones for dimer D_1 and D_2. The weak electronic coupling along layer-to-layer molecules contributes negligibly to mobility. The large variation of electronic couplings along directions will give rise to a 2D mobility distribution in the packing layer. For our studied PBI derivatives the electronic couplings of LUMOs could come to the same order of the ones of HOMOs. Table 2 list the maximum mobilities of hole and electron of some PBI derivatives. In these PBI derivatives A2 has the preferred transport properties for both hole and electron, with the hole and electron mobilities as large as 0.552 and 0.123 $cm^2 V^{-1} s^{-1}$. The close packing of the molecules in the solid state allows the strong electronic couplings of the π-conjugated orbitals which determines the high mobility. When attaching the two fluorine atoms at the bay position of the perylene core, electronic coupling between LUMOs has been enhanced significantly, about two orders of magnitude larger than that for HOMOs. The compound C1 shows favorable electron transport properties. The LUMOs of conjugated molecules show strong coupling interaction and the mobility for electrons can come to 0.514 $cm^2 V^{-1} s^{-1}$. For compound C1 the experimentally measured electron mobility is 0.35 $cm^2 V^{-1} s^{-1}$ by Schmidt [49] and our theoretical simulation provides the reliable results. For the PBI derivatives with four electron-withdrawing atoms, B2, B3 and B4, the charge transport mobilities are not satisfying. Because of the repulsion of the introduced electron-withdrawing atoms, the regular molecular packing of the PBI compounds has been distorted and the distance of the conjugated center has been lengthened. The mobilities measured in experiments are very sensitive to the experimental conditions. Schmidt et al. reported that the organic thin film transistor measurements of mobility are varied a lot when the substrate is modified or the temperature is changed [49]. Our theoretical charge transport investigation is under the ideal conditions at room temperature which could provide the reasonable results and assist to understand the detailed transport behaviors of the charge carriers.

The highly anisotropic character of molecular packing of organic single crystals gives rise to the highly anisotropic

Table 2
The calculated hole and electron transport mobility (in $cm^2 V^{-1} s^{-1}$) of some PBI derivatives. (The corresponding experimental values from reference [49] are in parentheses).

	A2	B2	B3	B4	C1
μ_{hole}	0.552	0.005	0.137	0.014	0.019
$\mu_{electron}$	0.123 (0.67)	0.002 (0.0005)	0.024 (0.0003)	0.002 (0.025)	0.514 (0.35)

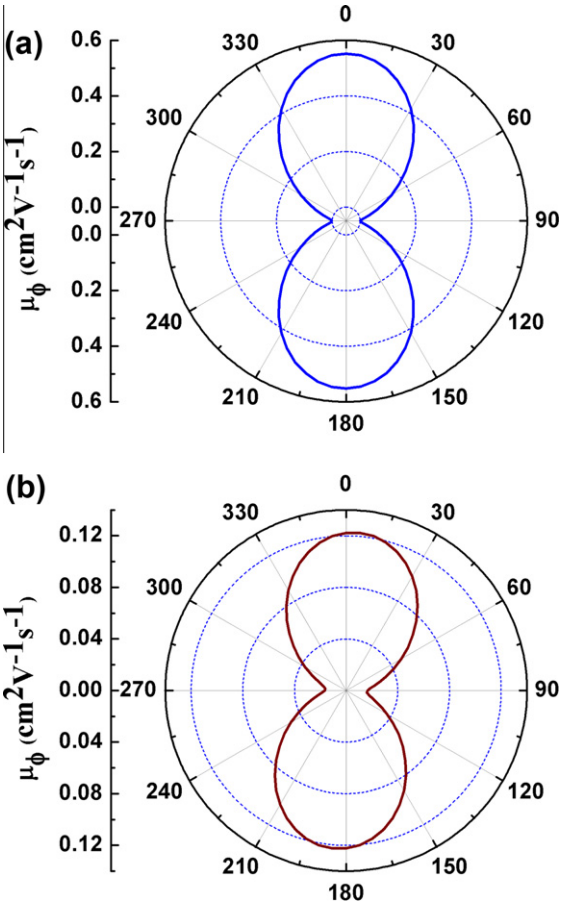

Fig. 6. The angular-resolution anisotropic mobility of A2 crystal: (a) hole mobility and (b) electron mobility.

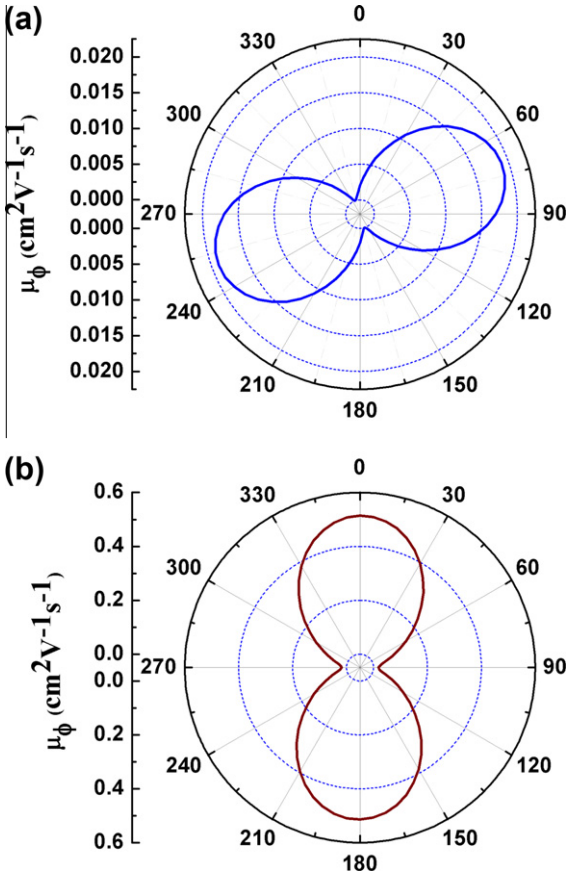

Fig. 7. The angular-resolution anisotropic mobility of C1 crystal: (a) hole mobility and (b) electron mobility.

mobility. Understanding the anisotropic mobility can assist in controlling the directions of transistor channel relative to reference direction of molecular crystal to obtain the highest charge mobility [50–52]. Figs. 6 and 7 describe the angular-resolution anisotropic mobilities of both hole and electron transport of compounds A2 and C1. We choose the direction of strongest electronic couplings of LUMOs as the reference direction (the 0° direction in the angular-resolution figures) and all the vectors of mobility project to this direction and then deduce the corresponding angular-resolution formula.

For the hole transport of compound A2, since the electronic coupling of HOMOs for dimer D_1 is very strong, the mobility maximum 0.552 $cm^2\ V^{-1}\ s^{-1}$ appears in this dimer direction. Differently the electronic coupling of LUMOs for dimer D_2 is comparable to the one for D_1, it will contribute to the mobility distribution. Thus the mobility maximum of electron transport is along about 5° in the angular-resolution figure. For compound C1 we could find the obvious difference of the angular-resolution mobility, it is because the strongest coupling of HOMOs occurs in D_2 while the strongest coupling of LUMOs occurs in D_1. The hole transport mobility maximum is 0.019 $cm^2\ V^{-1}\ s^{-1}$ when the angle is 71° in the angular-resolution figure and the electron transport mobility maximum is 0.514 $cm^2\ V^{-1}\ s^{-1}$ along dimer D_1 vector. Understanding the angular-resolution distribution of mobility and making use of the anisotropy of mobility can help us to improve the charge transport and get high-performance materials.

4. Conclusions

In summary we theoretically investigated the perylene diimde derivatives with electron-withdrawing substituents. These derivatives show the promising performance in terms of electronic, optical and charge transport properties. Attaching the electron-withdrawing substituents at the proper positions could improve the stability of the materials, enhance the electronic coupling and facilitate the hopping motions, efficiently, though these substituents would induce the increase of the reorganization energy inevitably. All the investigated derivatives have the strong absorption in the UV-Visible area which is highly desired by the organic solar cell applications. The molecular conformation of the organic semiconductor plays a significant role in determining the electronic properties, molecular stackings and transport behaviors. In all these derivatives, compound C1 which has two fluorine substituents at the bay positions shows the favorable electron transport ability with the mobility as large as 0.514 $cm^2\ V^{-1}\ s^{-1}$. Although the derivatives with

four halogen substituents at the bay positions, B1, B2, B3 and B4, stabilize the LUMO levels and increase the electron affinities, the distorted molecular geometries are adverse to the close packings, and hence leading to the low mobilities. The charge carriers mostly transport in the basal stacked organic layer which give rise to a 2D mobility distribution. The angular-resolution anisotropic mobility analysis shows the importance to control the directions of crystals in applications to improve the material performance. The theoretical investigations of the organic semiconductors are helpful to understand the intramolecular and intermolecular charge transport behaviors and beneficial to the materials design for the electronic applications.

performances of the ISFET device. A pH sensor that combined the commercial MOSFET and an extended-gate concept using V_2O_5 xerogel, tin oxide (SnO_2) and indium tin oxide (ITO) as the pH sensing material was investigated by various authors [10–12]. The pH probe coated with V_2O_5, SnO_2, and ITO as the pH sensing materials electrically connects with the extended gate electrode of the commercial MOSFET devices. The reference electrode used for the measurement of the FET characteristics is used as a floating electrode, while both the reference electrode and pH probe are immersed in the electrolyte. However, the selectivity of these sensing layers to other ions including K^+ and Ca^{2+} was not measured.

Despite the various advantages of the Si ISFET device, it also has some limitations, due to the rigidity and opacity of the Si substrate and difficulty of achieving monolithic integration with microfluidic components for lab-on-a-chip (LOC) or micro-total analysis systems (μ-TAS) for clinical use. For the facile integration of ISFET devices into the new concepts of LOC or μ-TAS based on transparent polymeric or glass substrates having the capability of electrochemical and optical detection, new ISFET devices based on thin film transistor technologies from the display industry look promising. Among the various ISFETs based on non-single crystalline Si channels [13–15], the organic FET (OFET) is a good candidate, because the OFET has shown considerable potential in many electronics applications, due to its light weight, low cost, mechanical flexibility, optical transparency, compatibility for large area applications, and simple fabrication compared to conventional MOSFET devices based on silicon [16,17]. Bio-chemical sensors based on OTFTs have been developed by functionalizing an organic semiconductor sensing layer to specific target species. Some groups have also developed organic ISFETs for H^+ sensing [18,19]. However, the application of organic ISFETs is still limited, because of their limited dynamic pH range from 4–10 [18–20], poor linear sensitivity behavior [18–20], slow response [19], and poor stability [18]. These issues are related to the inherent degradation of the organic semiconductor layers which are sensitive to moisture and oxygen. However, in the above-mentioned cases, the organic dielectric or semiconductor layers are directly exposed to the electrolyte. Also, organic ISFETs with a top gate structure have difficulties in terms of the fabrication of the H^+ sensing gate dielectric on top of the organic semiconductor layer, because of the damage incurred during the formation of the gate dielectric. The damage to the organic semiconductor can be prevented by using organic gate dielectrics layers, such as parylene or polyvinyl alcohol (PVA) layers. However, choosing oxide gate materials for H^+ sensing is challenging in this case, due to the large difference in the thermal expansion coefficients of inorganic and organic materials. Furthermore, the ions can be transported through the gate insulator, which gives rise to a leakage current, due to the formation of cracks in the sensing layer under the influence of the large electric field in the solution during the measurement. These factors will affect the stability of the sensor performance.

In our work, a bottom–gate OTFT structure with ITO-extended gate sensing electrode was successfully fabricated. The side-effects caused by the fabrication process were minimized to improve the stabilty of the organic ISFET for pH sensing. This structure could be used to develop a stable pH sensor with good linearity over a wide dynamic pH range of 2–12, high sensitivity of 57–59 mV/pH, and fast response. The ITO-extended gate electrode in the organic ISFET could be used for sensing the pH selectively in K^+ and Ca^{2+} containing solutions.

2. Experiments

Fig. 1 shows the cross-section view (a) and top view (b) of the pH sensor based on the ITO-extended gate OFET. The ITO glass substrates were purchased from Fine Chemicals Co., Ltd., (Korea). The resistivity of ITO is below 20 ohm/sq, its thickness is 80 nm, and its transmittance is 87%. The ITO-extended gate OFET with a channel length of 40 μm was fabricated on an ITO-coated glass substrate. The ITO layer on the ITO-coated glass substrate was selectively etched by an etchant solution consisting of 24 wt.% HCl followed by a photo lithography process for patterning to form a gate electrode for the OFET as well as H^+ sensing layer. Then, poly(4-vinylphenol) (PVP) was deposited by the spin coating pro-

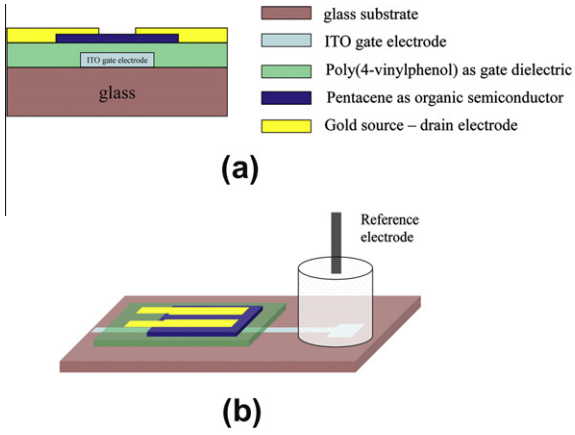

Fig. 1. Schematic of cross-section and top view of ITO-extended gate OFET device.

cess as a gate dielectric with a thickness of 250 nm. Pentacene as an organic semiconductor was formed by thermal evaporation at 80 °C with a thickness of 60 nm. Finally, gold was deposited with a thickness of 60 nm for use as the source and drain electrodes. To monitor the sensitivity of the ITO layer to H^+ ions, a polydimethylsiloxane (PDMS) well designed to contain the electrolyte was attached to the substrate, which has an extended-gate part attached using epoxy glue for sealing.

3. Results and discussion

Fig. 2 shows the electrical properties of a standard ITO bottom gate OFET, having a current on/off ratio of 10^5, field-effect mobility, μ, of 0.45 $cm^2 V^{-1}s^{-1}$, and threshold voltage, V_T, of −10.5 V. In the buffer solution, the measurement of the OFET using a saturated calomel electrode (SCE) as the floating gate electrode, the electrical properties were similar to those obtained for the standard device with the bottom gate electrode. To determine the sensitivity of the ITO-extended-gate electrode to H^+ ions, electrolytes with different pH values of 2, 4, 6, 8, 10, and 12 were placed one by one in the PDMS well. Due to the effect of bias stress on the pentacene OTFT [21–23] caused by the trapping of carriers from the gate bias-induced conduction channel into localized electronic states, a pre-measurement stabilization step should be performed to obtain the stable baseline of the electrical properties. As shown in Fig. 3(a), the measured drain current, I_{SD}, versus elapsed time at a source–drain voltage V_{SD} = −40 (V), voltage of the reference electrode V_{RE} = −40 (V), and pH of the solution of 7 shows that the I_{SD} value is stabilized after a measurement time of 10 minutes. At the initial stage, I_{SD} slightly increased from −116 μA to −140 due to the increase in the number of charges accumulated in the conduction channel under reference electrode bias. Then, I_{SD} decreases rapidly from −140 μA to −30 μA in 10 minutes because of the increase in the number of carriers trapped at the applied V_{RE} voltage [21,22]. From this point, the rate of decrease of I_{SD} over time is small. Therefore, it can be neglected and the investigation of the sensitivity of the ITO material to H^+ is carried out at this point.

The mechanism of H^+ ion sensing of the ITO-extended gate OFET can be explained based on the theoretical operation of the OFET and behavior of the ITO surface in the electrolyte, which are described by the Gouy–Chapman–Stern–Graham and Site-binding models [2]. The ITO material is a solid solution of indium (III) oxide (In_2O_3) and tin (IV) oxide (SnO_2), typically 90% In_2O_3 and 10% SnO_2 by weight. Thus, the ITO surface has various ionic states, including InOH, InO^-, $InOH_2^+$, SnOH, SnO^-, and $SnOH_2^+$.

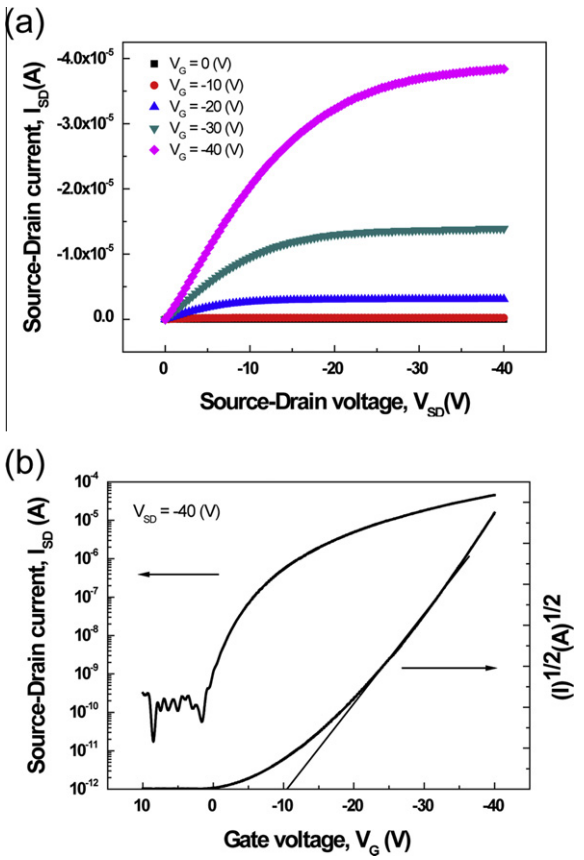

Fig. 2. The output and transfer characteristics of the standard ITO-extended bottom gate OFET device.

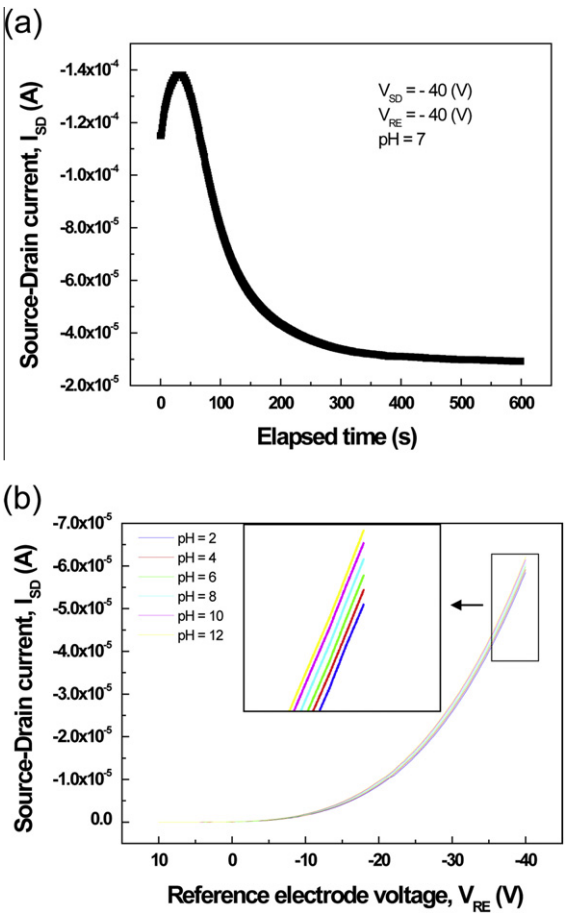

Fig. 3. Source–Drain current (I_{DS}) versus elapsed time at condition of V_{SD} = −40 (V), V_{RE} = −40 (V), and electrolyte with pH value of 7 in 10 min (a), and transfer characteristics of OFETs in various pH solutions (b).

Therefore, the interaction between the ITO surface and electrolyte can be explained by the above models. These models can be referenced elsewhere [2]. According to these models, there is an electrochemical surface potential, ψ, of ITO in the electrolyte solution. This potential decays exponentially within the critical distance given by $\lambda_D = \sqrt{\frac{\varepsilon\varepsilon_0 kT}{N_A q^2 \sum_i z_i^2 C_i}}$, where ε is the dielectric constant of the electrolyte, ε_0 is the permittivity of a vacuum, N_A is the Avogadro constant, C_i is the concentration of species i in the electrolyte, and z_i the corresponding ionic charge. Actually, the physicochemical change in the electrolyte can only be detected when it causes a change within the Debye length and, as a result, a change in the electrochemical potential at the interface [24]. Therefore, in the buffer solution, the H^+ ions exert a significant effect on the oxide surface, instead of on the companion negative groups.

To calculate the surface potential between the sensitive layer and the electrolyte, the equations given in references [25] and [26] can be used. From those equations, the pH sensitivity of the structure based on the ISFET is given by, $\frac{\delta\psi}{\delta pH} = 2.303\frac{kT}{q}\alpha$, where α is a dimensionless parameter that varies between 0 and 1. If α is 1, the ISFET has an ideal sensitivity of 59 mV per pH at 25 °C.

The OFET operates almost entirely in accumulation mode, which can be divided into two regions, in which the currents are in the linear and saturation regimes, as described by equations, $I_{linear} = \frac{\mu CW(V_G - V_T)V_{SD}}{L}$ and $I_{sat} = \frac{\mu CW}{2L}(V_G - V_T)^2$,respectively, where μ is the field-effect mobility, C the capacitance of the gate insulator, W the channel width, L the channel length, and V_T the threshold voltage. An important parameter for any FET device is the threshold voltage. It is the gate voltage required to turn the transistor "on" and is given by $V_T = V_{FB} + 2\psi_B + \frac{\sqrt{2\varepsilon_s qN(2\psi_B)}}{C}$ where the flat-band voltage, $V_{FB} = \frac{\phi_m}{q} - \frac{\phi_s}{q}$, ϕ_m is the metal work function, ϕ_s the semiconductor work function, ε_s the permittivity of free space, q the uinit charge, N the semiconductor doping concentration, and ψ_B the Fermi level from the intrinsic Fermi level ($\psi_B = |E_F - E_i|/q$). In the case where a reference electrode is used as the floating gate electrode instead of a metal gate electrode, the term $\frac{\phi_m}{q}$ is replaced by the terms that represent the reference electrode voltage (V_{RE}) and electrolyte ($\chi_{sol} - \psi$). At that time, the flat-band voltage is defined as: $V_{FB} = V_{RE} + \chi_{sol} - \psi - \frac{\phi_s}{q}$, where χ_{sol} is the surface dipole of the electrolyte and ψ is the ITO surface potential. Therefore, the threshold voltage is $V_T = V_{RE} + \chi_{sol} - \psi - \frac{\phi_s}{q} + 2\psi_B + \frac{\sqrt{2\varepsilon_s qN(2\psi_B)}}{C}$. Therefore, at the same applied V_{RE}, $\Delta V_T = -\Delta\psi$. This equation can be used for the calculation of the pH sensitivity, while plotting the transfer characteristics of the ITO-extended gate OTFT with various pH values of the electrolyte.

After the pre-measurement stabilization step, the transfer characteristics of the ITO-extended gate OTFT were measured with electrolytes having various pH values in the range from 2 to 12, as shown in Fig. 3(b). It can be seen that I_{SD} increased as the pH value of the solution increased. This can be easily explained by the fact that the increase in pH value means a decrease in the proton ion concentration. As a result, the proton ion concentration on the ITO surface decreases according to the Boltzman equation describing the relationship between the H^+ concentration on the solid surface $[H_s^+]$ and that in the electrolyte solution $[H_b^+]$, $[H^+]_s = [H^+]_b \exp(\frac{-q\psi}{kT})$ [2]. Therefore, the negative charge density will increase on the ITO gate surface as the pH value increases. This is equivalent to the increase in the negative bias value of the ITO bottom gate electrode causing the increase in I_{SD} due to the p-type semiconductor behavior of pentacene.

As mentioned above, the H^+ ions in the buffer electrolyte have an electrochemical interaction with the ITO surface, resulting in the change in V_T of the FET device. The change in V_T is equal to the change of the surface electrochemical potential of ITO (but with the opposite sign). Fig. 4(a) shows the curves of $(I_{SD})^{1/2}$ versus V_{RE} with varying pH from 2 to 12. From these curves, the threshold voltage can be extracted for each pH solution as shown in Fig. 4(b). From this data, if the pH of the buffer is changed from 2 to 4, the V_T value is changed from −10.78 to −10.664. Therefore, the difference in the threshold voltage, $\Delta V_T = 116$mV. This means that the difference in the ITO surface potential is −116 mV. This agrees with the theory

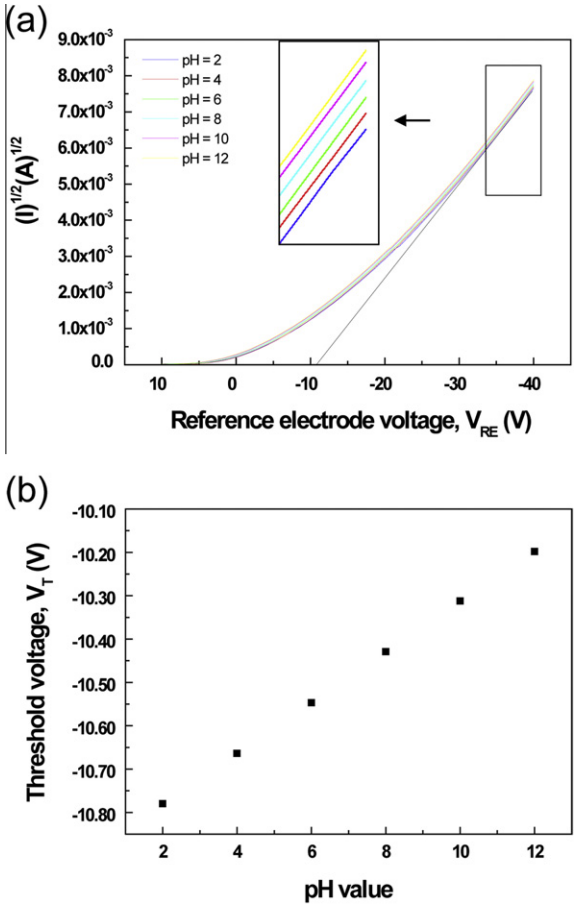

Fig. 4. Curves of $(I_{SD})^{1/2}$ versus V_{RE} with various pH solutions (a), and threshold voltage, V_T, in different pH solutions (b).

that as the pH value increases, the positive surface charge decreases. Fig. 4(b) shows the linear behavior of V_T versus the pH of the buffer solution and sensitivity of 57–59 mV/pH.

Actually, a pH sensor for real applications in biochemical engineering needs to have good selectivity to protons without any interference from other ions such as K^+, Ca^{2+}, Na^+, etc. Therefore, in this study, we investigated the selectivity of the ITO layer to K^+ and Ca^{2+} ions. Fig. 5(a) and (b) show the transfer characteristics of the ITO-extended gate OTFT for various K^+ and Ca^{2+} ion concentrations. The data show that the ITO surface is insensitive to the variation of the K^+ and Ca^{2+} ion concentrations, because there is no change in the V_T value obtained from the transfer characteristics. For the quantitative estimation of the interference of K^+ and Ca^{2+} ions to the pH measurement, the selectivity coefficient is measured. The selectivity is characterized by determining the selectivity coefficient, which is defined in the Nicolsky–Eisenman equation [27,28], $E = E_0 + \frac{RT}{z_A F} \ln\left[a_A + K^{pot}_{A,B}(a_B)^{z_A/z_B}\right]$, where z_A and z_B are the charge numbers of the primary ion, A, and of the interfering ion, B, respectively; a_A and a_B are the activities of the primary ion, A, and of the interfering ion, B, respectively; R is the gas constant (8.31 J $K^{-1}mol^{-1}$); F is the Faraday constant (96,485 C mol^{-1}); T is the temperature (K). The activity is related to the concentration by the activity coefficient, γ, as $a = \gamma c$ [29], where γ can be calculated from the Debye–Huckel equation which estimates the effects of interaction between ions in a solution. The Debye–Huckel equation is given by, $-\log\gamma = \frac{Az^2\sqrt{I}}{1+B\alpha\sqrt{I}}$ [29], where A and B are constants from the Debye–Huckel theory with value of 0.51 and 3.3×10^7, respectively at room temperature, I is the ionic strength, and α is the ion size parameters. The α values of 600 and 900 pm for Ca^{2+} and H^+ ions, respectively, and 300 pm for both K^+ and OH^- ions were used [29]. The ionic strength, I, is a measure of the total ions in the solution, weighted according to their charges, and affects the dissociation and solubility of different salt. It is defined by, $I = \frac{1}{2}\sum_i^n c_i z_i^2$ [29], where c_i and z_i are the molar concentration and charge number of ion i. The selectivity coefficient value $K^{pot}_{A,B}$ indicates the sensing selectivity to primary ion A compared to interfering ion B. The selectivity coefficient value depends on the nature of sensing layer or selective membrane as well as the experimental conditions such as ion concentration and methods of determination [27–29]. The traditional methods include the separate solution method (SSM) [28] and mixed solution method (MSM) [28]. In the SSM method, the electrochemical potentials are measured separately in solutions containing only primary ions A or interfering ions B. In the case of the MSM method, the electrochemical potentials are measured both in only primary ions A and in a mixed solution containing the primary ions A and interfering ions B with various concentrations. Based on Nicolsky–Eisenman equation, the selectivity coefficient in the MSM method can be calculated as, $K^{pot}_{A,B} = a_A\left(e^{\frac{(E_{AB}-E_A)z_A F}{RT}} - 1\right) / (a_B)^{z_A/z_B}$ [28].

The measurements for obtaining sensing selectivity of H^+ to K^+ and Ca^{2+} were carried out in both acid (pH 2 solution) and base (pH 12 solution) medium. The pH 2 and 12 solutions with presence of various KCl and $CaCl_2$ concentrations of 10^{-2}, 10^{-3} and 10^{-4} M, respectively, were used for investigations. Fig. 6 shows the transfer curves of the pH 2 solutions and pH 2 solutions in the presence of various KCl concentrations of 10^{-2}, 10^{-3} and 10^{-4} M. This data indicates that the K^+ ions have low interference to H^+ ions

Table 1
The ionic strength and activity coefficient calculation of experimented solutions.

Solution	Ionic strength (M)	Activity coefficient			
		$\gamma(H^+)$	$\gamma(K^+)$	$\gamma(oh^-)$	$\gamma(Ca^{2+})$
pH 2 solution	0.01	0.8895			
pH 2 solution with KCl 10^{-2} M	0.02	0.8475	0.8471		
pH 2 solution with KCl 10^{-3} M	0.011	0.8844	0.8842		
pH 2 solution with KCl 10^{-4} M	0.0101	0.8889	0.8887		
pH 12 solution	0.01			0.8893	
pH 12 solution with KCl 10^{-2} M	0.02		0.8471	0.8471	
pH 12 solution with KCl 10^{-3} M	0.011		0.8842	0.8842	
pH 12 solution with KCl 10^{-4} M	0.0101		0.8887	0.8887	
pH 2 solution with $CaCl_2$ 10^{-2} M	0.04	0.7917			0.3922
pH 2 solution with $CaCl_2$ 10^{-3} M	0.013	0.8750			0.5860
pH 2 solution with $CaCl_2$ 10^{-4} M	0.0103	0.8879			0.6214
pH 12 solution with $CaCl_2$ 10^{-2} M	0.04			0.7910	0.3922
pH 12 solution with $CaCl_2$ 10^{-3} M	0.013			0.5860	0.5860
pH 12 solution with $CaCl_2$ 10^{-4} M	0.0103			0.6214	0.6214

in the pH 2 solution due to the shift voltage between each curve is smaller than 1 mV at constant current. Based on activity coefficient values of each ion in the mixed solution, presented in the Table 1, the selectivity coefficient could be calculated according to the aforementioned equations. In the case of selectivity to K^+, in both acid and base medium (pH 2 and 12), the selectivity coefficient value is as low as 2×10^{-2}. An analogous measurement in the solutions of pH 2 and 12 containing $CaCl_2$ was carried out. The results show the Ca^{2+} ions had low interference effect on the pH 2 and pH 12 solutions. The selectivity coefficient value was measured to be 5×10^{-2}. As compared to the selectivity coefficient values of the order of 10^{-3} reported from the measurements using ion-selective electrode (ISE) for selectively H^+ sensing to Ca^{2+} and K^+ ions [27–29], the obtained values from the pH sensor with no selective membrane in our work are slightly higher but appropriate for selective H^+ sensing in the electrolyte containing Ca^{2+} and K^+ ions with no large interference.

4. Conclusion

In this work, an ITO-extended gate OFET pH sensor was successfully fabricated and showed good performance. Its sensitivity was as high as 57–59 mV/pH in the pH range of 2–12. The interfering effects of K^+ and Ca^{2+} ions were investigated. The results indicated weakly interfering effects exerted by the K^+ and Ca^{2+} ions showing the selectivity coefficient to K^+, K_H^+, $_K^+$, of 2×10^{-2} and to Ca^{2+}, K_H^+, Ca^{2+}, of 5×10^{-2}. Therefore, the ITO-extended gate FET device can be used as an ion selective sensor device for pH measurements in multi-ion electrolytes and cell-based biosensors without an ion-selective membrane. Furthermore, organic FETs with an extended gate structure can be used as a potentiometric transducer for bio-chemical applications, since the surface of the extended gate ITO can be easily modified with different sensing layers.

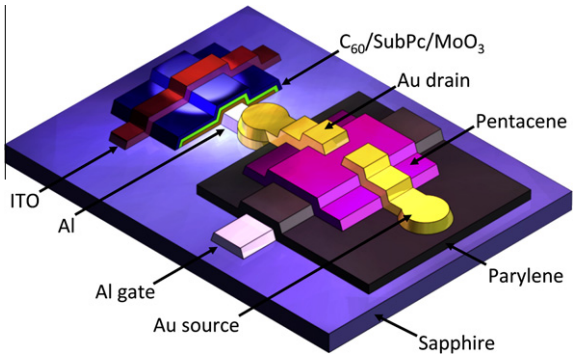

Fig. 1. Schematic diagram of the integrated passive pixel sensor consisting of a top-illuminated organic photodetector with an indium-tin-oxide (ITO) top contact in series with a pentacene organic thin film transistor. Layer compositions are indicated.

structure (500 Å C_{60}/90 Å SubPc/300 Å MoO_3) was thermally evaporated at a rate of 1 Å/s. A 500 Å-thick ITO anode was sputtered at a power of 20 W (rate = 0.1 Å/s) using an Argon plasma at a pressure of 2 mTorr. In Fig. 2c, inset, is a molecular structural formula of the donor, SubPc. After depositing the OPD layers, the samples were loaded into a parylene deposition system where 0.70 g of parylene C (dielectric constant, $\varepsilon_r = 3.15$) was coated onto the OTFT gate contact, forming a 2700 Å-thick insulator. Finally, the 500 Å-thick pentacene channel and the 400 Å-thick Au source and drain contacts were sequentially evaporated at the rates of 0.5 and 0.3 Å/s, respectively, to complete the OTFT. All features were defined using shadow masks attached in a high-purity N_2 ambient (<1 ppm H_2O and O_2), with the exception of a brief exposure to air before and after parylene deposition. The OPD dimensions (100 μm × 800 μm) and OTFT channel width-to-length ratio (W/L = 500 μm/30 μm) were set by shadow-masking during ITO and Au deposition, respectively.

Device performance was measured in air using a semiconductor parameter analyzer. Incident light for measuring the circuit dynamic range (*DR*) was provided by a mercury lamp with a spectral bandpass filter at a center wavelength of $\lambda = 580 \pm 2$ nm, matching a Hg emission peak as well as the absorption maximum of SubPc. The illumination intensity was varied using neutral density filters and measured using a calibrated Si photodetector. External quantum efficiency (*EQE*) was measured using a lock-in amplifier and monochromated light from a tungsten-halogen lamp chopped at ~200 Hz. Voltage was applied to the detector with a current amplifier at the input to the lock-in for biased *EQE* measurement. The circuit

(a) Output characteristics of the pentacene OTFT for V_{GS} = 0 V (short-dashed line), −10 V (dash-dotted line), −20 V (dotted line), −30 V (dashed line), and −40 V (solid line). (b) Transfer characteristics of drain current (I_{DS}) vs. gate-source voltage (V_{GS}) of the organic thin film transistor (OTFT) at a drain-source voltage of V_{DS} = −4 V (solid line), −5 V (dashed line), and −10 V (dash-dotted line). The square-root of the drain-source current (squares) and the fit (short-dashed line) are shown on the right-hand axis. (c) Current–voltage characteristics (I_{OPD}–V) of the organic photodetector (OPD) in the dark and under illumination at several different intensities. The incident wavelength is $\lambda = 580 \pm 2$ nm. *Inset*: Molecular structural formula of SubPc. (d) External quantum efficiency (*EQE*) of the integrated SubPc/C_{60} OPD under 0 V bias (solid line), −1 V (dashed line), and −2 V reverse bias (short-dashed line), compared to that of a control inverted OPD (open circles). The specific detectivity (D^*) at −1.5 V is shown on the right-hand axis (squares).

transient response was measured using an oscilloscope and a pulse generator with rise and fall times of 2 ns controlling the transistor gate.

The characteristics of the discrete pixel components were individually measured with results shown in Fig. 2. The OTFT output characteristic is shown in Fig. 2a. The drain OFF current is $I_{DS} = 27 \pm 3$ pA at $V_{DS} = -4$ V, and the ON/OFF ratio is 10^5 (Fig. 2b). The OFF current is comparable to that of a BC-OTFT[3] at small V_{DS}, while the ON current is improved by more than two orders of magnitude. The field-effect hole mobility, $\mu = 0.09 \pm 0.02$ cm^2/V s, was obtained using $I_{DS} = [\mu WC/2L](V_{GS} - V_{th})^2$ in the saturation region, where C is the gate-insulator capacitance, V_{GS} is the gate-source voltage, and V_{th} is the threshold voltage. The OTFT ON current is comparable to previously reported bottom-gate pentacene transistors employing a polymer gate dielectric, while the low OFF current is achieved with much smaller dielectric thickness (270 nm) than a previously reported thickness of >500 nm [10]. This is attributed to reduced gate leakage due to small gate-source overlap (<350 μm × 500 μm).

The current–voltage (I_{OPD}–V) response of the OPD is shown in Fig. 2c. Under a reverse bias of −1.5 V, the OPD dark current is $I_{Dark} = 20$ pA. Also, $EQE = 18.2\%$ at $\lambda = 580$ nm, and increases to 19.9% at −2 V due to increased polaron-pair dissociation at higher voltages [11] (Fig. 2d). The *EQE* of an analogous inverted discrete OPD is also shown in Fig. 2d. The *EQE* of both devices is within typical device-to-device variations. Over the range of incident optical powers used for this work (from 2.6 to 151 mW/cm^2), the OPD photocurrent is linear, resulting in a high detection *DR*. The photodetector specific detectivity (D^*) at −1.5 V is shown in Fig. 2d). Now, D^* is calculated using $D^* = \sqrt{A\Delta f}/NEP$, where A is the detector area, Δf is the bandwidth, and *NEP* is the noise equivalent power [2]. Under reverse bias, shot noise dominates the *NEP*, giving $D^* = \sqrt{A\Delta f} \cdot R/\sqrt{2qI_{Dark}}$, where R is the responsivity, and q is the elementary charge. At $\lambda = 580$ nm, $D^* = 9.4 \times 10^{11}$ cm Hz$^{1/2}$ W^{-1}.

The integrated pixel performance was characterized by measuring the current between the anode of the OPD and the source of the OTFT (I_{AS}) under various light intensities and V_{GS} (Fig. 3a). The pixel has a dark OFF current of $I_{AS} = 31 \pm 5$ pA and dark ON current of 950 ± 130 pA. The dark OFF current is consistent with that of the discrete OTFT within measurement error. The slight difference is due to the change in V_{DS} across the sample from testing the discrete OTFT ($V_{DS} = -4$ V) vs. testing the integrated pixel ($V_{AS} = -4$ V). The dark ON current of the pixel at $V_{AS} = -4$ V is noticeably higher than that of the OPD at −1.5 V in Fig. 2c. Nevertheless, this pixel performance is sufficient for application to a 30 × 30 sensor array.

The lowest detectable light intensity is 17 μW/cm^2, as shown in Fig. 3a, establishing a lower limit to the *DR*. Since the OPD photocurrent does not saturate within the testing range used, the upper limit is determined by the ON current (4.6 ± 0.05 μA) of the OTFT at light intensities >130 mW/cm^2. Furthermore, ΔI_{AS} is the difference between the ON current under illumination and in the dark at a gate bias, $V_{GS} = -39.5$ V. Fitting the pixel photocurrent ΔI_{AS} vs. incident power P gives $R = 0.083 \pm 0.003$ A/W, consistent with the *EQE* result (see Fig. 3b). The pixel showed a 12-bit dynamic range (corresponding to $DR = \Delta I_{AS,MAX}/\Delta I_{AS,MIN} = 4.1 \times 10^3$). The improved performance is due to the enhanced ON current of TC-OTFTs compared with previously reported BC transistors [3].

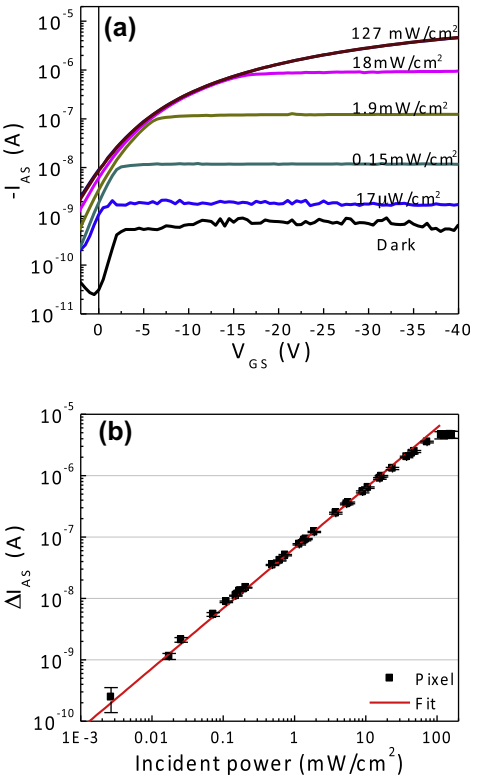

Fig. 3. (a) Transfer characteristics of anode-source current (I_{AS}) vs. V_{GS} of the pixel at an anode-source voltage of −4 V for various illumination intensities at $\lambda = 580 \pm 2$ nm. (b) Pixel photocurrent response, ΔI_{AS}, as a function of illumination power intensity (P) extracted from the transfer characteristics at $V_{GS} = -39.5$ V, where ΔI_{AS} is the difference between I_{AS} under illumination and in the dark. The line is a linear fit of to the data. The extent of the linear range of data gives the circuit dynamic range, equal to 12-bit.

The pixel response time was determined by measuring the voltage across a resistor between the source of the OTFT and ground. A pulsed V_{GS} from +2 V (OFF state) to −40 V (ON state) was applied while the device was kept under a constant $V_{AS} = -4$ V and an illumination intensity of 49 mW/cm^2. The resulting data were modeled by a bi-exponential decay following $-I_{AS} = I_0 + A_1 \exp[-(t - t_0)/\tau] + A_2 \exp[-(t - t_0)/t_{RO}]$, where I_0 is the steady state pixel current when the gate is ON, and t_0 is the time when the pulse is applied (Fig. 4). The read-out time was found to be $t_{RO} = 0.4 \pm 0.05$ ms. The resistance-capacitance charging time constant is $\tau = 29 \pm 8$ μs when using a 37.7 kΩ load, corresponding to the fast decay initially observed. Previously, it has been found that the optical response of analogous SubPc/C_{60} OPDs is on the order of nanoseconds [3,12], indicating that the circuit response time, t_{RO}, is limited by the discharging time through the OTFT channel. Note that t_{RO} is larger than the charge transit time across the channel (25 μs) as derived from the hole mobility, indicating that t_{RO} is primarily determined by charge trapping in the

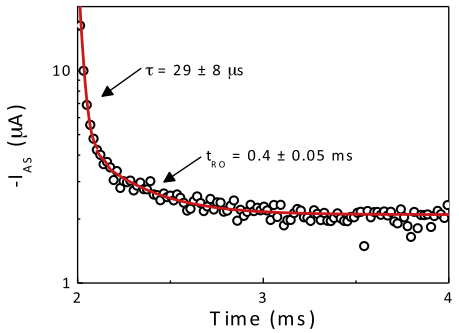

Fig. 4. Transient response of the pixel to a square voltage pulse applied at the transistor gate electrode measured using a 37.7 kΩ load. Also shown (dashed line) is a bi-exponential decay fit to the data. The time constants extracted from the fit are the read-out time of t_{RO} = 0.4 ± 0.05 ms, and the *RC* time constant of τ = 29 ± 8 μs.

pentacene layer. This response can be further improved by using a transistor with a higher mobility employing, for example, self-assembled monolayers at the insulator–channel interface that result in improved crystal orientation [10,13,14].

In conclusion, an organic integrated pixel based on a bottom-gate, top-contact pentacene transistor and an inverted SubPc/C_{60} photodetector has been demonstrated. It has a 12-bit dynamic range, an OFF current of 31 ± 5 pA, and a read-out time of 0.4 ± 0.05 ms. The circuit performance is adequate for use in video-rate, high-sensitivity focal plane arrays with dimensions of at least 30 × 30 pixels.

metal phthalocyanines (MPcs) [18–22], and 1,5-diaminoanthraquinone [23–25] – has been used to prepare various nanostructures for applications in organic electronics, especially photovoltaic devices and field emitters, with the advantages of low-cost, low-temperature processing and mechanical flexibility. Among those materials, MPcs, which feature a central metal atom bound to a π-conjugated ligand, have particularly attractive properties for their application in optoelectronic devices (e.g., light emitting diodes [26], gas sensors [27–29], field-effect transistors [30–33], solar cells [34–36], and field emission devices [20,21]). Most active layers of MPcs have been fabricated using deposition methods, including organic vapor-phase deposition (OVPD) [1,18,37,38], thermal evaporation [19,21], and molecule beam epitaxy (MBE) [39]. It has been reported [1,21,22,25] that the morphologies of thin films of MPcs depend on the type of deposition technique, the heat-treatment temperature, and the conditions of the substrates during the deposition process. Tuning these various growth conditions can have a dramatic effect on the resulting morphologies and electronic properties, thereby requiring further investigation of the potential use of such structures in optoelectronic devices.

When developing field emitters, the inter-fiber distance, the aspect ratio, and the density of the nanofibers are theoretically and experimentally important parameters for achieving efficient field emission (FE) performance. Under practical conditions, however, it can be difficult to control the inter-fiber distance at an ideal fiber density. Although higher-density nanofibers provide higher electron currents, electrostatic screening effects are observed in such films; therefore, high-density nanofiber films do not possess appropriate FE properties [40]. To decrease the screening effect, forming a pattern array of aligned nanofibers is a facile method of enhancing FE properties [41]. Moreover, a recent study found that the electric field gradient at the edge of an emission bundle is significantly higher than that at its center [42]. Therefore, the ability to design patterns of nanofiber films should allow efficient increases in FE performance.

In this present study, we used FePc as a starting material, instead of a precursor of the catalyst for CNT growth [43], to fabricate FePc nanostructures on Si and Ag substrates. Because the surface energy and temperature of a substrate are both important factors affecting the morphologies of FePc films, we sought appropriate conditions for the direct growth of FePc films featuring planar structures on Si surfaces (higher surface energy) and fiber-like structures on Ag surfaces (lower surface energy). We used scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HRTEM) to characterize these 1D FePc nanofiber films. By taking advantage of such selective growth at various substrate temperatures, we used micropatterned Ag/Si substrates to obtain the fine growth of FePc nanofibers on the patterned Ag regions and in-plane FePc structures on the remaining open areas of the Si surfaces. To study the enhancement in FE performance when using field emitters with such micropatterned geometries, we used a vacuum emission measurement (VEM) system to compare the FE characteristics and device stability tests relative to those of corresponding unpatterned devices.

2. Experimental details

FePc thin films were deposited using a thermal evaporator operated at a base pressure of 7×10^{-6} torr. A commercially available FePc powder (purity: 96%; Tokyo Chemical Industry) was used as received without further purification; it was sublimed onto two kinds of substrates (Si and Ag). The Ag substrates were prepared by depositing Ag films onto Si (1 0 0) substrates using an electron beam (e-beam) evaporator. Prior to e-beam evaporation of the Ag film, a Ti layer (thickness: 300 Å) was deposited on a cleaned Si substrate as an adhesion layer. Without breaking the vacuum, a thin layer of Ag (thickness: 1000 Å) was then deposited. The influence of the substrate temperature (T_{sub}) on the FePc film morphology during FePc thermal evaporation was tested at values of T_{sub} of 25, 120, 180, and 240 °C. The sublimation of the FePc powder was performed at a crucible temperature of 180 °C; the corresponding deposition rate, controlled by a quartz crystal microbalance, was 0.4 Å/s.

Top and cross-sectional views of the morphologies of the FePc thin films were investigated using a JEOL JSM-6500F scanning electron microscope. The profiles and fine structure of nanofibers were imaged and analyzed using a JEOL-2010 high-resolution transmission electron microscope. The phase and crystallinity of the FePc nanofibers were characterized using grazing-incidence X-ray diffraction (GIXRD), employing a Bruker D8 system with Cu Kα radiation. The incident angle of the X-ray beam was fixed at 0.2°. Contact angles and surface energies were determined on each substrate using a Krüss universal surface tester (model GH-100), the geometric mean approximation, and three standard liquids: water (H_2O), diiodomethane (CH_2I_2), and ethylene glycol [$C_2H_4(OH)_2$]. The surface energies of the substrates were measured using the Owens and Wendt method. The valence band [highest occupied molecular orbital (HOMO)] of the FePc materials was surveyed using photoelectron spectroscopy in air (PESA; AC-2 photoelectron spectrometer); the Riken Keiki apparatus detected the number of photo-emitted electrons per second (CPS) as a function of the photon energy, using a UV light source for excitation and a gas-flow Geiger counter. The relationship between CPS and the photon energy is described using the approximate equation [44]:

$$\mathrm{CPS}^{1/2} = \frac{M}{k}(h\nu - \phi) \quad (1)$$

where M is an emission constant, k is the Boltzmann constant, $h\nu$ is the photon energy, and ϕ is the work function. When the surface materials were bombarded under a gradually increasing amount of UV light, photoelectrons were emitted from the surface (from a depth of several to hundred angstroms) at a certain energy level, due to the photoelectron effect. These emitted photoelectrons were then counted by a detector and open counter. The value of ϕ was determined through linear extrapolation of $\mathrm{CPS}^{1/2}$ to zero yield [44], when the PESA data were fitted using the software supplied with the spectrometer. UV–Visible (UV–Vis) spectra (300–1100 nm) were recorded using a Shimadzu UV-3600 spectrophotometer.

The FE characteristics of the FePc nanofibers were determined using a VEM system under a base pressure of 5×10^{-6} torr. Indium tin oxide (ITO) plate glasses were used as anodes, positioned above the substrate surfaces at a distance of 60 μm. The FE instrument featured a plate-to-plate geometry; the active area of the FePc nanofibers was 0.06 cm^2 for the unpatterned devices and 0.006156 cm^2 for the micropatterned devices featuring 171 (19×9) squares, each with a width of 60 μm. Current density–electric field (J–E) curves of the FE devices were measured using a Keithley 237 instrument (accuracy: 10^{-13} A). The emission currents of the FePc nanofibers were monitored as a function of the sweep bias. Stability tests were performed for 3000 s under a constant applied field of 11 V/μm at room temperature. The patterned FE devices are denoted herein as "**FE-X-P**," where **X** refers to the FePc nanofiber films were prepared at the value of T_{sub}. In addition, the unpatterned FE devices are denoted as "**FE-X-N**".

3. Results and discussion

The growth mechanisms of organic thin films on substrates are complicated because of specific issues related to each type of organic molecule; for example, the effects of the surface energy of the substrate, noncovalent interactions at the molecule–substrate interface, and intermolecular forces between molecules. Stranski–Krastanov growth tends to be the mode most frequently observed for small organic molecules under thermal evaporation conditions [45]. Previous studies [21,34–36] have revealed that the surface energy and substrate temperature are both important factors controlling the morphologies of films of small organic molecules. Therefore, in this study, we selected Ag and Si, with surface energies of 34.8 and 41.3 mJ/m^2, respectively, as electrodes for the selective growth of micropatterned FePc nanofiber films for FE applications. Fig. 1 displays SEM images of the FePc films deposited on the Si and Ag substrates at various values of T_{sub}. At a value of T_{sub} of 25 °C, all of the FePc thin films on the Si and Ag substrates exhibited analogous and contiguous granular crystals with smooth morphologies [Fig. 1(A, E, and I)]. When we increased the value of T_{sub} from 120 to 240 °C, elongated FePc grain-like films were formed with the in-plane morphology on the Si surface [Fig. 1(B–D)]. In contrast, when the FePc layers were deposited on the Ag substrate at values of T_{sub} in the range 120–240 °C, we obtained high-quality FePc fiber-like films featuring out-of-plane 1D nanostructural morphologies [Fig. 1(F–H) (top-view) and (J–L) (cross-sectional view)]. Notably, we found a high-density of aligned FePc nanofibers in the films deposited on the Ag surface at a value of T_{sub} of 240 °C [Fig. 1(H, L)]. The variation in FePc morphology that occurred upon increasing the value of T_{sub} can be explained by considering the following equation [46]:

$$\gamma_s = \gamma^0[1 - (T_s/T_c)]^n \quad (2)$$

where γ_s is the surface energy at the substrate temperature T_s and γ^0 is the surface energy at the critical temperature (T_c); the value of n may be close to unity for cathodes. This formula suggests that the surface energy of the substrate (γ_s) decreases as the substrate temperature increases, thereby favoring the desorption and surface diffusion of FePc molecules. A decrease in surface energy weakens the molecule–substrate interactions, causing the molecule–molecule interactions (i.e., π–π and van der Waals interactions) to become dominant. When nonpolar molecules (e.g., Alq_3, PY, coronene) form 1D nanofibers, molecular stacking occurs mainly through π–π and van der Waals interactions. In the 1D nanostructure of the stacked planar FePc molecules, we suspect that both face-to-face (π stacking) and edge-to-edge (van der Waals interaction) intermolecular forces play an important role in the 1D self-assembly of the stacking molecules [4–9].

At the device level of field emitters, the field enhancement factor (β) is approximated by the aspect ratio (AR; length-to-radius ratio) of a 1D nanostructure, defined as AR = (mean length; L)/(mean radius; r_m). A 1D nanostructure having a higher AR will exhibit a larger geometrical field enhancement and a lower turn-on field [47]. In this study, we found that changing the deposition time adjusted the lengths of the nanofibers. Besides, both high-density and high-AR of aligned FePc nanofiber films can be easily achieved on the Ag surface at a value of T_{sub} of 240 °C. To further investigate the influence of AR effect on FE properties, we prepared FePc nanofiber films with different ARs by changing values of T_{sub} of 180 and 240 °C [Fig. 2(A and E)]. Furthermore, the histograms of the fiber length, radius, and AR [Fig. 2(B and F), (C and G), and (D and H)] were obtained for comparison, respectively, which were based on the cross-sectional SEM images of those structures. In the fabrication condition of T_{sub} of 180 and 240 °C, the values of L of these FePc nanofibers with an apparent difference were found to be 124 ± 41 and 699 ± 216 nm, while the values of r_m of these FePc nanofibers were analogous to be 21.9 ± 4.0 and 22.2 ± 4.3 nm, respectively. In addition, the mean values of ARs of individual FePc nanofibers were calculated to be 6.0 ± 2.6 and 30.3 ± 3.6, respectively.

Fig. 3(A) displays a TEM image and the corresponding selected area electron diffraction (SAED) pattern of a single FePc nanofiber, which we had deposited on the Ag substrate at a value of T_{sub} of 240 °C. The TEM image of this FePc nanofiber exhibits fringes, suggesting that the FePc molecules were stacked in short-range order at the edges of the nanofiber, but entangled randomly within the nanofiber. The SAED pattern presented in the inset indicates that the FePc nanofibers were polycrystalline. From studies of several polymorphs of phthalocyanine materials, it is well established that the processing conditions can result in different phase formations (e.g., polymorphs of α and β phases), which exhibit slightly different structural and electrical characteristics [18]. The structural difference between these two polymorphs is the tilt angle of the molecular plane with respect to the stacking b-axes, with the tilt angle of the α phase being smaller than that of the β phase [39]. In addition, the α-form of a FePc film can transform to the β-form during subsequent annealing or when deposited at higher temperature [48,49]. Fig. 3(B) presents GIXRD patterns of commercial FePc powders and the FePc thin films that we deposited on the Ag surface at various

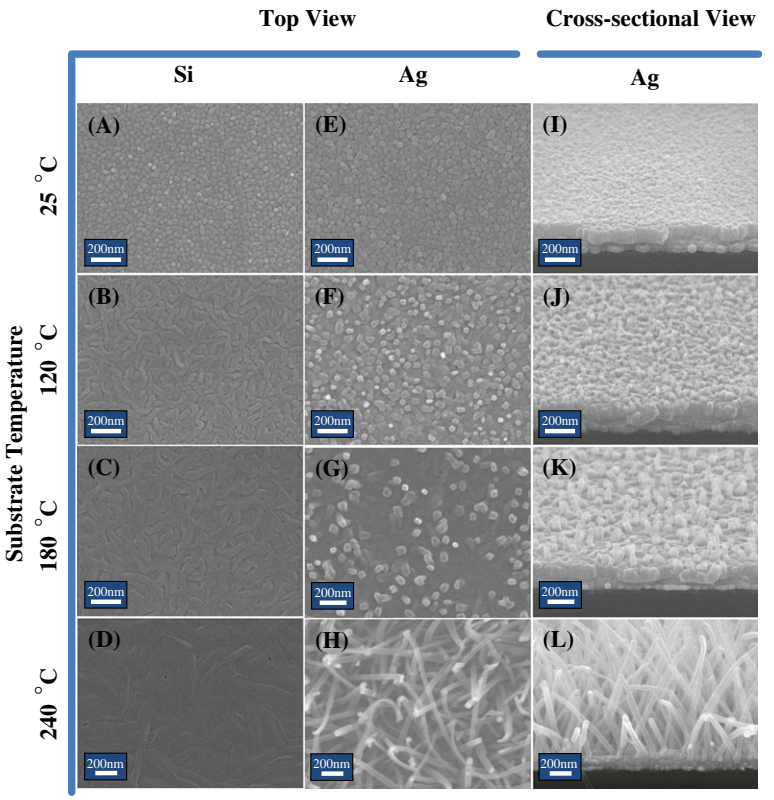

Fig. 1. Top-view and cross-sectional SEM images of FePc thin films deposited on Si and Ag substrates at values of T_{sub} of 25 (A, E, and I), 120 (B, F, and J), 180 (C, G, and K), and 240 °C (D, H, and L).

values of T_{sub}. The commercial FePc powders were crystalline in character; a single peak appeared at a value of 2θ of 6.96°, corresponding to the (2 0 0) peak of the α-FePc phase. The diffraction patterns of the thin films deposited on the Ag substrate at a value of T_{sub} of 25 °C suggested that they featured the same polymorphs as those deposited on sapphire at the same temperature [39]. The absence of diffraction patterns of the β-FePc phase (peaks at 7.01° and 9.6°) [39] suggested that the structure of the FePc nanofibers deposited on the Ag surfaces at a value of T_{sub} of 240 °C was that of the α phase, with preferential orientation along the (2 0 0) direction.

To further understand the energy levels of the FePc materials for FE applications, we used photoelectron spectroscopy [Fig. 4(A)] and UV–Vis spectroscopy [Fig. 4(B)] to measure the HOMO energy levels and obtain the energy gap. Using the supplied software, we fitted the PESA data through linear extrapolation of the value of $CPS^{1/2}$ to zero yields, obtaining a HOMO energy level for FePc of 5.01 eV relative to the vacuum level. The Q-band in Fig. 4(B), between 500–800 nm in the UV–Vis spectrum of the FePc films, revealed overlapping of the three main bands with maxima at 570, 630, and 710 nm. From the onset wavelength at 817 nm, we derived the energy gap and LUMO energy level for the FePc materials of 1.52 and 3.49 eV. Fig. 4(C) displays a schematic representation of the energy level diagram; the work function of the Ag cathode substrate was 4.8 eV. Therefore, electrons injected from the Ag substrate into the LUMO of the FePc materials would have to conquer an energy gap of 1.31 eV.

Next, we performed the selective growth of micropatterned FePc nanofiber arrays on the patterned Ag/Si substrates. In this electrode system, the Ag region would induce the formation of the fiber-like structure of FePc and the Si region would result in the flat grain-like structure. We prepared the patterned Ag substrate in three steps: (i) First, a purpose-made shadow mask was placed on the surface of Si substrate [Fig. 5(A and B)]. The pattern of this purpose-made mask featured a total of 171 (19×9) squares, each with a width of 60 μm. The active area of the device was 0.006156 cm^2. (ii) Next, 100-nm-thick Ag films were deposited on the substrate through e-beam evaporation [Fig. 5(C)]. (iii) Finally, the FePc nanofiber arrays were formed at a certain substrate temperature via thermal evaporation [Fig. 5(D)]. Fig. 6(A–D) display top-view and cross-sectional SEM images of the FePc thin films deposited on the patterned Ag substrate at 240 °C. In Fig. 6(B–C), it is evident that the vertical growth of nanofibers was restricted to the areas presenting the Ag film, where the pattern of the cathode featured nanofiber arrays with each square having a width of 60 μm and an interval of 45 μm between neighboring squares. From the point of view of practical applications, the fabrication of FePc nanofiber arrays on patterned Ag substrates at low temperature (<250 °C) through simple patterning method should be suitable for developing electronic devices. Fig. 6(D) pro-

vides a tilted-view, magnified SEM image of a FePc film grown on a region between Ag square patterns.

We examined the FE properties of the FePc nanofiber devices using a parallel-plate configuration with a spacing of 60 μm in a vacuum chamber under a pressure of 5×10^{-6} torr. The anode (ITO glass) was connected to the source monitor unit (SMU) of a Keithley 237 instrument; the cathode of the Ag substrate beneath the FePc nanofibers was grounded. We measured the emission current while increasing the applied voltage from 0 to 720 V with a sweep step of 20 V. To investigate the AR effect of FE properties, we examined the FE characteristics (J–E curve) of the patterned FePc nanofiber devices prepared at values of T_{sub} of 180 (**FE-180-P**) and 240 °C (**FE-240-P**), as shown in Fig. 7(A and B). The turn-on fields (defined as the applied field required for a current density of 10 μA/cm^2) of these patterned FE devices were 10 and 7.7 V/μm, respectively; at an applied field of 12 V/μm, the maximum current densities were 0.26 and 6.77 mA/cm^2, respectively. The Fowler–Nordheim (FN) equation describes the dependence of the emission current of a field emitter on the applied field [50]:

$$\ln\left(\frac{J}{E^2}\right) = \ln\left(\frac{A\beta^2}{\phi}\right) + \left(\frac{-B\phi^{3/2}}{\beta}\right)\left(\frac{1}{E}\right) \quad (3)$$

Flow chart of the growth of micropatterned FePc nanofiber arrays: (A) a P-type Si (1 0 0) wafer (heavy doped); (B) a purpose-made metal mask for Ag layer deposition using an e-beam evaporator; (C) the resulting patterned Ag arrays; (D) the well-aligned FePc nanofibers grown selectively on the patterned Ag arrays through thermal deposition.

where A and B are constants (1.54×10^{-6} A eV/V^2 and 6.83×10^3 V/eV$^{3/2}$/μm, respectively), J is the current density, E is the applied field, and ϕ is the local work function of the emitter material. By plotting $\ln(J/E^2)$ with respect to $1/E$, the slope of the line of best fit can be used to deduce the field enhancement factor (β):

$$\beta = -\frac{6.83 \times 10^3 \phi^{3/2}}{S} \tag{4}$$

where S is the slope of the FN plot. The linear FN plots of **FE-180-P** and **FE-240-P** reveal that the J–E characteristics of the FePc nanofibers followed the FN field emission mechanism, indicating that cold electrons tunneled

through the quantum energy barrier (i.e., quantum tunneling process) under an applied field [Fig. 7(D and E)]. The slopes of the FN plots for **FE-180-P** and **FE-240-P** were −183.8 and −141.8, respectively. Because the LUMO en-

ergy level (ϕ) of FePc was 3.49 eV, we estimated the values of β of these patterned FE devices to be 242 and 314, respectively. According to FN theory, β is strongly dependent on the geometric structure [51–54] (i.e., shape, size, alignment, crystallinity, AR) and density of the nanofibers grown on the cathode. In our system, **FE-240-P** exhibited efficient FE performance, in terms of a lower turn-on field, higher emission current and larger value of β, relative to that of **FE-180-P**, suggesting the higher AR of patterned devices were suitable for the FE application. To study the enhancement of patterned geometries in FE performance, we also performed the FE measurements of the unpatterned FePc nanofiber devices prepared at 240 °C (**FE-240-N**) as a reference. In the Fig. 7(C), the turn-on field of **FE-240-N** was 10.3 V/μm, and the maximal current density of that was 0.13 mA/cm^2 at an applied field of 12 V/μm. Fig. 7(F) reveals the slope of the linear FN plot for **FE-240-N**, getting that the value of β of **FE-240-N** was approximately 329. Notably, the maximal current density of **FE-240-P** was over 50 times greater than that of **FE-240-N**; that is to say, its FE properties had obviously improved. When the number-density of the nanofibers in each square pattern is sufficiently high [41], the individual nanofiber can be replaced by the square pattern, which can be considered as a single emitter in FE fabrication. In this study, the patterned FePc nanofiber arrays exhibited enhanced emission characteristics that resulted from the pattern design decreasing the screening effect [40]. Each FePc nanofiber square pattern could be regarded as an independent field emitter. Moreover, each individual FePc nanofiber square pattern, as an isolated emitter, allows the emission of electrons from the edges of the square pattern. The highly efficient FE current can be attributed to the edge effect at a certain level [42].

We performed stability tests of our aligned FePc nanofibers for 3000 s under an applied field of 11 V/μm at room temperature. Fig. 8 presents the plots of the FE current density versus testing time for **FE-180-P**, **FE-240-P**, and **FE-240-N**. The calculated mean current density was ca. 0.12 mA/cm^2 for **FE-180-P** [Fig. 8(A)], ca. 3.39 mA/cm^2 for **FE-240-P** [Fig. 8(B)], and ca. 0.04 mA/cm^2 for **FE-240-N** [Fig. 8(C)]. Particularly, **FE-240-P** exhibited remarkably stable emission current with fluctuations of less than 20%. Furthermore, we observed slowly increasing emission currents from all emitters over time. Relative to other organic FE devices [5,20,21], the comparable properties of the FePc nanofibers prepared at a low fabrication temperature and exhibiting a low turn-on field suggest their potential application in organic field emitters. The pattern design of the well-aligned 1D FePc nanostructures has advantages over other nanomaterials in that it allows FE improvement. Thus, this promising organic nanomaterial sustained a stable FE current, without any decay, during the measurement period, demonstrating that the patterned FePc nanofiber arrays, prepared at the value of T_{sub} of 240 °C, have great applicability for use in cold field electron-emitting devices.

4. Conclusions

By varying the surface energy and the temperature of the substrates during vacuum evaporation, the morphology of self-assembled FePc films can be controlled to form in-plane structures on Si surfaces (higher surface energy) and out-of-plane structures on Ag surfaces (lower surface energy). These temperature-enhanced and well-aligned 1D FePc nanofibers exhibited FE characteristics and followed FN behavior. Using such morphological control, we grew the patterned FePc nanofibers selectivity on previously patterned Ag/Si substrates; moreover, the higher AR of the patterned device (**FE-240-P**) exhibited better FE performance than **FE-180-P**. In the optimal growth condition of T_{sub} of 240 °C, the emission current of the device improved dramatically from 0.13 mA/cm^2 for the unpatterned device to 6.77 mA/cm^2 for the patterned device (when biased at an applied field of 12 V/μm), while the turn-on electric field of the device decreased accordingly from 10.3 to 7.7 V/μm. In FE stability tests, the current densities of **FE-240-P** exhibited fluctuations of less than 20%, revealing its stable and superior property within the duration of the measurement process. The enhanced FE performance and the stability of the emission current sug-

gest that this facile method for fabricating patterned FePc nanofiber arrays is suitable for their application in electron-emitting devices.

organic film. All these models are based on an assumption that the localized carriers (charged polarons) are spin sensitive to the external magnetic field and the internal hyperfine field of the hydrogen nucleus [13]. For the Zeeman mechanism, researchers seem to be also puzzled that why an extremely small Zeeman energy ($|-g\mu_B\vec{S}\cdot\vec{B}| \sim 10^{-5}$ eV for 1 T) can beat the thermal energy ($k_BT \sim 0.026$ eV at room temperature) to generate this OMFE. It is regretful that none of these models can give a quantitative explanation on the OMFE. Maybe a dynamic response theory of the spin to the magnetic field is needed to understand the OMFE, which there is not yet a report up to now. Recently the field-induced hopping mechanism has also been suggested [14], which believes that the hopping transport in OSCs is changed due to the Lorentz charge-magnetic field interaction but not the Zeeman spin-magnetic field one. However, the field-induced hopping mechanism still needs a further confirmation quantitatively for actual organic materials. In this paper, we try to give an analysis on the OMFE by calculating the magnetoresistance of an OSC based on the Zeeman mechanism. In our picture, the distinct properties of OSCs from that of inorganic counterparts are focused and it is found that the OMR is tightly related with these properties. We believe that this mechanism plays an important role in the understanding of OMFE. In the following section, the model and the method are presented. The results and discussions are shown in Section 3. Finally, in Section 4 a summary is given.

2. Model and method

Organic materials usually appear amorphous structure in the fabrication progress, such as spin coating or thermal evaporation. Theoretical investigation on the transport in an organic material or device is considered in two ways: one is based on the band transport mechanism and the disordered is partly included by considering the atomic position fluctuation [15]. Another is based on the hopping mechanism. In this mechanism, the transport is reflected by the Marcus formula of the hopping rate

$$\kappa_{ij} = \frac{2\pi}{\hbar}\tau^2 \frac{1}{\sqrt{4k_BT\pi\lambda}} \exp\left(-\frac{(\lambda+\varepsilon_j-\varepsilon_i)^2}{4k_BT\lambda}\right) \quad (1)$$

where τ_{ij} is the transfer integral and $\varepsilon_{i(j)}$ is the on-site energy. We give a simple estimate for MR based on the hopping mechanism. When an external magnetic field is applied, the on-site energy will become $\varepsilon_i \to \varepsilon_i \pm g\mu_B S_Z B$, due to the Zeeman effect. In this case, there exist four hoppings of π-electrons, i.e., from spin up to up, from spin down to down, from spin up to down and from spin down to up. Suppose the four hoppings take place with the same probability. The total hopping rate is

$$\kappa_{ij} = \frac{2\pi}{\hbar}\tau^2 \frac{1}{\sqrt{4k_BT\pi\lambda}} \exp\left(-\frac{(\lambda+\varepsilon_j-\varepsilon_i)^2}{4k_BT\lambda}\right) \times \left\{1+\left[\left(\frac{\lambda+\varepsilon_j-\varepsilon_i}{2k_BT\lambda}\right)^2 - \frac{1}{2k_BT\lambda}\right](g\mu_B S_Z)^2B^2\right\} \quad (2)$$

Assume the conductance is in proportional to the hopping rate, i.e., $\sigma \propto \langle\kappa_{ij}\rangle$, then the MR is obtained

$$MR = \frac{\sigma(0)-\sigma(B)}{\sigma(B)} = \frac{B^2}{B_0^2+B^2} \quad (3)$$

where $B_0^2 = \frac{1}{\left[\left(\frac{-(\lambda+\langle\varepsilon_j-\varepsilon_i\rangle)}{2k_BT\lambda}\right)^2 - \frac{1}{2k_BT\lambda}\right]g^2\mu_B^2S_Z^2}$. Although the expression is similar to the observed Lorentz fitting, the B_0 value in present formula is too large, which will result in an unobservable MR. Therefore, it seems to be difficult to obtain an apparent OMR based on present hopping picture. Of course here it is just a crude estimation. We have to take a much more comprehensive consideration on OMR in the frame work of hopping mechanism in the future.

Now let us consider the transport based on the band theory. To explain the large MR in silver chalcogenides, Xiong et al. considered the Zeeman splitting of the density of states (DOS) under an external magnetic field [16]. They showed that a nonmagnetic material could have a large MR when the DOS at Fermi level is sensitive to an external magnetic field (they also assumed a large Lande factor g in the calculation to enlarge the theoretical picture). As analyzed below, organic semiconductors should satisfy the condition and a large MR could be obtained even we do not take a large Lande factor.

Firstly we give the transport formula in organic semiconductors under a magnetic field. The conductance is mainly contributed from carriers at the Fermi level E_F, i.e., $\sigma \propto \rho(E_F)$, where $\rho(E)$ is the DOS of the system. For organic materials, the one-dimension model has been usually adopted. We give a schematic description of DOS in Fig. 1 for easier comprehension. In general, the spin of

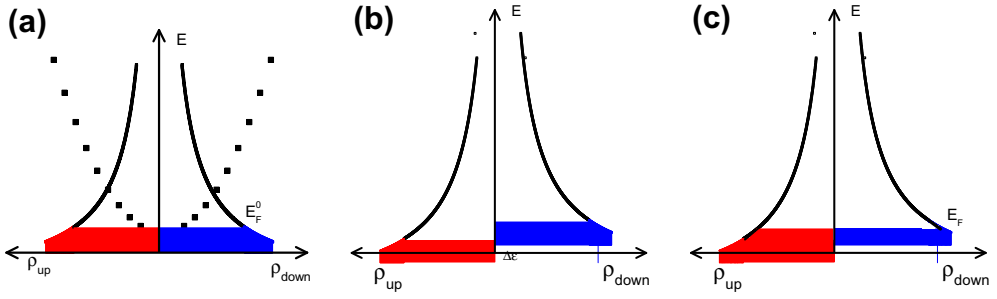

Fig. 1. Schematic description of the energy levels: (a) without an external magnetic field, the electrons of spin up and down are same, the dashed line is for the three-dimensional case; (b) apply an external magnetic field, the electron states are in nonequilibrium; and (c) after redistribution, a new Fermi level is formed.

electron can be divided into two parts, spin up and down and the corresponding DOS defined as $\rho_0(E)$ are degenerated in the absence of magnetic field, as shown in Fig. 1a, then the conductance $\sigma(0) \propto \rho(E_F) = 2\rho_0(E)$. When an external magnetic field is applied, energy levels of different spin would have opposite shifts by the Zeeman energy,

$$\Delta\varepsilon = -g\mu_B \vec{S}\cdot\vec{B} \tag{4}$$

where g is the Lande factor, μ_B is the Bohr magneton and $\vec{S}$ is the spin angular momentum. In some materials, such as silver chalcogenides, the Lande factor g is as large as 10^2 [16], its value in organic materials is 2 [17], the same as free electron. Of course a large g factor may enlarge the theoretical result. As Zeeman energy is a constant for the same spin, the shape of the DOS for spin-up and spin-down remain the same, which is shown in Fig. 1b. Due to the Zeeman energy splitting, some electrons shifting upwards will be converted into the electron shifting downwards. So the Fermi level of the material will change due to the redistribution of electrons as shown in Fig. 1c. The density of states will also change from $\rho_0(E)$ to $\rho_B(E)$. Then the MR is obtained,

$$MR = \frac{\sigma^{-1}(B) - \sigma^{-1}(0)}{\sigma^{-1}(0)} = \frac{2\rho_0(E_F^0) - \rho_B(E_F)}{\rho_B(E_F)} \tag{5}$$

where E_F and E_F^0 are the Fermi level with and without the magnetic field separately. The total DOS at the new Fermi level E_F under a magnetic field is given by,

$$\begin{aligned}\rho_B(E_F) &= \rho_\uparrow(E_F) + \rho_\downarrow(E_F) \\ &= \rho_0(E_F - |\Delta\varepsilon|) + \rho_0(E_F + |\Delta\varepsilon|)\end{aligned} \tag{6}$$

and E_F is derived from the conservation of the total electrons through the following relation,

$$\begin{aligned}\int_0^{E_F^0} 2\rho_0(E) &= \int_{-|\Delta\varepsilon|}^{E_F} \rho_0(E - |\Delta\varepsilon|)dE + \int_{|\Delta\varepsilon|}^{E_F} \rho_0(E + |\Delta\varepsilon|)dE \\ &= \int_0^{E_F+|\Delta\varepsilon|} \rho_0(E)dE + \int_0^{E_F-|\Delta\varepsilon|} \rho_0(E)dE\end{aligned} \tag{7}$$

From Eq. (5) we can see that MR is sensitive to the difference of DOS at Fermi level with and without the magnetic field.

To get MR of an organic semiconductor, we have to calculate the DOS with a concrete material. Here we take the most common small molecule Alq_3 as an example, which can be considered as a one-dimensional stack of planar conjugated molecules due to the highly one-dimensional motion of charge carriers [18]. Therefore a one-dimensional model can be adopted within which each molecule is reduced to a site with one molecular orbital, similar to the model for pentacene proposed by Troisi and Orlandi [15], so the Hamiltonian can be written as,

$$H = -\sum_j [\tau - \alpha(u_{j+1} - u_j)](|j\rangle\langle j+1| + |j+1\rangle\langle j|) \tag{8}$$

where $|j\rangle$ is the jth molecular orbital. The charge-transfer integral τ between the consecutive orbitals $|j\rangle$ and $|j+1\rangle$ is modulated by the term $\alpha(u_{j+1} - u_j)$ with α the electron–phonon coupling constant, and u_j is the jth molecular displacement from its equilibrium position. This model is almost identical to the SSH (Su–Schrieffer–Heeger) model used for a conducting polymer and can be solved with a self-consistently iteration method [19]. As indicated by the α term, there exists a strong electron–phonon interaction in organic semiconductors. The band structure obtained from Eq. (8) is tightly related to the doping or carrier concentration. We have to solve Eq. (8) with a given carrier concentration $n_e = N_e/N$. In addition, due to the feature of self-generation of carriers, the carrier concentration in organic materials is very low [18], in the following calculation, we consider a dilute doping with $n_e \leqslant 0.25$.

In OSCs, we suppose $\varepsilon_i = \varepsilon_j$, from the hopping rate of Marcus formula equation (1) and the Einstein–Smoluchowski relation, we have the charge carrier mobility,

$$\mu = \frac{e}{k_B T} P d^2 \tag{9}$$

where d is the average distance between neighboring localization sites, i.e., the stacking distance between two adjacent molecules. So the charge-transfer integral is given,

$$\tau = \left(\frac{k_B T \hbar \mu}{2ed^2\pi}\right)^{1/2} (4k_B T \pi\lambda)^{1/4} \left[\exp\left(\frac{\lambda}{4k_B T}\right)\right]^{1/2} \tag{10}$$

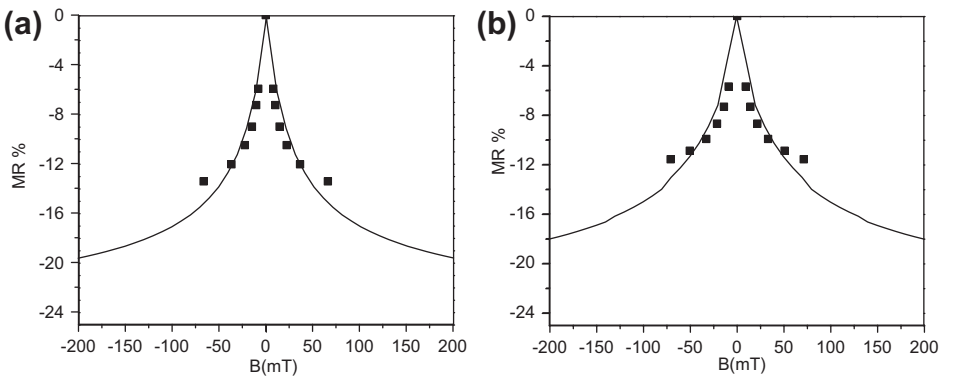

Fig. 2. Comparison between experimental measurements and our theoretical results (a) solid curve for carrier concentration $n_e = 0.2$, square corresponding to the bias 5 V; (b) solid curve for carrier concentration $n_e = 0.24$, circle corresponding to the bias 5.5 V. The charge-transfer integral τ is chosen as 20 meV and the electron–phonon coupling constant α is 110 meV/Å. Experimental data is extracted from Fig. 2 in Ref. [8].

We see that the charge-transfer integral is dependent on the carrier mobility and the distance between adjacent Alq_3 molecules in the stack. For most OSCs, the mobility is very small in the range of 10^{-6}–10^{-3} $cm^2/V \cdot S$. For example, polyparaphenylenevinylene (PPV) derivatives have a mobility of about 10^{-6} $cm^2/V \cdot S$ [20] and Alq_3 of about 10^{-5}–10^{-2} $cm^2/V \cdot S$ [18]. If we take the average distance $d = 4 - 7$ Å between two adjacent molecules and the reorganization energy $\lambda = 0.1$–0.3 eV [21], it is deduced a charge-transfer integral of tens meV near the room temperature. The electron–phonon coupling constant α is in the range of 80–140 meV/Å [15].

3. Results and discussion

For a given carrier concentration n_e, the electronic eigenvalues ε_μ are solved with a self-consistently iteration method. The DOS is obtained by the Lorentz line shape formula,

$$\rho(\varepsilon) = \sum_\mu \frac{1}{\pi} \frac{\delta}{(\varepsilon - \varepsilon_\mu)^2 + \delta^2} \tag{11}$$

where δ is the Lorentz parameter and $\sum_\mu$ is sum over all the eigenvalues. The Fermi level of the system is determined by the total number of iterant electrons (carriers) and the MR is calculated from Eq. (5). In the following calculations, the electron–phonon coupling constant α is chosen as 110 meV/Å which is a moderate value for organic materials. Fig. 2 shows the dependence of MR on the magnetic field. We see that (1) the MR is negative. The reason is the one-dimensional model adopted in present approach. From the quantum theory we know that the DOS $\rho_d(\varepsilon) \sim \varepsilon^{d/2-1}$ for a free electron system, where d is the spatial dimension. Apparently, $\rho_2(\varepsilon) \sim C$ and we obtain MR = 0 for a two-dimensional electron system from above formula. For a three-dimensional system, it has been derived MR > 0 [16]. For a one-dimensional system we obtain MR < 0. So we believe that most of the negative MR observed in experiments is due to the one-dimensional characteristic of organic materials; (2) the MR is sensitive to the carrier concentration or the doping (or injection from electrodes) of an OSC. It is found that a large MR value could be obtained in dilute doping case. For example, in Fig. 2a we can see that, under a magnetic field of 100 mT, for a fixed charge-transfer integral $\tau = 20$ meV, a MR value of 17 % can be obtained with the concentration of $n_e = 0.2$. However the MR value will decrease to 14.8% when n_e increases to 0.24 as shown in Fig. 2b; (3) the MR is also sensitive to the charge-transfer integral. As shown in Fig. 3, under a magnetic field of 100 mT, for the same carrier concentration $n_e = 0.2$, |MR| = 10% with the charge-transfer integral $\tau = 30$ meV, while this value will increase to 17% with the charge-transfer integral $\tau = 20$ meV. We give a comparison between our theoretical results and the experimental ones. It has been shown that the polyfluorene can have a well-defined chemical regularity [22] and its crystallinity is also explicitly pointed [23]. Therefore it is reasonable to adopt a band theory to describe the carrier transport in polyfluorene. The symbol in Fig. 2 shows the magnetoresistance of polyfluorene measured at different

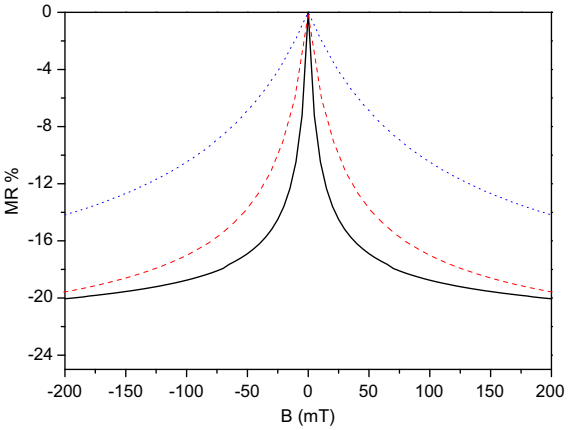

Fig. 3. Dependence of MR on the magnetic field with different charge-transfer integral. Dot: $\tau = 30.0$ meV, dash: $\tau = 20.0$ meV, solid: $\tau = 10.0$ meV. The electron–phonon coupling constant α is 110 meV/Å and the carrier concentration $n_e = 0.2$.

voltages [8]. A qualitatively consistency can be obtained and we can see that both the experimental measurements and our theoretical calculation show the two most prominent features of OMR: (I) its absolute value increases rapidly with B in the range of weak magnetic field, and (II) the OMR will reach a saturated value with a strong magnetic field.

Dependence of the OMR on the charge-transfer integral τ and carrier concentration n_e is easily understood. In the tight-binding model, the energy band width is about 4τ. If we wake $\tau = 20meV$, then the band width is about 80 meV, which is basically consistent to that in Refs. [20,24] based on the hopping mechanism. A small τ means a narrow band width and so a large DOS. As indicated in the investigation of SSH model, unless the full-band case (with $n_e = 2$), the energy band will be split into some subbands due to the strong electron–phonon interaction in organic materials. And only the lowest subband is fully occupied, which constitutes the valence band of an organic semiconductor. As indicated by the schematic of DOS in Fig. 1, with the decrease of the charge-transfer integral τ, the DOS changes more rapidly with energy; on the other hand, for a smaller carrier concentration, the valence band is narrower and the original Fermi level is closer to the edge of the band, then the differential of DOS with respect to energy is larger. As mentioned above, there is a large MR in materials with a narrow energy band and the DOS changing abruptly near the Fermi level. Therefore, a comprehensive MR is predicated in present mechanism in an OSC with a low mobility and small carrier concentration.

A fascinating and incomprehensible feature of the OMR is that it is weakly dependent on the temperature and still persists at room temperature. This is also a promising feature for practical utility in the future. From Eq. (10), we can see that in the range of room temperature, the charge-transfer integral τ increases slowly with the temperature. In Fig. 3 we can see that even there is a little increase in the charge-transfer integral τ, the absolute value of MR can still be sizable. Of course, in actual OSs, thermal effect

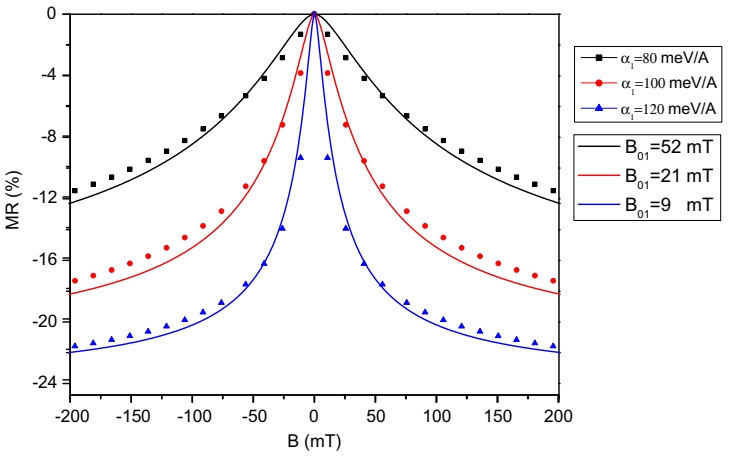

Fig. 4. The MR of an organic semiconductor with different electron–phonon coupling strength and the corresponding fitting curves. τ is chosen as 20 meV and $n_e = 0.2$. The symbols represent our theoretical results and solid curves are the fitting curves with $\Delta R(B)/R \propto B^2/(|B| + B_0)^2$. α_i (meV/Å) represents different electron–phonon coupling strength and B_i (mT) is the corresponding fitting constant.

will also affect the spin relaxation and so the MR. Here we only consider its influence on the charge-transfer integral. Our study shows that even the thermal effect is included, an observable MR can still be obtained in organic materials.

It has been mentioned that the OMR is well fitted with empirical formula $\Delta R(B)/R \propto B^2/(|B| + B_0)^2$ or $\Delta R(B)/R \propto B^2/(B^2 + B_0^2)$ depending on the material. In Fig. 4, we give the comparison between fitting curves of the empirical formula and our theoretical results. We can see that a well consistency is obtained between the non-Lorentzian shape empirical formula and our theoretical results. From Fig. 4 it is also find that the OMR is sensitive to the electron–phonon coupling α. In the present model $\alpha = 0$ means a rigid system or an inorganic one, and in this case there is nearly no MR. This result seems to coincide with the present observation that MR is difficult to appear in inorganic materials with such a small magnetic field of mT. With the increase of electron–phonon coupling, the value of MR will increase. From Fig. 4 we can see that, when the electron–phonon coupling α increases from 80 meV/Å to 120 meV/Å, the corresponding magnitude of OMR increases from 12% to 22%. As the electron–phonon coupling is an internal characteristic of organic materials, it is understandable to appear a large MR in OSCs. Furthermore, it is also found that the fitting parameter B_0 is relative to the electron–phonon coupling parameter α, which is an interesting conclusion, as, up to now, the exact source of B_0 seems to be unknown. It should be noticed that, in different experimental investigations, the fitting constant B_0 is dependent upon the concrete materials [25]. From our results, a large fitting constant corresponds to a weak electron–phonon coupling. Therefore, we speculate that MR in organic materials should be phonon dependent. It is also noted that a spin–phonon interaction model was suggested recently to explain OMR, which believes that the presence of a local bosonic environment is important in understanding the anomalous OMR [26]. In a recent article, Rybicki et al. also predicated that the spin precession must be a phonon-assisted progress in π-conjugated polymers [27].

4. Summary

In summary, we have performed a theoretical study on the mechanism of OMR based on the magnetic field-spin Zeeman interaction. Firstly we give a preliminary discussion based on the hopping mechanism and could not get a desired result. Then we performed a thorough investigation on the OMR based on the band conduction. It is found that the peculiar properties of the organic materials are important factors in the explanation of OMR. Also the value of OMR is found to be dependent on the charge-transfer integral and the concentration of carriers. It is known that the charge-transfer integral is different in various organic materials, and the carrier concentration can also be changed under different conditions. So the diversity of OMR obtained by different groups, though sometimes in the same organic material, could be explained by the dependence on the charge-transfer integral τ and (or) carrier concentration n_e. According to our model, the two most prominent features of OMR can be obtained. The peculiar electron–phonon interaction is crucial to help understanding the details of OMR. We fit our results to the empirical formula and find that the fitting parameter B_0 is phonon dependent.

ratio, and it is mainly originated from improper current suppression and imperfect carrier depletion in off state [12]. To reduce off-state current effectively and to enhance on/off ratio, it is essential to make current channel openings smaller and more uniform. Therefore, making gate pattern with shadow mask and evaporation technique is not feasible because obtaining sub-micron feature through vacuum evaporation method is extremely difficult and highly ordered patterns like porous shape cannot be acquired with shadow mask. Although conventional e-beam lithography has been used to make channel opening patterns with sub-micron feature size [13], it is an intrinsically expensive process. Polystyrene sphere based shadow mask method has also been used to obtain sub-micron porous channel opening patterns, namely colloidal lithography technique [14], but it is very difficult to obtain uniform channel opening patterns through this method. Therefore, in this study, we report a laser holography lithography method to form highly uniform nanoscale two-dimensional channel openings for VOFET devices. The laser holography has been recently used to make uniform photonic crystal structure in various optical applications like light-emitting diodes (LEDs) and photonic crystal slab waveguides [15,16]. It is a simple and maskless lithography technique which has many advantages in making well-aligned nanoscale reciprocal structures, but it has not been much used to make electrical device applications yet.

2. Experimental

The simplified process flow and schematic configuration of the fabricated VOFETs are illustrated in Fig. 1. Fig. 2 shows scanning electron microscope (SEM) images of top and cross-section views of the fabricated devices at several process steps. On a heavily doped silicon substrate which would act as a drain electrode, the first silicon nitride (SiN_x) layer, aluminum (Al) gate electrode layer, the second SiN_x layer, and chrome (Cr) hardmask layer have been sequentially deposited. Each SiN_x layer was formed by a plasma enhanced chemical vapor deposition (PECVD) process and its thickness was about 50 nm. Each metal layer (Al, Cr) was deposited with an e-gun evaporator. The thicknesses of Al gate and Cr hardmask layers were about 100 and 40 nm, respectively. After photoresist was spun-coated (Fig. 1a), the sample was exposed to the periodical line-shaped interference patterns generated from a laser holography system [15,16]. Negative type photoresist was used to make two dimensional (2-D) nanoscale patterns. After exposing the substrate to the laser holography line-shaped image two times in orthogonal directions and developing it in AZ®300 MIF developer, 2-D interference patterns (or holes) were formed in the unexposed area (Fig. 2a). The pitch between each channel opening could be controlled in 200 nm–1 μm range by adjusting the angle of stage where the sample is located. In this work, we fixed the pitch in 500 nm to obtain small and uniform porous patterns having holes with about 250 nm diameters. We expect that the gate controllability would be further enhanced by making channel openings smaller, because

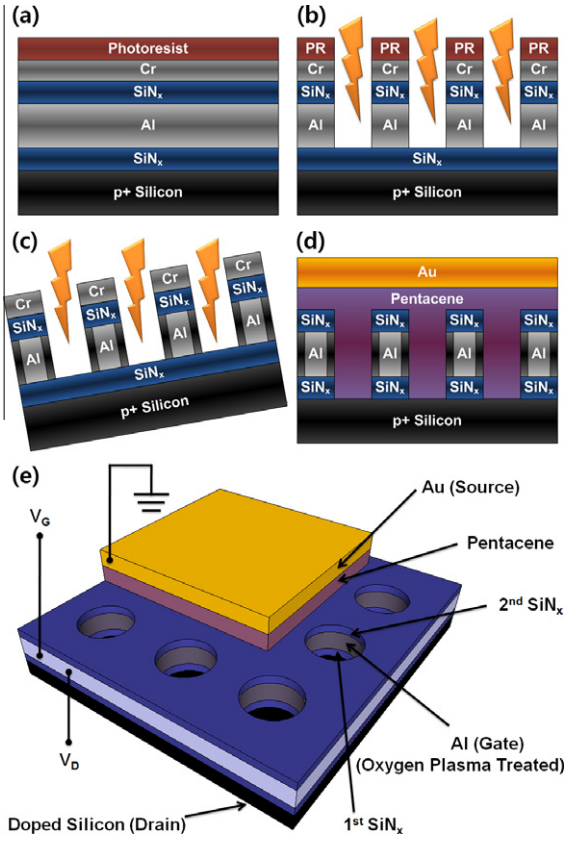

Fig. 1. (a)–(d) Fabrication processes and (e) a schematic configuration of vertical organic field effect transistors. the portion of the effective depletion region to the whole channel area, which is controlled by applied gate voltage, would be increased [14]. Since we need to perform additional plasma treatment process, however, the channel openings were maintained to be greater than 250 nm diameter considering overall device thickness, which is about 200 nm in this study.

By using these patterns, we etched the device structure through a reactive ion etching (RIE) process, producing the same holographic patterns for the vertical stack of Cr etch hardmask, the second SiN_x and Al gate layers (Fig. 1b). To reduce gate leakage current we have oxidized the Al gate sidewall surfaces. To effectively oxidize the sidewall, the sample was tilted in the plasma chamber during the plasma oxidation process. The oxygen plasma treatment (now O_2 plasma for 10 min) was performed four times for the same sample tilted in four different directions to equally oxidize the surface of the Al gate electrode sidewall (Fig. 1c). After removing the first SiN_x layer (Fig. 2b) with RIE process, pentacene (Tokyo Chemical Industry, P0030, 240 nm, @ 3 Å/s) and gold (Au, 100 nm, @ 2 Å/s) source electrode layers have been sequentially deposited using a thermal evaporation method (Figs. 1d and 2c and d). The

fabricated VOFETs were measured with a semiconductor parameter analyzer (Agilent 4155C) in air under dark conditions.

3. Results and discussion

Fig. 3a and b show the transfer characteristics and output characteristics of the fabricated VOFETs, respectively. Size of the measured device, i.e. size of Au source electrode was about 2×2 mm^2 for this result. Because VOFETs have short channel length, they can be operated even in low drain voltage region below 1 V. We investigated the transfer characteristics as we swept the gate voltage (V_G) from 2 to -2 V with -0.02 V step and increased the drain voltage (V_D) from 0 to -1 V with -0.2 V step. Current flow between source and drain electrodes (I_D) was effectively suppressed when positive V_G was applied. When positive voltage is applied to the gate electrode, energy barrier near the gate electrode is enhanced and the effective depletion region is expanded, which inhibits the current flow between source and drain electrode. On the other hands, when negative voltage is applied to the gate electrode, the current is increased due to the lowered energy barrier near the gate electrode and reduced effective depletion region. On/off ratio was obtained up to about 10^3 when -0.1 V was applied to V_D. It is noted that no additional ultra-thin organic semiconductor layers were inserted before pentacene deposition, which is known to improve on/off ratio [17] of the VOFETs. Therefore, on/off ratio can be further improved if organic multilayer approach is used. We also obtained output characteristics of the fabricated VOFETs for the same voltage range as in the transfer curves. Drain voltage was swept from 0 to -1 V with -0.01 V step, and the gate voltage was changed from 2 to -2 V with -0.4 V step. Like other VOFETs, our devices did not show saturation behavior when large V_D was applied [6,11]. Gate leakage current was maintained under hundreds of nano-amperes for relatively large V_G values. The mobility of pentacene in VOFETs was estimated by the space charge limited current (SCLC) model [8] because the conventional mobility extraction method which is widely used in OTFTs cannot be applied in VOFETs. Our current density to the applied drain voltage (J–V_D) was fitted quite well to the SCLC model, and the mobility extracted with SCLC model was estimated as 1.2×10^{-4} cm^2/Vs, which is a quite low value compared with conventional OTFTs, but common in vertical type transistor devices. Although VOFETs have shown low mobilities compared with lateral-type OTFTs, the short channel length of VOFETs which is 240 nm in current devices, and a number of channel openings covering each VOFET devices enable a large current driving capability even in low voltage regimes.

Fig. 4 shows the effect of plasma oxidation on Al gate sidewall surfaces of VOFETs, which in this case have channel openings with 1 μm diameter. It is indicated that the oxidized gate surfaces can suppress the gate leakage current levels originated from high gate bias exceeding Schottky barrier and improper Schottky junction formation between gate electrode and active layer. Especially, the effect of plasma oxidation is more prominent in an off-state, when positive voltages are applied to gate electrodes,

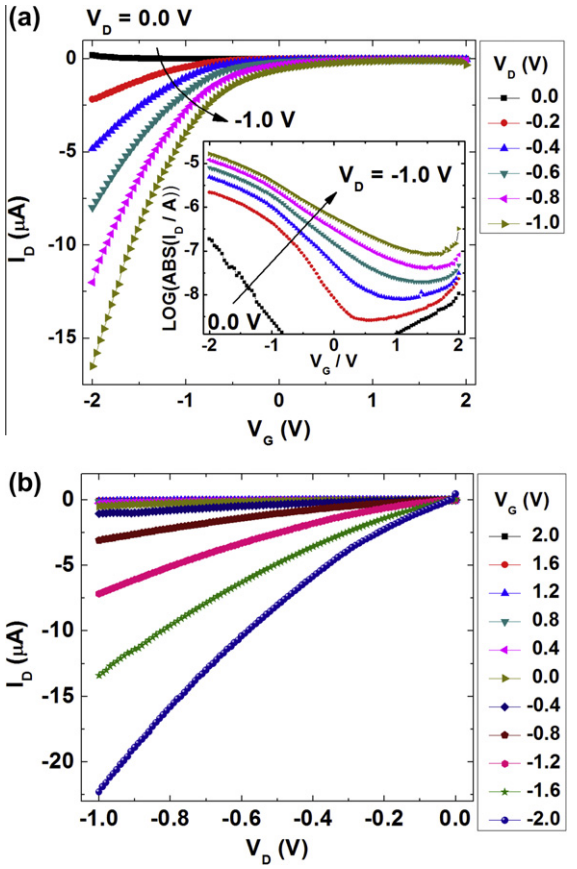

Fig. 3. (a) Transfer characteristics and (b) output characteristics of VOFETs with channel openings of about 250 nm diameter.

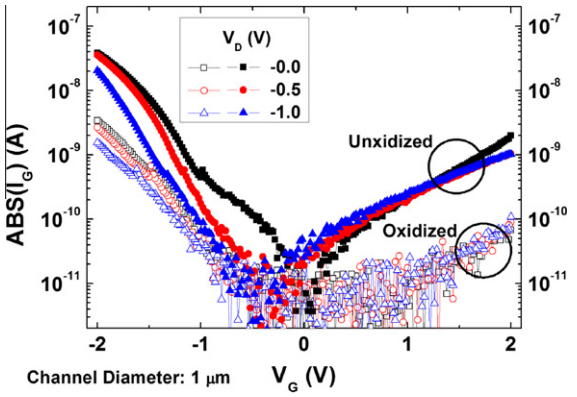

Fig. 4. Suppressed gate leakage current levels after plasma oxidation of gate electrode surfaces.

and this contributes to on/off ratio enhancement due to lower leakage current levels. Without these additional insulation structures, it is typically challenging to obtain proper transistor characteristics because maintaining Schottky contact for various semiconductor materials is challenging. An insertion of additional insulating structure by oxidizing gate electrode surface may allow us to use many semiconductor materials in the active layer. Although we can produce 2-D patterns only over 3×3 cm^2 area due to equipment limitation, it is noted that the laser holography lithography can produce reciprocal patterns over large area (>50×50 cm^2) [18]. Therefore, if this plasma oxidation process is combined together, our method can produce uniform 2-D nanoscale patterns for high performance VOFET arrays over large area substrate. Furthermore, adjusting exposure times and direction enables making various reciprocal lateral patterns such as lines and squarely or hexagonally aligned hole arrays. Since these patterns are well-aligned and have uniform shape generally, devices with minimal performance variation can be easily made.

4. Conclusion

In summary, we have used a laser holography lithography technique to make 2-D channel opening patterns in fabricating VOFET structures. Holographically generated small channel opening patterns were well-aligned and quite uniform in size and shape. The gate electrode sidewall was oxidized with oxygen plasma to further reduce gate leakage. The pentacene VOFET with the channel opening size of about 250 nm in diameter showed on/off ratio of about 10^3 without any further treatment. We believe that by introducing better gate electrode sidewall oxidation process and optimizing the channel opening size, the device performance can be further improved.

mode can be effectively controlled through the voltages applied independently to the top and bottom TFT gate electrodes. We also report on the characteristics of dual-gate devices made with indenofluorene–phenanthrene copolymer semiconductor.

2. Experimental

Fig. 1 shows the chemical structure of the indenofluorene–phenanthrene copolymer as well as the schematic cross-section of organic TFTs based on indenofluorene–phenanthrene copolymer semiconductor using recessed source/drain electrodes and dual-gate geometry. Device fabrication started with an n-type silicon substrate with a resistivity of 1–10 Ωcm, also used as the bottom-gate electrode. This is thermally oxidized to result in a 160 nm thick silicon dioxide gate insulator. All samples were sonicated in acetone, methanol and isopropyl alcohol for 5 min each, dried with nitrogen gas, baked in a 120 °C oven for 10 min to remove remaining water, and then exposed to UV ozone treatment for 5 min. Source/drain regions were patterned via a photolithographic process for all samples. In half the samples, the silicon dioxide was first etched to a depth of 40 nm for 1 min by a reactive ion etching to facilitate the formation of recessed source/drain contact. A 2.5 nm chrome adhesion layer and a 37.5 nm gold layer were blanket deposited by thermal evaporation to define the source/drain electrodes by a standard lift-off process on all samples (both regular and recessed source/drain). Sets of devices from each group of samples were then treated with nitrobenzenethiol (NBT) to form a SAM [16,17]. These samples were immersed in a dilute NBT solution in chloroform (10 mM) for 1 h, rinsed with ethanol to remove residual NBT, and then annealed at 120 °C for 30 min. The samples were exposed to hexamethyldisilazane (HMDS) vapor at room temperature for 16 h to improve the interface between the silicon dioxide gate dielectric and the organic polymeric semiconductor [18]. Both NBT and HMDS treatments were performed under an inert atmosphere.

The indenofluorene–phenanthrene copolymer solution was formed using toluene as the solvent (5 mg/mL concentration) with magnetic stirring at 50 °C for 10 h in an inert environment. The synthesis of the indenofluorene–phenanthrene copolymer has been described in detail by Schulte et al. [5]. The semiconductor film was formed by spin-coating for 45 s at 1600 rpm and then was pre-annealed at 110 °C for 30 min. The thickness of semiconductor layer measured by elipsometer is ~70 nm. The as-supplied polymeric dielectric Merck® D139 was employed as a passivation layer. D139 was spin-coated onto the semiconductor layer for 5 s at 500 rpm and then 50 s at 1000 rpm. After the spinning, the samples were cured by increasing the annealing temperature from 25 to 130 °C over 1 h.

To fabricate the dual-gate devices, a 50 nm titanium and gold–palladium double layer as gate electrode was deposited onto a silicon dioxide barrier layer on a silicon substrate by e-beam evaporation. A poly(vinyl cinnamate) dielectric layer (0.5 wt.% concentration in cyclopentanone) as bottom gate insulator was formed by spin-coating for 60 s at 1000 rpm. This layer was pre-annealed at 130 °C for 25 min in nitrogen atmosphere and then cross-linked by exposing to UV radiation source of e-beam aligner (7.5 mW/cm^2 of intensity and 365 nm of wave length) for 10 min. After deposition of a 40 nm chrome and gold double layer as source/drain electrodes, the indenofluorene–phenanthrene copolymer semiconductor layer and D139 layer as top gate insulator were spin-coated in order. Finally, a 50 nm gold layer as top gate electrode was deposited by thermal evaporation. The device fabrication was completed with a thermal post-anneal at 140 °C for 10 h. The spin-coating and thermal annealing of semiconductor and D139 layers were performed under nitrogen atmosphere.

3. Results and discussion

Fig. 2a and b shows the output characteristics of an amorphous indenofluorene–phenanthrene copolymer TFT using elevated source/drain electrodes and recessed source/drain electrodes without surface treatment. With the recessed source/drain electrodes, the on-current level increased by about a factor of 4 and the field-effect mobility increased from 0.018 to 0.055 cm^2/V-s as compared to

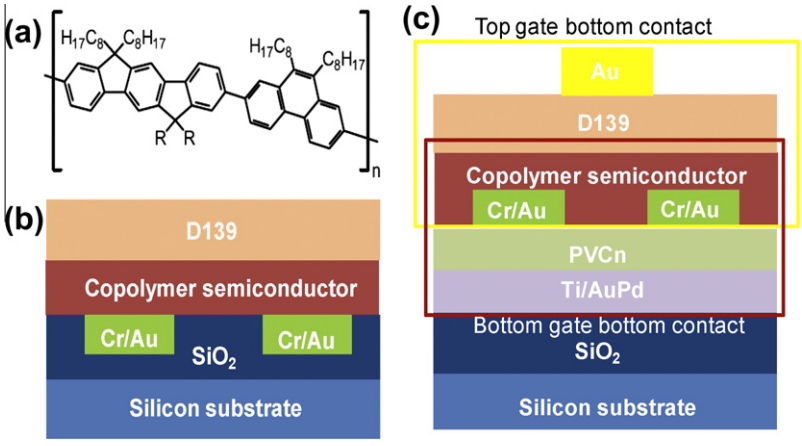

Fig. 1. (a) The chemical structure of indenofluorene–phenanthrene copolymer and a schematic cross-section of an amorphous polymeric thin film transistor based on indenofluorene–phenanthrene copolymer (b) using recessed source/drain electrodes (c) using dual-gate structure.

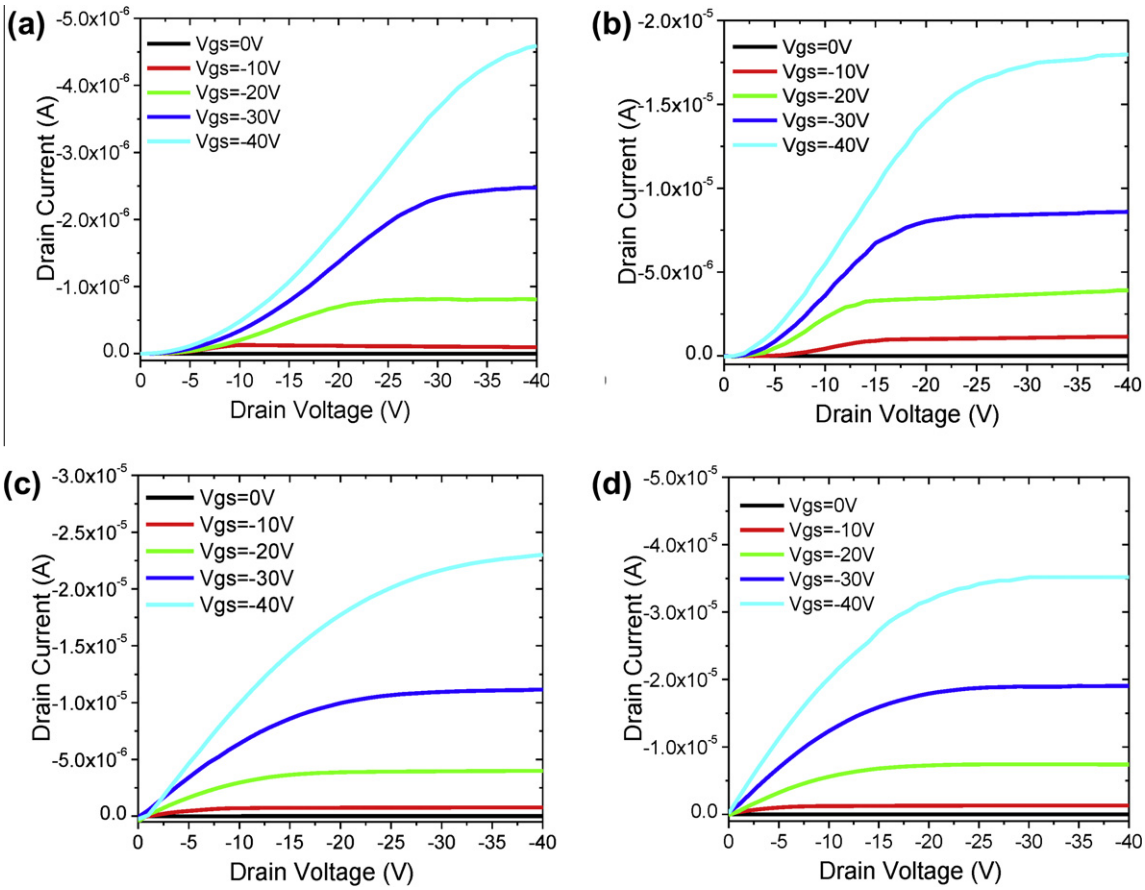

Fig. 2. The output characteristics of amorphous indenofluorene–phenanthrene copolymer TFT using (a) elevated source/drain electrodes without treatment (b) recessed source/drain electrodes without treatment (c) elevated source/drain electrodes with NBT treatment (d) recessed source/drain electrodes with NBT treatment.

the elevated structure. The super-linear behavior seen as low drain voltages in the elevated contact structure is attributed to a high injection barrier, which is reduced substantially by the adoption of recessed contacts as shown in Fig. 2. In order to further investigate the combination effect of recessed source/drain electrodes and the surface treatment of the electrodes, non-treated and NBT-treated samples based on both recessed and elevated source/drain structure have been compared. SAM surface treatments are expected to reduce contact resistance by improving the physical contact between the metal and semiconductor [10,11]. After applying surface treatments, the device performance for surface-treated samples is improved in both the recessed and elevated source/drain geometries as shown in Fig. 2c and d. The device employing surface-treated, recessed source/drain possesses a field-effect mobility of 0.144 cm^2/V-s, sub-threshold swing (S.S.) of 1.25 V/decade and on–off current ratio in excess of 10^5 in air. Fig. 3a shows the square root of drain current versus gate voltage with different conditions. Effective mobilities extracted by Fig. 3a increase due to the improved electrical contact. The use of NBT surface treatment, as shown in Fig. 3, improves hole injection between gold source/drain electrodes and the organic semiconductor layer [16,17]. Significantly, the combination of the use of surface treatments and the recessed source/drain geometry improves the effective mobility of amorphous indenofluorene–phenanthrene copolymer TFTs, which is about nine times higher than the non-treated, elevated source/drain sample.

The total resistance in TFT devices is the sum of the contact resistance and channel resistance [19,20]. If channel length decreases, the intrinsic channel resistance decreases and the relative influence in the contact resistance increases. Therefore, device characteristics such as the apparent field-effect mobility are influenced by significant contact resistance [20–22]. In order to investigate the dependence of contact resistance on channel length, a transmission line method can be used to extract the value of contact resistance [20,21]. The contact resistance can be calculated by determining the device on-resistance from the linear region mode operation and plotting the width-normalized on-resistance as a function of channel length for different gate voltages. The width-normalized contact resistance is extracted at the y-axis intercept of the extrapolated linear fits of the different gate voltages. Fig. 3b shows the width-normalized device resistance as a function of channel length at the gate voltages of −20, −30 and −40 V with the drain-source voltage of −2 V. This

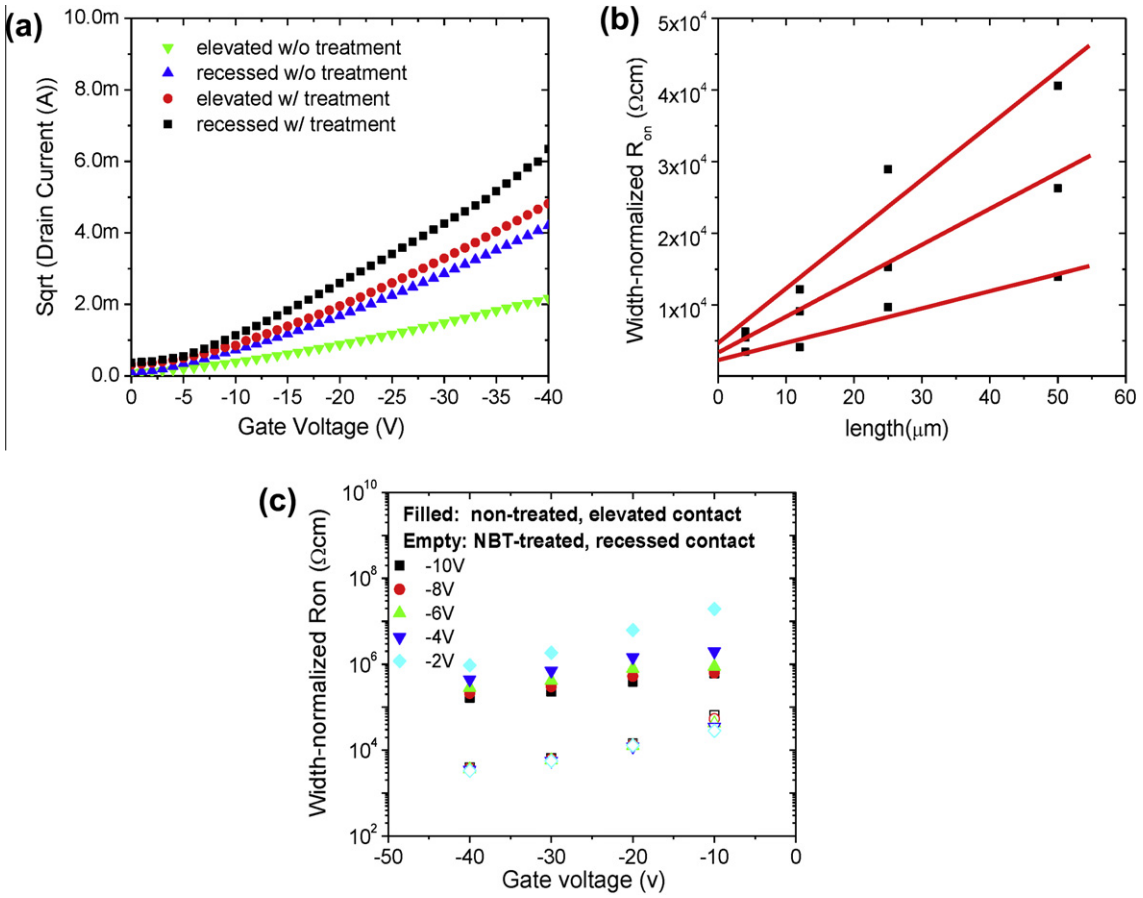

Fig. 3. (a) Square root of drain current vs. gate voltage with different conditions. (b) Width normalized resistance as a function of channel length at the gate voltages with fixed drain voltage using recessed source/drain electrodes with treatment. (c) Width-normalized resistances as a function of gate and drain voltage in recessed source/drain with treatment (filled) and elevated source/drain without treatment (empty).

was extracted from output characteristics curves on devices with channel lengths ranging from 4 to 50 μm. The width-normalized contact resistance was extrapolated from the graph to be 1275 Ωcm for devices employing recessed contacts modified with NBT surface treatment. Fig. 3c shows the width-normalized resistances as a function of gate and drain voltages in recessed source/drain with surface treatment and elevated source/drain without surface treatment. Width-normalized resistances of a non-treated TFT with elevated contacts are strongly influenced by drain voltage in linear mode operation. The schottky barrier is attributed to a high injection barrier, which influences the effective mobility. Furthermore, width-normalized resistances decrease with increasing drain voltage compared to surface-treated, recessed source/drain TFT, indicating there is the point of certain threshold of injection barrier.

Fig. 4a shows the transfer characteristics in the top-gate, bottom-gate and dual-gate modes of a dual-gate indenofluorene–phenanthrene copolymer TFT at the gate voltages ranging from −40 to 40 V with the drain-source voltage of −40 V. These TFTs possess a field-effect mobility of 0.2$cm^2V^{-1}s^{-1}$ when measured in the top-gate mode and 0.09$cm^2V^{-1}s^{-1}$ in the bottom-gate mode in air. The current of the top-gate device is lower than that of the bottom-gate device because polymer gate dielectric as top-gate insulator is thicker and has a lower capacitance per unit area (4 nF/cm^2) compared to silicon dioxide as bottom-gate insulator (20 nF/cm^2). The characteristics of the interface have a significant influence on the measured mobility [23,24]. The fabrication sequence of the top-gate device allows the use of an in situ process in which the semiconductor layer and the top-gate insulator layer can be deposited sequentially under an inert environment. For this reason, better quality interfaces can be obtained from top-gate devices. In addition, the effective area for charge injection in the top-gate bottom-contact device is larger than that in BGBC device, leading to improved contact properties.

Dual-gate mode operation results in improved performance such as increased on-current, reduced threshold voltage (V_{th}), improved S.S. and increased on–off current ratio compared to either single gate mode as shown in Fig. 4a. This is because interaction between charge carriers and interface between a semiconductor and a gate insulator layer is reduced. Fig. 4b shows the schematic illustration of interfacial energy band diagram in case of single-gate mode vs. dual-gate mode. In single-gate devices, charge carriers are more highly confined, leading to enhanced

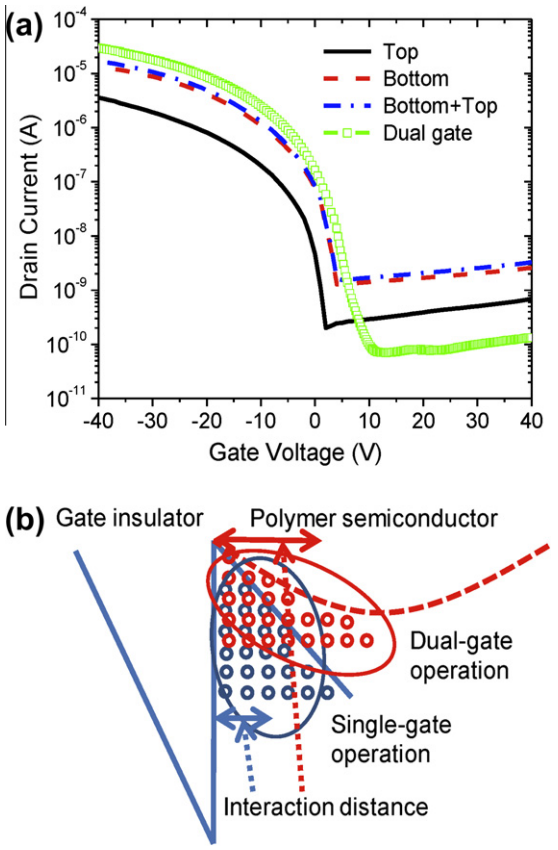

Fig. 4. (a) The transfer characteristics of top-gate, bottom-gate and dual-gate mode in indenofluorene–phenanthrene copolymer TFTs. (b) The schematic illustration of interfacial energy band diagram in case of single-gate mode vs. dual-gate mode.

interaction with interface. When the other gate bias is applied, interaction distance between charge carriers and interface in dual-gate mode becomes increased over singe-gate mode due to the band bending. It means that interface characteristics in dual-gate mode are improved due to the reduced interaction of charge carriers. Horowitz et al. reported that the mobility of charge carriers in organic FETs is lower closer to the interface compared to the bulk [25]. This is because of a greater interaction with the interface. The same effect is one of the factors responsible for the improved performance of dual-gate mode operation. Improved interface characteristics lead to improved S.S. and reduced V_{th} including increased on-current and on–off current ratio. Improved S.S. and reduced V_{th} can also explain why the current density from a dual-gate device is larger than the sum of current densities of both top- and the bottom-gate devices, as shown in Fig. 4a. We note that other reasons have been provided for improved performance of dual-gate devices such as gate screening effects and shift of V_{th} [13,26]. Such effects also result in improved performance of dual-gate devices. After the electric bias-stress is applied on each mode of operation, dual-gate mode exhibits greater stability than the single-gate modes. This is also a consequence of improved interface characteristics due to the reduced interaction of charge carriers with the interfaces. These results demonstrate that high mobilities can be achieved in amorphous polymer field-effect transistors. The mobility values we report are comparable to those reported for regioregular poly(3-hexyl thiophene), a liquid crystalline semiconductor that has been extensively investigated for over a decade by many groups [2–4,27]. Our work further demonstrates the importance of contact engineering on device performance for this class of materials. We have in previous work shown the effects of recessed source/drain regions on the performance of pentacene FETs [12]. The mobilities achieved at channel lengths of 4 μm suggest that such semiconductors will be useful in a number of applications such as displays.

4. Conclusion

In summary, the bottom gate bottom contact amorphous polymer semiconductor TFT based on indenofluorene–phenanthrene copolymer exhibits a field-effect mobility of 0.144 cm^2/V-s and a width-normalized contact resistance of 1275 Ωcm in air. In addition, we fabricated dual-gate indenofluorene–phenanthrene copolymer TFTs, which possess enhanced gate control as well as less instability caused by electrical bias stress compared to single gate TFT mode operation. Interface characteristics in dual-gate mode were improved due to the reduced interaction of charge carriers. The combination of suitable surface treatments of source/drain contact electrodes and the recessed source/drain geometry and device architecture of dual-gate configuration are the key to realizing such better device performances required for flexible electronic circuits and fabrication.

used to measure the difference between the Fermi level (E_F) and the highest occupied molecular orbital (HOMO). UPS with a resolution of 0.15 eV was measured using He I (21.22 eV) photon line from discharge source. The hole concentration as a function of the MoO_x mole percentage in the various MoO_x-doped pentacene channel layers was also investigated to study the doping mechanisms. Furthermore, the crystalline quality of the various MoO_x-doped pentacene channel layers was analyzed using an X-ray diffraction (XRD) system. The contact resistance was estimated using the gated-transmission line method (gated-TLM).

2. Experimental

Fig. 1 shows the schematic structure of the top contact organic thin-film transistors, in which the LiF buffer layer was inserted between the MoO_x-doped pentacene channel layer and the gold (Au) source/drain electrodes. The aluminum (Al) was deposited as the gate electrode on cleaned glass substrates. A 170-nm-thick polymethylmethacrylate (PMMA) was spread as dielectric layer using a spin-coated method. To investigate the influence of the various MoO_x-doped pentacene channel layers, a 30-nm-thick undoped pentacene and a 30-nm-thick MoO_x-doped pentacene with various MoO_x mole percentages were fabricated as the channel layer of the OTFTs. The former one is named as the conventional OTFTs and the latter ones are named as the MoO_x-doped OTFTs. The various MoO_x-doped pentacene channel layers were deposited by the co-evaporation system, and the mole percentage of carbon and molybdenum was determined by the X-ray photoemission spectroscopy (XPS). A 1-nm-thick LiF buffer layer was then deposited on the pentacene channel layer. Finally, a 100-nm-thick Au layer was thermally evaporated to fabricate the source and drain electrodes. The 1-nm-thick LiF buffer layer was deposited to modulate the work function and enhance the carrier tunneling behaviors [13]. All the deposition processes were performed under a base pressure of about 4×10^{-4} Pa. The channel length (L) and width (W) of the OTFTs were 50 and 400 μm, respectively. The electrical characteristics of the OTFTs were measured using an HP4156 semiconductor parameter analyzer.

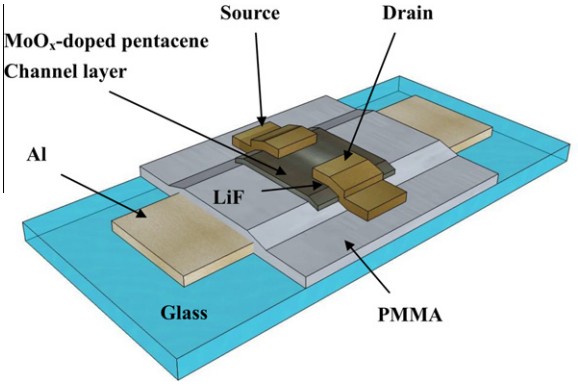

Fig. 1. The schematic structure of top contact organic thin-film transistors.

3. Results and discussion

The output drain-source current-drain-source voltage (I_{DS}–V_{DS}) characteristics of the conventional OTFTs and the 0.50% MoO_x-doped OTFTs were shown in Fig. 2. The associated transfer characteristics were shown in Fig. 3(a and b), respectively. According to the experimental measurement results, Table 1 listed the performances of the OTFTs with the conventional and the various MoO_x-doped

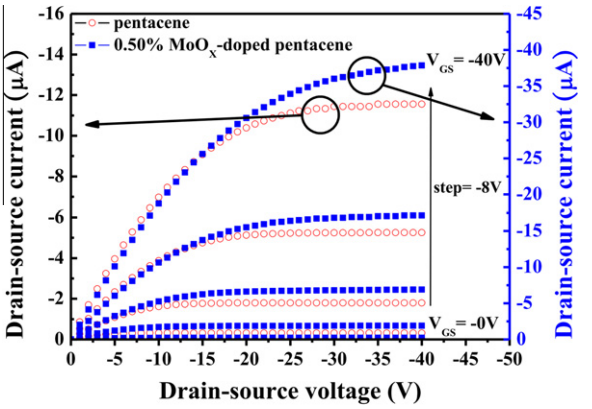

Fig. 2. Output characteristics of conventional OTFTs and 0.50% MoO_x-doped OTFTs.

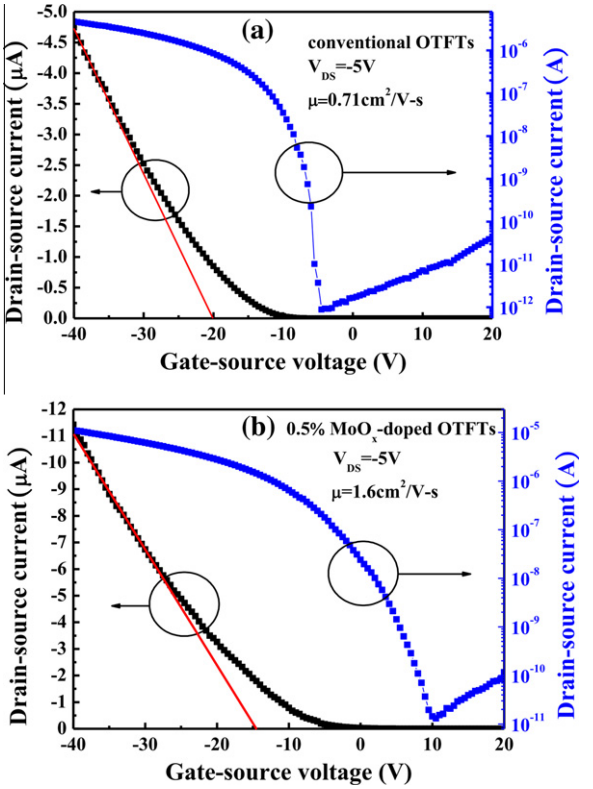

Fig. 3. Transfer characteristics of: (a) conventional OTFTs and (b) 0.50% MoO_x-doped OTFTs.

pentacene channel layers. It was found that the maximum output current was −11.6 μA of the conventional OTFTs operated at $V_{DS} = V_{GS} = -40$ V, where V_{GS} was the gate-source voltage. For operating at the same V_{DS} and V_{GS} conditions, the maximum output current of the OTFTs with the 0.50% MoO_x-doped pentacene channel layer increased by 3.2 times (−37.9 μA). As could be seen from Fig. 3(a and b) and Table 1, when the OTFTs with the MoO_x doping mole percentage varied from 0% to 0.50% operated at $V_{DS} = -5$ V and varied the V_{GS} from 20 to −40 V, the effective field-effect mobility changed from 0.71 to 1.60 cm^2/V-s, the threshold voltage changed from −21.2 to −14.8 V, and the on–off current ratio changed from 3.6×10^6 to 1.2×10^6. These experimental results indicated that the effective field-effect mobility of the 0.50% MoO_x-doped OTFTs increased 2.25 times compared with the conventional OTFTs. The decrease of the threshold voltage meant that the needed operation energy of the OTFTs decreased. The on–off current ratio of the OTFTs with 0.50% MoO_x-doped pentacene channel layer slightly decreased due to an increase of the off-current. Fig. 4(a and b) shows the drain-source current-gate-source voltage characteristics of the conventional OTFTs and 0.5% MoO_x-doped OTFTs by varying the drain-source voltage, respectively. As shown in Fig. 4(a and b), when the OTFTs with the MoO_x doping mole percentage varied from 0% to 0.50% operated at $V_{DS} = -40$ V and varied the V_{GS} from 20 to −40 V, the on–off current ratio changed from 5.0×10^5 to 3.8×10^3. It was deduced that the channel conductivity increased by doping MoO_x. Because OTFTs usually operated in the linear region, it is effective to improve the performance of OTFTs by using co-thermal method to dope MoO_x into pentacene as the channel layer.

Table 1
The device performances of OTFTs with various MoO_x-doped pentacene channel layers.

MoO_x doping (mol%)	I_{DS} (μA)	μ_{eff} (cm^2/V-s)	V_{TH} (V)	I_{on}/I_{off}
0	−11.6	0.71	−21.2	3.6×10^6
0.21	−34.7	1.22	−17.1	2.0×10^6
0.50	−37.9	1.60	−14.8	1.2×10^6
0.68	−37.5	1.50	−13.2	7.5×10^5
1.39	−32.8	0.88	−7.8	3.4×10^3

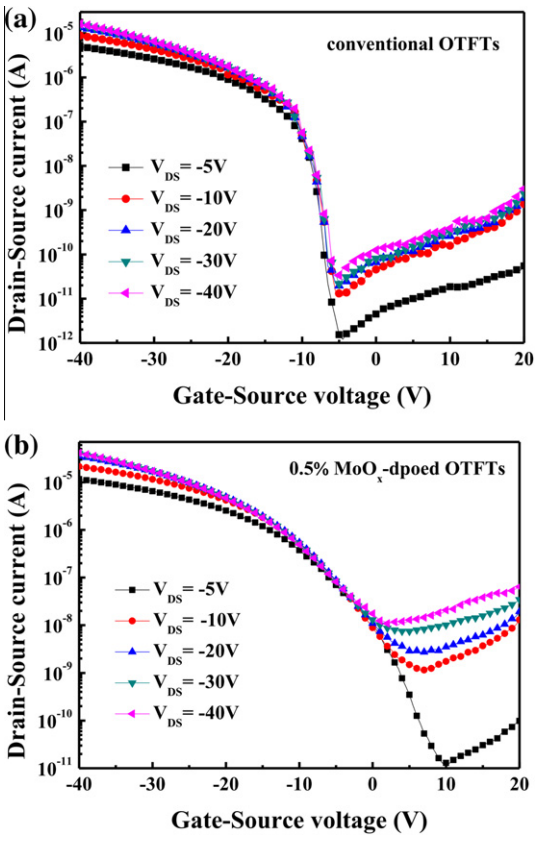

Fig. 4. Drain-source current-gate-source voltage characteristics of: (a) conventional OTFTs and (b) 0.50% MoO_x-doped OTFTs.

Based on the shift of the HOMO relative to the Au work function, the UPS was used to analyze the various MoO_x-doped pentacene channel layers. Since the conduction band energy (6.7 eV) of MoO_x was lower than the HOMO (5.20 eV) of pentacene, the energy difference led electron to transfer. For stabilization, the electrons on the HOMO of pentacene would transfer to the conduction band of the MoO_x. As shown in Fig. 4(b), the turn-on voltage ($V_{turn\text{-}on}$) of the 0.5% MoO_x-doped OTFT is a positive value. It verified that the OTFTs revealed normally turn-on depletion type characteristics. Therefore, the electrons on pentacene would transfer to the doped MoO_x. Consequently, the hole density of the MoO_x-doped pentacene increased with the doping concentration of MoO_x. The UPS experimental results were shown in Fig. 5(a). To clearly show the experimental results, the extended larger scale results were shown in Fig. 5(b). As shown in Fig. 5(b), the energy shift was 0.66, 0.36, and 0.30 eV respect to the Fermi level (E_F) corresponded to the MoO_x-doped mole percentage of 0%, 0.50% and 1.39%, respectively. The UPS measurement results verified that the HOMO of the MoO_x-doped pentacene increased with the doping percentage of MoO_x and gradually approached to the work function value of the Au. Therefore, the p-type characteristics were enhanced and the hole density and the hole mobility were increased for the MoO_x-doped pentacene channel layer with a higher mole percentage of MoO_x. However, when the mole concentration of MoO_x increased to a certain amount and the produced carrier concentration satisfied the thermal equilibrium condition, the hole concentration gradually approached to saturation with an increase of the MoO_x mole concentration due to the Fermi level pinning effect [14–16].

To investigate the carrier injection of Au/LiF/pentacene and Au/LiF/0.50% MoO_x-doped pentacene junction. The contact resistance of pentacene and 0.50% MoO_x-doped pentacene channel layer was estimated using the gated-TLM. Contact resistance (R_C) was extracted from the dependence of the total resistance (R_T) on the channel length (L). Fig. 6(a and b) shows the R_T as a function of L extracted from the measured results of the gated-TLM test structure of the pentacene and the 0.50% MoO_x-doped pentacene channel layers operated at $V_{DS} = -5$ V and

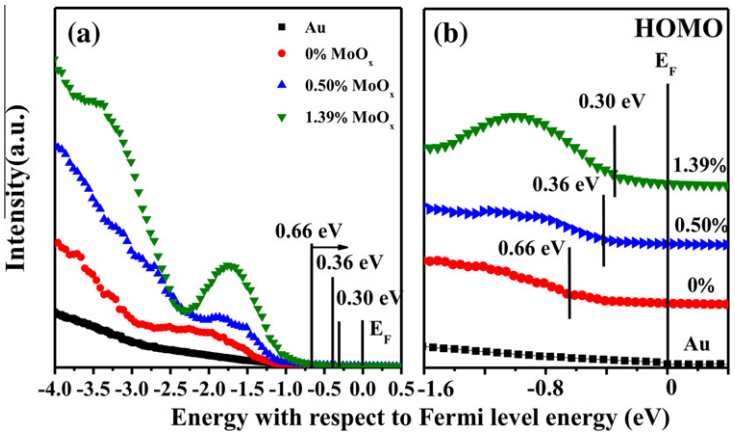

Fig. 5. (a) The energy shift of HOMO related to Au work function based on pentacene with various MoO_x doping percentages and (b) HOMO of MoO_x-doped pentacene thin films respected to Fermi level (E_F) for various MoO_x doping percentages.

various V_{GS} voltages, respectively. By fitting the line to the $L = 0$ of the R_T vs. L characteristics, the contact resistance R_C can be extrapolated. The contact resistance R_C of the OTFTs with the pentacene and the 0.50% MoO_x-doped pentacene channel layers operated at a gate voltage of -40 V was 1.57×10^7 and $8.12 \times 10^6\ \Omega$, respectively. These experimental results indicated that the contact resistance could be reduced in the OTFTs with the MoO_x-doped pentacene channel layer. Fig. 6(c) shows the dependence of the contact resistance (R_C) on the gate-source-voltage (V_{GS}) of the OTFTs with the pentacene and the 0.50% MoO_x-doped pentacene channel layers. According to the previous reports [10,17,18], the deep-lying electronic states of MoO_3 could enhance the hole hopping and hole-injection in organic thin films. Therefore, the reduction of R_C was attributed to that part of holes injected through the doped MoO_x.

Fig. 7 shows the XRD results of the 30-nm-thick various MoO_x-doped pentacene thin films. It could be seen that the crystallinity of the MoO_x-doped pentacene channel layer was kept at the similar performance until the MoO_x doping mole percentage was larger than 0.50%. Table 1 indicated that the output current and mobility of the OTFTs increased, when the doping mole percentage was lower than 0.50%. The performances of these behaviors were mainly affected by an increase of the hole concentration. When the MoO_x doping mole percentage was higher than 0.50%, it could be found that the associated crystallinity significantly degraded with increasing the MoO_x doping amount. When the MoO_x doping percentage increased, the influence of the crystallinity degradation was gradually serious. Therefore, the hole concentration and the hole mobility decreased with an increase of the MoO_x doping mole percentage larger than 0.50% due to the crystallinity degradation. Furthermore, when the MoO_x doping mole percentage was higher than 0.50%, the associated output current and the effective field-effect mobility of the OTFTs decreased with an increase of the MoO_x doping percentage due to the Fermi level pinning effect and the crystallinity degradation. The performance of the OTFTs was mainly affected by the degradation of crystallinity. The maximum output current and the hole mobility were obtained for the 0.50% MoO_x-doped pentacene. It was attributed to the trade-off between the increasing hole concentration and the crystallinity degradation. The results showed that the proper doping percentage of MoO_x could improve the performances of the pentacene-base OTFTs.

The threshold voltage (V_{TH}) of the OTFTs can be calculated using the following equation [19]:

$$V_{TH} = (\Phi_M - \Phi_s) - \frac{1}{C_{OX}}\left(Q_s + \int_0^t \frac{x}{t}\rho_{OX}(x)dx\right), \quad (1)$$

where Φ_M and Φ_s are the work function of the metal and the semiconductor, respectively, C_{OX} is the capacitance of the insulator, Q_s is the interface charge density between the semiconductor channel and the insulator, and $\int_0^t \frac{x}{t}\rho_{OX}(x)dx$ is the insulator charge density per unit volume. From Eq. (1), the V_{TH} value was mainly affected by the work function difference between the metal and the semiconductor channel, and the interface charge density of the semiconductor channel and the insulator. Fig. 5(a) shows that a rigid shift of all these features towards lower binding energy occurs as increasing the doping mole percentage. This phenomenon indicated that a corresponding shift of the Fermi level within the gap approached to the HOMO edge. It revealed that the hole density increased with an increase of the MoO_x mole percentage in the MoO_x-doped pentacene channel layer. Therefore, the increase of the hole concentration of the MoO_x-doped pentacene channel could compensate the crystallinity degradation and decreased the V_{TH} value. The V_{TH} value (-7.8 V) of the OTFTs with 1.39% MoO_x-doped pentacene was about one third of the conventional OTFTs (-21.2 V).

In this study, the electronic structure of the MoO_x was examined using XPS. The XPS spectrum of the Mo 3d was fitted and shown in Fig. 8. The spectrum was characterized by the complex mixture of Mo 3d(3/2) and Mo 3d(5/2) spin doublets molybdenum. The peaks of 228 and 232 eV are Mo 3d(5/2) and Mo 3d(3/2), respectively. The simulation spectra constructed by using Shirley fitting for peaks corresponding Mo 3d(5/2) and Mo 3d(3/2) were also shown in Fig. 8. The Mo 3d(5/2) binding energies of the oxidation

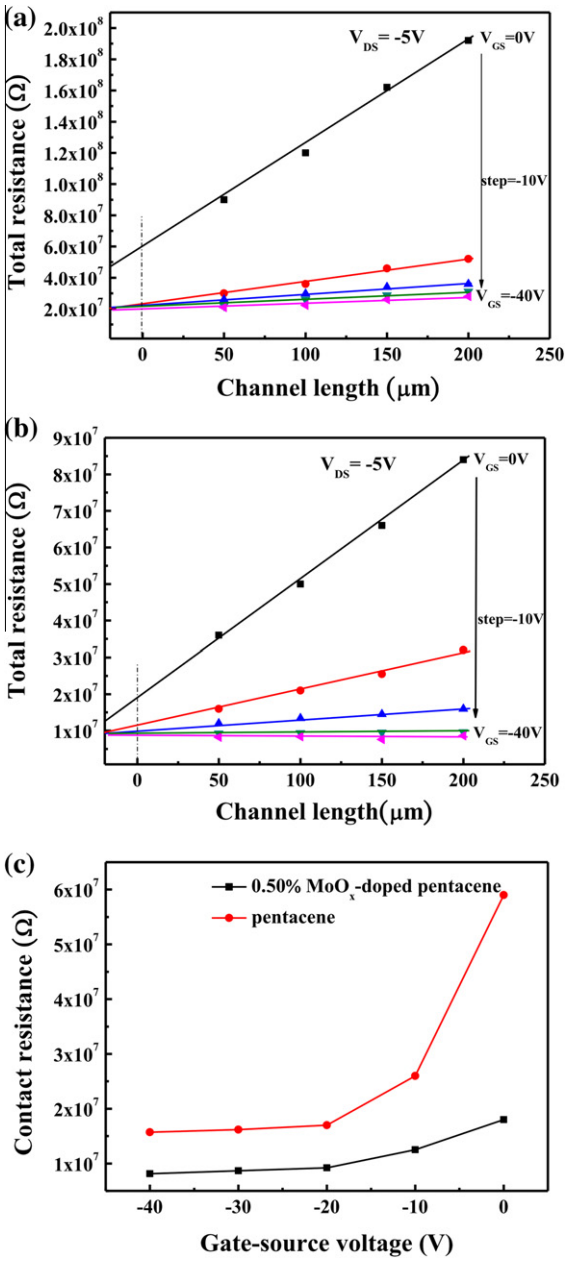

Fig. 6. Total resistance R_T vs. channel length L of: (a) pentacene channel layer and (b) 0.50% MoO_x-doped pentacene channel layer operated at $V_{DS} = -5$ V. (c) Contact resistance as a function of gate-source voltage of pentacene channel layer and 0.50% MoO_x-doped pentacene channel layer.

state of Mo^0, $Mo^{\delta+}$, Mo^{4+}, Mo^{5+}, and Mo^{6+} were located at 227.8, 228.7, 230.0, 231.2, and 232.6 eV, respectively [20–24]. A splitting energy of ~3.1 eV was used for Mo 3d(3/2) and Mo 3d(5/2) doublet [22]. Therefore, the Mo 3d(3/2) binding energies of Mo^0, $Mo^{\delta+}$, Mo^{4+}, Mo^{5+}, and Mo^{6+} were located at 230.9, 231.8, 233.1, 234.3 and 235.7 eV, respectively. The distribution area percentage of the Mo^0, $Mo^{\delta+}$, Mo^{4+}, Mo^{5+}, and Mo^{6+} was about 11.27%, 47.53%, 5.67%, 24.24%, and 11.29% of the total molybdenum, respectively. Based on the above mentioned

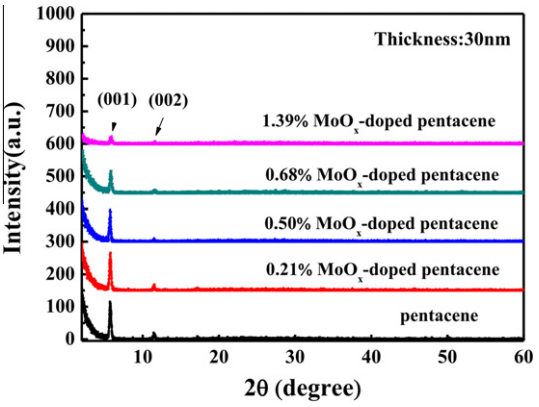

Fig. 7. X-ray diffraction spectra of 30 nm-thick various MoO_x-doped pentacene thin films.

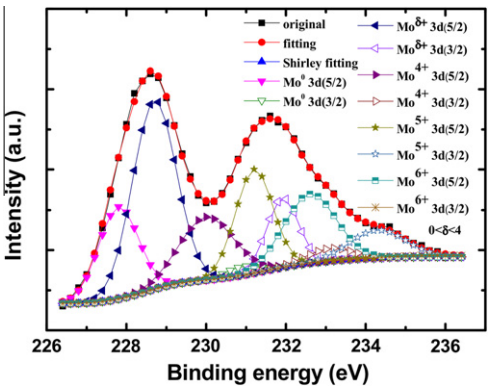

Fig. 8. The XPS spectrum of Mo 3d energy region for Mo oxide.

experimental results, the OTFTs with 0.50% MoO_x-doped pentacene channel layer exhibited the optimal effective field-effect mobility. In the optimal structure of OTFTs, the mole percentage of the Mo^0, $Mo^{\delta+}$, Mo^{4+}, Mo^{5+}, and Mo^{6+} in the 0.50% MoO_x-doped pentacene channel layer was 0.056%, 0.24%, 0.028%, 0.12%, and 0.056%, respectively. It could be found that the mole percentage of MoO_3 was 0.056% in the 0.50% MoO_x-doped pentacene channel layer.

4. Conclusions

Co-thermal evaporation system was used to dope MoO_x into pentacene as the MoO_x-doped pentacene channel layer of the OTFTs. Compared the OTFTs with the 0.50% MoO_x-doped pentacene with the conventional OTFTs, the maximum output current was increased from −11.6 to −37.9 μA, the effective field-effect mobility was enhanced from 0.71 to 1.60 cm^2/V-s, the threshold voltage was reduced from −21.2 to −14.8 V, and the on/off current ratio was slightly decreased from 3.6×10^6 to 1.2×10^6. The performance improvement was attributed to that the HOMO of the MoO_x-doped pentacene gradually approached to the Au work function with increasing the doping percentage of MoO_x, which led to reduce the

contact resistance and to enhance the p-type characteristics of the MoO_x-doped OTFTs by increasing the hole density and enhancing the hole-injection efficiency. However, when the MoO_x doping mole percentage was higher than 0.50%, the associated output current and the effective field-effect mobility of the OTFTs decreased with an increase of the MoO_x doping percentage due to the Fermi level pinning effect, the gradual increase of hole concentration, and significant degradation of crystallinity.

that the work function of the cathode metals could be tuned on a large scale by the individual molecular dipoles and the interface dipole formed upon chemisorption of the SAM organic molecules [19,20,26,27], leading to the improvement of device performances.

In our contribution, we discovered that by spin-casting the solvents commonly used to dissolve CPEs and SAMs on top of the organic layer before the deposition of the metal layer, the device performance was significantly enhanced. The quantum efficiency is increased by as large as 58% for low work function Ba/Al cathode. An interface dipole between the cathode and the EL layer induced by the solvent (either from the solvent's intrinsic dipole or the interaction between the solvent and the cathode metal), is identified by the Kelvin Probe Force Microscopy (KPFM) to be responsible for the reduction of the electron injection barrier, and further verified by the photovoltaic measurements. The process of solvent treatment to modify the organic/metal interface is simple, efficient, cost-effective and easy to be adopted in industrial manufacturing.

2. Experiments

Three conjugated polymers PFO ADS 329 (from American Dye Sources, Inc.), P-PPV, and MEH-PPV (both from Canton OLedking Optoelectric Materials Co. Ltd.), were used for device fabrication. While the solvent treatments work for all the polymer devices, we select P-PPV as the representative to demonstrate our work.

Before making the light emitting devices, the ITO substrates were thoroughly cleaned in sequence in ultrasonic bath of acetone, isopropyl alcohol, detergent, de-ionized water, isopropyl alcohol, and went through O_2 plasma for 20 min. A thin layer of PEDOT:PSS was spin-casted in air followed by 10 min' baking at 200 °C in nitrogen. After PEDOT:PSS annealing, a 75 nm thick poly[2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-*p*-phenylenevinylene] (P-PPV) layer was spin-casted from *p*-xylene solution. To treat the organic/metal interface by solvent, 60 μL of the selected solvent were spin-coated on top of the P-PPV layer with the spinning speed of 2000 rpm for 1 min. The device was completed by thermally evaporating the metal cathode consisting of either 4 nm Ba covered by a 120 nm Al in vacuum under a pressure of 3×10^{-4} Pa.

Samples for KPFM measurements were prepared by spin-coating P-PPV on stainless steel pucks 12 mm in diameter, and spin-coating respective solvent on top of the P-PPV film. The KPFM measurements were performed with both single-pass mode and lift-mode on Bruker's Multimode® 8 scanning probe microscope in a customized glove-box (MBraun). SCM-PIT probes (platinum–iridium coating, Bruker) were used throughout the measurements. All the sample preparations and KPFM measurements were carried out inside a nitrogen filled glove-box with both O_2 and H_2O below 0.1 ppm to minimize surface contamination. The CPD images were obtained on a 1×1 μm area, over which the averaged CPD values are used.

For other experiments' details, please refer to the Supplementary data.

3. Results and discussions

To demonstrate the effect of solvent treatment on OLEDs, the green light-emitting conjugated polymer P-PPV, was selected, and two solvents most widely used to dissolve CPEs and SAMs: methanol and ethanol, were chosen with the device structure of ITO/PEDOT (45 nm)/P-PPV (75 nm)/Ba (4 nm)/Al (120 nm). The current density (*J*)–bias (*V*)–luminance (*L*) characteristics, and the luminous efficiency's (LE) dependence on the current density are illustrated in Fig. 1a and b, respectively. Compared with the device without solvent treatment, which has the maximum quantum efficiency (QE) of 6%, LE of 17.0 cd A^{-1} and brightness of 57,291 cd m^{-2}, the device treated with ethanol has the maximum QE of 9.5%, LE of 26.9 cd A^{-1} and brightness of 83,575 cd m^{-2}. The device with methanol treatment exhibits similar performance improvement with the highest brightness of 74,663 cd m^{-2}, LE of 25.3 cd A^{-1} and QE of 9.0%. After modifying the organic/metal interface by ethanol, the maximum quantum efficiency was increased by 58%. Even at high working brightness (3000 cd m^{-2}), the devices treated with ethanol and methanol show a quantum efficiency of 8.5% and 6.6%, respectively.

In order to understand the functions of the organic/metal interface after solvent treatment, electron-only devices were fabricated with structure of ITO/Sn (130 nm)/P-PPV (75 nm)/Ba (4 nm)/Al (120 nm). The *J*–*V* characteristics are depicted in Fig. 1c. With methanol or ethanol treatment, the devices exhibits higher electron current than the device without solvent treatment at the same operation voltage after turn-on. The results indicate that using solvent can greatly improve the electron injection, leading to balanced charge density inside the active layer.

The electron injection improvement is due to the reduction of the electron injection barrier. Photovoltaic measurement is a direct measurement of the built-in potential which scales with the electron injection barrier height on the cathode side, when the anode and the organic layers are identical for all the devices [28]. Fig. 2 shows the *J*–*V* characteristics of the devices under white-light illumination (100 mW cm^{-2}). The open-circuit voltage (V_{OC}) increased from 1.85 V for the untreated Ba/Al device, to 2.10 and 2.20 V for ethanol and methanol treated devices, respectively. The significant enhancement of V_{OC} (0.25 V from ethanol and 0.35 V from methanol) clearly confirms that the electron injection barrier is substantially lowered at the organic/metal interface after interface modification. Reducing electron injection barrier helps electron injection and makes electron and hole density balanced inside the EL layer, improving the device performance as evidenced in Fig. 1b.

Some groups have reported that a change in molecular orientation can affect the work function/ionization energy [29]. In our studies, the polymers are PPV and PFO based which are nonpolar or low polar materials. They form stable and smooth films by spin-coating their solutions in the non-polar solvents such as *p*-xylene. Moreover, those polymers are not soluble in either ethanol or methanol. Therefore, it is highly unlikely that spin-coating a small amount of ethanol/methanol on a dense solid film could change the

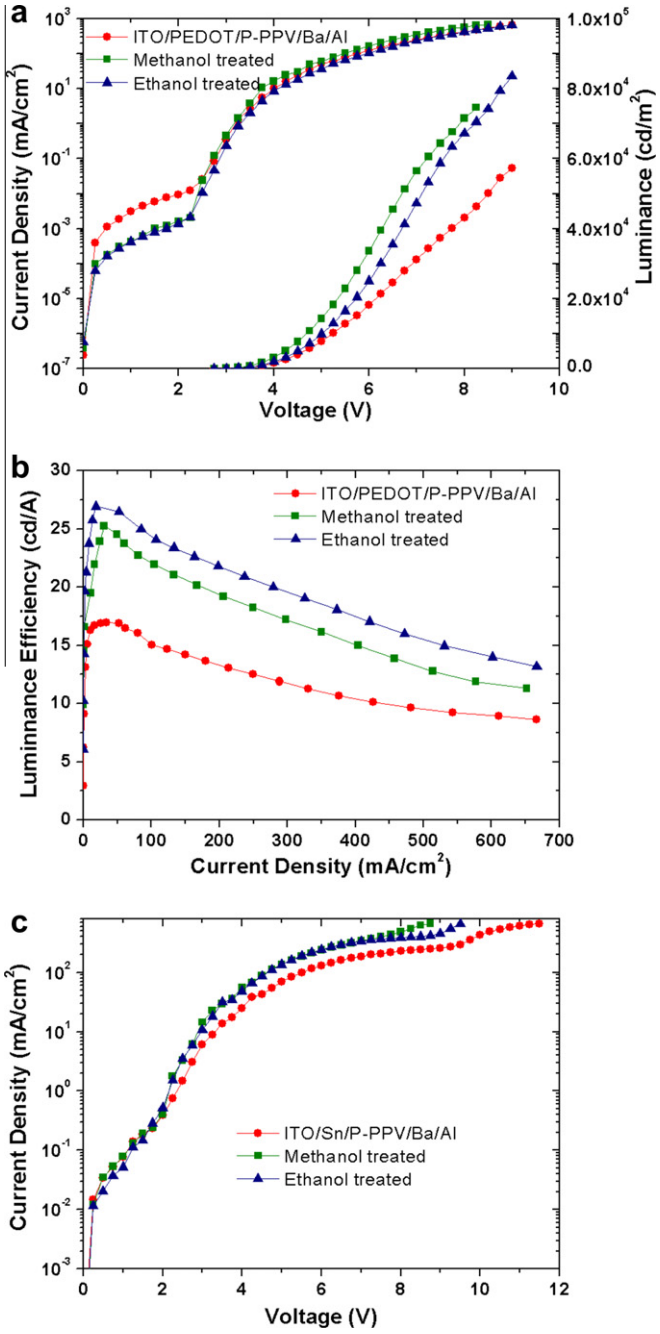

Fig. 1. (a) *J*–*L*–*V* and (b) LE–*J* characteristics of light-emitting devices with and without solvent treatment. (c) *J*–*V* characteristics of electron-only devices.

polymer molecule's orientation. We believe that the origin of the electron barrier reduction could be attributed to an interface dipole induced by the solvent. The dipole raises the vacuum level of the cathode, thereby reducing the electron injection barrier [30,31].

There are three possible mechanisms for dipole formation at the organic/metal interface: (1) interaction between the solvent and the polymer; (2) the solvent's intrinsic dipole; and (3) interaction between the solvent and the cathode. To study the interaction between the solvent and the polymer, the UV–Visible absorption, photoluminescence (PL) and electroluminescence (EL) spectra are carefully examined. The indistinguishable UV–Visible spectra obtained from the polymer films with and without solvent treatment (Fig. S1a) indicates that the solvent treatment did not change the ground-states of the bulk light-emitting materials. The identical PL spectra (Fig. S1a) and EL spectra (Fig. S1b) suggest that the application of solvent did not alter the excited-states of the bulk light-emitting materials. No difference in the atomic force microscopy (AFM) images and roughness of the active layer surface was found in the films with and without solvent treatment, implying that

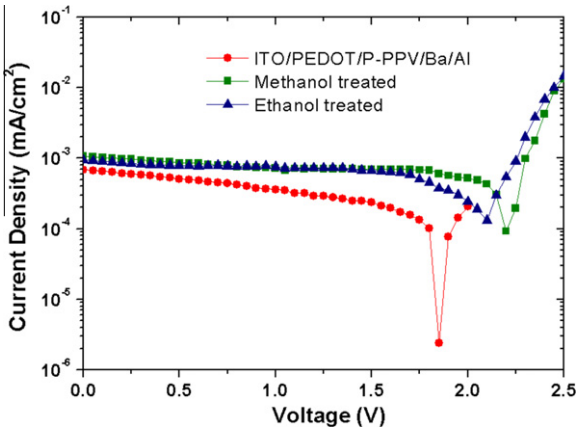

Fig. 2. Photovoltaic characteristics of the devices with and without solvent treatment.

the solvent did not modify the polymer film's morphology (Fig. S2). The film thickness also remained unchanged after solvent treatment. Adding the fact that the PL efficiencies of the neat P-PPV film with and without exposure to the methanol or ethanol are the same (Table S1), we conclude that even if there is interaction between the solvent and the polymer, the interaction is neither powerful enough to alter the polymer's bulk properties, nor strong enough to be detected by our currently available characterization techniques.

The existence of the solvent's intrinsic dipole on the organic surface can be directly verified by Kelvin Probe Force Microscopy. KPFM is used extensively to measure the surface potential at nanometer scale on various materials [32,33]. Before the solvent treatment, the contact potential difference (CPD) between the KPFM tip and the P-PPV surface is 0.499 V. After spin-coating the solvents, the CPD became 0.753 and 0.849 V for ethanol and methanol treated surfaces, respectively. The CPD images are shown in

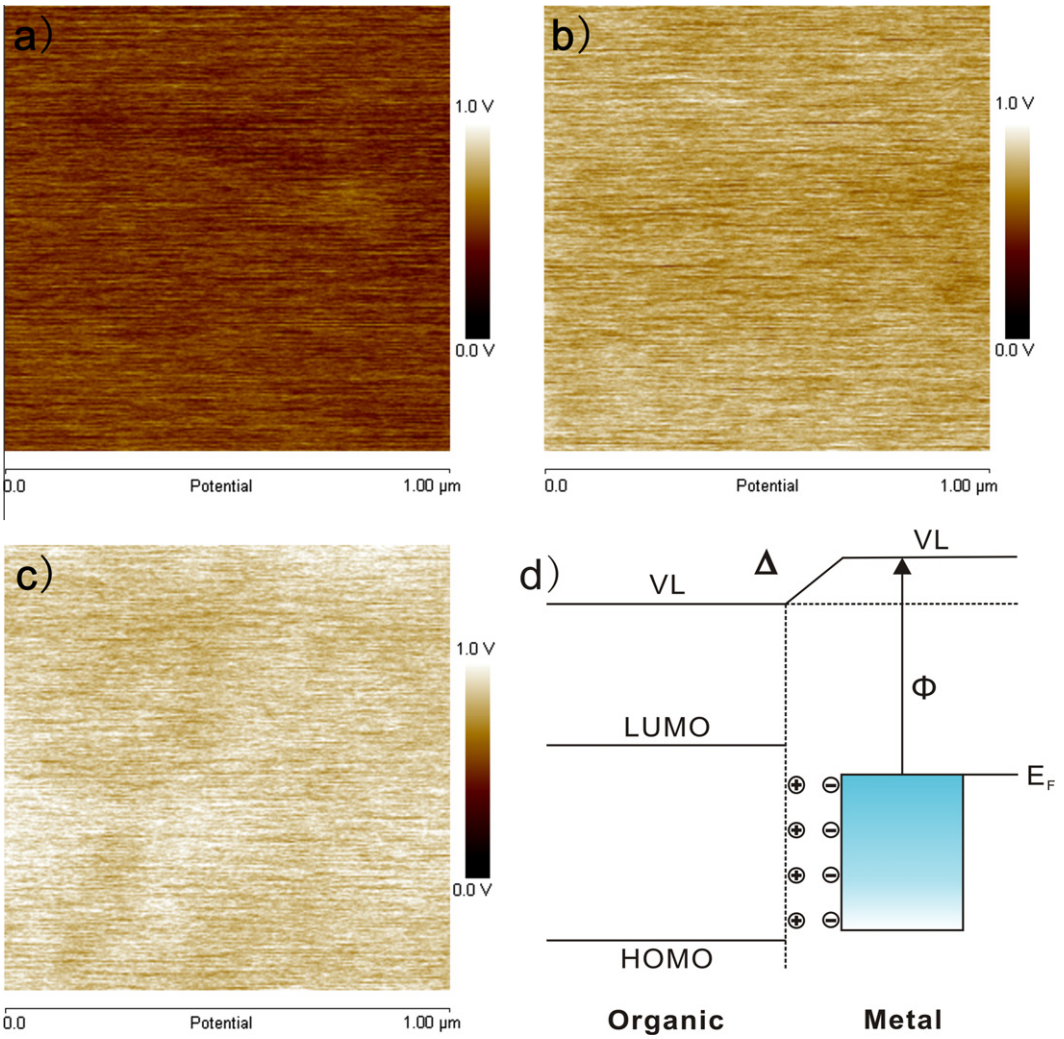

Fig. 3. Contact potential difference (CPD) images of P-PPV films (a) without solvent treatment, (b) with ethanol and (c) with methanol treatment. (d) The interfacial energy diagram of organic/metal interface with solvent treatment obtained from KPFM. Δ is the shift of VL and Fermi level (E_F) of the cathode by the interface dipole, and Φ denotes the metal's work function.

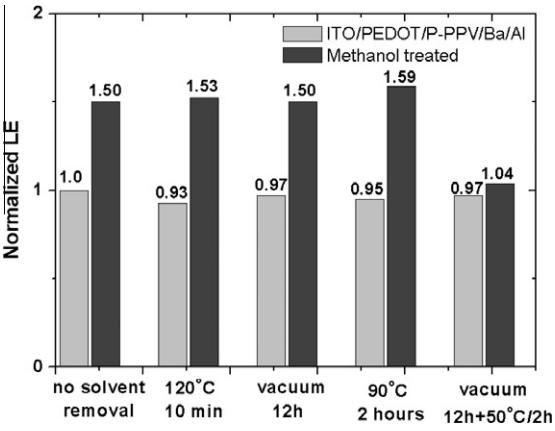

Fig. 4. Luminous efficiency of the light emitting devices with and without methanol treatment undergoing different solvent removal processes. All the LEs are normalized to the LE of the device without methanol treatment or any solvent removal process.

Fig. 3. The increase of CPD shows the surface potential of P-PPV is increased suggesting that the vacuum level (VL) of the cathode is correspondingly elevated by the solvent's intrinsic dipole as schematically illustrated in Fig. 3d. Of note, the 0.254 and 0.35 V surface potential increases are in precise agreement with the exact results of the photovoltaic measurements, which clearly demonstrates the solvent's dipole formation at the organic/metal interface.

It is well-known that the solvent can react with metal to release the metal ions. For example, the alcohol can react with low work function metal, such as Ba or Ca, to produce metal salt. Since the interaction between the solvents and the metal cannot be excluded, the interface dipole induced by the solvents is probably a result of the combined effects of the interaction between the solvent and the cathode metal, and the solvent's intrinsic dipole. Further experiments are being carried out to pin down the exact dipole formation mechanism.

Though the solvent did not change the polymer's bulk properties, it is difficult to remove the solvent completely from the organic surface. The most common solvent removal processes are vacuuming for 12 h [24], baking at either 80 or 120 °C for 10 min, and annealing at 90 °C for 2 h [15,34,35] before the cathode deposition. Our experiments showed that those solvent removal processes did not succeed in removing solvent. As depicted in Fig. 4, after spin-casting the methanol, the devices which went through the said solvent removal processes exhibited almost the same performances as those from the devices without undergoing the solvent removal processes. We found out that only by vacuuming the solvent treated devices at 10^{-4} Pa for 12 h followed by vacuum baking at 50 °C for 2 h before cathode deposition, the improved performance of devices treated with methanol returned to that of the devices without solvent treatment.

4. Summary

Reducing the electron injection barrier at the organic/metal interface to improve the OLED efficiency, and modifying that interface through surface engineering materials, such as CPE, SAM, surfactants, or metal compounds, become a hot research area. Our discovery shows that solvent treatment on the organic active layer can effectively modify organic/metal interface and improve the electron injection. In Ba/Al cathode devices, the quantum efficiency could be increased by 58%. KPFM and photovoltaic measurements demonstrate the existence of the interface dipole which lifts the vacuum level on the metal side, hence reducing the electron injection barrier, and enhancing the device performance.

and the interfacial layer. For example, charge trapping by the nanosized domains in the ZnO or TiO_2 layer fabricated by the sol–gel process can reduce the photovoltaic efficiency. Cs_2CO_3 and Al_2O_3 are insulators, so they can form an energy barrier for the electron transport from the active layer to ITO if they are too thick.

Here, we report inverted PSCs with PbO-modified ITO as the cathode. PbO was selected as the interfacial material because PbO is a semiconductor and has interesting optical properties [23–26]. It exhibits photoactivity over a wide range of wavelengths, so it can be used in imaging devices, electrophotography and electroradiography. It will be interesting to integrate this optically active material in solar cells. In addition, PbO can be easily processed by thermal evaporation [27–29]. Wang et al. used PbO/Al as the electron injection electrode in highly efficient organic light-emitting diodes [29]. We found that a high-quality PbO film could be readily deposited on ITO and it could effectively reduce the work function of ITO to 3.8 eV. The optimal inverted PSCs of P3HT:PCBM (P3HT = poly(3-hexylthiophene), PCBM = [6,6]-phenyl-C_{61}-butyric acid methyl ester) with PbO-modified ITO as the cathode exhibited a photovoltaic efficiency of 4.0%, which was even higher than that (3.5%) of control PSCs with normal architecture.

2. Experimental

2.1. Materials and fabrication of inverted PSCs

ITO glass with a sheet resistance of 15 Ω/v was purchased from Nikko Materials Co. All chemical regents, including P3HT, PCBM and PbO with a light yellow color and a purity of 99.999%, were obtained from Sigma–Aldrich. All chemicals were used as received.

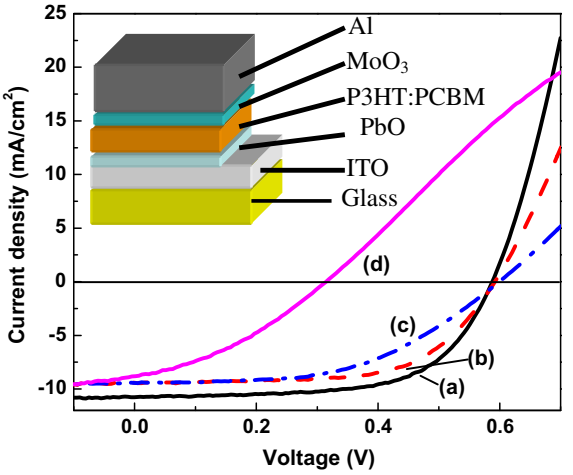

Fig. 1. *J–V* characteristics of PSCs under simulated AM1.5G illumination. (a) Inverted PSC, ITO/PbO/P3HT:PCBM (230 nm)/MoO_3/Al, (b) normal PSC, ITO/PEDOT:PSS/P3HT:PCBM (180 nm)/LiF/Al, (c) normal PSC, ITO/PEDOT:PSS/P3HT:PCBM (230 nm)/LiF/Al, and (d) inverted PSC, ITO/P3HT:PCBM (230 nm)/MoO_3/Al. The PbO thickness was 1 nm for device (a). The active layer of devices (a), (c) and (d) was prepared from 1,2-dichlorobenzene solution consisting of 25 mg ml^{-1} P3HT and 25 mg ml^{-1} PCBM, while the active layer of device (b) was coated from 1,2-dichlorobenzene solution consisting of 17 mg ml^{-1} P3HT and 17 mg ml^{-1} PCBM. The inset shows the architecture of inverted PSCs.

The architecture of inverted PSCs is presented in the inset of Fig. 1. The devices were fabricated through the following process. ITO glass substrates patterned with only half of the substrate surface covered with ITO were successively rinsed with detergent, de-ionized water, acetone, and isopropyl alcohol. Each rinsing step was carried out in an ultrasonic bath for 10 min. The cleaned and dried ITO glass substrates were treated with UV-ozone (JeLight UV Ozone cleaner 42) for 15 min before the deposition of PbO. A thin PbO layer was thermally deposited on ITO in a chamber of 1.6×10^{-6} mbar. The thickness of the PbO layer was controlled from 0.5 to 2.5 nm. Then, the ITO glass substrates deposited with PbO were transferred into a glove box filled with dried nitrogen. A 1,2-dichlorobenzene solution consisting of 25 mg ml^{-1} P3HT and 25 mg ml^{-1} PCBM was spin coated at 600 rpm for 40 s. The P3HT:PCBM films were slowly dried in covered petri dishes at room temperature. The dried P3HT:PCBM films had a thickness of *ca.* 230 nm. The P3HT:PCBM films were subsequently annealed at 120 °C for 10 min. The devices were completed by thermally depositing a 5 nm-thick MoO_3 layer and subsequently a 100 nm-thick Al layer on the P3HT:PCBM layer.

2.2. Characterizations of PSCs and materials

The PSCs were encapsulated in the glove box with a UV-curable epoxy and glass sheets and then taken out for the electrical testing. The photovoltaic performance of the devices was measured with a computer-programmed Keithley 2400 source/meter under a Newport Oriel class A solar simulator, which simulated the AM1.5G sunlight (100 mW cm^{-2}) and was certified to the JIS C 8912 standard. A Schott visible-color glass-filtered (KG5 color filtered) Si diode (Hamamatsu S1133) was used as a reference cell to correct the mismatch between the lamp and the AM1.5G solar spectrum. The active area of each device is 0.11 cm^2. Incident photon-to-current conversion efficiencies (IPCEs) of PSCs were measured with a 300 W Xenon Lamp (Oriel 6258) and a Cornerstone 260 Oriel 74125 monochromator.

The UV–Vis absorption spectra were acquired with a Shimadzu UV-1800 spectrometer. The X-ray diffraction (XRD) data were obtained with a Bruker D8 powder XRD diffractometer system. The Raman spectra were collected in a back scattering configuration with a Jobin Yvon Horiba LabRam HR800 Raman system using a 514.5 nm Ar^+ laser as the excitation source. The laser power was 2 mW, and the resolution was 2.4 cm^{-1}. The accumulation time for each sample was 900 s. X-ray photoelectron spectra (XPS) were taken using an Axis Ultra DLD X-ray photoelectron spectrometer with an Al K_α X-ray source (1486.6 eV). Ultraviolet photoelectron spectra (UPS) were collected using a VG ESCA 220i-XL Imaging UPS with the He I emission (21.2 eV) as the light source. The resolution of both XPS and UPS was 0.1 eV. Atomic force microscopic (AFM) images were acquired using a Veeco NanoScope IV Multi-Mode AFM with the tapping mode. The thicknesses of the polymer films were measured using an Alpha-Step IQ surface profiler.

Table 1
Photovoltaic performance of inverted and normal PSCs.

PSC	J_{sc} (mA cm^{-2})	V_{oc} (V)	*FF*	*PCE* (%)	R_s (Ω cm^2)	R_{sh} (Ω cm^2)
ITO/P3HT:PCBM/MoO_3/Al	8.80	0.31	0.355	0.98	22.3	102
ITO/PbO/P3HT:PCBM/MoO_3/Al[a]	10.8	0.59	0.632	4.00	3.70	9700

3. Results and discussion

3.1. Inverted PSCs with PbO-modified ITO as the cathode

More than 50 inverted PSCs were investigated. Their photovoltaic performance had good reproducibility. Fig. 1 shows the current density (*J*)–voltage (*V*) curves of an inverted PSC with ITO modified with a 1 nm-thick PbO layer as the cathode under AM 1.5G illumination (curve *a*). The *J*–*V* curve of a control inverted PSC with unmodified ITO as the cathode is also presented for comparison (curve *d*). The photovoltaic performances of these devices, including open-circuit voltage (V_{oc}), short-circuit current density (J_{sc}), fill factor (FF) and PCE, are summarized in Table 1. The inverted PSC with PbO-modified ITO exhibited high ph otovoltaic performances: V_{oc} = 0.59 V, J_{sc} = 10.8 mA cm^{-2}, FF = 0.632, and PCE = 4.00%. The photovol ta ic performance is much higher than the control inverted PSC. The PbO layer on ITO particularly improves the V_{oc} and FF values, which are only 0.314 V and 0.355 for the control inverted PSC.

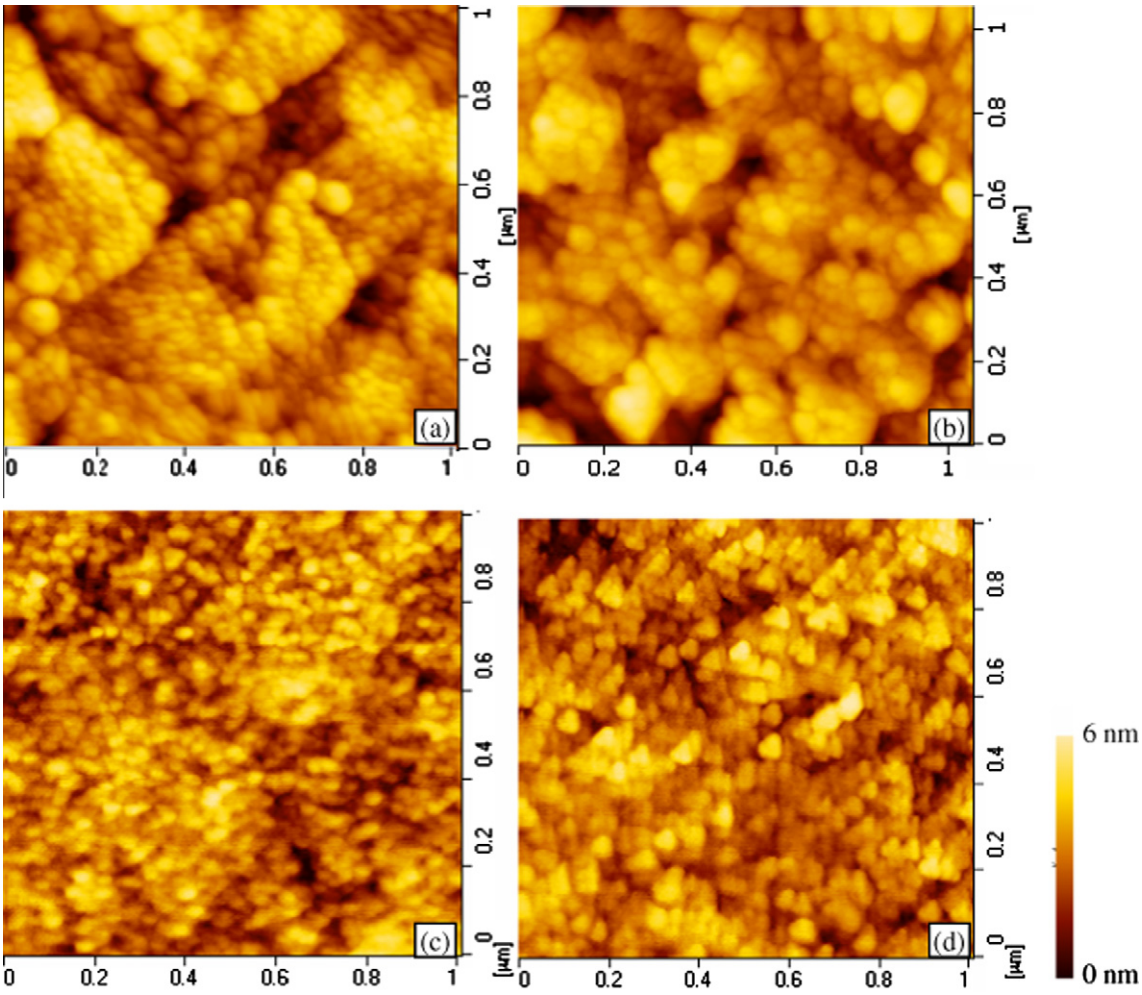

Fig. 4. AFM images of ITO substrates (a) unmodified and modified with a PbO layer of (b) 0.5 nm, (c) 1 nm, and (d) 2.5 nm in thickness.

The effect of the ITO surface modification on the photovoltaic performance is related to its effect on the shunt (R_{sh}) and series resistances (R_s) [30,31]. R_{sh} and R_s were estimated in terms of the slopes of the *J*–*V* curves at 0 and 0.7 V, respectively. The low V_{oc} value of the PSC with unmodified ITO indicates the non-ohmic contact between the active layer and the ITO electrode. The deviation of the *J*–*V* curve from the ideal solar cell model suggests that the R_s and R_{sh} values obtained in terms of the slopes at 0 and 0.7 V of the *J*–*V* curves are not so meaningful. But we still present these values in Table 1 to get some sense about the dependence of the apparent R_s and R_{sh} values on the work function of the electrode. They are 103 and 22.3 $\Omega\,cm^{-2}$, respectively, for the control inverted PSC with unmodified ITO. R_s decreases to 2.3 $\Omega\,cm^{-2}$, whereas R_{sh} increases to 9700 $\Omega\,cm^{-2}$ for the inverted PSC with PbO-modified ITO. These changes suggest that PbO helps the electron collection while suppresses the leakage current.

Fig. 1 also illustrates the *J*–*V* curves of two control PSCs with normal architecture. They were fabricated through a similar process. They have ITO coated with PEDOT:PSS as the anode and LiF/Al as the cathode. The active layers of the two normal PSCs were prepared from solutions of different P3HT and PCBM concentrations. One was coated from the same solution as for the inverted PSCs, whereas another was prepared from a 1,2-dichlorobenzene solution consisting of 17 mg ml^{-1} P3HT and 17 mg ml^{-1} PCBM. The latter solution is the optimal one for the normal PSCs. The PCEs of the two normal PSCs are 2.89% and 3.50%, respectively (Table 1). The efficiency of 3.50% is reasonable for normal P3HT:PCBM PSCs, though it is lower than that reported by Li et al. [32]. Both PCEs are remarkably lower than that of the inverted PSC with PbO-modified ITO. The main differences in the photovoltaic performances between the normal and inverted PSCs are the J_{sc} and FF values.

Presumably, the high PCE of the inverted PSC is related to the thick P3HT:PCBM layer [33]. It is thicker than the optimal thickness (180 nm) of the active layer for normal PSCs, so that more light can be absorbed. As shown in Fig. 2a, the absorption of the thick P3HT:PCBM film prepared from the 1,2-dichlorobenzene solution consisting of 25 mg ml^{-1} P3HT and 25 mg ml^{-1} PCBM is remarkably higher than that

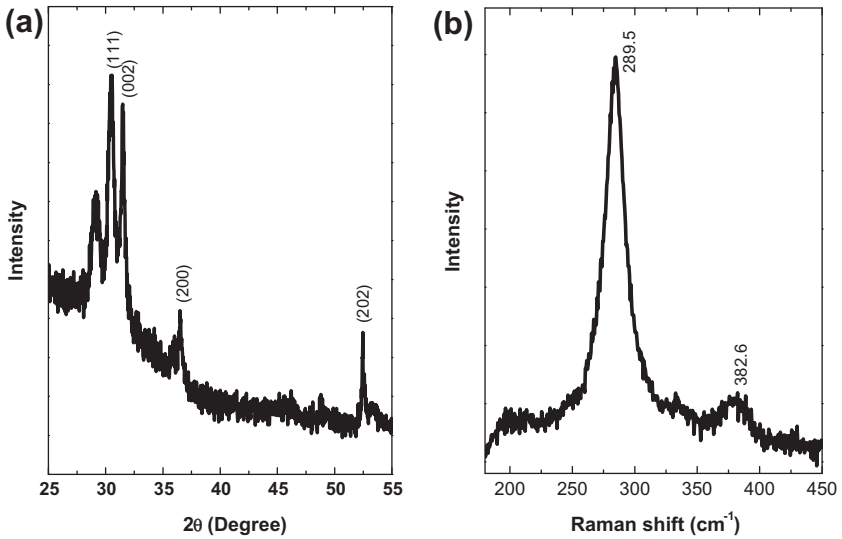

Fig. 5. (a) XRD and (b) Raman spectrum of a PbO film thermally deposited.

of the thin P3HT:PCBM film prepared from the solution consisting of 17 mg ml^{-1} P3HT and 17 mg ml^{-1} PCBM.

IPCE of the inverted PSC is saliently higher than that of the normal PSC with the P3HT:PCBM active layer of the same thickness (Fig. 2b). Because the integration of the product of the IPCE with the photon flux density over the whole range is related to J_{sc} of a PSC, the IPCEs of the two PSCs are consistent with their J_{sc} values. The main reason for the difference in the photovoltaic performances of inverted and normal PSCs is related to the distribution of P3HT and PCBM in the active layer along the vertical direction. As reported in literature, there is a vertical phase separation in the active layer [34–36]. The vertical phase separation is related to the difference in the surface energies of the polymer donor and organic acceptor. P3HT has a lower surface energy than PCBM, so it tends to accumulate at the air surface while PCBM is rich at the bottom of the active layer. The vertical phase separation can become more significant on ITO/PbO than ITO/PEDOT:PSS, because the former is more hydrophilic than the latter. As the results of the vertical phase separation, both the hole transport along P3HT into the top electrode and the electron transport along PCBM into the bottom electrode are promoted. Thus, the inverted architecture can benefit both the electron and hole collections.

Though the thick P3HT:PCBM film can absorb more light than the thin P3HT:PCBM film, the IPCEs of the normal PSCs with the thick and thin P3HT:PCBM active layers are comparable. This is also consistent with their J_{sc} values. The different PCEs for these two normal PSCs can be attributed to the low charge carrier mobilities. As mentioned above, there is a vertical phase separation in the active layer of both normal and inverted PSCs. PCBM accumulates at the bottom while P3HT accumulates at the top. Thus, the electrons transporting along PCBM to the bottom electrode can have a higher mobility than to the top electrode, while the holes transporting along P3HT to the top electrode is easier than to the bottom electrode. This can explain that the optimal P3HT:PCBM thickness of normal PSCs is lower

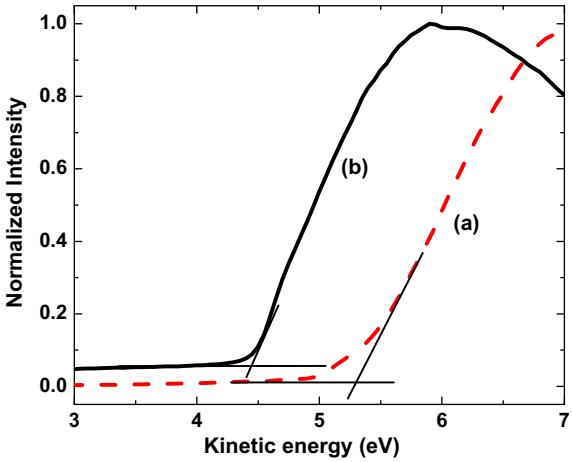

Fig. 6. UPS spectra of ITO substrates (a) unmodified and (b) modified with a 1 nm-thick PbO layer.

than that of inverted PSCs. The normal PSC with a thick P3HT:PCBM layer has higher R_s than that with a thin P3HT:PCBM layer. Though more light can be absorbed in the thicker layer, more charges get lost, giving rise to lower FF and PCE [37].

PbO films with different thicknesses were deposited on ITO substrates to study the PbO thickness effect on the photovoltaic performance of the inverted PSCs. Fig. 3 illustrates the variations of J_{sc}, V_{oc}, FF and PCE of the inverted PSCs with the thickness of the PbO layer. All four parameters increase with the increase of the PbO thickness when the thickness is below 1 nm. Presumably, PbO can fully cover all the ITO surface after its thickness is 1 nm or above. When the PbO layer is thicker than 1 nm, J_{sc} becomes insensitive to the further increase in the PbO thickness, and V_{oc} becomes flat. But both FF and PCE decrease with the further increase of the PbO layer. This can be

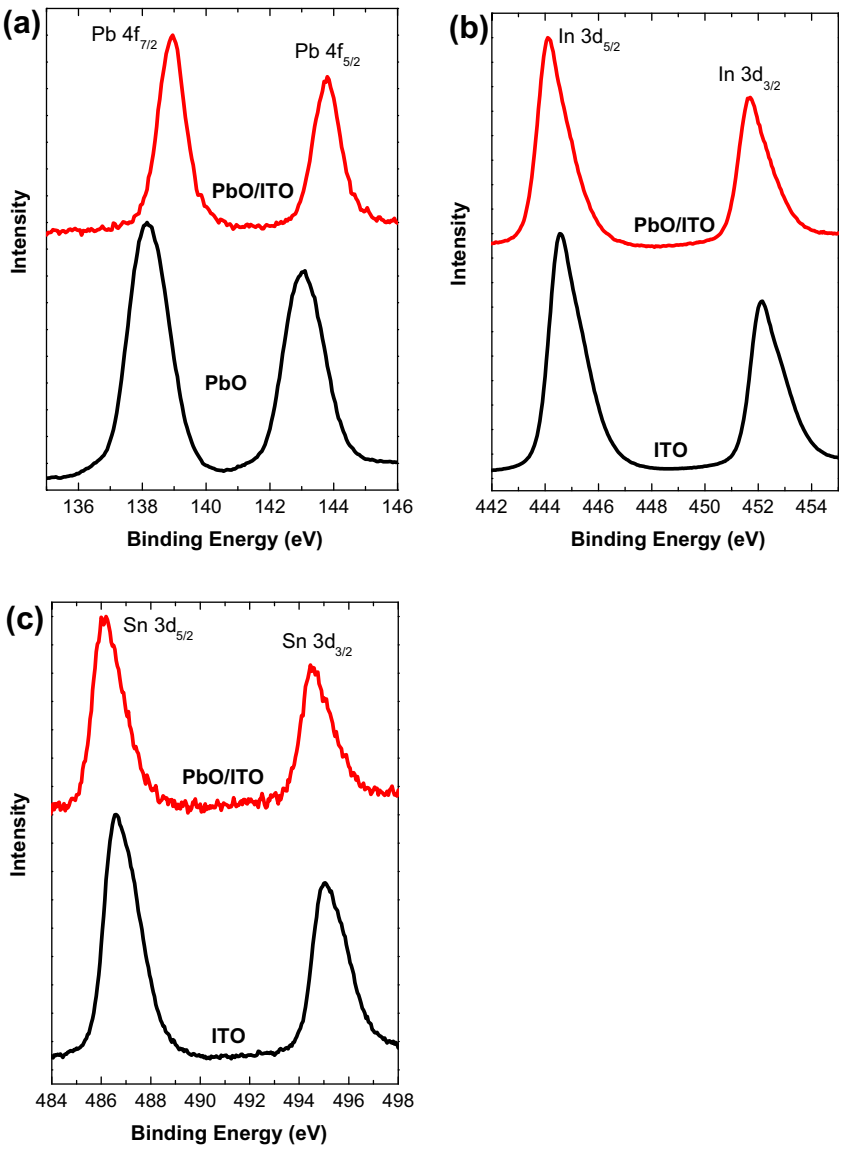

Fig. 7. XPS spectra of (a) Pb $4f_{7/2}$ and $4f_{5/2}$ of PbO and PbO/ITO, (b) In $3d_{5/2}$ and $3d_{3/2}$ of PbO/ITO and ITO, and (c) Sn $3d_{5/2}$ and $3d_{3/2}$ of PbO/ITO and ITO.

attributed to the resistance for the charge transport through the PbO layer.

Photovoltaic performance of PSCs depends on the charge collections at the anode and cathode. They are affected by the surface morphology of the cathode [38,39]. The morphology of the blank and PbO-modified ITO substrates was studied by AFM (Fig. 4). The blank ITO has a quite rough surface with a RMS roughness of 3.3 nm. The ITO surface becomes smoother after the deposition of a PbO layer. The RMS roughness reduces to 3.0, 0.9, and 1.0 nm for ITO substrates deposited with a PbO layer with a thickness of 0.5, 1.0 and 2.5 nm, respectively. These AFM images suggest that a 0.5 nm-thick PbO layer cannot fully cover the ITO surface while a PbO layer with a thickness of 1 nm or above can fully cover the surface. They are consistent with the photovoltaic performance of the corresponding inverted OPVs.

3.2. Mechanism for PbO on the work function of ITO

The high V_{oc} and PCE of the inverted PSCs suggest that the PbO-modified ITO can effectively collect electrons. There are two possible reasons accounting for it. One reason is that PbO can collect electrons like TiO_2 and ZnO, and another is that the work function of ITO is reduced through the PbO modification.

PbO has two kinds of crystalline structures, α-PbO with a tetragonal structure and β-PbO with an orthorhombic structure. The two PbO structures have different electronic structures. β-PbO has a band gap of 2.5–2.7 eV, whereas α-PbO has a band gap of 1.8–2.0 eV [40–42]. The two crystalline structures can be distinguished by XRD and Raman spectroscopy. XRD data indicate that PbO used in this study is β-PbO (Fig. 5a) [43,44]. This is confirmed by the

Raman spectrum of PbO (Fig. 5b) [45]. The Raman bands at 289.5 and 382.6 cm^{-1} are the A_g and B_{1g} modes of β-PbO.

The conduction and valence bands of β-PbO are 4.02 and 6.82 eV, respectively [46]. The conduction band is lower than the LUMO of PCBM that is 3.7–3.9 eV [47,48]. Thus, the hot electron transport from PCBM into a layer of β-PbO alone can cause energy loss during the electron collection. The work function of PbO-modified ITO substrates was investigated by UPS (Fig. 6). The cut-off edge of the PbO-modified ITO has a kinetic energy lower than that of the unmodified ITO by 0.9 eV. This indicates that the work function of the PbO-modified ITO is lower than that of unmodified ITO by 0.9 eV. Because the work function of unmodified ITO is 4.4–4.7 eV [49,50], the PbO-modified ITO substrates should have a work function of 3.5–3.8 eV. Thus, the effective electron collection by the PbO-modified ITO is not due to the conduction band of PbO but the surface modification of ITO, that is, it is related to the interactions between PbO and ITO.

The interactions between PbO and ITO were studied by XPS. Fig. 7 presents the XPS spectra of a blank ITO, a 1 nm-thick PbO deposited on ITO (PbO/ITO), and a PbO layer which was deposited on Si and had a thickness of 10 nm. The Pb $4f_{7/2}$ and $4f_{7/2}$ XPS bands appear at 138.2 and 143.1 eV, respectively, for PbO. They shift to 139.0 and 143.8 eV for PbO/ITO. The binding energies increase after the deposition of PbO on ITO. On the other hand, the XPS bands of In and Sn of ITO exhibited opposite shifts after the deposition with PbO. The two In $3d_{5/2}$ and $3d_{3/2}$ XPS bands appear at 444.6 and 452.1 eV, respectively, for the blank ITO. They shift to 444.1 and 451.6 eV, respectively, for PbO/ITO. The binding energies decrease after the deposition of the 1 nm-thick PbO layer on ITO. The binding energies of the two Sn 3d XPS bands also shift to red after the deposition of PbO on ITO. They are at 486.6 and 495 eV, respectively, for the blank ITO, and shift to 486.1 and 494.5 eV after the deposition of PbO. The XPS spectra of PbO and ITO suggest that electrons may transfer from PbO to ITO. This electron transfer may push up the Fermi level at the ITO surface and consequently lower the work function. The lone $6s^2$ electron pair of Pb^{2+} may take part in the electron transfer [42]. In addition, it has been understood that the lone $6s^2$ electron pair of Pb^{2+} give rise to a high dipole moment in PbO [51]. This dipole moment may also contribute to the reduction of the PbO-modified ITO.

4. Conclusions

In conclusion, a thin PbO layer can effectively lower the work function of ITO. The inverted PSCs with the PbO-modified ITO as the cathode show high photovoltaic performance. The optimal performances are: V_{oc} = 0.59 V, J_{sc} = 10.8 mA cm^{-2}, FF = 0.632, and PCE = 4.00% under simulated AM1.5G illumination. The optimal PCE of the inverted PSCs is significantly higher than the inverted PSCs with unmodified ITO and even higher than the optimal PCE (3.5%) of normal PSCs. The lowering in the work function of ITO by the PbO modification is attributed to the interactions between ITO and PbO.

us to use the same thermal evaporation process that is needed for organic light-emitting layers. Namely, it does not involve any damage to organic layers and the photolithography process as well. Those organic insulating molecules can be placed right on the ITO anode, just below the aluminum (Al) cathode, or both on the ITO anode and below the Al cathode (Fig. 1). Those evaporated right on the ITO anode prevent hole leakage via the spikes existing on the ITO edges. To suppress it effectively, the hole mobility of those organic insulating molecules should be as low as possible. Meanwhile, those evaporated just below the Al cathode block off the electron-leak pathway. As such, organic insulating molecules that have very low electron mobility are preferred. In practice, however, it is unknown which device configuration (Fig. 1) shows higher performance. To clarify it, we make a performance comparison among those devices in Fig. 1 in terms of the current efficiency and lifetime. With attempt to understand the complex device behaviors, especially the carrier transport, we also perform the numerical simulations of those configurations. It is demonstrated that blocking off both hole- and electron-leak pathways is highly desired to enhance the current efficiency and lifetime of the sputter-patterned ITO-based OLEDs.

2. Experiment and simulation

For systematic inquiries, we have fabricated two different OLED devices. A fluorescent green bilayer OLED that is composed of 50-nm-thick 4,4′-bis[*N*-(1-nathyl)-*N*-phenylamino]biphenyl (NPB) for a hole transport layer (HTL)

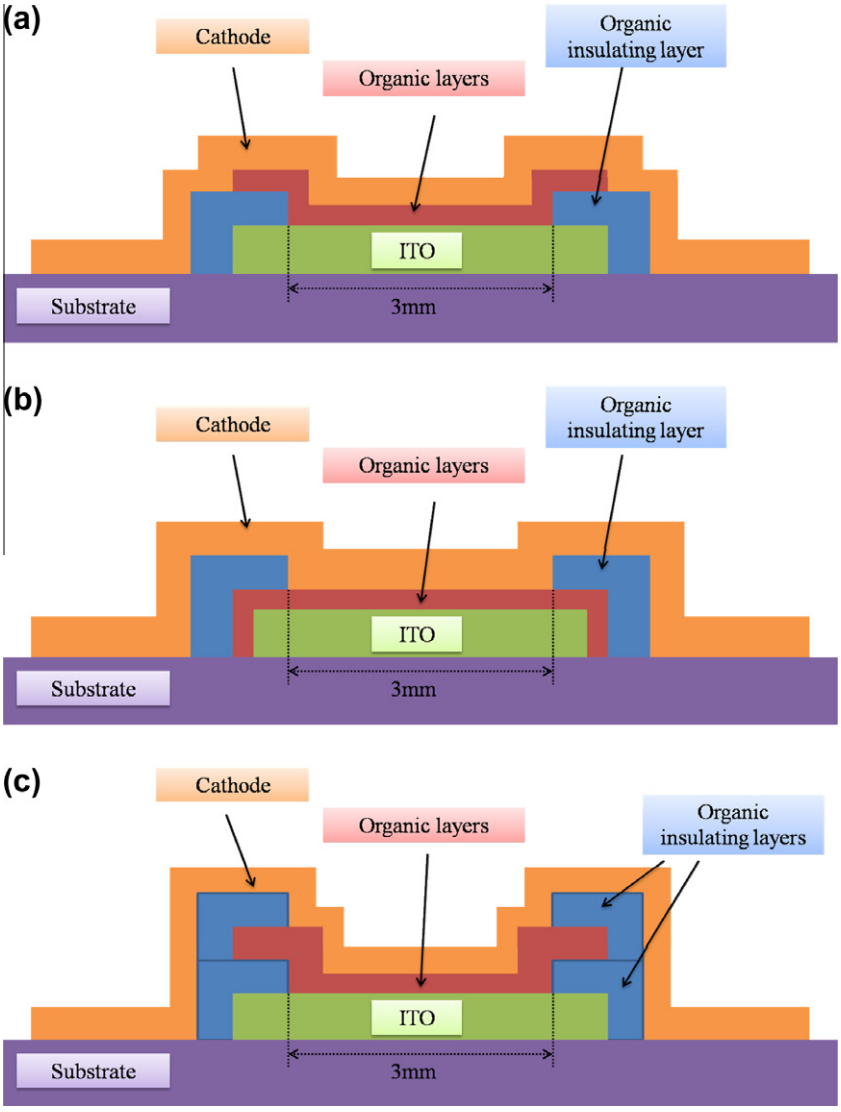

Fig. 1. Cross-sectional view of OLEDs with organic insulating molecules (a) on the ITO anode, (b) below the Al cathode, and (c) both on the ITO anode and below the Al cathode (the width of ITO is 4 mm).

and 45-nm-thick Tris-(8-hydroxyquinoline) aluminum (Alq_3) for an electron transport layer (ETL) was fabricated to make a numerical and experimental investigation of the leakage current cut-off capability of those organic insulating molecules. In this work, Alq_3 is used to prevent hole leakage, which has very low hole mobility ($\sim 1.2 \times 10^{-7}$ cm^2/Vs) [16], whereas NPB is used to block off the electron-leak pathway, which exhibits very low electron mobility ($\sim 1.0 \times 10^{-8}$ cm^2/Vs) [16]. For fluorescent green bilayer OLEDs, we used the commercial ITOs purchased from GEOMATEC Co., Ltd. and patterned them using the standard photolithography process with a patterned PI insulation layer (TORAY, Photoneece™ DL-1602). We intentionally covered the whole emission area (2 mm × 2 mm) with those organic insulating layers and then conducted numerical and experimental investigations of their leakage current cut-off capability. The other device we fabricated is a phosphorescent green multi-layer OLED device that consists of a 10-nm-thick LG-101 for a hole injection layer (HIL), 40-nm-thick NPB for a HTL, 30-nm-thick *N*,*N*′-dicarbazolyl-3,5-benzene (mCP) doped with tris(2-phenylpyridinate) iridium(III) ($Ir(ppy)_3$, 8 wt.%) for an emitting layer (EML), 7-nm-thick *m*-bis-(triphenylsilyl)benzene (UGH3) for a hole blocking layer (HBL), 30-nm-thick (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) (Bphen) for an ETL, 1-nm-thick lithium fluoride (LiF) for an electron injection layer (EIL), and 100-nm-thick aluminum (Al). Unlike fluorescent green bilayer OLEDs, we have fabricated the ITO anodes for phosphorescent green multi-layer OLEDs using a sputtering deposition system (SUNICOAT-IS3000, SUNIC SYSTEM) with a metal open mask under the DC power of 500 W and at the substrate heater temperature of 240 °C. The sputtered ITO films show the sheet resistance of 25Ω/□. For phosphorescent green OLEDs, those organic insulating molecules (NPB and Alq_3) were thermally evaporated using a metal open mask that covers the sputter-patterned ITO edges. As such, the total emission area of those devices is 3 mm × 4 mm (the width of ITO is 4 mm, which is the same as that of Al).

For numerical simulations, we have implemented a 1D numerical model that is composed of Poisson's equation, drift–diffusion equation, and singlet exciton rate equation [16,17]. This model is capable of capturing the current injection into organic materials, the hopping transport of carriers, the locally generated excited states (excitons), the radiative decay of excitons, as well as the interactions among the electric field, the carrier mobility, and the current injection. We have used this model to visualize the carrier density distribution over the device, which facilitates the analysis of the experiment results. To obtain steady-state solutions, we truncated the iteration when the average local deviation was a small fraction (10^{-5}) of the total current [16]. More details as to the model and its numerical implementation can be found in [16,17].

3. Results and discussion

Presented in Fig. 2 is the surface morphology of the patterned ITO edges. As discussed in [15], the sputter-patterned ITO edge has a very gentle slope and its surface roughness is very poor due to the emergence of a number of spikes. Once spikes exist over an emission area, then a short-circuit problem arises because an instant current crowding takes place right at the spikes. Namely, such spikes appeared on the slope of the ITO edges act as leak channels that increase non-emissive current component. As a result, the injected current into OLED lighting panels at a fixed driving voltage is getting increased without saturation. It appears more seriously for large-area OLED lighting panels [3]. Such an increase of the injected current brings in local heat generation during operation, causing a device failure and thus raising a reliability issue. Therefore, the sputter-patterned ITO edges should be covered with those organic insulating molecules.

We have first investigated the feasibility of using those organic molecules (NPB, Alq_3) as an insulating material. To this end, we fabricated three different fluorescent green bilayer OLEDs with those organic insulating layers, the energy level diagrams of which are depicted in Fig. 3, To make a comparative study, we also fabricated a bilayer OLED without any organic insulating layer included (Fig. 3a). In Fig. 3b, the leakage hole cut-off layer (HCl, i.e., Alq_3 layer for blocking off hole transport) is placed before HTL. Owing to a large energy barrier for holes between ITO and the HCl layer along with a low hole mobility of the HCl layer, the hole transport would be effectively hindered. On the contrary, the leakage electron cut-off layer (ECL, i.e., NPB layer for blocking off electron transport) is placed before the Al cathode in Fig. 3c. Similarly, the electron transport would be effectively blocked due to a large energy barrier for electrons between the ECL layer and the Al cathode along with a low electron mobility of the ECL layer.

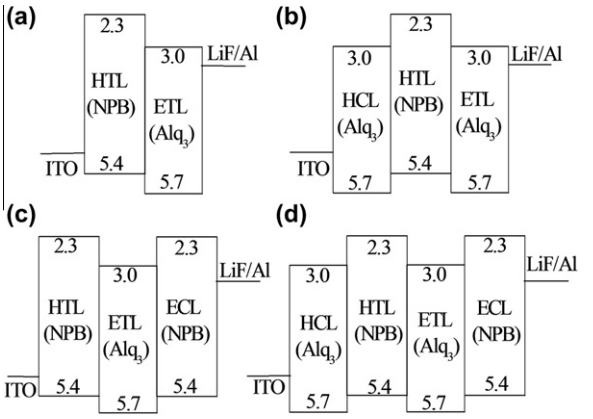

Fig. 3. Energy level diagram of fluorescent green bilayer OLEDs (a) without organic insulating molecule, (b) with leakage hole cut-off layer (HCl), (c) with leakage electron cut-off layer (ECL), and (d) with both HCl and ECL layers.

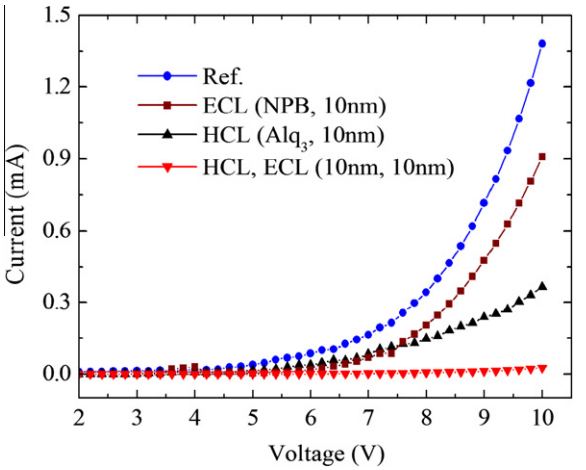

Fig. 4. Measured current versus voltage from fluorescent green bilayer OLEDs in Fig. 3.

