Fig. 1 shows bright-field TEM images of (a) undoped NPB, (b) ReO_3- and (c) MoO_3-doped NPB films containing 25 mol% dopant. MoO_3 and ReO_3, which both possess a larger work function than 6 eV, were selected as dopants because of their efficient charge transfer from various organic hosts. The undoped NPB film shows a featureless image and broad ring diffraction patterns (Fig. 1a and d), indicating the amorphous structure of the organic thin film. On the other hand, the NPB films doped with the metal oxides (MO) shows dark spots in the TEM images (Fig. 1b and c) that arise from nanoclusters. The dopant clusters have an amorphous structure in the doped films, as confirmed by their diffuse halos without sharp peaks in the diffraction pattern (Fig. 1e) [15]. Moreover, the dark spots do not exhibit the periodic lattice of the crystalline structure of ReO_3 in the high-resolution TEM (HR-TEM) image in Fig. 1f, in contrast to the evaporated intrinsic metal oxide, which displayed a nanocrystallite structure [16]. The TEM image of the MoO_3-doped film (Fig. 1c) appeared similar to those of the ReO_3-doped film (Fig. 1b), apart from the size distribution of the dopant clusters.

Statistical analyses of the nanoclusters were conducted using high angle annular dark field (HAADF) images instead of bright-field images because the HAADF images possessed definite contrast due to the different masses of the host and dopant molecules. To define the clusters in the image, the full gray-colored image was changed to a binary image with only black and white using the image analyzing software "Image J" [17]. The size and the number of the clusters were measured and counted from the binary images. Uncertainty coming from the small difference in contrast by the different exposure times and foci of the TEM images was removed by adjusting the contrast of the images to have the same total volume fraction of the clusters in the binary image as the theoretical volume fraction calculated through the density, molecular weight and

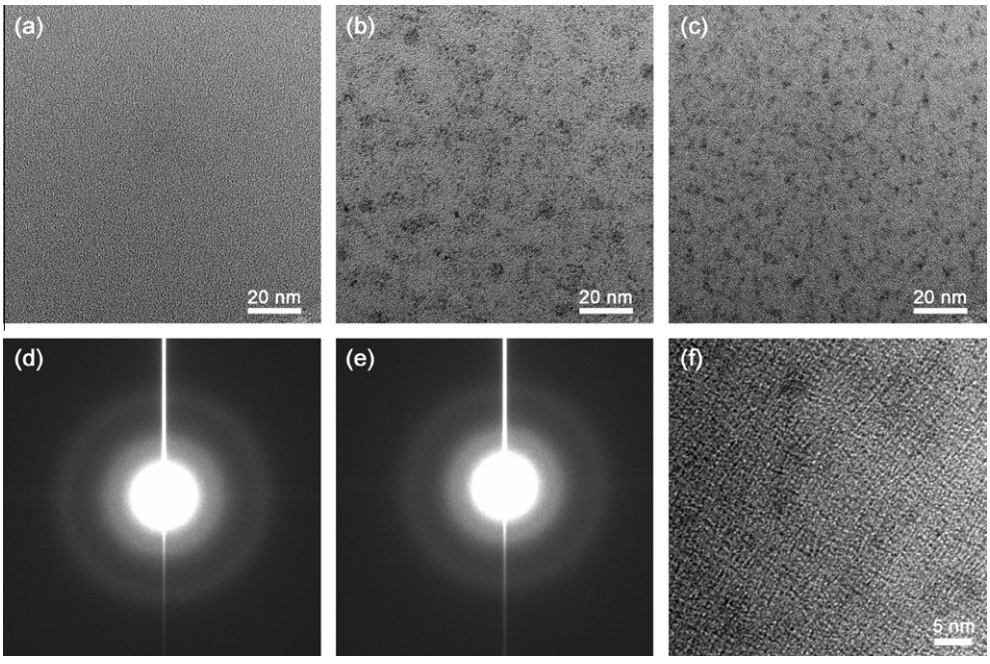

Fig. 1. Bright-field TEM image of (a) undoped NPB, (b) ReO_3- and (c) MoO_3-doped NPB (25 mol%). (d) and (e) Diffraction patterns of (a) and (b), respectively. (f) High-resolution TEM image of (b). The NPB film doped with MO shows dark spots in the image coming from the MO nanoclusters.

doping concentration. In the process, we assumed that every cluster has a spherical shape and is composed of dopant molecules. The cluster size of the two dopants was compared at two different doping concentrations. Fig. 2a and b display binary-treated, inverted HAADF TEM images of 10 mol% ReO_3- and MoO_3-doped NPB films (50 nm), respectively. The MoO_3-doped NPB film has a larger number of small clusters than the ReO_3-doped NPB film. In contrast, the ReO_3-doped NPB film has a larger number of clusters that exceed 2 nm in radius. Radius of nanoclusters was calculated under assumption that the shape of nanoclusters is a sphere. The cluster size distributions of the two different dopants are well described by the log-normal distribution (Fig. 2c). The log-normal distribution can be expressed as

$$f(r) = \frac{A}{r\sqrt{2\pi}\ln\ \sigma}\exp\left(-\frac{(\ln\ r - \ln\ r_c)^2}{2\ln^2\ \sigma}\right) \quad (1)$$

and is defined by the radius of the dopant cluster r, the area of curve A and the mean cluster radius and its standard deviation, r_c and σ, respectively [18].