Meanwhile, both hole and electron cut-off layers are placed in Fig. 3d. Shown in Fig. 4 are the *IV* curves measured from those OLED devices. As expected, the current flow is clogged the most in OLED with both hole and electron cut-off layers, followed by OLED with the single HCl layer (10 nm) and then OLED with the single ECL layer (10 nm). Though the current cut-off capability of OLEDs with the single insulation layer is higher than that of

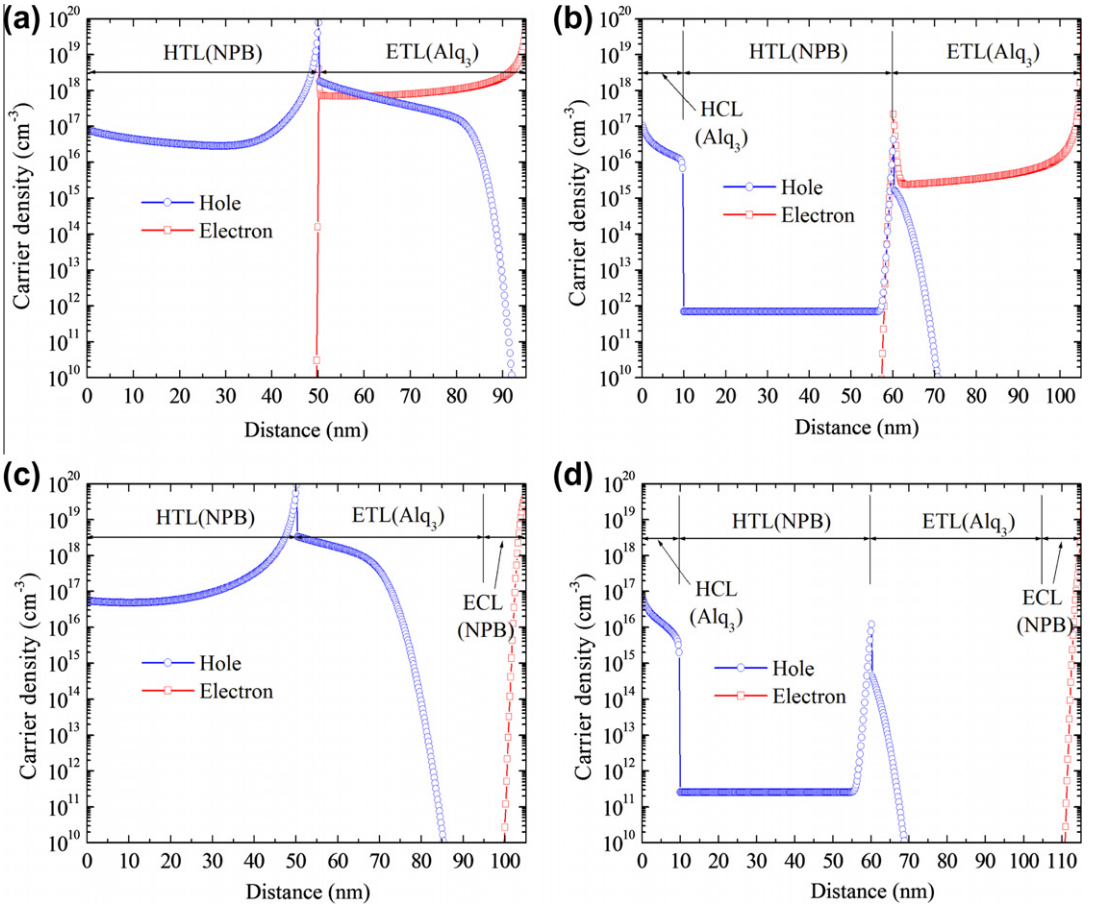

Fig. 5. Simulation results of carrier density distribution of fluorescent green bilayer OLEDs in Fig. 3 under the bias voltage of 9 V.

OLEDs without any organic insulating layer involved, yet it is not comparable with that of OLEDs with the dual (HCl and ECL) insulation layer. Meanwhile, the OLED structure with the single ECL layer shows poorer current cut-off property, compared with the OLED structure with the single HCl layer, the reason for which is uncertain. Furthermore, we have found that light emission occurs only from the bilayer OLED with the single HCl layer under a high bias condition. To find out these reasons, we performed the numerical simulations of those devices in Fig. 3 and presented the results of carrier density distribution in Fig. 5. As seen in Fig. 5a, when no organic insulating layer is involved, holes and electrons reach the HTL/ETL interface. Moreover, holes penetrate into the ETL layer since the hole mobility of HTL is almost two orders of magnitude higher than the electron mobility of ETL [16]. When the HCl (Alq_3) layer is presented, holes that reach the HTL/ETL interface are dramatically reduced as evident in Fig. 5b. Even so, some holes exist near the HTL/ETL interface, generating light emission through hole-electron recombination under a high bias condition. Similarly, when the ECL (NPB) layer is placed, electrons hardly reach the HTL/ETL interface. However, the hole density in Fig. 5c is observed to be much higher than the electron density in Fig. 5b near the HTL/ETL interface. Therefore, the OLED structure with the single ECL layer may show the poorest current cut-off capability, which is consistent with the experiment result in Fig. 4. When both HCl and ECL layers are presented, the carrier density at the interface is negligibly low as apparent in Fig. 5d. This result indicates that both hole- and electron-leak pathways should be blocked off to effectively suppress the leakage current that may occur in the sputter-patterned ITO-based OLEDs.

The current cut-off capability can be boosted by increasing their thickness. As shown in Fig. 6 where experiment and simulation results of *IV* curves are presented, the current flow is much reduced with increasing thickness of the ECL (NPB) layer. This result implies that one can improve the current cut-off capability using a single but thick organic insulating layer. However, it is observed that more current flows through OLED with the thicker (30-nm-thick) and single (ECL) insulation layer (Fig. 6), compared with current flowing through OLED with the thinner (totally 20-nm-thick) and dual (HCl and ECL) insulation layer (Fig. 4). This result also supports our conclusion that not only electron flow but also hole flow should be clogged because the total current density is determined by both hole and electron current densities flowing through the device.

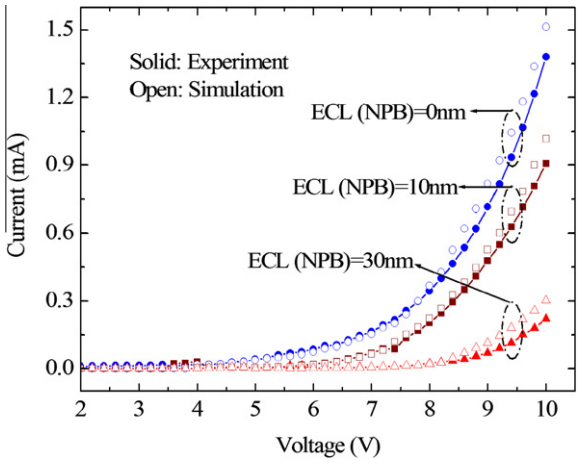

Fig. 6. Measured and simulated *IV* curves from the OLED structure with the ECL layer for different ECL layer thicknesses.

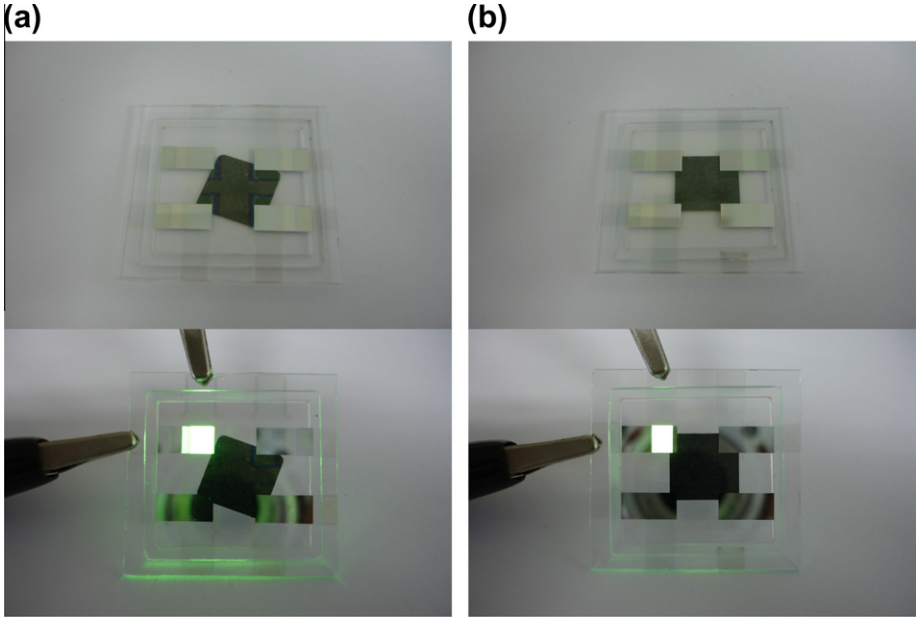

Fig. 7. Images of (a) OLED device with the HCl layer (top) and its green light emission (bottom) and (b) OLED device with the dual insulation layer (top) and its green light emission (bottom). The image of green light emission from OLED device with the ECL layer is similar to that (b) of OLED device with the dual insulation layer. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

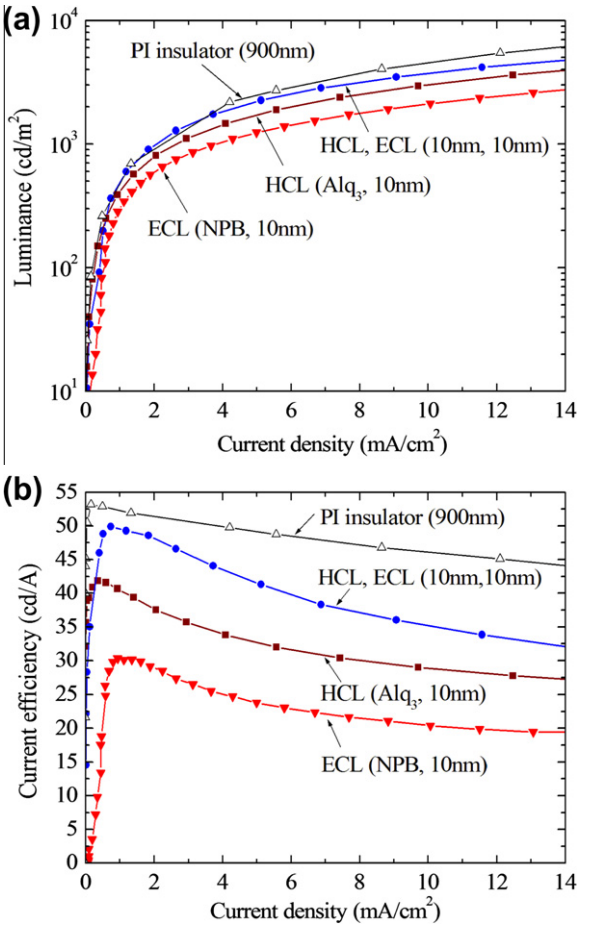

Fig. 8. Measured (a) luminance and (b) current efficiency versus current density of those OLED devices (Fig. 1) with organic insulating molecules.

For the practical applications of those organic insulating molecules, we have fabricated phosphorescent green multi-layer OLED devices where the sputter-patterned ITO edges are covered with the HCl or ECL layers. Fig. 7 shows the images of green light emission from those devices biased at 10 V. It is clearly seen to the naked eye that the emission area of OLED with the HCl layer is larger than that (3 mm × 4 mm) of OLED with the dual insulation layer. As discussed earlier, some holes existing near the HTL/ETL interface of OLED with the HCl layer in Fig. 5(b) generate green light emission through recombination with electrons, thereby blurring the boundaries between the real emission and non-emission areas. We have measured the luminance and current efficiency of those devices (Fig. 1) as a function of the current density and presented the results in Fig. 8. For comparison, we have also fabricated the OLED device based on the sputtered ITO and patterned PI insulation layer. The PI insulation layer is as thick as 900 nm, possibly exhibiting an excellent electrical insulation capability. Summarized in Table 1 are the luminance and current efficiency of those devices at a current density of 10 mA/cm^2. As expected, the OLED structure with the PI insulation layer shows the best device performance. Of those three devices with leakage current cut-off layers, however, the OLED structure with the dual insulation layer is shown to have the highest luminance (3784 cd/m^2 at 10 mA/cm^2) and current efficiency (35 cd/A at 10 mA/cm^2). At the same current density, the current efficiency of OLED with the single HCl layer is reduced to 29 cd/A, while it is further reduced to 20 cd/A for OLED with the single ECL layer. Such a large reduction in the current efficiency is due most likely to the presence of leak channels and poor leakage current cut-off capability. Since the leakage current originates dominantly from holes rather than electrons in OLEDs, the current efficiency of OLED with the single ECL (NPB) layer is reduced further. Therefore, it is more desired to place such an organic insulating layer right on the sputter-patterned ITO edges. However, the best use of them is to deploy them both on the ITO edges and below the Al cathode. Namely, one needs to prevent both hole and electron leakage in order to suppress effectively the overall leakage current and thus boost the device performance.

Table 1
Measured luminance and current efficiency of phosphorescent green multi-layer OLEDs (Fig. 1) at a current density of 10 mA/cm^2.

@10 mA/cm^2	OLED with ECL layer	OLED with HCl layer	OLED with both HCl and ECL layers	OLED with PI insulator
Luminance (cd/m^2)	2127	3042	3784	4556
Current efficiency (cd/A)	20	29	35	46

We have also measured the lifetime of those devices and presented the results in Fig. 9. At an initial luminance of 1000 cd/m^2, we measured T_{50} (in h), representing the duration from the start of testing to the time at which luminance is decreased to 50% of its initial value. As expected, the OLED structure with the PI insulation layer shows the longest lifetime. Of those three devices with

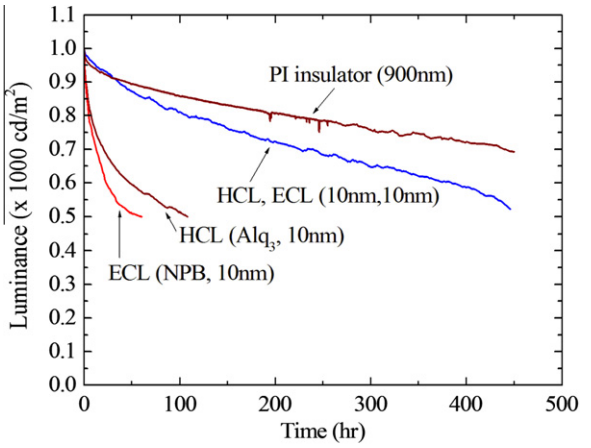

Fig. 9. Luminance as a function of time measured at an initial luminance of 1000 cd/m^2.

leakage current cut-off layers, however, the OLED structure with the dual insulation layer shows the longest lifetime (T_{50} of 446 h), followed by OLED with the single HCl layer (T_{50} of 108 h) and then OLED with the single ECL layer (T_{50} of 60 h). Such a lifetime reduction occurring on OLEDs with the single insulation layer is attributed to the leakage current. Namely, OLEDs with the single insulation layer should be operated at a higher bias voltage to compensate for the increased non-emissive current component (i.e., to exhibit the same luminance (1000nit)).

4. Conclusion

We have demonstrated the cost-effective fabrication of OLEDs using a sputter-patterned ITO and thermal evaporation of organic insulating molecules. We have found that organic insulating molecules are desired to be positioned right on the patterned ITO edges to suppress the leakage current dominated by holes. However, the best way to reduce the overall leakage current was to block off both hole- and electron-leak pathways by placing those organic insulating molecules both on the ITO edges and below the Al cathode. The OLED structure based on this scheme exhibited much higher current efficiency and longer lifetime, compared with OLED having the single insulation layer.

semiconductors. The problem there is that these two parameters cannot be obtained independently in a single measurement. It also does not yield the spatial distribution. While it can be done with an effort, it is not straightforward to obtain energetic distribution of states in the band gap from this type of measurement. Secondary ion mass spectroscopy (SIMS), which is the conventional method to study depth profiling of semiconductor with known doping agents, is not applicable to many organic semiconductors because the chemical species responsible for doping are not known. The popular methods to measure mobility in bulk organic semiconductors [8] are the well-established time-of-flight (TOF) [9–12], the space-charge limited current [13,14] (SCLC), and the charge extraction by linearly increasing voltage [15–17] (CELIV), and more recently the susceptance analysis techniques [18]. TOF requires relative thick films and large bias therefore it may suppress some features of real devices. In addition, determining mobilities for materials having a high carrier density, such as P3HT, is difficult because diffusive charge carriers will affect the drift of photogenerated charge carriers under an electric field. The SCLC method, on the other hand, is based on the analysis of current density versus applied voltage (J–V) characteristics in the dark and it is applicable to regular devices ($\sim$200 nm thick active layer). The SCLC method is usually applied to the large electric field regime where the carrier concentration is altered and the extracted mobility may not be accurate. The CELIV technique is the only one known method up to date to directly measure the charge carrier mobility in semiconductors with dispersive transport (disordered media). However, the CELIV technique requires a minimum amount of dark carrier concentration (10^{14}–10^{15} cm^{-3}) a requirement that is not always reached. Recently, there have been reports on mobility extraction based on susceptance analysis [18]. The validity of that method is established by complex fitting and simulation and limited to materials with non-dispersive transport only. It is worth mentioning that none of the aforementioned methods provides independent measurement of the carrier density.

The classic method to measure the carrier density in inorganic semiconductors is the capacitance–voltage (C–V) technique [1]. Unlike the conductivity method, the C–V technique is an independent measurement of carrier density (assuming the permittivity ε and the device area A are known). An inherent advantage of C–V technique is the depth profiling of carrier density in a planar device structure. Moreover, it is straightforward to integrate other methods associated with the C–V method such as admittance spectroscopy [19] and deep level transient spectroscopy [20] to obtain the energetic distribution of states in the bandgap. However, there have been very few applications of the C–V method to measure the carrier density in organic semiconductors [21–23]. We think the reason may lie in the frequency dependence of the capacitance. In this work, we present a method integrating the C–V and voltage-dependent admittance spectroscopy analysis to measure both the carrier density and mobility. We apply the method to the regioregular poly(3-hexylthiophene) (P3HT), a model polymetric semiconductor [24–26] as a proof of principle. After carefully analyzing the frequency effect on C–V measurement, we arrive at a general guideline on the measurement frequency for reliable measurement of carrier density. Furthermore, we take advantage of the frequency dependence to extract the carrier mobility from the same set of capacitance data.

2. Sample preparation

P3HT was obtained from Rieke Metals (90–93% regioregularity) and used as received. Preparation of P3HT film samples was carried out in a N_2 atmosphere glovebox. P3HT ($\sim$20 mg/mL) was dissolved in anhydrous chlorobenzene with heating (60 °C) and stirring overnight. Films were prepared by solution-casting on the substrate. Film thickness was measured on an Alpha-step profilometer (Veeco Dektak 8 Advanced Development Profiler). Indium tin oxide (ITO) substrates were cleaned sequentially in an ultrasonic solvent bath of detergent, acetone, deionized water, and isopropyl alcohol. A PEDOT–PSS (Clevios) layer of $\sim$30 nm was spin-coated onto the ITO at 4000 rpm for 30 s and then baked on a hot plate at 120 °C for 1 h. In order to obtain relative thick films, we drop-casted the P3HT onto the PEDOT–PSS-coated ITO substrate, followed by slow solvent evaporation. We note that the thick films prepared by such a method, while smooth with a roughness $\sim$6 nm confirmed by an atomic force microscope scan of 20 by 20 μm^2, yield non-uniform film thickness (varying by as much as $\sim\pm$1 μm across an area of 2.5 by 4.0 mm^2 as confirmed by a Dektak profilometer). Lastly, an Al (100 nm) layer was deposited by thermal evaporation through a shadow mask at a rate of 2 Å/s. The shadow mask was used to define six pixels per substrate where the active area is defined by the overlap of ITO anode and Al cathode as $\sim$0.11 cm^2.

It is generally accepted that the PEDOT–PSS layer forms a good ohmic contact with the P3HT layer [27,28]. The carrier transport in the device is then dominated by the Al/P3HT Schottky junction. The Schottky junction can be replaced by a p–n junction without affecting the validity of the discussion in this study. Since Schottky and p–n junction are basic building blocks of many practical devices, we can extend the applicability of this study to any actual planar diode-like devices such as solar cells and light-emitting diodes. We note that this ease-of-use is advantageous over the time-of-flight and susceptance analysis methods which generally exclude device structures with Schottky or p–n junctions.

3. Experimental methods

We used an Agilent 4294A impedance analyzer to measure the capacitance data. An automated program was developed to acquire capacitance and conductance data at various temperature (100–300 K), modulation frequency (40 Hz to 4 MHz), and DC bias (-3 to +0.5 V). We used an AC modulation voltage of 45 mV$_{rms}$ for all the data presented here. For temperature dependent measurements, the devices were mounted in a He-cooled cryostat. The temperature of the device was taken from a temperature sensor directly attached to the top of the device.

For completeness' sake, we briefly summarize the physics of C–V technique and then extend the discussion to our new method. The capacitance measurement relies upon the existence of a space-charge region in a p–n or Schottky junction. The capacitance, essentially the transfer function of charge response to small AC modulation of bias voltage, is inversely proportional to the width of the space charge region:

$$W = \sqrt{\frac{2\varepsilon}{qN}(V_{bi} - V)}, \tag{1}$$

where ε is the permittivity, q is the elementary charge, V_{bi} is the built-in potential, N is the carrier density, and V is the bias voltage. It is worth noting that when many trapped charges are present, this equation may overestimate W and lead to an underestimate of N [29]. Because V_{bi} is a constant at a specific temperature, W only depends on N and V, the latter being experimentally controllable. It is then possible to solve for N from the bias voltage dependence of capacitance. In the case of uniform doping, i.e., N is a constant, the C^{-2} versus V curve is a straight line. N can be calculated from the slope of this line and V_{bi} from its intercept with the horizontal axis. In case of non-uniform doping, one can obtain the carrier density depth profile $N(W)$ by calculating W from $1/C$ and N from the local slope (derivative) of C^{-2} versus V.

In a typical C–V measurement, an AC modulation voltage with frequency ω is combined with a DC bias voltage which is gradually swept across certain range. The range for DC bias voltage sweeping is typically in the reverse bias regime. Occasionally, it may overlap with the low forward bias regime. One should avoid the high forward bias regime where additional capacitance (e.g., due to diffusion of minority carriers or other means of carrier injection) and excessive conductance interfere with proper measurement and interpretation of capacitance data. We note that the susceptance analysis method has to be carried out at a forward bias [18] sometimes up to 12 V, which may invoke some measurement challenges in actual application.

The choice of modulation frequency ω is critical. The prerequisite of the C–V technique is that carriers are mobile and can respond to the AC bias at the modulation frequency. Due to the low conductivity, the dielectric relaxation frequency of organic semiconductors puts an upper limit to the usable modulation frequency. Recall that a semiconductor material characterized by conductivity σ and permittivity ε exhibits a dielectric relaxation at frequency $\omega_{dr} = \sigma/\varepsilon$. For a hypothetical organic semiconductor with carrier density $\sim 1 \times 10^{15}\ \mathrm{cm}^{-3}$, mobility $\sim 1 \times 10^{-4}\ \mathrm{cm}^2/\mathrm{V/s}$, and $\varepsilon = 4\varepsilon_0$ the dielectric relaxation frequency is $\sim$50 kHz. Below ω_{dr}, the carriers can keep up with the AC bias modulation therefore the semiconductor behaves like a conductor with $G_g = A\sigma/t$, where A is the area and t is the thickness. Above ω_{dr}, the carriers cannot keep up with the AC bias modulation therefore the semiconductor behaves like a capacitor $C_g = \varepsilon A/t$.

The dielectric relaxation frequency is further modified by the presence of a p–n or Schottky junction, which contributes to a depletion capacitance C_d. The equivalent-circuit model becomes the series connection of C_d with the parallel connection of the geometrical conductance $A\sigma/(t–W)$ and capacitance $\varepsilon A/(t–W)$ of the quasi-neutral region. The frequency dependence of the total capacitance C is:

$$C = C_d \frac{\omega^2\varepsilon^2 C_d/\sigma^2 C_g + 1}{\omega^2\varepsilon^2 C_d^2/\sigma^2 C_g^2 + 1}. \tag{2}$$

The frequency dependence of capacitance thus exhibits a step at a transition frequency ω_p, below which C approaches C_d and above which C approaches C_g. By taking the derivative of C with respect to ω, we arrive at the differential capacitance $\omega dC/d\omega$ whose negative peak corresponds to the transition frequency:

$$\omega_p = \frac{C_g\sigma}{C_d\varepsilon} = \frac{W}{t}\frac{\sigma}{\varepsilon}. \tag{3}$$

We see that the ω_p is the dielectric relaxation frequency ω_{dr} modified by the factor W/t. Because $W/t < 1$, ω_p is always less than ω_{dr}. This means that upper ceiling for usable modulation frequency in C–V measurement is further lowered by a factor of W/t. For our experiment, a more convenient parameter to use is the square of the inflection frequency:

$$\omega_p^2 = \frac{W^2}{t^2}\frac{\sigma^2}{\varepsilon^2} = \frac{2\sigma^2}{q\varepsilon N t^2}(V_{bi} - V). \tag{4}$$

It is obvious that ω_p^2 depends linearly on the bias voltage V. All variables in the linear coefficient are physical constants except σ and t, the latter can be independently measured by observing the geometrical capacitance under full depletion or by mechanical means such as a profilometer. If one plots ω_p^2 against bias V, the slope of the resulting line can be used to determine the conductivity σ and in turn mobility μ.

4. Results and discussion

Fig. 1 shows the capacitance measured at 100 Hz modulation frequency at room temperature. As a result of the evolution of depletion width with bias, C increases with

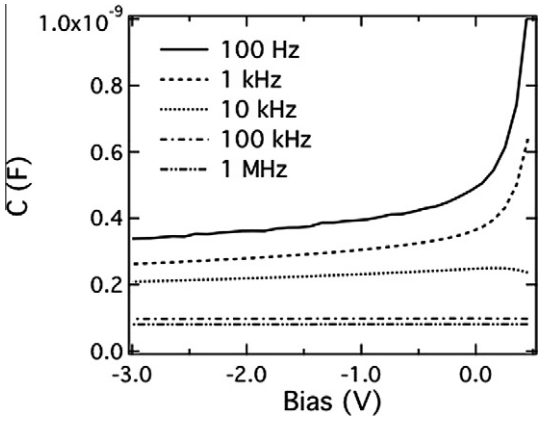

Fig. 1. The voltage dependence of capacitance measured in drop-casted P3HT device. Data were taken at $T = 295$ K and various modulation frequencies.

forward bias and decreases with reverse bias. The Mott-Schottky plot is shown in Fig. 2 based on capacitance data taken at 100 Hz. The built-in voltage (0.57 V) is extracted from the linear part of the Mott-Schottky plot [1]. Using conventional *C–V* analysis [1], i.e., from the derivative of $C^{-2}(V)$, one can obtain the carrier density *N* as a function of depletion width *W* (Fig. 3). Because *W* is measured from the metallurgical junction whose location in the device may be known, one can convert *W* to a measure of depth below the surface of a planar device structure. The *N* versus *W* plot is therefore one version of the carrier density depth profile, i.e., carrier density *N* as a function of depth from the surface. This valuable information is not available in other experimental methods discussed in Section 1. The gradual increase of *N* with *W* may be the real carrier density profile due to chemical and physical evolutions occurred during the formation of the P3HT thin film and the device. It could also be indicative of defect states within the bandgap, as observed in inorganic semiconductors [30] The determination of actual mechanism responsible for the depth profile of carrier density is subject to further study.

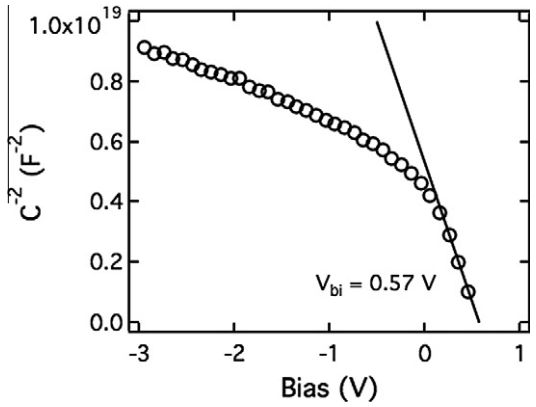

Fig. 2. The Mott-Schottky plot (C^{-2} versus bias) based on data measured in drop-casted P3HT at modulation frequency $\omega/2\pi$ of 100 Hz and $T = 295$ K. The line fitting is used to extract built-in voltage $V_{bi} = 0.57$ V.

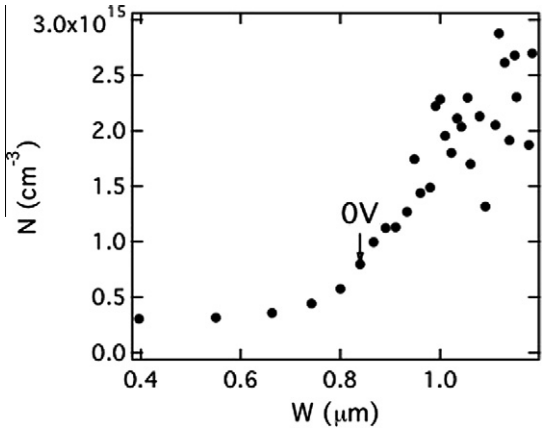

Fig. 3. The carrier density *N* versus depletion width *W* extracted by capacitance–voltage technique. Data were measured in drop-casted P3HT at modulation frequency $\omega/2\pi$ of 100 Hz and $T = 295$ K. The arrow marks 0 V bias.

The *C–V* data taken at 1 kHz (Fig.1, dashed) shows similar trend as that taken at 100 Hz (solid). The *C–V* data taken at 10 kHz (Fig. 1, dotted), however, is drastically different. This is because 10 kHz is approximately the modified dielectric relaxation frequency ω_p. The frequency effect is even more pronounced at 100 kHz (Fig. 1, dash-dotted) and 1 MHz (Fig. 1, dash-double-dotted) where the *C–V* data show little voltage dependence. At frequencies higher than ω_p, the carriers in P3HT cannot respond to the AC bias modulation. As a result, the *C–V* technique becomes ineffective as a probe for carrier density in P3HT. At very high frequencies (~1 MHz), only those carriers in the two contacts (i.e., in Al and PEDOT–PSS layers, as opposed to P3HT) can respond to the AC modulation. Because the P3HT layer is effectively "insulating" at these frequencies, the measured capacitance is nothing but the geometrical capacitance of a classic parallel plate capacitor consisting of two metallic contacts separated by the thickness of the P3HT layer. This geometrical capacitance does not vary with the bias voltage or measurement frequency, as shown by the *C–V* data taken at 100 kHz and 1 MHz.

The breakdown of assumptions in *C–V* technique is reflected in the extracted carrier density *N*. The frequency dependence of *N* (bias = 0 V) is plotted in Fig. 4 (filled dots). Below 2 kHz, the extraction of carrier density is consistent within a reasonable range: $6–10 \times 10^{14}$ cm^{-3}. The carrier density increases slightly with lower measurement frequency, indicating the existence of defect states within the bandgap. Because the emission of carriers from deep states obey the Boltzmann statistics [31,32], increasing the measurement frequency progressively excludes the deeper states from contributing to the "free" carrier density. Consequently, the apparent carrier density decreases slightly with frequency. As the frequency approaches 10 kHz, however, the extracted "carrier density" increases drastically. As we discussed earlier, extraction of *N* at these frequencies above the modified dielectric relaxation frequency is invalid. The very high carrier density extracted there is therefore reflective of

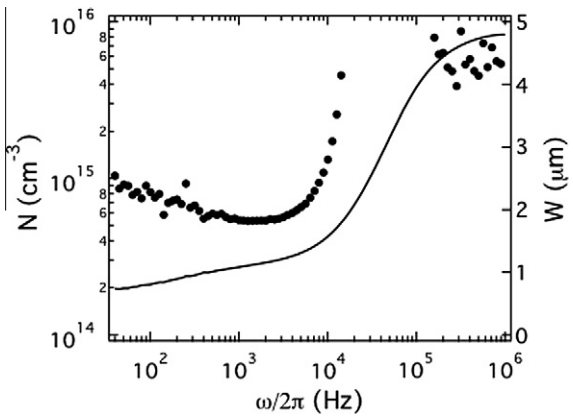

Fig. 4. The carrier density *N* (dots) and depletion width (line) extracted by capacitance–voltage technique plotted against the modulation frequency at which the data were taken. Data were measured in drop-casted P3HT at $T = 295$ K and 0 V bias.

the carrier density in the less conductive of the two contact layers, in our case, PEDOT–PSS.

The frequency dependence of depletion width W (Fig. 4, line) provides additional evidence of dielectric relaxation at high frequencies. Below 10 kHz, W is reasonable ($\sim$1 μm) and consistent with solution of Poisson equation. Above 10 kHz, W increases drastically before eventually reaching a plateau ($\sim$4.8 μm). This plateau agrees approximately with the low end of the physical thickness of the P3HT film confirmed by a Dektak profilometer (data now shown). This is direct proof that: at frequencies ($\sim$1 MHz) much higher than the modified dielectric relaxation frequency, the carriers in P3HT cannot respond to the AC modulation. At that point, the "depletion width" is essentially the thickness of the now "insulating" P3HT film.

The above frequency dependent data of C, N, and W show that it is important to keep below the modified dielectric relaxation frequency ω_p in order to obtain valid C–V measurement. We note that the upper ceiling of usable measurement frequency imposed by ω_p is a few orders of magnitude lower than that in the conventional inorganic semiconductors (e.g., 10^9–10^{12} Hz in Si). As a result, frequencies that are routinely used for C–V measurement in other semiconductors (10^5 Hz is considered quite normal for Si) may be too high for organic semiconductors. A corollary of this conclusion is that the measurement frequency (1 MHz) used in most deep-level transient spectroscopy [20] systems is also too high for organic semiconductors.

Now that we have reliably and independently extracted the carrier density N, we turn our attention to extracting carrier mobility from the bias dependence of the modified dielectric frequency. Fig. 5 shows the frequency dependence of the raw capacitance (solid) and differential capacitance $\omega dC/d\omega$ (dashed). The raw capacitance exhibits a step at certain transition frequency ω_p. Below ω_p, the data represent a reliable measurement of the depletion capacitance albeit with secondary modification by the defect states in the bandgap as discussed above. Above ω_p, the data instead represent a measurement of geometrical capacitance between the two contacts. The transition frequency ω_p is clearly identified as the position of the negative peak in the differential capacitance spectrum.

The transition frequency ω_p exhibits a monotonic decrease with forward bias. This is clearly visible in the shift of the negative peak of the differential capacitance spectrum (Fig. 6). As expected, the square of the transition frequency ω_p^2 exhibits a linear dependence on the bias voltage (Fig. 7). From the slope of this line, we can extract the conductivity σ and mobility μ using Eq. (4).

The conductivity and mobility of the same device are measured at a number of temperatures (Fig. 8). From the Arrhenius plots (Fig. 9), one sees that both parameters appear to be thermally activated. The activation energies are 0.24 ± 0.03 and 0.15 ± 0.01 eV for conductivity and mobility, respectively. It appears that that most of the contribution to thermal activation of conductivity comes from the temperature dependence of mobility [33]. The temperature dependence data of carrier density, although showing

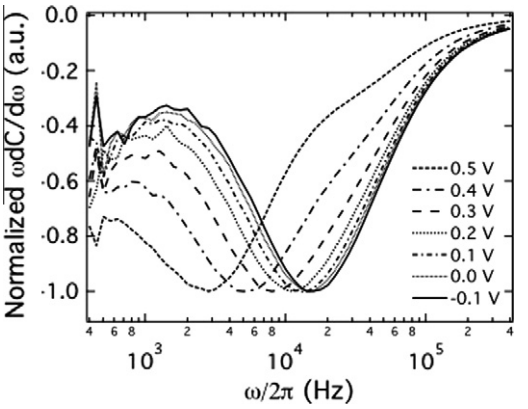

Fig. 6. The differential capacitance measured from a drop-casted P3HT device at 295 K and various biases. The transition frequency ω_p decreases with forward bias.

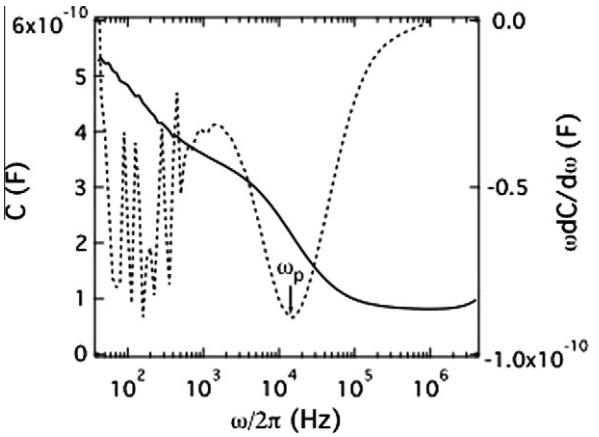

Fig. 5. The frequency dependence of capacitance (solid) and differential capacitance (dashed) measured from a drop-casted P3HT device at 295 K and 0 V bias. The arrow indicates the transition frequency ω_p at which the capacitance exhibits a step transition and differential capacitance exhibits a negative peak.

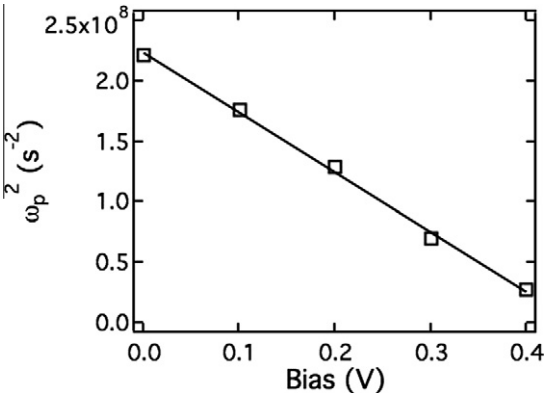

Fig. 7. The square of the transition frequency ω_p^2 identified from Fig. 6 exhibits linear dependence on bias voltage. From the slope (Eq. (4)), the conductivity $(4.9 \pm 2\%) \times 10^{-8}$ 1/Ω cm and mobility $(3.8 \pm 2\%) \times 10^{-4}$ cm^2/V/s were calculated using $N = 8.2 \times 10^{14}$ cm^{-3}, which was measured at 100 Hz at the same temperature.

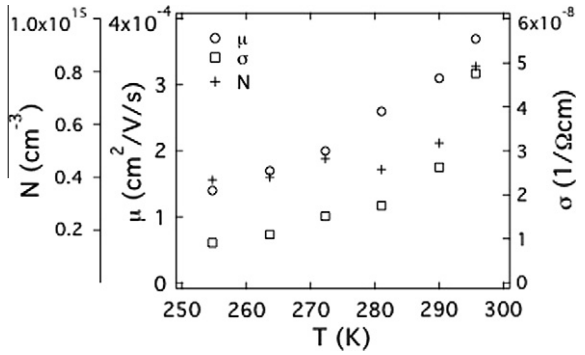

Fig. 8. The temperature dependence of carrier density, conductivity, and mobility in drop-casted P3HT. The relative error of conductivity and mobility is ±4%.

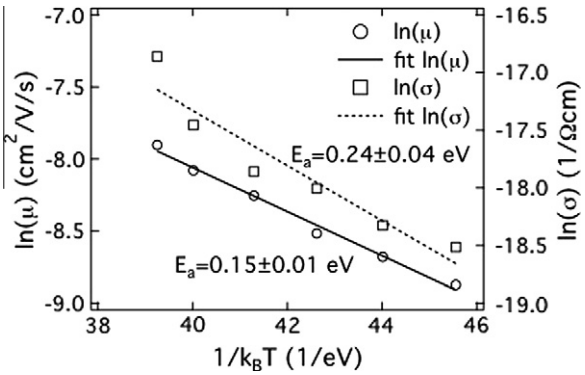

Fig. 9. The activation energies for the conductivity and mobility measured in drop-casted P3HT are extracted from the respective Arrhenius plots.

a general trend consistent with those of mobility and conductivity, are not good enough to extract a reliable activation energy. One possible mechanism for the temperature dependence of mobility in the measured temperature range is trap-limited mobility [34,35].

We note that there is a fair amount of scattering in the extracted carrier density (high 10^{14} to low 10^{16} cm^{-3}) and mobility (high 10^{-6} to low 10^{-4} $cm^2/V/s$). The reason for this wide scattering is mostly likely the lack of control in chemical and physical uniformity during the drop casting process and following fabrication of contacted devices. Our measurement results are consistent with previous reports on P3HT [7], where the origin of the free carriers has been attributed to the intrinsic defects susceptible to chemical treatment. We expect the method presented in this work to be applicable to a wide range of organic semiconductor materials and devices. Unlike the previously reported susceptance analysis method [18], our method does not rely upon any complex simulation and is applicable to materials of both dispersive and non-dispersive transport nature.

Our method requires the co-existence of a space charge region and a quasi-neutral region. Because most of the bias voltage is dropped over the space charge region, the voltage drop over the quasi-neutral region is assumed to be negligible. The extracted mobility is that of the quasi-neutral region which is under zero electric-field. In fact, the electric-field in the quasi-neutral region can not be experimentally adjusted without breaking the basic assumptions of our method. Therefore, our method is not suitable for studying the electric-field dependence of mobility. We note that other methods (e.g., TOF, susceptance analysis, CELIV, and SCLC) are suitable for measuring mobility in an electric-field.

For some techniques such as TOF, a very thick layer is required. The same is not true for our method. We use relatively thick P3HT layer because the depletion region width W at equilibrium is $\sim$1 μm (for a free carrier density N of $\sim 10^{15}$ cm^{-3}). The only necessary condition for our method to be applicable is that the layer of interest is not completely depleted. In other words, the layer thickness t needs to be larger than W. Because W roughly scales with $N^{1/2}$, it is possible to use thinner layers if free carrier density is higher. We have applied our method to layer thickness $\sim$300 nm for material with high free carrier density (e.g., $\sim 10^{17}$ cm^{-3} in P3HT:PCBM mixture, data not shown).

The range of bias useful for our method has two limiting values in forward and reverse biases, respectively. In reverse bias direction, the limit is reached when the layer of interest is completely depleted. At that point, the quasi-neutral region vanishes. In forward bias direction, a few things can happen: (i) there may be minority carrier injection which results in a diffusion capacitance. In a conventional p–n junction, this diffusion capacitance is proportional to the current density under forward bias, which increases exponentially with bias voltage. In other words, the diffusion capacitance [36] quickly outweighs the depletion capacitance (which increases roughly with the square root of bias voltage) at certain bias voltage. Beyond that point, the analysis in this work (as well as that in the conventional C–V measurement) is invalid because the capacitance is no longer dominated by the depletion mechanism. It is worth mentioning that other useful information such as carrier lifetime can be extracted from diffusion capacitance measurement [36]. (ii) The conductivity of the device increases rapidly. (In a conventional p–n junction, the conductivity is also proportional to the current density under forward bias, which increases exponentially with bias voltage.) At some point, the impedance analyzer can no longer measure capacitance accurately. In other words, the phase angle (ideally 90°) of the capacitance measurement becomes too small to be reliable. Admittedly, the carrier transport mechanism in OPV devices differ from that of a classical p–n junction. Nevertheless, the general guideline still holds to avoid using capacitance data at large forward bias for any depletion-capacitance-based analysis.

5. Conclusions

We have developed a method based on the capacitance–voltage–frequency experiment to simultaneously measure both the carrier density and mobility in organic semiconductors from the capacitance–voltage–frequency

experiment. Measurement using the P3HT as an example demonstrates the applicability of this method. Careful inspection of the frequency effect reveals that the conventional capacitance–voltage technique can provide reliable measurements of carrier density and its depth profile in organic semiconductors provided that certain conditions are satisfied. In particular, one needs to make sure that the measurement frequency is below the modified dielectric relaxation frequency, which is much lower in most organic semiconductors than in inorganic semiconductors. By exploiting the voltage dependence of the modified dielectric relaxation frequency, the conductivity and carrier mobility can also be extracted from the same experiment data. Mobility data measured from P3HT show positive temperature dependence within the measurement range (from 250 to 300 K). The activation energies of mobility and conductivity of P3HT are calculated as 0.15 ± 0.01 and 0.24 ± 0.03 eV, respectively. Our mobility extraction method is general and easy to apply because it does not assume any particular dispersive model of mobility *a priori* and it requires no complex fitting or simulation.

omy of scale both through straight-forward synthesis and processing. While a limited number of high mobility, environmental stable materials have been advanced [7,25–30], one of the key challenges, which remains and limits further progress, is the provision of straight-forward and meaningful comparisons between the electronic properties of different compounds. Such comparisons would allow for efficient materials design and screening but necessitates high reproducibility in synthesis, processing and reliable device fabrication and characterization.

Blending of organic semiconductors with insulating (semi-crystalline) polymers has been shown to be a useful strategy to address, among other things, the latter two issues [31–38]. In addition, blending with properly selected commodity polymers to the semiconducting material(s) should enable control over melt- and solution viscosity. In the case of small-molecular semiconductors, a suitable polymer matrix may furthermore be mandatory to meet the ink rheology requirements for specific printing steps in solution-processed devices. From a device point of view, blending is an interesting approach, as it may also lead to multi-component structures with a property matrix that is often not accessible with the individual components. The latter is possibly best exemplified by organic semiconductor:insulator blends, which – under appropriate processing conditions – feature excellent performance in organic field-effect transistors (OFETs) and organic photovoltaics (OPVs) at remarkably low semiconductor contents combined with highly desirable mechanical properties when a tough insulating component is utilized [31]. Besides improved and reliable film formation, blending promises the prospect for major cost reduction, truly "flexible" electronics and, often, significantly enhanced environmental stability of devices produced with them.

In the present study we explored bi-component blends comprising arylacetylenes and the insulating poly(vinylidene fluoride) (PVDF). PVDF was selected as the insulating component as this polymer has been shown to allow film processing at room temperature of, for instance, poly(3-hexylthiophene) (P3HT):PVDF binaries [33]; this in contrast to, e.g., blends based on high-density polyethylene which require deposition temperatures above ~70 °C [31,32]. For the semiconducting species, we focused on *small-molecular* arylacetylenes [39–50]. From a synthetic point of view these compounds exhibit a number of advantages, including availability of efficient synthetic protocols [51–59] that offer the possibility to access in large quantities a broad variety of molecules with specific geometries and flexibility in new conceptions of steric and conformational structures. In addition, their shape-persistent rod-like structures may be of beneficial use for the construction of a broad spectrum of nano and microstructures. A further major advantage of arylacetylenes is that they can be readily synthesized from easily accessible precursors, do not require exotic, rare materials, reducing risks regarding materials supply or costs; their production can easily be scaled up; and, finally, the compounds can readily be isolated in high purity.

Here, we concentrate on arylacetylenes with an anthracene [60,61] backbone, since this core may enable enhanced solubility and stability when compared to, for instance, pentacene, which has become a benchmark in the organic electronics field. Moreover, the anthracene core is a beneficial chromophore unit. Importantly, their chemical structure allows for derivatization with flexible chains at the terminal phenyl-ring systems to modulate the phase behavior and solubility of the resulting arylacetylenes. Those latter attributes permit to manipulate their solid-state structure over a large range of length scales, the influence of which on simple electronic characteristics being the subject of this study.

2. Experimental

2.1. Materials

9,10-Bis(phenylethynyl)anthracene (**1**) was purchased from Alfa Aesar GmbH & Co KG, Karlsruhe, Germany, and used as received. 9,10-Bis[3,4-bis(hexyloxy)phenylethynyl]anthracene (**2**) was synthesized according to a previously reported procedure [44]. Poly(vinylidene fluoride) (PVDF) (M_w = 534 kg/mol) was acquired from Aldrich, Steinheim, Germany. Cyclohexanone was purchased from Acros, Geel, Belgium, and used as received.

2.2. Sample preparation

Blends for thermal analysis and optical microscopy were prepared by co-dissolving the semiconducting species and PVDF in cyclohexanone (~2 wt.% total solids content) at 100 °C, followed by solvent evaporation at ambient conditions or at ~100 °C. Blends for OFETs were prepared by co-dissolving the different materials in cyclohexanone (~6 wt.% solids content) at 100 °C, followed by subsequent adjustment of the solution temperatures to the respective processing temperatures of 25, 50, 75 or 100 °C. To allow film fabrication under isothermal conditions, solutions, metal substrate holders and substrates (doped silicon–silicon oxide (Si–SiO_2)) were equilibrated for ca. 10 min at the designated temperature before spin-drop-casting active layers with a Laurell WS-400B-6NPP/LITE spin-coater at 500 rpm. Note, however, that dissolution temperatures below 100 °C could have been applied, if required, as indicated by the crystallization temperature/composition diagrams of the blend components (*cf.* Figs. 1 and 2b). In addition, the substituted derivative **2** allows fabrication of solutions that are stable under ambient conditions and, hence, can be stored at room temperature without featuring precipitation of the solutes.

2.3. Characterization

Differential scanning calorimetry (DSC) was conducted under N_2 atmosphere at a scan rate of 10 °C/min with a Mettler Toledo DSC 822^e instrument. For DSC analysis of **1**, **2** and PVDF in cyclohexanone, medium pressure 120 μl Mettler stainless steel crucibles sealed with Viton O-rings were utilized. The total sample weight varied between 20 and 40 mg. For characterization of the dried blend films, amounts of ~5 mg were sealed in Al standard 40 μl crucibles.

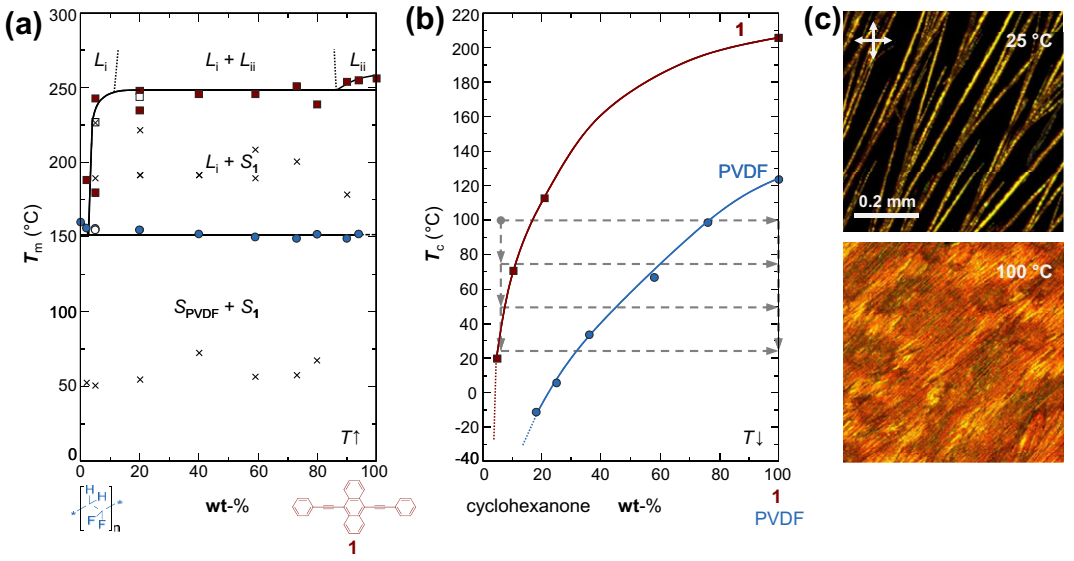

Fig. 1. (a) Binary non-equilibrium temperature/composition diagram of **1**:PVDF blends produced by co-dissolution in cyclohexanone, followed by solvent evaporation at ambient. The diagrams were constructed with peak temperatures recorded during first heating in differential scanning calorimetry (DSC, filled symbols) and polarized optical microscopy (open symbols). L_i, L_{ii} denote liquid phases and S_1, S_{PVDF} solid phases of compound **1** and PVDF, resp.; x indicates exceedingly minor endothermic transitions. (b) Superimposed crystallization temperature/composition diagrams of **1**:cyclohexanone and PVDF:cyclohexanone constructed with DSC peak crystallization temperatures in second cooling thermograms. The gray dashed lines indicate different processing routes applied for **1**:PVDF binaries with solvent removal at 25, 50, 75 or 100 °C, followed by cooling to room temperature. (c) Polarized optical micrographs of **1**:PVDF 40:60 blends solidified at 25 °C (top) and 100 °C (bottom), respectively (polarizer/analyzer indicated with white arrows).

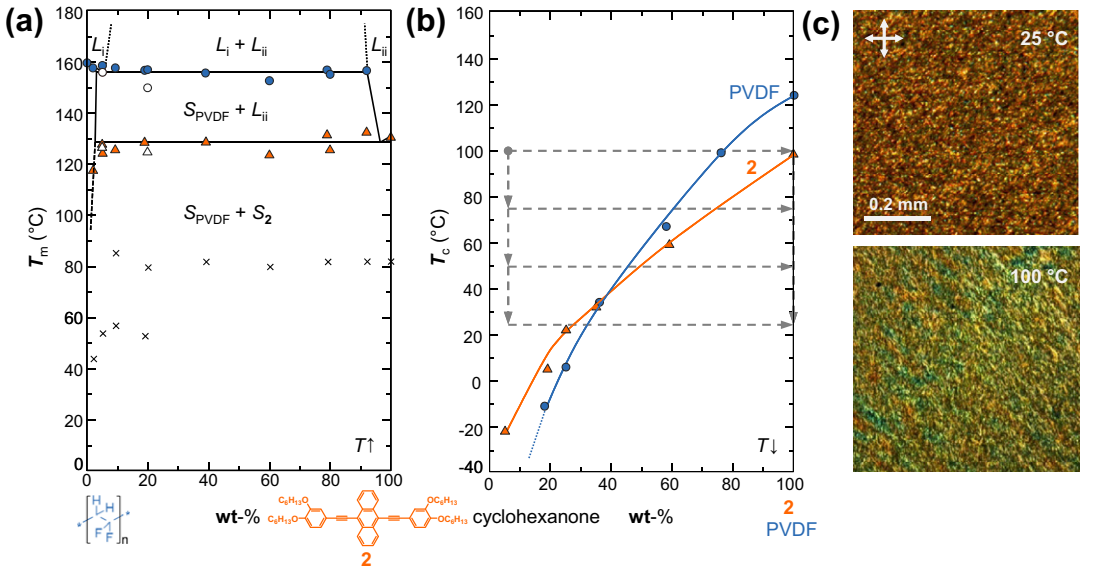

Fig. 2. (a) Binary non-equilibrium temperature/composition diagram of **2**:PVDF blends. L_i, L_{ii} denote liquid phases and S_2, S_{PVDF} solid phases of compound **2** and PVDF, resp.; x indicates exceedingly minor endothermic transitions. (b) Superimposed crystallization temperature/composition diagrams of **2**:cyclohexanone and PVDF:cyclohexanone constructed with DSC peak crystallization temperatures in second cooling thermograms. (c) Polarized optical micrographs of **2**:PVDF 40:60 blends solidified at 25 °C (top) and 100 °C (bottom), respectively (polarizer/analyzer indicated with white arrows).

Room temperature optical microscopy was carried out with a Leica DM4000M polarizing microscope. Variable temperature polarized optical microscopy was performed with a Leica DMRX microscope equipped with a Mettler Toledo FP82HT hot stage. For construction of temperature/composition diagrams of binaries of low semiconductor contents, blend films were heated at 10 °C/min in the hot stage under N_2 atmosphere; in these cases transition temperatures were deduced from the disappearance of birefringence of the respective crystalline phases. At higher

arylacetylene contents, peak endo- and exotherm temperatures recorded by DSC were employed.

Bottom-gate bottom-contact organic field-effect transistors were fabricated on highly doped Si-wafers with a thermally grown ~250 nm SiO_2 layer. The two layers served as the gate electrode and gate insulator, respectively. Au source and drain electrodes (30 nm thick) were defined by standard photolithography (channel length, $L = 10$ μm; channel width, $W = 10$ mm). Prior to use, the Si–SiO_2 substrates were cleaned in an ultrasonic bath with acetone and isopropyl alcohol, followed by drying with a nitrogen flow. Electronic characterization of the OFETs was carried out in a N_2 atmosphere with a Keithley 4200 semiconductor parameter analyzer.

3. Results and discussion

3.1. 9,10-Bis(phenylethynyl)anthracene:PVDF

In a first set of experiments, the phase behavior of blends of the commercially available 9,10-bis(phenylethynyl)anthracene **1** ($T_m = 256$ °C) and PVDF was explored. For this purpose, the non-equilibrium temperature/composition diagram of the **1**:PVDF binary was determined by differential scanning calorimetry (DSC) and variable-temperature polarized optical microscopy – see Fig. 1a. As is evident from this diagram, the small-molecular semiconductor and polymer insulator are largely incompatible, resulting in a classical monotectic behavior featuring an extremely large miscibility gap. The significant difference between the melting temperatures between the two components resulted in a $L_i + S_1$ two-phase region that extended over more than 100 °C.

The phase behavior of blends of **1**:PVDF naturally has a significant influence also when processing them from solution. This is illustrated with a 40:60 wt.% **1**:PVDF blend, the composition of which was selected to provide a good compromise between electronic characteristics and film forming properties. When cast at 25 °C from cyclohexanone (~2 wt.% total material content), the semiconducting:insulating binary formed a microstructure comprised of crystalline arylacetylene needles of hundreds of microns length coarsely distributed throughout a PVDF matrix (Fig. 1c). The formation of this solid-state structure is readily understood on the basis of the superimposed crystallization temperature/composition diagrams of the two respective components and the solvent cyclohexanone, presented in Fig. 1b. These diagrams indicate that during evaporation of the solvent from this blend, **1** solidified prior to PVDF essentially at all compositions. Due to the relatively large gap between the solidus of the two components, *i.e.* the significant difference in supercooling that is required for the semiconductor and insulator to solidify from cyclohexanone, a coarse, highly phase separated structure resulted, combining features of the microstructures that are observed when processing the neat blend components at that same temperature.

Not unexpectedly, increasing the rate of solidification of the two components by applying higher deposition temperatures, causing an enhanced rate of solvent evaporation, yielded a much finer and more homogeneous microstructure (*cf.* Fig. 1c), similar to those observed for α-quaterthiophene:polyethylene blends reported previously [32]. However, from a processing point of view – particularly with respect to printing – high-temperature operations are not particularly desirable, and, therefore we explored influencing the microstructure formation not by thermal means but by chemical modification of the semiconducting species.

3.2. 9,10-Bis[3,4-bis(hexyloxy)phenylethynyl]anthracene:PVDF

In order to beneficially alter the phase- and solidification behavior of the semiconducting:insulating arylacetylene:PVDF blends through adjustment of the physicochemical properties of the small-molecular compound by chemical modification, we elected to introduce four flexible hexyloxy side-chains at the terminal phenyl-ring systems. This compound **2**, consequently, featured a considerably lower melting temperature ($T_m = 131$ °C), and associated enhanced solubility in common solvents, compared to its unsubstituted counterpart **1**. The **2**:PVDF temperature/composition diagram is shown in Fig. 2a. From this diagram, it is clear that also this compound, like **1**, is largely incompatible with PVDF. However, due to its lower melting temperature, the temperature range between liquidus and solidus lines in the two systems is significantly reduced, *i.e.* from ΔT ~100 °C for **1**:PVDF blends to ~30 °C for the **2**:PVDF binaries.

The significantly increased solubility of **2** in cyclohexanone also resulted in a distinct shift of its solidus not only to lower temperatures but also higher concentrations (Fig. 2b). As a consequence, the (superimposed) crystallization temperature/composition diagrams of **2**:cyclohexanone and PVDF:cyclohexanone feature a crossover of the two solidus lines; and, hence, there exist two distinct regimes in which, in principle, the semiconductor can either crystallize prior to, or after the polymer. In either case, however, at any given concentration or temperature, below their liquidus the difference in supercooling experienced by both components is relatively small when compared to the above described binary. As a consequence, invariably the organic semiconductor **2** and PVDF solidified virtually simultaneously, yielding fine grained structures. Accordingly, in this system, the semiconductor solidified in a much finer microstructure than that observed for the neat species, both at room temperature and 100 °C (*cf.* Fig. 2c). Note, however, that above and below 40–50 °C the sequence of solidification reversed.

3.3. Electronic properties

Having the chemical means and corresponding processing protocols to readily adjust arylacetylenes:PVDF blend microstructure by either controlling composition or deposition temperature, we sought to elucidate the influence of solid-state morphology on the performance of devices fabricated with them, and also probed if their electronic characteristics were affected by the solubilizing side-chain substitutions. For this purpose, bottom-gate, bottom-

contact field-effect transistors were fabricated with binaries of PVDF comprising 40 wt.% of, respectively, **1** and **2**, casting them at 25, 50, 75 or 100 °C. Electronic characteristics of these devices are presented in Fig. 3 and in the Supplementary data.

What is immediately evident from the OFET data presented is that the performance of devices with **1**:PVDF binaries increased steadily with the deposition temperature. By contrast, processing conditions had only a minor influence on OFET performance of **2**:PVDF blends; however an optimum casting temperature was observed around 50 °C. These observations can be directly correlated with the superimposed temperature/composition diagrams presented in Figs. 1 and 2. As shown above for **1**:PVDF blends, a rapid solidification sequence of the two components, realized through thermal control of the rate of solvent evaporation, resulted in a finely phase-separated blend microstructure, apparently, enhancing device performance. In the case of compound **2**, the reduced melting temperature and increased solubility resulting from the introduction of side-chains, caused the two components under most conditions to solidify rapidly after each other, if not simultaneously, even when casting the active layer at room temperature. The resulting finely phase-separated bi-component layers invariably lead to good device characteristics. Deposition at more elevated temperatures (>50 °C), however, (slightly) affected OFET performance of **2**:PVDF blends in a negative manner, despite the observation that the degree of phase segregation in the binary film was not significantly different. We attributed this to the fact that in these cases the sequence of crystallization of the components is reversed at elevated temperatures, with the insulating polymer crystallizing *prior* to the active species. The latter observation is in agreement with previous work in which it was shown that this solidification mode not only does not promote the necessary percolation of the semiconducting species, but might even prevent that [31,62].

From the above it is clear that very similar device characteristics (charge-carrier mobility $\mu_{FET} \sim 5 \times 10^{-4}$ cm^2/Vs; ON–OFF ratio $\sim 10^3$) can be obtained for both arylacetylenes, provided that a finely phase-separated blend structure is induced. For all blend systems explored, devices were injection limited, resulting in a sub-linear dependence of source–drain currents, I_{sd}, at small source–drain bias, V_{sd} in the output characteristics (*cf.* Fig. 3). However, as the contact resistance seems to be comparable for arylacetylenes:PVDF OFETs, the electronic characteristics still allow meaningful comparison, even though, as a consequence of the limited charge injection, mobility values determined might be underestimated. Importantly, the melting-temperature-reducing and solubilizing hexyloxy side-chains in compound **2** did not negatively affect charge transport. Furthermore, this study shows that a key for providing meaningful comparisons between different semiconducting species – even simple derivatives – is to

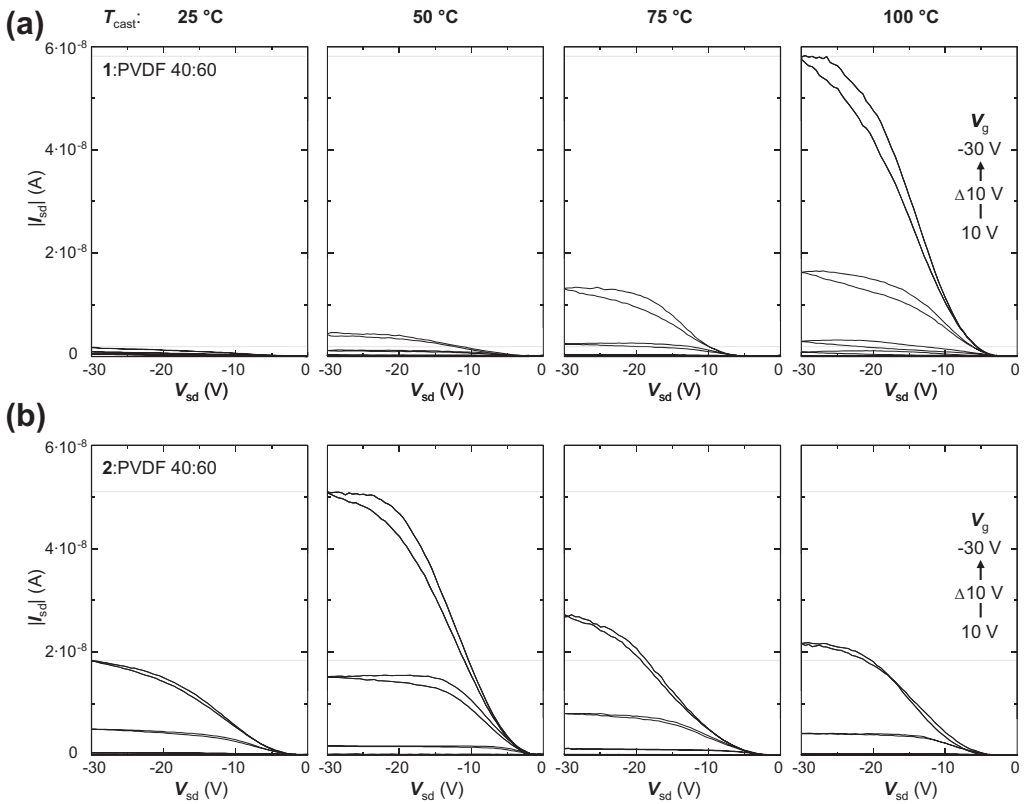

Fig. 3. (a) Output characteristics of bottom-gate bottom-contact OFETs (L = 10 μm; W = 10 mm) of **1**:PVDF and (b) **2**:PVDF 40:60 blend films fabricated at 25, 50, 75 and 100 °C. In all graphs, forward and backward scans are shown. Gray dotted lines indicate $I_{sd,max}$ of OFETs comprising **1**:PVDF blend films produced via solvent evaporation at 100 and 25 °C, respectively and **2**:PVDF binaries fabricated at 50 and 25 °C, respectively.

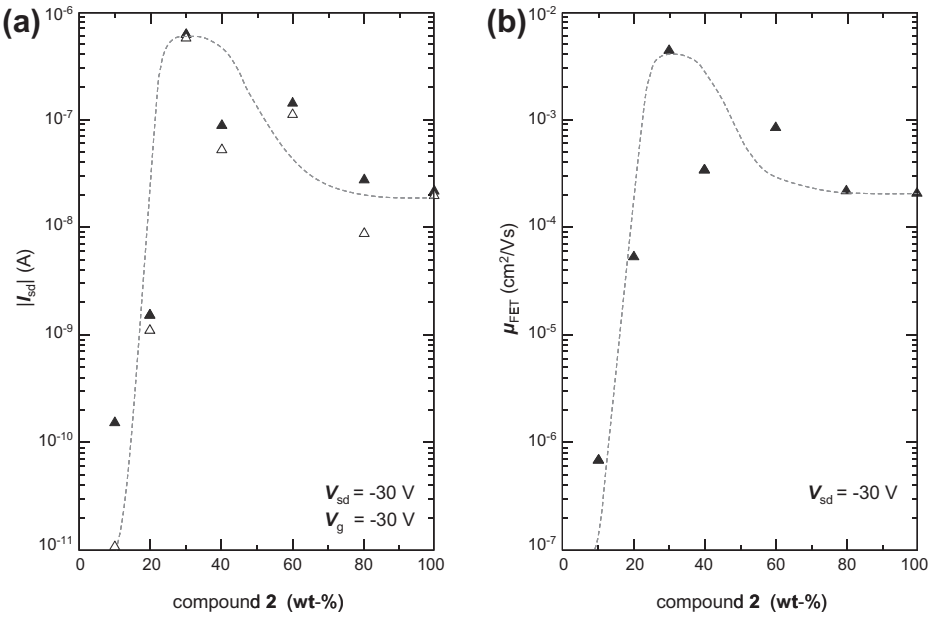

Fig. 4. (a) Source–drain currents, I_{sd}, of **2**:PVDF binaries of different compositions solidified at 50 °C at $V_{sd} = V_g = -30$ V, deduced from OFET transfer (filled symbols) and output characteristics (open symbols). (b) Corresponding field-effect mobilities deduced from the saturated regime in OFET transfer characteristics (dashed lines are a guide to the eye only).

select processing conditions that are adjusted to the phase behavior of the respective system to yield comparable structures of their solid state. Simple binary crystallization temperature/composition diagrams of the individual component in the solvent selected are useful to understand solidification kinetics and to identify a suitable processing window, both with respect of selection of deposition temperatures and solution concentrations.

3.4. Percolation

After having established optimum processing conditions of typical blends of PVDF with both semiconducting compounds **1** and **2**, we proceeded to explore the maximum content of the insulating polymer that could be added without dramatically deteriorating the electronic properties of such blends. For this purpose we concentrated on **2**:PVDF binaries as they allow for a significantly broader processing window both with respect of deposition temperature and composition when compared to the **1**:PVDF system. Thus, OFETs were fabricated with active layers of a range of compositions *via* solvent evaporation at 50 °C.

Remarkably, the electronic performance of the devices was found to *increase* by more than one order of magnitude when certain amounts of PVDF were added to the semiconductor, as indicated by the significantly increased source–drain currents and field-effect mobilities (Fig. 4). Maximum device performance was reached for a blend comprising only ~30 wt.% of the semiconductor **2**; the latter featured ON-currents of $\sim 5 \times 10^{-7}$ A, field-effect mobilities in the saturation regime of $\sim 4 \times 10^{-3}$ cm^2/Vs and ON–OFF ratios of 10^3 compared to corresponding values of, resp. $\sim 2 \times 10^{-8}$ A, $\sim 2 \times 10^{-4}$ cm^2/Vs and 10^2 for the neat compound **2**. Evidently, adding the insulating polymer PVDF to the small-molecular semiconductor enhanced the electronic performance of the latter species. We attribute this beneficial phenomenon to improved film-forming properties of such blends. At high small molecule content ($\geqslant$80 wt.%), film formation is dominated by that species and the amount of polymeric material appears to be insufficient to provide for the generation of continuous and homogenous active layers. As a consequence, the resulting brittle and discontinuous films featured negatively affected charge transport. On the other hand, blends comprising >70 wt.% of the insulating polymer appeared to feature a solid-state structure in which the organic semiconducting compound increasingly failed to form a percolating network required for electronic transport.

4. Conclusions

In summary, we presented blends of two small-molecular arylacetylene derivatives with the semi-crystalline, insulating polymer PVDF that exhibit FET characteristics comparable to those of the neat semiconductors. The chemical design of the two semiconducting compounds was selected in such a way that it allows facile synthesis protocols with readily accessible up-scaling options and permits control of their thermal properties. Beneficially, selection of processing controls was found to be more critical in obtaining optimum device performance than molecular design, which indicates that electronic characteristics can be tailored from the outset while processing parameters can be adjusted according to the phase behavior of the active compound.

In this work, a phosphine oxide based high efficiency green phosphorescent host material was synthesized for optimum charge balance in the emitting layer and it was combined with high efficiency deep blue emitting layer to obtain high quantum efficiency in PHWOLEDs. A high quantum efficiency over 25% was obtained from the green PHOLEDs, and a quantum efficiency of 21.6% and power efficiency of 47.0 lm/W were demonstrated from the PHWOLEDs using the new green host material. The quantum efficiency value achieved in this work is comparable to that the efficiency values reported in green PHOLEDs and WOLEDs without any out-coupling enhancement and p-i-n doping structure [15–17].

2. Experimental

2.1. Synthesis

The synthetic route of the 2,7-bis(diphenylphosphoryl)-3′-phenyl-9,9′-spirobi[fluorene] (BPSBF) is shown in Scheme 1.

2.2. Synthesis of 2-bromo-m-terphenyl (1)

A solution of *o*-bromoiodobenzene (5.14 g, 18.1 mmol), 3-biphenylboronic acid (3 g, 15 mmol), tetrakis(triphenylphosphine)palladium(0) (0.86 g, 0.75 mmol) and THF (30 mL) were stirred in a two-necked flask under nitrogen atmosphere for 30 min. Potassium carbonate (8.29 g, 2 M solution) was added to a reaction mixture dropwise over a period of 20 min. The resulting solution was refluxed overnight at 80 °C. The reaction mixture was extracted with dichloromethane and water, and the organic layer was evaporated with a rotary evaporator. The resulting powdery product was purified by column chromatography from n-hexane to give a white crystalline solid. The 2,7-dibromo-3′-phenyl-9,9′-spirobi[fluorene] (2) was synthesized according to the method that described in previous work [18].

2.3. Synthesis of 2,7-bis(diphenylphosphoryl)-3′-phenyl-9,9′-spirobi[fluorene] (BPSBF)

2,7-Dibromo-3′-phenyl-9,9′-spirobi[fluorene] (2) (1.35 g, 2.43 mmol) was dissolved in 30 mL of anhydrous tetrahydrofuran under argon and cooled to −78 °C and 1.2 eq. of *n*-butyllithium (2.5 M in hexanes, 2.43 mL) was added dropwise to give a bright yellow solution that thickened to a slurry. The stirring was continued for 3 h at −78 °C after which 1.12 mL (6.08 mmol) of chlorodiphenylphosphine was added giving a clear, pale yellow solution. The reaction was stirred for 10 h at room temperature before quenching with 10 mL of degassed methanol. Volatiles were removed under a reduced pressure to give an off-white solid that was digested in methanol, filtered, then digested in water, and filtered. The crude material was purified by column chromatography. The purified compound was reacted with 2 mL of 30% hydrogen peroxide in 10 mL of methylene chloride. The mixture was stirred overnight at room temperature. The organic layer was separated and washed with water and then brine. The extract was evaporated to dryness affording a white solid.

BPSBF Yield 40%. Tg 119 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.78 (d, 2H, J = 7.6 Hz), 7.64–7.29 (m, 28H), 7.03 (t, 1H, J = 7.3 Hz), 6.88–6.81 (m, 2H), 6.58–6.47 (m, 3H), 5.98 (d, 2H, J = 7.0 Hz). ^{13}C-NMR (100 MHz, $CDCl_3$) δ 150.4, 150.3, 146.9, 144.4, 143.2, 141.8, 140.4, 139.2, 133.8, 133.3, 132.9, 131.7, 131.2, 129.9, 129.1, 128.3, 128.1, 127.8, 127.0, 126.3, 121.0, 120.7, 120.3, 66.1. 2.4. General analysis

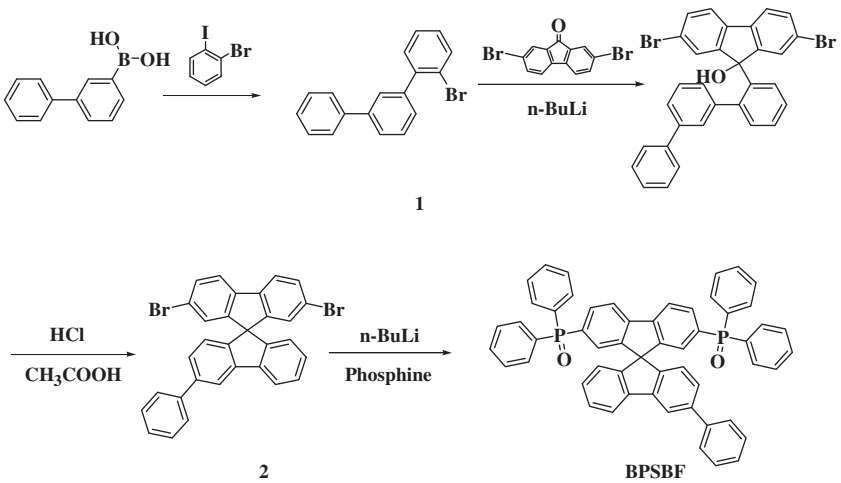
The ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Varian 200 (200 MHz) and 400 (400 MHz) spectrometers. The photoluminescence (PL) spectra were recorded on a fluorescence spectrophotometer (HITACHI, F-7000) and the ultraviolet–visible (UV–Vis) spectra were obtained using UV–vis spectropho-



Scheme 1. Synthetic scheme of BPSBF.

tometer (Shimadzu, UV-2501PC). Samples were dissolved in tetrahydrofuran at a concentration of 1.0×10^{-4} M. The differential scanning calorimetry (DSC) measurements were performed on a Mettler DSC 822 under nitrogen at a heating rate of 10 °C/min. The mass spectrometric analysis was performed using a JEOL, JMS-AX505WA spectrometer in fast atom bombardment mode. Cyclic voltametry measurement of organic materials was carried out in acetonitrile solution with tetrabutylammonium perchlorate at 0.1 M concentration. Ag was used as the reference electrode and Pt was the counter electrode. Organic materials were coated on indium tin oxide substrate and were immersed in electrolyte for analysis. Scan rate was 0.1 mV/s. Elemental analysis of the materials was carried out using EA1110 (CE instrument).

2.5. Device preparation and measurements

The device structure of green PHOLEDs was indium tin oxide (ITO, 150 nm)/*N*,*N*′-diphenyl-*N*,*N*′-bis-[4-(phenyl-*m*-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD)/*N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenylbenzidine (NPB, 5 nm)/*N*,*N*′-dicarbazolyl-3,5-benzene (mCP, 10 nm)/BPSBF:iridium(III) tris(2-phenylpyridine) ($Ir(ppy)_3$) (30 nm, 5% or 10%)/diphenylphosphine oxide-4-(triphenylsilyl)phenyl (TSPO1, 25 nm)/LiF (1 nm)/Al (200 nm). The PHWOLED had a device structure of ITO (150 nm)/poly-(3,4-ethylenedioxythiophene):polystyrenesulfonate (PEDOT:PSS, 60 nm)/NPB (5 nm)/mCP (10 nm)/9-(3-(9H-carbazole-9-yl)-phenyl)-3-(dibromophenylphosphoryl)-9H-carbazole (mCPPO1): bis((3,5-difluoro-4-cyanophenyl)pyridine) iridium picolinate (FCNIrpic) (10 nm, 3%)/BPSBF:$Ir(ppy)_3$: iridium(III) bis(2-phenylquinoline) acetylacetonate ($Ir(pq)_2acac$) (25 nm, 10%:0.7%)/TSPO1 (25 nm)/LiF/Al. A blue PHOLED with the device structure of ITO (150 nm)/PEDOT:PSS (60 nm)/NPB (5 nm)/mCP (10 nm)/mCPPO1:FCNIrpic (30 nm)/TSPO1 (25 nm)/LiF/Al was also fabricated as the standard deice. The device structure is shown in Fig. 1. A green PHOLED and a PHWOLED with mCPPO1 instead of BPSBF as the host material were also fabricated to compare BPSBF and mCPPO1 as the host material for green PHOLEDs. All devices were encapsulated with CaO getter and a glass lid after device fabrication. The device performances of the green and blue PHOLEDs were measured with Keithley 2400 source measurement unit and CS1000 spectroradiometer. The quantum efficiency of the devices was calculated from the device performances of green and white devices.

3. Results and discussion

It was reported in our previous work that high efficiency deep blue PHOLEDs can be fabricated using mCPPO1 as the host material in the emitting layer [14]. Deep blue emitting FCNIrpic was doped into the mCPPO1 and high quantum efficiency over 20% could be achieved. Therefore, the mCPPO1:FCNIrpic emitting layer can be used as the deep blue emitting layer in PHWOLEDs. The mCPPO1 host has the highest occupied molecular orbital (HOMO) of 6.13 eV and the lowest unoccupied molecular orbital (LUMO) of 2.64 eV. However, the mCPPO1 showed poor performances in green PHOLEDs and it cannot be used in PHWOLEDs with multilayer emitting structure. Therefore, a new green triplet host material is required to develop high efficiency PHWOLEDs with deep blue phosphorescent emitters.

A new green phosphorescent host material, BPSBF, was synthesized to develop high efficiency PHWOLEDs. Synthetic scheme of the BPSBF is shown in Scheme 1. The phenyl substituted bromobiphenyl group was prepared as the intermediate compound and the BPSBF was synthesized by ring closing reaction followed by phosphorylation. The BPSBF was designed as the electron transport type host material to fabricate high efficiency green PHOLEDs and stacked emitting layer structure for PHWOLEDs. It has a rigid phenyl substituted spirobifluorene core structure and diphenylphosphine oxide groups for efficient electron transport [19,20]. Therefore, the BPSBF can be stacked on blue phosphorescent emitting layer as the electron transport type green/red emitting layer due to electron transport properties of the BPSBF.

Density functional theory calculation was carried out using a suite of Gaussian 09 program to study the HOMO and LUMO distribution of the BPSBF. The nonlocal density functional of Becke's 3-parameters employing Lee–Yang–Parr functional (B3LYP) with 6-31G* basis sets was used for the calculation. As shown in the molecular orbital distribution of BPSBF in Fig. 2, the HOMO was dispersed over the phenyl group and the fluorene unit without the diphenylphosphine oxide, while the LUMO was distributed over the

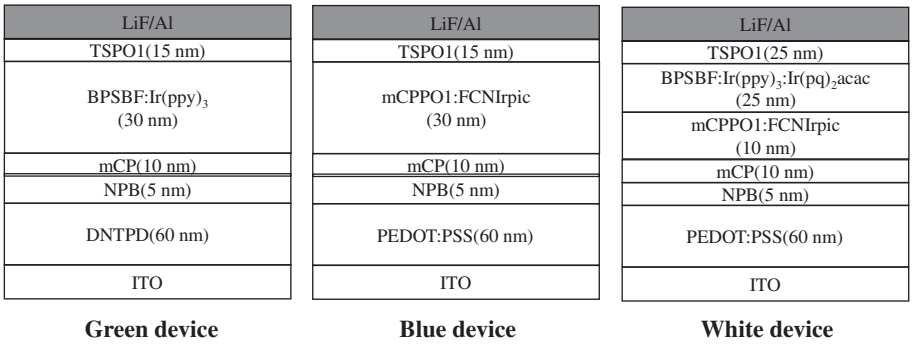


Fig. 1. Device structure of green, blue and white devices.

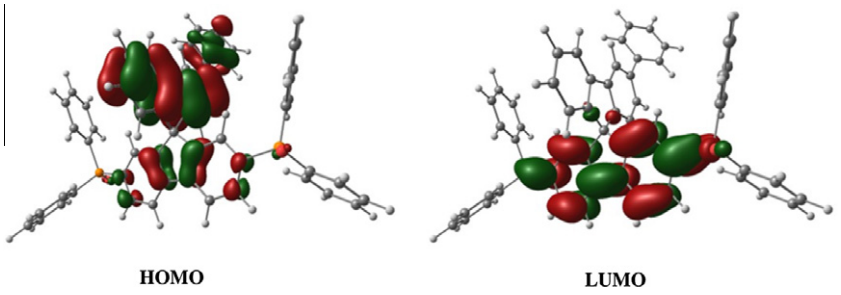

Fig. 2. HOMO and LUMO molecular orbital distribution of BPSBF.

fluorene unit substituted with the diphenylphosphine oxide groups. As the diphenylphosphine oxide unit has strong electron withdrawing properties, the HOMO was localized on the fluorene unit without the diphenylphosphine oxide and the LUMO was localized on the fluorene unit with the diphenylphosphine oxide. Compared with the spirobifluorene host without the phenyl substituent, the BPSBF showed uniform dispersion of the HOMO over the fluorene and phenyl substituent [21].

Photophysical properties of the BPSBF host material were studied using UV–Vis and PL spectra. UV–Vis and PL spectra of BPSBF host material are shown in Fig. 3. The BPSBF showed strong absorption peaks at 295 nm and 327 nm which are assigned to the absorption of the phenyl substituted spirobifluorene core. The bandgap was calculated from the absorption edge of the UV–Vis spectrum and it was 3.66 eV.

The PL emission was also originated from the phenyl substituted spirobifluorene core and it was observed at 356 nm. Low temperature PL spectrum of the BPSBF was also obtained to measure the triplet energy of the BPSBF and the triplet energy was 2.71 eV. The triplet energy of the BPSBF was high enough for energy transfer to green emitting phosphorescent dopant with a triplet energy around 2.40 eV. The triplet emission of the BPSBF was well overlapped with the metal to ligand charge transfer absorption peak of the green emitting $Ir(ppy)_3$ around 450 nm. Therefore, the BPSBF can be effective as the host material for green PHOLEDs. The HOMO energy level of the BPSBF was 6.53 eV from cyclic voltametric measurement and the LUMO level was 2.87 eV from the HOMO and bandgap from the UV–Vis measurement.

Green PHOLEDs with the BPSBF as the host material were fabricated to investigate the performances of BPSBF. Fig. 4 shows the device performances of BPSBF based green PHOLEDs. There was little change of the current density and luminance according to doping concentration. The quantum efficiency of the two devices was also similar irrespective of the doping concentration. The maximum quantum efficiency of the BPSBF green device with 10% doping concentration was 25.3% and the quantum efficiency at 1000 cd/m^2 was 22.0%. Although the efficiency value was not state of the art external quantum efficiency, high efficiency above 20% was obtained [15–17]. The high efficiency of the BPSBF based green PHOLEDs is due to balanced charge injection,

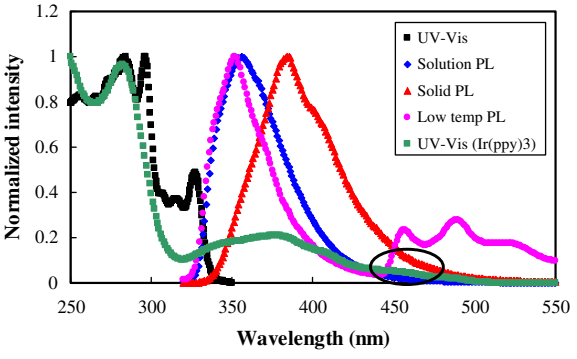

Fig. 3. UV–Vis and PL spectra of BPSBF.

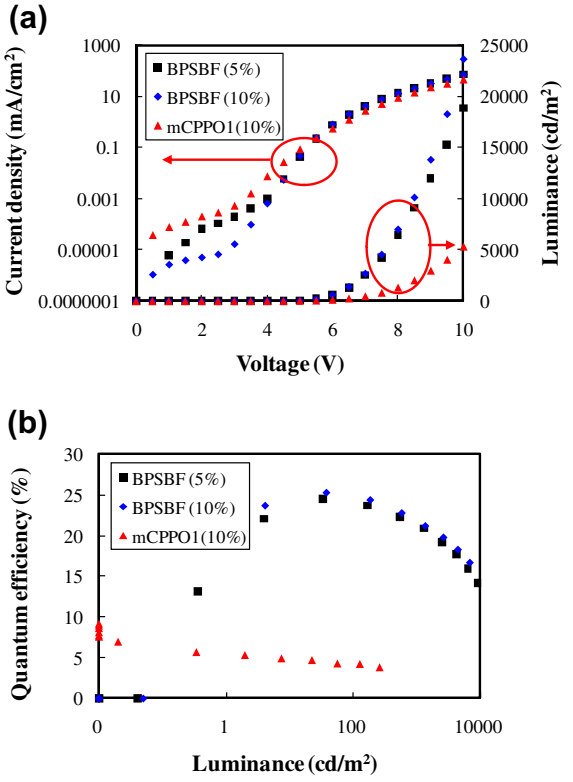

Fig. 4. Current density–voltage–luminance (a) and quantum efficiency–luminance (b) curves of BPSBF based green PHOLEDs.

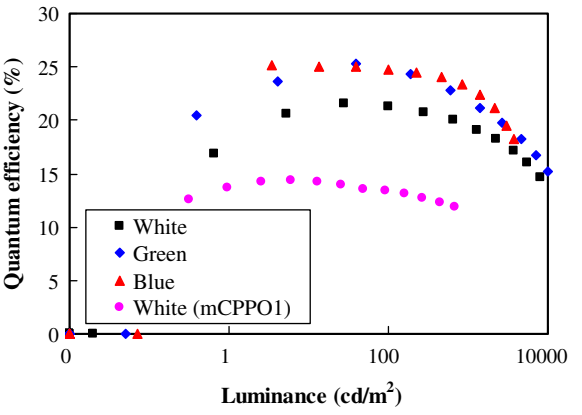

Fig. 7. Quantum efficiency–luminance curves of green, blue and white PHOLEDs.

efficient energy transfer and exciton confinement. Compared with the mCPPO1 host which was reported as the high triplet host for deep blue PHOLEDs, the BPSBF showed much higher quantum efficiency in green PHOLEDs.

As the BPSBF showed high quantum efficiency in green PHOLEDs, it was applied as the host material for PHWOLEDs with stacked blue/red:green emitting layer structure. Deep blue mCPPO1:FCNIrpic emitting layer was used to cover wide spectrum range and red/green BPSBF:Ir(ppy)$_3$:Ir(pq)$_2$acac emitting layer was stacked on the deep blue emitting layer. Fig. 5 shows the device performances of the PHWOLEDs with the deep blue emitting layer combined with BPSBF based red/green emitting layer. Blue device performances were also added for comparison. The current density and luminance of the PHWOLEDs were a little higher than those of the blue PHOLED, which is due to efficient electron injection though the BPSBF red/green emitting layer. The electron injection from TSPO1 electron transport layer to the BPSBF emitting layer is better than electron injection from TSPO1 layer to the mCPPO1 emitting layer, resulting in high current density and luminance in the PHWOLEDs. Energy level diagram of the PHWOLEDs is shown in Fig. 6. The current density and luminance of the PHWOLEDs with mCPPO1 as the host for red:green emitting layer were much lower than those of the PHWOLEDs with BPSBF as the host for red:green emitting layer.

Quantum efficiency–luminance curve of PHWOLEDs is shown in Fig. 7. Although the quantum efficiency of the PHWOLEDs was a little reduced compared with that of the blue or green PHWOLEDs, the PHWOLEDs showed high

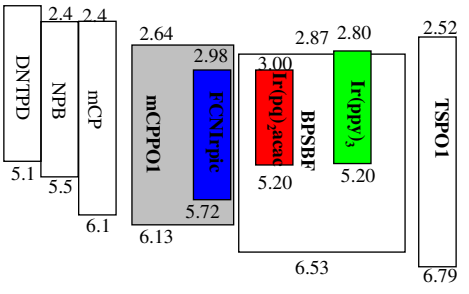

Fig. 6. Energy level diagram of white PHOLEDs.

quantum efficiency over 20%. The maximum quantum efficiency of the PHWOLEDs was 21.6% and the quantum efficiency at 1000 cd/m^2 was 19.6%. High quantum efficiency above 20% was obtained in PHWOLEDs without any tandem or outcoupling device structure [5]. In particular, this device showed much higher quantum efficiency than other WOLEDs with deep blue emitting material [3]. The high quantum efficiency of the PHWOLEDs with the mCPPO1:FCNIrpic and BPSBF:Ir(ppy)$_3$:Ir(pq)$_2$acac is due to high quantum efficiency of each emitting layer and device architecture for charge balance. The BPSBF based green PHOLED showed high quantum efficiency when mCP and TSPO1 were used as the hole transport layer and electron transport layer, respectively. In the PHWOLEDs, holes are injected from the mCPPO1 layer to the BPSBF layer, while electrons are injected from TSPO1 layer to the BPSBF layer. The mCPPO1 has similar HOMO level to mCP and hole density in the BPSBF emitting layer can be maintained similarly although it can be slightly decreased because of rather weak hole transport properties of mCPPO1 and hole trapping by FCNIrpic. In the case of the mCPPO1 emitting layer, the hole injection structure was not changed in the PHWOLEDs, while electron injection structure was changed. The BPSBF is better than TSPO1 in terms of electron injection due to two diphenylphosphine oxide groups. However, electrons are trapped by the red and green dopants, which do not increase the electron density in the mCPPO1 emitting layer. Therefore, the hole and electron density in each emitting layer is not greatly changed, resulting in charge balance in the whole emitting layer. In the case of the PHWOLEDs with mCPPO1 as the host for red:green emitting layer, the quantum efficiency was low due to low quantum efficiency in red:green emitting layer.

Power efficiency–luminance data of the PHWOLED are shown in Fig. 8. The maximum power efficiency of the PHWOLED was 47.0 lm/W and the power efficiency at 1000 cd/m^2 was 26.1 lm/W. Although no p type or n type doped charge transport layer was adopted in the device structure, high power efficiency was achieved because of high quantum efficiency of the PHWOLED. The maximum power efficiency of the green PHOLED could reach 59.0 lm/W. However, the power efficiency of the PHWOLEDs with the

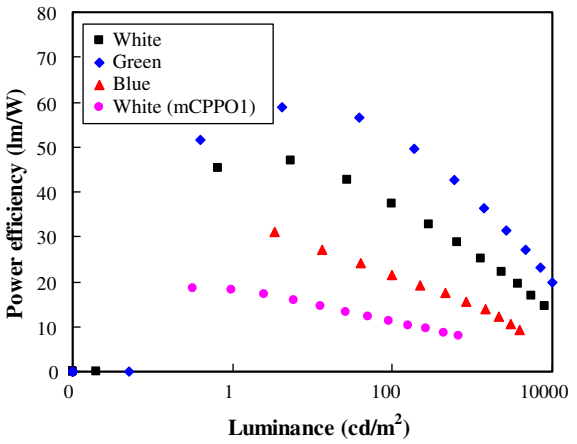

Fig. 8. Power efficiency–luminance curves of green, blue and white PHOLEDs.

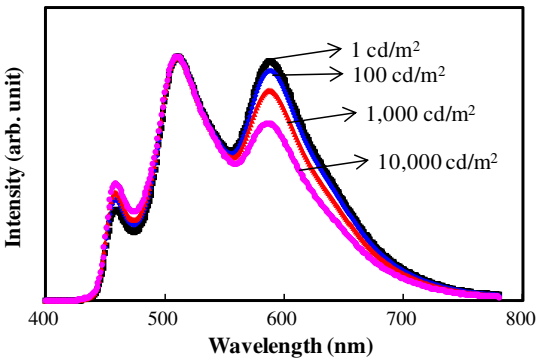

Fig. 9. Electroluminescence spectra of PHWOLED with BPSBF host.

mCPPO1 as the host for red:green emitting layer was low due to high driving voltage and low quantum efficiency.

Electroluminescence (EL) spectra of the PHWOLEDs are shown in Fig. 9. The PHWOLED covered wide spectral range from 440 nm to 750 nm. As the deep blue emitting FCNIrpic was used in the PHWOLEDs, deep blue emission with a peak maximum at 458 nm was observed in addition to green and red emission. Although green emission was a little stronger than red and blue emission, warm white spectrum for lighting application could be obtained. The color coordinate of the PHWOLED was (0.38,0.46) at 1000 cd/m^2. The change of the EL spectra according to the luminance is also shown in Fig. 9. The red emission was weakened at high luminance and the color coordinate was changed from (0.39,0.46) at 100 cd/m^2 to (0.35,0.46) at 10,000 cd/m^2. The color rendering index of the PHWOLEDs at 1000 cd/m^2 was 74.

4. Conclusions

In conclusion, high efficiency green and white PHOLEDs could be effectively fabricated using electron transport type BPSBF host materials. Above 20% quantum efficiency was achieved both in green and white PHOLEDs and the BPSBF type materials can be useful in future applications as the host for green and white PHOLEDs. Further study for the derivatives of BPSBF will follow for application as the host for PHWOLEDs.

Fluorescent microscopy is conventionally used to detect Zn^{2+} with the help of fluorescent indicators since techniques such as nuclear magnetic resonance and electron paramagnetic resonance spectroscopy cannot be utilized to detect spectroscopically silent Zn^{2+} with a closed-shell $4s^2 3d^{10}$ electronic configuration [14]. The fluorescence of Zn^{2+} indicators can be varied upon Zn^{2+} binding. Although the fluorescent microscope is suitable for fundamental research, however, it cannot be used to monitor Zn^{2+} in the human body. Besides, a fluorescent indicator has to be used before the examination, and the indicator might influence cell functions. A small-sized semiconductor optoelectronic device is therefore needed for a real-time and indicator-free detection of Zn^{2+} in liquid environment.

Using organic optoelectronic devices as components of sensors has been demonstrated to be a way to reduce the size of sensors [15–19]. Organic photodiodes (PDs) were used as optical detectors to monitor chemiluminescence reactions in microfludic systems [16,17]. Integrated sensors, utilizing a microfluidic system, an organic light-emitting diode (OLED), an organic PD, and two polarizers, were also demonstrated in a front detection geometry [18,19]. The microfluidic system was sandwiched between the OLED and the organic PD. The polarizers were utilized to suppress the excitation light at the detector. However, the integrated sensors in a front detection geometry are less compact than the one in a back detection geometry. Recently, real-time and indicator-free detection of oxygen and glucose has been demonstrated by an integrated sensor in a back detection geometry, composing of an OLED, a PD, filters, and a sensing unit as shown in Fig. 1(a) [15]. The sensing unit is a film made of a host polymer and a fluorescent indicator for certain analyte. The OLED is used to excite the sensing unit, and the PD is used to detect the photoluminescence (PL) of the sensing unit. However, there is no such sensing unit specific to Zn^{2+} and hence the integrated semiconductor device for a real-time and indicator-free detection of Zn^{2+} is still lacking.

In this work, a Zn^{2+} sensing film is developed by incorporating a fluorescent Zn^{2+} indicator 11,16-bis(phenyl)-6,6,21,21-tetramethyl-*m*-benzi-6,21-porphodimethene (BPDM-H) into a hydrogel host polymer poly(2-hydroxyethyl methacrylate) (pHEMA). The water permeable nature of pHEMA enables Zn^{2+} in liquid environment to diffuse into interior of the sensing film and react with BPDM-H. The surface area of the sensing film is increased by fabricating a micron-sized pillar array on the surface. The sensing film shows high stability, sensitivity and selectivity to Zn^{2+}. The response time is 30 s for 10^{-4} M Zn^{2+} concentrations and 3 s for 10^{-3} M Zn^{2+} concentrations. This sensing film is able to be used as the sensing unit in the integrated semiconductor optoelectronic devices for Zn^{2+} sensing.

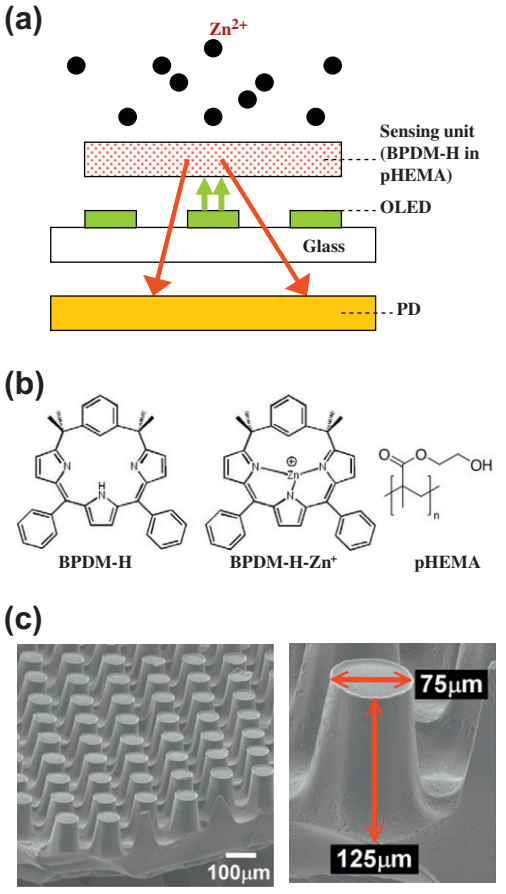

Fig. 1. (a) Schematic structure of an integrated semiconductor optoelectronic device with a sensing unit for detecting analyte, an organic light-emitting diode for excitation, and a photodiode for recording signal from the sensing unit. The sensing film is composed of BPDM-H and pHEMA. (b) Molecular structures of BPDM-H, BPDM-H–Zn^+, and pHEMA. (c) Scanning electron microscope images of the sensing film with a micron-sized pillar array on the surface.

2. Experimental

The Zn^{2+} sensing film is prepared from a mixture of BPDM-H, 2-hydroxyethyl methacrylate (HEMA), ethylene glycol dimethacrylate (EGDMA), and azobisisobutyronitrile (AIBN). BPDM-H is synthesized through an acid catalyzed condensation reaction at room temperature [20]. pHEMA with a three-dimensional network is synthesized by utilizing HEMA as a hydrophilic monomer, EGDMA as a hydrophobic cross-linker, and AIBN as a thermal initiator. The chemical structures of BPDM-H and pHEMA are shown in Fig. 1(b). HEMA is blended with EGDMA in the weight ratio 12:1, and then AIBN (1%) and BPDM-H (0.08%) are added. The sensing film of 180 μm with planar surface is prepared by pouring the blending solution into a cell and annealing at 80 °C for 10 min. As for the sensing film with a high surface area, a micron-sized pillar array on the surface is molded from a polydimethylsiloxan (PDMS) master which is replicated from a microfabricated SU-8 2100 (Shipley) film. To prepare the microfabricated SU-8 2100 film, the SU-8 2100 is spin coated on the glass substrate, and ultra-violet light (365 nm) is employed for exposure from the glass side with a mask [21]. After development, a patterned SU-8 structure with a pillar array is obtained. A layer of Ti(100 nm)/Au(100 nm) is then sputtered on the surface of a patterned SU-8 as an anti-adhesion layer. PDMS prepared in a 10:1 weight ratio of a silicone elasto-

mer with a curing agent (Dow Corning) is poured on the patterned SU-8 and baked at 65 °C for 1 h. The cured PDMS is peeled off and pressed on a mixture of BPDM-H, HEMA, EGDMA, and AIBN in a cell. After annealing at 80 °C for 10 min and demolding, the pattern on SU-8 is transferred to the surface of the sensing film, and the sensing film with a micron-sized pillar array on the surface is obtained as shown in Fig. 1(c). The PL spectra of the sensing film are monitored by a Hitachi F-4500 fluorescence spectrophotometer. Solutions of metal ions are prepared from $Zn(CH_3COO)_2$, $CaCl_2$, NaCl, $MnCl_2$, $CoCl_2$, and $MgCl_2$. The real-time detection of Zn^{2+} is carried out with a PDMS microfluidic channel with a sensing film inside the channel as shown in the inset of Fig. 4(a). A 635 nm laser is used for excitation and a fiber optic spectrometer (EPP2000, StellarNet) is used for monitoring PL with time.

3. Results and discussions

The fluorescent Zn^{2+} indicator BPDM-H in methanol has a broad absorption from 450 to 580 nm and a low background emission from 600 to 800 nm as shown in Fig. 2(a). After adding Zn^{2+} to the BPDM-H solution, the zinc(II) 11,16-bis(phenyl)-6,6,21,21-tetramethyl-*m*-benzi-6,21-porphodimethene cation complex (BPDM-H–Zn^+) is formed with a maximum chelation-enhanced fluorescence at 670 nm [16]. The chemical structures of BPDM-H–Zn^+ is shown in Fig. 1(b). As for the sensing film composed of BPDM-H and pHEMA, PL changes similar to the one of the BPDM-H solution in the presence of Zn^{2+}. Fig. 2(b) shows the PL spectra of the sensing film before and after introducing Zn^{2+}. Even if BPDM-H is trapped in pHEMA, BPDM-H functions still well and the formation of BPDM-H–Zn^+ after the addition of Zn^{2+} is not influenced. The sensing film is initially stabilized in water overnight without an apparent PL feature. BPDM-H could not be measured in water which means that BPDM-H is tightly trapped inside pHEMA without a detectable leakage. When Zn^{2+} is added, PL increases with time. The increase in PL stops once the sensing film is resettled in water without Zn^{2+}.

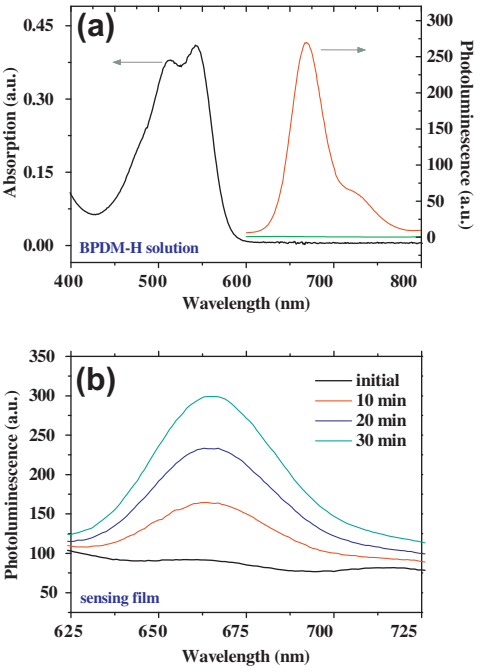

Fig. 2. (a) Absorption (black line) and PL spectra of BPDM-H in methanol. BPDM-H does not fluorescent itself (green line) until binding to Zn^{2+} (red line). (b) PL spectra of the sensing film before and after Zn^{2+} addition. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Since selectivity is an essential characteristic of a sensing film to be utilized in a biological system, physiologically important metal ions are used to investigate the selectivity of the sensing film. Fig. 3 shows the PL spectra of the planar sensing films treated with aqueous solutions of various metal ions (5×10^{-3} M) for 30 min. The sensing film is also treated by solutions with different pH values to understand its stability, and it is observed that the PL spectrum of the sensing film will not change from pH 5 to pH 7. Since the pH values of the various metal ion solutions are in the range from pH 5.5 to pH 6.5, the change in PL will not be caused by the pH values of the various metal ion solutions but by the metal ions in the solutions. The largest PL is observed in the presence of Zn^{2+} as shown in Fig. 3. Other ions do not induce remarkable increase in PL. The sensing film is very specific to Zn^{2+}, and such high selectivity of the sensing film makes it a reliable component to be used as the sensing unit of the integrated semiconductor optoelectronic devices.

The real-time detection ability of the sensing film is then investigated. The microfluidic channel is utilized to produce Zn^{2+} pulses, and PL at 670 nm is recorded with time. Hanks' balanced salt solution (HBSS) is used here since it is an important buffer maintaining osmotic balance and pH. The response time of the sensing film is defined as the time needed for PL larger than the noise level. As shown in Fig. 4(a), the PL intensity of the planar sensing film is initially stable in HBSS. When 10^{-4} M Zn^{2+} solution is injected into the microfluidic channel, PL is increased immediately and continually. The increase in PL is ceased after injecting HBSS into the microfluidic channel to replace Zn^{2+} solution. PL increases again when the channel is refilled with 10^{-3} M Zn^{2+} solution. PL increases faster for the sensing film in 10^{-3} M Zn^{2+} solution than in

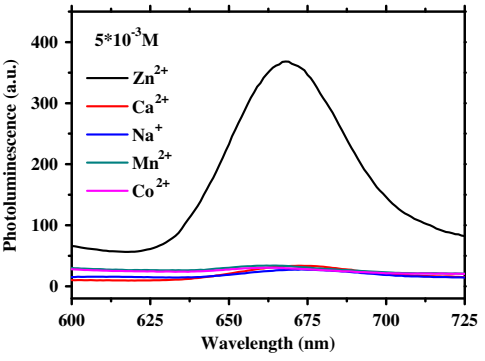

Fig. 3. The PL spectra of the sensing film submerged in a solution of various metal ions for 30 min.

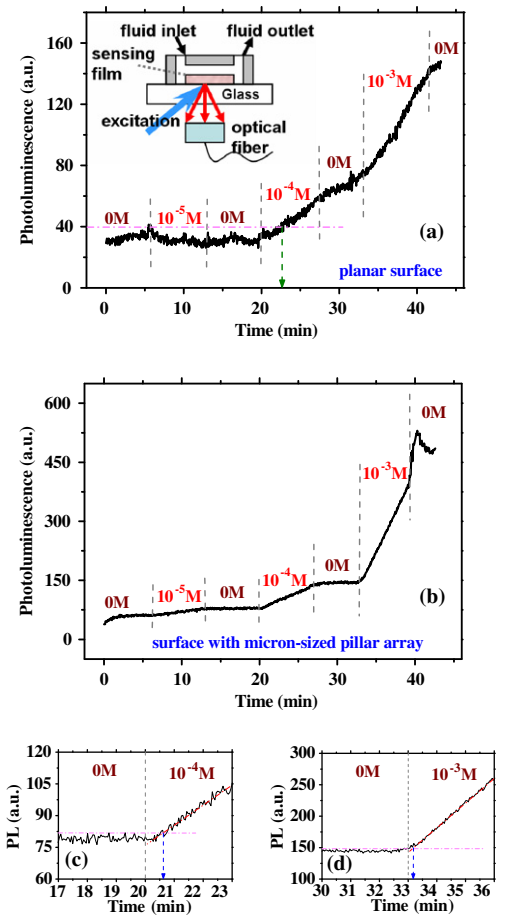

Fig. 4. PL variation with time of (a) the planar sensing film and (b) the sensing film with a micron-sized pillar array. Different Zn^{2+} concentration is injected at different time. The inset in (a) shows the experimental setup. The PL response of the sensing film with a micron-sized pillar array while (c) 10^{-4} M and (d) 10^{-3} M Zn^{2+} are injected.

10^{-4} M Zn^{2+} solution. The slope of the PL–time curve can therefore be used to identify Zn^{2+} concentration. The response time is 3 min for the Zn^{2+} concentration of 10^{-4} M for the planar sensing film. The long response time and low sensitivity of the planar sensing film make the sensor consume more time to give an accurate readout. To improve the response time of the sensing film, the surface area of the sensing film is increased by fabricating a micron-sized pillar array on the surface. The real-time detection characteristics of the sensing film with a micron-sized pillar array on the surface is shown in Fig. 4(b). In the presence of Zn^{2+}, the PL increment of the sensing film with a micron-sized pillar array is larger than that of the planar sensing film. As indicated in Fig. 4(c) and in Fig. 4(d), the response time is 30 and 3 s as Zn^{2+} concentration is 10^{-4} and 10^{-3} M, respectively. Increasing the surface area of the sensing film increases sensitivity. Fast response Zn^{2+} sensing film is realized.

4. Conclusion

In summary, a hydrogel sensing film with a micron-sized pillar array on the surface is realized for a real-time and indicator-free detection of Zn^{2+}. This sensing film shows high selectivity, sensitivity, as well as stability. A response time of 3 s is obtained while Zn^{2+} concentration is 10^{-3} M. The hydrogel sensing film is able to be used as the sensing unit in a solid-state Zn^{2+} biosensor.

Radiation sensors are an emerging application for semiconducting polymers [16]. The use of polymers – in the place of conventional inorganic semiconductors – opens up the possibility for large-area fabrication of sensors using low-cost, wet processing techniques, such as spin-casting, spray-casting, ink-jet or roll-to-roll printing [17]. Radiation sensors made from polymers exhibit greater mechanical flexibility in comparison to inorganic solids [5]. Furthermore, the elemental composition of most polymers (C, H, N and O) makes them an ideal candidate for dosimeters in medical applications, in which the detector requires a "human tissue-equivalent" interaction with radiation. (The average atomic number of muscle tissue is 7.4 [18].) Although radiotherapy and medical applications would benefit greatly from the improved accuracy of tissue-equivalent dosimeters, there are currently no low-cost, large-area devices with tissue-equivalence available.

Here, we present the first-ever measured charge transport properties of PTAA:TIPS-pentacene blends using a time-of-flight (TOF) photocurrent measurement technique. We correlate the raised mobility of the device with a four-fold increase in the X-ray detection sensitivity. Our results point to benefits in using TIPS-pentacene/polymer blends in applications that require high charge transport, such as light-emitting diodes, solar cells, and light sensors, to raise their performance to a higher level.

2. Materials and methods

The sensors employ layers (*ca.* 10 μm thick) of the polymer/molecule blend in a diode geometry. The details of the device preparation can be found elsewhere [19,20]. Briefly, slides of ITO-coated glass (Delta Technology Ltd., USA (CB-60IN)) were cleaned with acetone and deionised water. A 3 wt.% solution of PTAA (with an average molecular weight of 31 kg/mol) was prepared in toluene (99.99% purity, Sigma–Aldrich). Various concentrations TIPS pentacene (Sigma–Aldrich) were then added to the solution. It was homogenized for 10 min by stirring. Five different solutions were made: pure PTAA and PTAA blended with TIPS-pentacene with PTAA:TIPS molar ratios of 1:1, 1:10, 1:17 and 1:25. The solutions were spin-cast at 50 rpm for 30 s onto a clean substrate to provide a single layer of polymer. The films were dried under atmospheric conditions. Vacuum annealing was then performed at 100 °C for 12 h at pressure of 10^{-3} mbar, ensuring the temperature was kept below the solid-to-solid phase transition temperature of TIPS-pentacene at 124 °C [21]. Then, the thickness and average surface roughness of the active layer was measured using profilometry (Dektak Veeco). The device fabrication was completed by thermal evaporation of thin aluminum contacts on top of the active layer to create a Schottky contact.

A Leica DM 2500P microscope was employed to take polarized optical images. For energy dispersive X-ray analysis, an electron beam (Hitachi S-3200N electron microscope) with accelerating voltage of 20 kV and an X-ray detector (silicon drift detector, Oxford Instruments) was used.

For TOF measurements, an Al contact thickness of 50 nm and area of 9.6 mm^2 was deposited by thermal evaporation. The sample was held in a vacuum-tight steel box and was illuminated through the semi-transparent Al electrode. The 10 ns, 355 nm pulse of a Nd:YAG laser (Surelite Lasers, Continuum) was chosen to induce the optical excitation of the charge carriers. The intensity of the laser was attenuated by a neutral density filter in order to minimize the space-charge effect. To limit charge injection, the device was operated under a reverse bias by applying a negative voltage to the ITO electrode through a blocking resistor (10 kΩ). The resulting photocurrent pulses were recorded using a digital oscilloscope with a 50 Ω input terminal (Tektronix TDS 3032). Signal averaging and dark current subtraction were carried out to improve the quality of the data. The TOF experiments were performed in the dark, at room temperature, and under vacuum (3×10^{-1} mbar).

For X-ray photocurrent measurements, Al top contacts with a thickness of 100 nm and an area of 25 mm^2 were deposited via thermal evaporation. To prevent oxidation, the sensors were dip-coated in molten paraffin wax to create a barrier coating. The sensors were irradiated by 17.5 keV Kα X-rays from a molybdenum target X-ray tube (XF50 11, Oxford instruments, UK). While operating in a reverse bias, the sensor was exposed to the X-ray beam through the metal top electrode. The induced photocurrent was then measured using a voltage source-picoammeter (487, Keithley Instruments, UK). The dark current was subtracted from the measured X-ray photocurrent in order to provide a corrected value of the photocurrent. During exposure, the sensors were mounted in a steel box, in the dark and at room temperature, 10 cm from the X-ray source. Sensor sensitivity was calculated from the slope of a graph of X-ray photocurrent against dose rate and dividing by the active volume under the contact (see Supplementary data, Fig. 1A and B) [5].

3. Results and discussion

Fig. 1A–C show images obtained from polarized optical microscopy of films of PTAA blended with various concentrations of TIPS-pentacene. There is obvious crystallization of the TIPS-pentacene (confirmed separately via X-ray diffraction). The images reveal a needle-like crystal structure in which the crystal size increases with an increasing amount of TIPS-pentacene. The long-axis of the crystals lies in the plane of the film. Analysis of the Si distribution in the blend film using energy dispersive X-ray analysis in a mapping mode (not shown here) has revealed that crystals are uniformly distributed throughout the depth of the film. The average surface roughness of the films increases from 0.28 μm in a pure PTAA film to 5.3 μm for a film of PTAA blended with TIPS-pentacene in a 1:17 molar ratio. This roughening, which is also apparent in optical microscopy, is attributed to faceting from the TIPS-pentacene crystal formation.

Typical room-temperature transient hole TOF photocurrent measurements at two different applied voltages are presented in Fig. 2A for a device whose active layer consists of PTAA blended with TIPS-pentacene in a 1:17 molar ratio. Analysis over a range of applied voltages found an increase in the total collected charge (*i.e.* the area under the

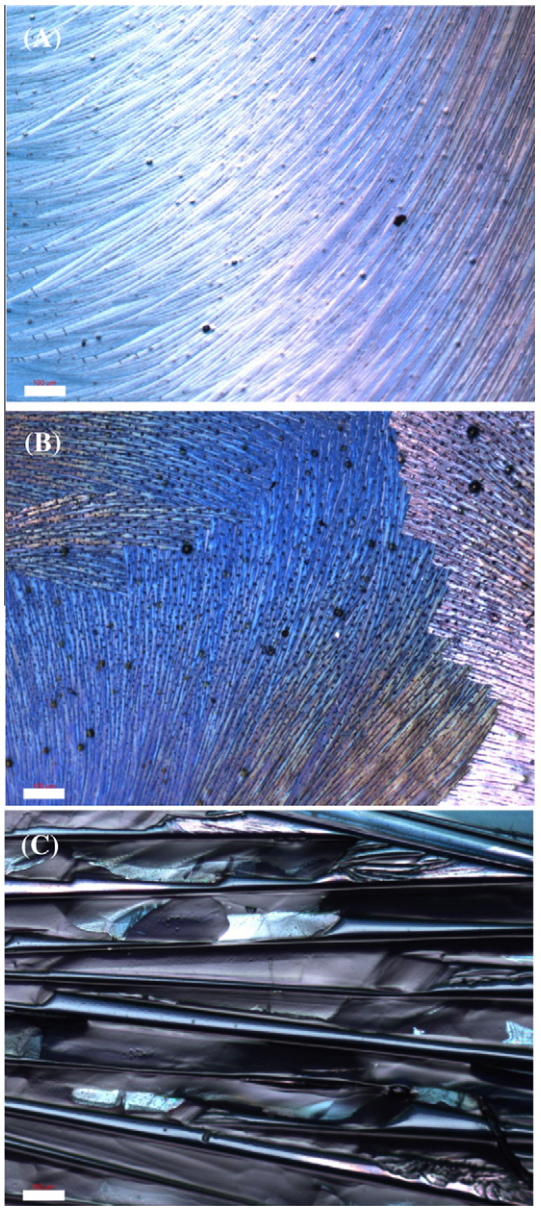

Fig. 1. Polarized optical images of PTAA blended with TIPS-pentacene in molar ratios of (A) 1:1, (B) 1:10 and (C) 1:17. The long axis of the crystals lies in the plane of the film. Scale bar is 100 μm.

transient curves) with an increase in the applied voltage. This observation is attributed to the field dependence of the carrier drift length, as has been found elsewhere [7,22]. The transient photocurrents in our devices exhibit some dispersive behavior, which is commonly observed in polymer-based systems [7,8,22–24]. An effective lifetime (τ) was found on a double logarithmic plot as the intersection of asymptotes to the plateau and the linear region of transient's trailing edge [25,26], as is shown in the inset of Fig. 2A. It is apparent in Fig. 2B that the reciprocal of the effective lifetime ($1/\tau$ depends linearly on the applied voltage (V) for all samples. The transit time for charge-carrier transport, τ_{tr}, is expected to be proportional to the applied field strength, E. Hence, the inverse linear trends in Fig. 2B are consistent with dispersive transport. However, in the limit of E approaching 0, then $1/\tau_{tr}$ is expected to approach 0. The data in Fig. 2B do not extrapolate through the origin, and hence there is evidence for lifetime-limited transport.

For films of film thickness, d, the charge carrier mobility, μ, can be calculated by

$$\mu = \frac{d^2}{\tau_{tr} V}. \quad (1)$$

In our system, there is a convolution of the effects of transit-limited and lifetime-limited transport in our measurements of τ, such that

$$\frac{1}{\tau} = \frac{1}{\tau_{lt}} + \frac{1}{\tau_{tr}}, \quad (2)$$

where τ_{lt} is the lifetime of the charge carrier and is independent of E. The intercept of the y-axis obtained from the best fit to the data in Fig. 2B will therefore provide an estimate of τ_{lt}. For the PTAA, τ_{lt} is approximately 1.7 ms. For the blend materials, there is some variation in τ_{lt}, but their average value is 460 μs. The $1/\tau_{lt}$ contribution to τ can be subtracted to provide τ_{tr}, and the gradient of the linear best-fit to the data in Fig. 2B provides μ via Eq. (1). The fact that the data fall on a linear trend over field strengths ranging from 3×10^4 to 4×10^5 V cm^{-1} indicates that there is not a strong field dependence of μ.

Ideally, the thickness, d, of a TOF sample should be in the range from 1 to 5 μm [27,28]. For the pure PTAA film and the blend film with a PTAA:TIPS-pentacene molar ratio of 1:1, d is 3 and 4 μm, respectively. However, a short circuit developed with the higher concentrations of TIPS-pentacene in thin devices, because of the high conductivity of the TIPS-pentacene and possible film imperfections. Therefore, in order to avoid this problem, thicker films were used in the TOF experiments for the 1:10, 1:17 and 1:25 samples (8, 12 and 12 μm, respectively). Furthermore, according to profilometry analysis, there is a large variation of the thickness in the 1:10, 1:17 and 1:25 sample because of the crystallization of the TIPS-pentacene leading to a range of crystal sizes, especially in the 1:17 and 1:25 samples. Hence, it should be noted that these are only average thicknesses.

Fig. 3 shows the increasing trend in the mobility with increasing TIPS-pentacene concentration. The field-averaged mobility in the 1:25 sample is 2.2×10^{-5} cm^2 V^{-1} s^{-1}, which is about 17 times higher compared to the value of 1.3×10^{-6} cm^2 V^{-1} s^{-1} in the PTAA device. The mobilities for the other three blends are consistently higher than that of the pure PTAA but lower than that of the 1:25 of PTAA:-TIPS-pentacene device.

To our knowledge, there has never been a report on the mobility measurement of TIPS-pentacene using the TOF technique. The reference mobility values for TIPS-pentacene have been obtained from measurements of field -effect transistor (FET) structures, which provide a different mobility value compared to TOF measurements because of the different charge carrier densities in the two types of device. It has been shown elsewhere that the

charge carrier density greatly affects the mobility [29]. The charge-carrier density is higher in a transistor configuration compared to a diode, and hence, in some materials, the measured mobilities are also higher. For instance, in P3HT, the hole mobility is found to be in the range of 0.1–0.3 cm^2 V^{-1} s^{-1} in a transistor [30,31] but only 10^{-4} cm^2 V^{-1} s^{-1} in a diode structure [9,28].

Moreover, in FET measurements charge transport is in the plane of the film, whereas it is "out of plane" for TOF measurements. The TIPS crystals are aligned in the plane of the film, and charge transport is measured in the TOF experiment in a direction normal to the crystal orientation. Therefore, field-effect mobility of TIPS-pentacene cannot be used as a reference value for measurements in a diode structure, as in solar cells or sensors. Hamilton et al. have reported the field-effect mobility value in the linear regime of about 0.7 cm^2 V^{-1} s^{-1} (1.1 cm^2 V^{-1} s^{-1} in the saturation regime) for the 1:1 by weight (1:50 molar ratio) of the PTAA:TIPS-pentacene blend system [15]. Based on their argument, the mobility of the blend system in the diode configuration is expected to be three orders of magnitude lower than in the field-effect structure or about 7×10^{-4} cm^2 V^{-1} s^{-1}. This number is about 30 times greater than the field-averaged mobility value found in our 1:25 PTAA:TIPS-pentacene device: 2.2×10^{-5} cm^2 V^{-1} s^{-1}.

Charge transport in conjugated polymer systems occurs through the hopping of charge carriers from one site to another. Barard et al. [22] have employed the correlated disorder model [32,33] to analyze the time-of-flight mobility data of a PTAA-based device. The effect of the positional disorder was found to be greater than the energetic disorder at room temperature and the mobility showed a weak negative field dependence. A large amount of positional disorder in our device could come from the microstructure of the PTAA:TIPS-pentacene blend film. In the optical images (Fig. 1), it is apparent that TIPS-pentacene is crystallized and forms ordered regions when the film is left to dry at room temperature. The ordered TIPS-pentacene crystals are embedded in the PTAA amorphous phase, creating a large PTAA/TIPS-pentacene interface. Due to better electronic coupling, the mobility in the TIPS-pentacene crystals is significantly higher than in the amorphous PTAA phase.

It is apparent in Fig. 3 that the introduction of TIPS-pentacene into PTAA has clearly resulted in an increase in the mobility of the device. At higher TIPS-pentacene concentrations, the mobility increases sharply. An increase in the mobility with increasing TIPS-pentacene concentration is expected from a shift of charge transport domination from PTAA to TIPS-pentacene, when the latter phase occupies a greater volume fraction. If the densities of the two phases are approximated as being equal, then weight fraction will equal the volume fraction. It can be estimated that the 1:25 composition will have a crystal volume fraction of 35%, which is 17 times higher than that of the 1:1 composition. The 1:25 system consists of a high fraction of polycrystalline TIPS-pentacene. Each TIPS-pentacene molecule in a crystal is strongly electronically coupled to its neighboring molecules, providing a faster route for charge carriers. The mobility of PTAA is negligible in comparison to that of a network of connected TIPS-pentacene crystals.

The question now arises as to how an increase in mobility in the blend will translate into device performance. Fig. 4A demonstrates the d.c. dark current–voltage characteristics for the PTAA-based diodes containing increasing

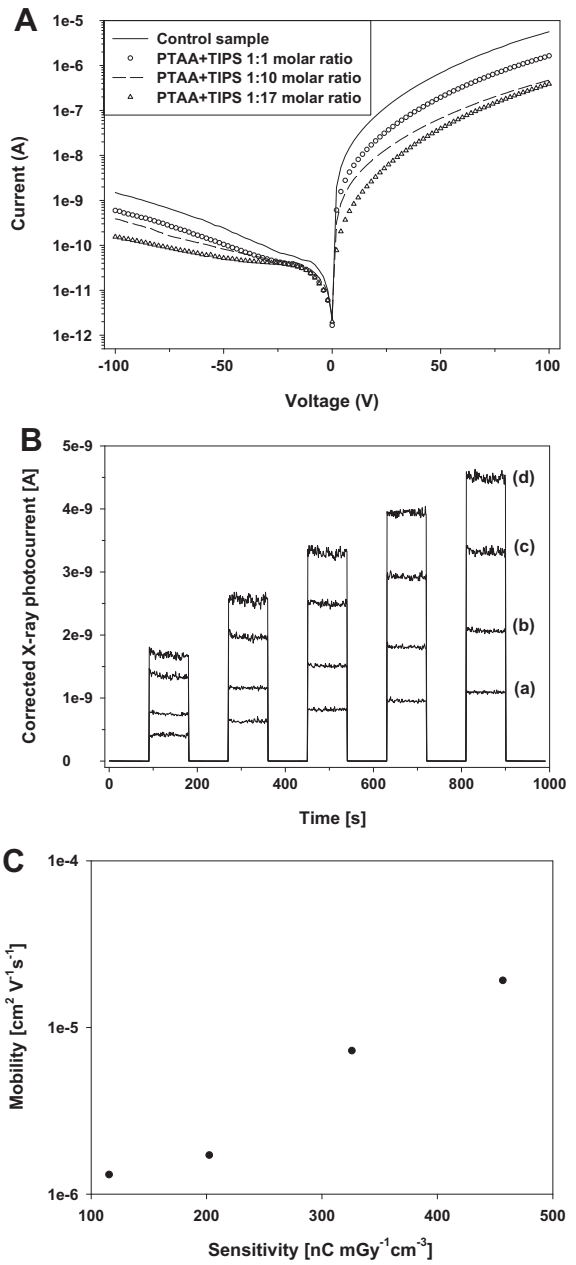

Fig. 4. (A) Semi-log current–voltage characteristics for the ITO/PTAA-based active layer/Al diodes when active layers are pure PTAA (solid line), PTAA blended with TIPS-pentacene of 1:1(○), 1:10 (dashed line), and 1:17 (Δ) by molar ratio. (B) Dynamic X-ray photocurrent for the ITO/PTAA-based/Al sensors with an active layer (10 μm thick) of (a) pure PTAA, and PTAA blended with TIPS-pentacene of in molar ratios of (b) 1:1, (c) 1:10, and (d) 1:17, when operated at 40 V. The devices were irradiated by 17.5 keV X-rays through an Al top contact with increasing dose rate from left to right: 13, 27, 40, 54 and 66 mGy s^{-1}. (C) Positive correlation between the X-ray sensitivity of the sensors and the charge-carrier mobility of their active material (PTAA or PTAA/TIPS-pentacene blend).

concentrations of TIPS-pentacene. According to surface profilometry, the thickness of the active layer for every sample is approximately 10 μm. Voltages ranging from −100 to 100 V were applied through the ITO back electrode. For the ITO/pristine PTAA/Al diode, the *I–V* curve shows a rectifying behavior with a reverse bias leakage current density of 6.12 nA/cm^2 at −100 V (field strength of 100 kV/cm). For the devices with the blend material of PTAA and TIPS-pentacene, the *I–V* characteristics still show a distinct Schottky rectification with a low leakage current in reverse bias. The reverse bias leakage current density for the devices with 1:1, 1:10 and 1:17 by molar ratio of PTAA:TIPS-pentacene are found to be 2.4, 1.56 and 0.6 nA/cm^2 at −100 V, respectively.

For device applications, experiments on X-ray sensors were conducted in which diode devices were irradiated through an Al top contact by an X-ray beam. The induced photocurrent was measured as a function of the dose rate to evaluate the performance of the sensor. Fig. 4B demonstrates dynamic photocurrent responses for devices biased at 40 V which have an active layer made of PTAA-doped with different concentrations of TIPS-pentacene. The dose rate was systematically increased from 13 to 66 mGy/s in increments of 13 mGy/s. The induced photocurrent from the sensors increases proportionally to the increasing of the X-ray dose rate, which can be attributed to a higher number of generated charge carriers. The rise and fall times are both less than the sampling rate of the instrument (<0.25 s).

The data confirm that the induced photocurrent can be significantly increased when the active layer contains TIPS-pentacene. For all applied dose rates and operational voltages, the X-ray photocurrent increases as the amount of TIPS-pentacene increases. For instance, at the X-ray dose rate of 66 mGy/s, it increases from about 1.8 nA for the PTAA sensor to approximately 9 nA for the 1:17 PTAA:-TIPS-pentacene sensor, at an operational voltage of −100 V.

The dependence of the X-ray photocurrent on the dose rate is used to define the sensitivity. A positive correlation between the radiation sensor's sensitivity and the charge carrier mobility for the PTAA and the PTAA:TIPS-pentacene devices is revealed in Fig. 4C. The sensitivity of the 1:17 device is highest, and its active material has the greatest mobility (Table 1). At the highest field strength, the sensitivity of the 1:17 device is 457 nC/mGy/cm^3, which is nearly four times that obtained for PTAA (116 nC/mGy/cm^3). As TIPS-pentacene has a relatively high charge carrier mobility, the rise in the sensitivity in the blend device can be assigned to an increase of the ability of the active material to transport charge carriers. However, even higher concentrations of TIPS-pentacene increase the conductivity of the blend too much to enable its use in a rectifying diode (with a low dark current) in a sensor. Thus, there is an upper limit to the increase in X-ray sensitivity that is possible through

Table 1
Charge-carrier mobility and X-ray sensitivity of PTAA and TIPS/PTAA Diodes.

Composition of active material	Charge-carrier mobility (10^{-6} cm^2 V^{-1} s^{-1})	X-ray sensitivity (nC mGy^{-1} cm^{-3})
PTAA	1.3	116
TIPS:PTAA = 17:1	19	457

the addition of TIPS-pentacene. Note that although the X-ray sensitivity of the 1:17 blend device is below what has been reported elsewhere for tissue-equivalent diamond detectors [34], polymers offer the distinct advantages of being lower in cost and able to coat large areas.

4. Conclusions

We have determined, for the first time, the influence of TIPS-pentacene on charge transport in PTAA/TIPS-pentacene blends using a time-of-flight technique. Our results have demonstrated that the mobility of the device increases with an increasing amount of TIPS-pentacene The value of mobility was found to be $2.2 \times 10^{-5}\,cm^2\,V^{-1}\,s^{-1}$, averaged for field strengths between 3×10^4 and $4 \times 10^5\,V\,cm^{-1}$ for the 1:25 PTAA:TIPS-pentacene blend, which is about 17 times higher than in PTAA over the same range of field strengths. Increasing mobility correlates very well with a fourfold increase in the X-ray detection sensitivity in the PTAA:TIPS-pentacene devices. The blend material presents the highest sensitivities reported to-date for organic, *tissue-equivalent* direct radiation sensors. The higher sensitivity and charge-carrier mobility are attributed to TIPS-pentacene crystals that provide a fast path for charge transport. The organic blends offer the potential for processing mechanically-flexible, large-area sensors for use in radiation protection and imaging applications. These diode structures also offer attractive properties for other applications, including light-emitting diodes, solar cells, and light sensors.

zinc- and indium-based oxides deposited by vacuum techniques, mainly by sputtering and atomic layer deposition [9–14]. In contrast to vacuum-based techniques, solution-based semiconductor deposition allows a simple and high throughput fabrication of inexpensive and large-area electronics. For this reason, solution-based metal oxide semiconductors recently gained a lot of attention. Several solution-based AOS materials have been reported as active channel layers in n-TFTs [15–18]. However, the applied annealing temperature to convert the soluble precursors into high performance AOS films lies mostly in the range of 350–500 °C. Applying lower annealing temperatures dramatically lowers TFT performance and often hardly results in functioning transistors [19]. Although complementary inverters have been reported with solution-processed ZnO and organic p-type TFTs [20], no scalable integration technology has been demonstrated yet, using solution-based metal oxide n-TFTs and organic p-TFTs for more complex complementary circuitry.

Here, we report on high performance n-type oxide TFTs based on solution-processable indium-based oxide formulations and processed at a maximum temperature of only 250 °C, which is compatible with flexible substrates such as polyimide. Using these oxide n-TFTs, we show a completely scalable integration process for hybrid inorganic–organic complementary logic superior to other complementary low-temperature processes.

2. Experimental

A schematic cross-section of the complete inorganic–organic inverter integration process is shown in Fig. 1. All transistors and hybrid inorganic–organic complementary circuits were fabricated on Si/SiO_2 substrates with a thermally evaporated and patterned gold layer, acting as the gate for both the organic p- and inorganic n-TFTs. Atomic layer deposition was performed to deposit 100 nm of Al_2O_3 high-k gate dielectric ($\varepsilon_r = 8$), which was subsequently patterned by photolithography and wet etching.

A 10 nm thick indium-based metal oxide active layer was deposited in air under ambient conditions by sequentially spin-coating and post-annealing a metal-organic precursor formulation (iXsenic S, developed by Evonik Industries). The post-annealing was performed on a hotplate for 2 h at 250 °C to remove residual solvents and to form the metal oxide film. Photolithography and wet etching were used to pattern the n-type channel regions. Next, a bilayer of Ti and Au (2–30 nm) was deposited by thermal evaporation and patterned by a lift-off process. The Ti–Au bilayer forms top source–drain contacts for the oxide n-TFTs and bottom source–drain contacts for the pentacene p-TFTs. In this way, the amount of processing and mask steps required for circuit fabrication is minimized.

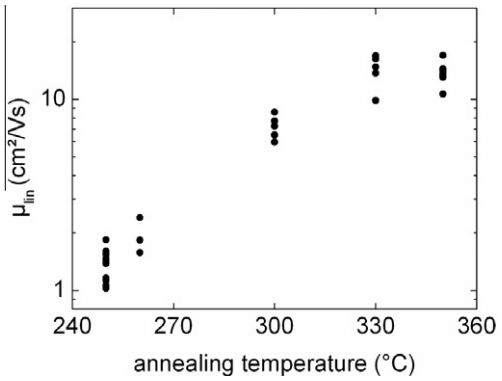

Fig. 2. The linear mobility values of discrete n-type metal-oxide TFTs after baking out at different temperatures (W/L = 2000/20 μm/μm). The distribution of the average linear mobility is shown over five successive experiments.

Subsequently, a 2 μm thick layer of the negative photoresist SU-8 2002 (purchased from MicroChem Corp.) is spin-coated over the entire substrate to protect the n-TFTs. Next, openings are photolithographically defined in the SU-8 layer above the active transistor areas of the p-channel TFTs. Because of the negative slopes of these SU-8 edges, the openings act as an integrated shadow mask and define isolated islands of pentacene after the deposition of 30 nm pentacene by thermal evaporation in ultrahigh vacuum [21]. To improve the pentacene film growth, the Ti–Au contacts and the Al_2O_3 dielectric were treated with self-assembled monolayers, respectively pentafluorothiophenol (PFTP) and phenethyltrichlorosilane (PETS) [22,23] before pentacene deposition. Then the entire substrate was capped with an encapsulation layer consisting of 3 μm parylene C, deposited by a vapor polymerization process. Finally, via holes are opened by photolithography and dry etching on the contact pad areas.

The current–voltage characteristics of the individual TFTs were measured with a HP 4156 parameter analyzer. The output characteristics of the ring-oscillators were examined with an oscilloscope. All measurements were performed under nitrogen atmosphere and under dark conditions.

3. Results and discussion

Fig. 2 shows the typical linear mobility values of the metal-organic precursor formulation iXsenic S before the integration and optimization of the inorganic–organic

hybrid process. A steady increase of the electron mobility is observed as the annealing temperature increases from 250 to 330 °C, after which the mobility plateaus at around 15 cm^2/V s. In this work the lower processing range at

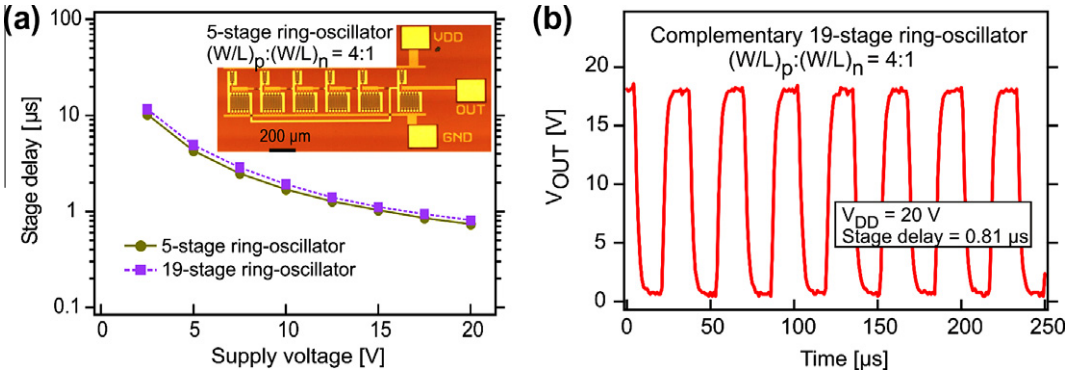

Fig. 6. (a) The stage delay of a 5-stage and 19-stage complementary ring-oscillator as function of the supply voltage. (b) Output characteristics of a 19-stage complementary ring-oscillator at a V_{DD} of 20 V.

250 °C was used for the development of the complementary technology, as the mobility reached at this temperature matches that of the organic p-type semiconductor.

Fig. 3a and b shows the typical transfer and output characteristics of a metal oxide n-TFT after integration. We were able to achieve high performance n-TFTs with saturation mobilities of ~2 $cm^2/(V\,s)$, an onset voltage of ~−1.5 V, a subthreshold swing of only ~0.19 V/decade, and an on–off current ratio of ~10^7. The channel length (L) and width (W) of the n-TFTs were 5 and 140 µm, respectively. The transfer and output characteristic of a discrete pentacene p-TFT is shown in Fig. 4a and b, the W/L ratio is 560/5 µm/µm. The integrated pentacene p-TFT exhibits a saturation hole mobility of 0.20 $cm^2/(V\,s)$, an onset voltage of ~2.8 V, and a subthreshold swing of ~0.35 V/decade. In both transistor types the off-current is below 10 pA.

The complementary circuits were designed with a $(W/L)_p$:$(W/L)_n$ ratio of 4:1, as shown in the optical microscope image of Fig. 5b. The resulting voltage transfer curves and corresponding gain curves of a complementary inverter are shown in Fig. 5a for different supply voltages. Good inverter behavior was obtained at supply voltages (V_{DD}) down to 2 V, making the presented hybrid technology well-suited for future low-voltage applications. The voltage transfer curve and its inverted curve at V_{DD} of 10 V are shown in Fig. 5c. The inverter transition point (V_{trip}) was at 4 V and a DC gain and noise margin (NM) of, respectively 3.8 and 1.9 V were obtained. In complementary logic the least performing transistor dictates the overall performance, in our case this is the pentacene p-TFT. Consequently, the inverter transition points of all transfer curves are below $V_{DD}/2$.

Fig. 6a shows the stage delay of a 5-stage complementary ring-oscillator as a function of the supply voltage. Excellent stage delays as low as 0.74 µs, corresponding to 113 kHz, were measured at a V_{DD} of 20 V. Also the spread of seven different 5-stage ring-oscillators, measured on the same substrate at a V_{DD} of 10 V was minimal, i.e. 1.78 ± 0.05 µs. The 19-stage ring-oscillators operate at 30.8 kHz, corresponding to a stage delay of only 0.81 µs at a V_{DD} of 20 V as shown in Fig. 6b. These results demonstrate that our hybrid technology has reached the level of reliability and yield required to fabricate more complex circuits in the future.

4. Conclusion

In summary, we fabricated state-of-the-art solution-based oxide n-type TFTs with saturation electron mobilities up to 2.05 $cm^2/(V\,s)$ after post-annealing at only 250 °C in air. Based on these high-performance n-TFTs and thermally evaporated pentacene p-TFTs, a completely scalable hybrid organic–inorganic complementary technology was developed.

Using this technology, hybrid complementary circuit building blocks, such as inverters and ring-oscillators were realized. Because the integrated p-TFT on-current was much lower compared to its n-type counterpart, a $(W/L)_p$:$(W/L)_n$ ratio of 4:1 was selected for the complementary circuits. Supply voltages as low as 2 V resulted in good circuit behavior, indicating that the presented technology is suited for future low-voltage applications. The 5-stage ring-oscillators operated up to 113 kHz, corresponding to stage delays as low as 0.74 µs at a V_{DD} of 20 V. Moreover 19-stage ring-oscillators were shown to operate at more than 30 kHz. This robust complementary thin-film technology holds promise for the realization of more complex circuitry in the future.

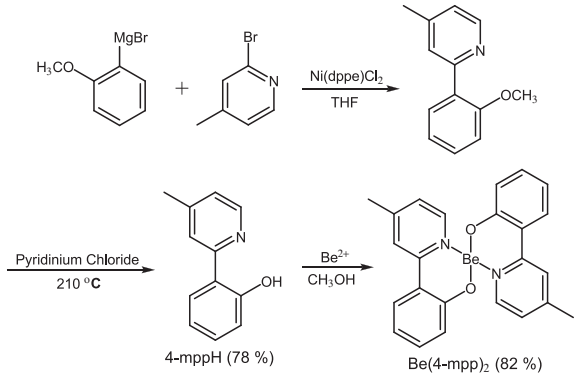
one novel blue-emitting molecule bis(2-(2-hydroxyphenyl)-4-methyl-pyridine)beryllium ($Be(4\text{-}mpp)_2$) is designed by introducing a sterically hindered methyl group onto the pyridyl ring of the ligand in the original complex $Bepp_2$, which leads to both the desired enhancement for the luminescent and charge carriers transporting properties of $Be(4\text{-}mpp)_2$, and the considerable optimization for the organic-solid interfacial characteristic between the hole transporting layer and the emitting layer. As expected, the simple double-layer device based on $Be(4\text{-}mpp)_2$ exhibits excellent pure and stable blue light with CIE (Commission International de I' Eclarirage) coordinates of (0.14, 0.09), and shows very high EL efficiency with the peak external quantum efficiency (EQE) of 5.4% and peak power efficiency (PE) of 4.2 lm W^{-1}, which are better overall than the EL performance of $Bepp_2$-based device [8]. The details about the corresponding synthesis, crystal packing structure, photophysical properties and EL performance of the new beryllium complex are reported herein.

2. Experimental

2.1. Materials and synthesis

NPB and Alq_3 were commercially available. The 2-(2-hydroxyphenyl)-5-metheyl-pyridine (4-mppH) and the beryllium complex were prepared following the synthetic route shown in Scheme 1 [9,8b]. The starting materials obtained from commercial suppliers were used without further purification. Anhydrous hexane was distilled with sodium benzophenone ketyl under nitrogen atmosphere, degassed by the freeze–pump–thaw method. All glass wares, syringes, magnetic stirring bars and needles were dried in a convection oven at least 4 h. Reactions were monitored with thin layer chromatography (TLC). Commercial TLC plates (Silica gel 60 F254, Merck Co.) were developed and the spots were seen under UV light at 254 and 365 nm. Silica column chromatography was done with silica gel 60 G (particle size 5–40 μm, Merck Co.). ^{1}H NMR spectra were recorded on a Bruker AVANVE 300 MHz spectrometer with tetramethylsilane as an internal standard. Mass spectra were measured on a GC/MS mass spectrometer. Elemental analyses were performed on a flash EA 1112 spectrometer.



Scheme 1. Synthesis of $Be(4\text{-}mpp)_2$.

2.1.1. Synthesis of 4-mppH

To an ice-cold mixture of $[Ni(dppe)Cl_2]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) (0.52 g, 1 mmol) and 2-bromo-4-methyl-pyridine (5.1 g, 30 mmol) in dry THF (30 ml) under a nitrogen atmosphere was added dropwise a solution of Grignard reagent prepared from 2-bromoanisole (6.74 g, 36 mmol). The mixture solution was allowed to attain room temperature and stirred for 12 h. The reaction was then quenched by addition of aqueous NH_4Cl and the THF was removed under reduced pressure. The resulting white precipitate was filtered off, washed with water and dried in air to give the product 2-(2-methoxyphenyl)-4-methyl-pyridine. It is sufficiently pure for use in the subsequent step. 2-(2-Methoxyphenyl)-4-methyl-pyridine was added in molten pyridinium chloride (from 30 ml pyridine and 35 ml concentrated HCl) under nitrogen for 3 h at 210 °C. After addition of water to the mixture and neutralization with aqueous KOH, the crude product was extracted with CH_2Cl_2 (3 × 60 ml), and the organic phase was washed twice with water (2 × 30 ml) and then dried over Na_2SO_4. The solvent was removed under reduced pressure. The residual yellow solid was purified by chromatography (silica, CH_2Cl_2) to give the light yellow powder product in 78% yield. MS: m/z = 185 (M^+). Anal. Calcd. for $C_{12}H_{11}NO$: C, 77.81; H, 5.99; N, 7.56. Found: C, 77.68; H, 5.79; N, 7.63. ^{1}H NMR in $CDCl_3$ (δ, ppm): 12.96 (1H, broad, s), 8.32 (1H, d, J = 5.2 Hz), 7.72 (1H, d, J = 5.2 Hz), 7.68 (1H, s), 7.32–6.74 (4H, m), 2.40 (3H, s).

2.1.2. Synthesis of $Be(4\text{-}mpp)_2$

In a 100-ml round bottom flask fitted with magnetic stirrer, $BeSO_4{\cdot}5H_2O$ (0.9 g, 5 mmol) and 30 ml methanol was slowly added to 4-mppH (1.85 g, 10 mmol) dissolved in 30 ml of methanol. Then the mixed solution was adjusted to pH 12 using NaOH and was stirred for 5 h at room temperature. Colorless solid precipitated from the solution. The solid product was collected by filtration and purified by recrystallization and sublimation methods (82% yield). MS: m/z = 377 (M^+). Anal. Calcd. for $C_{24}H_{20}N_2O_2Be$: C, 76.37; H, 5.34; N, 7.42. Found: C, 76.59; H, 5.26; N, 7.58. ^{1}H NMR in $CDCl_3$ (δ, ppm): 8.46 (2H, d, J = 5.2 Hz), 7.82 (2H, d, J = 5.2 Hz), 7.50 (2H, s), 7.15 (2H, t, J = 4.8 Hz), 6.95–6.76 (6H, m), 2.35 (6H, s).

2.2. Absorption, PL and electrochemical measurements

Absorption spectrum was obtained using a Shimadzu UV-2550 UV–vis spectrometer. PL spectra were recorded by a Perkin-Elmer LS-55 fluorescence spectrometer with a Xe arc lamp excitation source. The PL quantum yields were measured by use of quinine sulfate in 1 M sulfuric acid as a standard (Φ = 0.546) [10]. All solvents were degassed via three freeze–pump–thaw cycles. Electrochemical measurements were performed in anhydrous CH_2Cl_2 with a BAS 100 W bioanalytical electrochemical work station, using Pt as the working electrode, platinum wire as the auxiliary electrode, and a porous glass wick Ag/Ag^+ as the reference electrode. It was standardized against a ferrocene/ferrocenium couple with a scan rate of 100 mV s^{-1}. The highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels

of the emitting materials were calculated from the cyclic voltammetry (CV) data together with their absorption spectra. The proposed energy diagram of the materials used in OLEDs is shown in Fig. 2 (inset), where the values for NPB and Alq_3 are taken from literature [11].

2.3. Fabrication of the OLEDs and EL measurements

The devices were grown on a glass, which was precoated with indium tin oxide (ITO) having a sheet resistance equal to 20 $\Omega\,cm^{-2}$. The ITO glass was routinely cleaned by ultrasonic treatment in detergent solutions, followed by rinsed with acetone, boiled in isopropanol, rinsed in methanol, and then in de-ionized water. The glass was dried in vacuum oven between each cleaning step above. To reduce the possibility of electrical shorts on the ITO anode and increase the value of its work function, the ITO substrate was treated using a Plasma Cleaner (PDC-32G-2, 100 W) with the oxygen ambient. Prior to the deposition, all the organic materials were purified by sublimation method. The organic layers were sequentially deposited onto the substrate without breaking vacuum at a pressure of about 10^{-4} Pa. A very thin layer of LiF could enhance electron injection from aluminum cathode. A shadows mask with $2 \times 3\ mm^2$ openings was used to define the cathodes. The EL spectrum, brightness, CIE coordinates and the current-brightness–voltage characteristics of the devices were measured with a rapid scan system using a spectrophotometer (PR-650, Photo Research) and a computer-controlled, programmable, direct-current (DC) source (Keithley 2400). Luminance–voltage and current–voltage characteristics were measured at room temperature under an ambient atmosphere.

3. Results and discussion

3.1. π–π packing properties

Single X-ray diffraction study (CCDC reference number is 827923) revealed that there are strong intermolecular π–π stacking between 4-mpp ligands of the adjacent beryllium molecules in the solid state (Fig. 1), and the interplanar distance is approximately 3.3 Å, which is shorter than that shown in $Bepp_2$ (3.4 Å) [8b], and it is one rather short π–π interaction. Our earlier studies demonstrated that the high electron mobility of EL materials is due to the intermolecular interactions and intermolecular aromatic stacking could offer the charge transfer pathway [8a]. Therefore, the results above suggest that $Be(4\text{-mpp})_2$ should possess good charge transport property, which is an essential property for an excellent EL material, and indicates that it may be even higher than that of $Bepp_2$ for their interplanar distance alignment.

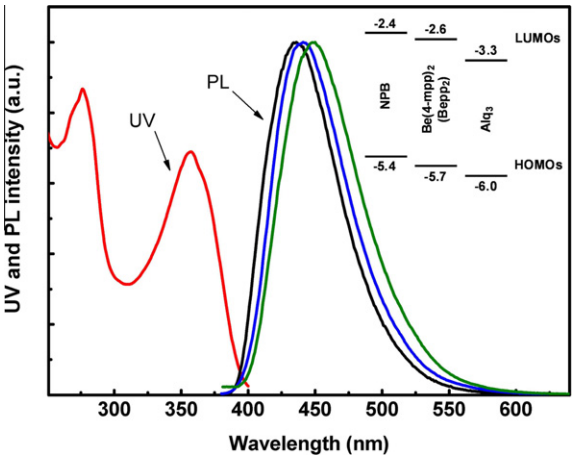


Fig. 2. UV absorption spectrum (red line) and PL spectrum (black line) of $Be(4\text{-mpp})_2$ in the chloroform solution. PL spectra of $Be(4\text{-mpp})_2$ (blue line) and $Bepp_2$ (green line) in the neat film. Inset: the proposed energy diagram of the materials used in OLEDs.

3.2. Photophysical properties

The UV/vis and photoluminescent (PL) spectra of $Be(4\text{-mpp})_2$ in chloroform solution and the PL spectra of $Be(4\text{-mpp})_2$ and $Bepp_2$ in their solid thin films deposited on quartz substrates were measured and shown in Fig. 2. The UV absorption spectrum of $Be(4\text{-mpp})_2$ in solution has maxima at around 360 nm, and under the excitation of UV-light of wavelength 365 nm, this complex shows strong blue emission at around 435 nm with the relative quantum yield of 0.37, which is much higher than that of $Bepp_2$ (0.27). In solid films, both complexes exhibits strong blue fluorescence with the similar half-maximum width about 65–70 nm, but the emission peak of $Be(4\text{-mpp})_2$

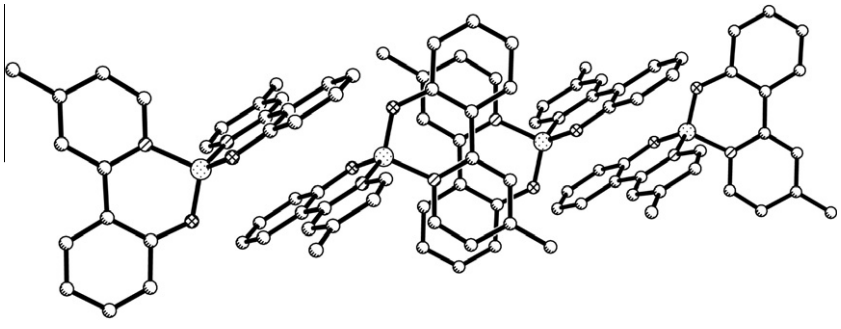

Fig. 1. Crystal packing diagrams of $Be(4\text{-mpp})_2$.

shows a slight blue shift compared with $Bepp_2$ due to the introduction of one methyl onto the ligand. It is consistent with the results studied on the emission characteristic of the metal–chelate complexes based on the pyridyl and hydroxyphenyl system reported previously [7a,d], where inserting an electron donating group at the 2- or 4-position of the pyridyl ring can achieve blue-shift in the emission spectrum. Nevertheless, the relatively weak electron donating ability of the methyl group could not lead to significantly detectable difference between the values of the corresponding HOMO and LUMO energy levels of $Bepp_2$ and $Be(4\text{-mpp})_2$ shown in Fig. 2 (inset).

3.3. EL properties

To investigate the EL properties, series of EL devices were fabricated. $Be(4\text{-mpp})_2$ acts as the neat emitting layer (EML) as well as the electron transporting layers (ETL) in device I, where NPB (4,4-bis(*N*-(1-naphthyl)-*N*-phenylamino)biphenyl) was used as a hole transport layer (HTL). For comparison, device II based on $Bepp_2$ with the same device structure and device III using $Be(4\text{-mpp})_2$ as the EML and Alq_3 as the ETL were prepared also, respectively. All the device structures are shown as follows:

(I) [ITO/NPB (40 nm)/$Be(4\text{-mpp})_2$ (50 nm)/LiF (1 nm)/Al].
(II) [ITO/NPB (40 nm)/$Bepp_2$ (50 nm)/LiF (1 nm)/Al].
(III) [ITO/NPB (40 nm)/$Be(4\text{-mpp})_2$ (20 nm)/Alq_3 (30 nm)/LiF (1 nm)/Al].

Fig. 3 shows the normalized EL spectra of device I–III at the brightness of 1000 cd m^{-2}. All of them have the similar emission peak at around 450 nm, but show much variation in the half-maximum width ranging from 60 to 110 nm. Compared with device II based on $Bepp_2$, which just show a sky-blue emission with the CIE coordinates of (0.16, 0.18) and obviously broader EL spectrum relative to the corresponding PL spectrum of $Bepp_2$ in the solid film shown in Fig. 2, device I using $Be(4\text{-mpp})_2$ as the neat EML display very narrow spectral shape that is consistent well with

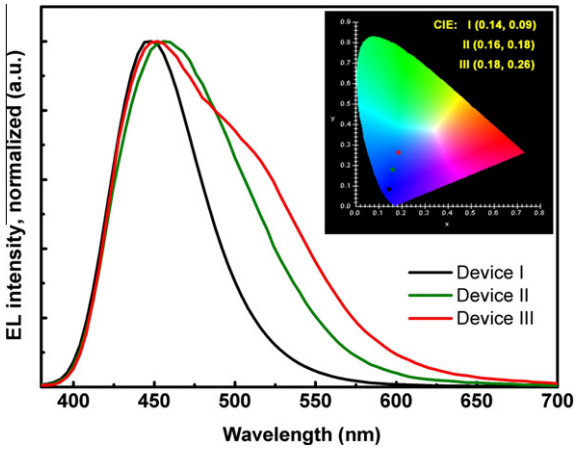

Fig. 3. EL spectra of device I, II and III at the brightness of 1000 cd m^{-2}. Inset: the corresponding CIE coordinates of device I, II and III at the brightness of 1000 cd m^{-2}.

the PL spectral characteristics of this complex (Fig. 2). The EL emission from device I is saturated blue light with CIE (0.14, 0.09) at the brightness of 1000 cd m^{-2} as shown in Fig. 3 (inset), which matches closely to the NTSC (National Television Standards Committee) blue standard (0.14, 0.08) and remain almost unchanged in the driving voltage range from 4 to 10 V. The possible reason for this enhancement in the blue-light quality is through introducing a sterically hindered methyl onto the pyridyl ring of the beryllium complex, which can optimize the organic-solid interface properties between the layers of NPB and $Be(4\text{-mpp})_2$ and then prevent the possible exciplex formation [3a,7c,12] that could lead to a broader EL spectrum such as in the NPB/$Bepp_2$ interface of device II. In the device III using Alq_3 as the ETL, an additional emission in the wavelength region from 500 to 550 nm is observed and increases as the applied voltage increased together with the dominant blue emission at 450 nm, which leads to a greenish-blue EL emission with the CIE coordinates of $x \geqslant 0.18$ and $y \geqslant 0.22$. The clear shoulder is attributed to the emission of Alq_3, which should come from such emission mechanism in this Alq_3-based device: because there is a large barrier height of 0.7 eV for electron injection from the LUMO (the lowest unoccupied molecular orbital) of Alq_3 to the LUMO of $Be(4\text{-mpp})_2$ (as shown in Fig. 2, inset), some electrons are confined within the Alq_3 layer and lead to the recombination of certain number of holes and electrons occurred at the ETL. The gradual increase in the emission intensity of the Alq_3 suggests that more holes can leak into the ETL and form more excitons with electrons in this layer as the voltage increased. This phenomenon indicates that Alq_3 is not a very favorable ET material for a blue emitter due to the inevitable green emission that will lead to a poor-purity blue EL emission.

The current density–voltage and luminance–voltage characteristics of device I, II and III were plotted in Fig. 4 (top) and Fig. 4 (bottom), respectively. Device I and II exhibit similar turn-on voltage of 3.0 V (recorded at 1 cd m^{-2}), which is lower than that of device III (3.5 V). Compared with device II and III, device I shows faster rise of the EL intensity and the current density after the onset voltages, and such trend becomes more obvious along with the driving voltage increased. The driving voltage of device I at the brightness of 100, 1000 and 10,000 cd m^{-2} are 4.7, 6.2 and 9.0 V, respectively, which are lower than those of device II (4.8, 6.4 and 9.7 V, respectively) and device III (5.3, 7.1 and 10.7 V, respectively). The faster response of the EL intensity as well as the current density of device I than those of device II should partly be attributed to the relatively higher quantum yield of $Be(4\text{-mpp})_2$ than that of $Bepp_2$, but also supports the hypothesis mentioned above that $Be(4\text{-mpp})_2$ might possess better electron-transporting ability than $Bepp_2$. In addition, the much lower LUMO level of Alq_3 than that of $Be(4\text{-mpp})_2$ causes a high election–injection barrier in device III, and thus leads to the higher driving voltage of device III than those of device I and II.

As a result, device I based on $Be(4\text{-mpp})_2$ as the EML and ETL exhibits the best overall EL performance, in terms of not only the improved color purity mentioned above, but also the significantly enhanced EL efficiency relative to the $Bepp_2$-based device II and Alq_3-based device III.

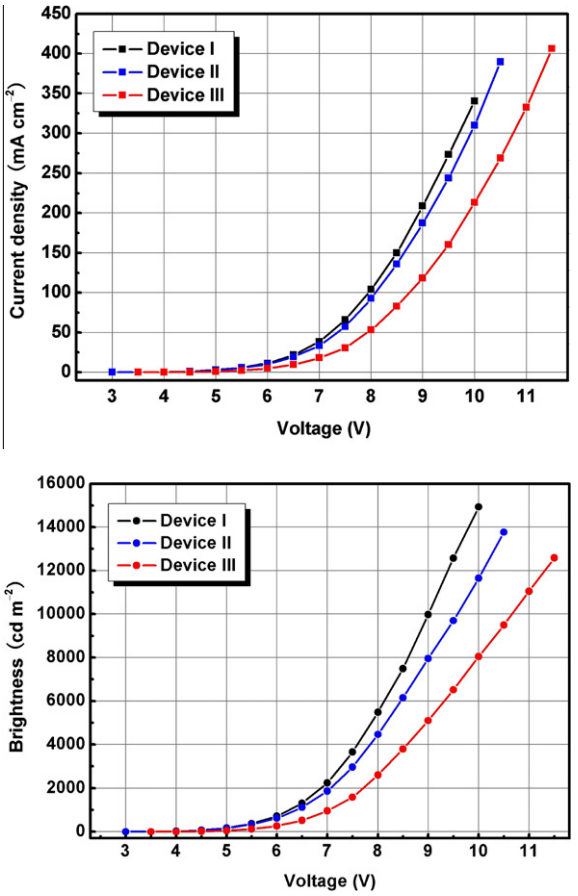

Fig. 4. Current density–voltage and brightness–voltage characteristics of device I, II and III.

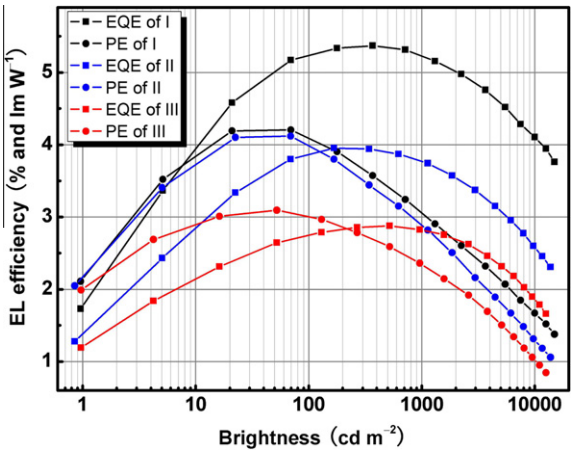

Fig. 5. EQE (external quantum efficiency)–brightness and PE (power efficiency)–brightness characteristics for the device I, II and III.

Fig. 5 shows the EQE (external quantum efficiency)–brightness and PE (power efficiency)–brightness characteristics for the device I, II and III. Device I shows the highest EL efficiency with the maximum EQE of 5.4% at 370 cd m^{-2} (5.5 V) and maximum PE of 4.2 lm W^{-1} at the brightness of 70 cd m^{-2} (4.5 V), compared with the corresponding peak values of device II (3.9% at 340 cd m^{-2} and 5.5 V, 4.1 lm W^{-1} at 70 cd m^{-2} and 4.5 V) and device III (2.9% at 520 cd m^{-2} and 6.5 V, 3.1 lm W^{-1} at 50 cd m^{-2} and 5.0 V). Obviously, although the PE level of device I shows just a little higher than that of device II, the EQE level device I is dramatically enhanced and exhibits much higher than that of device II within the whole range of the driving voltages. This should be attributed to the perfect blue EL emission with the CIE coordinates of (0.14, 0.09) of device I that is much bluer than that of device II, which leads to device I can release more photons than device II based on the similar lumen output of two devices [13]. Notably, the EQE values of device I at the practical brightness of 100 and 1000 cd m^{-2} in the fields of flat panel displays and solid-state lighting, remain as high as 5.0% that is much higher than those of device II, which indicates the better charge carrier balance and more efficient confinement of the excitons generated within the emitting layer in device I than in device II [11a,14]. These values of device I mentioned above are the highest EL efficiencies ever reported for such saturated and stable OLED (CIE: $x < 0.15$, $y < 0.10$) to the best of our knowledge, even including the devices utilizing doped [4,16] and non-doped emitting systems [4a,15]. In addition, it is noteworthy that the brightness– and current density–voltage curves of device I show no significant saturation behavior at high driving voltages and its EQE keeps more than 4.0% in very wide the brightness range (10–10,000 cd m^{-2}) corresponding to the current density range (0.2–200 mA cm^{-2}), which suggest that this simple and efficient double-layer device displays very good operational stability also. The fact that NPB is a well-known hole transporting material and no conventional ETM such as Alq_3 is required to achieve the highly efficient and deep-blue EL emission in Be(4-mpp)$_2$-based device demonstrates that Be(4-mpp)$_2$ can act as a desired bifunctional material: not only a bright blue emitter, but also a suitable ETM in EL devices, especially for the blue-emission OLEDs that need perfect color purity.

4. Conclusions

In summary, the high-performance blue OLED using one novel beryllium complex Be(4-mpp)$_2$ as the EML as well as the ETL has been developed. The simple double-layer device shows pure and stable blue emission with the CIE coordinates of (0.14, 0.09) and exhibits very high EL efficiency in terms of both the peak values (5.4% for EQE and 4.2 lm W^{-1} for PE) and the good operational stability. The dramatically enhanced EL properties of Be(4-mpp)$_2$ is realized easily through the minor modification for the molecular structure, which has proven to be a simple and effective strategy to improve both the luminescent and the charge carriers transporting properties of the host emitting materials. The gratifying bifunctional property suggests that this new beryllium complex has high potential as both an efficient deep-blue emitter or host and a competent electron transporting material, for the applications in large flat panel displays and solid-state lighting in future.

For Alq3 thin films sandwiched between Mg:Ag and either Al or Mg:Ag electrodes, Baldo and Forrest [8] observed very unique temperature and thickness dependent I/V characteristics that required implementation of a new model of injection into a disordered solid [8]. In the Baldo and Forrest model, it was hypothesized that disorder was enhanced near the metal–organic interface in such a way that the limiting charge injection process was not direct injection from the metal electrode into the disordered Alq3 film but rather injection from a highly disordered interfacial molecular layer into the somewhat less disordered bulk film. A possible physical origin of the interfacial disorder was suggested to be random variations in orientations of Alq3 molecules that result in strongly varying local interfacial dipoles [14] in the plane of the metal–organic interface.

Only a few scanned probe experiments directed at visualizing Alq3 film structure at the molecular level have been attempted. Alvarado and co-workers found that Alq3 diffused too rapidly on the surface to image by scanning tunneling microscopy (STM) at room temperature on Au(1 1 1) [15]. However, they were able to estimate the transport gap for Alq3/Au(1 1 1) using tip distance-versus-voltage spectroscopy [15,16]. More recently, linear Alq3 nanostructures were observed on ultrathin KBr films, but intermolecular distances were not reported [17]. Numerous studies have used atomic force microscopy to image the nanometer scale morphology of thick Alq3 films [18–20].

In the present paper we report scanning tunneling microscopy observations of the first layer of Alq3 on a Cu(1 1 0) surface that achieve single molecule resolution. These experiments show a poorly ordered interface that results from growth on a room temperature substrate and that persists after annealing up to about 590 K. While no long range order is observed in this first monolayer, intermolecular interactions are revealed by the formation of randomly-oriented chain-like aggregates of Alq3 molecules. We describe the origin of these disordered chain structures from anisotropic intermolecular interactions using model density functional theory (DFT) calculations.

2. Experimental methods

Experiments were carried out in an ultrahigh vacuum system with two interconnected chambers. One chamber (base pressure $<7 \times 10^{-11}$ torr) houses facilities for substrate cleaning and STM characterization. Another chamber (base pressure $\sim 1 \times 10^{-8}$ torr) is separated from the first by a gate valve and houses home-built organic evaporators and a quartz oscillator for flux monitoring.

The substrate was a Cu(1 1 0) single crystal (Princeton) cleaned by repeated cycles of 1 keV Ar^+ sputtering following by annealing for 20 min at ~700 K. During deposition, the Cu(1 1 0) crystal was held at room temperature. Powdered tris-(8-hydroxyquinoline) – Aluminum (“Alq3”, Sigma–Aldrich – 99.995%) was loaded as received into a degassed quartz crucible that could be heated by a tightly wrapped Tantalum filament coil. The Alq3 was outgassed for several hours in the deposition chamber prior to film growth. The stability of Alq3 flux was monitored with a quartz oscillator before and after deposition. Absolute flux calibration was carried out by direct STM imaging with molecular resolution.

STM imaging was carried out at room temperature with a commercial instrument (Omicron VT-STM-XA) operated in constant current mode with electrochemically-etched tungsten tips. Annealing experiments after Alq3 deposition were performed by heating the sample in the cleaning/STM chamber manipulator with an integrated PBN heater. Temperature was monitored by a K-type thermocouple attached near the sample and corrected by adding 120 K to estimate the real sample temperature. This correction is based on infrared pyrometry at temperatures greater than 820 K and is expected to be accurate only to about ±30 K.

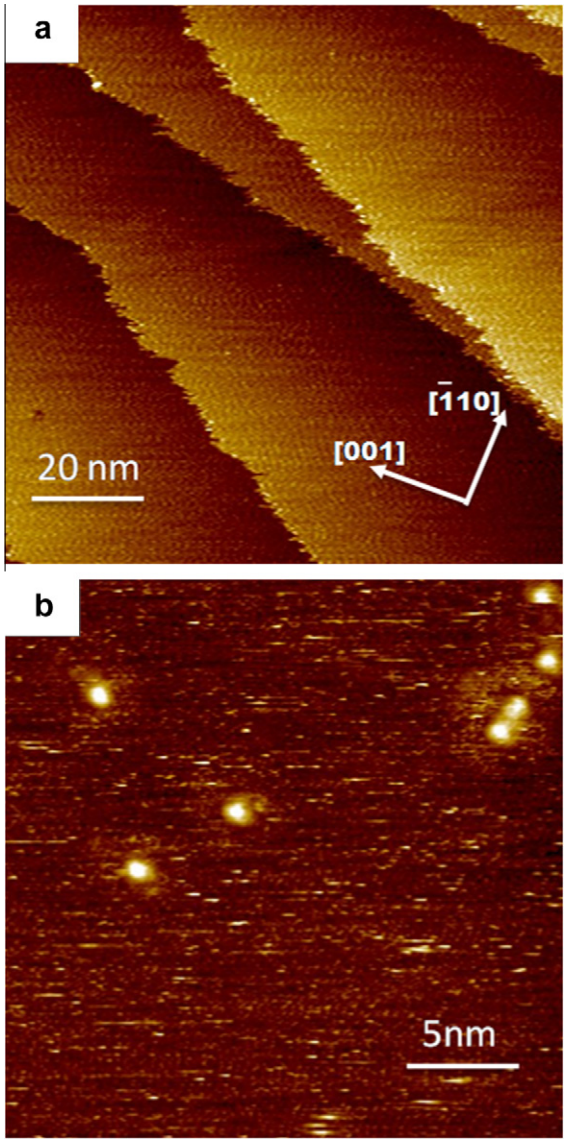

Fig. 1. (a) STM image (100 nm × 95 nm, −0.8 V, 30 pA) of the clean Cu(1 1 0) substrate; (b) STM image (25 nm × 25 nm, −1.0 V, 2 pA) after deposition of a small quantity (90 s deposition time) of Alq3. Single molecules are imaged as bright protrusions as indicated by the arrow.

3. Results

In Fig. 1a, an STM image of the large scale morphology of the Cu(1 1 0) substrate surface is shown. Relatively flat terraces separated by single-atom high steps can be seen. After a very short deposition of Alq3, it is possible to see a number of uniformly sized approximately circular protrusions on the terraces that are single Alq3 molecules (Fig. 1b).

Upon further deposition, Alq3 molecules begin to aggregate, displaying a strong tendency to form pairs as shown in Fig. 2a. These pairs are spaced typically just under 1 nm apart (center to center), which is a distance consistent with near-neighbor spacings in bulk Alq3 crystals [6]. We note that the pairing direction does not show any strong preference with respect to crystallographic directions in the plane of the Cu(1 1 0) surface. At these low coverages, there is apparently a significant mobility of some surface species as evidenced by the streaky noise surrounding bright molecular protrusions in STM images.

As the coverage of Alq3 increases in the first monolayer, a tendency to form chain-like aggregates is observed building from the paired molecules in Fig. 2a. This is shown in Fig. 2b–d where randomly-oriented chains of 3–7 Alq3 molecules can be seen. The spacing (0.8–1.0 nm) between near neighbor molecules in chains is similar to the spacing in pairs. The lack of long-ranged order and the tendency toward chain formation persist upon annealing up to 590 K as shown in Fig. 3. Fig. 3a shows an STM image of a Alq3 film deposited at room temperature and Fig. 3b shows the result of annealing the same film to 590 K. This observation indicates that the amorphous monolayer created by deposition of Alq3 on Cu(1 1 0) is a relatively stable structure. Despite significant open space on the surface, it was never observed to convert to an ordered molecular layer.

4. Discussion

4.1. Interfacial disorder

The most significant observation reported above is that the first monolayer of Alq3 is highly disordered when deposited onto a room temperature Cu(1 1 0) surface. Many other organic semiconductors exhibit ordered monolayers on this surface, templated by strong substrate–molecule interactions. For example, pentacene forms an ordered first layer with intermolecular spacings that have been argued to be determined by substrate-mediated interactions [21]. In addition, PTCDA has been shown to form ordered monolayers [22] (accompanying substrate surface reconstruction) followed by beautifully crystalline 3D islands [23,24].

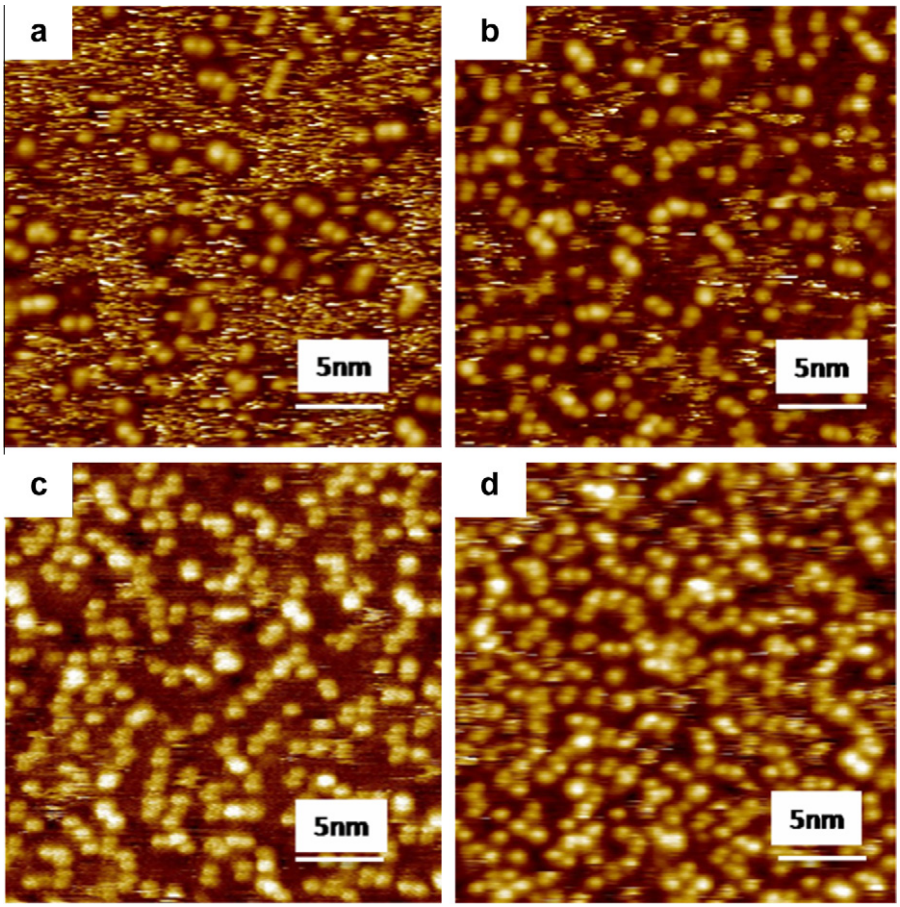

Fig. 2. Coverage-dependent STM images (all 25 nm × 25 nm) during the growth of the first monolayer of Alq3 on Cu(1 1 0); (a) 0.16 nm^{-2} (−1.3 V, 1 pA); (b) 0.33 nm^{-2} (−1.2 V, 5 pA); (c) 0.49 nm^{-2} (−1.4 V, 3 pA); (d) 0.63 nm^{-2} (−0.6 V, 1 pA).

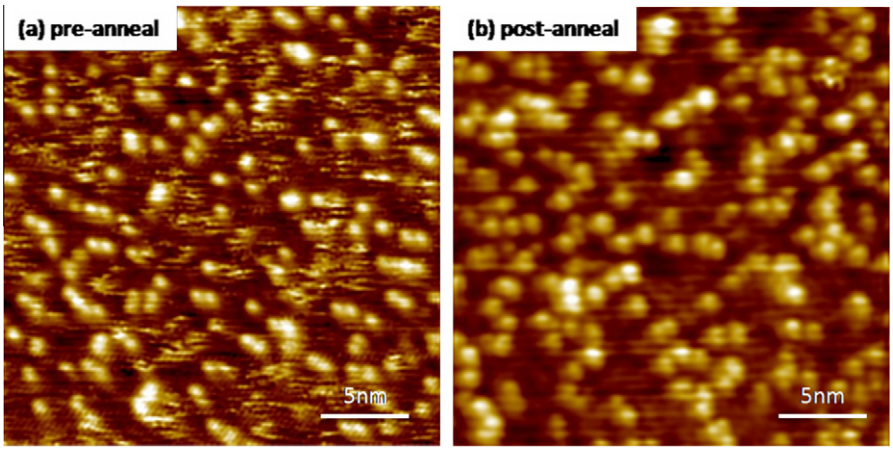

Fig. 3. (a) STM image (25 nm × 24 nm, −1.3 V, 10 pA) of an as-deposited Alq3 film with coverage of 0.25 ± 0.02 nm^{-2}; (b) STM image (25 nm × 24 nm, −1.2 V, 20 pA) of the same film as in (a) after annealing to 590 K. The coverage is 0.24 ± 0.02 nm^{-2}.

The fact that disorder in the first Alq3 layer is not easily removed by annealing suggests that it is the dominant structural motif on Cu(1 1 0) and that the well-known amorphous structure of Alq3 films can begin in the first layer. As mentioned in the Section 1, Baldo and Forrest suggested an Alq3 diode device model that included strong electronic disorder in the first few layers near the metal–organic interface [8]. Our observations are consistent with such a picture, since the observed structural disorder should translate into significant disorder in electronic density of states. This could result from random local electronic polarization environments due to variable local coordination number [25–27]. Alternatively, it could result from random local interface dipoles due to disorder in either molecular orientations or site location [28].

4.2. Alq3 chain formation

The single molecule resolution afforded by STM measurements allows an elaboration of the subtle details of disorder at the Alq3/Cu(1 1 0) interface. The prominence of linear structures in the disordered first monolayer of Alq3 on Cu(1 1 0) shows that intermolecular interactions are important enough to establish significant *local* molecular correlations at the metal–molecule interface. Such local ordering has been argued to be important in determining optoelectronic properties of thick organic films. [29] In addition, aggregation on the scale of a few molecules has been shown to influence exciton dynamics. [30].

In this section, we address the origin of the chain-like Alq3 structures using density functional theory (DFT) calculations of intermolecular interactions designed to capture some important aspects of the direct intermolecular interactions that are likely to be operative on a metal surface. In order to explain the observed tendency to form chain-like aggregates, it is necessary that intermolecular interactions are anisotropic to some degree. Such anisotropy is intuitively plausible for Alq3 since the molecule has a relatively low symmetry (C_1 point group for the most stable "meridional" isomer) and a large (∼5D) intrinsic dipole moment [31].

Previously, the adsorption configuration of Alq3 on aluminum surfaces has been studied using density functional theory by Yanagisawa et al. [31,32]. These calculations illustrate that the intrinsic dipole moment of the molecule is only slightly reduced when adsorbed on a Al(1 1 1) surface [31]. We hypothesize that adsorbed Alq3 molecules are not completely free to rotate out of the plane of the surface (i.e. they cannot change the orientation of their intrinsic dipole moment with respect to the surface normal). In this case, the crucial direct intermolecular interactions on a surface occur between Alq3 molecules each with a fixed orientation with respect to the surface plane. This orientation may vary from molecule to molecule on the surface but cannot change to optimize intermolecular interactions to achieve a bulk-like crystal structure [6].

Density functional theory calculations were carried out using the Gaussian 09 software package [33]. We optimized the geometry of an isolated *meridional* Alq3 molecule using Hartree–Fock calculations with a 3-21G basis set. This method was chosen based on reports that Hartree–Fock most accurately produces the experimentally-determined molecular geometry and dipole moment [34]. After single molecule optimization, we calculated single point energies (i.e. with no further optimization permitted) for pairs of molecules in different configurations as described below. These calculations were carried out using density functional theory (DFT) with a 3-21G basis set and the hybrid B3LYP functional in order to capture some aspects of non-covalent intermolecular interactions. This methodology is not ideal for highly accurate calculations of most non-covalently bound systems [35] and the binding energies that we report are likely to be underestimated. The goal of the calculations is to understand the anisotropy of intermolecular interactions for molecules that are geometrically constrained to mimic some effects of a substrate surface even though metal substrate atoms are not explicitly included in the DFT calculation.

Substrate-defined molecular orientation is implemented in our model DFT calculation (which does not include the substrate atoms) by maintaining the dipole moment vectors of adjacent molecules rigidly fixed in direction with respect

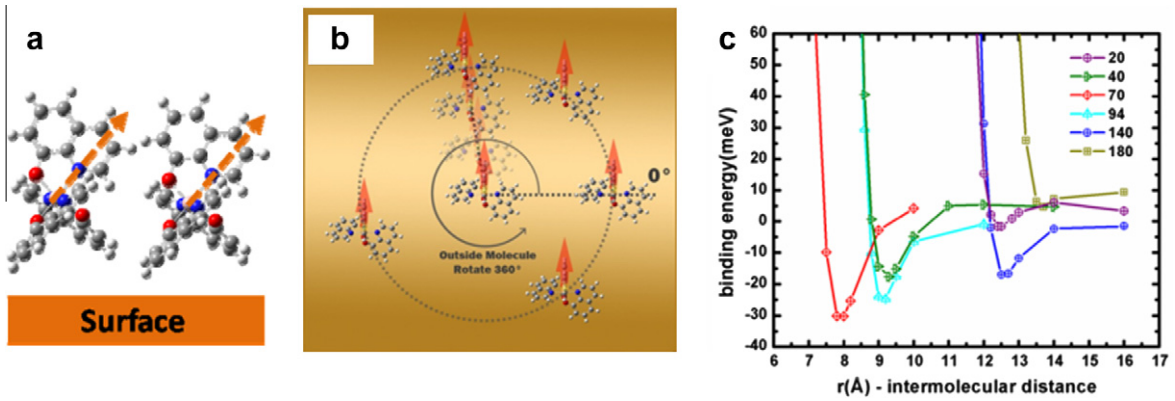

Fig. 4. (a) Schematic of relative orientation of dipoles for identically oriented molecules with respect to an imaginary surface plane; (b) Schematic depiction of model DFT calculations of the interaction between two Alq3 molecules with dipole oriented as indicated in part (a); (c) Binding energy as a function of intermolecular distance for different angular displacement of one molecule with respect to the other.

to an imaginary plane (Fig. 4a). We then rotated one molecule about the other as indicated schematically in Fig. 4b to determine whether there is an anisotropic intermolecular interaction given this orientation constraint. At each angular position, we calculated binding energy as a function of separation between molecules. The separation is reported here as the distance between central Al atoms on different molecules and the binding energy is calculated as the difference between the calculated total energy of a pair at each (r, θ) position and twice the energy of the single molecule (each calculated with 3-21G, B3LYP).

Two different relative orientations of adjacent molecules were considered to explore the favorable adsorption geometries (either dipole "up" or dipole "down") in the DFT studies of Yanagisawa et al. [31]. The first is shown in Fig. 4a and corresponds to adjacent dipole moment vectors both pointed in the same direction. This configuration mimics adsorption geometries in which adjacent molecules are either both "dipole up" or both "dipole down". The binding energy curves for different angles for this configuration are shown in Fig. 4c and exhibit an energy minimum at an angle near 70°. The intermolecular distance at the binding energy minimum in Fig. 4c is about 0.8 nm, consistent with intermolecular spacing observed in our STM studies. Due to the symmetry of this relative arrangement of two Alq3 molecules, only angles between 0° and 180° were calculated since angles from 180° to 360° would be repeat configurations with the roles of the two molecules reversed.

The second configuration considered is shown in Fig. 5a and corresponds to one molecule with an "up" dipole moment and the other with a "down" dipole moment (or *vice versa*). As shown in the calculated binding energies in Fig. 5b, the most significant favorable interaction occurs at an angle of 60° and in the range of about 200–240°. Intermolecular spacings of just under 0.7–1.0 nm at the binding energy minima are again consistent with STM experiments. In this case, the lower symmetry of the pair requires direct calculation for all angles between 0° and 360° since configurations do not repeat.

The anisotropic intermolecular interactions in these calculations are evident by reference to the polar plots in Fig. 6. Points in this figure correspond to the energy at the minimum in the binding energy curve along the radial coordinate (e.g. extracted from Figs. 4 and 5c) as a function of the angular displacement of the rotating molecule. In Fig. 6a, there is a clear set of angles within ±20° about 0°

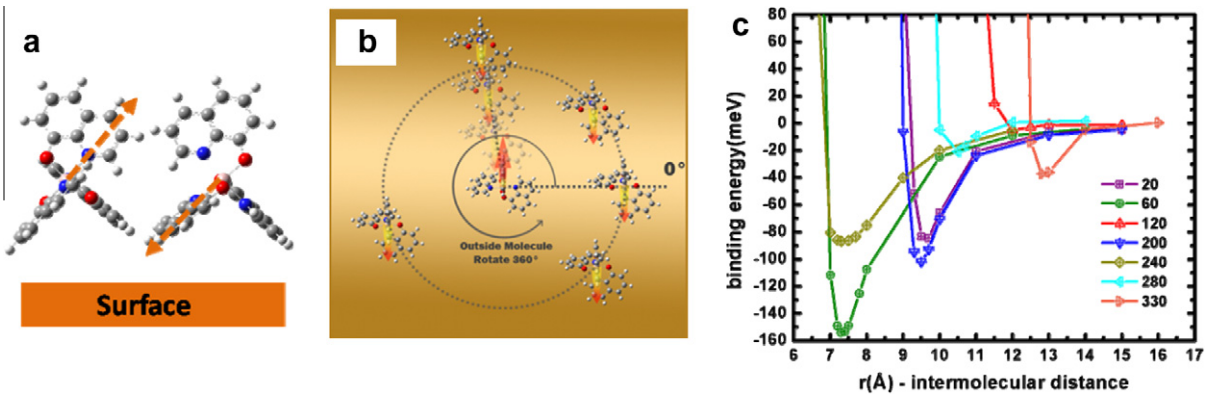

Fig. 5. (a) Schematic of the relative orientation of dipole moments of adjacent molecules differently-oriented with respect to an imaginary surface plane; (b) Schematic depiction of model DFT calculations of the interaction between two Alq3 molecules with differently-oriented dipoles as indicated in part (a); (c) Binding energy as a function of intermolecular distance for different angular displacement of one molecule with respect to the other.

where the interactions are least favorable or possibly repulsive. For most other angles there is a weak binding energy with a maximum at 70° and 250°. Fig. 6b shows a slightly different and weaker anisotropy for configurations with oppositely-oriented dipoles. In this case, there are favored orientations at 60°, 200°, and 240°. Weaker favorable interactions occur for other angles.

The anisotropy seen in Fig. 6 can explain the propensity for disordered chain formation observed in our STM studies. For the two adsorption configurations considered, there is a range of angles for which intermolecular interactions are least favorable. In addition, the range of angles where favorable interactions can occur is relatively broad. This would be expected to lead to anisotropic aggregation where the direction of linear aggregation is somewhat random due to the large angular range of favorable interactions. Our model calculations suggest that this mechanism for chain formation does not demand strict orientational order of Alq3 with respect to the substrate. Molecules could have several random orientations "frozen in" upon arrival at the surface and the general anisotropy inherent in intermolecular interactions would still favor quasi-linear aggregation as opposed to purely random adsorption.

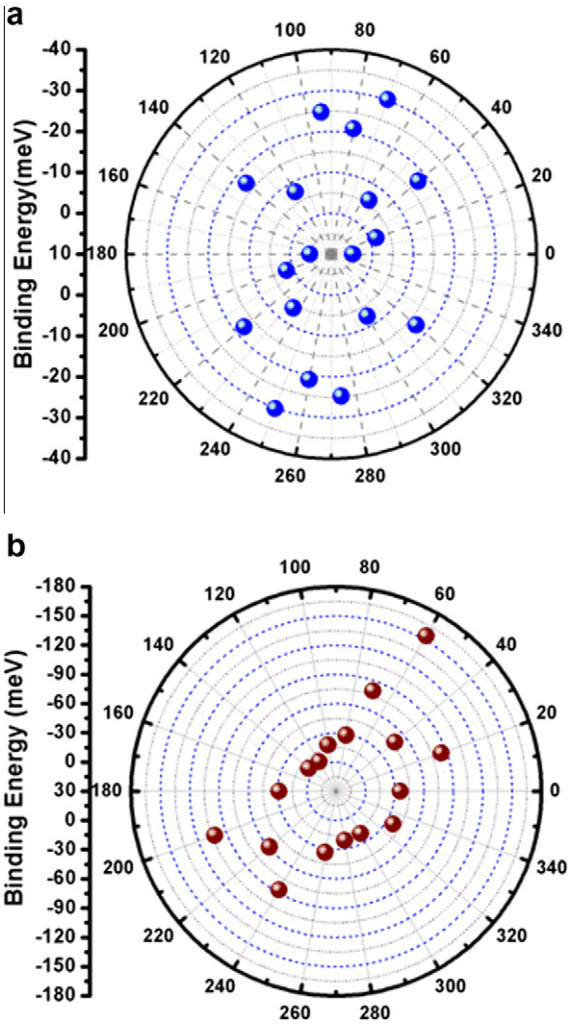

Fig. 6. (a) Polar plot of the depth of the energy of the minimum in each curve from Fig. 4c as a function of angular displacement; (b) Similar polar plot of the minima from Fig. 5c along with other angles.

From a more microscopic perspective, it is plausible that the anisotropic interactions partially originate from direct electrostatic dipole interactions between adjacent Alq3 molecules. The range of angles with favorable binding energies in the model DFT calculations in Fig. 4 suggests nearly head-to-tail dipolar interactions. In fact, the angular pattern of binding energies is reminiscent of the general shape of an electrostatic dipole potential. However, it is important to recognize that the molecular geometry is strongly anisotropic and would lead to chain like aggregation even in the absence of intrinsic molecular dipole moments. In particular, steric effects due to the propeller shape of the molecule will lead to anisotropic interactions even in the absence of a permanent dipole moment.

Direct electrostatic multipole interactions between molecules in the first monolayer on a metal surface have only been reported to drive structure formation in a few cases [36,37]. In general, such interactions would be expected to be strongly screened by the metallic substrate. This can be viewed as an interaction with induced "image dipoles" in the metal surface. However, in the case of Alq3, the charge separation within the molecule is associated with the chemical bonds between the ligands and the central Al atom. These bonds may be sufficiently separated from the metal surface that electrostatic screening does not significantly reduce electrostatic dipole interactions. We have checked that a simple model of screening does not qualitatively change the conclusions about anisotropy drawn from Fig. 6 by calculating the binding energy of a system that includes mirror image molecules to represent image dipoles at selected angles (not shown here). The image dipoles have the effect of making most binding energies more positive, but does not significantly change the general anisotropy of intermolecular interactions.

A complete microscopic understanding of the mechanism of intermolecular interactions would require further calculations that explicitly include the substrate. Of particular importance in such calculations would be the consideration of *substrate-mediated* intermolecular interactions that could result from the formation of hybrid metal–molecule interface states [38,39]. Furthermore, if there is charge transfer between the metal and the molecule, the resulting change in interface dipole could strongly modify intermolecular interactions. Strong charge transfer has recently been found to be a crucial consideration in determining intermolecular interactions at metal molecule interfaces [40].

5. Summary and conclusions

In summary, the growth of the first layer of Alq3 on a Cu(1 1 0) surface has been directly visualized with scanning tunneling microscopy. Strong disorder is observed in the first layer with no tendency toward long range ordering even for films annealed up to 590 K. However, a clear tendency for aggregation of molecules into dimers at low

coverage and randomly wandering chains at high coverage is observed. The formation of chain-like aggregates is attributed to the strong anisotropy of intermolecular interactions that is illustrated by model DFT calculations. Anisotropic interactions may have an electrostatic dipole contribution as well as contributions from intrinsic molecular shape anisotropy.

These observations are significant to ongoing consideration of the most accurate modeling approach for Alq3 device operation. In particular, the observation of strong disorder at the metal–organic interface is in accord with the suggestion of its crucial role in explaining macroscopic device current–voltage characteristics [8]. However, the film structure we observe is not completely random. Our STM measurements show chain-like aggregates that suggest the possibility of *correlated disorder* at the metal–Alq3 interface. Long range spatial correlations in electronic states in disordered organic films have been shown to be a crucial consideration for device modeling [41,42] and should be considered for injection limited transport in Alq3 films.

semiconductors. However, these approaches are difficult to apply to OLEDs because organic materials are generally soluble in the solvents used in lithography, and they experience optical and/or electrical deterioration when exposed to water, oxygen or high-energy electrons.

In order to avoid the degradation of the OLEDs, microstructuring has to start from the substrate, so that corrugation transmits through the organic layer to the opposite electrode. Periodic corrugation [22] on silica substrates by holographic lithography followed with RIE (reactive-ion etching) dry etching, and spontaneously formed quasi-periodic structure on glass substrate [23,24] have been reported. Although trapped optical modes were found coupled out, the substrate pattern transmission approach is encountered with problems such as electronic degradation since the ITO anode has to be sputtered on the corrugated substrates, which increase its surface roughness. It is obvious that the problem may be solved if microstructures are induced into a certain organic functional layer without affecting the flatness of the ITO film. Efforts have been paid along this line, for example, micromoulding [25,26] dendrimers above the ITO anode [27,28]. However, the complexity of the fabrication process and the high fluidity requirement to the polymer limits the practical application of the technology. Periodic change of the refractive index has been inscribed in the active materials without surface-relief structure in the OLEDs by holographic setup, and output characteristics of the OLEDs have been modified [29]. However, this method is restricted by realizing a polymer with both photosensitive and charge-transporting qualities to undergo a photoisomerization and act as functional layer in OLEDs. In addition, a necessity of large difference in the periodic changed refractive index for the highly efficient Bragg scattering is another limitation.

In this communication, we solve this problem by employing a one-step fabrication approach to introduce a

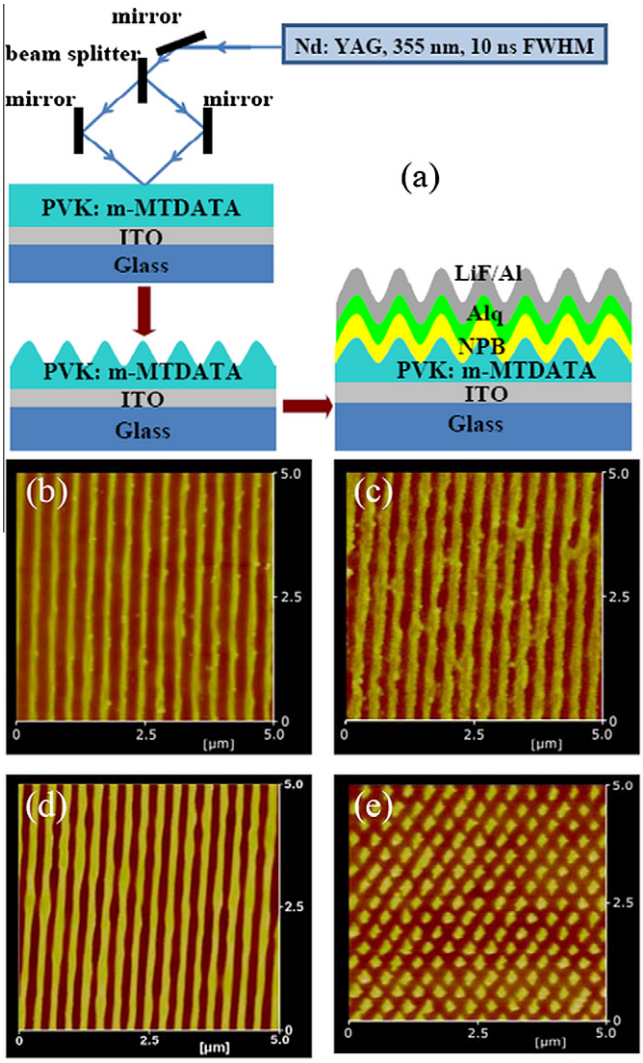

Fig. 1. Scheme of introducing periodic corrugation into OLED by laser ablation (a), and AFM images of the ablated corrugation. 1-D grating with period of 350 nm on the HTL (b) and the cathode surface of the OLED (c), the 1-D grating with period of 250 nm (d) and 2-D grating with 350-nm period on the HTL surface (e).

grating onto the functional layers of the OLEDs. Most polymers show a strong sensitivity to UV laser ablation condition and possess low ablation thresholds, so that a periodic grating can be directly recorded on the hole-transport layer (HTL) of OLEDs via laser ablation by two interference beams. Gratings with appropriate period and depth for Bragg scattering in OLEDs are easily obtained by adjusting the angle of the two beams and the laser fluence. Experimentally, three times enhancement in the current efficiency has been observed from the corrugated OLEDs with appropriate grating period. Theoretical simulations demonstrate that the power lost to both WG and SPP modes have been recovered. This one-step laser ablation on HTL provides a simple and facile approach with high resolution, high controllability and reproducibility to obtain periodically corrugated OLEDs.

2. Experimental details

2.1. Preparation of periodic microstructure by laser ablation

A conducting polymer widely used in polymer LEDs as a hole-transport material, poly(*N*-vinyl carbazole) (PVK) is chosen and it is spin-coated on the ITO glass for the fabrication of the corrugated HTL in OLEDs. 4,4′,4″-Tris(3-methylphenylphe-nylamino)triphenylamine (*m*-MTDATA) [30] was doped into the PVK with a concentration of 10% by weight to enhance the hole injection and transport of the HTL. The experimental scheme for laser ablation on PVK:*m*-MTDATA film and fabrication sequence of the corrugated OLED is illustrated in Fig. 1(a). The ablation experiments used a frequency-tripled Nd:YAG laser (Spectra-physics Company) with 3 nm pulse width, 10 ns pulse length, 10 Hz repetition rate and 355 nm wavelength. An ITO coated glass substrate was cleaned with acetone and ethanol. The HTL was spin-coated at 4000 rpm/s speed for 70 nm thicknesses. The sample was prebaked in vacuum for 30 min at 60 °C to evaporate the organic solvent. Then, the sample was exposed by two beams which were split from the UV laser with beam size of ~6 mm in diameter. The microstructure recorded on the polymer film with different period and depth was obtained by adjusting the writing angle and the laser power. The microstructure fabrication was conducted in air at room temperature using single laser pulse. The morphologies of the microstructure were characterized by an atomic force microscopy (AFM, Digital Instruments Nanoscope IIIA) in the contact mode and field emission scanning electron microscope (SEM, JSM-7500F, JEOL).

2.2. OLED fabrication and evaluation

Prepared ITO substrates coated with corrugated HTL were immediately brought into a thermal evaporation chamber. The 20 nm thick hole transporting layer of *N*,*N*′-diphenyl-*N*,*N*′-bis(1,1′-biphenyl)-4,4′-diamine (NPB), 50 nm thick emitting layer of tris-(8-hydroxyquinoline) aluminum (Alq_3) and cathode of LiF (1 nm)/Al (100 nm) were evaporated sequentially. Here, all layers were prepared by thermal evaporation in a high vacuum system with the pressure of less than 5×10^{-4} Pa. The active area of the devices was 2×2 mm^2. Their current density–voltage–luminance (*J*–*V*–*L*) characteristics were measured by Keithley 2400 programmable voltage–current source and Photo Research PR-655 spectrophotometer. The emission spectra at different observation angle were collected with a lens and then collimated and focused into the entrance slit of a 300-mm monochromator/spectrograph (SR-3031-A, Andor) to limit the angular acceptance to ~1°. The spectrogram of the emission was recorded using a charge coupled device (iDus, Andor). The OLEDs were placed on a rotation stage with the grooves parallel to the rotation axis. All of the measurements were conducted in air at room temperature.

3. Results and discussion

3.1. Investigation of periodically corrugated HTL by laser ablation

Laser ablation has been extensively studied, both theoretically and experimentally [31–33]. Several models have been proposed for ablation of polymers, involving photochemical effects (direct bond breaking) [34], photothermal effects (thermally broken bonds) [35], photophysical (mechanical stress) [36] or a combination of them. Although the chemical nature of the reaction that are involved is still not clearly verified, it does offer an alternative, simple and fast technique of direct generation of the microstructure on organic functional materials. Through combining with a multi-beam interference, the one-step fabrication of the microstructure can be faster and highly reproducible with the period from microns to sub 100 nm [37–39]. Shown in Fig. 1(b)–(e) is the atom force microscopy (AFM) images of a laser ablated grating on the PVK:*m*-MTDATA film and the cathode surfaces after deposition of organic and metallic cathode layers by thermal evaporation. As can be seen, the profile of the top surface was essentially a replication of the underlying nanostructure, therefore, forming a periodic corrugation throughout all the layers on the ITO substrate.

Due to the scattering and diffraction of the grating, the structured surface shows varied colors from structures of different periods, which are clearly observed by the naked human eyes as shown in Fig. 2(a). The microstructure on the PVK:*m*-MTDATA film in a large scale is investigated by scanning electron microscope (SEM) and shows homogeneous profile (the inset of Fig. 2(b). A 6-mm diameter area of uniform corrugation was produced with single-shot laser exposure, in another word, the exposure duration is only 10 ns. Provided that the laser pulse energy is sufficient after laser beam expansion, and assumed the laser repetition rate of 10 Hz, and the wafer transferring time of 0.1 s in a production line, the introduction of the microstructures in an entire wafer by single-pulse exposure takes only 0.1 s and as a result, the cost would be very low.

The controllability of the microstructure parameters is quite high. Experimentally, we found the groove depth is fully determined by the laser fluence at low laser energy

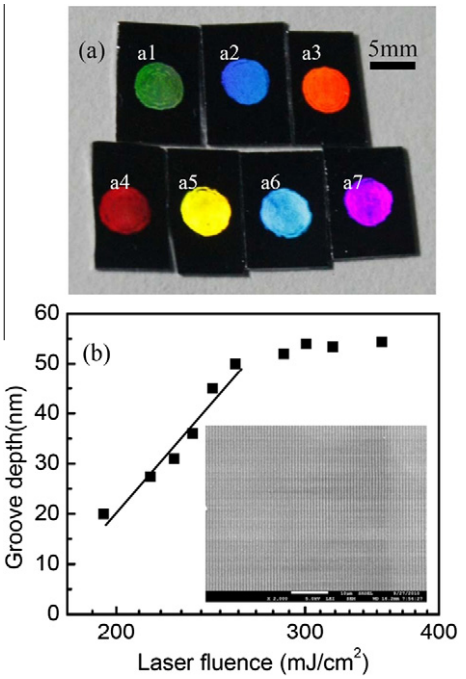

Fig. 2. (a) Photograph of the periodic corrugation on the PVK:*m*-MTDATA film with various period of a1 2000 nm, a2 1500 nm, a3 1000 nm, a4 800 nm, a5 600 nm, a6 400 nm, and a7 350 nm. (b) Etch depth by one-pulse laser ablation as a function of the laser fluence for 70 nm PVK:*m*-MTDATA film. The inset in (b) shows the large-scale SEM image of the grating on the PVK:*m*-MTDATA film with period of 800 nm and the scale bar represents 10 μm.

density (<270 mJ/cm^2), and it follows Beer's law [31], which sums up the light energy absorbed by the layer:

$$x_f = (1/\alpha)\ln(F/F_0) \quad (1)$$

where, x_f is the ablation depth per pulse. Other symbols denote: α, the linear absorption coefficient; F, the laser fluence, and F_0, the fluence threshold. The linear dependence of the ablation depth on the logarithm of the fluence is shown in Fig. 2(b), which is deviated, and is gradually saturated to ~55 nm after $F > 270$ mJ/cm^2. This derivation at high fluence is due to limitation of the ablation depth by the film thickness. The threshold fluence for the ablation of the two-beam interference on a 70-nm thick PVK:*m*-MTDATA film is $F_0 = \sim 180$ mJ/cm^2 (1.8×10^{11} W/m^2). This level of the laser irradiation, almost four-order lower than the laser-induced damage threshold of typical transparent solids, for example, 10^{15} W/m^2 for most fused silica [40], induce no any damage to the ITO substrate.

3.2. EL performance of the corrugated OLEDs

The tris-(8-hydroxyquinoline) aluminum (Alq_3)-based OLEDs with one-dimensional (1-D) periodic corrugation were fabricated according to the design in Fig. 1(a). Various grating period from 200 to 400 nm have been tested, and the grating depth is fixed at 40 nm. The devices structure is ITO/PVK:*m*-MTDATA (70 nm)/NPB (20 nm)/Alq_3 (50 nm)/LiF (1 nm)/Al (100 nm). To investigate the effect

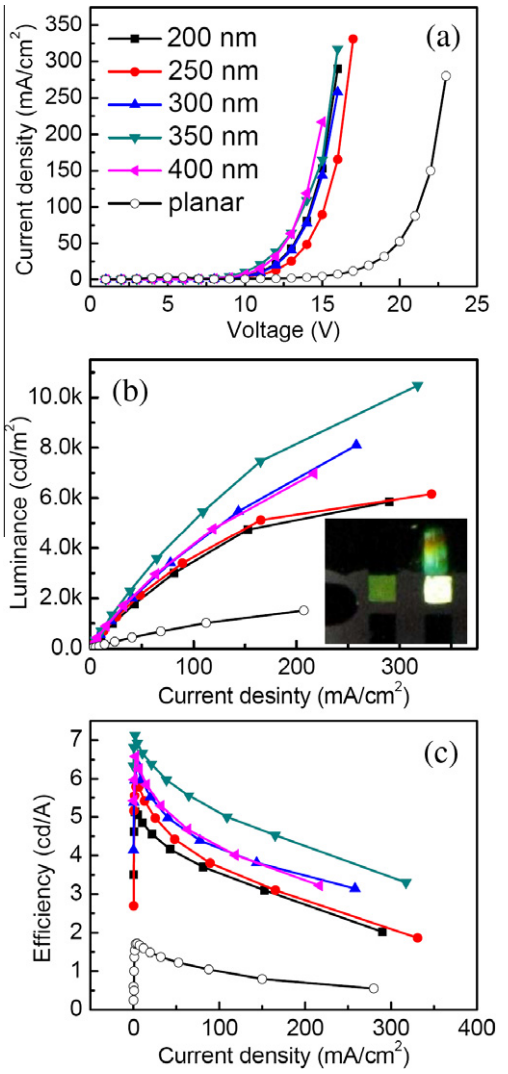

Fig. 3. EL performance of the corrugated and planar OLEDs. Current density–voltage (a), current density–luminance (b), current density–efficiency (c) characteristics. Inset in (b) shows the photograph of the operating corrugated and planar OLEDs at the same substrate and under same driving voltage.

of the grating, flat OLEDs were fabricated on the planar region of the ITO glass substrate. Considering that the average thickness of the corrugated HTL is decreased from 70 to 50 nm after laser ablation, the thickness of the HTL for the planar devices is designed to 50 nm to be equal to that of the corrugated HTL, so that the effect of the HTL thickness on the hole transport could be excluded. Actually, a 20-nm average difference between the HTL thickness before and after ablation has no much effect on the planar OLED performance through the comparison with experiment. The corrugated OLEDs show increased current density as shown in Fig. 3(a). The introduction of the corrugation has the effect on increasing the effective area of the operating devices, which would result in the increased current density. On the other hand, the ablation on the HTL has probably influenced the hole-transport

ability of the material, for which further study is needed. It can be clearly seen in Fig. 3(b) and (c) that the corrugated OLEDs exhibit much higher luminance and current efficiency than that of the planar devices and shows grating-period dependence. Both luminance and efficiency increase with the increasing grating period, and reach the maximum at 350 nm, and then decrease with further increment to 400 nm. In case of 350 nm, the luminance at the current density of 100 mA/cm^2 is 5100 cd/m^2 and the maximum current efficiency is 7.2 cd/A, respectively, while it is 910 cd/m^2, and 1.8 cd/A, respectively, for the planar devices. This corresponds to three times enhancement in the maximum current efficiency. The photograph of the operating OLEDs at the same substrate and under same driving voltage of 12 V (inset in Fig. 3(b)) indicates that much brighter emission can be obtained from the corrugated OLED.

3.3. EL spectra from the corrugated OLEDs

Understanding of the enhancement mechanism starts from analyzing the scattering of guided modes from a device by measuring its emission spectra as a function of observation angle. The scattered modes appear as additional emission peaks in intensity which shifts in wavelength as the angle varies. Fig. 4 shows the electroluminescent (EL) spectra measured from the experimental devices employing different grating period at several observation angles off to the surface normal. The EL spectra from the corrugated devices are more complex than that from the flat devices. Additional peaks with different wavelength are observed from the devices with varied grating period. The EL spectra at normal direction from the devices with different grating periods are summarized in Fig. 4(f) together with an EL spectrum from a planar

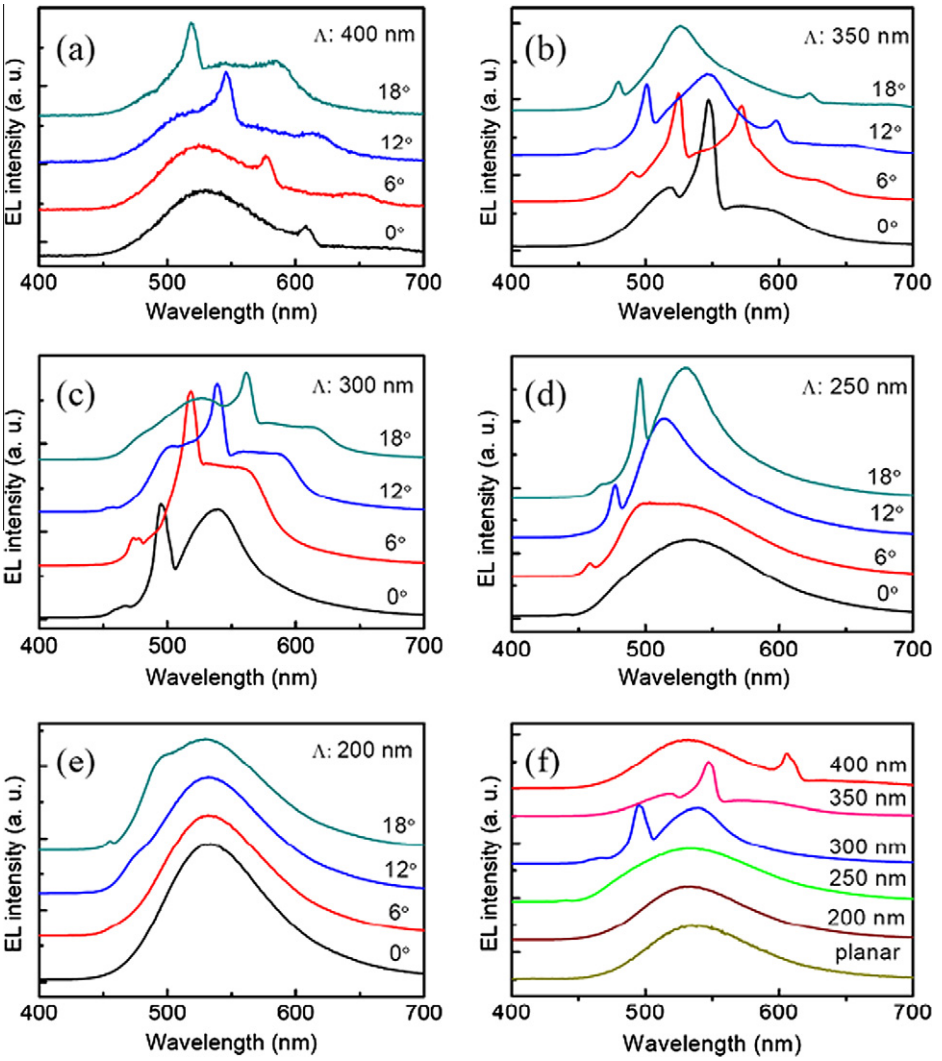

Fig. 4. The EL spectra at different observation angle from the corrugated OLEDs with various grating period (Λ). (a) 400 nm, (b) 350 nm, (c) 300 nm, (d) 250 nm, and (e) 200 nm. Their EL spectra at normal direction are summarized in (f).

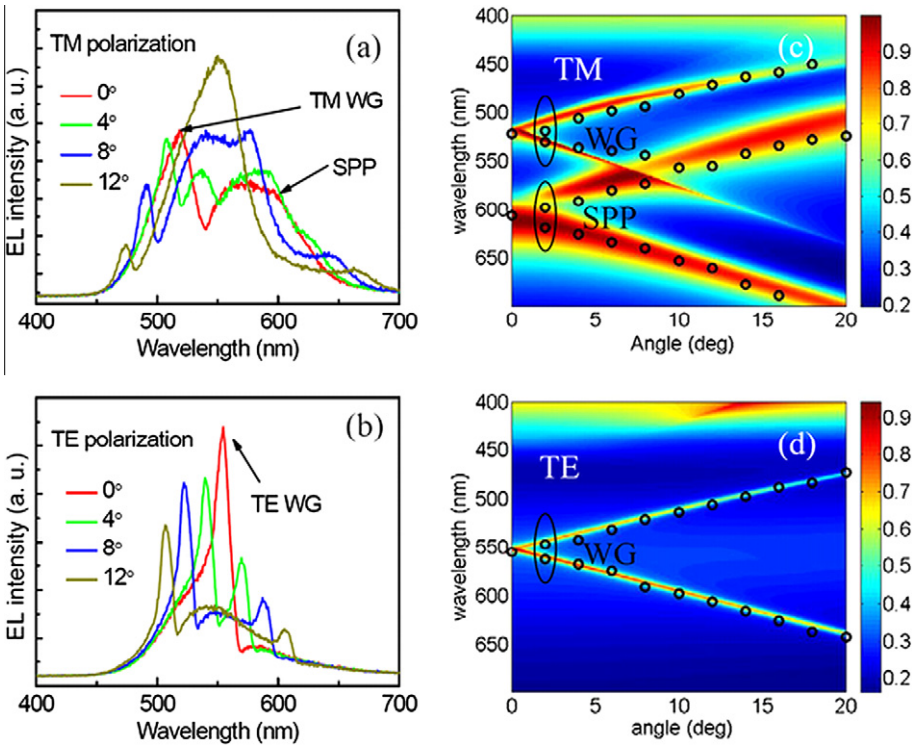

Fig. 5. Measured EL spectra with TM (a) and TE (b) polarization at different observation angle from the corrugated OLEDs with 350-nm grating. And the wavelength versus incident angle for the calculated dispersion relation of the corrugated OLEDs for TM (c) and TE (d) polarization. The measured dispersion relation extracted from the EL spectra (circles) is also shown in (c) and (d).

device at normal direction. All the additional peaks exhibit obvious blueshift with the decreasing grating period, and some of them then move out of the EL spectra for the grating period less than 250 nm. For the devices with 350 nm grating period, peaks at around 520, 547 and 595 nm are observed at normal direction, and the bandwidth of the peak at 595 nm is broader than that of the others. Each of them splits into two peaks, which shifts in wavelength with the increasing observation angle. Both TM and TE polarized EL spectra are also measured and shown in Fig. 5(a) and (b), which indicate that the modes corresponds to the emission peaks of 520 and 595 nm at the normal direction are TM polarized and that of 547 nm are TE polarized.

4. Simulated optical modes in the corrugated OLEDs

To establish the optical modes supported by the microstructured OLEDs, absorption spectra are simulated. A number of absorption maxima could be seen, if the incident light is coupled into modes supported by the structure. We apply the scattered matrix approach [41] to deal with our periodically microstructured OLED with metal and organic multilayered structure. The overall scattering of the OLEDs is determined by first evaluating a matrix of scattering parameters for each individual layer through the solving of Maxwell's equation, and then forming a scattering matrix for the entire structure by the relevant boundary conditions. As high as fifty orders spatial harmonics are taken into consideration. Given an incoming wave from the ITO glass side, the reflection waves have been computed. Absorption spectra are obtained from complementary relation between reflection and absorption. The grating with rectangular cross section and fill factor of 50% was employed and the refractive index of the organic materials employed in the OLEDs was measured by ellipsometry for the simulation. The dispersion map derived from the simulated absorption spectra for the corrugated device with 350 nm grating period and for both TM and TE polarization is shown in Fig. 5(c) and (d), in which the absorption intensity appears as a function of both incident angles and absorption wavelength. The dispersion relation curve constructed from the experimental EL emission spectra with both TM and TE polarization (Fig. 5(c) and (d)) are also plotted. It can be seen that there is excellent agreement between the theoretical calculation and experimental measurement. Actually both the calculated peak position at different angle and bandwidth of the emission spectra coincide with that of measured data very well. The optical modes within the device structure appear as EL maxima indicates an efficiently outcoupling of light from those optical modes, which are normally non-radiative, by the addition of the appropriate wavelength scale microstructure.

Both SPP and WG modes could be coupled out by the microstructure. The spatial magnetic field (H_y) distribution across the device structure as a function of position with

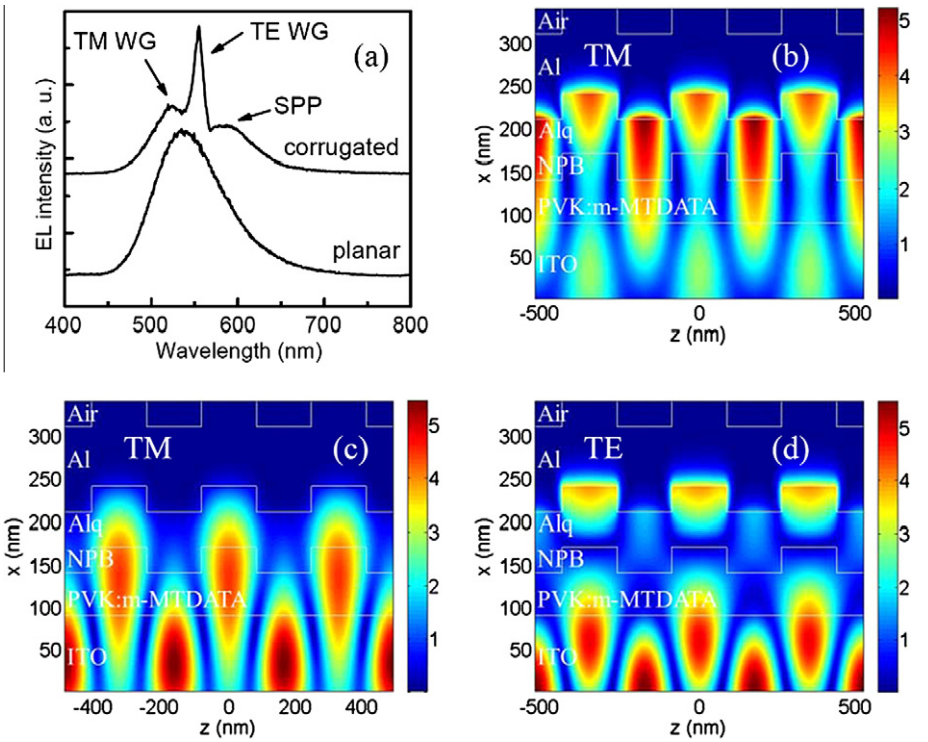

Fig. 6. EL spectra from both corrugated OLED with 350-nm grating and planar devices at normal direction (a), and distribution of the magnetic field intensity in the corrugated OLEDs at the wavelength of incident polarized light of 595 nm (b), 547 nm (c) and 520 nm (d), respectively.

the normal incident light is calculated to identify the optical modes for the devices with 350 nm grating period. Fig. 6 shows the field distribution at the illumination wavelength of 595, 547 and 520 nm, respectively, which corresponds to the three peak wavelength of the EL emission at normal direction. The field intensity is with maximum at the Al/Alq_3 interface and decay along the direction perpendicular to it at the wavelength of 595 nm

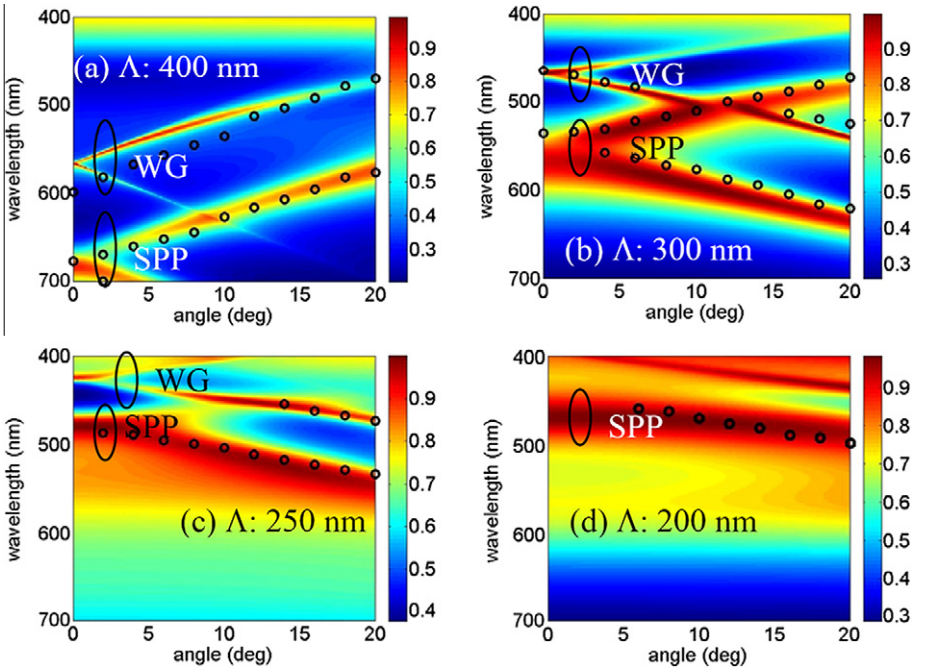

Fig. 7. Wavelength versus incident angle for the calculated dispersion relation of the corrugated OLEDs with various grating period (Λ) and for TM polarization. The measured dispersion relation extracted from the EL spectra (circles) is also shown.

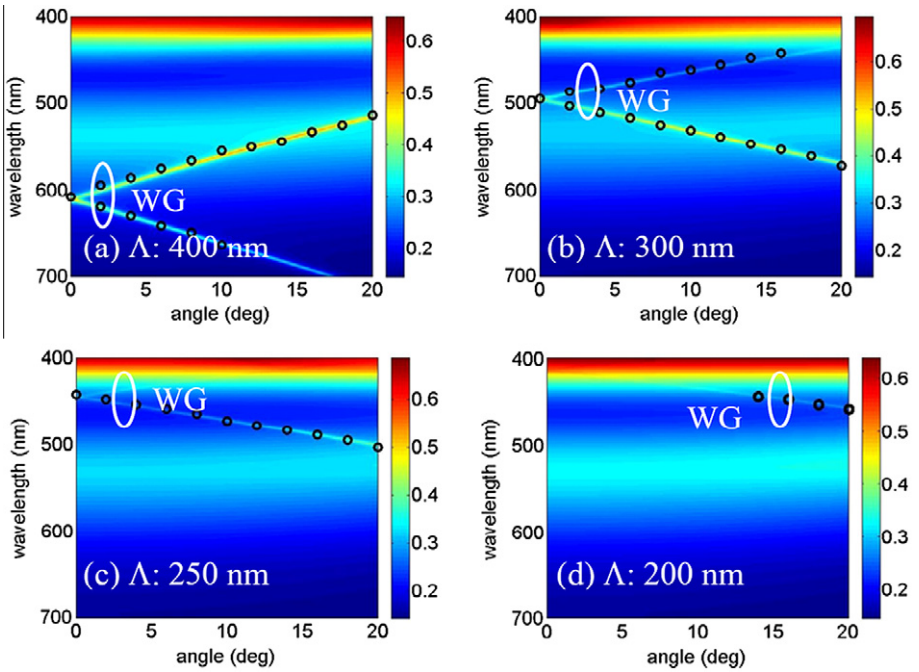

Fig. 8. Wavelength versus incident angle for the calculated dispersion relation of the corrugated OLEDs with various grating period and for TE polarization. The measured dispersion relation extracted from the EL spectra (circles) is also shown.

as shown in Fig. 6(b). We can conclude from this field distribution that the emission peak at 595 nm originates from SPP modes, since SPPs are surface wave and propagating along an interface between a metal and dielectric [42–46]. On the other hand, the field at the wavelength of 547 and 520 nm is mainly confined within the ITO and organic layers (Fig. 6(c) and (d)), which should be assigned to the TM and TE polarized WG modes due to the high refractive index of ITO and organic layers. Therefore the additional peaks shown in the EL spectra in Fig. 6(a) is identified as the SPP mode associated with the Al cathode/organic interface, and WG mode confined within the ITO and organic layers, respectively. This conclusion is applicable to the corrugated OLEDs with the various periods, except that the peak wavelength corresponding to the SPP and WG modes is shift with the different period, which has been verified by the following simulations.

The dispersion map derived from the simulated absorption spectra for the corrugated device with 400, 300, 250 and 200 nm grating period and for both TM and TE polarization is shown in Figs. 7 and 8, respectively, which also show agreement with the experimentally measurement extracted from the EL spectra. The extracted light emission from both the SPP and WG modes show blueshift with the decreasing of the grating period. Comparing the EL spectra from the corrugated and flat OLEDs at the normal direction (Fig. 4(f)), we can see that both the extracted SPP and WG modes located within the emission wavelength region of the Alq_3 emission for the device with the 350 nm grating period at the normal direction, which contribute to a more efficient outcoupling of the optical modes trapped in the devices and result in the highest EL efficiency for this OLED. Both the TM and TE polarized WG modes move out of the emission region of Alq_3 in case of the 200 and 250 nm grating period, while the emission band from the SPP mode becomes flat, which results in a smaller shift of the EL spectra at different observation angle and has been verified in Fig. 4(d) and (e). Therefore an improved viewing characteristic is expected. Our experimental and simulated data indicate that the power lost to both SPP and WG modes has been successfully recovered as light in far field for the corrugated OLEDs, which contributes to a much enhanced light extraction. It is possible to obtain a further improved light outcoupling by employing a 2-D grating due to its higher efficiency in coupling SPPs to far-filed radiation [47]. 2-D grating on the PVK:*m*-MTDATA by laser ablation has been realized (Fig. 1(e)), and further investigation are needed to explore its effect on the light outcoupling.

5. Conclusions

A periodic wavelength-scale corrugation has been introduced into OLEDs by one-step laser ablation of two interference beams, and enhanced outcoupling of radiation has been demonstrated. The introduction of this microstructure has allowed the observation of the emission originating from the SPP and WG modes, which are usually trapped within planar devices. An enhanced EL efficiency from the corrugated OLEDs has been observed. The microstructure has been directly formed on the HTL of the OLEDs by laser ablation without degradation of the device performance. While combining with the two-beam interference, both the period and the groove depth of the grating can be easily and precisely controlled, so that it is applicable to

OLEDs with different emission wavelength. With beam expansion, an entire wafer could be structured with one-shot nanosecond laser ablation, implying a broad industrial application prospect of the one-step efficient large-area approaches for OLEDs with much enhanced light outcoupling efficiency.

phase separation, domain size, and molecular orientation from electron diffraction [8], sample preparation for TEM measurements can be difficult. It requires deposition on a TEM grid which does not represent the actual morphology of the device. Cross-sectioning of the actual device may damage organic materials or alter their native morphology. Other major factors which limit accuracies are the beam damage and the strong charging of the molecular film when exposed to accelerated electrons especially when the substrate is an insulating gate oxide.

The X-ray absorption technique used here keeps electronic charging effects relatively low and can be even applied to insulating materials [9]. Scanning transmission X-ray microscopy (STXM) has recently been used to investigate the molecular orientation and composition/structure of thin films. It can be adapted to a wide range of sample environments, such as in magnetic fields [10], variable temperature [11], polymer [12] and environmental samples in aqueous media [13]. Moreover, the radiation damage caused by soft X-rays was shown to be low [14]. STXM has also been used to obtain information about the composition of organic materials [15] and their molecular orientation [9]. This information can be derived from the variation in the photon flux and the change in polarization in the carbon K edge region, based on the near edge X-ray absorption fine structure (NEXAFS) effect [16].

Recently, we used STXM to map the molecular orientation of pentacene underneath the Au contacts and in the channel regions of organic TFTs [9]. The goal of this current work is to investigate the effect of surface modification on the pentacene grain orientation distribution. We correlate the structural information with electronic information of pentacene TFTs. Pentacene was chosen because of its high charge carrier mobility and its strong linear dichroism effect for the π^* resonances at the carbon K edge between 283 and 287 eV. A pentacene molecule consists of five linearly fused aromatic rings. The two molecules in the unit cell of pentacene form a herringbone pattern with an angle of 53° [17]. In thin films, the long axis of the pentacene molecules were observed to only deviate by 6° from the substrate normal [17].

2. Results and discussion

The experimental setup is shown in Fig. 1. The transistor devices were built up on a SiO_2 coated SiN_x membrane which was used as a gate oxide. The SiO_2 was modified with the following silane molecules: octyltrichlorosilane (**1**), undecyltrichlorosilane (**2**), heptadecyltrichlorosilane (**3**), octadecyltrichlorosilane (**4**), as well as with (heptadecafluoro-1,1,2,2,-tetrahydrodecyl)trimethoxysilane (**5**), phenethyltrimethoxysilane (**6**), and 11-bromoundecyltrimethoxysilane (**7**). A pentacene film (30 nm thick, measured with a quartz crystal monitor) was then deposited on top. The transistor was completed by Au electrode

deposition as the source, drain, and gate electrodes as reported earlier [9]. The charge carrier mobility for pentacene TFTs on different surfaces is shown in Table 1.

The transistor devices are used directly for STXM studies. The X-ray beam was focused by a zone plate and after passing an order sorting aperture, a 30 nm large X-ray spot raster scans the sample area. The transmitted X-rays are detected by a photo detector. Through this approach, a two-dimensional image of the sample can be obtained. Linearly polarized X-ray radiation was used to study the molecular in-plane orientation.

A schematic top view on the pentacene molecules is shown in Fig. 2(a). The angles between the short unit cell axis "a" and the transition dipole moments $\mathbf{p}_1$ and $\mathbf{p}_2$ of the π^* orbitals are represented by δ with 2δ approximately 53° [3]. The absorbance $A(x,y)$ is maximal when the electric field vector of the X-rays **E** is parallel to the transition dipole moment of the molecule. The relation between $A(x,y)$, the polarization angle of the X-rays α_p, and the angle $\beta(x,y)$ between the short molecule axis "a" and the electric field vector **E** can be written as:

$$A(x,y) = a_0 t\left(1 + a_1 \cos^2(\alpha_p - \beta(x,y) - \delta) + a_1 \cos^2(\alpha_p - \beta(x,y) + \delta)\right) \quad (1)$$

Herein, a_0 is the absorption of the pentacene film with a thickness t, a_1 the strength of the linear dichroism effect, and α_p the X-ray polarization angle [9]. In the following the angle $\alpha_p - \beta(x,y)$, i.e. the orientation of the short unit cell axis "a" with respect to the horizontal axis, will be illustrated by different colors according to the color wheel scheme in Fig. 3(d).

Fig. 2(b) shows the X-ray absorption spectrum of a pentacene grain for two different polarization angles $\alpha_p = 0°$ and 90°. In the energy range of 283–287 eV the difference in the X-ray absorption intensity is very pronounced and is suitable for the determination of the molecular orientation. These resonances correspond to transitions of core electrons in carbon into unoccupied π^* states of the sp^2-hybridized carbon atoms [16].

The angular dependence of the absorbance for two single grains at 285.5 eV is plotted in Fig. 2(c). The X-ray polarization angle was varied between 0° and 90° with 10° step width. The data were fitted using Eq. (1). The STXM images on the bottom of Fig. 2(c) illustrate the changes in the X-ray absorption characteristic for every 30° and show which grains have been selected for plotting the angular dependent absorption behavior. Both the grains A and B show different angular dependences due to their different in-plane orientation. Even though there are two independent molecules in the pentacene unit cell, only one local minimum or maximum in the X-ray absorption spectrum between 0° and 90° was observed. The reason can be explained through the following trigonometric relation:

$$\cos^2(\alpha_p - \beta(x,y) - \delta) + \cos^2(\alpha_p - \beta(x,y) + \delta) = \cos^2(\alpha_p - \beta(x,y))\cos(2\delta) \quad (2)$$

where $\cos(2\delta)$ is constant since the angle between two adjacent molecules is fixed. This finding is important for the interpretation of X-ray microscopy data because regardless of the number of molecules present in the unit cell, there will only be one "average" signal from the

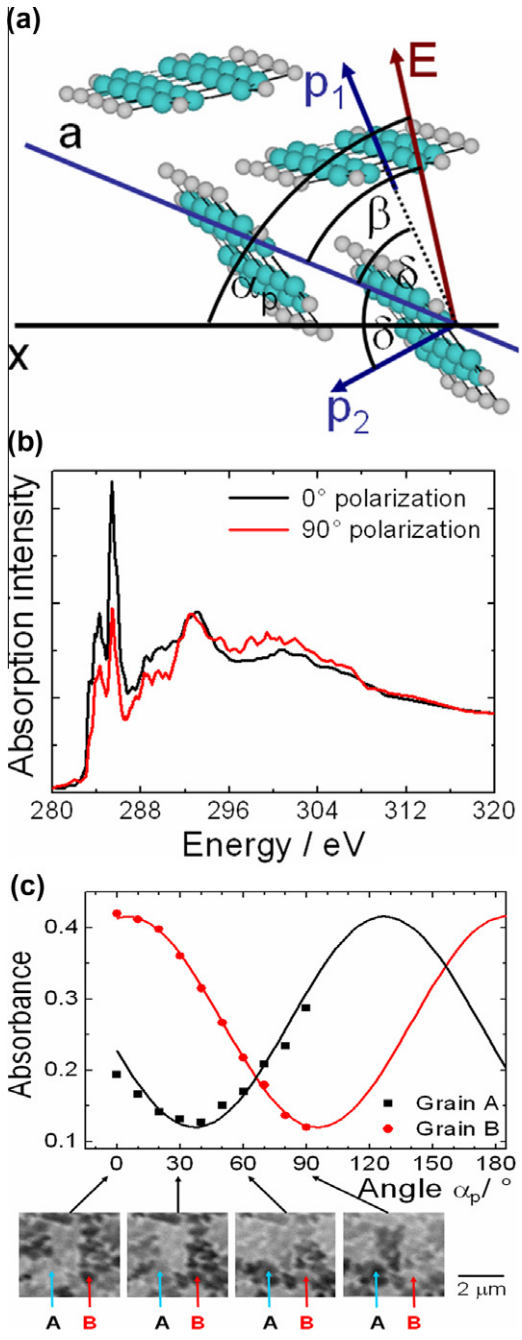

Fig. 2. (a) Top view on four pentacene molecules. The electric field vector **E** of the X-rays interacts with the transition dipole moments $\mathbf{p}_1$ and $\mathbf{p}_2$ of the π^* orbitals of the pentacene molecules. The X-ray polarization angle α_p is varied between 0 and 90°. The absorption intensity reaches its maximum when **E** and the short unit cell axis "a" are parallel to each other ($\beta = 0$). (b) X-ray absorption spectrum of a pentacene grain taken at two different polarization angles $\alpha_p = 0$ and 90°. (c) Angular dependency of the X-ray absorbance at the energy 285.5 eV for linearly polarized X-rays with angles α_p going from 0° to 90° in 10° steps. STXM images for 0°, 30°, 60°, and 90° are shown on the bottom. Measured values were fitted using Eq. (1). Absorbance values from 90° to 180° were extrapolated.

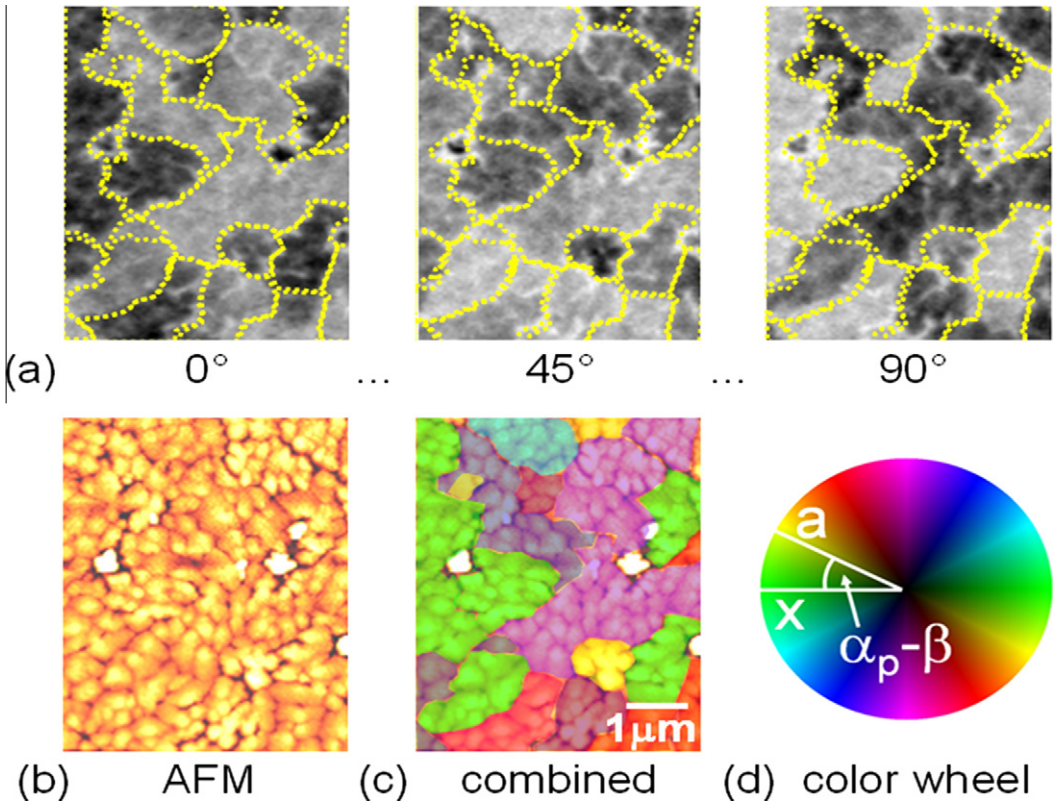

Fig. 3. (a) STXM images of a 30 nm thick pentacene film on a SiN_x membrane, coated with **4**. The measurements were performed using linearly polarized X-rays with $\alpha_p = 0°$, 45°, and 90°. The broken lines in the images illustrate the grain boundaries as determined by STXM. (b) An AFM image was recorded at the place where the STXM images were taken. (c) The gained information from the STXM measurements about the molecular orientation is combined with the AFM image. The different colors represent the in-plane orientation according to the color wheel scheme in (d). All images are on the same length scale, see bar in (c). (d) Color wheel scheme to illustrate the angle $\alpha_p - \beta$ between "*a*" and "*x*" where, e.g., green stands for 0°, red for 60°, and blue for 120°. (For interpretation of the references in color in this figure legend, the reader is referred to the web version of this article.)

X-ray absorption. The fitting procedure leads to $\alpha_p - \beta(x,y) = (127 \pm 2)°$ and $(5 \pm 2)°$ for grain A and grain B, respectively with $a_0 t = 0.268$ and $a_1 = 0.552$.

Fig. 3(a) shows the STXM images for three different linear polarizations. For the determination of the molecular orientation all data sets discussed herein consist of images taken in 15° increments from 0° to 90°. All the images collected are summarized in the supplementary material. The angle of the grains can be read according to the color wheel scheme in Fig. 3(d) where the colors green[1], red, and blue illustrate the angle of the short unit cell axis "*a*" of pentacene with an angle 0°, 60°, and 120°, respectively. Fig. 3(b) was recorded at the same position where the STXM images in Fig. 3(a) were taken. The AFM data themselves do not allow a determination of the real grain size due to crystal lobes and overgrowth. Only the combination with the STXM data provides clear evidence about the molecular orientation and, consequently, the grain size. Fig. 3(c) combines the topography information of the AFM with the information about the molecular orientation from the STXM measurements. From this image the average grain size can be determined and can be compared when changing, for example, the SAM on which the pentacene is grown.

Fig. 4 shows the grain orientation for pentacene films deposited on four alkyl silanes with different chain lengths (**1**–**4**), as well as silanes with different end groups of different polarity such as **5**–**7**. The grain size was observed to increase as the molecular chain length increases. The pentacene grains on fluorine **5**, phenyl **6**, and bromine **7** functionalized surfaces were observed to be much smaller in size (notice different length scales in the second line in Fig. 4). This trend was found to correlate with the surface roughness of the samples we prepared. For example, as the SAM surface roughness decreases in the sequence **5** → **2** → **3** → **4** (cf. Fig. S4 of the supplementary material), the grain size of the pentacene, deposited on top of the corresponding surface, increased.

The results of the statistical evaluation, performed on the images in Fig. 4, are shown in Fig. 5. The grain area varies strongly for different surfaces. The average values for the grain size are summarized in Table 1, together with the charge carrier mobility values of the corresponding transistor devices. The average grain size values increased from 0.54 µm^2 (**1**) to 1.5 µm^2 (**4**). The smallest values were

[1] For interpretation of color in Fig. 3, the reader is referred to the web version of this article.

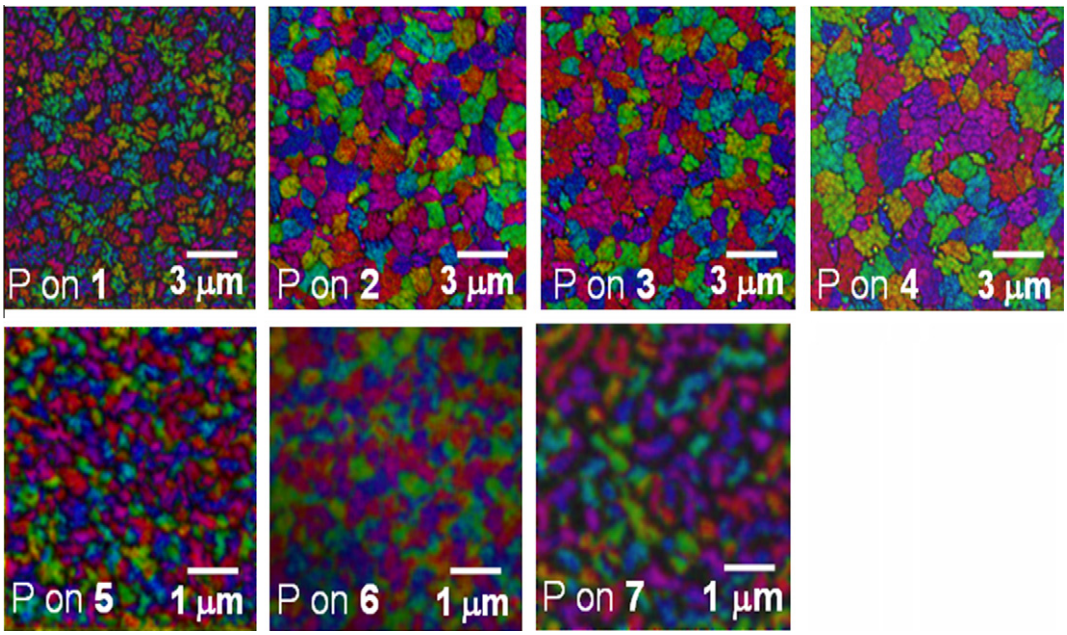

Fig. 4. Grain orientation, derived from STXM measurements, for pentacene (P) deposited on octyltrichlorsilane (**1**), undecyltrichlorsilane (**2**), heptadecyltrichlorosilane (**3**), octadecyltrichlorosilane (**4**), as well as with (heptadecafluoro-1,1,2,2,-tetrahydrodecyl)trimethoxysilane (**5**), phenethyltrimethoxysilane (**6**), and 11-bromoundecyltrimethoxysilane (**7**). Please notice the different length scales in the first and in the second row.

found for **5**, **6**, and **7** ranging from 0.06 to 0.15 μm^2 average grain size.

The charge carrier mobility, grain size, and relative grain boundary area for **1**–**4** are plotted in Fig. 6(a). The ratio of low- to high-angle grain boundaries is plotted in Fig. 6(b). The charge carrier mobility values are observed to be in the range of 0.2–0.6 $cm^2 V^{-1} s^{-1}$ for **1**–**4**, with **1** having the lowest value. With corresponding increase in the alkyl chain length, the grain size increased from **1** to **4**, as well as the corresponding mobility. In the same sequence, the ratio of the GB area to the total area covered by the grains decreased significantly. The ratio of low- to high-angle grain boundaries is nearly identical for pentacene grains grown on different SAMs. This is a clear indication that the charge carrier mobility is mainly influenced by the grain size or the area occupied by the grain boundaries.

The different chain lengths and polarities of the end groups are expected to affect the packing density and conformation of the molecular chain and the ultimate structure depends on all possible interactions [18]. Surfaces with alkyl chains less than about ten carbon atoms are mostly disordered due to the lack of cohesive interaction between the molecules. For longer alkyl chains the cohesive forces are sufficiently strong to force the SAM molecules in an upright position, resulting in dense monolayers with a very smooth surface, leading to very good conditions for the pentacene growth and a better performance of the OFETs. Previously, we have shown that the performance of organic semiconductors is directly related to their molecular packing, crystallinity, growth mode, and purity. Therefore, it is critical to understand how organic semiconductors nucleate and grow [19].

Our results are in agreement with recent findings, that large grains and consequently a smaller amount of grain boundaries leads to a higher performance of pentacene field-effect transistors. It is also known that the major part of the charge transport happens at the gate interface [20], therefore, imaging techniques are required which unravel the structure throughout the entire device and not only at the surface.

3. Summary

STXM was employed to unravel the grain size and orientation of pentacene based field-effect transistors. The transistor devices were built on a SiN_x membrane coated with SiO_2. The pentacene thin films were grown on different self assembled monolayers (SAMs) used to modify the SiO_2 dielectric surface. It was shown that the STXM technique allows determining the molecular in-plane angle with an accuracy of ±4° and it could be performed in tandem with AFM measurements. As the chain length of the SAMs increases, its surface roughness decreases. Therefore, the grain size of the pentacene, deposited on top, increases. In the same sequence, the ratio of grain boundaries to the total surface area is getting smaller resulting in an increase of the charge carrier mobility of the respective transistor device.

Previously it was inconsistent in literature whether a larger or smaller grain size will result in high charge carrier mobility. It was recognized that the grain size determined by AFM, which only looks at the top surface of the grains, could not be used to fully explain the observed trends. We have shown STXM to be a promising technique which

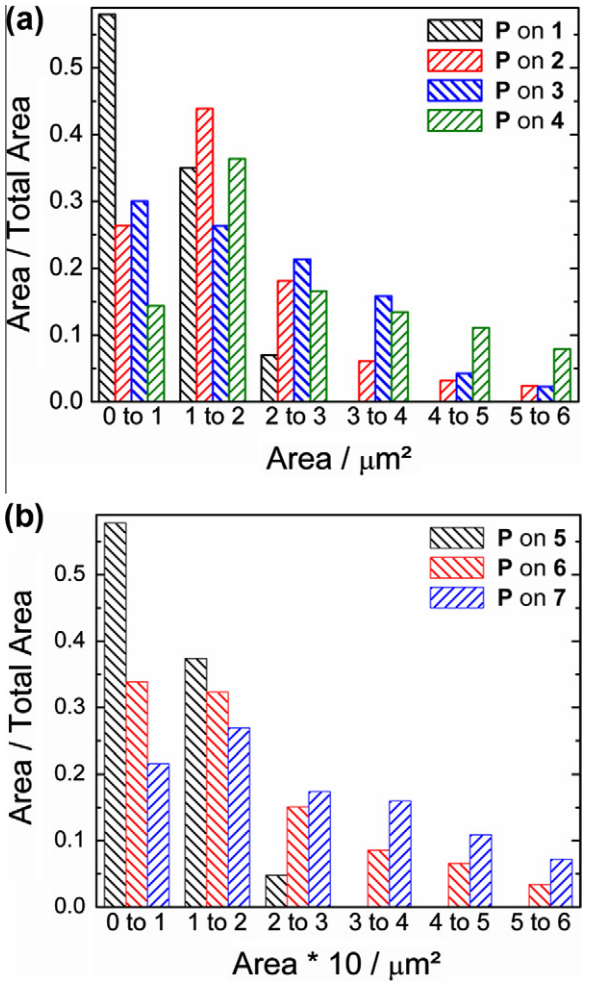

Fig. 5. Grain size distribution of pentacene (P) on different SAMs (**1**–**7**).

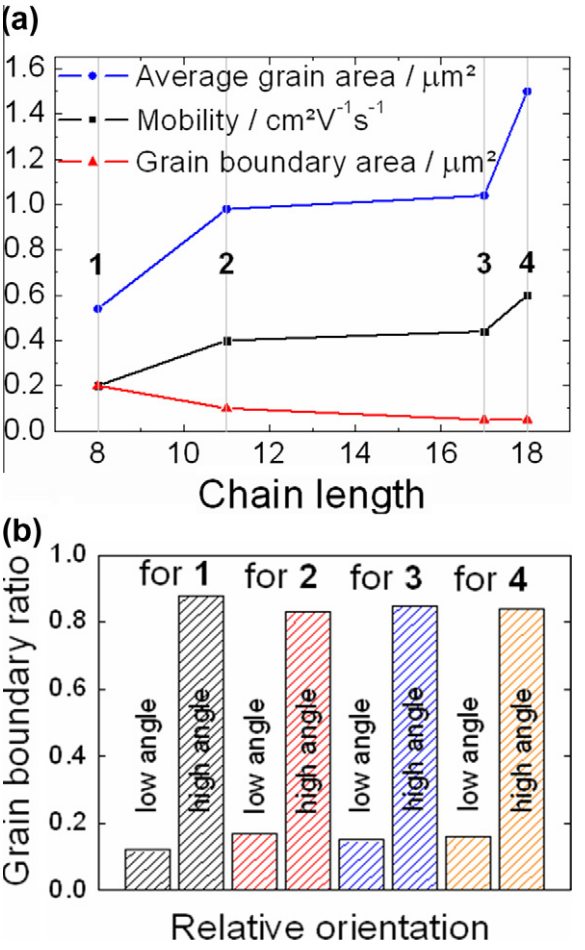

Fig. 6. Dependency of the charge carrier mobility, grain size, and grain boundary area on the chain length of the self assembled monolayer (a) and the grain boundary ratio (b).

can be used to image the grain size through the entire film. In this case, the determined grain size is indeed correlated with the charge carrier mobility. Therefore, we have demonstrated the utility of STXM for understanding charge transport in organic semiconductor materials.

4. Experimental

Materials: All trichlorosilanes were purchased from Gelest Inc. and used as received. Pentacene was purchased from Sigma–Aldrich and sublimed once prior to usage. Device substrates consisted of highly doped Si wafers with 100 nm silicon nitride as the gate dielectric.

Fabrication: The SiN_x membrane substrates were prepared at the Stanford Nanofabrication Facility from SiN_x coated Si wafers. After the membranes were prepared by wet etching a SiO_2 film (50 nm) was grown by chemical vapor deposition. The roughness of the SiO_2 film was determined by atomic force microscopy and is the same for all the substrates used in this paper. The substrates were cleaned with isopropanol and treated with UV ozone for 10 min. They were then modified with a monolayer of commercial available octyltrichlorsilane (**1**), undecyltrichlorsilane (**2**), heptadecyltrichlorosilane (**3**), octadecyltrichlorosilane (**4**), as well as with (heptadecafluoro-1,1,2,2,-tetrahydrodecyl)trimethoxysilane (**5**), phenethyltrimethoxysilane (**6**), and 11-bromoundecyltrimethoxysilane (**7**). For this purpose, the cleaned membrane substrates were placed in a desiccator with a heated metal block (200 °C). About 0.5 ml of **1**–**7**, respectively, were filled in a beaker and placed onto the block. The desiccator was pumped down to approx. 25 mTorr. The substrates were washed with isopropanol and dried with a nitrogen gun prior to deposition of pentacene. Pentacene (30 nm) was subsequently deposited at 60 °C on top of the coated membrane. The gate consists of aluminum (20 nm) and gold (5 nm) and was deposited on the backside of the membrane. [21]. Gold (30 nm) was deposited on the front side as source and drain electrode using the shadow mask technique (channel width: 0.3 mm, channel length: 0.05 mm).

Characterization: STXM measurements were carried out at beamline 11.0.2 at the Advanced Light Source in Berkeley, California, USA (Photon energy range: 280–320 eV;

zone plate resolution: approx. 35 nm) [22]. STXM measurements were performed at room temperature in He atmosphere. The electrical measurements on the organic devices were performed under ambient conditions using a Keithley 4200SCS semiconductor parameter analyzer. The atomic force microscope images of pentacene thin films were collected using a Park XE-70.

to ~5.4 eV for CF_X-modified Ag nanoparticles/ITO, which is advantageous to charge collection at the anode/organic interface in organic photovoltaic cells. Hence, a CF_X-Ag nanoparticles/ITO anode has advantages of (i) improved charge collection efficiency at anode/organic interface, and (ii) enhanced light absorption in the active layer of ZnPc:C_{60}-based OPV devices through broadband scattering of Ag nanoparticles.

2. Experimental

The thin film ZnPc:C_{60}-based OPV devices have a layer configuration of glass/ITO(160 nm)/Ag(1.5 nm)/CF_X-(~0.3 nm)/ZnPc:C_{60}(35 nm, 1:1)/C_{60}(25 nm)/4,7-diphenyl-1,10-phenanthroline (BPhen) (7 nm)/Ag(100 nm), in which the CF_X-modified Ag nanoparticles/ITO forms a composite anode. The composite anode is formed by the thermal evaporation of an ultra-thin Ag layer on ITO/glass followed by the subsequent modification of the Ag/ITO contact by an ultra-thin CF_X layer, deposited by a C_4F_8 plasma processing method [11]. After the formation of the composite electrode of CF_X-modified Ag nanoparticles/ITO, the active layer of ZnPc:C_{60}, electron transport layer of BPhen and cathode of Ag were then deposited through thermal evaporation. The OPV cells had an active area of 3.0 mm × 3.0 mm.

The current density–voltage (*J*–*V*) characteristics of the OPV cells were measured under air mass 1.5 global (AM1.5G) irradiation of 100 mW/cm^2 (300 W SAN-EI XEC-301S solar simulator; beam size: 4 inch diameter). The light intensity was determined by a monosilicon detector (with KG-5 visible color filter) calibrated by the National Renewable Energy Laboratory to minimize spectral mismatch. The surface work function of bare ITO and CF_X-modified Ag nanoparticles/ITO was examined using ultraviolet photoelectron spectroscopy with the Helium line (21.2 eV).

3. Results and discussion

ITO has been widely used as anode for applications in organic light-emitting diodes (OLEDs) and OPV cells. However, device formed on a bare ITO surface usually shows imperfection in device performance. The mitigation of this problem has involved ITO surface modification, e.g., using oxygen/UV-ozone plasma treatments or interposing an appropriate intermediate ultra-thin interlayer between the organic and ITO anode. A CFx-modified Ag surface was manifested to be an effective anode for OLEDs [11]. In this work, the modification of ITO using an ultra-thin Ag layer for application in OPV was investigated. It is found that CF_X-modified Ag nanoparticles/ITO forms an excellent anode for application in OPV cells. The performance of OPV devices involved an ultra-thin Ag layer can be influenced quite substantially as the Ag layer thickness increases, a Ag-based electrode with appropriate surface electronic and optical properties are desired for efficient operation of the OPV cells [12].

Scanning electron microscopy (SEM) images for the bare ITO and the CF_X-modified Ag nanoparticles/ITO surfaces are shown in Fig. 1 (a)–(d). The average size of the Ag nanoparticles ranges from ~10 nm to ~20 nm as the thickness of the Ag film increases from 1.5 nm to 10 nm – a consequence of coalescence with increasing time of deposition. As a thick Ag layer is expected to increase the energy loss attributable to reflection or scattering from the metallic layer, a 1.5 nm thick ultra-thin Ag layer which is non-continuous as shown in Fig. 1(b), was chosen such that the resulting anode retains a relatively high level of optical transparency and the beneficial contribution of plasmonic effect to enhance the light absorption in the active layer of the OPV devices.

In order to better understand the changes in surface work function of the ITO anode, the surface electronic properties of the modified ITO were studied using UPS measurement to determine the electronic structures on both bare ITO and CF_X-modified Ag nanoparticles/ITO surfaces. Fig. 2 shows the secondary electron edge in the UPS spectra measured for bare ITO, Ag nanoparticles/ITO and CF_X-modified Ag nanoparticles/ITO surfaces, which can provide information on the work function of the ITO surface. The spectra show that the work function of ITO (~4.4 eV) is reduced to ~4.1 eV with the incorporation of a 1.5 nm-thick Ag layer in ITO/Ag, but the combinatory layer of ITO/Ag/CF_X significantly increased the anode work function to ~5.4 eV. The work functions of ITO after UV-ozone and O_2 plasma treatments (not shown here) are about 5.1 eV and 5.4 eV, respectively.

In a previous work, a CF_X-modified Ag anode has been applied to improve carrier injection properties in organic light-emitting diodes [11]. In this work, we found that CF_X-modified Ag nanoparticles/ITO also exhibited a similar high surface work function nature. This clearly reveals that modification of ITO through Ag nanoparticles/CF_X conferred superior high surface work function suited for application in OPV devices. It is known that the interfacial energy level alignment at organic/electrode interface has a crucial impact on the device performance. The offset between the lowest-unoccupied-molecular-orbital of organic films and the Fermi level of an anode, e.g., ITO, is important for efficient charge collection in the OPV devices. The inset in Fig. 2 illustrates the schematic energy diagram of a ZnPc:C_{60}-based OPV cell studied in this work. As shown in the inset of Fig. 2, the difference in energy level between the work function of an ITO anode (~4.4 eV) and the highest occupied molecular orbital of ZnPc (5.17 eV [13]) at the ITO/ZnPc:C_{60} interface, can be reduced significantly after the ITO anode is modified with Ag nanoparticles/CF_X. The reduced electronic barrier at the ITO/CF_X-Ag nanoparticles/ZnPc:C_{60} interface may be favorable for charge extraction in OPV cells.

The OPV devices of ITO/Ag/CF_X/ZnPC:C_{60}/C_{60}/BPhen/Ag were fabricated along with two other control devices of ITO/ZnPc:C_{60}/C_{60}/BPhen/Ag, each with different surface treatment of the ITO anode prior to thermal evaporation of the organic layers. The two OPV control devices prepared for comparison studies are made with (i) an ITO anode treated with UV-ozone (control device-1) and (ii) an ITO anode treated with *in situ* O_2 plasma (control device-2). The incident photon to electron conversion efficiencies (IPCE) of the OPV devices and the two control devices over

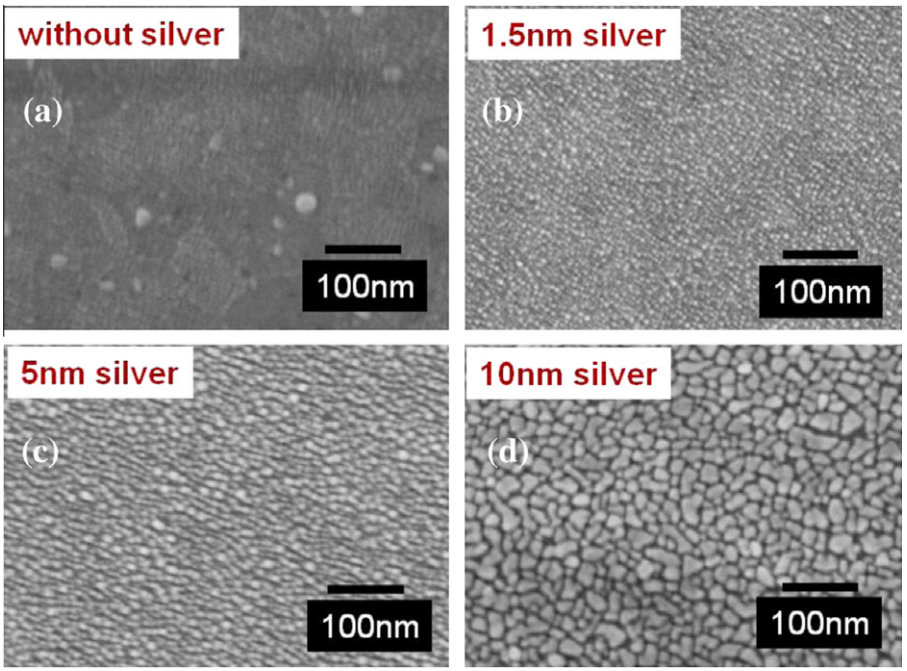

Fig. 1. SEM images of bare ITO and Ag nanoparticles modified ITO surfaces: (a) ITO/glass, (b) 1.5 nm-thick Ag on ITO/glass, (c) 5 nm-thick Ag on ITO/glass, and (d) 10 nm-thick Ag on ITO/glass.

the wavelength range from 300 nm to 800 nm were measured and the results are shown in Fig. 3. The general trend of the IPCE spectra of the OPV devices made with UV-ozone treated, O_2 plasma treated and CF_X-modified Ag nanoparticles/ITO electrodes is similar, consisting of two broad peaks (each divided into two local peaks) and a trough at 480 nm to 580 nm. With the exception of the trough where the IPCE of all OPV devices are similar, the IPCE of the OPV devices is notably higher than that of the O_2 plasma processed device which is in turn greater than that of the UV-ozone case. The *J–V* characteristics of the OPV devices are shown in Fig. 4. The short-circuit current density (J_{SC}), open circuit voltage (V_{OC}), fill factor (FF) and power conversion efficiency (PCE) of the OPV devices measured under AM1.5G irradiation are summarized in Table 1. It can be seen that the OPV devices with CF_X-Ag nanoparticles/ITO composite electrode has the best performance.

The work function measured for ITO treated with *in situ* O_2 plasma is about 5.4 eV, which is similar to that of a CF_X-modified Ag nanoparticles/ITO anode based on our UPS measurement (See schematic energy level diagram given as the inset of Fig. 2). This implies that the anode/organic interface in OPV devices with *in situ* O_2 plasma (control device-2) and the modified-ITO (OPV cell) would have very similar charge collection efficiency. Hence, similar IPCE for both OPV devices would be expected if this accounts for the main contribution to the improvement in device performance. Evidently, this has not been the case. Moreover, for the same surface work function, the incorporation of the Ag metallic layer would, in all likelihood, reduce the admission of light into the device and lower the IPCE. Therefore, an explanation involving only improved contact properties at anode/organic interface is not sufficient to account for the improved performance of the device concerned.

The increase in the power conversion efficiency of the OPV cells with an CF_X-modified Ag nanoparticles/ITO anode can be attributed to combinatory effects of (1) improved charge collection properties at the modified ITO/organic interface, and (2) enhanced absorption in the active layer of OPV cells through the advantages of broadband plasmonic enhancement effect [14,15]. From the SEM image (Fig. 1(b)) of the 1.5 nm-thick non-continuous Ag layer on ITO surface, it can be seen that the Ag nanoparticles have an average lateral dimension of ~10 nm. Localized plasmon resonance of Ag nanoparticles is known to be excited by incident light, the wavelength of plasmon resonance being dependent on the size and shape of the Ag nanoparticles and the permittivity of the surrounding dielectric background. Under conditions of plasmon resonance, the local electric field (tens of nm) around the Ag nanoparticles is strongly enhanced. The strong field aids the absorption of light in the organic photovoltaic devices, leading to enhanced device performance.

The optical absorption spectra measured for 1.5 nm-thick Ag nanoparticles on ITO are shown in Fig. 5. Deposition of Ag nanoparticles on ITO/glass evidently leads to higher absorption of the glass/ITO/Ag sample (*black curve*). As the Ag nanoparticles have a range of lateral dimensions of ~10 nm, the absorption is relatively broad extending over a wavelength range below ~550 nm. The mean size of the Ag nanoparticles at ~10 nm accounts for the broad absorption peak at $\lambda \sim 480$ nm. In comparison, the absorption peak is further shifted to 510 nm in the ZnPc:C_{60} blend layer deposited on CF_X-modified Ag nanoparticles/ITO (*blue curve*).

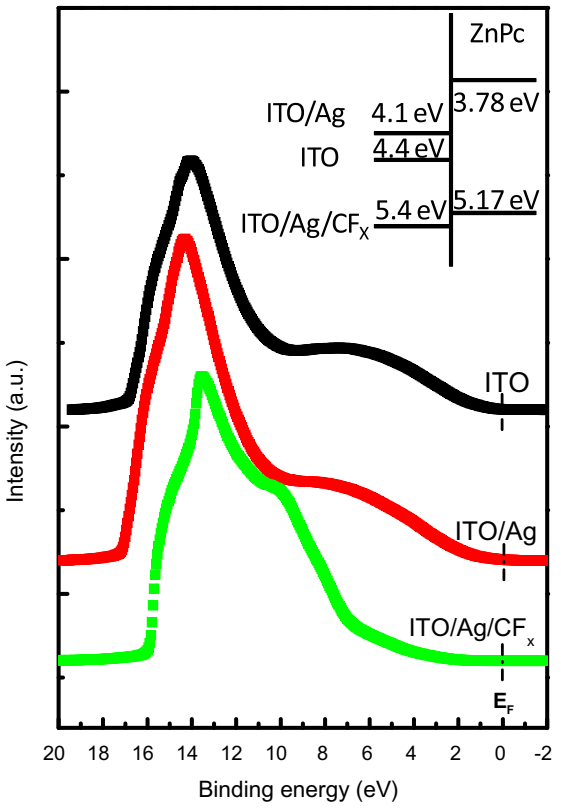

Fig. 2. Evolution of the secondary electron edge in UPS spectra measured for bare ITO, Ag nanoparticles/ITO, and CF_X-modified Ag nanoparticles/ITO surfaces (from top to bottom). The inset illustrates the schematic diagram of energy levels in ZnPc:C_{60}-based OPV devices with different anode contacts of ITO, Ag nanoparticles/ITO and CF_X-modified Ag nanoparticles/ITO.

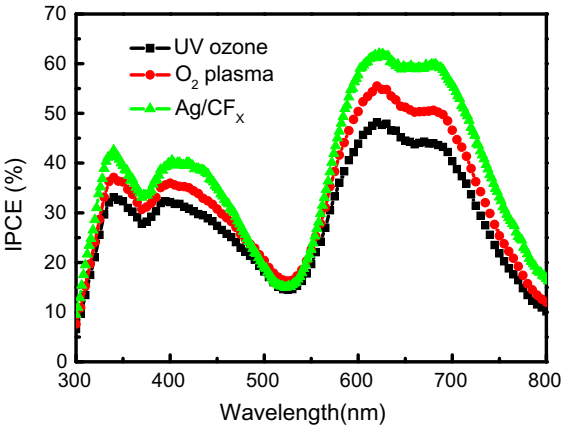

Fig. 3. Comparison of IPCE spectra measured for ZnPc:C_{60}-based OPV devices with different anode contacts: ITO with UV-ozone surface treatment (black square), ITO with *in situ* O_2 plasma treatment (red diamond) and CF_X-modified Ag nanoparticles/ITO anode (green triangle). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

As shown in Fig. 5, it can be gleaned that the incorporation of the ultra-thin Ag layer significantly improves the

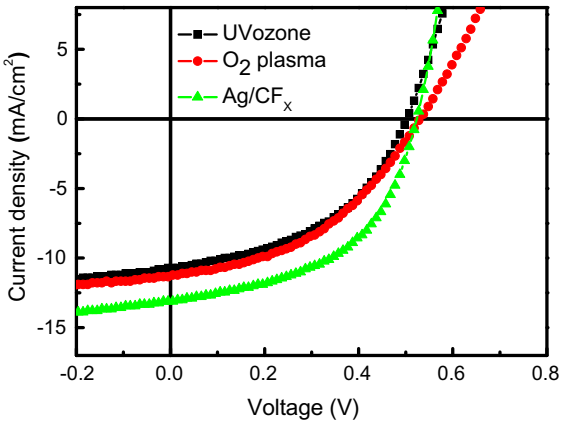

Fig. 4. *J–V* characteristics measured for ZnPc:C_{60}-based OPV devices fabricated on ITO treated with: UV-ozone surface treatment (black square), *in situ* O_2 plasma treatment (red diamond) and CF_X-modified Ag nanoparticles/ITO anode (green triangle). (For interpretation of the references to colors in this figure legend, the reader is referred to the web version of this article.)

Table 1
Photovoltaic characteristics of the ZnPc:C_{60}-based OPV devices with ITO anode treated with UV-ozone, O_2 plasma and modified with Ag nanoparticle/CF_X.

Anode	UV-ozone (Control device-1)	O_2 plasma (Control device-2)	Ag/CF_X
J_{SC} (mA/cm^2)	10.72 ± 0.50	11.13 ± 0.50	13.10 ± 0.50
V_{OC} (V)	0.50 ± 0.05	0.52 ± 0.05	0.52 ± 0.05
FF (%)	0.46 ± 0.05	0.47 ± 0.05	0.51 ± 0.05
PCE (%)	2.4 ± 0.1	2.7 ± 0.1	3.5 ± 0.1

absorption in an active ZnPc:C_{60} layer on the modified ITO anode over the wavelength range from ~420 nm to ~800 nm (*blue & green curve*[1]). The relative low absorption of ZnPc:C_{60} layer on CF_X/ITO over the wavelength range from ~420 nm to ~550 nm (*red curve*[1]) culminates to a local peak in the ZnPc:C_{60} layer on CF_X/Ag nanoparticles/ ITO (*blue curve*[1]), while the double peaks over the wavelength range from ~580 nm to ~800 nm is further enhanced. The absorption spectra of ZnPc:C_{60} on Ag nanoparticle/ITO (*green curve*[1]) show a similar trend. Examining the absorption spectra of ZnPc:C_{60} in greater detail reveals that a slightly higher absorption is observed for the ZnPc:C_{60} blend layer on Ag nanoparticles/ITO (*green curve*[1]) than the case with CF_X/Ag nanoparticles /ITO (*blue curve*[1]) for wavelength >610 nm, implying that the former would induce a higher absorption in devices. However, the work function of a bare ITO/Ag anode (Fig. 2) is not favorable to an efficient charge extraction at ITO/Ag/organic interface. The modification of the surface of Ag nanoparticles with CF_X is desired (*blue curve*[1]).

Comparing the absorption spectra of the glass/ITO/CF_X/ZnPc:C_{60} and glass/ITO/Ag/CF_X/ZnPc:C_{60} samples with the IPCE of the finished devices (glass/ITO/ZnPc:C_{60}/C_{60}/

[1] For interpretation to colour in the text, the reader is referred to the web version of this article.

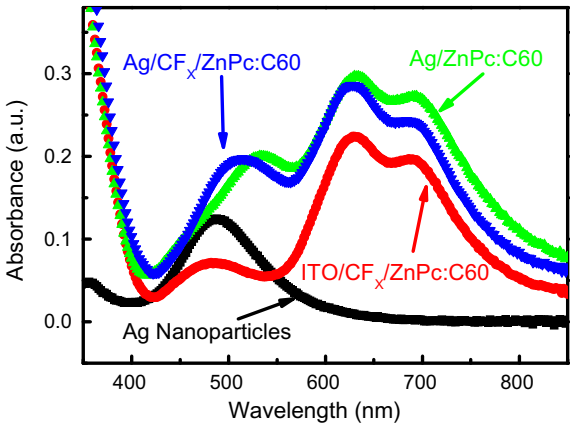

Fig. 5. Absorption spectra for Ag nanoparticles on ITO, 35 nm-thick ZnPc:C_{60} blend layer deposited on ITO/CF_X, on ITO/Ag nanoparticles, and ITO/Ag nanoparticles/CF_X.

BPhen/Ag and glass/ITO/Ag/CF_X/ZnPc:C_{60}/C_{60}/BPhen/Ag), a good correspondence in the broad absorption peaks over the wavelength range from ~580 nm to ~800 nm can be observed. It is obvious that the enhanced absorption brought on by the incorporation of the Ag nanoparticles layer translates into an improved spectral responsivity and hence the enhancement in the power conversion efficiency of the OPV devices. It is clear that the IPCE of the OPV devices with Ag nanoparticles/CF_X-modified anode remains higher than those with the bare ITO anode. This allows a notably higher short-circuit current density of 13.10 ± 0.50 mA/cm^2 to be achieved compared to 10.72 ± 0.50 mA/cm^2 in control device-1 and 11.13 ± 0.50 mA/cm^2 in control device-2, as summarized in Table 1. Our results reveal that the composite anode of Ag nanoparticles with inclusion of CF_X enhanced the performance of OPV cells through improved light harvesting in the OPV devices.

4. Conclusion

In summary, performance enhancement in ZnPc:C_{60}-based OPV devices is achieved through the composite CF_X-modified Ag nanoparticles/ITO anode. The CF_X-modified Ag nanoparticles/ITO is favorable for application in OPV devices due to its advantages of broadband plasmonic enhancement effect and improved charge collection efficiency at anode/organic interface. The CF_X-modified Ag nanoparticles/ITO anode yielded a promising power conversion efficiency of $3.5 \pm 0.1\%$ for ZnPc:C_{60} OPV devices, notably higher than that with a bare ITO anode ($2.4 \pm 0.1\%$ with UV-ozone treatment and $2.7 \pm 0.1\%$ with O_2 plasma treatment).

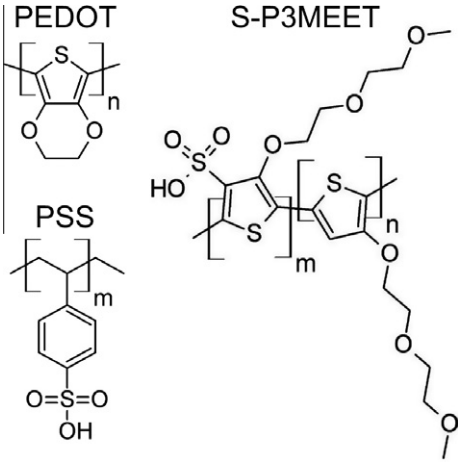

Fig. 1. Chemical structures of PEDOT:PSS and S-P3MEET.

with PEDOT:PSS, the barrier has been shown to be lower than expected in some cases [9].

Despite the widespread use of PEDOT:PSS, it is not without problems. It is highly acidic (pH = 1.2) and corrodes the ITO anode [10,11]. PEDOT:PSS is also hygroscopic and the water it uptakes can diffuse into the active layer or the cathode, reducing efficiency and device lifetime [12]. Additionally, the hole injection barrier could be limiting the performance of blue emitting OLED devices [13]. Another problem for OLEDs is that PEDOT:PSS's high parallel conductivity could lead to crosstalk between pixels in displays [14]. As a result, other materials have been investigated as replacements for PEDOT:PSS. OPV devices made with conductive oxide HTLs such as V_2O_5, MoO_3, and NiO have shown efficiencies comparable or better than PEDOT:PSS HTL devices [15–17]. The problem with oxides is that they do not work for all HOMO levels like PEDOT:PSS. There has also been significant work studying doped small molecules for OLEDs and OPVs [18,19]. The problem with organic small molecules is that they must be deposited under vacuum, which is not compatible with high-throughput manufacturing. A solution processable polymer/small molecule blend that has shown better hole selectivity is a blend of 4,4-bis[(*p*-trichlorosilylpropylphenyl)-phenylamino]biphenyl ($TPDSi_2$) and poly[9,9-dioctylfluorene-co-*N*-[4-(3-methlypropyl)]-diphenylamine (TFB) [20]. The problem with all of these alternatives is that because they are semiconductors, and not quasimetallic like PEDOT:PSS, they must be tuned for each donor/acceptor system, whereas PEDOT:PSS can accept holes from any polymer in an OPV. Despite this bevy of replacements, PEDOT:PSS is still used in almost all published results.

PEDOT:PSS is commercially available as an aqueous colloidal solution. In solution, the colloids are rich in hydrophilic PSS at the surface with PEDOT-rich centers. When these films are cast by spin coating this structure is maintained [6]. Scanning tunneling microscopy (STM) and cross-section atomic force microscopy (AFM) were used to show that spin-cast PEDOT:PSS films consist of a phase-separated structure [14]. Under the forces of spin coating the colloids flatten to form PEDOT rich layers that are vertically segregated by PSS-rich layers. In the PEDOT-rich lamella, PEDOT-rich "pancakes" are laterally separated by very thin or incomplete PSS-rich lamellas. This morphology results in anisotropic conductivity in PEDOT:PSS films. In the plane of the film, holes are conducted via three-dimensional variable range hopping, and normal to the film, conduction is via nearest-neighbor hopping [21]. Due to the different conduction mechanisms, the parallel ($\sigma_{||}$, in-plane) conductivity of PEDOT:PSS is three orders of magnitude larger than the perpendicular ($\sigma_{\perp}$, out-of-plane) conductivity [21].

In addition to having anisotropic conductive properties, PEDOT:PSS films also display anisotropic optical properties. The films are uniaxially anisotropic with the ordinary complex refractive index ($N_o = n_o + ik_o$) in the plane of the film and the extraordinary complex refractive index ($N_e = n_e + ik_e$) normal to the film and parallel to the optical axis, where n_i is the refractive index and k_i is the extinction coefficient ($i = o, e$) [22,23]. PEDOT films doped with iron (III) tris-*p*-toluenesulfonate also display uniaxial optical constants [24]. In each case, k_o looks metallic as it increases with increasing wavelength, which is attributed to free charge carrier absorption [22,24]. Free carrier absorption is based in the Drude model where the dielectric function is dependent on the number of free carriers per unit volume [25]. This model is consistent with band structure of PEDOT:PSS, which has a non-zero density of states at the Fermi energy [21]. In each of these studies, $\sigma_{||}$ was different, ranging from 10^{-3}–500 S/cm and as $\sigma_{||}$ increases so does the amplitude of the free charge absorption. From a classical perspective, this correlation between conductivity and free carrier absorption is expected as both are dependent on the number of free electrons. These studies also show varying levels of anisotropy between N_e and N_o. In contrast to N_o, N_e looks more like a dielectric than a metal [24]. Again we see a correlation between conductivity and optical properties as the low $\sigma_{\perp}$ of PEDOT:PSS would correspond to a low free charge density which would not result in a Drude model of the dielectric function.

The focus of this article is a new conductive polymer, sulfonated poly (thiophene-3-[2-(2-methoxyethoxy) ethoxy]-2,5-diyl) (S-P3MEET). Samples of all S-P3MEET solutions were generously provided by Plextronics, Inc. S-P3MEET is a copolymer whose structure is shown in Fig. 1. Like PEDOT, S-P3MEET is a conjugated polythiophene. The most significant difference between S-P3MEET and PEDOT:PSS is that S-P3MEET is self-doped by the sulfonate moieties that are bonded to some of the thiophene rings instead of having the dopant in solution. The sulfonate moieties dope the polymer by oxidizing it and generating a hole that can be delocalized over the conjugated backbone. Having the sulfonate moieties linked to the polymer has multiple advantages. One is that the sulfonate concentration is much lower in S-P3MEET than PEDOT:PSS, leading to a pH above 2. Also, the pure S-P3MEET films do not have any mobile dopants, which can have unintended results in devices. Our group recently showed that the high concentration of PSS at the HTL/active layer interface results in an oxidation of poly (3-hexylthiophene-2,5-diyl) (P3HT) upon heating and alters the electrical characteristics of OPV devices [8].

In this study we characterize three different preparations of spin coated S-P3MEET thin films. All of the solutions

contain S-P3MEET in a solution of water and ethylene glycol butyl ether. The solution containing only S-P3MEET is Plexcore® OC CFAJ10-100, hereto referred as AJ10. The two other solutions studied are Plexcore® OC CFAJ20-100 and CFAJ30-100. The AJ20 and AJ30 solutions have proprietary additives in the mixture, with AJ20 having the highest additive concentration. In this article, we characterize the electrical and optical properties of all films and determine how the additives alter the optical, electrical, and morphological properties of these films.

2. Experimental details

2.1. Materials and sample preparation

All substrates were rinsed with chloroform then ultrasonically cleaned in successive baths of acetone, Mucasol, and deionized water followed by rinsing and drying in a FSI Phoenix spin-rinse-dryer. Prior to spin coating all substrates were placed in a UV/Ozone plasma cleaner for 30 min. Thin films of PEDOT:PSS (Clevios P VP AI 4083; Heraeus), AJ10 (Plexcore® OC CFAJ10-100; Plextronics, Inc.), AJ20(Plexcore® OC CFAJ20-100; Plextronics, Inc.), and AJ30 (Plexcore® OC CFAJ30-100; Plextronics, Inc.) were prepared by spin coating (Specialty Coating Systems 6800) onto the substrates.[1] The polymer solutions were dispensed from a syringe fitted with a 0.45 μm filter. Spinning speed and time were varied to achieve the desired film thickness. After coating, the samples were placed on a hot plate set to 110 °C for 5 min to remove any remaining solvent from the films.

2.2. Measurements

1×1 in^2 glass substrates were cleaned as described in Section 2.1. For parallel (in-plane, $||$) measurements the slides were scored using a steel cutting wheel to divide the glass into nine (0.33×0.33 in^2) subsections. Following light rinsing with acetone, Mucasol, and deionized water, the substrates were transfered to a high vacuum chamber (MBraun). Four electrodes (1×5 mm^2, 1 mm spacing) composed of 5 nm of chromium followed by 95 nm of gold were deposited by thermal evaporation. Following electrode deposition the samples were rinsed again and cleaned in the UV/ozone plasma. For perpendicular (out-of-plane, $\perp$) measurements, one Cr/Au electrode was deposited onto glass. After electrode deposition, the substrates were lightly rinsed and UV/ozone cleaned. Films were spin-coated as described in Section 2.1 for both geometries. The perpendicular samples were returned to the high vacuum chamber and 100 nm of gold was deposited to give an active area of 0.35 cm^2. Electrical measurements were performed with a Keithely 2420 source measurement unit.

For ellipsometry measurements, silicon wafers with 300 nm of thermally grown oxide were used as the substrates. Films were spin-coated and annealed prior to measurement. Measurements were performed using a VASE model ellipsometer from the J.A. Woollam Co., Inc. Scans were performed at multiple angles of incidence from 55° to 85° in steps of 5°. The measurement range was 300 nm to 1000 nm in steps of 5 nm. Depolarization was measured and used to fit film thickness nonuniformity to improve modeling accuracy. Modeling of the optical properties of the substrate materials and polymer films was carried out using WVASE32® ellipsometric analysis software from the J.A. Woollam Co., Inc. All optical data was recorded in air and at room temperature. The oxide thickness was measured using published values of the optical constants of Si and SiO_2 [26]. The refractive index of the quartz was modeled using a Cauchy dispersion model and the extinction coefficient was modeled using a point-by-point fit.

Transmittance measurements of of the films on quartz slides were performed using a Perkin Elmer Lambda 750 UV/vis/NIR spectrophotometer. Measurements were recorded at wavelengths from 190 nm to 1700 nm in steps of 5 nm.

Atomic force microscopy (AFM) measurements were conducted in tapping mode using a Veeco Multimode 3 microscope. Silicon tips (K-Tech) with a spring constant of 5 N/m were used for imaging. Images were analyzed and processed using Veeco's Nanoscope Analysis software.

Work function values of polymer films were measured with a Kelvin probe (KP Technologies, Inc.). Samples were prepared by spin-coating films onto glass substrates coated with ITO. Work function values for aluminum with native oxide and UV/ozone cleaned gold were used to calibrate the work function of the probe tip [27].

Contact angle measurements were performed on a leveled goniometer stage. A droplet of deionized water was placed on the sample surface and the contact angle between the droplet and the surface was measured with the goniometer.

Thickness measurements of polymer films were performed using a Veeco Dektak 150 Stylus Profiler. Films were scratched with a knife blade to create a measurement step. The profiler was calibrated with two certified step-height standards from VLSI Standards, Inc.

3. Results and discussion

In the following sections, we use AFM along with Kelvin probe and contact angle measurements to study the film morphology and surface properties of S-P3MEET thin films. Then using conductivity measurements and spectroscopic ellipsometry we determine how the film morphology affects the conductive and optical properties of the S-P3MEET films. All measurements of S-P3MEET films are compared to standard PEDOT:PSS films.

3.1. Atomic force microscopy

The first step in the characterization of the S-P3MEET films is to measure the morphology of the surfaces using tapping mode AFM (TM–AFM). In TM–AFM, the cantilever tip is oscillated near its resonance frequency as it is scanned

[1] All Plexcore solutions used is this study are commercially available from Plextronics, Inc., 2180 William Pitt Way, Pittsburgh, PA 15238, USA. Tel.: +1 412 423 2030; fax: +1 412 423 2039, www.plextronics.com.

over the sample. The amplitude of this oscillation changes with surface topography and this change is used to generate the height image. An image of the phase of the oscillation of the cantilever can also provide useful information about a film's surface. Changes in surface forces will result in differences in phase lag between the cantilever oscillation and the feedback signal. This makes the phase image sensitive to changes in the surface composition.

TM–AFM scans were performed on the polymer films and the topography and phase images are shown in Fig. 2. Also, the root-mean-square roughness values for the topography (r_z) and phase (r_p) images are reported in Table 1. From the topography images and r_z values we can see that all of the AJ films are rougher than PEDOT:PSS, which is very smooth due to the thin PSS top layer that forms upon annealing [28,29]. Stylus profiler measurements also show that the AJ films are rougher than PEDOT:PSS films. On closer inspection of Fig. 2b and c, one notices that the areas of the different height regions are much smaller for AJ30 than for AJ20. In Fig. 2b we see

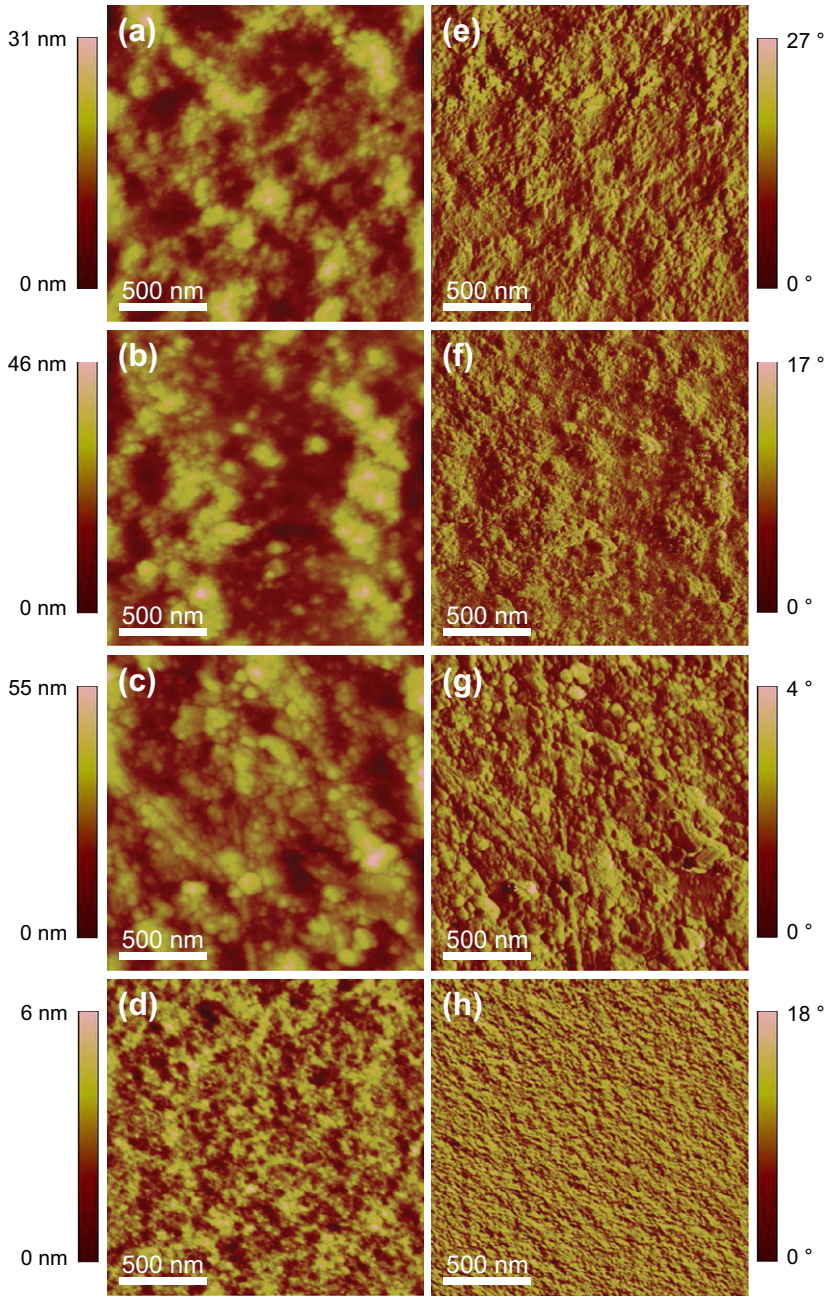

Fig. 2. $2 \times 2\ \mu m^2$ topography and phase AFM images of (a and e) AJ10, (b and f) AJ20, (c and g) AJ30, and (d and h) PEDOT:PSS on glass. Height and phase scales vary between samples.

Table 1
Topography (r_z) and phase (r_p) RMS roughness values from TM–AFM, work function (ϕ) values measured using the Kelvin probe method, and contact angle (θ_c) measurements measured between a water drop and film surface for AJ10, AJ20, AJ30, and PEDOT:PSS.

	r_z (nm)	r_p (°)	ϕ (eV)	θ_c (°)
AJ10	4.38	4.04	5.2 ± 0.1	22 ± 1
AJ20	6.52	2.35	5.3 ± 0.1	32 ± 1
AJ30	7.54	0.61	5.6 ± 0.1	46 ± 1
PEDOT:PSS	0.80	2.54	5.1 ± 0.1	14 ± 1

two ridges running vertically on the left and right sides of the images. Looking at the "valley" region in the phase data in Fig. 2f one can see islands of a lighter phase surrounded by a darker phase. This indicates that there may be some phase separation on the surface of the AJ20 film. A common feature between AJ20 and AJ30 is that the topography images both show a granular morphology. STM microscope images of PEDOT:PSS films also show a granular morphology [14]. The commonality of a granular morphology between AJ20, AJ30 and PEDOT:PSS further suggests that the additives may be causing a phase separated morphology in AJ20 and AJ30.

When comparing the data for the AJ films an interesting trend is noticeable. While AJ10 has the lowest r_z it also has highest r_p. On the other hand, AJ30 has the highest r_z but has the lowest r_p. It might seem counterintuitive that AJ10, which contains only S-P3MEET, would exhibit the largest range in the phase images until one considers the structure of the polymer. S-P3MEET (shown in Fig. 1) is a copolymer with two different repeat units. One contains only an ether side group, but the other has the addition of a sulfonate group. These groups will exert different attractive/repulsive forces on the the AFM tip, meaning that the different sections of the S-P3MEET polymer will have a different phase leading to an inhomogeneous phase image. We interpret the increase in homogeneity in the phase images of AJ20 and AJ30 to be caused by a high concentration of additives on the surface that make the surface more uniform in material content.

To confirm this we use two different techniques that are sensitive to the surface composition: Kelvin probe and contact angle (θ_c) measurements. A Kelvin probe measures the work function (ϕ), i.e. the energy required to remove an electron from the surface, giving a measure of the surface's electronic make up [30]. Measuring θ_c between a drop of deionized water and a material gives a measure of the hydrophobicity of the surface. The results from these two measurements are summarized in Table 1. For AJ10, the value of ϕ (5.2 eV) is close to PEDOT:PSS (5.1 eV), but PEDOT:PSS has a lower θ_c due to the layer of hyrdrophylic PSS on the surface. For AJ20 and AJ30 we see an increase in ϕ and θ_c. The increase in θ_c either means that the additives are hydrophobic or hydrophobic parts of the S-P3MEET polymer are at the surface. The increase in ϕ may also indicate that the additives are fluorinated. In a study of blue OLEDs the addition of a perfluorinated ionomer to PEDOT:PSS increased the work function by 0.20–0.65 eV depending on the ionomer concentration [13]. The authors also showed that the device efficiencies were improved when a higher work function PEDOT:PSS layer was used. This indicates that AJ30 may be preferable for use in OLEDs because its ϕ will result in a lower hole injection barrier into the HOMO of the polymer.

3.2. Conductivity

We next measured the conductivity of the S-P3MEET films. If S-P3MEET is to be used as a HTL in OPV or OLED devices it must be sufficiently conductive to efficiently transport charges between the anode and active/emissive layer. For these measurements shadow masks were designed so that the electrode geometries produced electric fields parallel or perpendicular to the surface normal. For the parallel conductivity measurements the shadow mask was modeled after the mask used by Nardes et al. [14] to allow for detection of any in-plane anisotropy. For all of the films, no in-plane anisotropy was found. All conductivity values reported represent an average of nine individual four-point conductivity measurements.

The parallel ($\sigma_{||}$) and perpendicular ($\sigma_{\perp}$) conductivity values measured in N_2 and at room temperature are reported in Table 2. PEDOT:PSS shows the highest $\sigma_{||}$ and is consistent with previously reported values [21]. For the S-P3MEET films we see a trend of decreased conductivity as the additive concentration increases (the additive concentration is highest in AJ20). This is not without precedent, as in PEDOT:PSS films conductivity decreases

Table 2
Conductivities of polymer thin films, parallel ($\sigma_{||}$) and perpendicular ($\sigma_{\perp}$) to the surface normal measured in a DC field in N_2 and at room temperature.

	$\sigma_{||}$ (S/cm)	$\sigma_{\perp}$ (S/cm)
AJ10	$(7.3 \pm 0.4) \times 10^{-4}$	$(1.2 \pm 0.1) \times 10^{-5}$
AJ20	$(5.3 \pm 2.1) \times 10^{-6}$	$(1.2 \pm 0.1) \times 10^{-5}$
AJ30	$(2.6 \pm 0.1) \times 10^{-4}$	$(1.1 \pm 0.1) \times 10^{-5}$
PEDOT:PSS	$(1.1 \pm 0.1) \times 10^{-3}$	$(0.7 \pm 0.1) \times 10^{-5}$

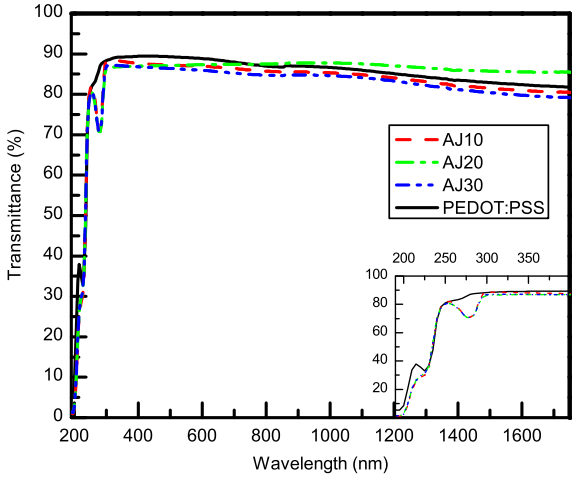

Fig. 3. Wavelength dependent transmittance spectra for films AJ10 (red, dash), AJ20 (green, dash-dot), AJ30 (blue, dash-dot-dot), and PEDOT:PSS (black, solid) of equal thickness (70 nm) on quartz in the spectral range of 190–1750 nm. The inset figure highlights the spectral range from 190 to 400 nm. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

as the ratio of PSS to PEDOT increases [31]. We conclude that the decrease in conductivity is due to the additives separating the conductive domains as was indicated by the TM–AFM images. Based on the relatively high conductivity of AJ30 it does not appear that the conductive domains are completely isolated from each other, however, the data for AJ20 indicates complete separation of conductive domains. The complete separation will prohibit any long-range hopping transport and limit conduction to a nearest-neighbor hopping mechanism, as is seen in $\sigma_{\perp}$ of PEDOT:PSS. The data for AJ30 suggests that the lower additive concentration diminishes long-range hopping, but does not eliminate it. The low $\sigma_{||}$ of AJ20 may make it preferable for use in pixilated OLED displays as crosstalk between neighboring pixels will be less likely than in displays with PEDOT:PSS.

Based on our interpretation of the parallel conductivity data, the conductive domains in AJ20 are fully separated from each other, but, in AJ30 films the conductive domains are only partially separated. The vertical separation between the conductive S-P3MEET domains is thick like the PSS-rich shells in PEDOT:PSS films. This is supported by the perpendicular conductivity values for AJ20 and AJ30 which are close to that of PEDOT:PSS. Interestingly, AJ10 displays similar vertical conductivity values to AJ20, AJ30, and PEDOT:PSS even though it does not have any mobile additives that are separating the conductive domains. It is possible that the different parts of the S-P3MEET

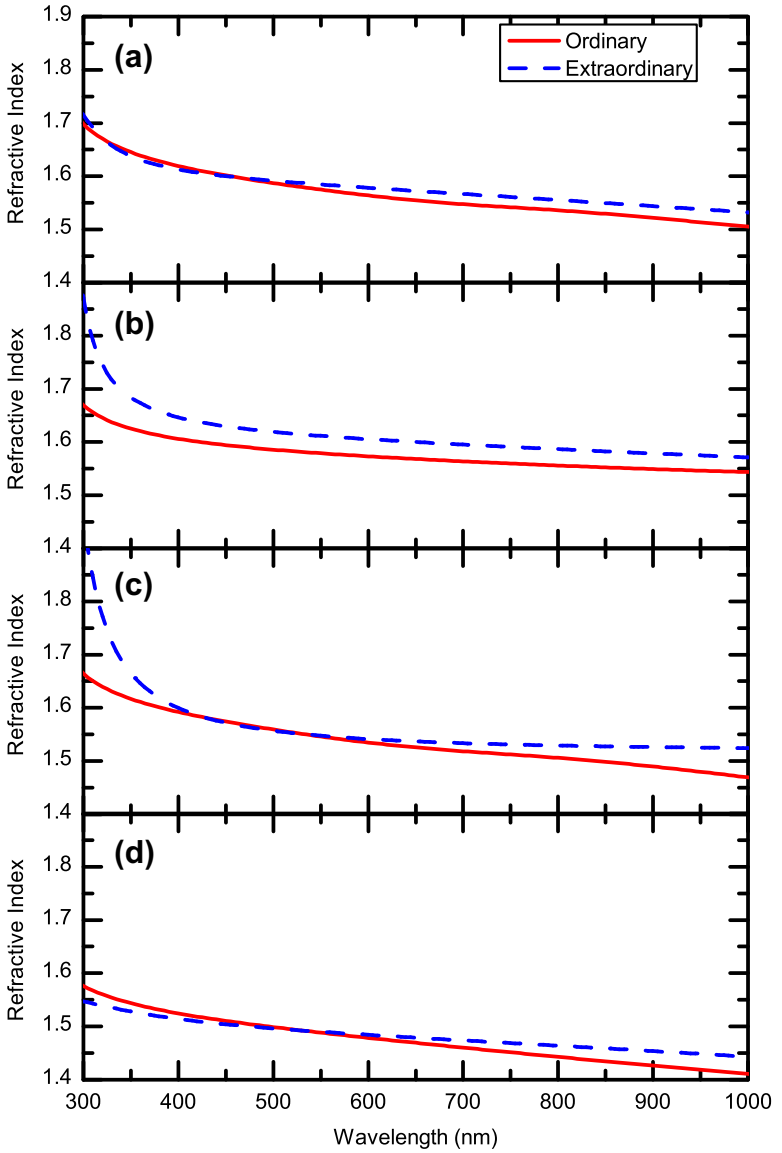

Fig. 4. Wavelength dependent ordinary (n_o, solid) and extraordinary (n_e, dashed) refractive indexes for (a) AJ10, (b) AJ20, (c) AJ30, and (d) PEDOT:PSS calculated from ellipsometric and transmission measurements of thin-films on Si/SiO_2 wafers and quartz slides.

polymer are segregating and the nonconductive regions are separating the conductive regions.

3.3. Optical properties

In addition to measuring the conductivity of the S-P3MEET films the complex optical properties were also measured. In this study we determined the optical properties of the S-P3MEET and PEDOT:PSS thin films using variable angle spectroscopic ellipsometry (VASE). Since none of the films have transparent regions it is not possible to fit the film thickness independently of absorption. In order to accurately fit the thickness and the optical properties a multiple sample analysis (MSA) was performed to reduce the correlation between film thickness and optical absorption. In an MSA experiment, samples with different film thicknesses are measured and fit simultaneously. In the fitting, the optical properties are assumed to be independent of film thickness. Through this procedure, the correlation between thickness and absorption is minimized. Measuring at multiple angles of incidence also reduces the correlation between fitting parameters because thickness is independent of wavelength. The thickness values derived from the fits were checked against the measured thickness from stylus profilometry. N_o is probed by s-polarized light at all angles and partially by p-polarized light at low angles. In contrast, N_e is only probed by p-polarized light at high angles of incidence. Since N_e is not probed strongly, models of it are less accurate than models of N_o.

In addition to VASE measurements, transmission spectroscopy, at normal incidence, was performed on the films on quartz substrates. By measuring at normal incidence

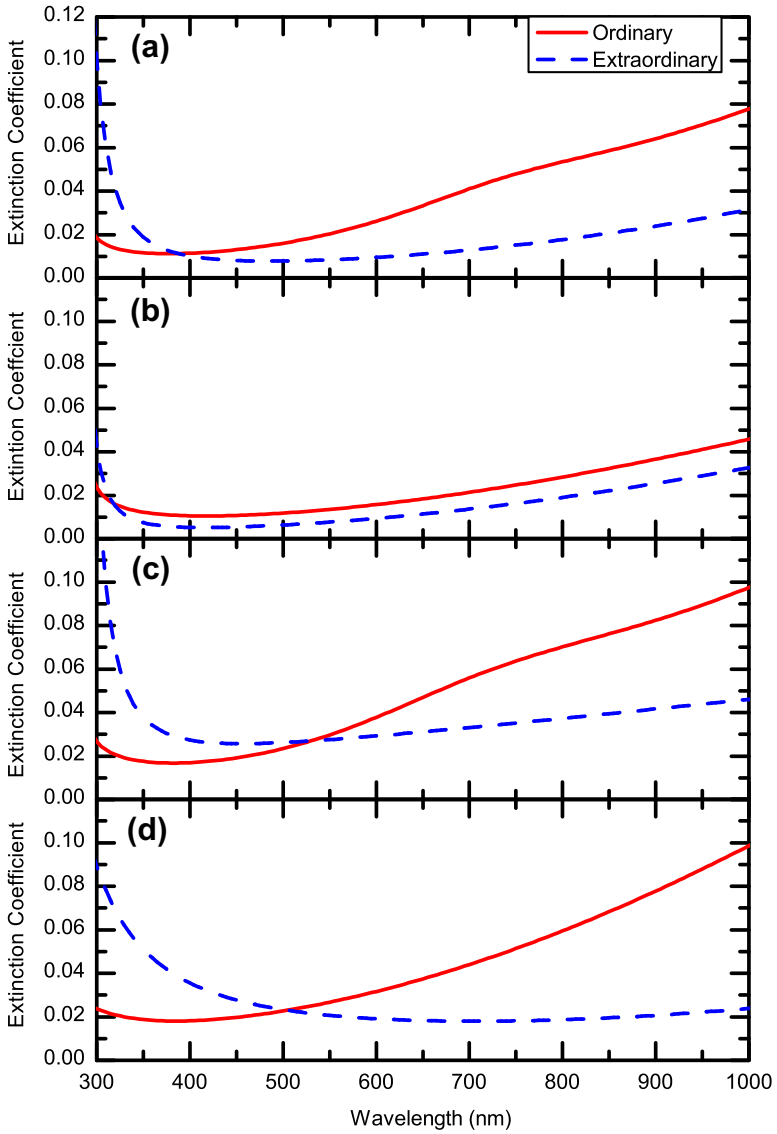

Fig. 5. Wavelength dependent ordinary (k_o, solid) and extraordinary (k_e, dashed) extinction coefficients for (a) AJ10, (b) AJ20, (c) AJ30, and (d) PEDOT:PSS calculated from ellipsometric and transmission measurements of thin-films on Si/SiO_2 wafers and quartz slides.

only N_o is probed. Quartz was selected as the substrate for these measurements because it is transparent much further into the UV than glass and allows the detection of peaks that would be obscured by the strong absorption of glass in the UV. The transmittance spectra for all of the films are presented in Fig. 3. All films exhibit high transparency in the visible region. We see that all films have peaks at 193 nm and 225 nm, which can be seen more clearly in the inset figure. The spectrum for PEDOT:PSS has a small shoulder from 250 to 280 nm, while the AJ films have a peak at 280 nm. These peaks can be attributed to π–π^* transitions in both S-P3MEET and PEDOT:PSS [22]. The transmittance spectra of AJ10, AJ30, and PEDOT:PSS show a broad absorption feature above 400 nm that increases into the infrared (IR), which is due to absorption from free charges. In contrast to AJ10, AJ30, and PEDOT:PSS, AJ20 does not have a free charge absorption feature as seen by flat transmittance above 400 nm. The lack of free charge absorption correlates well with the conductivity data as $\sigma_{||}$ for AJ20 is very low and thus has few free charges.

To fit the optical properties of the thin films, models were constructed using the WVASE32® software package from J.A. Woollam Co., Inc. The optical properties as a function of $h\nu$ were fit using multiple Lorentz oscillators as:

$$N = n + ik = \varepsilon^{1/2} = \left(\varepsilon_1(\infty) + \sum_{j=1}^{J} \frac{A_j}{E_n^2 - (h\nu)^2 - i\Gamma_j h\nu}\right)^{1/2}, \quad (1)$$

where A_j is the amplitude, Γ_j is the broadening, and E_j is the center energy of oscillator j, and $\varepsilon_1(\infty)$ is the dielectric function at infinite energy. When fitting, A_j, Γ_j, E_j, and $\varepsilon_1(\infty)$, Eq. (1) can be fixed or used as fit parameters to minimize the mean square error (MSE) between the generated values and experimental experimental. All films were initially modeled assuming an isotropic layer on top of layers of SiO_2 and Si, however, this model did not produce acceptable fits to the experimental data. To improve the fitting a uniaxial anisotropic layer was selected to model the polymer films.

To model N_o for all films, two oscillators had their energies fixed at 6.4 eV and 5.5 eV to account for the π–π^* transitions. All of the AJ polymers also had an oscillator with a fixed energy of 4.45 eV. Fixing the oscillator energies removes fitting parameters, decreasing correlations. For PEDOT:PSS, AJ10, and AJ30 an oscillator had its energy fixed at 0 eV (Drude oscillator) to account for the free charge contribution. For AJ20, the best fit was achieved without a free charge oscillator. For $\lambda < 300$ nm, only transmittance data was fit because of the limitations of the ellipsometer wavelength range. Also when fitting the data between 300 nm and 400 nm, the transmittance data was weighted at 400% of the ellipsometric data because the fiber optic cables in the ellipsometer have absorption peaks in the UV. In total, five oscillators were used to model N_o for AJ10, AJ30, and PEDOT:PSS while four were used for AJ20.

To fit N_e, only two oscillators were used in the models. Because it is not possible to measure the extraordinary axis with transmittance spectroscopy it is not possible to measure below 300 nm. As a result only the oscillator with its energy fixed at 4.5 eV was used to account for absorption in the UV. For the second oscillator, A_j, Γ_j, and E_j were used as fitting parameters. As was mentioned previously, the extraordinary refractive index is only probed slightly at oblique angles by p-polarized light resulting in less accurate fitting.

The ordinary and extraordinary refractive indices and extinction coefficients generated from the best fits are displayed in Figs. 4 and 5, respectively. The results for PEDOT:PSS are consistent with previously published optical constants for the same formulation [23]. Both figures show that AJ10, AJ30, and PEDOT:PSS are more anisotropic, especially when comparing k_o and k_e, than AJ20. This correlates well with the different amounts of anisotropy in the conductivity measurements as AJ20 has only slight conductive anisotropy when compared to the other films. For PEDOT:PSS, AJ10, and AJ30 the amplitude of the free electron oscillators are similar, again agreeing with the conductivity data. The similarities can also be seen in the k_o values shown in Fig. 5. In Fig. 4c, both n_o and n_e of AJ20 look similar to a Cauchy dispersion model, which is commonly used to model the refractive index of dielectrics. This, too, is consistent with the low conductivity of AJ20.

4. Conclusions

In conclusion, we have shown that all of the AJ solutions produce films that have anisotropic conductive and optical properties. The pure S-P3MEET films from the AJ10 solution have conductive and optical properties that are similar to PEDOT:PSS films, indicating that it may be a suitable replacement for PEDOT:PSS in OPV devices. Additives to the solutions are found to alter the morphology of the films. In AJ20 films, there is complete isolation of the conductive S-P3MEET domains, resulting in a low parallel conductivity and optical properties that look similar to a dielectric material. AJ20 may be well suited for use in pixelated OLED displays as its low parallel conductivity will limit crosstalk between pixels. The lower concentration of additives in AJ30 causes the conductive domains to only be partially separated, which slightly decreases the parallel conductivity of the film relative to AJ10, where as the optics are not significantly affected. The surfaces of AJ20 and AJ30 are also shown to be rich in additive molecules. The high work function of AJ30 films indicates it may be best suited for use in OPV devices with high open circuit voltage and in blue emitting OLEDs due to the lowered hole injection barrier. Future studies will seek to better understand the properties of S-P3MEET and the effect of additives on surface and bulk properties.

Acknowledgments

This work was supported by the US Department of Energy EERE Solar America Initiative under Contract No. DE-FG36 08GO18018. We thank Plextronics, Inc. for donating the materials used in this study. We would also like to thank Andre Knoesen and Diego Yankelevich for support with ellipsometry measurements.

compared to inorganic alkali metal compounds /Al, such as LiF/Al [13–14]. It was found out that the organic aromatic alkali metal complexes bilayer cathode could achieved high efficiency device even matching to chemical stable material such as 2-methyl-9,10-di-(2-naphthyl)-anthracene (MADN) as electron transport layer without n-doping [15–16]. The authors ascribed it to the better conductivity of alkali metal complexes and smaller LUMO differences between them and MADN. Meanwhile, in the advances within the OLED research field, the non-aromatic alkali complexes are believed to be difficult for the injection of electrons when it matches with the chemical stable material. Tris(8-quinolino-lato)aluminium (Alq_3), once a widely used electron transport materials, is no longer suitable for high-efficiency OLEDs due to its high highest occupied molecular orbital (HOMO) energy and instability in air [17–18]. If the electron can be injected from the simple alkali metal salts into the chemical stable materials, it will be beneficial for the development of novel electron transport material and constructing homogenous device.

Here we report a new alkali metal complex cesium pivalate ($(CH_3)_3CCOOCs$), which can be sublimated at low temperature and match with chemical stable materials such as MADN and chemical reactive material such as Alq_3, and also exhibits good electron injection properties.

2. Experimental section

2.1. Material and methods

All reagents and solvents were used as purchased from Aldrich and were used without further purification. ^1H NMR spectra were recorded on a Bruker-AF301 AT 400 MHz NMR spectrometer. Mass spectra were obtained on a 1100 LC/MSD Trap (positive and negative) mode. Thermal gravimetric analysis (TGA) experiments were performed under a nitrogen atmosphere on a SEIKO EXSTAR 6000 TG/DTA 6200.

2.2. Preparation of compounds

Pivalic acid (2.04 g, 20 mmol) was added into a solution of hydroxycesium (3.1 g, 20 mm) in dry $CHCl_3$ (50.0 mL). The reaction mixture was stirred at room temperature for 4 h. Then the mixture was poured into hexane. The precipitate was filtered to afford white solid powder, then they were purified by procedure sublimation in vacuum (1.0×10^{-4} Pa) at 180 °C. Yield: 85% (4 g). ^1H-NMR: (400 MHz, $CDCl_3$): δ (ppm) 4.65 (s, 9H), MS (APCI):132.79 $(m/z)^+$, 100.9$(m/z)^-$, calcd for $C_5H_9CsO_2$: 233.97.

2.3. Device fabrication

The device structure used for the evaluation of cesium pivalate complex as an electron injection material was indium-tin-oxide (ITO)/NPB (60 nm)/Alq_3 (50 nm)/$(CH_3)_3$ CCOOCs/Al (150 nm). Moreover, the device with structure of ITO/2-TNATA (60 nm)/NPB (10 nm)/Alq_3:2% C545T (40 nm)/MADN or Alq_3 (15 nm)/$(CH_3)_3CCOOCs$/Al was also constructed for the further investigation. 4,4′,4″-*tris*[*N*-(1-naphthyl)-*N*-phenylamino]triphenylamine (2-TNATA), *N*, *N*′-bis-(1-naphthyl)-*N*,*N*′-diphenyl,1,1′-biphenyl-4,4′-diamine (NPB), tris(8-quinolino-lato)aluminium (Alq_3) and 2,3,6,7-tetrahydro-1,1,7,7,-tetramethyl-1H,5H,11H-10-(2-benzothiazolyl) quinol (C545T) were used as the hole injection, hole transport, electron transport and green dopant materials, respectively. To rigorously evaluate the device performance, reference OLEDs with LiF as electron injection layer (EIL) were also prepared for the comparison. In the fabrication of devices, prior to the deposition of organic materials, the indium-tin-oxide (ITO)/glass was cleaned with a routine cleaning procedure and pretreated with UV–Ozone [19]. The structures of all the OLED devices are shown in Table 1. The current density–voltage–luminance characteristics of the devices were measured with a diode array rapid scan system using a Photo Research PR650 spectrophotometer and a computer-controlled, programmable, direct-current (DC) source. The interface electronic structure and variation in the work function were performed by XPS with Al Ka X-ray source (1486.6 eV) and UPS with He discharge lamp (UV light of 21.22 eV) (Thermo ELECTRON CORPORATION, ESCALAB 250).

3. Results and discussion

Cesium pivalate was prepared using pivalic acid and the hydroxylcesium, then further purified by train sublimation at around 180 °C, and characterized with ^1H NMR and ESI. The complex exhibits a high decomposition temperature (424 °C) (see SFig. 1) and low Ts around 180 °C, while LiF showed a high Ts of 717 °C. The Ts of $(CH_3)_3CCOOCs$ is nearly 244 °C lower than its decomposition temperature, suggesting that the complex does not decompose during the thermal evaporation process. To the best of our knowledge, there is no other non-aromatic organic salt has been reported that acts as an electron injection layer without decomposition and sublimating at so low temperature, which will be beneficial for the development new type electron injection material and process of industry.

The device with simple configuration ITO/NPB (60 nm)/Alq_3 (50 nm)/EIL/Al (150 nm) was fabricated firstly. As we know, the thickness of the EIL is critical to forming both

Table 1
Layers structure of OLED devices.

interfaces and the energy band bending region. In these research works, when Alq_3 was used as electron transport layer (ETL), the optimized thickness for $(CH_3)_3CCOOCs$ (device **2**) and LiF (device **1**) is 2 nm and 1 nm, respectively. As shown in Fig. 1a, the typical two layer device with $(CH_3)_3CCOOCs$ as electron injection material exhibits higher power efficiency than device with LiF, device power efficiency has been improved by 19% (1.97 lm/W for device **2** and 1.66 lm/W for device **1**) at the current density of 50 mA/cm^2. Also, the turn on voltage and drive voltage of the device **2** are both lower than that of the device **1** (See Fig. 1b), which means $(CH_3)_3CCOOCs$ has better electron injection ability than LiF.

Typical three layer OLED devices **3**, **4**, **5**, **6** were prepared for further evaluation of cesium pivalate as EIL (see Table 1). The EL properties of these devices are summarized in Table 2, with all devices showing good green light. As expected, device **4** shows higher power efficiency than device **3**. The improvement can be attributed to lowering of the work function of the cathode and n-doping of Alq_3 with alkali metals that were formed by the higher reactivity of $(CH_3)_3CCOOCs$ than LiF with hot Al atoms impinging on these salts during the vapor deposition. Interestingly, when MADN was used as the electron transport layer (device **6**), in the optimized thickness (2 nm), the bilayer cathodes $(CH_3)_3CCOOCs$/Al also exhibits good electron injection properties, the maximum current efficiency is up to 20 cd/A with Commission Internationale d'Eclairage ($CIE_{x,y}$) color coordinates of ($x = 0.30$, $y = 0.65$) at current density of 140 mA/cm^2. As to literatures [15–16], the MADN is an anthracene derivative which is difficult to be chemically reduced by alkali ions and be injected electron by non-aromatic salt. Is it the special properties of $(CH_3)_3CCOO^-$ ions? In order to demonstrate it, we further fabricated the devices with similar structure by varying the thickness of LiF (see SFig. 2). With the optimized LiF thickness of 4 nm, the device **5** also shows good performance despite its efficiency is lower than the device **6**. The reasonable explanation is that the optimized thickness of LiF changed dramatically (1–4 nm) when MADN was used to instead of Alq_3 as ETL and its electron inject properties to MADN were ignored by the authors [15]. In fact, cathode can inject electron through LiF into ETL for tunneling effect when the thickness of LiF arriving a reasonable level. This result indicates even when the ETL is a chemical stable material, the non-aromatic salts can also act as efficient EIL by varying the thickness of the layer. Anyway, as shown in Fig. 2b, devices **6** and **4** also show lower driving voltage than devices **5** and **3** for better electron injection ability. Meanwhile, the optimized thickness of $(CH_3)_3CCOOCs$ was stable when matching with different ETL, which means it possess more widely usage in electronic device than LiF. By the way, considering that high efficiency of device **4** and **6** may be caused by the high reactive Cs ion, the similar device structure using CsF as EIL is also tested. The result indicates that the device using $(CH_3)_3CCOOCs$ as EIL has much higher power efficiency than device with CsF when MADN was used ETL (see SFig. 3).

In order to explore the injection mechanism of MADN/LiF/Al and MADN/$(CH_3)_3CCOOCs$/Al interfaces, "electron-only" devices Al/MADN (150 nm)/EIL (x nm)/Al were fabricated. Here we use aluminum as the anode to avoid light emission, which can be assumed that only electrons are injected. Fig. 3 shows the J–V characteristics of the electron-only devices. It can be seen that the current density of the devices increases dramatically at the same voltage when the electron injection layer was changed from LiF to $(CH_3)_3CCOOCs$. Meanwhile, for LiF, the electron injection ability changed dramatically with the thickness from 1 nm

to 4 nm, which is consistent with the OLED performance in device **5** (SFig. 2).

Efficient film-forming properties of electron injection layer used in OLEDs are crucial for the performance of the devices, so the surface morphologies of thin films of the two EIL $(CH_3)_3CCOOCs$ and LiF were also examined. The deposited EIL films were sublimated on MADN (150 nm) with ITO as the substrate. As showed in Fig. 4, the AFM phase image of $(CH_3)_3CCOOCs$ shows a smooth and amorphous thin film, but the LiF film exhibits slight crystallization. The root-mean-square (rms) roughness of $(CH_3)_3CCOOCs$ and LiF films are 0.97 and 1.94 nm, respectively. This suggests that $(CH_3)_3CCOOCs$ possess better amorphous stability and film-forming properties than LiF, which indicates that the rigid t-butyl group influences the arrangement of the molecules in the thin films, and $(CH_3)_3CCOO^-$ ion is as excellent group in instructing electron injection materials.

To further understand the mechanism for enhanced electron injection at the atomic scale, the interface of Alq_3/$(CH_3)_3CCOOCs$, MADN/$(CH_3)_3CCOOCs$, and $(CH_3)_3CCOOCs$/Al have been studied by XPS and UPS. Fig. 5a shows the Cs $3d_{5/2}$ core level peaks of pure $(CH_3)_3CCOOCs$, Alq_3/$(CH_3)_3CCOOCs$, Alq_3/$(CH_3)_3CCOOCs$/Al film respectively. Compared with pure $(CH_3)_3CCOOCs$ film, it can be seen that after the deposition of $(CH_3)_3CCOOCs$ onto Alq_3, the peaks of Cs $3d_{5/2}$ shift towards high binding energy by 0.1 eV, which indicates that electron transfer from $(CH_3)_3CCOOCs$ to Alq_3 forming a n-doping ETL. When Al is deposited onto Alq_3/$(CH_3)_3CCOOCs$, the peaks shift towards high binding energy by 0.2 eV, indicating the n-doping is enhanced and ohmic connection may be formed at the Alq_3/Al interface because of the high reactivity of $(CH_3)_3CCOOCs$ with hot Al. Fig. 5b shows the Cs $3d_{5/2}$ core level peaks of pure $(CH_3)_3CCOOCs$,

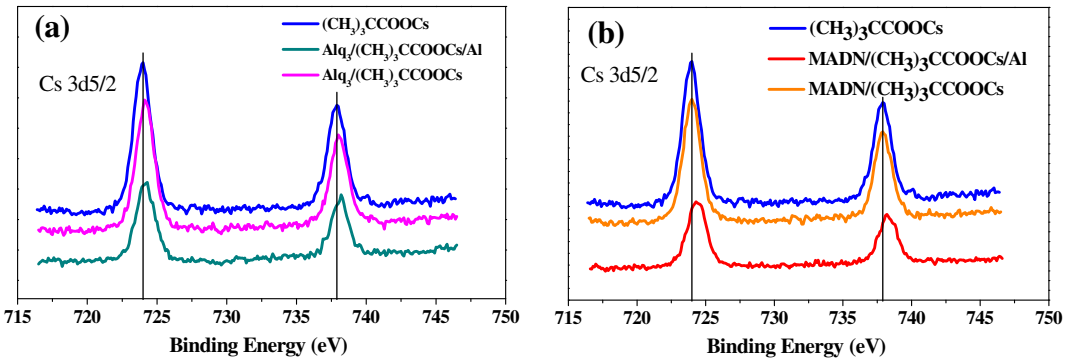

Fig. 5. XPS spectra of (a) $(CH_3)_3CCOOCs$, $Alq_3/(CH_3)_3CCOOCs$, and $Alq_3/(CH_3)_3CCOOCs/Al$ film; (b) $(CH_3)_3CCOOCs$, $MADN/(CH_3)_3CCOOCs$, and $MADN/(CH_3)_3CCOOCs/Al$ film.

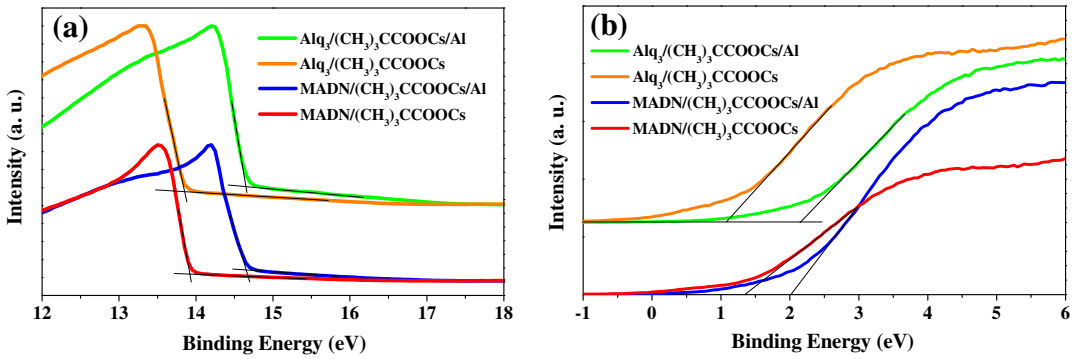

Fig. 6. UPS spectrum around (a) the secondary electron cut-off, and (b) the Fermi energy for a 2 nm thermally deposited film of $(CH_3)_3CCOOCs$, before and after the deposition of 2 nm Al.

$MADN/(CH_3)_3CCOOCs$, $MADN/(CH_3)_3CCOOCs/Al$ film, respectively. Different from that in Fig. 5a, after deposition of $(CH_3)_3CCOOCs$ onto MADN, there is no shift of the binding energy peaks, which indicate there is no electron transfer from $(CH_3)_3CCOOCs$ to MADN because MADN is a chemical stable compounds. However, when Al is deposited onto $MADN/(CH_3)_3CCOOCs$, the peaks shift towards the high binding energy by 0.3 eV, which means that electron transferring occurred and n-doping appeared. This also explains that why $(CH_3)_3CCOOCs$ has good match with the chemical stable compound and exhibits good electron injection properties in device **6**.

Fig. 6 shows the UPS spectrum for secondary electron cutoff region and the Fermi energy of the Alq_3, $MADN/(CH_3)_3CCOOCs$ (2 nm) and Alq_3, $MADN/(CH_3)_3CCOOCs$ (2 nm)/Al (2 nm), respectively. It can be clearly seen from Fig. 6a that the vacuum level shifted downwards after the deposition of Al onto $(CH_3)_3CCOOCs$ no matter using Alq_3 or MADN as ETL, which indicate the work function of cathode is reduced and the energy barrier for electron injection becomes small. Making two tangent lines along each curve in Fig. 6a, the variation of binding energy versus the intersection indicate the variation of vacuum level. It can be estimated that after the deposition of Al, the work function of cathode is reduced by about 0.82 and 0.73 eV for $Alq_3/(CH_3)_3CCOOCs$ and $MADN/(CH_3)_3CCOOCs$, respectively. By the way, it is obviously obtained from Fig. 6b that the Fermi energy of Alq_3, $MADN/(CH_3)_3CCOOCs$ (2 nm) also shifted toward a higher binding energy by about 1.1 and 0.71 eV, which indicated that the Alq_3, MADN become n-doped with the electron transfer because of the high reactivity of $(CH_3)_3CCOOCs$ with hot Al, this result is consistent with the XPS results.

4. Conclusions

In summary, a new electron injection material $(CH_3)_3CCOOCs$ was synthesized and evaluated by fabricating OLED devices using different electron transport materials in the device. $(CH_3)_3CCOOCs/Al$ cathode shows obviously enhanced electron injection ability into the electron transport material as compared to LiF/Al. Specifically, interposing of thin layer of $(CH_3)_3CCOOCs$ between the Al cathode and the MADN layer leads to a low driving voltage and higher efficiency device performance. It should be noted that, this non-aromatic alkali metal complex matching with chemical stable electron transport material properties was never be reported. At last, the EIL material can be sublimated under vacuum at about 180 °C, which is beneficial for the process of device fabrication. Further investigation on the mechanism of $(CH_3)_3CCOOCs$ as efficient EIL matching with MADN, and effect of $(CH_3)_3CCOOCs$ in the homojunction devices is ongoing.

to limited exciton dissociation [21]. On the other hand, having eliminated phase separation as a morphological parameter of consideration, these devices represent model systems with which we can probe how constituent crystallization affects device characteristics. Yet, planar-heterojunction polymer solar cells, especially those derived from solution processing [16–20], are notoriously difficult to fabricate as the need to create pristine interfaces between the organic semiconductors necessitates solvent orthogonality during deposition.

In this paper, we employ a combination of soft-contact lamination and polymer transfer techniques [16,17,22–24] to fabricate planar-heterojunction polymer solar cells having solution-processed components. More specifically, the electron donor and electron acceptor are deposited from solution onto independent substrates and processed in isolation before they are laminated to establish the charge transfer interface. Thermal annealing is intentionally avoided after lamination to prevent constituent interdiffusion [25]. This procedure obviates the need for solvent orthogonality during the deposition of the active layers. More importantly, it allows the independent processing of the electron donor from the electron acceptor; the constituent organic semiconductors can thus be subjected to different thermal annealing conditions before they are brought together. The ability to independently process the individual organic semiconductor layers in polymer solar cells having one pristine exciton dissociation interface provides an opportunity for us to elucidate how such processing conditions influence structural development, and uniquely allows us to correlate quantitative structural changes in the active layers with planar-heterojunction device performance without having to take complications associated with phase separation into account.

2. Experimental

The experiments reported herein were conducted with commonly studied poly(3-hexyl thiophene), P3HT, as the polymer donor and [6,6]-phenyl-C_{61}-butyric acid methyl ester, PCBM, as the electron acceptor. To elucidate how processing history influences constituent crystallization of P3HT and PCBM, and to assess how changes in their crystallinity affect device performance, we fabricated planar-heterojunction devices comprising P3HT and PCBM by soft-contact lamination and polymer transfer [16,17,22–24]. We have previously shown this soft-contact lamination and polymer transfer procedure to be highly versatile; planar-heterojunction devices comprising P3HT and a polymer acceptor of poly{[*N*,*N*′-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-alt-5,5′-(2,2′-bithiophene)}, P(NDI2OD-T2), have also been successfully fabricated [16].

Starting with the inverted device geometry [26,27], Fig. 1 illustrates schematically the procedure by which we fabricated P3HT/PCBM planar-heterojunction polymer solar cells. Pre-patterned ITO on glass substrates (15 Ω/sq.; Colorado Concept Coatings) were cleaned by sonication in acetone and isopropyl alcohol for 10 min each. A 1 wt.% titanium isopropoxide ($Ti[OCH(CH_3)_2]_4$; Aldrich; 99.999%) in isopropyl alcohol solution was then spin coated uniformly on the pre-cleaned ITO on glass substrates at 3000 rpm for 30 s. Hydrolysis at room temperature for 1 h and at 170 °C for 10 min resulted in a 40 nm-thick titania electron transport layer [26–29]. A 1 wt.% PCBM (American Dye Source, Inc.) solution in chloroform was spin coated directly on the titania electron transport layer at 3000 rpm for 60 s to create the electron acceptor layer. This procedure completed the construction of the bottom half of the planar-heterojunction polymer solar cells. To create the top half of the polymer solar cells, we first spin coated a 1.5 wt.% P3HT (Merck Chemicals, Ltd.) solution prepared in chlorobenzene at 500 rpm for 60 s on UV-ozone treated silicon wafers. This P3HT layer was then placed in direct contact with a featureless poly(dimethyl siloxane), PDMS, stamp (Dow Corning Sylgard 184 formulation). The thicknesses of the P3HT and PCBM layers were separately optimized; they were kept constant at 160 and 95 nm, respectively, in this present study. The entire assembly of P3HT sandwiched between PDMS and the silicon wafer was then immersed in water. Since water selectively wicks into the interface between hydrophobic P3HT and hydrophilic silicon [22], removal of the stamp subsequent to immersion resulted in the complete transfer of P3HT from

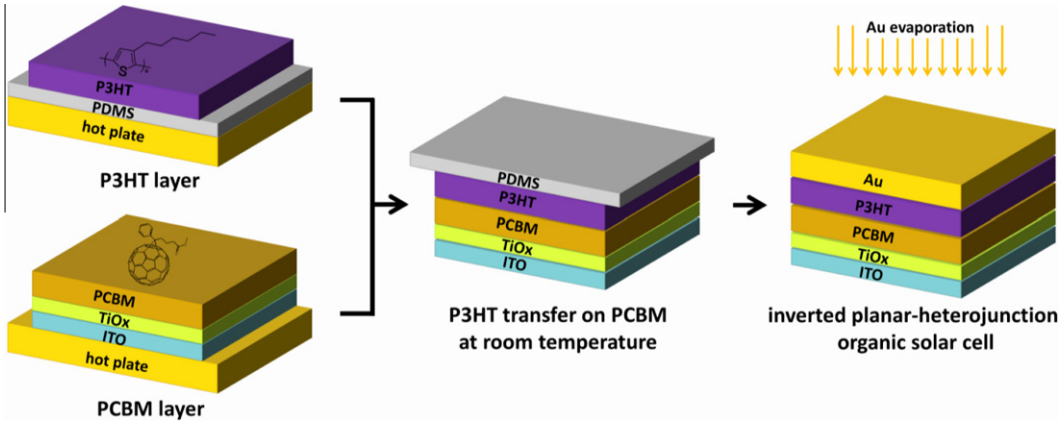

Fig. 1. Schematic illustration for fabricating planar-heterojunction polymer solar cells. The P3HT and PCBM layers are deposited and processed independently before they are brought together at room temperature to make electrical contact.

the silicon wafer onto PDMS. We then subjected the two components of the planar-heterojunction device – PCBM on titania and P3HT on PDMS – to independent thermal annealing at 170 °C for varying durations (from 1 to 10 min) in air and in a nitrogen-filled glove box before they were laminated against each other to establish the electron donor-electron acceptor charge transfer interface. Upon lamination, the PDMS stamp was carefully removed to complete the transfer of the P3HT layer onto PCBM. We can routinely transfer P3HT that is 2.5 cm × 1.5 cm onto PCBM though larger areas are possible. XPS measurements conducted on the polymer surface upon removal of the PDMS stamp reveal an absence of silicon signal; we therefore surmise that transfer of residual siloxane oligomers from PDMS to the polymer surface is negligible. Finally, we thermally evaporated 100 nm thick gold through a stencil mask on the active layer to define the anode with which holes are collected. The active area of our planar-heterojunction polymer solar cell is 0.18 cm^2. All the devices were tested in air. Given the rapid diffusion of PCBM into amorphous P3HT even at modest temperatures [25], the planar-heterojunction devices were not subjected to any additional thermal annealing after soft-contact lamination and polymer transfer to maintain the pristine interface between electron donor and electron acceptor.

Planar-heterojunction polymer solar cells were tested with a Keithley Model 2400 source measurements unit under AM 1.5 G 100 mW/cm^2 illumination. Current density–voltage (J–V) characteristics were acquired 10 min after flood illumination to fill shallow electron traps in the titania electron transport layer [26].

To characterize the structural changes associated with the constituent organic semiconductors upon thermal annealing, grazing-incidence X-ray diffraction (GIXD) was carried out on thin films of P3HT and PCBM prepared under the same conditions employed for device fabrication. GIXD measurements were conducted on beam line 11-3 at the Stanford Synchrotron Radiation Lightsource with an incident angle of 0.11° and an incident X-ray energy of 12.7 keV. An area detector was used to acquire the scattered X-rays. In addition to X-ray diffraction in the grazing geometry, we also acquired local specular scans on the P3HT (100) reflection (q = 0.37 $Å^{-1}$) by rocking the samples about its corresponding Bragg angle – from 1.55° to 1.80° – to capture all scattered intensity. For both grazing incidence and local specular data, the diffracted intensity was first background-subtracted before it was integrated along an annular region that contains the reflection of interest to derive the one-dimensional intensity as a function of the polar angle, χ. This one-dimensional trace is known as a pole figure. The pole figures extracted from the grazing incidence data and the local specular data were then stitched together to obtain the full pole figure [30,31], which we used to quantify the relative crystallinity of P3HT [30,32]. The polarization correction factor estimated for the P3HT (100) reflection is near unity (>0.99), so polarization correction was not applied to our analysis. The absorbance correction was also omitted since X-ray absorption in thin polymer films is small [30]. The full pole figure was then normalized with sample thickness to allow for comparison between samples [31]. The relative crystallinity is proportional to the integrated intensity according to $D_0C \propto 2\pi \int_0^{\pi/2} I(\chi)\sin(\chi)d\chi$. Local specular scans, however, were only acquired for P3HT and not PCBM because the incident angle required to acquire local specular data on PCBM is too high (q = 1.4 $Å^{-1}$; corresponding to a Bragg angle of 6.2°) [32]. Experiments conducted at such incident angles are compounded by non-negligible background contributions due to substrate penetration of X-rays and the lower intensity from the film resulting from the large incidence angle [32].

To assess charge transport along the vertical and lateral directions of PCBM thin films, we also fabricated single-carrier diodes and thin-film transistors comprising PCBM, respectively. Single-carrier diodes were fabricated and tested on pre-patterned ITO on glass according to previously published procedures [33,34]. Pre-patterned ITO on glass substrates were cleaned by sonication in acetone followed by in isopropyl alcohol for 10 min each, upon which the substrates were subjected to UV-ozone exposure for 10 min. We then spin coated an aqueous dispersion of poly(ethylene dioxythiophene) that is templated on poly(styrene sulfonate), PEDOT:PSS (Clevios P; used as-purchased from H.C. Starck), at 2000 rpm for 120 s. The PEDOT:PSS layer, ca. 140 nm thick, was then subjected to thermal annealing at 150 °C for 20 min. Following thermal annealing, a 1 wt.% PCBM solution in chloroform was spin coated at 3000 rpm for 60 s, resulting in an active layer that is 95 nm thick. To mirror the thermal treatments imposed during planar-heterojunction device fabrication, PCBM was also subjected to thermal annealing at 170 °C for varying durations in air and in a nitrogen-filled glove box. Thermal evaporation of 1 nm thick LiF and 40 nm aluminum completed the fabrication of single-carrier diodes comprising PCBM. These diodes have the same active area as the planar-heterojunction devices. These devices were tested with a Keithley Model 2400 source measurement unit under nitrogen to prevent oxidation of the aluminum contacts. Thin-film transistors comprising PCBM were fabricated in the bottom-gate, top-contact geometry using highly doped silicon and 300 nm thick silicon dioxide (Process Specialties, Inc.) as gate and gate dielectric, respectively. The wafers were initially subjected to a sequential solvent cleaning of sonication in acetone and isopropyl alcohol for 10 min each, and then exposed to UV-ozone for 10 min. To passivate the silicon dioxide surface, we spin coated 1,1,1,3,3,3-hexamethyldisilazane, HMDS (Seidler Chemical) on the pre-cleaned wafer at 3000 rpm for 60 s. The electrically-active channel was created by spin coating a 1 wt.% PCBM solution in chloroform at 3000 rpm for 60 s on the HMDS-treated surface. The PCBM layer was subjected to thermal annealing analogous to conditions imposed during planar-heterojunction solar cell and single-carrier diode fabrication. After thermal annealing, the substrates were transferred into a nitrogen-filled glovebox in which 60 nm of aluminum was thermally evaporated through a stencil mask as source and drain electrodes. The channel length and width were 100 and 1000 μm, respectively. Electrical characterization of PCBM thin-film transistors was carried out using an Agilent 4145B Parameter Analyzer in the same nitrogen-filled glove box to avoid oxidation of aluminum contacts.

Ultra-violet photoelectron spectroscopy (UPS) measurements were carried out on thin films of as-cast and thermally annealed PCBM. Thermal annealing occurred at 170 °C for 10 min either in air or in a nitrogen-filled glovebox. The base pressure of the ultrahigh vacuum chamber that is equipped with a He discharge lamp and a double-pass cylindrical mirror analyzer was 2×10^{-10} Torr. The photon energy for UPS measurements was 21.2 eV for HeI and 40.8 eV for HeII. These measurements provided estimates for the work function and the energy level of the highest occupied molecular orbital (HOMO) of PCBM. We also assessed the electronic band gap of PCBM thin films before and after thermal annealing by carrying out optical spectroscopy measurements on as-cast and thermally annealed PCBM across a UV–vis/NIR spectral range of 190–1100 nm using an Agilent 8453 spectrophotometer with 1 nm resolution. Thermal annealing was carried out in air or in nitrogen for 10 min.

3. Results and discussion

Fig. 2 shows the current density–voltage (J–V) characteristics of P3HT/PCBM planar-heterojunction polymer solar cells that were fabricated by soft-contact lamination and polymer transfer. Here, we explored the influence of thermal annealing of P3HT for varying durations in air and in nitrogen on solar cell device characteristics. As-spun as well as thermally annealed thin P3HT films were thus transferred onto unannealed PCBM according to the procedures outlined above and shown schematically in Fig. 1. P3HT films were annealed at 170 °C for 1, 5, and 10 min in air (top portion of Fig. 2a) and in a nitrogen-filled glovebox (bottom portion of Fig. 2a) prior to transfer. As-spun P3HT spontaneously contacted the underlying PCBM film upon transfer; thermally annealed P3HT films were slightly stiffer and required some external pressure to establish contact with PCBM upon transfer. The J–V characteristics of a representative planar-heterojunction polymer solar cell having unannealed P3HT and PCBM are shown with open squares in Fig. 2a. Of five devices tested, the open-circuit voltage (V_{oc}) was -0.41 ± 0.01 V and the short-circuit current density (J_{sc}) was 0.73 ± 0.01 mA/cm^2, resulting in an average efficiency of 0.13 ± 0.01%. While the V_{oc} of these devices are lower than those of conventional bulk-heterojunction devices [35,36], it is comparable to the V_{oc} reported for bulk-heterojunction polymer solar cells constructed in the inverted architecture tested immediately after device fabrication [26]. Previously, we found that prolonged exposure (>days) of inverted solar cells to air induces oxidation of P3HT, effectively increasing V_{oc} [26]. We believe this mechanism will be at play in our inverted planar-heterojunction devices as well. To eliminate potential complications due to extensive oxidation of P3HT in our present study, however, all the planar-heterojunction devices were tested immediately after fabrication. We further note that these planar-heterojunction devices exhibit efficiencies that are significantly lower than those typically reported for P3HT:PCBM bulk-heterojunction solar cells, presumably due to an extensive reduction in the density of donor–acceptor interface at which exciton dissociation and charge transfer occur in the planar-heterojunction

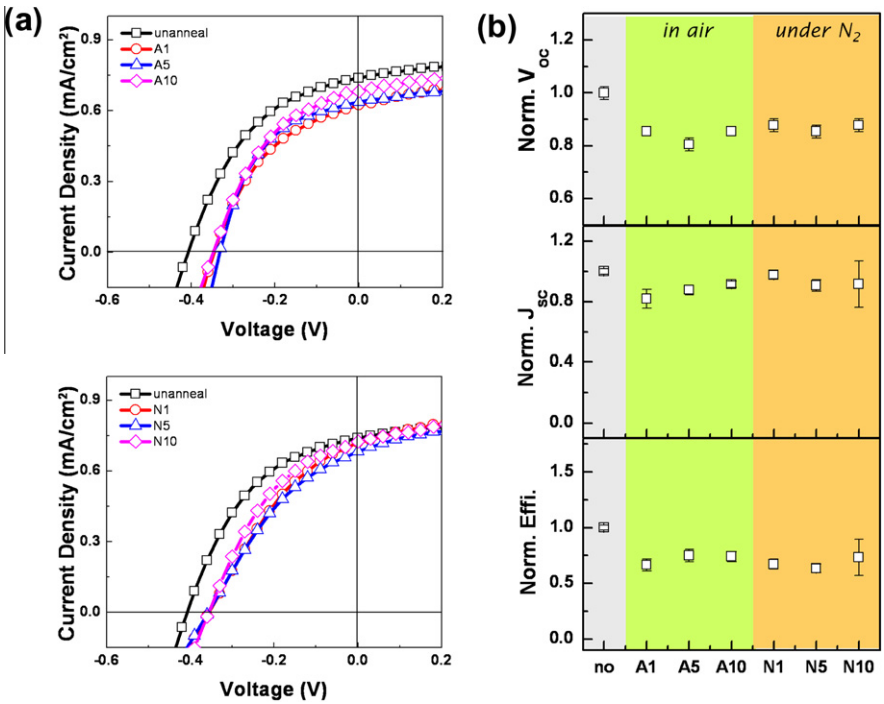

Fig. 2. (a) J–V characteristics of P3HT/PCBM planar-heterojunction solar cells in which the P3HT layer was annealed at 170 °C for 0, 1, 5 and 10 min in air (a; top graph) and in a nitrogen-filled glovebox (a; bottom graph) prior to polymer transfer. Normalized device characteristics are summarized in (b).

architecture [21]. Despite their low efficiencies, these devices represent model devices with which we can elucidate processing–structure–function relationships of P3HT and PCBM.

The *J–V* characteristics of planar-heterojunction devices comprising transferred P3HT that had been thermally annealed in air and in nitrogen are represented by open circles (annealing for 1 min at 170 °C), open triangles (5 min) and open diamonds (10 min). The characteristics of devices comprising thermally annealed P3HT appear to be largely independent of the processing history imposed upon P3HT prior to transfer. Specifically, of all devices tested, the average V_{oc} = 0.35 ± 0.01 V; the average J_{sc} = 0.66 ± 0.04 mA/cm^2, resulting in an average efficiency of 0.092 ± 0.006%. The normalized device characteristics are plotted in Fig. 2b; error bars represent standard deviations from five devices tested. We observe a small difference (about 10%) between the V_{oc} of devices comprising as-cast P3HT and those containing thermally annealed P3HT; this difference resulted in the lower efficiency we observe with devices having thermally annealed P3HT in Fig. 2b. We speculate that this difference may arise from changes in the dipole strength at the interface of as-spun and annealed P3HT with PCBM or to conformational changes in P3HT. Given that the V_{oc} change is small and the UPS resolution is 0.1 eV, we were not able to directly measure the changes in the energy level of P3HT. Consistent with our speculation, however, we previously measured interfacial dipoles as high as 0.3–0.4 eV at the interface between P3HT and PCBM domains in bulk-heterojunction active layers [37,38]. The J_{sc} of devices comprising thermally annealed P3HT is statistically the same as that extracted from devices comprising as-spun P3HT. This observation was initially surprising given that the thermal annealing of bulk-heterojunction polymer solar cells is reported to increase J_{sc} due to increases in P3HT and PCBM crystallinities within the active layers [16,39,40].

To understand why the J_{sc} of our planar-heterojunction solar cells does not change with P3HT annealing, we carried out GIXD experiments on thin films of P3HT prepared under the same conditions as those that were transferred for device fabrication. Fig. 3a contains X-ray diffraction patterns acquired on an as-cast P3HT thin film, as well as on those that were thermally annealed at 170 °C in nitrogen for 1, 5, and 10 min. The X-ray diffraction patterns look qualitatively similar; we observe intensities along the meridian at q = 0.37, 0.74, and 1.11 Å^{-1} in all P3HT films corresponding to the (100), (200) and (300) reflections of the lamellar stacks of P3HT; these lamellae are oriented in-plane, with the stacking periodicity out-of-plane [41]. Integrating the intensities in the X-ray diffraction patterns radially yielded the 1-D X-ray traces in Fig. 3b. The (h00) reflections, along with the (010) reflection of P3HT are highlighted for clarity. All the P3HT films are semi-crystalline, as evinced by the multiple higher-order reflections present in the X-ray diffraction traces. To quantify the relative crystallinity of the P3HT films, we acquired data in the local specular geometry and constructed full pole figures at q = 0.37 ± 0.1 Å^{-1} corresponding to the (100) reflection of P3HT. This procedure allows us to capture all the scattered intensities from the P3HT crystallites within the sample volume; see full pole figures in Supplementary material (Fig. S1). As such, the integrated intensities of the full pole figures provide relative

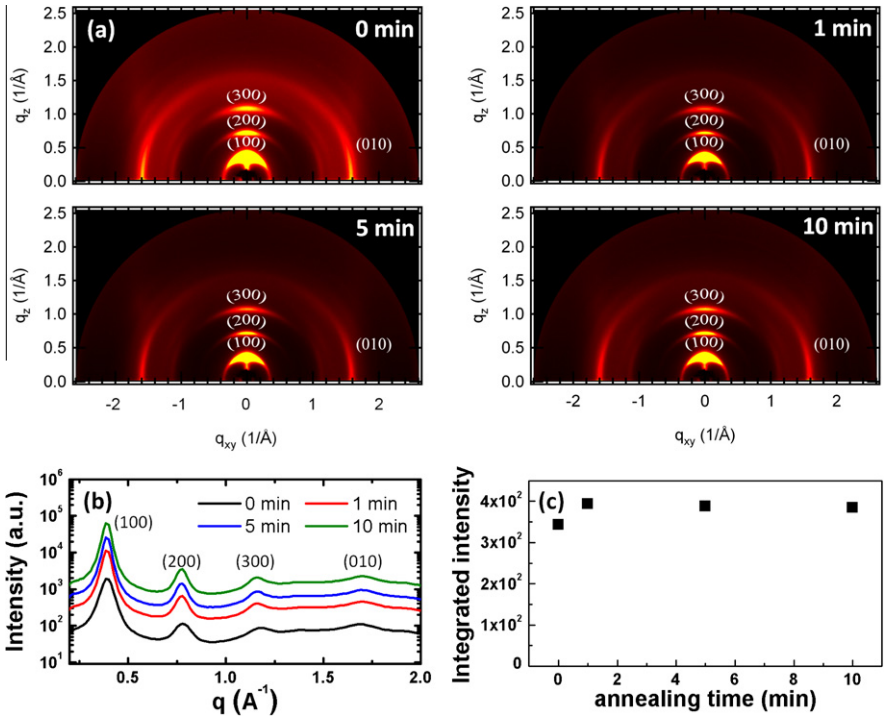

Fig. 3. (a) GIXD patterns of P3HT annealed at 170 °C for 0, 1, 5 and 10 min in nitrogen and (b) 1-D X-ray traces acquired by radially averaging across the X-ray patterns. (c) Integrated intensity of the full pole figure collected on the (100) reflection of P3HT indicates relative crystallinity in each film.

comparisons for the extent of crystallinity of P3HT films that were annealed for varying durations [30–32]. The integrated intensities extracted from the full pole figures are plotted in Fig. 3c. The integrated intensity increases by 15% when the P3HT film is subjected to thermal annealing at 170 °C for 1 min, reflecting a small increase in the extent of P3HT crystallinity. Subsequent annealing for longer durations does not alter the extent of crystallinity significantly, as indicated by the near-constant integrated intensity of the full pole figures. This observation is somewhat different from some reports of thermal annealing of bulk-heterojunction active layers comprising P3HT and PCBM where the crystallinity of P3HT has been reported to increase significantly [16,39,40]; the extent of which depends on the solvent from which the active layers were cast [42]. Rather, our experiments indicate that as-spun P3HT exhibits non-negligible crystallinity. Subjecting the thin film to a 1 min annealing increases P3HT crystallinity modestly, beyond which extended annealing does not further improve P3HT crystallinity. Our experiments thus suggest that P3HT – in the absence of PCBM – crystallizes readily and quickly upon solvent evaporation when cast from chlorobenzene; subsequent annealing does not significantly increase its crystallinity. Accordingly, the planar-heterojunction devices comprising these films exhibit near-constant J_{sc}'s that are independent of the duration P3HT was annealed.

The ability to independently process the constituent layers of the planar-heterojunction device also provides us with the opportunity to examine the effects of thermally annealing PCBM on solar cell performance. In this set of experiments, as-spun P3HT was transferred onto either as-spun PCBM or thermally annealed PCBM on titania for device construction. Analogous to the example above, PCBM was annealed at 170 °C for 1, 5, and 10 min in air and in a nitrogen-filled glovebox prior to P3HT transfer. We observe intimate molecular contact upon the transfer of P3HT onto both unannealed and annealed PCBM; the application of external pressure was thus not necessary.

Fig. 4a contains *J–V* characteristics of representative planar-heterojunction solar cells in which PCBM has been thermally annealed at 170 °C for varying durations in air (top graph) and in nitrogen (bottom graph). The *J–V* characteristics of the representative device having as-spun PCBM are shown as open squares; the *J–V* characteristics of representative devices comprising PCBM thin films that had been annealed for 1, 5, and 10 min are shown as open circles, triangles and diamonds, respectively. Of five devices with unannealed PCBM tested, the average J_{sc} was 0.73 ± 0.01 mA/cm^2 and the average V_{oc} was −0.41 ± 0.01 V, resulting in an average efficiency of 0.13 ± 0.01%. Unlike thermal annealing of P3HT, thermal annealing of PCBM results in drastically different device characteristics. The J_{sc} of these devices, for example, decreased drastically to 0.33 ± 0.01, 0.076 ± 0.003 and 0.049 ± 0.001 mA/cm^2 for devices in which PCBM was thermally annealed in air for 1, 5 and 10 min, respectively, prior to lamination. Accordingly, the fill factor for these devices also decreased with increasing annealing times (see Fig. S2 in Supplementary material). Planar-heterojunction devices in which PCBM was thermally annealed in nitrogen for 1 min showed a modest increase in J_{sc}; the J_{sc} decreased progressively upon subsequent annealing. Annealing PCBM in nitrogen thus

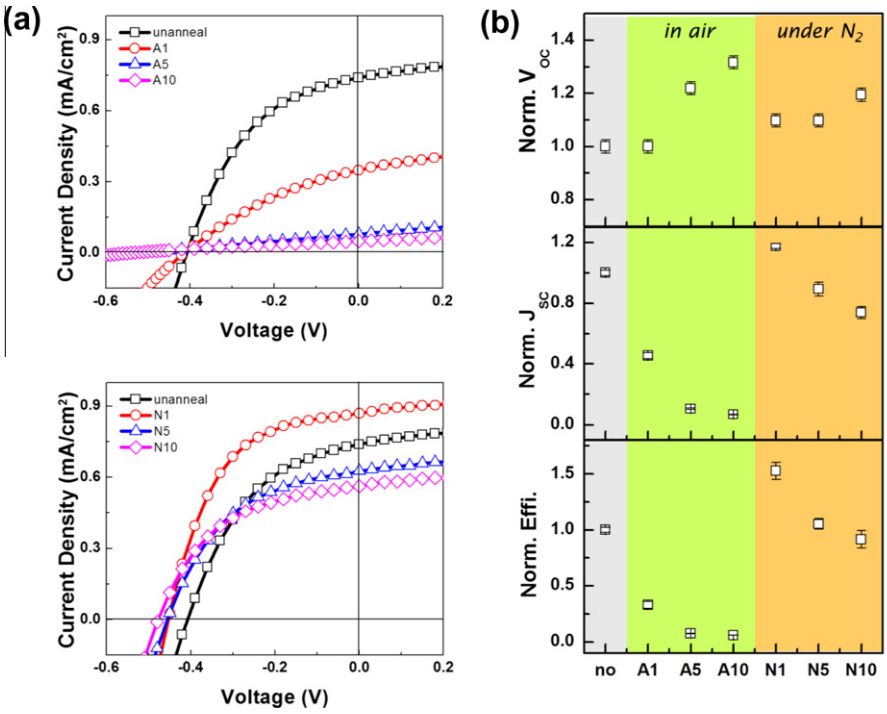

Fig. 4. (a) *J–V* characteristics of P3HT/PCBM planar-heterojunction solar cells in which the PCBM layer was annealed at 170 °C in air (a; top graph) and in nitrogen (a; bottom graph) for 0, 1, 5 and 10 min prior to polymer transfer. Normalized device characteristics are summarized in (b).

appears to impose the same fate to the devices as annealing PCBM in air, although the decrease in J_{sc} is less pronounced, presumably because irreversible chemical oxidation is avoided [43,44]. Compared to devices in which the processing of P3HT was explored, the present planar-heterojunction devices also show changes in V_{oc}'s when thermally annealed PCBM thin films are employed as the electron-accepting layer. The incorporation of PCBM that had been thermally annealed in air resulted in planar-heterojunction devices with increased V_{oc}. This trend of increasing V_{oc} is also observed in devices in which PCBM was thermally annealed in nitrogen, albeit to a smaller extent. For ease in comparison, we have plotted the normalized device characteristics in Fig. 4b. Given that the variations in J_{sc} (and accordingly, variations in fill factor) are more dramatic with thermal annealing of PCBM, the efficiencies of these devices mirror the trends of decreasing J_{sc}, as shown in the bottom panel of Fig. 4b. Collectively, the testing of our devices indicates the characteristics of our planar-heterojunction solar cells are more sensitive to the processing of PCBM compared to that of P3HT. This qualitative observation is in agreement with our prior study during which the structuring of PCBM and P3HT was quantified for a myriad of different processing conditions [32].

Thermal annealing of PCBM thin films prior to lamination can cause surface roughening due to structural rearrangement (e.g., crystallization). To verify that the decrease in J_{sc} is not due to poor electrical contact at the organic–organic charge transfer interface attributable to surface roughness upon P3HT transfer, we measured the J_{sc} of these same devices with increasing illumination intensity. Over the range of illumination intensity examined (50–250 mW/cm^2), we observe the same linear intensity dependence for all our devices regardless of PCBM annealing conditions; see Fig. S3 in Supplementary material. This observation strongly suggests that current generation in our devices is not limited by differences in exciton dissociation at the organic–organic planar-heterojunction interface. Rather, the decrease in J_{sc} observed in Fig. 4 stems from structural changes that are brought about by thermal annealing the electron acceptor thin films.

To quantify the structural development that has occurred with thermal annealing of PCBM, we turned to GIXD. Fig. 5 contains GIXD images acquired on PCBM thin films that were prepared under nitrogen using the same conditions as those in planar-heterojunction devices. The X-ray diffraction pattern acquired on unannealed PCBM appears featureless. After thermal annealing at 170 °C for 1 min, we observe the emergence of a broad halo at 1.4 Å^{-1} (see Fig. S4 in Supplementary material). Although this broad halo suggests that the film is largely amorphous, we cannot preclude the beginnings of nanoscale (2–3 nm sized) crystallites formation [45]. That the J_{sc} increases with a 1 min annealing in nitrogen is consistent with enhanced charge transport stemming from the presence of nanocrystallites of PCBM. This broad halo sharpens with further annealing of PCBM. Strikingly, we observe the development of six sharp spots coexisting with the amorphous halo in the X-ray diffraction pattern acquired on PCBM annealed for 10 min. The series of X-ray diffraction patterns in Fig. 5 therefore suggest progressive crystallization of PCBM with thermal annealing; the 1-D radially integrated plots of these X-ray diffraction patterns are provided in Supplementary material for completeness (Fig. S5). This crystallization behavior is consistent with that of PCBM cast from chloroform reported by Verploegen et al. [13]. Unfortunately, further quantification of the relative extent of PCBM crystallinity is challenging as local specular scans cannot be effectively carried out because the required X-ray incident angle of 6.2° brings about large background contributions [32]. There remain, however, large qualitative differences among the X-ray patterns presented in Fig. 5. In particular, the X-ray pattern acquired on PCBM that had been annealed for 10 min shows that the PCBM crystallites in this film are preferentially oriented. Tracing the scattered intensity at $q = 1.4$ Å^{-1} (through the sharp peaks) azimuthally reveals increases in intensity at $\chi = \pm 26°$ from the meridian (see Supplementary material, Fig. S4). While we are unable to determine the crystal structure and preferential orientation adopted by PCBM with only one diffraction peak, we note that the peak position observed here is consistent with one of the peaks observed of crystallized PCBM in

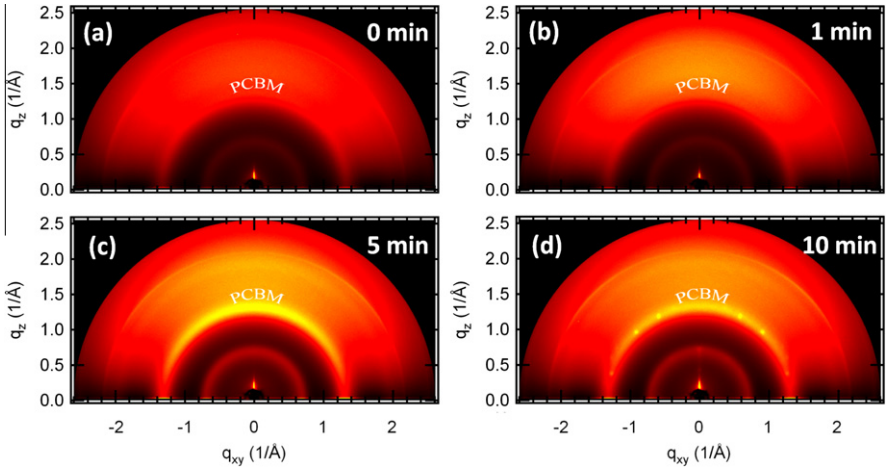

Fig. 5. GIXD images of PCBM layers (a) before and (b–d) after thermal annealing at 170 °C in nitrogen for (b) 1 min, (c) 5 min and (d) 10 min.

bulk-heterojunction polymer solar cells comprising P3HT and PCBM [16]. The sharpness of the spots in our present X-ray diffraction patterns, however, suggests that PCBM is substantially more oriented in the absence of P3HT. We further speculate that it may be the preferential orientation of the crystalline portions of PCBM that dramatically hinders vertical charge transport in our planar-heterojunction devices, ultimately resulting in reduced J_{sc}.

To validate our hypothesis, we evaluated the vertical charge transport of similarly prepared PCBM in single-carrier diodes. PCBM single-carrier diodes were fabricated according to previously published procedures and the electron mobility of PCBM was evaluated in the space charge limited current regime; representative data from one such single-carrier diode and its corresponding fit to extract out-of-plane electron mobility is shown in Fig. S6 of Supplementary material [33,34]. For reference, we also prepared thin-film transistors comprising similarly processed PCBM as active channels to evaluate its in-plane charge transport. The extracted electron mobility from these experiments is summarized in Fig. 6. Of four single-carrier diodes comprising unannealed PCBM, the average electron mobility is $1.56 \times 10^{-3} \pm 0.59 \times 10^{-3}$ cm^2/V s. With thermal annealing in air, we observe a progressive decrease in electron mobility. With thermal annealing in nitrogen, we observe first an increase in electron mobility before subsequent decreases upon further annealing. The electron mobility trends of the diodes comprising PCBM mirror those of the J_{sc} observed in our planar-heterojunction devices exactly. We thus attribute the initial increase in electron mobility in diodes to the development of nanocrystallinity of PCBM on annealing in nitrogen for 1 min; subsequent annealing induces a preferential orientation of PCBM crystals that hinders charge transport in the vertical. The absolute magnitude of the electron mobility (and the J_{sc} of planar-heterojunction devices in Fig. 5) is uniformly lower in diodes in which PCBM was annealed in air as opposed to in nitrogen, presumably because of chemical oxidation of PCBM at ambient conditions [43,44]. Interestingly, thin-film transistors comprising PCBM that were processed under nominally the same conditions exhibit comparable electron mobilities. Given that the mobilities of thin-film transistors can easily depend on dielectric treatment and the details of processing conditions, it is difficult for us to assign any real significance to the difference in the absolute values of the electron mobilities extracted single-carrier diodes and transistors. Collectively, our experiments indicate that thermal annealing of thin films of PCBM induces large-scale structural rearrangement; PCBM crystallizes with annealing at 170 °C and adopts a preferential orientation that we believe to hinder charge transport in the vertical, but not the lateral direction, on further annealing. Given that charge transport in thin-film transistors only occurs in the several nanometers near the dielectric surface [46], we thus speculate that the transistor electron mobility is less sensitive to PCBM crystallinity that develops on thermal annealing in the bulk of the film. The results in Fig. 6 also indicate that the electron mobility extracted from thin-film transistors – unlike that extracted from single-carrier diodes or planar-heterojunction solar cells – are largely independent of PCBM exposure to air. Again, since charge transport in thin-film transistors only occurs near the dielectric surface [46], our results suggest that the thermal annealing conditions in our study do not induce chemical oxidation of PCBM at the charge transport interface.

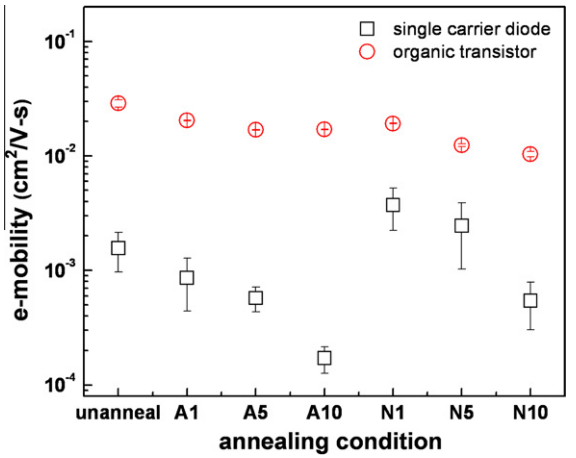

Fig. 6. Electron mobility of PCBM extracted from single-carrier diodes and thin-film transistors. PCBM was annealed at 170 °C in air and in a nitrogen-filled glovebox for varying times.

To assess the changes in V_{oc} observed in Fig. 4, we carried out UPS experiments on thin films of PCBM. Fig. 7a contains UPS data acquired on thin films of PCBM that were unannealed, and those that were annealed at 170 °C in air and in nitrogen for 10 min. UPS measurements on unannealed PCBM indicate a cut-off energy of 16.8 eV and a highest occupied molecular orbital (HOMO) edge that is 2.0 eV below the Fermi level (E_F), as extracted from the intersection between the steepest slope and the baseline. UPS measurements conducted on thermally annealed PCBM reveal similar shifts in both the cut-off energy and the HOMO edge. PCBM that had been annealed in air exhibits a cut-off energy of 16.5 eV and a HOMO edge of 1.7 eV below E_F. Thermal annealing in nitrogen as opposed to air also resulted in comparable shifts; the cut-off energy and the HOMO edge were estimated to be 16.4 and 1.7 eV below E_F, respectively. The energy levels of PCBM before and after thermal annealing are schematized in Fig. 7b. We observe a shift in the ionization potential of PCBM with thermal annealing. Optical spectroscopy experiments on the same films reveal the same absorption spectra for PCBM thin films before and after thermal annealing at 170 °C for 10 min in air and in nitrogen (see Fig. S7 in Supplementary material); these experiments indicate that the electronic band gap of PCBM is not altered with thermal annealing. Collectively, the UPS and absorption spectroscopy experiments thus imply a shift in the lowest unoccupied molecular orbital (LUMO) of PCBM corresponding to the shift observed in the HOMO with respect to E_F on thermal annealing. If this trend holds up when PCBM is brought into contact with P3HT, this shift would result in a larger difference between the HOMO energy level of P3HT and the LUMO energy level of PCBM, and accordingly, a higher V_{oc} in our planar-heterojunction devices. This energy level shift in PCBM with thermal annealing is independent of exposure to oxygen but appears to be highly dependent on its structural development. This

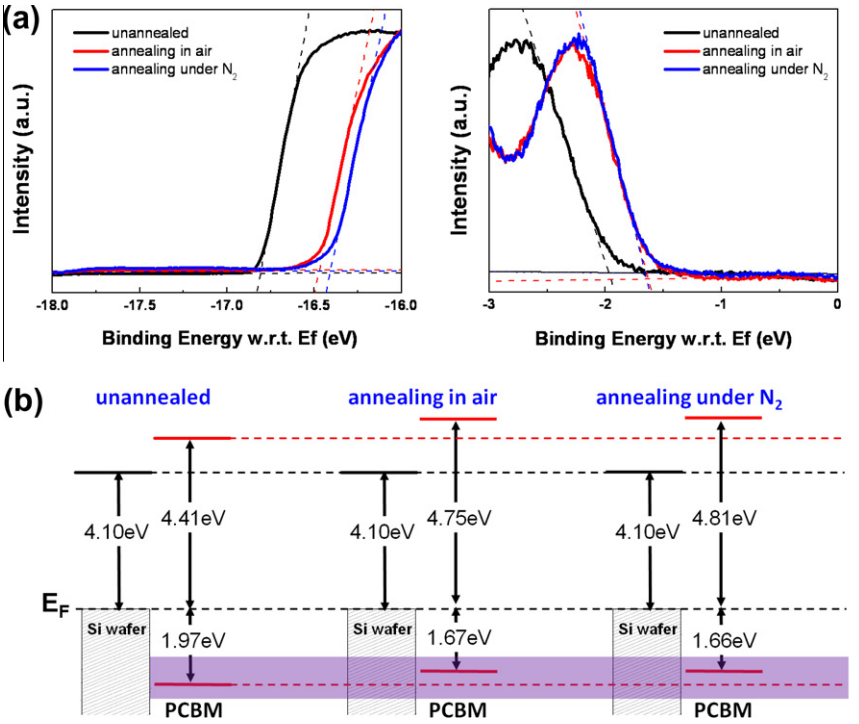

Fig. 7. (a) UPS spectra of PCBM before and after thermal annealing at 170 °C for 10 min. (b) Energy diagrams generated from UPS measurements indicate a shift in the HOMO energy level of PCBM after thermal annealing.

observation is reminiscent of prior reports in which the energy levels of organic semiconductor thin films are highly dependent on the details of structural order and preferential orientation [47].

4. Conclusions

The ability to laminate organic semiconductors and establish effective and efficient charge transfer interfaces has enabled us to fabricate model planar-heterojunction devices in which the processing of the constituent organic semiconductors can be systematically varied. Thermal annealing after lamination is intentionally avoided to eliminate constituent interdiffusion and maintain the pristine charge transfer interface. In our study, we showed the effective decoupling of the contributions of constituent crystallization to devices characteristics. In particular, thermally annealing P3HT thin films prior to lamination does not significantly alter J_{sc} because as-spun P3HT is already sufficiently crystalline to support charge transport. Thermal annealing PCBM, on the other hand, resulted in reduced J_{sc}. Our experiments indicate that PCBM partly crystallizes and hinders vertical charge transport on annealing, effectively reducing J_{sc}. This structural development is also correlated with a shift in the energy levels of PCBM, resulting in changes in V_{oc} in our planar-heterojunction devices.

Acknowledgments

This work was supported by the Photovoltaics Program at ONR (N00014-11-10328) and the SOLAR Initiative at the NSF (DMR-1035217). Partial funding by an NSF-sponsored MRSEC through the Princeton Center for Complex Materials (DMR-0819860) and by the Department of Energy (DE-FG02-04ER46165) is also gratefully acknowledged. Portions of this research were carried out at the Stanford Synchrotron Radiation Lightsource user facility operated by Stanford University on behalf of the US Department Energy, Office of Basic Energy Sciences.

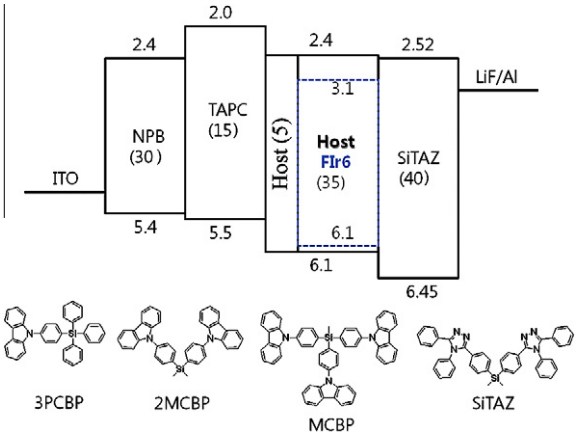

Fig. 1. Schematic energy level diagram of the single host emissive layer phosphorescent organic light-emitting devices (PHOLEDs) and molecular structures of the three different p-type hosts (3PCBP, 2MCBP, and MCBP) and electron transporting material (SiTAZ).

host [27]. Chopra et al. [28] and Lee et al. [29] reported on an efficient mixed-host system for a light blue PHOLED. Because of the scarcity of p-type host materials with high hole mobility and high T_1, they used a hole transporting material (TAPC, or TCTA) for the p-type host. However, highest occupied molecular orbital (HOMO) levels of the materials are too shallow to accommodate deep blue emitters, and moreover, the T_g of the materials are too low for practical applications. Therefore, the development of mixed host system with p-type host materials with high T_g, high T_1, high hole mobility, and deep HOMO level is urgently needed for real application of a mixed-host system in deep blue PHOLEDs. In this study, a carbazole-based p-type host material tris(4-(*N*-carbazolyl)phenyl)methylsilane (MCBP), exhibiting a high T_1 value of 3.05 eV, high T_g of 155 °C, and high hole mobility of 1.1×10^{-3} cm^2 V^{-1} s^{-1}, is introduced [30] for use in a mixed-host system. When it is used as a p-type material in a mixed-host system, a maximum external quantum efficiency of 19.0%, power efficiency of 23.5 lm/W, and deep blue color coordinates of (0.15, 0.23) are obtained, which are one of the best results ever reported for a mixed-host system in deep blue PHOLEDs. To address the origin of the high performance of the device using this material, three different p-type host materials are systematically examined.

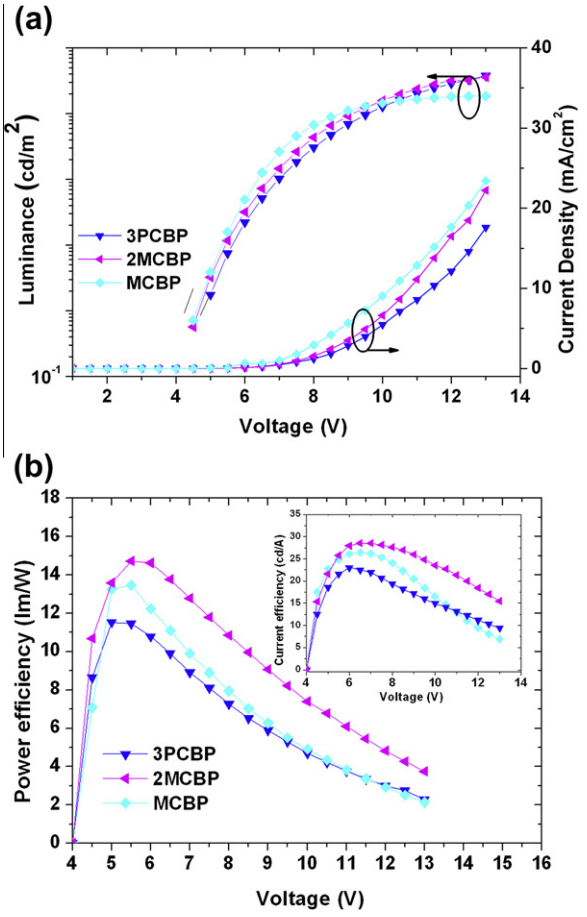

Fig. 2. Device characteristics of the PHOLEDs using single host systems with the device structure of ITO/NPB (30 nm)/TAPC (15 nm)/host (5 nm)/host:FIr6 (30 nm, 10 wt.%)/SiTAZ (40 nm)/LiF (0.5 nm)/Al (60 nm). 2. Experimental section

Mono(4-(*N*-carbazolyl)phenyl)triphenylsilane (3PCBP), bis(4-(*N*-carbazolyl)phenyl)dimethylsilane (2MCBP), tris(4-(*N*-carbazolyl)phenyl)methylsilane (MCBP), and bis(4-(4,5-diphenyl-4H-1,2,4-triazol-3-yl)phenyl)dimethylsilane (SiTAZ) were prepared using methods reported in the literature [30–36], and purified by train sublimation under

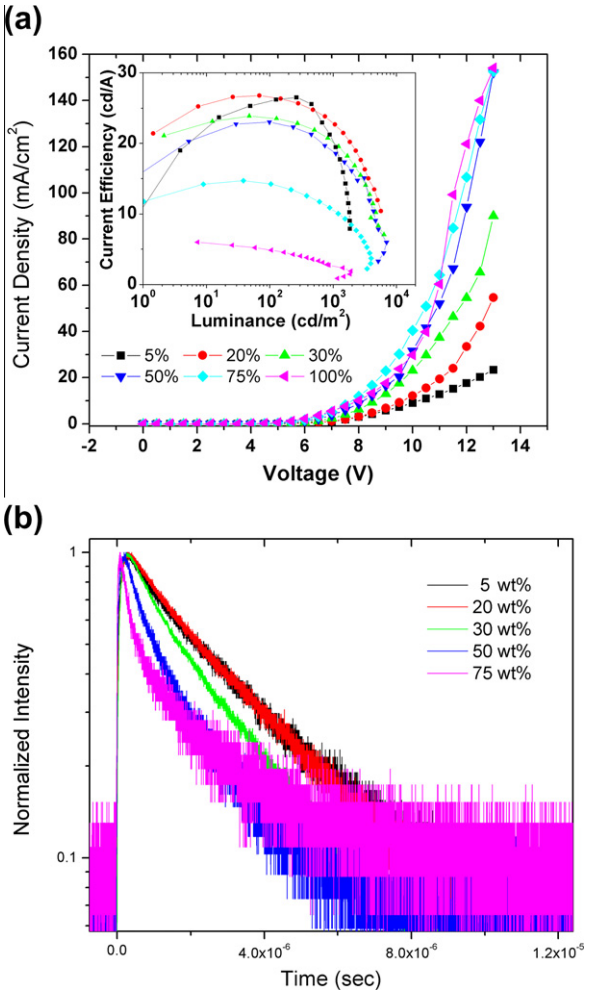

Fig. 3. (a) Current density–voltage and current efficiency–luminance curves of the device ITO/NPB/TAPC/MCBP/MCBP:FIr6 *x* wt.%/SiTAZ/LiF/Al as a function of FIr6 doping ratio. (b) Transient phosphorescence decay curves as a function of the doping ratio of FIr6 in MCBP films on fussed silica substrate.

5.4×10^{-5} Torr. Commercially obtainable organic materials were used as received for the experiments.

The hole mobility was measured by time of flight (TOF) transient photocurrent method. A nitrogen laser (GL-3300, Photon Technology International) was used as the pulsed light source. A 1 GHz digital oscilloscope (LC 572A, LeCroy) was used to measure the transient photocurrent signal.

For the transient photoluminescent decay measurements, a nitrogen laser (GL-3300, PTI) was used as an excitation light source and the phosphorescence light was passed through a monochromator (Oriel 77200), to which a photomultiplier tube (Oriel 77346) was attached at the exit slit.

The OLED devices were fabricated on glass substrates precoated with a 150 nm ITO layer with a sheet resistance of 10 Ω/square. The ITO glass was precleaned using a conventional solvent cleaning method. The ITO surface was cleaned again with a UV ozone treatment immediately before depositing the HTL. To confine triplet excitons into the EML, a thin interlayer of TAPC was inserted between the NPB and EML as a triplet exciton blocking layer because TAPC has a high triplet energy ($E_T \sim 2.9$ eV) and high hole mobility, as reported by Zheng et al. [37] As a deep blue emitter, iridium(III)[bis(4,6-difluorophenyl)pyridinato-N,C$^{2'}$]tetrakis(1-pyrazolyl)borate (FIr6) was chosen because it has high quantum yield and is commercially available. The ETL material, SiTAZ, was used for its high triplet energy (2.84 eV), deep HOMO level (6.45 eV), and high LUMO level (2.5 eV). The HOMO level is deeper than those of carbazole based hosts and FIr6 (6.1 eV), which is an important factor for hole blocking, whereas, the LUMO level is high enough to accommodate that of FIr6 (3.1 eV). The organic, LiF, and Al layers were deposited sequentially onto the substrate without breaking the vacuum. The current–voltage characteristics of OLEDs were measured using a source measure unit (Keithley 236). The electroluminescence spectra, luminance, and the CIE color coordinates were measured using a spectroradiometer (Photo Research PR650). Assuming Lambertian emission, the external quantum efficiency (EQE) was calculated from the luminance, current density, and electroluminescence spectrum.

3. Results and discussion

As summarized in Table 1, the materials exhibited various charge mobilitiy in the range of 10^{-5}–10^{-3} cm/V s [30,32,33]. Interestingly, carbazole based materials show systematic increase of hole mobility values in order of 3PCBP (9.9×10^{-5} cm/V s) < 2MCBP (3.5×10^{-4} cm/V s) < MCBP (1.1×10^{-3} cm/V s), as the number of 4-(*N*-carbazolyl)phenyl groups at the silicon core increases. MCBP is expected to be the most promising host material for deep blue PHOLEDs among the three materials studied, because of its high charge mobility, high thermal stability, and high triplet energy. In particular, the high hole mobility of MCBP would result in a high density of hole current due to its enhanced transporting properties. Therefore, high power efficiency would be expected if MCBP is used as a host for deep blue PHOLEDs. To examine the effects of hosts on device characteristics, a series of FIr6-based PHOLEDs were fabricated using three different host materials. As shown in Fig. 1, the PHOLEDs had the following device structure: ITO/NPB (30 nm)/TAPC (15 nm)/host (5 nm)/host:FIr6 (30 nm, 10 wt.%)/SiTAZ (40 nm)/LiF (0.5 nm)/Al (60 nm). Three different host materials were used in a single-host system with FIr6 10 wt.% doped EML layers, where the hosts are 3PCBP, 2MCBP, and MCBP, respectively. As shown in Fig. 2, all of the devices show efficient exothermic energy transfer from hosts to FIr6, which is evident from the high current efficiency of the devices, ranging from 23.6 to 28.9 cd/A. The devices exhibited driving voltages in the range of 6.4–7.7 V at 100 cd m^{-2}, which are high considering the mobilities of the host materials. The relatively high driving voltage can be ascribed to three causes. First, the thickness of EML (35 nm) of our device is relatively thick compared to the other reported devices [28]. Second, electron injection barrier from cathode into ETL is relatively high due to the high LUMO level of SiTAZ

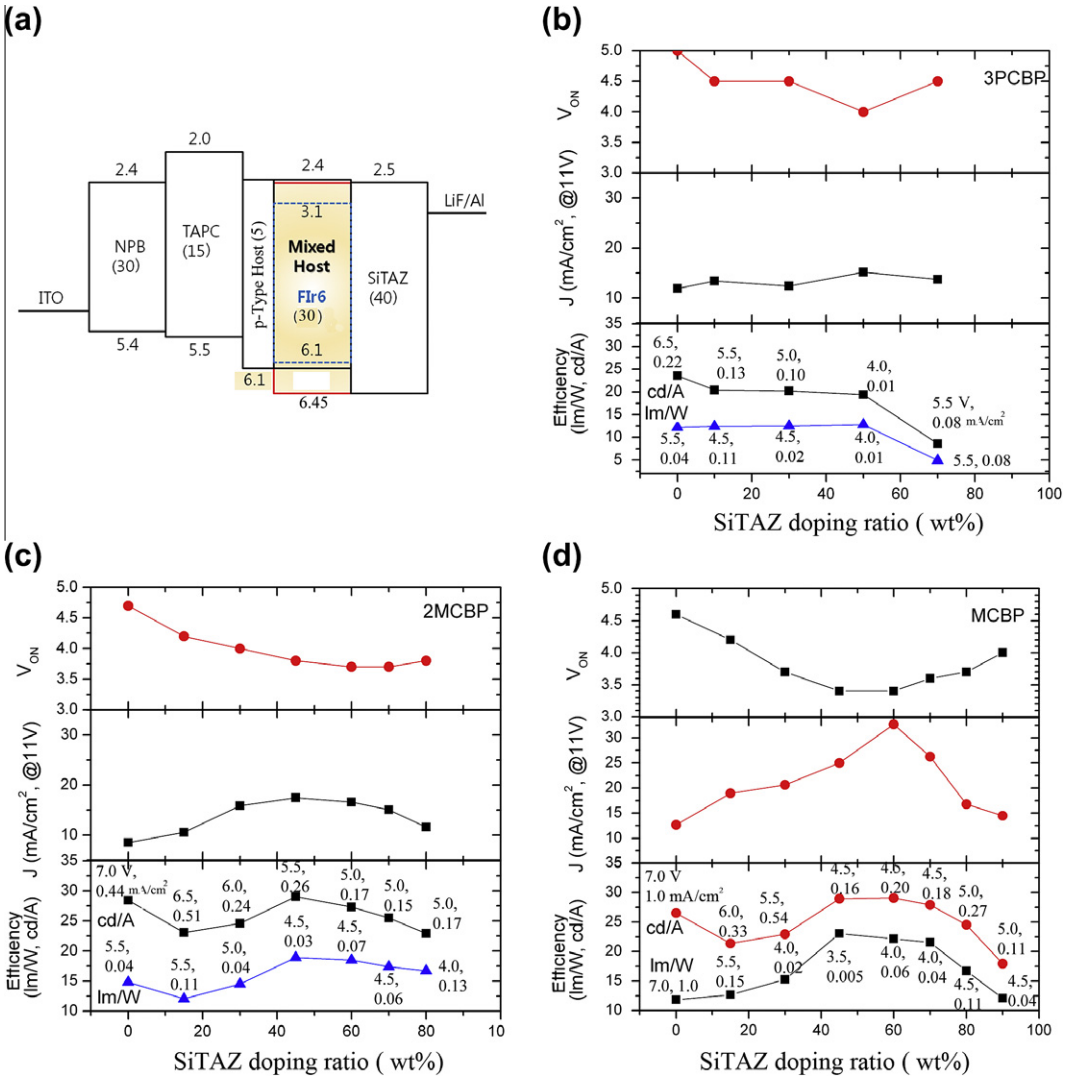

Fig. 4. (a) Schematic energy level diagram of the mixed-host emissive layer PHOLEDs. Dependence of V_{ON}, J, and maximum efficiencies on the doping ratio of SiTAZ for p-type hosts of (b) 3PCBP (c) 2MCBP and (d) MCBP, respectively. The device structure is ITO/NPB (30 nm)/TAPC (15 nm)/p-type host (5 nm)/mixed host:FIr6 (30 nm, 5 wt.%)/SiTAZ (40 nm)/LiF (0.5 nm)/Al (60 nm).

(2.5 eV), which is higher than that of conventional ETL materials in the range of 2.7–3.0 eV [36]. And the last one is low electron mobility of carbazole based host materials. The major way of electron current is by the recombination with holes carried by hosts or FIr6. For low doping concentration of FIr6, the recombination zone is limited near the interface of EML and ETL, resulting in accumulation of holes and electrons in this narrow region, and this may lower the overall conductance of current of the device [37].

The devices showed maximum power efficiency in the range of 12.3–15.0 lm/W. However, the differences in power efficiency are not as significant as expected from the hole mobility properties. These results could be anticipated from the point of view of the charge balance between hole and electron, or from the confinement of the emission zone in the EML layer [28]. The carbazole-based host materials show high hole mobility whereas most of the electron charges are carried by FIr6 as reported by Wee et al. [34]. At a low doping ratio of FIr6, the electron mobility is low and the emission zone is confined near the EML/ETL interface. To get high efficiency, the hole current should be balanced with the electron current in the emission zone, which is low at low doping ratios of FIr6. If we increase the doping ratio of FIr6 to get a high electron current in the emission zone, this may induce a stability problem due to repeated oxidation and reduction stress of the FIr6 [21]. Moreover, the doping ratios of FIr6 should not be increased over 30 wt.%, due to the self-quenching effect of Ir-based emitters [35]. Fig. 3 shows the dependence of doping ratio on the device characteristics. If the doping ratio of FIr6 is increased the current is increased accordingly. The current efficiency is increased until the doping ratio of 20 wt.%. However, from 30 wt.%, the current

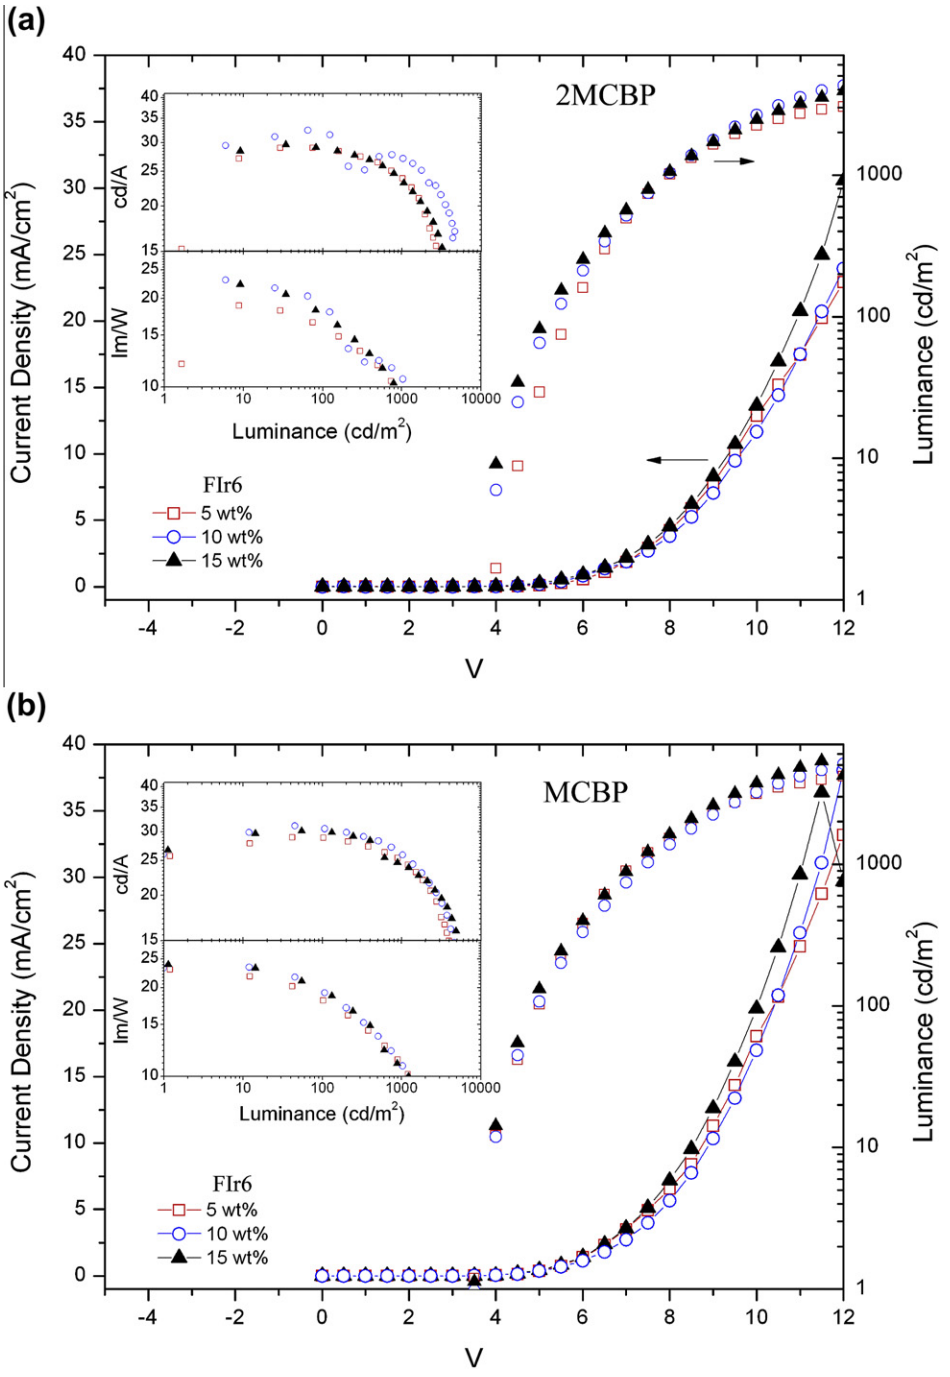

Fig. 5. Device characteristics as a function of FIr6 doping ratios in a mixed host of (a) 2MCBP:SiTAZ (1:1), and (b) MCBP:SiTAZ (1:1). The device structure is ITO/NPB (30 nm)/TAPC (15 nm)/p-type host (5 nm)/mixed host:FIr6 (30 nm, *x* wt.%)/SiTAZ (40 nm)/LiF (0.5 nm)/Al (60 nm).

efficiency decreases. The reason of decrease of current efficiency is supposed to be due to the self quenching of FIr6. Fig. 3(b) shows the transient photoluminescence decay of FIr6-doped MCBP films deposited on fused silica substrates at a wavelength of 460 nm and room temperature. Mono exponential decay curves were observed up to the doping ratio of 20 wt.%. However from 30 wt.%, the decay curve starts to be deviated from mono exponential curve, which is the evidence of self quenching of triplet energy. As a result, in a single-host device structure, hole mobility of the host material does not significantly influence on the power efficiency.

To circumvent the above problem, an n-type material, bis(4-(4,5-diphenyl-4H-1,2,4-triazol-3-yl)phenyl)dimeth-

ylsilane (SiTAZ) [36] is doped into p-type host materials, in which a low density of FIr6 (5 wt.%) is co-doped. SiTAZ has a high electron mobility of 6×10^{-4} cm^2 V^{-1} s^{-1}, a high triplet energy (E_T = 2.84), and wide band gap of 3.93 eV. Therefore, SiTAZ is expected to act as an n-type host. However, due to its deep HOMO level (6.45 eV), hole injection into this material is not easy. As a result this material does not show high efficiency when it is used as a single host of FIr6.

Fig. 4 shows the device characteristics of mixed-host systems with the device structure of ITO/NPB (30 nm)/TAPC (15 nm)/p-type host (5 nm)/mixed host:FIr6 (30 nm, 5 wt.%)/SiTAZ (40 nm)/LiF (0.5 nm)/Al (60 nm). In mixed host, SiTAZ is doped into three different p-type hosts, 3PCBP, 2MCBP and MCBP. The current density increases as the doping ratio of SiTAZ increases, shows a maximum value at a certain doping ratio, and decreases as the ratio increases over that value. The devices using 3PCBP show relatively poor characteristics, which is attributed to the low hole mobility of 3PCBP. Therefore, hereafter, only the other two materials are discussed in detail. The optimum doping ratios are between 45 wt.% and 60 wt.%. The same trends are observed for current and power efficiency. The maximum current and power efficiencies are 29.0 cd/A and 18.9 lm/W for 2MCBP, and 28.9 cd/A and 23.1 lm/W for MCBP. The current efficiencies are similar in the two systems, and efficiency roll-offs are commonly very small, showing high values of about 25 cd/A even at 1000 cd/m^2. In the case of power efficiency, the MCBP system shows higher value. This is the result of the higher current value of the MCBP system (32.67 mA/cm^2) than that of 2MCBP (17.47 mA/cm^2) at the same driving voltage of 11 V. The changes in turn-on voltages are more distinct. The turn-on voltage is reduced from 4.7 V down to 3.9 V, as the doping ratio of SiTAZ increases in the 2MCBP host. The same trends are also observed for MCBP, however, the minimum value is lower (3.4 V) than that of 2MCBP. The effects of co-doping of SiTAZ in the two hosts can be summarized as follows. First, turn-on voltages are lowered by 0.8 and 1.2 V for 2MCBP and MCBP, respectively. Second, the maximum current density increased by about 10 and 20 mA/cm^2 at the same driving voltage of 11 V, respectively. The differences in device characteristics can be attributed to the differences in hole mobility of the two hosts. The electron mobility of SiTAZ is higher than the hole mobility of 2MCBP and lower than that of MCBP. If SiTAZ is doped at the same amount in both of the hosts, the resultant hole mobility of the SiTAZ:2MCBP layer would be lower than that of SiTAZ:MCBP layer. The increased electron current is compensated for by the reduced hole current and vice versa. Therefore, the balanced net current is expected to be lower for 2MCBP than for MCBP. This results in enhanced hole and electron currents for the SiTAZ:MCBP layer with respect to those of the SiTAZ:2MCBP layer, and results in lower turn-on voltage of the device due to faster supply of enough current required to produce the light of 1 cd/m^2.

The device is finally optimized using 2MCBP and MCBP as p-type hosts and SiTAZ as n-type host in mixed host system as shown in Fig. 5a and b. In both of the devices, the ratios of SiTAZ in mixed host are set to 45 wt.%, because both devices show maximum power efficiency at this doping ratio. All of the device structures are the same as that of Fig. 4, except the doping ratio of FIr6. The optimum doping ratio of FIr6 is found to be 10 wt.% for both of the systems. Because most of the electron current is driven by SiTAZ, the increase in current caused by the increase of FIr6 doping ratio is not remarkable. 2MCBP device shows maximum current efficiency of 32.4 cd/A (EQE 19.5%), and maximum power efficiency of 22.5 lm/W. The MCBP device shows maximum current efficiency of 31.5 cd/A (EQE 19.0%), and maximum power efficiency of 23.5 lm/W. Even though the 2MCBP device shows higher current efficiency than that of MCBP device, the power efficiency of MCBP device show higher value than that of 2MCBP device, which is the direct result of higher current maintaining charge balance between electron and hole in the MCBP device (Table 2).

4. Conclusion

In conclusion, a series of p-type host materials with different hole mobility were tested in mixed-host system for use in efficient deep blue PHOLEDs, in which SiTAZ was used as a n-type host material. A maximum external quantum efficiency of 19.0% and maximum power efficiency of 23.5 lm/W was achieved at a low driving voltage and deep blue color coordinates of (0.15, 0.23), using MCBP as a p-type host. The origin of the enhanced device result was addressed systematically. The high hole mobility of MCBP could accommodate more electron current for maintaining

charge balance than the other carbazole-based materials, when it is mixed with an n-type material, SiTAZ, in a mixed-host EML. Moreover, together with its high hole mobility (1.1×10^{-3} cm^2 V^{-1} s^{-1}), its high glass transition temperature of 155 °C makes this material a promising candidate for achieving commercialization of deep blue PHOLEDs with high thermal stability.

transport through the device and can adversely affect the carrier mobility. Attempts to fabricate aligned organic nanostructures by template-assisted synthesis and field-assisted assembly have been reported [23–25]. But both of these processes require additional steps, either to remove the templates after the synthesis process (template-assisted) or involving an external electric or magnetic field (field-assisted). To cope up with this problem and to reveal the performance limits of organic semiconductor, various types of micro/nano sized organic single crystals based on π-conjugated aromatic molecules have been extensively studied [26–28]. Recent reports of selective growth of organic crystals by modification of surface properties by self-assembly [29] point to the need to move from a top down engineering approach of patterning to a bottom-up approach of self-organization. Still, the problem of crystal orientation and crystal morphology is mostly unresolved and requires particular attention. Aligned layers of small organic molecules can be grown by zone casting technique [30–32] for long range ordering or on rubbed dielectric substrates [33] or by techniques such as solution shearing and dip coating [34,35]. Self-aligned crystals with highly ordered crystalline structure can be developed by inkjet printing [36] or by the stamping (soft lithography) technique [37]. The growth and self-organization of organic crystals by a method based on isothermal evaporation of the solvent in a two-liquid system, similar to ink-jet printing, also led to the formation of aligned organic crystal [38].

In this study, we describe a novel method, where capillary induced force is used to grow ordered crystalline array of π-conjugated molecules from the solution phase and its use in fabricating different optoelectronic devices. The simple, cost-effective, solution based self-assembly approach to grow ordered crystalline array is suitable for large area fabrication and compatible with rigid as well as flexible substrates. This is rather impressive considering the fact that no additional surface treatment is required for the growth of aligned crystals array. Moreover, the proposed method to manipulate crystal morphology can be extended to other π–π stacked soluble organic molecules. The focus is on the method whose simplicity, flexibility in patterning, and demonstrated applications strengths suggest potentially broad utility and applicability. A systematic study of the orientation of crystals at the contact line during the drying process can further improve the theoretical understanding of pattern formation induced by solvent evaporation. Such knowledge may lead to a facile method of patterning and alignment of organic crystals, which is critical for many device applications [39,40].

2. Experimental section

The active organic semiconductors, 7,7,8,8-tetracyanoquinodimethane (TCNQ) and tetrathiafulvalene (TTF) were purchased from Aldrich Chemicals and were used as received. The substrate, which was used for the fabrication of ordered crystalline array, is indium tin oxide (ITO) coated glass substrate over which a polymer dielectric was deposited. To deposit the crystals, a 3–4 cm long glass capillary tube of outer wall diameter 1.0–1.1 mm was placed on top of the dielectric film. 5–10 μL TCNQ solution (having different solvents) was poured dropwise atop the tube which immediately spread along the length of the tube, also covering its sides. The film with the capillary tube was then placed on a hot plate, preset at temperature of 100 °C and baked for 1 h under ambient conditions. After complete evaporation of the solvent, crystals had grown on both sides of the tube in directions normal to its length. The details of the crystal growth technique was described in our earlier communication [41,42]. For the fabrication of OFET, we have used patterned ITO coated glass substrates as gate electrode. Cross-linked poly(4-vinyl phenol) (CL-PVP) was used as the gate dielectric. The precursor solution of CL-PVP was prepared by mixing poly(4-vinylphenol) (PVP) (M_w = 20,000 g/mol) (10 wt%) with a cross linking agent, poly(melamine-co-formaldehyde) (M_n = 511 g/mol) (5 wt%) and butanol (85 wt%). The mixture was stirred for 3 h at room temperature before use. The precursor solution of the dielectric was spun-cast over the ITO gate electrode. The spun cast films were soft-baked at 90 °C for 10 min on a hot plate in ambient conditions and baked further at 175 °C in a vacuum oven (10^{-3} Torr) for 45 min. The thickness of the dielectric film was measured to be around 400 nm (Dektak 3030). On top of the dielectric (or on the glass substrate), ordered arrays of TCNQ and TTF crystals were grown using a glass capillary tube. To complete the device fabrication, gold (Au) was thermally evaporated on top of the crystals to make the top contact source-drain electrodes (50 nm) under a high vacuum (5×10^{-6} Torr) at a rate of 0.3 Å/s. A shadow mask, used during the Au deposition ensured the rod shaped TCNQ crystals lying within the channel region and defined the channel length (L) and channel width (W) as 50 and 1000 μm, respectively. For the fabrication of photodetectors (PDs), the TCNQ and TTF crystalline arrays were grown on cleaned glass substrate by the same method and the top contact Au electrodes were deposited thermally with a channel separation of 30 μm. A HP4145B semiconductor parameter analyzer controlled by locally written LabView codes through a GPIB interface was used for the characterization of the devices under ambient conditions. X-ray diffraction measurement of the crystals was carried out using an X'pert Pro (Pananalytical) X-ray diffractometer (with Cu-Kα radiation). Atomic Force Microscopic (AFM) measurements were done with Nanoscope IIIa (Veeco, digital instruments). For the characterization of the devices under illumination, a common incandescent lamp (white LED) was employed as a light source.

3. Results and discussion

Fig. 1 shows the molecular structure of the compounds used in this study. Four different organic solvents, namely, acetone, chloroform, acetonitrile and toluene, were used to prepare several TCNQ solutions with equal concentrations (1 mg/ml) and to grow TCNQ crystals on dielectric coated glass substrates. Polarized optical microscopic (POM) images (Fig. 2) showed that dense arrays of long (micron-sized), elongated crystals were formed from each solvent, which is important from the standpoint of homogeneously covering a substrate in large area. Interestingly, it is found that the needle-shaped crystals grown in lower tempera-

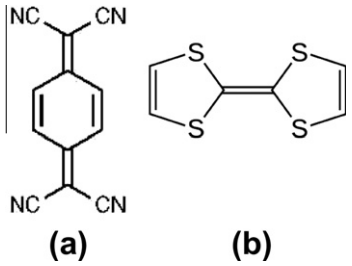

Fig. 1. Chemical structure of (a) 7,7,8,8-tetracyanoquinodimethane (TCNQ) and (b) tetrathiafulvalene (TTF) molecules.

ture (*ca.* 40 °C) are sparsely dispersed and isolated, making it difficult for any practical device fabrication. In contrast, crystals produced at higher temperature (*ca.* 100 °C) are longer, densely packed, regular and better aligned. With increasing evaporation of the solvent and shrinking of the solid/liquid interfacial area, the interaction between adjacent TCNQ molecules induced the formation of crystalline structures, while the gradient of concentration of the active material drives the formation of unidirectional growth of ordered microstructure.

When the temperature is raised, solvent evaporation at the edges is enhanced, which increases the diffusion of

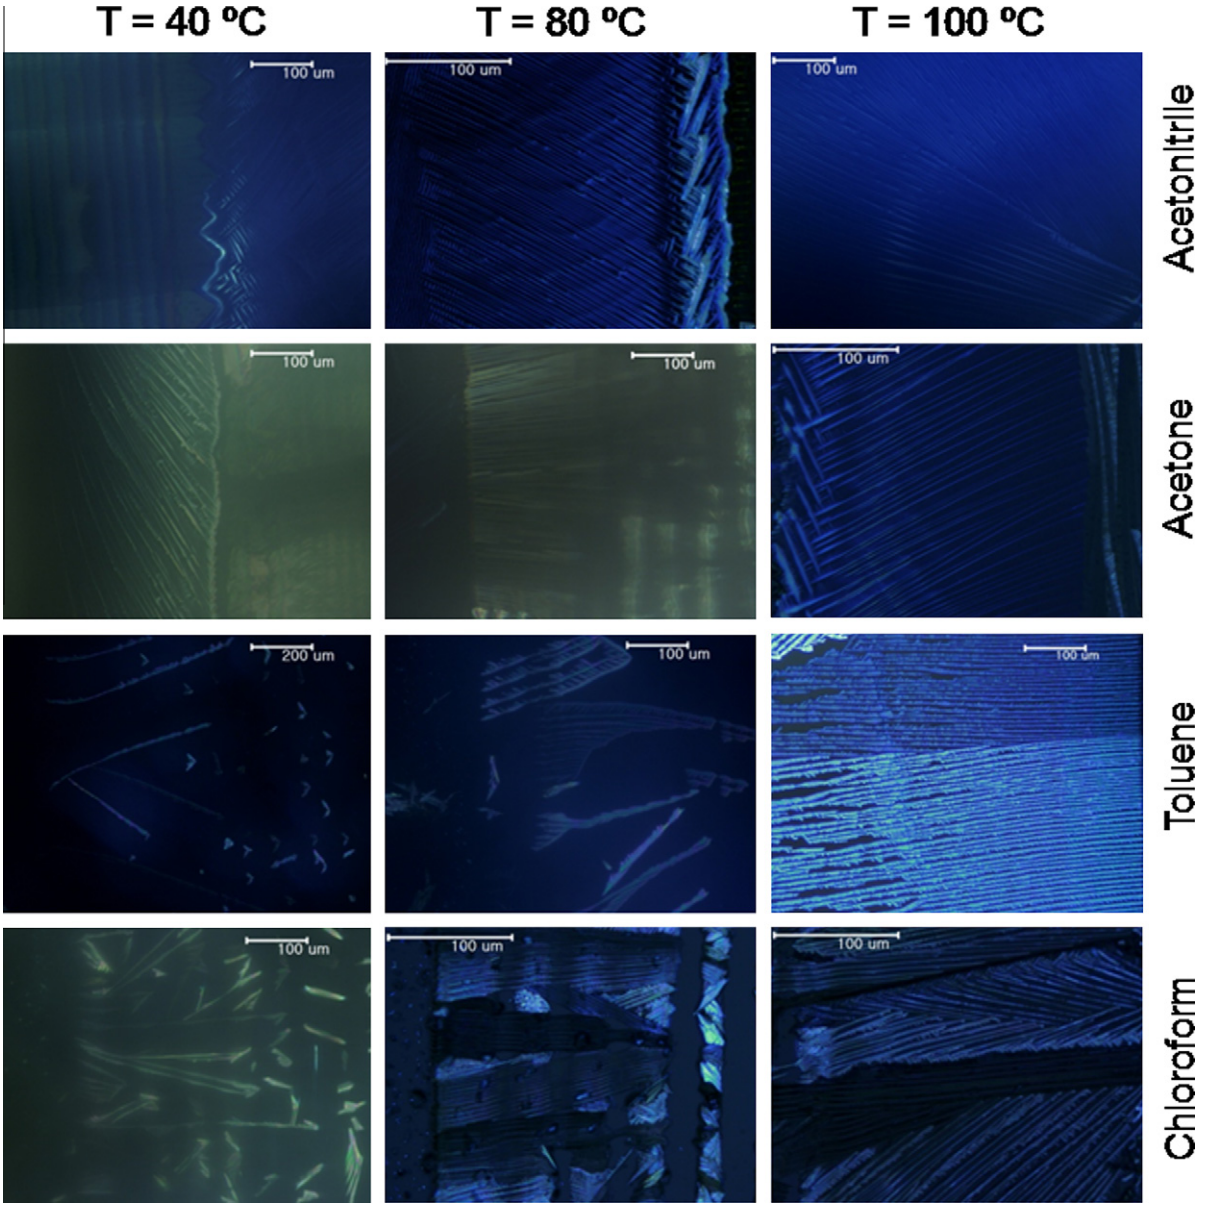

Fig. 2. (Color online) Optical microscopy (OM) images of TCNQ crystals grown on PVP-CL coated glass substrate under different conditions. The baking temperature (*T*) is constant along column-wise while solvent is constant along row-wise.

crystallites seeds towards the contact line and results in the nucleation of crystals and the self-assembly of molecules from the peripheral edge to the contact line of the solution with the tube. It is clear from Fig. 2 that, by casting from TCNQ solution with different solvent, densely packed crystal fibers having homogeneous width and lengths exceeding 200 μm are formed. Moreover, it is found that the use of acetonitrile as the solvent leads to thinner crystal fibers formation as compared to that with toluene or chloroform. The crystals grown at 100 °C from the solvent with lower boiling point, such as, acetone, acetonitrile are thinner than those grown from the solvent with higher boiling point (toluene), probably due to higher evaporation rate of the former, thus getting smaller time for the TCNQ crystallite seeds to self-assemble. On the other hand, toluene solution of TCNQ produced thicker crystals, because, higher boiling point (110–112 °C) of the solvent allowed more time and hence more crystallite seeds to diffuse and self-assembled for producing thicker micro crystalline structures. Additionally, the solubility of TCNQ in different solvents might play some role in forming different crystals. TCNQ, being non-polar molecule, has greater solubility in toluene and chloroform (non-polar) solvents compared to that in acetonitrile and acetone (polar solvent). As a result, toluene solution of TCNQ will contain more number of molecules than the acetone/acetonitrile solution of TCNQ, enabling more diffusion and assembling of crystal seeds for producing thicker crystal structures. All these results indicate that the dynamics of crystal growth is dependent significantly on the solvent used for the preparation of TCNQ solution.

To get more insight into the crystal formation and to find the dependence of the crystals growth on the concentration of TCNQ solutions, we have used toluene solutions of TCNQ having concentrations 1, 0.5, and 0.1 mg/ml. The crystals were grown in identical conditions with temperature setting at 100 °C. The results have been summarized in Fig. 3. It is found that when the concentration of TCNQ in the solution is low, short-length crystals with partial alignment are grown, whereas, higher concentration of TCNQ produced highly oriented and densely packed long, needle-shaped crystals which is highly essential for developing any practical circuitry.

To verify the crystallinity of the microrods of TCNQ, we have performed X-ray diffraction (XRD) analysis. Fig. 4 shows the XRD spectrum of TCNQ crystals grown over the dielectric coated ITO substrate. The peak at 25.88° arises solely due to the TCNQ crystals and is attributed to the (0 2 1) reflection for the crystals, corresponding to a lattice plane distance of 3.43 Å. The other peaks, which arise due to the bottom ITO surface, are well known and are widely reported [43]. The single peak in the XRD spectrum clearly indicates that the crystals formed by this capillary force method is single crystalline. For further investigation of TCNQ crystal structure, 2-dimensional grazing incidence X-ray diffraction (2D-GIXD) measurements were carried out. Simulated diffraction pattern based on a monoclinic structure belonging to $C_{2/c}$ space group and having unit cell parameters, $a = 8.906$, $b = 7.060$, $c = 16.395$ Å, and $\beta = 98.54°$ [44] are well consistent with the experimentally measured peaks. In our previous communication [41], we have shown from

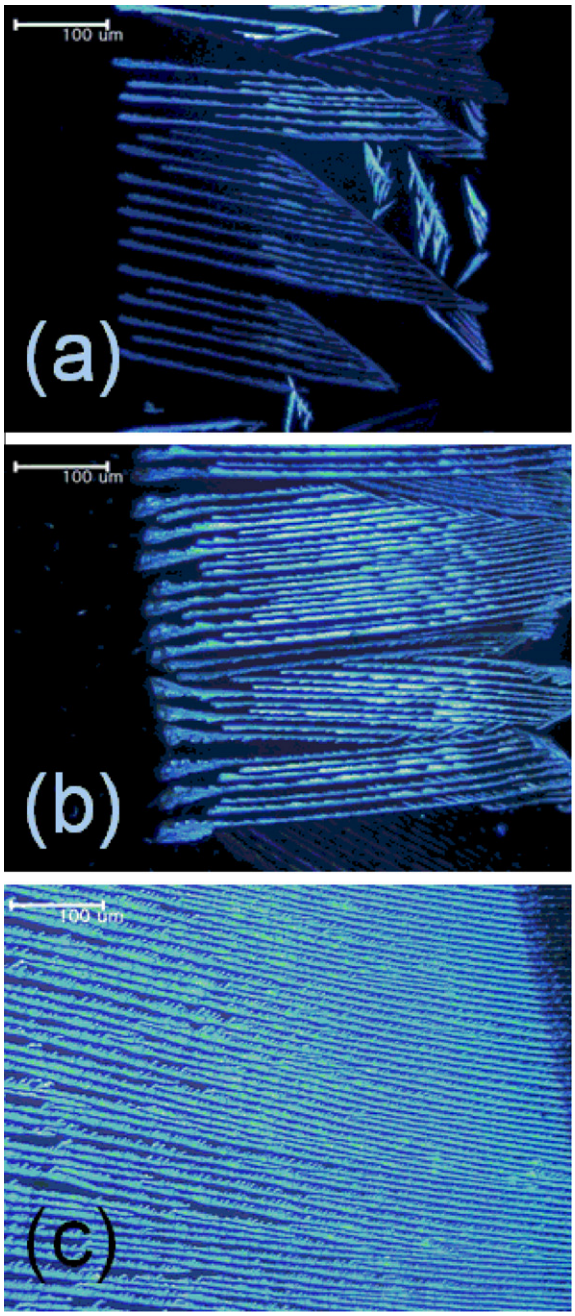

Fig. 3. (Color online) OM images of TCNQ Crystals deposited at 100 °C for various concentrations of TCNQ in toluene. TCNQ concentrations were (a) 0.1 mg/ml (b) 0.5 mg/ml and (c) 1 mg/ml.

the GIXD measurements that the growth of TCNQ crystals preferred along (0 2 1) direction and the diffraction patterns measured at parallel and perpendicular geometry (with respect to *c*-axis), indicated that the TCNQ crystals have highly preferred crystal orientation along the *c*-axis. As a result, 2-D GIXD analysis strongly suggests that the TCNQ crystals prepared by the proposed method have one directionally grown single crystalline nature.

Atomic force microscope (AFM) image of the TCNQ crystals shows that the crystals are aligned in one direction

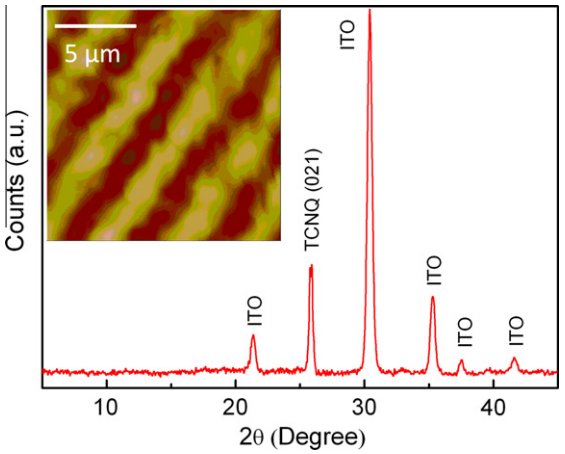

Fig. 4. (Color online) XRD spectra of TCNQ crystals grown on polymer dielectric deposited ITO substrate. (inset) Tapping mode AFM (phase) image of the TCNQ crystals.

and are well oriented. Fig. 4 (inset) shows the tapping mode AFM (phase) image of the ordered TCNQ micro crystals grown over the polymer dielectric surface. The typical height of the crystals as measured from the AFM height profile was ~25–29 nm and the length was found to be >200 μm.

Although the formation and growth of the ordered crystalline film may need further elucidation of its mechanism, it invariably represents a novel, facile approach for one-step fabrication of highly ordered organic micro-crystalline array. Significantly, this technique is applicable to preparing oriented crystals array of other organic compounds. For example, by using an identical procedure, aligned crystals of tetrathiafulvalene (TTF) (Fig. 5a) can be obtained. In this case also, the concentration of TTF was fixed at 1 mg/ml with a drying temperature of 100 °C. It is evident from the figure that the present method affords the formation of ordered microstructures for other molecules also. In order to verify the necessity and suitability of the capillary tube in the present method for best production of oriented and ordered crystals, we have performed a control experiment. We deposited TTF crystals from the same solution by drop cast (Fig. 5b) and spin cast (Fig. 5c) method and baked at 100 °C. It has been observed that, in both the cases, curved fibrillar structures (Fig. 5b and c) having no ordering and with random orientation of crystals domain have been developed. These results clearly indicate the necessity of the use of capillary tube for the production of ordered array of organic microcrystals.

To demonstrate the potential application of the present technique, we constructed photodetectors (PDs) from the TCNQ and TTF crystalline arrays. *I–V* measurements were performed on the device by a two-probe method under ambient conditions. Fig. 6a shows the typical *I–V* curves of TCNQ crystals based PD obtained in the dark and under continuous illumination by light. It shows that the photocurrent under illumination is markedly higher than that obtained in the dark. Moreover, the linear *I–V* characteristics both in dark and under light indicated that ohmic contact has been established at the semiconductor metal junction. Fig. 6b reveals that the time response of the device, where the light source was switched on and off periodically, is reversible and reproducible. It can be seen from the figure that as soon as the light was turned on, the current sharply increased to a high value demonstrating fast response of the device. The maximum current level is, however, same for all the cycles exhibiting highly stable photo characteristics. Under illumination, the device current increased to a value which is much higher compared to that in the dark. The ratio between the currents under light and in dark states was found to be ~40. The photoswitching characteristics of devices based on TTF crystals arrays is shown in Fig. 6c. With an applied bias of 10 V between the electrodes, when the light was switched alternately on and off, it caused the current of

the devices to show two distinct states: the "low" current state in the dark and the "high" current state in the light. The variation between these two states was fast and reversible, making it possible for the device to act as a high quality photosensitive switch. Here, we have observed a little persistent current effect (Fig. 6c) which may be ascribed to the remaining of some photocarriers even after switching off the light source.

To overrule the possibility of current increase due to temperature rise of the sample as a result of long time light exposure, we have compared the spectral characteristics of the light source with the absorption spectrum of the samples (Fig. 6d). The spectrum of the light source has a peak around 300 nm, where TTF has large absorption and a broad hump around 400 nm, where TCNQ has maximum absorption. The lamp used for the optical illumination was made of white LEDs and the power was adjusted to 4 mW/cm^2. Such a low power can not produce much heating effect to switch the conductivity of the sample. If the increase in current of the device under illumination occurred due to heating (temperature increase) of the sample, the current for a particular cycle would become higher than the corresponding current of the previous cycle. Thus, there would be gradual increase in current value in every cycle due to gradual increase in temperature. Moreover, upon switching the light off, the current would not have decreased sharply; rather, there would be slow and gradual decay of the current. Furthermore, we have observed the photoswitching characteristics of the sample for light pulses of very short duration (10 ms) also. These results indicate that the observed photoswitching characteristic of the device is a molecular phenomena, which occurs due to the absorption of photons, not due to the heating effect of the sample. Another possible reason for the photoswitching effect may be photoinjection from the electrodes. However, the photoinjection/photoemission of carriers from the metal (Au) electrode requires that the photon energy must at least be equal to the work function of Au (*ca.* 5.1 eV). However, the maximum energy of the illumination corresponding to minimum wavelength, *ca.* 300 nm, was found to be (4.1 eV) less than the work function of Au electrode. Also, TCNQ has maximum light absorption at ~400 nm which corresponds to energy ~3.1 eV, much less than that required for photoemission from Au electrode. These results proves that the observed photoswitching effect is not due to the photoinjection/photoemission from

the electrodes, rather it is an intrinsic effect, arising due to the absorption of photons by the TCNQ/TTF crystals and exciton dissociation at the metal/semiconductor interface.

When light with photon energy greater than the band gap of the material is absorbed, a number of excitons are generated which subsequently dissociated into free electrons and holes. Fig. 6d illustrates the UV–Vis absorption spectra of TCNQ and TTF showing that the maximum absorption of light occurred in the visible region of the spectrum. These, in turn, imply that upon illumination of light, additional mobile charge carriers (photocarriers) are generated, namely, holes in the highest occupied molecular orbital (HOMO) and electrons in the lowest unoccupied molecular orbital (LUMO) levels which will contribute to the resulting transport properties. The photocurrent generation in the crystals, which is indicative of the irradiation induced enhancement of carrier concentration, resulted in increase of the device current. All the results in Fig. 6 suggest the potential of the organic crystalline array to act as high quality optoelectronic switches.

Additionally, we have demonstrated that it is possible to design organic field-effect transistors based on these ordered crystalline arrays. Among the different architectures for measuring the organic field effect, we chose the bottom-gate, top contact architecture with ITO as the gate electrode and CL-PVP as the gate dielectric. The output (I_{DS}–V_{DS}) characteristics of TCNQ (*n-type*) and TTF (*p-type*) crystals based OFETs is shown in Fig. 7a. The characteristics of representative OFETs showed excellent gate modulation along with current saturation (Fig. 7a). The characteristics for TTF crystalline OFETs exhibited *p-type* (hole dominant) conduction (left panel, Fig 7a), whereas, the OFET based on TCNQ crystals showed *n-type* (electron dominant) conduction (right panel, Fig 7a). With increase in V_G, more charge carriers are accumulated in the interface between organic crystals and the gate dielectric near the channel region resulting in increase of the drain current (I_{DS}). From the transfer (I_{DS}–V_G) characteristics of the OFETs (Fig. 7b), we have estimated an on/off current ratio $\sim 10^3$ for both OFETs and saturation charge carrier mobility (μ) $\sim$0.02 and 0.05 $cm^2\ V^{-1}\ s^{-1}$, respectively, for TCNQ and TTF crystals based OFETs. The threshold voltage (V_{Th}) for TCNQ and TTF OFETs fabricated in this study were found to be 5 and −18 V, respectively. The performance (in terms of mobility, threshold voltage) of the current device is impressive and superior than the early report of TCNQ thin-film transistors [45,46], indicating that the intrinsic material performance was not fully realized in previous TCNQ OFETs with the polycrystalline films, presumably because of extrinsic influences, such as from grain boundaries, defects and traps.

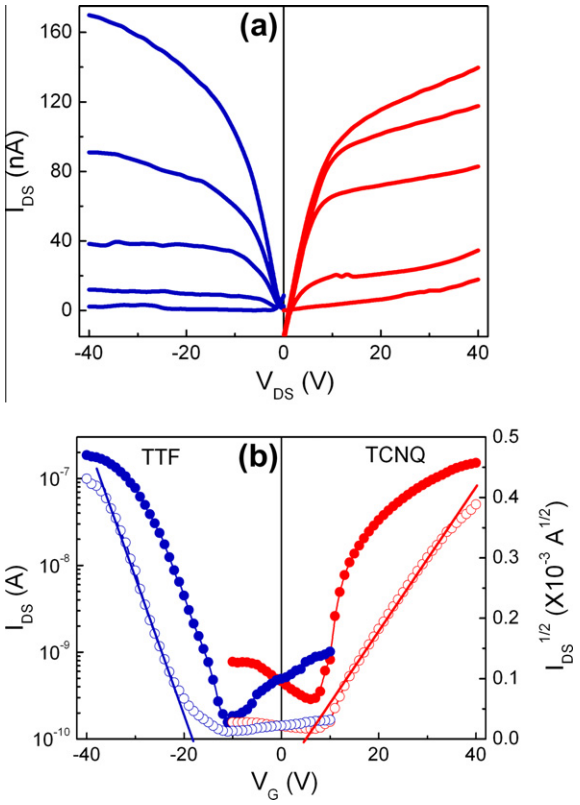

Fig. 7. (Color online) (a) Typical output characteristics of TTF (left panel) and TCNQ (right panel) crystalline array based OFET with $|V_G|$ ranging from 0 to 40 V (step 10 V). Absolute value of current is plotted in the vertical scale. (b) Transfer characteristics of the OFETs measured at $|V_{DS}|$ = 30 V.

4. Conclusions

In conclusion, we have shown that oriented array of different organic crystals can be prepared by a simple capillary force induced solution process. The microcrystalline structure can be prepared by solvent evaporation, and then self-aligned and -assembled into ordered films through one-step self-assembly method, requiring no additional surface treatment. Different processing conditions have been examined to understand the optimum solution for growing dense array of oriented crystals. The crystal dimensions and morphology depend not only on the active materials, but on solvent used, material concentration, and annealing temperatures also. In general, it can be concluded that higher material concentrations and higher temperatures lead to the formation of longer and well aligned micro crystalline arrays. This one-step method of combining growth and self-assembly of microcrystalline array in large-area is highly applicable for fabricating high performance optical and electronic devices. TCNQ and TTF micro crystalline array based devices including photodetectors and high-mobility organic transistors with good field-effect characteristics were demonstrated. This method for the fabrication of ordered organic micro/nanostructures could have significant potential for large-scale and low-cost optoelectronic applications. Additionally, the current method of patterning of a range of organic semiconductors for various device applications elucidates its potential broad utility and applicability.

A first order rate does not always exist. It is defined only if the "reactants" had time to equilibrate and the energy distribution over all degrees of freedom of the reactants follows the equilibrium distribution for that species. All rate theories, including for example transition state theory [5] for adiabatic reaction or Marcus theory for non-adiabatic charge [6] transfer reactions assume that the reactants are equilibrated. Thermal equilibration of the reactants guarantees that the process is memoryless, i.e. the probability of occurring does not depend on the particular way the reactants are generated. In condensed phase, the degrees of freedoms that need to be equilibrated are the vibrational degrees of freedom. For this reason the hopping rate is defined only if the vibrational relaxation rate $k_{vib-rel}$ is (much) larger than the hopping rate i.e.

$$k_{vib-rel} > k_{hop} \tag{2}$$

We know a lot about vibrational relaxation time in different environments thanks to a large number of spectroscopic measurements, which included measurements on organic solids [7]. In particular, at low temperature ($T \to 0$), there is a simple relation between the vibrational relaxation rate and the Raman line broadening $\tilde{\delta}$ (in cm^{-1}), namely $k_{vib-rel} = 2\pi c\tilde{\delta}$ with c being the speed of light (few papers discussing this relation are given in Refs. [7–9]). The broadenings are not identical for all vibrational modes, so there is not a single $k_{vib-rel}$, but sufficiently similar (within a factor of 2–3) to be considered a single experimental parameter for our purpose [9,10]. Moreover, for molecules with center of inversion the modes involved in the hopping are totally symmetric and Raman active, so that it is even possible to specifically consider the lifetime of the most relevant vibrational modes if desired. Note that, not surprisingly, the vibrational relaxation rate is much slower in solids than in liquids.

The inequality (2) can be written as $2\pi c\tilde{\delta} > \mu_{hop} k_B T/eL^2$ and can be better analyzed in the form

$$\mu_{hop} < \frac{2\pi c\tilde{\delta} eL^2}{k_B T} \tag{3}$$

which is the main result we want to discuss. All the quantities appearing in the equation above are experimentally accessible. If the measured charge mobility in a material is larger than the quantity in the right hand side of the equation, the transport cannot be described by hopping. In fact, mobilities that are faster than this threshold correspond to hypothetical hopping rates that are too fast compared to the vibrational relaxation and cannot be considered independent events.

To be more practical, we can set to $L = 6 \cdot 10^{-8}$ cm, a typical center-to-center distance between pi-stacked molecules (some experimental values are 3.6, 5.1, 7.2, and 7.6 Å for hexabenzocoronene [11], pentacene [12], rubrene [13] and TIPS-pentacene [14], respectively), $k_B T = 0.026$ eV, as at room temperature, and $\tilde{\delta} = 3\ cm^{-1}$ (a rather generous broadening, considering that the largest low temperature broadening in naphthalene is $\tilde{\delta} = 1.2\ cm^{-1}$ [9]) we obtain that, in order to be able to consider a hopping mechanism, we must have

$$\mu_{hop} \sim< 0.08\ cm^2\ V^{-1}\ s^{-1} \tag{4}$$

This is indeed a very low mobility, considering that the record mobility for crystalline semiconductors at room temperature is of the order of $\sim 10\ cm^2\ V^{-1}\ s^{-1}$ [13,15] and liquid crystalline materials can achieve mobility of $0.1\ cm^2\ V^{-1}\ s^{-1}$ [2]. The mobility value in Eq. (4) is not to be considered a rigid cut-off and the value must be adapted for molecules with a larger center-to-center distance or different Raman linewidths. The maximum value of μ_{hop} refers to the crystal direction with the largest mobility which is usually the direction with a relatively short intermolecular distance L.

The appropriate way of describing charge transport in organic solid has been discussed by theoreticians with a wealth of methods each valid under a number of conditions and the specialized literature analyzes how to compute the mobility from first principles in different regimes [16]. These theories also analyze from the point of view of quantum statistical mechanics and electronic structure calculations under what condition hopping transport is possible. The interesting aspect of the inequality in (3) is that it is valid regardless of all the technicalities of formal theories and, indeed, it bypasses them providing an immediate relation that can be used (and understood) to rule out the possibility of hopping transport in molecular materials.

To exemplify how useful such a relation can be, it may be worth summarizing the different methods used to compute the hopping mobility from first principles. In a large number of papers it was assumed that, in analogy with what happens in solution, Marcus equation can be used to describe the charge hopping process [11,17]. Marcus theory is not very accurate is solid phases, because it is valid when the nuclear degrees of freedom involved in the reaction can be treated classically and if the electronic coupling between molecules is so small that the process is non-adiabatic [6]. It is possible to use rate expressions that incorporate the quantum nature of the nuclear degrees of freedom [18] or that take into account the fact that the electronic coupling between molecules is relatively strong [19]. Virtually under any condition one can obtain a (more or less complicated) hopping rate expression, only provided that such rate exists! It is not uncommon that the rate of hopping between two molecules cannot be defined, as we have verified by inserting the appropriate numerical values in Eq. (3). In all the references given in this paragraph the experimental mobility is just too high to support a hopping mechanism and so it does not matter what the rate expression used is: the charge simply does not propagate by hopping and any theoretical effort made to improve the hopping rate is misplaced. It should be noted, incidentally, that hopping theories describe in a qualitatively correct way how the electronic structure is related to the mobility and they retain the ability to rationalize the differences between similar materials even when they are not the most suitable model.

The impossibility of describing the transport in terms of a sequence of hopping does not mean, of course, that it cannot be described in a different way. Chemical physicists are not unprepared to the situation of thermal relaxation

processes being not fast enough [20] and it is possible to study the quantum dynamics in this case using a variety of techniques, mostly based on the propagation of the density matrix [5]. The essential point for this paper is that, if the thermal relaxation is not fast enough, it is not possible to describe simply the time evolution of the probability of finding a system in a particular state (chemical kinetics approach). The charge dynamics is described instead by the evolution of the wavefunction which can be scattered, as a classical wave, by the crystal impurities and vibration creating genuinely quantum effects like the interference between wavefunctions propagating in different directions [21]. All the methods used to describe long range and long time evolution based on a collection of rates for individual processes (e.g. kinetic Monte Carlo methods) are bound to fail when interference and dephasing have to be taken into account. The inequality above (valid also if the molecules in the material are not all equivalent because of some static disorder effect) can be seen as a limiting condition for the applicability of any of these methods.

The considerable attraction of the chemistry community to the idea of charge transport as a series of hopping events is deeply rooted in the experimental evidence that, with very few exceptions [15,22], the transport is thermally activated, i.e. the mobility increases with temperature following Arrhenius law [23]. Thanks to few experiments on ultrapure samples [15] we now know that the activation energy in crystalline samples is not related to the hopping rate between adjacent molecules but to the rate of escape of charge carrier trapped by impurities [24] into delocalized states of the molecular crystal [25] (a mechanism that cannot be described as simple hopping).

In summary, we have shown in this paper that there is a maximum value of charge mobility compatible with a hopping transport model where the charge is transferred from molecule to molecule in independent events. We demonstrated a simple inequality, which involves only experimentally accessible quantities, without using any detailed knowledge of the system or involving any technicalities from quantum dynamics (see Fig. 1). The simple hopping transport model, made very common in chemistry by its simplicity and by the analogy with redox chemistry, is in practice never valid for the highest mobility crystalline materials. We purposely presented only results that can be fully justified with elementary arguments and avoided to take any position with respect to the actual transport mechanism in crystalline materials which is currently under debate in the technical literature [16]. Fortunately, as this paper shows, it is still possible to establish at least a firm point without even entering in the debate.

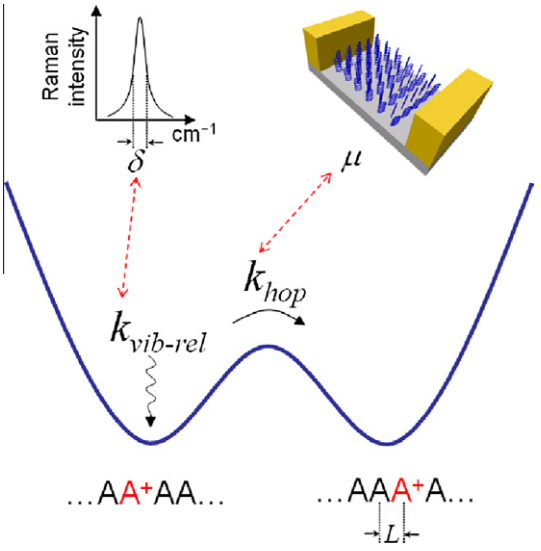

Fig. 1. Schematics of the argument presented in the main text. If one can define a hopping rate between two states such that the charge in the two states is localized in adjacent molecules (separated by a distance L), the hopping k_{hop} rate must be slower than the vibrational relaxation rate $k_{vib-rel}$. The first can be related to the experimentally measurable charge mobility μ and the second to the linewidth δ of vibrational spectroscopic measurements.

[10] The line broadening at room temperature can be few times larger than the broadening at low temperature because of the effect of pure dephasing (see Refs. [8,9]). If, for a particular system, one only knows the line broadening at room temperature the magnitude of can be still estimated with reasonable accuracy.

dyes for DSSCs application. Using this strategy, many novel D–π–A metal-free dyes with various donor moieties, such as coumarin [4], indoline [5], triarylamine [6], [bis(dimethylfluorenyl)amino]phenyl [7], phenothiazine [8], tetrahydroquinoline [9], carbazole [10], porphyrin [11], dithieno[3,2-*b*:2′,3′-*d*]thiophene [12], and pyrrole [13], have been designed and synthesized as efficient sensitizers for DSSCs in recent years. PCEs up to ~9% have been achieved for DSSCs using these metal-free dyes [4]. Moreover, highly impressive PCEs (~10%) and excellent stability were also reported in very recent publications [14]. Developing novel and highly efficient metal-free organic dyes applied in DSSCs is thus an area of strong current research activity [3].

The π-conjugated bridge connecting the donor and acceptor in the dye influences not only the region of light absorbed by the DSSCs but also the degree of electron injection from the dye's excited state to the TiO_2 surface. Aromatic moiety is usually used as efficient bridge in the design of dye molecules. Thiophene-based aromatic compounds have been demonstrated as the effective π-conjugated bridges by several research groups [15], including ours [6g]. Imahori et al. [16] investigated the effects of 5-membered heteroaromatic bridges on structures of porphyrin films and photovoltaic properties of porphyrin-based DSSCs. Recently, Wang and co-workers [17] also studied the influence of different heteroaromatic bridges on photovoltaic properties of triphenylamine-based organic dyes.

Aromatic hydrazone compounds are widely studied and used as organic nonlinear optical materials [18] and organic hole-transport materials for electrophotographic photoreceptors [19]. The main advantages of such compounds are the simple synthesis and high enough charge mobilities [19b]. Many triphenylamine- [20], carbazole- [21] and thiophene-based hydrazone [22] compounds were synthesized and used as glass-forming hole-transport materials. Squaraine-based compounds containing *N*,*N*-diphenylhydrazone moiety were synthesized and applied as efficient small molecule donors in bulk-heterojunction solar cells [23]. In addition, Tran-Van et al. recently reported on the synthesis and application of biscarbazole and terthiophene derivatives containing hydrazone functional groups as hole-transport materials in solid-state DSSCs [24]. However, aromatic hydrazones compounds until now are few studied as photoactive dyes for DSSCs. Therefore, we became interested in constructing metal-free organic dyes with hydrazone moiety to make use of its excellent hole-transport property for the electron donor.

Expanding on the foregoing points and as another try of our efforts to explore new metal-free dyes, we herein report on the design and synthesis of four D–π–A dyes (**HB**, **HP**, **HF**, and **HT**, as shown in Fig. 1) consisting of an *N*,*N*-diphenylhydrazone donor, a 2-cyanoacetic acid acceptor, and a different aromatic bridge, i.e., benzene, pyrrole, furan, and thiophene. The effects of the π-conjugated bridges on the photophysical, electrochemical and photovoltaic properties of these dyes were investigated in detail. To the best of our knowledge, this is the first time to develop hydrazones-based compounds as metal-free organic dyes used in DSSCs. Once again, our results indicate that π-conjugated bridge would have a large impact on photoelectronic properties of the metal-free dyes sensitized TiO_2 cells.

2. Experimental

2.1. Materials and reagents

1,1-Diphenylhydrazine hydrochloride, terephthalaldehyde, 2-furaldehyde, 2-thienaldehyde, thiophene, pyrrole, and 2-ethylhexyl bromide were purchased from commercial suppliers (Pacific ChemSource and Alfa Aesar) in analytical grade. 2-Carbaldehyde-*N*-ethylhexyl-pyrrole was synthesized according to the previous published procedure [25]. Toluene was dried and distilled over sodium/benzophenone. DMF, $CHCl_3$, and CH_3CN were dried over by accustomed methods and distilled before using. All other solvents and chemicals used in this work were analytical grade and used without further purification. All chromatographic separations were carried out on silica gel (200–300 mesh).

2.2. Characterization

^1H NMR spectra was recorded on a Bruker Avance 400 instrument. Ultraviolet–visible (UV–vis) spectra of the dyes were measured on a Perkin-Elmer Lamada 25 spectrometer. The PL spectra were obtained using Perkin-Elmer LS-50 luminescence spectrometer. FT-IR spectra were obtained on Perkin-Elmer Spectra One spectrophotometer. The elemental analysis of all compounds were performed with a Perkin-Elmer 2400 analyzer for C, H, N, and S determination. Electrochemical redox potentials were obtained by cyclic voltammetry (CV) using a three-electrode cell and an electrochemistry workstation (CHI830B, Chenhua Shanghai). The working electrode was a Pt ring electrode; the auxiliary electrode was a Pt wire, and saturated calomel electrode (SCE) was used as reference electrode. Tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) 0.1 M was used as supporting electrolyte in dry acetonitrile. Ferrocene was added to each sample solution at the end of the experiments, and the ferrocenium/ferrocene (Fc^+/Fc) redox couple was used as an internal potential reference. The potentials of dyes versus NHE were calibrated by addition of 0.63 V to the potentials versus Fc^+/Fc [6a]. The solutions were purged with argon and stirred for 15 min before the measurements. Electrochemical impedance experiments for DSSCs were carried out in the dark with an electrochemical workstation (ZAHNER ZENNIUM) at room temperature. Electrochemical impedance spectra (EIS) were scanned in a frequency range of 10^{-1}–100 kHz with applied potential set at open-circuit. The alternate current (AC) amplitude was set at 10 mV. Geometry optimization and electronic structure calculations of the hydrazone-based dyes were performed using B3LYP functional and 3-21G* basis set implemented in the Gaussian 03 program package. Molecular orbitals were visualized by GaussView 3.0 software.

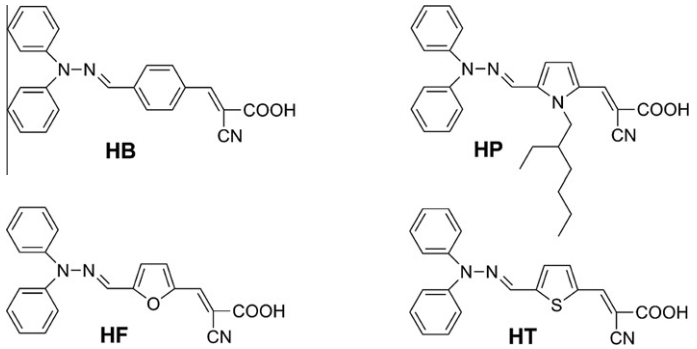

Fig. 1. Molecular structures of the dyes **HB**, **HP**, **HF**, and **HT**.

2.3. General procedure for fabrication and characterization of DSSCs

Fluorine-doped SnO_2 conducting glass (FTO) were cleaned and immersed in aqueous 40 mM $TiCl_4$ solution at 70 °C for 30 min, then washed with water and ethanol, sintered at 450 °C for 30 min. The TiO_2 colloid was prepared from 12 g P25 (Degussa AG, Germany) following the literature procedure [4]. First the 20–30 nm particles sized TiO_2 colloid was coated onto the above FTO glass by sliding glass rod method to obtain a TiO_2 film of 14 μm thickness after drying. Subsequently, the 200 nm particles sized TiO_2 colloid was coated on the electrode by the same method, resulting in a TiO_2 light-scattering layer of 5 μm thickness. The double-layer TiO_2-coated FTO glass were sintered at 450 °C for 30 min, then treated with $TiCl_4$ solution and calcined at 450 °C for 30 min again. After cooling to 100 °C, the TiO_2 electrodes were soaked in a CH_3CN solution with 0.5 mM dyes (and 1 mM chenodeoxycholic acid as a coadsorbent) and kept at room temperature under dark for 24 h.

The dye-adsorbed TiO_2 electrode washed with ethanol and dried. A drop of electrolyte solution was deposited onto the surface of the electrode and a Pt foil counter electrode was clipped onto the top of the TiO_2 electrode to assemble a dye sensitized solar cells for photovoltaic performance measurements. The electrolyte consisted of 0.5 M LiI, 0.05 M I_2, and 0.5 M 4-*tert*-butylpyridine (TBP) in 3-methoxypropionitrile and the efficient irradiated area of cell was 0.196 cm^2. The photocurrent–voltage (*J*–*V*) characteristics of solar cells were measured using a Keithley 2602 Source meter under the 100 Mw/cm^2 irradiation of a 500 W Xe lamp with a global AM 1.5 filter for solar spectrum simulation. Meanwhile, the photoelectric conversion efficiency was calculated. The measurement of monochromatic incident photon-to-current conversion efficiencies (IPCE) was performed by a Zolix DCS300PA Data acquisition system and other optical system.

2.4. Synthesis

The synthetic routes to the four dyes were shown in Scheme 1. The detailed synthetic procedures were as follows.

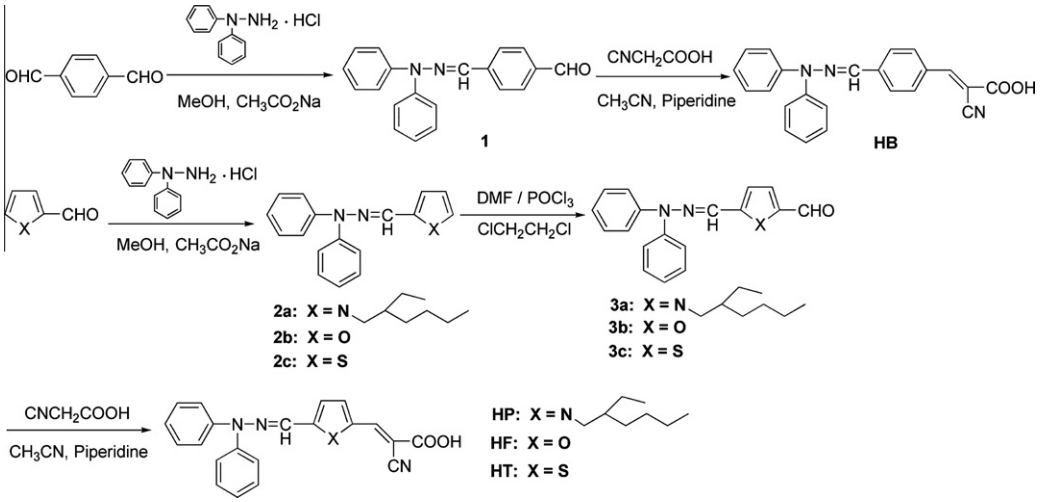
2.4.1. 4-Carbaldehyde-benzene-N,N-diphenylhydrazone (**1**)

Under nitrogen atmosphere, a solution of *N*,*N*-diphenylhydrazine hydrochloride (0.88 g, 4 mmol) in 30 mL of THF was added dropwise into the mixture of terephthalaldehyde (0.94 g, 7 mmol), sodium acetate (0.82 g, 10 mmol) and anhydrous MeOH (20 mL) at the room temperature. The mixture was refluxed for 24 h and the color changed gradually from yellow to dark brown. After cooling, the resulting mixture was quenched with 40 mL distilled water and extracted with chloroform. The combined organic layer was washed with distilled water and brine, dried over anhydrous $MgSO_4$. The solvent was removed by rotary evaporation. The crude product was purified by silica gel column chromatography with petroleum ether/dichloromethane (5/1, v/v) as eluent to yield **1** as a yellow solid. Yield: 67% (0.85 g). FT-IR (KBr, cm^{-1}): 1667 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 9.97 (s, 1H), 7.83–7.85 (d, 2H, *J* = 8.0 Hz), 7.73–7.75 (d, 2H, *J* = 8.0 Hz), 7.48–7.44 (m, 4H), 7.25–7.23 (m, 6H), 7.15 (s, 1H). Elem. Anal. Calcd. for $C_{20}H_{16}N_2O$: C, 79.98%; H, 5.37%; N, 9.33%. Found: C, 79.70%; H, 5.85%; N, 9.56%.

2.4.2. The general synthetic procedure of (**2**)

In a 100 mL three-necked flask, a solution of *N*-ethylhexylpyyrole-2-carbaldehyde (or 2-furaldehyde or 2-thienaldehyde, 5 mmol) in 30 mL of THF was added dropwise into the mixture of *N*,*N*-diphenylhydrazine hydrochloride (1.54 g, 7 mmol), sodium acetate (0.82 g, 10 mmol) and anhydrous MeOH (20 mL) under nitrogen atmosphere. The mixture was refluxed for 24 h and the color turned gradually from yellow to dark brown. After cooling, the resulting mixture was quenched with 40 mL distilled water and extracted with chloroform. The combined organic layer was washed with distilled water and brine, dried over anhydrous $MgSO_4$. The solvent was removed by rotary evaporation. The crude product was purified by silica gel column chromatography with petroleum ether/dichloromethane (4/1, v/v) as eluent.

*2.4.2.1. N-Ethylhexylpyrrole-2-carbaldehyde-N,N-diphenylhydrazone (**2a**).* Yield: 76% (1.42 g). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.46–7.42 (m, 5H), 7.24–7.17 (m, 5H), 7.10 (s, 1H), 6.88 (s, 1H), 6.67–6.65 (m, 2H), 4.34 (d, 2H, *J* = 5.6 Hz), 1.31–1.01 (m, 9H), 0.85 (t, 3H, *J* = 7.3 Hz), 0.72 (t, 3H, *J* = 7.2 Hz). Elem. Anal. Calcd. for $C_{25}H_{31}N_3$: C, 80.39%; H, 8.37%; N, 11.25%. Found: C, 80.40%; H, 8.47%; N, 11.66%.



Scheme 1. Synthesis of the **HB**, **HP**, **HF**, and **HT** dyes.

*2.4.2.2. Furan-2-carbaldehyde-N,N-diphenylhydrazone (**2b**).* Yield: 70% (0.92 g). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.43–7.39 (m, 6H), 7.20–7.27 (m, 5H), 7.08 (s, 1H), 6.46–6.42 (m, 2H). Elem. Anal. Calcd. for $C_{17}H_{14}N_2O$: C, 77.84%; H, 5.38%; N, 10.68%. Found: C, 77.52%; H, 5.47%; N, 10.80%.

*2.4.2.3. Thiophene-2-carbaldehyde-N,N-diphenylhydrazone (**2c**).* Yield: 72% (1.0 g). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.44–7.42 (m, 4H), 7.31 (s, 1H), 7.27 (s, 1H), 7.22–7.20 (m, 6H), 7.97–7.93 (m, 2H). Elem. Anal. Calcd. for $C_{17}H_{14}N_2S$: C, 73.35%; H, 5.07%; N, 10.06%; S, 11.52%. Found: C, 73.50%; H, 5.07%; N, 10.50%; S, 11.58%.

*2.4.3. The general synthetic procedure of (**3**)*

In a 100 mL three-necked flask, compound **2** (2 mmol) and dried DMF (0.23 mL, 3 mmol) were dissolved into 1,2-dichloroethane (20 mL). After the solution was cooled to 0 °C, $POCl_3$ (0.27 mL, 3 mmol) was added dropwise. The mixture was stirred at room temperature for 0.5 h and then heated up to reflux for another 12 h. After cooling to room temperature, saturated aqueous solution of NaOAc (20 mL) was added into the reaction mixture and stirred violently for 1 h. Then the resulting mixture was extracted with chloroform. The combined organic layer was washed with distilled water and brine, dried over anhydrous $MgSO_4$. Solvent was removed by rotary evaporation, and the crude product was purified by silica gel column chromatography with petroleum ether/dichloromethane (5/1, v/v) as eluent.

*2.4.3.1. 5-Formyl-N-ethylhexypyrrolel-2-carbaldehyde-N,N-diphenylhydrazone (**3a**).* Yield: 83% (0.67 g). FT-IR (KBr, cm^{-1}): 1666 ($\nu_{C=O}$). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 9.45 (s, 1H), 7.46–7.42 (m, 5H), 7.24–7.17 (m, 5H), 7.09 (s, 1H), 6.90 (d, 1H, J = 4.1 Hz), 6.67 (d, 1H, J = 4.2 Hz), 4.33 (d, 2H, J = 5.8 Hz), 1.26–1.03 (m, 9H), 0.83 (t, 3H, J = 7.1 Hz), 0.70 (t, 3H, J = 7.4 Hz). Elem. Anal. Calcd. for $C_{26}H_{31}N_3O$: C, 77.77%; H, 7.78%; N, 10.46%. Found: C, 77.40%; H, 7.97%; N, 10.66%.

*2.4.3.2. 5-Formyl-furan-2-carbaldehyde-N,N-diphenylhydrazone(**3b**).* Yield: 81% (0.39 g). FT-IR (KBr, cm^{-1}): 1665 ($\nu_{C=O}$). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 9.56 (s, 1H), 7.46–7.43 (m, 6H), 7.26–7.23 (m, 4H), 7.19 (d, 1H, J = 3.5 Hz), 7.07(s, 1H), 6.81 (d, 1H, J = 3.2 Hz). Elem. Anal. Calcd. for $C_{18}H_{14}N_2O_2$: C, 74.47%; H, 4.86%; N, 9.65%. Found: C, 74.32%; H, 4.77%; N, 9.80%.

*2.4.3.3. 5-Formyl-thiophene-2-carbaldehyde-N,N-diphenylhydrazone (**3c**).* Yield: 85% (0.52 g). FT-IR (KBr, cm^{-1}): 1668 ($\nu_{C=O}$). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 9.86 (s, 1H), 7.63 (d, 1H, J = 3.5 Hz), 7.62 (s, 1H), 7.48 (d, 1H, J = 3.5 Hz), 7.47–7.45 (m, 4H), 7.27–7.21 (m, 2H), 6.99–6.98 (m, 4H). Elem. Anal. Calcd. for $C_{18}H_{14}N_2OS$: C, 70.56%; H, 4.61%; N, 9.14%; S, 10.47%. Found: C, 70.50%; H, 4.67%; N, 9.16%; S, 10.53%.

2.4.4. The general synthetic procedure of sensitizers

Under nitrogen atmosphere, a mixture of compound **1** (or **3**, 1.2 mmol), 2-cyanoacetic acid (0.21 g, 2.4 mmol), piperidine (0.5 mL), and CH_3CN (30 mL) was refluxed at 80 °C for 24 h. After cooling, most of solvent was removed under vacuum and the residue was dropped into a mixture of petroleum ether and HCl (0.1 M) to form a precipitation. The crude product was further purified by silica gel column chromatograph eluted with dichloromethane/methanol (15/1, v/v) to obtain dyes.

2.4.4.1. 5-(2-Cyanoacrylicacid-3-yl)-benzene-2-carbalde-hyde-N,N-diphenylhydrazone (HB). Yield: 72% (0.32 g). FT-IR (KBr, cm^{-1}): 2227 ($\nu_{C\equiv N}$), 1693 ($\nu_{C=O}$). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.27 (s, 1H), 7.85 (s, 1H), 7.76–7.55 (m, 4H), 7.30–7.26 (m, 6H), 7.24–7.19 (m, 4H). Elem. Anal. Calcd. for $C_{23}H_{17}N_3O_2$: C, 75.19%; H, 4.66%; N, 11.44%. Found: C, 75.30%; H, 4.97%; N, 11.60%.

2.4.4.2. 5-(2-Cyanoacrylicacid-3-yl)-N-ethylhexylpyrrole-2-carbaldehyde-N,N-diphen-ylhydrazone (HP). Yield: 74% (0.42 g). FT-IR (KBr, cm^{-1}): 2210 ($\nu_{C\equiv N}$), 1670 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 8.04 (s, 1H), 7.84 (d, 1H, J = 4.5 Hz), 7.08 (s, 1H), 7.52–7.44 (m, 4H), 7.21–7.17 (m, 6H), 6.82 (d, 1H, J = 4.6 Hz), 4.05 (d, 2H, J = 7.4 Hz), 1.55–1.11 (m, 9H), 0.84 (t, 3H, J = 7.0 Hz), 0.75 (t, 3H, J = 7.3 Hz). Elem. Anal. Calcd. for $C_{29}H_{32}N_4O_2$: C, 74.33%; H, 4.88%; N, 11.96%. Found: C, 74.10%; H, 4.97%; N, 11.60%.

2.4.4.3. 5-(2-Cyanoacrylicacid-3-yl)-furan-2-carbaldehyde-N,N-diphenylhydrazone (HF). Yield: 72% (0.31 g). FT-IR (KBr, cm^{-1}): 2221 ($\nu_{C\equiv N}$), 1685 ($\nu_{C=O}$). ^1H NMR (400 MHz, $CDCl_3$): δ (ppm) 7.96 (s, 1H), 7.48–7.44 (m, 6H), 7.28–7.26 (m, 4H), 7.22 (d, 1H, J = 3.5 Hz), 7.03 (s, 1H), 6.82 (d, 1H, J = 3.5 Hz). Elem. Anal. Calcd. for $C_{21}H_{15}N_3O_3$: C, 70.58%; H, 4.43%; N, 11.76%. Found: C, 70.30%; H, 4.57%; N, 11.80%.

2.4.4.4. 5-(2-Cyanoacrylicacid-3-yl)-thiophene-2-carbalde-hyde-N,N-diphenylhydrazone (HT). Yield: 74% (0.33 g). FT-IR (KBr, cm^{-1}): 2213 ($\nu_{C\equiv N}$), 1673 ($\nu_{C=O}$). ^1H NMR (400 MHz, DMSO-d_6): δ (ppm) 8.36 (s, 1H), 7.82 (d, 1H, J = 3.4 Hz), 7.52 (s, 1H), 7.50 (d, 1H, J = 3.5 Hz), 7.37–7.26 (m, 6H), 7.19–7.17 (m, 4H). Elem. Anal. Calcd. for $C_{21}H_{15}N_3O_2S$: C, 67.54%; H, 4.05%; N, 11.25%; S, 8.59%. Found: C, 67.58%; H, 4.07%; N, 11.60%; S, 8.63%.

3. Results and discussion

3.1. Synthesis and characterization of sensitizers

The synthesis of the four hydrazone-based organic dyes **HB**, **HP**, **HF**, and **HT** is outlined in Scheme 1. The three dyes **HP**, **HF**, and **HT** were synthesized by the similar stepwise synthetic protocol. Firstly, the five-membered heterocyclic aldehyde (2-furaldehyde, 2-thienaldehyde or 2-carbaldehyde-*N*-ethylhexyl-pyrrole) reacted with *N*,*N*-diphenylhydrazine hydrochloride to afford five-membered heterocycle-based hydrazone **2a**, **2b** or **2c** according to the previous reports [22,23] in high yields. Then Vilsmeier formylation of **2a**, **2b** and **2c** afforded the key intermediates **3a**, **3b** and **3c** with good yields (81–85%), respectively. Finally, Knoevenagel condensation reactions of aldehyde derivatives **3a**, **3b** or **3c** with twofold excess of cyanoacetic acid afforded the target dyes **HP**, **HF**, or **HT** in acetonitrile using piperidine as catalyst. Compared to the former three dyes, the dye **HT** with the phenyl unit as the conjugated bridge was synthesized by a relatively simple procedure. *N*,*N*-Diphenylhydrazine hydrochloride was reacted with excess terephthalaldehyde to afford compound **1**. Then **1** reacted with cyanoacetic acid by Knoevenagel condensation to give the dye **HT**. The structures of all dye molecules were characterized unambiguously with FT-IR, ^1H NMR spectroscopy and elemental analyze.

3.2. Optical properties

In DSSCs, sensitizer is a key and unique component with a function of light harvesting. Its spectral response overlapped with the solar emission will affect the device photocurrent to a large extent; thus, we measured the ultraviolet–visible (UV–vis) absorptions of the dyes **HB**, **HP**, **HF**, and **HT** both in THF solutions and on TiO_2 films (Fig. 2 and Fig. 3, respectively). The characteristic data are collected in Table 1.

All the dyes exhibit two distinct absorption bands (Fig. 2): one absorption band is in the UV region (280–350 nm) corresponding to the π–$\pi*$ electron transitions of the conjugated molecules; and the other is in the visible region (380–550 nm) that can be assigned to an intramolecular charge transfer (ICT) between the *N*,*N*-diphenylhydrazone donating unit and the cyanoacrylic acid acceptor moiety [26]. It can be seen that the maximum absorption (λ_{max}) of the visible region red-shifts from 425 nm to 452 nm, 465 nm, and 469 nm for **HB**, **HF**, **HT** and **HP**, respectively. This red-shifted phenomenon may be ascribed to the different aromatic ability of the three five-membered heteroaromatic bridges. The aromatic ability of furan is larger than that of thiophene and pyrrole due to the stronger electronegative of oxygen element than that of nitrogen and sulphur elements. We can see that the λ_{max} values in the visible region shift to a lower energy with the decreased electronegativity of heteroatoms, which is in accordance with results of Wang et al. [17].

As depicted in Table 1, the molar extinction coefficient (ε) of the ICT bands of the four dyes ($15.9–24.6 \times 10^3$ M^{-1} cm^{-1}) are higher than that of the standard N719 sensitizer (14.2×10^3 M^{-1} cm^{-1}) [27], indicating a better ability of light harvesting of these new *N*,*N*-diphenylhydrazone-based metal-free organic dyes than that of classical organometallic dyes. Moreover, the ε of the ICT bands increases in the order of **HB** < **HT** < **HF** < **HP**, which suggests that **HP** should hold the best ability of light harvesting. The higher ε of the organic dyes allows a correspondingly thinner nanocrystalline film so as to avoid the decrease of the film mechanical strength. This also benefits the electrolyte diffusion in the film and reduces the recombination possibility of the light-induced charges during transportation [28].

When the dyes were attached on TiO_2 films, the absorption spectra may shift more or less as compared with that

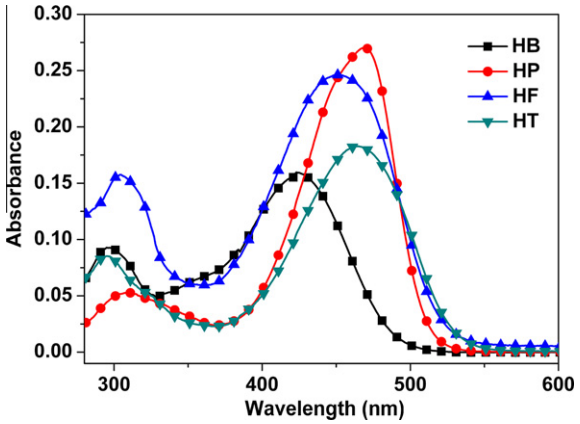


Fig. 2. Absorption spectra of the four dyes in THF solutions (10^{-5} M) at 25 °C.

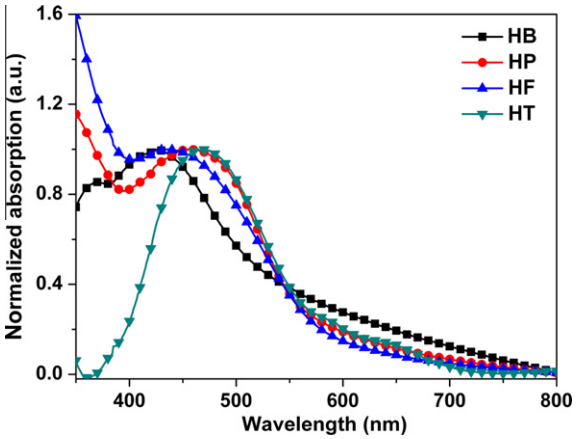

Fig. 3. Absorption spectra of the four dyes adsorbed on TiO_2 surface.

Table 1
Maximum absorption and emission data of the four dyes.

Dye	λ_{max}[a] ([c]ε/M^{-1} cm^{-1})		λ_{max}[b]/nm
HB	425(15,900)	295(9300)	418
HP	469(27,000)	310(5300)	457
HF	452(24,600)	304(15,800)	437
HT	465(18,300)	295(8500)	469

[c] ε is the molar extinction coefficient at λ_{max} of maximum absorption.

in solutions because of strong interactions between the dyes and the semiconductor surface, which can lead to form aggregates of the dyes on semiconductor surface, such as *H*-aggregation for the blue shift or *J*-aggregation for the red shift. From Figs. 2 and 3 and Table 1, it can be seen that absorption spectra of the dyes **HB**, **HP**, and **HF** on TiO_2 films displayed broader and a blue shift of 7 nm, 12 nm, and 15 nm, respectively, compared to those in THF solutions due to *H*-aggregation. However, the absorption spectrum of **HT** on TiO_2 film red shifted (4 nm) slightly in comparison with that in solution, indicating the dye possesses the *J*-aggregation on semiconductor surface. Another noteworthy feature in the spectra of dyes adsorbed on TiO_2 surfaces is an apparent tailing toward longer wavelength region (Fig. 3). In solutions the low energy edge of absorption bands does not exceed 550 nm (Fig. 1), yet on TiO_2 the absorption threshold extends to 750 nm. The long wavelength absorption should be result from the formation of a certain degree of aggregates on the surface of TiO_2. The absorption of aggregates is responsible for the induction of photocurrent in the regions of $\geqslant$600 nm (Fig. 5).

3.3. Electrochemical properties

While a good light absorption is an essential requirement for photovoltaic cells, the following charge generation from the closely bound electron–hole pair (Frenkel exciton) confined in a single organic molecule [29] also determines device operation. This process is triggered at the interface between a donor component and an acceptor component (dye and titania in DSSC), featuring a favorite energy alignment, although a hot electron injection is also possible [30]. Here we measured the oxidation potential of the four dyes by means of cyclic voltammetry (CV) to evaluate the possibility of electron transfer from the excited dye molecule to the conductive band of TiO_2. CV was performed in CH_3CN with 0.1 M Bu_4NPF_6 as a supporting electrolyte (Fig. 4). Table 2 summarizes all the electrochemical properties of the four dyes.

The first oxidation potential vs. NHE (E_{ox}), which corresponds to the highest occupied molecular orbital (HOMO vs. NHE), was calibrated by addition of 0.63 V to the potential (vs. SCE) vs. Fc/Fc^+ by CV (Table 2). The first oxidation potentials of the four dyes **HB**, **HP**, **HF**, and **HT** were measured as 1.23, 1.15, 1.28, and 1.29 V, respectively. It is easy to see that the negative shifts of the E_{ox} (0.08, 0.13, and 0.14 V) were observed for **HB**, **HF**, and **HT** vs. **HP**, respectively, which means that **HP** has the lowest HOMO level among the four dyes. The decrease of HOMO levels of the dyes could show a positive effect on the DSSCs performance due to the narrower gap between the HOMO level and the redox potential of iodine/iodide leading to less waste of energy [17]. We also can see that all the HOMO levels of four dyes are more positive than the iodide/triiodide redox couple (~0.42 V vs. NHE), indicating that the oxidized dyes formed after electron injection into the conduction band of TiO_2 could accept electrons from I^- ions in the electrolyte thermodynamically.

By neglecting any entropy change during light absorption, the reduction potential vs. NHE (E_{red}), which corresponds to the lowest unoccupied molecular orbital (LUMO vs. NHE), can be obtained from E_{ox} and E_{0-0} value determined from the intersection of absorption and emission spectra, namely, $E_{ox}-E_{0-0}$. The calculated LUMO levels of **HB**, **HP**, **HF**, and **HT** were −1.33, −1.36, −1.21, and −1.09 V vs. NHE (Table 2), respectively, which all are sufficiently higher than that of the conduction band (CB) level of TiO_2 (−0.5 V vs. NHE). Provided that energy gap (E_{gap}) between LUMO levels and CB level of TiO_2 of 0.2 eV is necessary for efficient electron injection [4a], these driving

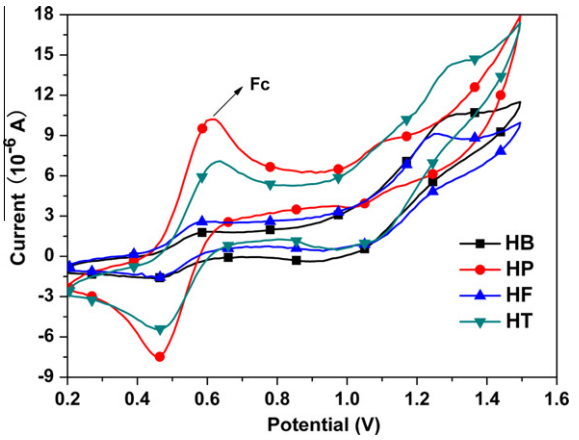

Fig. 4. Cyclic voltammograms of the three dyes: working electrode, Pt ring; auxiliary electrode, Pt wire; reference electrode, Hg/Hg_2Cl_2; scanning rate is 100 mV/s.

Table 2
Electrochemical data of the four dyes [a].

Dye	λ_{int}/nm	E_{0-0}/eV	E_{ox}/V vs. NHE	E_{red}/V vs. NHE	E_{gap}/V
HB	485	2.56	1.23	−1.33	0.83
HP	495	2.51	1.15	−1.36	0.86
HF	498	2.49	1.28	−1.21	0.71
HT	520	2.38	1.29	−1.09	0.59

[a] E_{0-0} values were calculated from intersection of the normalized absorption and the emission spectra (λ_{int}): $E_{0-0} = 1240/\lambda_{int}$. The first oxidation potential (vs. NHE), E_{ox} was measured in acetonitrile and calibrated by addition of 0.63 V to the potential versus Fc/Fc^+. The reduction potential, E_{red}, was calculated from $E_{ox}-E_{0-0}$. E_{gap} is the energy gap between the E_{red} of dye and the CB level of TiO_2 (−0.5 V vs. NHE).

forces are sufficiently large for effective electron injection. Therefore, the four dyes used as sensitizers will have sufficient driving force for electron transfer from the excited dye molecules to the CB of TiO_2 electrode. Noticeably, the relatively large E_{gap} of the dyes allow for the addition of the 4-tertbutylpyridine (TBP) into the electrolyte, which can shift the conduction band of TiO_2 negatively about 0.3 V and consequently improve the open-circuit voltage (V_{oc}) and total power energy conversion efficiency (PCE) [31]. The E_{gap} of the four dyes ranges from 0.59 (**HT**) to 0.86 eV (**HP**) (Table 2). Accordingly, an increased E_{gap} may yield higher V_{oc} and enhance the PCE considerably, which predicts the dye **HP** may give a higher V_{oc} and PCE.

These above-discussed results indicate that the introduction of aromatic cycles (benzene, pyrrole, furan and thiophene) in π-conjugated bridges could easily tune the absorption spectra and HOMO and LUMO energy levels of the dyes.

3.4. Molecular orbital calculations

In order to gain an insight into the molecular structure and electron distribution, density functional theory (DFT) calculations were performed on the four dyes using the Gaussian 03 program package. In particular we used B3LYP as exchange-correlation functional and 3-21G* as basis set. The electron distribution of the HOMO and LUMO of the dye**s** is shown in Table 3. It is obvious that the electron density of HOMO is localized mainly on the *N*,*N*-diphenylhydrazone moiety and is extended along the π-conjugated bridge to the central region of the molecule. On the other hand, the LUMO is localized over the cyanoacrylic unit through aromatic bridges. We notice that the HOMO–LUMO excitation induced by light irradiation could move the electron distribution from the *N*,*N*-diphenylhydrazone unit to the cyanoacrylic acid moiety via aromatic π-conjugated bridges and the photo-induced electron transfer from the dyes to the TiO_2 electrode can occur efficiently by the HOMO–LUMO transition.

3.5. Photovoltaic performance of DSSCs

DSSCs were fabricated using these dyes as the sensitizers, with an effective area of 0.196 cm^2, TiO_2 particles on FTO, and the electrolyte composed of 0.5 M LiI, 0.05 M I_2, and 0.5 M 4-*tert*-butyl-pyridine (TBP) in 3-methoxy-propionitrile. Fig. 5 shows incident photon-to-electron conversion efficiency (IPCE) as a function of the wavelength for the sandwiched DSSCs based on the four dyes as sensitizers. As shown in Fig. 5, the IPCE of **HP** sensitizer exceeds 60% in the spectral region from 400 to 520 nm, reaching its maximum over 80% at 425 nm, while other three dyes produce maximum IPCE about 60%. The relatively higher maximum IPCE for **HP** compared with other three dyes is well in agreement with the tendency of UV–vis absorption properties. In comparison with **HB** and **HF**, **HT** exhibits a broader IPCE spectrum. These results imply that **HP** and **HT** would show a relatively large photocurrent in DSSCs. Additionally, it should be noted that the four dyes still show weak IPCE response at the range of long wavelength region (650–750 nm), as shown in Fig. 5. We believe that this feature should be ascribed two reasons: one is the weak absorption band of the dyes on TiO_2 films at the range of 650–750 nm (see Fig. 3), which is consistent with our and the other reports [32]; the other is the effect of light scattering by TiO_2 nanoparticles, which increases the photocurrents for the weak absorption in that region.

Fig. 6 shows current density–voltage (*J*–*V*) characteristics of devices based on the four dyes. The detailed photovoltaic parameters of the short-circuit photocurrent density (J_{sc}), open-circuit photovoltage (V_{oc}), fill factor (FF), and power conversion efficiency (PCE) are listed in Table 4. According to Fig. 6, it is clear that the photovoltaic performances of the DSSCs can be evidently affected by the aromatic bridges in the dye molecules. The PCE increases in the order of **HB** (4.39%) < **HF** (4.66%) < **HT** (5.29%) < **HP** (7.18%). **HP** exhibits the best PCE due to both the highest J_{sc} (14.76 mA/cm^2) and V_{oc} (0.69 V) values. Obviously, the tendency of a gradually increased PCEs for the four dyes with various aromatic bridges shows be along with the increase of J_{sc}. Consistent with the increased tendency of IPCE, the measured J_{sc} increases in the order of **HB** (9.64 mA/cm^2) < **HF** (10.62 mA/cm^2) < **HT** (11.04 mA/cm^2) < **HP** (14.76 mA/cm^2). In view of the similar configuration and anchoring mode of the four sensitizers, we compare their ratios of molar extinction coefficients and the absorptivities of dye coated titania films, deducing that **HB** has a lower surface coverage than those of other three dyes. In addition, the remarkably increased J_{sc} value of **HP** compared with other three dyes can be ascribed to its relatively better light harvesting ability, reflecting in its better IPCE spectrum.

Generally, V_{oc} becomes low along with the decrease of aromatic ability of aromatic π-conjugated bridges. The improved V_{oc} value (0.69 V) of **HP** compared to other three dyes (0.61–0.67 V) could be attributed to the following two aspect reasons. One is that the additional hydrophobic alkyl chain of pyrrole bridge in **HP** can effectively retard the charge recombination between injected electron and I_3^- ions in the electrolyte, which is favorable for increasing the electron lifetimes and hence to improve V_{oc} [33a,6i,6h,11b]. We will discuss it in detail as the following electrochemical impedance spectroscopy studies. The other reason can be attributed to the comparatively lower-lying HOMO of the **HP** (estimated from the CV), which offers enough larger driving force for the reduction of the oxidized dye. This, in turn, will lead to a slower back

Table 3

electron transfer from TiO_2 to the dye and result in a lager V_{oc} value [33b].

It has been reported that chenodeoxycholic acid (CDCA) can enhance the performance of the DSSCs because CDCA can reduce the aggregation of the dyes on the TiO_2 surface [6g,8b,9a,34]. To investigate the influence of aggregation of dyes on the photovoltaic performance, CDCA was added into the dye solution as a coadsorbent and the relative photovoltaic data are also collected in Table 4. As shown in Table 4, after the addition of CDCA (1 mM) to the dye bath, PCEs of DSSCs based on the four dyes are increased by 16%, 8%, 19%, and 10% for **HB**, **HP**, **HF**, and **HT** respectively, which results from the significant improvement of J_{sc} values. The obviously improved PCEs of **HB** (5.11%) and **HF** (5.54%) indicate that CDCA plays a important role in suppressing the aggregation conformation of dyes on TiO_2 surface. In the case of **HP** (7.74%), the relatively little increase implies that the CDCA has a slight impact on the aggregation the dye, which can be ascribe to effectively inhibiting aggregation of alkyl group to pyrrole unit [6g,10a,33a]. The above photovoltaic results indicate strongly that coadsorption of CDCA is effective to improve solar cell performance by suppressing the aggregation conformation of dyes on TiO_2 surface.

[b] Dye bath: CH_3CN solution (0.5 mM) with addition of CDCA (1 mM). For all cells, the double-layer TiO_2 films are composed of ~14 μm transparent layer and ~5 μm scatter layer.

3.6. Electrochemical impedance spectroscopy studies

Electrochemical impedance spectroscopy (EIS) is a powerful technique of characterizing the important interfacial charge transfer processes in a DSSC. The EIS was measured in the dark to elucidate correlation of V_{oc} with those dyes. The Nyquist plots of DSSCs with four dyes are shown in Fig. 7. Three semicircles are observed in the Nyquist plots. The small and large semicircles respectively located in the high- and middle-frequency regions, are assigned to the charge transfer at Pt/electrolyte and TiO_2/dye/electrolyte interface, respectively [33]. Another small semicircle, which should have appeared at the low-frequency region, is overlapped by the middle-frequency large semicircle. The charge recombination resistance (R_{rec}) at the TiO_2 surface can be deduced by fitting curves from the range of the middle-frequency using a Z-view software. R_{rec} is related to the charge recombination rate between injected electron and electron acceptor (I_3^-) in the electrolyte, estimated by the large semicircle width. A large R_{rec} means the small charge recombination rate and vice versa. The R_{rec} values for **HP** and **HB** were estimated to be 186 and 97 Ω, respectively. In contrast, **HF** and **HT** were found to have relatively smaller R_{rec} values at 84 and 57 Ω, respectively. The result appears to be consistent with the larger V_{oc} values for the dyes **HP** (0.69 V) and **HB** (0.67 V). The significantly increased R_{rec} values of **HP** and **HB** imply the retardation of the charge recombination between injected electron and I_3^- ions in the electrolyte, with a consequent increase of V_{oc}.

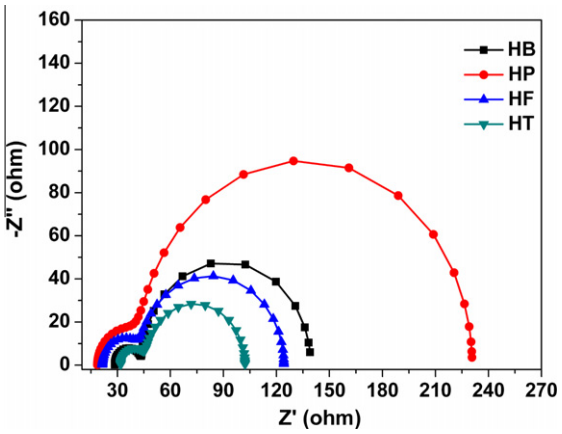

Fig. 7. EIS Nyquist plots for DSSCs based on the four dyes measured in the dark under −0.65 V bias.

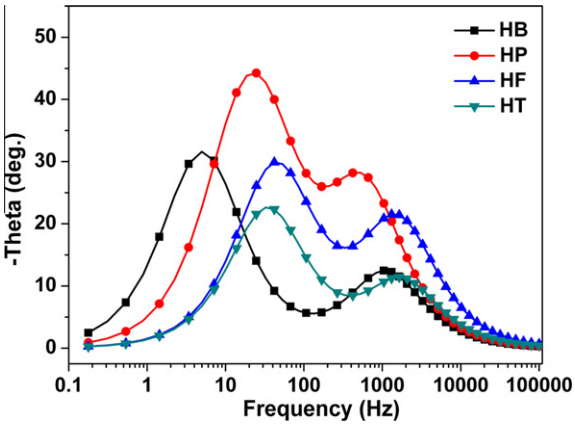

Fig. 8. EIS Bode plots for DSSCs based on the four dyes measured in the dark under −0.65 V bias.

At the same time, DSSCs based on **HP** and **HB** produced higher V_{oc} than **HF** and **HT**, which can be explained by the

electron lifetime. Fig. 8 shows the Bode plot for DSSCs based on **HB**, **HP**, **HF**, and **HT**. Two peaks in Fig. 8 located at the high-frequency (right) and middle-frequency (left) respectively correspond to the small semicircle (left) and large semicircle (right) in the Nyquist plots (Fig. 7). The reciprocal of the peak frequency for the middle-frequency peak is regarded as the electron lifetime since it represents the charge transfer process at the TiO_2/dye/electrolyte interface. It is evident that the electron lifetime for the DSSC based on **HT** and **HF** is smaller than those for DSSCs based on **HP** and **HB**, thereby explaining the V_{oc} increase from **HT** and **HF** to **HP** and **HB**.

4. Conclusions

In summary, we have designed and synthesized a series of novel hydrazone-based D–π–A dyes (**HB**, **HP**, **HF**, and **HT**), by employing different aromatic π-conjugated bridges such as benzene, pyrrole, furan, and thiophene in combination with the hydrophobic *N*,*N*-diphenylhydrazone donor and the hydrophilic cyanoacrylic acid acceptor. The effects of the aromatic π-conjugated bridges on the photophysical, electrochemical and photovoltaic properties of these dyes were extensively investigated. It was found that the absorption spectra and HOMO and LUMO energy levels can be conveniently tuned by alternating the aromatic bridges. Molecular orbital calculations showed that the HOMO–LUMO excitation could readily move the electron distribution from the *N*,*N*-diphenylhydrazone donor to the cyanoacrylic acid acceptor via aromatic π-conjugated bridges. We have also studied the influence of aromatic bridges on photovoltages through the electrochemical impedance experiments and achieved a preliminary conclusion that the high V_{oc} of **HP** based DSSC resulted from the relatively small charge recombination rate and long electron lifetime due to the additional hydrophobic alkyl chain of pyrrole bridge. DSSCs based on these dyes have achieved 5.11–7.74% PCEs when CDCA (1 mM) was added into the dye bath as a coadsorbent. For the first time we have proved that *N*,*N*-diphenylhydrazone and *N*-(2-ethylhexyl)-substituted pyrrole units can be employed as the effective and promising donor and π-conjugated bridge, respectively in D–π–A dyes, which expands the selection scope of building blocks for further dye design. Further structural modification of the π-conjugated bridge based on the series sensitizers to improve the photovoltaic performance is just ongoing.

FTO conductors having varied textures were characterized for their physical, electrical and optical properties and were subjected to device studies to establish the correlation between FTO textures and device characteristics/performances.

2. Experiments

2.1. Characterization of textured FTO

Six FTO transparent conductors on glass substrates (samples #1–#6) having different textures and properties were purchased from commercial sources (Solaronix, Hartford Glass, and Nippon Sheet Glass). Their properties obtained from characterizations described below are summarized in Table 1.

Scanning electron microscopy (SEM) and atomic force microscopy (AFM) were used to characterize the morphology, surface topography and roughness of FTO films. The sheet resistances of FTO films were measured by the Van der Pauw method. A UV–Vis spectrophotometer equipped with an integrating sphere was used to characterize the transmittance and scattering properties of the FTO films. In this work, two types of transmittance were characterized: the total transmittance (T_{total}) and the direct transmittance (T_{direct}). T_{total} was measured by using a monochromatic light beam normally incident onto sample and then using an integrating sphere to collect transmitted light over all angles. On the other hand, T_{direct} was measured by using a monochromatic light beam normally incident onto the sample and then collecting transmitted light only in the normal direction (within a 5° collection angle). The haze values of FTO films, which are defined as the ratio of the diffusively transmitted light against the total transmitted light [25], were then obtained by Haze = $(T_{total} - T_{direct})/T_{total}$ at some specific wavelength, which is useful indication of the optical scattering capability of a thin film.

2.2. DSSC fabrication

Fig. 1 shows the schematic device structure of the DSSC using the textured FTO as the transparent conductor for the incident light. In fabrication of devices, the FTO glass substrates were first cleaned in a detergent solution using an ultrasonic bath and then were rinsed with water and ethanol. A layer of 20-nm-sized anatase TiO_2 nanoparticles was then coated on the FTO by the doctor-blade method. After drying the film at 120 °C, another layer of 400-nm-sized anatase TiO_2 nanoparticles was then coated as the light scattering layer. The resulting working electrode was composed of a 12-μm-thick transparent TiO_2 nanoparticle layer (average particle size: 20 nm) and a 4-μm-thick TiO_2 scattering layer (average particle size: 400 nm) [26]. The thickness of the TiO_2 nanoparticle layer had been optimized by

Table 1
Characteristics of different textured FTO films and characteristics of DSSCs fabricated on these different FTO films.

Characteristics of FTO films							Characteristics of DSSCs				
FTO sample	Thickness (nm)	Grain size (nm)	Roughness (nm)	Sheet resistance (Ω/□)	T_{total} (550 nm) (%)	Haze (550 nm) (%)	J_{sc} (mA/cm^2)	V_{oc} (V)	FF	Eff. (%)	Rct (Ω)
#1	~400	~100–200	9.14	15	85	2	14.87	0.80	0.69	8.18	63.6

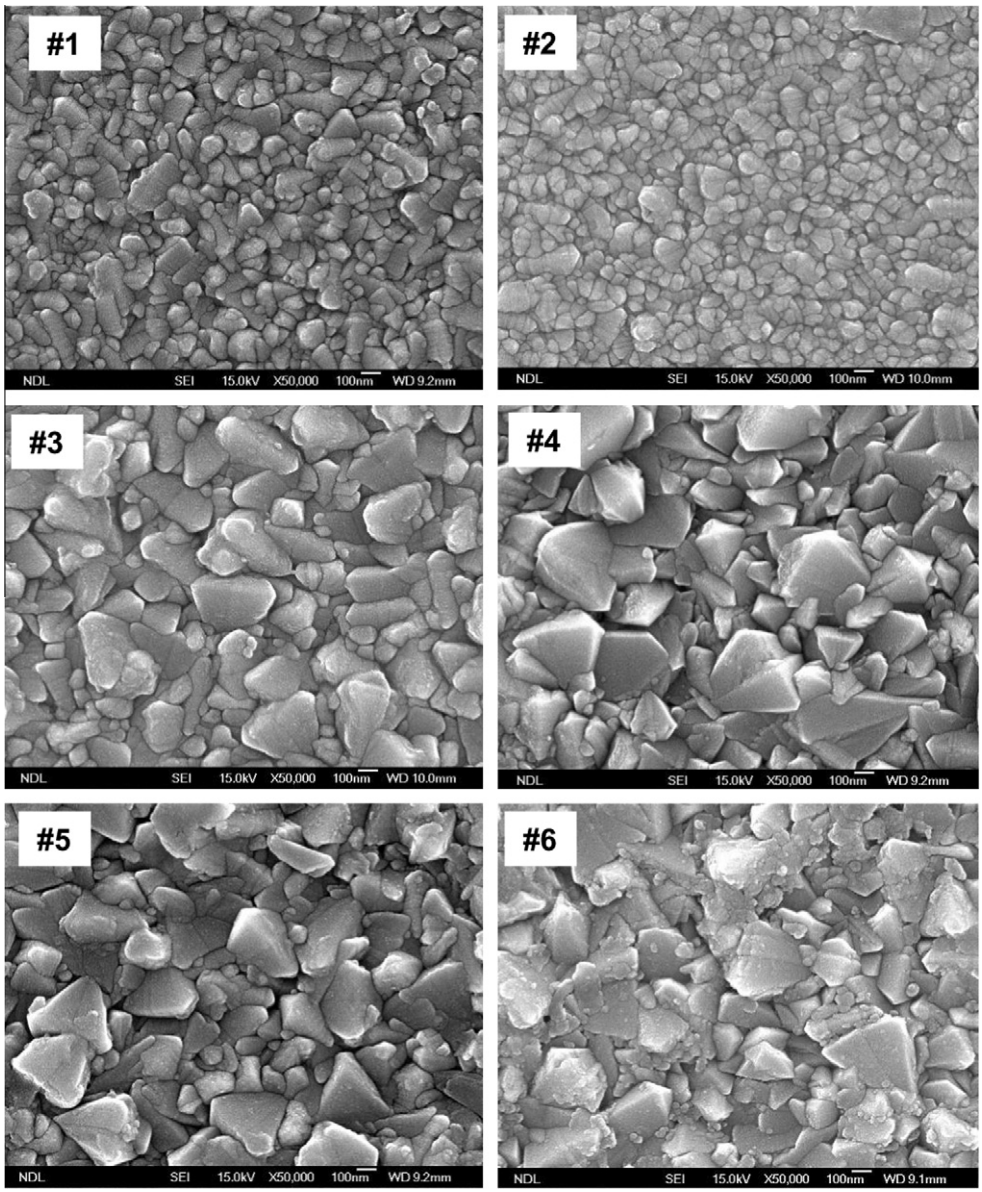

Fig. 2. SEM images of textured FTO samples #1–#6.

balancing the tradeoff between optical absorption and the electrical transport properties. The nanoporous TiO_2 electrodes were then heated in an atmospheric oven first by gradually ramping the temperature from 150 to 500 °C and then at 500 °C for 30 min. After cooling, the nanoporous TiO_2 electrodes were immersed into a dye solution at room temperature for 24 h for dye adsorption. The dye solution was composed of 0.5 mM ruthenium dye **N719**, [cis-di(thiocyanato)-N-N′-bis(2,2′-bipyridyl-4-carboxylic acid-4′-tetrabutyl-ammonium carboxylate) ruthenium (II)] [27], and 0.5 mM chenodeoxycholic acid (CDCA, as a co-adsorbent) in the acetonitrile/*tert*-butanol mixture (1:1) [28].

Counter electrodes of the DSSC were prepared by depositing 40-nm-thick Pt films on another glass substrates by e-beam evaporation. The dye-adsorbed TiO_2 working electrode and a counter electrode were then assembled into a sealed DSSC cell with a sealant spacer between the two electrode plates. A drop of the electrolyte solution [0.6 M 1-butyl-3-methylimidazolium iodide (BMII), 0.03 M I_2, 0.5 M 4-*tert*-butylpyridine, and 0.1 M guanidinium thiocyanate in a mixture of acetonitrile–valeronitrile (85:15, v/v)] was injected into the cell through a drilled hole [29]. Finally, the hole was sealed. An active device areas of 0.125 cm^2 was used for the device characterization.

2.3. DSSC characterization

The photocurrent–voltage (*I*–*V*) characteristics of the DSSCs were measured under illumination of the simulated

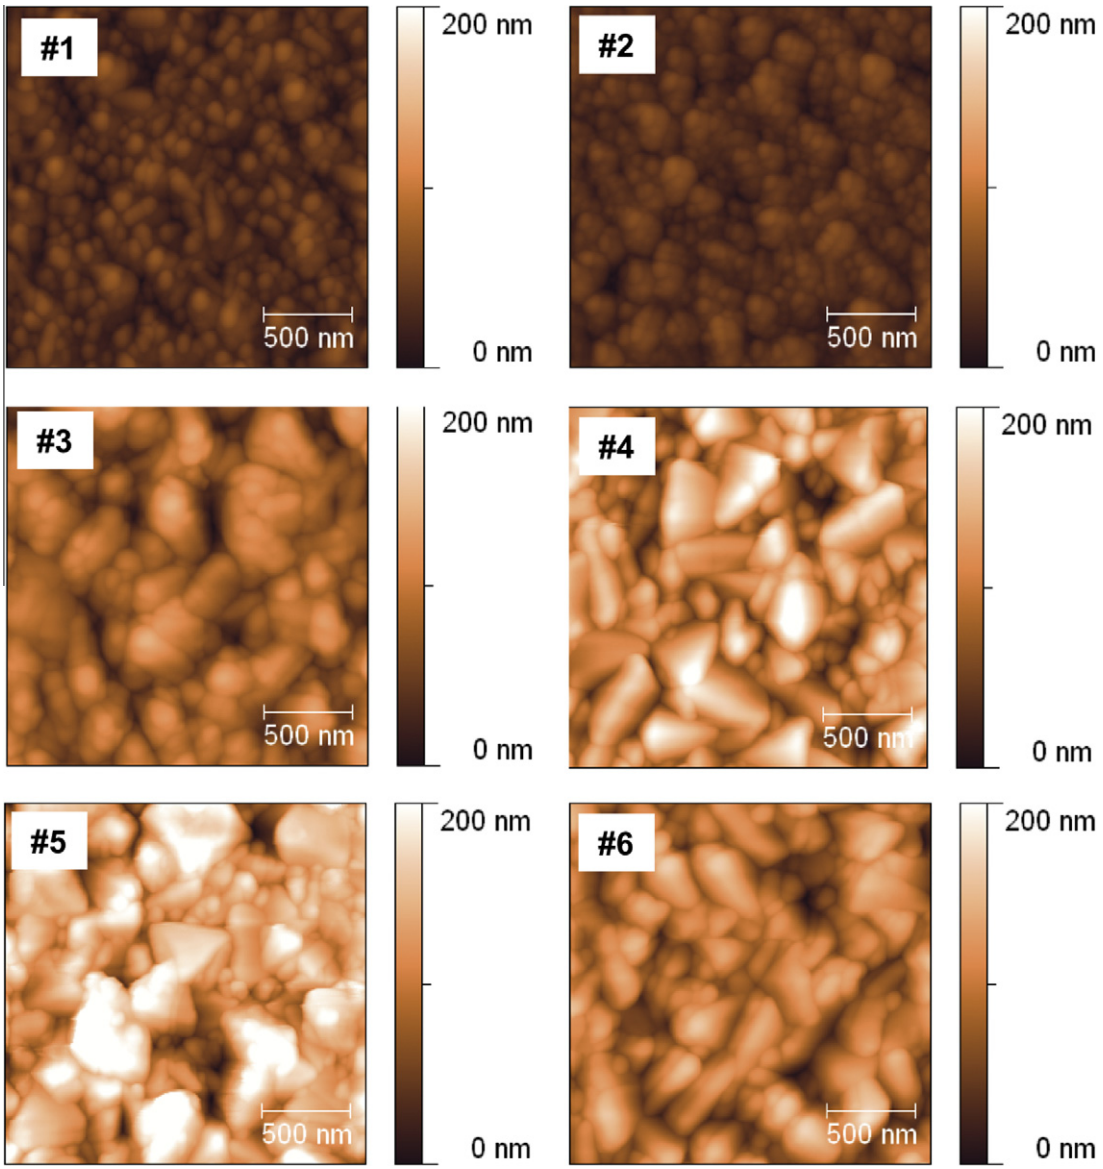

Fig. 3. AFM images of textured FTO samples #1–#6.

AM1.5G solar light from a 300-W Xenon lamp solar simulator. The incident light intensity was calibrated as 100 mW/cm^2. Photocurrent-voltage curves were obtained by applying an external bias voltage to the cell and measuring the generated photocurrent. The current–voltage characteristics of DSSCs were used to extract the short-circuit current density (J_{SC}), open-circuit voltage (V_{OC}), fill factor (FF), and power conversion efficiency (Eff.) of the DSSCs [30–32]. The incident photon-to-current conversion efficiency (IPCE) spectra of the devices were measured by using a 75-W Xenon arc lamp as the light source coupled to a monochromator. The IPCE data were taken by illuminating monochromatic light on the solar cells (with the wavelength from 300 to 800 nm) and measuring the short-circuit current of the solar cells [33]. The IPCE measurement was performed with a lock-in amplifier, a low speed chopper, and a bias light source under the full computer control.

In addition to the standard *I–V* and IPCE characterization of solar cells, in this study, the electrochemical impedance spectroscopy (EIS) was also used to analyze the internal impedance properties of DSSCs [34–36]. The electrochemical impedance spectroscopy of the cells was measured by using an impedance analyzer with a frequency range of 20–1 MHz. In this study, during the impedance measurement, the cell was under the constant AM 1.5G 100 mW/cm^2 illumination. The impedance of the cell (throughout the frequency range of 20–1 MHz) was then measured by applying a bias at the open-circuit voltage V_{OC} of the cell (namely, under the condition of no dc electric current) and by using an ac amplitude of 10 mV.

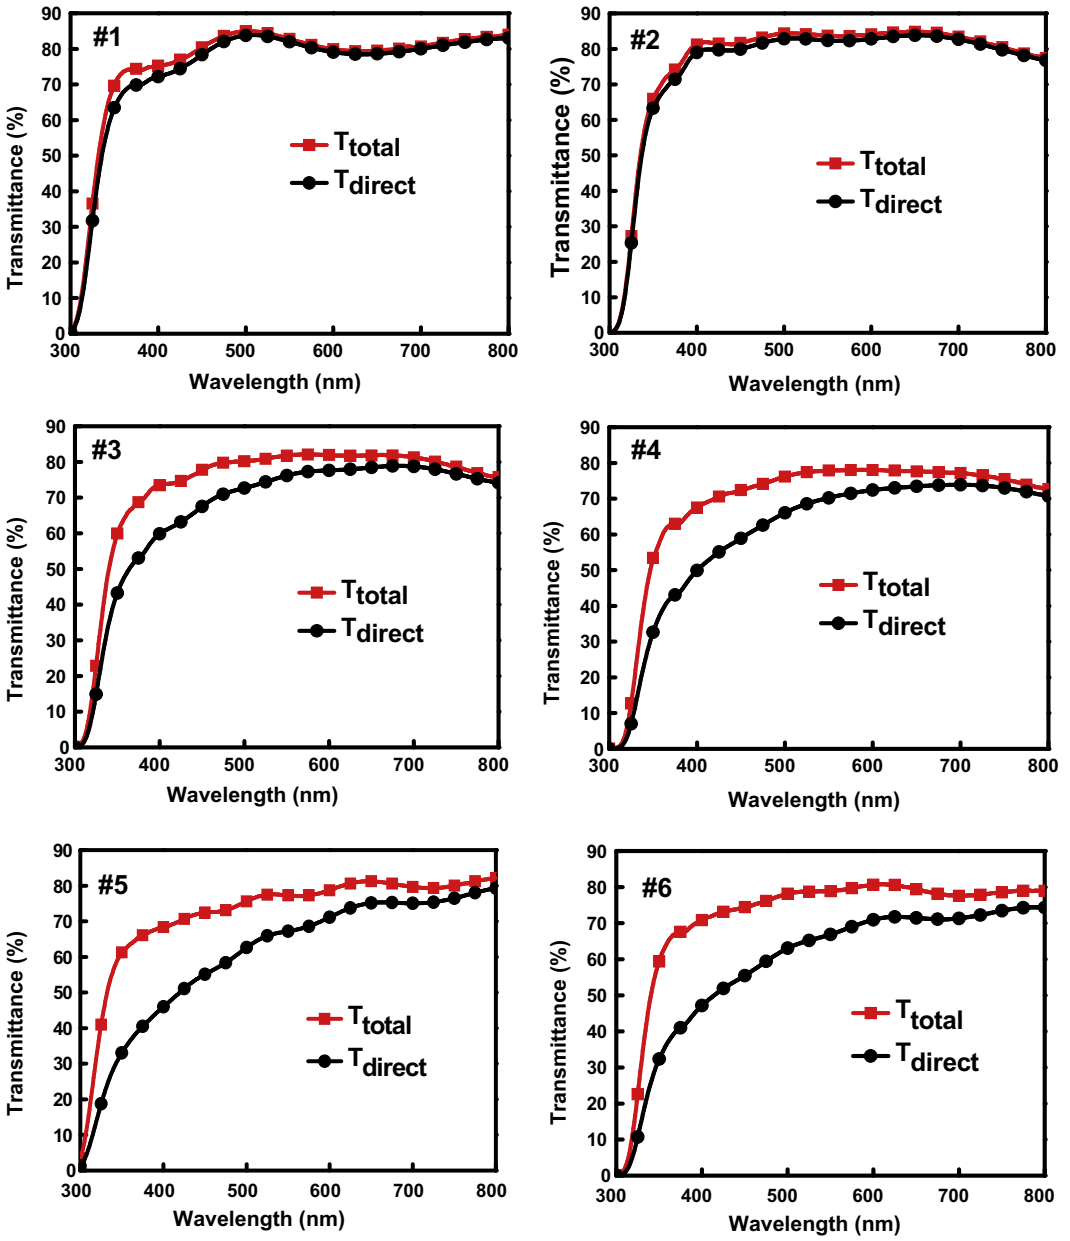

Fig. 4. Total transmittance (T_{total}) and the direct transmittance (T_{direct}) spectra of FTO samples #1–#6.

3. Results and discussions

3.1. Properties of textured FTO

Figs. 2 and 3 show the SEM and AFM images of the textured FTO samples #1–#6, respectively. In SEM images of Fig. 2, one sees that all FTO samples show grainy structures (textures) in the films. Samples #1 and #2 have smaller grain sizes of about 100–200 nm, while #3–#6 samples are composed of a mixture of larger grains and smaller grains. In #3, the sizes for smaller grains and larger grains are ~100–200 nm and ~300–400 nm, respectively. In #4–#6, the sizes of larger grains, with an average size of ~400 nm and with some grains even larger than 400 nm, are slightly larger than those in #3. Furthermore, larger grains in all #3–#6 samples exhibit the distinct pyramidal shape. While the sizes of the smaller grains in #4–#6 are also ~100–200 nm, they tend to show the pyramidal shape, in contrast with smaller grains in samples #1–#3. With the size of larger grains in #3–#6 (~400 nm) being similar to the optical wavelengths, one may expect a stronger scattering effect from these samples, compared to #1 and #2 samples. Topographical characteristics examined by AFM for #1–#6 samples are similar to/consistent with those observed by SEM. Yet the surface roughness can now be quantitatively determined from the AFM results.

#1 and #2 FTO films show smaller surface roughnesses of 9.14 and 9.91 nm, respectively, while samples #3, #4, #5 and #6 containing larger grains show significantly greater surface roughnesses of 23.72, 28.34, 36.41, and 38.42 nm, respectively. Indeed, the numbering of the FTO samples was based on their surface roughness (and haze as will be described). The grain sizes and surface roughnesses of all samples are summarized in Table 1, together with their sheet resistances measured by the Van der Pauw method and optical properties to be described below. All six FTO samples have small sheet resistances of 7–15 Ω/□.

Fig. 4 shows the total transmittance (T_{total}) and the direct transmittance (T_{direct}) spectra of FTO samples #1–#6. T_{total} and Haze (calculated from T_{total} and T_{direct} spectra) of FTO films #1–#6 at the wavelength of 550 nm are also summarized in Table 1. As can be seen in Fig. 4 and Table 1, the occurrence of larger grains (~400 nm, samples #3–#6) largely raises Haze values, and thus the optical scattering capability. From sample #1 to sample #6 (with increased surface roughness), the haze increases from 2% to 17%. The Haze tends to increase with the surface roughness and the highest haze of 17% was obtained in the FTO sample with the largest surface roughness (i.e. #6). The integrated total transmittance T_{total} of the textured FTO films is also critical for the overall efficiency of the DSSCs. A low T_{total} implies most of the incident light cannot transmit through the film (either directly or by scattering), but be scattered backward instead, not good for device efficiency. Therefore upon tuning the haze (and thus the scattering capability), simultaneously maintaining a high enough T_{total} is also important. In results of Fig. 4, it is seen that all six FTO samples exhibit rather high T_{total} of ~70–85% for a wide wavelength range above 400 nm. As shown in Table 1, at the wavelength of 550 nm, T_{total} of the six samples is in the range of 79–85%. Thus for these FTO samples, one acquires a haze value significantly varying from 2% to 17%, and yet still keeps similarly high total transmittance, making it possible to study effects of the haze/scattering of textured FTO films on DSSC characteristics without worrying about adverse effects of lowered overall transmittance.

3.2. Device characteristics of DSSCs using textured FTO

Fig. 5(a) and (b) shows the *I–V* and IPCE characteristics of six DSSCs fabricated on the six FTO samples, respectively. The photovoltaic characteristics of the six devices, including the short-circuit current J_{SC}, the open-circuit voltage V_{OC}, the fill factor FF, and the conversion efficiency (Eff.), are summarized in Table 1 and are also plotted versus the haze value of FTO in Fig. 6. From Figs. 5 and 6 and Table 1, one sees that the open-circuit voltage V_{OC} and the fill factor FF do not differ much among these six devices. Yet, the J_{SC} and power conversion efficiency of the six devices in general increases significantly with the texture sizes, the surface roughness, and the haze ratio of the FTO. The J_{SC} and the power conversion efficiency of DSSCs increased from (14.87 mA/cm^2, 8.18%) of the device on #1 FTO (haze = 2%) to (18.56 mA/cm^2, 10.1%) of the device on #6 FTO (haze = 17%). An enhancement of the conversion efficiency by ~24% was obtained with using the highly textured, large-roughness and high-haze FTO as

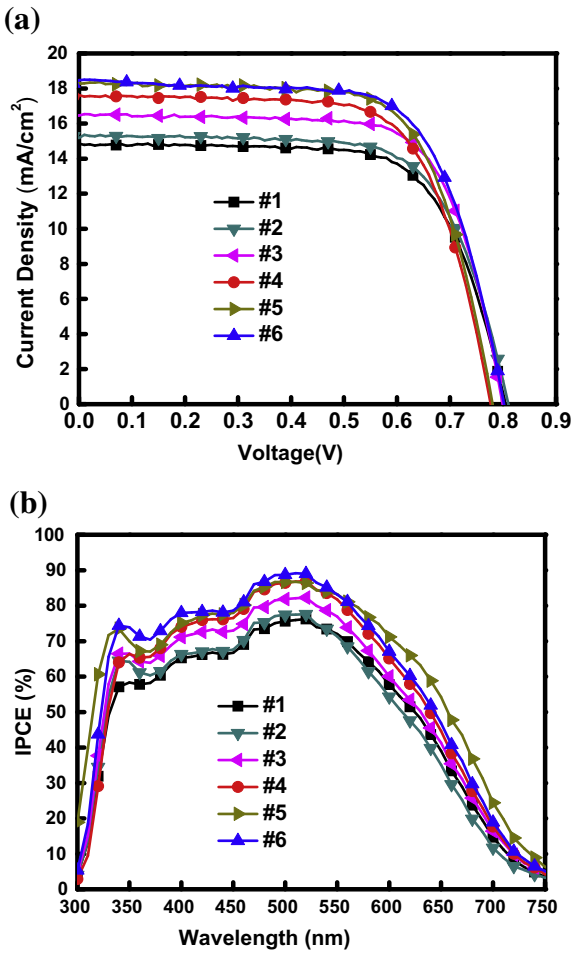

Fig. 5. (a) *I–V*, and (b) IPCE characteristics of DSSCs fabricated on the FTO samples #1–#6.

the bottom transparent conductor. Due to the availability of FTO substrates with even higher hazes, the highest haze tested in this work was 17%. Nevertheless, the trend in Fig. 6 suggests the possible direction for further enhancement. If one could prepare FTO substrates with even higher hazes and in the meantime maintain high total transmittance (it is noted that the total transmittance of the FTO samples gradually decrease with the haze), the DSSC efficiency may be further enhanced and/or optimized.

Since the surface texture, roughness, and the optical haze had no significant effects on the V_{OC} and the fill factor FF and all devices had the same TiO_2 thickness and device processing, the enhanced conversion efficiency must result from enhanced optical absorption in the devices. This is well supported by IPCE results shown in Fig. 5(b), in which one sees that the IPCE in generally increases with the optical haze of the FTO used over the broad absorption range, except for few situations. For instance, IPCE of device #5 is higher than that of device #6 for the short and long wavelength ranges, which may be associated with the detailed morphological and optical properties of the FTO samples. Yet even in this case, device #6 exhibits higher IPCE than device #5 for the major wavelength range of

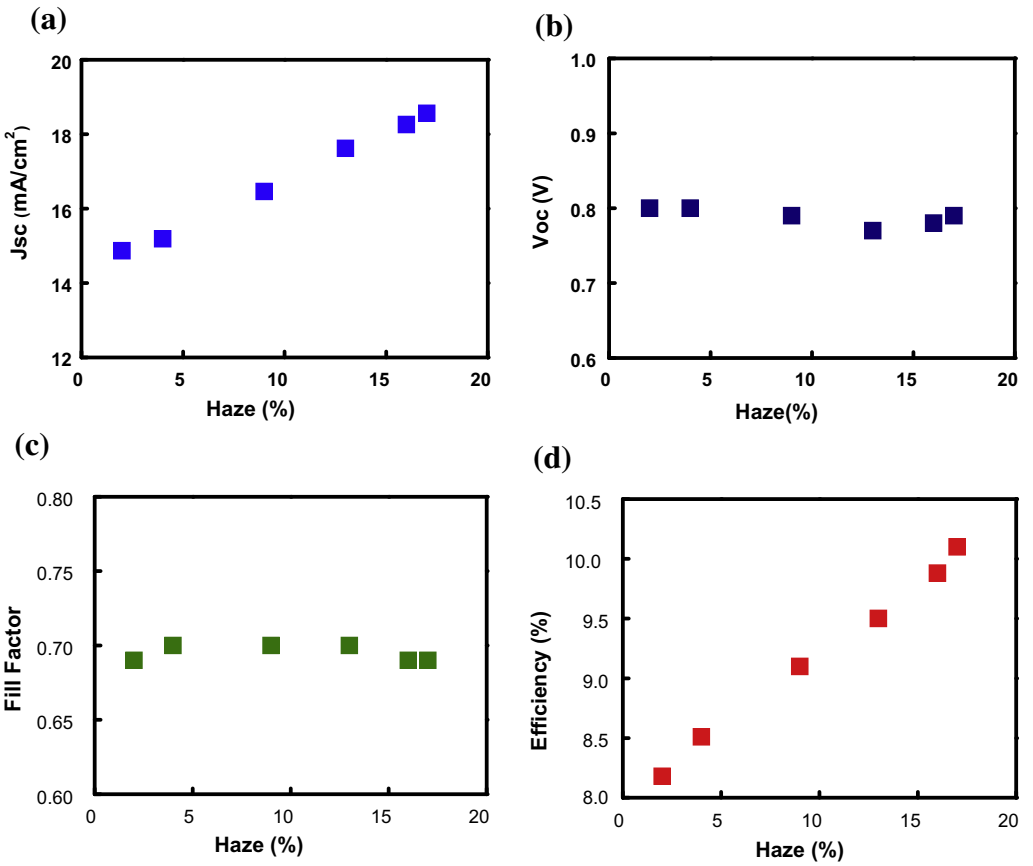

Fig. 6. (a) Short-circuit current J_{SC}, (b) open-circuit voltage V_{OC}, (c) fill factor FF, and (d) conversion efficiency (Eff.) are plotted versus the haze value of FTO samples.

350–550 nm, and it can be shown that integrating (IPCE spectrum × solar spectrum) over the wavelengths yields a higher calculated J_{sc} value for device #6. In general, the peak IPCE increases from ~75% of the device on a flatter/less textured FTO (#1, haze = 2%) to ~90% of the device on a much rougher/highly textured FTO (#6, haze = 17%). As a result, the short-circuit current J_{sc} (Fig. 5(a), Table 1) also shows a corresponding enhancement. These results suggest the highly textured and high-haze FTO can effectively scatter a portion of the incident light into larger oblique angles in the device, increasing the traveling distance of the incident light in the device. The highly textured and high-haze FTO may also effectively reflect (or backward scatter) the light reflected (or backward scattered) from the back scattering layer composed of large TiO_2 nanoparticles (~400 nm), enhancing the light trapping within the device. These factors together can contribute to significant enhancement of absorption (and thus J_{SC} and power conversion efficiency) in the device configuration.

3.3. Electrochemical impedance spectroscopy of devices

The effects of textured FTO on photovoltaic characteristics of DSSCs were further investigated by electrochemical impedance spectroscopy (EIS). EIS is a useful tool for characterizing interfacial charge-transfer processes in DSSCs, such as the charge recombination at the TiO_2/dye/electrolyte interface, electron transport in the TiO_2 electrode, electron transfer at the counter electrode, and ion transport in the electrolyte etc. [37]. In this study, EIS was conducted by subjecting the cell to the constant AM 1.5G 100 mW/cm^2 illumination and to the bias at the open-circuit voltage V_{OC} of the cell (namely, the condition of no DC current).

Fig. 7 shows the measured and simulated EIS Nyquist plots (i.e., minus imaginary part of the impedance $-Z''$ vs. the real part of the impedance Z' when sweeping the frequency) for DSSCs using various FTO samples. In the frequency range investigated (20–1 MHz), a larger semicircle occurs in the lower frequency range (~20–1 kHz) and a smaller semicircle occurs in the higher frequency range. The larger semicircles in the lower frequency range (~20–1 kHz) are not complete due to the limited frequency range of our instrument (the lowest frequency is not low enough). With the bias illumination and voltage applied, the larger semicircle at lower frequencies corresponds to the charge transfer processes at the TiO_2/dye/electrolyte interface [38], while the smaller semicircle at higher frequencies corresponds to the charge transfer processes at the Pt/electrolyte interface [39]. The intercept on the horizontal axis (Z') represents the series resistance of the device [35], which is associated with the sheet resistance of FTO. Consistently, FTO samples with larger sheet

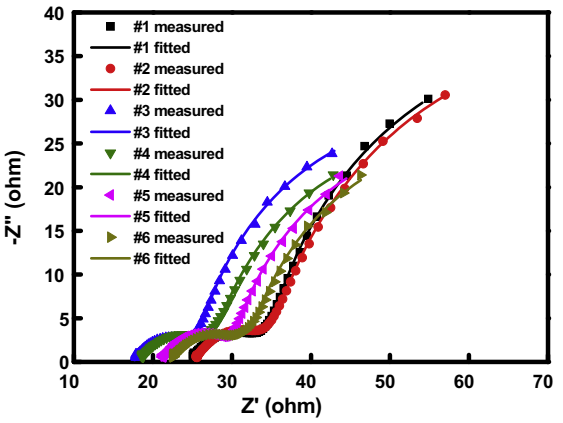

Fig. 7. Measured (symbols) and fitted (lines) EIS Nyquist plots for DSSCs fabricated on FTO samples #1–#6.

resistances show larger series resistances. Yet in general, the series resistances detected were still relatively small, not significant enough to produce visible difference in FF or J_{sc} of cells. The smaller semicircles corresponding to the platinum electrode show no difference between devices except for the varied parallel shifts caused by the series resistances of different devices. It indicates that the impedance at the Pt/electrolyte interface was not quite affected by the different textured FTO samples used (as one would expect).

On the other hand, the shape (width) of the larger lower-frequency semicircles somehow differs between devices. By fitting the measured impedance characteristics of Fig. 7 with equivalent circuits of DSSCs [40], the charge-transfer resistances R_{ct} (for the TiO_2/dye/electrolyte interface) for DSSCs fabricated on FTO samples #1–#6 can be extracted and are summarized in Table 1. The extracted R_{ct} decreases from 63.6 Ω of the device on #1 FTO (smallest texture, roughness, and optical haze; lowest conversion efficiency) to 43.1 Ω of the device on #6 FTO (largest texture, roughness, and optical haze; highest conversion efficiency). The decrease of R_{ct} with the increase of the DSSC efficiency indicates electron generation and transportation at the TiO_2/dye/electrolyte interface is enhanced with larger FTO textures and larger device efficiencies [41]. Among the six FTO samples, #6 FTO gives the smallest R_{ct}, which corresponds to the optimal light harvesting and electron generation due to the larger textural structures and strongest light scattering. Thus, the EIS results are in good agreement with results of the shot-circuit currents and the overall power conversion efficiencies of the DSSCs.

4. Conclusions

In conclusion, we investigated the influences of textures in the transparent conductor fluorine-doped tin oxides (FTO) on characteristics and performances of DSSCs. FTO conductors having varied textures were characterized for their physical, electrical and optical properties and were subjected to device studies to establish the correlation between FTO textures and device characteristics/performances. The results suggest that the highly textured and high-haze FTO can effectively scatter a portion of the incident light into larger angles in the device, enhancing the propagation length and trapping of the incident light within the device and contributing to significant enhancement of absorption (and thus J_{SC}, IPCE, and power conversion efficiency) in the device configuration. As a result, the conversion efficiency of the DSSC was enhanced from 8.18% to 10.1%, an improvement by 24%, with using the highly textured, large-roughness and high-haze FTO as the transparent conductor.

its polarization even after the external electric field was removed, and thus the feFETs were non-volatile. The ferroelectric transistors allowed reprogrammability and non-destructive read-out, and this offered an advantage over using ferroelectric capacitors, for which the read-out process would erase the polarization states.

The current performance of solution-processed organic memory has been sufficient to meet the requirement of short-term applications, including a pressure-sensor system [2] and a wireless communication sheet [4]. When incorporating memory devices into circuit systems, one of the main challenges involves device isolation and proper signal routing. In a memory array, there is potential cross-talk between neighboring devices. Addressing switches such as transistors or diodes are needed to isolate the neighboring cells. Previously in Ref. [4], memory cell isolation was achieved by combining one memory transistor with two addressing transistors, in which one addressing transistor controls the input voltage and the second one selects the readout signal. In this paper we describe a memory array design that uses only one addressing transistor in each memory cell, simplifying array design and reducing footprint requirements. This design can be applied as non-volatile random-access memory [5] to reduce power consumption. We have also examined device variations among the memory transistors, to determine how array performance could be improved.

Each memory cell is comprised of two transistors: one feFET (memory element) and one addressing transistor (signal switch). Both the feFET and the addressing transistors were in top-gate configuration and with p-type semiconductors. The typical transfer characteristics of an addressing transistor and of a memory feFET are plotted in Fig. 1(a) and (b), respectively. The transistors showed average saturation mobility of 0.2 $cm^2/V\,s$ for Flexink and 0.01 $cm^2/V\,s$ for PQT [23]. No significant hysteresis was observed in the addressing transistors during gate-voltage V_g sweeps, as shown by the measurement in Fig. 1(a). To use the feFETs as memory devices, the polarization of the ferroelectric dielectric was set by an input V_g. The remnant polarization affected the transistor source–drain current I_{sd}, and thus the I_{sd} hysteresis in Fig. 1(b) served as a record of the applied gate voltage. As the V_g pulse time was increased in Fig. 1(c), the output I_s became saturated. A V_g pulse length of 1 ms was the minimum switching time required for a feFET current to reach the plateau value. This timing requirement may be different depending on polarization direction (switching from positive to negative V_g versus negative to positive V_g) [21] and dielectric thickness [24]. The gate current in Fig. 1(d) shows peaks at ±25 V, indicating the coercive voltage where the ferroelectric dielectric switched polarization.

The effect of strain on feFET was examined for use in mechanically flexible applications. The transfer characteristics in Fig. 1(e) shows that current was reduced with tensile bending at 0.4% strain where radius of curvature = 1.5 cm. Nevertheless the characteristics recovered when the device was laid flat again and released from strain. The current reduction with bending has been previously observed in non-ferroelectric organic transistors [25], in which mechanical strain led to changes in dielectric capacitance and semiconductor mobility. The current in Fig. 1(f) was measured with source–drain voltage $V_{sd} = -10$ V and $V_g = 0$ V under tensile bending, after the feFET had been polarized at $V_g = +30$ V. Since PVDF-TrFE is a ferroelectric polymer, piezoelectric voltage was generated during bending and was observed as spikes at transitions. After the spikes, the I_{sd} was decreased by <5% under tensile strain of 0.4%, and the I_{sd} partially recovered when the substrate was relaxed to 0% strain. The reason for incomplete recovery was that, besides mechanical bending, the feFET current was also affected by electrical bias stress under constant V_{sd} bias. Without mechanical bending, electrical bias stress [26] alone would reduce I_{sd}, as indicated by the dashed line in Fig. 1(f). The measured feFET current change under constant V_{sd} is ~5% over 15 min, and this level of bias stress is comparable to the current change in previous studies [27,28] and is due to traps at the semiconductor–dielectric interface. The feFET remained functional up to tensile strain of 0.6% (radius of curvature of 1 cm) before it broke down with open circuit. The above results were promising for applying feFETs to mechanically flexible systems, but more detailed studies are needed to thoroughly characterize the influence of strain on feFET parameters and to elucidate the long-term effects of repetitive strain cycles on memory retention time.

To place the memory feFETs into an array, neighboring devices were isolated by addressing switches such as transistors or diodes preventing potential cross-talk. The schematics and the photograph of an active matrix array are shown in Fig. 2. The addressing transistor regulated the input voltage to a memory feFET within each cell. Although the cells in a column were connected to a common data-line, the input voltage was passed only to a specific feFET, by turning on its addressing switch through applying a voltage pulse to its select-line. The addressing transistors of neighboring rows were turned off by holding their select-lines at ground or positive voltage. The bus-lines B_N and the readout-lines R_N were maintained at ground during the memory input process. For the read-out process, the key to minimize cross-talk relied on that the readout-lines and bus-lines of feFETs were arranged perpendicular to each other and located on separate layers as shown in Fig. 2. To determine the memory state of cell C_{11}, a voltage pulse was applied to the bus-line B_1, and the feFET current or charge was measured from the read-out line R_1. The other bus-lines $B_2 \ldots B_N$ were maintained at ground potential. The measured current depended on the state of the feFET at cell C_{11} only and was not affected by other feFETs connected to the same readout line, because their bus-lines were grounded to not generate current.

The input signal to an addressed feFET and to its neighbor down the column is shown in Fig. 3(a) and (b), respectively, by monitoring the voltage at the feFET gate-electrode pad with a picoprobe [29]. The input voltage was transmitted to the intended feFET through its addressing transistor within 1 ms. The voltage at the neighboring feFET gate electrode has remained below 2.5 V (less than 20% of the input voltage at the data-line), indicating that neighboring cell was sufficiently isolated from cross-talk disturbance. Voltage overshoot due to capacitance feed-through [15] was observed during potential change in Fig. 3(a), but it was not deleterious to the signal routing

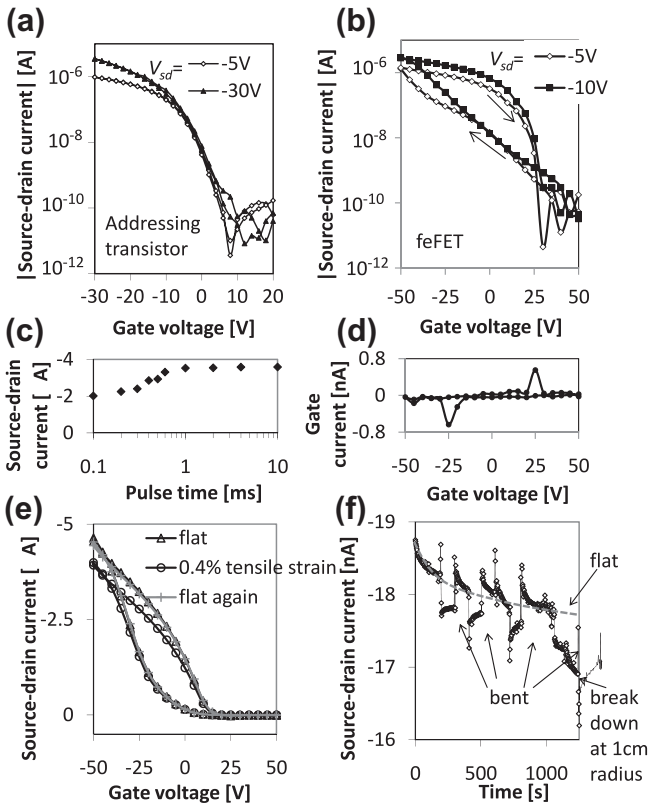

Fig. 1. Transfer characteristics of (a) an addressing transistor and (b) a memory ferroelectric transistor (feFET). (c) Current output of a feFET versus duration of the gate-voltage pulse, with $V_{sd} = -10$ V and $V_g = -30$ V. (d) Gate current of a feFET where $V_{sd} = 0$ V. (e) Transfer characteristics of a feFET with $V_{sd} = -10$ V in different strain conditions. (f) Source–drain current of a feFET under tensile strain cycles, measured at $V_{sd} = -10$ V and $V_g = 0$ V. The feFET had been previously polarized at $V_g = +30$ V. The sample was bent to radius of curvature = 1.5 cm, corresponding to 0.4% tensile strain. The voltage spikes were piezoelectric response of the ferroelectric dielectric. The dashed gray line indicates feFET current at 0% strain; the decrease in current is due to bias-stress effects.

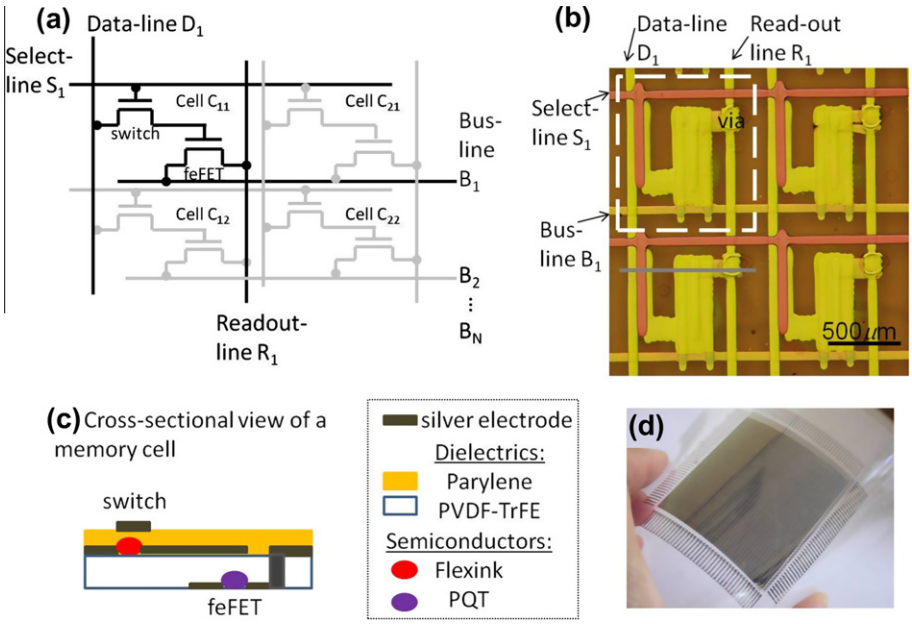

Fig. 2. (a) Schematics and (b) photograph of an active matrix memory array. The black lines in (a) and the white dash box in (b) indicate an individual cell. (c) Cross-sectional view at the location indicated by the gray line in (b). (d) A flexible memory array on plastic substrate.

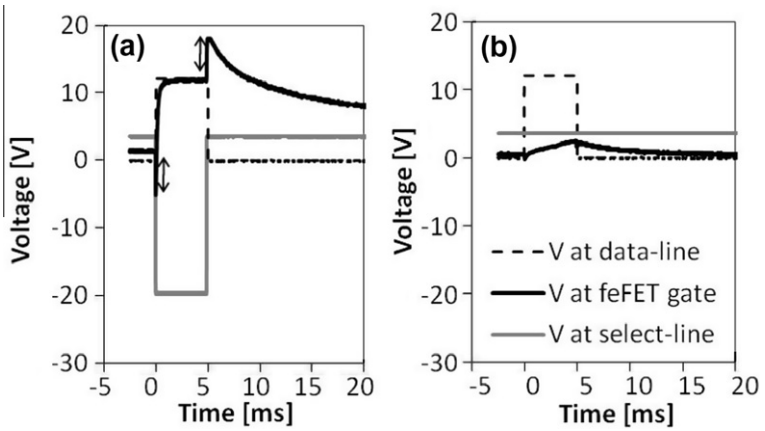

Fig. 3. Comparison between the oscilloscope traces of (a) an addressed feFET and (b) a neighboring feFET down the column. Voltage overshoot due to capacitance feed-through [15] was indicated by the arrows in (a).

process. It was observed that the rise and fall time of the feed-through voltage were not the same because of the difference in channel resistance at respective gate voltages ($V_g = -20$ V during rise, $V_g = 0$ V during fall). The feed-through voltage was due to the overlap between the gate and source electrodes and may be reduced by minimizing the overlapping area.

To write into a memory array as shown in Fig. 4, the select-line voltage was −15 V for turning an addressing transistor on and +10 V for off, and the input data-line voltage was a 5 ms pulse at −30 V for polarized state or at 0 V for unpolarized state, applied according to a checkerboard pattern. Eight hours after the pattern was recorded, the difference in dielectric polarization was obtained by charge amplifiers [30–32]. The read-out electronics applied a 130 μs pulse at −5 V to the bus-line of a selected cell and measured the feFET charge via the corresponding read-out line, while the remaining lines were held at ground. The results in Fig. 4(a) shows distinguishable memory states between neighboring feFETs in a 7 × 8 array. Signals of the two memory states differed by ~6000 readout units or 0.77 pC as seen in Fig. 4(b) (one readout unit corresponded to 800 electrons or 0.13 fC as explained in Ref. [30]). The histogram indicates signal variations of the two polarization states, with standard deviation of 580 units for unpolarized states and 1120 units for polarized states, indicating larger variation after polarization. In this proof-of-concept demonstration, the yield of working memory cells was low (~3.5%, since only the cells in Fig. 4(a) were detectable for a 40 × 40 array). The memory feFETs have been damaged during via processing step, in which solvent was printed to dissolve via holes in the dielectric [33]. Via holes were formed by printing solvent droplets, and eleven drops per site was required to dissolve the PVDF-TrFE film. In the photo in Fig. 2(b), the shape of via were oval instead of circular, due to misalignment of solvent drops. More severe misalignment caused shorts between the feFET gate and source–drain electrodes and was the main reason for low array yield. This misalignment issue can be mitigated by redesigning the cell layout and providing wider area for via process tolerance, or alternative via process such as laser ablation can be used. It should be feasible to improve the array yield in the future by improving layout design and equipment capability.

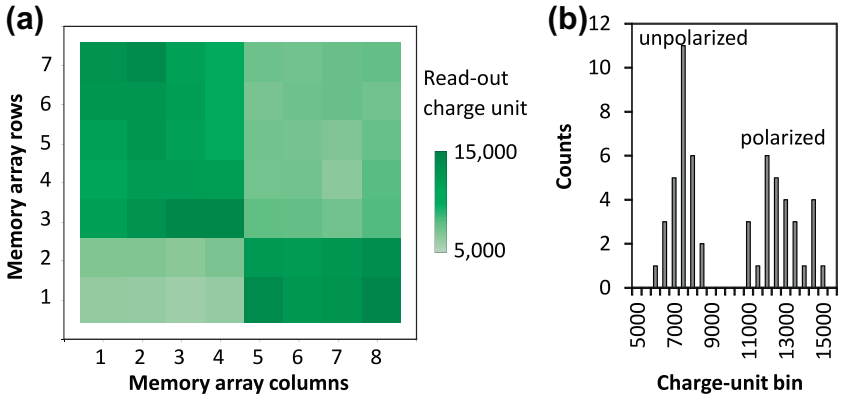

Fig. 4. (a) Memory states of a 7 × 8 array measured by charge sensors 8 h after the feFETs were polarized in a checkerboard pattern. The input voltages were 5 ms pulses at −30 V for the polarized state (dark green) or at 0 V for the unpolarized state (light green). One readout-charge unit corresponded to 800 electrons or 0.13 fC as explained in Ref. [30]. (b) Histogram of the memory cells in part (a). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 5 compared the output characteristics of twenty inkjet-printed feFETs that were fabricated in an array. The data were all obtained with $V_g = 0$ V and were taken by directly probing the electrodes of the feFETs. A polarization voltage of $V_g = -30$ V was used as it was the voltage limit for our array test setup. This voltage exceeded the coercive voltage of the ferroelectric dielectric Fig. 1(d) and enabled polarization switch, but it was still relatively low and the ferroelectric polarization was not saturated. The addressing transistors were not used for routing in these measurements, in order to only evaluate variations among the memory devices independent of other circuit components. Before polarization, the output current varied by a factor of 2 among the cells Fig. 5(a). After the polarization voltage was applied, the output characteristics varied by a factor of 3 and showed an increase in current variations among the cells Fig. 5(b). The polarized dielectric increased channel charge accumulation, and the feFETs reached saturation regime ($V_g - V_T < V_{sd}$) due to positive threshold voltage V_T. After two weeks since polarization, the output current was no longer saturated in Fig. 5(c), indicating shifts in threshold voltage due to charge trapping [27,28,34–36]. In Fig. 5(d), the values of output current at $V_{sd} = -20$ V showed the I_{sd} ratio between the polarized and unpolarized states was >25 (between 25 and 100). Although the feFET current has decreased to 50% of the initial values after a two-week interval, the memory states were still distinguishable. The decrease in current corresponded to the results from our previous study [36] of similarly inkjet-printed feFETs, in which the memory retention time was extrapolated to be roughly one month, with device variations taken into account.

Achieving consistent characteristics across an array is important for estimating the data-storage time of an array, because it will be limited by the cell with the worst retention time unless the low-performing cells are identified and excluded. Thus, in addition to improving the performance of individual feFETs, it is also desirable to understand and mitigate array variations in memory integration. Before polarization, the variations in output characteristics of Fig. 5(a) were mainly due to differences in mobility among the devices [15]. After the feFETs were polarized, the output characteristics became even less uniform with time. There were different rates of charge trapping among the polarized devices, leading to a widening range of output characteristics in Fig. 5(b) and (c) and larger variations for polarized states in Fig. 4(c). Therefore, besides semiconductor mobility, charge-trapping effects must be controlled to improve array uniformity. Techniques such as template annealing [37] or nano-embossing [38] might reduce charge-trapping effects in the dielectric to extend both the memory retention time and array uniformity.

In summary, inkjet-printed active-matrix memory arrays were demonstrated to show less than 20% cross-talk between neighboring cells. The readout signal from each feFET was isolated by using bus-lines and readout-lines on different layers to enable a memory design with two transistors per cell. The memory arrays were shown to retain data for at least 8 h and remained functional below 0.6% tensile strain. Array uniformity was reduced with time by different charge-trapping rates among the transistors. Thus, better control of charge trapping will improve the performance of individual feFETs as well as enhance array uniformity, to advance organic memory for flexible electronics.

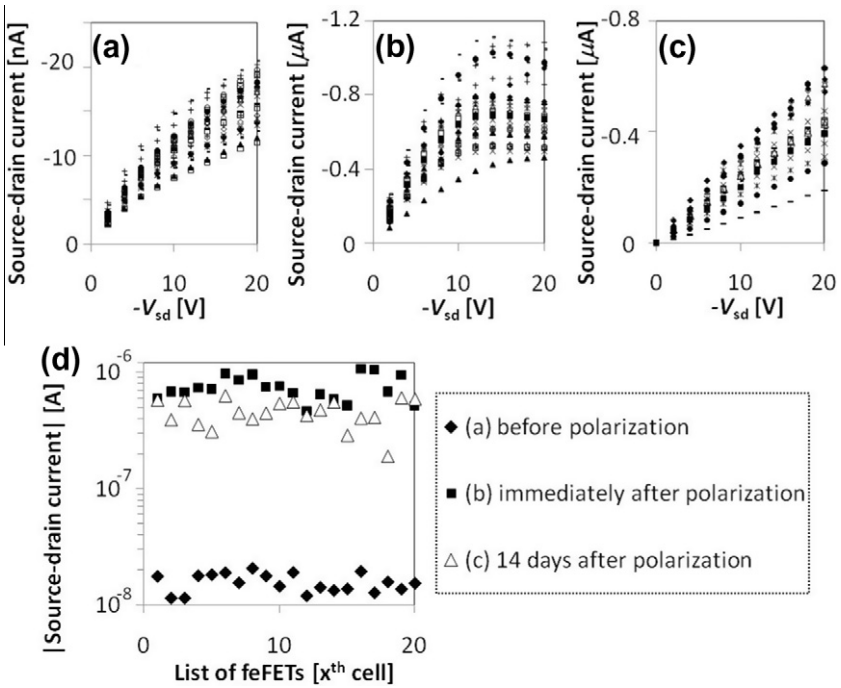

Fig. 5. Output characteristics of 20 feFETs (a) before polarization, (b) immediately after polarization at $V_g = -30$ V, and (c) after two weeks in the polarized state. These output characteristics were taken with $V_g = 0$ V. The graph (d) compares the values of output current at $V_{sd} = -20$ V.

2. Array fabrication

The memory devices were fabricated either on glass or on 125 μm poly(ethylenenapthalate) substrates. Both the addressing transistors and the memory feFETs were in top-gate configuration and were patterned with channel length L of 40 μm. The metal electrodes were inkjet-printed using a silver-nanoparticle solution from Cabot Corporation. The memory feFETs had channel width W of 1 mm and consisted of p-type semiconductor polythiophene (PQT). The memory gate dielectric was spin-coated from a solution of ferroelectric co-polymer poly(vinylidene fluoride-co-trifluoroethylene) (PVDF-TrFE, 65:35 ratio) in methyl-ethyl-ketone to form a 600 nm film with capacitance $C_f = 16$ nF/cm^2 and was processed as described in Ref. [36]. Interconnects through the PVDF-TrFE dielectric were made by inkjet-printing the solvent methyl-ethyl -ketone to locally dissolve away the dielectric to form via openings, yielding vias with resistance of 150 Ω, similar to the procedure in Ref. [33]. Subsequent layers for the addressing transistors were fabricated with $W/L = 15$ using the polymer blend semiconductor FS12 from Flexink and vacuum-deposited parylene-N as the gate dielectric (film thickness = 400 nm and capacitance = 5 nF/cm^2).

Acknowledgments

The authors would like to thank Jurgen Daniel, Raj Apte, and Chris Paulson for experimental assistance with the read-out electronics. We express our gratitude to Sanjiv Sambandan, Robert Street Gregory Whiting, and Leah Lavery for helpful discussions. We are very grateful to Xerox Research Center Canada for providing PQT, Iain McCulloch and Martin Heeney for providing Flexink, W.A. MacDonald of Dupont-Teijin Films for supplying the polyethylene naphthalate substrates, and E-ink for the electrophoretic media. This work is partially supported by Sensor Tape Program of the Defense Advanced Research Projects Agency (Contract No: W81XWH-08-0065). This document has been approved for public release by DARPA for unlimited distribution.

characterizations. Moreover, one should note that the tip/probe measures the potential at the free surface of the organic semiconductor (OSC) film and not at active channel/dielectric interface, implying systematic errors [10]. Therefore, in this paper we propose a TLM based on the dissipated power in the whole device, namely the Power TLM (P-TLM), which allows the evaluation of the contact resistance in linear region as well as in saturation regime, by means of usual *I–V* measurements. Thus, one can investigate the contact resistance with respect to not only gate bias but also drain voltage.

2. Experimental

Two types of organic transistors are employed in this work. One is the poly-triarylamine (PTAA) OFETs fabricated on gold-plated 125 μm-thick polyethylene-naphthalate (PEN), using a top-gate (TG) structure [11]. The 30 nm gold layer is patterned by photolithography with a line/space resolution down to 5 μm, forming the source and drain electrodes as well as the 1st level of interconnection lines between gates. Organic semiconductor (poly-triarylamine derivative) is deposited in solution by direct printing methods, defining patterns corresponding to individual devices and annealed under ambient atmosphere at 100 °C, leading to a final thickness in the range of 50–200 nm. The gate dielectric polymer is printed on the top of semiconductor and then annealed, leaving open areas for via holes with a final thickness of 1 μm, corresponding to the unit area capacitance $C_i = 1.5 \times 10^{-9}$ F/cm^2. Finally, a silver-ink conductor is printed on the top of dielectric and annealed at 100 °C, forming in the same step the gate electrodes for devices and the 2nd level for interconnection. The measured mobility (μ) is about 0.035 cm^{2}V^{-1}s^{-1} and threshold voltage (V_T) is around −9 V.

Another type is top-contact (TC) and bottom-contact (BC) pentacene OFETs [12]. They were fabricated on heavily doped Si (100) wafers covered with a 50 nm thick SiO_2 layer, which ultimately serve as the gate electrode and the gate insulator ($C_i \approx 8 \times 10^{-8}$ F/cm^2), respectively. After the surface was ultrasonically cleaned with acetone and isopropyl alcohol, the substrates were immersed in a mixture of sulfuric acid and hydrogen peroxide to fully remove organic contaminants. After that, the substrates were immersed in 10 Mmol chloroform solution of octadecyltrichlorosilane (OTS) to form a self-assembled monolayer (SAM) on the SiO_2 surface. For the BC OFETs, the source and drain electrodes are deposited directly on the SiO_2 surface. Here that was done by a sequential evaporation of 5-nm-thick MoO_3 and 35-nm-thick gold through a metal mask, where MoO_3 was used as an adhesion or charge injection layer. Next a pentacene (Aldrich, purified using temperature gradient sublimation) layer was vacuum-deposited (rate of 0.01 nm/s at room temperature, final thickness of 50 nm). In the TC devices the pentacene layer was deposited first and then the source and drain electrodes were formed by thermal evaporation of Cu through a metal mask. The observed $\mu \approx 0.3$–0.4 cm^{2}V^{-1}s^{-1}(TC)/0.04–0.1 cm^{2}V^{-1}s^{-1}(BC) and $V_T \approx -2$ V $-$ 0.7 V(TC)/0.7 V $-$ 2.3 V(BC).

3. Methods

The Power-TLM relies on the fact that the total power dissipated P_{tot} in the whole device volume can be calculated, according to Joule's law as [13]:

$$P_{tot} = \int_{\Omega} \rho J^2 d\Omega \tag{1}$$

where ρ and J are the local resistivity and current density, respectively. The advantage of using Eq. (1) for evaluating the dissipated power is that it is independent of the specific conductor shape and thus of the current flow distribution. Therefore, one can separately evaluate the power dissipated in each region of the device, i.e., contact and channel regions such as,

$$P_{tot} = P_s + P_{ch} + P_d \tag{2}$$

where P_s, P_d and P_{ch} are the power contribution coming from source, drain and channel regions, respectively. So, for a given drain current I_D circulating in the device, one can calculate an equivalent total resistance by normalizing Eq. (2) as,

$$R_{tot} \equiv \frac{P_{tot}}{I_D^2} = \frac{V_D}{I_D} = \frac{P_s}{I_D^2} + \frac{P_{ch}}{I_D^2} + \frac{P_d}{I_D^2} = R_s + R_{chEq} + R_d \tag{3}$$

where R_{chEq} is the channel equivalent resistance. In the absence of contact resistance ($R_{sd} = 0$), it would simply be equal to V_D/I_D and, by turn, scales as (L/W). In the presence of contact resistances, the channel power reads $P_{ch} = V_{Deff}I_D$, where V_{Deff} is the effective (intrinsic) drain voltage applied to the channel, we have $R_{chEq} = V_{Deff}/I_D$. As I_D is governed by the effective (intrinsic) gate voltage (V_{Geff}) and the effective drain voltage, one can simply denote $I_D = (W/L)F(V_{Geff}, V_{Deff})$ with F being the intrinsic transistor characteristics per unit aspect ratio and hence, $R_{chEq} = (L/W)[V_{Deff}/F(V_{Geff}, V_{Deff})]$. In other words, R_{chEq} of different transistors always varies $\sim(L/W)$, for the same gate and drain biasing.

In linear regime, the channel can be regarded as a linear resistance $R_{ch} = L/[W\mu C_i(V_G - V_T)]$ if μ (the effective mobility) is constant but it sometimes reveals a power law dependence of $(V_G - V_T)$ [4,12], e.g., in amorphous polymer OFETs where the carrier transport is nearly via hopping. In this case, Eq. (3) is nothing but the base of the conventional TLM since the total output resistance is a linear superposition of channel and contact resistance, i.e., $R_{tot} = R_s + R_{ch} + R_d$, where the unique channel length dependent contribution is $R_{ch} \sim (L/W)$.

In non-linear regime, the channel cannot be treated as a linear resistance but could be still equivalent to $R_{chEq} = P_{ch}/{I_D}^2$ also scaling as $\sim(L/W)$, as discussed above. Therefore, one can find that Eq. (3) is a universal expression for power TLM (P-TLM): R_{chEq} varies as L/W but R_{sd} only follows $\sim(1/W)$, irrespective of linear/saturation operation. Hence R_{sd} can be extracted from the plot of the W normalized R_{tot} with respect to L, if the channel width is not uniform in the transistors' group, similar to the conventional TLM.

4. Results and discussion

4.1. Application to PTAA OFETs

Fig. 1a shows typical output characteristics for a PTAA OFET. At small V_D, the $R_{tot}(=V_D/I_D)$ represented by the reciprocal of the slope of illustrated straight lines is constant, indicating the ohmic operation. As V_D is increased over the limit of $V_{Dsat} = (V_G - V_T)$, the normalized $R_{tot} \times W$ increases also with V_D, as shown in Fig. 1b for a set of devices with various L and at fixed $V_G = -30$ V. Fig. 1c clearly shows that these $R_{tot} \times W$ (at $V_D = -30$ V) exhibit a linear variation with respect to L, providing $R_{sd} \times W$ in the y-axis intercept. However, we frequently encounter difficulties in applying P-TLM as found in the conventional TLM, mainly obtaining negative $R_{sd} \times W$, in particular at small gate voltages. This is due to the parameter variation from transistors-to-transistor (e.g., μ, C_i and V_T), and it is even amplified in saturation regime and in longer channel devices [6]. Hence the modified-power TLM (MP-TLM) becomes useful, $R_{tot} \times W/L$ are plotted as a function of $1/L$ and $R_{sd} \times W$ is evaluated from the slope of the fitting line, instead of the intercept [6]. Indeed, the linear regression giving the slope versus $1/L$ minimizes the impact of channel parameters scattering and maximizes the influence of small L, i.e., large $1/L$ values where the contact resistance plays an important role in the overall output resistance. In addition, compared to the channel resistance the contact resistance generally exhibits much smaller dispersion from transistor-to-transistor. Fig. 1d shows the MP-TLM for the same extraction seen in Fig. 1c, one can readily find a better linear regression, implying greater accuracy.

The two power TLM extractions are applied at various V_D, as shown in Fig. 2a and b. The obtained $R_{sd} \times W$ is shown in Fig. 2c. Note that the contact resistance represented by the intercepts in y-axis (P-TLM, cf. Fig. 2a) or the slopes (MP-TLM, cf. Fig. 2b) for this transistors' group of linear fitting lines remain constant at small V_D and afterward increases with V_D. The former constant $R_{sd} \times W$ in linear regime is reasonable because the small drain voltage doesn't significantly affect the source and drain access resistance. However, as V_D is much increased, the channel will be pinch-off on the drain side and thereby, R_d increases with V_D while R_s remains the same [9,14]. One may notice the large deviation between the results obtained by the two power-TLMs, as seen in Fig. 2c. This might be due to the drain voltage dependences of the channel equivalent resistance R_{chEq} and it causes an additional variation in various transistors of different channel length while V_D is changing. This dispersion in R_{chEq} is reduced in MP-TLM extraction where the linear regression slope is directly governed by the contact resistance and its dispersion arising from V_D dependences is smaller than R_{chEq} for a same basing condition and as a result, the contact resis-

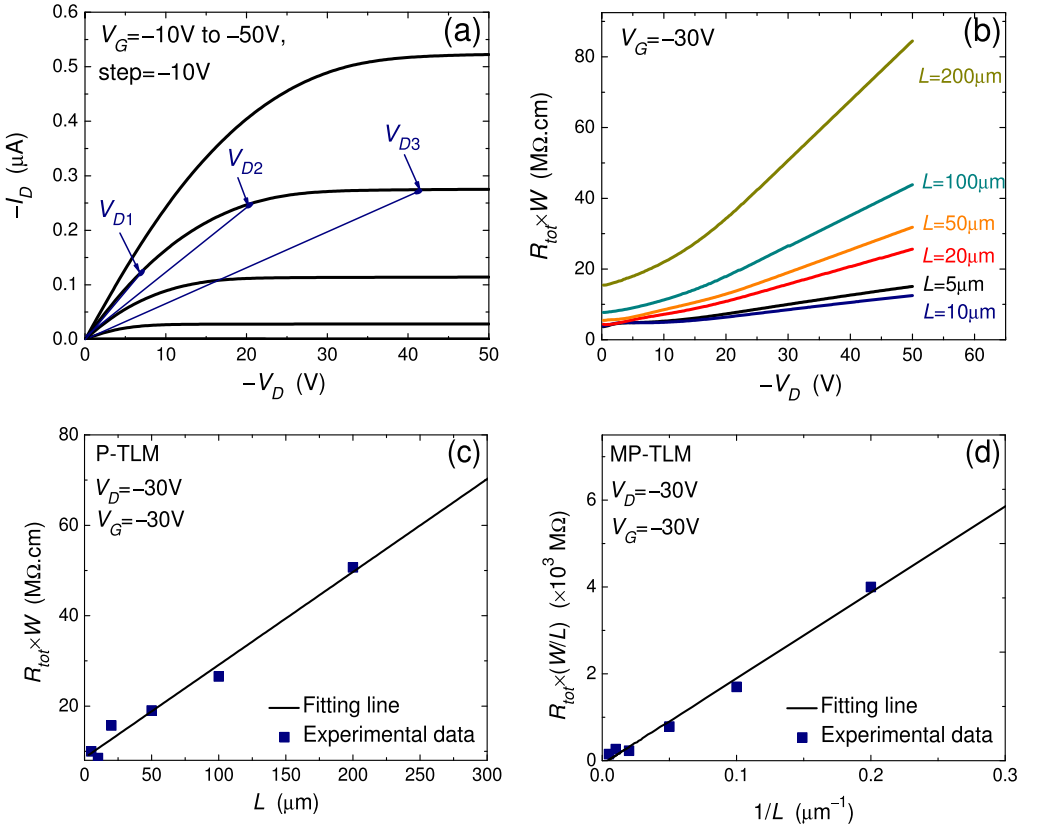

Fig. 1. (a) Output characteristics of a PTAA OFET (W = 1000 μm, L = 100 μm), where three data points at various V_D are chosen to illustrate the output resistance ($R_{tot} = V_D/I_D$, represented by the reciprocal of the straight lines' slope) variation versus V_D, as shown in (b), for a set of transistors with various L. (c) and (d) are the P-TLM and the MP-TLM extraction, respectively, at a fixed V_G and V_D.

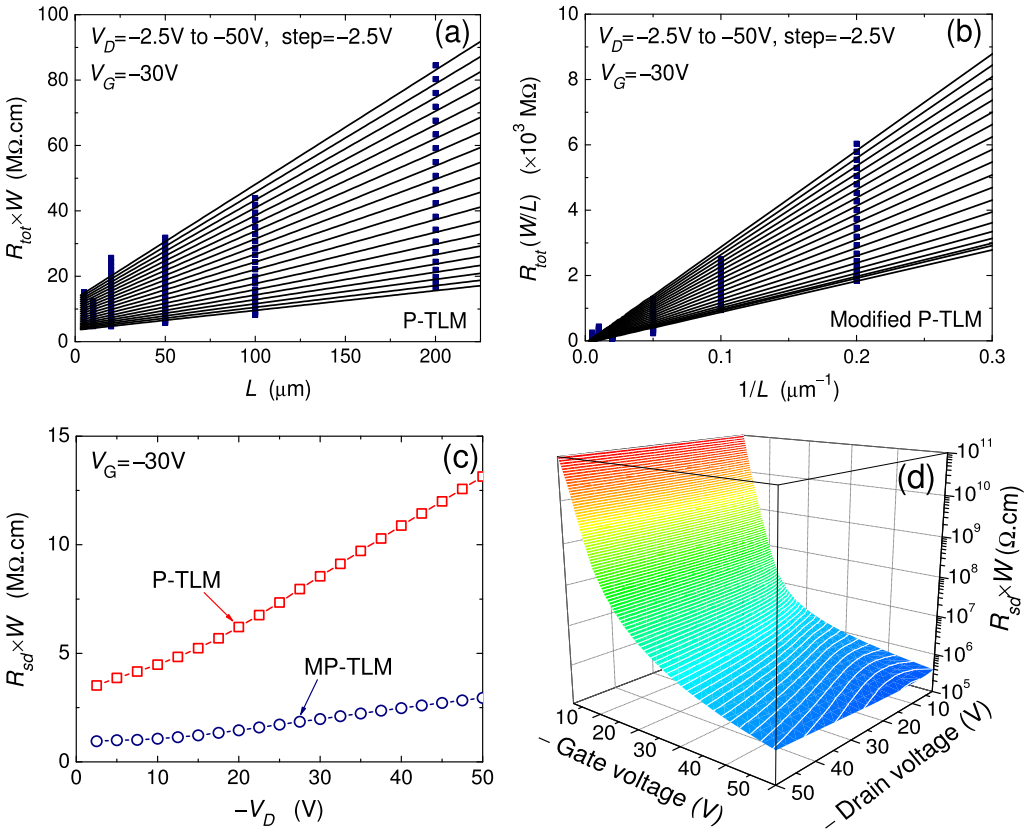

Fig. 2. (a and b) are P-TLM and MP-TLM extractions for the above PTAA OFETs, respectively, at various drain voltages and at fixed $V_G = -30$ V. (c) Shows the extracted results by the two power TLMs. (d) Shows the global contact resistance extracted by MP-TLM, at various V_G and V_D.

tance dependences on V_D and V_G can be more reliably reflected in MP-TLM extractions. Moreover, in view of the greater accuracy and higher stability of MP-TLM, it is preferred for the next analysis. The overall $R_{sd} \times W$ (at various V_D and V_G) are shown in Fig. 2d, strong gate-voltage dependence and relatively weak drain-voltage dependence can be observed.

4.2. Application to pentacene OFETs

Next, the same procedure is applied on two groups of TC/BC pentacene OFETs (with bottom-gate and uniform $W = 500$ μm). The evaluated R_{sd} is shown in Fig 3a and b, for TC and BC group, respectively. Compared to BC counterparts (cf. Fig. 3c), the TC OFETs show much stronger gate-voltage dependence, consistently with the literature [9,12,15,16]. In staggered transistors (e.g., TC/BG OFETs here), carriers must traverse the entire semiconductor film in the contact region where the bulk conductivity strongly depends on the carrier density modulated by the gate voltage. This bulk resistance dominates the overall contact resistance, manifesting a strong gate-voltage dependence [9,16,17]. In coplanar devices (e.g., BC/BG OFETs here), the channel directly connects the two electrodes. Thus R_{sd} is predominantly controlled by the contribution in a low conductive access region in the immediate vicinity of the contacts, in which a large number of defects reside in [10,14,18]. Such a defect-rich access region is sometimes characterized as a depletion area at negative gate biases. Its width is varied by V_G, leading to an R_{sd} gate-voltage dependence [18]. However, its variation range is much smaller than that for the bulk resistance (dominant component in TC OFETs) and hence, the TC contact resistances quickly decrease with V_G and become smaller than those for BC devices at higher gate voltages, in line with our previous results [12]. Note also that the TC OFETs show stronger drain-voltage dependence than BC ones, cf. Fig. 3c and d. This is because in staggered transistors increasing V_D weakens the channel accumulation in the drain region and thus lowers the contact bulk conductivity at drain contact. This feature is not significant for coplanar devices due to the directly connected channel and/or the depletion space screening from the lateral electrical field. One may find a rapid increase in BC contact resistance with V_G at small gate voltages and high drain voltages (e.g., Fig. 3b and c), this might be due to an extraction error or could result from a significant decrease of R_s at weak accumulation and in saturation regime, as reported in Ref. [14].

5. Summary

In summary, a power-TLM for full biasing contact resistance evaluation has been presented. By estimating the dissipated power in access region and in the channel, the

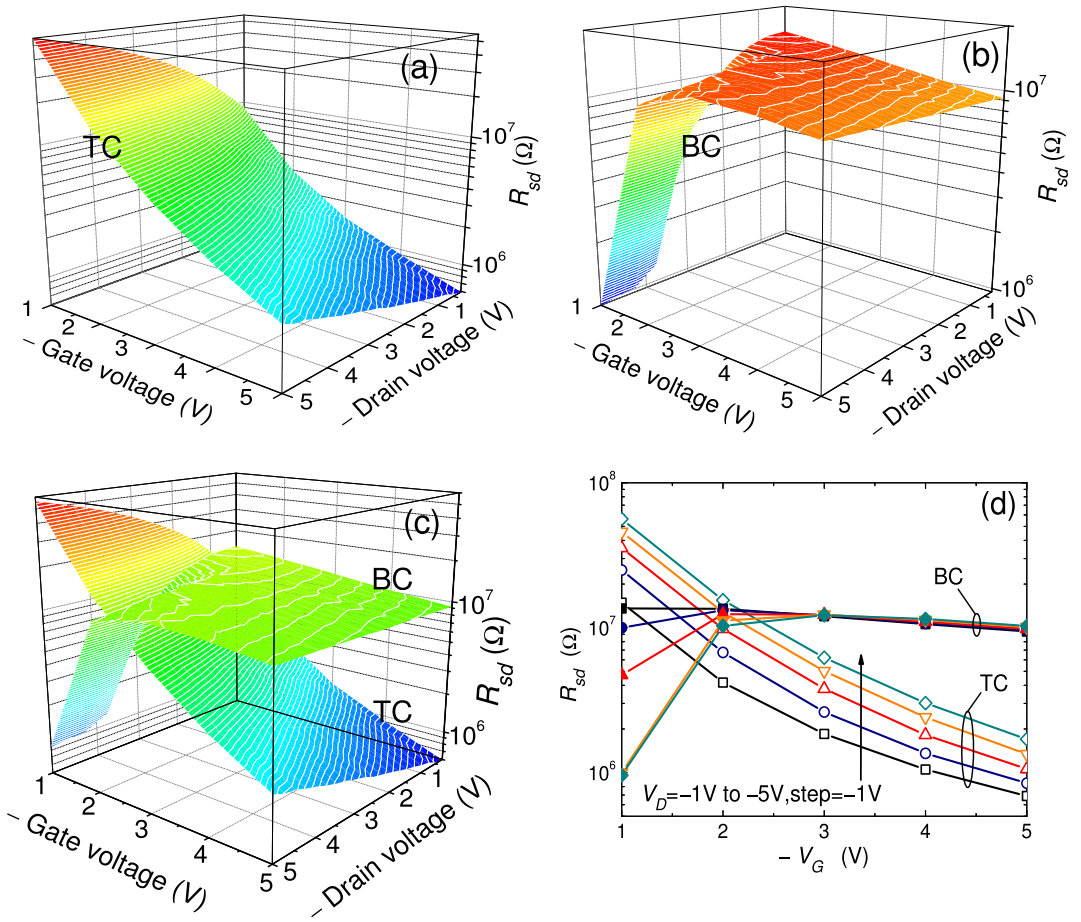

Fig. 3. Contact resistance obtained by MP-TLM in a set of TC (a) and BC (b) pentacene OFETs. (c) Shows the comparison of the contact resistance in TC and BC group. (d) Shows the gate-voltage dependence at various V_D.

channel equivalent resistance is found to always scale as $\sim(L/W)$ and the contact resistance follows $\sim(1/W)$, no matter whether the organic transistors operate in linear regime or not. This result reveals that the conventional TLM can be also applied to non-linear regime, and thus enabling a full biasing (i.e., all range of gate/drain voltages) contact resistance extraction. To ensure stable application of this power-TLM, particularly at small gate voltages, and in order to improve the extraction accuracy its modified form (i.e., MP-TLM) becomes mandatory. The contact resistance in PTAA OFETs is found to be strongly attenuated by the gate voltage but slightly increased with the drain voltage, due to the channel pinch-off at drain contact. The results of pentacene OFETs indicate that compared to the BC counterparts the contact resistance in TC OFETs exhibit much stronger gate- and drain- voltage dependences. Therefore, MP-TLM is proved as a useful approach to directly investigate the gate and drain bias dependences of contact resistance by using output characteristic measurements.

successfully demonstrated [5]. However, single layer blue PhOLEDs [2,5a,6] reported as far were not satisfactory yet, giving challenges for material scientists. The most popular blue emitter FIrpic has revealed its bipolar charge carrier transport behavior by using the time-of-flight (TOF) transient photocurrent technique [7]. Accordingly, highly efficient single layer blue PhOLED should be feasible if one uses FIrpic dispersed into a tailor-made high triplet energy host with suitable energy levels for direct carriers injection. In this paper, we report a novel high triplet energy host material: 3,3′,3″-phosphoryl tris(9-phenyl-9H-carbazole) (POCz3) for efficient single-layer blue PhOLEDs. The device: ITO/PEDOT:PSS/POCz3 (3 nm)/POCz3:FIrpic 20 wt.% (80 nm)/LiF/Al gives a maximum external quantum efficiency (η_{ext}) of 9%, power efficiency (η_p) of 10.4 lm/W, and current efficiency (η_c) of 21.3 cd/A. To the best of our knowledge, this work represents an unprecedented example of realizing a single-layer blue PhOLED with remarkable device characteristics.

2. Results and discussion

2.1. Materials

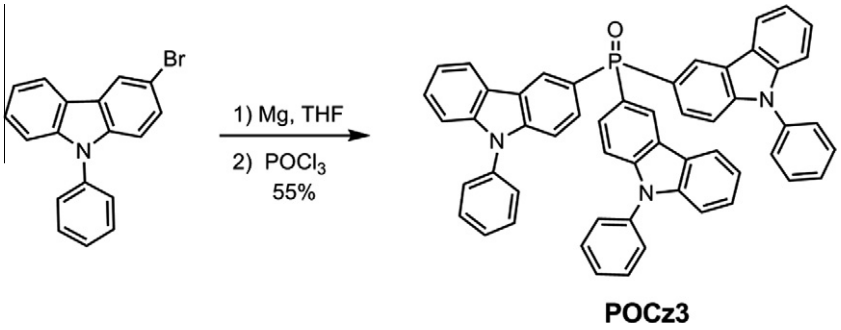
The most successful host materials used for FIrpic are carbazole derivatives [8]. Without extended π-conjugation from the carbazole core, carbazole-based host materials usually exhibit high triplet energies. Thus, the triplet excitons can be efficiently confined within the emitting layer. However, typical FIrpic-based blue PhOLEDs incorporated with carbazole-based hosts require multilayer structures for facilitating the hole/electron injections into the emitting layer. In order to enhance the electron injection capability of carbazole, structural modification by introducing electron deficient moiety onto the carbazole core is necessary. Recently, triarylphosphine oxides have been reported to perform facile electron injection and transport properties [9–11]. The combination of the structural features of carbazole and phosphine oxide had led to promising bipolar hosts for blue PhOLEDs with excellent device characteristics [12]. The HOMO level of carbazole compound can be modulated by introducing appropriate substitutions at the C3 and/or C6 positions of carbazole [13–14], giving the opportunity of developing potential host materials for single layer device. Scheme 1 depicts the structure of the new bipolar host material POCz3, which was synthesized in one step with reasonable yield from a known precursor. The 3-bromo-9-phenylcarbazole reacted with magnesium turning in THF to give a Grignard solution, which was then quenched with $POCl_3$ to give the desired product POCz3 in 55% yield. The structural identity of POCz3 was confirmed by satisfactory ^1H, ^{13}C and ^{31}P NMR spectra, high-resolution mass spectrometry (HRMS).

2.2. Physical properties characterizations

POCz3 exhibits a high thermal tolerance [5% weight loss occurred at 395 °C, determined by thermogravimetric analysis (TGA)] and a distinct glass transition temperature (T_g) of 163 °C analyzed by differential scanning calorimetry (DSC). Therefore, POCz3 can form homogeneous and stable amorphous films upon thermal evaporation, which is a crucial criterion for OLED application.

The photophysical property of POCz3 as compared to that of parent compound 9-phenyl carbazole is shown in Fig. 1. Apparently, the introduction of phosphine oxide onto the carbazole ring only brings out limited perturbation on the photophysical property of carbazole. In solution, POCz3 exhibits a strong absorption band range from 260 to 300 nm that is attributed to the typical π–π* electronic transition of carbazole, whereas the weak absorption bands (300–350 nm) are ascribed to the n–π* transitions of carbazole. The emission spectrum of POCz3 is almost superimposable to that of 9-phenyl carbazole. The phosphorescent spectrum of POCz3 was obtained at 77 K (in EtOH). Again, there is no significant difference on the triplet energy upon introducing the electron deficient phosphine oxide to the carbazole as compared to that of 9-phenyl carbazole. The difference between the fluorescence (351 nm) and phosphorescence (408 nm) spectra corresponds to an exchange energy of ca. 0.67 eV between the singlet and triplet of POCz3. The triplet energy (E_T) of 3.03 eV (defined as the 0–0 transition in phosphorescent spectrum) is sufficiently high for POCz3 to confine the triplet excitons of the blue phosphorescence emitter FIrpic (E_T = 2.7 eV) within the emitting layer.

Fig. 2 displays the cyclic voltammograms of POCz3 and 9-phenyl carbazole in CH_2Cl_2 using a glassy carbon electrode with 0.1 M of nBu$_4$NPF$_6$ as electrolyte. The oxidation of POCz3 showed typical electrochemical behavior of C3



Scheme 1. The structure and synthesis of bipolar host POCz3.

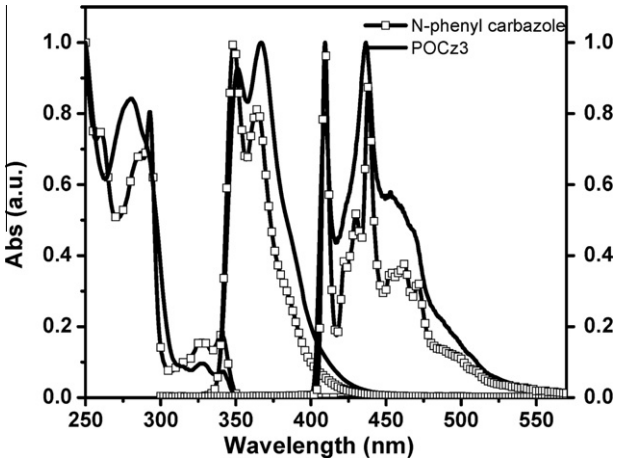


Fig. 1. A comparison of UV–vis absorption, photoluminescence (PL) (CH_2Cl_2), and phosphorescence (EtOH, 77 K) spectra of POCz3 and its parent counterpart N-phenyl carbazole.

and C6 unprotected carbazole derivatives, which usually performed a lower reduction peak originated from the more conjugated dimeric species generated from the coupling of carbazole cationic radicals. It is noteworthy that the oxidation onset of POCz3 is evidently shifted from 1.28 V of 9-phenyl carbazole to 1.44 V. Thus, the highest occupied molecular orbital (HOMO) energy of POCz3 is strongly affected by introducing the electron-withdrawing phosphine oxide. The electron deficient substituent is also beneficial to the reduction behavior of POCz3, in which one quasi-reversible reduction potential, onset potential at −2.25 V, was observed in dimethylformamide (DMF) using a glassy carbon electrode with 0.1 M of nBu$_4$NClO$_4$ as electrolyte. For practical evaluation, the HOMO of POCz3 were measured using UV photoemission spectroscopy (AC-2) to be −5.5 eV, and the lowest unoccupied molecular orbital (LUMO) energy was deduced to be −1.8 eV by adding the energy gap of POCz3 to the HOMO energy.

To further understand the charge-carrier transport properties of POCz3, we used the time-of-flight (TOF) technique [15] to evaluate the carrier mobilities. Fig. 3(a) displays representative TOF transient for electrons of POCz3. The transit time, t_T, can be evaluated from the intersection point of two asymptotes in the double-logarithmic representation of the TOF transient. It is then used to determine the carrier mobilities, according to the equation $\mu = d^2/Vt_T$, where d is the sample thickness and V is the applied voltage. Fig. 3(b) reveals that the field dependence of the electron mobility follows the nearly universal Poole–Frenkel relationship, with values in the range from 1.4×10^{-6} to 6.4×10^{-6} cm^2/Vs for fields varying from 4×10^5 to 6.8×10^5 V/cm.

In contrast, the TOF transient for holes exhibited weak photocurrent signals, which could not be used to determine the hole mobility. From the chemical structure of POCz3 (Scheme 1), the carbazole unit is a good hole transport unit and is effective in improving the hole transport property of the organic material. Hence, we also prepared hole- and electron-only single-carrier devices, to evaluate the bipolar transport behavior. We used high-LUMO 4,4′-bis[*N*-(1-naphthyl)-*N*-phenylamino]biphenyl (NPB, μh of 10^{-3} cm^2/Vs order) [16] to limit the electron carrier in hole-only devices and low-HOMO 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, μe of 10^{-7} cm^2/Vs order) [17] to limit the hole carrier in electron-only devices. As shown in Fig. 4, POCz3 shows bipolar transport property. However, the current density of electron-only device is larger than that of hole-only device at the same voltage, indicating the superior capability of POCz3 to transport electron other than hole-transport. This result is in agreement with the observed TOF mobility that only electron mobility can be resolved.

2.3. Device characteristics

The energy levels diagram of single-layer blue PhOLEDs with host molecule POCz3 and blue emitter FIrpic is depicted in Fig. 5. It is obvious that the energy level alignment allows energetically favorable electron injection from cathode directly into FIrpic (energy barrier ∼0.1 eV) instead of POCz3 which gives an energy barrier ∼1.2 eV.

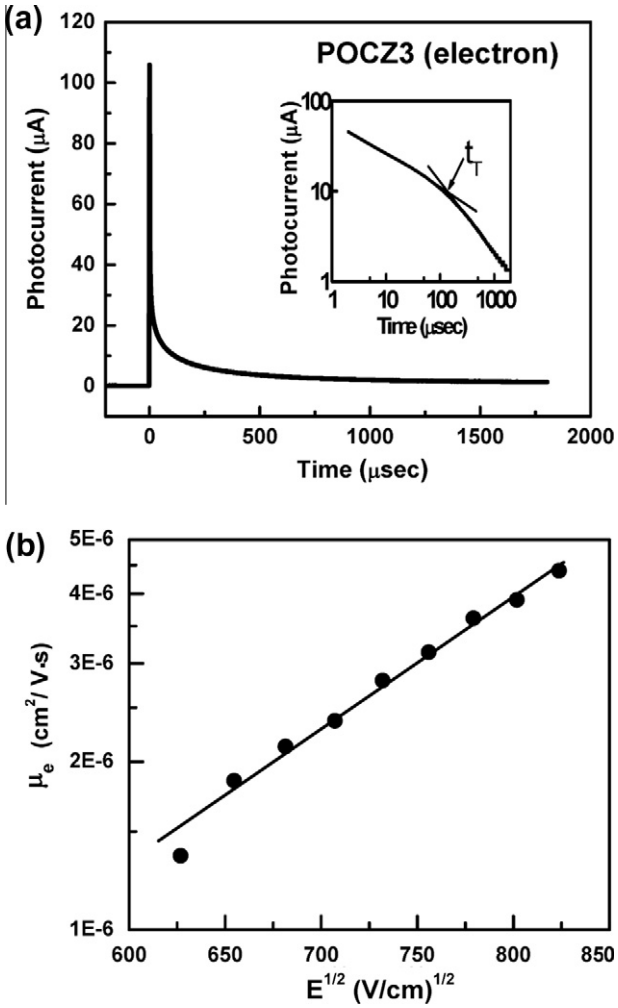

Fig. 3. Typical transient photocurrent signals for POCZ3 (2.8 μm thick): (a) electron at $E = 5.4 \times 10^5$ V/cm. Insets are the double logarithmic plots of (a). (b) Electron mobility plotted with respect to $E^{1/2}$ at ambient temperature.

In contrast, the HOMO energy level of POCz3 allows hole injection from anode and transporting by way of host to reach to FIrpic. Based on the promising physical properties of POCz3, a single layer blue PhOLEDs with POCz3 as host for FIrpic was fabricated with the device configuration as ITO/PEDOT:PSS/POCz3:FIrpic/LiF/Al.

It is inevitable that the recombination zone should be as away as possible from both electrodes for avoiding exciton quenching. Thus, the thickness of the single layer device needs to be carefully optimized. We used the typical doping concentration 10 wt.% of FIrpic for devices configured as ITO/PEDOT:PSS/POCz3:FIrpic (x nm)/LiF/Al, where the thicknesses x were varied as 70 nm, 80 nm, and 90 nm, respectively. The J–V and efficiency characteristics of these devices are shown in Fig. 6.

It is clear that the devices have higher driving voltages as the thickness of POCz3:FIrpic layer increases. Among these three devices, the single-layer device with thickness of 80 nm gave the optimal maximum external quantum efficiency (EQE) of 7.1% at brightness of 100 cd/m^2, and showed slow efficiency roll-off as the EQE keeps at 6.4% at the brightness of 1000 cd/m^2. As a consequence, we utilized 80 nm as the optimal thickness of the emitting layer in the following experiments. It should be noted that the hole-injection material PEDOT:PSS may act as a strong quencher of blue phosphorescence, rendering low device efficiency. In order to suppressing the possible triplet exciton diffusion, a neat thin film of POCz3 was introduced between the PEDOT:PSS and emitting layer comprised of POCz3 and FIrpic. Thus, we fabricated two devices with device configuration of ITO/PEDOT:PSS/POCz3 (x nm)/ POCz3:FIrpic 10.0 wt.% (80 nm)/LiF/Al, where the thickness x of POCz3 is 3 and 5 nm, respectively. Fig. 7 shows the J–V and external quantum efficiency-brightness characteristics of these two devices as compared to those of the parent device. Fig. 7(b) shows the EL spectra of the devices with and without introducing a thin film of POCz3 as exciton confinement layer. As shown, all devices have almost identical EL spectra which gave blue light originating from the FIrpic, indicating that the triplet excitons of FIrpic are

efficiently confined within the POCz3:FIrpic layer. The device with POCz3 as the interfacial layer (5 nm) achieves higher efficiency of 7.7% as compared to that of the parent

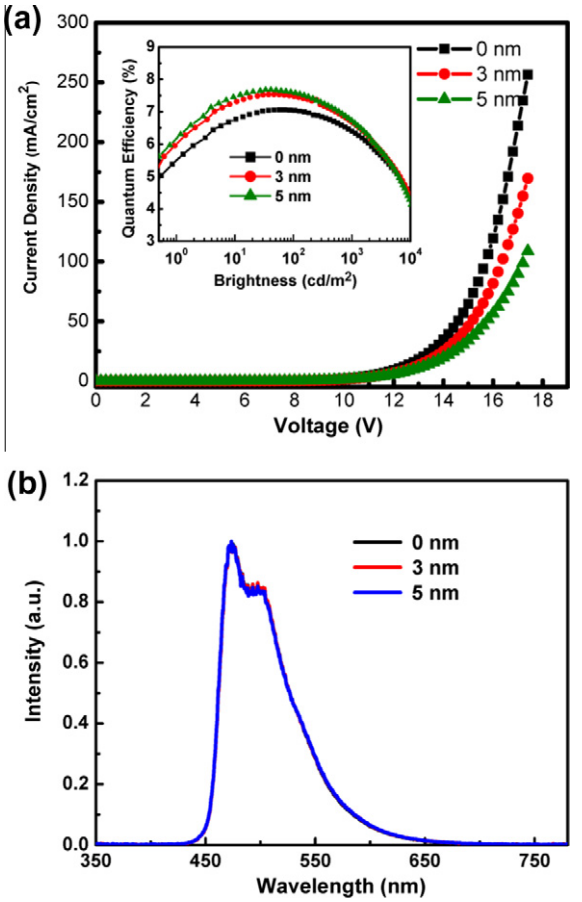

Fig. 7. (a) Current–voltage and external quantum efficiency–brightness characteristic of the exciton confined devices, (b) EL spectra of the devices with different thickness of exciton confinement layer.

device due to the exciton confinement effect. However, due to the low hole transport ability of POCz3, the driving voltages are higher with the thickness of interfacial POCz3 layer increases. As a consequence, a 3 nm neat thin film of POCz3 was utilized as the exciton confinement layer in the following experiments.

In the case of direct injection and transport on the dopant, the increase of the doping concentration may lead to enhanced probability of carrier injection and transport channels, resulting in higher device efficiency [6]. In order to improve device efficiency, four devices of varied concentrations of FIrpic were fabricated with a configuration of ITO/PEDOT:PSS/POCz3(3 nm)/POCz3: FIrpic *x* wt.% (80 nm)/LiF/Al, where the doping concentration *x* was varied as 10, 15, 20, and 25 wt.%, respectively, in order to determine the optimal dopant concentration. J–V–L curve and efficiency characteristics of these devices are shown in Fig. 8. The driving voltage decreases as the concentration of dopant concentration increases from 10 to 20 wt.%. There was limited difference on driving voltage between the doping concentration of 20 and 25 wt.%. This result indicates that device with higher FIrpic concentration imparts better carrier injection and more transport channels. Fig. 8(b) shows that maximum external quantum efficiency (power efficiency) enhanced

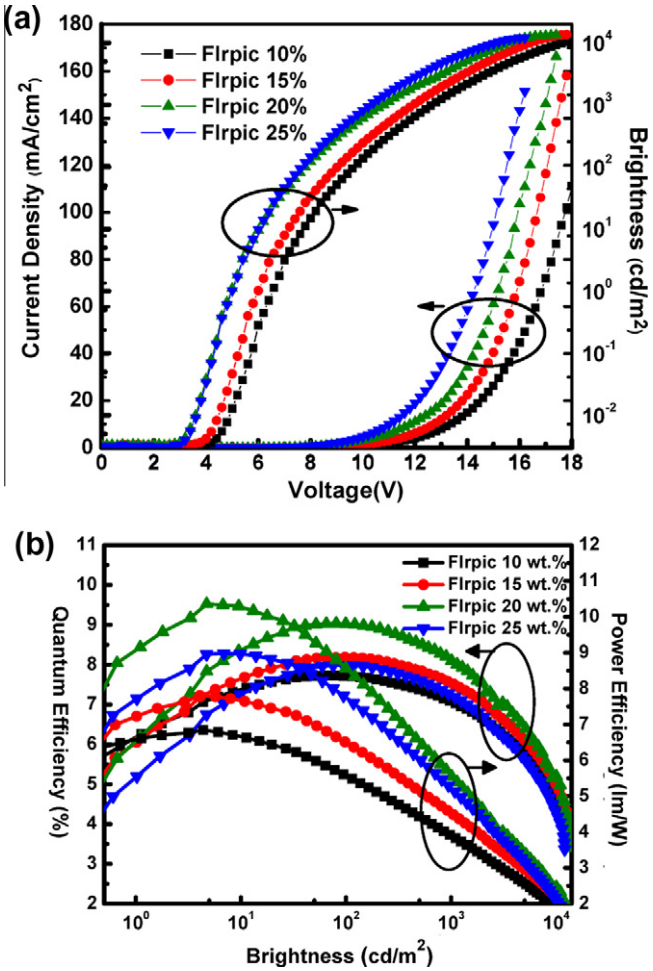

Fig. 8. (a) Current–voltage–brightness characteristic, (b) external quantum efficiencies and power efficiencies of single layer blue PhOLEDs.

from 7% (6.7 lm/W) to 9% (10.4 lm/W), when the FIrpic concentration increases from 10 to 20 wt.%. At higher doping concentration, more carriers can be directly injected and transported on FIrpic, leading to better device efficiency. However, at dopant concentration reaches to 25 wt.%, the efficiency decreased dramatically due to the triplet–triplet annihilation and concentration quenching effects. With the optimized dopant concentration of 20 wt.%, the device

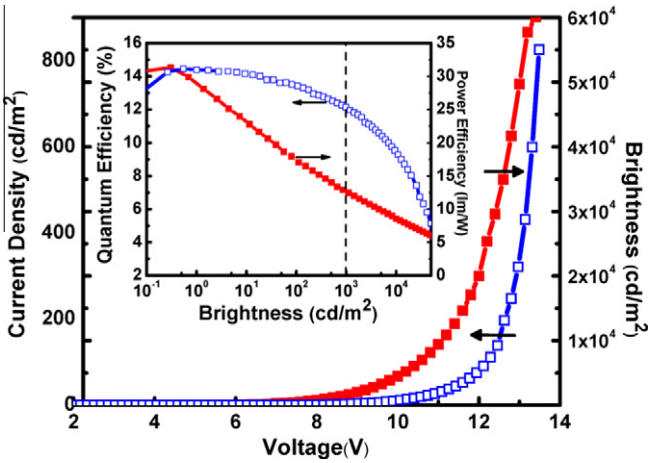

Fig. 9. Current–voltage–brightness and efficiency characteristic of POCz3 hosted three-layer blue PhOLEDs.

achieves the best performance, yielding maximum external quantum efficiency 9%, power efficiency 10.4 lm/W, and current efficiency 21.3 cd/A. The efficiencies of this optimized device show low roll-off effect with comparably high η_{ext} (8.1%), η_p (5.6 lm/W), and η_c (19.6 cd/A) when the brightness was increased to 1000 cd/m^2.

For evaluate the potential usefulness of POCz3 as a suitable host in multilayer OLEDs, a three-layer device using hole transport material 1,1-bis[4-[*N*,*N*-di(4-tolyl)-amino] phenyl]cyclohexane (TAPC) with high hole mobility (1×10^{-3} cm^2/Vs) and electron transport material 1,3,5-tri(m-pyrid-3-yl-phenyl)benzene (TmPyPB) with high electron mobility (1×10^{-3} cm^2/Vs) were fabricated. Considering the triplet exciton confinement within the FIrpic (E_T = 2.65 eV), a thin neat film of POCz3 (E_T = 3.03 eV) was introduced between TmPyPB (E_T = 2.78 eV) and POCz3:FIrpic. After optimizing charge balance by tuning the thickness of TAPC and TmPyPB, the J–V–L and efficiency characteristics of a three-layer device was shown in Fig. 9 with device configuration: ITO/TAPC (40 nm)/POCz3:FIrPic 8.0 wt.% (25 nm)/POCz3 (5 nm)/TmPyPB (50 nm)/LiF (0.8 nm)/Al. This device exhibits maximum luminance 60098 cd/m^2 and maximum external quantum efficiency and power efficiency of 14.5% and 31.3 lm/W, respectively. This device shows slow efficiency roll-off as the η_{ext} retains at 12.1% as the brightness is 1000 cd/m^2.

3. Conclusion

In summary, an efficient one-step synthesis gives a new bipolar host material POCz3 with high triplet energy and good thermal/morphological stabilities useful for efficient single-layer and tri-layer blue PhOLED devices. The introduction of electron-withdrawing phosphine oxide renders POCz3 to give a shallow HOMO energy suitable for injecting hole from anode and transporting through to reach to the bipolar blue phosphorescence dopant FIrpic, and recombining with the electrons direct-trap from the cathode. This strategy was evidenced by the higher device efficiency as doping concentration of FIrpic increased due to enhanced probability of carrier injection and transporting channels. With the optimized dopant concentration of 20 wt.%, and incorporates a thin POCz3 film as exciton diffusion blocking layer between PEDOT:PSS and the emitting layer comprised of POCz3:FIrpic, the single-layer blue PhOLED achieves maximum external quantum efficiency of 9%, power efficiency of 10.4 lm/W, and current efficiency of 21.3 cd/A which are comparable to the common multilayer PhOLEDs devices. A three-layer device with a double confinement effect exhibits maximum luminance 60098 cd/m^2 and maximum EQE (power efficiency) of 14.5% (31.3 lm/W). We believe that these results can trigger the molecular design of new bipolar host materials for more cost-effective PhOLEDs.

4. Synthesis of POCz3

Mg (243 mg, 10 mmol) in a 50 mL double-necked round-bottomed flask, equipped with a reflux condenser and an addition funnel, under an atmosphere of argon, few anhydrous THF was added in the flask. 3-bromo-9-phenylcarbazole (3.22 g, 10 mmol) and anhydrous THF (10 mL) in the addition funnel were added dropwise to the flask and the reaction mixture was refluxed until Mg is disappeared. Return to room temperature, $POCl_3$ (0.28 mL, 3 mmol) was added in the Grignard reagent. The resulting pale-yellow solution was stirred for 8 h. The mixture was quenched with saturated aqueous solution of NH_4Cl (10 mL). The aqueous layer was extracted with dichloromethane (3×20 mL), and the combined organic layers were washed with water (2×20 mL), dried ($MgSO_4$), and concentrated under reduced pressure. The residue was purified through column chromatography (SiO_2; EtOAc/hexane 1:1) to yield POCz3 as a white yellow solid (4.3 g, 55%) ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.67 (d, *J* = 12 Hz, 3H), 8.09 (d, *J* = 7.6 Hz, 3H), 7.76 (td, *J* = 10, 1.6 Hz, 3H), 7.62–7.55 (m, 12H), 7.50–7.41 (m, 12H), 7.27 (td, *J* = 7.2, 2.4 Hz, 3H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 142.5, 141.2, 136.9, 129.8, 129.7, 129.6, 129.4, 127.8, 127.0, 126.5, 125.3, 125.2, 124.7, 123.6, 123.3, 123.1, 122.9, 120.7, 120.5, 110.0, 109.8, 109.6; ^{31}P NMR (161 MHz, $CDCl_3$) δ 33.9; HRMS(M/z, FAB$^+$) Calcd. For $C_{54}H_{36}N_3OP$ 774.2596, found 774.2674.

wearability comfort [6]; the aim of many research groups has therefore become the development of a specific treatment on cotton yarns with the purpose of obtaining conductive fibres while preserving cotton's unique set of physical and comfort properties.

Several different methods for the realization of conductive cellulose fibres have already been described in the literature [7–14]. These procedures may be roughly grouped into two different categories. On one hand, cotton's conductivity was increased by incorporating metal particles onto cotton modified with polymer brushes [7] or carbon nanotubes (CNTs) [8] into cellulose yarns. With these techniques, very high values of conductance per length unit (up to 1 S cm^{-1}) were achieved. The majority of reported works on conductive cotton, however, have focused on grafting conductive polymers (CPs) onto cellulose fibres by in-situ, liquid-phase polymerization [9–13] or simple soaking the cellulosic substrates in polymeric aqueous solutions [14]. The most commonly used CPs are π-conjugated polymers including polythiophenes (such as PEDOT) [9,12,14], polypyrrole [10,13] and polyaniline [11]. Incorporation of CPs into cotton fibres has shown to raise the conductance per length unit of the native fibre from $\sim 10^{-12}$ to 10^{-1} S cm^{-1}.

Surprisingly enough, even though it has been shown that the incorporation of metallic (e.g. Au, Ag, Pt) nanoparticles (NPs) into CPs films may result in the formation of highly conductive layers, characterized by conductivities several orders of magnitude greater than the values obtained for the CPs alone [15,16], the deposition of such composites on cotton substrates has not yet been attempted.

In this paper, we present a novel technique in which conductive Au NPs are deposited onto the cotton surface and subsequently interconnected with a layer of conductive polymer. The electrical properties of these samples are compared to those of yarns on which only Au NPs or only a CP layer was deposited, in order to evaluate the effect on the electrical behaviour of the combination of the two deposition processes.

We will show that the deposition of a metal NPs/CP composite on plain cotton yarns determines a dramatic increase of its conductivity so that treated yarns may be used as electrical connectors in order to bias or to interconnect electronic devices, behaving thus as relatively low resistance resistors.

Moreover, to demonstrate practically the possibility of using cotton fibres to fabricate organic textiles circuits, two different kinds of transistors have been realized.

The first device is based on the concept of OECT, first developed in planar form [17] and also realized in form of yarn based on a nylon fibre [18] and more recently on silk [19].

An OECT is made up of two electrodes, source and drain, connected by an active layer called channel realized using a conductive polymer which can be electrochemically doped/de-doped [20]. The channel conductivity is modulated by applying a voltage on a third electrode, the gate, immersed in an electrolyte solution in contact with the channel. The gate voltage drives the electrolyte cations into the channel where they cause its de-doping and, as a consequence, a decrease of the current flowing between the source and drain terminals. Channel de-doping is a reversible process: when the gate voltage is brought back to zero, the channel conductivity increases again.

The second example of active device realized on a cotton yarn is based on the concept of organic field effect transistor (OFET). In this case, the conductivity of the channel, made of a semiconductor deposited between two metal contacts (source and drain), is modulated by the voltage applied to a gate electrode, capacitively coupled with the device channel [21]. The transistor current is modulated by varying the voltage on the gate. To realize a yarn-shaped OFET, a multilayered structure based on a conductive yarn (that acts as the gate of the device) is used. This cylindrical structure is able to act as a transistor, according to a model that takes into account its geometrical characteristics [22] giving rise to results very similar to those obtained with planar structures.

2. Materials and methods

2.1. Preparation of Au NPs/PEDOT:tos coated conductive cotton yarns

The procedure for the deposition of Au nanoparticles on cellulosic substrates has been already reported in previous publications [23].

After conformally coating cotton yarns with high packing surface density of Au NPs, a thin layer of tosylate-doped PEDOT (PEDOT:tos) was deposited on the yarns by means of a vapour phase polymerization (VPP) process. Such a procedure has already been described in detail in the literature [24,25] for the deposition of thin PEDOT:tos films on planar substrates. In our case, we prepared a solution of 125:25:1 wt% of isopropanol:Fe(III)–tosylate:pyridine in which the yarns were soaked for 10 min and then dried on a hot plate at 80 °C for 3 min.

After polymerization of EDOT monomer into PEDOT, the samples were dried in an oven at 50 °C for 30 min. Then they were rinsed into ethanol for 10 min and finally dried in a vacuum oven at room temperature for 12 h.

This procedure is described in the cartoon presented in the Supplementary data.

Conductive cotton fibres were used as source, drain and gate electrodes in the assembly of cotton-made electrochemical transistors (see Section 2.6).

2.2. Preparation of PEDOT:poly(styrenesulphonate) coated semiconductive yarns

The cotton yarns were soaked in an aqueous dispersion of PEDOT:poly(styrenesulphonate) (PEDOT:PSS) (CLEVIOS™ PH 500, H.C. Starck, used as received) for 48 h at 6 °C. Samples were then baked on a hotplate at 145 °C for 60 min. After baking, samples were soaked in ethylene glycol (EG) (anhydrous, 99.8%, Sigma–Aldrich, used as received) for 3 min at room temperature. Then they were baked on a hotplate at 145 °C for 60 min. Such semiconductive yarns were used for the realization of the channel of organic electrochemical transistors.

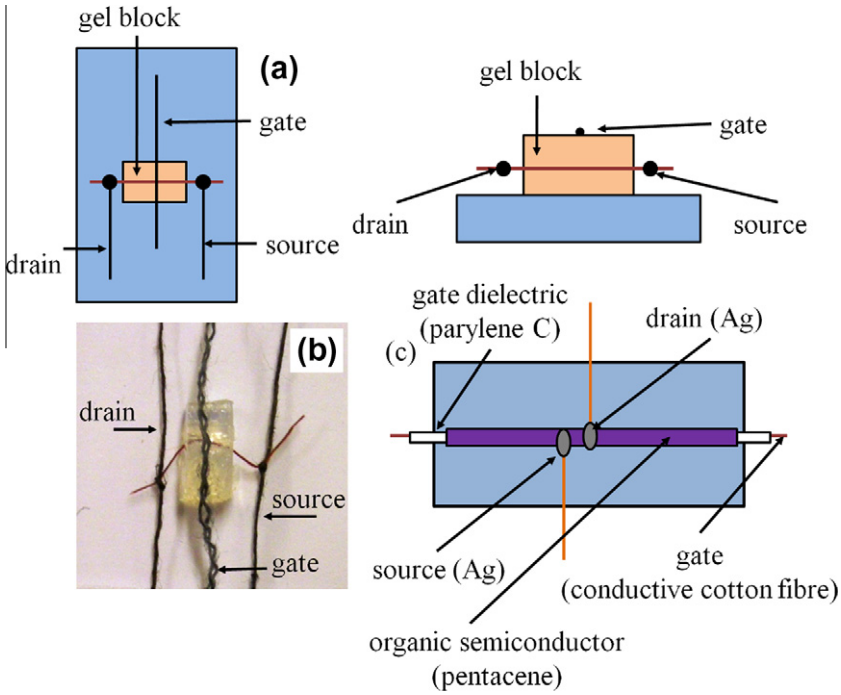

Fig. 1. Organic transistors realized on a cotton fibre. (a) Scheme of an OECT on cotton yarns seen both from the above (left) and from a lateral perspective (right). (b) Actual picture of the transistor. (c) Scheme showing the structure of an OFET fabricated on a cotton yarn.

2.3. Microscopic and spectroscopic analysis of conductive cotton yarns

Short pieces (1 cm) of conductive cotton yarns were immersed into small blocks of epoxy resin and baked at 80 °C for 24 h in order to achieve the complete solidification of the resin. Such blocks were then sectioned by means of a microtome (Dupont Sorvall MT500 Ultramicrotome) obtaining slices with a thickness of approximately 90 nm. The samples slices were placed onto a copper microgrid and analysed with a Tecnai FEI F20 TEM STEM microscope. This instrument is also equipped with a Gatan tridium spectrometer for electron energy loss spectroscopic analysis, so that on the samples treated with both Au NPs and PEDOT:tos an energy-dispersive X-ray spectrum (EDX) was acquired.

2.4. Electrical characterization of conductive cotton yarns

Resistance per unit length was measured using a four probe method, performed using a couple of Keithley 2636 SYSTEM Source Meters. More in detail, a current of 10 μA was injected by means of a couple of electrodes (outer electrodes) connected to the yarn and placed at a distance of 2 cm. Another couple of electrodes (inner electrodes) was inserted between the external electrodes, connected to the yarn and placed at a distance of 1 cm in order to measure the voltage drop resulting from the current passage; resistance was measured as the ratio between this potential drop and the current injected. For each yarn type, 10 samples were acquired.

2.5. Mechanical characterization of conductive cotton yarns

Conductive cotton fibres were characterized by means of stress–strain measurements performed using a TA Instruments DMA Q800 Dynamic Mechanical Thermal Analysis (DMTA) equipment. The samples measured were 4 cm long, the stress applied varied from 0 to 18 N with steps of 0.3 N. Percentage elongation was measured with respect to the sample's original length.

2.6. Cotton-based organic electrochemical transistors assembly

First, a 250 mM solution of KCl in deionized water was prepared. Bacto™ Agar (DIFCO Microbiology) was employed as gelling agent (3.75% in weight). The solution was heated up at 90 °C and vigorously stirred for 60 min. To improve solidification, the gel was stored at 6 °C for 24 h before being used. The gel is used in the OECT assembly to realize the ionic bridge between the gate and the channel. A piece of semiconductive yarn (1 cm, prepared as described in Section 2.2) was inserted into the centre of a small parallelepiped of electrolyte gel (approximately: 6 mm^3) with the help of a needle. Two conductive yarns (2 cm long, prepared as described in Section 2.1) were fixed at the end of the semiconductive yarn with a simple knot and then connected to the power supply by means of a couple of micrograbbers (Fig. 1a and b). Another conductive yarn was fixed on the top of the electrolyte gel block and used as the gate electrode.

2.7. Cotton-based organic field effect transistors assembly

The core of the organic field effect transistors (OFET) is a yarn treated with PEDOT:PSS/EG (prepared as described in Section 2.2), which acts as the gate electrode of the final device. The gate dielectric layer was realized by depositing a thin film of poly(chloro-p-xylylene) (usually known as Parylene C) with a nominal thickness of 1.5 μm on the entire yarn surface through a chemical vapour deposition (CVD) process performed using a PDS 2010 LABCOTER deposition system. Such a dielectric film was obtained starting from 3.3 g of dichloro-[2,2]-paracyclophane (dimer), vapourized at 175 °C at a pressure of around 1 mmHg. The dimer vapours are then pyrolized at 690 °C at a pressure of around 0.5 mmHg to form the gaseous monomer which is eventually deposited at room temperature at a pressure of around 0.1 mmHg on the substrate surface, where polymerization of monomers occurs. After that, a thin pentacene (nominal thickness 50 nm) film was deposited by thermal evaporation at pressure below 2×10^{-5} mbar, at a constant rate of ca. 4 Å min^{-1}. Source and drain electrodes have been realized by depositing two drops of conductive silver paint on the previously realized structure. The silver paint drops have been placed by means of a very sharp needle, in this way, a typical channel length of approximately 200 ± 50 μm have been obtained, whereas the channel width is usually given by the average semicircumference of the employed yarn (Fig. 1c).

2.8. Electrical characterization of OECTs and OFETs

Each transistor was characterized by acquiring the Ids–Vds curves. The source electrode was grounded while the voltage applied to the drain was:

- Varied from 0.5 to −0.5 V with steps of −0.01 V (forward curve) and then again from −0.5 to 0.5 V with steps of 0.01 V (backward curve) for OECTs.
- Varied from 0 V to −60 V with steps of −1 V for OFETs.

During the acquisition of each curve, the gate voltage was fixed at a specific value and then increased in correspondence with the acquisition of the next curve (gate voltage range: $0 \div 0.4$ V, step width: 0.1 V for OECTs; $20 \div -100$ V, step width −20 V for OFETs).

OECT samples were also characterized by the acquisition of drain current vs. time curve. In this case, drain voltage was kept constant at −0.5 V while gate voltage varied abruptly from 0 to 0.4 V (square wave) every 60 s.

3. Results and discussion

Fig. 2 shows a example of the use of the described conductive cotton yarn for connecting a LED to a battery. It is noteworthy that the flexibility of this yarn (made according to the procedure described in Section 2.1) is such that the connection is made through a simple knot. The described yarn treatment in fact modifies the yarn conductivity without significantly compromising its mechanical features.

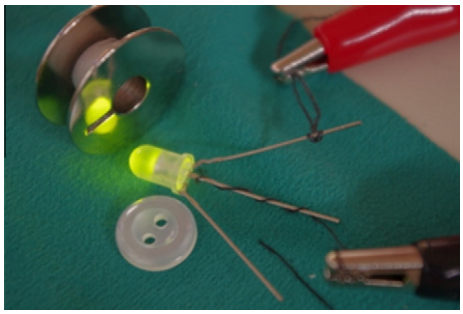

Fig. 2. Light emitting diode (LED) biased by means of conductive cotton yarns.

To investigate the modifications induced in the conductive yarn structure, transmission electron microscopy (TEM) analysis of the cross section of the treated yarns was performed and the obtained results are shown in Fig. 3. Gold nanoparticles clearly appear as an external coating (Fig. 3a). Conversely, it was found that PEDOT:tos is not confined to the yarn's external surface but penetrates among the yarn inner fibres in a very irregular way (Fig. 3b). For this reason, it was not possible to obtain a precise measurement of the samples' cross-sectional conductive area.

Fig. 3d shows an energy-dispersive X-ray spectroscopy (EDX) spectrum of a sample treated with both Au NPs and PEDOT:tos (cross section shown in Fig. 3c). EDX was performed to identify the chemical composition of the materials deposited on the cotton yarn surface: the spectrum confirmed the presence of both Au NPs (Au peaks) and PEDOT:tos (S peaks, caused by the sulphur atoms contained into the thiophene rings). The sharp Cu peak which appears in the spectrum is due to the copper grid on which the samples slices were placed during the analysis.

All conductive cotton samples were electrically characterized with a four-point probe method in order to eliminate possible contributions of contact resistances.

The following types of samples were compared:

Type 1: Cotton yarns as received;
Type 2: Cotton yarns covered with Au NPs;
Type 3: Cotton yarns covered with PEDOT:tos;
Type 4: Cotton yarns covered with Au NPs and subsequently covered with a layer of PEDOT:tos.

Since, as previously mentioned, a precise determination of the samples cross section was not possible, the electrical performance of the different fibres has been compared in terms of resistance per unit length.

The mean values of the electrical resistance of all samples types are summarized in the first column of Table 1: the most conductive samples were type 4. The unmodified cotton specimens show a resistance of $(3.1 \pm 0.9) \times 10^8\ \Omega\ cm^{-1}$; the deposition of nanoparticles onto the cotton fibres does not seem significantly influence the resistance value, which remains of the same order of magnitude. However, when PEDOT:tos layers are deposited over plain cotton yarns, the resistance value of the modified fibre is reduced by three orders of magnitude.

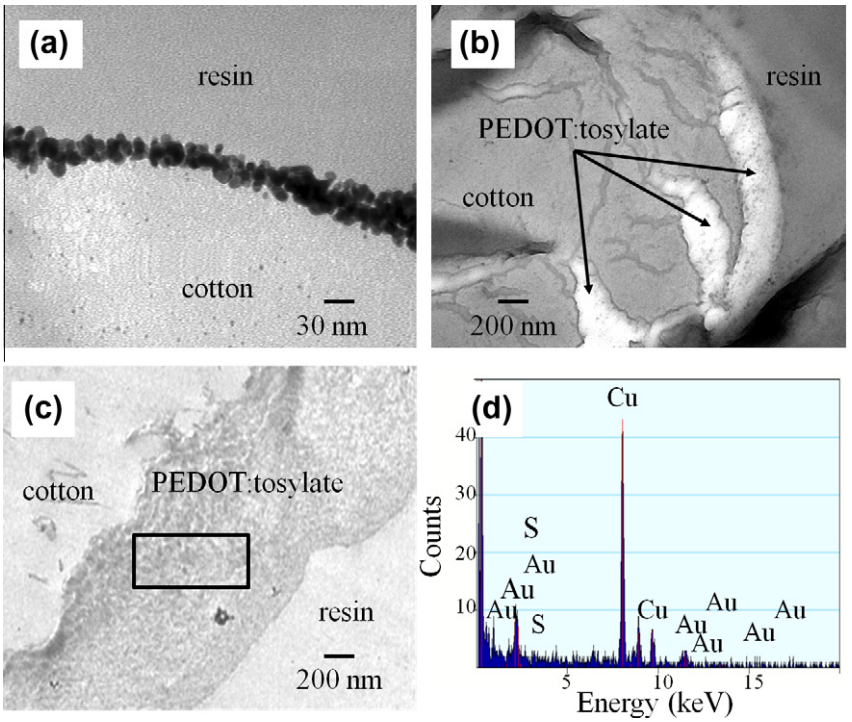

Fig. 3. Transmission electron microscope (TEM) analysis of the cross section of the conductive cotton fibres. (a) Cross section of a cationic cotton fibre uniformly coated with Au nanoparticles. (b) (Bright Field TEM image) Cross section of a fibre coated with PEDOT:tos. (c) (Dark Field TEM image) Cross section of a fibre treated with Au nanoparticles and a conductive polymer layer (PEDOT:tos). The rectangle in the conductive layer indicates the area in which the EDX spectrum (see inset d) was acquired. (d) EDX analysis performed on the area shown in (c).

Table 1
Electrical and mechanical data of the conductive cotton yarns.

Yarn type	Resistance per unit length ($\Omega\,cm^{-1}$)	Young's modulus (MPa)	Stress at break (MPa)	Elongation to break (%)
1. Plain cotton	$(3.1 \pm 0.9) \times 10^8$	342 ± 75	10.3 ± 3.3	4.4 ± 1.8
2. Cotton + Au NPs	$(1.1 \pm 0.1) \times 10^8$	140 ± 60	8.2 ± 1.9	11.0 ± 5.3
3. Cotton + PEDOT:tos	$(186.8 \pm 0.2) \times 10^3$	331 ± 82	4.0 ± 1.3	2.5 ± 1.0
4. Cotton + Au NPs + PEDOT:tos	$(24.7 \pm 0.3) \times 10^3$	142 ± 18	4.3 ± 1.0	4.4 ± 0.9

An unexpected further reduction of one order of magnitude in resistance is then achieved when PEDOT:tos is deposited on NPs coated cotton fibres, which clearly proves a Au NPs-enhanced conductivity phenomenon. These experimental results demonstrate that a natural cotton fibre can be made conductive by a conformal coating with thin layers of a conductive polymer, hence increasing the conductance by about three orders of magnitude. More importantly, when the PEDOT:tos layers are deposited on a Au NPs previously treated substrate, a further increase, up to four orders of magnitude, in conductance is observed.

Further investigations are being performed to establish the exact nature of the electrical transport mechanism in the treated fibres and the synergistic role of the Au NPs.

Such treated yarns were then mechanically characterized by measuring static stress vs. strain curves. Three mechanical parameters were acquired: Young's modulus, stress at break and elongation before breaking (also called elongation to break, indicated as εb); the mean values of such parameters for the different types of conductive yarns are reported in Table 1 (see Supplementary data for the full statistical analysis). On a typical curve of a yarn treated with Au NPs + PEDOT:tosylate compared to plain cotton, shown in Fig. 4, two main observations can be made: first

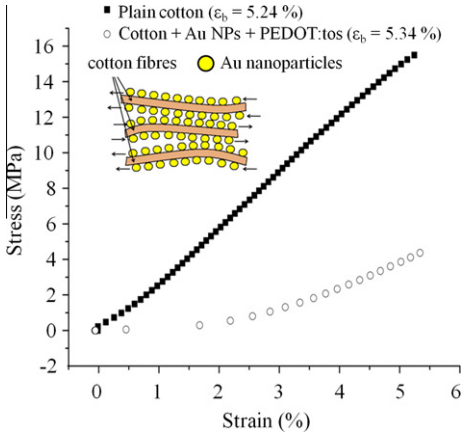

Fig. 4. Stress strain curves on conductive cotton yarns.

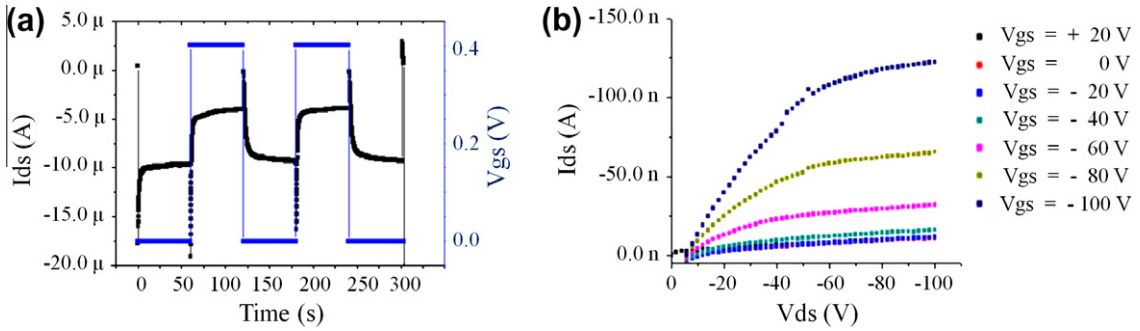

Fig. 5. Electrical characteristics of organic transistors on cotton yarns. (a) Drain current and gate voltage vs. time characteristics of an all cotton-made OECT. (b) Id–Vd curves acquired on a cotton-made OFET.

the maximum elongation before breaking appears to be similar for both samples, thus indicating that the main mechanical property of interest for evaluating the ability of the yarn to be woven or knit are preserved in treated yarns. Secondly, the treated yarn can reach larger strain values before starting to experience elongational stress (represented by the slope of the curve in the initial phase). This unusual effect, that was observed only in NPs-treated samples (with and without PEDOT:tos, see the full statistical analysis of all kinds of yarns in Table 1) may be tentatively attributed to a "lubricant" effect due to the conformal nature of the NPs coating which seems to enable them to slide on one another following the application of the mechanical stimulus (see the inset in Fig. 4). These observations demonstrate that the proposed treatment does not stiffen the cotton yarns that, at the same time, still possess mechanical properties apt for weaving purposes.

Finally, active electronic devices have been made starting from natural cotton fibres.

As for the transistors characterization, it can be seen from Fig. 1a and b that the OECT structure includes an electrolyte in gel form. Being this based on water, it is strictly necessary that the OECT channel (in this case the yarn) is impermeable to water. Cotton yarns simply soaked in PEDOT:PSS cannot be used as such as the contact with a water-based electrolyte solution would cause on one hand the dissolution of PEDOT:PSS and on the other hand, the possible absorption of water and the consequent ionic conduction of the yarn through the adsorbed water: in any case, the loss of the transistor action. To avoid this problem, after the deposition of PEDOT:PSS, the samples were treated with ethylene glycol (EG). The effect of this treatment is twofold: on one hand it dramatically decreases PEDOT:PSS solubility in water, on the other EG is also able to increase its conductivity [26,27]. In the SD section, the comparison (in terms of electrical resistance and water-resistance) between yarns soaked in PEDOT:PSS with and without ethylene glycol treatment is presented.

Fig. 5a shows the electrical characteristics of the cotton-made OECT. It is noteworthy that source and drain contacts were made by a simple knot between the yarn that acts as the device channel (i.e. the semiconductive yarn obtained with the procedure described in Section 2.2) and two conductive cotton yarns (i.e. the conductive yarns obtained with the procedure described in Section 2.1) used to connect the device to the source/measure units. This is a very basic example of textile circuit entirely based on cotton yarns. Despite the non optimal ratio between the on and off currents, the transistor effect is clearly achieved. It is noticeable that we have attempted also to obtain an OECT device using the conductive cotton yarn (i.e. the conductive yarn obtained with the procedure described in Section 2.1) but we never obtained a transistor action with this yarn, i.e. its conductivity cannot be modulated by the exchange of ions with the electrolytic solution. This aspect is under further investigation.

The structure of the yarn-shaped organic field effect transistor (OFET) is shown in Fig. 1c. The core of the OFETs is a yarn treated with PEDOT:PSS/EG as described above, which acts as the gate electrode of the final device. Even if the PEDOT:PSS/EG yarn nominally behaves as a semiconductor, its resistance per unit length ($2 \times 10^3\ \Omega\ cm^{-1}$), is such that at the voltage values used for operating the gate in the OFETs, it may be considered as a conductor. In addition, the contact with any external agent able to modulate its conductivity is prevented in the OFET, as the gate is coated with an insulating layer. Clearly, also conductive cotton yarns based on Au NPs and PEDOT:tos could be used for this function but the yarn treated with PEDOT:PSS was preferred because its external surface is smoother and this feature improves the quality of the dielectric layer deposition. Fig. 5b shows an example of the electrical characteristics of the OFETs. The insulating layer capacitance was measured and found to be 2.17 nF cm^{-2} (corresponding to an estimated thickness of the insulating layer of 1.5 µm). The OFET mobility mean value (over 20 devices measured) is $1.3 \pm 1.0 \times 10^{-2}\ cm^2\ (V^{-1}\ s^{-1})$ and the threshold voltage is -24 ± 5 V. These values are not too different from those taken from typical curves of planar OFETs with comparable aspect ratios. Relatively high values of the threshold voltage may be attributed to the thickness of the insulating layer.

4. Conclusions

In conclusion, we presented an innovative method based on the combination of two deposition processes which can be used in order to obtain conductive yarns starting from common cotton fibres, which are by

themselves intrinsically insulating. The electrical and mechanical characterization of these fibres showed that these yarns can be successfully used as conductors, in order to bias electronic devices. Cotton was also successfully employed as a basis for realizing two kinds of active devices based respectively on the concept of organic electrochemical transistor and of organic field effect transistor. Our study demonstrates the possibility of realizing a fully textile circuit, including passive and active elements, and paves the way for a future complete integration between electronics and textiles.

Acknowledgements

Prof. Ennio Bonetti is gratefully acknowledged for the fruitful discussions about the mechanical measurements conducted on the yarns.

G.M. would like to thank Dr. Sang Yang for the fruitful discussions concerning the polarization of OECTs and Alwin Wan for the help with the polymerization of PEDOT:tosylate process.

A.B. and G.M. gratefully acknowledge EU Commission for funding the Integrated Project #26987 "Proetex".

G.G.M. would like to thank ReynoldsTech for building the tool for vapour deposition of conducting polymers.

J.P.H. acknowledges the US Department of Agriculture for partially funding this work under projects NRI-NCZ09462 and CRIS-Hatch NYC-329433.

P.C. acknowledges Regione Autonoma della Sardegna (RAS) for funding his research activity under the PO Sardegna FSE 2007-2013, L.R.7/2007, CRP Prot. No. 1399/207.

This work made use of the electron microscopy facility of the Cornell Center for Materials Research (CCMR) with support from the National Science Foundation Materials Research Science and Engineering Centers (MRSEC) program (DMR 0520404). This work was performed in part at the Cornell NanoScale Facility, a member of the National Nanotechnology Infrastructure Network, which is supported by the National Science Foundation (ECS-0335765).

molecules can obtain high energy from the applied electric field. These highly excited molecules are easily ionized, which causes leakage current and dielectric breakdown [31,32]. In practical applications, curing is crucial to make the dielectric layer insoluble in the liquid deposition of soluble organic semiconductors. Other effective paths to reduce hysteresis include addition of SiO_2 buffer layer, which blocks the electron injection from the gate electrode [33], but the addition of an inorganic layer is not advantageous due to the undermined flexibility and the high cost of vacuum process.

The current polymer/cross-linker system complicates the manufacturing process, and requires high processing temperatures [33,34]. High curing temperatures above 180 °C are generally required to eliminate hysteresis in polymer insulated FETs, preventing the use of conventional plastic films (T_g < 150 °C), such as polycarbonate and polyethylene naphthalate as a substrate for flexible OFETs. The commonly used PVP/poly(methylated melamine-co-formaldehyde) blends require 180–200 °C to achieve hysteresis-free OFETs [28,29]. Our previous report about acid/epoxide functioned polyacrylate (PB174) gate insulator was effectively cured at 230 °C to eliminate hysteresis behavior [35]. Most recently, several cross-linking agents such as dianhydrides [2] and chlorosilanes [36] were proposed to cross-link PVP at low temperatures around 110 °C, but no successful elimination of hysteresis behavior was demonstrated. Hysteresis-free FETs with organosiloxane-based organic–inorganic hybrid dielectrics of poly(methyl silsesquioxane) (PMSQ) were reported [10] while low-temperature curable polymer gate dielectric for hysteresis-free OFETs is still under investigation.

Here we report a novel low-temperature curable polyacrylate type copolymer (L-PA) gate dielectric, and the investigation of its favorable curing condition to permit hysteresis-free OFETs and MIS (metal–insulator–semiconductor) capacitors. Reaction mechanisms and related temperature ranges, surface properties of the gate dielectric and the morphological features of semiconductor layers were also studied and correlated to electrical performance. Optimal conditions were identified that produce hysteresis-free OFETs through low-temperature curing.

2. Experimental

L-PA (sample name: TAB18-binder, supplied by LG Chem. Co., Ltd.) was dissolved in propylene glycol methyl ether acetate (PGMEA) to obtain 10 wt.% polymer solution. The molecular structures of each repetitive unit and corresponding mass ratios of the random copolymer L-PA are demonstrated in Fig. 1. The film was formed with spin-coating on piranha cleaned n-type heavily doped silicon wafers at 3000 rpm for 1 min inside the high purity Ar-filled glove box. And then the film was baked in an annealing furnace for 30 min at various temperatures of 110 °C, 140 °C and 170 °C to study the temperature effects on the

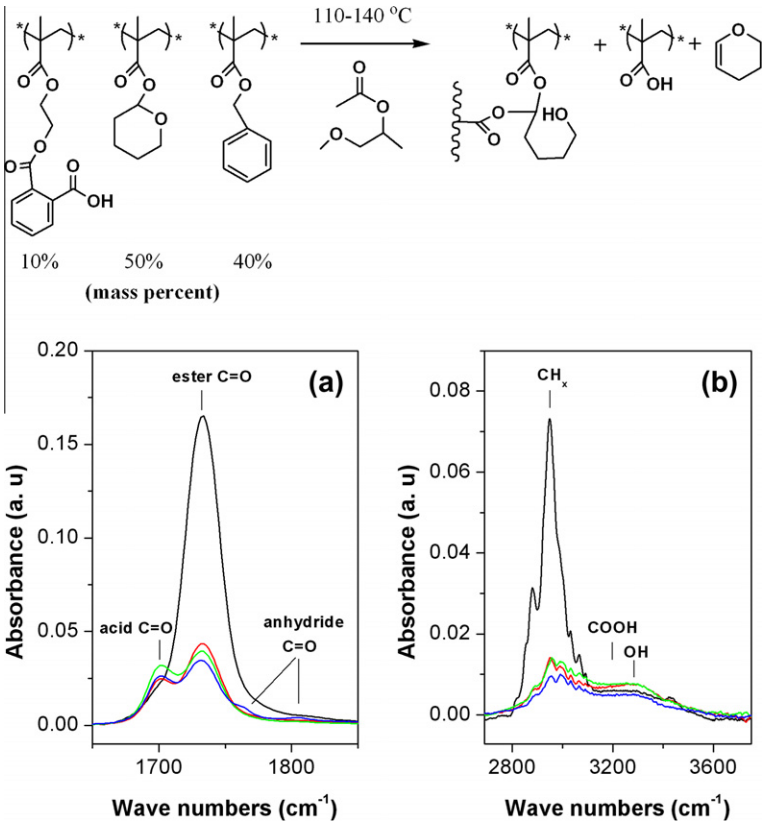

Fig. 1. Repetitive units, mass percents and reaction mechanisms for L-PA copolymer as well as FT-IR spectra of as deposited (—), 110 °C (—), 140 °C (—) and 170 °C (—) baked L-PA films: (a) C=O vibrations at low wave numbers and (b) O–H, C–H vibrations at high wave numbers.

film properties and device performance. The unbaked and baked films were correspondingly referred to as L-PA-as dep., L-PA-110, L-PA-140 and L-PA-170. It was expected that cross-linking reaction as illustrated in Fig. 1 occurred during the bake. Pentacene, which was purchased from Aldrich Chemical Co., was deposited onto the gate dielectric using an organic molecular beam deposition system at a rate of 0.2–0.3 Å/s and a moderate substrate temperature of 50 °C. The thickness of the pentacene layer was 60 nm for OFETs and for morphology study with AFM. For MIS capacitors and metal/insulator/metal structures (MIM), Au top electrode was deposited with evaporation through a shadow mask to make a circular dot area of 8.02×10^{-4} cm^2. For OFETs, Au electrodes were deposited in an evaporator and patterned by a shadow mask with a channel width of 1500 μm and a channel length of 150 μm.

FT-IR (Nicolet 700) spectra of the solid films were recorded in a transmission mode. Contact angle measurements were conducted using a face contact angle meter (Model CA-A, manufactured by Kyowa Kaimenkagaku Co., Ltd.). Thickness was obtained from Woolham Co. VASE32 ellipsometer. To study the roughness of the dielectric surface as well as pentacene morphology, AFM (Dimension™ 3100 microscope, Digital Instruments) was adopted. Capacitance–voltage (*C*–*V*) characteristics of the MIS capacitors were measured to study the hysteresis behavior, using HP 4284A Precision LCR meter (Agilent Tech.) at 1 MHz. Leakage current density and electrical performance were characterized with HP5270A (Agilent Tech.).

3. Results and discussion

3.1. Reaction mechanism

FT-IR in a transmission mode was used to monitor reactive functional group changes in the cross-linking process, as demonstrated in Fig. 1a and b. As seen in Fig. 1a, the bands between 1650 cm^{-1}–1850 cm^{-1} were attributed to the stretching vibrations of different carbonyl groups (C═O). Peaks centered at 1701 cm^{-1} and 1733 cm^{-1} were assigned to carboxylic acid and ester groups, and the double peak centered at 1762 cm^{-1} and 1805 cm^{-1} was from anhydride groups. Under 110 °C and 140 °C, ester groups partially broke up into carboxylic acids and vacuum-removable small molecules. At the same time, carboxylic acid groups attacked the precursor, producing cross-linked structures, with reaction mechanism demonstrated in Fig. 1. The resultant hydroxyl (OH) group centering at ~3300 cm^{-1} and the broad band carboxylic acid dimmers between 2800–3500 cm^{-1} were observed as shown in Fig. 1b. When baking temperature was increased up to 170 °C, carboxylic acids were converted into an ambient-unstable anhydride species as a side reaction.

To further confirm the reaction mechanisms, DSC and TGA were carried out for L-PA bulk polymer. DSC analysis was conducted to investigate the temperature ranges of heat adsorption or release during heating. As shown in Fig. 2, two major regions were confirmed with a sharp peak centered at 148.2 °C and a broad peak centered at 244.0 °C.

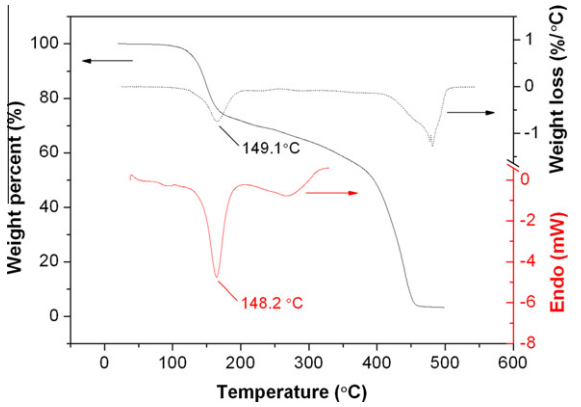

Fig. 2. Thermogravimeric analysis (TGA) (in black) and differential scanning calorimetry (DSC) (in red) characteristics for L-PA bulk polymer. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

This implied two major chemical reactions with heat release within the two temperature ranges.

TGA was adopted to confirm reaction temperature ranges by monitoring the weight loss during heating, which was caused by the release of gaseous product during chemical reactions. A 25% weight loss within 100–160 °C was correlated to 2H-pyrrane removal from the weight loss of 6-membered ester ring in the copolymer. The film thickness was drastically reduced from 293 nm (L-PA-as dep.) to 241 nm for L-PA-110, 221 nm for L-PA-140, and 208.2 nm for L-PA-170, further confirming the two weight loss processes.

3.2. Film properties

As displayed in Fig. 3a and b, AFM images of the dielectric surface exhibited root-mean-square (RMS) roughness between 0.22–0.32 nm, which was smooth enough to have negligible affects on pentacene deposition mode [17]. Fig. 3c and d shows the AFM images of 60 nm pentacene films deposited on L-PA-as dep. and L-PA-140. The relatively small pentacene grains on L-PA-as dep. were due to the higher dielectric surface energy, which caused stronger interactions between the dielectric surface and the pentacene molecules during the deposition. High dielectric surface polarity was reported to lead to smaller grains [37] with larger grain boundary area, which is considered to be a trap site disrupting the charge transport in organic semiconductors [38]. In contrast, pentacene exhibited well defined terraces and larger dendritic grains on L-PA-140, whose surface energy was relatively low. Surface energy, which was reported to drive molecular stacking mode in pentacene deposition [39], was determined from the contact angle measurement using distilled water and diiodomethane as the probe liquids [40]. As summarized in Table 1, the surface energy was decreased with the heat treatment.

3.3. Metal–insulator–metal structures

Dielectric strength and leakage current density are two key parameters to evaluate electrical robustness of a gate

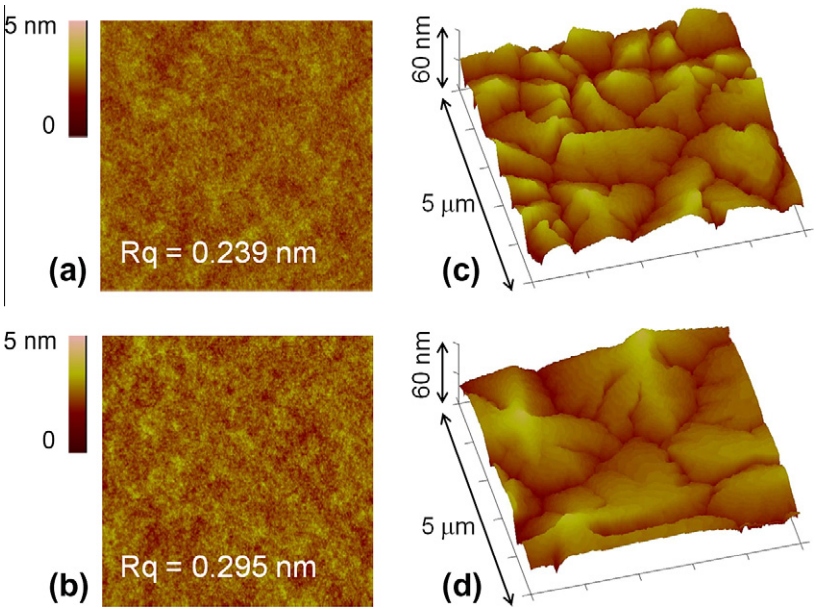

Fig. 3. 5 × 5 μm² AFM images of dielectric surfaces, (a) L-PA-as dep., (b) L-PA-140, and pentacene grains on (c) L-PA-as dep. and (d) L-PA-170.

Table 1
Roughness, contact angle and surface energy of the dielectric surface.

Temperature (°C)	Roughness (nm)	Contact angle (°)		Surface energy (mJ/cm²)
		(H_2O)	(CH_2I_2)	
As dep.	0.239	72.2	27.2	46.4
110	0.278	75.2	30.4	44.8
140	0.295	75.4	31.0	44.5
170	0.314	79.5	31.6	44.2

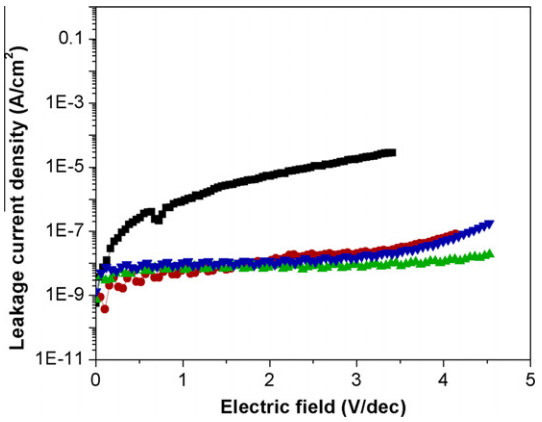

Fig. 4. Leakage current density–electric field (*J*–*E*) characteristics of Au/insulator/n + Si type MIM structures with as deposited (└■─), 110 °C (-○-), 140 °C (-▲-) and 170 °C (-▼-) baked L-PA films. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

dielectric, which can be examined from typical current density–electric field (*J*–*V*) curves, as displayed in Fig. 4. No observable electrical breakdown within our instrumental limit of 4.5 MV/cm implied a high dielectric strength for the film. Leakage current densities at 1 MV/cm were as low as 5×10^{-9}–10^{-8} A/cm² for cured L-PA110–L-PA170, which was superior to other polymer dielectric and even comparable with some inorganic materials [35]. The high dielectric strength and low electrical leakage were attributed to both the linear type polymeric chain and effective cross-linked structures. Linear type chains can aggregate into a dense film with low free volume. The migration and discharge of the ionized molecules cause degradation to carbon and gaseous products, acting as the most popular polymer dielectric breakdown mechanism [35]. Effective cross-linking further densified the dielectric film and produced a network through chemical bonding between polymeric chains reducing the possibility of electrical penetration. This could be achieved at the low processing temperature down to 110 °C.

3.4. Metal–insulator–semiconductor capacitors

By measuring the *C*–*V* (capacitance–voltage) characteristics with MIS capacitor, hysteresis can be observed as seen in Fig. 5. From the shift of the flat band voltage (ΔV_{FB}) in the forward and backward sweep, the charge trap density (N_{trap}) at insulator/semiconductor interface and in the bulk of insulators can be calculated [41–43]. As seen in Fig. 5, the forward and backward curves nearly overlapped with each other, and hence exhibited negligible hysteresis. In the previous reports [28,29,35,44,45], processing temperatures higher than 180 °C were required to reduce the hysteresis behavior for cross-linked polymer.

The maximum capacitance (C_{max}) values in *C*–*V* curve was 6.92 pF, 7.37 pF, 7.62 pF and 7.65 pF for L-PA-as dep., L-PA-110, L-PA-140 and L-PA-170 and the dielectric constant was 4.65, 4.01, 3.78, and 3.65, respectively.

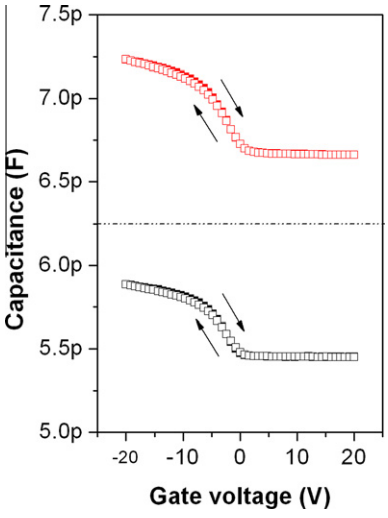

Fig. 5. Forward (└■—) and backward (○) sweeps for *C–V* characteristics of n + Si/insulator/pentacene/Au MIS capacitors with as deposited (in black) and 140 °C baked (in red) L-PA films. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.5. Organic field-effect transistors

Top-contact pentacene FETs were fabricated utilizing as deposited and baked L-PA copolymer thin films as a gate insulator. The transfer and output curves of OFET with L-PA-as dep. and L-PA-140 are compared in Fig. 6a–c and the electrical parameters of the OFETs are summarized in Table 2.

OFET with L-PA-as dep. showed μ of 0.27 $cm^2/V\,s$, on/off current ratio (I_{on}/I_{off}) of 10^4, and subthreshold slope (SS) of 3.58 V/dec, while these parameters were evidently improved with baked dielectrics. OFET with L-PA-140 showed optimized μ of 0.91 $cm^2/V\,s$, I_{on}/I_{off} of 10^6 and SS of 1.81 V/dec and it was confirmed that the optimum curing temperature was 140 °C. The significant improvement in μ was due to the larger pentacene grains, as confirmed in Fig. 3c and d [46]. The relationship between the dielectric surface energy of L-PA-as dep., L-PA-110 and L-PA-140 and the corresponding device field-effect mobility is shown in Fig. 7. The degraded electrical parameters of OFET with L-PA-170 may be attributed to ambient-unstable species, such as anhydrides, which were formed from the side reaction at higher temperature. Also a processing temperature higher than 150 °C is less attractive for fabricating devices on low-cost flexible plastic substrates. The optimized I_{on}/I_{off} of the OFET with L-PA-140 confirmed the most effective cross-linking reactions at 140 °C. As compared in Fig. 6c, the saturated drain current in the output characteristics for L-PA-140 device was almost 4 times higher than L-PA-as dep. This current level satisfied the requirement of the driving transistor for OLED displays (larger than 10 μA) [47,48].

Also the device with cured dielectrics exhibited negligible hysteresis during the full voltage sweep (from 10 to −40 V and then from −40 to 10 V) in both transfer and output characteristics, as shown in Fig. 6a–c. As shown

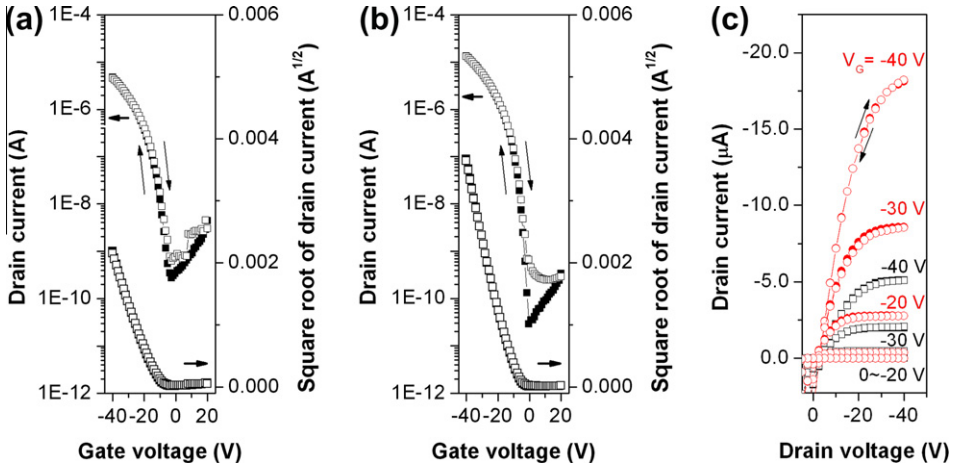

Fig. 6. (a) Output characteristics for OFET with L-PA-as dep. and (b) L-PA-140 with forward (└■—) and backward (○) sweeps. (c) Comparison of output characteristics for OFET with L-PA-as dep. (in black) and OFET-L-PA-140 (in red). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

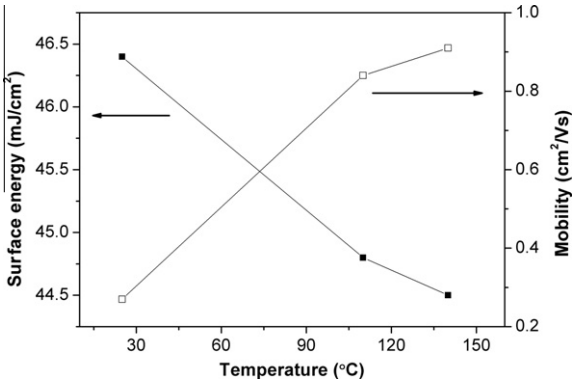

Fig. 7. Surface energy and field-effect mobility as a function of the curing temperature.

in Table 2, ΔV_{th} for L-PA insulated OFETs is small and the optimal ΔV_{th} of 0.43 V was achieved with the 140 °C baked dielectric. The L-PA film baked at 110 °C for 2 h produced small hysteresis gap of ~0.40 V in the transistor transfer characteristics with comparable electrical properties: μ of 0.90 $cm^2/V\,s$, I_{on}/I_{off} ~10^6 and even smaller SS of 1.13 V/dec.

The SS values are closely associated with charge trap density at the pentacene/dielectric interface [49], and the upper limit of the trapped charge density (N_{trap}^{max}) were estimated to be $2.55 \times 10^{12}/cm^2$, $1.32 \times 10^{12}/cm^2$, $9.32 \times 10^{11}/cm^2$, $1.06 \times 10^{12}/cm^2$ for L-PA-as dep., L-PA-110, L-PA-140 and L-PA-170 devices, respectively. Charge trap from electronic defect states at the semiconductor/gate dielectric interface, should be as small as possible, since it causes instability in the threshold voltage of OFET. N_{trap} was decreased as the curing temperature increased up to 140 °C.

4. Conclusion

We reported hysteresis-free pentacene FETs with low-temperature self-curable L-PA copolymer as a gate insulator. Negligible hysteresis could be achieved with thermal cross-linking reaction under a low temperature range between 110–140 °C. The optimized L-PA cured at 140 °C showed high dielectric strength (>4.5 MV/cm) and low leakage current density (5×10^{-9} A/cm^2 at 1 MV/cm) and OFET with this dielectric showed the mobility of ~0.91 $cm^2/V\,s$, on/off current ratio of ~10^6 and low inverse subthreshold slope of 1.13 V/dec. This result showed that L-PA gate dielectric is a promising candidate for low-temperature curable, hysteresis free OFETS.

structure allows for an extended conjugation of the carbazole units over the biphenyl structure leading to a decrease in triplet energy to around 2.56 eV [13]. If the conjugation between the constituting units in carbazole derivatives is minimised the triplet energy can be maintained at a high level. Many approaches to confine the conjugated system in carbazole derivatives have been described in literature. One way to minimise the conjugation in carbazole based host materials introduced by Tokito et al. is to attach two methyl groups in the 2,2′-positions of the central biphenyl in CBP leading to the host material 4,4′-bis(9-carbazolyl)-2,2′-dimethylbiphenyl (CDBP) [14,15]. Due to the steric hindrance the biphenyl is forced into a tilted conformation which reduces the conjugation in the molecule and concomitantly enlarges the triplet energy to 2.79 eV. We recently reported a series of CBP-based materials with high triplet energies using a similar concept by introducing methyl and trifluoromethyl substituents in the 2,2′-positions of the central biphenyl unit [16,17]. Another design concept is to choose different linkers between the carbazole units such as a single phenyl ring instead of biphenyl in *N*,*N*′-dicarbazolyl-3,5-benzene (mCP) [18,13] or non-conjugated units as, for example, an aliphatic cyclohexyl ring, an oxygen-bridge [19] or a diphenylsilane linker [20]. In mCP another effect reduces the conjugation: instead of the *para*-connection, the two carbazole moieties are *meta*-linked over the phenyl ring [21,22]. A major drawback of mCP however is its high crystallinity. Matrix materials with carbazole units linked to a biphenyl in the 3,3′-positions have been described in a patent of Adachi and Forrest [23] and a number of following patents. In the scientific literature *meta*-linked CBP derivatives are to the best of our knowledge only reported in a theoretical study about heterofluorene linker groups between the two carbazoles as alternatives to biphenyl [24]. Besides the high triplet energy a host material has to reveal a stable amorphous phase at device operating temperatures [25]. This ensures homogeneous mixing of the emitter within the matrix material and minimises the effects of concentration quenching. In addition the use of organic glasses in OLEDs helps to avoid

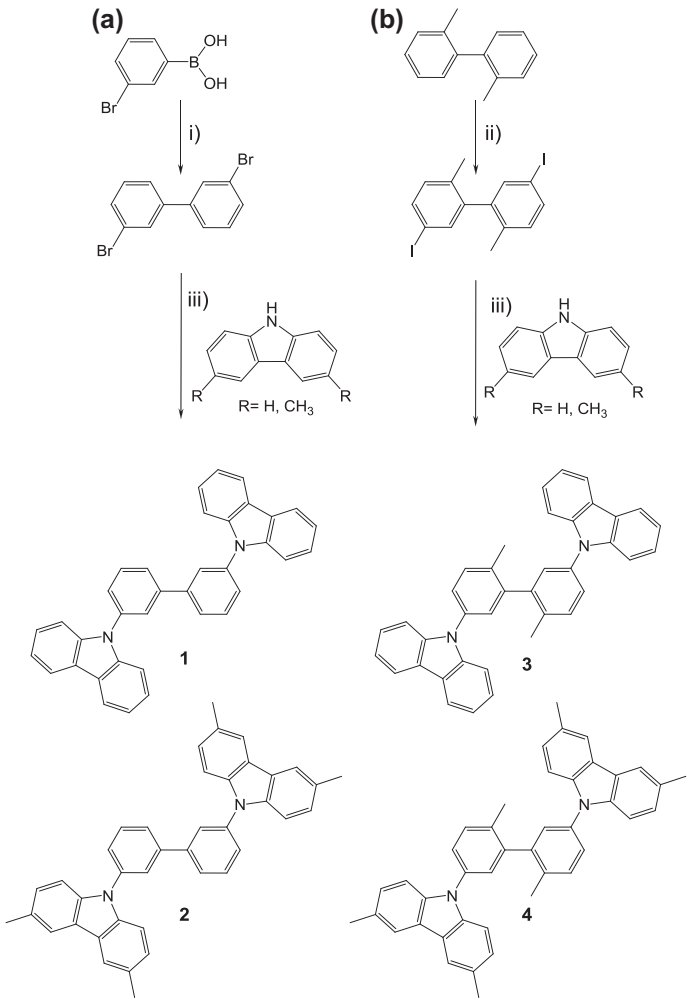

Fig. 1. Chemical structures and synthetic routes to (a) *meta*-linked CBP derivatives **1** and **2** and (b) twisted *meta*-linked CBP derivatives **3** and **4**. Reagents and conditions: (i) $Cu(OAc)_2$, DMF, 100 °C, 90 min; (ii) I_2, HIO_3, H_2SO_4, H_2O, CCl_4, acetic acid, 80 °C, 18 h; (iii) Cu, K_2CO_3, 18-crown-6, *o*-dichlorobenzene, reflux, 24 h.

grain boundaries which may act as trap states [26,27]. Organic glasses can be obtained by avoiding strong intermolecular forces like hydrogen bonding or π–π stacking between the molecules. A very common design concept for molecular glasses is the space-filling star-shaped topology, as in the well-known hole transporting organic glass 4,4′,4″-tris(carbazol-9-yl)triphenylamine (TCTA) [28]. Furthermore, the introduction of bulky substituents leads to a larger intermolecular distance and a hindrance in packing and therefore to amorphous behaviour. For example, in 9-(4-tert-butylphenyl)-3,6-bis(triphenylsilyl)-carbazole (CzSi) [29] and 3,5-di(*N*-carbazolyl)-tetra-phenylsilane (SimCP) [30] packing of the molecules is avoided by introducing bulky triphenylsily groups. However, the separation of the conducting units usually leads to a decrease in charge carrier mobility.

In this work we describe the preparation, the thermal and optical characterisation of four *meta*-linked CBP-derivatives. Materials revealing high triplet energies and amorphous behaviour with high glass transition temperatures are achieved by attaching the carbazole units at the *meta*-position of the phenyl rings of the biphenyl moiety in combination with a selective methyl substitution at the *meta*-CBP structure. The high triplet energy allows the use as host materials for the pure blue carbene emitter *mer*-tris(*N*-dibenzofuranyl-*N*′-methylimidazole)iridium (III) (Ir(dbfmi)). The molecular structures of the host materials **1**–**4** are depicted in Fig. 1.

2. Experimental

2.1. Materials

All chemicals and reagents were used as received from commercial sources without further purification. The solvents for reactions and purification were all distilled before use.

2.2. Characterisation

^{1}H and ^{13}C NMR spectra were recorded with a Bruker AC 300 (300, 75 MHz) and $CDCl_3$ as solvent. All data are given as chemical shifts δ (ppm) downfield from $Si(CH_3)_4$. For optical measurements, 10^{-5} M cyclohexane (Ultrasolv®) solutions of the materials as well as thin films on quartz substrates were prepared by spincoating. The UV/Vis spectra were measured in solution and on neat films with a Hitachi U-3000 spectrometer. Fluorescence spectra in solution were obtained from a Shimadzu spectrofluorophotometer RF-5301PC using excitation at 300 nm. Phosphorescence spectra of thin films have been measured at 5 K (Helium cryostat Optistat CF from Oxford Instruments) applying the technique of time-gated spectroscopy (with fluorescence and phosphorescence lifetime spectrometer FLSP 920 from Edinburgh Instruments). For differential scanning calorimetry measurements (DSC) a Diamond DSC apparatus from Perkin Elmer was used (heating/cooling rate 10 K min^{-1}, nitrogen). Thermogravimetric analysis (TGA) was performed on a Mettler Toledo TGA/SDTA815e machine at a heating rate of 10 K/min under nitrogen. Cyclic voltammetry measurements were carried out in absolute solvents measuring at a platinum working electrode versus a $Ag/AgNO_3$ reference electrode. Each measurement was calibrated against an internal standard (ferrocene/ferrocenium redox system). The purity of the target compounds was checked with a Waters size exclusion chromatography system (SEC) for oligomers (analytical columns: cross-linked polystyrene gel (Polymer Laboratories), length: 2 × 60 cm, width: 0.8 cm, particle size: 5 μm, pore size 100 Å, eluent THF (0.5 mL/min, 80 bar), polystyrene standard).

2.3. Computational methods

The transport levels of the materials used were determined via density functional calculations. For the ionisation potential and the electron affinity first the geometry of the neutral as well as the charged states were optimised using the BP86-functional [31,32] in combination with a split-valence basis set (SV(P)) including polarisation functions on all heavy atoms [33]. For iridium an effective core potential was employed [34]. For the energetics we performed single point calculations at the optimised geometries using the same functional in combination with a TZVP-basis set [35]. To account for dielectric solid state effects a UPS/IEPS-calibrated version of the conductor like screening model (COSMO) [36] was used in conjunction with these single point calculations. All calculations were carried out with the turbomole program package [37].

2.4. Synthetic procedures

The synthesis of tris[(3-phenyl-1*H*-benzimidazol-1-yl-2(3H)-yliden-1,2-phenylene]-irdidium (DPBIC) [38], 2,8-bis(triphenylsilyl)-dibenzofuran (DBFSi) [39], *mer*-tris(*N*-dibenzofuranyl-*N*′-methylimidazole)-iridium (III) (Ir(dbfmi)) [5,39] and 3,6-dimethyl-carbazole [16] is described in literature.

3,3′-Dibromobiphenyl was synthesized according to a procedure reported by Demir et al. [40] Yield: 43%. EI-MS *m/z*: 312 (100, M$^+$), 232 (5), 152 (95). ^{1}H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.70 (dd, 2H), 7.52–7.46 (m, 4H), 7.31 (dd, 2H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm): 142.11, 131.16, 130.74, 130.50, 126.09, 123.33.

5,5′-Diiodo-2,2′-dimethylbiphenyl: 2,2′-Dimethylbiphenyl (9.9 g, 54 mmol) in 120 mL of acetic acid and 5.5 mL of water were heated to 90 °C to get a clear solution. After the addition of iodine (10.9 g, 43 mmol), iodic acid (5.7 g, 32 mmol), 5.5 mL of sulphuric acid and 5.5 mL of tetrachloromethane the solution was stirred at 80 °C for 18 h. The excess of iodine was removed by adding a solution of sodium hydrogen sulphide. The product was extracted with dichloromethane and washed several times with water. After drying the organic layer over anhydrous sodium sulphate, the solvent was evaporated. The resulting yellowish oily product was recrystallised from ethyl acetate to yield 6.9 g (16 mmol, 30%) of a white solid. EI-MS *m/z*: 434 (100, M+), 180 (50), 165 (47). ^{1}H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.58 (dd, 2H), 7.42 (ds, 2H), 7.00 (d, 2H). 1.99 (s,

6H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm): 142.30, 137.65, 136.56, 135.48, 131.83, 90.41, 19.38.

2.5. General procedure for the Ullmann- type reaction

Dihalogenobiphenyl (2.3 mmol), carbazole (5.06 mmol), potassium carbonate (2.5 g, 18.4 mmol), copper powder (0.58 g, 9.2 mmol) and 18-crown-6 (0.12 mg, 0.46 mmol) were refluxed in 15 mL of *o*-dichlorobenzene in an argon atmosphere for 24 h. Copper and inorganic salts were filtered off and the solvent was evaporated. Column chromatography on silica gel with mixtures of hexane/tetrahydrofurane as eluent yielded the products **1**–**4** as white solids.

3,3′-Bis(carbazolyl)biphenyl (**1**): Yield: 47%. EI-MS *m*/*z*: 484 (100, M+), 316 (10), 234 (39). ^{1}H NMR (300 MHz, CDCl3), δ (ppm): 8.17 (d, 4 H), 7.88 (m, 2H), 7.75 (dt, 2H), 7.70 (dd, 2 H), 7.60 (dt, 2H), 7.51 (d, 4H), 7.43 (dt, 4H), 7.31 (dt, 4H). (^{13}C NMR (75 MHz, CDCl3), δ (ppm): 142.42, 141.19, 138.82, 130.84, 126.80, 126.52, 126.39, 126.10, 123.79, 120.71, 120.40, 110.08.

3,3′-Bis(3,6-dimethylcarbazolyl)biphenyl (**2**): Yield: 55%. EI-MS *m*/*z*: 540 (100, M+), 345 (5), 270 (24). ^{1}H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.92 (m, 4H), 7.86 (m, 2H), 7.70 (dt, 2H), 7.66 (dd, 2H), 7.57 (dt, 2H), 7.38 (d, 4H), 7.24 (dd, 4H), 2.56 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm): 142.38, 139.63, 139.24, 130.70, 129.55, 127.52, 126.41, 126.05, 125.76, 123.84, 120.56, 109.75, 21.74.

3,3′-Bis(carbazolyl)-6,6′-dimethylbiphenyl (**3**): Yield: 50%. EI-MS *m*/*z*: 512 (100, M^+), 329 (8), 257 (17), 166 (12). ^{1}H NMR (300 MHz, $CDCl_3$), δ (ppm): 8.15 (d, 4H), 7.55–7.39 (m, 14H), 7.32–7.26 (m, 4H), 2.33 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm): 142.51 141.25 135.65, 135.46, 131.85, 127.96 126.45, 126.26, 123.67, 120.65, 120.20, 110.09, 20.11.

3,3′-Bis(3,6-dimethylcarbazolyl)-6,6′-dimethylbiphenyl (**4**): Yield: 55%. EI-MS *m*/*z*: 568 (100, M^+), 358 (15), 284 (29), 192 (24). ^{1}H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.90 (s, 4H), 7.52–7.45 (m, 4H), 7.41–7.38 (m, 4H), 7.33 (d, 4H), 7.21(d, 4H), 2.55 (s, 12H), 2.30 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm): 142.47, 139.72, 136.06, 134.98, 131.70, 129.30, 127.69, 127.39, 126.10, 123.70, 120.49, 109.74, 21.73, 20.06.

2.6. OLED fabrication

The organic layers were deposited by thermal evaporation in high vacuum (<10^{-6} mbar) onto indium-tin-oxide (ITO, 10 ohm/square) precoated glass substrates. Prior to use the ITO glass was degreased using organic solvents and cleaned using an UV-ozon oven for 30 min. The organic layers and the metal cathode were evaporated without breaking the vacuum. The current density–luminance–voltage (J–L–V) characteristics of the OLEDs were measured by a Keithley source meter 2400 and a Konica Minolta CS-200, respectively. EL spectra were taken by a CCD spectral analyser by Zeiss. EQEs were calculated from the luminance, current density, and EL spectrum, assuming a Lambertian distribution.

3. Results and discussion

3.1. Synthesis

In Fig. 1a the synthetic route to the *meta*-linked CBP derivatives **1** and **2** is depicted. In a copper-mediated homocoupling reaction 3-bromophenylboronic acid reacts to 3,3′-dibromobiphenyl [40]. An Ullmann-type reaction of dibromobiphenyl with carbazole or 3,6-dimethylcarbazole [16] yields the host materials.

To obtain the twisted *meta*-linked CBP-derivatives **3** and **4**, first, 5,5′-diiodo-2,2′-dimethyl-biphenyl was prepared by direct iodination [41] of 2,2′-dimethylbiphenyl with iodine and iodic acid in acetic acid (Fig. 1b). Via 2D ^{1}H NMR experiments (see Supporting Information) the selective iodination at the 5- and 5′-positions of the biphenyl could be confirmed. Here, the inductive effect of the methyl groups in the 2- and 2′-positions of the biphenyl increases the electron density in the 5- and 5′-positions and favours the electrophilic attack of I^+. We consider this 5,5′-diiodo-2,2′-dimethylbiphenyl unit as a versatile building block for the synthesis of materials with confined conjugation which, to the best of our knowledge, has not been described in the literature before. The tilted *meta*-linked CBP derivatives **3** and **4** were prepared via the Ullmann-type reaction of 5,5′-diiodo-2,2′-dimethylbiphenyl with carbazole or 3,6-dimethylcarbazole [16].

Mass spectrometry, ^{1}H and ^{13}C NMR spectroscopy were used to identify the materials. The data are given in the experimental part. All materials were purified by repeated zone sublimation.

3.2. Thermal properties

We examined the thermal properties of the *meta*-linked CBP derivatives **1**–**4** by thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC) in nitrogen atmosphere at a scanning rate of 10 K min^{-1}. All results are summarised in Table 1.

Both the *para*-linked CBP and the *meta*-linked **1** show crystalline behaviour in the DSC experiment. For the *meta*-derivative **1** the melting and the crystallisation are observed at around 10 °C lower temperatures than for CBP. Methyl substitution at the pendant carbazoles in **2** leads to a material with a much lower tendency to crystal-

Table 1
Thermal properties of CBP and the *meta*-linked host materials **1**–**4**.

	T_g (°C)	T_m (°C)	T_{cr} (°C)	T_{id}[a] (°C)
CBP	–	283	205[b]	365
1	–	271	191[b]	315
2	107	270	184[c]	349
3	108	237	176[c]	319
4	120	212	–	319

T_g: glass-transition temperature, T_m: melting temperature, T_{cr}: crystallisation temperature and T_{id}: initial decomposition temperature.

[a] T_{id} is the temperature at which an initial mass loss was observed in a thermogravimetric experiment with a heating rate of 10 K min^{-1} in a nitrogen atmosphere.

[b] Observed during cooling scan.

[c] Observed only during the heating scan.

lise. The glass transition of **2** is observed at 107 °C and the recrystallisation is observed at a high temperature of 184 °C. In compound **3** the introduction of methyl groups only at the central biphenyl unit leads to nearly the same glass transition temperature of 109 °C and nearly the same recrystallisation temperature of 176 °C. The biphenyl substitution in combination with the methyl substitution at the carbazoles increases the T_g even to 120 °C for compound **4**. Moreover, for compound **4** crystallisation is observed neither in the cooling nor in the heating cycle which renders **4** the derivative of the series with the highest tendency to form a molecular glass. This thermal investigation shows that the introduction of additional methyl groups at the central biphenyl and/or the adjacent carbazole moieties of the *meta*-linked molecular structure has beneficial effects on the thermal properties, i.e. amorphous materials with high T_gs in the range of 107–120 °C are obtained.

3.3. Optical properties

The room temperature UV/Vis absorption and fluorescence spectra of 10^{-5} M cyclohexane solutions of **1**–**4** are depicted on top of Fig. 2. Compounds **1** and **3** as well as compounds **2** and **4** show very similar spectra. In each compound the absorption and photoluminescence behaviour is dominated by optical transitions localised on the carbazole units. Since the chromophore in compounds **1** and **3** and in compounds **2** and **4** are identical it is not surprising that these two pairs of materials show nearly the same absorption and fluorescence spectra. For compound **2** and **4** the additional methyl substituents on the chromophore 3,6-dimethylcarbazole cause a bathochromic shift of 13 nm in the absorption and emission spectra compared to compounds **1** and **3**.

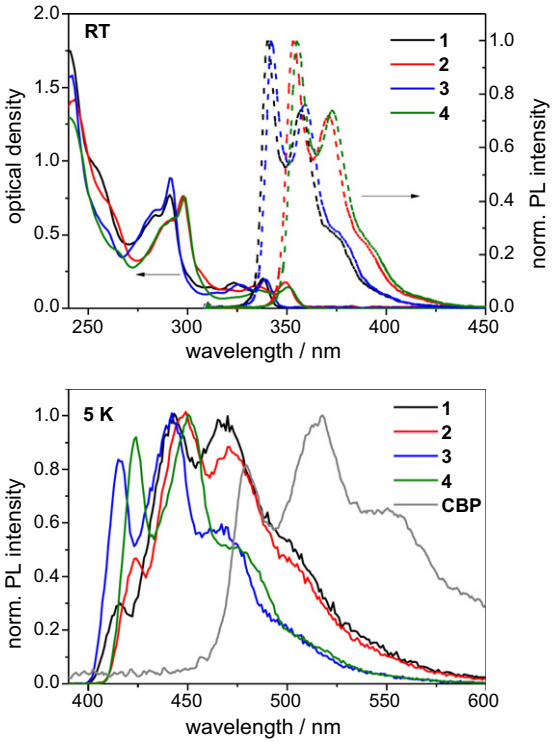

Fig. 2. Top: absorption and fluorescence spectra of **1**–**4** taken in 10^{-5} M solutions in cyclohexane at 300 K. Bottom: normalised phosphorescence spectra of CBP and **1**–**4** measured in 2 wt.% solid solution of the compounds in PMMA at 5 K.

As a prerequisite for the application of **1**–**4** as host materials, their triplet energy has to be higher compared to that of the blue phosphorescent emitter. By measuring phosphorescence at low temperatures the triplet energies can be experimentally determined as the highest energy peak of luminescence.

In order to understand how the *meta*-linkage of the carbazole units affects the triplet energy we compare the phosphorescence spectra of the *para*-linked CBP and the *meta*-linked derivative **1**–**4**. The most striking difference in the normalised spectra (see Fig. 2, bottom) is the remarkable blue shift in phosphorescence of **1**–**4** compared with CPB. The emission of **1**, for example, is shifted to lower wavelengths by 65 nm compared with CBP, corresponding to triplet energies ($\Delta E(T_1–S_0)$) of 2.98 eV for **1** and 2.58 eV for CBP. This is a proof of the design concept of *meta*-connection to achieve high triplet energies. In fact, the methyl substitution at the central biphenyl moiety is expected to lead to even higher triplet energies by introducing torsion between the phenyl rings of the biphenyl unit as is well known from CDBP. However, in the case of the *meta*-linked host materials the additional twisted molecular structure has only minor effects on the emission characteristics. Similar to the emission at room temperature, compounds **1** and **3** and compounds **2** and **4** reveal the highest energy peaks at the same wavelength, while the shape of the phosphorescence spectra is different. In the case of the twisted methyl substituted biphenyl containing compounds **3** and **4** the 0–0 transition is more pronounced and the width of the spectra is smaller than for **1** and **2**. As an effect of the methyl substitution at the 3- and 6-positon of the carbazole units we observe again a small bathochromic shift of ca. 10 nm for compounds **2** and **4** compared to **1** and **3**.

All results of the photo physical investigations of CBP and the *meta*-linked matrix materials **1**–**4** are summarised in Table 2.

3.4. Cyclic voltammetry

The electrochemical behaviour of **1**–**4** was investigated by cyclic voltammetry in a conventional three-electrode setup using a platinum working electrode, a platinum wire as counter electrode, and a $Ag/AgNO_3$ reference electrode. Particularly, the oxidation behaviour of **1**–**4** in dichloromethane solutions was studied. From the half-wave potential of the first oxidation relative to ferrocene the HOMO value of the compounds can be deduced. By adding the optical band gap to the HOMO value the LUMO value can be estimated. As the cyclic voltammetry is measured in solution and not in the solid state the values of HOMO and LUMO may differ from the solid state values in an OLED. Both the experimentally received and the calculated values for the energy levels of CBP and of **1**–**4** are listed in

Table 2
Optical properties and energy levels of CBP and the *meta*-linked host materials 1–4.

	Solution	Film	Solution	Film	Film	Calculated		Experimental	
	λ_{EA}[a] (nm)	λ_{EA}[b] (nm)	λ^{RT}_{em}[c] (nm)	λ^{5K}_{em}[d] (nm)	λ^{5K}_{em}[e] (nm)	HOMO (eV)	LUMO (eV)	HOMO[g] (eV)	LUMO[h] (eV)
CBP	350	357	356, 374	484	477	−5.58	−1.78	−5.63	−2.16
1	344	354	340, 357	421	415	−5.71	−1.77	−5.65	−2.15
2	357	365	353, 370	452[f]	421	−5.48	−1.71	−5.56	−2.17

4	358	369	355, 373	431	421	−5.44	−1.47	−5.53	−2.17

[a] Absorption edge measured in 10^{-5} M cyclohexane solutions at room temperature.
[b] Absorption edge measured on neat films at room temperature.
[c] Wavelengths of the intensity maxima of the fluorescence at 300 nm excitation of 10^{-5} M cyclohexane solutions at room temperature.
[d] Measured on film samples (100%) at 5 K.
[e] Measured in 2 wt.% PMMA at 5 K.
[f] No 0–0 transition is observed.
[g] Estimated from the half-wave potential of the first oxidation in the cyclic voltammetry experiment.
[h] Estimated from the HOMO values and the optical band gap (determined from the UV/Vis absorption onset of neat films).

Table 2. The *meta*-linked compounds **1** and **3** with unsubstituted carbazole units reveal almost the same energy levels as for CBP. In contrast, **2** and **4** show ca. 10 mV higher HOMO levels which can be attributed to the inductive effect of the additional methyl groups in the 3- and 6-positons of the carbazole units. The cyclic voltammetry experiments show that the behaviour upon oxidation is clearly dominated by the molecules' site with the highest electron density, i.e. the carbazole moieties. Contrary to the theoretical expectations, the substitution on the central biphenyl unit does not affect the HOMO levels and fairly no effects of the different substitution pattern on the LUMO levels are observed.

Charge transport processes in organic semiconductors involve the formation of radical anions and cations. Thus, investigations of the electrochemical stability can give information about the stability of the materials in OLED devices. To evaluate the electrochemical stability of the materials we carried out multicycle experiments. The cyclic voltammograms showing five repeated oxidation cycles of **1** and **2** in 2×10^{-3} M dichloromethane solutions are given as Supporting Information. In the case of **1**, the oxidation cycles are not reproducible. After the first reduction into the uncharged molecule at 0.88 V an additional reduction at around 0.59 V is observed. The latter can be attributed to new oligomeric species formed during dimerisation reactions at the active 3- and 6-positions of the carbazole units after the first oxidation of the molecule [42,43]. As the oligomeric species is oxidised more easily the corresponding oxidation process takes place at a lower voltage of around 0.70 V. In contrast, **2** reveals a fully reversible oxidation behaviour. The methyl substitution at the adjacent carbazole units blocks the electroactive 3- and 6-positions and renders the oxidised species stable against dimerisation in solution. The same stability of the radical cations was also found for compound **4** in contrast to **3**.

3.5. Blue phosphorescent organic light-emitting diodes

Common blue phosphors as for example FIrpic and FIr6 show blue emission tailing to the green region with emission maxima at 472 nm (CIE colour coordinates $x = 0.17$, $y = 0.34$) [14] and 458 nm (CIE colour coordinates $x = 0.16$, $y = 0.26$) [44], respectively. For solid state lighting, phosphors with a more saturated blue emission would be beneficial. Due to the high triplet energy of more than 2.9 eV the host materials **1**–**4** should be suitable for saturated blue emitters. Thus, we have tested the host materials with the pure blue carbene emitter Ir(dbfmi) with a $\lambda_{em} = 450$ nm and CIE colour coordinates of $x = 0.16$, $y = 0.18$.

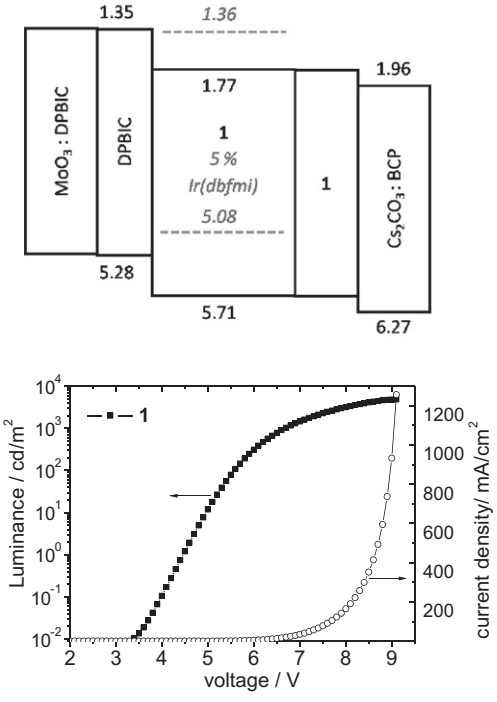

Fig. 3. Top: energy level diagram of the OLED device with the configuration ITO/PEDOT:PSS/MoO_3-doped DPBIC (10 nm)/DPBIC (10 nm)/**1**: Ir(dbfmi) (5 %, 20 nm)/**1** (10 nm)/Cs_2CO_3-doped BCP (20 nm)/Cs_2CO_3 (1 nm)/Al (100 nm) employing **1** as host for Ir(dbfmi); ionisation potentials and electron affinities obtained from calculations are indicated. The grey dotted lines represent the levels of the emitter Ir(dbfmi). Bottom: luminance-voltage plot (filled symbols) and current density–voltage characteristic (open symbols).

The first OLED device setup is shown in Fig. 3. On top of the ITO glass substrate poly(3,4-ethylene-dioxythiophene):poly(styrenesulphonate) (PEDOT:PSS) was applied by spin coating as hole injection layer followed by 10 nm DPBIC p-doped with molybdenum(VI) oxide as hole transporting layer. An additional 10 nm thick layer of DPBIC followed as exciton and electron blocker. The 20 nm emission layer consisted of 5% Ir(dbfmi) doped into the *meta*-linked CBP host materials. Ten nanometer of the host material were deposited as hole and exciton blocking layer followed by 20 nm of caesium carbonate doped 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) as electron transporting layer. As cathode 1 nm Cs_2CO_3 and 100 nm aluminium were deposited.

The turn-on voltage at 1 cd m^{-2} of 4.5 V is quite high and luminances of 100 and 1000 cd m^{-2} are achieved at voltages of 5.6 and 6.8 V, respectively. In some cases we observed a small contribution of the hole transporting material DPBIC to the emission. This indicates that the exciton formation is shifted towards the hole conducting layer. We attribute this to the high energy barrier for hole injection from the DPBIC into the emission layer causing as well the high turn-on voltage. In contrast, electrons do not have to overcome major energy barriers.

To improve the hole injection into the emission layer we coevaporated the hole transporting DPBIC into the emission layer providing a barrier free path for holes. The optimised device setup and the molecular structures of the materials used are shown on top of Fig. 4. Ten nanometer molybdenum(VI) oxide doped DPBIC as hole transporting layer and an additional 10 nm thick layer of DPBIC were used as exciton and electron blocker. The 20 nm thick emission layer comprises a mixed matrix system of the carbazole containing host materials **1**–**4** with DPBIC and the blue emitter Ir(dbfmi) in the ratio 75:20:5. 2,8-Bis (triphenylsilyl)-dibenzofuran (DBFSi) (5 nm) was used as exciton and hole blocking material followed by 5 nm BCP and 40 nm BCP n-doped with Cs_2CO_3. As cathode 1 nm Cs_2CO_3 and 100 nm aluminium were deposited.

In the electroluminescence spectrum of the optimised device setup the pure emission of the phosphor Ir(dbfmi) can be observed with CIE-coordinates of $x = 0.16$ and $y = 0.18$ (Fig. 4, bottom). The CIE-coordinates do not change within the voltage range between 4.2 and 8.2 V. By decreasing the hole injection barrier in the mixed matrix

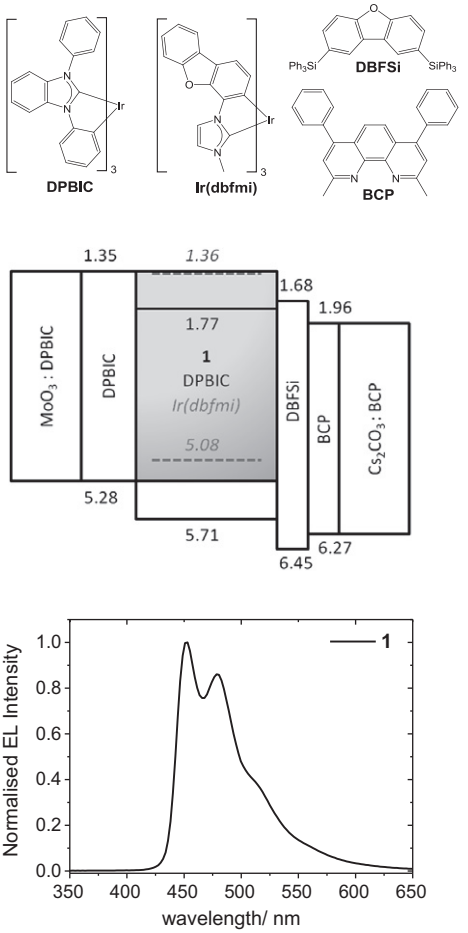

Fig. 4. Top: energy level diagram of the optimised OLED device with the configuration ITO/PEDOT:PSS/MoO_3-doped DPBIC (10 nm)/DPBIC (10 nm)/**1**: DPBIC:Ir(dbfmi) (75:20:5, 20 nm)/DBFSi (5 nm)/BCP (5 nm)/Cs_2CO_3-doped BCP (40 nm)/Cs_2CO_3 (1 nm)/Al (100 nm) employing **1** as host for Ir(dbfmi) with chemical structures of the materials used; Ionisation potentials and electron affinities obtained from calculations are indicated. The grey dotted lines represent the levels of the emitter Ir(dbfmi). Bottom: electroluminescence spectrum of the devices with **1** as host material for Ir(dbfmi) at 4.25 V. CIE coordinates: $x = 0.16$, $y = 0.18$.

η_C: Current efficiency; η_P: power efficiency; η_{ext}: external quantum efficiency.

system the exciton formation zone could be successfully separated from the hole transporting layer. Moreover, the applied voltages at 100 and 1000 cd m^{-2} could be significantly lowered, to 3.5 and 4.4 V, respectively, in the case of host **1** (see Fig. 5).

Peak luminances are 5300 cd m^{-2} for **1**, 5000 cd m^{-2} for **2**, 10,800 cd m^{-2} for **3** and 9300 cd m^{-2} for **4**. For hosts **1** and **3** higher luminances are reached at lower voltages than for **2** and **4**. Comparing the efficiencies of the four *meta*-linked CBP-derivatives **1**–**4**, the compounds **2** and **4** with methyl substituents at the 3- and 6-positions of the carbazole units show significantly lower efficiencies than **1** and **3**. As evident from the current density–voltage-plot in Fig. 5, higher operation voltages are needed in the devices employing the host materials **2** and **4**. One possibility might be that the transport properties of **2** and **4** with methyl substituents at the carbazole units are worse compared to **1** and **3** with unsubstituted carbazole units. In contrast, **1** and **3** give similar performances with slightly better values for **3** at higher luminances. The highest efficiency was achieved for **3** with an external quantum efficiency of 8.7% and a power efficiency of 10.2 lm W^{-1} at 100 cd m^{-2} and 6.1% and 6.0 lm W^{-1} at 1000 cd m^{-2}. These efficiencies are comparable to those of Ir(dbfmi) in the phosphine oxide based host material PO9 recently reported by Sasabe et al. [5] At a brightness of 1000 cd m^{-2} they reported an external quantum efficiency of 6.2% which compares well with the external quantum efficiency of 6.1% we found for the host material **3**. All performance data are summarised in Table 3.

The large differences in device performance as evident from Table 3 are quite surprising as the chemical structures of all hosts **1**–**4** are very similar. These findings show that each combination of emitter and host needs to be chosen very carefully as the host-emitter-system is very sensitive to even small structural variations which may change the charge-carrier balance in the device or the chemical compatibility of host and emitter. Both effects in conjunction with the relatively long triplet lifetime of Ir(dbfmi) of ~20 μs [5] could negatively influence the device performance.

4. Conclusions

We have described a series of CBP derivatives with a *meta*-linkage of the carbazole moieties to the central biphenyl unit. By selective methyl substitution at two sites of the basic *meta*-CBP structure, the 3- and 6-position of the pendant carbazoles and at the 6- and 6′-position of the biphenyl unit, the tendency to crystallise could be lowered. Glass transition temperatures in the range of 107–120 °C were achieved. The *meta*-linkage reduces the conjugation of the molecules effectively, leading to high triplet energies in the range of 2.93–2.98 eV compared with 2.58 eV for CBP. Here, the additional twist by the methyl substitution at the biphenyl unit does not increase the triplet energy any further, but narrows the phosphorescence spectra of **3** and **4** compared with **1** and **2**. Introducing methyl groups at the 3- and 6-position of the pendant carbazole units in the matrix materials **2** and **4** leads to electrochemical stability of the oxidised species in cyclic voltammetry. First results from OLED tests show that *meta*-linked CPB-derivatives are suited host materials for blue emitters, e.g., Ir(dbfmi), with pure blue emission at 450 nm. The highest efficiencies were achieved with the twisted *meta*-linked derivative **3** giving external quantum efficiencies of 8.7% and 6.1% and power efficiencies of 10.2 and 6.0 lm W^{-1} at 100 and 1000 cd m^{-2}, respectively.

Acknowledgements

We thank Irene Bauer for the help during synthesis and characterisation of the host materials and Christian Bonsignore and Mustapha Al-Helwi for their support during the device fabrication and characterisation. We also thank Dr. Ingo Münster, Dr. Evelyn Fuchs and Dr. Soichi Watanabe for scientific discussions. Financial support from the BMBF project TOPAS 2012 (FKZ 13N 10447) is gratefully acknowledged. P.S. thanks the Universität Bayern e.V. for a grant. Supporting Information is available online.

and charges inside the EMLs may suffer faster degradation condition due to bimolecular phenomena such as exciton-charge quenching process [5,6].

We use delayed electroluminescence (EL) measurements to gain insights about the phenomena governing the EL efficiency loss with prolonged electrical driving of PHOLEDs. In this work, PHOLEDs containing HBLs of 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) or BAlq, two widely used hole blocking materials, are investigated The study also utilizes specially designed PHOLEDs that include a 4-[dicyanomethylene]-2-t-butyl-6-(1,1,7,7-tetramethyljulolidyl-9-enyl)-4H-pyran (DCJTB)-doped "sensor" layers. The results show a strong correlation between the extent of hole blockage capacity of the HBL and the rate of deterioration in device EL efficiency, pointing to the major role that the build-up of hole space charges in the emitting layer (EML) plays in EL degradation. In this regard, the use of a strongly blocking material significantly increases the build-up of holes in the EML, and accelerates EL degradation.

2. Experimental

Indium-tin-oxide (ITO) is used as an anode, and 100 nm thick Mg:Ag capped with Ag is employed as a cathode. The ITO substrates are cleaned with water, acetone and isopropanol in an ultrasonic bath followed by O_2 plasma treatment. All the organic materials and the cathode metals are deposited using thermal evaporation in vacuum condition at a base pressure of about 4×10^{-6} torr. In this study, PHOLEDs based on archetypical *4,4′-bis(carbazol-9-yl)biphenyl* (CBP) and *tris(2-phenylpyridine)iridium(III)* ($Ir(ppy)_3$) host–guest phosphorescent system in the emitting layer are used. *N,N′-di(naphthalene-1-yl)-N,N′-diphenyl-benzidine* (NPB) and aluminum tris(8-hydroxyquinoline) (Alq_3) are utilized as hole transport layer and electron transport layer (ETL), respectively. In devices with HBL, a 10 nm thick layer of BCP or BAlq is inserted between the emitting layer and the ETL. In devices with sensor layer, DCJTB is doped at 1 vol.% in a ~5 nm thick portion of the ETL, adjacent to the EML or HBL. Detailed device structures and measurement techniques are outlined in the following section.

3. Result and discussion

Fig. 1 shows changes in EL intensity with driving time in devices of the following structures:

- ITO/NPB (50 nm)/CBP:$Ir(ppy)_3$ (92%:8%, 40 nm)/Alq_3 (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as No HBL).
- ITO/NPB (50 nm)/CBP:$Ir(ppy)_3$ (92%:8%, 40 nm)/BAlq (10 nm)/Alq_3 (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BAlq HBL).
- ITO/NPB (50 nm)/CBP:$Ir(ppy)_3$ (92%:8%, 40 nm)/BCP (10 nm)/Alq_3 (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BCP HBL).

All devices are driven using an AC driving scheme [14] at an average current density of 20 mA/cm^2. The initial luminance and driving voltage of these devices are as shown in Table 1. As can be seen from the figure, the device with BCP HBL shows a significantly lower EL stability compared to the other two devices. The other two devices, on the other hand, show similar EL stability trends. We also measured the EL stability, also using AC driving, at the same initial luminance of 2000 cd/m^2. The results are shown in the inset of Fig. 1. Clearly in both aging schemes, the device with the BCP HBL shows much lower EL stability, whereas the devices with BAlq HBL and no HBL demonstrate the similar EL stability trends. We note that the observed stability is similar to that reported by some groups for the same device structure [15,16] but lower in comparison to other reports [17]. The wide variation in stability can be attributed to variations in ITO and organic materials obtained from different suppliers. In our case, the materials are purchased from the Luminescence Technology and are used as received.

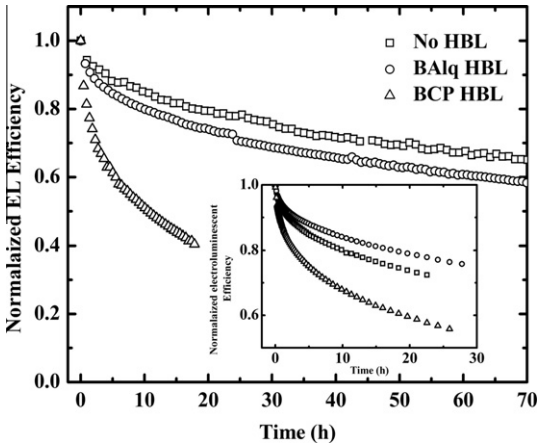

Fig. 1. Normalized EL efficiency versus time of devices without HBL and with BAlq and BCP HBLs, under AC driving at an average current density of 20 mA/cm^2. Inset: Normalized EL efficiency versus time of an identical set of devices also driven using AC driving at an initial luminance of 2000 cd/m^2.

To investigate the extent by which the HBLs reduce the leakage of holes from the EML towards the cathode, and any possible correlations with the observed changes in device stability when a HBL is used, we study a series of similar devices that contain a DCJTB-doped zone in the ETL, to act as a sensor layer. Fig. 2 shows a schematic energy band diagram of these devices, whereas Table 2 gives the driving voltage and EL intensity at 20 mA/cm^2 current density. Clearly the driving voltage of these devices is very similar to those without the sensor layer (<0.5 V) demonstrating that the presence of the sensor layer does not significantly

Table 1
Electrical and optical characteristics of the devices at 20 mA/cm^2 current density.

Device	Voltage (V)	Brightness (cd/m^2)	CIE
No HBL	10.4	1790	0.330, 0.597
BAlq HBL	10.58	2850	0.337, 0.597
BCP HBL	10.87	4130	0.331, 0.602

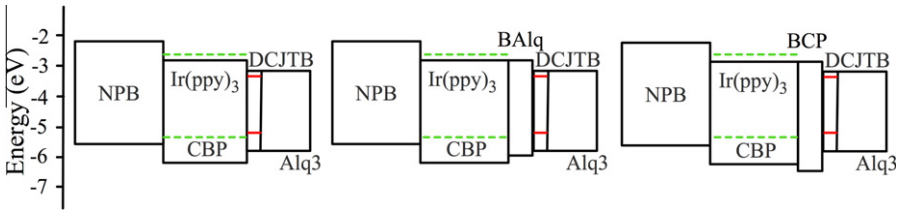

Fig. 2. Schematic structure of devices A, B and C. Layer thicknesses used for these devices are as follow: NPB = 40 nm, CBP:Ir(ppy)$_3$ = 40 nm, Alq$_3$ = 25 nm, Alq$_3$:DCJTB = 5 nm, BAlq = 10 nm, and BCP = 10 nm.

Table 2
Electrical and optical characteristics of the devices at 20 mA/cm^2 current density.

Device	Voltage (V)	Brightness (cd/m^2)	CIE
A	10.8	1640	0.371, 0.576
B	10.6	3200	0.345, 0.601
C	10.9	4660	0.336, 0.605

modify charge injection and transport in the devices. We also measured the EL stability of these devices and found to be very similar to ones without sensor layer. Fig. 3 shows EL spectra collected from the same devices. As expected, all devices show strong emission bands in the green range, with the characteristic Ir(ppy)$_3$ peak at 511 nm. The spectrum of device A is slightly broader in the red range, suggestive of some red emission from DCJTB sensor layer as would be expected due to the absence of HBL. To gain more insights about differences among these devices, we study them using delayed EL measurements. In this technique, a device is driven using a square pulse driving scheme, with a forward bias of 10 V and a pulse width of 0.5 ms (the pulse is sufficiently long for prompt EL to reach its steady-state intensity). The optical shutter opens to collect delayed EL around 0.3 ms after the forward bias is turned off, which is significantly longer than the lifetime of Ir(ppy)$_3$ triplet state lifetime (<1 μs) to ensure the absence of any contributions from prompt EL in the collected signal. As such, any collected signal will arise from the radiative decay of excitons that are formed, after the bias

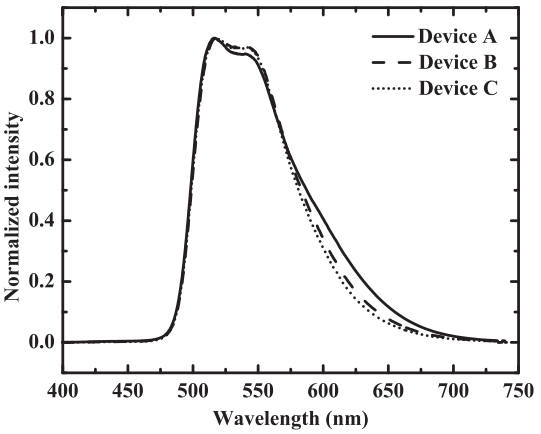

Fig. 3. Prompt EL spectra of devices A, B and C.

is removed, by means of (i) delayed recombination of detrapped charges, or (ii) various bimolecular exciton interactions. In order to distinguish between these processes, a 0.5 ms reverse bias pulse, of magnitude −10 V, is applied on the devices during the delayed EL signal collection, and subsequent changes in delayed EL characteristics are recorded. The detailed timing setup for delayed EL measurement was reported in our previous work [18], and is shown schematically in Fig. 4. As can be seen from the figure, delayed EL spectra show much more pronounced emission from DCJTB (611 nm peak band) in case of devices A (no HBL) and B (BALq HBL), but not in case of device C (BCP HBL) revealing that, unlike BCP, hole blockage by BAlq is only partial. The fact that emission from the DCJTB sensor layer is much more pronounced in delayed EL (i.e. Fig. 5) versus prompt EL (i.e. Fig. 3) can be attributed to the fact that holes are much less mobile in Alq$_3$ (due to its very low hole mobility) and therefore get essentially trapped on reaching the ETL. As residual electrons get swept back from the EML and HBL towards the cathode by the reverse bias pulse, they recombine with these trapped holes producing the observed delayed EL from the sensor layer. Regardless of the exact mechanism, the results in Fig. 5 convincingly prove that more holes reach the ETL in case of device B (BAlq HBL) than in case of device C (BCP HBL).

Finding that the use of a marginally blocking HBL (i.e. BAlq) results in a marginal decrease in device EL stability (from Fig. 1), whereas the use of a strongly blocking HBL (i.e. BCP) results in a significant decrease in EL stability, the question whether the observed changes in EL stability in Fig. 1 are due to variations in the extent of accumulation of holes in the EML naturally arises. To determine the relative concentration of trapped charges in the EML of these devices, we measure changes in their delayed EL intensity

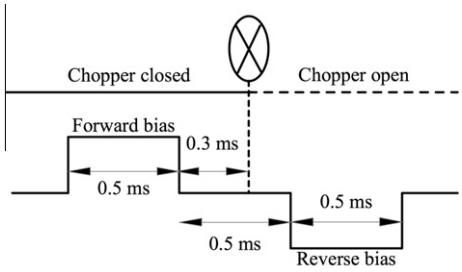

Fig. 4. Schematic diagram of the driving and signal collection timing scheme.

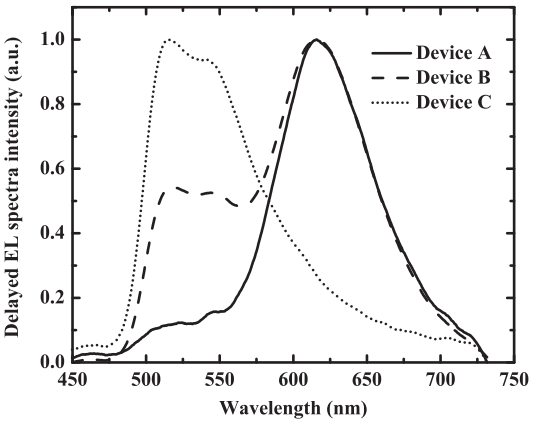

Fig. 5. Delayed EL spectra of devices A, B and C.

with time, monitoring the effect of the reverse bias pulse, following the previously established methodology [13]. For these measurements, devices without the sensor layer, (and therefore identical to the ones used in EL stability measurements of Fig. 1) are used in order to ensure that all delayed EL originates from the EML. Fig. 6a–c shows the delayed EL signal versus time elapsed from the end of the forward bias pulse obtained from the devices without HBL, with BAlq HBL and with BCP HBL, respectively; collected before and again after 20 hours of electrical aging at 20 mA/cm^2 current density in each case (denoted by "fresh" and "aged" on the figures in each case). As can be seen from the figures the application of the reverse bias causes a sudden increase in delayed EL intensity, which appears as a spike. The appearance of spike is an indication of a sudden release of trapped charges, which then recombine producing electroluminescence. A comparison of the spike heights in the fresh devices correlate with the expected variation in the extent of a hole space charge build-up in the EML among the three devices, with the device without the HBL showing the smallest spike (hence the smallest space charge), whereas the device with the strongly blocking HBL (i.e. BCP) demonstrating the highest spike (hence the largest space charge). Furthermore, a comparison of the spike heights due to aging reveals that the device without the HBL demonstrates the smallest increase, whereas the device with the strongly blocking HBL (i.e. BCP) demonstrates the largest increase, indicating the largest increase in the number of trapped charges in the EML upon prolonged electrical driving in the latter. The results therefore show a strong correlation between the accumulation of holes in the EML and the loss in EL efficiency of the PHOLEDs. In this regard, the efficiency loss may be due to increased exciton-polaron annihilation, which, as a bimolecular interaction, will increase with the concentration of holes trapped in the EML. The increase in trapped charges with electrical aging suggests that the effect may also be associated with an increase in concentration of deep charge traps, which can act as non-radiative recombination centers, and hence also contribute to the loss in device efficiency.

Although the results show a clear correlation between the extend of charge accumulation by the HBL and device stability, it is possible that variations in device stability also arise from chemical reactions between Ir(ppy)$_3$ and the HBL, as was observed in Ir(MDQ)$_2$acac based PHOLEDs before [12]. To test this possibility, we study a series of devices containing a neat CBP layer in between the EML and the HBL and compare them with control devices that do not have the neat CBP layer. The devices structure is as follows:

- ITO/NPB (50 nm)/CBP:Ir(ppy)$_3$ (92%:8%, 35 nm)/CBP (5 nm)/BAlq (10 nm)/Alq$_3$ (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BAlq-5 nm CBP spacer).
- ITO/NPB (50 nm)/CBP:Ir(ppy)$_3$ (92%:8%, 40 nm)/ BAlq (10 nm)/Alq$_3$ (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BAlq-Control).

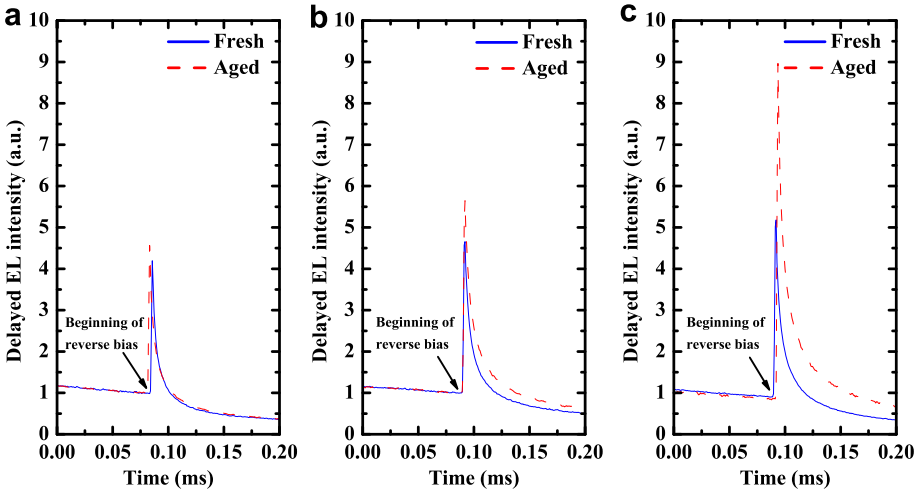

Fig. 6. Delayed EL intensity of devices (a) without HBL, (b) with BAlq HBL and (c) with BCP HBL, collected before (fresh) and after aging (aged) for 20 h at 20 mA/cm^2 current density.

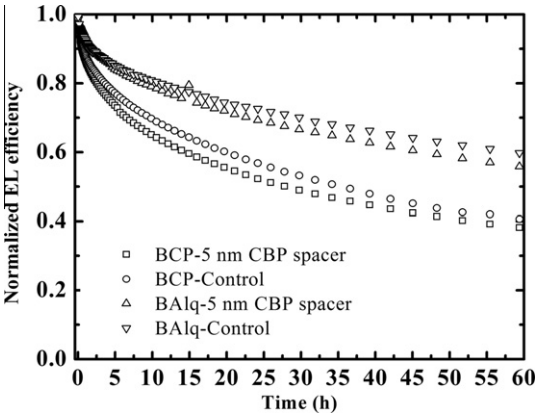

Fig. 7. Normalized EL efficiency versus time of devices with and without CBP spacer layer under AC driving at an average current density of 20 mA/cm^2.

- ITO/NPB (50 nm)/CBP:Ir(ppy)$_3$ (92%:8%, 35 nm)/CBP (5 nm)/BCP(10 nm)/Alq$_3$ (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BCP-5 nm CBP spacer).
- ITO/NPB (50 nm)/CBP:Ir(ppy)$_3$ (92%:8%, 40 nm)/BCP (10 nm)/Alq$_3$ (30 nm)/Mg:Ag/Ag (9:1, 100 nm) (named as BCP-Control).

Fig. 7 shows the EL stability of the devices. As can be seen from the figure devices with the neat CBP spacer layer show similar EL stability to the corresponding control devices indicating that reactions between the emitter and HBL do not play a major role in our devices, which can perhaps be attributed to the fact that we are using a different emitter.

To that end, device stability is strongly influenced by the use of a HBL, where the use of a strongly blocking material (e.g. BCP) will significantly increase the build-up of holes in the EML, and hence accelerate the EL degradation of the device.

4. Summary and conclusions

In summary, delayed EL measurements are used to investigate electroluminescence stability in PHOLEDs containing typical HBLs. The results show a strong correlation between the extent of hole blockage capacity of the HBL and the deterioration in device EL efficiency, pointing to the major role that the build-up of hole space charges in the emitting layer plays in EL degradation. In this regard, the use of a strongly blocking material (e.g. BCP) significantly increases the build-up of holes in the EML, and accelerates EL degradation.

In this paper, highly efficient blue phosphorescent OLEDs have been achieved by using a new emitter, iridium(III) bis[(3,4,5-trifluorophenyl)-pyridinato-N,$C^{2'}$] picolinate (F_3Irpic). Using the typical mCP host, blue emission with a maximum power efficiency of 18.1 lm/W has been realized. The power efficiency can be further increased to 33.7 lm/W by using a host of UGH2. Performance of the device is among the best reported for blue OLEDs.

2. Experimental details

The cyclometalating ligand 1-(3,4,5-trifluorophenyl)-pyridine was prepared via a Suzuki coupling reaction between 1-bromopyridine and 3,4,5-trifluorophenyl boronic acid. Synthesis of the final Ir complex involved two key steps. In the first step, $IrCl_3$ was reacted with excess of the synthesized ligands to produce a chloro-bridged Ir dimer. This dimer can be readily converted to the monomeric complex F_3Irpic by replacing the bridging chlorides with Picolinic Acid in the presence of Na_2CO_3. The synthetic pathway towards the preparation of F_3Irpic is outlined in Scheme 1. The identity was confirmed by 1H-nuclear magnetic resonance, elemental analysis, and mass spectrometry. MS (m/z): 730; ^{1}H NMR (Acetone, 300 MHz): δ: 7.16–7.21 (t, 1H), δ: 7.36–7.40 (t, 1H), 7.65–7.66 (d, 2H), 7.75–7.88 (m, 2H), 7.92–8.00 (m, 3H), 8.13–8.20 (m, 4H), 8.67–8.69 (d, 1H). Anal. Calcd. for $IrC_{28}H_{14}N_3O_2F_6$: C, 46.03; H, 1.93%; N, 5.75%. Found: C, 45.63; H, 2.00%; N, 5.70%.

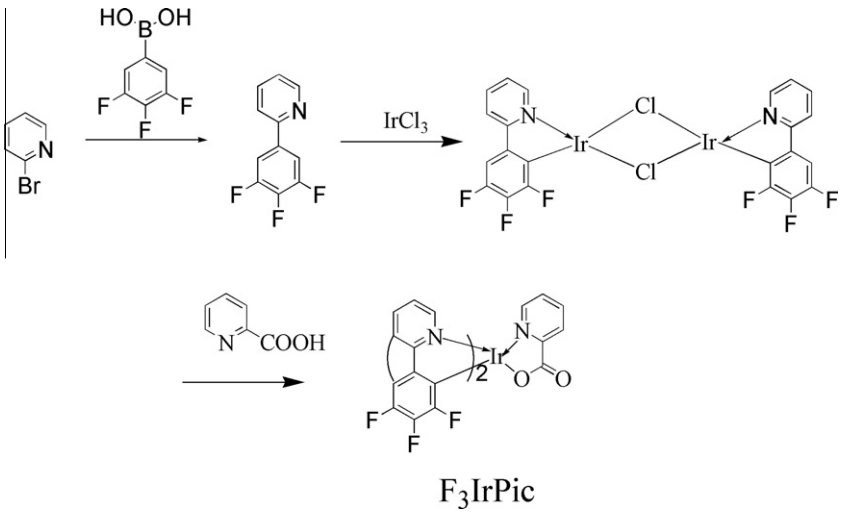
Absorption and photoluminescence spectra were recorded, respectively with a Perkin–Elmer Lambda 2S UV–Vis spectrophotometer and a Perkin–Elmer LS50B luminescence spectrophotometer. The highest occupied molecular orbital (HOMO) value of the Ir complex was measured via ultraviolet photoelectron spectroscopy (UPS). The lowest unoccupied molecular orbital (LUMO) value was determined from the difference between the HOMO energy and the band gap determined from the optical absorption edge.

OLEDs were fabricated by vacuum deposition on ITO-coated glass substrates with a sheet resistance of 30 Ω/square. Before deposition, the ITO substrate was first carefully cleaned, dried in an oven at 120 °C, and then treated with UV-ozone before loaded into a deposition chamber. Organic layers were then sequentially deposited onto the ITO substrate at a rate of 2–4 Å/s and a pressure below 5×10^{-6} mbar. Electroluminescence (EL) spectra and CIE color coordinates were measured with a Spectrascan PR650 photometer. Current–voltage–luminescence characteristics were measured with a computer-controlled Keithley 236 source meter under ambient conditions.

3. Results and discussion

Iridium(III) bis[(3,4,5-trifluorophenyl)-pyridinato-N,$C^{2'}$] picolinate (F_3Irpic) was synthesized in house. The molecular structure of F_3Irpic (Scheme 1), which has been confirmed with ^{1}H nuclear magnetic resonance, mass spectrometry and elemental analysis, is similar to that of FIrpic except for the three fluorine atoms substituted at the 3,4,5-position of the phenylpyridine ligand. Fig. 1 shows the absorption and photoluminescence (PL) spectra of F_3Irpic in dilute dichloromethane solution. The PL spectrum of F_3Irpic shows a blue emission with a main emission peak centered at 479 nm and a smaller peak at 509 nm. The shape of the PL spectrum is similar to that of FIrpic except for a red-shift of 8 nm [18]. On the other hand, the photoluminescence quantum yield of F_3Irpic in chloroform solution was measured to be 0.67 using FIrpic (Φ_f: 0.50) as a calibration standard, which is higher than that of FIrpic. The higher PL quantum yield of F_3Irpic should be attributed to more fluorine atoms substituted in the ligand than FIrpic [20].

OLEDs were made by doping F_3Irpic in mCP with a device structure of ITO/NPB (40 nm)/*x*% F_3Irpic:mCP (30 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm). In the devices, ITO (indium tin oxide) and LiF/Al are the anode and the cathode, respectively; 4,4′-bis[*N*-(1-naphthyl)-*N*-phenyl amino] biphenyl (NPB) is the hole transporting layer (HTL), and aluminum



F_3IrPic

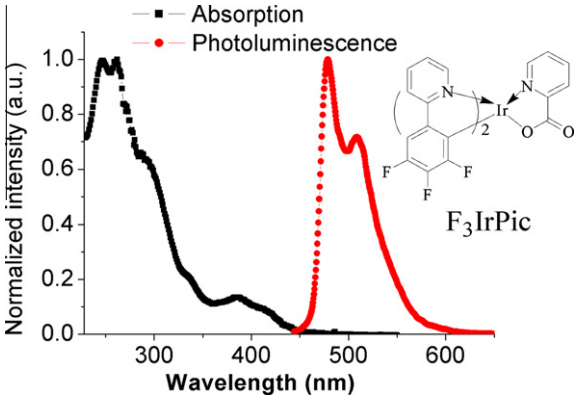

Fig. 1. Absorption and emission spectra of F_3Irpic, inset is its molecular structure.

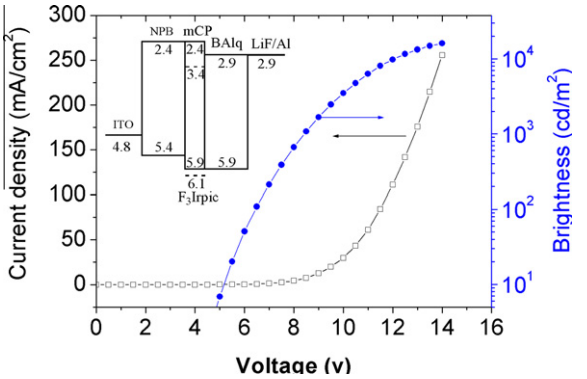

Fig. 3. *I–V–L* characteristics of the device, inset is the energy level diagram of the device.

(III) bis(2-methyl-8-quinolinato)4-phenylphenolate (BAlq) is the electron transporting layer (ETL). The F_3Irpic doped mCP layer is the emission layer (EML).

The devices with different concentration of F_3Irpic shows almost the same EL spectra (Fig. 2) as the PL spectrum (Fig. 1) of the Ir complex. Current and power efficiency of the best performing device (4% F_3Irpic in mCP) are shown in inset of Fig. 2. This device shows a maximum external quantum efficiency of 9.8%. The corresponding power (current) efficiency is 18.1 lm/W (25.9 cd/A), which is much higher than that of a similarly structured device using FIrpic dopant (7.5%, 8.9 lm/W) [19]. The good performance of the device should be attributed to the higher PL quantum yield of F_3Irpic than FIrpic. Current–brightness–voltage characteristics of this F_3Irpic (4%):mCP device are shown in Fig. 3. It has a turn-on voltage (at a brightness of 1 cd/m^2) of 4.3 V and delivers a maximum brightness of 15 000 cd/m^2 at a voltage of 13.5 V and a current density of 215 mA/cm^2. A schematic energy level diagram for the device is shown in the inset of Fig. 3. The HOMO level of F_3Irpic determined with UPS is 6.1 eV. The LUMO level as determined from the HOMO level and the optical absorption edge is 3.4 eV. As shown in the energy level diagram, the HOMO level of F_3Irpic (6.1 eV) is lower than that of mCP (5.9 eV). This suggests that the F_3Irpic might not be effective trap for the holes and thus decreases the chance of forming exciton in the phosphorescent emitter.

To address this problem, the mCP host was replaced by UGH2 which has a much larger energy gap. Chemical structure and the corresponding energy level diagram for the device are shown in Fig. 4. It can be noted that the HOMO and LUMO levels of the Ir complex are entirely bracketed by those of the UGH2 host. This suggests that the Ir molecules would be effective traps for both electrons and holes injected into the UGH2 layer. This is clear beneficial for exciton formation at the Ir molecules. It was found that the optimized device has a configuration of ITO/NPB (40 nm)/mCP (10 nm)/8% F_3Irpic:UGH2 (20 nm)/BAlq (40 nm)/LiF (0.5 nm)/Al (80 nm). The mCP layer is used as an interim layer to facilitate hole injection from the HTL into EML to overcome the large energy difference (1.8 eV) between NPB and UGH2.

Current efficiency–brightness–power efficiency characteristics of F_3Irpic:UGH2 device are shown in Fig. 5. This device shows blue emission (see inset of Fig. 5) with a peak centered at 482 nm and a sub-peak at 512 nm. The F_3Irpic:UGH2 device gives a maximum external quantum efficiency of 14.3%. The maximum power (current) efficiency of the device is 33.7 lm/W (37.6 cd/A), which is much higher than that of the F_3Irpic:mCP device. The high efficiency of the device is considered to arise from the following three aspects. Firstly, the high PL quantum yield of the F_3Irpic contributes to the high device efficiency; secondly, the good device structure can facilitate the injection and transport of electrons and holes; thirdly, the energy levels of F_3Irpic are entirely bracketed by UGH2, which induced the effective traps of the dopant for both electrons and holes injected into the host. Similar to other phosphorescent OLEDs, efficiency of the device decreases as the brightness increases. However, it is interesting to note that even at a brightness of 1000 cd/m^2, the efficiency of the device is still higher than 20 cd/A (9 lm/W). As far as we know, performance of this device is among the best values reported for blue OLEDs.

In summary, highly efficient blue phosphorescent OLEDs have been achieved by using a new emitter iridium(III)

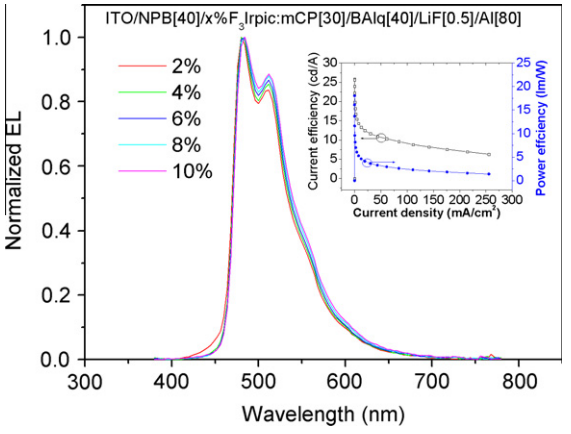

Fig. 2. EL spectra of the device at different doping concentrations, inset is the current efficiency–current density–power efficiency characteristics.

bis[(3,4,5-trifluorophenyl)-pyridinato-N,$C^{2'}$] picolinate (F_3Irpic). For a mCP:4%F_3Irpic device, blue emission with a maximum power efficiency of 18.1 lm/W has been realized, which is much higher than that of similarly structured FIrpic based device. The emission peak is located at 480 nm with a subpeak at 511 nm. By using an optimized device structure with a host of UGH2, performance of the device is substantially increased to give a maximum power efficiency up to 33.7 lm/W and an almost unchanged EL spectrum.

efficiency remain unsatisfied for high color gamut full color display or high color rendition illumination applications.

Au, one of the metals with low absorption, low reflection and high transmission, would be potentially an ideal cathode material for top-emitting WOLEDs [17]. However, few works have been reported on using Au as a low reflection and semitransparent cathode for top-emitting WOLEDs [18], mainly due to the high work function (~5.1 eV) of Au, rendering it unsuitable as a cathode material for injecting electrons. In this work, we demonstrate that with a 5 nm Yb (Ytterbium) modification layer, Au can be an excellent cathode for injecting electrons. The Au based tri-cathode-layer Yb (5 nm)/Au (15 nm)/MoO_3 (35 nm) exhibits an average reflection of 9.8% over the visible wavelength, significantly lower than 24% for the Ag based tri-cathode-layer Yb (5 nm)/Ag (15 nm)/MoO_3 (30 nm). By employing the low reflection Au based tri-cathode-layer, the microcavity effects have been weakened largely. Thus, high efficiency and high color rendition top-emitting WOLEDs with evenly separated R, G and B emission peaks have been achieved. At a high luminance of 1000 cd/m^2, the top-emitting WOLEDs exhibit an efficiency of 23 cd/A, 10.5 lm/W, a 1931 Commission International de L'Eclairage (CIE) coordinate of (0.36, 0.42) and a high color rendering index (CRI) of 85. The top-emitting WOLEDs demonstrated here would be an ideal candidate for high resolution full color active-matrix display or indoor lighting applications.

2. Experimental

Bis(3,5-difluoro-2-(2-pyridyl)phenyl)-(2-carboxypyridyl) iridium(III), FIrPic, and bis(2-benzo[*b*]thiophen-2-yl-pyridine)(acetylacetonate)iridium(III), Ir(btp)$_2$(acac) with main emission peak at 475 and 612 nm were selected as sky blue and saturated red emitter, respectively. In order to generate the white spectra with three evenly separated R, G and B emission peaks, a new yellowish-green emitter bis(5-(trifluoromethyl)-2-*p*-tolylpyridine) (acetylacetonate)iridium(III) **1** with emission peak at 544 nm was specially designed and employed in this study [1]. The top-emitting WOLEDs were fabricated in a multi-source vacuum chamber at a base pressure of around 5×10^{-7} Torr with structure glass/Al (100 nm)/MoO_3 (8 nm)/NPB (20, 30, 40 nm)/6% Ir(btp)$_2$(acac):CDBP (10 nm)/4% **1**:CDBP (3 nm)/12% FIrPic:CDBP (5 nm)/TAZ (40 nm)/Yb 5 nm/Au (or Ag) (15 nm)/MoO_3 (35, 30 nm), (NPB: *N*,*N*′-bis(naphthalen-1-yl)-*N*,*N*′-bis(phenyl)-benzidine; CDBP: 4,4′-bis(carbazol-9-yl)-2,2′-dimethylbiphenyl; TAZ: 3-(4-biphenyl)-4-phenyl-5-*tert*-butylphenyl-1,2,4-triazole), where Al, MoO_3 and NPB function as reflective anode, hole-injection and hole-transporting layer, respectively, CDBP works as host, TAZ serves as exciton-blocking and electron-transporting layer, Yb/Au (or Ag)/MoO_3 acts as semitransparent tri-cathode-layer. The energy level and molecular structure of the emitters are shown in Fig. 1. The transmission and reflection spectra of the tri-cathode-layer were characterized by UV–Vis spectrophotometer. The current density–voltage–luminance characteristics of the devices were measured by the HP4145B semiconductor parameter analyzer and a calibrated UDT PIN-25D silicon photodiode. The electroluminescent (EL) spectra were obtained with the PR650 spectrophotometer.

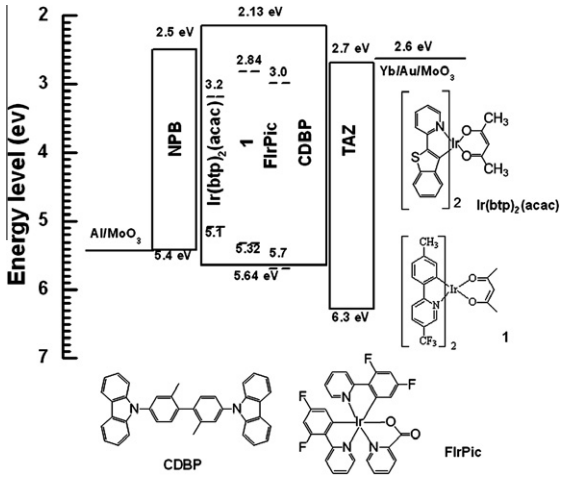

Fig. 1. Energy level and molecular structure of the materials employed in this study. The values of energy level are taken from literature.

3. Results and discussion

To alleviate the microcavity effects of the top-emitting WOLEDs, important parameters which affect the interference are analyzed first. The top-emitting OLEDs with the emission layers sandwiched between two reflective metal electrodes can be treated as a Fabry–Perot cavity optically [8,9,13,19–22]. Light emitting from the top semitransparent electrode and light reflected by the bottom reflective electrode interfere with each other. The emission intensity at λ is enhanced when the cavity effective length L_{eff} satisfies the below equation [8,20]:

$$L_{eff} = \frac{(\phi_{tm} + \phi_{bm})\lambda}{4\pi} + \sum_i n_i d_i = m\frac{\lambda}{2}\ (m:\ \text{integer}), \qquad (1)$$

where ϕ_{tm} and ϕ_{bm} are the phase shift of the light reflected by the top and bottom electrode, respectively; n_i and d_i are the refractive index and thickness of the organic layers, respectively. The cavity behaves like an optical filter which modulates the free space emission with the modulation spectra given by [8,13,19–21]:

$$I_{cav}(\lambda) \propto \frac{1 + R_1 + 2\sqrt{R_1}\cos\left(\frac{4\pi L_1}{\lambda} + \phi_{bm}\right)}{1 + R_1R_2 - 2\sqrt{R_1R_2}\cos\left(\frac{4\pi L}{\lambda} + \phi_{bm} + \phi_{tm}\right)} T_2, \qquad (2)$$

where L_1 is the optical distance between the exciton main recombination zone and the bottom reflective electrode; L is optical length of the organic layers; R_1 and R_2 are the reflectance of the bottom and top electrode, respectively; T_2 is the transmittance of the top electrode. The full width at half maximum (FWHM) of the $I_{cav}(\lambda)$ can be estimated by [8,9,13]:

$$\text{FWHM} = \frac{\lambda^2}{2L_{eff}} \times \frac{1 - \sqrt{R_1R_2}}{\pi\sqrt[4]{R_1R_2}}, \qquad (3)$$

From Eq. (3), one can see that larger reflectance of either electrode results in smaller FWHM, implying a stronger interference presented in the cavity. In order to obtain

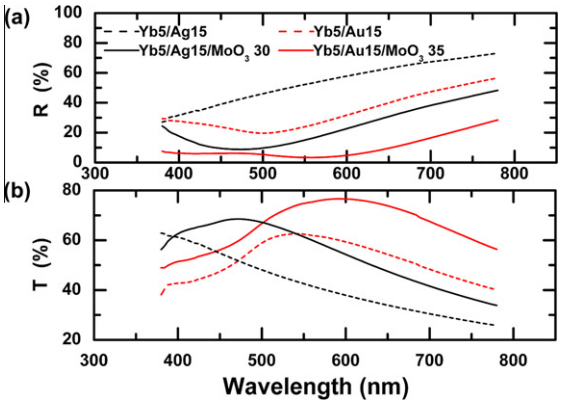

Fig. 2. Reflection (a) and transmission (b) spectra of the Ag and Au based semitransparent cathodes as measured by UV–VIS spectrometer.

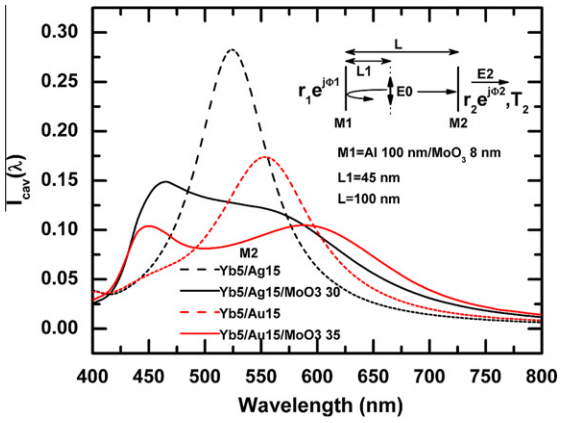

Fig. 3. Simulated cavity modulation spectra. Inset shows the physical model used in the simulation. The reflectance, phase shift and transmistance of the bottom anode $M1$ = Al 100 nm/MoO_3 8 nm and top cathode $M2$ are calculated by the transfer matrix method. The refractive indexes of the materials employed are taken from literature.

broadband emission spectra, one has to maximize the FWHM by reducing the reflection of either electrode. It is more desirable to reduce the reflection of the top electrode, since reducing the reflection of the bottom electrode, though effective, are at a cost of decreasing the light coupling efficiency.

Among the metal materials, thin film of Ag and Au are two mostly selected semitransparent top electrode materials due to their intrinsically low absorption and high transmission. Fig. 2 compares the measured reflection and transmission spectra of the Ag and Au based semitransparent top cathodes. It can be seen that the Au based top cathodes exhibit a substantially lower reflection over the visible wavelength than that of the Ag. Also, at yellow to red color, the transmittance of the Au based top cathodes is higher than that of the Ag based top cathodes. For example, the average reflectance (transmittance) of Yb (5 nm)/Au (15 nm) is 34% (52%), significantly lower (higher) than 54% (42%) for Yb (5 nm)/Ag (15 nm). By capping the semitransparent top cathodes with an index matching layer with optimized thickness, the reflectance (transmittance) of the Au and Ag based top cathodes are further reduced (enhanced). For example, the average reflectance (transmittance) has been remarkably reduced (enhanced) from 34% (52%) for the Au top cathodes without index matching layer to 9.8% (66%) for the Au top cathodes with 35 nm MoO_3 index matching layer. The low reflection of Yb (5 nm)/Au (15 nm)/MoO_3 (35 nm) suggests a good possibility of achieving a weakened interference cavity, and hence top-emitting WOLEDs with broadband emission spectra may be expected by employing this low reflection top cathode.

To evaluate the interference effects of the cavity with the low reflection top cathodes, cavity modulation spectra $I_{cav}(\lambda)$ are simulated. Although Eq. (2) provides a simple calculation formulation for $I_{cav}(\lambda)$, important parameters like dipole orientation, ***s***, ***p*** polarization, light emitting angles, exciton recombination zone and diffusing length are omitted. It is thus inaccurate to use Eq. (2) to describe the optical characteristics of the cavity. A rigorous electromagnetic modeling is adopted to accurately simulate the modulation spectra of the cavity [22]. Fig. 3 inset shows the physical model used in the simulation. Organic layers with thickness of L = 100 nm are sandwiched between the bottom reflective anode $M1$ = Al (100 nm)/MoO_3 (8 nm) and top semitransparent cathode $M2$. The distance between the exciton main recombination zone and the bottom anode is assumed to be $L1$ = 45 nm. The exciton diffusing length is assumed to be 15 nm. The reflectance, transmittance and phase shift of $M1$, $M2$ are calculated by the transfer matrix method by considering ***s***, ***p*** polarization. The modulation spectra of the cavity with different $M2$ are shown in Fig. 3. It can be clearly seen that with lower reflection $M2$, the modulation spectra exhibit wider FWHM. For example, with $M2$ = Yb (5 nm)/Ag (15 nm), the spectra exhibit a clear interference peak at 525 nm and a FWHM of only 78 nm; thus it is unlikely to obtain broadband white emission spectra in such cavity due to strong modulation of the cavity at green color. While by replacing Ag with low reflection Au, the intensity of the interference peak is suppressed and the FWHM is broadened to 110 nm. Further capping an optimized index matching layer reduces the reflection of $M2$ and broadens the FWHM accordingly. For example, the FWHM is broadened to 194 nm and 256 nm for $M2$ = Yb (5 nm)/Ag (15 nm)/MoO_3 (30 nm) and $M2$ = Yb (5 nm)/Au (15 nm)/MoO_3 (35 nm), respectively. Due to alleviation of the interference, the cavity with $M2$ = Yb (5 nm)/Au (15 nm)/MoO_3 (35 nm) exhibits a rather flat modulation intensity from 440 to 600 nm, implying a good possibility of obtaining broadband white emission spectra with equal R, G and B intensity in such cavity.

To verify this assertion, top-emitting WOLEDs with different top cathodes were fabricated. Fig. 4 shows the EL spectra of the devices with different top cathodes. For devices with Yb (5 nm)/Ag (15 nm) cathode, due to strong interference at λ = 525 nm as predicted by the simulated cavity modulation spectra, the green emission is enhanced significantly while the blue and red emission are suppressed, resulting in unbalanced white spectra as shown in Fig. 4a inset. For the devices with Ag and Au based tri-cathode-layer, the cavity length was tuned deliberately

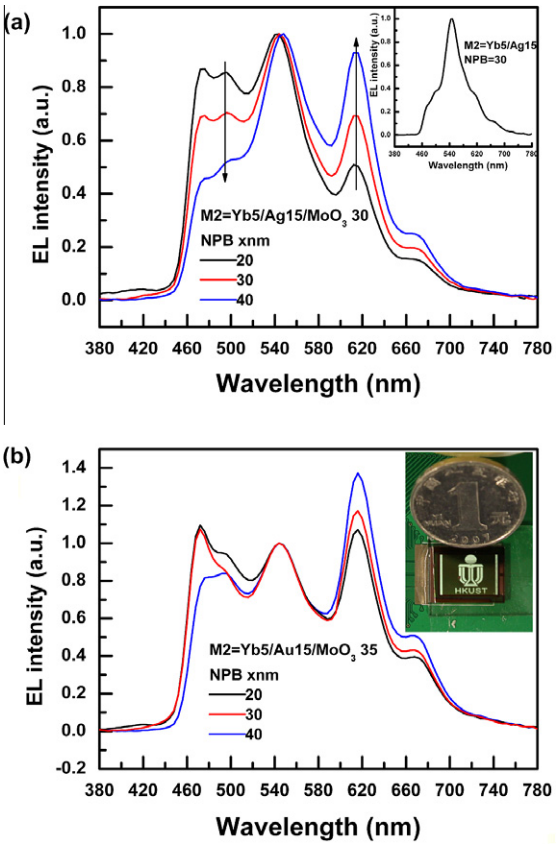

Fig. 4. (a) EL spectra of the devices with Ag based tri-cathode-layer. Inset shows the EL spectra of the devices with Yb (5 nm)/Ag (15 nm) top cathode. (b) EL spectra of the devices with Au based tri-cathode-layer. Inset shows a photo of the Si based SVGA+ microdispaly developed in this study. All devices were driven at 8 V for measuring the EL spectra.

by changing the thickness of NPB to further compare the interference effects of the cavity with different top cathodes. As shown in Fig. 4a, for devices with Ag based tri-cathode-layer, as NPB thickness increases, the blue emission decreases quickly while the red emission enhances rapidly, which may be attributable to the interference effects or shifting of the recombination zone. Also, the spectra exhibit slightly red-shift as the cavity length increases, a typical phenomenon in interference cavity. However, for the devices with Au based tri-cathode-layer, the white spectra only exhibit a slighted change as the increased of cavity length, which may be mainly caused by the shifting of the recombination zone. Noted that, both devices have the same emission and injection layers, thus the exciton recombination zone should also be identical. The severe change and red shifting white spectra as the increased of cavity length of the devices with Ag based tri-cathode layer are therefore most likely caused by interference effects; hence to obtain balanced white emission, one should carefully tune the thickness of the cavity length. While the relatively stable white spectra as the increased of cavity length of the devices with Au based tri-cathode-layer implies a much weakened interference effect; hence broadband white spectra with evenly separated R, G, B peaks and equal intensity are much easier to obtain, as shown in Fig. 4b. At NPB = 30 nm, the white spectra exhibit a CIE coordinate of (0.36, 0.42) and a high CRI of 85, rendering such top-emitting WOLEDs to be ideal candidate for display or lighting applications. We have successfully applied such top-emitting WOLEDs in the Si based microdisplay with SVGA+ resolution, as shown in Fig. 4b inset. It is noted that the emission color of the demonstrated top-emitting WOLEDs is not pure white and the CIE coordinate is far from (0.33, 0.33). To remedy this deficiency, deep fluorescent blue emitter like 4,4′-bis(9-ethyl-3-carbazovinylene)-1,1′-biphenyl (BcZVBi) may be employed to replace the sky blue emitter FIrPic [1].

The viewing characteristics of the white spectra are further examined. As shown in Fig. 5a, for the devices with Ag based tri-cathode-layer, the red emission decreases while the blue emission increases as the increased of viewing angle, mainly due to the reduction of cavity length viewed from an oblique angle. While the red emission remains unchanged regardless of the change of viewing angle for the devices with Au tri-cathode-layer as shown in Fig. 5b, again confirms a neglectable interference effect. However, the blue emission decreases as the increased of viewing angle, which is attributable to the strong absorption of the Au at the blue color region. At oblique angle, light see a thicker Au layer than that of their cousins at normal angle, thus leading to lower blue emission intensity at oblique angle. Fig. 5c and d show the EL spectra under different driving voltages. At high voltage, the exciton recombination zone shifts towards the green/red emission layer, thus one observes a decreasing blue emission and an increased red emission. The CIE coordinates changing from (0.34, 0.40) at 6 V to (0.36, 0.42) at 10 V for the devices with Au based tri-cathode layer.

Fig. 6 compares the key characteristics of the top-emitting WOLEDs with the Ag and the Au tri-cathode-layer. Both devices show similar current density–voltage–luminance and efficiency–luminance characteristics due to their identical structures; for example, both devices turn on at 3.8 V for 1 cd/m^2 and at ~7 V for 1000 cd/m^2, indicating that with the modification of Yb electron injection layer, Au works excellently as a cathode [17,23] despite its high work function. The devices with the Au based tri-cathode-layer exhibit a slightly higher efficiency than that of the devices with the Ag based tri-cathode-layer, which may be mainly due to the higher transmission of the Au based tri-cathode-layer than that of the Ag based tri-cathode layer [17]. For example, at a typical application luminance level of 1000 cd/m^2, the devices with the Au tri-cathode-layer demonstrate an efficiency of 23 cd/A and 10.5 lm/W, higher than 21 cd/A and 9.1 lm/W for the devices with the Ag based tri-cathode-layer. Further optimization, for example, electrical doping the charge transporting layer [24], employing new emitters/host with high carrier mobility and efficiency, applying out-coupling techniques [25,26], can be employed to boost the device performance.

4. Summary

In conclusion, the interference effects of the microcavity can be greatly alleviated by reducing the reflection of the

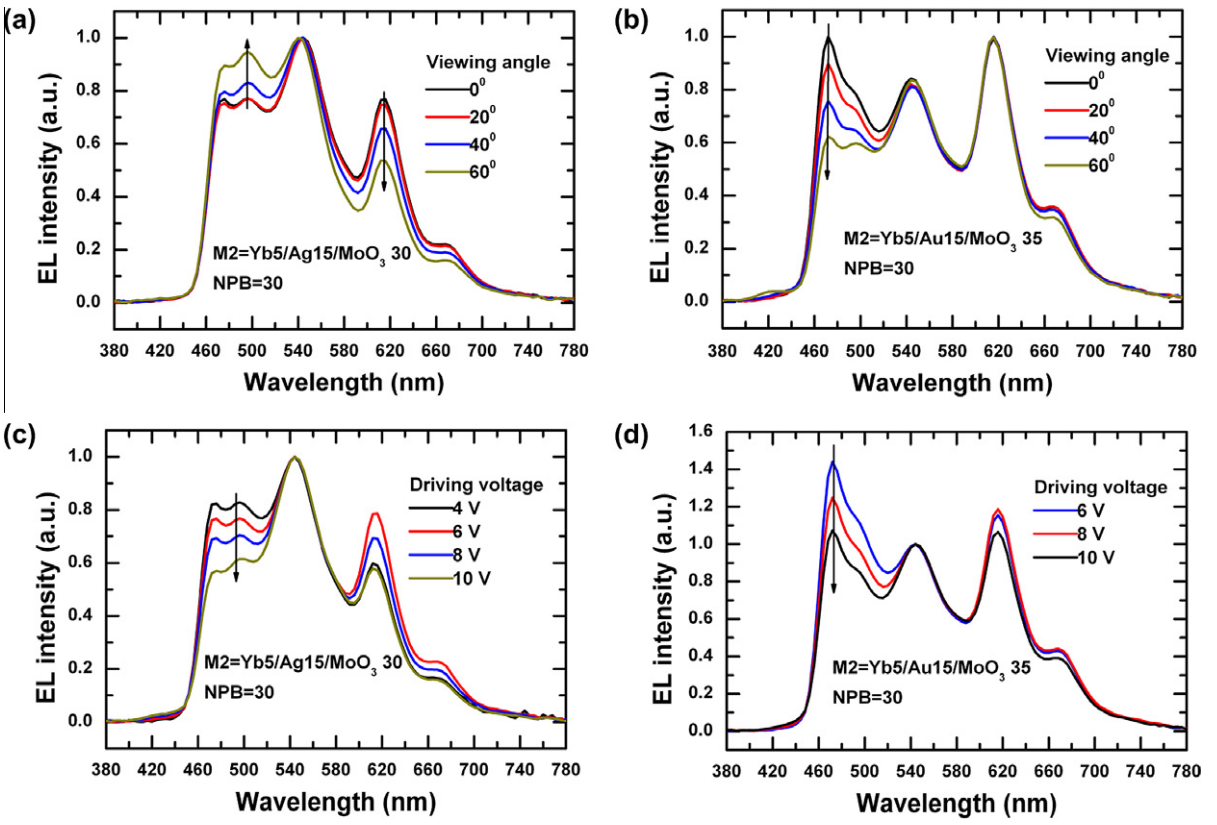

Fig. 5. (a) EL spectra of the devices with Ag based (a) and Au based (b) tri-cathode-layer at different viewing angle. EL spectra of the devices with Ag based (c) and Au based (d) tri-cathode-layer at different driving voltage.

top cathode. Au, modified by a 5 nm Yb electron injection layer, can not only be an excellent cathode for injecting electrons, but also exhibits lower reflection and higher transmission than that of the mostly used Ag top cathode. By employing the low reflection Yb (5 nm)/Au (15 nm)/MoO_3 (35 nm) cathode, top-emitting WOLEDs with evenly separated R, G and B emission peaks have been demonstrated. At a luminance of 1000 cd/m^2, the top-emitting WOLEDs exhibit a CIE coordinate of (0.36, 0.42), a high CRI of 85 and an efficiency of 23 cd/A, 10.5 lm/W. As well, the spectra of the top-emitting WOLEDs demonstrate a very weak angle dependence due to the neglectable interference effects. The top-emitting WOLEDs demonstrated here, which have been successfully applied in the Si based microdisplay, would be an ideal candidate for high resolution active-matrix display or indoor lighting applications.

Acknowledgments

investigate the subcells directly within the tandem device and to monitor the impact of the top cell coating on the bottom cell performance.

2. Experimental

ITO-coated glass substrates were structured and plasma etched (Diener Pico) with Argon for 120 s at 30 W and a base pressure of 0.38 mbar. Afterwards, the substrates were spin-coated (Laurell CZ-650 series, 1000 rpm, 55 s) with a dichlorobenzene solution loaded with 48 mg/ml of PCBM ([6,6]-phenyl-C61-butyric acid methyl ester, Solenne) and P3HT (poly(3-hexylthiophene), Rieke) in a ratio of 0.9:1.0 and dried under ambient solvent atmosphere for 15 min leading to a 160 nm thick photo active layer. Thin layers of $LiCoO_2$ (~1 nm) and Al (4 nm) were then sputtered (von Ardenne Anlagentechnik GmbH CS 730 S) to define the work function of the bottom cell cathode and to provide additional protection from sputter damage by the following sputtered n-type ZnO:Al (doping: 2-wt.% Aluminum) layer (15–300 nm). The recombination layer was plasma etched using the same parameters like for ITO with the etching time reduced to 60 s. Next, a layer of PEDOT:PSS (Orgacon pH-neutral (pH = 7) from Agfa (abbr. PpH, 60 nm) or Baytron P AI 4083 from H.C. Starck diluted 1:1 with deionized water (abbr. P4083, 20 nm)) was spincoated with 5000 rpm for 55 s. For the top cell absorber, the same P3HT:PCBM blend was used as for the bottom cell. The 160 nm thick top cell layer was spincoated with 1000 rpm for 55 s and dried under ambient solvent atmosphere for 15 min. The cathode was evaporated (Balzers) in UHV ($<10^{-3}$ Pa) incorporating a 1.2 nm LiF interlayer and the 120 nm aluminum cathode.

Current voltage analysis was carried out with a WACOM solar simulator (class AAA, AM 1.5G) and a Keithley 238 current source measure unit.

3. Discussion

We fabricated tandem solar cells comprising different ZnO:Al recombination layer thicknesses. A P4083 p-type layer in the top cell was included in each case. The tandem cell open-circuit voltage was used as an indication of device performance. For a functional tandem device, the open-circuit voltage must be approximately twice the single-cell open-circuit voltage. Our result is presented in (Fig. 1, ♦). We can identify two regions: one stable area above 45 nm thickness which is the maximum value of the open-circuit voltage. A region with decreasing open-circuit voltage of linear tendency is found for decreasing recombination layer thickness. Since the P4083 is acidic and might damage the recombination layer, we replaced it with a PpH formulation [5] (▲). Interestingly, we observe the same behavior for the open-circuit voltage like before except that the linearily decreasing region is shifted approximately 20 nm to thinner recombination layers. This observation is consistent with SEM measurements which showed the loss of 10–20 nm ZnO:Al due to etching when P4083 was coated on top. Undiluted P4083 formulations resulted in increasing losses of ZnO:Al of up to 50 nm.

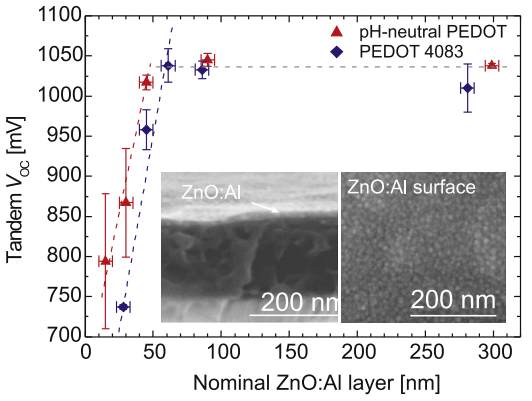

Fig. 1. Tandem cell open circuit voltages for various ZnO:Al recombination layer thicknesses which have to be at least 45 nm thick to achieve properly working devices. SEM cross section and surface image of a with 15 nm ZnO:Al coated bottom cell show a closed layer.

Hence we propose that more diluted P4083 formulations would suppress significant material losses of ZnO:Al and allow its use for even thinner recombination layers. This procedure would be advantageous since PpH is known to have an altered work function compared to P4083 [6] and may be less compatible to some materials energy levels.

The distinctive statistical spread in (Fig. 1) of the open circuit voltage for 15 nm and 30 nm tandem devices utilizing PpH can be attributed to a not absolutely homogeneous layer deposition of the sputter equipment. For deposition of ZAO we use a round sputter target and the reference layer thickness has been taken from the center position while the actual ZAO layer thickness decreases with increasing distance to the target center. For very thin layers slight changes in the ZAO layer thickness will result in a significant alteration of the open circuit voltage. Further, we also looked at the statistical spread of the fill factor as well as the short circuit current (Fig. 2). There, the relative error was in the same order of magnitude as for the open circuit voltage and diminished with increasing

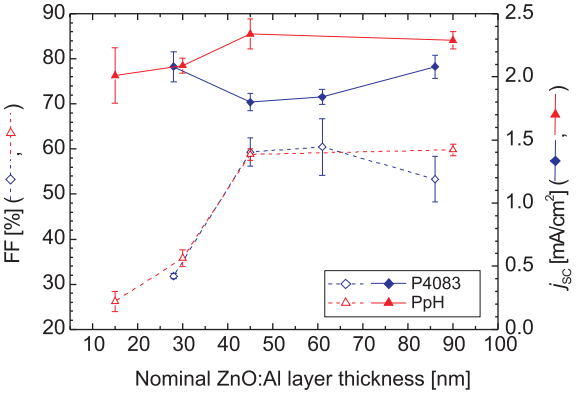

Fig. 2. Fill factor and short circuit current for different ZnO:Al layer thicknesses. For the FF we observe the same behavior as for the open circuit voltages while the short circuit current is only slightly dependent on the ZnO:Al layer thickness.

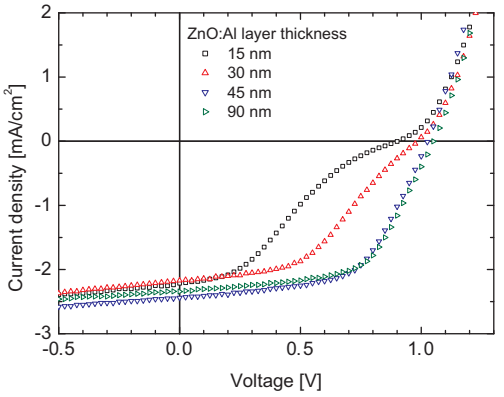

Fig. 3. Current–voltage characteristics for different ZnO:Al recombination layers coated with PpH. Functional devices are obtained for ZnO:Al layers around 45 nm.

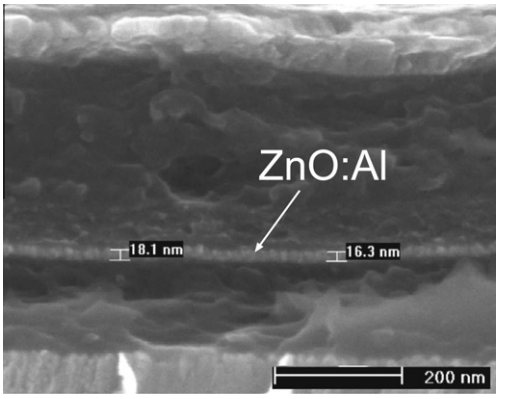

Fig. 4. SEM cross section of a tandem device comprising a nominal 15 nm ZnO:Al layer in combination with PpH.

layer thickness while the improvement of the fill factor can be mainly ascribed to the reduction of the S-shape behavior.

Tandem devices comprising a PpH layer are further investigated by evaluating the shape of the current voltage characteristics (Fig. 3). For ZnO:Al layers around 45 nm thickness we obtain functional tandem devices with a normal *IV* shape. Tandem cell *IV*s comprising thinner recombination layers result in S-shaped curves which are more pronounced for thinner layers. Here we would like to point out that even for the best obtained devices comprising 15 nm ZAO and 900 mV open circuit voltage the S-shape is still present. The S-shape only occurs in the fourth quadrant without affecting other regions. Since this effect is only observable for very thin layers, we first investigated the integrity of the ZnO:Al layer. SEM measurements (Fig. 1, bottom images) of the thinnest (15 nm) sputtered recombination layer show a closed surface layer confirmed by the top view and is also approved by Fig. 4 which shows a closed ZnO:Al layer after PpH coating in a completed tandem device. Further, SEM top view images of 45 nm and 90 nm ZnO:Al show increasing grain size for extended sputter time and layer thickness. According to Guillén and Herrero [19], smaller grain sizes will lead to reduced charge carrier densities and low mobilities which could result in charge accumulation and S-shape formation. These characteristics are consistent with our observation of increased tandem series resistance when the ZnO:Al layer thickness was decreased. Another possible mechanism is interface degradation leading to S-shape *IV* curves due to oxidation of the aluminum interlayer. Thin ZnO:Al layers might not be able to prevent sufficiently oxygen diffusion into the aluminum interlayer thus forming an insulating layer. Though the process leading to S-shape *IV* curves cannot be concluded definitively, both explanations result in low electron mobility and charge accumulation at the cathode side of the recombination layer and are modeling the S-shape.

By increasing its thickness to 300 nm, ZnO:Al is suitable as an intermediate electrode ($\sigma \approx 1100$ S/cm) for subcell characterization (Fig. 5). In this three-terminal structure it is also possible to monitor the bottom cell after each top cell coating step. For this purpose the bottom cell was annealed (135 °C for 10 s) after sputtering the middle

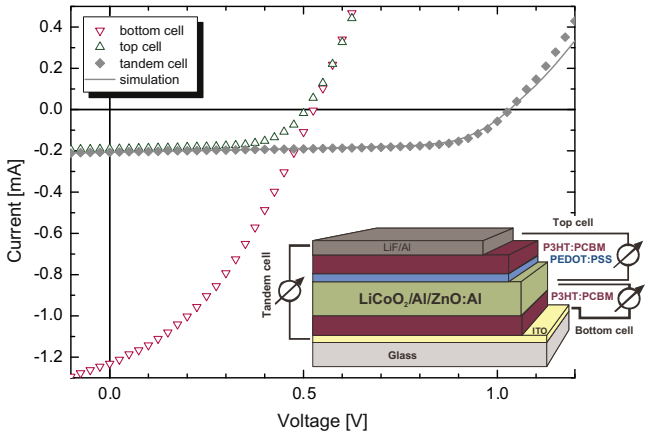

Fig. 5. *IV* characteristics of a complete tandem solar cell and its subcells. The subcells *IV*s can be used to simulated tandem *IV* by voltage summation at equal subcell currents and is in good agreement to the experimental curve. The deviation of the series resistance is due to the (double) utilization of the ZnO:Al as electrode leading to an increased resistance.

electrode to remove sputter damage [20–22]. Our result is presented in Fig. 6 and shows only slight deviations in the short-circuit current after each process step. We attribute the loss in current to degradation of the P3HT bottom cell caused by the long exposure time to ambient atmosphere during device fabrication of the top cell and subsequent device characterization. We conclude from these findings that the top cell coating process has no substantial impact on the bottom cell performance and also that the 300 nm ZnO:Al recombination layer acts as a protection layer.

In a parallel investigation, the impact of P4083 on ZnO nanoparticle layers was investigated and compared to the results from sputtered ZnO:Al layers. Measurements revealed that the ZnO is more susceptible to etching than ZnO:Al layers with an increased loss of material: approx. 50 nm even for diluted P4083. Taking the material loss into account, we were able to build working tandem devices comprising P4083 and a ZnO nano particle layer with device parameters that are comparable to devices utilizing PpH (Fig. 7). For these devices the bottom cell absorber thickness has been adjusted to 50 nm in order to improve

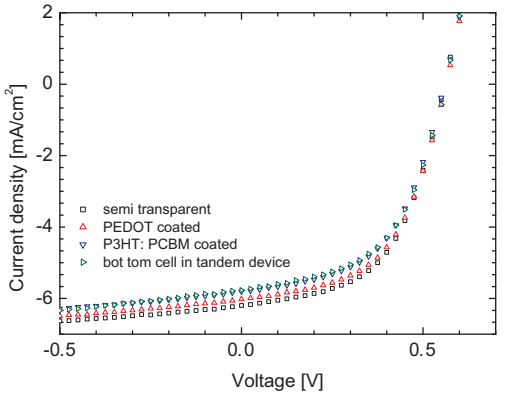

Fig. 6. Bottom cell measured with the ZnO:Al recombination layer as electrode. The measurement was carried out after each subsequent top cell coating step and shows no substantial impact. The deviation is attributed to the normal degradation of the non-encapsulated P3HT bottom cell.

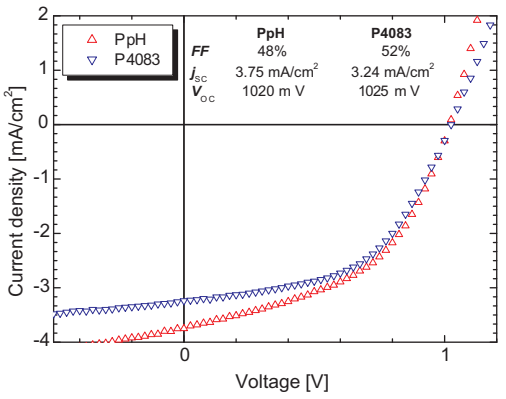

Fig. 7. *IV* characteristics of tandem cells comprising ZnO nano particles in the recombination layer in combination with PpH and P4083 which show comparable device parameters.

the overall current of the tandem device and a 1:2 vol. diluted PpH was used to get a 30 nm PEDOT:PSS layer like for ZnO:Al comprising tandem solar cells. The results show that tandem solar cells comprising ZnO nanoparticles instead of sputtered Zno:Al as recombination layer lead to similar results regarding the impact of PEDOT:PSS acidity. However, the long-term chemical stability of a ZnO/PEDOT:PSS or ZnO:Al/PEDOT:PSS junction might be affected and thus requires sufficiently effective encapsulation barrier against moisture to prevent interface degradation.

4. Conclusion

Sputtered ZnO:Al was used as a recombination layer and middle electrode in tandem solar cells with P3HT:PCBM absorber layers. Although P4083 is acidic and removes a thin layer of about 20 nm ZnO:Al, the choice of PEDOT:PSS formulations had no impact on the device performance. The removed layer can be compensated by increasing the initial ZnO:Al layer thickness accordingly. Moreover, we propose that ZnO:Al loss due to P4083 can be reduced by using more diluted formulations. The ZnO:Al was more resistant against etching than ZnO nanoparticles which were successfully used as recombination layer in combination with P4083. Properly working tandem devices required a ZnO:Al recombination layer of at least 45 nm thickness. Below this critical thickness, S-shape behavior in the *IV* curve was observed which we attribute to low electron mobility at the bottom cell recombination layer interface. In-device characterization of subcells enabled the investigation of subsequent top cell layer coating. No negative impact on the bottom cell performance was observed.

operation is <2 V [15]. There are many types of aromatic hydrocarbons other than picene, *i.e.*, one-dimensional (1D) and two-dimensional (2D) extended aromatic hydrocarbons. In 1D extended hydrocarbon molecules, there are two types of molecules, [*n*]acnene and [*n*]phenacene; [*n*]acene consists of a linear fusion of benzene rings, while [*n*]phenacene consists of a zigzag fusion of benzene rings; [11]phenacene has already been synthesized [16]. Very recently, we reported characteristics of FET with thin films of [7]phenacene, and with various solid gate dielectrics [17]. The p-channel operation at absolute threshold voltage $|V_{TH}|$ as low as 20 V was realized for [7]phenacene FET with Ta_2O_5 gate dielectric, and the stable FET operation exhibiting the μ as high as 0.75 $cm^2 V^{-1} s^{-1}$ was also recorded [17]. For the lower $|V_{TH}|$ operation, *i.e.*, higher density of carrier-injection, the ionic liquid gate dielectrics should be tried for the [7]phenacene.

In this letter, we have fabricated the [7]phenacene TFTs with two ionic liquids, [1-ethyl-3-methylimidazolium][bis(trifluoromethanesulfonyl)imide] (emim[TFSI]) and [1-butyl-3-methylimidazolium][hexafluorophosphate] (bmim[PF_6]); the molecular structure of [7] phenacene is shown in Fig. 1(a). The characteristics of [7]phenacene TFTs with ionic liquid gate dielectrics are investigated in order to establish the application of 1D extended hydrocarbons to low-voltage operated transistors and to clarify the hole-accumulation process in the transistors, *i.e.*, the device physics of organic TFTs with ionic liquids. Here, we refer expediently as [7]phenacene TFT for the transistor with ionic liquid since its operation mechanism is different from the EDL FET, as is described later. The operation mechanism in [7]phenacene TFT with ionic liquid is identified in this study. On the other hand, [7]phenacene transistor with solid gate dielectric is defined as [7]phenacene FET because of its clear field-effect transistor operation.

2. Experimental

Sample of [7]phenacene was synthesized and purified to be ~99.9% according to the previous report [18]. A commercially available SiO_2 (400 nm)/Si wafer was washed by acetone and methanol, H_2O_2/H_2SO_4 and ultrapure water. [7]phenacene thin film FETs with solid gate dielectrics of SiO_2 (400 nm) and HfO_2 (50 nm) were fabricated for a comparison with those with ionic liquids. The surface of SiO_2 was coated by hexamethyldisilazane (HMDS). The HfO_2 was not formed on SiO_2/Si but on Si substrate by use of ion beam spattering, and the surface was covered with parylene (25 nm). Thickness of [7]phenacene thin films were 30 nm except for the devices (thickness of 60 and 480 nm) used for measurement of thickness dependence of I_D–t plot (Fig. 5(b)) and the device (thickness of 60 nm) used for investigation of I_D evolution with different ionic liquids (Fig. 5(c)). Thickness of Au source/drain electrodes is 50 nm. The thin films of [7]phenacene and Au source/drain electrodes were formed by thermal evaporation at 10^{-7} Torr. The molecular structures of two ionic liquids, emim[TFSI] and bmim[PF_6], are shown in Fig. 1(a). The liquid of emim[TFSI] was used as gate dielectric in the [7]phenacene TFT device, and the gel of bmim[PF_6] was used as the gate dielectric. The bmim[PF_6] gel was prepared according to the following procedure. (1) Poly(styrene-*b*-ethylene oxide-*b*-styrene) [PS-PEO-PS] and

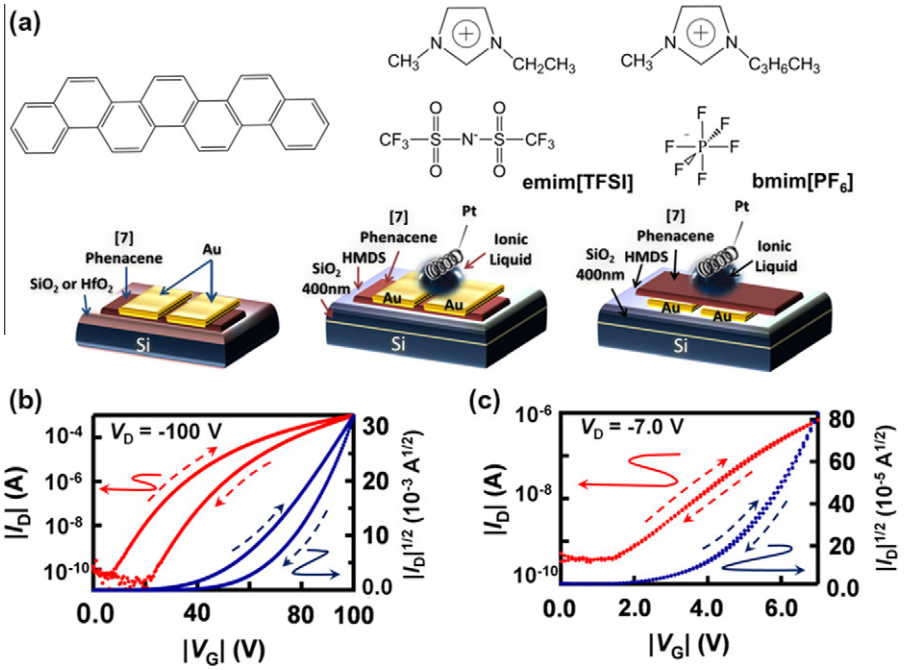

Fig. 1. (a) Molecular structures of [7]phenacene and ionic liquids (emim[TFSI] and bmim[PF_6]). Device structures of [7]phenacene thin film FETs with solid gate dielectrics (left), those of [7]phenacene FETs with ionic liquid gate dielectrics in the different device structures (middle and right). Transfer curves of [7]phenacene FET with (b) SiO_2 and (c) HfO_2 gate dielectrics. $V_D = -100$ V for (b) and $V_D = -7.0$ V for (c).

bmim[PF6] were dissolved at weight ratio of 1:9 in CH_2Cl_2, and the solution was stirred for 16 h at room temperature and CH_2Cl_2 were evaporated. (2) The remaining solid was heated at 343 K under Ar atmosphere for 7 h.

All device structures of [7]phenacene transistors with solid and ionic liquid gate dielectrics are shown in Fig. 1(a). The capacitance per area of EDL, C_{IL}, with the ionic liquids, emim[TFSI] and bmim[PF6], were estimated to be 9.3 and 9.7 μF cm^{-2}, respectively, and the capacitance per area of oxide gate insulator, C_O, for SiO_2 and HfO_2 were estimated to be 8.1 and 83 nF cm^{-2}, respectively. The C_{IL} and C_O were determined by extrapolating the $C_{IL}(v)$ and $C_O(v)$ measured at AC frequency v of 20 Hz–1000 kHz to 0 Hz; the obtained capacitance corresponds to DC capacitance. The AC bias voltage of 1.0 V was applied to determine the capacitance per area. Actually, the C_{IL} is twice as high as the capacitance per area, C_{area}, measured directly for ionic liquid because of the formation of two EDLs under AC bias application.

Platinum (Pt) wire coil was contacted to the ionic liquid as gate electrode (see Fig. 1(a)). The channel length L and channel width W were 30 μm and 2.2–4.8 mm, respectively, except for devices used for obtaining I_D–t plots shown in Fig. 5(b) and (c) where L = 30 μm and W = 200 μm. The transistor characteristics were measured in an Ar-filled glove box, and the reproducibility of characteristics was confirmed with at least three devices. The μ values were determined from the saturation drain currents for all transistors using normal MOS formula. The values of C_O were used for estimation of μ's in [7]phenacene FETs with solid gate dielectrics, while the C_{IL} values were used for estimation of μ's in [7]phenacene TFTs with ionic liquids.

3. Results and discussion

Transfer curves of [7]phenacene thin film FETs with SiO_2 and HfO_2 (left device structure in Fig. 1(a)) are shown in Fig. 1(b) and (c), respectively. Clear p-channel FET characteristics are observed in both FET devices. The maximum absolute drain current $|I_D|^{max}$ reaches 10^{-4} A at gate voltage V_G of −100 V and drain voltage V_D of −100 V for the [7]phenacene FET with SiO_2 gate dielectric. The μ for [7]phenacene FET with SiO_2 gate dielectric was estimated to be 8.4 x 10^{-1} cm^2 V^{-1} s^{-1} from the saturation drain current measured at V_D = −100 V, and the $|V_{TH}|$ was 55 V. Thus, the μ was quite high but the high absolute V_G, $|V_G|$, was necessary for FET operation. Furthermore, the on–off ratio and subthreshold swing S were 4.2×10^7 and 5.8 V decade^{-1}, respectively, for [7]phenacene FET with SiO_2 gate dielectric. The on–off ratio is quite high but the S is not so good. Thus, the serious problem for the [7]phenacene FET with thick SiO_2 gate dielectric is the high voltage operation caused by the low C_O of SiO_2 gate dielectric.

On the other hand, the μ value for the [7]phenacene FET with HfO_2 gate dielectric was 1.6×10^{-2} cm^2 V^{-1} s^{-1} from the saturation drain current measured at V_D = −7 V, and the $|V_{TH}|$ was 4.5 V. This device operates at low voltage but the μ is still lower by approximately a factor of 50 than that for [7]phenacene FET with 400 nm thick SiO_2 gate dielectric. The on–off ratio and S were 1.8×10^3 and 1.5 V decade^{-1}, respectively, for [7]phenacene FET with HfO_2 gate dielectric. In this device, the S is not so good regardless of the low $|V_{TH}|$. Nevertheless, the best record of μ (8.4×10^{-1} cm^2 V^{-1} s^{-1} for [7]phenacene FET with SiO_2) and the best record of $|V_{TH}|$ (4.5 V for [7]phenacene FET with HfO_2) are improved in comparison with the values, $\mu = 7.5 \times 10^{-1}$ cm^2 V^{-1} s^{-1} and $|V_{TH}|$ = 22 V, reported previously [17]. For a realization of [7]phenacene transitor exhibiting both high μ and low $|V_{TH}|$, we turn to ionic liquid gate dielectrics.

For [7]phenacene TFTs with ionic liquids, we adopted two types of device structures as shown in middle and right of Fig. 1(a). In this text, the transistor characteristics of the device shown in middle of Fig. 1(a) are mainly investigated. Here, in the middle device structure, the ionic liquids are directly contacted to the Au source/drain electrodes, but the conductivity was not observed between

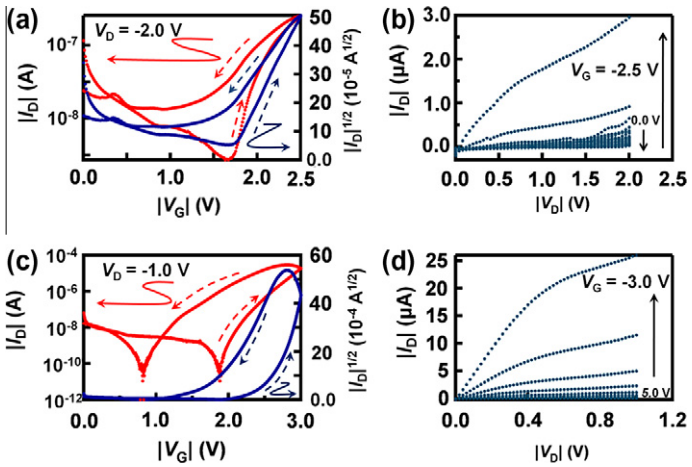

Fig. 2. (a) Transfer and (b) output curves of [7]phenacene thin film FET with emim[TFSI]. (c) Transfer and (d) output curves of [7]phenacene thin film FET with bmim[PF_6]. The device structure refers to the middle device in Fig. 1(a). V_D = −2.0 V for (a) and V_D = −1.0 V for (c). The V_G in the output curves are also shown in graphs, (b) and (d).

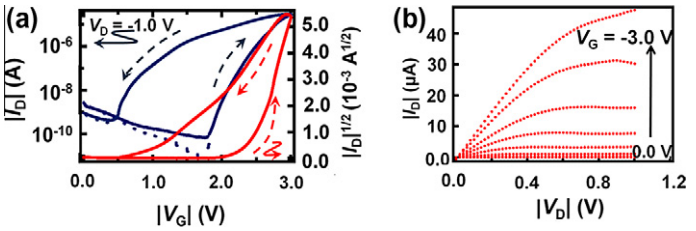

Fig. 3. (a) Transfer and (b) output curves of [7]phenacene thin film FET with bmim[PF_6]. The device structure refers to the right device in Fig. 1(a). $V_D = -1.0$ V for (a). The V_G in the output curves are also shown in graph, (b).

electrodes without [7]phenacene thin films, indicating the ion conductivity is negligible in ionic liquids.

Transfer and output curves of [7]phenacene TFT with emim[TFSI] (middle device structure in Fig. 1(a)) are shown in Fig. 2(a) and (b), respectively. The p-channel transistor characteristics are observed in this TFT device, and the μ was estimated to be 1.0×10^{-3} cm^2 V^{-1} s^{-1} from the transfer curves in saturation regime measured at $V_D = -2.0$ V and the $|V_{TH}|$ was 1.7 V. This device operated at very low $|V_{TH}|$, but the μ is lower than the μ values, 8.4×10^{-1} and 1.6×10^{-2} cm^2 V^{-1} s^{-1}, in [7]phenacene FETs, respectively, with SiO_2 and HfO_2. The [7]phenacene TFT with emim[TFSI] may not provide the prospective for practical application of [7]phenacene owing to the extremely low μ value ($\sim 10^{-3}$ cm^2 V^{-1} s^{-1}) regardless of the low $|V_{TH}|$. The on–off ratio and S were 93 and 200 mV/decade, respectively. This S is smaller by one or two orders of magnitude than those for [7]phenacene FETs with solid gate dielectrics, but the on–off ratio is quite low. The low on–off ratio originates from the off-current as high as 10^{-9} A. Such a high off-current was found in poly(3-hexylthiophene) (P3HT) FET with polymer electrolyte, and the phenomenon was attributed to the ionic charge current produced by using drop of gate electrolyte [19]. The use of ionic liquid drop may also cause the high off-current in our device, although the off-current of [7]phenacene TFT with emim[TFSI] is actually much smaller than that in the P3HT FET with electrolyte gate drop [19].

The output curves show a weak ambipolar property that the I_D decreases with an increase in $|V_G|$ from 0.0 to 1.0 V. The transfer curve also shows a slow increase with a decrease in $|V_G|$ below 1.7 V, suggesting the ambipolar property in this TFT. Here it should be pointed out that such a behavior observed in the P3HT FET with polymer electrolyte gate dielectric was not attributed to the ambipolar electronic current but additional ionic current caused by electrochemical reaction [20]. This fact implies that the interpretation of the ambipolar like behavior observed is not so simple in [7]phenacene TFT with emim[TFSI] gate dielectric. The discussion on the electrochemical reaction in [7]phenacene TFTs with ionic liquids is fully described later.

Transfer and output curves of [7]phenacene TFT with bmim[PF_6] (middle device structure in Fig. 1(a)) are shown in Fig. 2(c) and (d), respectively. The p-channel characteristics are also observed in this TFT device, and the μ was estimated to be 2.6×10^{-1} cm^2 V^{-1} s^{-1} from the transfer curve at $V_D = -1.0$ V in saturation regime, and the $|V_{TH}|$ was 2.7 V. This device operates with the high μ value comparable to that, 8.6×10^{-1} cm^2 V^{-1} s^{-1}, recorded for [7]phenacene FET with thick SiO_2 gate dielectric. Namely, the [7]phenacene TFT with bmim[PF_6] realizes both high mobility and low voltage operation. The on–off ratio and S were 1.9×10^7 and 89 mV/decade. The on–off ratio is also comparable to that for [7]phenacene FET with thick SiO_2 gate dielectric, and the S is close to the theoretical limited value, 60 mV/decade at room temperature. This S value is smaller by one–two orders of magnitude than that for [7]phenacene FETs with solid gate dielectrics. The output curves did not show the ambipolar properties, contrary to those for [7]phenacene TFT with emim[TFSI] (Fig. 2(b)). Thus [7]phenacene TFT with bmim[PF_6] is substantially superior to that with emim[TFSI].

We further made [7]phenacene TFT with bmim[PF_6] in the device structure shown in right of Fig. 1(a) and investigated its transport characteristics. The transfer and output curves are shown in Fig. 3(a) and (b), respectively. P-channel characteristics were observed and the μ, |VTH|, on–off ratio and S were evaluated to be 2.8×10^{-1} cm^2 V^{-1} s^{-1}, 2.5 V, 2.9×10^7 and 107 mV/decade, respectively, from the transfer curve in saturation regime (VD = −1.0 V). These values are almost consistent with those for [7]phenacene TFT with bmim[PF_6] (middle device in Fig. 1(a)). This result is a little surprising for us, because [7]phenacene thin film FET was expected not to operate in the device structure shown in right of Fig. 1(a), from the analogy of picene thin film FET [3]. The picene thin film FET with SiO_2 gate dielectric and Au source/drain electrodes did not operate in the bottom contact structure in which the picene thin films are deposited and formed on Au source/drain electrodes. Actually, it is found, for the picene thin film FET in the bottom contact structure, that the large hole-injection barrier-height is formed between Au source/drain electrodes and the picene thin films, *i.e.,* the formation of picene thin film on Au electrodes produces large hole-injection barrier. It is natural for us to predict large hole-injection barrier-height for [7]phenacene FET, because the crystal structure of [7]phenacene thin films on the SiO_2 and the electronic structure are similar to those of picene [17], and the [7]phenacene thin films are formed on Au electrodes in right of Fig. 1(a). The fact, that the excellent transistor characteristics for [7]phenacene TFT in the device structure shown in right of Fig. 1(a) is observed, suggests the destruction of the hole-injection barrier, which is probably owing to high density of hole accumulation at channel region of [7]phenacene thin films. This result is consistent with the

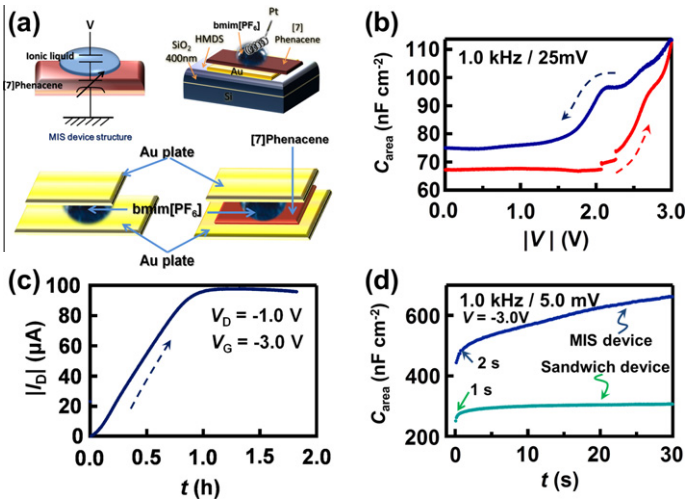

Fig. 4. (a) Schematic representation of MIS device (top left), and device structures of [Pt(wire coil)–bmim[PF_6]-[7]phenacene-Au(thin films)] MIS device (top right) , [Au(plate)–bmim[PF_6]-Au(plate)] sandwich device (bottom left) and [Au(plate)–bmim[PF_6]-[7]phenacene-Au(plate)] MIS device (bottom right). The bias voltage applying to the MIS device is represented as *V*. (b) C_{area}–*V* plot measured in the [Pt(wire coil)–bmim[PF_6]-[7]phenacene-Au(thin films)] MIS device. (c) $|I_D|$ plot as a function of *t* measured in [7]phenacene FET with bmim[PF_6] (middle device in Fig. 1(a)). (d) C_{area}–*t* in the [Au(plate)–bmim[PF_6]-Au(plate)] sandwich device and the [Au(plate)–bmim[PF_6]-[7]phenacene–Au(plate)] MIS device. The AC frequency is 1 kHz for (b) and (d), while the AC bias voltage for estimating capacitance is 25 and 5 mV for (b) and (d), respectively. The DC bias voltages are also shown in graphs of (c) and (d), *i.e.*, $V_D = -1.0$ V and $V_G = -3.0$ V in (c), and $V = -3.0$ V in (d).

fact that [7]phenacene TFT is electrochemical (EC) transistor, as described later.

Fig. 4(a) shows the schematic representation of metal–insulator-semiconductor (MIS) device (top left in (Fig. 4(a)), Pt–bmim[PF_6]-[7]phenacene-Au (top right in Fig. 4(a)), which implies two series of capacitors; metal, insulator and semiconductor refer to Pt electrode, bmim[PF6] and [7]phenacene, respectively. In this device, the Au electrode was grounded. The C_{area} measured in the MIS device is plotted as a function of absolute applied bias voltage |*V*|, as shown in Fig. 4(b). Here it is important to notice that the *V* is the same role as the V_G in the TFT device. Actual measurement condition is described in figure caption of Fig. 4(b). As seen from Fig. 4(b), the C_{area} drastically increases with an increase in |*V*| above 2.0 V. The $|V_{TH}|$ for C_{area}–*V* plot can be estimated to be 2.3 V. The transfer curves of TFTs corresponding to this MIS device are shown in Fig. 2(c) and Fig. 3(a). The $|V_{TH}|$ for the TFT device was 2.5–2.7 V as described previously, whose value is consistent with 2.3 V estimated from C_{area}–*V* plot (Fig. 4(b)). This C_{area}–*V* curve shows the hole accumulation above 2.3 V in forward application of |*V*|.

The time (*t*) dependence of the absolute maximum drain current, $|I_D|^{max}$, for [7]phenacene TFT with bmim[PF_6] measured at $V_D = -1.0$ V and $V_G = -3.0$ V is shown in Fig. 4(c); the device structure is shown in middle of Fig. 1(a). The value increases monotonously with an increase in *t* and almost saturates above 1 h, suggesting time necessary for the hole accumulation. The I_D in [7]phenacene TFT with bmim[PF_6] (Fig. 4(c)) reaches 100 μA at 1 h. Furthermore, the time scale (~1 h = 3600 s) of I_D evolution in [7]phenacene TFT with bmim[PF_6] is different from that (~1 s) in EDL FETs [19–23]. This suggests that the I_D evolution in [7]phenacene TFT with bmim[PF_6] cannot be related to that for EDL FET but to electrochemical doping of PF_6^-, *i.e.*, the [7]phenacene TFT is a electrochemical (EC) TFT. Thus, the evolution of $|I_D|$ (Fig. 4(c)) may be an indirect indication of penetration of PF_6^- to bulk region of [7]phenacene thin films; as described later, the penetration of PF_6^- ions can produce large amounts of holes into the bulk region to realize the absolute I_D as high as 100 μA.

Here it is important to say that the time required for EDL formation is probably approximately 1s because the C_{IL} for Au–bmim[PF_6]-Au sandwich device (bottom left in Fig. 4(a)) was detected at 20 Hz – 1 kHz and AC bias voltage of 1 V without DC bias voltage, as described in the experimental section. Next the C_{area} for Au–bmim[PF_6]-Au sandwich device was measured at 1 kHz and AC bias voltage of 5 mV and DC bias voltage of −3 V. The C_{area} is plotted as a function of *t* in Fig. 4(d), where the starting time corresponds to the time when the DC bias voltage is applied. This experiment was carried out to know the formation process of EDL under DC bias voltage application ($V = -3$ V); this bias voltage is consistent with the V_G of −3 V used for I_D–*t* measurement (Fig. 4(c)). The C_{area} rapidly increases within 1 s and saturates above 20 s.

Furthermore, we measured evolution of C_{area} in the Au–bmim[PF_6]-[7]phenacene–Au MIS device. The *t* dependence of C_{area} in the MIS device is shown in Fig. 4(d). The C_{area} increases rapidly up to 2 s and saturates above 90 s. This C_{area}–*t* curve reflects both EDL formation and penetration of PF_6^- into [7]phenacene thin films by application of −3 V. The time scale is shorter by one–two orders of magnitude than that of I_D–*t* plot shown in Fig. 4(c). The C_{area}–*t* plot in Au–bmim[PF_6]-Au detects only the EDL formation process, while that in the Au–bmim[PF_6]-[7]phenacene–Au MIS device detects both processes of EDL and

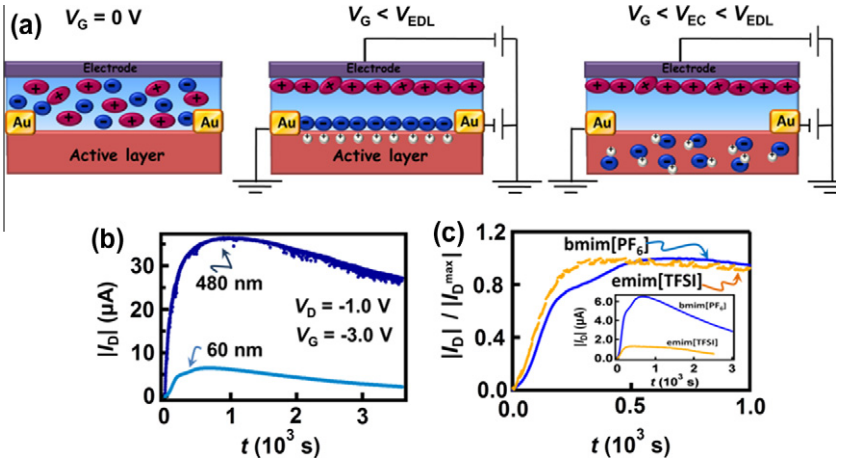

Fig. 5. (a) Schematic representation of ionic liquid capacitor at each V_G. EDL and EC capacitors are shown, respectively, in middle and right of (a). (b) $|I_D|$–t plots for 60 and 480 nm thick [7]phenacene TFTs with bmim[PF_6]. (c) Normalized $|I_D|$–t plots for [7]phenacene TFTs with emim[TFSI] and bmim[PF_6]; normalization is performed by dividing the measured $|I_D|$ by the maximum $|I_D|$. Inset of (c): $|I_D|$–t plots for [7]phenacene TFTs with emim[TFSI] and bmim[PF_6]. Thickness of [7]phenacene is 60 nm for (c). The L and W are the same in all devices in (b) and (c), as described in the experimental section.

electrochemistry (penetration of PF_6^-). The time, <2 s, required for EDL formation in the MIS device is consistent with that in Au–bmim[PF_6]-Au device, implying that the penetration process of PF_6^- to [7]phenacene thin films does not affect the EDL formation in short time region. As a consequence, the penetration process starts in longer time region than several seconds. To sum up, the time, <2 s, required for EDL formation (Fig. 4(d)) is exactly shorter than the time scale for I_D evolution by penetration of PF_6^- (Fig. 4(c)).

It is found that the polymer FETs with polymer electrolytes and ionic liquids show two types transistor operation, EDL FET (electrostatic carrier doping) and EC transistor (electrochemical doping) [19–23]. We fully discuss characteristics of [7]phenacene EC TFTs based on the model presented for polymer FETs. As seen from Fig. 5(a), when V_G is not applied to ionic liquid ($V_G = 0$), the anions and cations are dissolved in ionic liquid. When negative bias voltage is applied to ionic liquid ($V_G < V_{EDL} < 0$), the EDLs are formed on both the active layer side and gate electrode side; the V_{EDL} refers to the threshold voltage for EDL FET. The cations (anions) are close to gate electrode (active layer). Holes are accumulated in one or two monolayer(s) of active layer at the interface between active layer and ionic liquid. The anions may penetrate into the active layer together with hole carries when high negative V_G is applied ($V_G < V_{EC} < V_{EDL}$); the V_{EC} means the threshold voltage for EC TFT and the V_{TH} determined from transfer curves (Figs. 2 and 3) in [7]phenacene TFTs with ionic liquids corresponds to V_{EC}. Holes are weekly bound to anions, but at sufficiently high hole density, the screening of the Coulomb attraction occurs and metallic behavior is observed in channel region. This transition is recognized as 'Mott-transition' by Yuen et al. [22]. The channel region is the whole of active layer, *i.e.*, the region in which anion penetrate. Thus the EC TFT is a bulk transistor, and the performance is reversible. Here it should be noted that the I_D values in forward transfer curves in Fig. 2(a) and (c), and Fig. 3(a) are too low below $|V_{TH}| = |V_{EC}| \sim 2$ V despite of the formation of EDL. This suggests the localization of holes caused by the strong Coulomb attraction force between PF_6^- (or $TFSI^-$) and hole at EDL region. In other word, the [7]phenacene TFTs with emim[TFSI] and bmim[PF_6] may not provide the detectable I_D owing to the strong attractive force even if the EDL capacitor is formed.

It is interesting to know whether the electrochemical doping may occur in the transistors with single crystals (SC) of organic semiconductor since ion diffusion/penetration may be prevented because of high crystallinity and a few grain boundaries. In the case of organic thin films used in this study, the ion diffusion/penetration may effectively occur because of existence of many defects and grain boundaries, leading to EC transistor. Actually, a slow increase in I_D shown in Fig. 4(c) reflects the characteristics of electrochemical doping into three dimensional (3D) bulk region of [7]phenacene thin films. To investigate characteristics of [7]phenacene SC transistor with ionic liquids is of importance to clarify the microscopic process of electrochemical doping or ion penetration/diffusion to active layer. The investigation with SC transistor is now in progress.

Fig. 5(b) shows the $|I_D|$–t plots for two [7]phenacene TFTs with bmim[PF_6] which have different thickness of [7]phenacene thin films (60 and 480 nm); the V_D and V_G applied are −1.0 and −3.0 V, respectively. If the [7]phenacene TFT with bmim[PF_6] is an EC TFT, the maximum $|I_D|$ should be different owing to the different thickness, since the EC TFT is based on electrochemical doping of PF_6^- to the whole region of [7]phenacene thin films. Both $|I_D|$ values increase with an increase in t and gradually decrease above 1000 s. As seen from Fig. 5(b), the maximum $|I_D|$ for 480 nm thick [7]phenacene TFT is six times as high as that for 60 nm thick TFT, supporting that these TFTs operate in bulk region of [7]phenacene thin films and the TFT is an EC transistor. The reason why the decrease in $|I_D|$

above 1000 s is observed remains to be clarified, but the tendency is observed for most of $|I_D|$–t data (Fig. 4(c), Fig. 5(b) and (c)). A recent preliminary experiment with spin probe method shows a clear decreases in hole-concentration in the time region when the $|I_D|$ decreases [24]. That is, the decrease is not associated with localization of holes. Further investigation is necessary for clarifying the origin.

Furthermore, we discussed on hysteresis in transfer curves of [7]phenacene TFTs with emim[TFSI] and bmim[PF_6] (Figs. 2(a) and (c)). The hysteresis in [7]phenacene TFT with bmim[PF_6] is larger than that with emim[TFSI]. The reverse transfer curve in [7]phenacene TFT with bmim[PF_6] is much higher than the forward transfer curve. We measured the I_D as a function of t for [7]phenacene TFTs with emim[TFSI] and bmim[PF_6], and the normalized $|I_D|$–t plots are shown in Fig. 5(c); the normalization is done by dividing the $|I_D|$ by the maximum $|I_D|$ value. The $|I_D|$ evolution in TFT with bmim[PF_6] is slower than that with emim[TFSI], *i.e.*, the penetration of PF_6^- into [7]phenacene thin films is slower. The slower penetration/diffusion of PF_6^- can reasonably explain the characteristics or hysteresis observed in transfer curves (Fig. 2(a) and (c)), because the slow diffusion may provide a slow response for decrease in $|V_G|$ and it may still cause an increase in $|I_D|$ when $|V_G|$ decreases.

However, the behavior observed in Fig. 5(c) cannot be explained by the simple idea that small size of anion (PF_6^-) more rapidly penetrates into the thin films than large size of anion ($TFSI^-$). Here, we have to consider that the bmim[PF_6] is gel and emim[TFSI] is liquid (not gel). If the viscosity of ionic liquid is taken into account, larger hysteresis in [7]phenacene TFT with bmim[PF_6] may be reasonably explained because high viscosity of bmim[PF_6] gel leads to low diffusion coefficient, *i.e.*, PF_6^- ions cannot effectively penetrate into thin films. Therefore, the slow penetration of PF_6^- causes the hysteresis in transfer curve because of a slow response for applied V_G.

As seen from inset of Fig. 5(c), the $|I_D|$ is higher by an order of magnitude in [7]phenacene TFT with bmim[PF_6] than that with emim[TFSI], which is consistent with the characteristics of transfer/output curves shown in Fig. 2. The results suggest that bmim[PF_6] is a better ionic liquid for electrochemical doping than emim[TFSI]. This may be due to that anion size (PF_6^-) is so small that large amounts of PF_6^- can be doped into the [7]phenacene thin films, although long time is required to completely penetrate, producing high absolute I_D in [7]phenacene TFT with bmim[PF_6].

4. Conclusion

We fabricated [7]phenacene TFT with two different ionic liquids. The low voltage operation and high field-effect mobility are realized in [7]phenacene TFT with bmim[PF_6]. The device performance is superior to the low-voltage operated [7]phenacene FET with HfO_2, indicating availability of bmim[PF_6] gel. Furthermore, the excellent device performance of [7]phenacene TFT with bmim[PF_6] in the device structure shown in right of Fig. 1(a) suggests the destruction of hole-injection barrier by high density of hole accumulation, which may present one way for the smooth carrier injection in organic transistor, *i.e.*, high-density carrier-accumulation. If this is the case, we may expect the destruction of not only hole-barrier but also electron-barrier in this type of TFTs. The most important conclusion of this study is that [7]phenecene TFT operates electrochemically, *i.e.*, EC TFT (not EDL FET). The operation mechanism was confirmed from I_D–t and C_{area}–t measurements (Figs. 4 and 5). The time scale of transistor characteristics in [7]phenacene TFTs with emim[TFSI] and bmim[PF_6] is different from that in typical EDL FETs [19–23]. Thickness dependence of thin films in I_D–t plot in [7]phenacene TFT with bmim[PF_6] provided a conclusive evidence that this TFT operated electrochemically in bulk region of thin films. We stress the importance to clarify the operation mechanism in organic thin film transistors with ionic liquids, for new application of organic transistors with ionic liquid gate dielectrics. The technique of EC transistor, or electrochemical doping with ionic liquid may be available for high density carrier accumulation to control physical properties of organic materials.

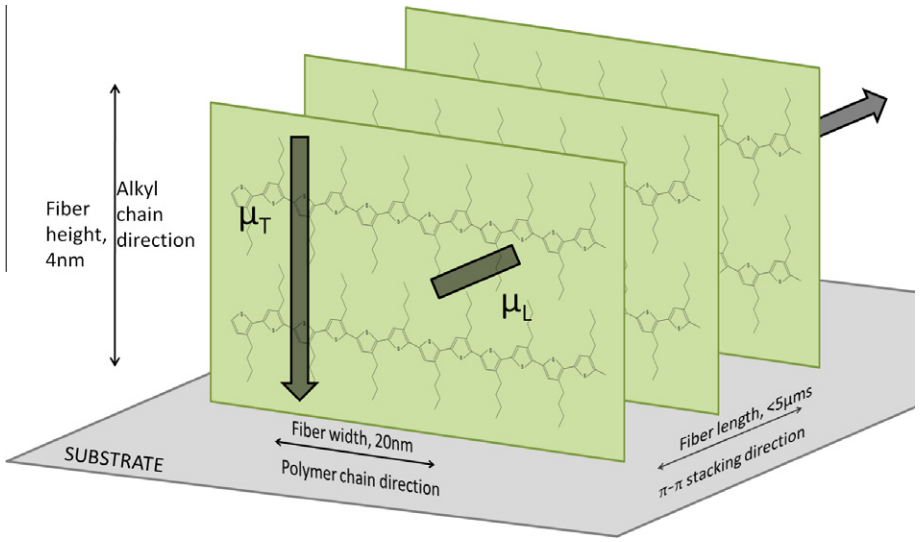

Fig. 1. Schematic of the P3BT nanofiber and the two investigated charge transport directions. μ_T is the transversal mobility and μ_L is the longitudinal mobility.

along the height of one NF, μ_T for transversal mobility. With this approach, charge transport anisotropy in P3AT NFs will be evidenced, since we find at least four orders of magnitude difference between μ_L and μ_T.

2. Experimental

P3AT NFs were synthesized as described in Ref. [8]. P3AT denotes a family of conjugated polymer of which the number of C atoms in the side chain can vary. In this study, we use poly(3-butylthiophene) (P3BT), four C atoms, poly(3-hexylthiophene) (P3HT), six C atoms, and poly(3octylthiophene) (P3OT), eight C atoms. The M_n values [in kg mol^{-1}] as obtained by GPC *versus* polystyrene standards in chlorobenzene at 60 °C Ref. [8] were (PDI between parentheses) 19.5 (2.29) for P3BT, 23.6 (1.95) for P3HT, and 28.0 (1.66) for P3OT. Regioregularities as obtained by ^{1}H-NMR Ref. [8] were 96.5, 94.0, and 97 for P3BT, P3HT and P3OT, respectively. Nanofibers were prepared in *o*-chlorotoluene (P3BT), *p*-xylene (P3HT) and pinane (P3OT) as described in Ref. 8 at 0.4, 1 and 0.5 wt.% concentrations and then diluted to the concentrations of 0.005 to 0.001 wt.% used in this work. From tapping mode AFM measurements (for which the resolution is better than in CAFM), NFs heights and widths are typically 4 nm and 20 nm respectively, independent of the alkyl chain length. It is known that when used with appropriate high work function electrodes, such as Au or Pt, they behave like p-type semiconductors [11].

The transistor structure used consists of a highly n-doped Si wafer (acting as the gate electrode) with a SiO_2 gate dielectric on top of it (gate capacitance per unit area, C_o = 16.9 nF cm^{-2}). A self-assembled monolayer of hexamethyldisilazane (HMDS) was used to passivate the SiO_2 layer. A thin drain electrode (10 nm Pt layer on top of 2 nm Ti adhesion layer) was patterned by standard photolithography. Thin electrodes were chosen to prevent NFs disruptions. The source, drain and gate electrodes were connected by a voltage source internal to the AFM and an external one (Keithley 2400), both sources being grounded to the tip potential. The NFs were deposited on the transistor by drop-casting.

The Veeco multimode AFM equipped with the Nanoscope IIIa controller, the quadrex module and the CAFM module were used. We employed two kinds of CAFM tip: $PtIr_5$ and Au coated tips from Nanosensors. Both tips give similar results and have a spring constant of 0.2 N/m. To avoid any degradation on the soft polymer NFs a low contact force (∼0.3 nN, deduced from force-curve measurements) was employed. Assuming a Young's modulus for P3BT [12] of ∼1 GPa, a tip radius of 25 nm (typical for CAFM tips) and using the Hertz mechanic model [13], we find a contact radius of ∼2 nm. To avoid sample contamination and tip oxidation, all the measurements were performed in a home-made glove box with oxygen concentration lower than 50 ppm and humidity concentration lower than 10 ppm.

3. Results and discussion

CAFM is a current sensitive AFM technique in which a metal coated AFM tip scans a sample under a user defined bias voltage. CAFM can be used in the spectroscopic mode and in the imaging mode. In the spectroscopic mode, the tip is fixed on a specific position on the sample while an *I*/*V* characteristic is performed. In the imaging mode, topography and current maps are simultaneously recorded at fixed voltage and enable to distinguish high and poor conductive regions.

3.1. Longitudinal transport, μ_L

The measurements shown in this paragraph are for P3BT. Longitudinal charge transport is studied by building

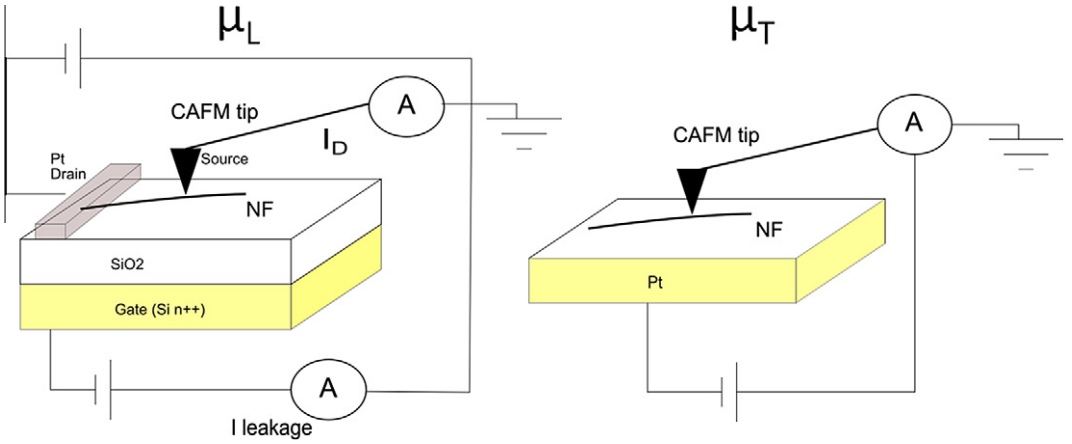

Fig. 2. Left: transistor structure for measuring longitudinal mobility, μ_L. Right: sandwich structure for measuring transversal mobility, μ_T.

a transistor with one electrode being the mobile CAFM tip, as depicted in Fig. 2. The purpose is to measure the current flowing from the drain electrode to the CAFM tip via the NFs which are deposited in between. Fig. 3A and B show the topographic image of the NFs and the corresponding current map for a fixed drain voltage V_D and a varying gate voltage V_G. We observe that the correlation between both maps is remarkable: the current is zero where no NFs are present in the topography, which is logic since there is no pathway for holes to flow from the tip to the drain electrode. On the other hand, when the tip touches a NF we see that the current becomes positive since an electrical transport channel is found. When scanning the sample from the top to the bottom of the image, V_G is progressively decreased and leads to an increase of the NFs conductivity as this is expected for a p-type semiconductor. This indicates that the gate electrode is well connected. If alternatively, we fix the CAFM tip on one NF and perform, in the spectroscopic mode, several V_D sweeps at different fixed V_G, we obtain the output characteristic of Fig. 3C showing the linear and saturation regimes. This proves that our transistor is operating properly.

We have checked that our measurements are non-destructive since two successive mappings on the same area give very similar topographic and current maps. However, when we increase the current flowing through the individuals NFs (by changing adequately V_D and V_G) up to a value of about 5 nA, we have observed that the current jumps immediately to zero. In other words, the maximum current I_{max} we have measured without NFs destruction is about 4 nA. Taking 20 nm for the width of a NF and 1 nm for the thickness of the accumulation layer, we obtain a maximum current density of about 2 kA/cm^2, near the value (700 A/cm^2) reported by Ref. [9].

Compared to a standard transistor structure with two fixed electrodes, the main benefit of this mobile electrode transistor is that we can choose the quantity of NFs under investigation. In particular, by placing the tip very close to the drain electrode and by depositing NFs from very dilute dispersions, it is possible to measure μ_L on one single NF.

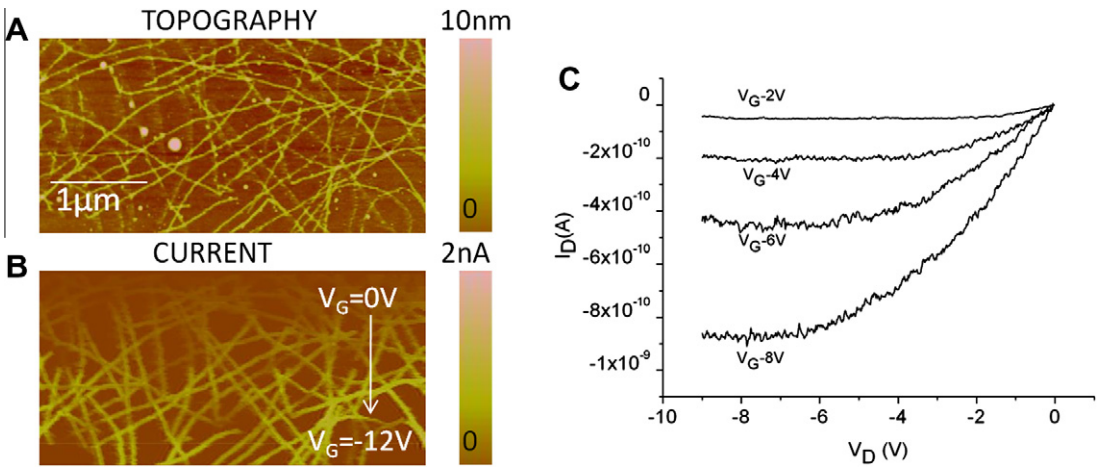

Fig. 3. (A and B) show the topography and current images obtained on P3BT NFs at fixed $V_D = -4$ V and changing V_G. The current is increased as V_G is decreased. Fig. 3C shows the output characteristic when the tip is fixed on a P3BT NF demonstrating the expected linear and saturation regimes for a p-type semiconductor.

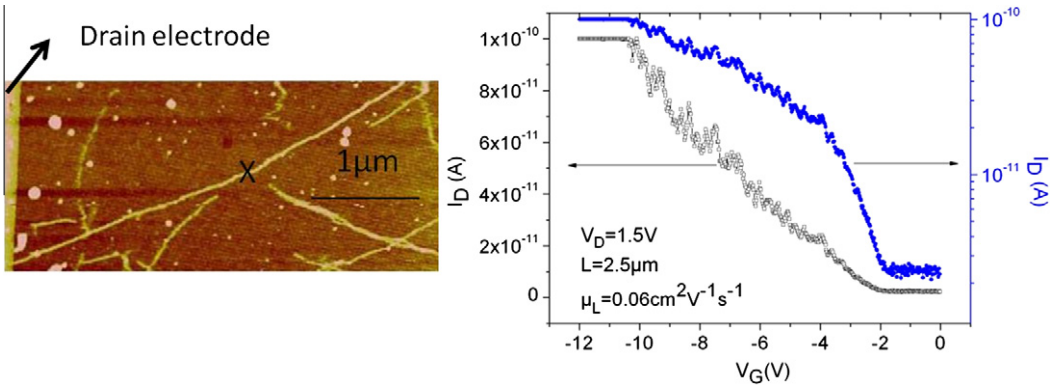

Fig. 4. Topographic image of one P3BT NF touching the drain electrode at the left extremity of the image and the transfer characteristic taken at point X from which μ_L is fitted.

The strategy is illustrated on Fig. 4. First, an isolated NF touching the drain electrode is located. This is done without drain bias which would cause instabilities in the image due to the metal–metal contact. Once the target NF is identified and the image is very stable, the tip is fixed on the desired location and a transfer characteristic is performed as shown in Fig. 4. After the I/V measurement is done, we check that the NF is not destroyed by re-imaging the NF.

Before extracting any mobility values, some interesting points can be deduced from the transfer characteristic. We observe that the onset voltage, i.e. the voltage at which conduction starts in the log plot, is close to zero. This is an indication that the transistor does not suffer from hole and electron trapping which are known to move the onset voltage towards negative and positive voltage respectively [14]. This is due to our home-made glove box which prevents oxygen and water contamination.

Because the tip radius is small (~25 nm) and the channel length (<3 µm) is smaller than for conventional transistors, we have to check that the contact resistance R_c is not limiting the current measurements. This can be done in the imaging mode where we measure the current along one NF in function of the NF length as described in detail in Fig. 5.

The total resistance R_{tot} can be written as the sum of the contact resistance and the channel resistance: $R_{tot} = R_c + R_{channel} = R_c + \frac{\rho L}{Wh}$ with L the channel length, W the channel width and ρ the NFs resistivity. The extrapolation of the measured resistance at zero length gives an estimation of the contact resistance. As depicted in Fig. 5, we find $R_c \sim 1\ G\Omega \pm 1\ G\Omega$. Although this number can seem huge, the worst case value (2 GΩ) is still small enough compared to the intrinsic NF resistance to be considered as not influencing the results. The reason is that with the CAFM-based transistor on one single NF, we usually measure current lower than 100 pA at a bias of a few volts. This provides a minimum value for the total resistance of 20 GΩ much higher than the worst case R_c value. This conclusion that R_c is not perturbing the measurements can also be deduced from the slope of the transfer characteristic at highly negative V_G. If R_c was limiting the results, we would have observed a decrease of the absolute slope of the curve at high negative V_G, which is not the case.

Finally, the longitudinal mobility μ_L is extracted from the slope of the transfer characteristic in the negative gate voltage region: $\mu_L = \frac{L}{WC_oV_D} \cdot \frac{\partial I_D}{\partial V_G}$ where $W = 20$ nm (equals here to the width of one NF), I_D is the transistor current

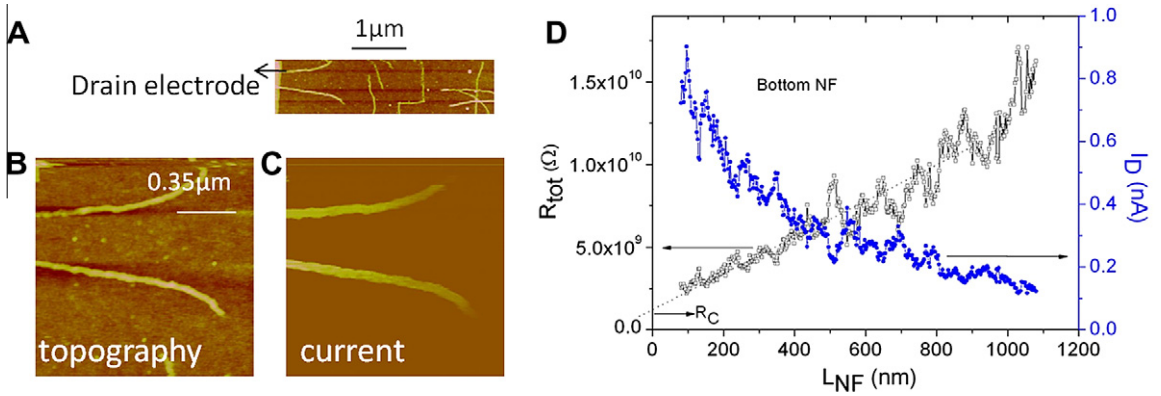

Fig. 5. Evaluation of the contact resistance. (A): topographic map showing two independent NFs touching the drain electrode. (B and C): zoomed topographic and current maps of A where the drain electrode is 80 nm on the left of the image. (D): Current profile along the bottom NF of C (LNF denotes the length of the NF starting from the drain electrode). From the extrapolation of the total resistance R_{tot} at zero length, we can extract the contact resistance R_C.

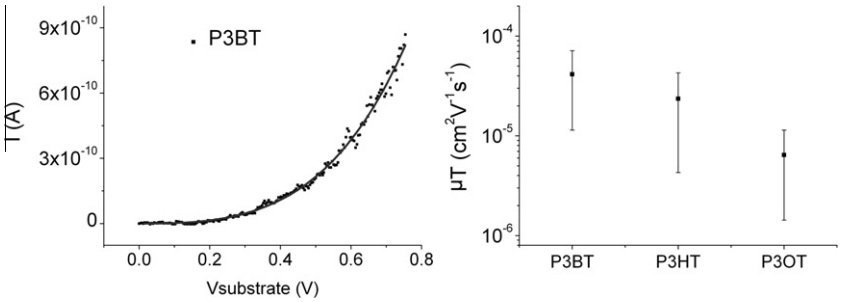

Fig. 6. Typical transversal *I*/*V* curve obtained on single P3BT NF (dots: experimental points, line: fit to Eq. (2)) and the transversal mobility for P3BT, P3HT and P3OT NFs.

and *L* the NF's length between the drain electrode and the X label as deduced from the topographic map. The measurement was done on about ten independent P3BT NFs and led to the following result: μ_L 0.07 ± 0.03 $cm^2\,V^{-1}\,s^{-1}$. It corresponds to a hopping time between two chains of about 100 ps.

There have been several papers reporting that the longitudinal mobility on films of NFs [11] and web of NFs [2] is not influenced by the alkyl side chain length. The same question arises for one single NF. To our knowledge, there are no reports on isolated P3BT NF and only two reports on P3HT NF: one from Merlo et al. [6] (0.06 $cm^2\,V^{-1}\,s^{-1}$) and one very recent by Shimomura et al. [10] (0.05 $cm^2\,V^{-1}\,s^{-1}$). We see that our mobility value for P3BT (0.07 $cm^2\,V^{-1}\,s^{-1}$) is very comparable to these P3HT values. This is a suggestion that μ_L is alkyl chain length independent for one single NF.

Using the acoustic deformation potential scattering theory [15] the mobility in one ideal single crystal has been calculated to be 31 $cm^2\,V^{-1}\,s^{-1}$ for P3HT [16] which is almost three orders of magnitude higher than μ_L. Moreover, we note also that μ_L is not larger than best mobility values ($\sim$0.1 $cm^2\,V^{-1}\,s^{-1}$) for semi-crystalline self-organized P3HT films [17,18] for which it has been proved that the molecular orientation at the dielectric interface is the crucial factor [11]. These comparisons confirm the fact that one NF cannot be seen as one single crystalline region but instead is a superposition along its length of single crystalline regions with a characteristic length around 5 nm as suggested by the authors of Ref. [10]. Density functional theory calculations on crystal structure of P3HT have suggested that a likely structural disorder is one in which one of the polymer backbone within a lamella runs in the direction opposite to the majority [19].

From a technological point of view, we consider that the knowledge of μ_L and I_{max} is interesting for applications engineers to decide whether the NFs can be used or not as interconnecting wires in molecular electronics.

3.2. Transversal transport, μ_T

To investigate charge transport along the height of one NF, we used the sandwich geometry depicted in Fig. 2. The NFs were drop-cast and gently N_2 flushed on a conducting substrate. We have chosen Pt for its low roughness (<1 nm) and the fact that its work function (5.6 eV) is close to the highest occupied molecular orbital of P3BT ($\sim$5.3 eV). Since the NFs are deposited on a metal and the NFs surface coverage is low, measurements in the imaging mode (mapping at constant voltage) would lead to metal–metal contacts and consequently to shortcut currents which are orders of magnitude out of range, making the amplifier saturated and the images unstable. Consequently, measurements are forbidden in the imaging mode and restricted to the spectroscopic mode. In order to get reproducible and non-destructive measurements, we follow an appropriate strategy. Firstly, we acquire several successive topography maps at zero bias until the images are very stable. Secondly, we zoom in successively several times until the tip can be positioned on the target NF. Thirdly, the *I*/*V* characteristic is recorded. Finally, after zooming out, the same area is imaged and compared with the image before the *I*/*V* sweep to check that the NF is not destroyed by the measurement. To check the tip cleanliness, which is critical when investigating soft materials, *I*/*V* sweeps on the Pt electrode were regularly done in a short voltage range (+/− 100 mV to limit the current). Tips with a linear *I*/*V* response (ohmic behavior) were considered as good and used for the NFs while tips with other responses were disregarded.

A typical *I*/*V* curve obtained on a single P3BT NF is shown in Fig. 6. Due to the high work function of tip and bottom electrode, we can rule out electron current and consider our device as hole only. Diode characteristics on conjugated polymer are usually associated with space-charge limited current (SCLC) transport [20] and fitted by the Mott-Gurney law [21,22]: $J_{plannar} = \frac{9}{8}\varepsilon_r\varepsilon_0\mu_{T,V}\frac{V^2}{h^3}$ where *J* is the current density, ε_r (=3) is the relative dielectric permittivity of the active layer, ε_0 is the permittivity of free space, *V* is the applied voltage, and *h* is the NF height. Usually, a Poole–Frenkel form is used to take into account the field dependence of the mobility $\mu_{T,V}(V) = \mu_T e^{0.89\gamma(V/h)^{0.5}}$ (1) where μ_T is the zero field mobility, γ is proportional to the field dependence of the mobility. These equations are valid for devices with two plane electrodes where the field lines are perpendicular to the electrodes. For CAFM measurements, the geometry is much different at the tip sample contact and it leads to a current density significantly higher close to the tip. Reid et al. [23] have shown that the use of the standard above equations on CAFM data causes a mobility overestimation by up to three orders of magnitude depending on the ratio of the tip contact diameter, *d*, to the sample thickness, *h*. They propose the following correction: $\frac{J_{CAFM}}{J_{plannar}} = \frac{8}{9}\alpha\delta\left(\frac{h}{d}\right)^{1.6\pm0.1}$ (2)

where $\alpha = 8.2$ and $\delta = 7.8 \pm 1$. In our case, $h = 4$ nm and $d = 4$ nm which gives a correction factor of about 57.

We have performed measurements on isolated NFs of P3BT, P3HT and P3OT (at least ten independent NFs of each) and fitted the I/V curves to Eq. (2). However, the classic way to prove indisputably the SCLC character of the transport is to check that the current scales as $\propto 1/L^{1.4}$ (or $\propto 1/L^3$ for the planar device). Unfortunately, we cannot tune our sample thickness since the NF's height is fixed. Irrespective of the polymer, we find a typical value for γ of $\sim 1 \times 10^{-4}$ $m^{1/2} V^{-1/2}$ which is of the same order of magnitude as for reported values on conjugated polymers studied with CAFM [23,24]. On the other hand, we have found a remarkable dependence for μ_T with the alkyl side chain length as observed on Fig. 6. As explained in the experimental part, the NFs thickness is found to be alkyl chain length independent and therefore is not responsible for the variability of μ_T. The transversal mobility μ_T is found to decrease with the number of carbon atoms on the side chain. This suggests that longer alkyl chains reduce the efficiency of charge hopping from polymer chain to polymer chain. This statement is only valid if the NFs are oriented with the alkyl chain direction perpendicular to the substrate like depicted in Fig. 1. A detailed structural characterization of the NFs concluded that all of the polymer NFs strongly orient with the alkyl chain direction perpendicular to the substrate [8]. Moreover, the passivation of SiO_2 with HMDS is known to promote the same orientation. Then, we argue that the big majority of NFs segments orient like in Fig. 1 even if we cannot rule out that locally on some spots the NFs are slightly twisted or turned.

To our opinion, a better accuracy than one order of magnitude on μ_T seems difficult to reach because important factors like the contact force and contact diameter which have shown to play a crucial role [25] are hard to control or evaluate. In particular, the contact force has tendency to increase while scanning the sample probably due to tip voltage induced contact forces.

To our knowledge, charge transport investigation along the NF height is reported here for the first time. It is interesting to see that μ_L is three to four orders of magnitude higher than μ_T even if the applied field is much bigger for the transversal configuration [26] which is known to increase the mobility. This was expected since it is known that the fiber direction is a fast charge transport direction (through the π-orbital's overlap) while the alkyl side chain direction is much slower. It is also valuable to point out that, even if small, μ_T is not zero and therefore this has to be taken into account when designing devices architectures where transversal current in NFs is undesired.

4. Conclusion

In conclusion, charge transport in one single P3AT NF has been investigated along two distinct directions. We have developed a CAFM-based transistor which allows us to measure the longitudinal mobility along the length, corresponding to the π–π stacking direction, of one NF: $\mu_L = 0.07 \pm 0.03$ $cm^2 V^{-1} s^{-1}$. Then, in a second configuration, NFs were used in a sandwich structure and we have found a transversal mobility along the height, corresponding to the alkyl chain direction, of one NF: $\mu_T \sim 10^{-5}$–10^{-6} $cm^2 V^{-1} s^{-1}$ depending on the length of the alkyl side chain. With this approach charge transport anisotropy in P3AT NFs has been evidenced, yielding at least four orders of magnitude difference between μ_L and μ_T. We consider that the knowledge of I_{max}, μ_L and μ_T is an important step towards the use of conjugated polymer nanofibers in electronic applications.

organic/organic interface had a direct and pronounced impact on the performance of up-conversion devices (external efficiency, turn-on voltage, etc.) MoO_3-doped CuPc as the interface layer, the device showed the highest photon-to-photon conversion efficiency of 0.81 W/W%.

2. Experiment

The inorganic detector structure was prepared using *n*-GaAs substrate in a VEECO GEN-II molecular beam epitaxy (MBE) system. In the MBE chamber the surface oxide was desorbed at 580 °C, and a GaAs layer was grown as a buffer. Then, the thirty $In_{0.2}Ga_{0.8}As$/GaAs multiple quantum wells (MQWs) were grown under an Ga/In flux ratio of 2.2, which 8-nm-thick InGaAs wells were separated by 20-nm-thick GaAs barrier layers. Finally, the *p*-GaAs layer was grown as the interface layer for the up convertor. Fig. 1 shows a sketch of the up convertor. The first step in the device fabrication was to grow a 150-nm-thick SiO_2 layer on the top surface of the *p*-GaAs layer using plasma-enhanced chemical vapor deposition. This was for the purpose of preventing short circuits between the top electric contact and the underlying semiconductor substrate since the OLED layers would be only 140 nm thick. Square windows were patterned using standard photolithography and were chemically etched onto the SiO_2 layer. A metal contact In was deposited onto the back side of the *n*-GaAs substrate of the $In_{0.2}Ga_{0.8}As$/GaAs MQWs sample, serving as the common bottom contact for the up conversion devices. The *p*-GaAs surface is boiled in a mixture of sulfuric acid and phosphoric acid (H_2SO_4:H_3PO_4 = 3:1) to remove oxides for 5 min, then, ultrasonic cleaned in ethanol for 10 min, finally, washed in deionized water.

Then, the sample was placed into an organic molecular beam deposition system (OMBD) with the vacuum about 3×10^{-7} Torr. The OLED layers were deposited on top of the exposed *p*-GaAs areas. *N*,*N*′-bis-(1-naphthl)-diphenyl-1,1′-biphenyl-4,4′-diamine (NPB), 10-(2-benzothiazolyl)-2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-1H,5H,11H-(1)-benzopyropyrano (6,7,8-i, j) quinolizin-11-one (C545T):tris(8-hydroxyquinoline)aluminum (Alq_3) and Alq_3 were used as hole transport, emitting and electron transport layers, respectively. And the thickness of NPB, C545T:Alq_3 and Alq_3 in these devices are 75, 30 and 30 nm, respectively. The MoO_3, CuPc and MoO_3-doped CuPc as hole injection layer in OLED, or the interface layer between inorganic detector structure and OLED, were investigated. On the top of organic layers of these devices are LiF (1 nm)/Al (25 nm) cathodes under identical conditions, which is partially transparent to green light.

The emission area of the devices was 0.01 cm^2 as determined by the overlap area of the anode and the cathode. The current density–voltage–luminescence (*J*–*V*–*L*) characteristics of the devices were measured by a ST-86LA spot photometer and a computer controlled Keithley electrometer 2400 at room temperature in ambient atmosphere. Veeco NanoScope 3D atomic force microscope (AFM) measurements were performed to characterize the surface morphology of the MoO_3-doped CuPc films and *p*-GaAs.

3. Results and discussion

We designed and fabricated the light up-conversion devices from 980 to 520 nm by direct tandem integration of an OLED and an inorganic photo detecting structure. As shown in Fig. 1, in this hybrid device, the *p*-GaAs top layer

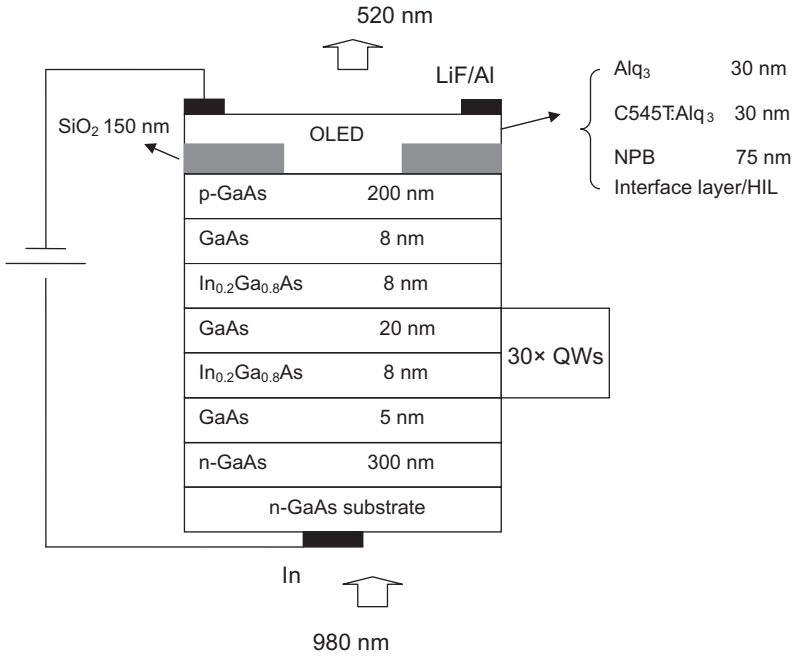

Fig. 1. Schematic diagram of up conversion device.

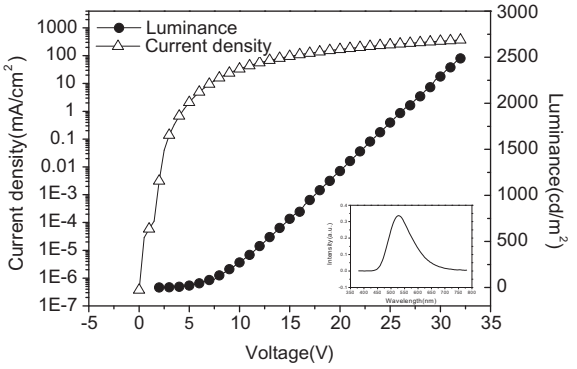

Fig. 2. Current density–voltage–luminance characteristics of device A under a 980 nm IR illumination. Inside picture is the spectrum of device A at 20 V.

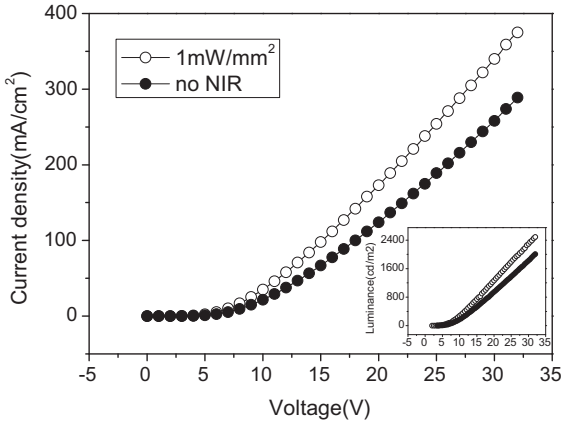

Fig. 3. Current density-voltage characteristics of device A under no IR and 1 mW/mm^2 illumination. Inside picture is the luminance–voltage characteristics of device A.

of inorganic photo detecting structure as the anode of the OLED. Under bias condition, the OLED component is under forward bias and the *p–i–n* detector component is under reverse bias. The input IR light was absorbed by the InGaAs/GaAs MQWs layer generating photocarriers, the photocarriers were then injected into the organic layers in OLED and emit green light from Al cathode surface. The injection of hole from *p*-GaAs layer is modulated by incoming 980 nm light. The interface layer between the organic and inorganic layers thus plays a vital role in such up-conversion devices.

Therefore, we fabricated three up convertor devices, which chose different interface layer (or hole injection layer in OLEDs), MoO_3-doped CuPc (device A), MoO_3 (device B) and CuPc (device C) [15]. The thickness of interface layer is 5 nm in all devices. Firstly, Fig. 2 shows the luminance–voltage–current density curves of the device A under a 980 nm IR illumination. The input NIR power density was around 1 mW/mm^2. The device with MoO_3-doped CuPc layer (50 V/V%, volume ratio) show significantly reduced operation voltages. The operation voltage of 2.8 V at 0.1 mA/cm^2 was achieved (The turn-on voltage is 2.6 V at 1 cd/m^2). As the device bias continued to increase, the current density (photocurrent density plus dark current density) increased rapidly up to ~200 mA/cm^2 at 20 V. Correspondingly, the output luminance of green emission (peaked at 520 nm) from OLED component arrived at 1264 cd/m^2 at 20 V. The luminance of this up-convertor device was even brighter than that of a LCD screen (about 200 cd/m^2). The results indicated that holes were injected from *p*-GaAs to organic layers efficiently, and the inorganic-organic interface had an excellent electrical connection in this device. Fig. 3 is plotted the voltage-current density of device A at no IR and 1 mW/mm^2 illumination, thus the turn-on voltage of the integrated device is increased from 2.8 to 3.8 V at same current density when there is no IR irradiation. Under dark condition (i.e., no input NIR illumination), the brightness of the device is also small, only 942 cd/m^2 at a bias of 20 V resulted from dark current density. OLED external power efficiency (W/A) can be calculated by assuming that the upconversion device is a Lambertian source, according to reference [11], the calculated optical power efficiency (W/A) = luminance efficiency $\times \pi/488$. The 488 lm/W is the effective power conversion constant that is normalized by the OLED emission spectrum (peaked in 520 nm). The overall external up conversion efficiency can then be calculated by multiplying the detector responsivity (A/W) and the OLED optical power efficiency (W/A), and the results are plotted in Fig. 4. It can be found that the highest external power efficiency of 0.015 W/A is achieved at the bias of

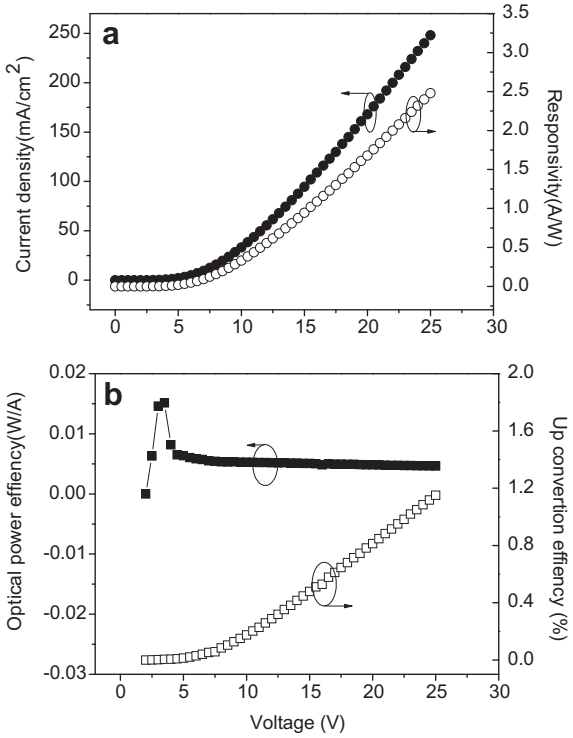

Fig. 4. (a) Current density and device responsivity versus voltage of device A and (b) optical power efficiency and up conversion efficiency versus voltage of device A.

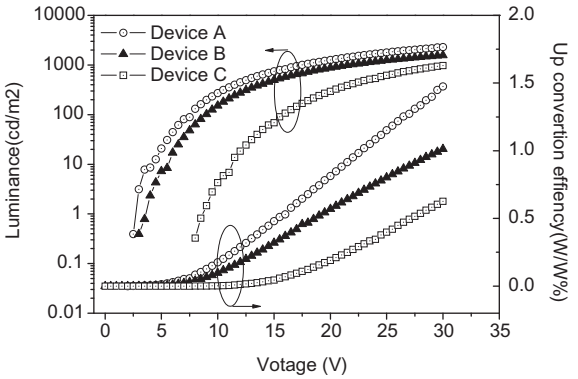

Fig. 5. Luminance and up conversion efficiency versus voltage characteristics of devices A, B, and C listed.

Table 1
The performance of devices A, B, and C in this work.

Device	Driving voltage at 1 cd/m^2 (V)	Luminance at 20 V (cd/m^2)	Upconversion efficiency at 20 V (W/W%)
A	2.6	1264	0.81
B	3.6	885	0.56
C	8.6	295	0.19

3.5 V, then it began to decrease to about 0.005 W/A at 10 V with little change in the bias. However, the overall external up conversion efficiency increased with the voltage, agreeing with the aforementioned current density-voltage characteristics. It increased up to around 0.81% W/W at a bias of 20 V. Under a bias of 20 V and an input 980 nm near infrared radiation of 1 mW/mm^2, the NIR induced green-light luminance reached up to 1264 cd/m^2, which was visible even under normal daytime light condition. Secondly, by comparing the three interface layers for device performance, we found that the appropriate interface layer is crucial for the organic and inorganic composite light up conversion device. As shown in Fig. 5 and Table 1, the turn-on voltage is 2.6, 3.6 and 8.6 V at 1 cd/m^2 for devices A, B, and C, respectively. Then, at the bias of 20 V, device brightness and upconversion efficiency is on the order of device A > device B > device C. Thus, these molybdenum oxide and organic materials composite as interface layer between the inorganic photo detecting structure and OLED is better than the single oxides or organic materials.

Fig. 6 shows AFM images of 50 V% MoO_3-doped CuPc (a), MoO_3 (b), and CuPc (c) films on glass substrates, the *p*-GaAs surface (d) of the inorganic photo detecting structure. The surface root-mean-square (RMS) roughness of 50 V% MoO_3-doped CuPc (a), MoO_3 (b), CuPc (c) and the *p*-GaAs surface (d) are 0.94, 2.06, 2.52 and 0.70 nm, respectively. The doped film owns a best smooth surface in these

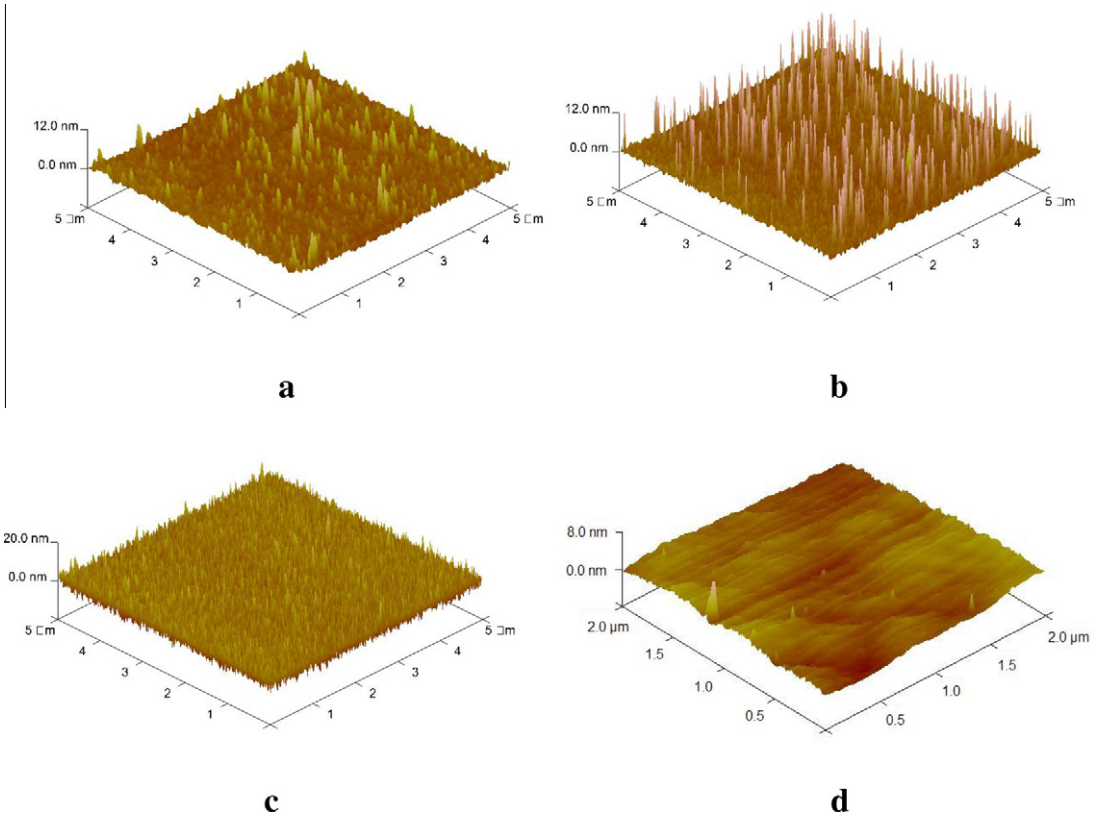

Fig. 6. The AFM images of 50 V% MoO_3-doped CuPc (a), MoO_3 (b), CuPc (c) films (about 50 nm) on glass substrates and the *p*-GaAs surface (d) of the inorganic photo detecting structure.

three organic layers. Moreover, the surface roughness of the composite films and *p*-GaAs are very small, but very close which is helpful for the ultimate device performance.

4. Conclusions

In conclusion, we have demonstrated the design, fabrication, and characterization of a hybrid optical up-convertor from 980 to 520 nm through direct tandem integration of an inorganic $In_{0.2}Ga_{0.8}As/GaAs$ MQWs photodetector and an OLED. Efficient carrier injection across the inorganic-organic interface was achieved by the insertion of a thin MoO_3-doped CuPc layer. The NIR induced green-light luminance reached up to 1264 cd/m^2 at a bias of 20 V under an input 980 nm NIR power density of 1 mW/mm^2. The appropriate interface layer of the hybrid devices lowered the turn-on voltage to 2.6 V for an output luminance of 1.0 cd/m^2. The maximum external upconversion efficiency of an optimized device at 20 V is 0.81%. It is worthy to note that large leakage current in this photo-detector affects the detector responsivity, thereby further affecting the device performance of the up-convertor. We think that surface leakage current caused by surface defect states is the key ingredient in our devices. In the following work, we are continuing to examine this issue related to surface passivation to reduce the leakage current, and thus further improve the performance of the up-convertor.

niques are commonly used to deposit polymer films due to their high solubility in various solvents; the long polymer chains facilitate uniform film formation across the entire substrate. In general, small molecules exhibit better electrical and optical properties than polymers; therefore, development of solution-based patterning techniques for small molecule devices is of great interest [8,9].

Recent advances in film deposition and patterning techniques have enabled the fabrication of micro-OLEDs with fine pixel sizes. Micro-pixels are commonly prepared by patterning the anode or cathode by using photolithography, and blocking the electrode contacting area with insulating materials [5]. Organic small molecules can be deposited with solution-based techniques with the proper solvent. Techniques such as an ink-jet printing [10,11], roll to roll processing [12], or screen printing [13,14] have been demonstrated, but these techniques have limited resolution due to large droplet size and spreading of the solution. Micro/nano-contact printing techniques have been developed as a substitute for traditional fabrication techniques utilizing solution-processible characteristics [15–17].

Besides precise patterning, uniform film deposition is required over large areas and the organic materials must function properly in the display. Organic materials must maintain a uniform amorphous state during the fabrication process since device performance strongly depends on the morphological properties of the film, affecting color purity, device efficiency, and device lifetime. OLEDs require balanced electron and hole current transport to generate efficient electroluminescence [18]. Electron transport materials (e.g. Alq3) are chemically and environmentally sensitive to their processing and operating conditions. Any morphological transformation such as cluster formation or crystallization may alter the overlap of the π molecular orbitals, negatively impacting OLED function via red-shift of the emisson spectrum or decrease in quantum efficiency due to increased non-radiative recombination rates. In addition, the device could experience a significant decrease in lifetime [19–21]. Therefore, proper fabrication techniques and materials properties will be necessary to minimize imperfections so as to achieve functioning devices [22,23].

Here, we demonstrate a pixel patterning method by combining spin-casting with a structured hydrophobic surface to achieve directed self-assembly of Alq3 pixels with well-defined pixel size and long-range order. OLED structures based upon Alq3/TPD have been studied widely since these materials typically produce efficient performance for green emitting displays [24,18]. The device structure in this report consists of stacks of PEDOT/TPD/Alq3/LiF/Al [25,26]. This solution-based spin-on patterning technique can resolve the problems of local pixel placement and size through the use of photolithography, which allows higher resolution patterning of OLED pixels compared to shadow masking; here, we demonstrate pixels as small as 10 μm. A potential application of the spin-on patterning technique is in microdisplays [27]. A microdisplay is a moderate to high-resolution, small-diagonal display that is typically placed closer than 10-in. (~25 cm) to the eyes. Desired resolutions are 800 × 600 and 1280 × 1024 (SVGA, XGA, and SXGA formats), with active areas between 5 and 80 mm^2 and pixel sizes between 5 and 30 μm [28].

2. Experimental

2.1. Materials

Tris(8-hydroxyquinoline) aluminum (Alq3, Aldrich) was purified by sublimation and *N*,*N*-bis(3-methylphenyl)-*N*,*N*-diphenylbenzidine (TPD, Aldrich) was used as received. Poly(3,4-ethylendioxythiophene)-poly (styrenesulfonate) (PEDOT) (2.8 wt. % dispersion in H_2O, low-conductivity grade) was diluted with 1:1 ratio in DI water and sonicated before deposition. Octadecyl-trichlorosilane (OTS, Gelest, Inc.) was used as received. Chloroform (ACS reagent) was used as received without further purification. ITO/glass was purchased from Delta technology (ITO thickness: 100 nm, substrate thickness: 0.7 mm, sheet resistance, R_s: 1525 Ω, nominal transmittance: > 78%).

2.2. Thin film characterization

P-type silicon wafers [100] (1–10 Ω cm) were used as substrates to prepare Alq3 films for morphology scanning by atomic force microscopy (AFM), X-ray diffraction (XRD), and photoluminescence (PL) intensity versus wavelength. The wafer was diced into rectangular pieces, sonicated for 10 min at room temperature, rinsed with DI water, and then cleaned with a hot 'piranha solution' (25% concentrated hydrogen peroxide, 75% concentrated sulfuric acid) for 1 h to remove organic contaminants and strip the native silicon dioxide surface layer. Finally, the treated substrates were sonicated and thoroughly rinsed with DI water and dried in dry nitrogen flow. Alq3 solution was prepared with a concentration of 0.5 wt.% in chloroform in a clean room with short-UV filtered lighting to prevent photo-oxidation in the solution state. Alq3 solution was then spin-cast at 3000 rpm for 30 s on the cleaned Si substrate, which results in uniform 50 nm Alq3 thin films.

2.3. Pixel patterning

The pixel patterning process is illustrated in Fig. 1. Micro-channel or square well arrays with widths ranging from 10 to 100 μm and depths of 0.2 μm covering a total active area 6 × 6 mm^2 were fabricated in silicon using standard micro-fabrication techniques. A 500 nm silicon dioxide layer was grown by thermal oxidation as a wet etching mask. The SiO_2/Si wafers were cleaned as follows: sequential ultrasonic rinse in acetone, methanol, isopropyl alcohol, DI water, and baked at 200 °C prior to deposition of photoresist. The microchannels or wells were patterned by photolithography using Shipley 1813 positive photoresist and then developed with Shipley 352. The photoresist-patterned wafer was baked on a hot plate at 120 °C for 5 min. The wafer was etched with buffered oxide etch (BOE) to define the KOH etching mask in SiO_2. The patterned wafer was then etched to 0.2 μm with 60 wt.% KOH at 60 °C with high speed stirring to prevent formation of vapor on the Si surface, and then the SiO_2 mask was removed with BOE. The wafer was diced into 13 × 13 mm^2 squares. The diced substrates were oxidized by oxygen plasma for 1 min, resulting in a fresh silicon oxide layer

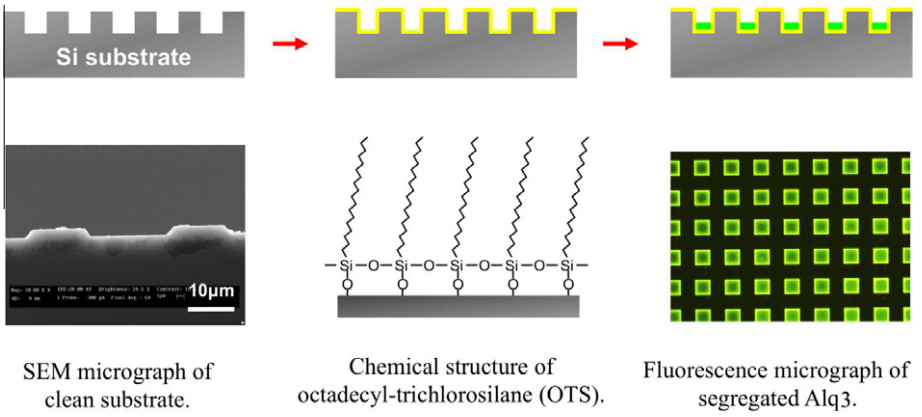

Fig. 1. Schematic of the spin-casting process onto pre-patterned substrates.

of 1.0–1.2 nm with a high density of silanol (Si–OH) groups. The substrates were treated in 1 mM OTS/toluene solution for 1 h and rinsed thoroughly with toluene and chloroform in an ultrasonic bath for 10 min each, leaving a monolayer with thickness 2–3 nm [29]. The OTS treated substrates were hydrophobic with a water contact angle of $\sim 100°$. Alq3 solution was prepared as before and drop-cast through a 0.4 μm pore size filter onto the spinning patterned substrate at 3000 rpm for 30 s. The addition of hydrophobic OTS to the surface discourages the adsorption of Alq3, thereby resulting in selective deposition in the pre-patterned micro-channels or wells [30,31]. The organic molecules on top are unstable and move toward the edges of the substrate during spinning, but the organic molecules on the bottom are trapped in the pre-patterned micro-channels or wells.

2.4. OLED fabrication

The bottom-emitting structure with a PEDOT hole injection layer consists of the following layers: ITO/PEDOT/Alq3:TPD/LiF/Al, as shown in Fig. 2. Despite the advantages of solution-based techniques, the solvent used can chemically destroy any pre-deposited layers. Therefore, here we make use of a single emissive layer consisting of a mixture of Alq3 as the electron transport and emissive material and TPD as the hole transport material. Mixed layers have been reported before, with vapor phase deposition [19] and spin-casting [32].

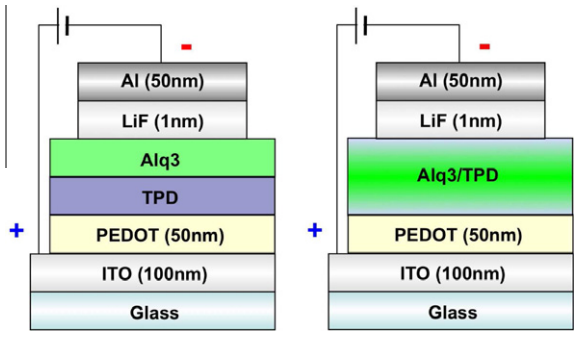

Fig. 2. Bottom emitting structure of Alq3-based OLED (left) and modified OLED structure incorporating TPD and Alq3 into the same layer (right).

The process of fabricating a bottom-emitting structure using the spin-on patterning technique is presented in Fig. 3. Insulating micro-channels and wells were fabricated in SiO_2 using microfabrication techniques. Two types of devices were made-pixel patterned devices and reference (i.e. large pixel) devices. For pixel patterned devices, insulating micro-wells were fabricated in SiO_2/ITO/glass as follows. SiO_2 was deposited onto ITO/glass substrates (bottom-emitting structure) by plasma-enhanced chemical vapor deposition (PECVD, Oxford Plasmalab 80) to a thickness of 0.2 ± 0.01 μm as determined by ellipsometry (Woollam V-VASE) and contact profiling (Tencor P-10 Profilometer). Substrates were ultrasonically-cleaned in DI water and wells of widths 10–100 μm were patterned in photoresist as described previously, across a 6×6 mm^2 area. The patterned substrates were dry-etched by RIE (Oxford Plasmalab 80) using CF_4 with etching rate 35–37 nm/min. Substrates were treated with 1 mM OTS as described previously. For reference devices, the SiO_2 layer was patterned into four 11×2 mm^2 macro-pixels, and OTS treatment was not performed.

Diluted PEDOT was filtered through a 0.4 μm pore size filter and spin-cast at 3000 rpm for 1 min, yielding ~50 nm film. The PEDOT film was cured in an oven at 120°C for 1 h to drive off water solvent and improve adhesion, then taped off to remove residue on the top of pre-patterned wells. An Alq3/TPD mixture was dissolved with 1 wt.% in chloroform in an ultrasonic bath for 10 min. This mixture was drop-cast through a 0.4 μm pore size filter on the spinning substrate, resulting in a thickness of the active organic layer of ~100 nm.

For electrical tests, the substrates were protected from light until being loaded into a thermal evaporation system. LiF and Al were sequentially deposited as the electron injection layer and cathode, respectively, with a base pressure less than 10^{-6} Torr. The devices were completed by packaging with an optical adhesive (Norland Product Inc.), covered by a thin glass slide under long wavelength UV exposure. Pertinent fabrication procedures were performed in a glove box with nitrogen ambient to prevent photo-oxidation of the organic films.

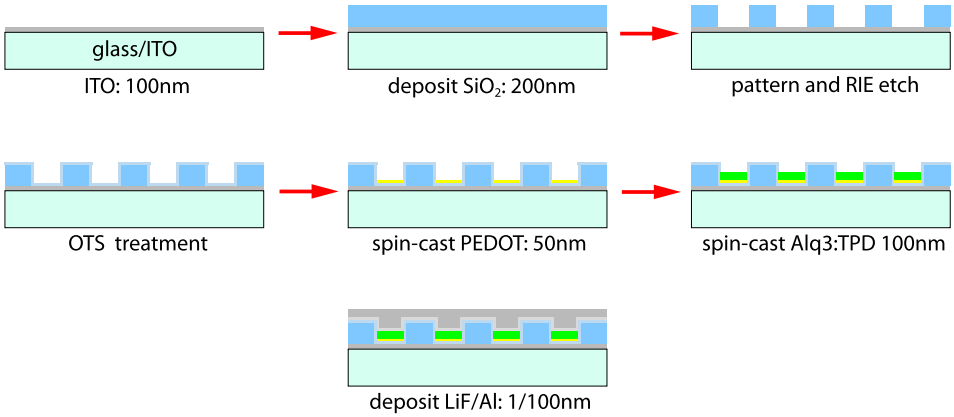

Fig. 3. Process flow for fabrication of bottom emitting OLED by using the spin-on method.

2.5. OLED characterization

All organic film thicknesses were measured by ellipsometry (Woollam V-VASE) and surface profilometry (Tencor P-10). Amorphous Alq3 film morphology was observed by atomic force microscopy (AFM) using intermittent-contact mode with low spring force constant (40 N/m) and resonance frequency 325 kHz. The quality of the film was assessed by RMS roughness measurement. XRD investigation was carried out with a Cu K-alpha standard radiation source ($\lambda = 1.54060$) with an acceleration voltage of 45 kV and a current flow of 40 mA. The PL intensity versus wavelength was measured by a SPEX fluorolog (HORIBA Jobin Yvon Inc.) at excitation wavelength 365 nm. The excitation source is a xenon lamp which is filtered through a monochromator with bandwidth approximately 15 nm (−5/+10). Collection is performed through a second monochromator connected to a photomultiplier tube for detection. EL spectra (luminescence intensity versus wavelength) were measured by a multichannel spectrometer. Luminescence–current–voltage characteristics (L–J–V) were measured by using a digital voltmeter (computer controlled Keithley 236 source). The completed OLEDs were mounted onto the surface of a silicon photodiode module (PIN-10D, OSI optoelectronics) in the forward emission direction for EL measurement. All of the measurements were performed in air.

3. Results and discussion

3.1. Characterization of spin-cast films

The morphological properties were investigated by atomic force microscopy (AFM) and X-ray diffraction (XRD). AFM scanning of spin-cast Alq3 showed smooth and uniform films with no obvious cracks or pinholes, with 2.9 Å RMS surface roughness, as indicated in Fig. 4. Interestingly, spin-casting produced a smoother surface than thermal evaporation (RMS roughness 3.7 Å). XRD scans indicated that Alq3 films prepared by both thermal evaporation and spin-casting are in the glassy amorphous state.

Fig. 4(c) shows the typical photoluminescence (PL) emission peak of Alq3 film around 520 nm. The PL spectrum can be disturbed by impurities, stress, or morphological deformations in the film during the deposition process. If the film undergoes stress during deposition, the PL emission peak blue shifts, while the formation of crystalline structures in the film causes the emission peak to red shift [23,2,3]. Thus, PL measurement provides a sensitive diagnostic of film

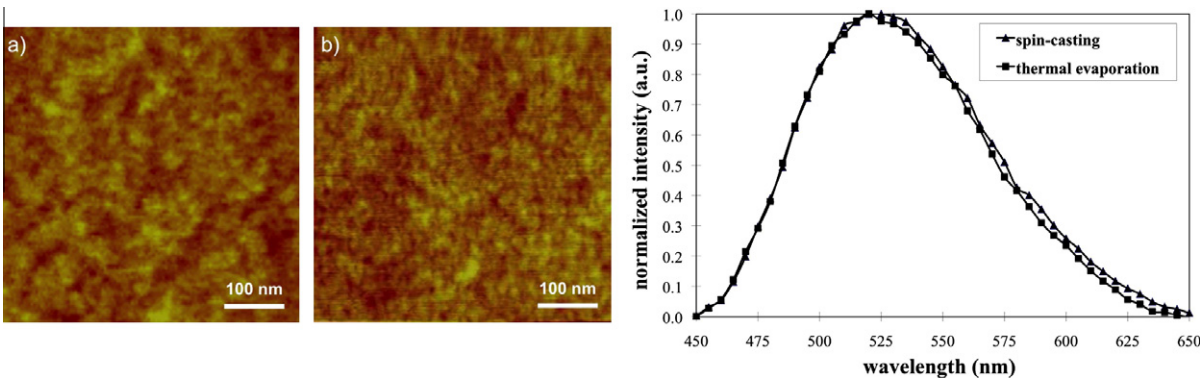

Fig. 4. AFM topographic scans across 500 × 500 nm areas: (a) thermally evaporated film (thickness 50 nm, RMS roughness 3.7 Å) and (b) spin-cast film (thickness 50 nm, RMS roughness 2.9 Å). PL spectra of Alq3 film (c) deposited by thermal evaporation (square symbol) and by spin-casting (circle symbol). The excitation wavelength is 365 nm.

properties. As shown in Fig. 4, the emission spectra of spin-cast and thermally-evaporated Alq3 films are consistent.

3.2. Pixel patterning

The organic films formed in the pre-patterned channels and wells with pixel sizes ranging from 10 to 100 μm were observed by fluorescence microscopy, as shown in Fig. 5. Without OTS treatment, a uniform film of Alq3 forms across the entire substrate.

3.3. Reference OLED characterization

We tested the effect of spin casting a hole injection layer PEDOT between the ITO interface and the Alq3:TPD organic layer prepared by spin-casting (previous reports

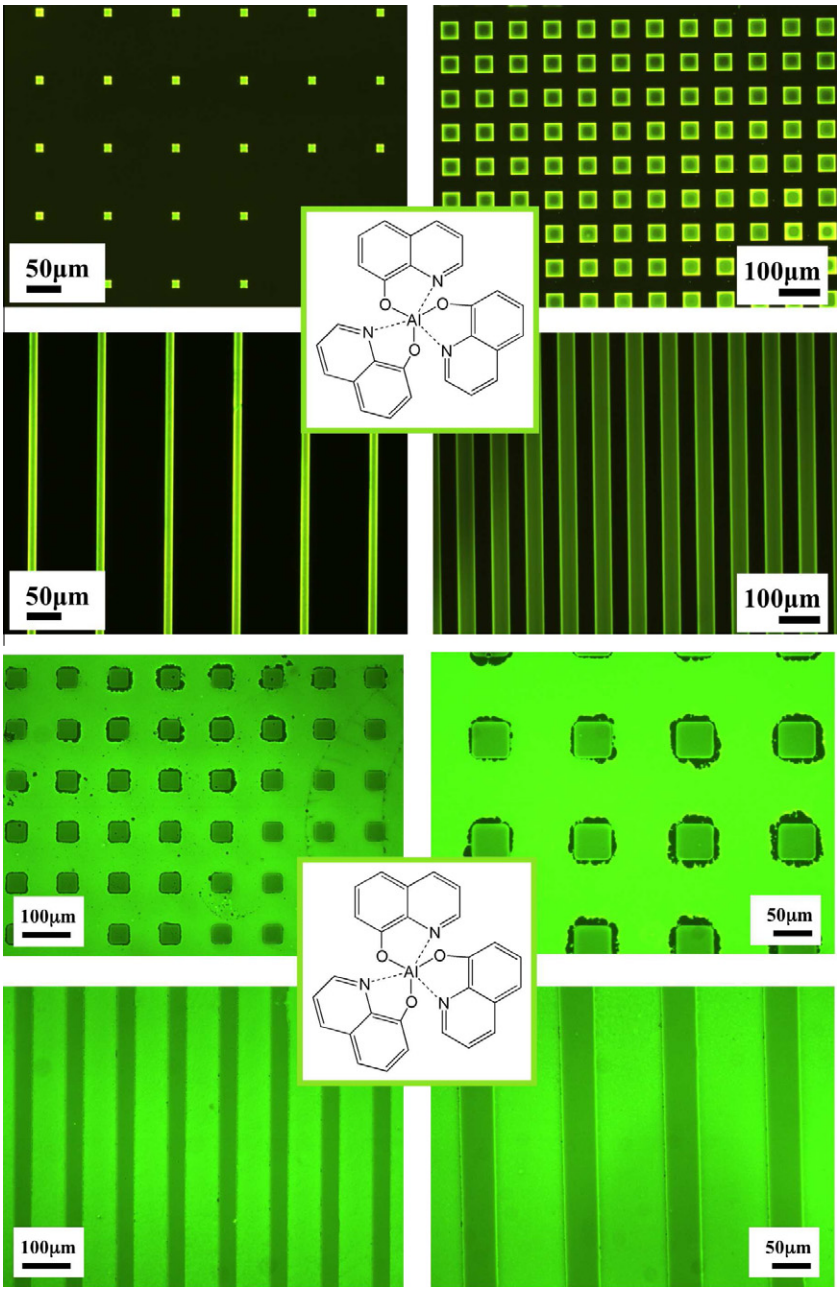

Fig. 5. Photoluminescence images of spin-cast Alq3 onto patterned substrates treated with the OTS monolayer (upper group) and without the OTS monolayer (lower group). The widths of the square pixels (wells) are 10 μm (top left) and 50 μm (top right), and the widths of the stripe pixels are 10 μm (bottom left) and 50 μm (bottom right), respectively. Excitation is at 365 nm.

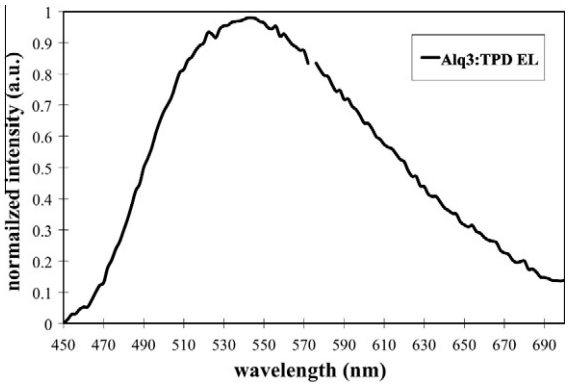

Fig. 6. Electroluminescence spectrum of the reference OLED using a mixed Alq3:TPD layer.

of using PEDOT have been with evaporated Alq3 and TPD layers). A smooth organic interface results in reduction of electrical shorts and the threshold voltage. Roughness characterization by AFM shows that the PEDOT layer is smoother (RMS roughness: 4.1 Å) than the underlying ITO layer (RMS roughness: 8.4 Å), but subsequent deposition of Alq3:TPD increases roughness (RMS roughness: 7.5 Å). The low roughness of our results may be due to the polished ITO/glass substrate, which is smoother than ITO/glass used in other published reports (RMS ~ 1–3 nm) [33]. For comparison, a report of Alq3/TPD evaporated onto ITO obtained RMS roughness of 1.7 nm [34].

Fig. 6 shows the electroluminescence spectrum of the Alq3:TPD based OLED, which shows the expected broad peak starting from 450 to 800 nm and maximum EL intensity at 542 nm. This spectrum is close to that of typical Alq3-based OLEDs but red-shifted compared to the PL spectrum of spin-cast Alq3 film. The shifting is likely due to mixing of Alq3 and TPD [19,32].

Fig. 7 shows the L–J–V characteristics of devices with and without the PEDOT layer. The effect of PEDOT is to reduce the turn-on voltage to ~6 V from ~7.5 V without PEDOT (here, we define the turn-on voltage as the applied voltage required to obtain light emission above the background level). PEDOT reduces the energy barrier by about 0.2 eV between the anode (ITO) and HTL (TPD) layers, which improves hole injection and transport [35]. Charge injection and transport are primarily responsible for operating voltage and luminous efficiency. We do not expect to obtain higher efficiency than a single heterojunction device prepared by thermal evaporation since we use a mixed HTL:ETL layer to achieve a one step patterning process. The PEDOT device shows lower current density above 11 V and lower electroluminescence intensity above 13 V as compared to the non-PEDOT device. However, electroluminescence as a function of current density exhibited by the PEDOT device shows that it operates more efficiently than the non-PEDOT device. This is because the hole current is limited by injection and PEDOT increases hole injection to TPD, which drives an increase in the electron/hole recombination rate.

3.4. Patterned OLED characterization

In the spin patterning technique, obtaining an amorphous film with uniform surface coverage in the pre-patterned regions is the main objective, because the local current density with applied voltage strongly depends on film qualities [34]. Fig. 8 shows scanning electron microscopy (SEM) and photoluminescence images of the patterned OLED pixels. The SEM images (a) and (b) were taken after dry-etching the SiO_2 layer. The photoluminescence images were taken after deposition of the OTS monolayer and spin-casting of the Alq3:TPD layer. One limitation of this spin-on patterning technique is that the solution is driven into the edges of the pre-patterned channels or wells. Sample (c) is prepared by spin-casting Alq3:TPD on an OTS treated substrate without a PEDOT layer. The image clearly shows accumulation of organic at the edges, which will eventually drop device efficiency. Uniform thickness is important since the operating voltage required for light emission is strongly dependent on the thickness of the organic materials. PEDOT can be deposited on the OTS treated pre-patterned substrate as a hole injection layer. In addition, the PEDOT layer prevents edge accumulation as shown in photoluminescence image (d) through the increased affinity of Alq3:TPD to PEDOT.

The micro-patterned device without the OTS layer operates without current leakage, and with lower threshold voltage (about 4.4 V) and higher current density as compared to the reference device, as shown in the J–V curves of Fig. 9. Furthermore, from the L–J plot, it is clear that the EL efficiency is higher. This may be due, in part, to the fact that our patterned device structure bears similarity to the low-index grid structure that has been shown to significantly increase light extraction (i.e. external quantum efficiency) [36].

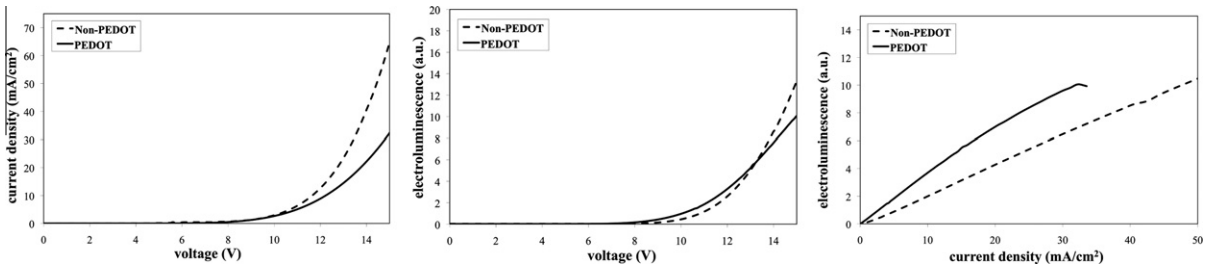

Fig. 7. J–V (left), L–V (middle) and L–J (right) characteristics of unpatterned reference OLED based upon a spin-cast Alq3:TPD layer with and without PEDOT. The active area is 0.22 cm^2.

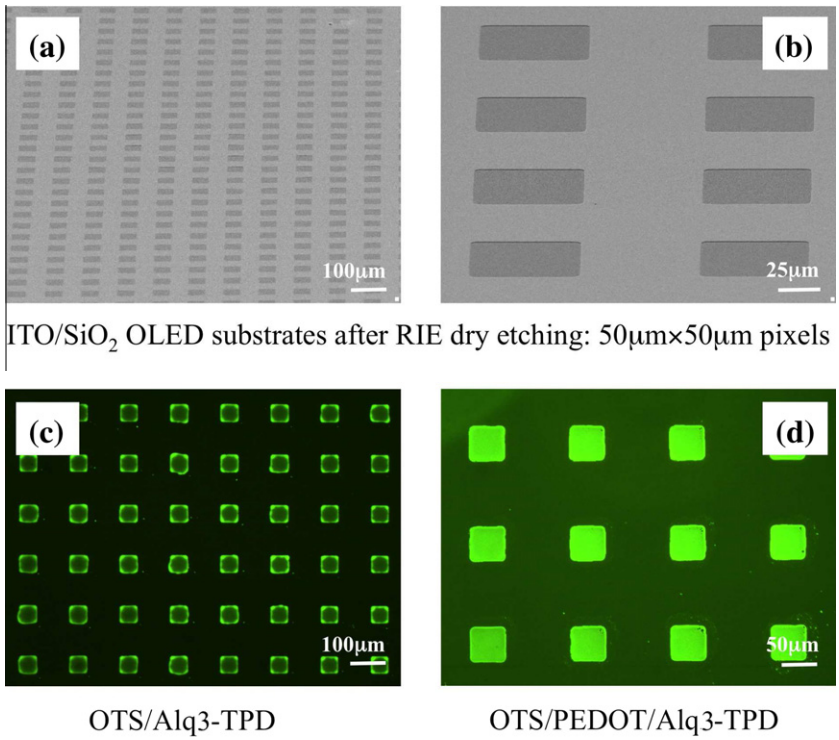

Fig. 8. Scanning electron microscopy images: (a) and (b) pixel size 50 μm; photoluminescence images of 50 μm OLED pixels: (c) without PEDOT, (d) with PEDOT. Excitation is at 365 nm.

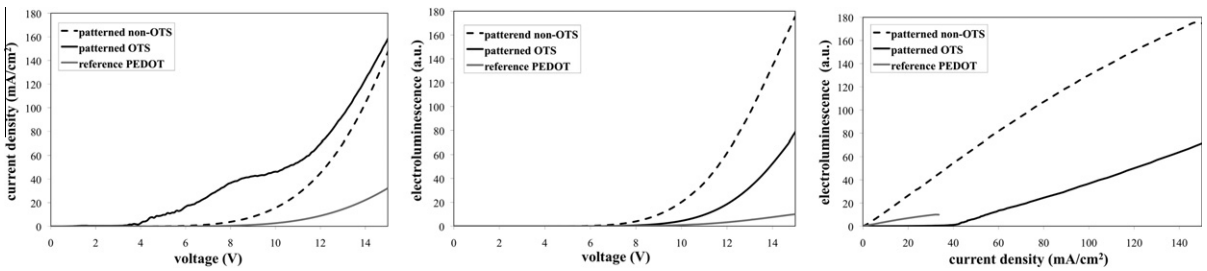

Fig. 9. J–V (left), L–V (middle) and L–J (right) characteristics of pixelated OLED based upon a spin-cast Alq3:TPD layer for non-OTS and OTS devices. Total active pixel area is 0.04 cm^2.

In the micro-patterned OTS device, there is no current leakage observed at low voltages, but an abrupt change of current occurs in the J–V characteristics beyond 4 V, with a turn-on voltage about 5.8 V. This device operates with higher current density than the non-OTS device, which could be the result of a thinner active layer, increased hole injection, and/or reduced resistance through the OTS layer at the inorganic–organic interface, perhaps via incomplete OTS coverage. The EL intensity of the OTS device at the same voltage is lower, suggesting that the increased current density leads to Joule heating rather than resulting in light emission. Indeed, the EL intensity versus current plot shows that the non-OTS device is more efficient, warranting further study on the role of the OTS layer on the electrical properties of the device, along with optimizations in the fabrication process.

4. Conclusions

In summary, we have demonstrated a solution-based patterning technique for fabricating high-resolution Alq3 OLED pixels based upon spin-casting combined with a structured surface consisting of etched channels or wells. The structured surface is modified with OTS, which serves to direct solution into the etched areas. This method achieves precise pixel placement and geometry, and long-range order dictated by photolithographic methods. However, we need to better understand the role of OTS on the electrical device properties, and further efforts to improve device performance are needed. It should be noted that OTS is a well-known gate dielectric layer for OTFT's [37]. The functional role of OTS in this fabrication method is as a hydrophobic layer [38], so organic monolayers with other

terminal ends should be investigated for possible improvements in device performance. In general, this technique should also be compatible with conjugated polymers [30,38] and may offer a promising solution to front-end patterning of molecular organic semiconductors for high resolution large-area, low-cost display applications.

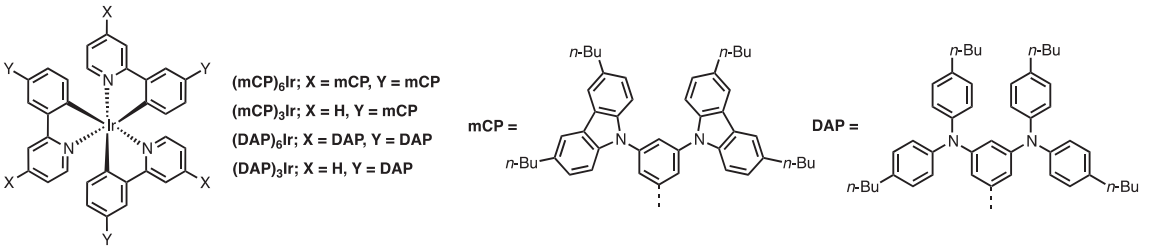

Scheme 1. Chemical structure of the iridium complexes.

bulky dendrons, **(mCP)$_6$Ir** and **(DAP)$_6$Ir** (Scheme 1). Both of the complexes showed higher PLQE in a neat film than that of half-surrounded **(mCP)$_3$Ir** and **(DAP)$_3$Ir**, well-supporting the results reported in the literature [9]. Solution-processed OLED with **(mCP)$_6$Ir** showed high efficiencies, 19 lm/W, 32 cd/A, and 12% of external quantum efficiency at 100 cd/m^2, and 11 lm/W, 25 cd/A, 9.1% at 1000 cd/m^2. The energy levels of the surrounding dendrons intensely affected the charge injection into the emitting layer and the device performance.

2. Results and discussion

Scheme 2 shows synthesis route of **(mCP)$_6$Ir**, **(DAP)$_6$Ir**, and **(DAP)$_3$Ir**. The ligands of the complexes, **2**, **5**, and **6**, were synthesized via several steps of palladium catalyzed coupling reactions. The complexes were prepared from the two steps of complexation. First, a mixture of iridium chloride trihydrate and excess of the ligands afforded dichloro bridged dimer complexes, **7**, **8**, and **9**. Second, the dimers were reacted by the ligands with silver trifluorom-

Scheme 2. Fig. 1. Photoluminecence spectra of **(mCP)$_3$Ir** (solid line), **(mCP)$_6$Ir** (circle), **(DAP)$_3$Ir** (triangle), and **(DAP)$_6$Ir** (square) in a neat film.

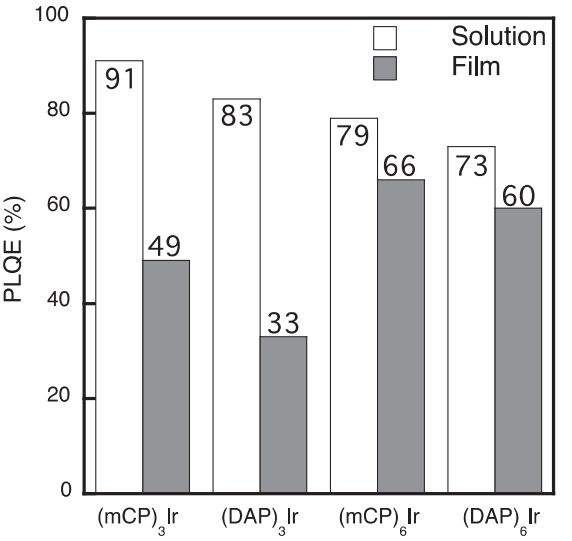

Fig. 2. Photoluminescent quantum efficiencies (PLQEs) of the compounds in a neat film or a toluene solution (2×10^{-6} mol L^{-1}).

ethane sulfonate to give homoleptic functionalized complexes. The complexes were fully characterized by ^{1}H-NMR, matrix-assisted laser desorption/ionization time-of-flight (MALDI) mass spectrometry (MS), and elemental analysis.

Photoluminescence of the neat film of the complexes fully-surrounded by the six bulky dendrons showed the peaks around 580 nm for **(mCP)$_6$Ir** and 577 nm for **(DAP)$_6$Ir**, and the spectra were red-shifted compared with the emission of the less-surrounded complexes around 514 nm for **(mCP)$_3$Ir** and 528 nm for **(DAP)$_3$Ir** (Fig. 1). These results indicated that substitution on 3-position of phenyl ring did not change emission color of Ir(ppy)$_3$, but substitution on 4-position of pyridine ring made the emission red-shifted. The emission of Ir(ppy)$_3$ is mainly ascribed to triplet metal-to-ligand charge transfer (^{3}MLCT) transition. Its highest occupied molecular orbital (HOMO) corresponds to *d* orbital of Ir and lowest unoccupied molecular orbital (LUMO) correspond to π^* orbital of ppy ligand, especially pyridine part of the ligand. That is why electron-donating group on pyridine ring decrease the energy gap of π–π^* and LUMO level, on the other hand the same electron-donating group on 3-position of phenyl ring does not affect the pyridine ring because of less π-conjugation via *meta*-linkage [27,28].

PLQEs of the complexes in the neat film are important parameter to estimate the shielding effect of the surrounding dendrons to Ir(ppy)$_3$. PLQEs of the toluene solution and the films were measured by using an integrating sphere system under 331 nm excitation (Fig. 2). In a diluted solution, all complexes showed higher PLQE than 70%, which are comparable to 85% of unsubstituted Ir(ppy)$_3$. This result demonstrated that these surrounding dendrons are optically inert and does not affect the emission efficiency of Ir(ppy)$_3$ core. The fully-surrounded complexes, **(mCP)$_6$Ir** and **(DAP)$_6$Ir**, showed high PLQE even in a neat film, which is comparable to PLQE in a dilute solution. On the other hand, the half-surrounded complexes, **(mCP)$_3$Ir** and **(DAP)$_3$Ir**, showed much lower PLQE in a neat film than that in a dilute solution. These complexes are facial isomers, therefore, in **(mCP)$_3$Ir** and **(DAP)$_3$Ir**, a some space around pyridyl groups of Ir(ppy)$_3$ core are opened and their three dimensional structure is like a hemisphere, shown in Fig. 3, resulting in only partial suppression of concentration-quenching in a neat film of an iridium complex. However, in **(mCP)$_6$Ir** and **(DAP)$_6$Ir**, the bulky host dendrons fully surrounded Ir(ppy)$_3$ and effectively prevented the intermolecular interaction between Ir(ppy)$_3$s. There are still small amount of reduction of PLQEs from a solution to a neat film, due to the concentration-quenching even in the fully-substituted complexes. The substituted host dendrons are not enough large to completely suppress the interaction between the core complexes. Adachi et al. reported that an average distance between iridium complexes in a doped film critically influenced on PLQE [29]. Förster type energy transfer between Ir(ppy)$_3$ cores through an overlap of the emission and the absorption causes a decrease of neat film PLQY. If the average distance between iridium complexes is shorter than Förster radius, a strong quenching occurs. The stronger quenching of **(mCP)$_3$Ir** in the neat film than that of **(mCP)$_6$Ir** is due to the shorter average distance between the cores derived from a less number of bulky host dendrons of **(mCP)$_3$Ir** than that of **(mCP)$_6$Ir**. Substitution of more branched and larger dendrons to the core complexes are desirable to achieve the complete suppression of concentration-quenching.

HOMO level of the complexes and the surrounding host dendrons themselves, 3,5-(3,6-di(*n*-butyl)carbazol-9-yl)benzene **DAP** and 3,5-(*N*,*N*-di(4-(*n*-butyl)phenyl)amine) benzene **mCP**, were estimated from ionization potentials measured by photoelectron yield spectroscopy (Fig. 4). LUMO levels of **DAP** and **mCP** were estimated from the difference of optically obtained energy gap and ionization potential. LUMO level of the dendrimer complexes are still unknown because the optically obtained energy gap dose

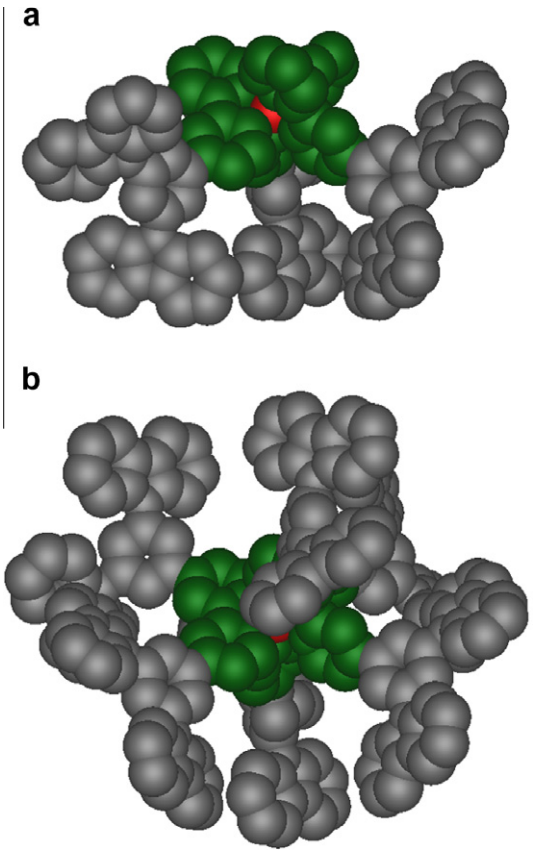

Fig. 3. The optimized structures of: (a) **(mCP)$_3$Ir** and (b) **(mCP)$_6$Ir** by PM6 calculation. The butyl groups were replaced to hydrogen in calculation.

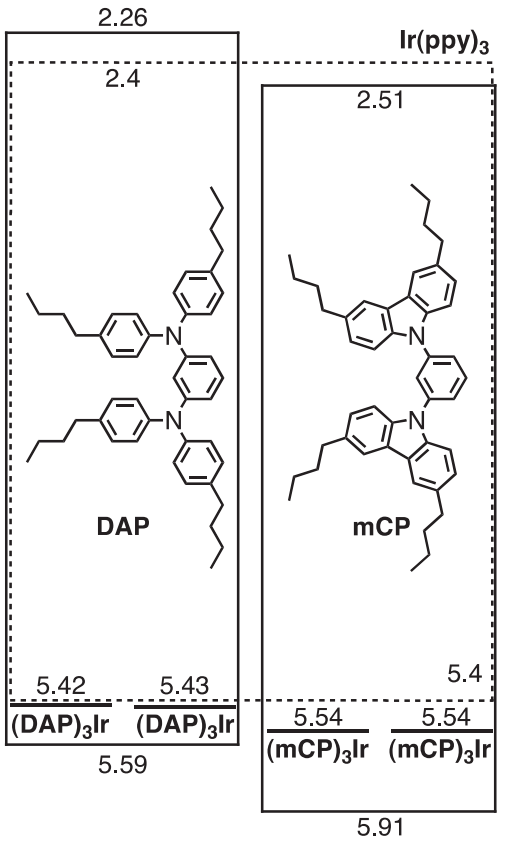

Fig. 4. HOMO and LUMO levels of the surrounding host groups, **DAP** (fine solid line) and **mCP** (fine solid line), and Ir(ppy)$_3$ (dotted line), and HOMO levels of the complexes (thick solid line). Chemical structure of **DAP** and **mCP**.

not correspond to HOMO–LUMO gap in the case of Ir(ppy)$_3$ derivatives. HOMO levels of the dendrimer complexes were close to that of Ir(ppy)$_3$, rather than that of the surrounding host dendrons. This result suggest that HOMO are mainly located on the central Ir(ppy)$_3$ group.

Single layer devices with the configuration of ITO/poly(3,4-ethylenedioxythiophene) (PEDOT): poly(styrene sulfonic acid) (PSS) (40 nm)/**(DAP)$_3$Ir**, **(DAP)$_6$Ir**, or **(mCP)$_6$Ir** (120 nm)/LiF (1 nm)/Al (100 nm) and double layer devices with the configuration of ITO/PEDOT:PSS (40 nm)/**(DAP)$_3$Ir**, **(DAP)$_6$Ir**, or **(mCP)$_6$Ir** (60 nm)/bis-4,6-(3,5-di-4-pyridylphenyl)-2-methylpyrimidine (B4PyMPm) (60 nm)/LiF (1 nm)/Al (100 nm) were fabricated. In single layer devices, **(DAP)$_3$Ir** and **(DAP)$_6$Ir** exhibited higher current density than **(mCP)$_6$Ir**, probably because HOMO level of **(DAP)$_3$Ir** and **(DAP)$_6$Ir** are shallower than **(mCP)$_6$Ir** to enhance hole injection from PEDOT:PSS (Fig. 5). Therefore, hole current should be dominant in single layer devices. However, in contrast to the result of the current density–voltage plots, **(mCP)$_6$Ir** showed higher luminance than the others. As well as the luminance, current efficiencies of the single layer device with **(mCP)$_6$Ir** were much higher than those of the other two complexes. This improvement showed that the surrounding **mCP** dendron has better electron injection and/or electron transport property than **DAP** dendron to improve charge balance. The double layer devices were fabricated using B4PyMPm as an electron transporting and hole-blocking material on the emitting layer. **DAP**-surrounding complex, **(DAP)$_3$Ir** and **(DAP)$_6$Ir**, showed higher current density, as well as single layer device. This results suggest that hole current is still excess even in the device with electron transporting layer. High luminance was obtained at much lower voltage, and the efficiency were drastically improved. In the device with **(mCP)$_6$Ir**, thickness of the emitting layer was reduced from 60 to 40 nm to improve charge balance, resulting in increasing efficiencies (Table 1). Current efficiency of the device with **(mCP)$_6$Ir** was 32 cd/A, 19 lm/W, 12% at 100 cd/m^2, and 25 cd/A, 11 lm/W, 9.1% at 1000 cd/m^2. There have been several reports on solution-processed phosphorescence OLED with dendrimer iridium complexes, and their high efficiencies, as mentioned in Section 1. However the most of papers emphasized peak efficiencies at a low current density and luminance, and did not revealed the efficiencies at practically high luminance, e.g. for lighting application. The efficiencies with our fully-surrounded Ir(ppy)$_3$ are one of high values among the solution-processed OLED ever reported.

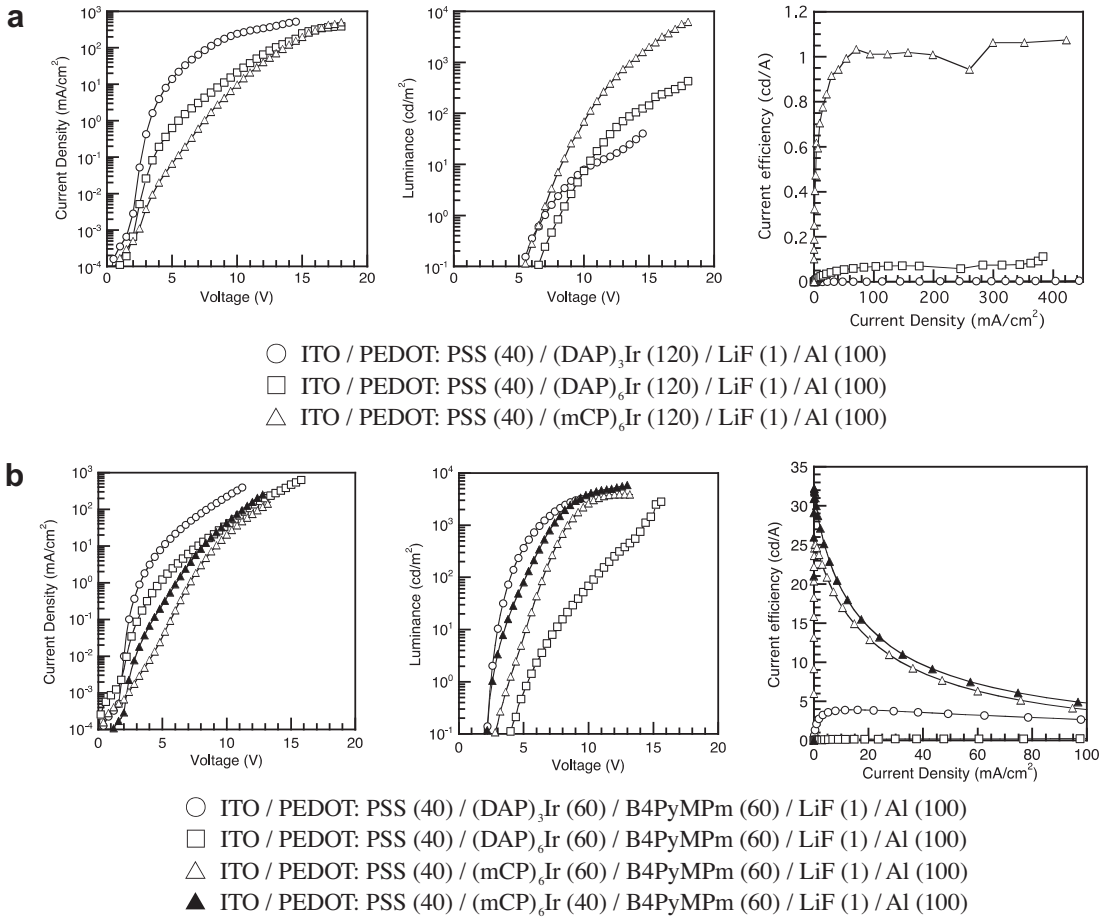

Fig. 5. Current density–voltage, luminance–voltage, and current efficiency–voltage characteristics of the single layer device (a) and the double layer device (b).

Table 1
Efficiencies of the solution-processed OLEDs.

Device structure	Compound	100 cd/m^2				1000 cd/m^2			
		Voltage (V)	η_P (lm W^{-1})	η_C (cd A^{-1})	η_{EXT} (%)	Voltage (V)	η_P (lm W^{-1})	η_C (cd A^{-1})	η_{EXT} (%)
Single layer	**(DAP)$_3$Ir**	–	–	–	–	–	–	–	–
	(DAP)$_6$Ir	13.9	0.016	0.071	0.028	–	–	–	–

	(mCP)$_6$Ir[a]	5.2	19	32	12	7.3	11	25	9.1

[a] Thickness of emitting layer is 40 nm.

3. Conclusion

We synthesized the solution processable iridium complexes for OLEDs, surrounded by diphenylamine derivatives or carbazole derivatives. The fully surrounded complexes, **(DAP)$_6$Ir** and **(mCP)$_6$Ir**, by six host dendrons showed high PLQE in a neat film, comparable to their PLQE in a dilute solution, demonstrating that the surrounding host dendrons efficiently suppressed intermolecular interaction between central Ir complexes and prevented concentration quenching. Not only PLQE of the complex but also energy levels and charge transporting property of the surrounding host dendron are important to achieve high efficiencies in a device. The complex, **(mCP)$_6$Ir**, fully surrounded by six carbazole type hosts showed much better performance, compared with the complexes surrounded by arylamine type hosts, because of well balanced charge injection and transporting in the devices.

4. Experimental

4.1. Measurements

^{1}H-NMR spectra were measured in deuterated solvents on a JEOL ECX 400 MHz spectrometer. Mass spectra were recorded on a JEOL JMS-K9 for electron impact-ionization (EI) or an Applied Biosystems Voyager DE-PRO for matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) from dithranol (DITH) in linear or reflection mode. Elemental analyses were carried out by the Elemental Analysis Service, Yamagata University, Japan. Thermal gravimetric analysis (TGA) was performed on Seiko SII EXSTAR 6000 and TGA/DTA 6200 analyzers. Differential Scanning Calorimetry (DSC) was performed on a Perkin–Elmer Diamond DSC calorimeter. Ionization potentials were measured with a photoelectron spectrometer surface analyzer (RIKEN KEIKI AC-3). UV–visible absorption spectra were recorded of solutions in chloroform or films on quartz with a Shimadzu UV-3150 spectrometer. PL spectra were recorded on a Jobin Yvon Fluoromax-4 fluorometer. PL quantum efficiencies were measured on a Hamamatsu C9920-01 calibrated integrating sphere system under nitrogen. Light emitting devices were fabricated on indium tin oxide (ITO) coated glass substrates, which were prepared by ultrasonication sequentially in detergent, methanol, 2-propanol and acetone, then exposed to UV–ozone under ambient conditions for 15 min. PEDOT:PSS was spin-coated as an anode buffer layer on pre-cleaned ITO substrate. On the top of PEDOT:PSS layer, dendrimers were spin-coated from 1,2-dichloroethane or toluene solution. The electron transporting material B4PyMPm was deposited by thermal evaporation at less than 1×10^{-4} Pa. The aluminum cathode was deposited through a shadow mask at less than 1×10^{-4} Pa. The active area of each device is 2 mm × 2 mm. Layer thickness calibration was performed using a Dektak 3 surface profilometer. The EL spectra were measured on a Hamamatsu PMA-11 photonic multichannel analyzer. The current–voltage (*I–V*) characteristics and luminance of the devices were measured using a Keithley 2400 Source Meter and Konica Minolta CS-200 chromameter, respectively. External quantum efficiencies were calculated assuming a Lambertian emission pattern and considering all spectral features in the visible region.

5. Materials

2-(3-(3,5-Dichlorophenyl)phenyl)pyridine **1**: a mixture of 2-(3-bromophenyl)pyridine (1.20 g, 5.13 mmol), 3,5-dichlorophenylboronic acid (1.97 g, 10.3 mmol), K_2CO_3 (1.42 g, 10.3 mmol), and THF (100 ml) was deoxygenated by bubbling N_2 for 30 min. After that, $Pd(PPh_3)_4$ (0.240 g, 0.208 mmol) and degassed deionized water (5.2 ml) were added in the mixture, and then the mixture was refluxed under N_2 for 24 h. The mixture was allowed to cool to room temperature, and then diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo and the residue was purified by column chromatography over silica using a chloroform–ethyl acetate mixture (30:1) as eluent to give the compound **1** (1.26 g, 82%). δ_H(400 MHz, CD_2Cl_2) 8.67 (1H, d, J = 4.1 Hz), 8.23 (1H, s), 8.02 (1H, d, J = 7.3 Hz), 7.82–7.76 (2H, m), 7.61–7.53 (4H, m), 7.37 (1H, t, J = 1.8 Hz), 7.27 (1H, td, J = 5.7, 1.8 Hz). *m/z* [EI] 299: (M^+). Found: C, 67.74; H, 3.60; N, 4.45. $C_{17}H_{11}C_{l2}N$ requires C, 68.02; H, 3.69; N, 4.67%.

2-(3-(3,5-Bis(di-(4-*n*-butylphenyl)amino))phenyl)phenyl)pyridine **2**: the compound **1** (0.500 g, 1.67 mmol), di(4-(*n*-butyl)phenyl)amine (1.41 g, 5.00 mmol), sodium *tert*-butoxide (0.721 g, 7.50 mmol), $Pd_2(dba)_3$ (0.114 g, 0.125 mmol), and $P(Cy)_3$ (0.0701 g, 0.250 mmol) in a sealed tube was degassed in vacuo and filled with N2. After that, degassed toluene (5.0 ml) was added into the mixture, and then the mixture was refluxed for 24 h. After the mixture was allowed to cool to room temperature, diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using chloroform and a hexane–chloroform mixture (from 1:0 to 0:1) as eluent to give the compound **2** (0.929 g, 71%). δ_H(400 MHz, CD_2Cl_2) 8.62 (1H, d, J = 5.0 Hz), 7.97 (1H, s), 7.88 (1H, d, J = 6.4 Hz), 7.74–7.67 (2H, m), 7.41–7.38 (2H, m), 7.22 (1H, td, J = 5.7, 1.4 Hz), 7.04–6.97 (16H, m), 6.81 (2H, d, J = 2.3 Hz), 6.67 (1H, t, J = 1.8 Hz), 2.52 (8H, t, J = 7.8 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.58–1.50 (8H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.38–1.29 (8H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.90 (12H, t, J = 7.4 Hz, -$CH_2CH_2CH_2\underline{CH_3}$). *m/z* [EI] 791: ($M^+$). Found: C, 86.49; H, 7.75; N, 5.24. $C_{57}H_{63}N_3$ requires C, 86.65; H, 8.04; N, 5.32%.

4-Bromo-(2-(3-bromophenyl))pyridine **3**: the mixture of 3-bromophenylboronic acid (2.81 g, 14.0 mmol), 2,4-dibromopyridine (3.31 g, 14.0 mmol), K_2CO_3 (3.87 g, 28.0 mmol), deionized water (14 ml), and toluene (60 ml) was deoxygenated by bubbling N_2 for 30 min. After that, $Pd_2(dba)_3$ (0.385 g, 0.420 mmol) was added, and then the mixture was refluxed for 36 h. After the mixture was allowed to cool to room temperature, diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a hexane–dichloromethane mixture (from 1:0 to 0:1) as eluent to give the compound **3** (1.76 g, 40%). δ_H(400 MHz, $CDCl_3$) 8.50 (1H, d, J = 5.0 Hz), 8.14 (1H, t, J = 1.8 Hz), 7.89–7.87 (2H, m, ArH), 7.56 (1H, d, J = 7.8 Hz), 7.43 (1H, dd, J = 5.3, 1.4 Hz), 7.34 (1H, t, J = 8.0 Hz). *m/z* [EI] 313: (M^+), Found: C, 42.41; H, 2.02; N, 4.45. $C_{11}H_7Br_2N$ requires C, 42.21; H, 2.25; N, 4.48%.

2-(3-(3,5-Dichlorophenyl)phenyl)-4-(4-(3,5-dichlorophenyl)phenyl)pyridine **4**: the compound **3** (1.75 g, 5.59 mmol), 3,5-dichlorophenylboronic acid (4.26 g, 22.3 mmol), K_2CO_3 (1.55 g, 11.2 mmol), deionized water (5.6 ml), and toluene (95 ml) was deoxygenated by bubbling N_2 for 30 min. After that, $Pd(PPh_3)_4$ (0.224 g, 0.194 mmol) was added, and then the mixture was refluxed for 24 h. After the mixture was allowed to cool to room temperature, diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a hex-

ane–chloroform mixture (from 1:0 to 0:1) as eluent to give the compound **4** (2.01 g) as a crude. The crude product was directly used for next step without further purification. δ_H(400 MHz, $CDCl_3$) 8.73 (1H, s), 8.18 (1H, s), 7.99 (1H, dt, *J* = 7.1, 1.8 Hz), 7.84 (1H, s), 7.58–7.50 (6H, m), 7.40 (1H, t, *J* = 1.8 Hz), 7.37 (1H, dd, *J* = 5.0, 1.8 Hz), 7.30 (1H, t, *J* = 1.8 Hz).

2-(3-(3,5-Bis(di(4-*n*-butylphenyl)amino))phenyl)phenyl)-4-(3-(3,5-bis(di(4-*n*-butylphenyl)amino))phenyl)pyridine **5**: the mixture of di(4-*n*-butylphenyl)amine (18.0 g, 64.0 mmol), crude **4** (3.56 g), sodium *tert*-butoxide (8.85 g, 96.0 mmol), and toluene (80 ml) was deoxygenated by bubbling N_2 for 30 min. After that, $Pd_2(dba)_3$ (1.47 g, 1.60 mmol), PCy_3 (1.79 g, 6.40 mmol) was added, and then the mixture was refluxed for 24 h. After the mixture was allowed to cool to room temperature, diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a hexane–chloroform mixture (from 1:0 to 0:1) and a hexane–chloroform mixture (from 1:0 to 1:3) as eluent, respectively, to give the compound **5** (7.30 g, 57%). δ_H(400 MHz, CD_2Cl_2) 8.52 (1H, d, *J* = 5.0 Hz), 7.99 (1H, s), 7.74 (1H, s), 7.65 (1H, s), 7.36 (2H, d, *J* = 4.6 Hz), 7.16 (1H, s), 7.04–6.96 (32H, m), 6.78 (4H, t, *J* = 2.1 Hz), 6.72 (1H, t, *J* = 1.8 Hz), 6.66 (1H, t, *J* = 1.8 Hz) 2.51 (16H, t, *J* = 7.6 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.57–1.50 (16H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.37–1.28 (16H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.90 (24H, t, *J* = 7.3 Hz, -$CH_2CH_2CH_2\underline{CH_3}$). [MALDI:DITH] (*m*/*z*) 1424.9: (MH^+). Found: C, 86.55; H, 8.48; N, 4.84. $C_{103}H_{117}N_5$ requires C, 86.81; H, 8.28; N, 4.91%.

2-(3-(3,5-Bis(3,6-di(*n*-butyl)carbazol-9-yl)phenyl)phenyl-4-(3,5-bis(3,6-di(*n*-butyl)carbazol-9-yl)phenyl))pyridine **6**: the mixture of 3,6-di-*n*-butylcarbazole (7.21 g, 25.8 mmol), crude **4** (1.91 g), palladium(II) acetate (0.231 g, 1.03 mmol), K_2CO_3 (10.7 g, 77.4 mmol), and *o*-xylene (40 ml) was deoxygenated by bubbling N_2 for 30 min. After that, P(*t*-Bu)$_3$ (0.75 ml, 3.10 mmol) was added, and then the mixture was refluxed for 24 h. After the mixture was allowed to cool to room temperature, diethylether was added. The organic layer was washed by deionized water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a hexane–chloroform mixture (from 1:0 to 1:1) as eluent to give the compound **6** (3.84 g, 51%). δ_H(400 MHz, CD_2Cl_2) 8.75 (1H, d, *J* = 5.0 Hz), 8.45 (1H, s), 8.06 (1H, s), 8.04 (1H, d, *J* = 1.8 Hz), 7.98 (2H, d, *J* = 1.8 Hz), 7.95 (2H, d, *J* = 1.8 Hz), 7.91 (8H, s), 7.88 (1H, t, *J* = 1.8 Hz), 7.78–7.76 (2H, m), 7.61–7.56 (2H, m), 7.49 (8H, dd, *J* = 8.2, 5.0 Hz), 7.22 (8H, dt, *J* = 8.2, 2.0 Hz), 2.77 (16H, t, *J* = 7.8 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.70–1.63 (16H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.43–1.34 (16H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.93 (24H, t, *J* = 7.3 Hz, -$CH_2CH_2CH_2\underline{CH_3}$), [MALDI:DITH] (*m*/*z*) 1417.17: (MH^+), Found: C, 87.14; H, 8.02; N, 4.88. $C_{103}H_{109}N_5$ requires C, 87.30; H, 7.75; N, 4.94%.

7: the mixture of **2** (1.00 g, 1.27 mmol), iridium chloride trihydrate (0.186 g, 0.527 mmol), deionized water (8.5 ml), and 2-ethoxyethanol (36 ml) was heated at 130 °C for 24 h under N_2. After the solvent was removed in vacuo, the residue was washed with K_2CO_3 aq. (0.33 M, 6.0 ml) and deionized water to give crude compound **7**. The crude product was directly used for next step without further purification.

5.1. $(DPA)_3Ir$

The mixture of **7** (0.933 g), **5** (1.25 g, 1.58 mmol), silver trifluoromethanesulfonate (0.162 g, 0.632 mmol), and diglyme (31 ml) was heated at 130 °C under N_2 for 114 h. After the mixture was allowed to cool to room temperature, insoluble part was removed by column chromatography over silica using dichloromethane as eluent. The solvent was removed in vacuo, and then the residue was purified by chromatography over silica using a dichloromethane–hexane mixture (2:3) as eluent. Further purification by preparative TLC using a dichloromethane–hexane mixture (15:8) as eluent gave the complex **$(DPA)_3Ir$** (0.415 g, 31%). δ_H(400 MHz, CD_2Cl_2) 7.81–7.78 (3H), 7.60–7.55 (6H), 7.48–7.45 (3H), 7.03–6.94 (48H, m), 6.88–6.84 (3H), 6.78–6.72 (8H), 6.66–6.59 (6H), 2.54 (24H, t, *J* = 7.5 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.52–1.72 (24H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.32–1.52 (24H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.94 (36H, t, *J* = 7.3 Hz, -$CH_2CH_2CH_2\underline{CH_3}$). δ_C(100 MHz, CD_2Cl_2) 14.1, 22.7, 34.0, 35.3, 115.2, 116.1, 119.2, 122.4, 122.6, 124.4, 128.6, 129.2, 132.9, 136.5, 137.2, 137.5, 143.9, 144.4, 145.6, 147.4, 149.4, 160.8, 166.2. [MALDI:DITH] (*m*/*z*) 2559.68: (MH^+). Found: C, 80.40; H, 7.17; N, 4.88. $C_{171}H_{186}IrN_9$ requires C, 80.24; H, 7.32; N, 4.93%.

8: the mixture of **5** (2.50 g, 1.75 mmol), iridium chloride trihydrate (0.258 g, 0.731 mmol), deionized water (12 ml), and 2-ethoxyethanol (49 ml) was heated at 130 °C for 24 h under N_2. After the solvent was removed in vacuo, the residue was washed with K_2CO_3 aq. (0.33 M, 38 ml) and deionized water to give crude compound **8** (2.41 g). The crude product was directly used for next step without further purification.

5.2. $(DAP)_6Ir$

The mixture of **8** (2.41 g), **5** (4.80 g, 3.37 mmol), silver trifluoromethanesulfonate (0.225 g, 0.877 mmol), and diglyme (15 ml) was heated at 130 °C under N_2 for 192 h. The mixture was allowed to cool to room temperature, and then purified by column chromatography over silica using a dichloromethane–hexane mixture (1:2 and 1:3, respectively) as eluent. Further purification by preparative TLC using a dichloromethane–hexane mixture (1:3) as eluent gave the complex **$(DPA)_6Ir$** (0.526 g, 16%). δ_H(400 MHz, CD_2Cl_2) 7.72 (3H, s), 7.52 (3H, s), 7.31 (3H, d, *J* = 5.9 Hz), 7.00–6.94 (96H, m), 6.70–6.63 (21H, m), 6.59–6.55 (6H, m), 2.51 (48H, t, *J* = 7.7 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.57–1.50 (48H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.37–1.28 (48H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.89 (72H, t, *J* = 7.3 Hz, -$CH_2CH_2CH_2\underline{CH_3}$). δ_C(100 MHz, CD_2Cl_2) 166.1, 161.1, 149.6, 149.3, 149.2, 147.1, 145.6, 145.1, 144.2, 140.0, 138.1, 137.4, 137.1, 133.0, 129.3, 129.2, 128.8, 124.7, 124.3, 122.3, 120.9, 116.9, 116.8, 115.98, 115.95, 115.3, 114.4, 35.2, 33.97, 33.95, 22.7, 14.0. [MALDI:DITH] (*m*/*z*) 4462.45: (MH^+), Found: C, 83.30; H, 7.83; N, 4.64. $C_{309}H_{348}IrN_{15}$ requires C, 83.13; H, 7.86; N, 4.71%.

9: the mixture of **6** (1.70 g, 1.19 mmol), iridium chloride trihydrate (0.175 g, 0.496 mmol), deionized water (8.0 ml), and 2-ethoxyethanol (33 ml) was heated at 130 °C for 24 h under N_2. After the solvent was removed in vacuo, the residue was washed with K_2CO_3 aq. (0.33 M, 24 ml) and deionized water to give crude compound **9** (1.79 g). The crude product was directly used for next step without further purification.

5.3. *(mCP)$_6$Ir*

The mixture of **9** (1.46 g), **6** (2.89 g, 2.03 mmol), silver trifluoromethanesulfonate (0.498 g, 1.94 mmol), and ethyldiglyme (10 ml) was heated at 150 °C under N_2 for 133 h. The mixture was allowed to cool to room temperature, and then purified by column chromatography over silica using a dichloromethane–hexane mixture (1:3) as eluent, twice, to give the complex **(mCP)$_6$Ir** (0.316 g, 16%). δ_H(400 MHz, CD_2Cl_2) 8.28 (3H, s), 8.09 (3H, s), 7.93–7.89 (15H, m), 7.86 (24H, dd, J = 4.6, 1.4 Hz), 7.82 (3H, t, J = 1.8 Hz), 7.61 (3H, t, J = 1.8 Hz), 7.44 (12H, d, J = 8.7 Hz), 7.40 (12H, d, J = 8.2 Hz), 7.34–7.29 (6H, m), 7.15–7.11 (27H, m), 2.72 (48H, t, J = 7.6 Hz, -$\underline{CH_2}CH_2CH_2CH_3$), 1.67–1.59 (48H, m, -$CH_2\underline{CH_2}CH_2CH_3$), 1.41–1.31 (48H, m, -$CH_2CH_2\underline{CH_2}CH_3$), 0.92 (72H, t, J = 7.3 Hz, -$CH_2CH_2CH_2\underline{CH_3}$). δ_C(100 MHz, CD_2Cl_2) 166.5, 162.2, 148.0, 147.9, 145.4, 144.6, 141.3, 140.5, 139.9, 139.2, 139.0, 137.8, 135.1, 134.7, 132.0, 129.3, 126.7, 126.6, 124.8, 123.7, 123.6, 123.5, 122.9, 122.7, 121.9, 121.6, 119.6, 119.4, 117.4, 109.5, 109.3, 35.5, 34.42, 34.40, 29.7, 22.4, 13.8. [MALDI:-DITH] (m/z) 4439.73: (MH^+), Found: C, 83.58; H, 7.10; N, 4.78. $C_{309}H_{324}N_{15}$ requires C, 83.58; H, 7.35; N, 4.73%.

chlorobenzene (CB) or 1,2-dichlorobenzene (DCB) for film casting. Solvent choice and solution concentration have been shown to be critical factors for polymer OPV device performance [23–25] due to the variation in nanocrystalline domain sizes that occurs in each case. This warrants an investigation of the interaction between these organic solvents and MPc thin films for small molecule OPV devices.

Here we use GLAD to fabricate nanostructured ZnPc films for improving OPV device performance. GLAD is a physical vapor deposition technique that employs substrate rotation (described by the angle variable ϕ) and oblique substrate angles relative to the incoming vapor flux (α) during deposition, in order to create porous columnar films [26–29]. We fabricate a variety of planar and nanostructured ZnPc films and study the effects of exposure to CB and DCB. By identifying sensitivities to these solvents, we are able to optimize the performance of ZnPc/PCBM devices through control of the initial ZnPc film morphology and the choice of solvent used to cast PCBM.

2. Experimental

2.1. ZnPc thin film deposition and characterization

ZnPc was acquired from Sigma–Aldrich and was purified at least twice via thermal gradient sublimation at 400 °C. All ZnPc thin films were deposited at high vacuum ($<2 \times 10^{-7}$ Torr) in a GLAD apparatus [27] with a throw distance of 34 cm. Unless otherwise stated, films were grown by using a source temperature of 390–400 °C resulting in a deposition rate of 0.7 Å/s at normal incidence. All GLAD films were preceded by a 10 nm planar layer grown at normal incidence immediately prior to GLAD deposition, to prevent any direct contact between the anode and the acceptor. All GLAD films described here are slanted post (SP) films made using the ϕ-sweep substrate motion technique [19,30–32]. Unless otherwise stated, we used a substrate rotation angle of $\gamma = 30°$ and one full sweep cycle per 4–5 nm of film growth when using the ϕ-sweep technique.

Solvent-treated films were achieved by either placing four drops ($\sim$200 μL) of solvent on the film surface from a glass pipet and spinning the solvent off at 1000 rpm (spin treatment), or by bathing the film sample in 5 mL of solvent in a glass petri dish for 10 min and then allowing the solvent to volatilize off the film under ambient conditions after removal from the bath (soak treatment). For device fabrication, the soak treatment was replaced with a drop treatment whereby four drops of solvent were placed on the film surface and allowed to volatilize under ambient conditions. The drop treatment provides very similar morphologies to the soak treatment.

Images were acquired using a Hitachi S-4800 field emission SEM. UV–Vis absorbance data was acquired using a Perkin Elmer Lambda 900 UV/VIS/NIR spectrophotometer. Absorbance was calculated as the negative logarithm of the transmittance spectrum.

XRD patterns were collected using a Bruker D8 diffractometer equipped with a Cu source and scintillometer using 1.0 mm antiscatter and 0.6 mm receiving slits. Diffractometer calibration and instrument resolution was determined using a silver behenate reference standard. XRD peak fits were performed with gnuplot 4.4 using pseudo-Voight peak shapes and linear backgrounds between 5.5° and 8.1° scattering angle for patterns collected using theta/two theta geometry. Detector resolution was determined to be 0.21° FWHM; uncertainty in peak position was ±0.04°.

2.2. OPV device fabrication and characterization

OPV devices were fabricated on anodes of ITO on glass (8–12 Ω/□, Delta Technologies), coated with a thin layer of PEDOT:PSS (Clevios P VP Al 4083). ITO was cleaned via sonication in IPA followed by an oxygen plasma etch. PEDOT:PSS was applied undiluted, spun at 4000 rpm for 30 s, and baked at 80 °C for 10 min in air. Following ZnPc deposition, PCBM (American Dye Source) was applied at 30 mg/mL in either CB or DCB (Sigma–Aldrich), and spun in air for 30 s at 1000 rpm. The top electrode, consisting of 15 nm bathocuproine (BCP, Sigma–Aldrich) and 80 nm Al (Lesker), was deposited through a shadow mask over five rectangular device areas of 0.20 cm^2 each, in a glovebox evaporator.

Current–voltage characteristics of OPV devices were taken in air using a Keithley 2400 source meter, under AM 1.5 G simulated irradiation (Oriel 91191 1000 W). Light intensity was calibrated against a KG-5 filtered Si reference cell (PV Measurements, Inc., model PVM624). Device performance numbers are reported as averages over several (5–10) devices.

Depth profiling was performed via secondary ion mass spectrometry (SIMS), by alternating sputtering and analysis processes using a ToF SIMS IV instrument (ION-TOF GmbH). A chopped 25 keV Bi^+ ion beam with a current of 0.7 pA was used as the primary source to analyze an area of 40×40 μm^2, while O_2^+ was used as the sputtering source, operated at 1 kV/55 nA over a crater area of 200×200 μm^2.

3. Results and discussion

3.1. ZnPc thin film structuring

3.1.1. Nanostructured ZnPc films via GLAD

Thin films of ZnPc were grown under several sets of conditions by varying the film thickness, the angle between the incoming vapor flux and the substrate normal (α) and the substrate rotation behavior during deposition (described by the angle variable γ). In Fig. 1 we show a planar ZnPc film compared to several slanted post (SP) GLAD films grown using different α values, which illustrates the effect of α on morphology. In particular, the film porosity increases with α, as expected due to increased shadowing [28]. With the exception of the film in Fig. 1b, which was grown with no substrate motion, a ϕ-sweep substrate motion program was used to grow each GLAD film, as specified in Section 2.

Ideally, the donor layer morphology would have columns with diameter close to that of its exciton diffusion

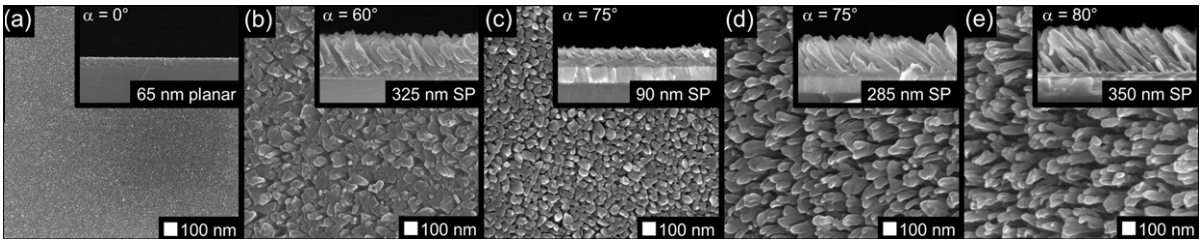

Fig. 1. Aerial and cross-sectional views of various planar and slanted post (SP) ZnPc thin films. The angle of incidence (α) is shown in each case. The substrates in each case are (a, b) Si and (c–e) PEDOT:PSS coated ITO.

length (15 nm for ZnPc [33]), with a thickness or length of around 200 nm [34]. The films shown in Fig. 1d and e begin to mimic this arrangement and are grown to even greater thicknesses while maintaining relatively uniform average column diameters.

3.1.2. Solvent effects on ZnPc films

One route to completing active layer fabrication using nanostructured ZnPc films is to fill them with PCBM in solution. In this case, it is critical to understand the sensitivity of ZnPc films to the solvents used for PCBM casting. To investigate this, we exposed planar and nanostructured ZnPc films to CB and DCB under different conditions, the results of which are shown in Fig. 2. The first condition mimics device fabrication conditions, by spinning the solvent off the film surface immediately after it is applied (the spin treatment, shown in Fig. 2a and b). The second condition involves placing the film sample in a bath of solvent for 10 min and then removing the sample and allowing the solvent to volatilize under ambient conditions (the

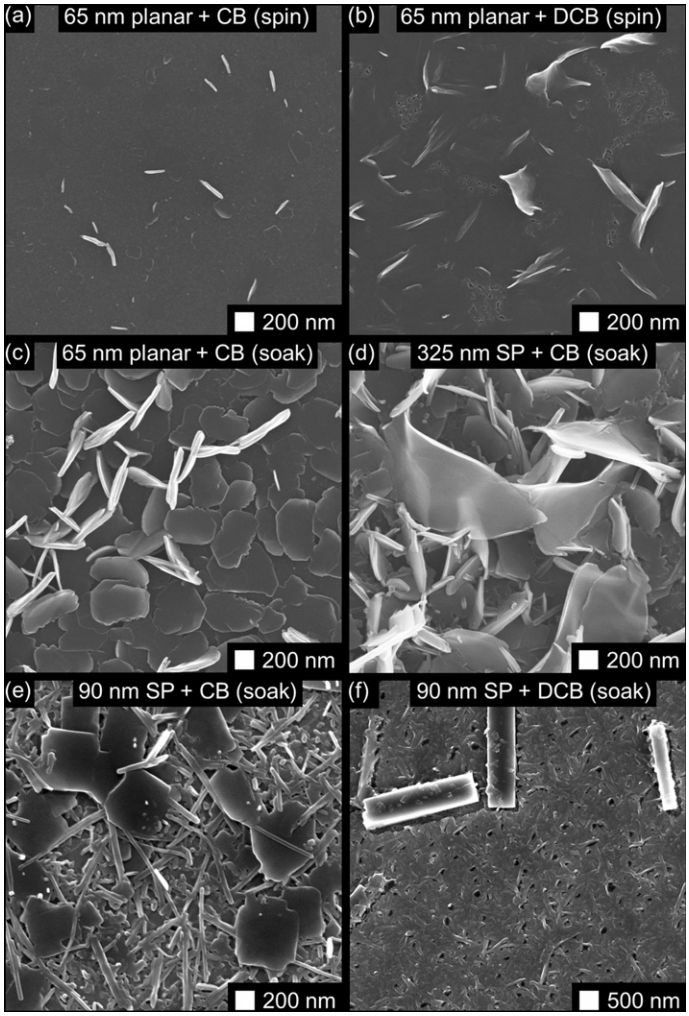

Fig. 2. Aerial views of solvent-treated ZnPc thin films. The untreated versions of these films are shown in Fig. 1.

soak treatment, shown in Fig. 2c–f). This is a similar approach to what has been used previously to improve the performance of CuPc films in OPV devices [13,14]. In addition, we measured absorbance spectra of the solvents after soaking ZnPc films to identify dissolved material (shown in Fig. S1.1 of the Supplementary data). From this we determined the solubility of a ZnPc thin film to be 0.2 μg/mL in CB and 0.5 μg/mL in DCB, based on the molar extinction coefficient determined by Whalley [35]. Modest solubility of ZnPc and other MPc complexes has been observed elsewhere as well [14,36–39].

The films exhibited a significant degree of recrystallization as a result of these solvent exposures, with each combination of solvent treatment and ZnPc film morphology yielding a unique morphology. The film surface can be roughened even with very short solvent exposure times, as seen in Fig. 2a and b. In this case, DCB appears to have a much stronger effect, suggesting that solvent choice may be a critical factor under device fabrication conditions. A greater degree of recrystallization occurs for longer exposure times, with CB generally leading to platelet formations (most evident in Fig. 2c) and DCB leading to large rectangular box structures (Fig. 2f). Similar ZnPc structures have been prepared before, albeit with radically different conditions [40]. Interestingly, the platelet thicknesses closely match the exciton diffusion length of ZnPc (15 nm [33]), which should provide strong exciton dissociation efficiency. Thus, an ordered arrangement of such structures could be expected to perform well in photovoltaic devices. However, additional changes in the film structure were evident after the solvent exposure, from both a crystallinity and absorbance perspective.

The XRD data in Fig. 3 shows the ZnPc films' crystallinity changes due to the solvent treatment. In all cases, the most prominent observed peak was α (010), centered at ca. 6.82° scattering angle, consistent with what has been observed previously for MPc films [41].The α (010) peak intensity is enhanced by the solvent treatment for the planar film, but decreases significantly for the SP film. In both cases, the DCB-treated film showed a higher α (010) peak than the CB-treated film. Interestingly, the α (001) peak, centered at ca. 7.37° scattering angle, became much stronger in the SP film upon solvent treatment with DCB.

The absorbance profiles shown in Fig. 4 also reveal significant changes in the film as a result of solvent exposure. Spin treatments did not affect absorbance significantly, except for DCB on a planar film where we observed a new peak in the 850 nm region. For the soak treatments, we observed significant changes to the Q band (500–800 nm), suggesting compositional changes in addition to the morphological changes. We investigate the photovoltaic properties of some of these solvent textured films in the following section, but for now we note that ZnPc films respond differently to these two solvents, while being sensitive to both.

3.2. ZnPc/PCBM OPV devices

3.2.1. Bilayer devices: choice of solvent and solution temperature

As a control study, bilayer OPV devices were fabricated with the following architecture: ITO (120 nm)/PEDOT:PSS

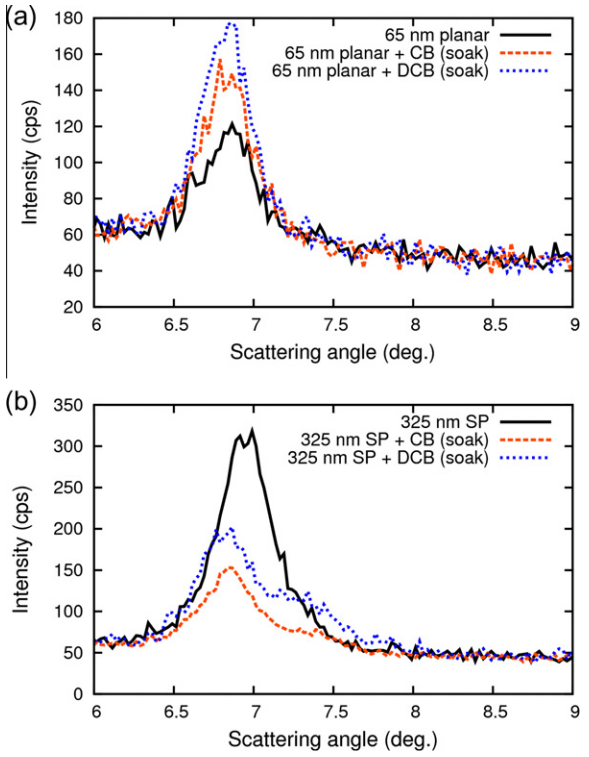

Fig. 3. Effects of solvent treatments on the XRD patterns of (a) planar and (b) nanostructured ZnPc thin films.

(40 nm)/ZnPc (50 nm)/PCBM (70 nm)/BCP (15 nm)/Al (80 nm). We varied the PCBM solution temperature to vary the interaction between the ZnPc film and the solvent. Cross-sectional views of these devices are shown in Fig. 5, which reveal subtle distinctions in the abruptness of the ZnPc/PCBM interface. Though the overall active layer thickness remains constant, the most well-defined boundary between ZnPc and PCBM occurs when the PCBM is applied cold (Fig. 5a). *I–V* curves for these devices are shown in Fig. 6, and device performance metrics are summarized in Table 1.

As seen in the *I–V* curves, the solution temperature has little impact when using CB as the solvent. However, a significant improvement is seen in the photocurrent when we switch the solvent to DCB. We postulate that the difference between using CB and DCB is due to a different degree of material mixing at the ZnPc/PCBM interface. Specifically, the interface may become more of a mixed heterojunction structure when using DCB than CB due to a greater degree of solubility. We investigate this further in the following sections.

The ZnPc layer used here is thicker than what is typically used in such devices, the purpose of which is to allow an investigation of the unique structures in the solvent-treated films (which, under 50 nm thickness, cease to form platelet structures) as well as to provide an absorption-matched comparison to thicker GLAD-structured devices. Both of these tasks are addressed in the following section.

3.2.2. Nanostructured devices

Photovoltaic devices were fabricated with the same layer structure as in the previous section, but here we

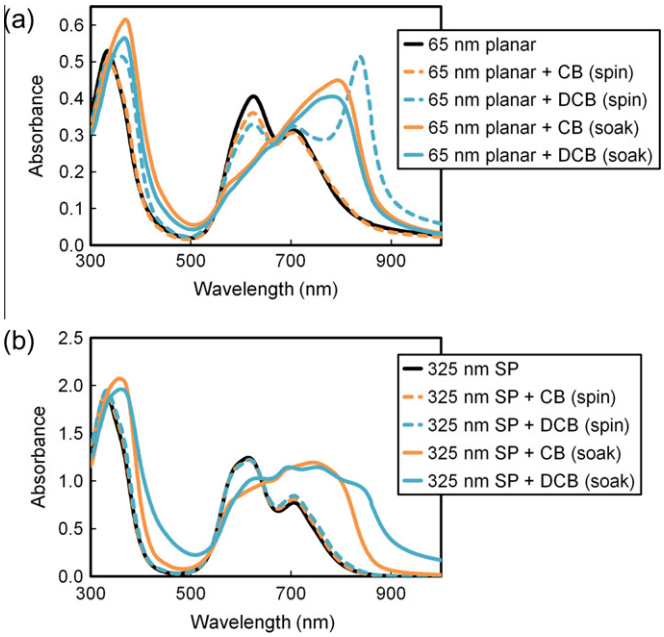

Fig. 4. Effects of solvent treatments on the absorbance of (a) planar and (b) nanostructured ZnPc thin films.

replace the planar layer with structured ZnPc films. The structuring is accomplished either by depositing with GLAD or by direct exposure of a planar film to solvents using a drop treatment, which affords very similar morphologies to the soak treatment discussed earlier. Fig. 7 shows cross-sectional views of the PCBM-coated ZnPc films for each of these two approaches. Fig. 7a is the PCBM-coated version of a 50 nm planar ZnPc film treated with CB and Fig. 7b is the PCBM-coated version of Fig. 1c. We noted that the PCBM solutions in both CB and DCB wet the ZnPc films very well, enabling effective filling of the structured films.

With the solvent-structured approach, the platelets seen in Fig. 2c largely maintain their structure during the coating process (Fig. 7a), which translates into sharp peaks and ridges across the PCBM coating. These contours are still apparent after depositing the BCP/Al electrode (see Fig. 7c), which suggests that CB is not as able to dissolve ZnPc when being used as the PCBM carrier.

When using the slanted post (SP) ZnPc structured film, the PCBM coating not only fills the film completely but also

leaves a much smoother top surface (shown in Fig. 7b). In addition, the overburden could be controlled by varying the spin speed during PCBM application. OPV devices were made with several of these structured morphologies and thicknesses. Additional bilayer devices were also made, with a 20 nm thick ZnPc layer (as is common for these devices). We ensured that the bilayer devices had comparable absorption to the structured devices in order to isolate the effects of morphology alone on photovoltaic performance (see Fig. 8). The results of all these devices are summarized in Table 1, and current–voltage behavior of the key structured devices is shown in Fig. 9. EQE measurements were performed (see Supplementary data), which showed that the relative contributions of the different absorption bands did not vary significantly when using different ZnPc morphologies or PCBM solvents.

As shown in Fig. 9, solvent treatment prior to PCBM coating hindered device performance in both cases. Despite somewhat ideal structures being formed with CB treatment, the performance drop is likely due to the disorder present in the film morphology as well as potential

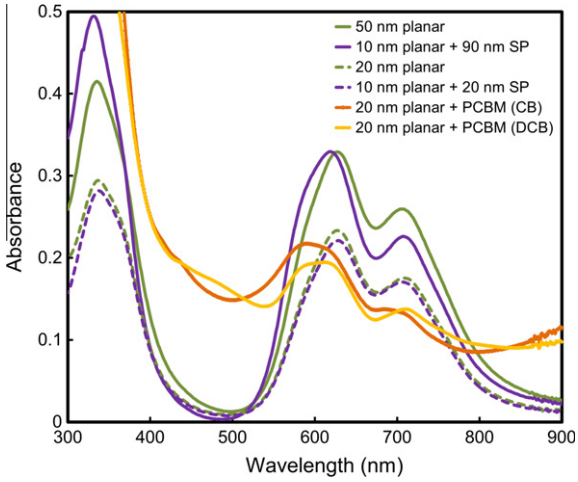

Fig. 8. Absorbance of various planar, structured, and PCBM-coated ZnPc thin films.

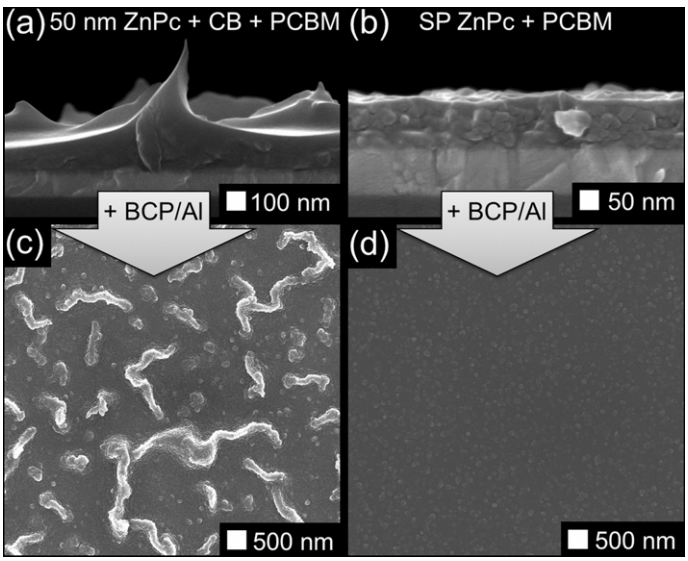

Fig. 7. Cross-sectional views of PCBM coated ZnPc films and aerial views of the corresponding Al electrode on each. The ZnPc film and solvent used in each case was (a, c) 50 nm planar + CB, CB, and (b, d) 90 nm SP via GLAD, DCB.

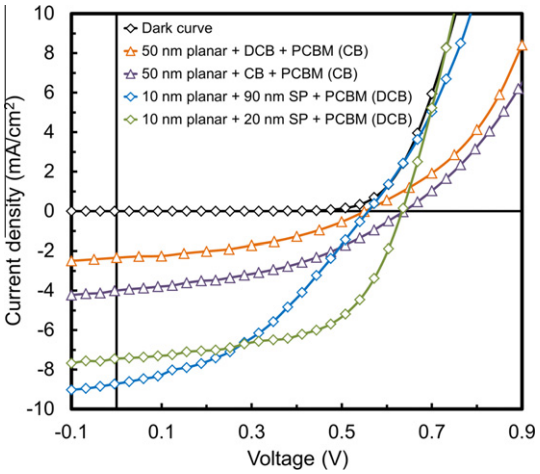

Fig. 9. Current–Voltage behavior of various structured ZnPc/PCBM OPV devices.

changes in film composition, as discussed earlier. In the case of DCB treatment, the structures created are far from ideal to begin with (large rectangular boxes with dimensions of 500 nm or greater, as shown in Fig. 2f). We confirmed by SEM that these large box structures were not dissolved during PCBM coating and were still present after complete device fabrication. Thus, the lower performance is not surprising. However, the fact that photovoltaic activity is still seen in these devices likely means that some of the ZnPc material remains as a planar layer, while the rest is organized into box structures.

Upon examining the performance of the SP films in devices, we see that the thicker film is able to generate the highest short circuit current density (J_{sc}).This is due to the increased light absorption, as shown in Fig. 8. However, the large active layer thickness allows the poor charge carrier properties of these organic materials to limit the collection of free charges, leading to a low fill factor (FF). In addition, exposure to air may be a greater concern for thick structured ZnPc films, whose larger surface area could permit more severe contamination than less textured films. As a result, the highest photoconversion efficiency is still observed when using the thin structured ZnPc film (10 nm planar + 20 nm SP). In this case, an average photoconversion efficiency of 2.86% is achieved when using DCB as the PCBM solvent. The best result among these devices was 3.0%, which is near the performance of some of the best ZnPc devices to date [9,42,43]. It is possible that these results could be further improved by using $PC_{71}BM$ in place of $PC_{61}BM$, as demonstrated elsewhere [44,45].

Overall, the ZnPc morphology improvements created with GLAD provide photoconversion performance enhancement regardless of the amount of material in the

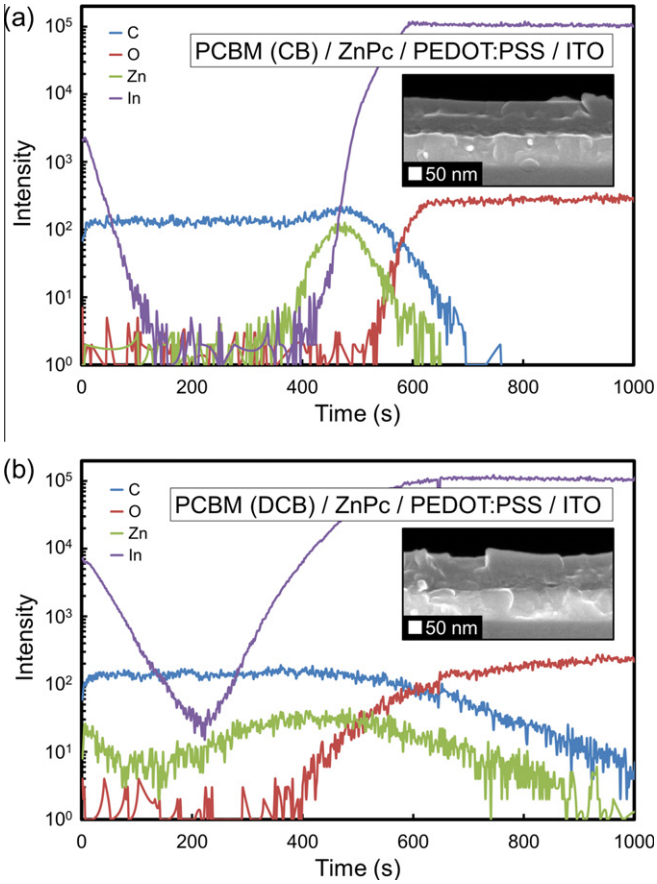

Fig. 10. SIMS depth profiles for thin bilayer ZnPc/PCBM OPV devices, without top electrodes, using (a) CB and (b) DCB as the PCBM solvent.

device. In other words, with all else being equal, a 10 nm planar + 90 nm SP film always outperforms the 50 nm planar film. Similarly, a 10 nm planar + 20 nm SP film always outperforms the 20 nm planar film. We note that the series resistances of the devices using a 50 nm planar film are nearly 50% higher than for devices using a 10 nm planar + 90 nm SP film. Remarkably, the series resistances of thick GLAD-structured devices is as low as the thinnest planar and nanostructured devices. In this case it is evident that the nanostructured architecture promotes better charge transport while containing the same amount of material as the bilayer device. The absorbance profiles of these films are used as grounds to determine that they contained a comparable amount of material (see Fig. 8). Also, in Fig. 8 we see that as the films grow thicker and their morphologies deviate more significantly (between planar and GLAD), so do their absorbance profiles. This is similar to that observed previously with SP CuPc thin films [19].

The absorbance profiles reveal an important difference between the thin bilayer devices prepared using CB vs. DCB as the PCBM solvent, and that is the amount of material stripped off by the solvent during the coating process. We note that the ZnPc absorbance peak around 600–620 nm is lower when using DCB than when using CB, suggesting that DCB is more able to dissolve the ZnPc material while holding 30 mg/mL PCBM. Along with the depth profiles in the following section, this supports the notion that the superior performance observed when using DCB over CB is due to more significant mixing at the interface.

3.3. Depth profiling of thin bilayer device architectures

To further investigate the degree of material mixing at the interface between ZnPc and PCBM, we performed depth profiling via secondary ion mass spectrometry (SIMS) on thin bilayer devices that used either CB or DCB as the PCBM solvent, without a top electrode. Thus, the architecture of the analyzed samples is: ITO (120 nm)/PEDOT:PSS (40 nm)/ZnPc (20 nm)/PCBM (40 nm). The results are shown in Fig. 10.

We see that when using CB as the PCBM solvent, the Zn is well-confined to a specific interval. However, when using DCB as the solvent, the Zn is spread throughout the entirety of the device and is even present at the surface. This further supports the notion that the difference in photovoltaic performance between using CB and DCB (as seen in Table 1) is related to the degree of ZnPc/PCBM mixing during the PCBM casting process.

Finally, it is interesting to note that in each case there was a significant amount of indium present at the surface of the PCBM layer. Migration of indium has been observed previously in OPV devices [46] and OLEDs [47,48]; its impact on these devices will be left for future study.

4. Conclusion

The effects of organic solvents on ZnPc thin films were studied and used to optimize nanostructured ZnPc/PCBM OPV devices. We observe significant recrystallization of ZnPc thin films upon exposure to CB and DCB, which tend to create platelet formations and box structures, respectively, regardless of the initial film morphology. We find that the overall ZnPc film morphology is maintained when coating with PCBM in these solvents, but a degree of material mixing occurs that is dependent on the solvent. This indicates that a planar donor layer can yield either a bilayer or mixed heterojunction, depending on the solvent used to cast the acceptor. When using a nanostructured donor layer, such as a GLAD film, the end result can then be a combination of the interdigitated donor and acceptor layers with a mixed heterojunction forming throughout the acceptor region. This provides an alternative approach to the well-established co-deposition techniques that are routinely used in fabricating mixed heterojunction OPV active layers, while additionally allowing the use of ideal donor layer morphologies.

Photovoltaic performance in our ZnPc/PCBM OPV devices appears to be strongly related to ZnPc film morphology and thickness, as well as PCBM solvent. Our best result in this work is achieved with a 10 nm planar + 20 nm slanted post ZnPc film morphology while using DCB as the PCBM solvent, which exhibits photoconversion efficiencies of up to 3.0%. This work provides motivation for continued optimization of small molecule OPV devices through a combination of direct donor material structuring and optimal solvent choice for casting the acceptor layer (or vice versa).

possible to bring organic materials into degenerate semiconductor or metallic regimes by incorporating relatively small amounts of conductive fillers [2]. Thus, developing polymer-based composites using thermoelectric and conducting fillers is a logical and promising strategy for creating a new class of thermoelectric materials with sufficient mechanical properties, including flexibility.

In 2008, Yu et al. [2] fabricated carbon nanotube (CNT)/PVAc composites and investigated their thermoelectric properties upon CNT addition. The researchers showed that the electrical conductivity can be dramatically increased by creating a network of CNTs in the composite, while the thermal conductivity and Seebeck coefficient remained relatively insensitive to the filler concentration. A thermoelectric figure of merit (*ZT*) greater than 0.006 was achieved with a CNT concentration of 20 wt.% at room temperature. The study by Yu et al. was the first investigation into the use of CNT/polymer composites as thermoelectric materials. In 2010, Kim et al. [3] reported a maximum *ZT* of ~0.02 at room temperature for a polymer composite containing 35 wt.% SWCNTs. In the study, the main polymer matrix was copolymer latex containing vinyl acetate and ethylene. The stabilizer that was used to disperse the CNTs in water was PEDOT:PSS, a widely used conducting polymer, which was doped with DMSO. Electrically insulating gum Arabic (GA) also was studied for a comparison. Composites were made with two different CNTs (XM-CNT and SWCNT) at 2–15 wt.% CNT concentrations and 1:1–1:4 ratios of CNT to PEDOT:PSS; the structures were dried at room temperature and/or 80 °C. In the preparation procedure, CNTs were added to the conducting polymer as fillers to impart more electrical conductivity and ensure a high thermoelectric figure of merit. Meng et al. [4] and Yao et al. [5] fabricated composites consisting of a CNT network as the main matrix and polyaniline (PANI), a conductive polymer, as a coating additive to the CNTs. Meng et al. reported significantly enhanced Seebeck coefficients and power factors in the multi-walled CNTs (MWCNT)/PANI composites, which were several times larger than either of their individual components. The best *ZT* value obtained was 0.003 for a 15.8 wt.% MWCNT/PANI composite. Yao et al. fabricated single-walled CNTs (SWCNT)/PANI composites with a maximum ZT of 0.004 at 41.4 wt.% SWCNT.

In the above cited studies, the effect of the CNT type on the thermoelectric performance of the CNT/polymer composite was not investigated. It has been known that different types of CNTs exhibit different electrical conductivities and Seebeck coefficients. At 300 K, the Seebeck coefficients of individual SWCNTs and MWCNTs are about 42 μV/K [6] and 82 μV/K [7], respectively. The Seebeck coefficients of SWCNT and MWCNT films [4,8] are comparable and have values of around 20–25 μV/K. With regard to electrical conductivity, metallic SWCNT rope exhibits values around 10,000–30,000 S/cm [9], while electrical conductivities of approximately 200–2000 S/cm have been obtained for individual MWCNTs [10,11]. For films or networks composed of CNTs, electrical conductivity becomes one or two orders of magnitude lower than that of individual CNTs and varies depending on the degree of aggregation. While the electrical conductivity of SWCNT films is about 2000 S/cm [12], that of MWCNT mat is approximately 10 S/cm [13].

Given the aforementioned findings, the CNT type would directly influence the thermoelectric performance of their composites. In this study, the thermoelectric properties of CNT/Nafion nanocomposite films with three different types of CNTs were investigated. The CNT/Nafion nanocomposites were prepared from aqueous solutions of CNT/Nafion and SWCNTs, few-walled CNTs (FWCNTs), and MWCNTs were employed in the structures. A water soluble polymer, Nafion, which also contains hydrophobic nature in its backbone, has exhibited good affinity with CNTs and provides enhanced solubility in an aqueous solution without additional surfactants. As a result, films on a substrate were readily fabricated by the doctor blading method. The electrical properties of the CNT/Nafion nanocomposites were primarily affected by the CNTs since the Nafion acts as an electrically non-conducting matrix, while the thermal conductivity of the composites was dominated by the Nafion matrix; electrical and thermal transport are separated. The electrical conductivity and Seebeck coefficient of the nanocomposites were measured as a function of the type and concentration of CNTs at room temperature. For all three kinds of CNTs, both the electrical conductivity and the Seebeck coefficient increased as the concentration of CNTs was increased. While the electrical conductivity was dependent on the type of CNT, the behavior of the Seebeck coefficient was relatively independent of the CNT type. This indicates that high-energy-charges can participate in transport processes irrespective of the type of CNT.

2. Experimental

2.1. Preparation of CNT/Nafion nanocomposites

SWCNT (ASA-100F), FWCNT (CMP-310F), and MWCNT (CM-95) that are purchased from Hanwha Nanotech were purified according to the "Fenton Chemistry Method" reported by Wang et al. [14] Briefly, pristine CNTs were stirred in 1 N HCl and H_2O_2 (7/3 by weight) at 60 °C for 4 h. The resulting CNTs were filtered and washed with deionized water until the filtrated solution had a pH of 7. The pristine CNTs were heated for 4 h at 292 °C before the Fenton Chemistry purification in order to remove amorphous carbon impurities. The purity of the CNTs, as determined by thermogravimetric analysis (TGA), was >95%. The purified CNTs were mixed with a Nafion solution in deionized (DI) water (5% by weight, Aldrich). The solution was then briefly sonicated (30 min) and stirred overnight. The CNT/Nafion composite solutions were cast onto glass plates that were cleaned by sequential washing with ethanol and acetone under sonication. The composite solution was then doctor-bladed to form the films. The thickness of the film is 2–5 μm.

2.2. Characterization

The four-probe method was used to measure the electrical conductivities of the CNT/Nafion nanocomposites. A

Keithley 2400 was employed as a source meter. The Seebeck coefficient was extracted by applying a temperature gradient along the sample while measuring the thermoelectric voltage. Two T-type thermocouples were used to measure temperatures and voltages simultaneously. Two thermoelectric devices, one as a heat source and another as a heat sink, were used to create a temperature gradient across the samples. The measured Seebeck coefficient was calibrated due to the Seebeck coefficient of the Cu wire of the T-type thermocouple, which is 1.7 μV/K [15]. The thermal conductivity of the samples was extracted by measuring the thermal diffusivity using the laser flash technique (Netzsch LFA 457 MicroFlash) and the specific heat as measured with a differential scanning calorimeter (Netzsch Differential Scanning Calorimeter (DSC) 200).

3. Results and discussion

For the preparation of the CNT/polymer composites, an effective dispersion of CNTs within the polymer matrix is quite a challenge since CNTs have poor solubility due to strong van der Waals interactions. Nafion, a water soluble perfluorosulfonated polymer, has been successfully used to solubilize CNTs in alcoholic solutions so as to form homogeneous composites [16,17]. The hydrophobic main chain of Nafion can wrap the surface of CNTs, while the polar side chain can provide solubility in polar solvents. A photo of a diluted SWCNT/Nafion composite (5 wt.% SWCNT in Nafion) solution in DI-water is shown in Fig. 1(a). A stable homogeneous dispersion of the composites is clearly evident. Stability was reasonably maintained at various SWCNT concentrations. Photos of aqueous SWCNT/Nafion composite solutions over a range of SWCNT/Nafion weight ratios (1/9–5/5) are shown in Fig. 1(b). The dispersion stability was intact after one month, indicating that the Nafion can efficiently solubilize a significant amount of CNTs for a long period of time. The aqueous dispersion and the solution stability of FWCNT and MWCNT-based composites were even more improved because SWCNTs have a stronger tendency toward self-aggregation [18–20]. CNT/Nafion composite-based films were prepared using the doctor blade method, which is popular for micron-thick polymer film fabrication. The fabrication of crack-free CNT/Nafion composite films via a solution process has been demonstrated by Luo et al. [17]. The resulting films exhibited enhanced mechanical properties with strong flexibility and high electrical conductivity. A doctor-bladed SWCNT/Nafion composite film (5 μm thick) on a glass plate is shown in Fig. 1(c). The surface of the films was relatively smooth without noticeable cracks.

Scanning electron microscopy (SEM) images of a 7 wt.% SWCNT/Nafion composite and a 50 wt.% SWCNT/Nafion composite are shown in Fig. 2(a) and (b), respectively. The SWCNTs were homogeneously dispersed within the Nafion matrix, which is indicative of effective wrapping of the SWCNTs by the Nafion in an aqueous solution. As the SWCNT/Nafion ratio was increased, more SWCNTs were observed in the SEM images (Fig. 2(a) and (b)), which indicates that the SWCNTs were homogeneously dispersed within the composite films.

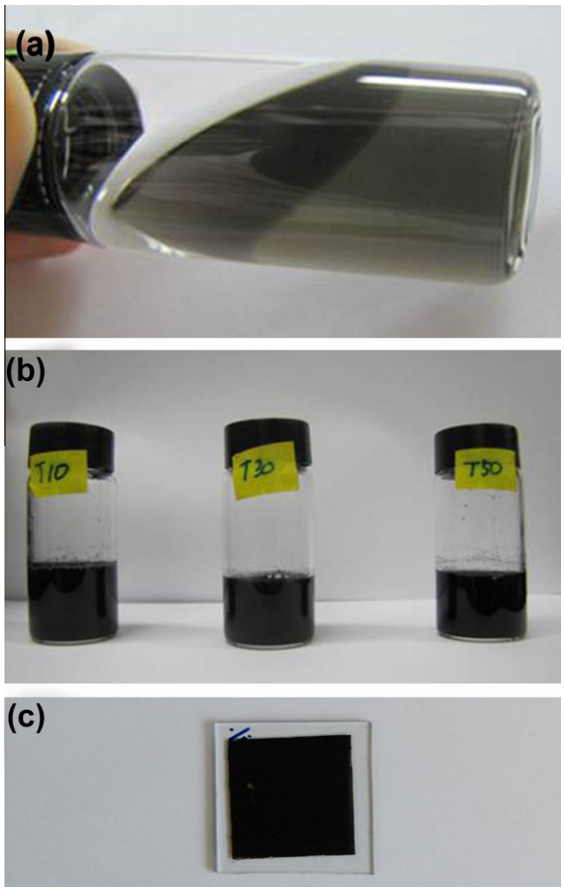

Fig. 1. Photos of (a) a diluted SWCNT/Nafion (5 wt.% SWCNT in Nafion) solution in deionized (DI) water, (b) a range of SWCNT/Nafion composite (1/9–5/5 by weight ratio) solutions in DI water one month after preparation, (c) a SWCNT/Nafion composite film prepared via the doctor blade method. The film was relatively uniform with a thickness of ~5 μm.

The electrical conductivities of the CNT/Nafion nanocomposites are shown in Fig. 3(a). The electrical conductivities of all of the composites increased as the CNT concentration was increased. These conductivities saturated at ~30 wt.% CNT loading in Nafion. Note that even the lowest CNT concentration (10 wt.%) in the composites is much higher than the conventional percolation threshold of CNT/polymer composites (~ a few %), thus the electrical conductivity at 10 wt.% CNT loading was not significantly lower than in the 30 wt.% CNT-loaded films (they were the same order of magnitude), which indicates the efficient percolation of charges. The optimized electrical conductivity of the CNT/Nafion composites (13 S/cm) was similar to the values obtained in a previous report (12.5 S/cm) [17], although the CNT loading in that study was 10 wt.% more than in our composites. Such a result indicates that our composites contained well-dispersed and efficiently interconnected CNTs within a matrix of Nafion. The SWCNT/Nafion composites exhibited relatively lower conductivities when compared to the FWCNT and MWCNT-based composites. For fully connected CNT networks, the electrical conductivity can be somewhat limited by the CNT–CNT contact resistance [21,22]. Taking

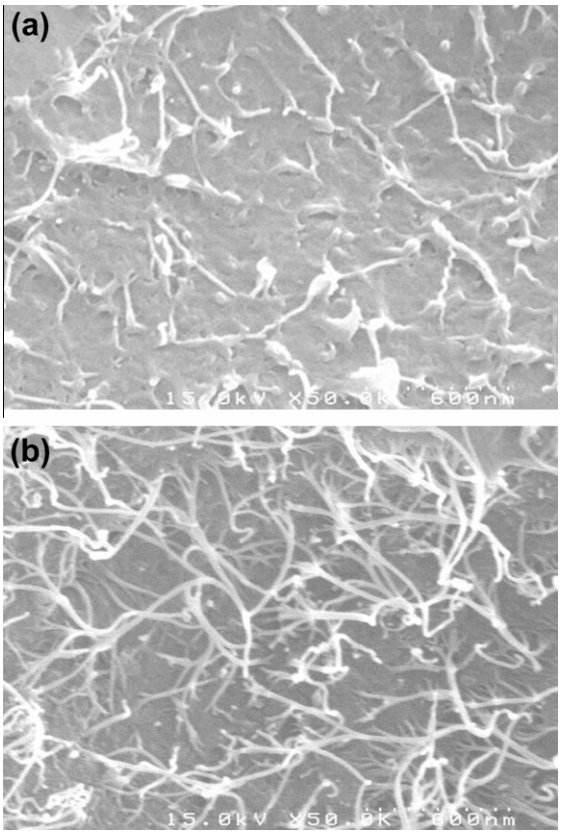

Fig. 2. Scanning electron microscopy (SEM) images of SWCNT/Nafion composites: (a) 7 wt.% and (b) 50 wt.% of SWCNTs in Nafion.

into account that the conductivity of individual CNTs is dependent on various factors such as the surface functionality, tube diameter, length, wall thickness, and bundle size, the conductivity of the composites will be governed by the electrical properties of the CNTs themselves and the contact resistance among the Nafion-wrapped CNTs. In the case of a SWCNT-based mat or composite films, the conductivity significantly varies depending on the ratio of metallic to semiconducting tubes. This is because the contact resistance between semiconducting and metallic junctions is significantly greater than that in metallic–metallic junctions [23]. Since our SWCNTs possessed a typical composition (1:2 for metallic:semiconducting) [23], the higher electrical conductivities of the FWCNT and MWCNT-based composites are not surprising and are consistent with the findings of other reports [24,25]. Based on Fig. 3(a), we deduce that a CNT concentration of 30% should be enough to obtain an optimum electrical conductivity. The highest observed electrical conductivity in this study was 13 S/cm from the 30 wt.% MWCNT/Nafion composites.

The Seebeck coefficients of the CNT/Nafion nanocomposites with respect to the CNT concentration are shown in Fig. 3(b). All of the films, irrespective of the type and concentration of CNTs, exhibited p-type conduction, which means that the majority of charge carriers are holes. When charge carriers from the thermoelectric effect are transported in

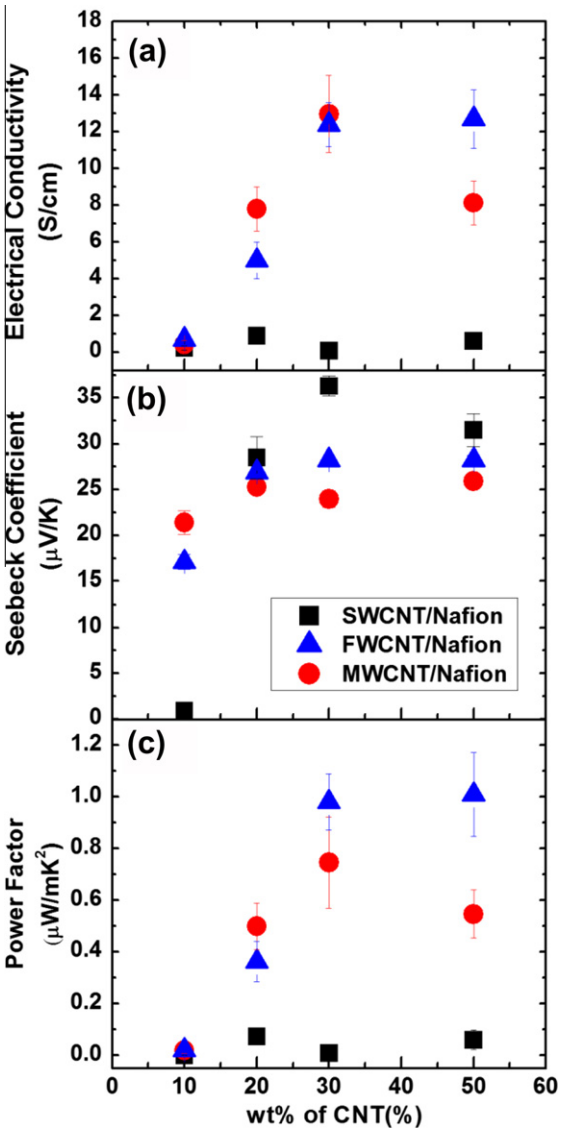

Fig. 3. (a) Electrical conductivity [S/cm], (b) Seebeck coefficient [μV/K], and (c) power factor [W/m-K^2] versus CNT weight percent.

conducting networks (CNTs in this study) within a non-conducting matrix, such as Nafion, the Seebeck coefficient of the composites should depend on the Seebeck coefficient of the networked materials. As mentioned previously, although the Seebeck coefficients of individual CNTs are dependent on the type of CNT (the Seebeck coefficients of the SWCNTs and MWCNTs are about 42 μV/K [6] and 82 μV/K [7], respectively), the Seebeck coefficients of SWCNT and MWCNT mats [4,24] are comparable to each other and are approximately 20–25 μV/K. The Seebeck coefficient is related to the transport of energetic charges, whereas the electrical conductivity is related to the transport of all mobile charges [2,3]. Charge transport in CNT mats is hindered by junctions such as metallic CNT-semiconductor CNT junctions, metallic CNT–metallic CNT junctions, etc. The fact that the Seebeck coefficients of CNT

mats are independent of the CNT type suggests that energetic charges transported regardless of the junction types in SWCNT mats. In our nanocomposites, behavior similar to that seen in CNT-based mats was observed. The Seebeck coefficients of the CNT/Nafion composites which contains >20 wt.% of CNTs ranged from 25–35 μV/K, and there was no significant difference among the types of CNTs (SWCNT, FWCNT, MWCNT) whereas the dependency on the types of CNTs was observed in the 10 wt.% CNT loaded composites. The CNT/Nafion nanocomposites have a different morphology from the CNT mats: Nafion-wrapped-CNTs are connected to each other in the composites, whereas the pure CNTs are connected in the mats. The fact that the Seebeck coefficients of CNT/Nafion composites with higher CNT concentration (20 wt.%) are independent of the type of CNT is an indicator that energetic charges have sufficient energy to transport through the Nafion-wrapped CNTs. This inter-CNT resistance should be even higher than that in CNT mats. Resistance due to metallic CNT-semiconductor CNT junctions should not be affected. Therefore, the Seebeck coefficient of CNT/Nafion nanocomposites should be independent of the CNT type. However, in the composites with 10 wt.% CNT loading, the higher inter-CNT resistance of the Nafion-wrapped CNT could influence to the transport of the energetic charges thus the Seebeck coefficients of the composites. The lower CNT loaded (10 wt.%) composites exhibited relatively reduced values of Seebeck coefficients; especially the SWCNT/Nafion (10 wt.%) displayed much lower values of Seebeck coefficient (0.9 μV/K) than other samples. This result indicates that both the connectivity of CNTs and the inter-CNT resistance determine the Seebeck coefficients of the composites.

The power factors ($S^2\sigma$) of the CNT/Nafion composites are shown in Fig. 3(c). Since the Seebeck coefficients were almost independent of the CNT type and the electrical conductivities were dependent on the type of CNT at the high CNT concentrations, the composites exhibiting higher electrical conductivities possessed higher power factors. The power factor of the FWCNT/Nafion composites was as high as 1 μW/m-K^2, whereas one-tenth of this power factor was observed in the SWCNT/Nafion composites. The thermal conductivity of the 5 wt.% FWCNT/Nafion composites was determined to be ~0.3 W/m-K at room temperature. The thermal conductivity of CNT mats is around 30 W/m-K [26], whereas that of polymer in general is around 0.2 W/m-K at room temperature. This suggests that weak van der Waals bonding in the Nafion significantly contributes to thermal transport. It has been previously reported that the thermal conductivity of CNT/polymer composites is relatively insensitive to the CNT concentration [4,5]. CNT/Nafion thermal conductivity is dominated by the polymer matrix, whereas the electrical transport is dominated by the CNTs themselves. In this scenario, electrical transport can be separated from thermal transport. While the estimated thermoelectric figure of merit of ~0.001 for the CNT/Nafion films is not comparable to that of inorganic materials at this time, the work presented here demonstrates that separating electrical and thermal transport should serve as a scheme to increase the thermoelectric figure of merit.

4. Conclusions

We investigated the thermoelectric properties of CNT/Nafion nanocomposites using various types of CNTs. It was found that the electrical conductivities of the CNT/Nafion composites were primarily affected by the type and concentration of CNTs since the Nafion act as an electrically non-conducting matrix. For all three kinds of CNTs, both the electrical conductivity and the Seebeck coefficient increased as the concentration of CNTs was increased. While the electrical conductivity was dependent on the type of CNT, the behavior of the Seebeck coefficient was relatively insensitive of the CNT type. The Seebeck coefficient is related to the transport of energetic charges, whereas the electrical conductivity is related to the transport of all mobile charges [2,3]. Therefore, energetic carriers that contribute to the Seebeck coefficient would not see barriers such as the metallic CNT-semiconductor CNT junctions in SWCNT/Nafion nanocomposites at high enough concentration. The thermal conductivity of the composites was governed by the polymer matrix. As such, electrical and thermal transport can be separated. This study could prove quite useful in the design and synthesis of polymer composites for thermoelectric applications.

intensity of such a DC device is dominated by the wavelengths corresponding to the emission of underlying blue OLED and emission from the down conversion material. Therefore, the device spectra are not very broad and limit the color rendering index (CRI). Our approach tries to overcome this disadvantage: We fabricate white top-emitting OLEDs with a heterosystem of two different organic layers. Utilizing two down conversion materials helps to obtain a DC device with a broad emission spectrum, an improved CRI, and a better control of color coordinates with thickness of down conversion materials.

2. Experimental

The blue OLED device consists of glass substrate/aluminum 40 nm/silver as bottom contact 15 nm/hole transport layer *N*,*N*,*N*′,*N*′-tetrakis (4-methoxyphenyl)-benzidine (MeO-TPD) doped with 2 wt.% Novaled dopant (NDP2) 25 nm/electron blocking layer *N*,*N*′-di(naphthalen-2-yl)-*N*,*N*′-diphenyl-benzidine (α-NPD) 10 nm/fluorescent blue emitter system 2-methyl-9,10-bis(napthalen-2-yl) anthracene (MADN) doped with 1 wt.% of 2,5,8,11 -tetra-tert-butylperylene (TBPe) 10 nm/hole blocking layer tris(8-hydroxy-quinolinato)aluminum (Alq_3) 10 nm/electron transporting layer 4,7-diphenyl-1,10-phenanthroline (BPhen) coevaporated with cesium (Cs) 10 nm/semi-transparent top contact Ag 15 nm. The dopant NDP2 has similar electrical properties to a known dopant F4-TCNQ, but F4-TCNQ is known to contaminate the evaporation chamber, therefore NDP2 is used. The thicknesses for different layers of the blue device are optimized by optical simulation [17]. The DC materials used in this study are the deep red emitter 4-dicyanomethylene-2-methyl-6-*p*-dimethylaminostyryl-4*H*-pyran (DCM) doped at 1 wt.% in an Alq_3 matrix and a yellow fluorescent dye *N*4,*N*41′-bis-(4-tert-butyl-phenyl)-*N*4,*N*4′-di-fluoranthen-3-yl-diphenylether-4,4′-diamine (OYSE). The OLED structures of the fabricated devices A, B, and C are shown in Fig. 1.

The thicknesses of DC layers are determined by previous experiments on bottom emitting devices. All devices are fabricated in an UHV chamber (Kurt Lesker) with a base pressure $<10^{-7}$ mbar. The deposition rates for all materials are in the range of 0.2–1.5 Å/s and thicknesses are measured with quartz crystals. The photoluminescence spectra of single layers are measured with the luminescence spectrometer Fluoromax from HORIBA Jobin Yvon GmbH. Transmission and reflection measurements are done at the spectral photometer UV-3101 from Shimadzu Deutschland GmbH. The current–voltage characteristics of the devices are measured by source measure unit (Keithley SMU2400) and a silicon photodiode (HAMAMATSU). The spectral emission is detected by an absolute calibrated CAS100 spectrometer. Angular resolved electroluminescence spectra are measured with a goniophotometer. The efficiencies are calculated with respect to the goniophotometer measurements [18].

3. Results and discussion

Fig. 2 shows the absorbance and photoluminescence spectra of 80 nm films of the down conversion materials on quartz substrates superposed with the photoluminescence spectrum of MADN:TBPe. The photoluminescence spectrum of MADN:TBPe exhibits peak at 460 nm followed two shoulders at 490 nm and 525 nm. It can be observed that DCM and OYSE have high absorption at the wavelength corresponding to maximum emission (460 nm) of the blue OLED. DCM and OYSE have strong emission in the deep red (670 nm) and in the yellow region (556 nm), respectively. In the system Alq_3:DCM, the Alq_3 host allows Foerster energy transfer to DCM and also acts as a spacer for DCM molecules to prevent the quenching of emission [19]. For an efficient Foerster energy transfer from the host to the dopant there should be a strong overlap between the photoluminescence spectrum of the host and absorption spectrum of the dopant, which is illustrated in Fig. 2. Further, there is a significant overlap of blue emit-

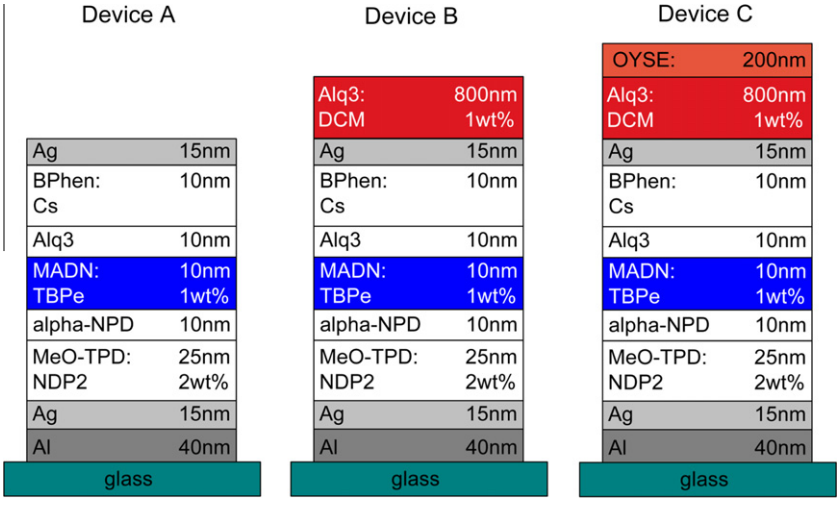

Fig. 1. Layer architectures of the fabricated devices. Additionally to the blue top-emitting OLED (device A), a single down conversion layer of Alq_3:DCM (device B) and a heterosystem of Alq_3:DCM/OYSE (device C) is applied. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

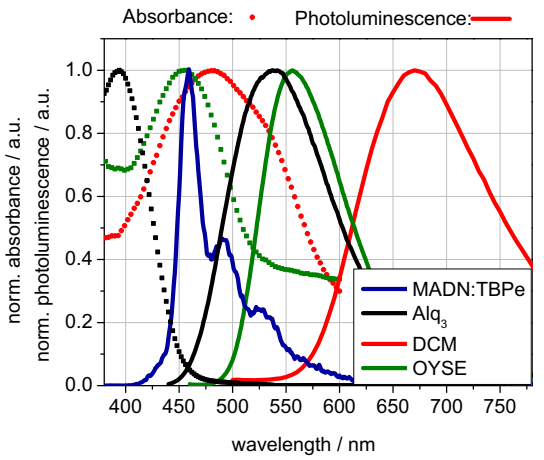

Fig. 2. Absorbance spectra of the materials Alq_3, OYSE and DCM and photoluminescence spectra for Alq_3, OYSE, DCM and MADN:TBPe for single layers. The DC materials are chosen such that there is a high overlap between the photoluminescence spectrum of blue material and the absorbance of the DC materials to enable efficient energy transfer. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

ter photoluminescence spectrum with the absorption spectrum of DCM. Direct absorption of blue light by DCM and re-emission is also likely to contribute to DC device spectrum. The peak wavelength of photoluminescence spectrum exhibits a red shift with increased doping of DCM in Alq_3 with maximum photoluminescence intensity at around 1 wt.% [20]. The incorporation of an OYSE layer serves to fill the spectral gap between red and blue regions of the visible spectrum.

The majority of DCOLEDs reported in literature are bottom emission OLEDs [9–14]. Usually an ITO coated glass substrate separates the organic layer of the OLED stack and DC layer. The mechanism of color conversion in such devices can simply be attributed to light absorption and re-emission by the DC layers. For an Alq_3:DCM DC layer, blue light absorbed by Alq_3 can be transferred non-radiatively to DCM dopant molecules by Foerster energy transfer. However, in top-emitting OLEDs a second mechanism of color conversion may operate in parallel to absorption and re-emission. Previously it has been demonstrated that in systems, where two organics films are separated by a thin metallic layer, radiative energy transfer can occur from the decaying dipoles of the emitter to acceptor molecules in the other organic layer, mediated by the surface plasmon polaritons (SPPs), existing on both sides of the metal [21–23]. For both devices B and C the emitting dipoles are close to the 15 nm thick Ag top contact (20–30 nm). It is likely that the energy from decaying blue emitting dipoles can couple to SPP modes near surface of thin Ag film and this energy can then be further transferred to DCM dopant via the SPPs existing on the other side of the metal.

The inset in Fig. 3 shows the current–voltage (I–V) curves for the devices A, B, and C. It is noteworthy, that the I–V curves of all devices are almost identical. This shows that the DC layers have no effect on the electrical properties of the device. Fig. 3 illustrates the normalized

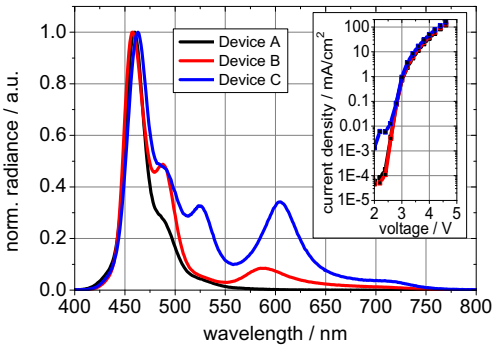

Fig. 3. Normalised EL spectrum for the devices A, B and C. The emission from Alq_3:DCM and OYSE proves the principle of down conversion in top-emitting OLEDs. Inset: I–V characteristics of devices A, B and C have very similar behavior. This demonstrates the additional DC layer(s) have no impact on the electrical behavior of the device.

EL spectrum at 1000 cd/m^2 of the devices A, B, and C. The spectra of devices B and C have peaks at 580 nm and 602 nm, respectively. These maxima arise from the light generated in the DC layers. These peaks do not exactly correspond to the photoluminescence maximum of DC materials but rather to a peak which represents the net sum of emission from individual DC materials. The shoulder observed at 525 nm in MADN:TBPe photoluminescence spectrum is suppressed in electroluminescence spectra of devices A and B due to the cavity structure. Further, the blue part of the spectra of the devices B and C are much broader compared to the reference blue device A, which is related to an additional capping layer effect [24].

The device C exhibits cold white CIE color coordinates of (0.27, 0.26) with a color rendering index of 60 and correlated color temperature (CCT) of 17,200 K (Fig. 4). A shift towards the planckian locus is observed for the devices B and C. The warm white point A can be achieved by an enhanced contribution of OYSE and Alq_3:DCM, which might be realized with thicker DC layers.

Furthermore, it is observed that the electroluminescence spectrum of device C is stable with variation of the applied current. The blue emitting device A exhibits an electroluminescence (EL) spectrum which is stable against

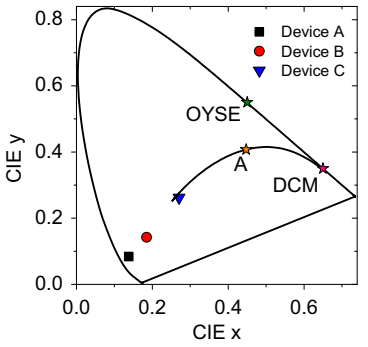

Fig. 4. CIE color coordinates for the three devices. By tuning the layer thicknesses of the down conversion layers an adjustment of the coordinates towards the planckian locus is realized.

the measurement angle θ ($0° < \theta < 90°$) as shown in Fig. 5(a), while for the device C the spectrum has a strong angular dependence as depicted in Fig. 5(b). The blue part of the spectrum for devices A and C show a similar angular dependence. For the device C, the change in angular spectra is most pronounced in the yellow and red parts of the emission spectrum which also corresponds to the maximum of photoluminescence from the DC materials OYSE and Alq_3:DCM, respectively. This is due to the fact that the down converted light undergoes strong microcavity effects when it enters the cavity through the semitransparent cathode. At the normal observation angle for device C, the emission from OYSE is not clearly visible. However, at angles of 40–50° one can clearly see the spectral contribution from both OYSE and Alq_3:DCM. To make the angular spectrum more stable, one could utilise a scattering layer or a microlens foil on top of the DC layer.

To have a more accurate estimate of the amount of down conversion, one must consider the light emitted not only in the forward direction but also for larger viewing angles. Therefore the photon flux (PF) of the devices A, B, and C is calculated by measuring and integrating the EL spectra from viewing angles of 0–90°. The photon flux is depicted in the following formula by

$$PF = \frac{2\pi}{hc} \int \int \lambda I_e[\lambda, \theta] \sin\theta d\lambda d\theta$$

where h and c represent Planck's constant and speed of light in vacuum, respectively. I_e denotes the spectral radiant intensity as a function of wavelength λ and viewing angle θ.

In Fig. 6, the relative contribution to the photon flux by the down conversion components in devices B and C is depicted. The strong absorption of the DC layers lead to a loss of blue light. In the case of Alq_3:DCM, the peak of the blue emission is reduced by a factor of 1.8; for the heterosystem Alq_3:DCM/OYSE by a factor of 6.2. Hence, the contribution of blue, yellow, and red light can be well adjusted using thickness variations of the DC-layers.

Fig. 7 shows the external quantum efficiency (EQE) and luminous efficacy of the devices in dependence of the current density. The EQE of device A is higher than of devices B and C. Interestingly, the EQE is reduced almost by a factor of 2 when applying the heterosystem. The decrease is mainly due to the limited photoluminescence quantum yield (PLQY) and absorption by the down conversion materials, PLQY for Alq_3:DCM is nearly 60% [25] and 69.4% for OYSE. The luminous efficacy is enhanced for the devices

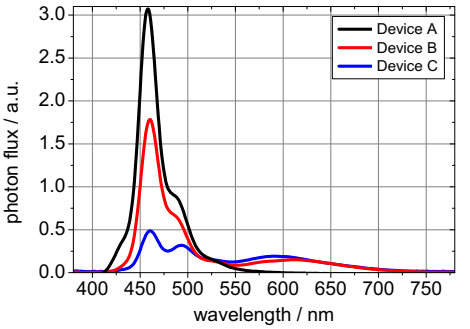

Fig. 6. Photon flux for the three devices at a current of 3 mA. The strong decrease in the blue spectrum is due to absorption by Alq_3:DCM and OYSE.

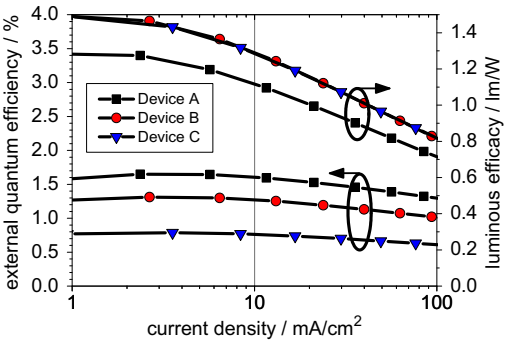

Fig. 7. External quantum efficiency (EQE) and luminous efficacy (LE) vs current density for devices A, B and C. The blue device shows nearly twice the external quantum efficiency of the heterosystem DCOLED. The down conversion devices B and C have higher luminous efficacy than the blue system as the device spectra are pronounced in the region of the eye sensitization curve. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

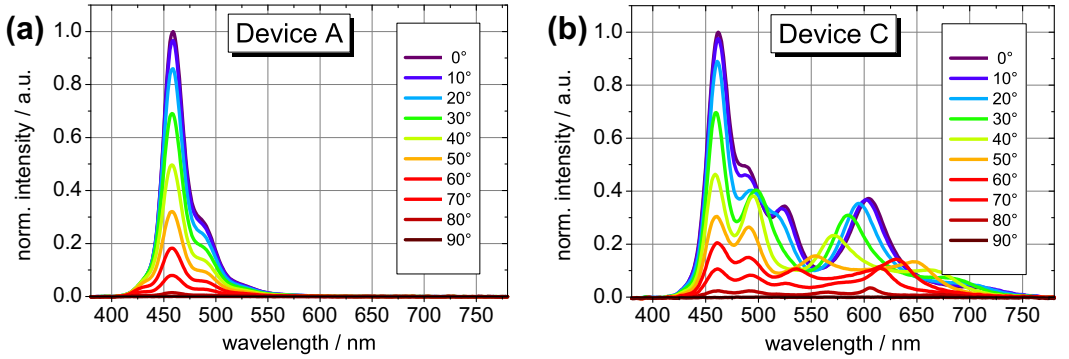

Fig. 5. Angular dependent EL spectrum for device A and C at 3 mA. The spectra are normalized to the peak of the 0° spectrum. While the blue OLED (a) shows an angular stable spectrum, the DC-OLED (b) exhibits a strong shift only in the yellow and red parts of the spectrum with increasing viewing angle. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

with DC layer, which is a result of the stronger overlap of the spectrum with the eye sensitization $V(\lambda)$ curve.

4. Conclusion

Top emitting white organic LEDs are demonstrated with a single- and a heterosystem of organic DC layers. For the heterosystem, the conversion in both layers has been demonstrated. The white OLED has a broad emission spectrum with spectral contributions from each of the two down conversion materials. At 1000 cd/m^2 the white DCOLED has color coordinates of (0.27, 0.26) with the current efficacy, luminous efficacy and external quantum efficiency values of 1.4 cd/A, 0.88 lm/W and 0.83%, respectively. The DC device efficiencies can be substantially increased by using phosphorescent blue emitters instead of fluorescent ones. Furthermore, DC layer thicknesses can be optimized in terms of the color point and light outcoupling.

acid (PTCDA) has been used at the anode, whereby the improved stacking of the ClAlPc molecules led to an increase in short-circuit current density J_{sc} of 25% [10]. For organic transistors, the use of self-assembled monolayers (SAMs) is a well-established technique for the control of the growth [11]. Using this approach, the molecular orientation of ClAlPc molecules could be changed from face-on (parallel to the substrate) to edge-on (normal to the substrate) by treating a SiO_2 substrate with octadecyltrichlorosilane [12]. For OPVCs, SAMs have been used to treat the anode, though here the aim has typically been to adjust the ITO work function, rather than adjusting the growth of subsequent layers [13–16].

To obtain a BHJ that combines good transport properties with efficient exciton separation, the control of morphology and growth is even more critical. For example, the co-evaporation of a planar phthalocyanine (Pc) and C_{60} at room temperature will typically lead to an amorphous film [17,18]. Compared to the pure CuPc layer these amorphous films have poor hole mobilities, limiting cell efficiency. By applying an elevated substrate temperature (T_{sub}) during Pc:C_{60} deposition, the efficiency can be improved compared to deposition at room temperature [19]. Also here, the growth surface can have a large impact on the solar cell performance, with films grown on 3,4-polyethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS) showing a different morphology and lower efficiency compared to devices with films grown directly on ITO [20].

For ClAlPc, Li et al. showed that the surface area of the films could be increased by using oblique angle vacuum deposition [21]. This resulted in an increase in J_{sc} in their ClAlPc/C_{60} cells, thereby showing that ClAlPc cells could be improved with a bulk heterojunction approach. First promising results for co-evaporated ClAlPc:C_{70} BHJ cells have already been reported [22], where T_{sub} was shown to have a strong impact on the growth of the blend, with nanocrystal formation at an elevated temperature from 370–390 K. Consequently, J_{sc} and *FF* were enhanced significantly, resulting in a power conversion efficiency of 4.1%.

In this article, we will further investigate the growth of ClAlPc for BHJ solar cells. We will focus on the use of structural templating layers, an approach which has already proven successful in planar heterojunction cells, but has not been thoroughly investigated for their role to improve BHJ-based cells. The two different surfaces we compare as templating layers are molybdenum oxide (MoO_3) and MoO_3 treated with a SAM of 1H,1H,2H,2H-perfluorodecyltrichlorosilane (FDTS). First, pure ClAlPc films were grown on top of these surfaces, and the influence of T_{sub} on the film properties was investigated. Planar HJ solar cells were then produced from these pure films to probe how the different growth properties affect the ensuing solar cell performance.

Next, we proceed by growing co-evaporated ClAlPc:C_{60} films at elevated T_{sub} in order to grow crystalline BHJ layers. Here, we observe a significant device performance improvement depending on the presence of an initial pure ClAlPc templating layer underneath the BHJ layer. Bulk heterojunction solar cells produced with these blends all show increased current with respect to the planar HJ devices, with power conversion efficiencies (η) greater than 4%.

2. Experimental

Glass substrates coated with ITO (Kintec, 85 nm, sheet resistance <20 $\Omega\,\square^{-1}$) arevv cleaned by subsequent ultrasonic treatment in detergent, de-ionized water, acetone, and iso-propanol, for 5 min each, followed by an ultraviolet-ozone treatment for 900 s. On the samples for film characterization, a 25 nm thick layer of PEDOT:PSS (HC Starck Clevios P) was deposited. Prior to FDTS surface modification, 10 nm of MoO_3 is evaporated at a rate of $\sim$1 Å s^{-1} and pressure of $\sim10^{-7}$ Torr in a vacuum chamber. Then FDTS is applied by vapor phase deposition in a home-built oven under reduced pressure (140 °C, 30 min.).

The MoO_3 ($\sim$550 °C), ClAlPc ($\sim$350 °C), C_{60} ($\sim$380 °C) and bathocuproine (BCP) ($\sim$150 °C) materials are evaporated at a rate of $\sim$1 Å s^{-1} in a vacuum chamber at a pressure of $\sim10^{-7}$ Torr. The mixed ClAlPc:C_{60} (1:1) layer was formed by keeping both rates constant at 0.5 Å s^{-1}. Deposition rates are determined from calibration of the film thickness, measured ex-situ by spectroscopic ellipsometry (Sopra GESP-5). All organic materials are purified before loading into the chamber by thermal gradient sublimation. T_{sub} was elevated with heat lamps, calibrated by thermocouple measurements. Before subsequent layers were deposited on the heated layer, samples were cooled to $\sim$40 °C. The cathode, Ag ($\sim10^{-7}$ Torr; 1.5 Å s^{-1}), is deposited through a shadow mask, without breaking vacuum.

X-ray reflectivity (XRR) measurements were performed on a PANalytical X'Pert Pro Materials Research Diffractometer using Cu Kα radiation. An integration time of 7 s per 2θ of 0.01° was used for scanning $\theta/2\theta$. Absorptance spectra are measured with a Shimadzu UV-1601PC. The surface morphology was studied with atomic force microscopy (AFM) using a Picoscan PicoSPM LE scanning probe in tapping mode. Static contact angle measurements were performed on MoO_3 and ClAlPc films with an OCA-20 contact angle meter from DataPhysics Instruments GmbH with SCA20 software.

Electrical characterization of the solar cells is performed with a Keithley 2602 measurement unit. Cells are measured in the dark (see supplementary information) and under 100 mW cm^{-2} AM1.5G simulated solar illumination. Solar illumination is applied using an Abet solar simulator, calibrated with a Fraunhofer certified photovoltaic cell. For all studied device architectures, 6 cells with active areas of 0.134 cm^2 were measured, where the best performing (highest power conversion efficiency) is reported here.

A commercial set-up (Bentham) is used to measure the external quantum efficiency (*EQE*). Light from a Xe arc lamp (300–670 nm) and a quartz halogen lamp (670–900 nm) is chopped, coupled into a monochromator and aimed at the device. The resulting current is sent through a Bentham477 current pre-amplifier, then arriving in the Bentham485 lock-in amplifier. Calibration is done with a certificated Si cell. The integration of these EQEs over the solar spectrum [23] is listed in Tables 1 and 2 as J_{EQE}. The same optics and measurement setup is used with a DTR6 integrating sphere to determine the reflection.

Table 1
J_{sc}, V_{oc}, *FF* and efficiency η measured for 100 mW cm^{-2} AM1.5G simulated solar illumination. J_{EQE} is the current density as calculated by integration of the *EQE* over the AM1.5G solar spectrum.

3. Results and discussion

3.1. Effect of substrate surface and temperature on planar HJ cells

3.1.1. Characterization of pure ClAlPc films

Four samples are prepared to study the influence of temperature and substrate surface on the film growth of ClAlPc:

a) ITO/25 nm PEDOT:PSS/5 nm MoO_3/50 nm ClAlPc (T_{sub} = room temperature (RT))
b) ITO/25 nm PEDOT:PSS/5 nm MoO_3/FDTS/50 nm ClAlPc (T_{sub} = RT)
c) ITO/25 nm PEDOT:PSS/5 nm MoO_3/50 nm ClAlPc (T_{sub} = 105 °C)
d) ITO/25 nm PEDOT:PSS/5 nm MoO_3/FDTS/50 nm ClAlPc (T_{sub} = 105 °C)

To study the orientation of the ClAlPc molecules with respect to the substrate, an X-ray reflectivity (XRR) measurement is performed. The PEDOT:PSS in the structures functions as a flattening layer on top of ITO in order to get a well-defined XRR signal. For ClAlPc grown at RT, only peaks at $2\theta = 21.2°$ (not shown) and $2\theta = 30.1°$ are detected, corresponding to peaks of the ITO substrate (Fig. 1a and b). The absence of ClAlPc peaks suggests the films have very limited crystalline order and are likely amorphous. At T_{sub} = 105 °C, the ClAlPc films exhibit an increased crystallinity. For the films on MoO_3, (Fig. 1c) a peak at $2\theta = 27.1°$ (d = 3.3 Å) corresponds to diffraction from the (001) plane of phase I ClAlPc [24,12], indicating that the ClAlPc molecules are parallel to the substrate (face-on orientation). This can be expected when the substrate-molecule interactions are strong [25]. In order to quantify these interactions, contact angle measurements were performed with four different liquids (de-ionized water, ethylene glycol, diiodomethane and decane) in order to calculate the polar and dispersive component of the surface energy by applying the Owens–Wendt–Rabel–Kaelble method [26]. Due to the rather apolar nature of organic semiconductors, it is mainly the dispersive component that can be correlated to the substrate-molecule interaction. For ClAlPc a dispersive component of 30.2 mN/m was derived, compared to 25.5 mN/m for MoO_3, thereby indicating that ClAlPc-MoO_3 interactions are significant.

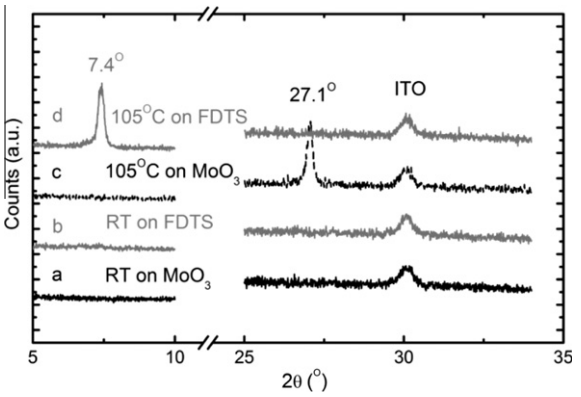

Fig. 1. X-ray reflectivity measurements of (a) ITO/PEDOT:PSS/MoO_3/ClAlPc (RT); (b) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc (RT); (c) ITO/PEDOT:PSS/MoO_3/ClAlPc (105 °C); (d) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc (105 °C). A constant offset is added between the graphs for visual clarity; in between $2\theta = 10°$ and $2\theta = 25°$ no ClAlPc peak was observed, hence the break.

For FDTS, a peak at $2\theta = 7.4°$ (d = 11.9 Å) implies that the ClAlPc molecules adopt an edge-on orientation (Fig. 1d). Molecule–molecule interactions are stronger than substrate-molecule interactions in this case (dispersive component of the surface energy is 11.2 mN/M for FDTS [26]), favoring a growth where the ClAlPc molecules are facing each other rather than the substrate.

Due to the fact that different phases of ClAlPc have distinct absorption features [27], the absorption of the pure thin films is also characterized. The ClAlPc films grown at RT both show a very similar quite featureless absorptance profile, with the Q-band peaking at a wavelength of λ = 760 nm, consistent with an amorphous film growth (Fig. 2a and b) [28]. When grown at 105 °C, the films show

quite different absorptance profiles, suggesting that not only orientation of the molecules is influenced by the substrate, but that the crystalline phase of the ClAlPc is also substrate-dependent. On MoO_3, the Q-band absorption maximum shifts slightly to $\lambda = 770$ nm, while a more pronounced shoulder appears at $\lambda = 716$ nm (Fig. 2c). This absorption profile is very similar to that of phase I of titanyl phthalocyanine (TiOPc) [27]. In phase I, the phthalocyanine molecules are slightly distorted, thereby lifting the doubly degenerate excited state and splitting it into two absorption bands whose transition moments are orthogonal [27]. On FDTS, the Q-band peak undergoes a very pronounced red-shift to $\lambda = 824$ nm, with a profile that was previously identified to belong to phase II (Fig. 2d), a phase with an even stronger molecular distortion. This phase is further distinguished by very close π-π atomic contacts and a highly polarized excited state [28].

Topographical AFM images reveal rather smooth films when grown at RT, with root mean square (*rms*) roughness values of 2.6 nm on MoO_3 (Fig. 3a) and 3.9 nm on FDTS (Fig. 3b). As a consequence, the ratio of the surface area and the projected area are close to one, as expressed by the folding ratios (*FR*) of $FR_{MoO3,RT} = 1.03$ and $FR_{FDTS,RT} = 1.11$, respectively. At 105 °C, rougher films with larger crystallites are observed. On MoO_3, the crystallites have a pyramidal structure, with a high roughness of *rms* = 35.6 nm and an increased surface area with $FR_{MoO3,105\ °C} = 1.38$ (Fig. 3c). In order to study the initial stages of film growth, a sample with a thinner ClAlPc thickness of 5 nm was characterized (Fig. 3c bis, *rms* = 13.4 nm). Here, ClAlPc was found to grow in an island (i.e., Volmer–Weber) mode, as described before for ClAlPc growth on SiO_2, whereby ClAlPc adatoms aggregate in discrete islands that preferentially expand in the vertical direction [12]. On FDTS, the crystal shapes look more disk-like, while the 50 nm ClAlPc film is slightly smoother than on MoO_3 with *rms* = 14.7 nm and $FR_{FDTS,105\ °C} = 1.21$ (Fig. 3d). In Fig. 3d bis, a 5 nm thick ClAlPc film grown in the same conditions covers almost the whole substrate (*rms* = 4.8 nm). This suggests that this growth mode can be described as the Stranski–Krastanov or layer-island growth mode [12]. In fact, upon close inspection of Fig. 3d bis, molecular planes can even be discerned.

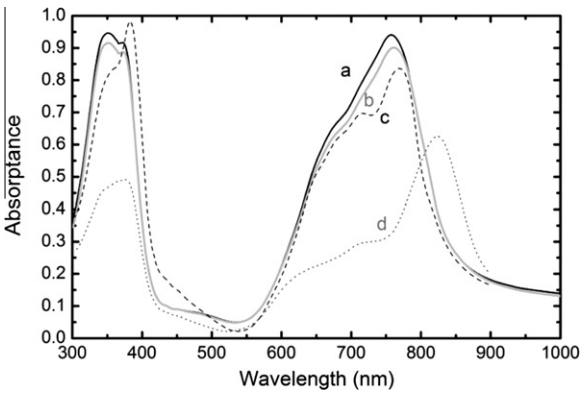

Fig. 2. UV–Vis absorptance of (a) ITO/PEDOT:PSS/MoO_3/ClAlPc (RT): black solid curves; (b) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc (RT): grey solid curves; (c) ITO/PEDOT:PSS/MoO_3/ClAlPc (105 °C): black dashed curves; (d) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc (105 °C): grey dotted curves.

In summary: at RT, ClAlPc grows as a conformal, amorphous film independent of the substrate surface. When the substrate is heated to 105 °C, the grown films are rougher and more crystalline in nature. On MoO_3, the ClAlPc molecules will be face-on and in phase I, whereas on FDTS, molecules adept an edge-on and phase II orientation.

3.1.2. Characterization of ClAlPc/C_{60} planar HJ solar cells

In order to study whether the investigated film properties have an influence on solar cell performance, the following devices are produced:

a) ITO/5 nm MoO_3/20 nm ClAlPc (T_{sub} = RT)/40 nm C_{60}/10 nm BCP/100 nm Ag
b) ITO/5 nm MoO_3/FDTS/20 nm ClAlPc (T_{sub} = RT)/40 nm C_{60}/10 nm BCP/100 nm Ag
c) ITO/5 nm MoO_3/20 nm ClAlPc (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag
d) ITO/5 nm MoO_3/FDTS/20 nm ClAlPc (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag

When comparing the solar cells grown at RT, it can be noticed that MoO_3 devices show slightly higher V_{oc} and fill factor (V_{oc} = 0.8 V and *FF* = 62%) compared to FDTS devices (V_{oc} = 0.7 V and *FF* = 52%) (c.f. Fig. 4 and Table 1). This can best be explained by the fact that MoO_3 forms a better electrical contact with ClAlPc than FDTS, due to a better alignment between the work function of the electrode and the ClAlPc highest occupied molecular orbital (HOMO) [14,29]. The samples on FDTS also show a higher J_{sc} of 6.3 mA cm^{-2} than those on MoO_3 (J_{sc} = 4.9 mA cm^{-2}). We suspect that the MoO_3 contact dissociates or quenches excitons [30,31]. The FDTS would then act as an exciton blocking layer [32], thereby hindering the loss of excitons at the contact.

The solar cells on MoO_3 exhibit a lower V_{oc} (V_{oc} = 0.72 V) and *FF* (*FF* = 49%) when the samples were heated during ClAlPc deposition (c.f. Table 1c). Here it is not clear whether this lower performance is related to the phase change from amorphous to phase I, or to the roughening of the donor layer (see Fig. 3c), which causes more shunting currents (see suppl. Info).

On FDTS, the heating results in a dramatic reduction of V_{oc} to 0.53 V. This shift we attribute to the phase change from amorphous ClAlPc to phase II. It was previously reported by Alloway et al. that ClAlPc grown edge-on on perylenetetracarboxylicdianhydride-*N*,*N*′-bis (butyl)imide (C4-PTCDI) has a lower ionization potential (E_{HOMO} = 5.1 eV) than ClAlPc with face-on orientation on PTCDA (E_{HOMO} = 5.4 eV) [33]. This shift in ionization potential was then attributed to a speculated phase-change. As it is well established that V_{oc} is strongly correlated to the difference in HOMO of the donor and the lowest unoccupied molecular orbital (LUMO) of the acceptor [34–36], such an energy shift can explain the lower V_{oc} observed here. Most striking is the current density increase to J_{sc} = 8.9 mA/cm^2. Together with a *FF* of 65%, this gives rise to a considerable planar HJ cell efficiency of $\eta = 3\%$. In order to get better insight as to the origin of this photocurrent increase,

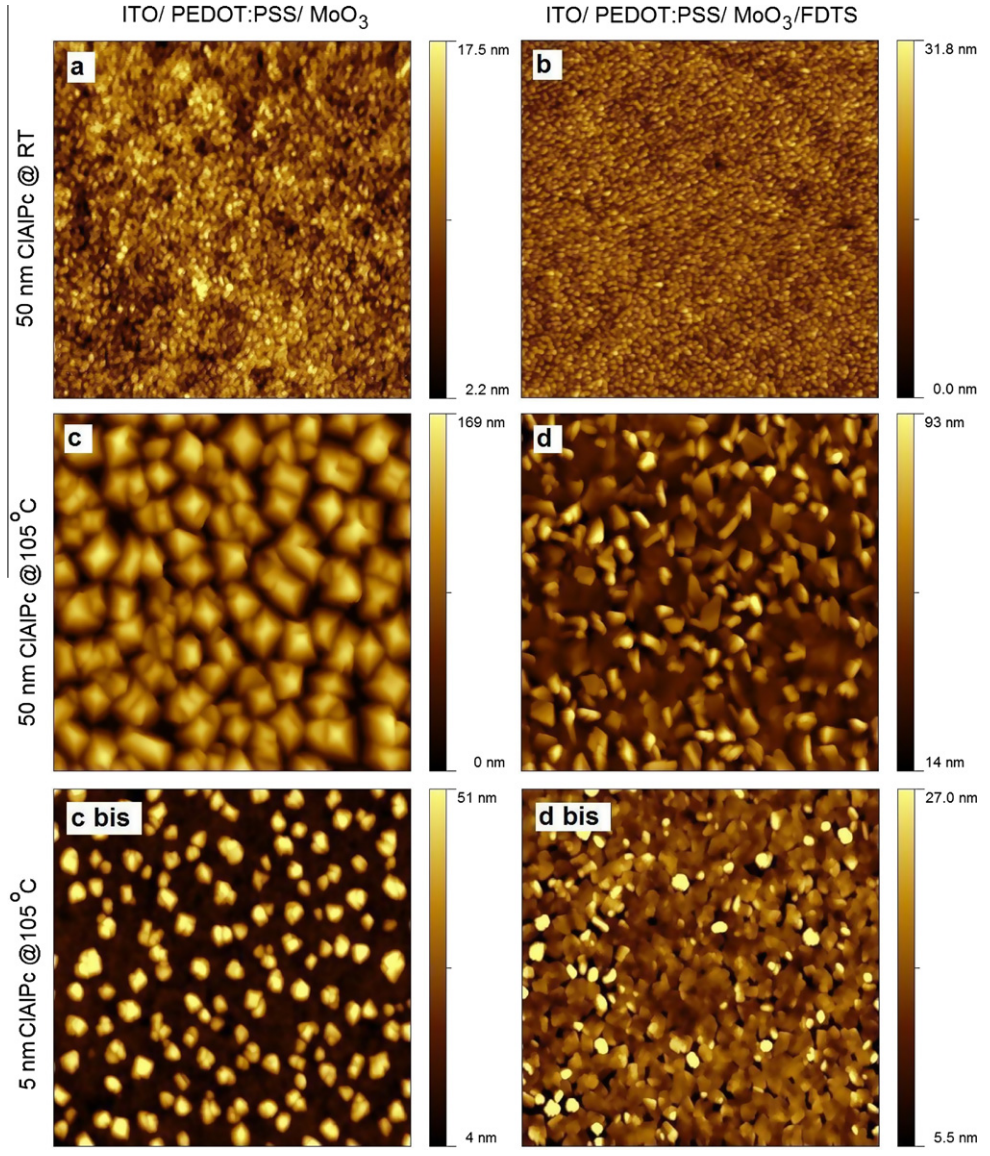

Fig. 3. Topographic AFM images (2500 × 2500 nm). (a), (b), (c) and (d) labeled as in Figs. 1 and 2. (c bis) and (d bis) are similar samples as (c) and (d), but with only 5 nm ClAlPc instead of 50 nm ClAlPc.

spectral response and reflectivity measurements are performed.

When we compare the external quantum efficiency (*EQE*) spectra of the heated ClAlPc cells on MoO_3 and FDTS (Fig. 5c and d respectively), we can see that two effects lead to a higher J_{sc} on FDTS. First: the red-shifted absorption profile on FDTS allows the cell to harvest a broader portion of the solar spectrum, and second: the *EQE* of the cells on FDTS is overall higher. A similar effect has been observed before for solvent annealed, phase II TiOPc. [37] The *EQE* can be further analyzed with the following formula [38]:

$$EQE(\lambda, V) = \eta_A(\lambda)\eta_{ED}\eta_{CT}(V)\eta_{CC}(V) \quad (1)$$

Here, η_A is the absorption efficiency. The reflectivity of the device shown in Fig. 5 (dashed and dotted curves) represents η_A: all light that is not reflected (100−*R*, in %) is absorbed in either the organic layers, the substrate, or the electrodes. Therefore, η_A alone cannot explain the increased EQE on FDTS, as the absorption on FDTS around $\lambda = 700$ nm is lower than that on MoO_3. Exciton diffusion efficiency (η_{ED}) expresses how many excitons reach the D/A interface before recombination. This can typically be improved by either increasing the D/A surface or by increasing the exciton diffusion length. According to the AFM data (Fig. 3) the D/A area should be higher on MoO_3 ($FR_{MoO3,105\ °C} = 1.38$) than on FDTS ($FR_{FDTS,105\ °C} = 1.21$), so according to this effect one would rather expect higher J_{sc}

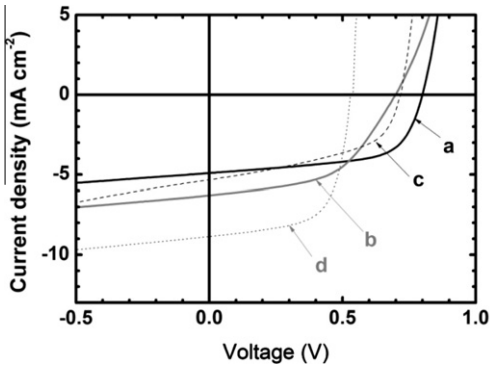

Fig. 4. Current density–voltage (*J–V*) curves for 100 mW cm^{-2} AM1.5G simulated solar illumination, of (a) ITO/MoO_3/ClAlPc (RT)/C_{60}/BCP/Ag: black solid curves; (b) ITO/MoO_3/FDTS/ClAlPc (RT) /C_{60}/BCP/Ag: grey solid curves; (c) ITO/MoO_3/ClAlPc (105 °C) /C_{60}/BCP/Ag: black dashed curves; (d) ITO/MoO_3/FDTS/ClAlPc (105 °C) /C_{60}/BCP/Ag: grey dotted curves.

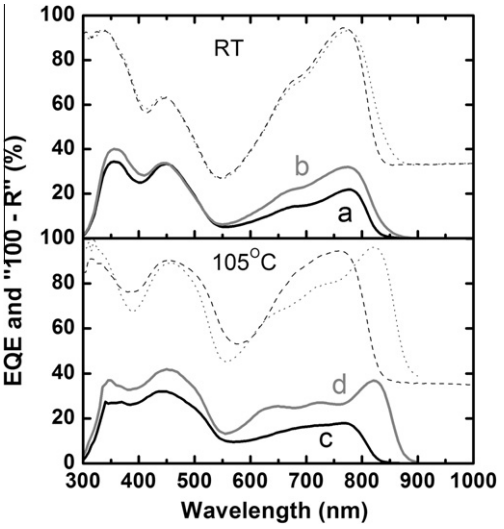

Fig. 5. Measured external quantum efficiency (*EQE*) and absorption spectra (100−R, in %) of devices on MoO_3 (EQE: black solid curves, 100−R: dashed curve) or on FDTS (EQE: grey solid curves, 100−R: dotted curve), with ClAlPc processed with the substrate at room temperature (top panel) or at 105 °C (bottom panel).

on MoO_3. Moreover, an increase of the exciton diffusion length in ClAlPc does not explain why the *EQE* signal of C_{60} (the peak around $\lambda = 460$ nm) also increases on FDTS. When charges are dissociated, they still need to reach an electrode and they will do so with a charge collection efficiency η_{CC}. For η_{CC} to be able to explain the device trends, however, one would expect this to be correlated with the *FF* of the devices, and for the devices at RT this seems not to be the case. There, the device on FDTS shows the highest EQE (Fig. 5a and b), while it has at the same time a lower *FF* than the device on MoO_3 (Table 1a and b).

Following this process of elimination, it seems that the increased *EQE* on FDTS is most likely related to a more efficient charge transfer process (η_{CT}) at the D/A interface. The difference in η_{CT} on MoO_3 and FDTS is likely related to both the different phase and the different orientation of the ClAlPc molecules in the cells.

3.2. Effect of substrate surface and temperature on bulk heterojunction cells

3.2.1. Characterization of co-evaporated ClAlPc:C_{60} films

To investigate how co-evaporated ClAlPc:C_{60} blends grow on different substrates, the following structures were fabricated:

a) ITO/25 nm PEDOT:PSS/5 nm MoO_3/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)
b) ITO/25 nm PEDOT:PSS/5 nm MoO_3/FDTS/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)
c) ITO/25 nm PEDOT:PSS/5 nm MoO_3/5 nm ClAlPc (T_{sub} = 105 °C)/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)
d) ITO/25 nm PEDOT:PSS/5 nm MoO_3/FDTS/5 nm ClAlPc (T_{sub} = 105 °C)/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)

Here, all the ClAlPc:C_{60} blends (ratio 1:1) are evaporated at 105 °C as we are aiming to grow crystalline, phase-separated BHJ layers. For structures (g) and (h), a 5 nm ClAlPc templating layer was grown before blend deposition, to see whether such a film can influence the growth of the overlying blend.

The XRR measurements show that the ClAlPc component in the blend still grows preferentially face-on on MoO_3 and edge-on on FDTS (Fig. 6e and f). However, the intensity of the peaks at, respectively, $2\theta = 27.1°$ and $2\theta = 7.4°$, is lower for the blended layers than for the pure layers of Fig. 1. When the 5 nm pure ClAlPc layer is grown before blend deposition, XRR signals become more pronounced, especially for the samples on FDTS. As the increase in signal is too strong to come from the 5 nm film itself, we ascribe this to a templating effect. The pure ClAlPc layer grows as a crystalline seed layer, which then templates the growth of the blend towards a similar preferred crystalline orientation [39].

The absorptance spectra of the blends on MoO_3 (Fig. 7e and g) more closely resemble that of the pure

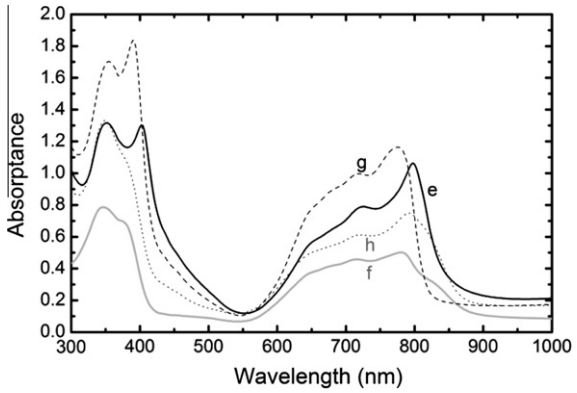

Fig. 7. UV–Vis absorptance of (e) ITO/PEDOT:PSS/MoO_3/ClAlPc:C_{60} (105 °C): black solid curves; (f) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc:C_{60} (105 °C): grey solid curves; (g) ITO/PEDOT:PSS/MoO_3/ClAlPc (105 °C)/ClAlPc:C_{60} (105 °C): black dashed curves; (h) ITO/PEDOT:PSS/MoO_3/FDTS/ClAlPc (105 °C)/ClAlPc:C_{60} (105 °C): grey dotted curves.

film (Fig. 2c), when a templating layer is applied. So, in addition to a preferred orientation, the templating layer can also help to achieve a certain ClAlPc phase in the blend. On FDTS (Fig. 7f and h), both films show a red-shifted Q-band absorption shoulder at $\lambda > 800$ nm. These absorption signals are not as pronounced as the signal for a pure ClAlPc film on FDTS (Fig. 2d), but also here the templating layer helps to reinforce this red-shifted absorption feature.

According to AFM images, growing ClAlPc:C_{60} blends directly on MoO_3 results in very rough films with *rms* = 51.4 nm (Fig. 8e). Islands 0.5 μm in size are formed, and the space in between the islands is filled with smaller crystallites. These islands have a more irregular shape than those of the 50 nm pure ClAlPc film grown under similar conditions (Fig. 3c). As already shown in Fig. 3c bis, the templating layer consists of crystallites with a height of about 40 nm and width of 100–200 nm, spread over the surface. When the ClAlPc:C_{60} blend is grown on top of this layer, they form islands with a very similar spacing as the template crystallites (Fig. 8g). This hints that the pure ClAlPc crystallites of the templating layer form nucleation sites, around which the subsequently deposited ClAlPc:C_{60} blend grows. This results in smaller, more closely spaced ClAlPc:C_{60} islands compared to the film without a templating layer.

Images of the blends grown on FDTS, with and without a templating layer, are shown in Fig. 8f and h. Also here, it can be seen that the templating layer (Fig. 3d bis) has an impact on the growth of the blend layer, although in this case the use of a templating layer leads to larger islands.

3.2.2. Characterization of bulk heterojunction devices

The co-evaporated films studied above were then incorporated into bulk heterojunction solar cells with the following structures:

a) ITO/5 nm MoO_3/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag

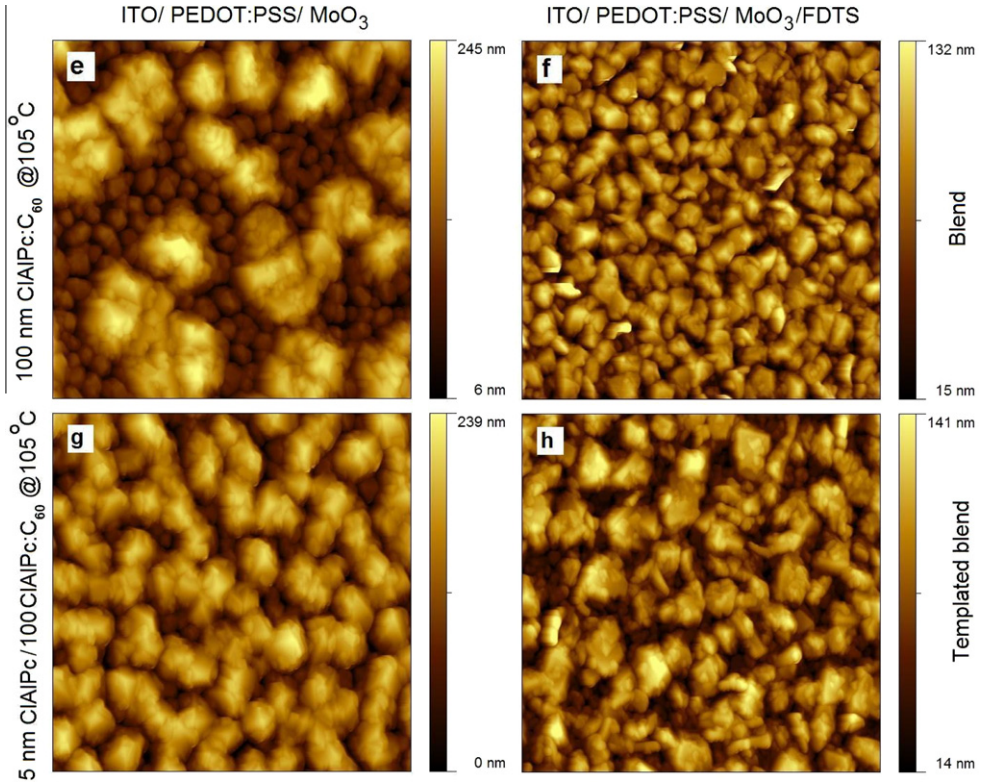

Fig. 8. Topographic AFM images (2500 × 2500 nm). (e), (f), (g) and (h) labeled as in Figs. 6 and 7.

b) ITO/5 nm MoO_3/FDTS/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag
c) ITO/5 nm MoO_3/5 nm ClAlPc (T_{sub} = 105 °C)/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag
d) ITO/5 nm MoO_3/FDTS/5 nm ClAlPc (T_{sub} = 105 °C)/100 nm ClAlPc:C_{60} (T_{sub} = 105 °C)/40 nm C_{60}/10 nm BCP/100 nm Ag

All of the produced bulk heterojunction cells show an increased J_{sc} compared to the planar HJ cells (Fig. 9 and Table 2). The planar HJ cells were partially limited by exciton diffusion, but within a bulk heterojunction the generated excitons do not have to diffuse as far to reach a D/A junction. The *EQE* spectra and reflectivity data (plotted as 100−*R* (%)) are shown in Fig. 10. These spectra make clear that the current of all these devices is generated over a wide wavelength region, ranging from λ = 300–800 nm. Reflectivity data show that near λ = 700 nm, about 90% of incident light gets absorbed, while both the *EQE* and "100−*R*" spectra are becoming relatively featureless. This indicates that absorption is nearing saturation. But while about 90% of the light gets absorbed in the devices, maximum *EQE* is only ≈40%. This indicates that even in the BHJ devices, internal quantum efficiency is still quite low, leaving room for possible future enhancement. Integration of the *EQE* over the AM1.5G solar spectrum is listed in Table 2 as J_{EQE}. Differences in between J_{sc} and J_{EQE} can be attributed to spectral mismatch between the solar simulator and the ideal AM1.5G spectrum.

Both for devices on MoO_3 and on FDTS, the use of a 5 nm ClAlPc templating layer results in an improved *FF*. (On MoO_3: $FF_{no\ template}$ = 32% versus $FF_{templated}$ = 61%; On FDTS: $FF_{no\ template}$ = 49% versus $FF_{templated}$ = 54%). This improved *FF* is ascribed to the higher crystallinity of the templated films, and hence better morphology and transport.

Unlike planar HJ cells, the templated bulk heterojunction structures can combine relatively high J_{sc} with decent *FF*s. But similar to the planar HJ cells, the BHJ cells on FDTS show a decreased V_{oc}. As a result, highest performance is on MoO_3, where the best cell reached a power conversion

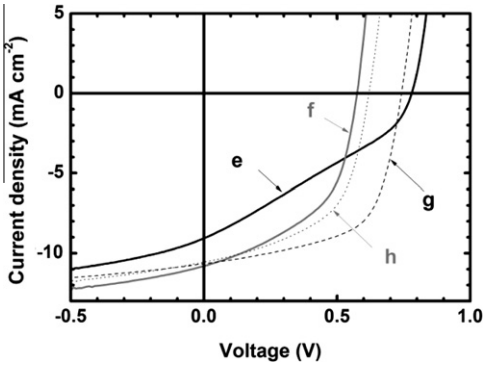

Fig. 9. Current density–voltage (*J*–*V*) curves for 100 mW cm^{-2} AM1.5G simulated solar illumination, of (e) ITO/MoO_3/ClAlPc:C_{60} (105 °C)/C_{60}/BCP/Ag: black solid curves; (f) ITO/MoO_3/FDTS/ClAlPc:C_{60} (105 °C)/C_{60}/BCP/Ag: grey solid curves; (g) ITO/MoO_3/ClAlPc (105 °C)/ClAlPc:C_{60} (105 °C)/C_{60}/BCP/Ag: black dashed curves; (h) ITO/MoO_3/FDTS/ClAlPc (105 °C)/ClAlPc:C_{60} (105 °C)/C_{60}/BCP/Ag: grey dotted curves.

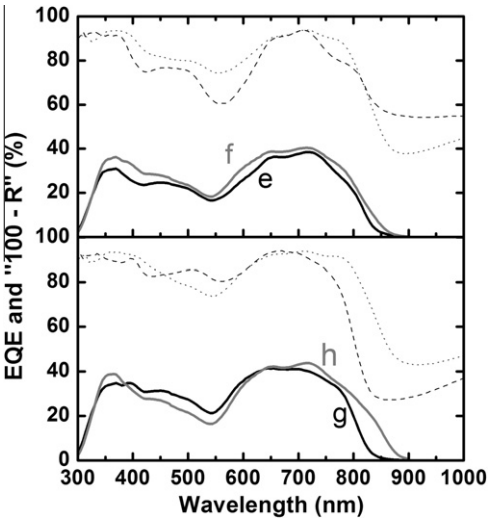

Fig. 10. Measured external quantum efficiency (EQE) and absorption spectra (100−R, in %) of bulk heterojunctions on MoO_3 (EQE: black solid curves, 100−R: dashed curve) or FDTS (EQE: grey solid curves, 100−R: dotted curve), with ClAlPc processed directly on the substrate (top panel) or on top of a ClAlPc templating layer (bottom panel).

of η = 4.8%. When this value is corrected for spectral mismatch, a value of $\eta_{corrected} = (J_{EQE} \times FF \times V_{oc})/P_{light}$ = 4.2% is obtained.

4. Conclusion

In conclusion, we have investigated ClAlPc films grown on either FDTS or MoO_3. At RT, the ClAlPc films grow amorphous, independent of the surface. When heated to 105 °C, ClAlPc grows face-on on MoO_3, with a phase I-like absorption profile. On FDTS, the film is characterized as edge-on, phase II. These films are then used to fabricate planar HJ cells. On FDTS, the induced phase is accompanied by a lower V_{oc}, but also by a higher current, leading to 3% efficient planar HJ cells. The higher current on FDTS compared to MoO_3 is believed to be caused by two effects: the FDTS surface would quench fewer excitons than the MoO_3 surface, and the exciton charge transfer would be more efficient for phase II ClAlPc.

Next, ClAlPc and C_{60} are co-evaporated on FDTS and MoO_3 substrates. In order to achieve an enhanced crystallinity, a thin pure "templating" layer of ClAlPc proved advantageous. When the films were used in bulk heterojunction cells, the more crystalline films grown on top of a templating layer showed higher *FF* than devices without templating layers. The use of the co-evaporated bulk heterojunctions ensured high photocurrents, independent of the growth surface. Here, the higher V_{oc} of devices on MoO_3 was beneficial, with devices showing efficiencies greater than 4% as a result.

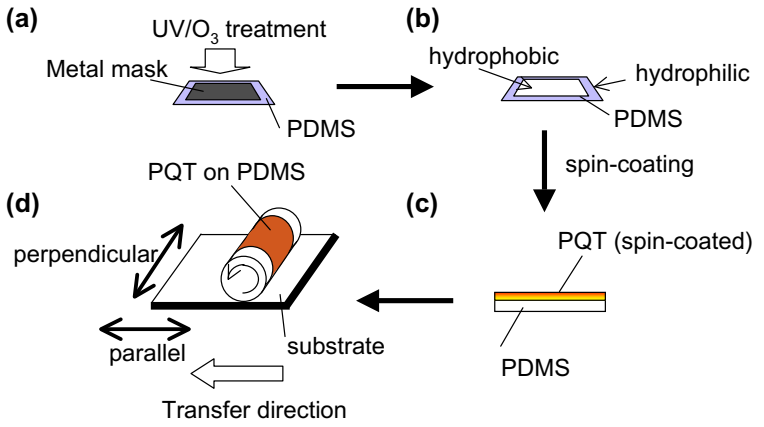

Fig. 1. Schematic diagram of roll-transfer printing. (a) and (b) Creation of a peripheral hydrophilic region on the PDMS stamp. (c) Spin coating the PQT film onto the PDMS stamp. (d) Roll-transfer printing of the PQT film onto the substrate.

toluene solution [16]. Our roll-transfer printing method is illustrated in Fig. 1. A 0.5 wt.% toluene solution of PQT (M_w = 18,000, American Dye Source Inc.) was spin-coated onto a poly(dimethylsiloxane) (PDMS) stamp (SIM-260, ShinEtsu Chem.). Before use, traces of remaining siloxane oligomers were extracted from PDMS using a Soxhlet extractor with hexane. Prior to spin coating, the peripheral area of the PDMS stamp was treated with a UV/O_3 cleaner to form a hydrophilic region, which allows the formation of a PQT film on hydrophobic region. The obtained PQT thin film (~50-nm thick) was dried in a Petri dish for 10 min, before laminating the inked stamp on a glass cylinder (ϕ = 40 mm). The inked stamp was then applied to the substrate heated on a hot plate (80–150 °C), and printing was achieved by rotating the cylinder. OFET fabrication was completed by evaporating Au source–drain electrodes on the PQT surface. The channel length and width were 50 μm and 1.5 mm, respectively.

FET measurements of the fabricated devices were performed under ambient condition. The polarized UV–vis absorption was measured using the PQT films printed on OTS-treated glass substrates (Corning 7059) and normalized at a wavelength of 540 nm. In-plane grazing-incidence X-ray diffraction (GIXD) measurements were performed using Cu-Kα X-rays (~8.0 keV) with a rotating target energy of 9 kW (45 kV–200 mA) and an incident beam angle of 0.2°.

3. Results and discussions

Fig. 2(a) shows the polarized UV–vis absorption spectra of a PQT film fabricated using the roll-transfer printing method at a substrate temperature of 130 °C. Absorption peaks at 512, 547, and 587 nm are identified as absorptions of π–π lamella stacking [17]. The transferred PQT film clearly exhibits strong optical anisotropy, and light polarized parallel to the transfer direction is more strongly absorbed than that polarized perpendicular to the transfer direction, indicating that the main chains of PQT are uniaxially aligned in the transfer direction. Fig. 2(b) shows the relationship between the transfer temperature and optical

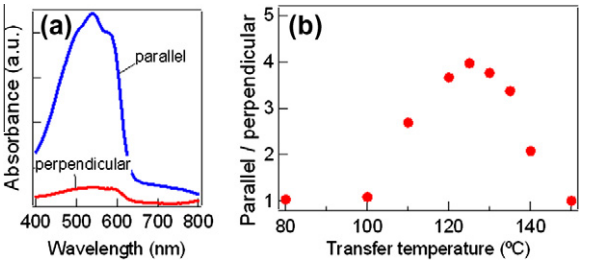

Fig. 2. (a) Polarized UV–vis absorption spectra of the PQT film prepared by roll-transfer printing at 130 °C on an OTS-treated glass substrate. (b) Effect of the transfer temperature on optical anisotropy in the transferred PQT film.

anisotropy. When the substrate temperature is kept at 80 °C (solid phase) in the transfer process, the transferred films are found to be isotropic. The optical anisotropies appear when the transfer temperature is increased to above 100 °C and disappear above 140 °C, between which corresponds to the temperature range that PQT possesses the thermotropic liquid crystal phase [15]. At a transfer temperature of 150 °C, PQT films show isotropic properties because of the transition from a liquid crystal to an isotropic phase. These results clearly show that film transfer at liquid–crystal phase temperatures is an essential factor for achieving uniaxial alignment.

Fig. 3 shows the in-plane GIXD patterns in the perpendicular and parallel directions of a PQT film transferred at 130 °C before and after annealing at 135 °C for 5 min. In Fig. 3(a) and (b), the peak at $2\theta = 21.2°$, produced by π-stacking (0 1 0), and a broad structure around $2\theta = 24.2°$, caused by high-density π-stacking (0 1 0), are observed [17]. The peak intensity in the parallel direction is greater than that in the perpendicular direction, which clearly shows that the main chains of PQT molecules are aligned in the parallel direction. Further, the in-plane GIXD patterns do not have a lamella diffraction peak, indicating that the thiophene rings of the aligned PQT molecules are oriented perpendicular to the substrate (edge-on structure), as illustrated in the inset of Fig. 3. After annealing, the peak

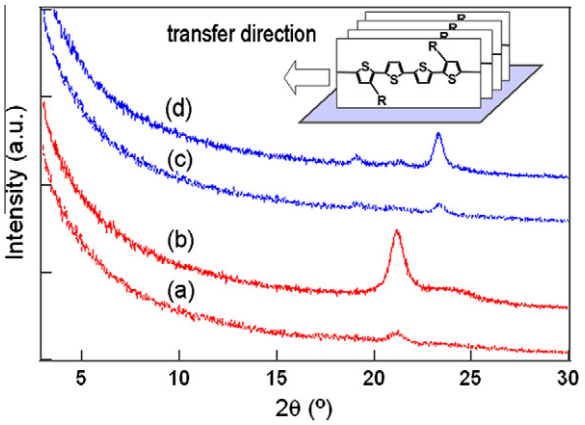

Fig. 3. In-plane GIXD patterns of the PQT film prepared by roll-transfer printing at 130 °C before and after annealing at 135 °C for 5 min in vacuum. GIXD patterns were measured (a) perpendicular and (b) parallel to the transfer direction in the as-prepared film. GIXD patterns were measured (c) perpendicular and (d) parallel to the transfer direction in the annealed film. The inset shows the molecular conformation in a PQT film prepared by roll-transfer printing.

intensity at $2\theta = 21.2°$ decreases and that at $2\theta = 24.2°$ increases (Fig. 3(c) and (d)), indicating that the crystal structure becomes denser by annealing. We note that the anisotropy of peak intensity persists, indicating that the uniaxial alignment is preserved even after annealing.

Fig. 4(a) and (b) shows the typical electrical characteristics (output and transfer curves) of PQT FETs fabricated using the roll-transfer printing method, measured in parallel and perpendicular to the transfer direction, respectively. The devices were fabricated at a transfer temperature of 140 °C and then annealed at 135 °C for 5 min (the highest mobility was achieved with this condition). The PQT film exhibits strong anisotropy of field -effect mobility. The mobilities in the parallel direction show high values of 0.17 ± 0.02 cm^2/Vs, which are 8 times

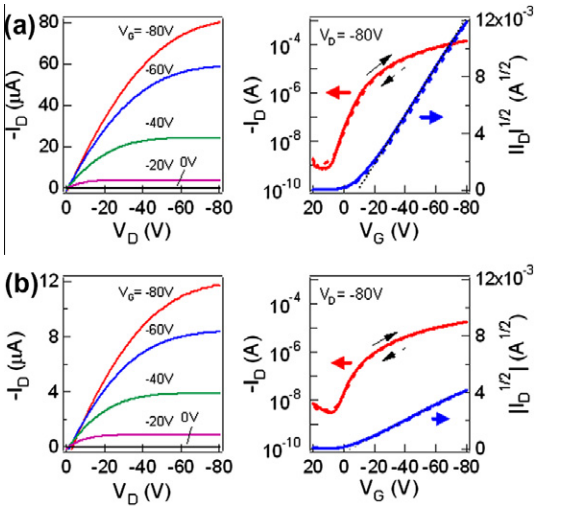

Fig. 4. Typical output (drain current I_D–drain voltage V_D) and transfer (I_D–gate voltage V_G) curves of PQT FETs fabricated by the roll-transfer printing method in (a) parallel and (b) perpendicular directions.

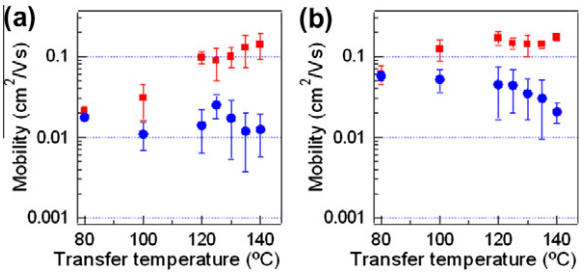

Fig. 5. Effect of the transfer temperature on the mobility anisotropy in PQT films (a) before annealing and (b) after annealing at 135 °C for 5 min in vacuum.

greater than those in the perpendicular direction (0.021 ± 0.006 cm^2/Vs).

Fig. 5(a) and (b) shows the relationships between the transfer temperature and the mobility anisotropy before and after annealing at 135 °C for 5 min, respectively. It can be seen in Fig. 5(a) that the PQT films transferred at 80 °C are electrically isotropic and those transferred in the liquid crystal phase (120–140 °C) exhibit strong electrical anisotropy, implying that the molecular alignment is attributed to the roll transfer at liquid crystal phase temperatures. For transfer temperatures above 140 °C, the transfer-printing process was impaired by the dewetting of the film, and reliable data could not be obtained. We also see that mobility anisotropy increases when the transfer temperature exceeds 130 °C, and a relatively strong mobility anisotropy appears even below the solid-to-liquid crystal transition temperature (110 °C) [15]; this result somewhat differs from the results of optical absorption measurements. An increase in the mobility anisotropy at higher temperatures can be caused by an improvement in the film crystallinity associated with increasing temperature. A PQT film transferred at 100 °C is electrically anisotropic, but optically almost isotropic. Since PQT shows a gradual transition from the solid to the liquid crystal phase [15], the film partially changes to a liquid crystal at 100 °C, which leads to uniaxial alignment at the substrate surfaces. The observed mobility anisotropy can be attributed to the molecular alignment just above the substrate surface because the charge transport in OFETs mainly reflects molecular ordering at the insulator/semiconductor interface [1]. On the contrary, heat conduction is not sufficient for causing phase change across the entire region of the film during printing, and this results in a small optical anisotropy. We believe that the driving force of molecular alignment is the shear stress associated with the roll-transfer processes and that molecular alignment easily occurs by relatively low shear stress when PQT is in the liquid crystal phase. We note that annealed films still show large mobility anisotropies, although their ratios are decreased as compared with those of the as-prepared films (Fig. 5(b)). Higher mobilities in the annealed devices would result from the crystal phase changing to the high-density π-stacking of the PQT molecules, as shown in Fig. 3.

The average mobility in the parallel direction is approximately 0.17 cm^2/Vs when the film was transferred at 140 °C, which is almost 3 times higher than that in isotropic

films such as the film transferred at 80 °C (0.06 ± 0.01 cm^2/Vs) and spin-coated films (0.06 ± 0.02 cm^2/Vs, not indicated in Fig. 5). The maximum mobility in the parallel direction is 0.28 cm^2/Vs, which is higher than that of isotropic PQT films in the previous literature (0.2 cm^2/Vs) [18]. Electrical anisotropies of polythiophene films have been reported previously; however, in many cases, the mobilities achieved are relatively low [12,14]. One of the reasons for a low mobility is responsible for polymer chain conformation. Nagamatsu et al. reported that anisotropic polyalkylthiophenes prepared by the friction transfer method are stacked parallel to the substrate (face-on structure) [11]. This face-on structure is less suitable for lateral charge transfer than the edge-on structure [19,20]. In contrast, PQT films fabricated by the roll-transfer printing method have an edge-on structure, and therefore, their charge mobility in the lateral direction is very high, which is advantageous for conventional OFETs. Moreover, the present roll-transfer printing method does not need any alignment layers for molecular ordering, which allows the fabrication of a semiconductor film even on hydrophobic substrates such as an OTS-treated SiO_2 substrate. This is another advantage for achieving high-performance OFETs because hydrophobic self-assembled monolayers are well known to enhance molecular ordering, which leads to the enhancement of charge mobility.

4. Conclusions

In summary, we have presented the roll-transfer printing method to fabricate the aligned thin film of polymer semiconductors. The method is based on the enhancement of shear-stress effects associated with roll-transfer printing in the thermotropic liquid crystal phase of polymer semiconductors. We have shown that roll-transfer printed PQT films are uniaxially aligned parallel to the transfer direction and have an edge-on structure. We also observed the anisotropic electrical properties of OFETs associated with the molecular alignment. The enhanced mobility in the parallel direction is at least 8 times higher than that in the perpendicular direction, and the highest mobility achieved was 0.28 cm^2/Vs. Our results suggest important strategies for fabricating high-performance OFETs by printing.

However, in terms of more practical device applications, solid-state device structure is more preferable to CAFM or STM testbeds [12]. Furthermore, with CAFM or STM tools, it is not trivial to perform temperature-variable electrical characterizations to investigate charge conduction mechanisms, and it is generally difficult to determine the actual contact junction area. Therefore, a more comprehensive study based on a statistical analysis of the electrical properties induced by conformational changes in azobenzene-derivative molecules using a solid-state device structure is important for understanding the conduction mechanism and for more practical device applications.

In this study, we report the electrical properties of azobenzene-derivative ([4-(phenylazo)phenoxy]hexane-1-thiol) molecular junctions in which the azobenzene moiety is linked to an alkanethiol (with six carbon atoms). Specifically, we studied the photo-induced conductance changes between the trans- and cis-isomers of this molecule through statistical analysis. The absorption spectrum was determined by UV–Vis spectroscopy to confirm the conformational changes between trans- and cis-isomers by an external light trigger. In addition, temperature-variable electrical characterization and transition voltage spectroscopy analysis were performed to understand the charge transport mechanisms in both isomers.

2. Experimental

As schematically described in Fig. 1a, the molecular junctions were fabricated on a p-type Si (100) substrate covered by a thermally grown 6000 Å-thick SiO_2 layer. Conventional optical lithography was used to pattern the bottom electrodes prepared from Au (800 Å)/Ti (50 Å) using an electron-beam evaporator. Photoresist (PR) (AZ1512) was spin-coated on top of the bottom electrodes for electrical isolation. After isolation, square holes with side length of 30–100 μm were created through PR layer by optical lithography to expose the Au bottom electrodes. The devices with PR patterns were then annealed for at least 2 h at 180 °C to make the PR layer insoluble in ethanol during the formation of self-assembled monolayers (SAMs) on the Au bottom electrode. We used an azobenzene-derivative ([4-(phenylazo)phenoxy]hexane-1-thiol) consisting of two phenyl rings linked by an N=N double bond. These azobenzene-derivative molecules have two distinct isomers: trans- (extended form) and cis-isomer (compact form) depending on the wavelength of irradiating light (Fig. 1d). We prepared trans- and cis-isomer devices in the following way. First, SAMs (~1 mM) of trans-isomer were formed on the Au bottom electrode in a nitrogen-filled glove box with an oxygen level less than ~10 ppm for 1–2 days under visible light irradiation (400–500 nm). After the formation of trans-isomer azobenzene SAMs, several devices were illuminated by UV light (365 nm) in a darkroom for one hour, a period of time sufficient to guarantee a complete conformational change from the trans- to cis-isomer. Next, poly(3,4-ethylene-dioxythiophene) stabilized with poly (4-styrenesulphonic acid) (PEDOT:PSS) was spin-coated onto the tops of all devices to prevent electrical shorts between bottom Au electrode and a deposited Au top electrode [13,14]. The Au top electrode was deposited through a shadow mask using the electron-beam evaporator, which acted as a self-aligned etching mask during the removal of exposed PEDOT:PSS. Finally, the remaining PEDOT:PSS outside the junctions was removed by reactive ion etching using O_2 gas.

The current–voltage (I–V) characterization of the fabricated molecular devices was carried out using a probe station and a semiconductor parameter analyzer (HP4155A) in ambient air at room temperature. And, the temperature variable I–V characterization was also performed in a cryostat system (ST-100 from Janis Co.) at the temperature ranging from 77 to 290 K. The absorption spectra of the azobenzene-derivative molecules in chloroform were characterized by using a UV–Vis spectroscopy measurement (PerkinElmer Lambda 750).

3. Results and discussion

3.1. photo-induced isomers

The photo-induced isomers of azobenzene derivatives are distinguished by the different physical and optical properties of the two configurations (trans- and cis-isomers), which can be observed through changes in their respective absorption spectra, dipole moments, refractive indices, and molecular conformations [15,16]. Before fabricating molecular devices, we measured the absorption spectra of the azobenzene derivative in chloroform to confirm the conformational changes upon external light irradiation. Fig. 2a shows the absorption spectra of our azobenzene derivatives in chloroform using UV–Vis spectroscopy. Generally, the absorption spectra of azobenzene derivatives are characterized by two distinct band peaks consisting of an intense band peak near 350 nm (UV region) and a weak band peak between 400 and 450 nm (visible region) [17]. The absorption transition near 350 nm is denoted as the $\pi\pi^*$ transition, which represents the rotation motion of the upper phenyl ring at the site of the N=N double bond for the trans-cis photoisomerization process. The absorption transition between 400 and 450 nm is denoted as the $n\pi^*$ transition, which represents the inversion motion of the upper phenyl ring at the same site [18]. The $n\pi^*$ transition is known to be prohibited for the trans-isomer, but it is allowed for the cis-isomer [19]. However, although the $n\pi^*$ transition of the trans-isomer is originally forbidden, a small amount of $n\pi^*$ transition peak is observed due to vibronic coupling between the $n\pi^*$ and $\pi\pi^*$ states [19].

In the trans-isomer, the two band peaks near 350 nm and between 400 and 450 nm were observed by UV–Vis spectroscopy (the blue curve in Fig. 2a). The $\pi\pi^*$ transition peak is relatively dominant compared with the $n\pi^*$ transition peak. After the trans-isomer was irradiated with UV light for 90 min in a darkroom, the intensity of the $n\pi^*$ transition peak increased because the $n\pi^*$ transition is allowed for the cis-isomer, and the $\pi\pi^*$ transition peak decreased (however, it was still intense compared with the $n\pi^*$ transition peak). From this photo-induced transition, we estimated the ratio of trans- to cis-photoisomerization from the spectra in solution. From the ratio of absorbance peak between trans- and cis-isomers at ~350 nm, the

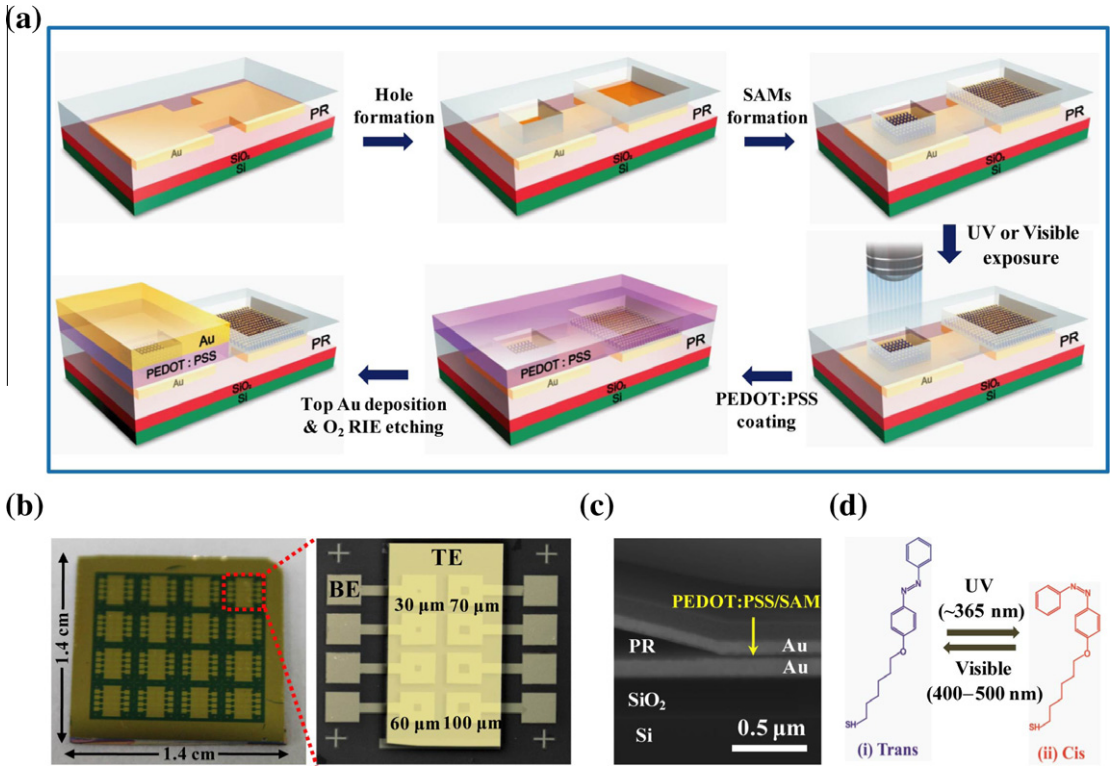

Fig. 1. (a) The process flow of device fabrication. (b) Photographic and SEM images of molecular junctions. Fig. 2. (a) Absorption spectra of trans- (blue) and cis- (red) isomers in chloroform. Inset shows the evolution from cis- to trans-isomer upon visible light (~436 nm) exposure. The two green circular symbols represent the isosbestic points. (b) The evolution of water contact angle of the trans-isomer (blue symbols) and cis-isomer (red symbols) on Au substrate after UV (~365 nm) and blue light (~412 nm) irradiation, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

trans- to cis-isomerization was found to be ~63%. This value suggests that all of the trans-isomers in solution are not completely changed to cis-isomers.

Furthermore, we investigated the conformational changes from the cis- to trans-isomer for the azobenzene derivative. Inset of Fig. 2a shows the evolution of the absorption spectrum of the cis-isomer (red curve) with visible light (~412 nm) exposure at 10-min intervals. The $\pi\pi^*$ transition peak of the cis-isomer increased and the $n\pi^*$ transition peak decreased upon visible light irradiation. After an hour of visible light irradiation, the cis-isomer was completely converted back into the trans-isomer. Note that the solvent of chloroform may evaporate during the UV–Vis measurement, but the effect of solvent evaporation would be negligible at least during the period of our measurement time, because the two isosbestic points did not change noticeably.

To elucidate the trans-cis photoisomerization behavior of azobenzene derivative on Au surface, it is necessary to confirm the conformational changes by external light. The

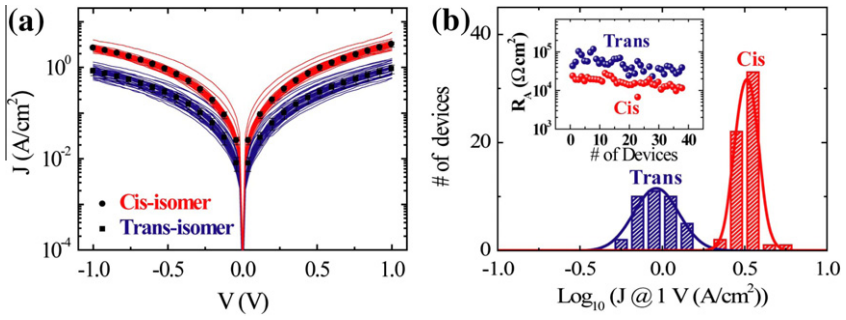

Fig. 3. (a) *J–V* curves on a logarithmic scale for trans-isomer (blue) and cis-isomer (red). The symbols and error bars represent the average and standard deviation of the current density for all the measured devices (~50 devices for each isomer case), respectively. (b) A histogram of *J* at 1 V for the trans- and cis-isomers. The solid lines are Gaussian fitting curves. The inset shows the distribution of the resistance-area products (R_A) for the trans- and cis-isomers. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

evolution of the water contact angle on Au surface of azobenzene SAMs was monitored as a function of external irradiation wavelengths in Fig. 2b. Before UV light irradiation (~365 nm) on SAMs, the contact angle of pristine SAMs was about 81 ± 0.4°. After UV light irradiation for 90 min in a dark room, the contact angle decreased to 78 ± 0.6°, which is attributed to the trans- to cis-isomerization [21]. And, after subsequent visible light irradiation (~412 nm) for 90 min, the contact angle increased to 91 ± 4° due to cis- to trans-isomerization.

Also, we conducted the repeatable cycling measurements and confirmed the water contact angle values were reproducible for two cycles. This difference of water contact angle on trans- and cis-isomer on Au surface is mainly attributed to different top contact group and dipole moment [22]. The top contact group of trans-isomer is constituted by hydrophobic CH_3 group. In the cis-isomer, the azo (N=N bond) or phenyl group is exposed by UV light irradiation. Therefore, the surface wettability for two isomers is different.

3.2. Electrical properties and charge transport mechanism

Using the metal–molecule–metal device structure shown in Fig. 1, we statistically studied the electrical properties of the two isomers. Fig. 3a shows the current density–voltage (*J–V*) characteristics of the trans- and cis-isomer-based molecular junctions. We plotted the *J–V* curves for ~50 molecular junctions of each isomer in Fig. 3a. The important point is that the current densities of the cis-isomer junctions were higher than those of the trans-isomer junctions. To statistically compare the electrical characteristics of the trans- and cis-isomers, histograms of the logarithmic current densities (log*J*) at 1 V were plotted for both isomers, as shown in Fig. 3b. The histograms of the trans- and cis-isomer did not overlap (except for slight tails) and had distinct ranges of current density. The representative current densities were determined as the mean values of Gaussian fittings of the histograms and were found to be ~0.93 and 3.21 A/cm^2 for the trans-isomer and cis-isomer junctions, respectively. It is noted that the photoisomerization from trans- to cis-isomer might be suppressed in SAMs as compared with that in solution because the azobenzene derivatives in self-assembled monolayers are highly densely packed and subsequently there is lack of free volume in the interior of the monolayers [20]. Therefore, it is considered that the ratio of photoisomerization in SAMs may become smaller than that in solution.

Because the junction areas were different in our case (with side lengths of 30–100 μm), we considered the product of the resistance (*R*) and area (*A*), i.e., R_A (=$R \times A$), to be a junction-area-compensated quantity [23]. The obtained resistance-area products R_A of the trans- and cis-isomers were well distributed, as shown in the inset of Fig. 3b. The average R_A values were determined to be $(4.73 \pm 2.20) \times 10^4$ and $(1.40 \pm 0.40) \times 10^4\ \Omega\,cm^2$ for the trans- and cis-isomers, respectively.

To investigate the conduction mechanisms of the trans- and cis-isomers, a temperature-variable characterization was performed. Fig. 4a shows an Arrhenius plot [ln(J) versus 1/*T*] with curves at different biases ranging from 0.6 to 1.0 V in increments of 0.1 V. The temperature was varied from 77 to 290 K in increments of 40 K. For the trans-isomer (top of Fig. 4a), there were no significant changes in the slopes of the Arrhenius curves as the temperature was varied. This temperature-independent behavior indicates that the main charge transport mechanism in the trans-isomer is a tunneling in the measured bias range [24]. For the cis-isomer (bottom of Fig. 4a), the Arrhenius plot also showed a negligible temperature dependence (except for a very slight dependence at high temperature), suggesting that the overall conduction mechanism in the cis-isomer is also tunneling. If tunneling is the main conduction mechanism, the junction current density varies exponentially with the distance of tunneling pathway. The current density (*J*) for the molecular junction is described as:

$$J = J_0 \exp(-\beta\, d) \quad (1)$$

where J_0 is a constant, *d* is the tunneling distance, and β is the tunneling decay factor that represents charge transport efficiency through the molecules [25].

The molecular tunneling distances of the trans- and cis-isomers between the two electrodes were estimated using the Cambridge Scientific Chem3D software at 22.73 and

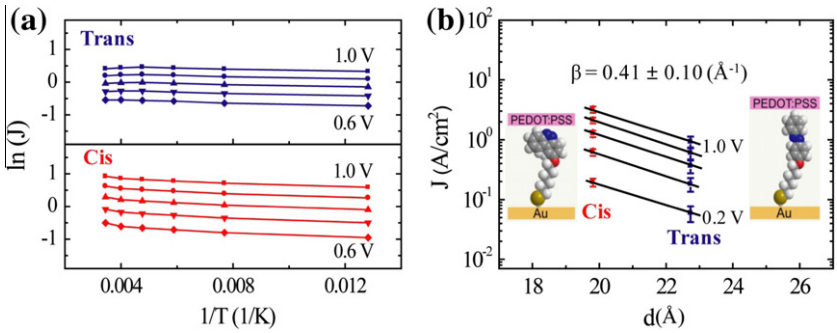

Fig. 4. (a) Arrhenius plot [ln(J) versus 1/T] for the trans- and cis-isomers at different voltages ranging from 0.6 to 1.0 V (0.1 V step). (b) A semilog plot of J as a function of molecular tunneling distance (d) for the trans- and cis-isomers at different voltages. The slopes represent the tunneling decay factor β (~0.41 Å^{-1}).

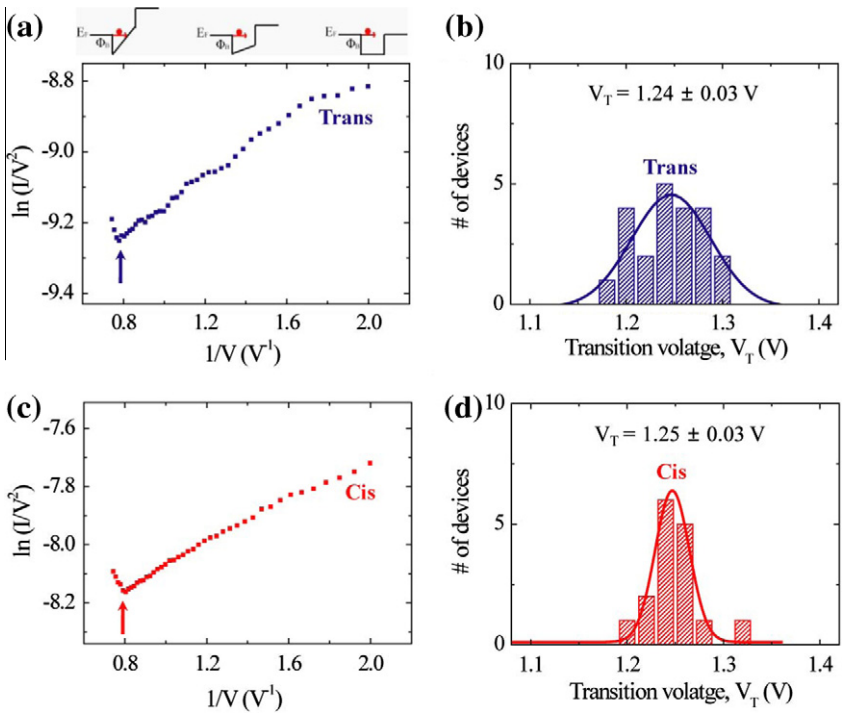

Fig. 5. (a and c) Representative plots of ln(I/V^2) versus ($1/V$) for the trans- and cis-isomers. The arrows indicate the transition point from DT to FN tunneling for the trans- and cis-isomers. (b and d) The statistical histograms of transition voltage (V_T) for the trans- and cis-isomers.

19.81 Å, respectively. Details of the determination of the molecular tunneling distances for the trans- and cis-isomers are provided in Fig. S2 in the Supplementary Data. Because the current density of the molecular tunneling junctions obeys (Eq. (1)), we plotted a semilog plot of the current density versus molecular tunneling distances for the trans- and cis-isomers, as shown in Fig. 4b. The estimated tunneling decay factor β was then obtained from the slopes [25] and found to be 0.41 ± 0.10 Å^{-1} at different biases. The observed β value in our study is similar to previously reported values in the literature [26,27]. Note that there is a variation in tunneling distance between the two electrodes because of defects in molecular layer [28] and imperfect interconversion of the molecules. Therefore, the experimental values of J are log-normally distributed as shown in Fig. 3b, and the estimated decay constant (β) represents the averaged degree of decay in our molecular junctions.

It is useful to analyze the tunneling transport with a conventional energy band model [29,30]. In the tunneling regime, when the applied bias is less than the barrier height ($V < \Phi_B/e$), charge transport exhibits direct tunneling (DT), and the barrier shape appears as a trapezoidal shape. On the other hand, when the applied bias is larger than the barrier height ($V > \Phi_B/e$), the charge transport is the field emission (or Fowler-Nordheim, FN) tunneling,

and the barrier shape appears as a triangular shape [29]. The important point is that the transition of the charge transport from DT to FN tunneling accompanies an inflection in a plot of $\ln(I/V^2)$ versus $(1/V)$ [30]. This inflection point is called the transition voltage (V_T), and this technique is termed transition voltage spectroscopy (TVS) [29,31]. The TVS method provides useful information about the location of the frontier molecular orbital (the highest occupied molecular orbital (HOMO) or lowest unoccupied molecular orbital (LUMO)) with respect to the Fermi level of the electrodes. Therefore, from the analysis of V_T by TVS characterization, one can estimate the energy offset between a metal electrode's Fermi energy and the frontier molecular orbital, which provides an estimated value of the barrier height (Φ_B); note V_T may not be identical to Φ_B. Plots of $\ln(I/V^2)$ versus $(1/V)$ for the trans-isomer (blue curve) and the cis-isomer (red curve) are shown in Fig. 5a and c, respectively (here, the applied bias was from 0 to 1.5 V). In the low-bias regime, this plot exhibits a logarithmic decay in the DT transport regime. Between the two charge transport regimes, an inflection point in the plot of $\ln(I/V^2)$ versus $(1/V)$ was observed (indicated by arrows). This inflection point is the transition voltage (V_T); it was determined to be ~1.25 V for both the trans- and cis-isomers (a small difference in V_T for the two isomers is within the error range). Fig. 5b and d shows statistical histograms for the V_T values of the trans- (22 devices) and cis-isomers (16 devices); Statistically, the V_T value was determined to be 1.24 ± 0.03 for the trans-isomer and 1.25 ± 0.03 V for the cis-isomer. This suggests that the energy offset, i.e., the barrier height (Φ_B), is also similar for both isomers regardless of the conformational change [32]. Note that the difference of conductance between the two isomers has also been reported in terms of the changes in their molecular electronic properties [33] (The details are described in the Supplementary Data).

To probe the positions of the HOMO levels of the SAMs on Au, we performed ultraviolet photoelectron spectroscopy (UPS) for each isomer. The UPS method has been used to estimate the work functions of metals and the HOMO levels of organic thin films [34,35]. We observed no significant difference between the HOMO levels of the trans- and cis-isomers on an Au substrate from the UPS measurements (for details, see Fig. S3 in the Supplementary Data). The UPS measurement result indicates that the electronic structure (HOMO level) of our molecule did not change on conversion from the trans- to the cis-isomer, meaning that the barrier height was also similar for the two isomers. Therefore, based on our study, we suggest that the main origin of the higher conductance of the cis-isomer is the difference in the molecular tunneling distance rather than the barrier height. This was confirmed by the fact that the V_T values of the trans- and cis-isomers are indeed similar: ~1.25 V (Fig. 5).

4. Conclusions

In conclusion, we performed a statistical study on the electrical characteristics of an azobenzene-derivative molecular junction in a solid-state device platform. This molecule was reversibly converted from its trans- to cis-isomer by irradiation with UV light (~365 nm) and from its cis- to trans-isomer with visible light (400–500 nm). The conductance of cis-isomer (compact form) was higher than that of trans-isomer (extended form). From the temperature-variable electrical characterization, transition voltage spectroscopy analysis, and ultraviolet photoelectron spectroscopy measurement, the current density difference between the two isomers can be explained by the reduction in the molecular tunneling distance through the molecules sandwiched between the two electrodes.

titanium oxide (TiO*x*) [12–15], zinc oxide (ZnO) [16–20], LiF [21], cesium carbonate (Cs_2CO_3) [22–25], indium sulfide (In_2S_3) [26], or self-propagating molecule-based assemblies (SPMAs) [27], are usually used as an ECL in such inverted PSCs, due to their large band gaps and the well electron extraction property.

For the fabrication of thin films of inorganic n-type semiconductors as the ECL, a variety of growth methods have been employed, including sol–gel [28], thermal deposition, and atomic layer deposition (ALD) [18,29]. Among these fabrication techniques, the ALD possesses several unique capabilities, including uniform film growth, low processing temperature, low defect density, and precise control of chemical composition and film thickness at a maximum rate of one monolayer per cycle. ALD has been used to form an ECL (i.e., ZnO and TiO_2) and encapsulating films (e.g., Al_2O_3) for PSCs [18,29–31].

In this work, the feasibility of ALD-grown cadmium sulfide (CdS) film as an ECL in the inverted PSCs is explored. CdS being an n-type compound semiconductor with high electron affinity, wide direct band gap (2.4–2.5 eV), relatively high electron mobility, and environmental stability, is widely used as an n-type buffer layer for thin film photovoltaic devices [32,33], and can be fabricated by various techniques, such as ALD [34], chemical vapor deposition (CVD) [35], atomic layer epitaxy (ALE) [36], pulsed laser deposition [37], and so on. Here, the ALD-grown CdS films were obtained at relatively low temperature with high uniformity, and efficient inverted PSCs with a blended poly(3-hexylthiophene):[6,6]-phenyl C61 butyric acid methyl ester (P3HT:PCBM) photoactive layer were achieved by integrating with an ALD-grown CdS film as an ECL.

2. Experiment

2.1. Atomic layer deposition process

The CdS films with various thicknesses were grown by ALD on pre-cleaned and 15 min UV-ozone treated ITO glass substrates, which were conducted by a Savannah 100 ALD system from Cambridge Nanotech, Inc. The ALD growth process of polycrystalline CdS films on ITO substrates is schematically shown in Fig. 1, which was performed under the optimum operating conditions using the dimethyl cadmium (DMCd) and *in situ* generated H_2S precursors [34]. The temperature of ITO-coated glass substrates with a sheet resistance of 20 Ω/sq was kept at 150 °C, which is suitable to protect conductive substrates and to avoid the breakdown of DMCd precursor. The process pressure was 2×10^{-1} Torr with high-purity N_2 (flow rate = 10 sccm) as the carrier and purging gas. As depicted in Fig. 1, the optimized ALD cycle settings for CdS films were followed with 0.015 s pulse of H_2S, 10 s purge of N_2, 0.015 s pulse of DMCd, 10 s purge of N_2. The thickness of ALD-deposited CdS films per cycle was determined to be ~0.35 Å by alpha-SE™ Spectroscopic Ellipsometer. As demonstrated previously [34], the growth rate of CdS films is self-limited and will be saturated with respect to the DMCd pulse time of 0.4 s, and the N_2 purge time of 10 s is sufficient to remove the excess reactants.

2.2. Fabrication of inverted devices

The device structure of the inverted PSCs was ITO/CdS/P3HT:PCBM/MoO_3/Al. Throughout the device fabrication process, all the process parameters were fixed except for the film thickness of the CdS layer. After the deposition of CdS films by ALD, the resulting substrates were transferred into a N_2-filled glove box for the preparation of the P3HT:PCBM photoactive layer, which was spin-coated from a 1:1 weight-ratio solution in chlorobenzene with a concentration of 40 mg/mL, followed by annealing on a hot plate at 130 °C for 20 min in glove box. The thickness of the resulting P3HT:PCBM blend film was determined to be approximately 125 nm. Then, to complete the PSC devices, the samples were transferred into the high vacuum chamber with a base pressure of 1×10^{-6} Torr for the thermal evaporation of a 1.5 nm-thick MoO_3 layer as a buffer layer for hole collection and a 100 nm-thick Al anode through shadow masks. The device area, as defined by the overlap between the ITO and Al electrodes, was 0.1 cm^2. For comparison, the inverted devices employing CdS films with four different thicknesses were fabricated with the identical process parameters during the same batch processing.

2.3. Thin film and device characterization

The thickness of CdS films was calibrated by the alpha-SE™ Spectroscopic Ellipsometer. Surface morphology and roughness were characterized with atomic force microscopy (AFM) (Veeco MultiMode V) in tapping mode. The UV–vis absorption and transmission measurements of the samples were recorded at room temperature with a Perkin Elmer Lambda 750 UV/Vis/NIR spectrophotometer. High-resolution transmission electron microscopy (HRTEM) images and selected area diffraction (SAD) patterns were taken by an FEI Tecnai G2 F20 X-TWIN operated using an accelerating voltage of 200 kV with samples by separating CdS from the ITO substrate. The contact angle of water on the surfaces of CdS films was determined by SCA20 contact angle measurement system (sessil drop method). Elemental composition and the electronic structures of the films were determined by ultraviolet and X-ray photoelectron spectroscopies (UPS and XPS) in a Kratos AXIS Ultra-DLD ultra-high vacuum system (a base pressure of 3×10^{-10} Torr) with HeI excitation (21.22 eV for UPS) and monochromatic Al Kα source (1486.6 eV for XPS). Details of the experimental setup for UPS and XPS measurements have been given elsewhere [38,39].

Photovoltaic measurements were conducted at room temperature in air without any device encapsulation. The current density–voltage (*J–V*) characteristics of the inverted PSC devices were examined with a programmable Keithley 2612 source meter under simulated air mass (AM) 1.5G illumination (Newport-Oriel solar simulators with integrated intensity = 100 mW/cm^2), which was calibrated with a silicon photodiode.

3. Results and discussion

The surface morphology and roughness of the ALD-grown CdS films on ITO glass surfaces were investigated by AFM. Fig. 2 shows the AFM micrographs of ALD-grown CdS films with a thickness of 3.5 nm (100 cycles), 10.5 nm (300 cycles), 17.5 nm (500 cycles), and 38.5 nm (1100 cycles), respectively, where the film thickness is dependent on the cycle numbers. It is evident in Fig. 2 that there is negligible change in the surface features for CdS films with increasing thickness, in which uniform CdS films composed of similar distinct crystal grains can be observed. The root mean square (RMS) roughness values, as summarized in Table 1, are almost identical with respect to the variation in film thicknesses. The crystallinity of the ALD-grown CdS films has been estimated by HRTEM. As shown in Fig. 3, the HRTEM image and SAD pattern confirm the presence of polycrystalline CdS grains. However, due to sulfur vacancies as discussed later by XPS measurement, the non-stoichiometric structure in ALD-deposited CdS films results in the derivation of the SAM pattern in comparison with zinc blende (cubic) and wurtzite (hexagonal) crystals of CdS [34]. As reported in the literature, the polycrystalline CdS film by ALD is the mixture of zinc blende (cubic) and wurtzite (hexagonal) crystals, and the transition between these two phases strongly depends upon factors such as deposition method, temperature, time, and precursors [34].

In order to characterize the composition of ALD-deposited CdS films, the XPS measurements were carried out. Fig. 4 shows the XPS spectra for the ALD-grown CdS films with different thicknesses, where the Cd 3d and S 2p XPS core level spectra exhibit symmetric line shapes. With increasing the CdS thickness, the binding energies of Cd $3d_{5/2}$ (and S $2p_{3/2}$) peaks gradually shift from 405.5 eV (and 162.0 eV) to 405.9 eV (and 162.3 eV), respectively. According to the quantitative analysis of Cd 3d and S 2p core level spectra, the atomic Cd-to-S ratio were determined to be approximate 1.60:1, as listed in Table 1. It is found that the CdS films by ALD are not stoichiometric within the error of the XPS characterization due to the sulfur vacancies, whereas there is no noticeable change in the spectral shape.

The key factors of ALD-grown CdS films affecting the electrical properties of the CdS ECL were examined to obtain the optimal performance from the inverted PSCs. Fig. 5 plots the *J–V* characteristics of inverted PSCs employing CdS films as an ECL under AM 1.5G irradiation with the intensity of 100 mW/cm^2 and in dark. Table 1 summarizes the device parameters. Reasonable photovoltaic effect was observed with the incorporation of CdS film. It is noted that when the CdS thickness is less than 3.5 nm, the device exhibits an antidiode behavior with a poor performance, resulting in short-circuit current density (J_{SC}) of 9.88 mA/cm^2, open-circuit voltage (V_{OC}) of 0.55 V, fill factor (FF) of 39.71%, and the PCE of only 2.16%. However, with the increase of CdS thickness, the PSC devices shows a remarkable improvement with the increase of CdS thickness, and the device with 17.5 nm-thick CdS yields the best device performance, providing the PCE of 3.33%. The major improvement in device performance with the incorporation of 17.5 nm-thick CdS film arises from the higher FF and V_{OC}, while the J_{SC} remained almost unchanged. These results clearly demonstrate that CdS can act as an efficient ECL to enhance the efficiency of inverted PSCs. In addition, the further increase of CdS thickness leads to a reduction in J_{SC} and V_{OC}. For instance, the inverted device incorporating a CdS film with a thickness over 38.5 nm shows a reduced PCE (2.6%) with lower J_{SC}, V_{OC}, and FF.

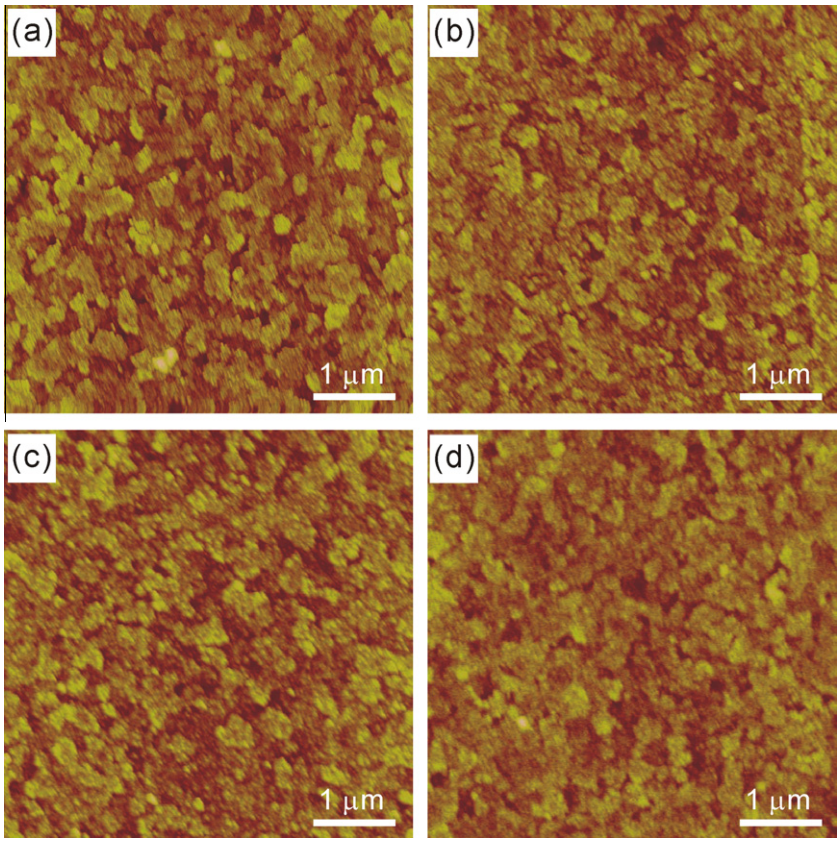

Fig. 2. AFM images of ALD-grown CdS films on ITO substrates with the thicknesses: (a) 3.5 nm, (b) 10.5 nm, (c) 17.5 nm, and (d) 38.5 nm.

Table 1
Characteristics of ALD-grown CdS films and device performance parameters of inverted polymer solar cells with CdS as the electron collection layer. The series resistance (Rs) was determined from the dark *J*–*V* characteristics shown in Fig. 5(b).

CdS (nm)	Roughness (nm)	Cd/S ratio	Contact angle (°)	V_{OC} (V)	J_{SC} (mA/cm^2)	FF (%)	PCE (%)	Rs (Ω)
3.5	2.16	1.77	49.5	0.55	9.88	39.71	2.16	1495.5
10.5	1.93	1.62	54.5	0.59	9.07	57.97	3.10	58.82
17.5	2.07	1.67	55.8	0.61	8.94	61.11	3.33	59.65

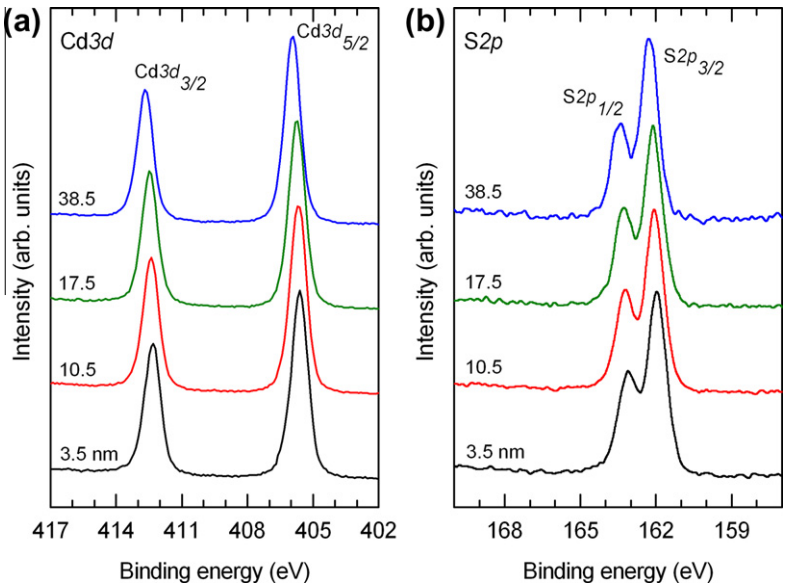

Fig. 4. (a) Cd 3d and (b) S 2p XPS core level spectra of ALD-grown CdS films with different thicknesses.

To understand the influence of ALD-grown CdS films with different thicknesses on the device performance, the optical transmittance of the CdS films on ITO glass was performed with UV–vis spectroscopy. The transmittance spectra of the CdS films shown in Fig. 6 indicate the thickness-dependent transmittance in the range below 500 nm. The inset of Fig. 6 shows the absorption spectra of the CdS film, the P3HT:PCBM layer, and CdS/P3HT:PCBM bilayer, respectively, where an increase in the absorption below 500 nm is clearly seen due to the strong absorption of CdS film near the band gap edge of CdS. In addition, it is obvious that the film thickness did not appear to have impact on the band gap except for the transmittance.

It has been demonstrated that controlling the surface energy of the buffer layer can result in an enhanced performance of the inverted PSCs due to the optimized morphology of the photoactive layer [40]. As shown in Table 1, the contact angle of water on the surface of CdS films was measured, revealing little fluctuation of the surface energy with respect to the variation of CdS film thickness. It has also been confirmed that the morphology of the P3HT:PCBM films spin-coated on CdS/ITO substrates are insensitive to the CdS surface, exhibiting the similar morphology (not shown here). As reflected by the contact angle measurement, the surface energy of the CdS films cannot be speculated to the reason behind the efficiency variation in inverted structure PSCs.

Further surface property studies were carried out by UPS measurement on the electronic structures of CdS films. Fig. 7(a) shows the secondary electron cutoff of the ALD-grown CdS films with different thicknesses on ITO substrates, which can be used to determine the work function of CdS films by the intercept between the background level and the extrapolation of the leading edge in the high binding energy region. According to the UPS measurement, the work function of UV-ozone treated ITO substrate is determined to be 4.8 eV, while the corresponding work function of CdS films deposited on the ITO surface is reduces to about 3.9 eV, which keeps almost identical with respect to the variation of the film thickness. On the other hand, the valence band maximum (VBM) of the CdS films can be determined from the UPS spectra in Fig. 7(b), which locates at 2.2 eV below Fermi level (E_F). Taking into account the band gap obtained from the UV absorption edge in the inset of Fig. 6, the conduction band minimum (CBM) of the CdS film is 0.2 eV above E_F, indicating the n-type semiconducting property of the ALD-grown CdS films.

Fig. 8 displays the secondary-electron cutoff and the zoom-in HOMO region of 10 nm-thick P3HT:PCBM blend spin-coated on ALD-grown CdS films with various thickness. It is evident that the UPS signals of the highest occupied molecular orbital (HOMO) features are dominated by the P3HT component due to the accumulation of P3HT at the blend surface, which is consistent with previous reports [41]. As shown in Fig. 8(a), the spin-coating of the blended P3HT:PCBM layer on CdS films only induces a slight vacuum level shift (~0.1–0.2 eV) within the error of the UPS measurement, leading to a work function of ~3.8 eV. The ionization potential (IP) value of P3HT extracted from the UPS spectra is around 4.55 eV by taking into account the work function of ~3.8 eV and HOMO edge of 0.75 eV below E_F. However, the energy levels of PCBM cannot be clearly distinguished from the UPS spectra of the P3HT:PCBM blend layers due to the vertical phase separation as demonstrated previously [41], and will be assumed to be vacuum-level (VL) aligned with that of P3HT [42].

The electronic structures of the MoO_3/P3HT:PCBM interface were also investigated, since a stable MoO_3 thin film was selected as the hole extraction layer in the inverted configuration. Fig. 9 shows UPS spectra of the corresponding interface with increasing MoO_3 overlayer thicknesses. It is obvious that deposition of the MoO_3

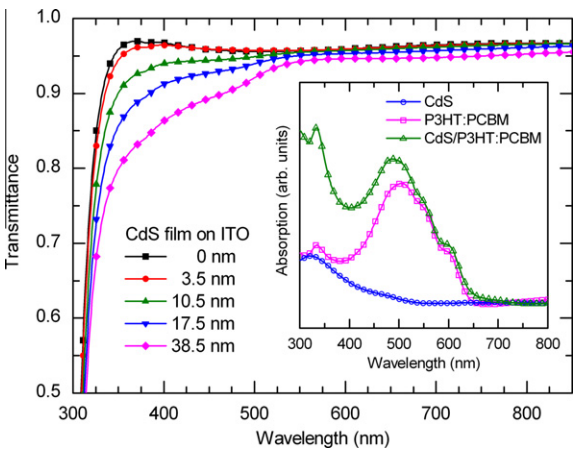

Fig. 6. Optical transmittance spectra of ALD-grown CdS films with various thicknesses on ITO substrate. The inset shows the absorption spectra of 17.5 nm-thick CdS, 125 nm-thick P3HT:PCBM, and the CdS/P3HT:PCBM layers, respectively.

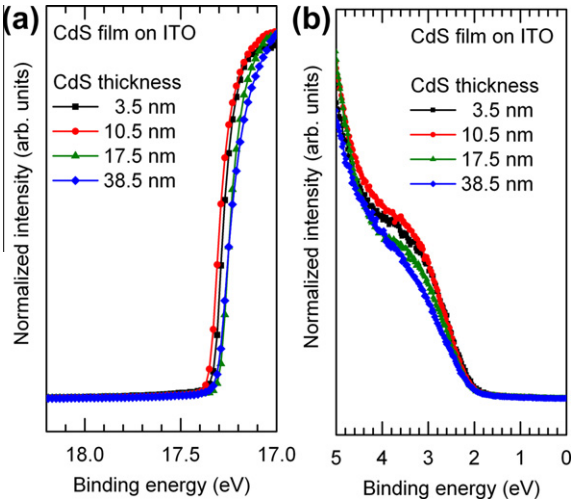

Fig. 7. (a) The secondary electron cutoff region and (b) enlarged HOMO region of the UPS spectra of CdS films deposited on ITO substrates with various thicknesses.

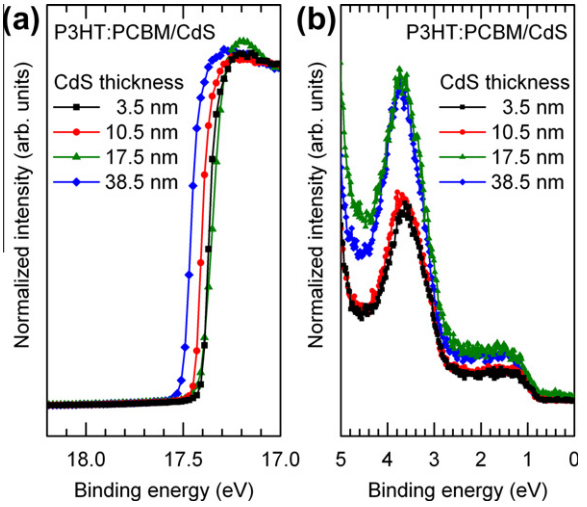

Fig. 8. (a) The secondary electron cutoff region and (b) enlarged HOMO region of the UPS spectra of a 10 nm-thick P3HT:PCBM layer spin-casted on various CdS films.

overlayer results in a progressive shift (~1.4 eV) of the secondary electron cutoff towards lower binding energy region, which corresponds to the increase of the work function and the formation of interface dipole. According to Fig. 9(b), the VBM of a 1.5 nm-thick MoO_3 layer is estimated to be at 2.8 eV below E_F. Considering the energy gap of 3.1 eV, MoO_3 exhibits an n-type semiconductor property with E_F slightly pinned below the CBM, which is in good agreement with previous reports [43].

Using the results from UPS measurements, the energy level offsets directly at the interface can be accurately determine by considering the interface dipole formation. Fig. 10 illustrates the energy level diagram for the inverted PSC with a CdS ECL. Here, HOMO (or VBM) positions are

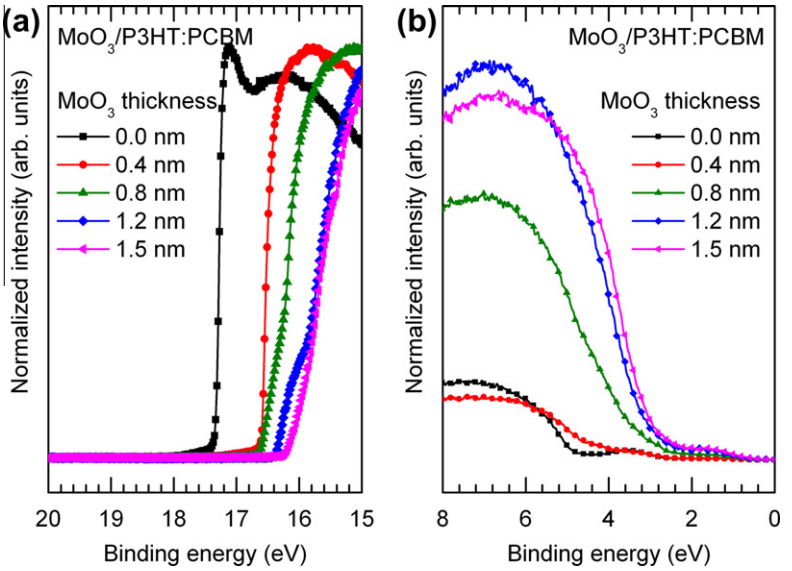

Fig. 9. (a) The secondary electron cutoff region and (b) the enlarged HOMO region of the UPS spectra of the incremental deposition of a MoO_3 layer on the P3HT:PCBM film.

extracted from the UPS spectra, and the lowest unoccupied molecular orbital (LUMO) (or CBM) positions are estimated by adding the energy gaps. E_F is aligned across the interfaces in a thermodynamic equilibrium state, and the VL shift determined by the secondary electron cutoff is compensated with the interface dipole formation (Δ). In addition, the HOMO and LUMO levels of PCBM in the P3HT:PCBM blend were referred to the values of pristine PCBM layer in the literature [41], which are aligned with that of P3HT with a common VL. It is evident that the energy level lineup across the inverted PSC is not consistent with the traditional concepts of common VL alignment [42]. In addition, Fig. 10 implies that the CdS film between ITO cathode and P3HT:PCBM layer provides a better energy level matching due to the well-aligned CBM of CdS film with the LUMO of the electron acceptor PCBM. Therefore, the ALD-grown CdS film is indicative of efficient electron collection and transport from the P3HT:PCBM photoactive to the ITO cathode.

To get additional insight into the origin of the observed PCE enhancements with respect to the variation of CdS thickness, the contact resistance of the inverted devices was examined from the dark *J–V* characteristics in Fig. 5(b). As shown in Table 1, a strong correlation between the series resistance (Rs) and the resultant device performance can be obtained. The Rs variation of inverted PSC with ALD-grown CdS films follows the PCE results. For ALD-grown CdS films with a thickness lower than 17.5 nm, the Rs decreases with the CdS thickness, and then increases with a thicker CdS film. As a result, a higher Rs can lead to a reduction in FF and J_{SC}, hence a reduction in PCE [44]. The results clearly reveal that the Rs might be one of the reasons behind the improved efficiency of inverted structure PSCs with ALD-grown CdS films as an ECL.

4. Conclusions

In summary, efficient inverted polymer solar cells were achieved by using ALD-grown CdS films as the electron collection layer. The CdS films by ALD using DMCd and *in situ* generated H_2S precusors can be obtained at relatively low growth temperatures ($\leqslant$150 °C) with high uniformity, and the sulfur vacancy induces an n-type semiconducting property as determined by UPS and XPS measurements. The suitable energy level alignment at the ITO/CdS/PCBM interface is favorable to electron extraction through CdS to the ITO cathode. With the optimized CdS film thickness, the power conversion efficiency increases to 3.33% under AM1.5G 100 mW/cm^2 irradiation. The results define a promising pathway for the fabrication of efficient inverted polymer solar cells.

can effectively increase the electrical conductivity to several hundred Siemens per centimeter. However, due to the low Seebeck coefficient, the highest ZT can only reach $\sim 10^{-3}$ around room temperature, which is still insufficiently high for practical application. The ICPs with specific dopants indeed provide the excellent and stable electric conductivities needed, but it is generally difficult to obtain a high Seebeck coefficient simultaneously. A significant enhancement in ZT has been achieved by synthesizing specially designed copolymers with a high electrical conductivity, e.g., poly(2,5-dimethoxyphenylenevinylene-co-phenylenevinylene) and poly(2,5-diethoxyphenylenevinylene-co-phenylenevinylene), which exhibit a greatly improved ZT of $\sim 10^{-2}$ and $\sim 10^{-1}$, respectively [15,16].

As a popular commercial conducting polymer, the water-dispersible poly(3,4-ethylenedioxythiophene):poly (styrenesulfonate) (PEDOT:PSS) has become one of the most promising conductive polymers and has been widely applied in modern photoelectronic devices [17]. The TE investigations for PEDOT:PSS can be traced back to 2002, when Kim et al. established that the Seebeck coefficient decreases with the addition of the dielectric solvent of dimethyl sulfoxide (DMSO) [10]. The topic began to attract growing interest until in 2009 numerous results were published regarding both as-received PEDOT:PSS and blended composites [10–12,18]. Although the addition of DMSO has been widely accepted as an effective approach to greatly increase the electrical conductivity by several orders of magnitude, in the meantime, the Seebeck coefficient also drastically decreases, even with a very small addition, e.g., 0.5 wt.%, and seems to have less change with the variation of the DMSO concentration [11].

Due to the difficulty of independently controlling the Seebeck coefficient and electrical conductivity, blending of different organic/inorganic TE materials provides a simple and potential way to individually optimize these two parameters of the blended TE composites. For instance, Zhang et al. have demonstrated one design of organic–inorganic hybrid films, i.e., one Bi_2Te_3 granular layer coated with one thick PEDOT:PSS layer, and obtained a power factor of $\sim 16\ \mu W/mK^2$, which is much lower than their theoretical prediction using a simplified ideal model [12]. See et al. have also presented an in situ synthesis of the composite of the Te nanorods and PEDOT:PSS, which has a maximum Seebeck coefficient of 163 μV/K and power factor of $\sim 70\ \mu W/mK^2$ [18]. All these hybrid results indicate that no matter whether the TE heteromaterials are integrated in parallel or serial methods, the final TE performance is directly correlated with that of the individual components [12]. It is thus of great importance and meaningful to make efforts to enhance the TE performance of all components, especially the polymers, such as the PEDOT:PSS polymers in the above cases.

In this paper, the effects of the ammonium formate (AF) dopants on the Seebeck coefficient, electrical conductivity, power factor and microstructures of the commercial PEDOT:PSS films are presented. It has been reported that AF can cut off alkyl groups or side chains from benzene [19]. The results motivated us to examine if AF can be a promising dopant to effectively tune the electrical properties of conducting polymers. In addition, since AF will decompose into formamide and water with the presence of heat [20], in our experience, a two-step drying process was specially designed to form PEDOT:PSS films with nano/micro-fractures in which significant phonon scattering may occur, reducing the thermal conductivity of the films. During the first drying step at lower temperature, the only solvent, water, will be gently removed to create dried AF blended PEDOT:PSS films and a very small fraction of the AF dopants will also decompose into the gas phase. The following higher-temperature step will make the trapped solid AF dopants almost decompose to simultaneously form open or closed voids or channels randomly distributed over the films.

2. Experiment

Commercial PEDOT:PSS and AF were purchased from H.C. Starck (Clevios PH 500, 1.0–1.4 wt.%) and Showa Chemical Inc., respectively, and used without further purification. The received PEDOT:PSS solution was doped with 5, 10, 20 and 50 wt.% AF, and respectively denoted as P5, P10, P20, and P50. It must be noted that the weight percentages mentioned above are expressed only by the respective weight percentages of the solid content irrespective of the water solvent, not the whole solution mixture. The 5 wt.% DMSO doped and raw PEDOT:PSS solutions were also prepared for comparison. The chemical structures are shown in Fig. 1. The glass slides were cut into $2.5 \times 2.5\ cm^2$ pieces as the substrates and washed with ultrasonic cleaning processes in detergent, deionized water, and isopropyl alcohol, sequentially. An approximate 100 μL of each prepared PEDOT:PSS solution was dropped onto the as-cleaned glass substrate using a micropipette and spread evenly. The deposited sample was firstly dried in air at 40 °C for 1 h mainly to drive off the H_2O solvent and then kept at 80 °C for another 1 h to further remove the residual solvent as well as to evaporate the AF dopants.

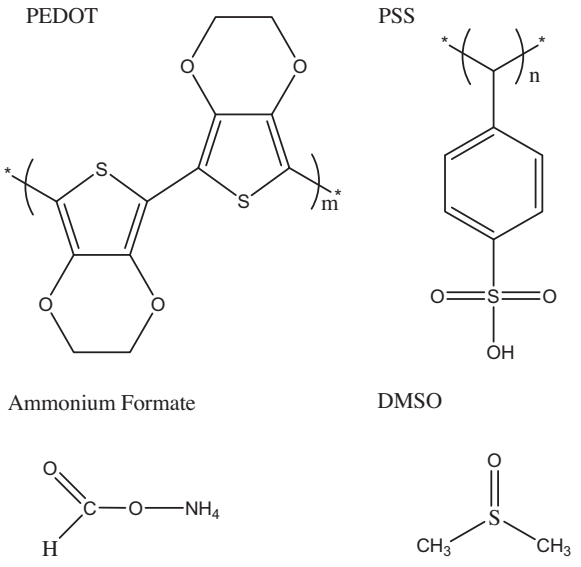

Fig. 1. Chemical structures of PEDOT, PSS, AF, and DMSO.

The final thickness of each dried PEDOT:PSS film was in the range of ~4–6 μm.

The sheet resistance and the electrical conductivity were measured with an automated four-point probe system (Resistest RT-80/Resistage RT-80, Napson Corporation). The corresponding carrier concentration and Hall mobility were characterized with a Hall system (Accent HL5500). The cross-section SEM images provided the accurate thicknesses needed. For the Seebeck coefficient measurement, a maximum temperature gradient of 10 °C was created between two electrodes with an interval of 1.0 cm. The Seebeck voltage and temperature difference were recorded in situ for obtaining the Seebeck coefficients. The samples for the scanning electron microscope (SEM; JSM-6500, JEOL) were broken in liquid nitrogen to avoid plastic deformation of the films. Thermogravimetry analysis (TGA, Q500, TA instruments) was deployed not only to understand the decomposition process of AF but also to characterize the thermostability of the produced films. All TGA samples were pre-heated at 40 °C for 10 min. The time-resolved decomposition of the as-received AF powders at 80 °C and the temperature-dependent weight loss of the prepared PEDOT:PSS films up to 800 °C were respectively recorded. The furnace chamber was constantly purged with nitrogen to minimize the effect of oxygen and to serve as a carrier gas, taking waste out of the chamber. The UV–Vis absorption spectra were recorded with a UV–Vis spectrophotometer (Evolution 300, Thermo Scientific). Thermal conductivity was analyzed by placing a free-standing polymer film between two stacking copper pillars. A heat source generates heat from the bottom of the lower pillar and heat flows upward, through the sample, and then into the upper pillar. Temperatures were measured at certain points of the two pillars to calculate the speed of the heat flow and thermal conductivity of the polymer film.

3. Results and discussion

Fig. 2 shows the cross-section and top-view SEM images of the unmodified and AF-doped PEDOT:PSS films, respectively. In contrast to the very smooth and flat surface of the unmodified PEDOT:PSS, the surface roughness as well as the morphological defect within the film, e.g., the cracks, voids and column structures, obviously increase with the increase of the AF dopant, especially when the AF exceeds 20 wt.%. It is difficult to spread the PEDOT:PSS solution with AF dopants over 50 wt.% since the strong ionic interaction among the AF salts will make the solution gel.

In order to identify the role of AF on the fracture structures, TGA analysis was performed on the as-received AF powders to understand its decomposition behavior. As can be seen in Fig. 3(a), the weight of the AF powders decreases approximately as a linear function with the heating time at 80 °C and approaches complete decomposition after 100 min. It is thus clear that the structural fractures of the PEDOT:PSS films as observed in Fig. 2 were mainly created

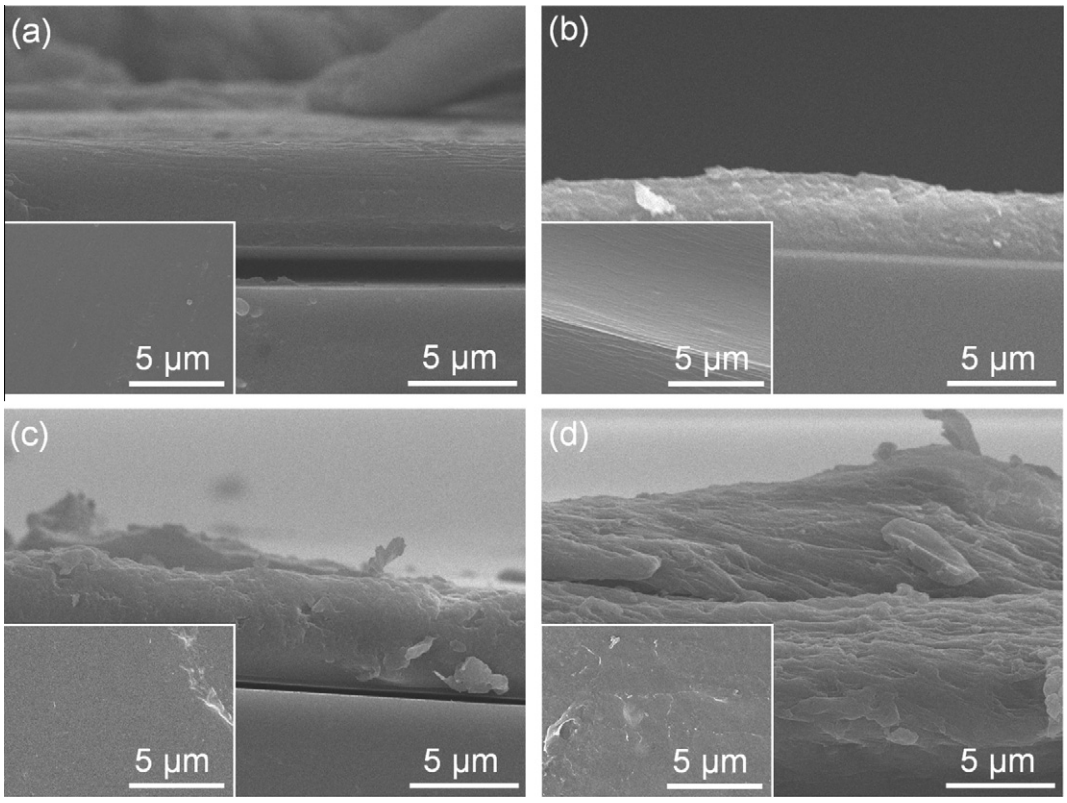

Fig. 2. The cross-section and top-view (inset) SEM images of (a) PH 500, (b) P10, (c) P20, and (d) P50. (e) Image of the close-up of the crack formed during sample preparation.

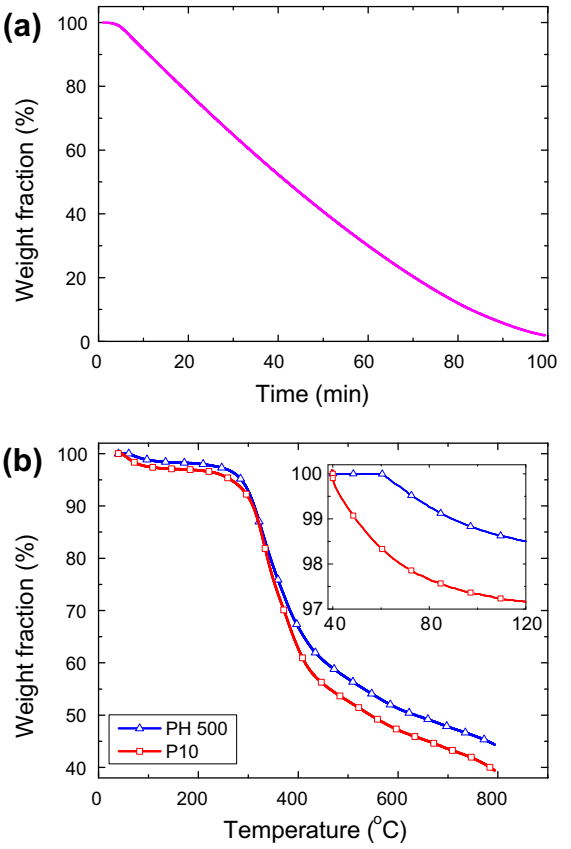

Fig. 3. TGA curves of (a) as-received AF powders and (b) PH 500 and P10.

during the second drying process, i.e., 80 °C for 60 min, due to the violent decomposition of AF at this condition. Because of the lower mechanical strength of the PEDOT:PSS film, the decomposition gas will be released toward the film surface or just trapped in the films. When the three-dimensional pores or channels are open to atmosphere, the inner gas will be exhausted by the gravity of the PEDOT:PSS films to form collapsed two-dimensional interfaces.

Fig. 3(b) is the temperature dependence of the weight loss of PH 500 and P10 from 40 to 800 °C. Basically, the TGA curves for PH 500 and P10 are quite similar to our expectation, since PH 500 is the only main component for both cases. A drastic weight loss of P10 found at the very beginning stage up to ~100 °C should originate from the further decomposing of the residual AF, as discussed above. As can be seen, at 80 °C, i.e., the temperature of the second drying step, the weight loss difference between PH 500 and P10 remains at less than 1.5%, indicating the possible residual level of AF. The adding of AF seems not to affect the thermostability of the PH 500 films. As displayed, the substantial decomposition for both PH 500 and P10 found at ~300 °C is close to that for traditional Polyimide (PI), which is commonly used for flexible substrates in electronic devices. Therefore, the thermostability of the present AF-doped PH 500 film is sufficient for future applications of the soft thermoelectric devices.

Table 1
Seebeck coefficients (S), sheet resistances (R), electrical conductivities (σ), and power factors (P) of the as-received and modified PEDOT:PSS films.

	R (Ω/□)	σ (S/cm)	S (μV/K)	P (μW/mK^2)
PH 500	825.57	1.21	12.4	0.019
DMSO-doped	2.93	524.30	11.6	7.06
P5	21,590	0.11	30.6	0.010
P10	619,100	0.019	220.0	0.092
P10′	323,640	0.036	436.3	0.69

P10′:P10 solution stored at 10 °C for 1 month.

Table 2
Carrier concentrations (n), Hall mobilities (μ_H), and calculated electrical conductivities (σ_H) of the as-received and modified PEDOT:PSS films.

	n (cm^{-3})	μ_H (cm^2/Vs)	σ_H (S/cm)
PH 500	5.5×10^{18}	2.96	2.64
DMSO-doped	1.1×10^{21}	3.81	670
P10	4.3×10^{17}	1.43	0.0984

Table 1 summarizes the measured thermoelectric properties of the as-received and modified PEDOT:PSS films. The most notable changes are that the electrical conductivity of the AF doped film decreases by one to two orders of magnitude compared to the unmodified PH 500. For further evaluation of the electrical conductivity, Hall measurements were carried out and the results confirmed that all the prepared films were hole-type carrier domination. In the p-type semiconductors, the electrical conductivity σ can be expressed by the relationship:

$$\sigma = e\, n\, \mu_H \tag{2}$$

where e, n, and μ_H is the electronic charge, carrier concentration, and Hall mobility, respectively. As can be seen in Table 2, the electrical conductivity of the pristine and modified PEDOT:PSS films obtained from the product of these two competing factor, n and μ_H, is of the same order of magnitude as that measured by 4-point probe method as shown in Table 1, indicating the reliability of the present measurements. Obviously, the largely decreased electrical conductivity of the AF doped PEDOT:PSS film (P10), was mainly caused by the one-order-of-magnitude reduction in the carrier concentration. This probably results from the interaction between the AF molecules and PSS monomers, and thus inhibits the role of the carrier supplier of PSS for PEDOT. Checking the results in Table 2, the Hall mobility shows relatively less variation (<50%) with dopants, either the DMSO or the AF.

In addition to the electrical conductivity, it is noteworthy that the Seebeck coefficient for P10 as displayed in Table 1 is ~20 times higher than that for as-received PH 500 as well as the widely-synthesized DMSO-modified PH 500. Generally, the Seebeck coefficient will be affected, either increasing or decreasing, even with only slight doping, e.g., the DMSO, but will not effectively vary with the doping concentration. It is surprising in the present case that the Seebeck coefficient significantly enhances with the AF doping concentration.

A theoretical derivation of Seebeck coefficient (S) is expressed as [21]:

$$S(T) = \frac{1}{eT}\frac{\int [E_F(T) - E]\delta\sigma(E)dE}{\int \delta\sigma(E)dE} \quad (3)$$

where E_F is the Fermi level and $\delta\sigma(E)$ the differential conductivity at energy E. This equation holds for both band and hopping transport. With the further assumption of unipolar charge carrier transport at one narrow transport level (E_T), Eq. (3) can be written as:

$$S(T) = \frac{E_F(T) - E_T}{eT} \quad (4)$$

The energy difference E_F(T)−E_T is correlated to the carrier concentration as well known [22]. The variation of about one order decrease of the carrier concentration will great increase the $E_F(T)$−E_T, and thus enhance the Seebeck coefficient according to Eq. (4). Similar tendency between the carrier concentration and thermoelectric properties, including the electrical conductivity and the Seebeck coefficient can also be observed in doped organic semiconductors [21].

In addition to the direct evidence of the carrier concentration influence on the electrical conductivity and Seebeck coefficient, here we further consider another phenomenon that might happen in the present AF doped system and affect these two parameters, σ and S. It has been reported that AF can substitute double bonds sites and cut off side groups with the presence of catalysts [19,23,24]. Thus, it is reasonable to consider that the double bonds on PEDOT will be partially damaged by AF. The conjugation length of PEDOT will thus be reduced and the lowered density of states of the conducting bands and valence bands lead to a wider band gap. Martin et al. have experimentally proven the correlation between the conjugation length and the band gap by analyzing UV–Vis spectra of samples with a precisely controlled conjugation length from one oligomer to six oligomers. They found that the UV–Vis absorption energy E_{abs} (eV) were found to be ruled by the following equation derived from Kuhn's electron gas model [25].

$$E_{abs} = V_0 + \left(\frac{h^2}{4mL_0^2} - \frac{V_0}{4}\right)\frac{1}{N + 0.5} \quad (5)$$

where V_0 is the amplitude which corrects the free electron gas model, h the Plank constant, m the mass of the electron, L_0 the unit length of the conjugation, and N the number of conjugated bonds. Since N is much larger than 0.5 in the present case, the absorption energy E_{abs} shows a linear relation with $1/N$. As a result, the blue shift of the UV–Vis peak should increase with the decreasing of conjugation length. The slight decrease of the Hall mobility of P10 as observed in Table 2 might also be correlated to the possible decrease of conjugation length. The UV–Vis spectra of the prepared films shown in Fig. 4 represent a large blue shift for the AF-doped PH 500, which provides reliable evidence of the widening of the band gaps. As previously discussed, the widened band gap should mainly originate from the great decrease of the carrier concentration of the AF doped films.

According to the definition of the power factor, either increased electrical conductivity or especially the Seebeck coefficient is of great importance to enhance the power factor. However, these two parameters generally cannot be increased simultaneously due to the inverse relation to the gap between E_T and E_F of the material, i.e., when the gap becomes wider, a higher Seebeck coefficient can be obtained, whereas a lower electrical conductivity will be presented. This trade-off has also been one of the major problems for all categories of thermoelectric materials. Although the electrical conductivity decreases by two orders of magnitude due to the doping of 10 wt.% AF (P10), the one order of magnitude increase in the Seebeck coefficient leads to an overall one order increase in the power factor, compared with the pristine PH 500. A similar tendency can also be found in the case of P5.

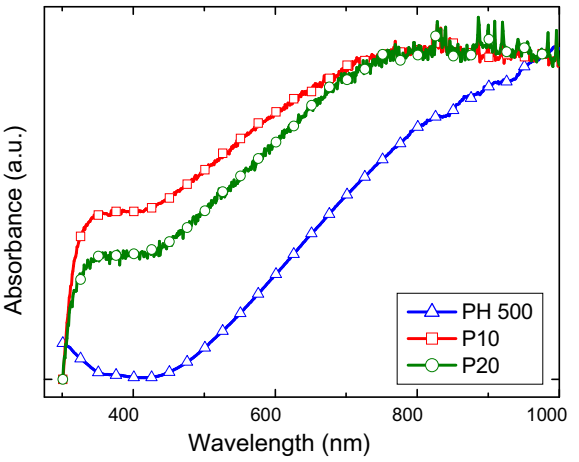

Fig. 4. The normalized UV–Vis absorption spectra of PH 500, P10, and P20.

In order to investigate the AF doping effect on the phonon scattering and to estimate the ZT value, the thermal conductivity of P10′ was measured near the room temperature. The obtained thermal conductivity of 0.18 W/mK is close to that of the PH 500 film with 5% DMSO (0.32 W/mK) [26] and PH 500 pellet with 10% DMSO (0.17 W/mK) [27] been reported. The estimated ZT value of P10′ would thus be 1.1×10^{-3} at room temperature. This result indicates that not only can electrical conductivity modification improve the ZT value, but TE behavior can also be enhanced by modifying the Seebeck coefficient to a comparative value regarding other works.

Another interesting phenomenon is observed that when the prepared AF doped film is stored at lower temperatures (~10 °C) in refrigerator for a period of time, the Seebeck coefficient increases with the storage time. For instance, the Seebeck coefficient of P10 rises from the initial 220 to 436.3 μV/K after 1 month storage. The solution was kept in a refrigerator at all times and only taken out for sample coating. The mechanism of this effect on especially the Seebeck coefficient is not clear so far.

4. Conclusion

In summary, we have successfully incorporated AF into Clevios PH 500 with various concentrations from 5 to 50 wt.% to form continuous films with distinct

thermoelectric properties and microstructures. With the increase of the AF doping, the Seebeck coefficient discernibly varied in a pretty wide range in which a maximum of 436.3 μV/K was found for 10 wt.% AF (P10′), i.e., ~40 times greater in magnitude, compared with 12.4 μV/K for pure PH 500. The greatly increased Seebeck coefficient, as well as the accompanying decreased electrical conductivity, probably originates from the reduction of the conjugation length of PEDOT by AF, as evidenced by the UV–Vis spectra. The best power factor obtained is 0.69 $\mu W/mK^2$, which is one order higher than that of pristine PH 500, but it is still lower than PH 500 blend with 5 wt.% DMSO, due to its lack of electrical conductivity. Nevertheless, this work provides a new procedure to increase the Seebeck coefficient of the polymer by simple blending, which has not previously been reported. In addition, AF also plays an important role in the formation of the closed or open pores and channels by thermal decomposing of AF, as can be seen in SEM images. These nano/micro-defects are considered to effectively scatter phonons and thus to further enhance the thermoelectric performance.

formation of a coffee ring along the initial contact line of the droplet which leads to a non-uniform morphology of the surface and a sparse active layer matrix [7]. This consequently leads to poorly performing solar cells since it prevents the escalating and elongating of P3HT crystals which are crucial for high efficiency, as proven by the improvements made by the thermal annealing process. Therefore, some research groups have tried new ways to avoid these inevitable problems. Green et al. reported spray deposited P3HT:PCBM films from various organic solvents with different boiling points [8]. Recently, Park et al. showed that the fabrication of sprayed solvent over-layer method gives highly efficient devices [9]. Furthermore, Susanna et al. presented high power conversion efficient solar cell by optimizing the parameters of the spray system, especially using a co-solvent mixture [10].

In this work, we specially investigate the film formation, surface topography and the morphology of active layer through additional solvent spray coating with various solvents, such as chlorobenzene (CB), chloroform (CF), ortho-dichlorobenzene (DCB) and ortho-dichlorobenzene/mesitylene (DCB/Mes). Furthermore, we studied the causes behind low fill factors (*FF*) and short circuit current-densities (J_{sc}) that occur in conventionally spray coated films. This additional solvent spraying immediately follows the active layer deposition by spray coating of mixed solution of P3HT:PCBM in CB that followed the spray coating of the electron-blocking layer of poly (3,4-ethylenedioxy thiophene):poly(styrene sulfonate) (PEDOT:PSS). We also investigated the combination of this additional solvent spraying process with post-annealing one so as to improve the phase separation of bulk heterojunction.

2. Experimental

We prepared thin films and solar cells based on a 1:0.8 mixture of P3HT (Rieke Metal) and (6, 6)-phenyl-PCBM (Nano C) dissolved in CB using both spray coating and spin-coating processes. Indium-tin-oxide (ITO) coated glass substrates (Geomatec, 5 Ω/cm^2) were first patterned by etching and then cleaned thoroughly with a sequence of solvents: detergent, deionized water, acetone and isopropanol, for 10 min each in an ultrasonic bath. The cleaned substrates were purified further by oxygen plasma treatment with oxygen for 10 min. The substrates were then spin coated with a 0.45 μm filtered PEDOT:PSS solution (Clevios P), purchased from HC Starck, at 4000 rpm for 60 s to produce a 40 nm thick layer. The substrates were subsequently heated on a hotplate in air at 200 °C for 10 min to remove excess water. The active layer containing a mixture of P3HT and PCBM was prepared with a concentration of 22.5 mg/ml stirred in ultrasonic cleaner at 50 °C for 2 h. Then, for the spray coating process, the airbrush was powered by N_2 gas at 70 psi, a relatively low pressure that ensures fine atomization and prevents blowing off the droplets already deposited on the substrate. The distance of the airbrush from the substrate was 10 cm. For the additional spray coating, pristine CB, CF, DCB and DCB/Mes were sprayed onto the active layers for 1 min at a rate of about 100 μl/min. The wet solvent on the active layer was evaporated for about 5 s. Additional control of the deposition conditions was achieved by varying the solution flux and the speed of the airbrush relative to the substrate.

Thermal annealing was performed at 150 °C in a glove box. Then after titanium tetraisopropoxide in ethanol (10 μl/3 ml) was spin coated at 4000 rpm as precursor of TiO_x layer, it was left at room temperature for 20 min to hydrolyze and form TiO_x. Aluminum (100 nm) top electrodes were deposited by thermal evaporation in ultra-high vacuum 5×10^{-3} Pa. The photovoltaic characteristics were measured under nitrogen atmosphere using an Agilent 4156C parameter analyzer under AM1.5G (100 mW/cm^2) simulated illumination using a solar simulator with a 1000 W Xenon arc lamp.

UV–visible absorption spectra were obtained using a Shimadzu UV-1601PC UV–visible spectrophotometer. Thin polymer films were deposited onto previously cleaned quartz slides with the same settings used for the production of solar cells.

The two-dimensional local characteristics of OSCs were obtained by laser beam induced current (LBIC), which was uniquely equipped to produce quantitative maps of local quantum efficiency with relative ease. To investigate the effect of the additional solvent sprayed on the morphology of the active layer, X-ray diffraction (XRD) and surface profiler were used. The morphology of the active layer was observed by transmission electron microscopy (TEM) (JEOL, 2000FX).

3. Results and discussion

The device performance of spray coated films was investigated based on the common device configuration: glass-ITO/PEDOT:PSS/P3HT-PCBM/additional pure solvent/TiO_x/Al. Because single droplets are deposited by the nitrogen gas pressure on the substrate, the surface of the active layer is more irregular compared to the film of spin-coated devices. The film is formed by the spreading of droplets and the combining of adjacent droplets with the vaporization of the organic solvents. The film morphology is not only affected by the characteristic of solution such as vapor pressure, boiling point, surface tension but also the flux of the droplets and ambient condition. If the droplets are not sprayed at a high solution flow rate or a solvent with very low vapor pressure is not used, the independent droplets are accumulated rather than interconnected with each other.

The images of surface profiler after additionally spray coating various solvents are presented in Fig. 1. Due to residues and pinholes, the scale bar of Fig. 1(b) and (c) range widely from 1 μm to 2 μm. The surface profile of both however indicates that there is no remarkable change in the film when compared to the film in Fig. 1(a). However, the surface topography of Fig. 1(d) and (e) indicates significant differences in the film formation. The second spray deposition redissolves the sprayed active layer and some dissolved droplets merge to form a larger one more easily. The difference in the surface film forming dynamics is attributed to low vapor pressure of DCB. In case we spray excess quantity of DCB solvent, all droplets are redissolved

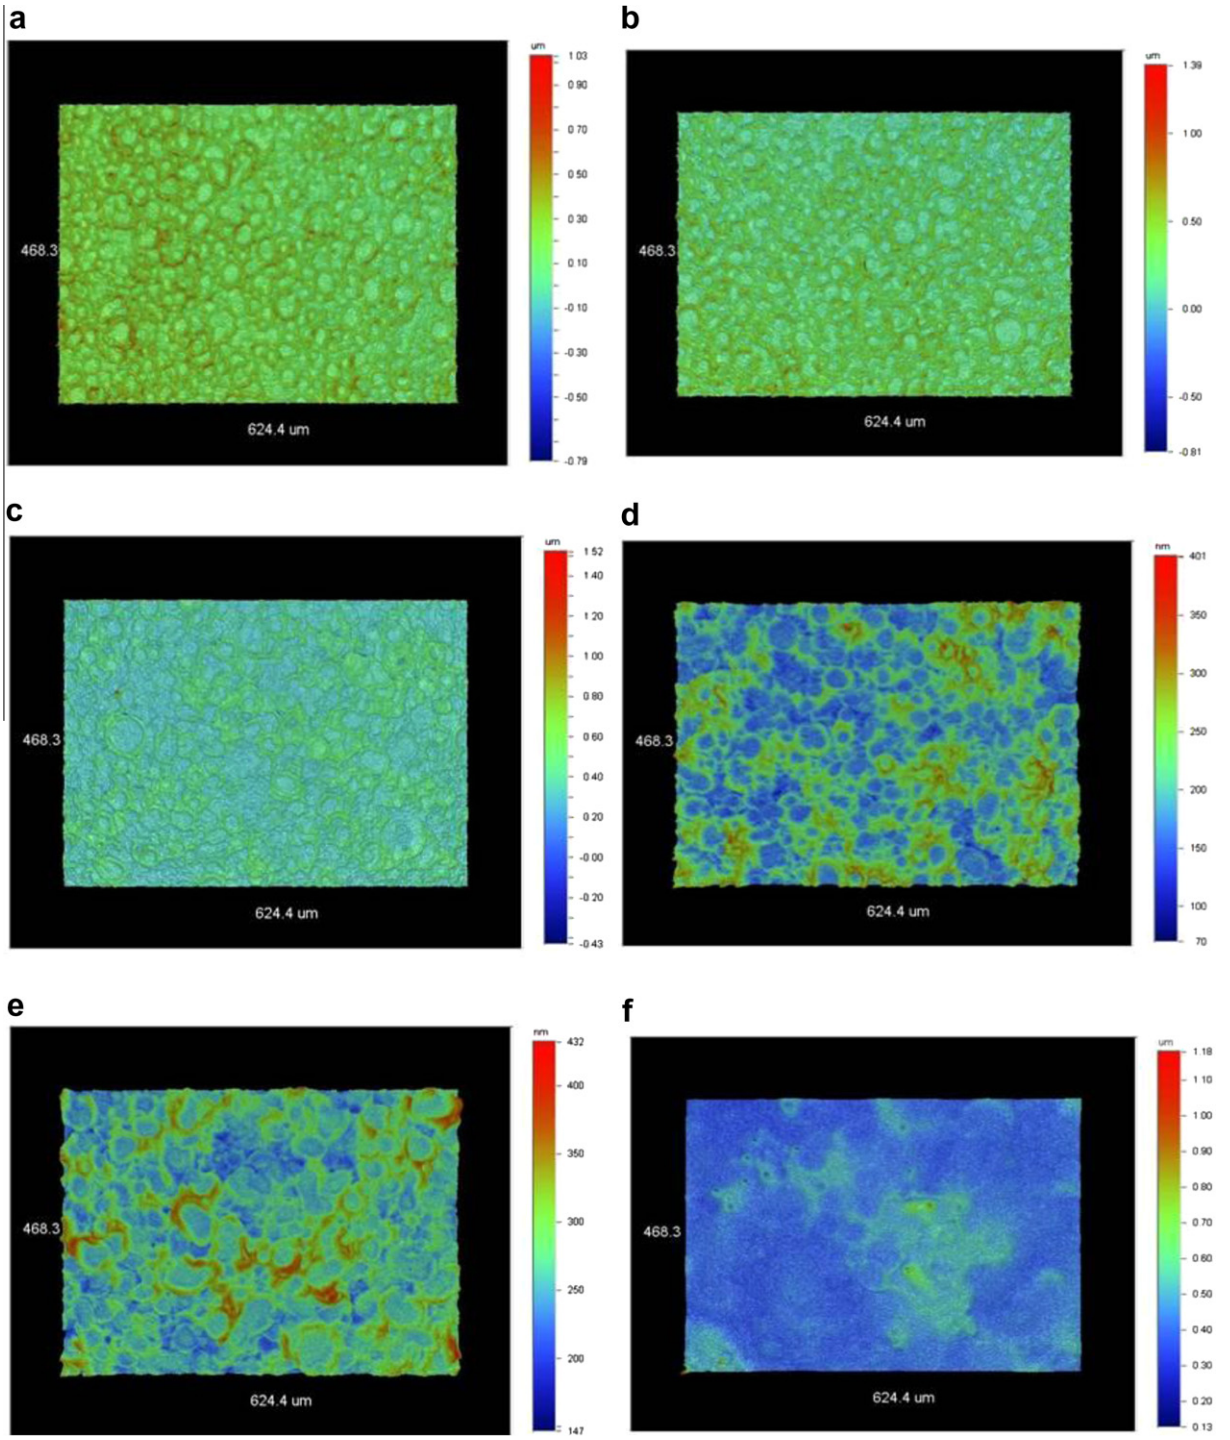

Fig. 1. Surface profiles representing the surface topographies of glass-ITO/PEDOT:PSS/P3HT-PCBM/additional solvent coating. Each device was fabricated by (a) without any solvent (b) CB (c) CF (d) DCB/Mes (e) DCB (F) excess DCB. Note that the scale bars of the color indexes for each deivce were different one another.

and form three distinct regions; partly undissolved region, entirely dissolved region and residue region. If we can select the photoactive area to examine the efficiency, we would expect that the performance is higher than the spin coated one occasionally (see Table 1), taking into account the solvent annealing effect and good roughness. However, excess solvent coated device is not reproducible and compatible for large area cell.

Nanomorphological change achieved by additional solvent spray was reflected in the performance enhancement

in characteristic properties of OSCs as summarized in Table 1. The device fabricated from additionally sprayed with CB has V_{oc} = 0.57, J_{sc} = 5.13 mA/cm^2, FF = 0.51 and E_{ff} = 1.51%. Notably, the J–V characteristic of the device sprayed with DCB (V_{oc} = 0.58, J_{sc} = 6.67 mA/cm^2, FF = 0.50 and E_{ff} = 1.95%) are similar to the performance of spin coated devices in air. The value of RMS and thickness of active layer represent that CB and CF solvent just add up, whereas DCB and DCB/Mes solvent dissolve and reconstruct the previous layer.

Based on this result, we selected DCB solvent for additional solvent spray and continue to investigate the change of morphology in four cases, (a) CB solution of P3HT-PCBM spray coating (ref.) (b) ref./annealed (c) ref./DCB solvent spraying (d) ref./DCB solvent spraying/annealed, as shown in Fig. 2. Comparing Fig. 2(a) and (c), it is evident that the numerous pinholes and the thick edge of the droplet partially disappear after the additional solvent spraying. This can be due to the dissolution and interconnection of isolated active layer droplets in the presence of DCB droplets. This is confirmed by the significant reduction of the surface roughness in rms of the devices in Fig. 2(a) and (c), which have values of 68.22 nm and 34.84 nm, respectively. However, it can be said that the morphology of surface in micrometer scale does not seem to be affected by thermal annealing at 150 °C as there are no remarkable change between Fig. 2(a)–(d). The computed surface roughness in rms only differs slightly between pre- and post-annealing for conventionally sprayed (68.2 nm and 63.4 nm, respectively) and additionally solvent sprayed (34.8 nm and 28.8 nm, respectively) devices. Therefore, we suggest that the ridge-like features remain in surface unless physical change such as melting occurs in the

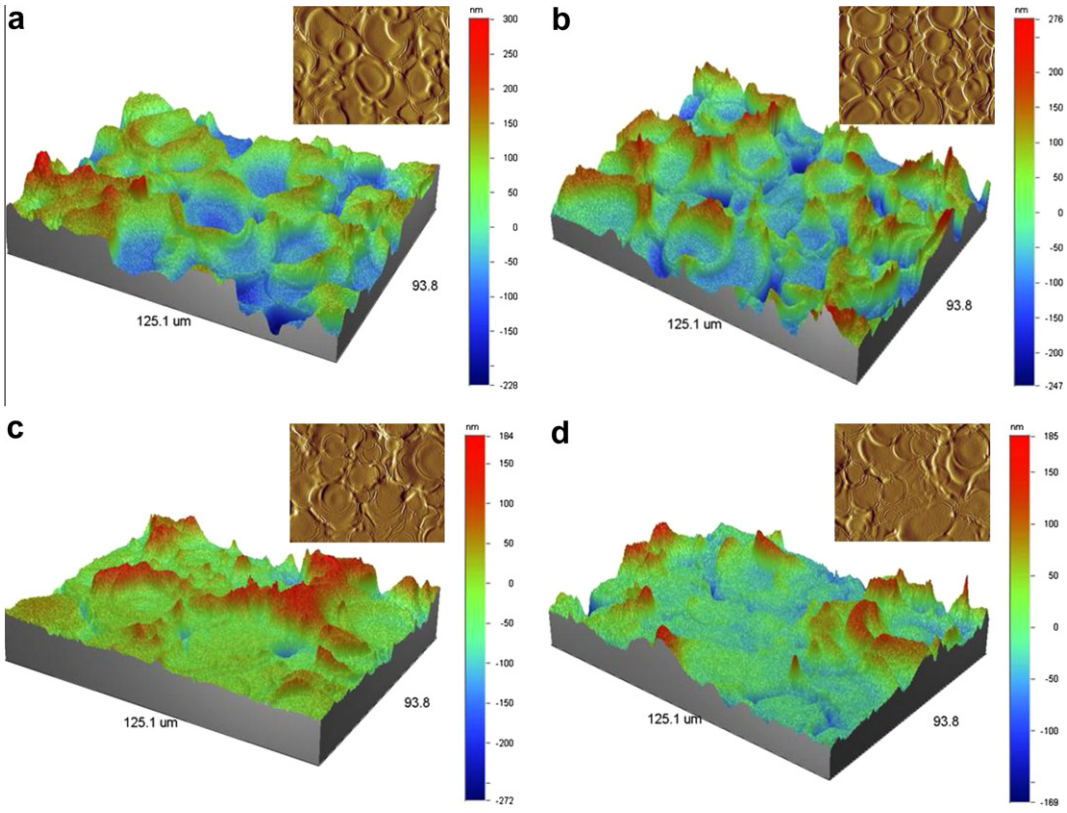

Fig. 2. Surface profiles representing the surface topographies of glass-ITO/PEDOT:PSS/P3HT-PCBM/solvent coating with or without annealing. boundary. Nevertheless, it was reported that a high surface roughness does not really connote poor device performance for spray coating [11]. However when the surface roughness also reflects the distribution and physical change of the droplets inside the layer as above, the measured rms of the surface is a good criterion for estimating the final device performance.

The images of LBIC also show distinctively spatial and non-uniform distribution of droplets in conventional spray coated device. The image of Fig. 3(a) proves that pinholes are largely present on the surface of the conventionally sprayed device and was distributed over a large area, as indicated by the irregular and yellowish color. As for the device with additional solvent spraying in Fig. 3(b), a more homogenous red coloring is observed, which indicates higher current density generated in the light. The dark red color in Fig. 3(b) is consistent with better result of the *J–V* characteristic curves, as mentioned below.

When the nanoscale morphology of the active layer is examined by TEM, in Fig. 4(a) the film of the conventionally sprayed device shows aggregation made of sparse dots. This is largely due to atomized droplets from the nozzle during the spray coating process that have relatively lower opportunities to form donor–acceptor domains compared to droplets in a successive coating method such as spin coating. The insufficient donor–acceptor interpenetrating networks formed in spray coating cannot efficiently induce charge separation and transport. Moreover, though phase separation has occurred in thermal annealing, the effect of heat treatment would be restricted because the droplet is physically isolated each other, as shown in Fig. 4(b). However, the film with the additionally sprayed DCB exhibits a different morphology, as shown in Fig. 4(c). White, hair-like nanofibers increase conspicuously so that the total image becomes blurred. This morphological characteristic is more pronounced, that is, light and darkness is more contrasted as phase separation is accelerated, after thermal annealing (see Fig. 4(d)).

To find out how the additional sprayed solvent works for enhancing the crystallization of P3HT, we examined the XRD pattern of each device in Fig. 5(a). The effect of the rate of spray coating to P3HT crystallization was also studied in Fig. 5(b). Usually, the rate of spray coating is controlled by the carrier gas pressure. For the slow spraying process used for the construction of the devices in Fig. 5(b), the rate is that of the conventional spray method, wherein the carrier gas pressure is 70 psi. This carrier gas pressure is the minimum that can be used such that spray coating could still be done in this experiment. Meanwhile, the use of the fast spray coating rate (300 psi) kept the P3HT:PCBM layer wet and slowed down the drying time brought a similar effect of solvent annealing [4]. This may be the cause why the crystallite size of P3HT for fast sprayed device is larger as compared to the slow sprayed device, as shown in Fig. 5(b). Interestingly, the additional solvent sprayed device in Fig. 5(a) has a comparable high peak to the fast sprayed one. This indicates that the additional solvent spray process could also induce the solvent annealing effect. The difference however between the fast spraying and the additional solvent spraying is that with the additional spray coating process, elimination of most of the pinholes and thick edges of the active layer is also possible due to the dissolution (viz. dissolving) of the previously sprayed droplets. Moreover, the thickness and roughness of the active layer is more reproducible and easier to control through the additional spray coating process. The normalized XRD pattern shows the effect of the additional solvent coating at the peak of P3HT crystalline with diffraction angle at $2\theta = 5.6°$, which corresponds to (100) packing. As shown in Fig. 5(a) devices with additional solvent sprayed shows sharp and intensive peak at $2\theta = 5.6°$, while the conventional device exhibits a relatively broader and lower peak. Although we can expect that the fast sprayed device has higher efficiency, the practical application to the fabrication of commercial devices would be difficult because of low reproducibility and tough handling. Therefore, additional solvent coating in conjunction with slow-speed spray coating fabrication can be a good alternative. Since this method promotes the reduction of unavoidable disadvantages in the spray coating process by prolonging the drying time and promoting the reorganization of the matrix in the P3HT:PCBM layer. This is con-

firmed by the measured crystallite size as summarized in Table 2. The mean size of the polymer crystallite, L, was estimated from Bragg's law and Scherrer's relation [12]. The crystallite size of P3HT in a conventionally spray coated device changed from 7.92 nm to 11.37 nm after thermal annealing. On the other hand, the crystallite size has almost doubled, L = 14.67 nm, after the additional solvent spray process. The enhancement probably result from the reorganizing P3HT:PCBM matrix with the long drying process.

On the basis of the result above, we can predict a structural change upon additional solvent spraying and thermal annealing in this experiment. Upon thermal annealing, the V_{oc} was found to decrease, while both the J_{sc} and the FF increased significantly. This phenomenon is attributed mainly to an enhancement of the charge-carrier transport, by a larger hole mobility, a reduced dispersivity, and a reduced recombination kinetics [13–16]. X-ray investigations allowed the development of a microscopic picture of the annealing process, as depicted in Fig. 6. This macroscopic representation of the active layer before and after the spray coating and annealing process was developed from the spin-coating model presented in Ref. [12]. Several detailed morphological studies revealed that the organization of the P3HT:PCBM is modified upon annealing [13,17,18], with fibrillar-like P3HT crystals embedded in a matrix believed to comprise mostly of PCBM nanocrystals and amorphous P3HT[12]. Fig. 6(a) and (b) illustrates the process of a typical enhancement of the external quantum efficiency (EQE) upon thermal annealing in a conventional device. However, we can forecast that the morphological limitation in a spray coated active layer like isolated droplets holds back reorganization of the P3HT:PCBM and eventually blocks the enhancement upon thermal annealing in Fig. 6(b). This is because of the coffee ring effect [7] wherein a thick boundary effectively binds every droplet tightly. When additional solvent droplets with low vapor pressure such as DCB are sprayed on an active layer, the solvent enter into the space of previously deposited droplets, as shown in Fig. 6(c). Upon contact, the solvent droplets immediately dissolve the dried droplets and the thick boundary, filling up the gap between them. Then, two droplets start to connect to form a larger droplet. The repetitive recombination of droplets allows for the formation of semi-crystalline lamellar morphologies with higher order architectures. That is, by taking the additional solvent spray coating process, solvent annealing effect can be obtained by controlling the total time of spraying and flow rate of sprayed droplets. In addition, this

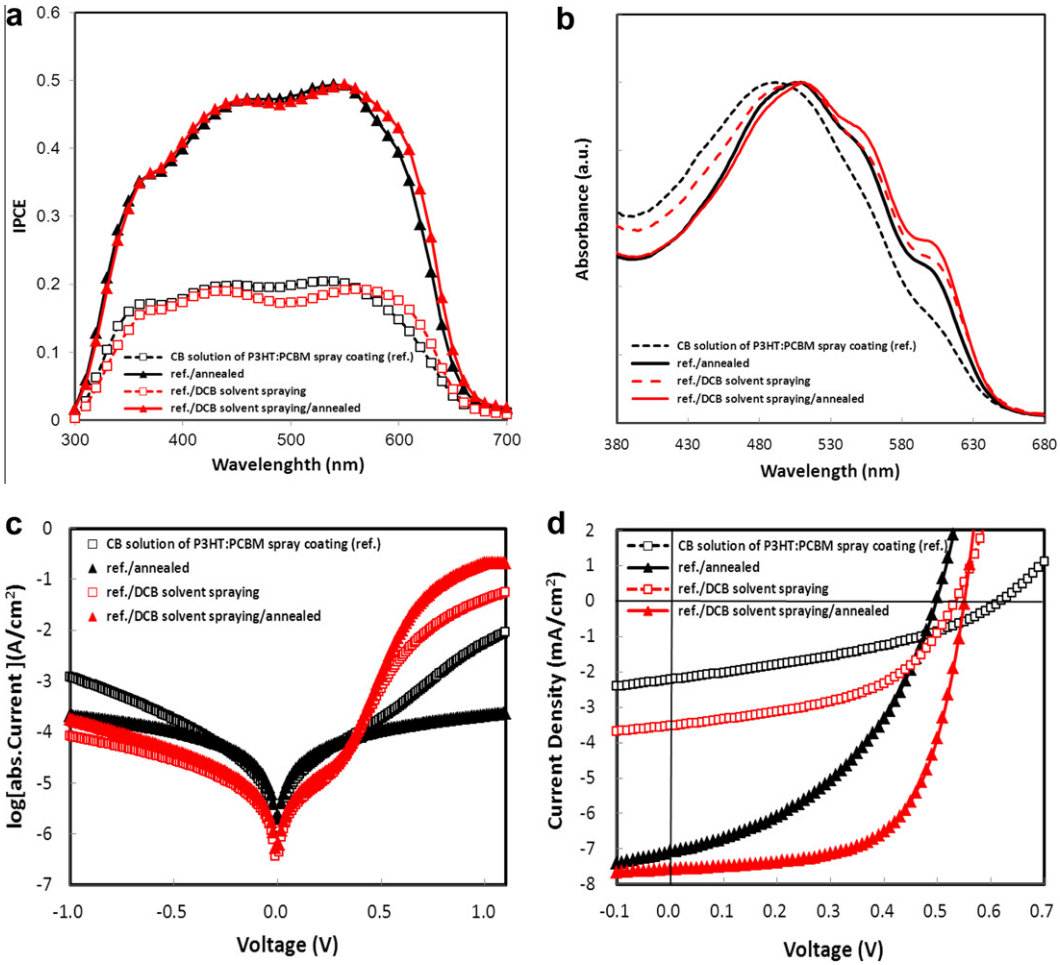

Fig. 7. (a) the corresponding *IPCE* spectra (b) UV–vis spectra (c) dark current (d) *J–V* curve of OSCs of glass-ITO/PEDOT:PSS/P3HT-PCBM/solvent spray coating with or without annealing/TiO_x/Al (100 mW/cm^2, AM 1.5G) fabricated by the spray coating.

solvent annealing effect provides well-developed morphology to maximize the effect of thermal annealing, such that PCBM nanocrystals and amorphous P3HT have a higher chance to connect and reorganize in a matrix. In the cases that the amount of additional solvent and spray time is not sufficient, the boundary between droplets is not perfectly dissolved, as depicted in Fig. 6(c) and (d).

Fig. 7(a) shows characteristics of the incident photon-to-current efficiency (IPCE) curves, for devices with additional solvent spraying. It is found that devices with additional solvent spraying has the maximum IPCE at 560 nm, broader peak above 600 nm wavelength compared to an untreated one. It is interesting that the current density calculated by the integration of the IPCE graph is not much different between the device with and without the additional solvent spraying, despite the considerable difference in efficiency, as shown in Fig. 7(d). The IPCE result indicates that the majority of enhancement of efficiency results from charge-carrier transport and the balance between hole and electron mobility. The effect of additional solvent spraying on P3HT:PCBM layer is also observed in the obtained UV–vis spectra, as shown in Fig. 7(b). For P3HT:PCBM films, the solvent annealed films have the most prominent vibronic features, indicating strong interchain–interlayer interactions among the P3HT chains as well as good polymer ordering in the blend films [19–22]. The quick removal of the solvent like in spray coating favors a uniform P3HT:PCBM distribution and prevents the formation of highly ordered lamella by disrupting the interchain interactions between P3HT chains. Since the thickness of each active layer was controlled to be the same at 230 nm, the characteristically vibronic absorption shoulder at 600 nm originates from the enhancement of crystallinity of P3HT. The vibronic shoulder of the additionally solvent sprayed active layer, without thermal annealing, shows a peak similar to that of a conventional device with thermal annealing. It means that the additional solvent spraying contribute to enhancement of crystallinity. It is also assumed that the additional solvent coating induces improvement of photovoltaic characteristic somewhat, although it is not as remarkable as thermal annealing.

The notable result of additional solvent spraying process is revealed in the *J–V* characteristic curves as shown in Fig. 7(d). It shows the optimal device performance is obtained upon annealing at 150 °C for 30 min, with 3.06% power conversion efficiency (PCE), which is twice the PCE

of a conventionally sprayed device (1.49%). The main reason for the higher PCE of the additional solvent spray coated OSC is slightly increased V_{oc} and higher *FF*. Although the factors affecting *FF* have not been completely identified yet, it has generally been accepted that *FF* is derived from the morphology of the active layer, charge-carrier transport, the balance between hole and electron mobility, and the interface of layers in OSC [23]. The particular distinguishable feature is that the shunt resistance (R_{sh}) increases after the additional solvent spraying, as shown in Fig. 7(c). Considering that the R_{sh} depends on the internal condition of layer, we can expect that the additional solvent spraying induce improvement of the morphology of active layer by delaying drying time while solvent droplets penetrate into previous droplets of active layer and allow for redissolution and diffusion.

4. Conclusions

We have investigated the film formation, surface topography and the morphology of active layer of OSCs through spray coating with various additional solvent. Since the additional solvent spraying process, especially with DCB, is accompanied by a slow drying process and the reorganization of the P3HT:PCBM matrix, it effectively induces a larger crystallite of P3HT and helps overcome the non-uniform morphology of the matrix. All of the morphological changes in a P3HT:PCBM system after this process and subsequent thermal annealing resulted in improvement of photon absorption, better exciton dissociation, and more efficient and balanced transportation of free charges to the electrodes, reflected in higher values of *FF* and J_{sc}. All of this therefore corresponds to better overall efficiencies for corresponding solar cell devices. The additional spray coating of DCB solvent resulted in the doubling of the performance, compared to conventionally sprayed devices. In conclusion, this additional solvent spraying is promising as an auxiliary method to overcome some inevitable hindrances of spray coating. In addition, this simple method can be applied to other coating method such as an inkjet printing, which has relatively similar surface and morphology.

is in contact with the OLED device. Moreover, such a material should be capable of absorbing gas emitting from the OLED device or moisture diffusing into the device from the outside. In our previous study [14], we filled a thermally conductive epoxy resin in a glass cover. However, it can not absorb oxygen or moisture because no moisture getter material is involved. The typical getter materials include zeolite tablet or powder, an oxide (BaO, CaO), or a reactive metal (such as Ba and its alloys with other metals such as Al) [15]. CaCO3 particles were calcinated into highly crystalline calcium oxide (CaO) nanoparticles, which are used as active materials for water absorption [15]. Fine zirconium powders were used as the active materials in a porous zirconium–graphite getter (named as SAES Getters), which is not for oxygen but for hydrogen sorption [16]. Those getters are not readily filled into the glass cap. Recently, SAES Getters Co., Ltd., developed a liquid getter (AqvaDry), which is UV- or thermally curable. Such a liquid getter can be easily filled into the glass cap. Moreover, it is highly transparent once it is UV-cured. In this paper, we investigate the thermal and barrier properties of the moisture getter-filled encapsulations for OLEDs. It is demonstrated that the heat dissipation capability of the moisture getter-filled encapsulation is degraded due to a bad contact between the OLED device and the heat transferring getter. However, it is enhanced by coating the liquid getter on a flat glass cover and sealing the OLED device with it. Though the thermal property is enhanced with this scheme, yet its barrier property is degraded. We demonstrate that both thermal and barrier properties can be enhanced by simply increasing the thickness of an Al cathode in the presence of buffer layers.

2. Experiments

For experiments, we purchased UV-curable liquid getter (AqvaDry ODF-U) from SAES Getters Co., Ltd. The UV-cured 50-μm-thick moisture-getter film shows the optical transmittance more than 95% within the visible wavelength range and the refractive index of 1.493. The moisture capacity of 350-μm-thick getter film with the area of 1.5 cm × 1.5 cm is 2.42 mg, which is almost equivalent to that of a commercial DYNIC getter [17]. It discharges moisture over 200 °C, indicating that it does not discharge again under normal operating conditions of OLEDs. The liquid getter was coated on cover glasses using a bar-coater (YBA baker applicator, YOSIMITSU, JAPAN). The coated liquid-getter films were UV-cured for 30–60 s under 60 mW/cm^2 UV power. To eliminate remaining gas, we carried out a thermal annealing on a hot plate at 90 °C for 1 h. We fabricated phosphorescent green OLED devices that consist of a 150-nm-thick indium–tin-oxide (ITO) for anode, 10-nm-thick LG-101 for a hole injection layer (HIL), 25-nm-thick 4,40-bis[*N*-(1-nathyl)-*N*-phenylamino] biphenyl (NPB) for a hole transport layer (HTL), 25-nm-thick 4,4′-*N*,*N*′-dicarbazolylbiphenyl (CBP) doped with tris(2-phenylpyridinate) iridium(III) (Ir(ppy)$_3$, 8 wt.%) for an emitting layer (EML), 10-nm-thick *m*-bis-(triphenylsilyl) benzene (UGH3) for a hole/exciton blocking layer (HBL), 30-nm-thick LG-201 doped with lithium quinolate (LiQ, 50 wt.%) for an electron transport layer (ETL), and 150-nm-thick aluminum (Al) for cathode. The emission area of OLED is 4 mm^2. To seal OLEDs, an epoxy resin (XNR 5570-B1, Nagase ChemteX Corp.) is dispensed on the edge sides of the glass cover and cured using a UV lamp (Ultra violet cure M/C, SEI MYUNG VACTRON). The epoxy resin exhibits the moisture permeability of 18 g/m^2·day at 60 °C and 90% relative humidity and the glass transition temperature of 144 °C. We attached a Polynetwork flexible heat sink (PN-FHB050 N) [18] in the form of bonding sheet to the outer surface of the glass cover. It consists of a 50-μm-thick copper sheet and 35-μm-thick thermal radiation layer. The bonding sheet has the thermal conductivity of 0.86 W/m-K. All encapsulation process was carried out in a glove box below 10 ppm H_2O.

As a glass cover, we have used two different types of glasses. One is a hollow glass cover and the other one is a flat glass cover. The liquid getter is filled in the hollow glass cover (Fig. 1(b)), whereas it is coated on the flat glass cover (Fig. 1(c)). For comparison, we have used those hollow glass covers that are different in depth (100 and 350 μm). Namely, the 0.7-mm-thick glass cover is hollowed out so that its thickness becomes 100 or 350 μm and thus the moisture getter can be filled therein. In this paper, an OLED device based on this method is referred to as a getter-filled hollow glass-encapsulated OLED (GFHG-OLED). The liquid getter filled in the hollow glass cover is shrunk during the UV-curing process, possibly leaving a nitrogen gas-filled gap and thus blocking off the heat transfer. It is avoidable by coating and UV-curing the liquid getter on the flat glass cover. We have also employed those flat glass covers that are different in thickness (0.2 and 0.7 mm). An OLED device based on this scheme is

referred to as a getter-coated flat glass-encapsulated OLED (GCFG-OLED). Just in case that the moisture getter may cause damage to the organic layers, we have inserted a buffer layer that consists of a 40-nm-thick NPB and 50-nm-thick lithium fluoride (LiF) in both devices.

3. Results and discussions

We have first investigated the optical transmittance of moisture getter-filled glass encapsulations for different time slots. To this end, the glass substrate without OLED device involved was encapsulated with the 100-μm-thick hollow glass cover where the moisture getter is filled. We carried out a stress testing of the samples at 85 °C and 85% relative humidity. During the stress testing, we took out the samples from a thermo-hygrostat and measured their transmittance using UV/Vis spectrometer (PG Instrument Ltd.) with glass as the reference. The initial transmittance of the 100-μm-thick moisture getter-filled encapsulation was measured to be 95% at 520 nm. It is observed from Fig. 2 that the initial transmittance decreased gradually with time. As the moisture getter absorbs oxygen or moisture, its color is changed to white and thus its transmittance is decreased. Because there is no out-gassing involved in this case, such a reduction in transmittance arises mainly from oxygen or moisture diffusing through the epoxy seal over time.

As a reference device, we fabricated an OLED device based on the conventional glass encapsulation where a moisture getter sheet (DYNIC Corp.) was inserted. We measured the surface temperature distribution of the device with and without the heat sink and presented the results in Fig. 3(a and b). Shown in Fig. 3(c) is the transient variation of the maximum surface temperature measured at 8 V. It is observed that heat is dissipated only by 7.7 °C (60.2 → 52.5 °C) with the heat sink. Such a small reduction in the surface temperature even in the presence of the heat sink is attributed to the fact that remaining nitrogen gas

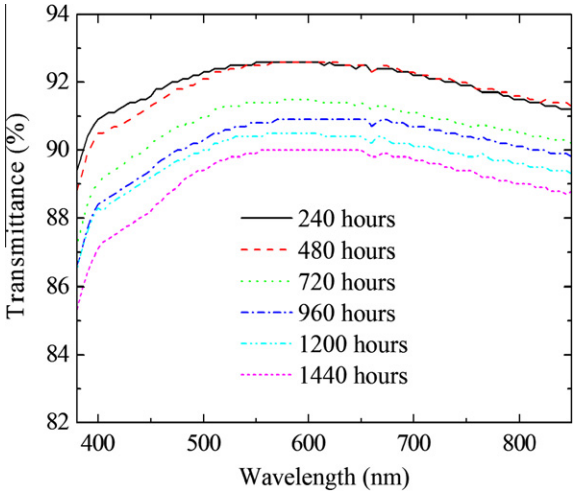

Fig. 2. Measured transmittance of 100-μm-thick moisture getter-filled glass encapsulation for different time slots at 85 °C and 85% relative humidity.

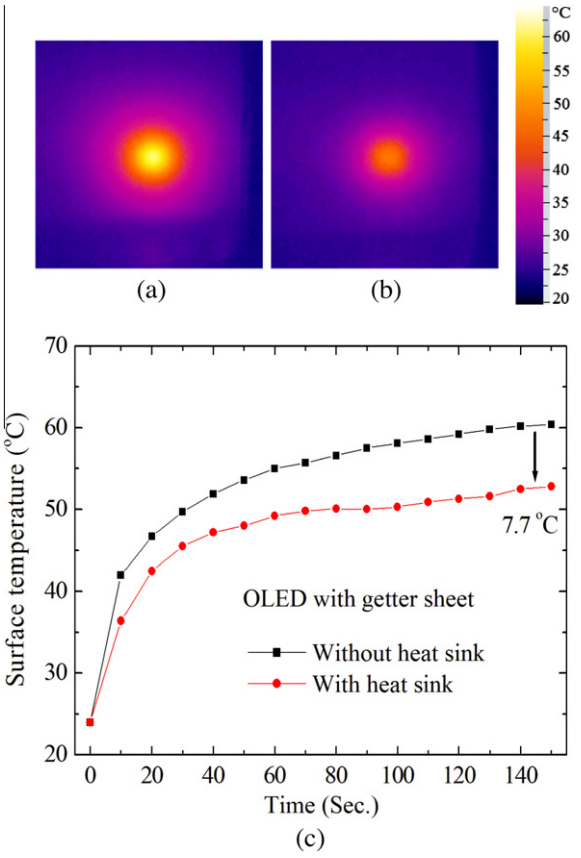

Fig. 3. Surface temperature distribution over the conventional glass-encapsulated OLED (a) without and (b) with heat sink, and (c) transient variation of the maximum surface temperature measured at 8 V.

blocks off the heat transfer from the OLED device to the heat sink because nitrogen gas has the thermal conductivity of 0.024 W/m K [19], which is much lower than that (≈1.0 W/m K) of glass.

With attempt to dissipate heat more effectively, we fabricated GFHG-OLEDs and measured their thermal property as presented in Fig. 4. Using the 350-μm-thick hollow glass cover, however, the maximum surface temperature is reduced only by 10 °C (from 60 to 50 °C) with the heat sink. Although the maximum surface temperature is reduced further (62.3 → 46.8 °C) using a thinner (100-μm-thick) hollow glass cover, such a small reduction in heat is unexpected because the thermal conductivity of UV-cured getter is close to 0.1–0.3 W/m·K, which is much higher than that of nitrogen gas. It is most likely that there still exists a nitrogen gas-filled gap between the OLED device and the moisture getter, which is induced by the shrinkage of the liquid getter during the UV-curing process. Therefore, such a gas-filled gap is unavoidable using a hollow glass cover.

To eliminate the gas-filled gap completely, we employed a flat glass cover where the liquid getter is bar-coated. With this scheme, we fabricated GCFG-OLEDs and measured their thermal property as presented in Fig. 5. It is clearly seen even with the naked eye (Fig. 5(a and b))

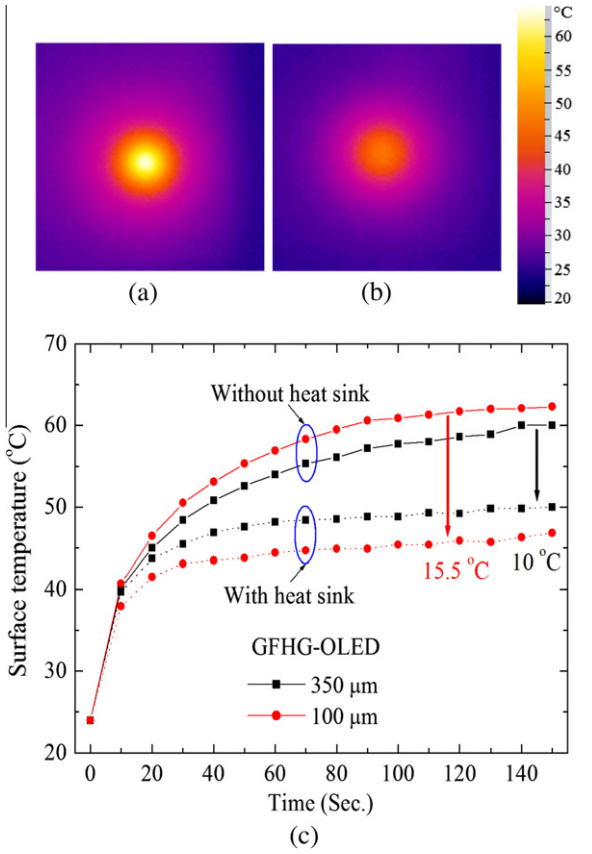

Fig. 4. Surface temperature distribution over the 100-μm-thick GFHG-OLED (a) without and (b) with heat sink, and (c) transient variation of the maximum surface temperature measured at 8 V for different thicknesses of hollow glass.

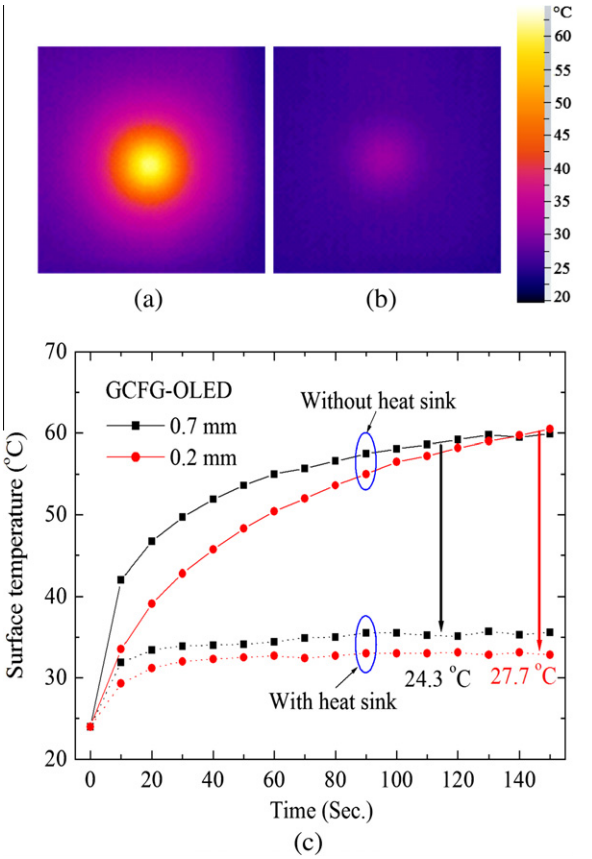

Fig. 5. Surface temperature distribution over the 0.2-mm-thick GCFG-OLED (a) without and (b) with heat sink, and (c) transient variation of the maximum surface temperature measured at 8 V for different thicknesses of flat glass.

that heat is dissipated to a great extent. The maximum surface temperature is reduced by 24.3 °C (from 59.9 to 35.6 °C) with the 0.7-mm-thick flat glass cover, while reduced further by 27.7 °C (from 60.5 to 32.8 °C) with the 0.2-mm-thick flat glass cover. Comparing with the results in Fig. 4, the surface temperature is reduced more than 10 °C. This result indicates that a contact at the interface between the organic device and the moisture getter is excellent and consequently heat is dissipated effectively through the thermally conductive moisture getter.

To investigate the gas diffusion barrier property of those getter-filled glass encapsulations, we measured the luminance variation of those devices over time at 85 °C and 85% relative humidity and presented the results in Fig. 6. The initial luminance of the devices was 1500 cd/m^2. It is evident that GCFG-OLEDs show poorer gas diffusion barrier, compared with GFHG-OLEDs. Although a removal of gas-filled gap enhances the heat dissipation in GCFG-OLEDs, it seems that a direct contact of the moisture getter with the OLED device causes damage to the organic layers even in the presence of the buffer layer. This was confirmed by the emission images measured by microscope (ECLIPSE L300, NIKON) in Table 1. Once oxygen or moisture diffuses into the OLED device, there appear dark spots that are non-emissive area. Those dark spots are extended over

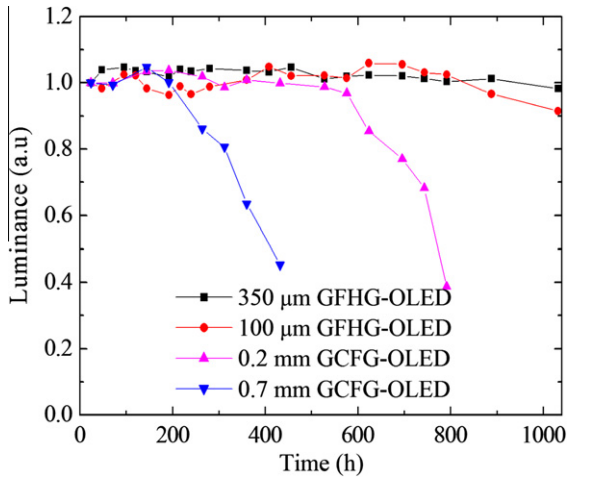

Fig. 6. Luminance of those OLED devices as a function of time under conditions of 85 °C and 85% relative humidity.

time and thus shorten the device lifetime. As evident in Table 1, the dark spots are extended much earlier in GCFG-OLEDs than in GFHG-OLEDs. In GCFG-OLEDs, the moisture

getter absorbs out-gases from the OLED device or moisture diffused from the outside. However, the organic device is damaged once the moisture getter absorbs them because the moisture-absorbed getter is in directly contact with the organic layer. Otherwise, the dark spots would be expanded as slowly as in GFHG-OLEDs. Moreover, the boundary between the dispensed epoxy resin and the coated moisture getter on the flat glass cover is not clear. If the moisture getter is located close to the epoxy resin as depicted in Fig. 1(c), there arises some damage to the getter during the epoxy dispensing and UV-curing process. Namely, the UV-cured getter reacts with the moist epoxy to produce oxidative degradation, which obviously speeds up an expansion of dark spots, especially near the edge sides of the glass cap in GCFG-OLEDs [see Table 1]. Meanwhile, the conventional glass encapsulation shows the best gas barrier performance because a DYNIC getter sheet inserted into the hollow glass cover stays away from the epoxy resin and no direct contact with the organic layers is involved.

To reduce damage to the moisture getter by the epoxy resin, we left a little space (3 mm) between them. In this case, care is taken to ensure that the moisture getter area is larger than the organic light-emitting area. We also increased the thickness of the Al cathode to enhance the passivation effect or rather reduce damage induced by the direct contact between the moisture getter and the organic device. It is known that the Al cathode also works as a passivation layer since it covers the organic light-emitting layers. As such, the passivation effect is expected to be

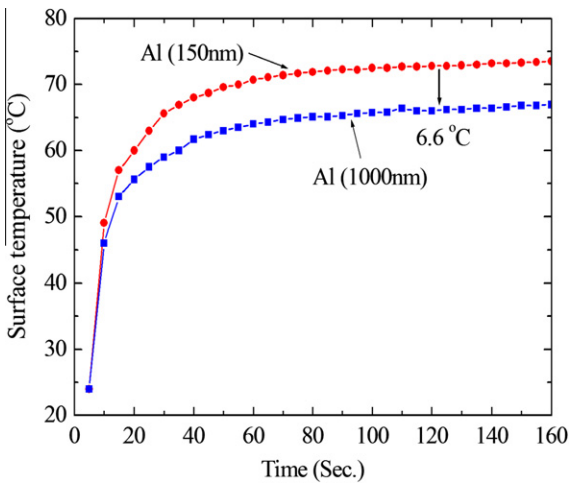

Fig. 7. Transient variation of the maximum surface temperature of conventional glass-encapsulated OLEDs with heat sink for different Al thicknesses.

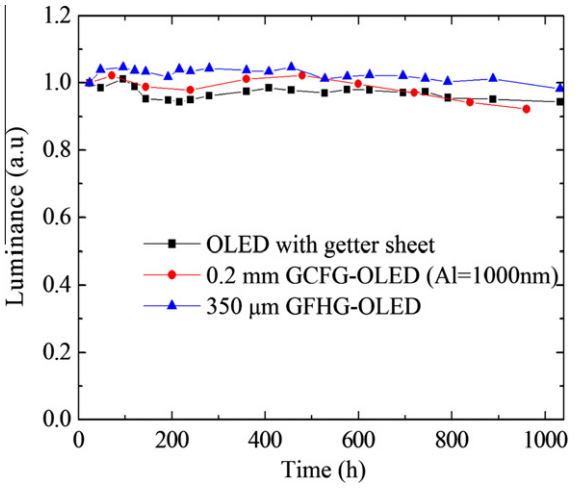

Fig. 8. Luminance of OLED devices as a function of time under conditions of 85 °C and 85% relative humidity.

enhanced by simply increasing the thickness of the Al cathode. This scheme also reduces the surface temperature because heat is dissipated horizontally through the thick Al metal. To verify it, we increased the thickness of the Al cathode from 150 to 1000 nm for the conventional glass-encapsulated OLEDs and measured their surface temperature. As evident in Fig. 7, the maximum surface temperature is reduced by 6.6 °C (from 73.5 to 66.9 °C), which is induced obviously by the thick Al cathode. Considering these, we fabricated GCFG-OLEDs and measured the luminance variation with time at 85 °C and 85% relative humidity. The initial luminance of each device was the same as that (1500 cd/m^2) in Fig. 6. As evident in Fig. 8, the operating lifetime of the GCFG-OLED is much enhanced, which is even comparable with the conventional glass-encapsulated OLED. The increased operational lifetime of GCFG-OLED results from the enhanced gas diffusion barrier property, which is obtained by the thick Al cathode and a reduction of damage to the moisture getter by the epoxy resin. Furthermore, heat was dissipated more (by 30.5 °C from 62.4 to 31.9 °C) with the flexible heat sink, compared with the result (by 27.7 °C) in Fig. 5(c). This result demonstrates that the thermal conductivity of OLED can be enhanced further by the use of the high thermal conductivity GCFG encapsulation. If the gas diffusion barrier property of encapsulation is as good as the conventional glass encapsulation, a higher thermal conductivity encapsulation is preferred because it can effectively dissipate the Joule heat and thus boost the thermal stability [20]. Due to Joule heating induced by high current injection during operation, there arise thermal degradations such as a reduction of luminance, short lifetime, and large spectral shift of OLEDs, which are mainly related to the low glass transition temperature (T_g) of organic molecules. Therefore, the use of the high thermal conductivity GCFG encapsulation along with a heat sink is demanded to ensure the stable operation at high luminances.

4. Conclusion

We investigated the thermal and barrier properties of moisture getter-filled glass encapsulations for OLEDs. It was found that, in the presence of a slim and flexible heat sink, the getter-coated flat glass encapsulation showed the best thermal performance, followed by the getter-filled hollow glass encapsulation and then the conventional glass encapsulation. However, the getter-coated flat glass encapsulation exhibited the poorest gas diffusion barrier property because the moist surface of the getter damages the organic layers. We demonstrated that the barrier property of the getter-coated flat glass-encapsulated OLEDs was much enhanced by increasing the thickness of the Al cathode in the presence of the buffer layer, which also brought in a further reduction of the surface temperature.

holes due to shadowing of the molecular beam. Further device performance improvement was achieved by inserting a thin pentacene electron-blocking layer before NCA growth to prevent electron current leakage to the anode.

2. Experimental

Pentacene (purchased from Sigma–Aldrich) was deposited by GLAD on glass substrates coated with 20 Ω/square indium tin oxide (ITO) in a high vacuum chamber (base pressure $\sim 3 \times 10^{-7}$ mbar). A computer-controlled stepper motor was used to facilitate sample rotation about the substrate surface normal. The molecular flux incidence angle α and the substrate rotation rate ω were set to 85° and 6 rounds per minute, respectively during nanocolumn (NC) growth. The distance between the center of the substrate and the evaporation source was 15 cm, and the deposition rate at the substrate was ca. 1 Å/s, as monitored by a quartz-crystal microbalance which vertically faced the evaporation source.

OPVCs were fabricated by spin-coating PCBM dissolved in chlorobenzene (28 mg/ml) onto the NCA at 25 rounds per second in a nitrogen glove box. The pentacene/PCBM interdigitated structures were subsequently annealed at 85 °C for 20 min to remove residual solvent and to facilitate improved PCBM infiltration into the voids between the pentacene NCs. An 8 nm thick exciton-blocking layer of bathocuproine (BCP) [12,13] was deposited onto the structure before a 100 nm thick Sm cathode was evaporated in high vacuum (base pressure $\sim 8 \times 10^{-8}$ mbar). The current density–voltage characteristics in dark and under illumination (2.5 mW/cm^2, Solux C6 halogen lamp, close to daylight spectrum in the visible region) were measured in vacuum (2×10^{-8} mbar) with a Keithley 2400 sourcemeter, and the sample morphology was investigated with a HITACHI S-4100 field-emission scanning electron microscope (SEM), after sputter-coating the samples with a thin conductive Au layer.

3. Results and discussion

The formation of nanocolumns is due to a shadowing effect of molecular islands with respect to the incoming material flux, aggravated by the large oblique incident deposition angle. During deposition a large fraction of the flux is captured by taller grains that continue growing at the expense of their dying neighbors. Fig. 2(b)–(d) shows representative topography and cross-section micrographs of pentacene columnar structures grown by GLAD on ITO. Compared with the typical flat and homogeneous morphology of vertically deposited pentacene thin films on ITO, displayed in Fig. 2(a), almost square shaped crystalline pentacene nanocolumns (NCs) and large gaps between them persist for the deposition using GLAD. The polycrystalline structure of pentacene NCs, which is important to obtain high charge carrier mobility for a low solar cell series resistance, has been demonstrated earlier by Zhang et al. [7]. The diameter of the columns in our samples is predominantly in the range of 120–180 nm and the column area-density is about 3×10^7 mm^{-2}. The cross-section view (Fig. 2(c) and (d)) reveals that the height of the individual columns is rather uniformly about 210 nm, except few higher protrusions. There are always small gaps between columns, even for locally high area-densities.

The interpenetrating donor–acceptor structure was obtained by PCBM solution spin coating onto the pentancene NCAs. As shown in Fig. 3(a), spin coating with low concentration PCBM solution (18 mg/ml in chlorobenzene) left the underlying pentacene NCs still clearly visible. Although such a highly corrugated surface easily leads to electrical shorts [14,15], our observation implies that pentacene NCs still stand vertically on the ITO substrate, not impeded by PCBM spin coating, and that PCBM infiltration into gaps between NCs occurred, as can be seen in Fig. 3(b). With a higher concentration PCBM solution (28 mg/ml), a rather smooth surface was obtained and the gaps were filled adequately by PCBM (see Fig. 3(c) and (d)).

The structure of all investigated OPVC variants is shown in Fig. 4. For comparison with OPVCs that have pentacene NCs, an optimized bi-layer planar heterojunction OPVC employing ITO/PEDOT:PSS/50 nm pentacene/30 nm PCBM/8 nm BCP/100 nm Sm (structure A) were fabricated at room temperature, as suggested in [16]. Interdigitated OPVC fabrication was done by BCP and cathode (Sm) deposition in high vacuum (structure B). The BCP thin film was used as

an exciton-blocking layer and as protection-layer for the active donor/acceptor layer during metal deposition. The current density–voltage characteristics of interdigitated OPVCs and reference bi-layer cells (measured at 2.5 mW/cm^2 illumination from a halogen lamp) are shown in Fig. 5, the characteristic parameters summarized in Table 1. The open-circuit voltage (V_{oc}) of the cell with structure B is slightly increased from 0.47 V to 0.50 V. However, the short circuit current density (J_{sc}) of interdigitated cells with structure B is more than doubled compared to that of the reference bi-layer cell under the same illumination condition. The improved performance of interdigitated cells is

attributed to the increased active interface area due to the pentacene NCs. From the SEM images we estimate an increased interface area with NCs by a factor of three, which in principle could increase J_{sc} threefold as well, if there are no other factors impacting device performance. Since J_{sc} in structure B OPVCs was only doubled compared to structure A, we expect additional effects to play a role. Considering the characteristics of devices in the dark, shown on a logarithmic scale in Fig. 6, a much lower area specific shunt resistance of structure B devices was obtained (approx. 0.02 MΩ cm^2) compared to that of structure A devices (approx. 2.86 MΩ cm^2) [17]. The reason of the low shunt resistance could be due to current leakage paths produced by infiltration of the PCBM acceptor phase to the bottom electrode, which do not occur in the planar bi-layer reference device.

To eliminate the problem of leakage paths, a 10 nm thick pentacene film was deposited on ITO before growing pentacene NCs as an electron-blocking layer, shown as structure C in Fig. 4(c). As seen from Fig. 7, there is no marked difference of pentacene NCs compared to those in Fig. 3 except for the thin pentacene electron-blocking layer, except for a slightly decreased FF. A remarkably increased J_{sc} resulted (see Fig. 5 and Table 1), owing to the increased shunt resistivity (approx. 1 MΩ cm^2), see Fig. 6. Hence, the influence of current leakage paths is reduced but not eliminated totally. We suggest that employing a heavily p-doped thin film as electron-blocking layer might be helpful to further improve device performance. Nevertheless, the characteristics of interdigitated OPVCs employing pentacene NCs were improved significantly improved by utilizing the thin electron-blocking layer. The J_{sc} improvement now reached more than 90% of the expected threefold increase due to increased active

Table 1
Characteristic performance parameters of OPVCs. Open circuit voltage (V_{oc}), short circuit current (J_{sc}), fill factor (FF).

	Structure A	Structure B	Structure C
V_{oc} (V)	0.47	0.50	0.51
J_{sc} (mA cm^{-2})	0.17	0.36	0.47
FF	0.51	0.51	0.48
$V_{oc}J_{sc}$FF	0.04	0.09	0.12

interface area. While we cannot provide power conversion efficiency values under standard illumination conditions (due to our experimental setup in vacuum, see experimental section), we estimate that devices with structure C (interdigitated) have an efficiency of ca. 4%, as opposed to only ca. 1.5% for those with structure A (planar), at 2.5 mW/cm^2 illumination from a halogen lamp with an emission spectrum close to daylight in the visible region.

4. Conclusion

In conclusion, vertically aligned crystalline pentacene NCs with a diameter of ~160 nm were grown by GLAD. Interdigitated OPVCs structures were achieved by spin-coating PCBM onto the pentacene NCs, which lead to a threefold increase of active donor/acceptor interface area compared to planar bi-layer structures. By employing an additional planar thin pentacene electron-blocking layer, J_{sc} was increased from 0.17 mA cm^{-2} to 0.47 mA cm^{-2}, corresponding to over 90% of the expected increase due to larger interface area. The remarkable conversion efficiency of OPVCs based on NC structures proves that it is an effective architecture to eliminate charge transport and exciton diffusion bottlenecks while maximizing the interface area. Other materials as donors and/or acceptors employed in similar structures will most likely lead to significant further improvements in OPVCs performance in the future.

To employ R2R gravure for properly simulating and integrating all printed fTFTs (PTFTs) on plastic foils, at first, each components of PTFTs should be able to R2R gravure print on poly(ethylene terephthalate) (PET) foils with reliable physical dimensions. In other words, gate electrodes, dielectric layers, active layers and drain–source electrodes should be R2R printed on PET foils with sophisticated and reliable structures. However, printing reliable fTFTs using R2R gravure is strongly depending on the rheology of inks for printing electrodes, dielectrics and active layers. Furthermore, those inks should be cured with minimum influences on the substrates under 150 °C for less than 5 s to provide practical printing speed with plastic or paper webs. Since inks to meet above requirement in R2R gravure are only commercially available for electrodes and dielectric layers, but not for active layers, we are using an inkjet with dispersed individual single walled carbon nanotubes (SWNTs) solution as an active ink to print SWNT network structures as active layers. Furthermore, since the network structures of SWNTs as active layers on SiO_2 dielectric layer with Si wafer show reasonably low operation voltages (<20 V) [18,19] employing inkjet printed SWNT network structures as active layers on all gravure printed gate electrodes, dielectric layers and drain–source electrodes on PET foils will be very valuable approach to introduce a practical way of producing fTFTs. Therefore, although whole fTFTs could not be printed by R2R gravure at this moment, it is very valuable to verify that R2R gravure printed gate electrodes, dielectric layers and drain–source electrodes on plastic film are eligible with inkjet-printed active layers using SWNT ink and expandable to integrate PTFTs on the plastic foils with well matched to their simulation results.

In this paper, we would like to show that all printing process based on R2R gravure and inkjet on plastic foils is reliable and integrable fTFTs for the production of flexible and costless macro-electronic devices such as RFID tags, sensors and signage. For this purpose, basic building blocks in integrated circuits such as fTFTs, inverter and ring oscillator, were printed. Furthermore, we analyzed frequency performance and electrical properties related to the SWNT network of the printed circuits by referring a previously reported organic semiconductor based PTFT model [20] and spice simulation model which may enable to describe the static and dynamic behaviors of the printed SWNT based PTFTs with sufficient accuracy.

In printing fTFTs on plastic foils, R2R gravure (AVACO, Korea) (Fig. 1a) and inkjet (DMP-2800, Dimatix, USA) (Fig. 1b) were used with PET foils (SKC, Korea) with the thickness of 70 μm. For R2R gravure-printing precursors, containing gate electrodes, dielectric layers, drain–source electrodes and wires, silver nanoparticle based gravure inks (PG-007, Paru Co., Korea) and a high dielectric ink based on $BaTiO_3$ nanoparticles (PD-100 Paru Co., Korea) were respectively used by adding appropriate amounts of ethylene glycol and hexanol to control viscosity and surface tension. The optimized viscosities and surface tensions of silver nanoparticles and $BaTiO_3$ nanoparticles with R2R gravure printing speed of 12 m/min were respectively the viscosity of 200 cP and the surface tension of 30–36 mN/m. To directly employ SWNTs in printing fTFTs as an active material with a reasonable on current level and on–off ratio for the production of PTFTs, well dispersed individual SWNTs (HiPco, Carbon Nanotechnology Laboratory, Rice University) in aqueous solution with sodium dodecylsulfate (SDS) was inkjet printed on the R2R gravure printed gate electrodes, dielectric layers and drain–source electrodes on PET, called precursor at here (Fig. 2a). In this work, inkjet printed all SWNT network layers were dried under vacuum oven at 35 °C for 1 h and then, gently washed by DI water to remove SDS residues. The resulting devices were further dried under vacuum at 35 °C for 1 h.

Using mentioned R2R gravure printer and inks, we obtained the parabolic gate electrodes (Fig. 3a) with a peak thickness of 680 nm, a line width of 297 μm and a surface roughness of about 30 nm, and dielectric layer with a peak thickness of 2.48 μm and a surface roughness of 200 nm (Fig. 3b). The drain–source electrodes were continuously R2R gravure printed at 3rd printing unit in Fig. 1a using the same gravure inks to print gate electrodes. The height of drain–source electrodes were about 680 nm as shown in the cross-sectional SEM image (Fig. 3b). The details of R2R gravure printed electrodes could be referred from our previous report [9]. For the active layer, we considered SWNTs, having high intrinsic mobility and stability, as a network structure of active layer because the network structure of SWNTs will overcome the surface roughness of the printed dielectric layers and long channel length (150 μm) [13,21–23]. We used a long channel length to compensate the limit of overlay printing registration accuracy of 20 μm. To print active layers on the R2R gravure printed precursors, we print well dispersed individual SWNTs as an active layer by using inkjet printer (Dimatix Materials Printer, 16 nozzles at 254 μm spacing) as shown in Fig. 1b. In this work, since drive (low current) and load (high current) PTFTs were needed to design printed circuits, inverter and multi-stage ring oscillator, using only p-channel PTFTs, we changed the network density of SWNTs in the active layer by managing inkjet printing times (drive: printing one time and load: printing three times) to adjust I_{DS} (drain/source current) instead of having different physical dimensions such as channel length and width. This will be a big advantage of using printing method in integrating SWNT based TFTs over the photolithography.

Fig. 2 shows the R2R gravure printed precursor (Fig. 2a) (include gate, dielectric layer, drain and source electrodes) and all printed fTFT (Fig. 2b) with a channel length of L = 150 μm and width of W = 3000 μm. All electrical characterization of PTFTs was carried out under ambient conditions using a semiconductor parameter analyzer (Agilent 4155C), and typical IV characteristics were shown in Fig. 4. The variation in the output characteristics as shown in Table 1 is mainly originated from the misalignment of printed drain–source electrodes on the printed active layer which causes uneven parasitic capacitances. Because of this effect, the effective channel mobility is changed. Another reason for the uneven electrical characteristics of the PTFTs may due to the variation in the surface roughness, waviness and thickness of the electrodes and dielectric layer through R2R gravure printing process. To find out a key factor among major factors influencing on PTFTs, we measured and calculated mobility based on the attained

parasitic capacitances generated by misalignment between printed gate and drain–source electrodes. As shown in Table 1, the influence of parasitic capacitance on the major parameters such as transconductance, mobility and threshold voltage is dominant. Therefore, the minor things such as the variation in the surface roughness, waviness and thickness of the gravure printed electrodes and dielectric layer would not consider in this paper. Although the at-

tained mobilities of SWNT based PTFTs (Table 1) are modest, the mobility can be simply improved by reducing the channel length and defect sites of network structure of SWNTs. Table 1 shows the measured and the calculated output at V_g of −10 V for each 10 different PTFTs (five driver fTFTs, five load fTFTs) with the consideration of parasitic capacitances between gate–drain and gate–source electrodes. Since those parasitic capacitances are strongly relied on the overlay printing registration accuracy and waviness of printing process between gate and drain–source electrodes, the electrical properties of PTFTs are strongly depending on the overlay printing registration accuracy of the R2R gravure printing process. Based on the observed electrical characteristics and standard equation for Si based TFT, we have extracted the parameters of electronic property of the PTFTs to design simulation model which describes the static and the dynamic behaviors of all printed SWNTn–fTFTs with sufficient accuracy.

The modeling of the PTFTs was performed using AIM-extract and AIM-spice software. The software includes various TFT models. Among of them, we employed the level 15 model (amorphous-silicon TFT model) [24] which shows the behavior of organic semiconductors in similar [20,25,26]. The parameters for the PTFT were determined in two steps. In the first step, the mobility was calculated from the measured output and transfer characteristics following standard equations [20] (refer the Supplementary Information). In the second step, the parameter extractor

of AIM-spice was used to fit the whole parameter set for the level 15 model. Using the extracted value from the PTFTs, a good agreement between simulation and experimental results could be achieved. Fig. 4a and b shows the *IV* characteristic curves of the PTFT simulation model (blue[1] dash line) and the measured values (black solid line) of the drive and load transistor.

The inverter is the most basic building block for the construction of electronic circuits. Fig. 5a shows p-channel based inverter which consists of drive p-channel PTFT and load p-channel PTFT with same physical dimension. In this work, the network density of SWNTs at the channel was tuned by jetting times of inkjet to control the current levels instead of having different physical dimension. Fig. 5b shows the measured inverter transfer characteristic curve (black solid line) and the simulation model (blue dash line) for p-channel based all printed inverter with gain of 3.4.

Using the described SWNTn–PTFT and inverter model, a five-stage ring oscillator circuit was simulated and then printed. Fig. 6a shows the optical image of the printed five-stage ring oscillator. This circuit is composed of five inverters, each inverter consisted of two p-channel PTFTs. To measure the ring oscillator frequency performance, the output stage of the five-stage ring oscillator was connected in series with a voltage follow circuit and a common voltage of −10 V was applied. The ring oscillator starts oscillating if the supply voltage reaches an onset value, which depends on circuit design, overlap capacitance, threshold voltage, and on/off ratio. With the five-stage ring oscillator mentioned above, the onset voltage was about

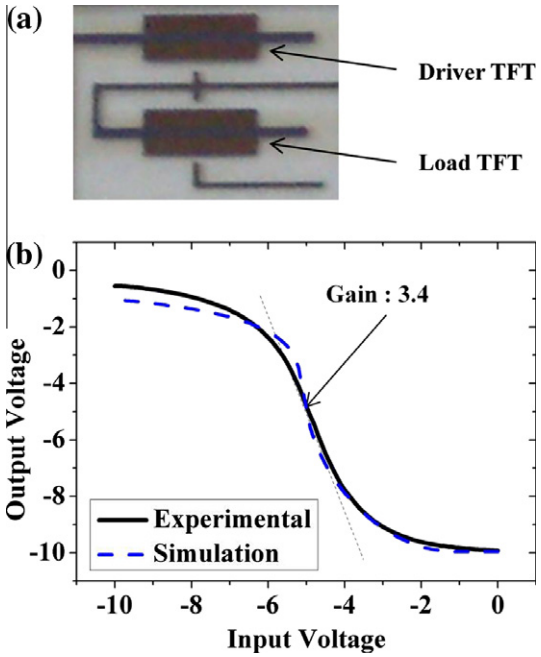

Fig. 5. Optical image of printed inverter (a), and simulated and measured dc characteristic curve of the printed inverter.

−8 V, and with a supply voltage of −10 V, a frequency of 114.6 Hz was reached (Fig. 6b, black solid line). This is equivalent to a stage delay of 1.75 ms.

The ring oscillator frequency is limited by the charging and discharging time of the capacitive load of a stage output, which is the sum of the input capacitance of the following stage and a parasitic capacitance. Therefore, the

[1] For interpretation of color in Figs. 4–6 the reader is referred to the web version of this article.

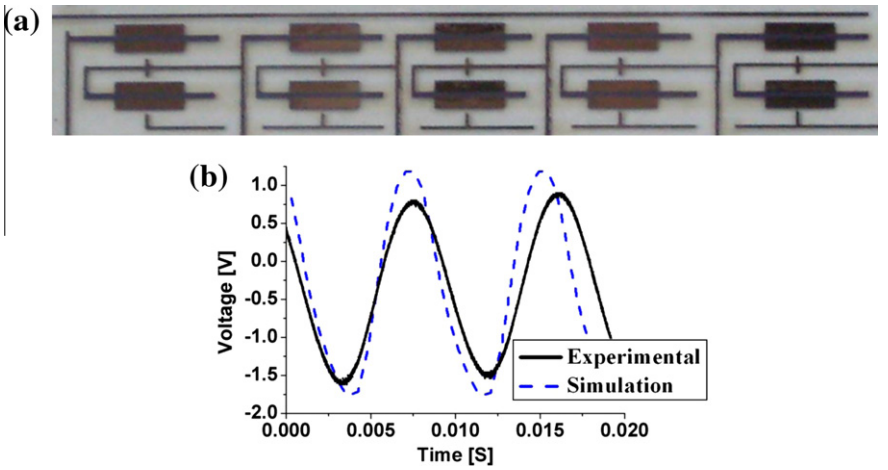

Fig. 6. Optical image of all printed p-channel inverter based five-stage ring oscillator (a) and simulated and measured output signal of the printed five-stage ring oscillator.

delay per stage of a ring oscillator could be estimated by using the RC (resistor–capacitor) charging/discharging circuit which can be written as Eq. (1) [27]

$$t = M \times R \times C = M \times C \times \frac{V_{OSC}}{I_{DS}} \quad (1)$$

where, M is the constant value which has 5–10 in RC circuit, C is the total overlap capacitance in the five stage ring oscillator, V_{osc} is the oscillation amplitude, and I_{DS} is the current that is switched. In our five-stage ring oscillator, C = 28 pF, V_{osc} is 2.58 V, and the I_{DS} is measured with semiconductor parameter analyzer (Agilent 4155C) to be 0.76 μA. The total delay of all the stages is calculated to be $(10 \times (10 \times C + C_{probe}) \times V_{osc}/I)$ = 9.95 ms (equivalent to a stage delay of 2 ms). C_{probe} is the probe capacitance which is 13 pF for the probe used in our measurement. In this research, all electrical measurements of the PTFT, inverter, and five-stage ring oscillator were carried out under ambient conditions using a semiconductor parameter analyzer (Agilent 4155C) and set up with DC power supply (HP 1245), a function generator (Tektronix AFG 3022), LCR meter (Agilent E4980A), and a digital oscilloscope (Tektronix DPO 4032).

The simulation result (Fig. 6b, blue dot line) shows the amplitude of 2.91 V and oscillation frequency of 123.1 Hz in a good agreement with the measured output signal (Fig. 6b, black solid line). However the amplitude of the simulated output is higher than measured output. The reason for this discrepancy could be caused by the input impedance of the measurement equipment. This load on the output of the oscillator can be responsible for the lower oscillation amplitude and frequency.

In summary, R2R gravure and inkjet printing process were employed for the fabricating the SWNTn–TFTs on plastic foils to show the possibility of all R2R gravure printed circuits. Based on the fully printed SWNTn–PTFTs on PET foils, we have made a simulation model for an inverter and a five-stage ring oscillator. The inverter had gain of 3.4 with a good agreement between simulation and experimental results. Based on the known our knowledge, the attained gain of 3.4 under the operation voltage of 10 V is highest one among fully printed fTFTs on plastic foils. The printed ring oscillator exhibited 114.6 Hz of oscillation frequency and 1.75 ms per stage of propagation stage delay at Vds = −10 V. The calculated oscillation frequency based on each inverters and simulation model of five-stage ring oscillator respectively had a stage delay time of 1.99 and 1.62 ms at Vds = −10 V with high output voltage accuracy. The mismatch between simulated and experimental values is pretty acceptable with a circuit design using reasonable number of transistors, but may be noticeable as increasing number of transistors because electrical performance of TFTs is going to more strongly influenced on the roughness of gate dielectric layers and even small misalignment of drain–source electrodes [28–30]. Therefore, controlling roughness of R2R gravure printed dielectric layers and overlay printing registration accuracy need to be first addressed for the integration of SWNTn–PTFTs on plastic foils. This result indicates that more complex circuits can be easily simulated with the viewpoint of static and dynamic behavior, and the circuits made of all printed fTFTs can be applicable to flexible electronics with a modest supply voltage (<20 V) in mass production.

process of ITO thin film and sputtering process also increases the complexity of device fabrication.

Although many efforts have been made on the T/SOLEDs, fabricating white T/SOLEDs with microcavity effects still leaves a door open. The difference in luminance, efficiency and chromaticity coordinates for the emission from both sides was hardly avoided in T/SOLEDs owing to an asymmetric structure of light propagation. In this article, we designed and fabricated a new type of SWOLED with the same electrode composition of a semitransparent multilayer of $(Ag/Alq_3)_2$ and $(Alq_3/Ag)_2$ as the cathode and anode, respectively. The device showed few differences in luminance, efficiency and spectra from both sides. Furthermore, this kind of electrode can be potentially fabricated on the soft substrate for flexible OLEDs, like the similar structure electrodes (for example, ITO/Ag/ITO, Al/Alq_3/Al, ZnS/Ag/WO_3) utilized in flexible OLEDs [27–29].

We designed SWOLED (device A) consisting of glass substrate/$(Alq_3/Ag)_n$/MoO_3 (1.5 nm)/4,4′,4″-tris(3-methylphenyl-phenylamino)-triphenylamine (*m*-MTDATA, 30 nm)/*N*,*N*′-bis-(1-naphthyl)-*N*,*N*′-diphenyl-1, 1-biphenyl-4,4′-diamine (NPB, 10 nm)/4,4′-bis(2,2′-diphenylvinyl)-1,1′-biphenyl (DPVBi, 15 nm)/4,4-*N*,*N*-dicarbazole-biphenyl (CBP, 3 nm)/CBP:bis(2-(2-fluorphenyl)-1,3-benzothiozolato-*N*, C2′)iridium(acetylacetonate) [$(F–BT)_2Ir(acac)$] (7 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen, 35 nm)/LiF (1 nm)/Al (1 nm)/$(Ag/Alq_3)_n$. In this device, *m*-MTDATA, NPB, DPVBi, CBP:(F–BT)2Ir(acac), Bphen, and LiF/Al/Ag/M/A/M were used as the hole injection layer (HIL), hole transporting layer (HTL), blue emitting layer, orange emitting layer, electron transporting layer (ETL), respectively. The neat CBP was introduced to separated blue and orange emitting layers to avoid the Dexter energy transfer between the two emitters. For comparison, the bottom-emitting device (ITO glass substrate) with the same organic layers (device B) and 100 nm Al as a cathode was fabricated. The thickness of each layer was optimized according to the analysis below. The deposition of layers and the measure of devices characteristics were described before [16]. The transmission spectrum was measured by means of ultraviolet/visible spectrometer (UV 1700, Shimadzu).

Fig. 1a shows the transmittance and reflectance spectra of the electrodes with different thickness of Alq_3. Considering the transmittance and electrical characteristics of the electrodes, a thin Ag layer can have high transmittance and a thick Ag layer can have high conduction, 22 nm Ag layer is chosen. As can be seen, the peak of transmittance/reflectance shift to longer wavelength as the thickness of Alq_3 increased. As depicted in Ref. [30], two resonant cavity modes are necessary in our devices. In order to obtain high effective microcavity devices, a moderate transmittance and reflectance is need near the resonant wavelengths (RWs) 448 and 590 nm, so 80 or 85 nm Alq_3 is chose. Fig. 1b shows the absorption spectra of the electrodes. We can see that a larger absorption is obtained at long wavelength region. Considering the absorption of the electrodes, 85 nm Alq_3 layer is better due to lower absorption of electrode than that of 80 nm Alq_3.

In addition, we calculated the cavity emission by considering wavelength-independent intrinsic luminescence spectra of the emitters [31] in order to clarify the microcavity effect in the device and optimize the parameters of device A. The peak wavelength of the resonant cavity mode is dependent on the optical thickness of the cavity region and the Bragg peak wavelength of the electrodes [32]. Thus, in order to adjust the position of the resonant peak, we only change the thickness of the hole injection layer and electron transporting layer and hold other layers constant when altering the optical thickness of the cavity region. Fig. 2a and b shows the cavity emission from Ag side (cathode side) and glass side (anode side), respectively. Different thickness active layers, 90, 100, 110, 130, and 150 nm are adopted and the thickness of the electrodes is constant, 22 and 85 nm for Ag and Alq_3, respectively. We can see that two resonant peaks are obtained and the RWs shift towards longer wavelength region with the active layers thickness increasing. In order to obtain high effective device we choose the thickness of 100 nm for active layers considering the emission peaks of blue (DPVBi, emission peak at 448 nm) and yellow [$(F–BT)_2Ir(acac)$, emission peak at 548 and a shoulder peak at 590 nm] emitters. Meanwhile, we can see that almost the same emission can be obtained from both sides of the device.

In addition, we can also confirm the position of the resonant peak by utilizing the Fabry–Perot peak condition

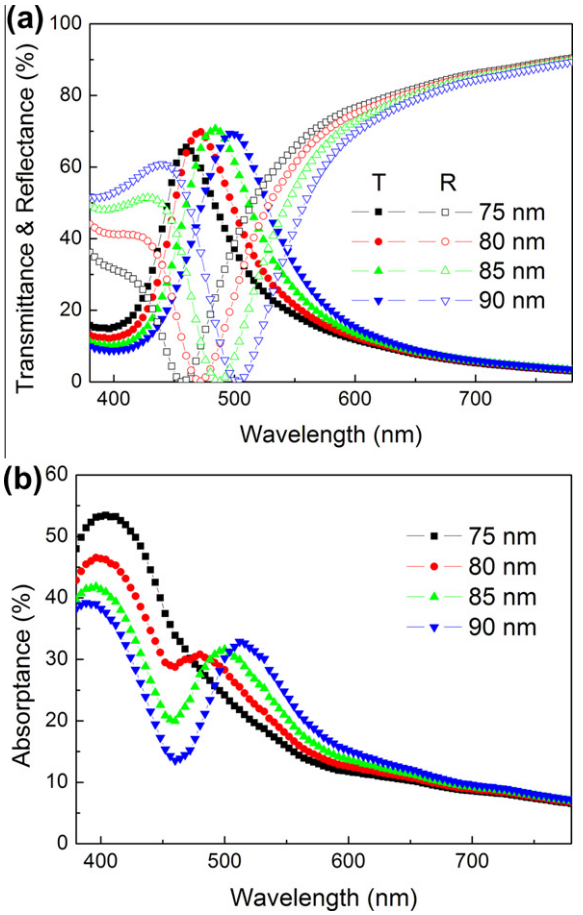

Fig. 1. (a) The transmittance, reflectance and (b) absorption spectra of the electrodes with different Alq_3 thickness.

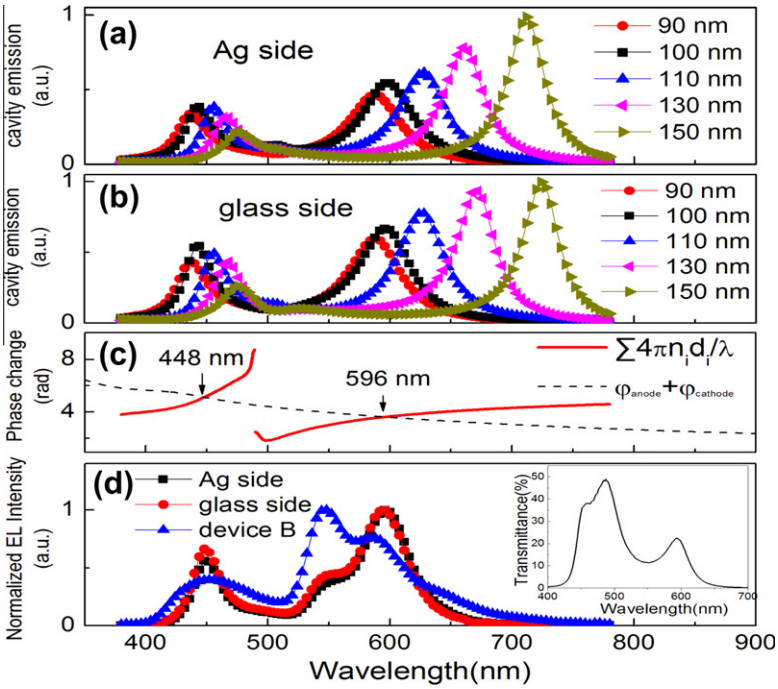

Fig. 2. The cavity emission from (a) Ag side (cathode) and (b) glass side (anode) with different thickness active layers; (c) the calculated round-trip phase changes for 100 nm organic layers between two electrodes and the phase changes for two electrodes; (d) the normalized measured EL spectra for devices A and B. Inset is the measured transmission for device A.

[33]. The resonant wavelength (RW) condition of the microcavity for normal incidence is determined by the below equation:

$$\sum_i \frac{4\pi d_i n_i(\lambda)}{\lambda} - \varphi_{\text{cathode}}(0,\lambda) - \varphi_{\text{anode}}(0,\lambda) = 2m\pi$$

where λ is the emission wavelength, $\varphi_{\text{cathode}}(0, \lambda)$ and $\varphi_{\text{anode}}(0, \lambda)$ are the angle- and the wavelength-dependent phase changes on reflection from top cathode and bottom anode, respectively, and m is an integer that defines the mode number (in our work, we choose $m = 0$), $n_i(\lambda)$ and d_i are the refractive index and thickness of organic layers.

Fig. 2c shows the calculated round-trip phase changes for 100 nm organic layers sandwiched between two reflection electrodes [i.e., $\varphi_1(\lambda) = \Sigma 4\pi n_i(\lambda) d_i/\lambda$], and the phase shift at two reflective electrodes [i.e., $\varphi_2(\lambda) = \varphi_{\text{cathode}}(\lambda) + \varphi_{\text{anode}}(\lambda)$] in forward direction. The points of the intersection of $\varphi_1(\lambda)$ and $\varphi_2(\lambda)$ are the RWs of the device. Two RWs at 448 and 596 nm will occur in the designed device. The detail calculations were described before [14,15]. Fig. 2d shows the normalized measured EL spectra at voltage of 8 V for devices A and B in forward direction. The spectrum of the device B shows two main peaks at 448 and 548 nm originating from DPVBi and $(F–BT)_2Ir(acac)$, respectively. The shoulder peak is at 590 nm. Device A shows two resonant emission peaks at 448 and 596 nm for both sides, which are in excellent agreement with the calculated results. It can be seen that the spectra for Ag- and glass-side have only little difference. In other words, we can obtain almost the same emission from both sides with this structure. Comparing these two devices, the narrower full width at half maximum (FWHM) of the DPVBi and $(F–BT)_2Ir(acac)$ emission in device A is observed (for example, the FWHM of the $(F–BT)_2Ir(acac)$ is 90 nm for device B and 28 nm for device A). This result also indicates that strong microcavity effect is occurred in this SWOLED. Inset shows the measured transmittance of the device in forward direction. As can be seen, the device has two transmission peaks at 487 and 592 nm and a shoulder peak at 456 nm, which is the characteristic of periodic structure electrodes.

Fig. 3a and b shows the normalized EL spectra at viewing angle of 0°, 30°, and 60° and a voltage of 8 V for Ag side and glass side, respectively. As can be seen, the experiment results (solid symbols) are in excellent agreement with the simulated results (open symbols) and the details of calculation is described before [16]. With the viewing angle increasing, the RWs shift to a shorter wavelength due to the microcavity effect for either Ag side (upper) or glass side (down). A white emission was obtained with CIE coordinates (0.424 and 0.347) [(0.402 and 0.344)] at a viewing angle of 0° and changing to (0.419 and 0.379) [(0.399 and 0.376)] at 30° and (0.368 and 0.456) [(0.351 and 0.458)] at 60° for Ag side (glass side). Fig. 4a and b shows the normalized measured EL spectra at voltage of 6, 8, and 10 V for device A in forward direction, for Ag side and glass side, respectively. We can see that the spectra are fairly stable over a range of operation voltages for both sides. In other words, the CIE coordinates are stable within the operation voltage, which are very important in displays and lighting. Fig. 3c indicates the measured angular distribution of the

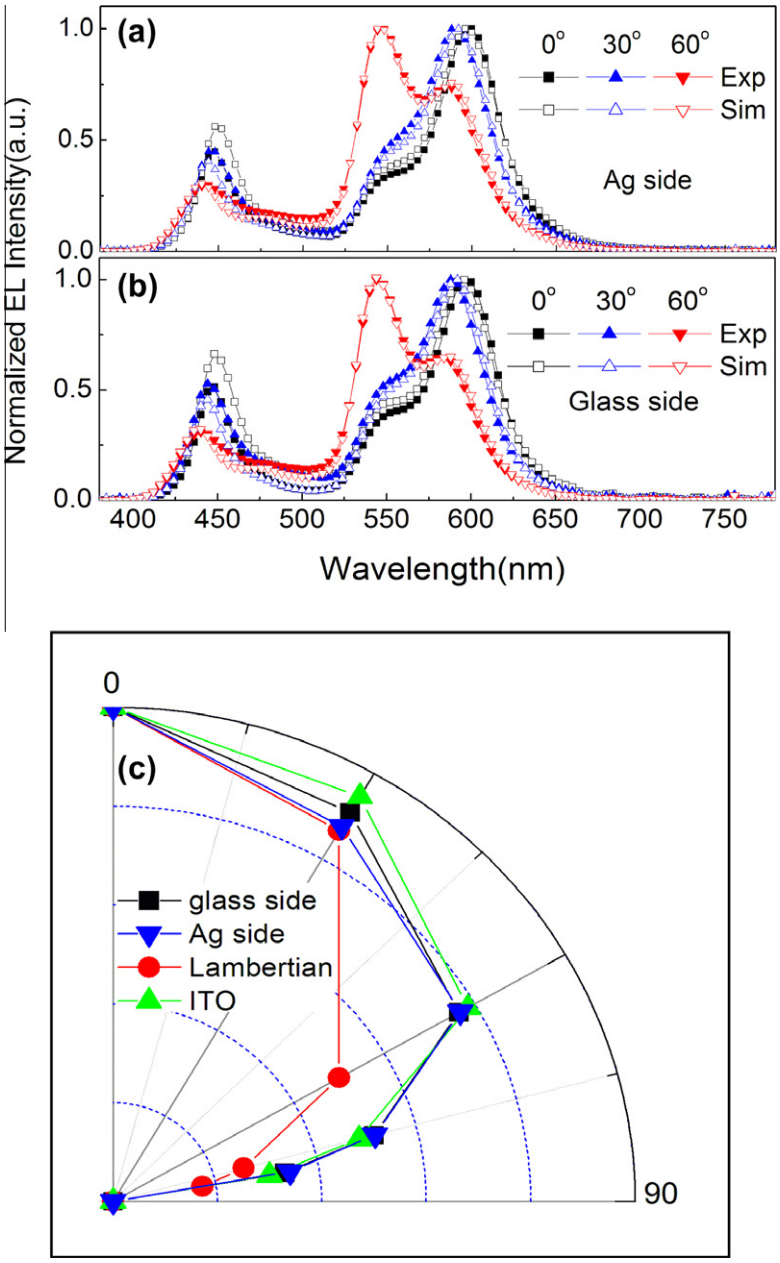

Fig. 3. (a) The normalized experimental (Exp) and simulated (Sim) EL spectra at different viewing angles and voltage of 8 V for (a) Ag side and (b) glass side; (c) the measured angular distribution of the devices and the red solid circle represents a Lambertian-type distribution. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

devices and the red solid circle represents a Lambertian-type distribution. We can see that the emission of SWOLED has the similar angular distribution as that of ITO-based OLED, which is a super-Lambertian distribution [16].

Fig. 5a shows the current density–luminance–voltage characteristics of the SWOLED. There is only little difference in luminance from both sides. For example, at the driving voltage of 10 V, the luminance for the Ag side and glass side is 2550 and 2423 cd/m^2, respectively. Fig. 4b shows the forward direction efficiency of the device A and B. The maximum efficiencies from Ag side and glass side of the SWOLED are 4.14 and 4.32 cd/A, respectively. The maximum total EL efficiency of the device is 8.46 cd/A, which is comparable to the corresponding bottom-emitting WOLED (9.20 cd/A).

Fig. 6 shows the transmittance, reflectance, and absorption spectra of the cathode (electrode 1) and anode (electrode 2). As can be seen, the two electrodes almost have the same spectral response, which ensures the uniform optical characteristics of the two sides for the SWOLED.

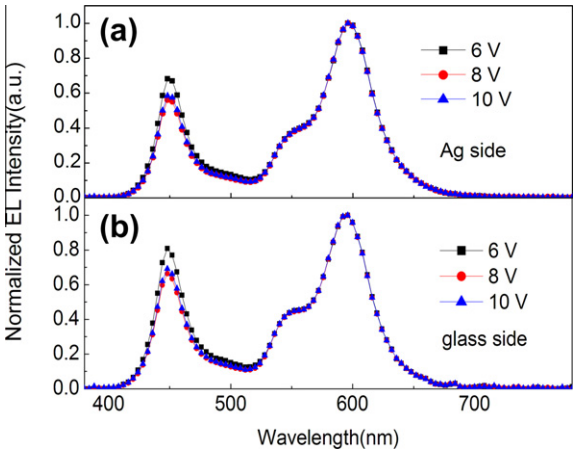

Fig. 4. The normalized measured EL spectra of device A at voltage of 6, 8, and 10 V, (a) Ag side and (b) glass side.

The loss due to the absorption by multilayer electrode is about 30%. The absorption at the RW is 20% (RW = 448 nm) and 15% (RW = 596 nm). Fig. 7 shows the ratio of air mode, glass mode, and nonemissive mode (waveguide mode and surface plasmon polaritons) to the total emission as a function of wavelength simulated by numerical method of the finite-difference time-domain (FDTD) [34]. The inset is the normalized PL spectra of the DPVBi and

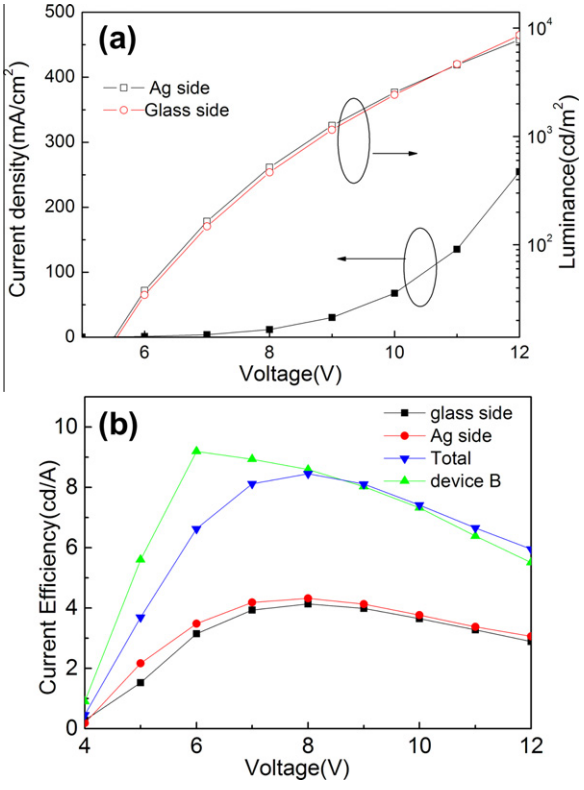

Fig. 5. (a) The voltage–current density–luminance characteristics of the devices; (b) the efficiency–voltage characteristics.

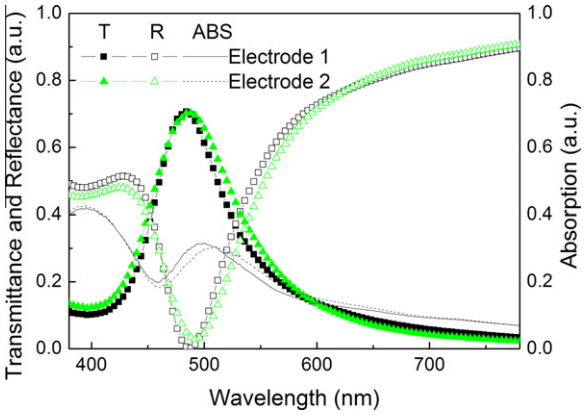

Fig. 6. The transmittance, reflectance and absorption spectra of the electrodes.

CBP:$(F–BT)_2Ir(acac)$. Thus, the light extraction efficiency of the SWOLED could be defined as $\eta_{ext} = \int_{380}^{780}[k_1 S_b(\lambda) + (1-k_1)S_y(\lambda)]\eta_{air}(\lambda)d\lambda$, where k_1 is the weight of the blue emission to the white emission. $S_b(\lambda)$ and $S_y(\lambda)$ are the photoluminescence (PL) spectrum normalized with its area of the blue and yellow emitting material. $\eta_{air}(\lambda)$ is the air mode of the SWOLED as function of wavelength. According to the EL spectra of the SWOLED, the weight of the blue emission to the white emission is about 40%. Thus, the calculated light extraction efficiency of the SWOLED is 11.3% which is less than that of the bottom device (~20%). However, the radiative quantum efficiency of the emissive materials will increase in the microcavity device due to the presence of the Purcell effect [35]. The calculated Purcell factor for the blue and yellow emitting material is 2.3 and 3.2 in the SWOLED, respectively. The PL quantum efficiency of DPVBi and CBP: $(F–BT)_2Ir(acac)$ are 0.4 and 0.62. Then, the improvement of the radiative quantum efficiency of DPVBi and $(F–BT)_2Ir(acac)$ is about 50% and 35%, respectively. As a result, the efficiency of the SWOLED is comparable to that of the corresponding bottom-emitting OLED.

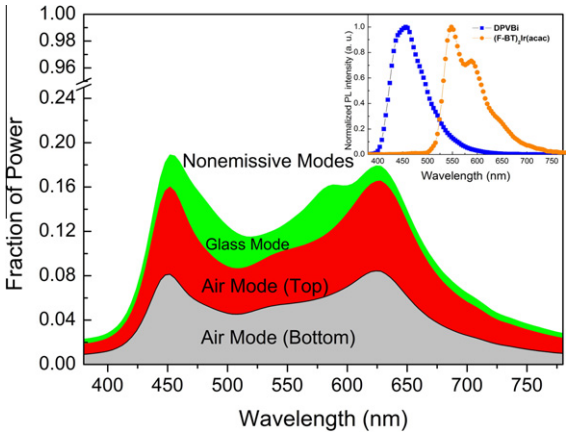

Fig. 7. The ratio of air mode, glass mode, and nonemissive mode to the total emission as a function of wavelength.

In summary, the SWOLED with $(Ag/Alq_3)_2$ electrodes was demonstrated, which showed few differences in luminance, spectra and efficiency. The total efficiency of the SWOLED is comparable to the corresponding bottom-emitting OLED. By changing optical thickness of the cavity region, we can adjust the RWs of the device. In fact, we can also adjust the optical characteristics (including the RWs and transmittance) of the device by adjusting the parameters of the electrodes. The results will provide guidance in fabrication of OLEDs with optimum performance, such as high efficiency, pure color emission, required transmittance, and flexible devices. At present, the SWOLEDs have the cavity effect which leads to an angular dependent EL emission. However, the devices can be used as the screens of mobile phones and smartphones that do not need high quality at a large viewing angle.

[30] In our work, we achieve white light emission by complementary color, blue (emission peak at 448 nm) and yellow (emission peak at 548 nm). So a cavity with two resonant cavity modes is enough. The device with electrode $(Ag/Alq_3)_2$ can has two peak wavelengths according to our report [Ji et al., Curr. Appl. Phys. 11 (2011) 1410], so we choose $n = 2$ in this work. The peak wavelength of the resonant cavity mode is dependent on the optical thickness of the cavity region and the Bragg peak wavelength of the electrodes as depicted in Ref. [32]. We choose 85 nm Alq_3 layer to make the electrode have two Bragg peak wavelengths near 448 and 590 nm.

semiclassical Marcus charge transfer (CT) rate theory [8] has long been used to describe the charge transport in organic semiconductors [9–11]. By comparison, it has been known for more than 10 years that charge mobility of highly pure and defect-free molecular single crystals decreases with temperature following a negative power law [12,13], which has been taken as strong evidence for band-like transport in organic semiconductors. Later, a temperature-independent mobility has been observed in pentacene OTFTs which further complicates the charge transport mechanism [2]. In fact, there are structural defects in organic semiconductors [6,14] which can create localized electronic states to influence the charge transport [15,16]. To include the effect of traps for charge transport, a multiple trapping and release model has been developed where charge transport occurs in delocalized bands, but is restrained by a distribution of shallow traps near band edges [17–19]. Most of the charge carriers are assumed to be trapped in localized states. The amount of released charge carriers to an extended-state transport level depends on the energy level of the localized states, the temperature, and the gate voltage. However, unlike inorganic semiconductors where atoms are strongly bound by covalent interactions, molecules in organic semiconductors are held together by weak interactions between adjacent molecules [20,21], which results in a narrow bandwidth. Furthermore, the strong thermal fluctuation of transfer integrals can destroy the translational symmetry of the electronic Hamiltonian [22], so the mean free path of charge carriers becomes shorter than the lattice constant at high temperature [23]. Thus, the extended-state transport is unlikely in organic semiconductors. To avoid the band-like picture, a variable-range hopping model has then been proposed [24]. In this model, the charge transport is governed by thermally activated tunneling of carriers between localized states, but a carrier may either hop over a small distance with a high activation energy or hop over a long distance with a low activation energy. While this theory seems to be able to explain the gate voltage and the temperature dependence of the mobility in the literature, it still suffers from a lack of physical justification [25]. Instead, the picture of carrier hopping between neighboring localized states has successfully described the charge transport in organic semiconductors [26–28] although the band-like transport cannot be explained from the hopping model with the semiclassical Marcus CT rate theory. To reconcile the discrepancy, a quantum CT rate theory with first-order perturbative nature has been used to study the charge transport in organic semiconductors [29,30]. It is found that the nuclear tunneling effect can largely reduces the activated energy between two adjacent localized states, which then leads to the band-like transport in organic semiconductors. The importance of quantum treatment for the nuclear degrees of freedom has also been pointed out during the simulation for organic photovoltaic material [31]. Thus, it is helpful to understand the charge transport in organic semiconductors by using a CT rate theory beyond the semiclassical Marcus CT rate theory. Along this way, it is found that the molecular packing in organic semiconductors often makes the first-order perturbative approximation in the semiclassical Marcus CT theory invalid [32], so a quantum CT rate theory without weak electronic coupling approximation has been applied to study the charge transport in perfect organic semiconductors [33]. To simulate the mobility in polycrystalline organic semiconductors, the effect of traps should be further included. It has been widely accepted that traps are mainly located at boundaries between grains in polycrystalline organic semiconductors [34–36], which are believed to be bottlenecks to the charge transport in OTFTs [16,37]. Among the models of grain boundaries (GBs) focusing specifically on the role the GBs play in the charge transport through organic semiconductor devices, most share an element that electrostatic barriers are present at the grain–grain interfaces which arise from traps localized at the GBs, whereas grains are basically free of traps [15,34,35,38]. These simulations have shown that it is necessary to consider the conduction processes through both the grains and the boundaries separating them for a deeper understanding of the device and satisfying the needs of the circuit designer.

In the present paper, we propose a model for charge transport in the polycrystalline organic semiconductors, where the charge transport is governed by hopping, i.e., the thermally activated tunneling of carriers between adjacent localized states, but energy barriers are present at boundaries between grains which can scatter the charge carriers when the charge carriers try to hop across the GBs. The present authors have ever used sexithiophene crystal structures in high-temperature (HT) and low-temperature (LT) phases which have been shown in Fig. 1 to show the influence of molecular packing for the mobility versus temperature [33]. In the present paper, we continue to use these two crystal structures to investigate the effect of traps for charge transport in polycrystalline organic semiconductors so that the effect of molecular packing can be seen at the same time. Since the charge transport in OTFTs is mainly confined within the first few layers of the organic semiconductor/insulator interface [39], the present work only deals with two-dimensional (2D) charge transport properties [33]. The paper is organized as follows: In Section 2, we describe the theoretical model and method to calculate the CT rates and to simulate the charge mobility in polycrystalline organic semiconductors. In Section 3, we display the numerical results and discussions. The conclusion is drawn in Section 4.

2. Theoretical methodology

2.1. Model for polycrystalline organic semiconductors

Atomic force microscope images of organic semiconductors have shown that a polycrystalline organic material is composed of small crystallitic grains joined together by GBs between them [6]. These grains have a distribution of sizes and irregular shapes, and the angle between the orientations of the adjoining grains is often large. The boundary between grains consists of a few molecular layers of disordered molecules resulting from different orientations of neighboring grains. Thus, the polycrystalline organic semiconductor has a complex microstructure. To

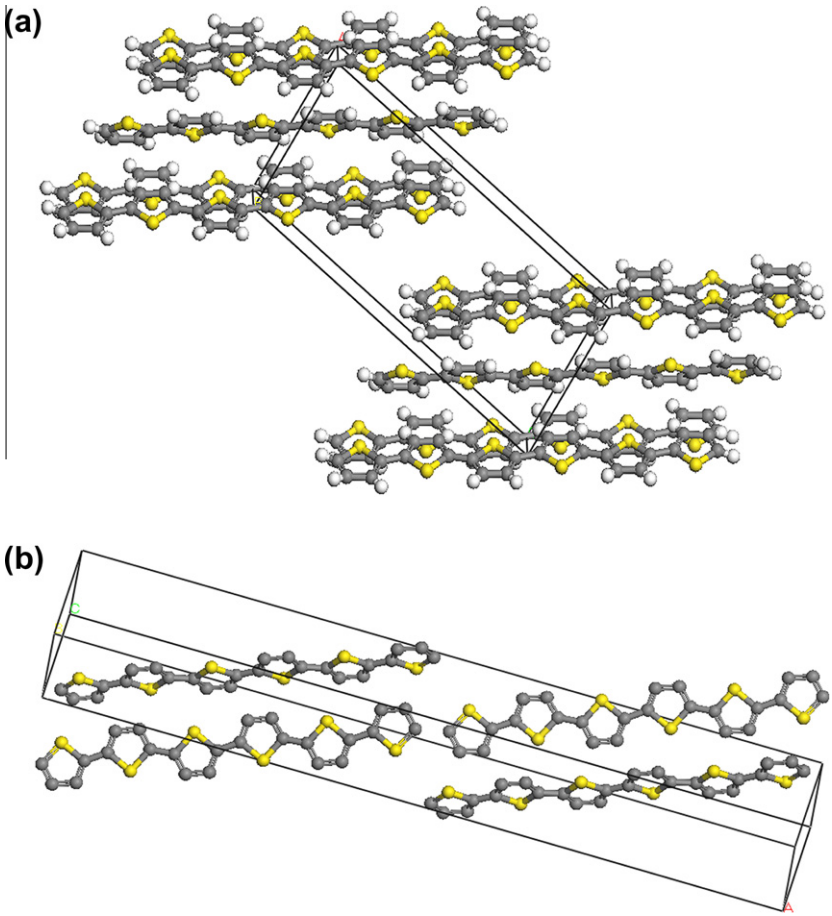

Fig. 1. Crystal structures of sexithiophene: (a) the unit cell of the HT phase; (b) the unit cell of the LT phase.

simplify the model, we notice that Gaussian distributions of grain sizes lead to little variation of the mobility with respect to the model with uniform grain sizes [38]. Meanwhile, the mobility has a strong dependence on the grain size [40,41] showing that charge transport is mainly limited by GBs [42]. In addition, theoretical calculations have shown that in most cases the width of GBs is negligibly small as compared to the grain size [34]. Therefore, we assume that the crystals in OTFTs are composed of identical square crystallites having a grain size of L nm. We also assume that the molecules are arranged in a periodic manner within each crystallite so no scattering takes place in the grains. We further assume that the boundary between grains is of negligible thickness compared to L so scattering only takes place when charge carriers try to hop across the GBs. In fact, these assumptions have been widely used to simulate the charge transport in polycrystalline inorganic semiconductors [43,44].

2.2. Method for charge transfer rates and mobilities

Recently, we have proposed a quantum CT rate theory without weak electronic coupling approximation to simulate the charge transport in perfect organic semiconductors [33]. Based on the above assumptions we have made, the CT rates in the grains of polycrystalline organic semiconductors can be computed with the quantum CT rate theory without weak electronic coupling approximation. Since the details of the quantum CT rate theory without electronic coupling approximation has been shown in our recent work [33], a brief description for this theory is given below.

The carrier hopping between neighboring molecules in organic semiconductors is a self-exchange two-state CT reaction, so the system can be described by a spin-boson Hamiltonian [45]:

$$H = V\sigma_x + \sum_{j=1}^{N}\left[\frac{p_j^2}{2m_j} + \frac{1}{2}m_j\omega_j^2\left(x_j - \frac{c_j}{m_j\omega_j^2}\sigma_z\right)^2\right]. \quad (1)$$

Here, N is the number of intramolecular vibrational modes, V is the electronic coupling between the donor and acceptor states, x_j and p_j are the position and momentum of the jth normal mode with mass m_j and frequency ω_j, respectively, c_j is the coupling strength between the charge carrier and nuclear vibration for the jth normal mode, and $\sigma_x = |1\rangle\langle 2| + |2\rangle\langle 1|$ and $\sigma_z = |1\rangle\langle 1| - |2\rangle\langle 2|$ are the Pauli matrices. It has been shown that the frequency ω_j and the reorganization energy λ_j can be easily computed

[29,33,46] from the normal mode analysis with DUSHIN program [47], so the coupling strength c_j can be obtained with the relationship $c_j^2 = \frac{1}{2} m_j \omega_j^2 \lambda_j$. Meanwhile, the electronic coupling between the donor and acceptor states can be obtained from a direct method [48,49], which has been shown to be reliable in the literature [32].

Having obtain the Hamiltonian for the CT reaction, we start from the real-time flux–flux correlation function (FFCF) [50], then the rigorous quantum mechanical rate constant can be written as

$$K = \int_{-\infty}^{\infty} dt C_{ff}(t), \tag{2}$$

where the real-time FFCF $C_{ff}(t)$ has the form

$$C_{ff}(t) = \frac{V^2}{\hbar^2 Z} \mathrm{Tr}\left[e^{-\beta H} e^{iHt/\hbar} \sigma_y e^{-iHt/\hbar} \sigma_y\right]. \tag{3}$$

Here, $Z = \mathrm{Tr}[e^{-\beta H}]$ is the sum of partition functions for the donor and acceptor states, $\sigma_y = i(|2\rangle\langle 1| - |1\rangle\langle 2|)$ is the Pauli matrix, and $\beta = 1/k_B T$ where T is the temperature and k_B is the Boltzmann constant. It has been shown that the CT rates are often dominated by stationary phase point trajectories in imaginary time [51]. For the self-exchange CT reaction, one of the stationary phase points occurs at a pure imaginary time $\tau_{st} = i\beta\hbar/2$ [52]. The integral in Eq. (2) can then be translated to an integral over the line $t' = \tau_{st} - t$ through the standard contour integral methodology:

$$k = \int_{\tau_{st}-\infty}^{\tau_{st}+\infty} dt C_{ff}(\tau_{st} - t). \tag{4}$$

When the Wick's rotation $t \to -i\tau$ is introduced, Eq. (4) in terms of the time integral of the real-time FFCF becomes the imaginary part of the integral of imaginary-time FFCF

$$k = \mathrm{Im} \int C_{ff}(\tau_{st} + i\tau) d\tau \tag{5}$$

with the imaginary-time FFCF

$$C_{ff}(\tau) = \frac{V^2}{\hbar^2 Z} \mathrm{Tr}\left[e^{-(\beta\hbar - \tau)H/\hbar} \sigma_y e^{-\tau H/\hbar} \sigma_y\right]. \tag{6}$$

To calculate the imaginary part of a diverging integral in Eq. (5), the saddle point approximation is made for the imaginary-time FFCF, that is, we write the imaginary-time FFCF as $C_{ff}(\tau_{st} + i\tau) = e^{-\phi(\tau_{st} + i\tau)}$ and expand $\phi(\tau_{st} + i\tau)$ at τ_{st} to get $\phi(\tau_{st} + i\tau) \approx \phi(\tau_{st}) - \frac{1}{2}\phi''(\tau_{st})\tau^2$, then the quantum CT rate constant is expressed as

$$K = C_{ff}(\tau_{st}) \sqrt{\frac{2\pi}{C''_{ff}(\tau_{st})/C_{ff}(\tau_{st})}}. \tag{7}$$

It is obvious that the imaginary-time FFCF at τ_{st} is required to obtain the CT rates in the grains. A path integral Monte Carlo route has been given to compute the imaginary-time FFCF [33], which is a simplified version of the calculation of real-time correlation functions by Cao et al. [53].

For the charge transport at GBs, it has been accepted that there exists an energy barrier at each boundary between grains [15,34,35,38]. When the grain size is small, the traps can be seemed to be uniformly distributed, so Horowitz et al. have shown a relationship between the mobility and the energy barrier E_{gb} at GBs as $\mu = \mu_0 e^{-E_{gb}/k_B T}$ where μ_0 is the trap-free mobility in grains [40]. It has been shown that the extended-state transport model is invalid above 150 K for oligoacenes [23] which have larger transfer integrals than the sexithiophene and the CT rates are present in sexithiophene crystals [32,33]. Therefore, a different assumption is made in the present paper that the energy barrier has a direct relationship with the CT rate (k_{gb}) at GBs:

$$K_{gb} = k e^{-E_{gb}/k_B T}. \tag{8}$$

The reason for such assumption is that the molecules near GBs are usually distributed irregularly [6,40], so the electronic couplings between molecules in different grains change rapidly and can vary several orders of magnitude [30,54] which can prevent charge carriers to transport from one grain to the other grain and may be a possible origin of the energy barriers at GBs. Thus, the energy barrier E_{gb} can represent the extent of molecular disorder near the boundaries between grains. While the relationship between k_{gb} and E_{gb} cannot be accurately expressed with Eq. (8), we do not expect the results to be qualitatively different as long as k_{gb} increases strongly with decreasing the barrier height at GBs, which has been verified by different group [24,38]. When the CT rates in the grains and across the GBs have been obtained, a random walk method is then used to simulate the charge mobility with Einstein relation $\mu = eD/k_B T$ [29,46,55] where the diffusion coefficient $D = \lim_{t\to\infty}(l(t)^2/4t)$ for the 2D charge transport. The averaged squared displacement $l(t)^2 = \frac{1}{K}\sum_{i=1}^{K} l_i(t)^2$ can reach an approximately linear function of simulation time t when the number K of trajectories for random walk is 5000 (Fig. 2). Then the effect of the GBs in polycrystalline organic semiconductors is naturally included into the charge mobility. If the grain size is small enough such that the charge carrier is scattered by the GBs for each hopping, the hopping time is $e^{E_{gb}/k_B T}$ times larger than that in perfect organic semiconductors, so Horowitz et al's relation $\mu = \mu_0 e^{-E_{gb}/k_B T}$ is easily obtained.

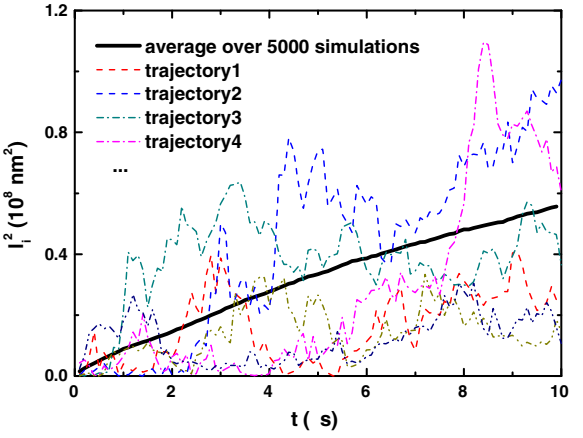

Fig. 2. Squared displacement $l_i(t)^2$ versus simulation time for a 2D sexithiophene layer with L = 60 nm and E_{gb} = 100 meV at room temperature. Each thin line represents an individual simulation of the random walk. The thick solid line means the average over 5000 simulations.

3. Results and discussion

The present model is only used to investigate the charge transport in sexithiophene polycrystals above 200 K because the energy band model is inapplicable above this temperature [23] where the thermal fluctuation can destroy the translational symmetry of the electronic Hamiltonian. The CT rates in perfect organic semiconductors based on the sexithiophene crystal structures in HT and LT phases have been obtained with Eq. (7) in our previous work [33], which can be used as the CT rates in the grains for the present model. Then the CT rates at GBs can be easily obtained from Eq. (8) if the energy barrier at GBs is given. The structural defects in polycrystalline organic semiconductors usually form shallow traps at GBs [16,41,56] and the barrier height from the traps can be changed by tuning the gate voltage [37,40]. It has been shown that the barrier height varies from 0 to 150 meV in sexithiophene for different gate voltages [34], so the energy barrier in this region is used into Eq. (8) to calculate the CT rates at boundaries between grains.

Fig. 3 shows the charge mobility of the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase for different energy barriers at GBs. The grain size varies from 60 to 300 nm in Fig. 3, which has been obtained as a function of substrate temperature in oligothiophene field-effect transistors [40]. The charge mobility in perfect organic semiconductor [33] is also shown there. It can be seen in Fig. 3(a) that the mobility increases with decreasing temperature showing that the charge transport is band-like for perfect organic semiconductor, but the mobility becomes slightly thermally activated in Fig. 3(b) when the barrier height is 25 meV, so the increase of mobility with increasing temperature can be easily obtained when the barrier height at GBs is small. When the barrier height increases to 50 meV, it is shown in Fig. 3(c) that the mobility increases consistently with temperature in the investigated temperature region for all the grain sizes, so the charge transport becomes increasingly thermally activated as the barrier height increases. However, the situation is much different when the sexithiophene crystal structure in LT phase is used to simulate the charge transport in the polycrystalline organic semiconductor. We can see in Fig. 4(b) that the mobility decreases with increasing the temperature when the barrier height is 25 meV. The thermally activated mobility cannot be observed for all the grain sizes. When the barrier height is 50 meV, Fig. 4(c) shows that the mobility increases obviously with temperature for the grain size of 60 nm and increases slightly with temperature when the grain size is 180 nm, but the mobility is almost unchanged below 350 K and then decreases slightly with increasing temperature when the grain size increases to 300 nm. When the barrier height increases to 75 meV, the thermally activated

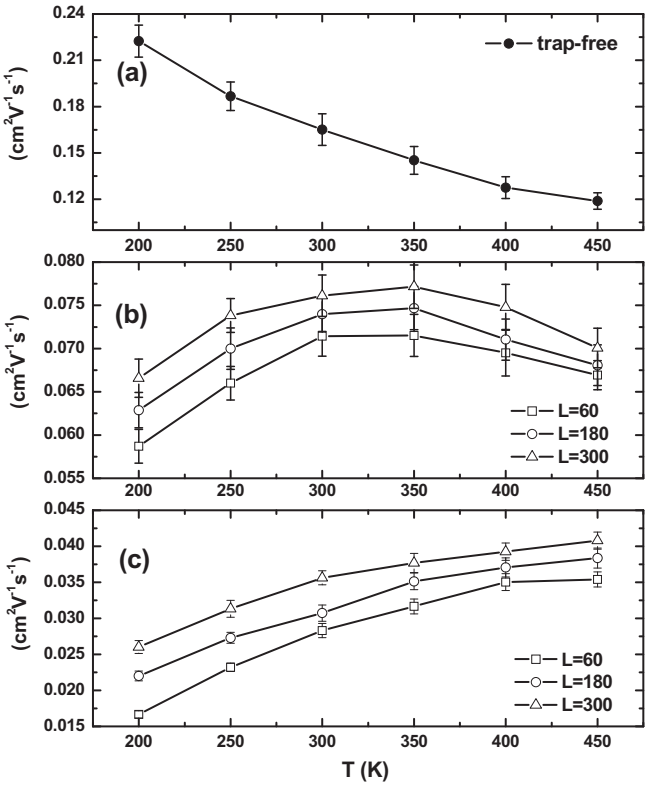

Fig. 3. The hole mobility as a function of temperature for the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase: (a) for E_{gb} = 0 meV or trap-free; (b) for E_{gb} = 25 meV; (c) for E_{gb} = 50 meV. The solid circles represent the trap-free mobilities; the hollow squares represent the mobilities for the grain size of 60 nm; the hollow circles represent the mobilities for the grain size of 180 nm; the hollow triangles represent the mobilities for the grain size of 300 nm.

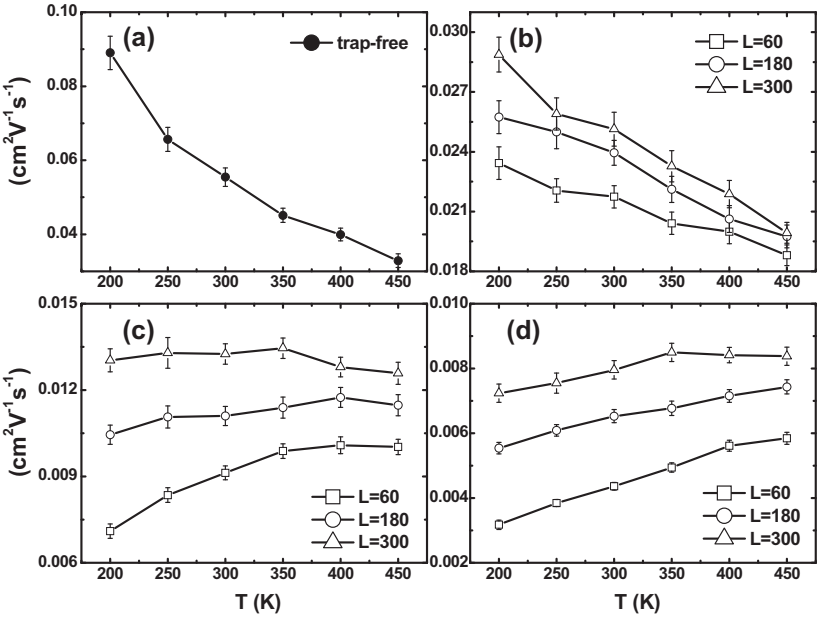

Fig. 4. The hole mobility as a function of temperature for the polycrystalline organic semiconductor based on the sexithiophene crystal structure in LT phase: (a) for E_{gb} = 0 meV or trap-free; (b) for E_{gb} = 25 meV; (c) for E_{gb} = 50 meV; (d) for E_{gb} = 75 meV. The symbols are the same as those in Fig. 3.

mobilities are observed in Fig. 4(d) for all the grain sizes. The comparison between Figs. 3 and 4 shows that the barrier height at GBs for mobility to become thermally activated is larger in HT phase than that in LT phase. This difference can be easily understood from the molecular packing in grains which actually correspond to the sexithiophene crystal structures of the HT and LT phases in Fig. 1, respectively [33]. For the HT phase, there is a displacement of about one thiophene along the long molecular axis in Fig. 1(a) for the adjacent molecules in one molecular layer. This packing manner makes the high occupied molecular orbitals of adjacent molecules in a monolayer being bonding or antibonding which can lead to large electronic couplings. However, in the LT phase, the displacement along the long molecular axis for the neighboring molecules in a monolayer is about half a thiophene ring width in Fig. 1(b), so there is some mixing between bonding and antibonding overlaps in the LT phase and the electronic couplings are then smaller than those in the HT phase [46]. It has been shown that the non-perturbative effect of these electronic couplings in the HT phase reduces the CT rates much more than those in the LT phase especially in low temperatures [33]. The CT rates, thus the mobilities, become less dependent on temperature in the HT phase than those in the LT phase, which have been shown in Figs. 3 and 4(a). When the traps at GBs are considered, the mobilities in the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase are easier to be thermally activated. This may be the reason that the thermally activated mobility is often obtained from experiments for sexithiophene field-effect transistors [37,40]. Recently, Yamagishi et al. have indicated that the intrinsic charge transport is band-like inside the trap-free grains, but the mobility decrease monotonically with decreasing temperatures for the whole polycrystalline organic semiconductors where the boundaries between grains are present [15], which is in excellent agreement with the present model. That is, Figs. 3 and 4 show that the mobility in grains decreases with increasing temperature while the mobility for the whole polycrystalline organic semiconductors can increase monotonically with increasing temperature when the barrier height at GBs is large. Thus, the quantum treatment for the nuclear degrees of freedom is required for understanding the band-like transport in grains [29,31] while the traps at GBs are responsible for the mobility to be thermally activated [40]. The mobilities from experiments for polycrystalline OTFTs have combined the effects of nuclear tunneling and traps at GBs. When the barrier height at GBs is much small, the contribution of band-like transport in grains will be predominant for the mobility of the whole polycrystalline organic semiconductors, so the mobility from experiments for polycrystalline OTFTs can decrease with increasing temperature. This may provide a possible explanation for the recent experiment by Sakanoue and Sirringhaus where the band-like transport has been observed for the whole polycrystalline organic semiconductors with the barrier height of several micro-electron volts at boundaries between grains [56].

The mobility has been shown to vary greatly in experiments when the sexithiophene thin films were deposited on different substrates in OTFTs. For example, the measured mobility is 0.025 $cm^2 V^{-1} s^{-1}$ when the sexithiophene thin film was deposited directly on a thermally oxidized silicon wafer [57] while the mobility can reach 0.08 $cm^2 V^{-1} s^{-1}$ when the surface of the silicon dioxide was treated with a self-assembled monolayer prior to the deposition of the sexithiophene on the substrate [58].

Thus, the properties of semiconductor/insulator interfaces are critically important to the operation of OTFTs [59]. Later, a robust connection between organic semiconductor/insulator interfaces and energy barriers at GBs has been demonstrated [60,61]. Since the majority of charge carriers in OTFTs are confined within the first few layers of the organic semiconductor/insulator interface [39], any variation of energy barriers within these layers will affect the charge carrier motion. To see this more clearly, we show the relationship between charge mobility and barrier height at GBs in Fig. 5 for the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase. The mobility for perfect organic semiconductors ($E_{gb} = 0$) [33] is also shown there. It is obvious in Fig. 5 that the mobility decreases rapidly as the barrier height increases even if the energy barrier at GBs is very small. For example, the mobility is about 0.16 $cm^{-2} V^{-1} s^{-1}$ when there is no energy barrier at GBs while the mobility decreases to about 0.07 $cm^{-2} V^{-1} s^{-1}$ when the barrier height at GBs is 25 meV. While the rapid variation for mobility with energy barrier at GBs is observed, we notice that the present results are still coincident with experiments [25,57,58]. The mobility (0.08 $cm^2 V^{-1} s^{-1}$) for sexithiophene in Ref. [58] corresponds to the result in Fig. 5 where a small barrier height is present at boundaries between grains while the mobility (0.025 $cm^2 V^{-1} s^{-1}$) for sexithiophene in Ref. [57] corresponds to the mobility where a large barrier height is present at grain boundaries. Comparing the preparing process for OTFTs in Refs. [57,58], it seems to show that the interface treatment with a self-assembled monolayer in organic semiconductor/insulator interface can largely reduce the energy barrier at GBs although the detailed relation between interface and energy barrier at GBs is still open for further studies. Recently, Marumoto et al. have shown that the trapping time of charge carriers at the interface greatly decreases in rubrene field-effect transistors by interface treatment with a self-assembled monolayer [62], which can be explained with the present model. When the energy barrier at GBs is largely reduced by interface treatment with a self-assembled monolayer, the CT rates at GBs are much larger than those without interface treatment with a self-assembled monolayer, so the charge carrier has a larger probability to hop across the boundaries between grains and then the trapping time in one grain is largely reduced. In addition, we can see in Fig. 5 that the influence of grain sizes is much small as compared to that of boundaries between grains. As the grain size increases from 60 to 300 nm, the mobility varies slightly in the investigated region of energy barrier. Therefore, the GB is the main bottleneck to field-effect mobility measured for the whole polycrystalline materials which is consistent with the previous conclusion [15,16,38].

The relation between mobility and grain size has also been shown in experiments for OTFTs, but incompatible conclusions have been made in the literature [38,40,63]. For example, Horowitz and Hajlaoui have shown that the mobility increases roughly linearly with increasing the grain size [40,63] while Carlo et al. have shown that the mobility decreases dramatically with decreasing the grain size when the grain size is small [38]. However, it is surprisingly found that the above discrepancy can be easily reconciled from the present model. When the grain size is small, we can see in Fig. 6(a) that the mobility increases rapidly as the grain size increases from 0 to 60 nm especially when the energy barrier at GBs is large, which

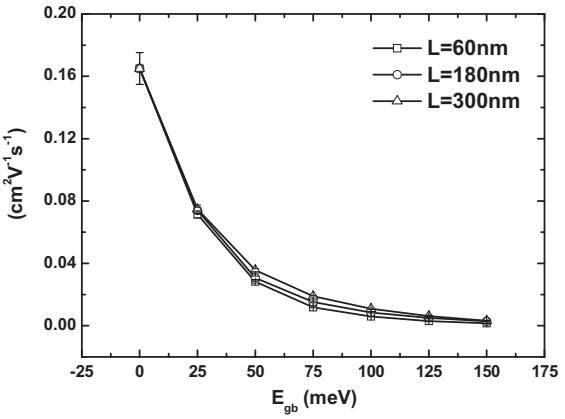

Fig. 5. The hole mobility as a function of energy barrier at grain boundaries for the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase at 300 K. The hollow squares represent the mobilities for the grain size of 60 nm; the hollow circles represent the mobilities for the grain size of 180 nm; the hollow triangles represent the mobilities for the grain size of 300 nm.

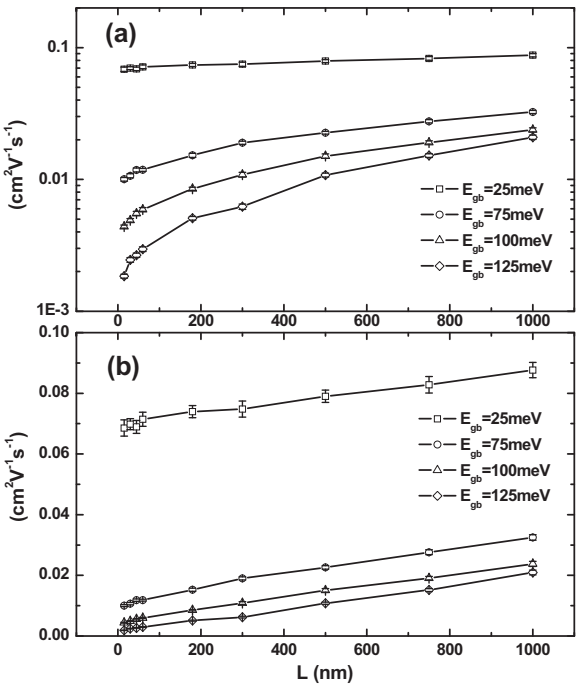

Fig. 6. The hole mobility as a function of grain size for the polycrystalline organic semiconductor based on the sexithiophene crystal structure in HT phase at 300 K: (a) linear plot; (b) log-linear plot. The hollow squares represent the mobilities for E_{gb} = 25 meV; the hollow circles represent the mobilities for E_{gb} = 75 meV; the hollow triangles represent the mobilities for E_{gb} = 100 meV; the hollow diamonds represent the mobilities for E_{gb} = 125 meV.

shows that a high energy barrier at GBs is responsible for the rapid increase of mobility with grain size. When the grain size is larger than 60 nm, we can see in Fig. 6(b) that mobility shows a roughly linear increase with grain size no matter when the barrier height at GBs is large or small, which is in good agreement with Horowitz et al. model [40]. Thus, a roughly linear dependence of mobility on grain size can be predicted from the present model for large grain size although the linear relationship between mobility and grain size has not been presumed in the present model.

4. Conclusion

In summary, we propose a model to simulate charge transport in polycrystalline organic semiconductors where the trap-free grains are separated by boundaries between them and the carrier hopping between adjacent molecules is believed as the basic transport process. The CT rates in grains are calculated from a quantum CT rate theory without weak electronic coupling approximation while the charge transport at GBs is controlled by an energy barrier between grains. The polycrystalline organic semiconductors based on the sexithiophene crystal structures in HT and LT phases are used to show the effect of GBs for charge transport. It is found that the nuclear tunneling effect is required for understanding the band-like transport in grains while the traps at GBs are responsible for mobility to be thermally activated. Meanwhile, the mobility in HT phase is easier to be thermally activated that in LT phase, which is due to that the electronic couplings in the HT-phase crystal structure are larger than those in the LT-phase crystal structure. Thus, we conclude that the charge transport in polycrystalline organic semiconductors is not only influenced by the traps at GBs but also by molecular packing in grains. It is also found that the mobility shows a roughly linear relationship with the grain size when the grains size is large while the rapid change of mobility with grain size is observed for small grain size, which reconciles the discrepancy for mobility versus grain size in experiments. Finally, we point out that the energy barrier at boundaries between grains is mainly responsible for mobility degradation observed in devices even if the barrier height is much small, so the efforts for improving the mobility should be put on reducing the barrier height during the preparing process of OTFTs. The energy barriers at GBs are still undetermined in the present study. This is due to that the present authors have fully realized that the energy barriers at GBs have close relationship with many factors, such as the organic semiconductor/insulator interface [64] which has beyond the scope in this paper and is left to a future work.

making it (also) an ideal tool for patterning on foil in, for example, a R2R line.

Flexibility is introduced in an organic electronic device by the substrate material, typically being a polyester, polyimide or polycarbonate [13,14]. Paper has been reported for the fabrication of flexible electronic devices [15], although the rough surface is limiting the usage of it. Of the polyesters, poly(ethylene terephthalate) (PET) and poly(ethylene naphthalate) (PEN) are often used [16–18] and are well-studied [19,20], combining good mechanical properties and a reasonably high resistance to oxygen and water vapor penetration, making them good candidates for R2R integration. The gas permeability can be further decreased by the deposition of barrier layers such as Ormocer [21].

The fabrication of flexible electronic devices requires a process with good registration of the involved layers, in particular the registration of the source–drain contacts to the gate layer for TFTs. Flexible organic transistors have been fabricated by photolithographic patterning [22–26], stamping methods [27] and inkjet printing [28,29], all showing different advantages and disadvantages regarding registration, process temperature, feature size and device performance [1,28,30]. With conventional printing techniques, typical channel lengths in the range of 10 μm are obtained, limiting the bandwidth to 10 kHz for printable semiconductors with typical mobilities of 0.01 $cm^2/V\,s$ [31]. Fast, sub-micron transistors are, other than with conventional patterning techniques such as photolithography, readily available by NIL, being an intrinsically sub-micron and truly nanometer patterning technique. Organic thin film transistors have been demonstrated with source–drain contacts defined by thermal NIL on foil [32] and by UV NIL on glass [33], both having a photolithographically patterned bottom gate. On PET foil, gate structures have been patterned by UV NIL, followed by a backside exposure step defining the source–drain contacts in a self-aligned fashion using the previously defined gate as photomask [31].

In this study we report common gate TFTs on flexible PEN foil, in which interdigitated source–drain contacts are defined by SFIL. As such, this report aims to improve upon earlier reports [31–33] by the combination of electrode design (interdigitated), imprint process (SFIL) and choice of foil substrate (PEN). Future developments will require patterning of the gate as well and implementation into R2R for large-area device fabrication. The devices targeted here do not require any alignment step due to the chosen architecture, and can therefore be seen as the first step towards fully patterned, flexible TFTs with all functional layers defined and registered by UV NIL. The foil has been reversibly glued to a carrier for improved handling and dimensional stability during the process. SFIL has been chosen as the patterning process not only for its potential for high resolution patterning, but also and foremost for its potential for implementation in R2R. The semiconductor has been inkjet-printed, and the electronic performance of the fabricated flexible TFTs has been characterized.

2. Results and discussion

2.1. Design and process scheme

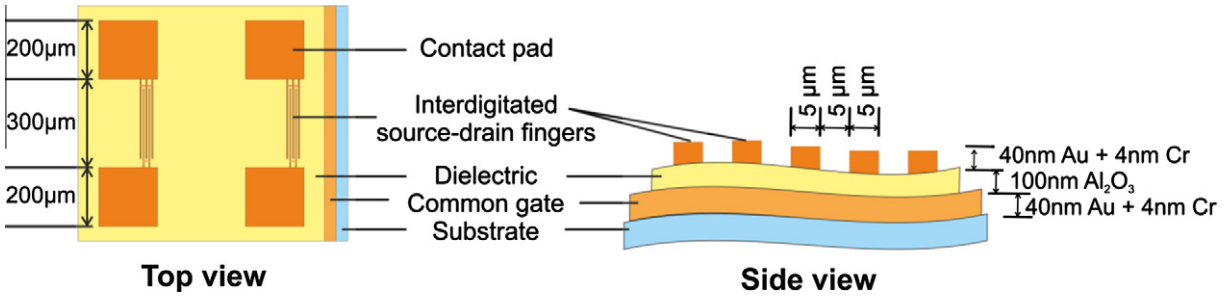
Scheme 1 shows a schematic top and side view of the here fabricated flexible thin film transistors (TFTs) in a bottom contact, bottom and common gate architecture. Source and drain, patterned by SFIL, are made of five interdigitated, 5 μm wide and spaced fingers.

Scheme 2 shows the process flow for the fabrication of common gate flexible TFTs with an SFIL-defined source–drain layer. Substrates are made of PEN foil, reversibly glued to a carrier (foil-on-carrier; FOC), coated with a metal–insulator–metal (MIM) stack. A UV-curable resist is dispensed on the substrate and brought into contact with a UV-transparent template (Scheme 2A). The template is demolded after exposure and curing of the resist with UV light, leaving an inverse replica of the template features on the substrate (Scheme 2B). The remaining residual layer is removed by reactive ion etching (Scheme 2C). Unprotected Au and Cr are subsequently removed by wet etching and ion beam etching. The remaining resist is stripped off by O_2 plasma (Scheme 2D). In the final step, two types of self-assembled monolayers (SAMs), pentafluorobenzenethiol (PFBT) and trichlorophenylsilane (TCPS) (Fig. 1), are applied before the semiconductor is deposited by inkjet-printing of a blend of 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS pentacene) and polystyrene (PS) (Scheme 2E).

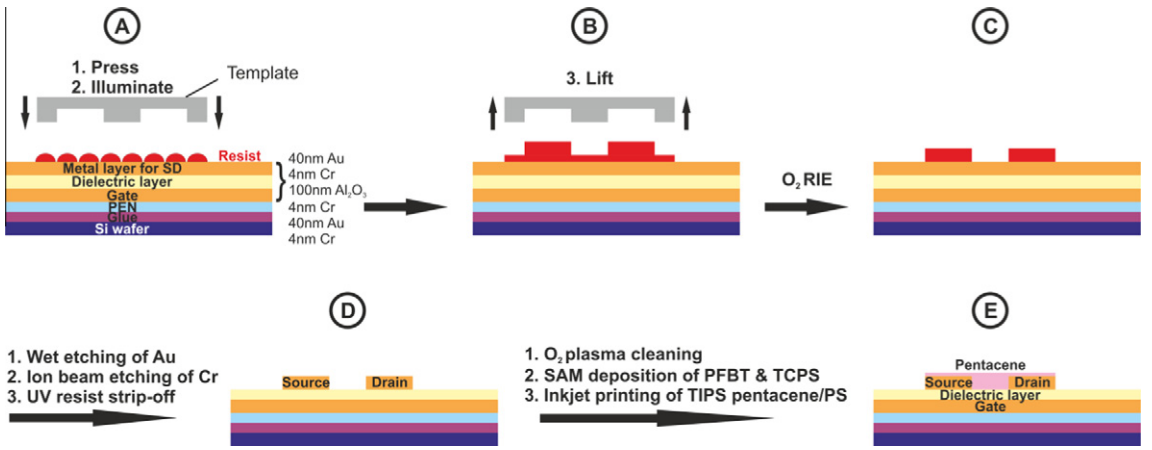
2.2. Fabrication

The dimensional stability and flatness of the 125 μm thick PEN foils was improved by reversibly gluing them to a carrier (foil-on-carrier; FOC), allowing conformal contact during imprinting and a reduced residual layer thickness. The MIM layer on the FOC was deposited by electron-beam evaporation of subsequently 5 nm Cr, 40 nm Au and 5 nm Cr (common gate), 100 nm Al_2O_3 (dielectric), and 5 nm Cr and 40 nm Au as the source–drain layer. Cr was used as an adhesion promoter. The quality of the imprint and the residual layer thickness remaining after imprinting are dominated by the waviness of the fabricated FOC. Significant effort has therefore been devoted to reduce the waviness and bending of the FOCs.

In first attempts, PEN foil was laminated manually, and later on with a lamination tool, onto a glue, followed by thermal curing. The difference in expansion coefficients between the PEN foil, glue and Si wafer led to such a drastic bowing of the FOC (>30 μm) that it could not be taken up by the vacuum chuck in the imprint tool. Contacting of the template on the FOC, homogeneous filling and residual layer formation were not possible due to the waviness of the foil. In the here developed FOC fabrication technique, the glue was replaced by the thermoplast poly(methyl methacrylate) (PMMA) and spincoated on a Si wafer. The PEN foil was activated by a short plasma treatment and pressed against the PMMA at an elevated temperature of



Scheme 1. Schematic top and side view of the TFT architecture. The source–drain layer defined by SFIL is patterned on top of the stack of dielectric and common gate. For each TFT, five interdigitated 5 μm wide and spaced fingers are connected to either the source (three fingers) or drain (two fingers) contact pads, having a width of 200 μm.



Scheme 2. Process flow for the fabrication of common gate TFTs with imprinted source–drain fingers. In the first step pL amounts of resist are drop-dispensed on the MIM stack-covered foil-on-carrier. (A) The template is pressed into the liquid UV-resist and cured for 10 s. (B) After demolding of the template (C) the thin residual layer is removed by O_2 RIE. (D) Pattern transfer into the top metal layer is followed by wet etching of the Au in KI:I_2:H_2O 4:1:40 and ion beam etching of the 5 nm Cr layer. (E) After the resist is stripped off with O_2 plasma, PFBT and TCPS self-assembled monolayers (SAMs) are deposited onto the surface and a blend of TIPS pentacene/PS is inkjet-printed on top of the interdigitated source–drain fingers.

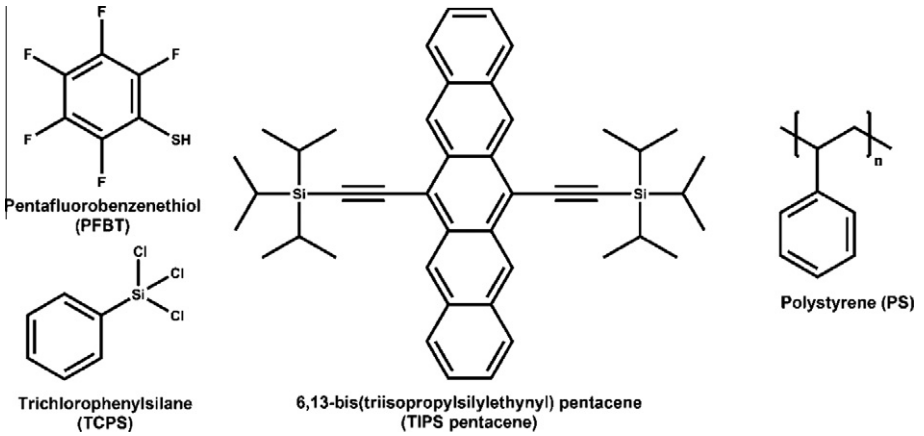


Fig. 1. Molecular structures of PFBT and TCPS, deposited as self-assembled monolayers on the Au structures and on the dielectric Al_2O_3, respectively, and of the semiconductor blend components TIPS pentacene and PS.

190 °C under 40 bar pressure with a non-patterned Si wafer in an embosser tool (Eitre 6 from Obducat). The here developed FOC fabrication technique allowed imprinting on FOCs with a bowing of less than 10 μm and surface

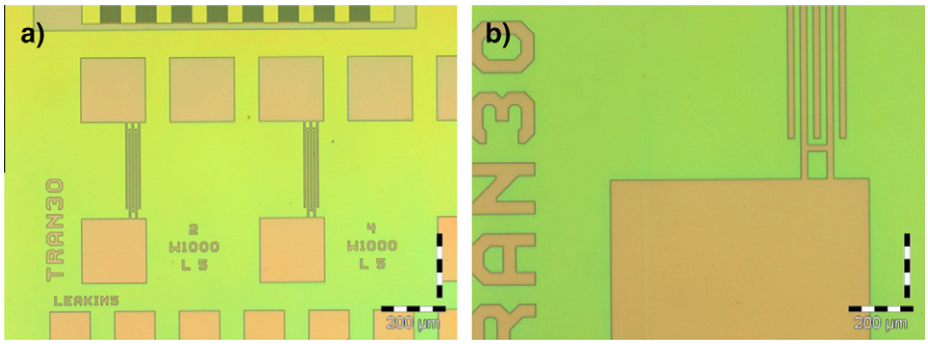

Fig. 2. Optical microscopy images of 5 µm wide and spaced interdigitated line structures connected to 200 µm wide contact pads after imprinting (Scheme 2B). The substrate is a MIM-coated PEN foil reversibly glued to a carrier.

waviness of ~1 µm (see Supporting information for surface contour plots).

The UV-transparent quartz template used as the template for imprinting, contained test features in the dimensional range of 750 nm up to 1.4 mm and the TFT features as shown in Scheme 1 on an active area of 15×15 mm^2 with a depth of 200 nm.

In the first step towards flexible, common gate TFTs with an SFIL-patterned source–drain layer, a low viscosity, organic, and UV-curable resist (MonoMat™) was field-by-field drop-dispensed in pL amounts onto the substrate (Scheme 2A). The template was brought into contact with the resist droplets under low pressure (2–3 N) and at room temperature. Capillary force action pulled the template further down spreading the resist over the active area and filling thereby the structures in the template within 60 s. Broadband UV light was guided through the template curing the resist within 3 s, leaving an inverse replica of the template features on the substrate after demolding (Scheme 2B). An anti-sticking layer (RelMat™) applied to the template before imprinting allowed easy demolding and complete pattern transfer with no residues left on the template. With the field-by-field imprinting technique SFIL, it was possible to imprint the entire FOC (diameter 100 mm) with a throughput of approximately 2 min per field.

The optical microscopy images in Fig. 2 display 5 µm wide and spaced lines connected to 200 µm square pads directly after imprinting on MIM-coated FOC. The overall residual layer thickness and the filling height of the structures were relatively homogeneous, as can be deduced from the absence of color deviations within the layers. The contrast in color suggests sharply defined edges of the imprinted structures. Pinholes and other filling errors were not observed.

After imprinting, the residual layer was removed by oxygen-based reactive ion etching (O_2 RIE) (Scheme 2C). A residual layer thickness of 80 nm was determined by profilometry before etching. Especially in the residual layer removal step, the waviness of the FOC plays an important role. Features imprinted on top of a hill of the wave have a thinner residual layer compared to features imprinted in the valley. Removal of the residual layer of features in the wave valleys partially coincides with complete removal of the features on the hills if the feature height is less than the wave height.

The source–drain areas remained covered with resist, allowing selective wet etching of the unprotected Au. The underlying Cr adhesion layer had to be removed by ion beam etching (IBE), as wet etching also lifted the Al_2O_3 dielectric layer underneath, due to weak adhesion of the oxide to the underlying gold layer. Improvement of adhesion was attempted by inserting an additional thin layer of Cr on top of the unpatterned gate metal just before oxide deposition. However, the adhesion was not sufficient to withstand the wet etching step. After IBE, the remaining resist was stripped off by O_2 plasma (Scheme 2D).

Fig. 3 shows optical microscopy images of the features after residual layer removal, wet etching of the Au, dry etching of the Cr layer, and resist strip-off. Additional examples of successful sub-micron features patterned by SFIL on FOC are given in the Supporting information. The bright yellow color indicates the Au features on the (orange colored[1]) Al_2O_3 dielectric layer. The features appear sharply defined and no pinholes were observed, deduced from the absence of bright spots in the closed orange layer.

As the TFT was made in a bottom-contact, bottom-gate architecture, the final layer added to the device was the organic semiconductor. A PFBT SAM was deposited from ethanol solution on all gold contacts to modify the charge injection [34]. TCPS was deposited by vapor deposition on all oxide surfaces to reduce electron trapping. SAMs are known to improve the molecular order of the deposited semiconductor [35]. A blend of TIPS pentacene:PS in a 2:1 w/w ratio, was inkjet-printed at a substrate temperature of 70 °C from tetraline solution onto the interdigitated source–drain fingers, leading to TIPS pentacene crystals grown from the edge to the center of the inkjet-printed droplets [36].

Fig. 4a shows an optical microscopy image of inkjet-printed TIPS pentacene/PS on the interdigitated source–drain fingers patterned by SFIL. Accurate control of the dispensing unit allowed the deposition of one drop of semiconductor on each of the four TFTs. A microscope

(a) One drop of TIPS pentacene/PS inkjet-printed on each of the four interdigitated 5 μm wide and spaced source–drain fingers. (b) Crossed polarizer optical microscopy image of one drop of TIPS pentacene/PS inkjet printed on the source–drain fingers showing a crystal growth from the edge to the center.

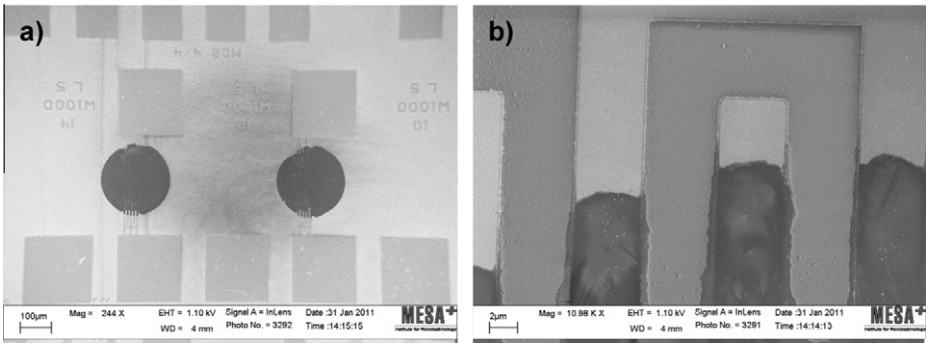

Fig. 5. High resolution SEM images after semiconductor deposition of (a) two TFTs, and (b) part of the source drain fingers displaying a line edge roughness of ~70 nm caused by wet etching.

image taken with cross polarizers shows the crystal orientation of the birefringent TIPS pentacene crystals, pointing to the center of the drop (Fig. 4b).

The high resolution SEM images in Fig. 5 show the final TFTs after semiconductor deposition, displaying a line edge roughness (LER) of about 70 nm caused by the short (10 s) wet etching of the gold. Any LER introduced by imprinting, representing an exact replica of the LER of the template, is negligibly small in comparison to the LER caused by wet etching of the gold.

2.3. Electrical characterization

Electrical characterization of the SFIL-patterned flexible TFTs was performed in a non-illuminated glove box under N_2 atmosphere. The contact to the common gate was

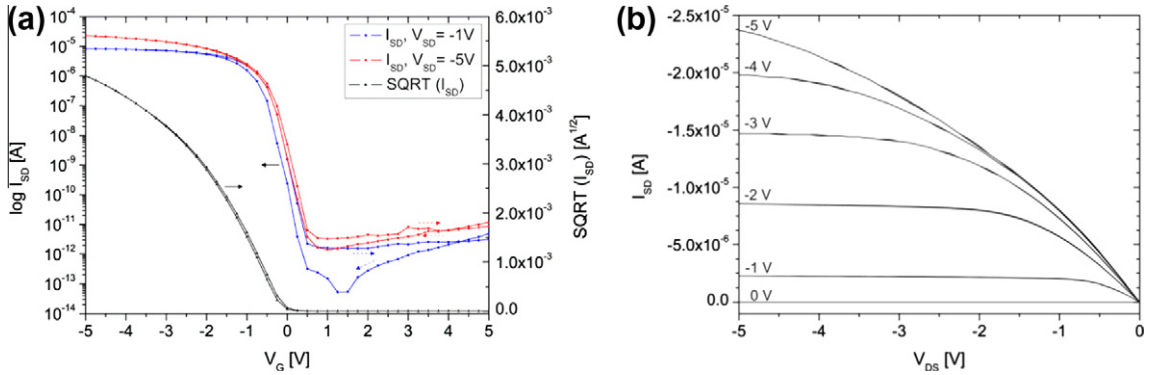

Fig. 6. (a) Transfer characteristics of an SFIL-patterned TFT in a bottom contact, bottom gate architecture. Channel length and width are 5 and 766 μm, respectively. A 100 nm thick Al_2O_3 layer served as the gate dielectric, and a blend of TIPS pentacene/PS as the semiconductor. The dashed arrows indicate the sweep direction (gate swept from +5 V → −5 V → +5 V). (b) Output characteristics of the same transistor. V_G was varied between 0 and −5 V at a step of −1 V.

established by penetrating the dielectric layer with one of the probe station needles. The source and drain contact pads were each gently contacted with another probe needle. The gate voltage was varied from 5 to −5 V in a double scan and the bias over source and drain (V_{DS}) held at −1 and −5 V. The transfer and output characteristics of the best out of six transistors with a channel length L = 5 μm and a channel width W = 766 μm arranged in a comb structure are given in Fig. 6 (see Supporting information for the transfer characteristics of the five other transistors).

From the semi-logarithmic plot (log I_{SD} vs. V_G), a subthreshold swing (SS) of 190 mV/dec, an on/off ratio of 2×10^7, and a switch-on voltage of V_{SO} = 0.4 V were obtained. The switch-on voltage was taken as the gate voltage at which the drain current is one order of magnitude higher than the off-current I_{off} [33]. From the plot of the square root of I_{SD} vs. V_G, a gate-dependent mobility of μ_{SAT} = 0.56 $cm^2\ V^{-1}\ s^{-1}$ at V_G = −0.75 V (average over all six transistors: $\mu_{SAT} = 0.37 \pm 0.08\ cm^2\ V^{-1}\ s^{-1}$) and a near-zero threshold voltage of V_{th} = −0.1 V were determined. To place the here obtained TFT data in a context, they were compared with data reported in literature for TFTs with either the same blend of inkjet-printed TIPS pentacene/PS or similar device structure and channel dimensions with the source–drain electrodes in a comb structure. The averaged mobility obtained for photolithographically defined bottom-contact, bottom-gate TFTs on poly(ethylene terephthalate) foil with a (sputtered) Al_2O_3 gate dielectric and inkjet printed TIPS pentacene on SAM-treated contacts and a channel width over length of 1000 μm/5 μm is $\mu = 0.22 \pm 0.03\ cm^2\ V^{-1}\ s^{-1}$ [37]. The mobility obtained here using imprinting is slightly higher, possibly caused by an improved LER or cleaner interfaces. Previously reported TFTs with TIPS pentacene/PS (67 wt%) blend inkjet printed on photolithographically patterned Au source–drain electrodes on highly doped n^{++} Si wafers with 140 nm thermally grown SiO_2, showed an improved mobility of $\mu_{sat} \approx 0.73\ cm^2/V\ s \pm 23\%$ for a channel length of 5 μm [36]. The on/off current and the threshold voltage of these non-flexible TFTs are very similar to the here obtained values. Only a steeper SS of 67 mV/dec was obtained. A steep SS and low V_{th}, are usually taken as evidence for a high-quality gate dielectric – semiconductor interface with few charge trapping centers [36]. The higher mobility reported for the non-flexible TFTs is believed to be due to the higher quality thermally grown gate dielectric, compared to the e-gun evaporated SiO_2 deposited on the here presented SFIL-patterned flexible transistors. The results shown here confirm that high-quality TFT devices can be made using NIL which holds promise for facile R2R production and further extension to sub-micron and nanoscale feature sizes.

3. Conclusions

In this paper we show the feasibility of SFIL as a patterning technique on flexible PEN foil for the fabrication of bottom-gate (common) and bottom-contact flexible TFTs. The here developed lamination process to create FOCs is a significant improvement to achieve better imprinting uniformity, but obviously does not impose any limitation on the flexibility of the device on foil in real-life applications as the foil can be easily delaminated afterwards. Using this R2R-compatible and downscalable technique in combination with inkjet printing excellent flexible TFTs with a performance comparable with state-of-the-art devices fabricated by optical photolithographic patterning [36–38] were obtained.

Future plans concern the fabrication of flexible, patterned-gate TFTs with all functional layers patterned by the room temperature, low pressure and high precision technique SFIL. The channel length of the flexible, all-patterned TFTs will also be reduced to the sub-micrometer regime. Downscaling into the sub-micrometer regime will result in an increased impact of the LER on the performance and dimensions of the device. Wet etching of the gold is at this stage the main factor introducing LER. Therefore, an etch process with an improved LER control, such as ion beam etching, should be introduced. The final flexible TFT fabrication process is envisioned to be R2R imprinting. R2R processing requires a patterning process independent of any alignment step, as the critical source–drain to gate overlay cannot be registered precise enough. Therefore, efforts are undertaken toward the development of a self-aligned imprinting process, implementing the fabrication

lessons learned here. As soon as device layout, process parameters and R2R implementation have been achieved, other performance issue such as mechanical stability and environmental stability will be addressed as well.

4. Experimental

4.1. Materials and methods

Imprint resist MonoMat and anti-sticking layer RELMAT were purchased from Molecular Imprints Inc. Teonex® Q65a poly(ethylene naphthalate) foil (PEN, 125 μm thick) was purchased from Dupont Teijin. 6,13-Bis(triisopropyl-silylethynyl) pentacene (TIPS pentacene) was synthesized according to literature [39]. Polystyrene (PS) $M_w \approx 9.58$ kDa ($M_n = 9.32$ kDa, PDI = 1.03) was purchased from Fluka. 1,2,3,4-Tetrahydro-naphthalene (tetraline) was purchased from Merck.

4.2. Foil-on-carriers (FOC)

FOCs were made by laminating the PEN foil to a glue, previously deposited on a double-side polished wafer. As glue, a 6 wt% solution of poly(methyl methacrylate) ($M_w = \sim 38$ kDa) dissolved in toluene, both purchased from Aldrich, was spincoated on a double-side polished wafer. The stack of glue-coated wafer, activated foil and a double-side polished (unpatterned) wafer with an 1H,1H,2H,2H-perfluorodecyltrichlorosilane anti-sticking layer applied by chemical vapor deposition, were loaded in an embossing tool (Eitre® 6 from Obducat, Malmö, Sweden). The foil was glued to the wafer by heating up the stack to 190 °C under 40 bar pressure for 500 s. The top wafer (with anti-sticking layer) was demolded at a temperature of 95 °C from the finished FOC. The PEN foil could be delaminated again from the carrier by heating to a temperature of 150 °C or by dissolving the PMMA in acetone.

The MIM layer was deposited on the FOC by e-gun evaporation of subsequently 5 nm Cr, 30 nm Au and 5 nm Cr forming the common gate, 100 nm Al_2O_3 as gate dielectric, and 5 nm Cr and 30 nm Au as source–drain metal.

4.3. Step-and-flash imprint lithography (SFIL)

The UV-transparent quartz template used for the experiments was fabricated by standard e-beam lithography and RIE techniques. The template contained, on an active area of 15×15 mm^2, test features in the dimensional range of 750 nm up to 1.4 mm and the TFT features as shown in Scheme 1 with a depth of 200 nm.

SFIL was performed with an Imprio 55 tool from Molecular Imprints Inc. The imprints were carried out at room temperature and under a force of 3 N. For improved adhesion of the imprint resist (MonoMat™), the Au surface of the FOC was activated just before use by a short O_2 plasma treatment of 5 min at 300 W and 18 sccm O_2 (Apparatus Tepla 300E). MonoMat™, after field by field drop dispensing on the substrate, filled the template within 60 s and was cured through the backside of the template for 3 s with broad band UV light (exposure dose of 80 mJ/cm^2 and $\lambda = 230$–360 nm).

4.4. Residual layer removal

The thin residual layer left after imprinting was removed by anisotropic O_2 plasma based reactive ion etching in a home build tool (Etske). At a chamber pressure of 10 m Torr and 20 sccm O_2 the residual layer was removed within 1 min at 20 W.

4.5. Direct etching

RIE opened windows in the resist layer which uncovered the Au/Cr metal layer. The 30 nm Au layer was removed by 10 s wet etching in a solution of $KI:I_2:H_2O$ 4:1:400. The 5 nm Cr adhesion layer was removed by Ar Ion beam etching with an Oxford Ionfab 300, removing the Cr layer within 3 min, controlled by an endpoint detection system.

4.6. Resist strip-off

Remaining resist was stripped off in a Tepla 300E, by generation of an 300 W O_2 plasma (18 sccm) for 10 min.

4.7. Self-assembled monolayers

PFBT was deposited by 15 min exposure to a 10 mM PFBT solution in ethanol, followed by rinsing with ethanol and N_2 blow drying. N_2 was utilized as carrier gas bubbling through TCPS in a closed chamber at atmospheric pressure for 15 min to deposit TCPS on all oxide areas. The substrates were baked 2 min at 100 °C on a hotplate after flushing the chamber with N_2 to remove the side product (hydrochloric acid) of the condensation reaction.

4.8. Semiconductor deposition

An ink-jet printing setup with a high-precision vertical translation stage and a Microfab glass nozzle (type MJ-ATP-01-50-DLC, 50 μm orifice diameter) was used to print the blend of TIPS pentacene (20 mg/ml):PS (10 mg/ml) in a blending ratio of 2:1. Droplets with a volume of 50 pL were jetted on demand, onto transistor substrates kept at a temperature of 70 °C. All printing experiments were performed in ambient clean room conditions [36].

Acknowledgments

The author would like to thank Hans Mertens and Shuo Kang for their support in dry etching of the Cr adhesion layer and Bas van der Putten for SAM depositions. The program Lithography on flexible substrates of the Holst Centre is acknowledged for financial support.

Since a successful hybridization of RG-O/conducting polymer requires RG-O platelets to be fully exfoliated in a suspension and provide a modified and active sites for the hybridization, we used PIL to modify the surface of RG-O platelets. The specific PIL of poly(1-vinyl-3-ethyimidazolium) salts was explored to stabilize RG-O platelets to be suspended in organic solvent, and provide an effective linkage during the polymerization of PEDOT molecules on the RG-O surface. The resulting hybrid material of RG-O and PEDOT are found to be readily dispersed as a colloidal system without any agglomeration and its film showed synergistic effects in terms of electrical conductivity and thermal stability.

2. Experimental

2.1. Synthesis of graphene oxide and poly(ionic liquid)

Graphite oxide (GO) powder was prepared from graphite flakes using modified Hummers method [17,18]. Briefly, 5 g of graphite (Bay carbon SP-1) and 3.75 g of $NaNO_3$ were placed in a flask. Then, 375 mL of H_2SO_4 was added while stirring in an ice-water bath, and 25 g of $KMnO_4$ were slowly added for 1 h. Stirring was continued for 2 h in the ice-water bath. The reaction mixture was washed with deionized water, and reacted with a 30 wt.% aqueous solution of H_2O_2 to complete oxidation. The ions of oxidant and other inorganic impurity were removed by repeating cycle of centrifugation, removal of the supernatant liquid, and redispersing the solid using 3 wt.% HCl aqueous solution. Finally, the solid was dispersed again in water using ultrasonication for 2 h and centrifuged at 6000 rpm for 30 min to remove the multilayered species.

PIL of poly(1-vinyl-3-ethylimidazolium) salts bearing the bis(trifluoromethylsulfonyl)amide anion (NTf_2^- or $CF_3SO_2–N–SO_2CF_3$) was synthesized according to a previously reported procedure [19,20].

2.2. Poly(ionic liquid)-mediated thermal reduction of graphene oxide in propylene carbonate

Graphene oxide (G-O) suspension with a concentration of 1 mg/mL was obtained by dispersing GO powder in propylene carbonate (PC) with the aid of mild sonication

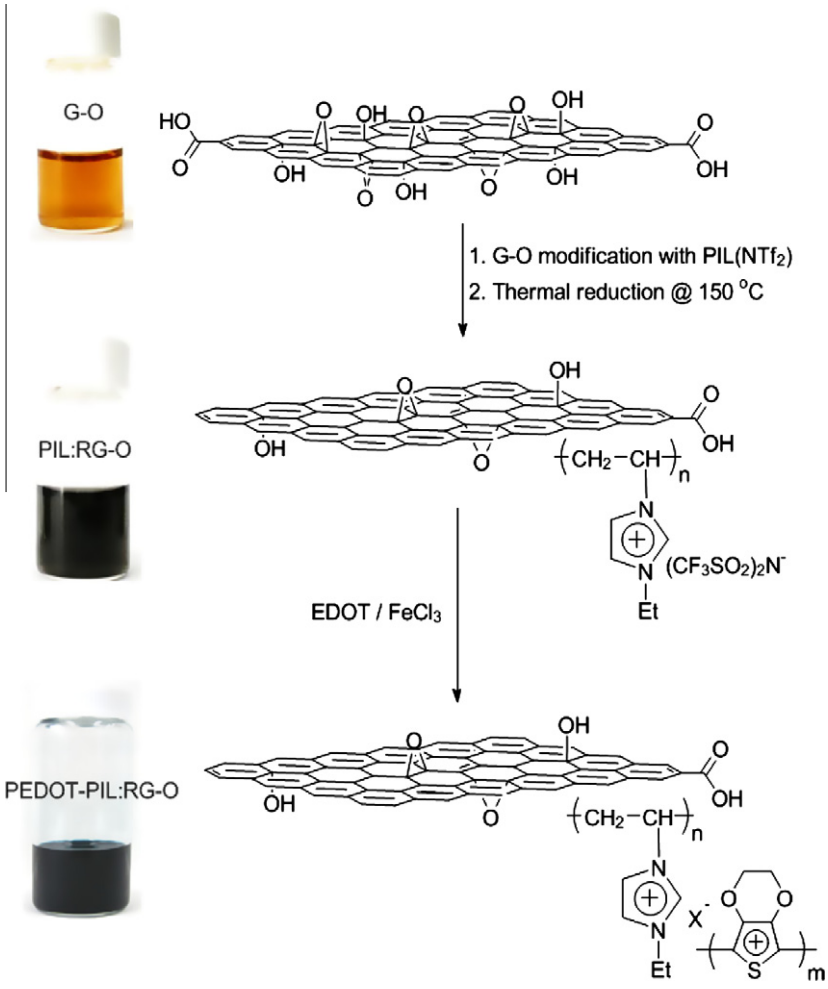

Fig. 1. The process for preparation of PIL:RG-O hybrids with conducting polymer PEDOT using poly(ionic liquids).

for 30 min. Then, PIL was added to the G-O suspension in PC and stirred for 30 min to produce PIL-modified G-O. PIL-modified G-O was prepared with different ratios of PIL/G-O (1/1, 3/1, 5/1, 10/1) by weight. In a typical process, 300 mg of PIL(NTf_2^-) were dissolved in 30 mL of anhydrous PC and added to 60 mL of G-O suspension. Under continues stirring, heating these mixture at 150 °C for 3 h yielded a thermally reduced RG-O modified with PIL (PIL:RG-O), as previously reported [21]. After cooling, a part (*e.g.*, 10 mL) of heated suspension was filtered through a Omnipore membrane (JGWP, 0.2 μm pore size, Millipore, Ireland) to obtain the resultant PIL:RG-O, followed by drying at 80 °C in vacuum for 2 days.

2.3. Hybridization of PIL-modified reduced graphene oxide and conducting polymer

The as-prepared PIL:RG-O suspension was subjected to hybridization with PEDOT. In situ polymerization of EDOT was carried out by chemical oxidative method in PIL:RG-O suspension. Typical preparation procedure for the PIL-mediated hybridization of RG-O and PEDOT (PEDOT-PIL:RG-O) composites is as follows: a mixture of EDOT (0.268 g), 1.25 mL of PIL:RG-O suspension and 60 mL of PC were introduced into a 250 mL one-necked round bottom flask and stirred for 1 h. The chemical polymerization was effected by the addition of a solution of Iron(III) chloride ($FeCl_3$, 0.30 g in 20 mL PC) into the mixture and the reaction was continued under vigorous stirring for 48 h at room temperature, yielding organic solvent dispersible PEDOT-PIL:RG-O composites. For comparison, the PIL-modified PEDOT (without any RG-O) (PEDOT:PIL) sample was also prepared separately under same conditions.

2.4. Characterization

Fourier transform infrared (FT-IR) spectra were recorded on a Nicolet Avatar 320 using KBr pellets. X-ray photoelectron spectroscopy (XPS) measurements were performed with ESCA2000 (VG Microtech) system using a monochromatized aluminum Kα anode. Raman spectra were recorded over 500–4000 cm^{-1} with an excitation wavelength of 642.8 nm using RFS-100/S Raman spectrometer equipment. Thermogravimetric analysis (TGA) measurement was performed at a heating rate of 10 °C min^{-1} under nitrogen flow using a NETZSCH STA 409 PC/PG

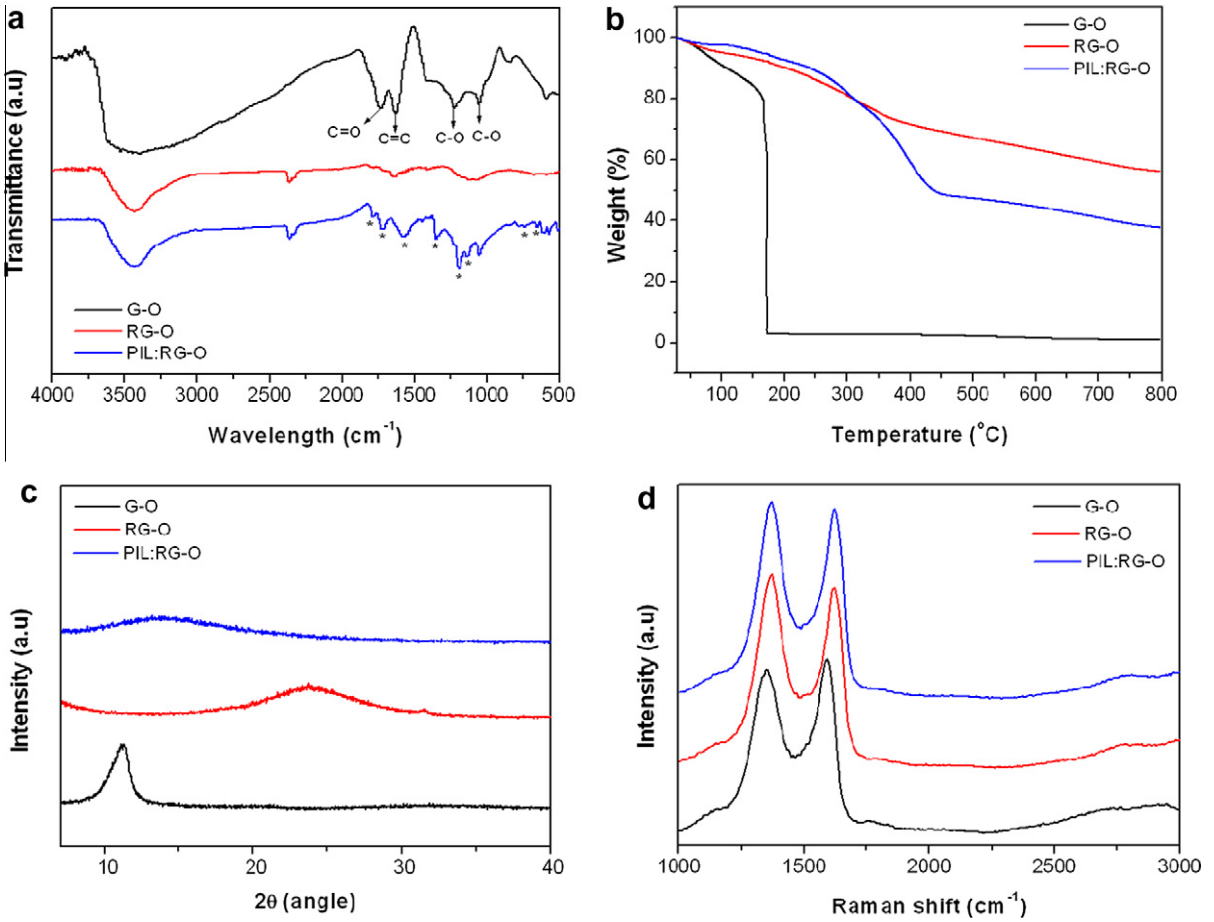

Fig. 2. (a) FTIR, (b) TGA, (c) XRD, and (d) Raman spectra of G-O (black curve), RG-O (red curve) and PIL:RG-O (blue curve). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

instrument. X-ray diffraction (XRD) data were collected on a Rigaku D/Max Ultima II Powder X-ray diffractometer. Scanning electron microscopy (SEM) images were recorded using a JEOL JSM-700F microscope operated at 15.0 kV. High resolution transmission electron microscopy (HR-TEM) images were obtained using a TECNAI 20 operating at 200 kV and equipped with energy dispersive X-ray fluorescence spectrometer for EDX analysis. Atomic force microscopy (AFM) measurements were performed in tapping mode with an AFM XE-100 (Park System). The surface resistance was obtained using a four-point probe method (CMT-SR2000N) at room temperature.

3. Results and discussion

A hybrid of RG-O and PEDOT was obtained through a two-step procedure illustrated in Fig. 1. The first step involved thermal reduction of G-O in the presence of PIL and this process typically resulted in the RG-O modified with PIL. In the second step, we carried out in situ chemical polymerization of EDOT in PIL:RG-O suspension using $FeCl_3$ as an oxidizing agent. This process leads to the formation of a hybridized material PEDOT-PIL:RG-O that are homogeneously dispersed as a colloidal system in PC.

3.1. Thermal reduction of the PIL-functionalized graphene oxide in propylene carbonate

The addition of PIL into G-O suspension in propylene carbonate (PC) typically yielded the PIL-modified G-O by the electrostatic interaction between the cation in PIL and negatively charged G-O platelets. Then, heating this suspension at 150 °C led to the reduced graphene oxide modified with PIL. Fig. 2a shows the FT-IR spectra of G-O, RG-O and PIL:RG-O. The spectra of G-O sheets (black curve) showed C=O (1725 cm^{-1}), aromatic C=C (1621 cm^{-1}), carboxy C–O (1382 cm^{-1}), epoxide/ether C–O (1231 cm^{-1}), and alkoxy/alkoxide C–O stretches (1027 cm^{-1}). The RG-O (red curve) showed a decrease in C=O and C–O stretch peak intensities, indicating de-oxygenation of the RG-O sheets after thermal reduction. In the FT-IR spectra of PIL:RG-O (blue curve), the peaks at 1792, 1569, 1352, 1189, 744, and 647 cm^{-1} correspond to the PIL(NTf_2^-), indicating an adsorption of PIL(NTf_2^-) onto the RG-O surface.

Fig. 2b shows the TGA data of RG-O (red curve) and PIL:RG-O (blue curve) in comparison with pristine G-O (black curve). G-O shows a continuing weight loss of

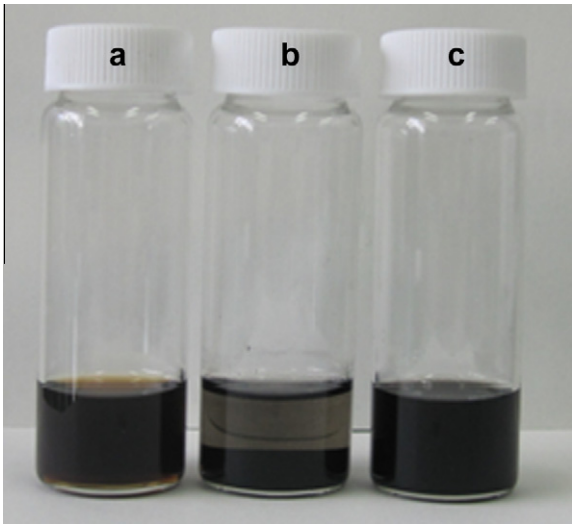

Fig. 3. Photograph of (a) G-O, (b) RG-O, and (c) PIL:RG-O dispersed in propylene carbonate after 3 days of free-standing.

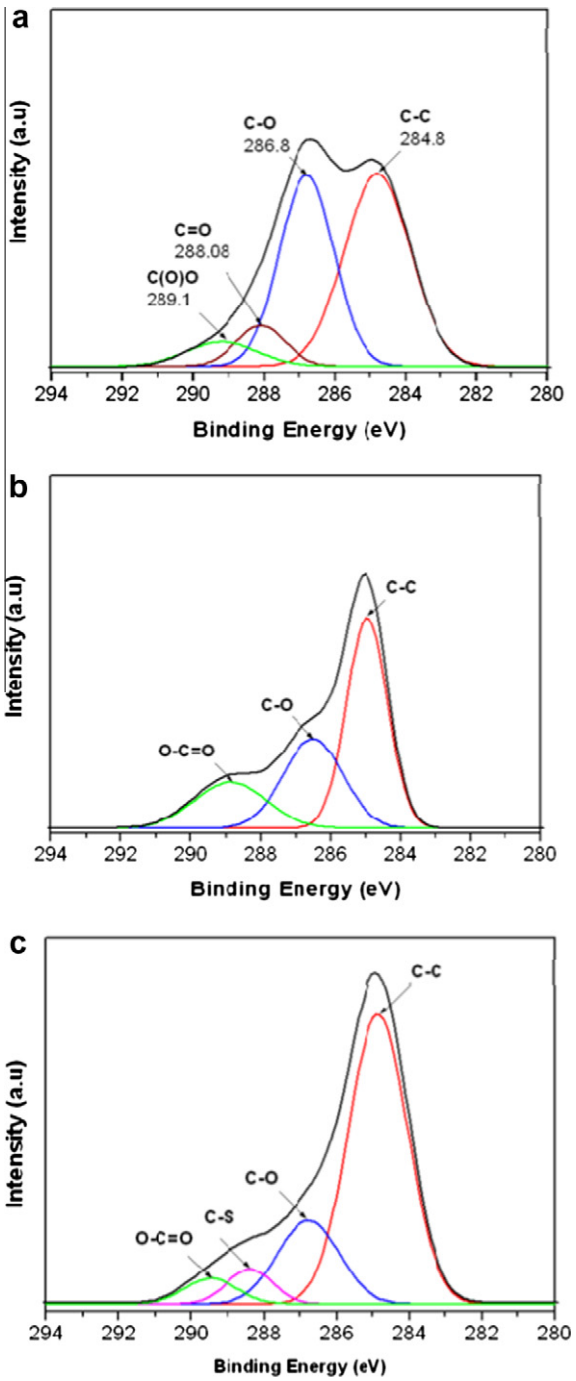

Fig. 4. C 1s XPS spectra of (a) G-O, (b) RG-O, and (c) PIL:RG-O.

7–8% in the temperature range up to 80 °C, and this is related to the removal of physisorbed water. A weight loss around 168 °C can be ascribed to the decomposition of different oxygen containing groups in the G-O layer [22]. The weight loss of RG-O (red curve) is much smaller due to a decreased amount of oxygen functional groups in the RG-O. For the case of PIL:RG-O (blue curve), the weight loss of 25% occurs from 316 to 428 °C, possibly due to the decomposition of the surface-bound PIL molecules.

The XRD patterns of G-O, RG-O and PIL:RG-O are shown in Fig. 2c. Similar to the previous report, G-O and RG-O showed a XRD peak at $2\theta = 11.2°$ and 23.8°, indicating an interlayer spacing of ~0.78 nm and ~0.36 nm. The decreased interlayer spacing for RG-O is due to the removal of oxygen-based functional groups on the basal plane by thermal reduction. Compared with RG-O, the PIL:RG-O showed a broad peak at $2\theta = 13.9°$, indicating an increased interlayer spacing of ~0.62 nm. This suggests that PIL are coated on the surface of RG-O surface and act as a spacer for RG-O platelets with an increased interlayer spacing.

Raman spectroscopy was employed to investigate a change in the graphitic structure during the reduction process of RG-O and PIL:RG-O as shown in Fig. 2d. The Raman spectrum shows a typical D band (1332 cm^{-1}) and G band (1560 cm^{-1}) for G-O, which corresponds to the presence of sp^3 defects and tangential vibration of sp^2 carbon atoms in hexagonal plane, respectively. While the intensity ratio of D and G band (I_D/I_G) of G-O is about 0.82, the I_D/I_G of RG-O increased to 1.12 due to a decrease in the average size of the sp^2 carbon network upon thermal reduction of the exfoliated G-O [22,23]. In case of PIL:RG-O, the I_D/I_G was measured as 1.03 which is lower than that of RG-O. This suggests that PIL:RG-O has decreased density of defects compared with RG-O without PIL.

The thermal reduction of G-O in the presence of PIL produces a suspension of PIL:RG-O in PC. While the reduction of G-O without PIL resulted in an agglomerated RG-O sheets which can be viewed as black particles in the vial (Fig. 3b), the PIL:RG-O was found to be dispersed as a homogeneous colloidal system with no visible agglomerates (Fig. 3c). This dispersion can be filtered to obtain PIL:RG-O platelets that can be re-dispersed in a wide range of organic solvents such as PC, acetone, acetonitrile (AN), dimethylformamide (DMF), *N*-methyl-pyrollidone (NMP) and nitromethane (NM). It should be noted that an increase in the amount of PIL added to G-O suspension enhances the stability of suspension (Fig. S-1, supporting information). When the PIL/G-O weight ratio is equal to or lower than 3/1, PIL:RG-O in PC precipitated out after several days, suggesting that PIL concentration was not sufficient to fully stabilize RG-O platelets in PC. On the other hand, when the ratio is higher than 5/1, the dispersion remained stable for more than 6 months.

The chemical composition of G-O, RG-O, and PIL:RG-O was investigated by XPS. The C 1s XPS spectrum of G-O (Fig. 4a) can be deconvoluted into four main components

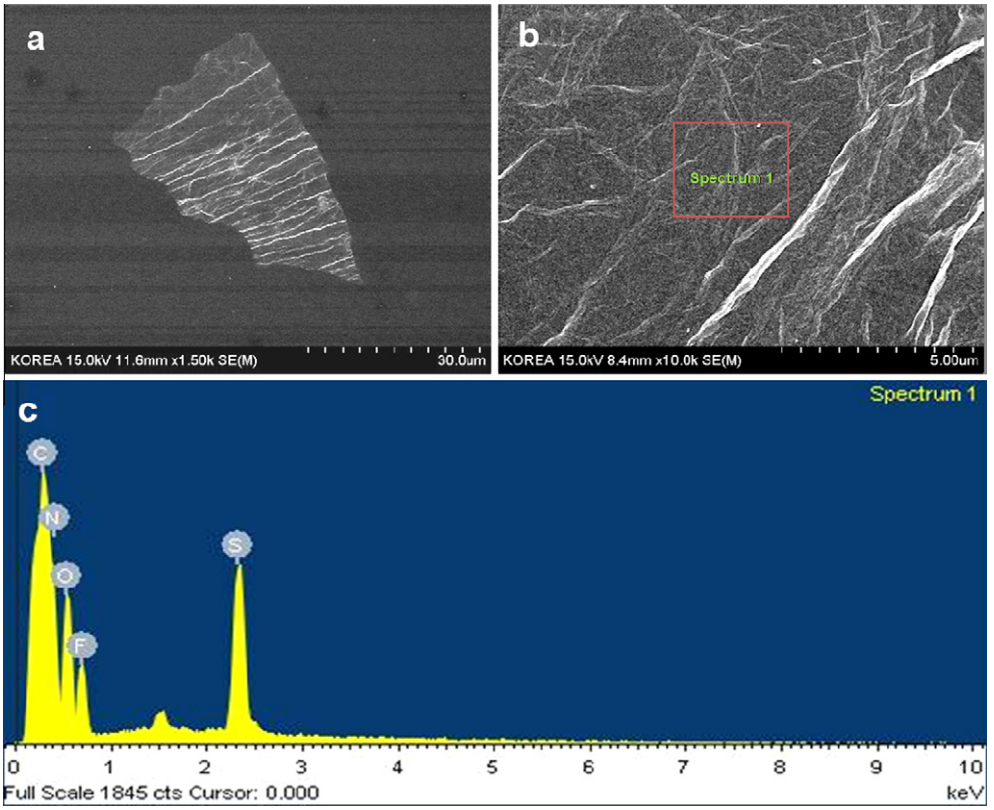

Fig. 5. (a and b) SEM image with different magnification of PIL:RG-O and (c) the EDX spectra corresponding to panel b.

corresponding to carbon atoms in different functional groups: the non-oxygenated ring C (284.8 eV), the C in C–O bonds (286.8 eV), the carbonyl C (C=O, 288.0 eV), and the carboxylate carbon (O–C=O, 289.1 eV). As shown in Fig. 4b, RG-O sample showed a decreased intensity of these oxygen groups confirming the effective removal of oxygen groups by thermal reduction [21]. The C 1s XPS spectrum of PIL:RG-O (Fig. 4c) also shows the removal of oxygen groups on the G-O basal plane and the subsequent restoration of sp^2-hybridized carbon network. Moreover, the C/O atomic ratio calculated from the XPS spectra is 2.0, 6.2 and 8.6 for G-O, RG-O and PIL:RG-O, respectively. The higher C/O atomic ratio observed for PIL:RG-O is attributed to the fact that the thermal reduction of G-O platelets occurred more rapidly in the presence of PIL, than in a control experiment with no PIL present [21]. The rapid reduction of suspended G-O described here may come from the reducing capability of imidazolium-based PIL, which has been previously reported for ionic liquid reduction of Au precursors [24]. Additionally, there is a new component at 288.4 eV corresponding to the C in the C–S bonds of NTf_2^- (CF_3SO_2–N–SO_2CF_3) anion, suggesting the existence of PIL on the RG-O surfaces.

A top-view SEM image of PIL:RG-O deposited on Si/SiO_2 substrates (Fig 5a) reveals that the RG-O platelets are individually isolated. In Fig. 5b, it can be seen that the surface of RG-O was covered with a thin layer of PIL molecules, which is also evidenced by energy dispersive X-ray (EDX) analysis in Fig. 5c.

TEM was used to investigate the level of exfoliation and the dispersion. As can be seen in Fig. 6a, PIL:RG-O material was observed as thin platelets with some folded area and small fragments. In the selected area electron diffraction (SAED) patterns (inset of Fig. 6a), a ring-like pattern consisting of many diffraction spots was observed indicating a random overlay of individual RG-O platelets coated with PIL, or from folds that cause overlays [21]. Fig. 6b shows an AFM image and height profile from the sample, confirming that PIL:RG-O are comprised of large-scale (several μm) and isolated graphitic sheets with some winkles. From the AFM height profile, the thickness of PIL:RG-O was measured as 1.64 nm that is higher than that of theoretical thickness of a single layer graphene (0.34 nm) [25], G-O platelets exfoliated in water (~1 nm) [26,27], and RG-O in PC (~0.6 nm) [21]. The higher thickness value for PIL:RG-O is likely due to the PIL coating of RG-O platelet [28].

Fig. 7 shows the surface resistivity vs. weigh ratio of PIL/G-O. The surface resistivity was measured for PIL:RG-O

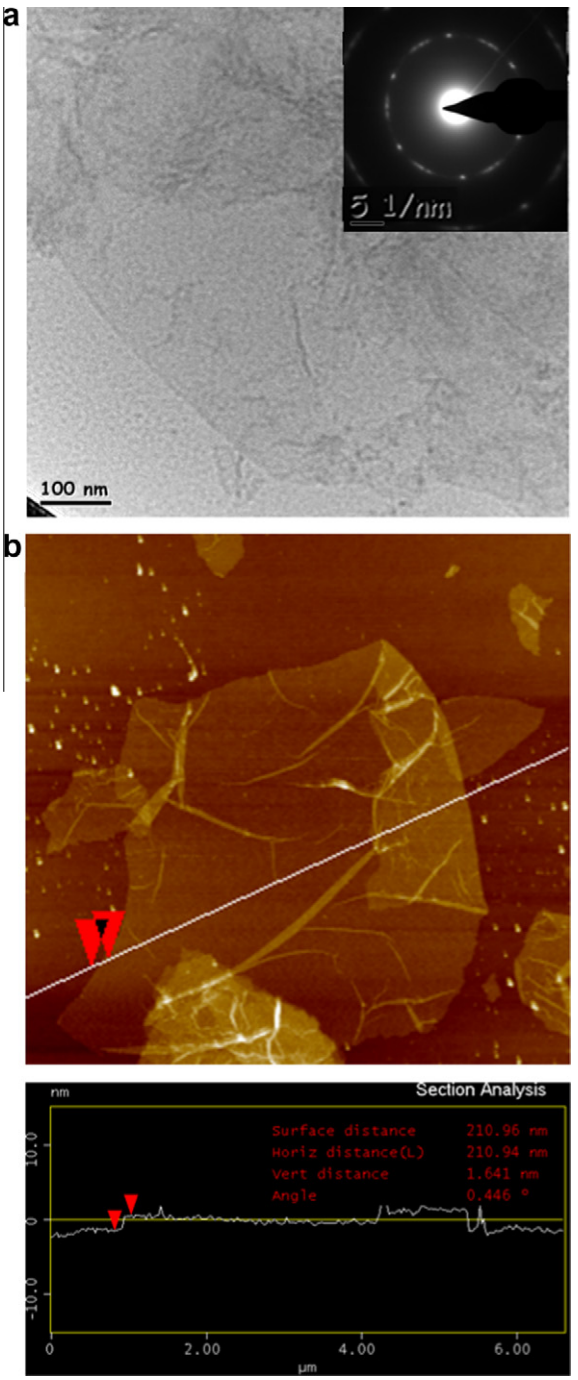

Fig. 6. (a) TEM and (b) AFM histogram shows the statistic analysis of PIL:RG-O sample. The inset in (a) is the SAED patterns from PIL:RG-O sheet.

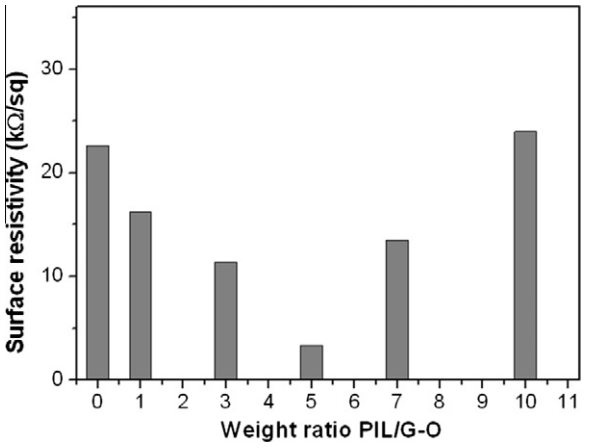

Fig. 7. The surface resistivity of PIL:RG-O films with different weight ratios of PIL vs. G-O.

using a standard four-probe method. For the measurement, the PIL:RG-O paper-like films with the film thickness of ~534 nm (Fig. S-2, SI) were prepared by casting PIL:RG-O suspension on the Si/SiO2 wafer. The randomly stacked PIL:RG-O film was peeled off the substrate and subject to the resistivity measurement. The surface resistivity of PIL:RG-O decreases from 22.6 to 3.3 kΩ/sq with increasing PIL/G-O ratio of up to 5. This result suggest that the sp^2-carbon network is more effectively restored in the PIL:RG-O than RG-O. However, when PIL/G-O ratio is above 5, the surface resistivity increases to 23 kΩ/sq, indicating that an excess of PIL negatively affects the electrical connectivity of PIL:RG-O platelets. Therefore, the optimized PIL/G-O ratio was set as 5 and further experiments were carried out.

3.2. Hybridization of PIL-modified reduced graphene oxide and conductive polymer

In this section, we describe the preparation and characterization of PEDOT-PIL:RG-O composites by in situ polymerization of EDOT (Fig. 1, step 2), in which EDOT is polymerized in the presence of PIL:RG-O. The driving force for the formation of hybridized PEDOT and PIL:RG-O is likely due to electrostatic attraction between opposite charges. Since the growing PEDOT chains have positive charge and PIL carries a negative charge by NTf_2^- anions, it is conceivable that PIL on the RG-O surface function as a charge balancing stabilizer to the positively doped PEDOT chains during the polymerization process.

Fig. 8a shows the FT-IR spectra of the PEDOT-PIL:RG-O composite and pristine PEDOT-PIL. The characteristic bands for the PEDOT-PIL:RG-O composites appear in the range of 500–4000 cm^{-1}, showing almost the same numbers and positions of the main peaks as in the pristine PEDOT:PIL; C–C stretching in the thiophene ring (1350 cm^{-1}), vibration modes of the ethylenedioxy group (1207 and 1093 cm^{-1}), S–O stretched vibration (988 cm^{-1}) and vibration modes of the PIL(NTf_2^-) (1790, 1400 and 780 cm^{-1}). However, there were two additional peaks at 1725 and 1634 cm^{-1}, corresponding to the stretching modes of the aromatic C=C in RG-O sheets.

The chemical composition of the PEDOT-PIL:RG-O composites were also investigated by XPS spectra. The C 1s XPS spectrum (Fig. 8b) of the composite film can be deconvoluted into four main components corresponding to carbon atoms in different functional groups: the non-oxygenated ring C (284.9 eV), the C–O (286.4 eV), C–S (287.7 eV) and the C=O (289.5 eV). Moreover, the S 2p core-line spectra (Fig. 8c) showed the peak at 168.2 eV (NTf_2^- anion in the PIL dopant), and the lower binding energy peaks at 165.3 and 164.1 eV (spin-split doublets of sulfur atoms in PEDOT backbone), which confirms the existence of PEDOT.

SEM was used to observe the fine morphological structure of the composites. Fig. 9 shows representative SEM images of PEDOT-PIL:RG-O. In the top-view image (Fig. 9a), the conducting polymer formed a continuous phase with the RG-O submerged in the polymer phase, while cross-section image (Fig. 9b) shows stacked RG-O sheets of which their surfaces are likely to be covered with PEDOT. A TEM image of the composite sample (Fig. 9c)

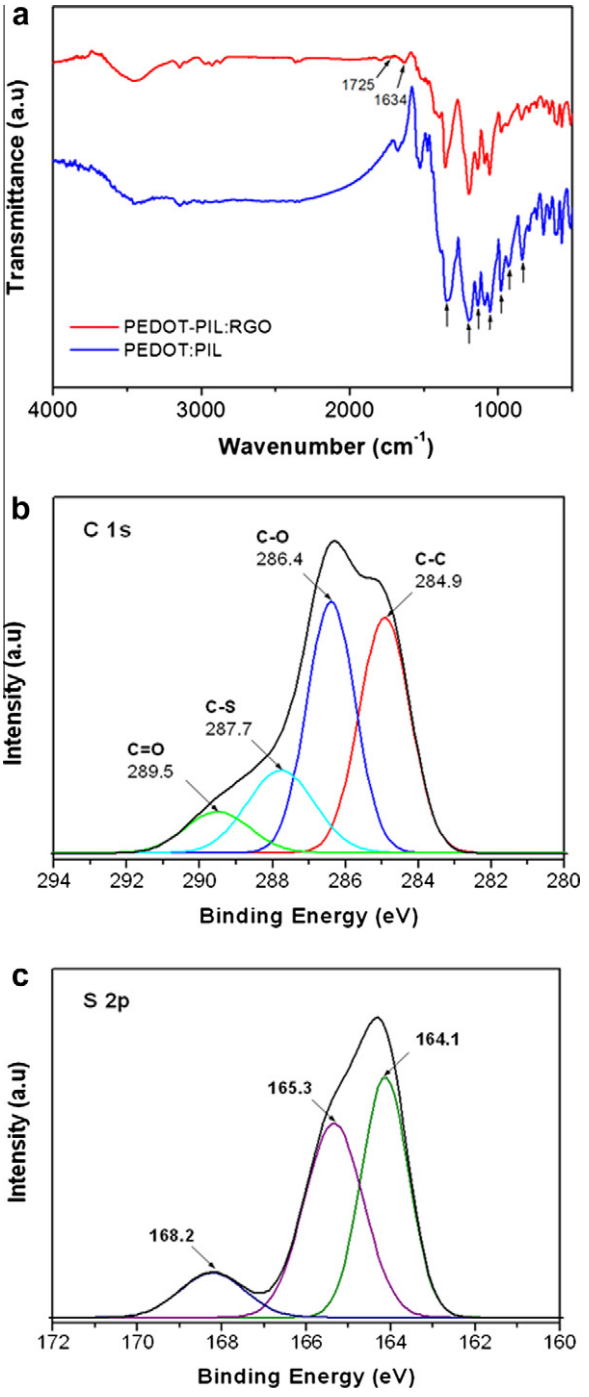

Fig. 8. (a) FTIR curves of PEDOT-PIL:GR-O (blue line) and pristine PEDOT-PIL (red line). (b) C 1s and (c) S 2p spectra of PEDOT-PIL:RG-O composites. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

displays that each RG-O sheet is encapsulated by PEDOT. The PEDOT attachment on the RG-O sheet was also confirmed by the EDX analysis (Fig. S-3), in which the sulfur from the PEDOT was found. AFM image (Fig. 9d) also reveals that PEDOT-PIL:RG-O is composed of thin platelets

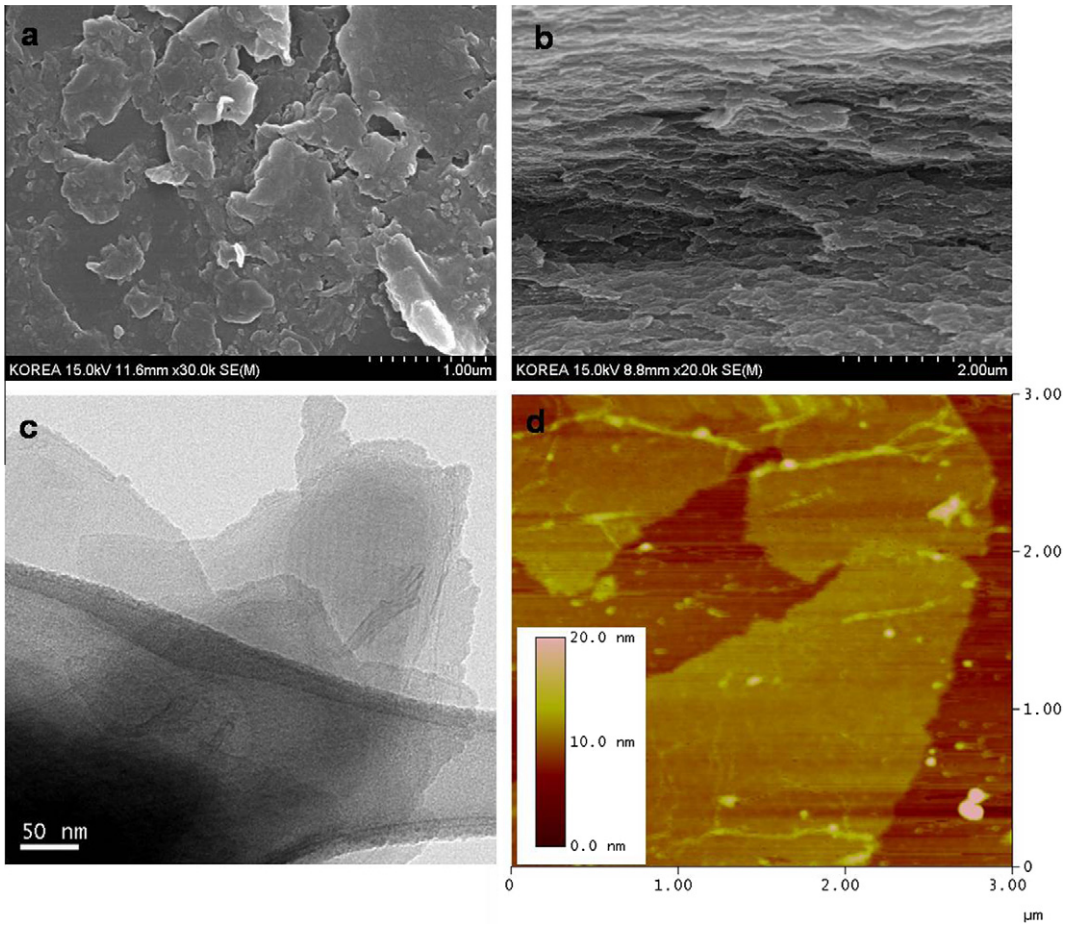

Fig. 9. (a) Top-view, (b) cross-section SEM image, (c) TEM image of PEDOT-PIL:RG-O composites, and (d) AFM image of PEDOT-PIL:RG-O composites.

with some wrinkles. The large surface area of RG-O was covered by a thin layer of PEDOT with the total thickness 10–15 nm.

In order to investigate the role of PIL:RG-O on the electrical properties of conducting polymer composites, slab samples were prepared by solvent casting PEDOT–PIL:RG-O suspension onto the filter, followed by drying at 80 °C for 2 h and further annealing at 200 °C for 3 h under argon atmosphere. The conductivity of sample was calculated from the value of sheets resistivity and thickness (measured by SEM). As shown in Fig. 10a, while the PIL-modified PEDOT sample (PEDOT:PIL without RG-O) showed a conductivity of 0.92 S/cm, PEDOT-PIL:RG-O hybrid composite showed enhanced conductivity values of up to 20 S/cm with increasing PIL:RG-O contents in the composites. The conductivity value of the composite film increases sharply with increasing PIL:RG-O loading level up to 0.3 wt.%, and then saturates over PIL:RG-O concentration, which gives an estimation that a percolation threshold is in the proximity of 0.1 wt.%. This percolation threshold value is comparable to the values previously reported in graphene/polystyrene composites [29,30]. Moreover, the enhancement of conductivity observed for this composite is consistent with other graphene/conducting polymer composites including PEDOT/G-O composites (5 S/cm) [31], polypyrrole/GO composites (7 S/cm) [32], graphene/polyaniline composites mediated by PIL (7.5 S/cm) [33], and graphene/polyaniline nanofiber composite samples (16.8 S/cm) [34]. Such enhancement could be explained by the better electrical connectivity between the RG-O platelets afforded by interconnecting PEDOT chains.

To evaluate the possible application of hybrid composite as a transparent electrode, 1.3 wt.% of PEDOT-PIL:RG-O composites (with 0.3 wt.% of RG-O in the composite) was dispersed in AN and coated on PET film to form 500-nm-thick conductive layer. This film showed a surface resistivity of 1.5×10^4 Ω/sq with light transmittance of 86.0% at 550 nm. Considering the optical transmittance of PET film itself 87.6%, PEDOT-PIL:RG-O caused a transmittance loss less than 2%. Moreover, upon treatment of $SOCl_2$ solution for 1 h the PEDDOT-PIL:RG-O composite film shows further decrease in the surface resistivity to 5.3×10^3 Ω/sq. On the other hand, the hybrid composites can be spin-coated onto glass substrate to form a homogeneous conductive composite film with a thickness of 50 nm layer as shown in Fig. 10b. The PEDOT-PIL:RG-O film was showed a surface resistivity of 9.6×10^4 Ω/sq with a transparence of 91.18%. Subsequently, the sample was annealed at 200 °C for 3 h to remove the residual solvent and oxygen-containing functional groups from RG-O. After

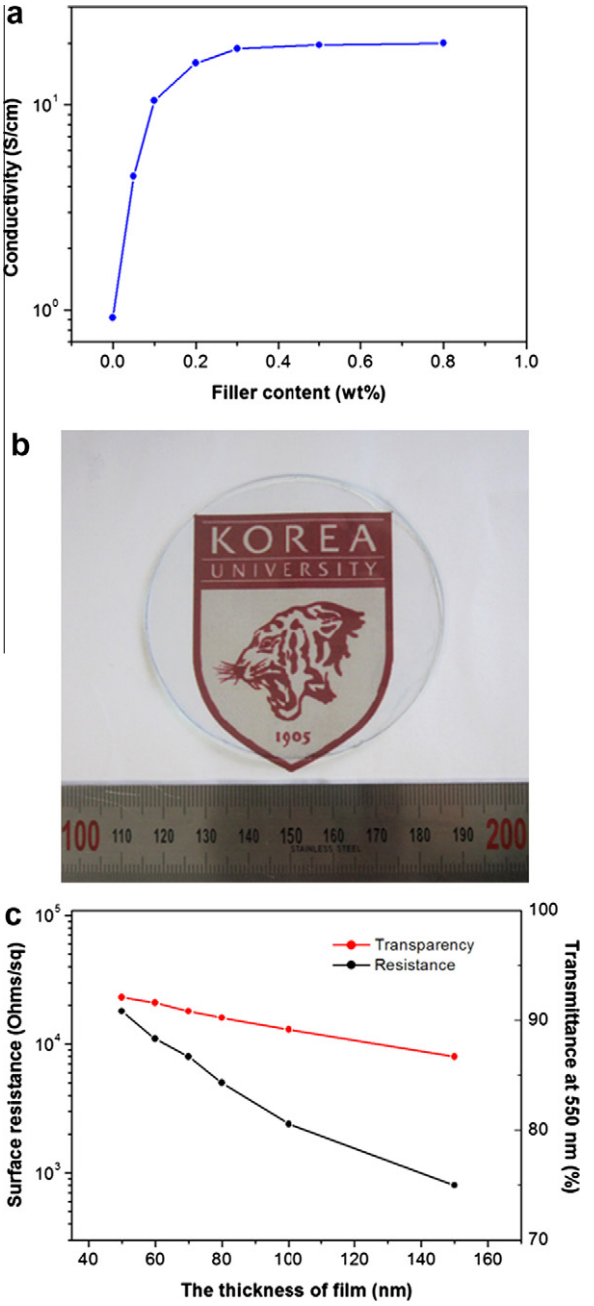

Fig. 10. (a) The electrical conductivity of PEDOT-PIL:RG-O composite films as a function of PIL:RG-O content in the composites. (b) A photograph of PEDOT-PIL:RG-O on glass substrate using a spin-coating method with KU logo underneath. And (c) sheet surface resistance and transmittance varies with different thicknesses of films.

annealing we found that the surface resistivity of film decreased from 9.6×10^4 to 1.8×10^4 Ω/sq without any significant change in light transmittance. In Fig. 10c, the surface resistivity and transmittance varies with thicknesses of films. As the film thickness increases, the surface resistivity decreases at the expense of light transmittance. For example, a surface resistivity of 800 Ω/sq can be obtained with 150 nm film thickness, but transmittance was decreased to 86.8%. The transparent and conductive properties of the present film are consistent with other reports involving graphene/poly(3,4-ethylenedioxy thiophene) composite films [35,37], RG-O thin films [38–42], and lower than that of the aqueous dispersible graphene/PEDOT:PSS composite electrode in term of conductivity [43,44]. However, at the same time, the hybrid materials described here have additional advantages in that it is dispersible in a range of organic solvents and free of water with no acidic moieties like PSS, which may be valuable for its long-term utilization in many practical applications such as organic light emitting diodes and organic photovoltaic cells [45,46].

The thermal stability of the PEDOT-PIL:RG-O composites was also investigated and compared with that of pristine PEDOT:PIL as shown in Fig S-4. The PEDOT:PIL showed an onset degradation temperature at 298 °C and a weight loss was ~78%. On the other hand, the PEDOT-PIL:RG-O hybrid composite showed the decomposition temperature of 312 °C, with the weight loss of ~54%. These results suggest that the coupling of PIL:RG-O and PEDOT could delay the thermal degradation of PEDOT chains due to a strong interaction between PEDOT matrix and PIL:RG-O. Therefore, the advantage of this method for fabricating RG-O/conducting polymer is that PIL-modified RG-O not only enhances the solubility of reduced graphene oxide, but also functions as ionic stabilizers and/or counterions of conducting polymer to facilitate the formation of homogeneous composites on the molecular scale.

4. Conclusions

In this work, we have demonstrated hybridization of graphene/PEDOT composite with an aid of PIL. Here, PIL coating on the surface of the RG-O platelets plays dual roles by increasing the solubility of RG-O in organic solvents and providing effective anchoring sites to bond with PEDOT chains. It was found that this results in good electrical conductivity due to inter-sheets enhanced carrier hopping. This non-acidic, organic solvent dispersible PEDOT-PIL:RG-O hybrid composites holds a great potential for application in optoelectronic devices especially where transparency, electrical conductivity, and stability properties are required.

propanol followed by DI water. The bottom PEDOT:PSS electrode was spin coated onto the plastic substrate at 1500 rpm for 30 s followed by 5000 rpm for 30 s to get a smooth film. The film was dried at 110 °C for 30 min in air. P(VDF-TrFE) copolymer powder was dissolved in methyl ethyl ketone (MEK) to get a 2 wt.% solution. The filtered solution was then spun on the PEDOT:PSS film at 6000 rpm for 60 s followed by a soft bake for 30 min at 80 °C. The films were then annealed in vacuum at 140 °C for 4 h to improve the crystallinity [2,13,16]. The PEDOT:PSS electrodes were approximately 110 ± 10 nm thick and P(VDF-TrFE) film was ~100 ± 10 nm thick, measured using a Dektak profilometer. Finally, the top PEDOT:PSS electrode was spun and etched using RF oxygen plasma with patterned gold (Au) layer as a hard mask. For comparison, a sample with Au and Pt as top and bottom electrodes, respectively was also made with the same P(VDF-TrFE) thickness.

Surface morphology was studied using Atomic Force Microscopy (Agilent 5400) and Scanning Electron Microscopy (Nova NanoSEM 630 FESEM). The crystallinity and inter-planar distance of polymer chains was evaluated using Grazing Incidence X-ray Diffraction (Bruker D8 Discover) while the bonding and dipole orientation was analyzed using Fourier-transform infrared spectroscopy (FT-IR, ThermoScientific Nicolet iS10). The electrical characterization was performed using the Keithley 4200 semiconductor analyzer while polarization-voltage and fatigue tests were done using the Premier Precision II ferroelectric tester (Radiant Technologies Inc.).

3. Results and discussion

Fig. 1(a) and (b) shows the surface morphology of platinum and PEDOT:PSS surfaces, respectively. The root mean square (R_{rms}) roughness values for Pt and PEDOT:PSS over 1 μm^2 area are comparable and are 0.44 nm and 0.55 nm, respectively. Fig. 1(c) and (d) shows P(VDF-TrFE) films grown on Pt and PEDOT:PSS surfaces, respectively. The data show that the P(VDF-TrFE) film grown on the polymer surface is smoother than on the Pt surface with a roughness value of 1.28 versus 2.3 nm. Fig. 1(e) and (f) shows Scanning Electron Microscopy (SEM) images of P(VDF-TrFE) films grown on Pt and PEDOT:PSS. The figure indicates a difference in the nucleation and grain growth rates of the films on the two respective electrodes. The average grain size of P(VDF-TrFE) is much smaller (~75–80 nm) when grown on a polymer, compared to a metal surface (~160–170 nm). This result should not be surprising since the surface roughness of the bottom electrode has an effect on nucleation rate of the P(VDF-TrFE) film, with rougher surface leading to higher nucleation rate [17]. The higher nucleation rate limits the grain growth leading to smaller grains, as observed in our films. Additionally the higher nucleation rate and smaller grain size leads to a smoother P(VDF-TrFE) film on PEDOT:PSS as suggested by the AFM data.

Grazing Incidence X-ray Diffraction (GIXRD) was used to compare the phase and orientation of the P(VDF-TrFE) films on the respective electrodes. Fig. 2 shows that P(VDF-TrFE) films on Pt substrate exhibit a peak centered at $2\theta \sim 19.95°$, characteristic of the ferroelectric β phase and reflection from the (110) and (200) planes. The inter-planar distance was calculated to be approximately 4.44 Å and is consistent with earlier studies [16]. In comparison, the P(VDF-TrFE) films grown on PEDOT:PSS exhibit a peak at $2\theta \sim 19.53°$, indicating a larger inter-planar distance. The XRD peaks indicate that the P(VDF-TrFE) films on Pt electrodes have larger crystallite size than films on PEDOT:PSS electrodes, with a full-width-half-maxima (FWHM) of 1.67° and 2.2°, respectively, as confirmed by the SEM images.

In P(VDF-TrFE) films, it is important that the chain direction (*c* axis) is oriented parallel to the film surface because polarization is induced in the *b*-axis direction, perpendicular to the chain axis [18–20]. There have been some studies on techniques to control the preferential orientation of P(VDF-TrFE) chains by nano-imprint lithography and using nanostructured electrodes [20,21]. We have analyzed the orientation of the P(VDF-TrFE) films as a function of growth on polymer and metal electrodes under identical annealing temperatures (140 °C) and thickness (100 nm). The dipoles in P(VDF-TrFE) strongly interact with the applied field, when it is perpendicular to the dipole direction. We used *p*-polarized FT-IR analysis of the ferroelectric polymer films, which has an electric field component parallel to the plane of the substrate. It has been reported that the FT-IR bands at 1288 and 850 cm^{-1} are associated with CF_2 symmetric stretching vibration and are characteristic bands of the trans-zigzag formation (β phase)-indicating dipole moments parallel to the *b* axis [16,18,19]. It can be easily seen from Fig. 3 that 1288 cm^{-1} peak is relatively stronger on the film grown on Pt, therefore *b* axis (and dipoles) of the polymer is perpendicular to the film. The 1400 cm^{-1} band which is characteristic of the CH_2 wagging vibration has dipoles parallel to the polymer chain *c* axis. For a baseline region of 1417.48–1378.43 cm^{-1}, the area under the 1400 cm^{-1} band shows that this peak is relatively stronger on PEDOT:PSS (Area of 0.2074) compared to Pt (Area of 0.1431). This indicates that for P(VDF-TrFE) films grown on PEDOT:PSS electrodes, a significant portion of the copolymer chain tilts vertically, which is undesirable for vertical polarization as most dipoles are parallel to substrate. All other peaks in the FT-IR spectrum of P(VDF-TrFE) film grown on PEDOT:PSS can be attributed to the PEDOT:PSS layer itself as can be seen from the IR spectra of the PEDOT:PSS in Fig. 3.

Ferroelectric behavior of our capacitors was tested using polarization–electric field hysteresis measurements. In Fig. 4, the hysteresis loops for the all-polymer device show a remnant polarization (P_r) of 7.5 $\mu C/cm^2$ and coercive field (E_c) of 60 ± 5 MV/m. These values show a remarkable improvement compared to earlier studies using polymer electrodes on plastic substrates. Xu et al. [22] had earlier reported a P_r of 7.6 $\mu C/cm^2$ and an E_c of 130 MV/m with an all polymer capacitor with Polyaniline and PEDOT:PSS as top and bottom electrodes, respectively on a plastic substrate. Our all polymer, flexible and transparent device also compares well with the device with metal electrodes which show a P_r of 7.5 $\mu C/cm^2$ and E_c of

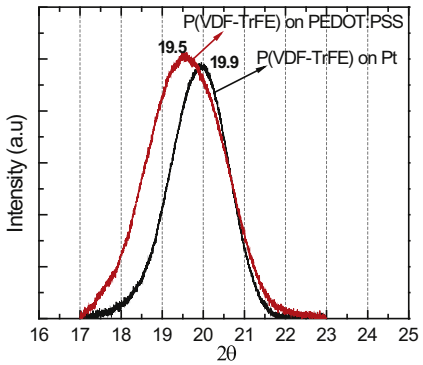

Fig. 2. Grazing Incidence XRD spectra of P(VDF-TrFE) films on Pt and PEDOT:PSS electrodes.

54 ± 5 MV/m. The slightly higher coercive field could be attributed to the smaller grain size as well as the unfavorable orientation of P(VDF-TrFE) chains on the polymer electrode as seen from the FT-IR data. Fig. 5 shows that the switching current response of the all polymer devices is almost identical to the device with metal electrodes with a peak switching current density ~20 μA/cm^2.

Leakage current mechanisms in dielectric films are usually controlled by space charge limited current (SCLC), interface limited Schottky emission (SE) or bulk limited Frenkel-Poole (FP) emission. Schottky emissions involve carrier injection from the electrodes into the conduction band of the dielectric over a barrier height while FP emissions involves field-assisted thermionic emission of carriers trapped in the dielectric film [23,24].

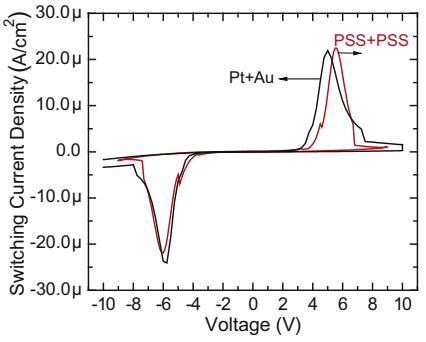

Fig. 5. Switching current response from devices with platinum/gold electrodes and with PEDOT:PSS top and bottom electrodes.

The best fit of *J–V* response for the all-polymer device is plotted for ln(*J*) versus $V^{1/2}$ as seen in the inset in Fig. 6. Linear behavior of this plot suggests that leakage current is controlled either by Schottky or Frenkel Poole emission. FP emissions are independent of the work functions of the electrodes and display symmetric *I–V* characteristics [23,25]. A look at Fig. 6, shows the asymmetry of the leakage current response which confirms that FP emission is unlikely in our devices.

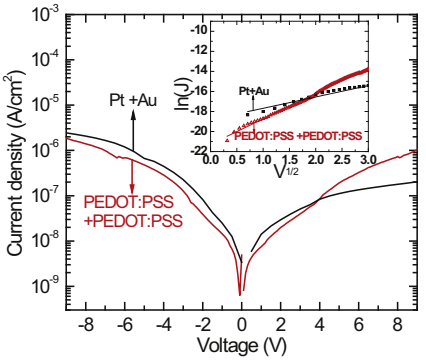

Fig. 6. *I–V* characteristics of devices with platinum/gold electrodes and PEDOT:PSS electrodes. The inset shows a plot of current density versus voltage$^{0.5}$ measured at room temperature.

The Schottky controlled leakage current is given by:

$$J = AT^2 exp\left(\frac{aE^{0.5} - \emptyset_B}{kT}\right) \quad (1)$$

where *A* is the effective Richardson's constant, *T* is temperature, *E* is applied electric field, $\emptyset_B$ is barrier height and *a* is a constant [23].

According to Fig. 6, the current response in our devices shows dependence on the work functions of the electrodes, confirming an interface limited Schottky emission process. The device with metal electrodes shows lower leakage current in the forward bias regime because of the higher work function of bottom Pt electrode (5.65 eV) compared to the top Au electrode (5.1 eV). The devices with PEDOT:PSS top and bottom electrodes show symmetric *I–V* curves. The Highest Occupied Molecular Orbital (HOMO) for PEDOT:PSS is 5.3 eV which explains the slightly lower leakage current compared to the Au top electrode devices in the reverse bias regime.

There have been various studies published on the effect of applied voltage profile, frequency, crystallinity and operating temperature on polarization fatigue, but most of these studies were done using metal electrodes [26–30]. Xu et al. [14,15] reported much improved fatigue properties at different temperatures when using conducting polymers as interface layers but this was done on Si substrates. Another study using Polyaniline and PEDOT:PSS polymer electrodes on flexible substrates showed poor fatigue performance (58% retention after 10^5 cycles) and concluded the need to study different polymers for improvement of fatigue properties [22].

The fatigue performance of our devices was studied as a function of electric field. Fig. 7 shows fatigue test results performed at applied electric fields of 55, 80 and 100 MV/m at a frequency of 1 kHz. These fields correspond to the coercive, intermediate and saturation fields, respectively. It can be seen from Fig. 7(b) that the device with PEDOT:PSS polymer electrodes performs considerably better compared to metal electrodes [Fig. 7(a)]. At a field of 100 MV/m, the all polymer device retains about 80% of its initial polarization after 10^6 cycles, while the device with metal electrodes retains only about 55%. It has been

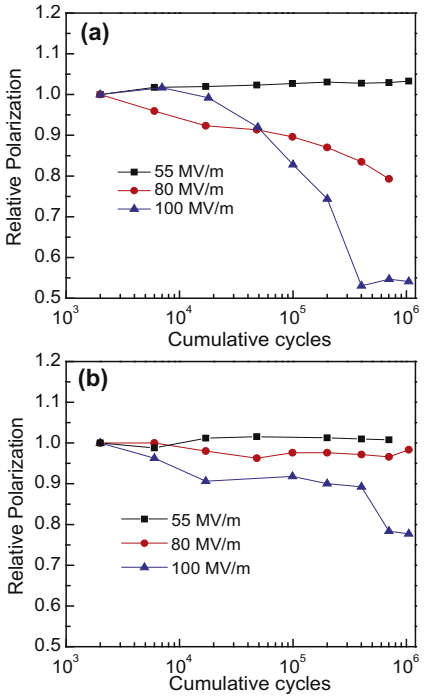

Fig. 7. Electrical fatigue properties of P(VDF-TrFE) films showing relative polarization for P_r (a) with platinum and gold electrodes (b) with PEDOT:PSS electrodes.

proposed that fatigue in P(VDF-TrFE) film is related to the injection of charges from electrodes which are subsequently trapped at crystallite boundaries and defects, inhibiting ferroelectric switching and leading to faster fatigue rates [26,29,30]. It is likely that the use of polymer electrodes reduces charge injection into the PVDF-TrFE (due to lower carrier concentration in the polymer compared to metal electrodes), resulting in less trapped charges, therefore lower fatigue rates, as shown in Fig. 7.

4. Conclusion

In summary, we have fabricated all-polymer, flexible and transparent ferroelectric capacitors on PEN substrate. Electrical characterization showed that the all-polymer capacitors showed comparable ferroelectric properties ($P_r \sim 7.5$ μC/cm^2, $E_c \sim 60 \pm 5$ MV/m) and I–V characteristics to capacitors with metal electrodes. At the same time our polymer devices have much improved fatigue performance compared to ferroelectric capacitors with metal electrodes and previously published polymer electrodes.

was synthesized according to the method described before [11]. All the materials were purified twice by thermal gradient sublimation before experiments. The device structure is shown in Fig. 2b inset. Six nanometer *p*-6P film was sublimed onto SiO_2/Si(n++) substrate at the substrate temperature of 180 °C. 1.8 nm TiOPc film was sublimed subsequently onto the *p*-6P film to form a weak epitaxy growth (WEG) ultrathin film as reported [12]. The deposition was performed under a pressure of 10^{-4}–10^{-5} Pa at a rate of about 1 nm/min. The finger electrodes were sublimed with a shadow mask on top of the organic film in another vacuum chamber to obtain TiOPc ultrathin film device. Each device contains seven pairs of fingers with each finger of 3 mm length and 100 μm distance between each other. About 1 nm F_{16}CuPc was directly depositated onto the 1.8 nm TiOPc device at room temperature substrate to obtain bilayer device. One nanometer WEG F_{16}CuPc film was also prepared to obtain F_{16}CuPc ultrathin film device for contrast.

2.2. Films characterization and sensor test

The morphology and surface potential of the organic thin films were characterized by SPI 3800N instrument (Seiko Instruments Inc.) by tapping mode and lift mode, respectively. A freshly cleaved highly oriented pyrolytic graphite (HOPG) is used as standard to determine the tip work function of KPFM measurements [13]. The wide angle X-ray diffraction (XRD) pattern was taken from a D8 discovery thin-film diffractometer with Cu Kα radiation (=1.54056 Å). The selected voltage and current were 40 kV and 35 mA, respectively.

All the devices have been stored in air for 48 h before sensor test. The electrical measurement was taken by Keithley 2636A double channel source measurement at the voltage of 1 V. Two mass flow controllers (MFC) (BROOKS 5850S) were used to control the flow rate of air stream used as carrier gas and NO_2 stream to generate diluted NO_2 sample of 2, 3 and 4 ppm. The flow rate in

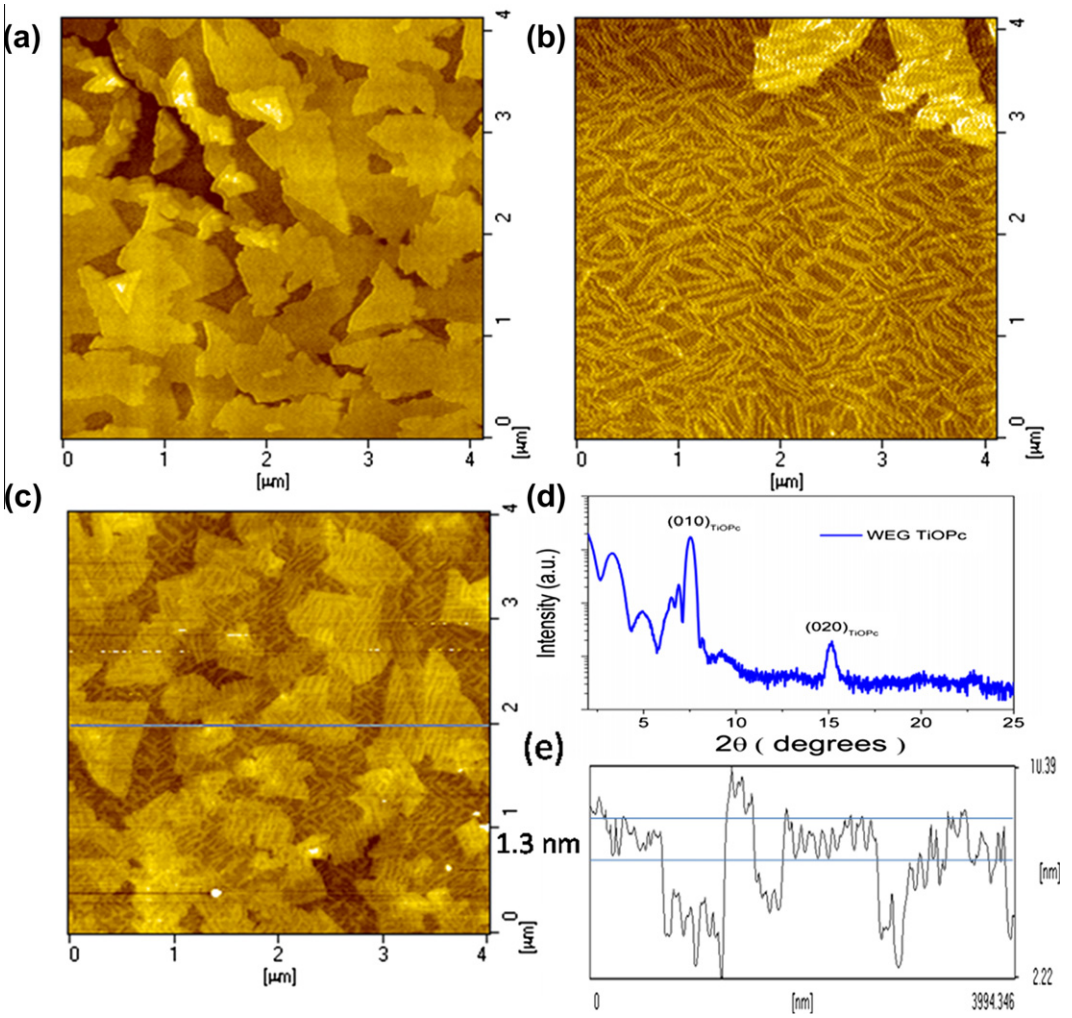

Fig. 1. Surface morphology of (a) TiOPc monolayer, (b) 1 nm WEG F_{16}CuPc film and (c) F_{16}CuPc–TiOPc bilayer film. The X-ray diffraction of 20 nm WEG TiOPc is shown in (d) and the section profile of bilayer is shown in (e).

the test was fixed at 120 sccm (standard cm^3 per min) and the gas inlet tubes were made of PTFE to avoid analyte adsorption. The sensor test was realized by exposing the devices to a constant flow of NO_2 gas doses in a homemade PTFE test chamber which was of 50 ml internal volume at the temperature of 295 K and relative humidity of 18%. Each dose in Fig. 2a lasted 10 min and the carrier gas air was used during the interval. Measurement with longer NO_2 exposure time of 30 min with 150 min carrier gas interval was also performed for bilayer device to study the response and baseline character, shown in Fig. 2b. Two devices were placed in the chamber for simultaneous mounting at a time.

3. Results and discussion

The morphology of the WEG TiOPc and F_{16}CuPc film is shown in Fig. 1a and b. The film is made up of packed lamellar-like crystals with a lamella size of about 1 μm. The XRD of 20 nm WEG TiOPc film is shown in Fig. 1c. Results prove that TiOPc molecules are standing up on the *p*-6P film in Phase II (triclinic, space group *P*1, $a = 12.166$ Å, $b = 12.584$ Å, $c = 8.641$ Å, $\alpha = 96.28°$, $\beta = 95.03°$, and $\gamma = 67.86°$), and (0 1 0) is the contact plane [14,15]. The sharp diffraction peaks also demonstrate that the WEG TiOPc film is highly oriented, the π–π conjugation direction is parallel to substrate which is consistent with the carrier transport direction. Subsequently, 1 nm F_{16}CuPc was deposited on the TiOPc ultrathin film to form a bilayer film. The top layer F_{16}CuPc presents a discontinuous stripe-like morphology on TiOPc surface shown in Fig. 1b. The section profile is shown in Fig. 1d. F_{16}CuPc grown on TiOPc layer has an average height of 1.3 nm, which means the F_{16}CuPc is standing up on the TiOPc lamella and its π–π conjugation direction favors the heterojunction formation. The root mean square (RMS) roughness of the TiOPc film is 1.6 nm and of bilayer film is 2.1 nm. The nanostructure has led to more grain boundaries although it does not significantly enrich the surface area of the bilayer device.

As we focused on the heterojunction effect in gas sensing, only one kind of analyte was used in sensor measurement. The NO_2 gas sensing property is performed under 1 V voltage for all the devices. The sensing character of 6 nm *p*-6P film has been proved before to have no detectable signal toward NO_2 and gas response of the WEG film mainly comes from the phthalocyanine layer [16]. The relative response is shown in Fig. 2a and the bilayer device shows a significant increase compared with TiOPc and F_{16}CuPc ultrathin layer device. The relative response to 2 ppm NO_2 is 3.48 for ultrathin TiOPc layer and is 0.16 for 1 nm F_{16}CuPc film, both are much smaller than that of 9.56 for bilayer device. The 1 nm WEG F_{16}CuPc film shows very weak positive response to NO_2 due to its poor continuity. Positive response is rarely reported for n-type semiconductor and the reason is not clear, the weak signal suggests that the film thickness has strong influence on device performance. The obvious positive response of TiOPc film and bilayer film indicates that the devices work in the hole transport mode and the carriers are mainly transported in TiOPc layer in bilayer device due to TiOPc layer continuity.

The response of ultrathin TiOPc film shows obvious two steps of adsorption, an initial fast step and a followed slow step. However, the response of 1 nm F_{16}CuPc film is extremely poor and it shows no clear sign of slow adsorption step. It also reflects in bilayer device that the transition from initial fast to slow adsorption is not that obvious, which may be a combined effect of the top layer F_{16}CuPc and bottom layer TiOPc. These devices did not reach their saturation region during the test so measurement with longer NO_2 exposure time of 30 min and a followed 150 min carrier gas interval was performed for TiOPc–F_{16}CuPc bilayer device, shown in Fig. 2b. It can be seen that the bilayer device still shows no clear sign of reaching saturation region but its response shows NO_2 concentration dependence is similar to that measured in Fig. 2a. This is quite normal for organic semiconductor gas sensor due to the slow adsorption and desorption effect especially at room temperature.

The baseline of TiOPc–F_{16}CuPc bilayer device has lifted 2.8 nA at the end of the test in Fig. 2a, however, it has lifted 1.8 nA at the end of the test with long exposure and recover time shown in Fig. 2b. This means that the bilayer device is hard to fully recover to baseline value even in 150 min, so this portion of the response is irreversible. In our earlier report, KPFM results of film doping revealed that grain boundaries took longer time to release the adsorbed analytes than crystal grains. The bilayer film has F_{16}CuPc nanocrystalline on its surface and this means that there are much more grain boundaries on bilayer surface than on bare TiOPc layer surface. The slow desorption effect is enhanced by adding F_{16}CuPc layer so the bilayer is

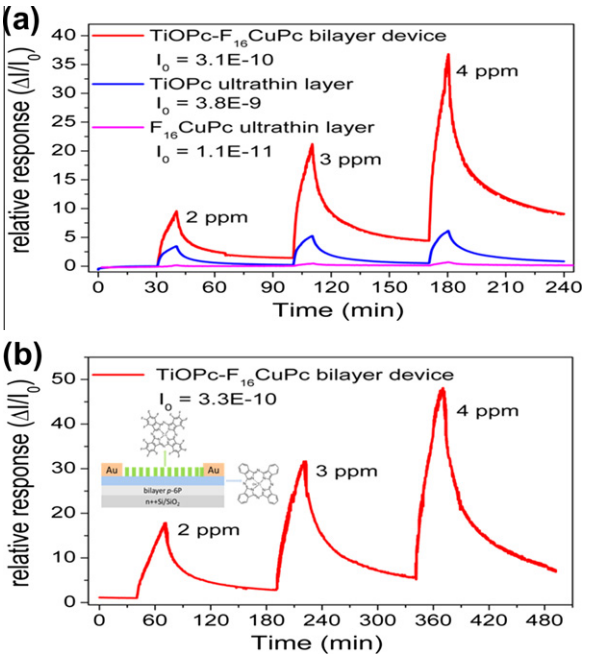

Fig. 2. (a) Relative response of the three devices to NO_2 pulse as a function of time. The relative response is defined as normalized increase of device current. (b) The section view of bilayer device structure and the molecular structure of F_{16}CuPc and TiOPc.

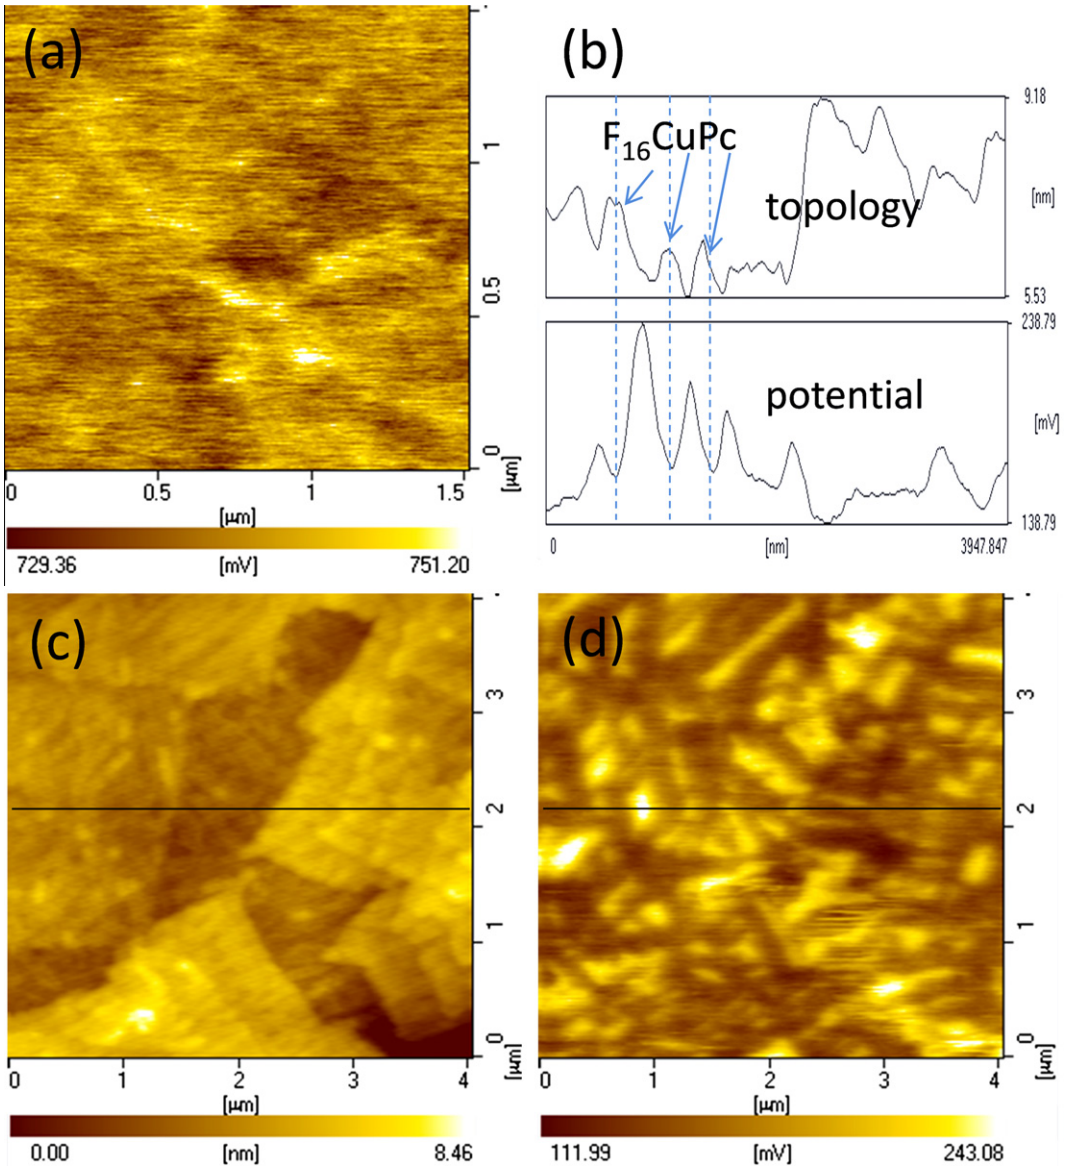

Fig. 3. KPFM results of (a) WEG TiOPc monolayer. (c) Topology of bilayer and (d) the relevant KPFM results of bilayer. The section profile of bilayer is compared in (b).

slow in desorption. The *p*-6P layer could also be slightly doped by NO_2 due to slow diffusion effect as it is exposed through gaps of TiOPc islands [16]. These are the reasons for the baseline shift in these devices.

Previous reports demonstrated that surface grain boundaries are the main adsorption sites in the film [17], and there are energy barriers at the grain boundaries [18]. In polycrystalline film the crystal size is hard to precisely control and the nano-sized crystalline does not favor the carrier transport. In WEG TiOPc film, the exposed surface area is mainly crystal grains which is homogeneous and favors the carrier transport. By depositing 1 nm F_{16}CuPc, the TiOPc crystal grain is covered with F_{16}CuPc nanocrystalline which forms heterostructure and changes the redox character of the film. The analytes adsorbed at bilayer surface generate hole carriers, and adjust the barrier height and affect the device conductivity.

In order to interpret the heterostrcture at the interface of the bilayer device, we measured and compared the surface potential of TiOPc ultrathin film (Fig. 3a) and TiOPc–F_{16}CuPc bilayer film (Fig. 3d) by KPFM method [19]. The surface potential value is obtained by measuring the difference of Fermi energy level between the sample and the scanning tip in our KPFM setup. According to Anderson rule, the Fermi level aligned at the interface thus the change of surface potential at the film interface represents the change of local vacuum level, which indicates the energy band bending at the interface. The surface potential

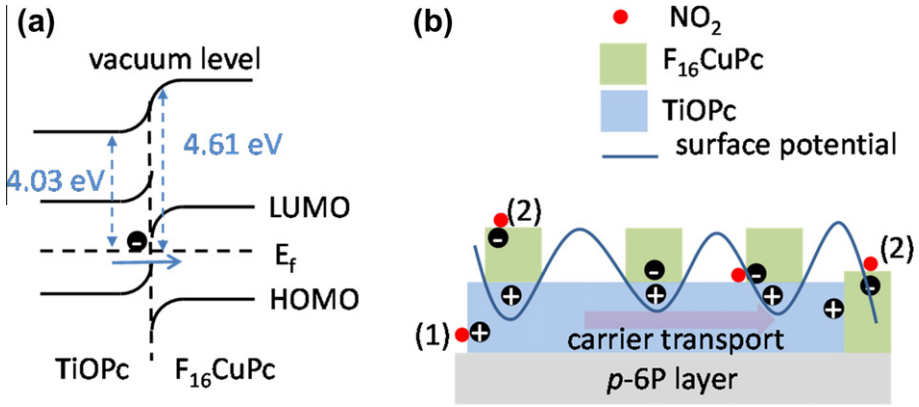

Fig. 4. (a) Interface electronic structure of TiOPc and F_{16}CuPc based on KPFM results. (b) Sensing model of bilayer sensor. Process (1) is related to TiOPc native grain boundary NO_2 adsorption and process (2) is related to local electron accumulating area (heterojunction area) NO_2 adsorption.

of TiOPc ultrathin film is 4.03 eV and that of TiOPc–F_{16}CuPc bilayer is 4.61 eV. This means the local vacuum level of TiOPc–F_{16}CuPc bilayer is higher than that of TiOPc layer, which indicates an upward bending of the local vacuum level of F_{16}CuPc layer referencing to the TiOPc layer. The schematic interfacial electronic structure is obtained (Fig. 4a) according to the band gap and electron affinity of TiOPc and F_{16}CuPc material, which is the intrinsic properties of semiconductor. The energy band of TiOPc is bending upwards and that of F_{16}CuPc is bending downwards. This means the F_{16}CuPc layer is electron accumulating and the TiOPc layer is hole accumulating at the interface. But as the F_{16}CuPc layer is only 1 nm and the film is poorly continuous, its band bending is far from saturation region.

Fig. 3b gives the section profile of bilayer film in topography (Fig. 3c) and potential (Fig. 3d). The dashed line points at the peak in topography of F_{16}CuPc crystalline and it corresponds to the valley in potential image. It proves directly that the F_{16}CuPc nanocrystalline has formed obvious electron rich area on bilayer surface. There is a surface potential fluctuation varying from 30 to 80 mV between the top F_{16}CuPc layer and the bottom TiOPc layer. As the heterojunction effect can be controlled by varying the top layer thickness or by choosing different top layer materials, the surface potential of bilayer can be tailored to fit different analytes. There is report on using functional material as top layer to realize sensor selectivity, here we use a physical way to control device response [20]. The conductivity is slightly decreased for the bilayer device although hole carriers are accumulated in the TiOPc lamellas. The reason is complex because the initial conductivity of TiOPc ultrathin film is in 10^{-9} level and the decrease is not obvious.

According to the above analysis, Fig. 4b gives the model of bilayer sensor. The transport channel is mainly in TiOPc layer as is suggested by film morphology. As is reported before, crystal grains and grain boundaries are all involved in analyte adsorption in WEG film [16]. The grain boundaries take the leading role in gas sensing in 1.8 nm TiOPc film shown as process (1). After the heterojunction is formed in the bilayer, the electron rich F_{16}CuPc area on the bilayer surface lowers down the activation energy for analyte reduction and these F_{16}CuPc crystallines help to adsorb analytes. The generated carriers adjust the F_{16}CuPc–TiOPc heterojunction so to influence the TiOPc layer conductivity, shown as process (2). It is necessary to point out that a small portion of F_{16}CuPc has reached down to *p*-6P layer as there are gaps between TiOPc islands. The joint area between F_{16}CuPc and TiOPc also forms heterojunction. The heterojunction area acts as extra active sites on the surface, and it plays a role much alike the grain boundaries without hindering the film conductive path in TiOPc layer. The NO_2 molecules adsorbed by F_{16}CuPc accept electrons and thus adjust the band bending of heterojunction and TiOPc conductivity. As the film surface owns more active sites, the bilayer shows obvious enhanced relative response and its detection limit reaches ppb level.

4. Conclusions

In conclusion, we have successfully fabricated a TiOPc–F_{16}CuPc bilayer gas sensor with heterojunction formed at their interface. The bilayer device shows obvious increase in relative response than ultrathin TiOPc film and F_{16}CuPc film at room temperature to NO_2 below 5 ppm. The detection limit of bilayer device is down to 250 ppb. The enhanced response is attributed to the p–n heterojunction formed at bilayer interface. The heterojunction effect has led to electron accumulating area at bilayer film surface and it makes the film more reductive to NO_2. The F_{16}CuPc nanostructure on TiOPc surface act as extra active sites besides grain boundaries and they adsorb analyte more effectively. We suggest that it provides a new manner to obtain highly sensitive room temperature gas sensor.

efficient solid-state emitters based on pyrene, such as 1,3,6,8-tetrakis[4-(1,2,2-triphenylvinyl)phenyl]pyrene (TTPEPy) [10] and 1,2-diphenyl-1,2-dipyrenylethene (DPDPyE) [11]. Non-doped OLEDs fabricated by using TTPEPy, and DPDPyE as emitters exhibit sky-blue, and green lights with high efficiencies up to 12.3, and 10.2 cd/A, respectively. However, pyrene has seldom been considered for the construction of yellow or red luminescent materials [12]. In this work, we present our study on a novel yellow emitter 1,3,6,8-tetrakis[(triisopropylsilyl)ethynyl]pyrene (TTIPSEPy), which consists of a 1,3,6,8-tetraethynylpyrene core and four triisopropylsilyl peripheral substituents. The single crystal structure, thermal stability, electrochemical and photophysical properties of TTIPSEPy are investigated. Multiplayer OLEDs using TTIPSEPy as non-doped emitter are fabricated and studied.

2. Experimental

2.1. General

Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl under nitrogen immediately prior to use. 1,3,6,8-Tetrabromopyrene [13] was prepared according to the literature method. All the other chemicals and regents were purchased from Aldrich and used as received without further purification. ^{1}H and ^{13}C NMR spectra were measured on a Bruker AV 300 spectrometer in deuterated chloroform using tetramethylsilane (TMS; $\delta = 0$) as internal reference. UV spectra were measured on a UV-2450 spectrophotometer. Photoluminescence was recorded on a RF-5301pc spectrofluorometer. The MALDI-TOF mass spectrum was recorded on a GCT premier CAB048 mass spectrometer. Elemental analysis was performed on an Elementary Vario EL analyzer. Cyclic voltammetric measurement on sample film was carried out in a conventional three-electrode cell containing 0.1 M Bu_4NPF_6 in acetonitrile solution at room temperature. A platinum working electrode, a platinum wire counter electrode, and an Ag/AgCl reference electrode were used for the measurement. The experiment was calibrated with the ferrocene/ferrocenium (Fc/Fc^+) redox system.

2.2. Synthesis

1,3,6,8-Tetraiodopyrene: *n*-Butyllithium (1.6 M in hexane, 6 mL, 9.6 mmol) was added dropwise into a THF suspension solution (100 mL) of 1,3,6,8-tetrabromopyrene (1 g, 2 mmol) at −78 °C. After the solution was stirred for 3 h, iodine (4.2 g, 9.6 mmol) was added into the solution in three portions. After being warmed to room temperature and stirred for 2 h, the mixture was poured into water. The precipitate was filtrated, washed by saturated sodium thiosulfate solution and water and dried under vacuum to a constant weight. The obtained pale green solid (1.2 g), 1,3,6,8-tetraiodopyrene, was used for the following reaction directly without further purification and characterization due to its poor solubility in common organic solvents.

1,3,6,8-Tetrakis[(triisopropylsilyl)ethynyl]pyrene (TTIPSEPy): 1,3,6,8-Tetraiodopyrene (0.7 g, 1 mmol) was added into a mixture of (triisopropylsilyl)acetylene (1 g, 6 mmol), copper(I) iodide (20 mg, 0.1 mmol), $Pd(PPh_3)_4$ (0.11 g, 0.1 mmol), and triphenylphosphine (10.5 mg, 0.04 mmol) in dry 100 mL diisopropylamine. After the solution was purged with nitrogen for half an hour, the reaction was refluxed under nitrogen for 24 h. After filtration and solvent evaporation, the residue was purified by silica gel column chromatography, using *n*-hexane/dichloromethane as eluent. TTIPSEPy was obtained as a greenish yellow solid in 92% yield (0.85 g). ^{1}H NMR (300 MHz, $CDCl_3$), δ (TMS, ppm): 8.67 (s, 4H), 8.28 (s, 2H), 1.26–1.23 (m, 84H). ^{13}C NMR (75 MHz, $CDCl_3$), δ (TMS, ppm): 135.2, 132.8, 127.7, 124.4, 119.7, 105.4, 98.9, 19.5, 12.1. HRMS: m/z 922.8466 (M^+, calcd 922.6120). Anal. Calcd for $C_{60}H_{90}Si_4$: C, 78.02; H, 9.82. Found: C, 77.95; H, 9.78.

2.3. X-ray crystallography

Crystal data for TTIPSEPy: $C_{60}H_{90}Si_4$, $M_w = 923.68$, triclinic, P-1, $a = 11.1306(3)$, $b = 11.7481(3)$, $c = 12.8102(3)$ Å, $\alpha = 77.772(2)$, $\beta = 75.612(2)$, $\gamma = 65.072(2)^\circ$, $V = 1460.43(6)$ Å^3, $Z = 1$, $D_c = 1.050$ g cm^{-3}, $\mu = 0.136$ mm^{-1} (MoKα, $\lambda = 0.7107$ Å), $F(000) = 506$, $T = 173.0$ K, $2\theta_{max} = 50.00$ (99.0%)°, 16,974 measured reflections, 5688 independent reflections ($R_{int} = 0.0349$), GOF on $F^2 = 1.019$, $R_1 = 0.0783$, w$R_2 = 0.1769$ (all data), Δe 0.505 and −0.225 eÅ^3.

Deposited crystal data number: CCDC 817287 for TTIPSEPy.

2.4. Device fabrication and measurements

In a general procedure, indium-tin oxide (ITO)–coated glass substrates were etched, patterned, and washed with detergent, deionized water, acetone, and ethanol in turn. PEDOT:PSS (Baytron P® Al 4083) was spin coated onto the ITO substrates under ambient atmosphere yielding a layer of 10 nm, and then it was baked at 120 °C for 30 min to remove residual water. All the organic layers were subsequently thermally deposited in a vacuum chamber at a base pressure of 8×10^{-5} Pa. After that a 100-nm-thick Ag capping layer was deposited through a 2-mm-wide opening array to fulfill the device fabrication. In all devices, a thin layer of Ca about 8 nm was deposited to enhance the electron injection ability on the Ag cathode. A quartz crystal oscillator placed near the substrate was used to monitor the thickness of each layer, which was calibrated ex situ using Ambios Technology XP-2 surface profilometer. The active area of device was 6 mm^2. EL spectra and chromaticity coordinates were measured with a SpectraScan PR650 photometer. Current density–voltage–luminance measurements were recorded simultaneously using a Keithley 4200 semiconductor parameter analyzer combined with a Newport multifunction 2835-C optical meter, with luminance was measured in the forward direction. All device characterizations were carried out under ambient laboratory air at room temperature.

3. Results and discussion

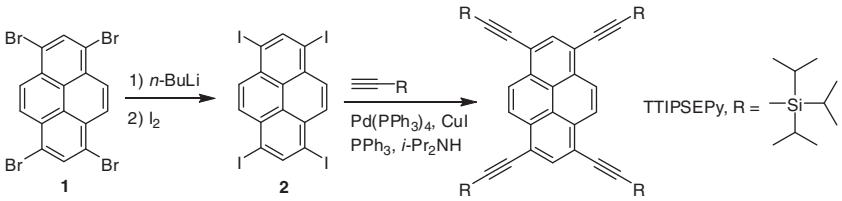
The synthetic route to TTIPSEPy is illustrated in Scheme 1. TTIPSEPy was facilely synthesised by Sonogash-

ira coupling of 1,3,6,8-tetraiodopyrene with (triisopropylsilyl)acetylene in a high yield of 92%. Thermogravimetric analysis gave a decomposition temperature of 377 °C for TTIPSEPy, indicating that the compound was thermally stable for application in OLEDs. The single crystals of TTIPSEPy were grown from hexane/dichloromethane mixture and analyzed by X-ray diffraction crystallography. The crystal structure and B3LYP/6-31G(d) calculated molecular orbital amplitude plots of HOMO and LUMO of TTIPSEPy are shown in Fig. 1. The pyrene ring is well conjugated with four exterior acetylene units. The electron clouds in both HOMO and LUMO are distributed on this conjugated backbone, suggesting that the central conjugation system predominantly controls the photophysical properties of this compound in the disperse phase.

TTIPSEPy exhibits fine-structured absorption spectrum with absorption maximum at 440 nm in dilute THF solution (Fig. 2A), associated with the π–π^* transition of the conjugated backbone. The film of TTIPEPy shows absorption maximum at 442 nm, which is slightly red-shifted comprared with that in solution. The absorption edge of TTIPSEPy in solution is very sharp and is located at 458 nm, whereas that in film is broad and extends up to 540 nm (Fig. 2B). A new absorption shoulder is observed in the wavelength range of 450–540 nm that can be assigned to the charge-transfer transitions induced by *J*-aggregation. TTIPSEPy shows blue emission with a peak at 446 nm and a shoulder at 472 nm in dilute THF solution, which resembles to that of 1,3,6,8-tetrakis[(trimethysilyl)ethynyl]pyrene [14], indicating that the different–sized trialkylsilyl substituents at periphery have little influence on the emission property of the 1,3,6,8-tetraethynylpyrene core in solution. The fluorescence quantum yield (Φ_F) of TTIPSEPy in THF solution is 8.7%, measured by a relative method using 9,10-diphenylanthracene (Φ_F = 90% in cyclohexane) as standard. This Φ_F value is lower than those of pyrene and most pyrene derivatives [9], probably due to the self-absorption effect as implied by the partial overlapping of absorption and emission spectra (Fig. 2A) in solution. Howerve, the PL of TTIPSEPy becomes redder and broader in the single crystal state. The emission spectrum red-shifts to green region with two emission peaks at 490 and 510 nm. Moreover, the PL further moves to yellow region in the solid amorphous film with emission maxiumum at 553 nm, which is bathochromatically shifted by 107 nm compared with that in solution (Fig. 2B). Concerning the PL of 1,3,6,8-tetrakis[(trimethysilyl)ethynyl]pyrene, its emission maximum in film state is located at ~650 nm, and is strongly red-shifted by about 200 nm than that in solution [14]. The hypsochromic shift in PL of TTIPSEPy film relative to 1,3,6,8-tetrakis[(trimethysilyl)ethynyl]pyrene film can be interpreted as that the more bulky triisoporpylsilyl substitutents have reduced π–π interactions to some extent in film state. Nevertheless, the broader absorption and the bathochromically shifted PL of TTIPSEPy in film compared with those in solution clearly suggest that there are strong intermolecular interactions between TTIPSEPy molecules in the condensed phase. TTIPSEPy exhibits a high Φ_F value of 100% in film, measured by a calibrated integrating sphere, being more than 10-fold higher than that in solution. The unity emission efficiency of TTIPSEPy in film reveals that it is an outstanding solid-state emitter.

To further understand the optical property of TTIPSEPy in the solid-state, we investigate the crystal structure of TTIPSEPy. As displayed in Fig. 3A–C, the pyrene rings of two adjacent TTIPSEPy molecules are stacked in a parallel pattern. However, the overlapping between adjacent pyrene rings is inadequate, which undermines the strong π–π interactions between TTIPSEPy molecules in crystalline. CH$\cdots\pi$ hydrogen bonds with a distance of 2.856 Å are formed between the hydrogen atoms of the triisopropylsilyl groups in one TTIPSEPy molecule and the π cloud of the pyrene ring in another molecule. A distance of 5.614 Å is found between the parallelly located acetylene units of the adjacent TTIPSEPy molecules. These findings suggest that weak intermolecular interactions may exist in the crystals, which accounts for the redder PL of TTIPSEPy in crystalline state, as compared to that in solution. However, the remarkable bathochromatic shift in PL of TTIPSEPy film should stem from strong π–π interactions between pyrene rings. The proposed *J*-type packing model of TTIPSEPy molecules in film state is illustrated in Fig. 3D, where the TTIPSEPy molecules are stacked parallely and closely, and strong π–π interactions are formed between pyrene rings. The formation of such kind of *J*-aggregation should be responsible for the drastic bathochromatic shift and notable emission efficiency enhancement in film state [11,15,16].

Cyclic voltammetry measurement was carried out to determine the energy levels of TTIPSEPy in film state. Fig. 4 shows the cyclic voltammogram of TTIPSEPy film, in which oxidation and reduction peaks are found at 1.45 and −1.68 V, respectively. The onset oxidation potential of TTIPSEPy film is at 1.01 eV, corresponding to the estimated HOMO energy level of −5.41 eV [HOMO = $-(E^{ox}_{onset} + 4.4)$ eV]. This value is quite close to that of a widely used hole transport material *N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenyl-benzidine (NPB, −5.4 eV) [5], indicating that the holes can be facilely injected to TTIPSEPy film. The



Scheme 1. Synthetic route to TTIPSEPy.

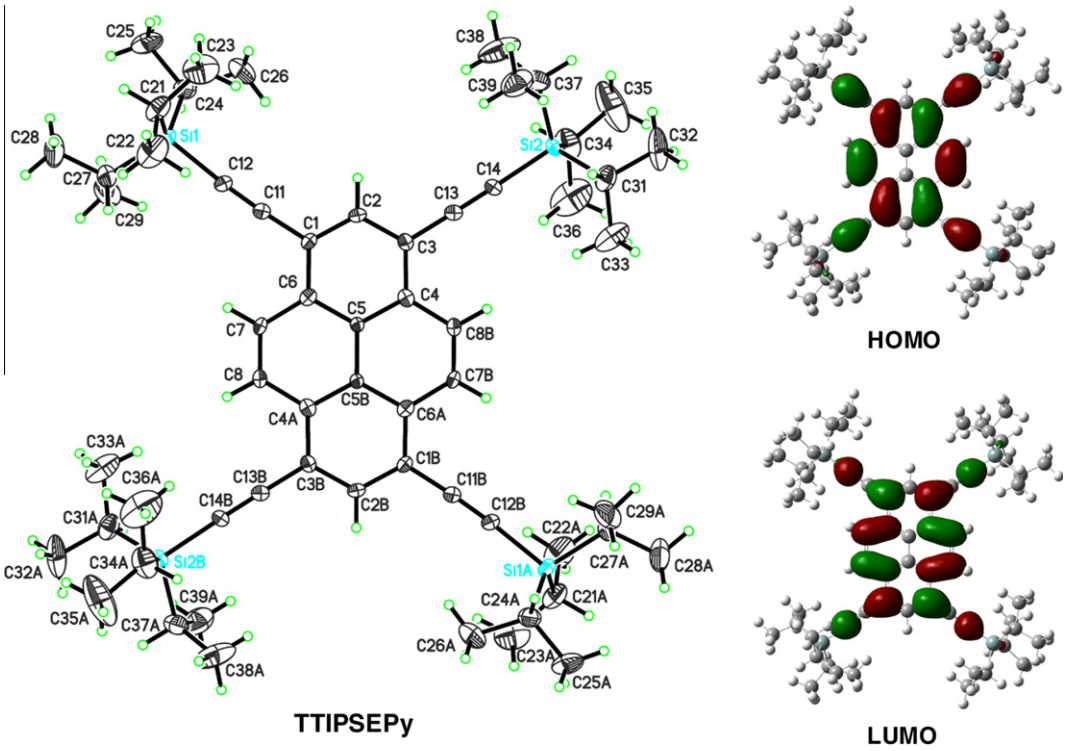


Fig. 1. ORTEP drawing and B3LYP/6-31G(d) calculated molecular orbital amplitude plots of HOMO and LUMO of TTIPSEPy.

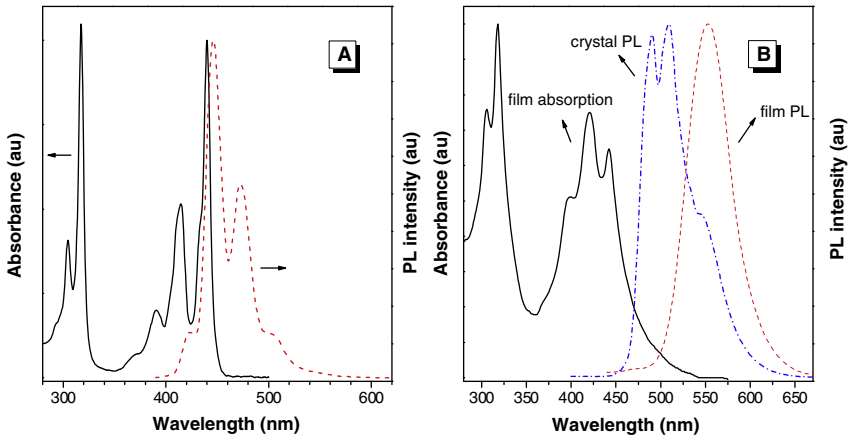

Fig. 2. Absorption and PL spectra of TTIPSEPy (A) in dilute THF solution (10 μM) and (B) in the solid state.

onset reduction potential (E^{re}_{onset}) of TTIPSEPy film is found at −1.21 V, from which the LUMO energy level of −3.19 eV is derived [LUMO = $-(E^{re}_{onset} + 4.4)$ eV]. The value is lower than those of electron transport materials aluminum(III)bis(2-methyl-8-quinolinato)4-phenylphenolate (BAlq, −2.7 eV) [17] and 1,3,5-tris(2-*N*-phenylbenzimidazolyl)benzene (TPBI, −2.7 eV) [18], and equal to that of 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP, −3.2 eV) [19], indicating that TTIPSEPy film is in favor of electron injection and transport. The rather low LUMO energy level is presumably due to the electron-withdrawing effect of triisoporpylsilylacetylene [20]. The energy band gap (E_{exp}) calculated from the electrochemically determined HOMO and LUMO energy levels is 2.22 eV, which is in good accordance with that obtained from the threshold of absorption spectrum of TTIPSEPy film (2.30 eV).

The highly efficient solid-state PL of TTIPSEPy encouraged us to investigate its application in non-doped OLEDs. We fabricated multilayer devices by vapor deposition process with the configurations listed in Table 1. A control device was also fabricated adopting rubrene as emitter. The EL spectra and performance curves of the devices are displayed in Figs. 5 and 6, respectively. Devices A and B with a configuration of ITO/PEDOT:PSS (10 nm)/NPB (35 nm)/

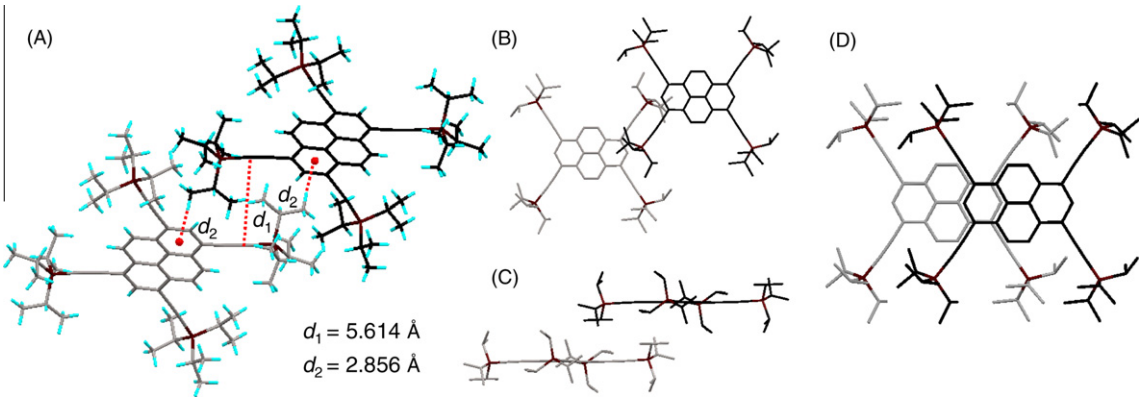

Fig. 3. (A) C–H···π hydrogen bonds between adjacent molecules of TTIPSEPy in crystals. (B) Top and (C) side views of adjacent molecules of TTIPSEPy in crystals along the plane of pyrene ring. (D) Proposed stacking pattern of TTIPSEPy molecules in the film state.

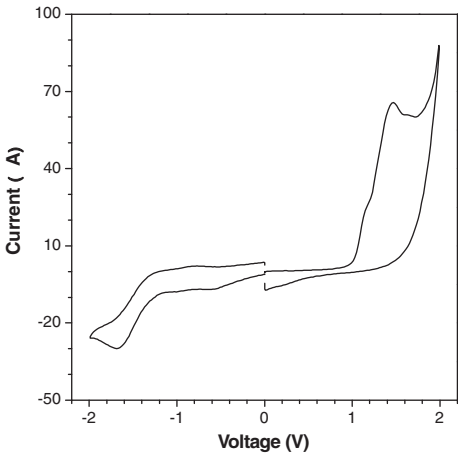

Fig. 4. Cyclic voltammogram of TTIPSEPy film measured in acetonitrile containing 0.1 M Bu_4NPF_6, scant rate 100 mV/s.

TTIPSPEy (*x* nm)/BCP (36 nm)/Ca (8 nm)/Ag (100 nm), where *x* = 13 nm for device A and *x* = 25 nm for device B, are turned on at a quite low voltage of 2.2 V. They emit yellow light peaked at 560 nm, corresponding to the Commission International de l'Eclairage (CIE) chromaticity coordinates of (0.44, 0.53). Both devices show stable EL, whose spectra profiles change little against applied voltage increases (Fig. 5A). These EL spectra are close to the PL spectrum of the TTIPSEPy film, revealing that both EL and PL originate from the same radiative-decay process of singlet excitons. The EL efficiency is enhanced obviously when the thinkness of TTIPSEPy layer increases as indicated in Fig. 6C. Device B shows a maximum current efficiency ($\eta_{c,max}$) of 7.1 cd/A, and a maximum power efficiency ($\eta_{p,max}$) of 8.3 lm/W, which are much higher than those of device A (4.2 cd/A, and 3.6 lm/W). In general, thickening the emitting layer will enhance the recombination efficiency of holes and electrons in it, and consequently improves the device efficiency. We also investigated the effect of electron-transporting layers on the performances of the devices. When keep TTIPSEPy thickness unchanged and use different electron-transporting layers in devices C and D, the EL spectra vary slightly (Fig. 5B) but the turn-on voltages, L_{max} and $\eta_{c,max}$ change remarkably (Table 1). The turn-on voltages of devices C and D are 4.4 and 5.0 V, respectively, which are more than 2-fold higher than that of device B. Device D with a configuration of ITO/PEDOT:PSS (10 nm)/NPB (35 nm)/TTIPSEPy (25 nm)/TPBI (36 nm)/Ca (8 nm)/Ag (100 nm), where TPBI is used as electron-transporting as well as hole-blocking layer, exhibits the highest L_{max} and $\eta_{c,max}$ (Table 1). It radiates brilliantly yellow light peaked at 552 nm (CIE = 0.41, 0.56) with a L_{max} of 26,400 cd/m^2 and a $\eta_{c,max}$ of 9.2 cd/A. On the other hand, the data attained from TTIPSEPy-based devices A–D are much better than those from rubrene-based control device E (Table 1, Fig. S2 and S3). They are also

Table 1
EL properties of TTIPSEPy and rubrene in non-doped OLEDs.[a]

EML	ETL	λ_{EL} (CIE) (nm)	V_{on} (V)	L_{max} (cd/m^2)	$\eta_{c,max}$ (cd/A)	$\eta_{p,max}$ (lm/W)

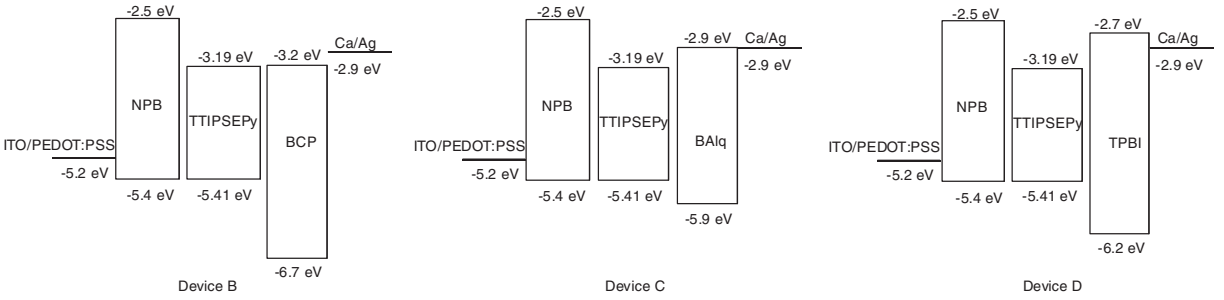

Fig. 7. The energy band structures of devices B–D.

close to the best results of rubrene-doped devices in literatures [3]. Such good EL performances are attributable to the high Φ_F in the solid-state and matched energy levels of TTIPSEPy.

To get a better understanding of the mechanism behind the changes in performances of devices B–D, the energy levels of TTIPSEPy and various electron-transporting layers are taken into consideration. Fig. 7 illustrates the energy level diagrams of devices B–D. The LUMO energy level of BCP (−3.2 eV) is lower than those of BAlq (−2.9 eV) and TPBI (−2.7 eV), which facilitates the electron injection. Moreover, the electron mobility of BCP (1.0×10^{-3} $cm^2 V^{-1} s^{-1}$) [21] is 100-fold higher than that of TPBI (1.0×10^{-5} $cm^2 V^{-1} s^{-1}$) [22]. Both factors account for the lowest turn-on voltage of device B. On the other hand, the HOMO energy level of TPBI (−6.2 eV) is lower than that of BAlq (−5.9 eV), which confines holes and excitions in the emitting layer more effectively. Meanwhile, the higher LUMO energy level of TPBI faciliates more efficient electron injection to emitting layer from TPBI layer. The combination of these two effects in device D leads to the highest L_{max} and $\eta_{c,max}$ values among these devices.

4. Conclusion

In summary, a novel simple-structured chromophore composed by a 1,3,6,8-tetraethynylpyrene core and four

triisopropylsilyl peripheral substituents (TTIPSEPy) is synthesised and characterized. TTIPSEPy is thermally stable and shows yellow PL with unity emission efficiency in film state. High performance non-doped OLEDs have been fabricated using TTIPSEPy as emitter, exhibiting yellow EL (CIE = 0.41, 0.56) with luminance and efficiency up to 26,400 cd/m^2 and 9.2 cd/A, respectively. To the best of our knowledge, these values are better than those of non-doped yellow fluorescent OLEDs ever reported [6]. The facile synthesis and outstanding PL and EL properties of TTIPSEPy suggest that it is a promising candidate for the fabrication of non-doped yellow and white OLEDs. Systematic investigations on structure–property relationship of similar chromophores constructed by 1,3,6,8-tetraethynylpyrene cores and different-sized peripheral substituents are in progress.

of these derivatives [9]. Increasing the number of thiophene units, on the other hand, leads to reduction of the ionization potential (IP) as well as the optical band gap [12]. Thus, use of dicyanovinyl endgroups and variation of oligomer backbone result in oligothiophene structures for which an efficient exciton dissociation in heterojunctions to the acceptor C60 takes place [12]. For planar heterojunction (PHJ) solar cells based on DCVnTs, power conversion efficiencies (PCE) of up to 3.4% with an open circuit voltage of up to 1 V were reported [13]. Most recently, optimization of the mixed layer morphology by use of substrate heating resulted in PCEs of 4.9% in DCV6T-Bu(1,2,5,6):C60 and 5.2% in DCV5T:C60 mixed heterojunction solar cells [14,15].

In this work, in contrast to Ref. [14], we study neat vacuum deposited films of the α-ω-bis-(dicyanovinylen)-sexithiophene DCV6T-Bu(1,2,5,6) (DCV6T-Bu), comprising six thiophene rings and four butyl side-chains at the first, second, fifth and sixth thiophenes (see inset of Fig. 1). Compared to the formerly introduced in Ref. [16] DCV6T-Et(2,2,5,5) (DCV6T-Et), which comprised two ethyl side chains at the second and fifth thiophene, DCV6T-Bu has the same thiophene backbone and differs only in the side chain length and pattern. The molecular structure of the reported material was intentionally modified utilizing longer side chains with asymmetrical substitution aiming at enhanced solubility, thus improved purity upon synthesis, and promotion of self-organization. We report on the morphology and optical properties of the neat DCV6T-Bu films, discussing the effect of the molecular structure on the molecular arrangement and packing in the solid state. We show that more ordered film morphology is obtained as a result of the modified substitution in DCV6T-Bu as compared to DCV6T-Et. Deposition on substrates at elevated temperature leads to enhanced crystalline growth as confirmed by the presented structural and spectroscopic data. On the basis of these results, using the charge extraction by linearly increasing voltage (CELIV) method, we study the hole mobility of heated and nonheated DCV6T-Bu films. Finally, contrary to Ref. [14] dealing with the optimization of mixed heterojunction solar cells, here, we discuss the performance of DCV6T-Bu/C60 PHJ solar cells comparing devices with and without deposition at elevated substrate temperature.

2. Experimental

The samples for the ultraviolet–visible (UV–Vis) absorption spectroscopy, X-ray diffraction (XRD), atomic force microscopy (AFM) measurements as well as the solar cell devices were prepared by thermal evaporation in high vacuum at a base pressure of $\leqslant 6 \times 10^{-6}$ mbar and deposition rate of 0.1–0.2 Å/s. Nominal layer thicknesses were determined using quartz crystal monitor calibrated beforehand using a second crystal placed at the sample position.

UV–Vis absorption spectroscopy and AFM measurements were carried out on DCV6T-Bu films deposited on quartz glass substrates. Neat or precovered with 15 nm C60 (Bucky, USA) Si wafers were used as substrates for the XRD studies. Two CELIV devices and two solar cells comprising DCV6T-Bu/C60 PHJs were prepared on indium tin oxide (ITO)-precovered glass substrates (Thin Film devices Inc., sheet resistance of 30 Ω/sq). All substrates were cleaned subsequently in acetone, ethanol and isopropanol, and after that blow-dried in nitrogen. The nominal thickness of the DCV6T-Bu layers was 20 nm for all samples grown on quartz glass, independent of the substrate temperature (assumed density $\rho = 1.3$ g/cm^3). For the XRD measurements, 50 nm DCV6T-Bu films were deposited on 30 °C- and 6 nm, 10 nm, and 50 nm on 90 °C-substrates, respectively.

The absorption of the layers in the UV–Vis spectral range was measured in transmission mode using a two-beam spectrometer UV 3100 (Shimadzu Corporation). The

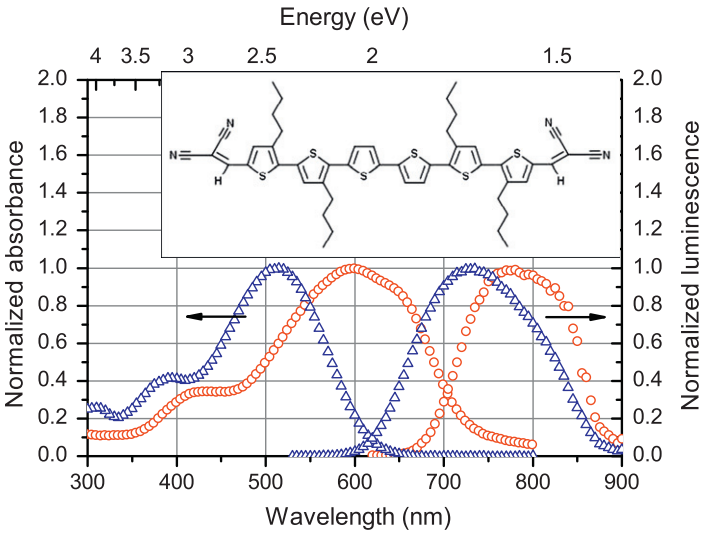

Fig. 1. Normalized absorbance and PL spectra of DCV6T-Bu in dichloromethane solution (open triangles) and in thin film (open circles). The thickness of the film is 30 nm. PL is measured by excitation at the corresponding wavelength of maximum absorption. Inset: chemical structure of the DCV6T-Bu(1,2,5,6) molecule.

surface topography of the samples was studied by AFM using a Digital Instrument NanoScope IIIa microscope in tapping mode. XRD investigations were carried out by means of X-ray diffractometer URD-6 (Seifert FPM, Germany) designed in Bragg–Brentano geometry using monochromatized Cu-K_α radiation with wavelength of 1.5418 Å. The XRD patterns of the samples were recorded in symmetrically coupled ω-2θ specular scan mode, where 2θ is the diffraction angle and $\omega = \theta$ is the X-ray incidence angle. Other details of the XRD experiment could be found in [17].

The mobility of DCV6T-Bu was measured using the charge extraction by linearly increasing voltage method (CELIV) as described in Refs. [18,19]. The CELIV devices were built of DCV6T-Bu/C60 planar heterojunctions in the layer structure (thickness given in brackets in nm): ITO / C60 (20) / DCV6T-Bu (x) / Au (10) / Al (90) with x = 57 nm and x = 60 nm for device I and II, respectively. For comparison of the effect of different DCV6T-Bu film morphologies on the hole mobility, device I was prepared at room temperature (RT) substrate (T_{sub} = RT), while for device II a substrate temperature of (90 ± 10)°C (T_{sub} = 90 °C) was used during the deposition of DCV6T-Bu. Both electrons and holes are extracted from the devices. However, the presented experiments determine the hole mobility of DCV6T-Bu, since the signal is dominated by the slower carrier and electrons in C60 have the by far higher mobility, reported to be as high as 6 cm^2/Vs [23]. A blue light emitting diode is used to illuminate the CELIV devices prior to applying the voltage pulse in order to increase the amount of extractable charges.

The layer structures of solar cells A and B are (thickness given in brackets in nm): ITO / n-C60 (10) / C60 (15) / DCV6T-Bu (10) / BPAPF (5)/ p-BPAPF (50)/ NDP9 (1) / Au (40).

Device A was produced without substrate heating, meaning the substrate temperature (T_{sub}) during all deposition steps was around 24 °C, whereas in device B a substrate temperature T_{sub} = (90 ± 5)°C was applied during the deposition of the DCV6T-Bu layer in order to facilitate enhanced crystalline growth. We produced three solar cells of device type A and four solar cells of device type B on one substrate, respectively. The deviations between the characteristic parameters of the nominally equal solar cells were <1% in the open circuit voltage V_{oc}, <2.5% in the fill factor FF, and <2% in the short circuit current j_{sc}. For the hole transport layer (HTL) 9,9-bis[4-(N,N-bis-biphenyl-4-yl-amino)phenyl]-9H-fluorene (BPAPF, Lumtec) was used because this material provides a high IP of 5.6 eV, determined by ultraviolet photoelectron spectroscopy (UPS), and is therefore well matched to the IP of DCV6T. This is important to avoid transport barriers between the HTL and the donor [20–22]. For doping of C60, the n-dopant NDN1 from Novaled AG (Dresden, Germany) was used with a ratio of 3 wt% (weight percent). BPAPF was doped with the p-dopant NDP9 from the same company and a ratio of 10 wt%. DCV6T-Bu (Heliatek GmbH, Dresden, Germany) and the dopants were used as received without further purification. C60 and BPAPF were purified by thermal gradient sublimation at least twice before deposition.

The current-voltage (J-V) characteristics were recorded with a source measure unit 2400 Sourcemeter (Keithley) under a sun simulator 16S-003-300 (Solar Light Company Inc.), using an aperture mask of 3.0 mm^2. The nominal area given by the overlap of ITO ground contact and metal top contact is 6.2 mm^2. The intensity is monitored by the calibrated reference diode S1337-33BQ (Hamamatsu) and subsequently corrected for mismatch, in order to provide intensity values corresponding to standard sun spectrum AM1.5G. For the external quantum efficiency (EQE) measurement, a homemade setup based on a xenon arc lamp, a monochromator (Cornerstone 260), and a lock-in amplifier (Signal Recovery SR 7265) was used. The setup was calibrated with the same reference diode S1337-33BQ (Hamamatsu).

All measurements discussed above were performed at RT.

3. Results and discussion

3.1. Morphology and optical properties

In solution, the absorption behavior of DCV6T-Bu is similar to that of the previously studied DCV6T-Et [16]. As can be seen in Fig. 1, the absorption band is broad and featureless. It thus relates to rotational disorder of the thiophene rings in the dissolved state. The photoluminescence (PL) spectrum is slightly structured, suggesting planarization of the molecule upon excitation [24]. Simultaneously, the peak to peak shift between absorption and emission is rather large, 0.72 eV, thus indicating significant change in conformation upon excitation. In the thin film, the absorption and PL peak positions are shifted to lower energies. The displacement of absorption and emission bands relative to solution and the observed broadening of absorption indicate solid state aggregation resulting from increased molecular interactions.

The molecular structure of DCV6T-Bu obviously influences the spectral response of the material in the solid state. Compared to DCV6T-Et [16], the absorption band of the DCV6T-Bu film is shifted further to longer wavelengths by about 23 nm and displays pronounced vibronic substructure evident by the shoulder at 650 nm. The presence of absorption fine structure is generally attributed to planarization of the thiophene backbone in the solid state [25] and indicates the better self-organization of the DCV6T-Bu molecules in the thin film deposited on RT-substrate. The high absorption coefficient with a maximum value of $(3.2 \pm 0.3) \times 10^5$ cm^{-1} [14] and the broad spectrum in the visible range of DCV6T-Bu are prerequisites for a promising performance when utilized as absorber material in organic solar cells.

An XRD pattern of a 50 nm DCV6T-Bu film deposited on Si substrate kept at RT is depicted in Fig. 2. As can be seen, in contrast to the DCV6T-Et derivative which is characterized by a rather amorphous structure when deposited on RT-substrate [16], the DCV6T-Bu film shows an XRD reflection at 2θ = 7.83°. In the ω-2θ scan mode, only Bragg reflections from lattice planes oriented parallel to the sample surface can be detected. The derived interplane distance d equals 11.29 Å. Using the Scherrer equation with constant K set to 0.94 [26] and an appropriate instrumental correction, a

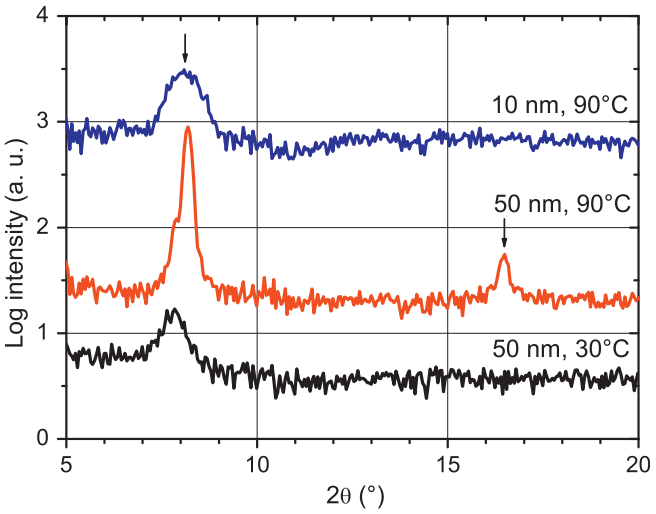

Fig. 2. XRD patterns of DCV6T-Bu deposited on Si-wafer kept at RT and 90 °C temperature. The substrate contribution is subtracted from the XRD patterns. The XRD patterns of the different samples are shifted vertically for easier comparison. The observed XRD reflections are indicated by arrows. The corresponding film thicknesses and substrate temperatures are displayed in the graph. Determined values of interplane distances and crystallite sizes are summarized in Table 1.

Table 1
Central-angle 2θ position, corresponding interplane distance d and full width at half maximum (FWHM) of the observed XRD reflections, and calculated crystallite size D for DCV6T-Bu films of various thickness grown on neat Si wafer and on 15 nm-thick C60 underlayer at different substrate temperatures.

DCV6T-Bu on Si	2θ (°)	d (Å)	FWHM (°)	D (nm)
50 nm / 30 °C	7.83	11.29	0.64	13.4 ± 0.2
50 nm / 90 °C	8.19	10.78	0.22	49 ± 4
10 nm / 90 °C	8.09	10.92	1.03	8.1 ± 0.1
DCV6T-Bu on C60				
10 nm / 90 °C	8.20	10.78	1.28	7.0 ± 0.1
6 nm / 90 °C	8.15	10.84	1.59	5.5 ± 0.1

crystallite size D along the substrate normal of 13.4 nm is determined (see XRD data in Table 1). Accordingly, the XRD result affirms that the modification of the alkyl side chains from ethyl to butyl and the alteration in substitution pattern promote better molecular arrangement at RT-deposition of DCV6T-Bu compared to the previously introduced DCV6T-Et [16].

XRD patterns of DCV6T-Bu films with thickness of 10 nm and 50 nm deposited at 90 °C substrate temperature on Si are depicted in Fig. 2. According to the increasing number of XRD reflections and their intensity, the XRD patterns of the films grown on elevated substrate temperature evidence better crystallinity compared to the film grown on RT-substrate. The interplane distance d, corresponding to scattering planes parallel to the substrate surface, is reduced to 10.78 Å for the 50 nm sample (vs. 11.29 Å for the 50 nm at RT-substrate), pointing at film relaxation induced by the substrate heating. Similar film relaxation is established upon increasing film thickness (cp. data in Table 1). The crystallite size D along the substrate normal equals 8.1 nm and 49 nm for the 10 nm and 50 nm film, respectively. Thus, the films grown on heated substrate are crystalline through the whole film thickness. The larger interplane distance observed for DCV6T-Bu as compared to that of DCV6T-Et (cp. to d = 8.5 Å for DCV6T-Et film grown at 90 °C-substrate, Ref. [16]) might be related to the longer alkyl side-chains, resulting in a less dense packing of the DCV6T-Bu molecules. Correspondingly, although having the same thiophene backbone and end groups, both derivatives might crystallize in different structures due to the different side chain length and substitution pattern. Knowledge of the crystal structure is essential to rationalize the molecular orientation in the films as well as the solid state absorption spectra and transport properties. However, crystal structure determination needs an extensive analysis of suitable single crystals which we were not able to grow up to now. In Ref. [17] an attempt is performed to index the reflections observed in the XRD pattern of DCV6T-Bu powder and to make assumptions about the possible unit cell. Accordingly, the reflections in the XRD patterns of the DCV6T-Bu films (Fig. 2) correlate to nearly parallel orientation of the DCV6T-Bu molecules inclined at about 19° with respect to the substrate as described in Ref. [17].

In addition to the films deposited directly on Si, layer arrangement relevant to a real OPV stack was also investigated by means of XRD. Fig. 3 depicts the XRD patterns of 6 nm and 10 nm DCV6T-Bu films grown on 15 nm-thick C60 underlayer. The reference C60 film is at least X-ray amorphous. Its XRD pattern exhibits an enhanced intensity in vicinity of 2θ-angle position of the 111 C60 reflection [27]. The DCV6T-Bu films on top of C60 are crystalline with interplane distances decreasing with film thickness and crystalline domains extending vertically over the whole film thickness (see data in Table 1). Thus the films on C60 underlayer follow the tendencies observed for the neat films grown directly on Si at 90 °C substrate temperature. Accordingly, they show enhanced crystallinity when deposited on substrate at elevated temperature which is a

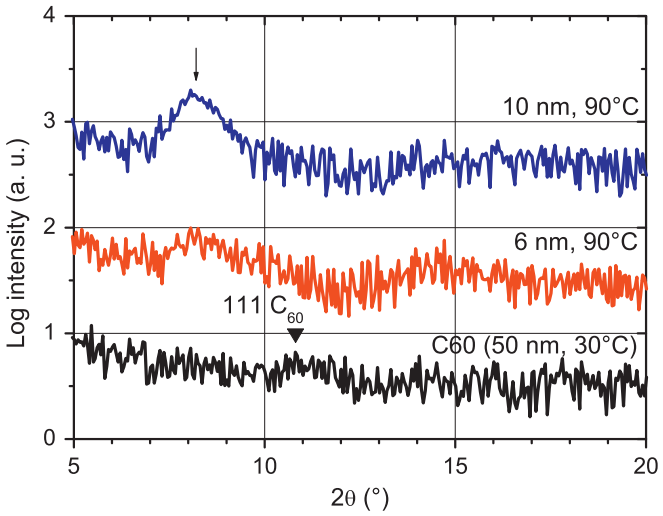

Fig. 3. XRD patterns of DCV6T-Bu films deposited at 90 °C substrate temperature on top of 15 nm C60 underlayer. The XRD pattern of neat C60 underlayer is presented for comparison. The studied film thicknesses and substrate temperatures are indicated in the graph. The substrate contribution is subtracted from the XRD patterns. For the purpose of comparison, the XRD patterns of the different samples are shifted vertically. The observed XRD reflection of DCV6T-Bu is marked by an arrow. The theoretical 2θ-angle position of the 111 C60 reflection according to [27] is indicated by triangle. Determined values of interplane distances and crystallite sizes are summarized in Table 1.

beneficial quality for OSC application since better transport properties are expected.

Extensive analysis and details on calculations of the XRD, and additionally X-ray reflectivity data concerning the DCV6T-Bu films deposited on the neat and precovered by C60, or other organic layers used in OPV stacks, Si-wafers will be published elsewhere [17].

Fig. 4 displays the alteration in the absorption response of the neat DCV6T-Bu films in dependence on substrate temperature. Upon increasing substrate temperature the absorption band gradually shifts to longer wavelengths and a distinct structure evolves. At temperatures above 100 °C the low energy peak shifts by about 16 nm compared to the initial shoulder at RT-substrate. Additionally, at the high energy side a shoulder shifting from 550 nm to 560 nm can be distinguished. Accordingly, the film grown at 90 °C substrate temperature is characterized by the highest overall absorption (integrated from 300 nm to 850 nm) while the films grown at yet higher temperatures show enhanced absorption at longer wavelengths. The changes in DCV6T-Bu absorption are similar to the alterations reported for regioregular poly(3-alkylthiophenes) [28,29], attributed to increased interchain interactions and hence are explained by a better molecular arrangement induced by the

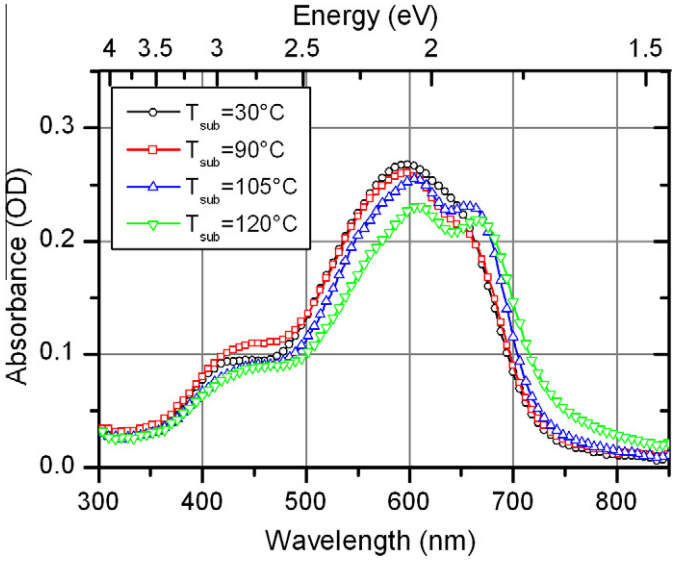

Fig. 4. Absorbance of DCV6T-Bu films deposited at different substrate temperatures on quartz glass. All films are 20 nm thick.

substrate heating. The results of absorption spectroscopy are in agreement with the presented XRD data, which reveal evolution of the film morphology toward enhanced crystallization upon growth at elevated substrate temperature. Heating of the substrate facilitates molecular surface diffusion, thus allowing ordered films with larger crystallites. Consequently, configurational disorder is reduced resulting in the well-resolved vibronic fine structure apparent in the absorption band. On the other hand, the closer packing of the molecules induced by the crystal structure leads to increased molecular interactions giving rise to the observed red shift. In solar cell application the red shift of absorption adapts better to the sun spectrum and hence more photons can be harvested.

The morphology of the DCV6T-Bu films probed by AFM is presented in Fig. 5. On RT-substrate, the film is characterized by a smooth surface with root mean square roughness (rms) of only 1.4 nm. Due to the rapid nucleation process at this temperature, condensation results in a large number of fine and homogeneous grains. With increasing substrate temperature up to 90 °C, the grains agglomerate to build chain-like aggregates. Correspondingly, the surface roughness increases, reaching values of about 2 nm. This morphology relates to stronger tendency to crystallization and is thus consistent with the results from UV–Vis absorption and XRD analysis. Higher substrate temperature leads to increased molecular surface diffusion which favors the lateral growth. For the 105 °C-substrate, the surface becomes rougher with clusters reaching lateral sizes up to 200 nm. Thus, higher substrate temperature promotes the film organization and consequently results in enhanced crystalline growth. Further increase of the substrate temperature to 120 °C causes a change in the film morphology to even larger clusters with lateral size of 500 nm to 800 nm and height of 12 nm to 20 nm, being more or less separated from each other. The surface roughness is enhanced to a considerable value of 6.7 nm and the clusters comprise distinct steps and terraces. The step height is estimated to lie between 1.0 nm and 1.5 nm and thus corresponds to the interplane distance d of about 11 Å for heated DCV6T-Bu films determined by XRD. Compared to the maximum length of a DCV6T-Bu molecule, estimated to be about 3.2 nm, the step height suggests a parallel or at least strongly tilted orientation of the molecule long axis toward the substrate plane for the sample deposited at 120 °C substrate temperature. This conclusion is in line with the strong absorption of the films that indicates a significant component of the molecular transition dipoles oriented parallel to the substrate as well as with the derived from XRD molecular inclination of 19° [17]. However, according to the presented AFM results, the very coarse morphology with large clusters and voids in-between might be the cause for the decrease in absorption, observed for the DCV6T-Bu films grown at high substrate temperatures.

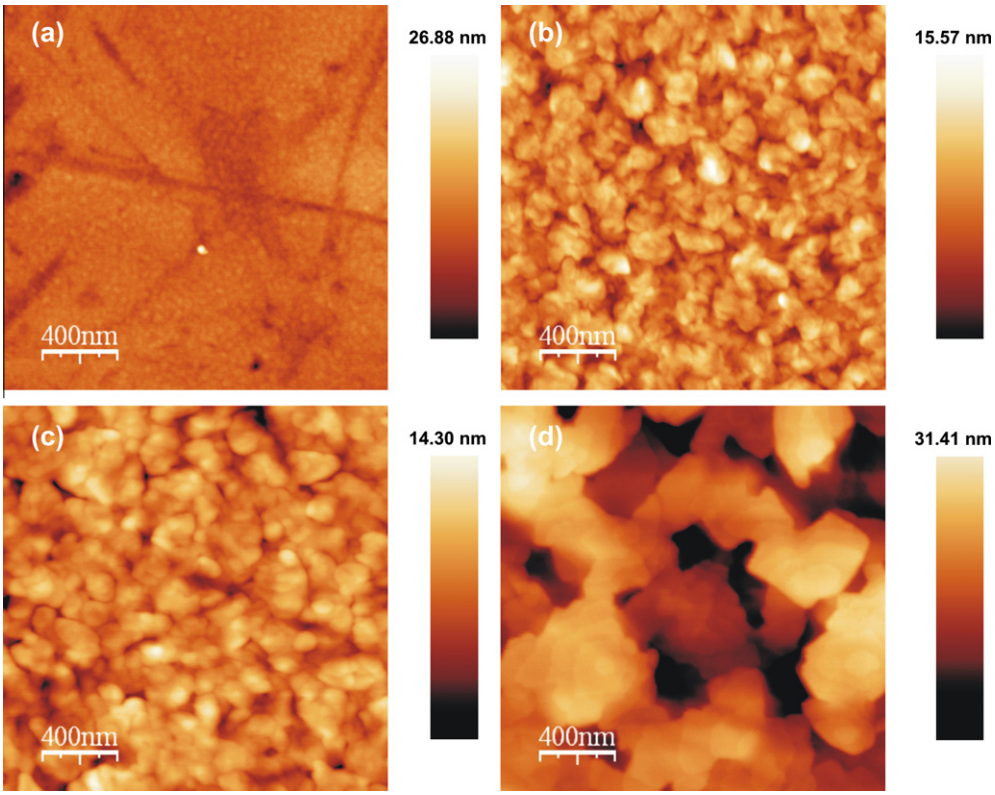

Fig. 5. AFM micrographs of DCV6T-Bu grown on quartz glass substrates kept at different substrate temperatures during deposition: (a) 30 °C, (b) 90 °C, (c) 105 °C, and (d) 120 °C. The films are 20 nm thick.

3.2. Electrical properties

As the morphology of the neat DCV6T-Bu films changes toward increased crystallinity when grown on a heated substrate, mobility variation of the charge carriers is expected. In order to prove the effect of modified morphology on the charge transport properties, CELIV measurements on devices comprising DCV6T-Bu films deposited at RT (device I) and ~90 °C (device II) substrate temperature were carried out. Fig. 6 shows the evaluated hole mobility values for the CELIV-devices I and II as Arrhenius plot. In both devices a clear thermal activation of mobility is observed, as can be seen from the linear development in both graphs. The corresponding activation energy for device I (T_{sub} = RT) and II (T_{sub} = 90 °C) are 186 meV and 87 meV, respectively. The lower activation energy value for the heated device II is consistent with its higher crystallinity, which is expected to lower the energetical disorder of the molecular states, thereby reducing the average barrier height between hopping steps during the charge transport. However, comparing the mobilities measured at a temperature of 300 K and an electric field of 90,000 V/cm (i.e. 0.9 V applied at 100 nm), mobility values of $\mu = 1.0 \times 10^{-6}$ cm^2/Vs for device I and $\mu = 3.1 \times 10^{-7}$ cm^2/Vs for device II, respectively, are obtained. Another sample, nominally equal to device I, exhibited mobility of 2.4×10^{-7} cm^2/Vs. Thus, contrary to the general expectation that charge carrier mobility could be increasing in the more crystalline phase, there is no significant increase of μ in the heated device II compared to the nonheated device I. Since the accurate crystal structure of DCV6T-Bu is not yet determined, it is difficult to clarify the reasons for this behavior. It could be speculated that, despite the expected preferred orientation of planar molecules lying nearly parallel to the substrate, self organization at elevated substrate temperature does not facilitate a better π-stacking in upright direction. We thus suggest a rather parallel to the substrate plane growth direction of the π-stacks and nearly perpendicular to the substrate plane butyl side-chains. Hence, in spite of the relative high molecular order, the low mobility values are interpreted to be a result of impeded charge transport by the alkyl side-chains.

3.3. Solar cells

Fig. 7 shows the J-V characteristics of solar cell devices A and B comprising DCV6T-Bu/C60 PHJs. In these cells we utilize a DCV6T-Bu layer thickness of only 10 nm, mainly out of two reasons. Firstly, the obtained hole mobility is very low and thus it is to be expected that larger layer thicknesses would impede efficient extraction of holes, thereby decreasing the fill factor (FF). This effect was already presented in Ref. [21] for the derivative DCV6T-Et. Secondly, the thickness of 10 nm lies in the range of the exciton diffusion length, and thus a higher layer thickness would lead to inefficient exciton collection [21]. For better comprehension, in Fig. 7 the J-V characteristics of only one out of several measured solar cells is exemplarily displayed for device type A and B, respectively. However, the deviations between nominally equal solar cells are such small that the displayed characteristic parameters are valid for all measured solar cells, besides in solar cells of type A fill factors in the range of 67–68% were measured while in solar cells of type B the FF differs in the range of 66–68%. Comparing devices A and B, it can be seen that both provide a nearly equal open circuit voltage around V_{oc} = 0.80 V and FF. However, device B, prepared at T_{sub} = 90 °C during deposition of the DCV6T-Bu layer, exhibits higher short circuit current of density 4.0 mA/cm^2 while device A, prepared without substrate heating, reaches only 3.4 mA/cm^2. From Fig. 8, showing the EQE of the corresponding solar cells of type A and B, it can be seen that the improvement of photocurrent in the heated device B originates from higher EQE in the wavelength range of DCV6T absorption. Especially in the red absorption region, i.e. from 550 nm to 700 nm, the EQE is increased and we also observe a more distinct formation of the lowest energy absorption feature (at 650 nm), similar to the findings of the UV–Vis spectra of DCV6T-Bu single layers. Although for the presented set of samples grown on quartz glass

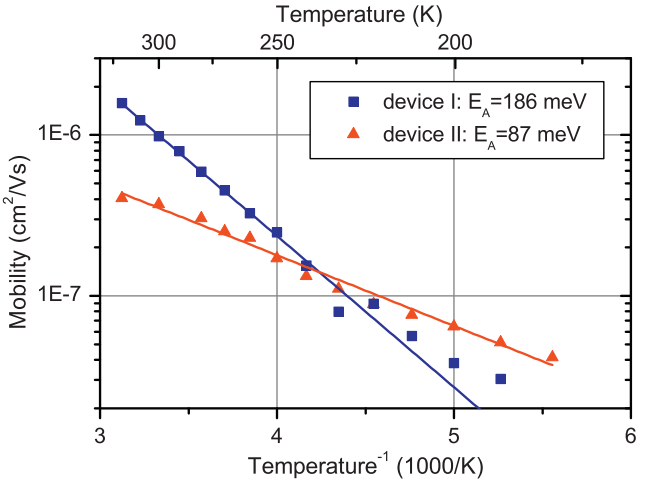

Fig. 6. Thermal activation of mobility measured by CELIV at devices I (T_{sub} = RT) and II (T_{sub} = 90 °C) at a voltage of 2.5 V.

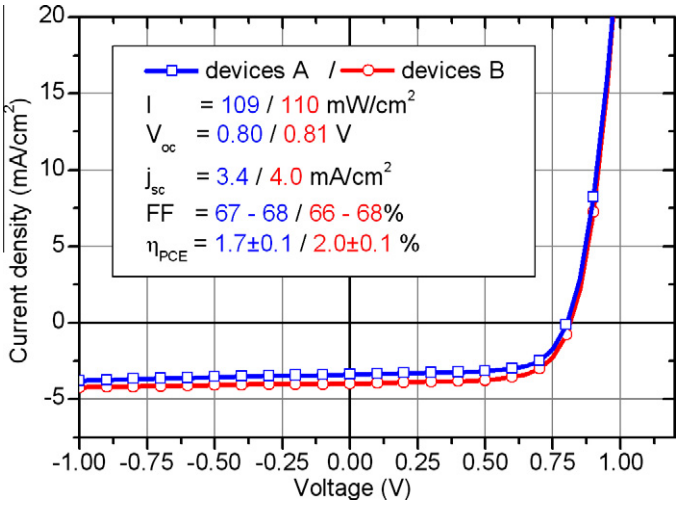

Fig. 7. Current-voltage (J-V) characteristics of one solar cell of type A and B, respectively. The characteristic parameters of the solar cells A and B are given in the inset. All devices comprise a DCV6T-Bu/C60 PHJ. The substrate temperature during deposition of the DCV6T-Bu layer is T_{sub} = 24 °C and T_{sub} = 90 °C, respectively. For measurements, an aperture mask of 3.0 mm^2 was used while the nominal area is 6.2 mm^2. The intensity and subsequently the efficiency are corrected for spectral mismatch.

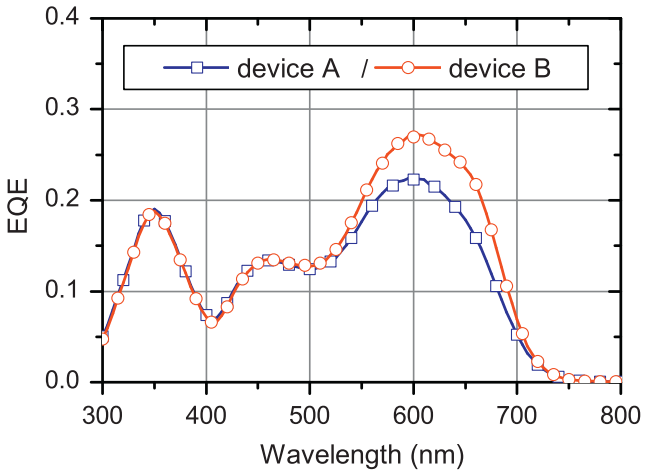

Fig. 8. External quantum efficiency (EQE) spectra of one solar cell of type A and B, respectively. These devices comprise DCV6T-Bu/C60 PHJs. The substrate temperature during deposition of the DCV6T-Bu layer is T_{sub} = 24 °C and T_{sub} = 90 °C, respectively.

(Fig. 4) the absorbance of the RT-film in the region 550–650 nm is slightly higher than that of the 90 °C-film, our studies show that in general for neat DCV6T-Bu and DCV6T-Et layers the increase of substrate temperature from RT to 90 °C during deposition results in enhanced absorption at longer wavelengths. This behavior is observed for films on glass or quartz glass substrates, and also for films having a hole transport material as an underlayer (e.g. compare to data in Ref. [14]). Furthermore, in the case of DCV6T-Bu we do not expect considerable alteration of the DCV6T-Bu growth morphology on C60 compared to that on quartz glass. Parameters, such as surface roughness and crystalline state of the substrate (or underlayer) could affect the molecular surface diffusion and thus for example the molecular orientation or the degree of crystallinity of the DCV6T-Bu film. Quartz glass and C60 have similar surface roughness of about 1–1.8 nm and are amorphous or in the case of C60 at least X-ray amorphous. Thus, we assume that the higher EQE at substrate temperature of 90 °C is due to the increase of absorption of the DCV6T-Bu layer grown on C60 in the heated solar cell device B. Finally, device B reaches a higher power conversion efficiency of PCE = 2.0 ± 0.1% than device A with PCE = 1.7 ± 0.1%. The solar cell improvement upon substrate heating during DCV6T-Bu deposition only arises from the higher photocurrent, which we attribute to the improvement of DCV6T-Bu absorption, especially in the red wavelength region. However, we do not observe indications for better charge transport capabilities, since the FF is unaffected. This is consistent with the CELIV results, showing no substantial increase of charge carrier mobility in the DCV6T-Bu layers grown on heated substrates.

4. Conclusions

Compared to the formerly introduced DCV6T-Et(2,2,5,5) [16], which comprises four ethyl side chains, the modified molecular structure of DCV6T-Bu results in optimized morphology with better molecular arrangement in the solid state. For DCV6T-Bu neat films, growth on RT-substrate already results in ordered aggregation. Self-organization is further improved when substrate heating during film deposition is used. The enhanced crystalline growth is verified by XRD studies, showing that the films deposited at elevated substrate temperature are crystalline across the whole film thickness. Red shifted absorption with distinct vibronic substructure and rough three-dimensional film morphology are attributed to the better structural order and thus are consistent with the results of XRD analysis. However, although the modified morphology should result in favorable transport properties, CELIV measurements indicate that the DCV6T-Bu hole mobility does not improve upon substrate heating. On the other hand, lower activation energy is derived for the 90 °C-device, which is consistent with the improved molecular organization in the heated DCV6T-Bu film. In DCV6T-Bu/C60 PHJ solar cells an increased photocurrent is observed when DCV6T-Bu is grown at elevated substrate temperature. This is attributed to the changes in DCV6T-Bu absorption. The charge transport capabilities seem unaffected by the heating, as can be seen from the FF, which does not change at elevated substrate temperature and thus supports the results of CELIV measurements.

in a nitrogen atmosphere at a heating rate of 10 °C/min. The cyclic voltammetry measurements were performed by a procedure described earlier [10].

UV light source was high-pressure mercury lamp with standard wavelength distributions (280–400 nm) and output power of ~1800 mW/cm^2. Radiation dosage was controlled by irradiation time.

Thin films of polycarbazole **PKOx** were prepared by spin-coating from its toluene solution (2–10 mg/ml), which additionally contained 7 wt.% of {4-[(2-hydroxytetradecyl)-oxyl]-phenyl}-phenyliodonium hexafluorantimonate (**PhIA**) as initiator for the cationic polymerization of oxetane units. The films were irradiated by the UV light source for about 2 min at room temperature. Afterwards, to further advance the crosslinking process in the growing network, the films were annealed at 120 °C for 5 min. Then the cross-linked films were rinsed with toluene and finally heated to 180 °C for 5 min to remove the radical cations formed upon polymerization. The resulting polymer networks were found to be insoluble in any common solvent. The cross-linking experiments were done with films of thickness of 15–100 nm. We have also tested thermal cross-linking of the polymers, however the obtained layers were partially soluble and were not suitable for preparation of OLEDs.

PKOx-based multilayer electroluminescent devices were fabricated on glass substrates and had the typical structure of the organic layers sandwiched between a bottom ITO anode and a top metal cathode. Before use in device fabrication, the substrates were prepared as described earlier [11]. The insoluble hole transporting networks were made by spin-coating a 15–100 nm layer of the polycarbazole **PKOx** containing the initiator onto the substrates and by following cross-linking as described earlier. 100 nm layer of green light emitting polymer (**GEP**) – poly(9,9-dioctylfluorene)-*co*-(2,5-dioctyloxyphenylene-*co*-benzothiadiazole) [12] was spin-coated from toluene solution onto the cross-linked network. Ca/Al electrode was done at a pressure of 310^{-6} mbar in vacuum evaporation equipment. Device without hole injecting/transporting layer (configuration: ITO/**GEP**/[Ca/Al]) and PEDOT-based device (ITO/PEDOT/**GEP**/[Ca/Al]) were also prepared for comparison.

The current–voltage and luminance–voltage characteristics of the devices were recorded using a computer controlled Keithley 2400 source meter and a PR650 Spectrometer. All measurements were performed at ambient conditions in air.

2.2. Materials

1,5-Cyclooctadiene (COD), 2,2′-bipyridyl (ByPy) and bis(1,5-cyclooctadiene)nickel (Ni[COD]$_2$) were purchased from Aldrich. All the chemicals were used without further purification.

3,6-Diiodo-9-(2-ethylhexyl)carbazole (**1**) was prepared by alkylation of 3,6-diiodo-9H-carbazole in a two phase system [11]. 3,6-Diodo-9-[6-(3-ethyloxetan-3-ylmethoxy)hexyl]carbazole (**2**) was prepared by the reaction of 3,6-diodo-9-(6-bromohexyl)carbazole with 3-hydroxymethyl-3-ethyl-oxetane [13].

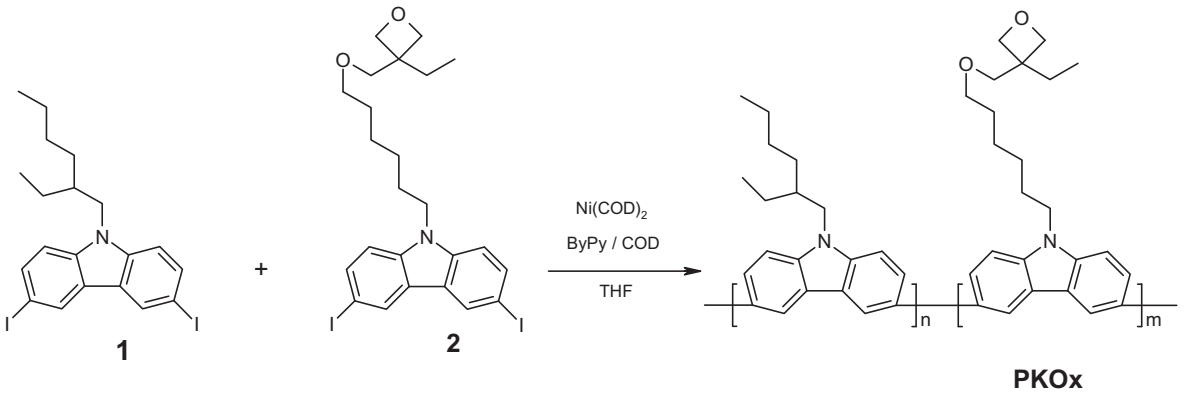
Poly{(9-(2-ethylhexyl)-3,6-carbazole)-stat-9-[6-(3-ethyloxetan-3-ylmethoxy)hexyl]-3,6-carbazole} (**PKOx**). The co-polymer was prepared according to general procedure of Yamamoto polycondensation for dihaloaromatic compounds using Ni[COD]$_2$ as a coupling agent [14]. 3,6-Diiodo-9-(2-ethylhexyl)carbazole (**1**) (0.41 g, 0.78 mmol), 3,6-diodo-9-[6-(3-ethyloxetan-3-ylmethoxy)hexyl]-carbazole (**2**) (0.48 g, 0.78 mmol), ByPy (0.56 g, 3.6 mmol) and Ni[COD]$_2$ (1.05 g, 3.82 mmol) were placed into a Schlenk tube under argon. Dry THF (10 ml) and COD (0.31 ml) were added, and the reaction mixture was stirred at 80 °C for 2 days. The polymer was extracted into chloroform, and the organic phase was washed with water and dried over $MgSO_4$, and the solvent was removed by rotary evaporation. The residue was dissolved in chloroform and precipitated into methanol/2 M HCl. After extracting the crude solid with acetone and re-precipitation, the polymer was obtained in 51% with number-average molecular weight of 17,000 and polydispersity of 1.7. ^{1}H NMR ($CDCl_3$): δ = 0.72–0.98 (m, 9H, $3 \times C\underline{H}_3$), 1.12–1.71 (m, 16H, $2 \times C\underline{H}_2CH_3$, $OCH_2C\underline{H}_2C\underline{H}_2C\underline{H}_2$, $-C\underline{H}_2C\underline{H}_2C\underline{H}_2CH_3$), 1.78–1.93 (m, 2H, $NCH_2C\underline{H}_2CH_2$), 2.01–2.19 (m, 1H, $C\underline{H}[CH_2-]_3$), 3.23–3.44 (m, 4H, $CC\underline{H}_2O$ and $OC\underline{H}_2CH_2$), 3.82–4.44 (m, 8H, $2 \times C\underline{H}_2$ of oxetane ring, $NC\underline{H}_2CH_2-$, $NC\underline{H}_2CH-$), 7.19–7.46 (m, 4H, ArH), 7.62–7.83 (m, 4H, ArH), 8.32–8.74 (m, 4H, ArH). IR (KBr): 3058 (CH_{ar}), 2953, 2925, 2853 ($CH_{aliphatic}$), 1496, 1462 (C=C_{ar}), 1310 (C–N), 1112 (C–O–C), 879, 824, 802 (CH=CH).

3. Results and discussion

The synthetic route towards the carbazole-based copolymer (**PKOx**) is shown in Scheme 1. The random copolymerization of the monomers 3,6-diiodo-9-(2-ethylhexyl)carbazole (**1**) and 3,6-diodo-9-[6-(3-ethyloxetan-3-ylmethoxy)hexyl]carbazole (**2**) was accomplished under standard Yamamoto conditions [14] using bis(1,5-cyclooctadiene)nickel(0), 2,2′-bipyridyl, and cyclooctadiene as the coupling agent. The actual percentage of incorporated *N*-alkylcarbazol-3,6-diyl moieties from comonomer **1** was calculated by comparing the relative intensities of the $(-CH_2)_3C\underline{H}$ proton signal of the 2-ethylhexyl group at about 2.1 ppm to the intensity of the $-NCH_2C\underline{H}_2-$ signals ($\delta \sim 1.85$ ppm) of the monomer **2**. The estimated composition of the copolymer was very close to that which was predicted from the monomer feed ratio (1:1).

The newly synthesized copolymer was first characterized by IR and ^{1}H NMR spectroscopy. The characterization data are in good agreement with the proposed structures. The material was well soluble in common organic solvents, such as chloroform and THF at room temperature. Transparent thin films of these materials could be prepared by spin coating from solutions.

The thermal behavior of the copolymer **PKOx** was studied by DSC and TGA under nitrogen atmosphere. The material demonstrates high thermal stability. An initial mass loss is observed at a temperature of >390 °C (TGA with a heating rate of 10 °C/min). The copolymer was obtained as amorphous material. When a sample of **PKOx** was



Scheme 1.

heated a glass transition temperature T_g was observed at 119 °C. Cooling down and repeated heating again revealed only the glass transition.

The electrochemical properties (redox behavior) of the new copolymer was studied by cyclic voltammetry for an determination of the HOMO energy level that controls the hole injection (and transport) properties. Our cyclic voltammetry measurements were calibrated with a ferrocene standard [15]. In the anodic scan, the onset of oxidation for **PKOx** occurred at 0.82 V corresponding to a HOMO value of *ca.* −5.2 eV, according to an empirical relationship proposed by De Leeuw [16]. The LUMO energy of the copolymer was estimated by subtracting the optical band gap to be *ca.* −1.85 eV.

The copolymer **PKOx** as cross-linkable material was used for the preparation of insoluble hole transporting layers. Photoinitiated cross-linking of thin **PKOx** layers containing 2–7 wt.% of cationic photoinitiator **PhIA** was carried out as described in Section 2. The solubility of the cross-linked layers was studied by recording UV–vis spectra of the layers before and after rinsing with toluene which is suitable solvent both for the non-cross-linked **PKOx** layer as well as for the green polymeric emitter (**GEP**, poly(9,9-dioctylfluorene)-*co*-(2,5-dioctyloxyphenylene-*co*-benzothiadiazole) as the emitter layer. If the cross-linking was carried out with 2–5 wt.% of the photoinitiator, the films were still partially soluble. In contrast, cross-linking with 7 wt.% of the photo-initiator yielded fully insoluble films as documented by practically unchanged absorption spectra of the films (Fig. 1 shows the UV–vis results for **PKOx** films crosslinked by using 7 wt.% of the photoinitiator **PhIA**).

The crosslinked **PKOx** networks were then tested as hole transporting layers of double-layer OLEDs with the configuration ITO/crosslinked **PKOx**/**GEP**/(Ca/Al). The hole transporting layers were made by spin-coating solutions of copolymer and initiator onto ITO substrates as *ca.* 50 nm thick layers followed by photo-crosslinking as described in Section 2. Poly(9,9-dioctylfluorene)-*co*-(2,5-dioctyloxyphenylene-*co*-benzothiadiazole) **GEP** was used as green polymeric emitter.

When a positive voltage was applied to the OLED devices a bright green electroluminescence of the GEP

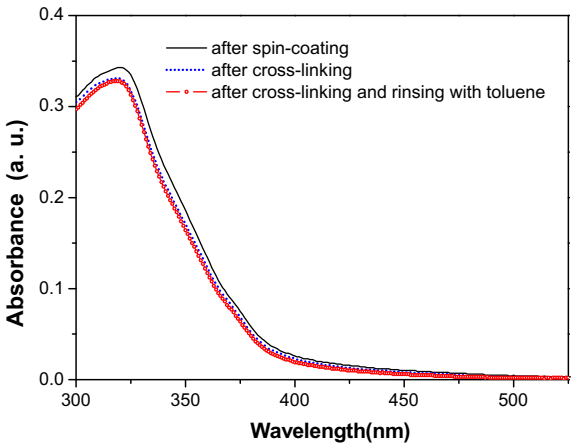


Fig. 1. Absorption spectra of **PKOx** films after spin-coating, cross-linking and rinsing with toluene.

emitter was observed with an emission maximum peaking at *ca.* 528 nm (see Fig. 2). This implies that the hole transporting **PKOx** network allows for an efficient hole injection

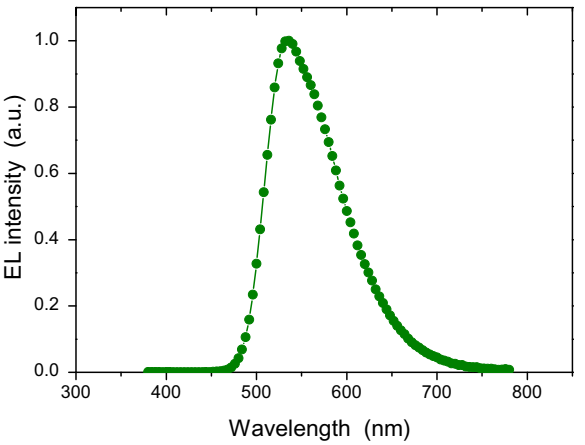

Fig. 2. Normalized electroluminescence spectrum of the device: ITO/crosslinked **PKOx**/**GEP**/(Ca/Al).

at the anode followed by charge carrier recombination with electrons (injected at the cathode) within the emissive GEP layer. No spectroscopic sign for exciplex formation at the interface between hole transporting and emitter layer was observed.

Fig. 3 shows OLED characteristic of the described device. The plots for a device (configuration: ITO/PEDOT (50 nm)/GEP/[Ca/Al]) containing a PEDOT hole transporting layer is also presented in the Fig. 3 for comparison. The rather low turn-on voltage of 3.5 V, defined as the voltage where electroluminescence (EL) becomes detectable, the maximum brightness of *ca.* 15000 cd/m^2, and the relatively low operational voltage (~6 V@100 cd/m^2) of the device suggest that the cross-linked **PKOx** material acts as an efficient hole transporting layer. The comparison with PEDOT-based OLED shows that both the devices show similar efficiencies; however only the device with the cross-linked **PKOx** layer demonstrates a stable operation at voltages up to 16 V. It should be mentioned that a device without hole injecting/transporting layer (configuration: ITO/GEP/[Ca/Al]) demonstrated an efficiency only of 0.2 cd/A.

The cross-linked copolymer layers were also tested in multilayer devices with the configuration ITO/PEDOT/crosslinked **PKOx**/GEP/(Ca/Al) containing both a PEDOT layer for hole injection and **PKOx** layers of different thickness for hole transport. The OLED devices in general exhibit low turn-on voltages of 4–4.5 V, a maximum brightness of 8300–13,700 cd/m^2 (@16–20 V), and a maximum photometric efficiency of 8.2–8.5 cd/A (see Fig. 4). Among these OLEDs, devices containing a hole transporting **PKOx** layer of *ca.* 30 nm displayed the best overall performance (turn-on voltage of *ca.* 4 V and a maximum photometric efficiency of *ca.* 8.5 cd/A). Hereby, the hole transporting **PKOx** network improves both device efficiency and operational stability at high voltages if compared to devices without the **PKOx** layer. The device characteristics observed for our devices are also superior to those of related multilayer systems containing structurally different carbazole-based networks as hole injection layer and the GEP emitter as reported earlier [7,8]. The device characteristics compare to those of many related cross-linkable systems recently reviewed in literature [3,4,6].

In conclusion, carbazole-based copolymers containing side-chain oxetanyl groups as photo-crosslinkable moieties have been successfully synthesized and characterized. Insoluble, photo-crosslinked layers of these copolymers have been obtained as thin films. The crosslinked networks have been tested as hole injection/hole transporting layers of OLED devices in combination with a green polymeric emitter (GEP). Our best devices exhibited a low turn-on voltage of *ca.* 4 V, combined with a maximum brightness of 13,700 cd/m^2 and a maximum photometric efficiency of *ca.* 8.5 cd/A.

interface area and loss of excitons by enhanced charge carrier collection due to improved mobilities and closed percolation paths.

The series of oligothiophenes end capped with the acceptor group dicyanovinyl DCV_2-nT ($n = 3,4,5,6$) has been studied intensely [11–13,15,18]. The increase of the thiophene chain shifts the highest occupied molecular orbital (HOMO) upwards while the lowest unoccupied molecular orbital (LUMO) is less affected. Photoinduced absorption spectroscopy (PIA) showed that this directly influences the energy and charge transfer processes between the oligothiophene and the commonly used acceptor C_{60} [15].

In the paper, the influence of morphological change induced by the deposition on substrates of different temperature (T_{sub}) on charge separation and transport is investigated for dicyanovinyl–quinquethiophenes. The molecular structure of DCV_2-5T (Bu_4) is shown in Fig. 1. In blend layers with the acceptor fullerene C_{60} efficient charge separation occurs. Neat and blend layers with C_{60} (1:1 by volume) deposited at room temperature ($T_{sub} = 30$ °C) as well as blend layers with C_{60} (1:1 by volume) deposited at $T_{sub} = 80$ °C are investigated by their optical properties (absorbance) and by photoinduced absorption spectroscopy (PIA). The visible signatures of triplet excitons and donor cations in PIA are investigated with respect to existing recombination models. Hence, their lifetime and effective generation rate are determined. This procedure is carried out for four different measurement temperatures: 10, 100, 200, and 295 K. Likewise, lifetimes and generation rates for the heated and unheated samples are compared. The PIA results are complemented by mip (metal-intrinsic-p-doped) solar cell devices. In order to shed more light on the nature of the detected cation signatures, we carry out impedance spectroscopy on the solar cell devices and determine time constants for trapped and free charge carriers.

2. Material and methods

DCV_2-5T (Bu_4) is synthesized according to a route published elsewhere [14]. The materials are purified prior to sample preparation: DCV_2-5T (Bu_4) is purified by recrystallization and degassing, C_{60} (Bucky, USA) is purified twice by vacuum gradient sublimation. The thin films are prepared via thermal vapor deposition in ultra high vacuum on glass substrates, solar cells on tin-doped indium oxide (ITO) coated glass (Thin Film Devices, USA, sheet resistance of 30 Ω/sq.) with a base pressure of 10^{-8} mbar and evaporation rates of 0.2 Å s^{-1}. The film thickness is controlled by quartz crystal monitors which are calibrated in advance for every material evaporated.

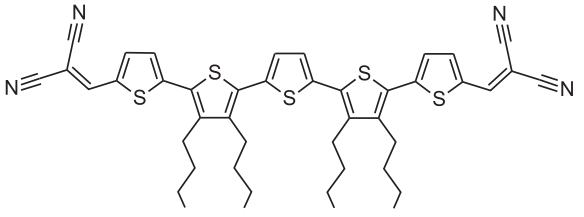

Fig. 1. Molecular structure of DCV_2-5T (Bu_4) with the butyl side chains attached to the second and fourth thiophene ring.

Linear absorption measurements are conducted with a UV–vis spectrometer (Shimadzu UV-2101/3101).

Flat and bulk heterojunction solar cells are prepared layer by layer without breaking the vacuum and are encapsulated after processing using a glass cover under nitrogen atmosphere. The layer structure of the bulk heterojunction solar cells is as follows: ITO/15 nm C_{60}/20 nm DCV_2-5T (Bu_4):C_{60} (1:1 by volume)/5 nm 9,9-bis[4-(*N*,*N*-bis-biphenyl-4-yl-amino) phenyl]-9H-fluorene (BPAPF, Lumtec, Taiwan; ionization potential measured by UPS 5.6 eV)/50 nm BPAPF doped with p-dopant NDP9 (Novaled AG, Germany) with a doping concentration of 10 wt.%/1 nm NDP9/50 nm Au. BPAPF is purified at least twice by vacuum gradient sublimation prior to sample preparation; NDP9 is used as received. We use this proprietary material due to a better processability, but doping of materials with low lying HOMO can be achieved in a comparable way using WO_3 [19]. The flat heterojunction layer structure is similar to the bulk layer stack: ITO/15 nm C_{60}/6 nm DCV_2-5T (Bu_4)/5 nm BPAPF/50 nm BPAPF:NDP9 (10 wt.%)/1 nm NDP9/50 nm Au. The cell area for bulk and flat heterojunction cells is 6.4 mm^2.

External quantum efficiency (EQE) measurements for solar cell devices are conducted at a custom-made setup utilizing a xenon arc lamp, a monochromator (Newport Cornerstone), and a lock-in amplifier (Signal Recovery 7265 DSP). A silicon reference diode (Hamamatsu S1337) is used to calibrate the setup.

$J - V$ characteristics are measured using an automated setup consisting of a source-measure unit (Keithley SMU 2400) and an AM 1.5G sun simulator (KHS Technical Lighting SC1200). The intensity is monitored with a silicon photodiode (Hamamatsu S1337). The mismatch between the spectrum of the sun simulator and the AM 1.5G spectrum is determined by taking these spectra as well as the spectral responses of the reference diode and the sample (from EQE measurements) into account.

Photoinduced absorption (PIA) is measured with a custom-made setup using the 532 nm mode of an frequency doubled CW Nd:YVO_4 laser (spectra physics Millenia) as pump beam which is chopped by an acousto optical modulator (AOM). The pump intensity is around 20 mW on a spot of 3 mm diameter and can be reduced by several orders of magnitude employing the AOM and neutral density filters. The probe beam is provided by a tungsten halogen lamp. The PIA signal is recorded in a transmission geometry, passes a monochromator and is detected either by a silicon photodiode or, for the near infrared region, an indium-galium-arsenide photodiode by utilizing lock-in techniques. The samples are cooled down to 10, 100, and 200 K, by keeping them in helium vapor in a continuous flow cryostat (Janis Research STVP-100). Room temperature measurements 295 K are performed as well. The PIA spectra are recorded from 2.07 eV (600 nm) down to 0.78 eV (1590 nm) and are corrected for luminescence of the sample. To determine lifetimes the modulation frequency of the pump beam can be varied from 1 to 10^6 Hz. PIA-samples contain neat and blend layer of one

compound on the same substrate and are encapsulated with a cover glass in a glovebox under nitrogen atmosphere attached to the vacuum chamber system used for evaporation.

Impedance spectroscopy measurements are performed in dark and under illumination at room temperature with an Autolab PGSTAT302N. The probe signal has an amplitude of 15 mV (rms) and the frequency is varied from 100 Hz to 1 MHz for the measurements under illumination and from 100 mHz to 1 MHz in dark. Illumination is provided by a halogen lamp. The results are presented in terms of Modulus and Phase of the complex impedance. Additionally the real part of the dielectric constant is used, assuming unitary vacuum capacitance: $\varepsilon(\omega) = Y(\omega)/(j\omega C_v)$ such that the real part of the dielectric permittivity coincides with the device capacitance function.

3. Results and discussion

3.1. OSC devices

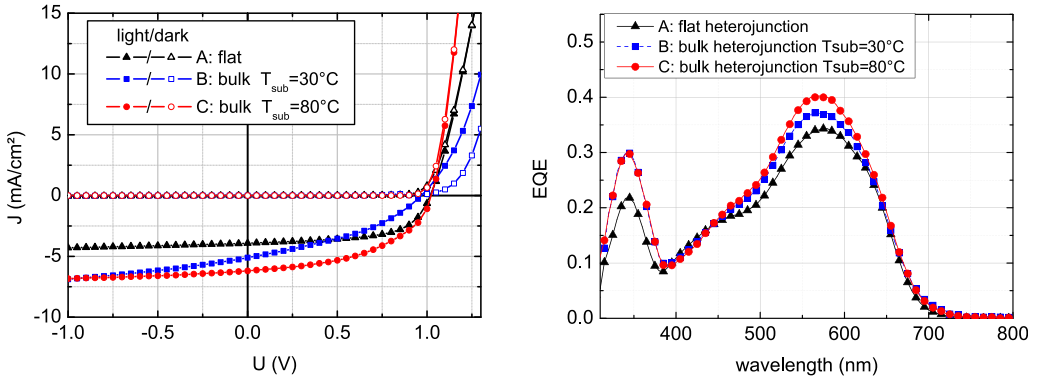
Three solar cell devices are presented to illustrate the improved device performance caused by substrate heating during the active layer deposition. A flat heterojunction device with a 6 nm layer of DCV_2-5T (Bu_4) (device **A**), a bulk heterojunction device with a 1:1 by volume blend layer DCV_2-5T (Bu_4):C_{60} with a thickness of 20 nm (device **B**), and a bulk heterojunction with the same device structure but the substrate heated to 80 °C while the active layer is deposited (device **C**). Fig. 2a shows the $J - V$ characteristics of the three devices, Fig. 2b shows the corresponding EQE curves. The device parameter are summarized in Table 1. Device **A** exhibits a high fill factor (FF) of 61% and the open circuit voltage (V_{oc}) of 1.02 V corresponds to former values obtained with DCV_2-5T (Bu_4)[13,15]. The device shows good performance with only little recombination losses as can be seen from the good saturation factor $Sat. = J(0\,V)/J(-1\,V)$.

The main part of the photocurrent is due to DCV_2-5T (Bu_4) as can be seen in the corresponding EQE spectrum (compare also the neat and blend layer absorption spectra in Fig. 3). For the bulk layer device **B** J_{sc} increases due to the increased content of D and A. However, *FF* and V_{oc} decrease compared to the flat junction caused by increased recombination. The saturation factor increases which hints to a strong voltage dependence of charge carrier collection. The bulk layer device deposited at elevated substrate temperatures (T_{sub} = 80 °C) **C** clearly shows improved performance compared to the unheated device: *FF* increases again and V_{oc} reaches the value of the flat junction (device **A**), J_{sc} increases and accordingly the device efficiency increases. However, recombination losses still lead to a lower *FF* than in the flat junction and consequently to a slightly larger saturation factor. The EQE spectra show that the contribution of the donor material to the photocurrent is increased by substrate heating while the contribution of C_{60} remains constant.

3.2. Absorption

In Fig. 3 the absorbance of blend layers of DCV_2-5T (Bu_4):C_{60} (1:1 by volume) for different substrate temperatures 30 °C (i.e. room temperature), 80 °C, and 110 °C is shown. For comparison, the absorbance of a neat layer DCV_2-5T (Bu_4) at room temperature is depicted. The blend layer spectra consist of a broad absorption band between 1.5 and 3.0 eV which is due to the absorption of the donor molecule (compare to the neat layer spectrum), the contribution at energies above 3.0 eV is attributed to C_{60}. The strong background and increase for energies above 4.0 eV is caused by the substrate and the encapsulation of the sample (both glass) which could not be corrected by reference measurements here. For the 80 °C sample slight changes compared to the room temperature absorbance can be observed: the red shoulder gets slightly more pronounced and the absorption maximum is slightly decreased.

For even higher substrate temperatures of 110 °C the spectrum is shifted to the blue compared to the blend layers at lower substrate temperatures and even to the neat layer spectrum. A blue shifted absorption spectrum has been attributed to a lower degree of molecular ordering



(a) J-V characteristics (b) EQE spectra

Fig. 2. Solar cell characteristics and EQE spectra of a flat heterojunction comprising 6 nm of DCV_2-5T (Bu_4) (device **A**), a bulk heterojunction with a 20 nm blend layer DCV_2-5T (Bu_4):C_{60} (1:1, by volume) (device **B**), and a bulk heteorjunction with the same device architecture like device **B** but with the active layer deposited at a substrate temperature of 80 °C (device **C**). The stack design is described in Section 2.

Table 1
Solar cell parameters corresponding to the characteristics shown in Fig. 2a. The intensity is mismatch corrected with respect to the reference diode.

	V_{oc} (V)	J_{sc} (mA/cm^2)	*FF* (%)	*Sat.*	*I* (mW/cm^2)	η (%)
A: flat	1.02	3.7	61	1.0	99	2.3
B: bulk T_{sub} = 30 °C	0.97	4.7	38	1.4	100	1.7
C: bulk T_{sub} = 80 °C	1.02	5.8	49	1.1	100	2.9

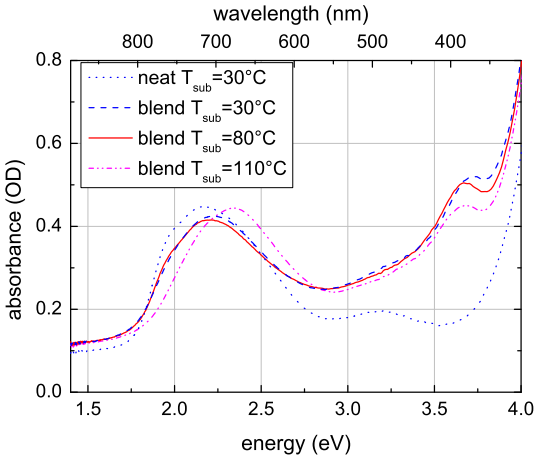


Fig. 3. Absorbance of a neat layer DCV_2-5T (Bu_4) (30 nm, dotted blue line) and a 1:1 (by volume) blend layer DCV_2-5T (Bu_4):C_{60} (60 nm, dashed blue line), both layers are deposited at room temperature. The absorbance of a 1:1 (by volume) blend layer DCV_2-5T (Bu_4):C_{60} (60 nm) is shown for different substrate temperatures: 80 °C (red line) and 110 °C (pink dashed dotted line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

[20]. The neat layer at room temperature shows the preferred conformation in which DCV_2-5T (Bu_4) molecules arrange due to self assembly, here also the attached alkyl side chains have major impact on the neat layer nanomorphology [21]. A vibronic substructure is slightly visible with a shoulder at 1.7 eV and the absorbance is larger than in the blend layer. The neat layer morphology seems to be suppressed when blending the material with C_{60}. However, an increased crystallinity of the donor material can be achieved by substrate heating [11].

3.3. PIA spectroscopy

Long-living photoexcited species and their recombination dynamics are investigated with photoinduced absorption spectroscopy performed with standard CW photomodulation techniques. The signal dependence on the modulation frequency and the pump intensity provides information on the lifetimes and the recombination mechanisms of the metastable states. The PIA signal $-\Delta T/T$ depends on the absorption cross σ of the observed transition, the film thickness d, and the density of photoexcited states n. When assuming small signals $|-\Delta T/T| \ll 1$ and thin films, the signal is given by [23]

$$-\frac{\Delta T}{T}(E,t) = \sigma(E) dn(t),$$

where n can be described by the monomolecular rate equation

$$\frac{dn(t)}{dt} = g(t) - \frac{1}{\tau} n(t),$$

with the monomolecular lifetime τ, and the generation of the excited state $g(t)$ which is proportional to the excitation intensity I. The sample is excited with a modulated pump laser (modulation frequency ω). A sinusoidal generation $g(t) = \alpha\gamma\ I(1 + \cos(\omega t))$ is chosen, where α is the absorption of the ground state and γ denotes the quantum efficiency of the generated photoexcitation. The analytical stationary solution is complex and the *in phase* (*IPh*) and *out of phase* (*OPh*) components are [24–26]:

$$\left(-\frac{\Delta T}{T}\right)_{IPh} = d\sigma\alpha\gamma I \frac{\tau}{1+(\omega\tau)^2} \qquad (1)$$

$$\left(-\frac{\Delta T}{T}\right)_{OPh} = d\sigma\alpha\gamma I \frac{\omega\tau^2}{1+(\omega\tau)^2}$$

Hence, under quasi steady state conditions ($\omega\tau \ll 1$) the PIA signal depends on the lifetime of the excited state and its effective generation rate ($g' = d\sigma\alpha\gamma I$). Note that g' has the units s^{-1} only if the intensity is counted as photon-flux I_p ($[I_p] = \#cm^{-2}\,s^{-1}$, number of photons per area and second) rather than as power per area ($[I] = mW\,cm^{-2}$). Both intensity notations can be correlated by $I = E_p I_p$, using the photon energy $E_p = h\,c\lambda^{-1}$, with the Planck constant h, the velocity of light c and the excitation laser wave length λ = 532 nm. The effective generation rate g' is not an absolute measure of the quantum yield of the respective species, since the absorption cross-section σ of the excited

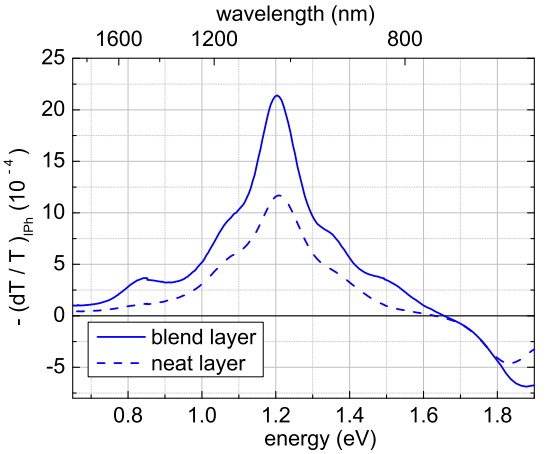

Fig. 4. Neat (dashed blue line) and blend layer (blue solid line) PIA spectra of DCV_2-5T (Bu_4) measured at 10 K. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

species is generally not known. Generation rates displayed in the following are effective generation rates.

In Fig. 4 PIA spectra at 10 K for a neat layer DCV_2-5T (Bu_4) and a blend layer DCV_2-5T (Bu_4):C_{60} (1:1 by volume) deposited at room temperature are shown. In the neat layer a dominant contribution (1.2 eV) accompanied by two shoulders is observed. In the blend layer two additional features can be observed at 0.8 eV and 1.5 eV. From time dependent density functional theory calculations (see Ref. [15]) the feature at 1.2 eV is assigned to a transition of the DCV_2-5T (Bu_4) triplet exciton while the contributions at 0.8 eV and 1.5 eV are attributed to transitions of the DCV_2-5T (Bu_4) cation. The shoulders of the triplet peak might be due to vibronic transitions of the triplet exciton.

By varying the modulation frequency at a fixed spectral position, e.g. the maxima of the spectra shown in Fig. 4, the lifetime and the effective generation rate of the corresponding state can be determined. For the triplet exciton in neat and blend layers we find that a model comprising two monomolecularly decaying species yields the best fitting results. We here determine a long living species (τ = 200–300 μs) with very low effective generation rates and a short living species ($\tau \approx$ 50–80 μs) with an effective generation rate one order of magnitude higher than the long living species. Lifetime analysis at the spectral position of the shoulders yields similar results as the main maximum which is a hint for the shoulders being part of vibronic modes of the triplet exciton. The origin of the two species is discussed elsewhere [21].

The cation transitions (0.8 and 1.5 eV in the blend layer) exhibit different dynamics than the triplet excitons. For higher frequencies the slopes of *IPh* and *OPh* show deviations from the −2 and −1 behavior (typical for mono- and bimolecular dynamics). This deviation indicates dispersive recombination, i.e. a mono- or bimolecular process superimposed by a distribution of lifetimes [28,29]. In the simplest case dispersive recombination can be modelled with the empirical Cole–Cole model [31]. The expressions for the *IPh* and *OPh* component transfer to:

$$\left(-\frac{\Delta T}{T}\right)_{IPh} = d\sigma\alpha\gamma I\tau \frac{1+\cos(\frac{\pi a}{2})(\omega\tau)^a}{1+2\cos(\frac{\pi a}{2})(\omega\tau)^a+(\omega\tau)^{2a}}, \qquad (2)$$

$$\left(-\frac{\Delta T}{T}\right)_{OPh} = d\sigma\alpha\gamma I\tau \frac{\sin(\frac{\pi a}{2})(\omega\tau)^a}{1+2\cos(\frac{\pi a}{2})(\omega\tau)^a+(\omega\tau)^{2a}}$$

where $0 < a \leqslant 1$ denotes the degree of dispersion (a = 1 equals pure monomolecular/bimolecular decay).

The two cation transitions exhibit lower effective generation rates compared to the triplet exciton and lifetimes around 400–500 μs, the degree of dispersion is reflected in the fit parameter a which shows values around 0.8.

Fitting curves can be found in the Supplementary informations in Fig. 12. The fit parameters g' and τ are summarized in Table 2 for the central triplet transition as well as the cation transitions for the neat and blend layer at 10 K for an intensity of 35 mW/cm^2. Fit parameter for the whole intensity range can be found in the Supplementary information Fig. 13. The generation rate of the triplet exciton in the neat layer is only slightly lower than in the blend layer but the lifetimes in neat and blend layer differ by 30 μs. The differences in the amplitude of the triplet transition are thus caused to major extent by the different lifetimes of triplet excitons in neat and blend layer. Schueppel et al. [15] explained the enhanced triplet amplitude in DCV_2-5T (Bu_4):C_{60} by an indirect population of the triplet level via a bound charge transfer state (CT). The DCV_2-5T triplet level is claimed to be energetically lower than the CT state and a fraction of the CT excitons recombine to the triplet exciton, hence a part of the initially created excitons is lost in the triplet state [15,30]. We do not find a significant difference in the effective generation rates of triplets in neat and blend layers. However, the triplet excitons in the blend layer can either be generated intrinsically (as in the neat layer) via intersystem crossing (ISC) or by a back transfer via a CT state.

3.3.1. Temperature dependence

To understand the PIA spectra taken at more realistic temperatures for OSC device operation than 10 K, i.e. room temperature (295 K), it is crucial to be aware of the signal evolution with the measurement temperature. In Fig. 5a the PIA spectrum of DCV_2-5T (Bu_4):C_{60} is shown for 10, 100, 200 and 295 K. The signal decreases with increasing measurement temperature. This can mainly be assigned to the decrease of the excited state lifetime: at low temperatures the molecular vibrations are mostly frozen while for higher temperatures molecular vibrations become more prominent and increase the non-radiative decay of excited states. Hence, the additional decay channel present at higher temperatures leads to smaller excited state lifetimes.

Fig. 5b shows the temperature dependent spectra of DCV_2-5T (Bu_4):C_{60} normalized to the triplet transition at 1.2 eV. Here, the cation transitions grow with temperature compared to the triplet exciton. A third transition of the DCV_2-5T (Bu_4) cation at 1.7 eV becomes visible, as predicted from DFT calculations [15]. A detailed analysis of the excited state dynamics with temperature exhibits a decrease of the triplet (1.2 eV) lifetime as well as the

Table 2
Fit parameters for DCV_2-5T (Bu_4) (neat) and DCV_2-5T (Bu_4):C_{60} (blend) layers at 10 K derived from the fitting procedure described above. For the triplet peak only the values of the short living species are shown since it is dominating the spectrum and most likely is due to triplet excitons. The excitation intensity is 35 mW/cm^2.

		Triplet 1.2 eV		Cation 1.5 eV		Cation 0.8 eV	
	I (mW/cm^2)	g' (s^{-1})	τ (μs)	g' (s^{-1})	τ (μs)	g' (s^{-1})	τ (μs)
Neat	35	2.3	51	–	–	–	–
Blend	35	2.9	84	0.28	580	0.35	450

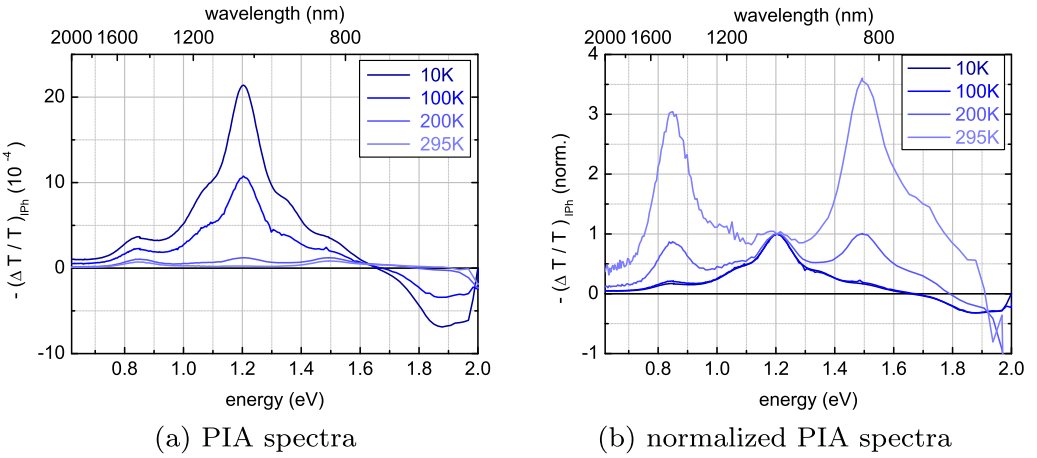

Fig. 5. PIA spectra of DCV_2-5T (Bu_4):C_{60} deposited at room temperature in dependence of the measurement temperature. The left side depicts the actual spectra whereas the right side shows the same spectra normalized to the triplet transition at 1.2 eV.

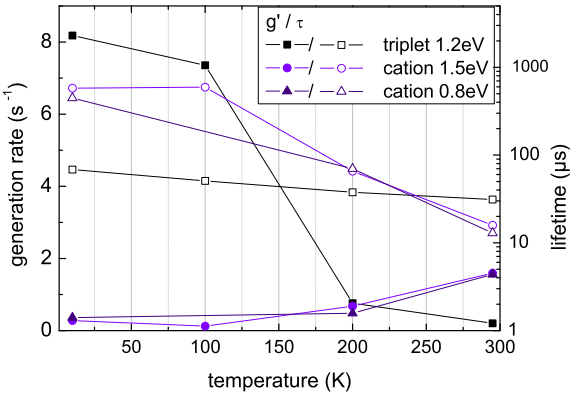

Fig. 6. Lifetimes and effective generation rates for triplets (black open and filled squares), the cation at 1.5 eV (light violet open and filled circles) and the cation at 0.8 eV (dark violet open and filled triangles) in DCV_2-5T (Bu_4):C_{60} in dependence of measurement temperature. The values are taken at an excitation intensity of 35 mW/cm^2. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

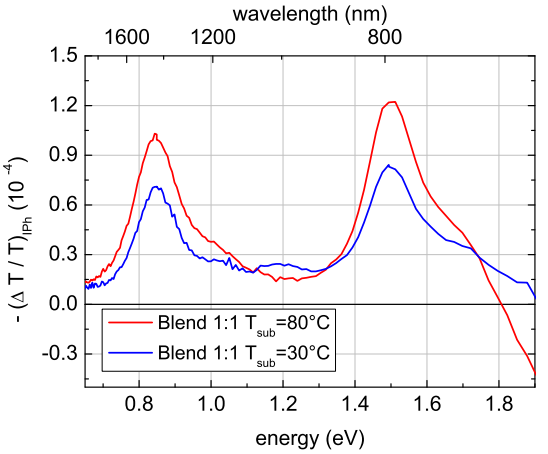

Fig. 7. PIA Spectra of a DCV_2-5T (Bu_4):C_{60} blend layer deposited at room temperature (blue line) and a DCV_2-5T (Bu_4):C_{60} layer deposited at 80 °C (red line). The spectra are taken at a temperature of 295 K. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

effective generation rate with increasing temperature. Likewise, the effective cation generation increases while the temperature rises. The cation lifetime decreases with increasing temperature but with a much steeper slope than the triplet lifetime. The simultaneous increase in effective cation generation and decrease in effective triplet exciton generation as well as the above assumption that triplet excitons in the blend are created via a CT state hint for an improved charge generation involving temperature activated processes. The lifetimes and effective generation rates for triplets and cations derived for the four different temperatures are depicted in Fig. 6.

3.3.2. Comparison of heated and unheated blend layers at room temperature

The PIA spectra of blend layers deposited on heated and nonheated substrates at a measurement temperature of 10 K do not show significant differences. The data is shown in the Supplementary informations. Fig. 7 shows the PIA spectra of a blend layer DCV_2-5T (Bu_4):C_{60} deposited at room temperature (blue curve) and of a blend layer DCV_2-5T (Bu_4):C_{60} deposited at a substrate temperature of 80 °C (red curve) measured at 295 K. The peaks are due to optical transitions of the donor cation (1.5 and 0.8 eV). The transition of the DCV_2-5T (Bu_4) triplet exciton (1.2 eV) is no longer visible since its lifetime is strongly decreased at 295 K. In the blend layer deposited at room temperature, there is still a slight hint of the triplet transition, while in the heated blend layer there is no trace of the triplet transition left. The amplitude of the cation signatures in the heated layer is stronger than in the blend layer deposited at room temperature. The excitation conditions are comparable for both spectra (the excitation intensity is even slightly lower for the heated sample, comp. Table 5). An analysis of the recombination dynamics reveals the

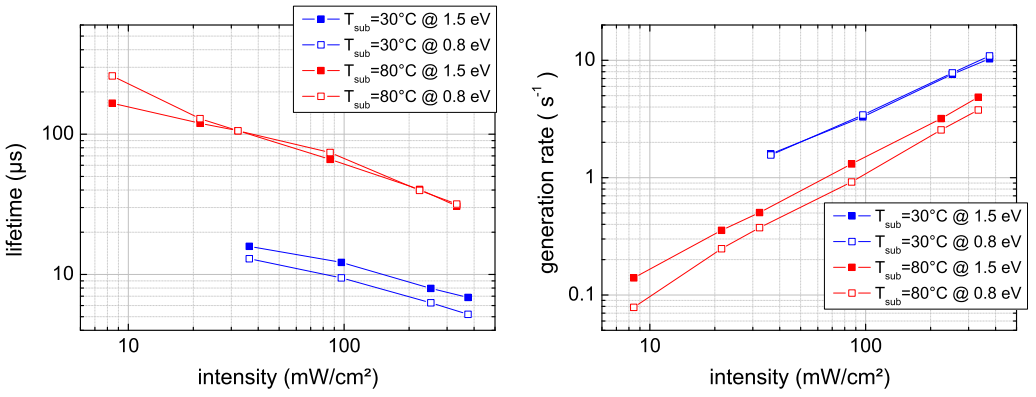

Fig. 8. Lifetimes and effective generation rates evaluated for the cation transitions (1.5 and 0.8 eV) in DCV_2-5T (Bu_4):C_{60} deposited at room temperature (blue symbols) and deposited at 80 °C (red symbols) in dependence of excitation intensity. The data is fitted with a dispersive recombination model (Eq. 2). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 3
Fit parameter for DCV_2-5T (Bu_4) and DCV_2-5T (Bu_4):C_{60} layers at 295 K derived from the fitting procedure described above. The excitation intensity is 100 mW/cm^2.

		Cation (1.5 eV)		Cation (0.8 eV)	
T_{sub} (°C)	I (mW/cm^2)	g' (s^{-1})	τ (µs)	g' (s^{-1})	τ (µs)
30 °C	100	3.4	12	3.5	9
80 °C	100	1.5	61	1.1	67

origin of the increased amplitude in the heated layer to be a strongly increased cation lifetime. For data evaluation again the dispersive model is chosen (Eq. 2). Fig. 8a shows the lifetime evaluated for the two cation transitions in the heated and the unheated layer in dependence of the excitation intensity. The values determined for lifetime and effective generation for the two different cation transitions match each other well. It is evident that the cation lifetime in the heated blend layer exceeds that of the unheated layer by almost one order of magnitude. The intensity dependence of the lifetime suggests a bimolecular mechanism being responsible for the recombination of cations. The effective generation rate on the other hand is larger in the unheated layer by almost a factor of three. Table 3 summarizes the effective generation and lifetime of cations for an excitation intensity of 100 mW/cm^2. The fit parameter a is constant with intensity and for both the heated and the unheated layer shows a value of ≈0.7.

Clarke et al. recently showed by transient absorption techniques that for polymer-fullerene blends a post process annealing of the film resulted in an acceleration of recombination dynamics assigned to a reduction in the trap depth of the system [32]. They further stated that the origin of trap states must be structural/conformational, i.e. upon annealing the molecule planarizes which leads to smoother energetical distribution of states. They also observed an increase in charge carrier generation upon annealing, which was attributed to a change in the ionization potential of P3HT [33] affecting the driving force that leads to charge separation. Contrary to this we observe a decrease in cation generation upon substrate heating. However, studies on PFB:F8BT showed a systematic decrease in charge carrier generation with annealing temperature [34].

The area under the cation peaks in the PIA spectrum in Fig. 7, should correlate with the short circuit current of the solar cell devices presented in Section 3.1. The area under the peaks is determined by using a gaussian fit. Comparing the heated and unheated layer yields a ratio of

$$\overline{g'\tau} = \frac{[A_{1.5\ \mathrm{eV}} + A_{0.8\ \mathrm{eV}}]_{\mathrm{heated}}}{[A_{1.5\ \mathrm{eV}} + A_{0.8\ \mathrm{eV}}]_{\mathrm{room\ temperature}}} = 1.7$$

while the ratio of the short circuit currents only yields a value of 1.2, thus, is not clearly correlated. The question is whether the observed cation transitions belong to free carriers that contribute to the photocurrent or if the signature is mainly caused by trapped holes that do not contribute to the current.

For P3HT:PCBM systems lifetimes of trapped carriers were determined to be in the range from 3 µs to ms, while free carriers were determined in the range below 3 µs [32].

3.4. Impedance spectroscopy

To investigate the characteristic time constants of free and trapped carriers in blends of DCV_2-5T (Bu_4):C_{60}, we analyze the impedance spectra of the solar cell devices **B** and **C** (comp. Section 3.1). Since PIA is an optical measurement carried out on layers without external voltage applied or current flowing, a direct comparison with the impedance spectroscopy (IS) results is not possible. However, IS can provide important information on the dynamics of charge carriers, giving us the possibility to distinguish trap states and free charges from their characteristic lifetimes [35,36].

In order to perform the electrical characterization under the same conditions as analyzed by PIA, we focus first on the open-circuit case at different light intensities, since no charges are extracted as for the PIA measurements. The resulting impedance spectra are presented in a Bode

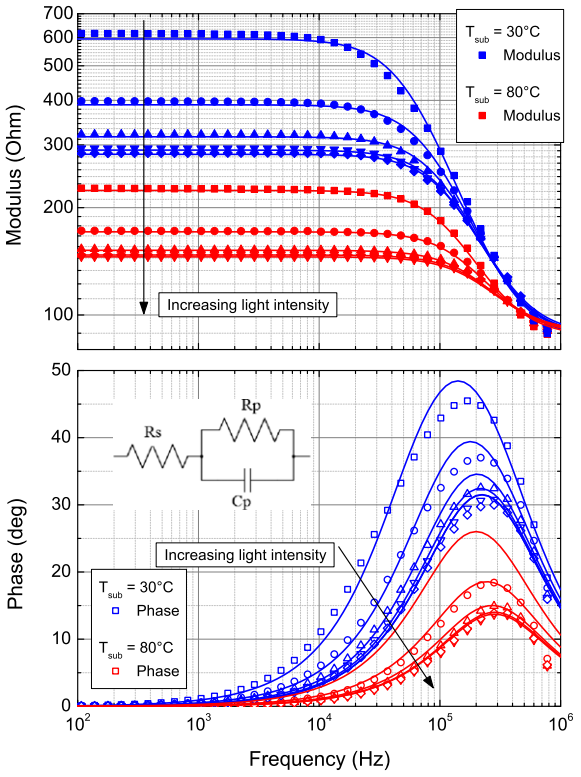

Fig. 9. Bode plot for solar cell devices **B** (blue symbols) and **C** (red symbols). The fitting curves are presented as continuous lines and the equivalent circuit used is shown as inset. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

plot (Fig. 9). From the Bode plot we observe that the solar cell impedance spectra can be divided in two regions. For high frequencies the absolute value of the impedance presents a plateau and the phase approaches low values, it means that a resistor in line with a capacitor is dominating the response. For lower frequencies the phase reaches a maximum value and then decreases, while the modulus increases until a second plateau at small frequencies. This behavior is typical of an RC parallel connection. The equivalent circuit used to fit the data is therefore composed by a series resistance and one RC parallel element. The series resistance takes into account the ohmic contribution of the contacts and the transport layers. The value of the capacitor is composed by two different contributions: the polarization of the intrinsic layers, that is the geometrical capacitance, and the accumulation of photo-generated charges, also called chemical capacitance or diffusion capacitance [37].

The fitting circuit is shown in Fig. 9 and the resulting curves are shown as continuous lines. The fitting results are presented in Table 4, together with the estimated density and lifetime of the free charges. The chemical capacitance is calculated from the parallel capacitance C_p subtracting the geometrical value of the intrinsic layer. The latter is estimated from capacitance measurements in dark under different reverse bias voltages (not shown). The calculation of accumulated free charge density is performed by multiplying the chemical capacitance by the applied open-circuit voltage. The effective lifetime is the characteristic time of the parallel RC circuit, still considering as capacitance the chemical capacitance and is shown in Fig. 10 varying the illumination intensity. The results are affected by errors coming from the geometrical capacitance estimation, the voltage drop across the series resistance and uncertainties in the fitting results. We estimate the overall error to be in the range of 10–20%, still acceptable for an estimation of the order of magnitude for both charge density and lifetime. The charge carrier lifetime in the heated device **C** is by a factor of 1.4 larger than in the unheated device **B**.

From the IS measurements it is apparent that the free charges have an effective lifetime in the range of 1–5 μs for a measured charge density in the range of 1–3×10^{17} cm^{-3}, in agreement with previous results for polymer solar cells [38,39].

The cation lifetimes observed from PIA are almost one order of magnitude higher. There is therefore the possibility that they belong to trap states and not to free charges. By analyzing the capacitance spectra it is in principle possible also to observe the effect of trap states in the device electrical response, visible as an additional capacitance for frequencies lower than the characteristic trapping–

Table 4
Equivalent circuit values obtained by fitting the measured spectra shown in Fig. 9 at different illumination intensities. The charge density and lifetime are calculated from the C_p after subtracting the geometrical capacitance of the intrinsic layer.

I (mW/cm^2)	R_s (Ω)	R_p (Ω)	C_p (F)	Charge density (10^{17} cm^3)	Charge lifetime (μs)
*Device **B***					
250	85.59	509.3	5.8266E−9	1.40	2.65
410	86.76	301.9	6.2256E−9	1.51	2.32
510	87.24	228.9	6.4857E−9	1.57	2.14
570	87.49	202.6	6.5917E−9	1.62	2.03
610	88.51	193.8	6.5817E−9	1.63	1.93
*Device **C***					
240	87.23	136.3	9.3506E−9	2.35	3.73
380	88.5	82.61	1.0956E−8	2.76	3.09
480	89.37	62.47	1.2282E−8	3.11	2.86
520	89.92	57.4	1.2482E−8	3.16	2.70
600	89.74	55.81	1.2798E−8	3.24	2.73

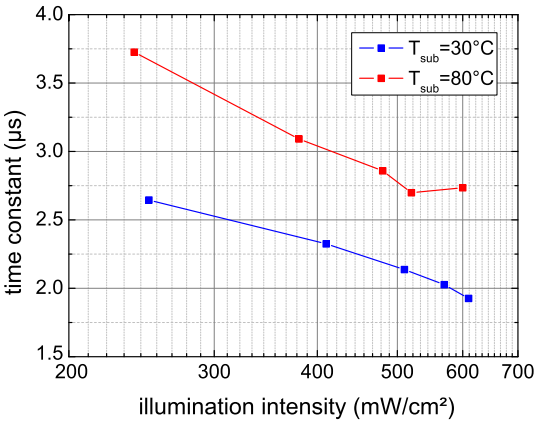

Fig. 10. Effective charge carrier lifetime for the unheated device **B** (blue squares) and the heated device **C** (red squares). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

detrapping time-constant [40,41]. This is unfortunately not possible under illumination, since the high density of photo-generated charges induces a capacitance drop at low frequencies as consequence of the strong recombination process [42]. The capacitance function of device **B** and **C** under different illumination is depicted in Fig. 15 in the Supplementary informations. We therefore measure the solar cells in dark at 0 V bias, again without current flowing. The measured spectra are shown in Fig. 11. In this case, the parallel resistance reaches very high values since no free charges are produced inside the intrinsic layers and the conductivity is drastically reduced. Under these conditions, the impedance phase reaches much higher values and it is possible to measure the capacitance function down to very low frequencies. From the capacitance spectra there is no significant trap contribution visible above 1 Hz. For lower values an increase is visible, at least for the device evaporated on heated substrate, which presents an imaginary part of the impedance large enough (higher phase) to be measured without too much noise.

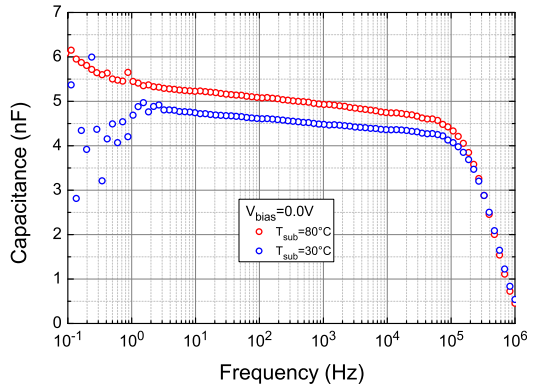

Fig. 11. Capacitance function of the solar cell devices **B** (blue symbols) and **C** (red symbols) measured in the dark at 0 V bias. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

We can conclude from the IS investigation, that free charges have a lifetime in the range of 1–5 µs, while trap states are not giving a significant contribution for these devices and they start to respond with a characteristic time in the range of 1 s. From the comparison with PIA results, we also conclude that the observed cation states are most probably carriers that are not entirely free, but can rather be classified as shallow traps that still contribute to the photocurrent. The higher charge density observed in device **C**, together with the increased lifetime and improved fill factor and saturation of the IV curves (Fig. 2), are indications of reduced recombination for the active layer being deposited on a heated substrate. The observed increase in lifetime upon heating is visible both in optical and electrical measurements and can be attributed to a better spatial arrangement of the donor and acceptor phase, which improves the spatial separation of charges and percolation paths, and thus preventing bimolecular recombination.

4. Conclusion

The device performance of solar cells using an active bulk heterojunction layer of DCV_2-5T (Bu_4):C_{60} (1:1, by volume) deposited on heated substrates increases compared to devices deposited at room temperature. We have shown that the improved device performance can be correlated to an increase of the lifetime of charge carriers, that we attribute to a better phase separation in the heated bulk layer.

Aims and scope

Organic Electronics is a primary journal whose interdisciplinary focus is organic materials, devices and phenomena, with application to devices such as organic light emitting diodes, thin film transistors, photovoltaic cells, etc.

Papers suitable for publication in this journal cover such topics as photoconductive and electronic properties of organic materials, thin film growth and characterization, charge and exciton transport, organic electronic and optoelectronic devices, etc.

Organic Electronics provides the only forum for both applied and fundamental contributions spanning the many different disciplines addressing the wide range of electronic properties and applications of organic materials. A Letters section is included for rapid publication of short articles announcing significant and highly original results.