The log-normal distribution characteristics indicate that the dopant clusters predominantly aggregate on the substrate by diffusion [19]. The formation of clusters during the growth of the thin film on a substrate can in general be described by two stages: an initial stage where newly arrived seed monomers agglomerate, namely the nucleation stage, and then a second stage involving diffusion of molecules that increases the size of the agglomerate, i.e., the growth stage [20]. Therefore, the size distribution of the clusters is influenced by the amount of initial clusters supplied by the evaporated gas and the diffusion processes that are affected by the substrate temperature and phase equilibrium properties between the dopant and host [20–22]. Generally, inverse power law dependence of the cluster size is observed in the initial stage, when seed generation is dominant. In contrast, when the diffusion process is dominant, the size distribution follows a Gaussian distribution or log-normal distribution with a certain average size that depends on the substrate temperature [19]. Therefore, the log-normal distribution of cluster size observed in these systems indicates that the formation of the clusters is dominated by diffusion of the dopants instead of nucleation.

Although all of the dispersion characteristics of the dopants can be described by the log-normal distribution, the details of the distribution vary for different dopants and doping concentrations. The average radius and standard deviation of MoO_3 nanoclusters in a 2 mol% MoO_3-doped NPB film are 0.7 and 1.5 nm, which are much smaller than those of the ReO_3 nanoclusters in the 2 mol% ReO_3-doped NPB film at 1.2 and 2.4 nm, respectively. The small standard deviation and average size of the MoO_3 aggregates indicate that these clusters have a much narrower size distribution in small size. When the doping concentration ratio increases to 10 mol%, the average radius and standard deviation increase to 1.1 and 1.7 nm for the MoO_3-doped and 1.4 and 2.6 nm for the ReO_3-doped NPB films, respectively. These different dispersion characteristics may stem from the intrinsic physical properties of the dopants, including the size of the monomers, evaporation temperature or the structure of molecules, and requires further investigation.

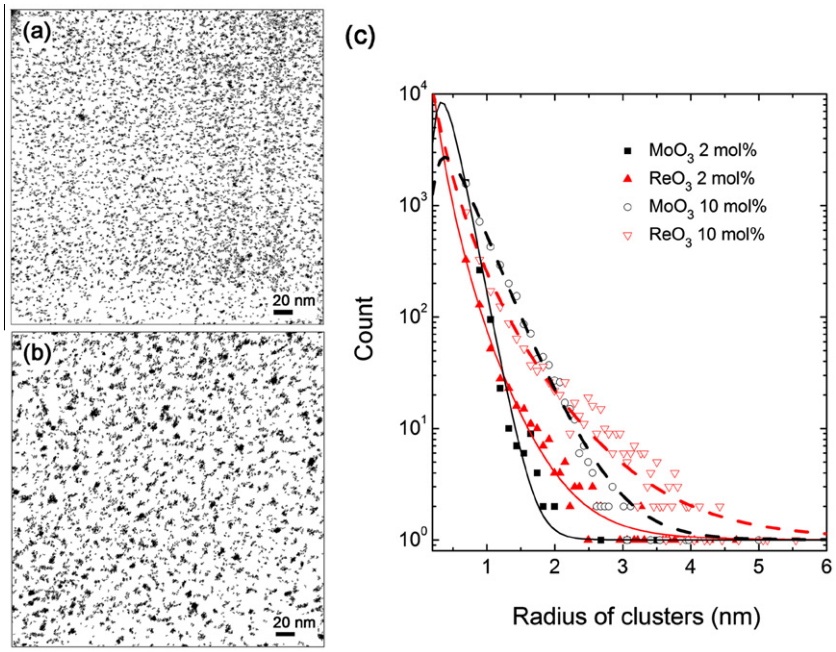

Fig. 2. Binary-treated, inverted HAADF image of NPB films (50 nm) doped with 10 mol% (a) MoO_3 and (b) ReO_3. HAADF images were processed prior to statistical analyses using the image analyzing software "Image J". (c) Histogram of the cluster size and fitting curve for a log-normal distribution of NPB doped with 2 (solid squares, solid line) and 10 mol% (open circles, dashed line) MoO_3 and 2 (solid triangles, dotted line) and 10 mol% (open triangles, dashed-dotted line) ReO_3.

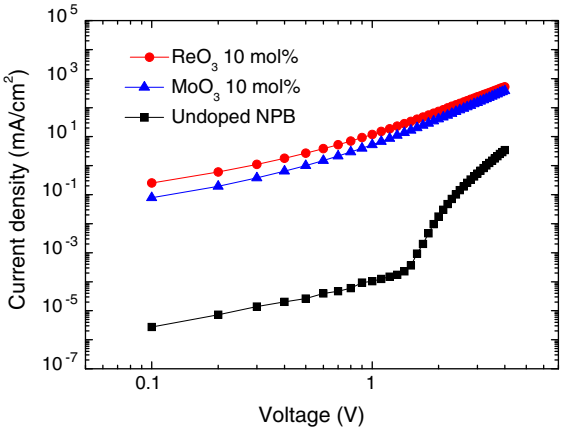

Fig. 3. *J–V* characteristics of hole-only devices containing undoped (squares) or 10 mol% ReO_3- (circles) or MoO_3-doped (triangles) NPB films. The hole-only devices consisting of ITO/MoO_3- or ReO_3-doped NPB (50)/Ag (50) show that ReO_3 has better charge generation efficiency than MoO_3.

Dispersion efficiency of the dopants defined by the number ratio of the nanoclusters to dopant molecules was calculated as follows. Firstly, the number of the clusters was counted from the binary images shown in Fig. 2. The number of nanoclusters under 1 nm^2 (530 $pixel^2$) was included by the extrapolation of fitted log-normal distribution curves instead of the counting process, because these spots are confused with the contrast fluctuation in the TEM images. In the case of 10 mol% ReO_3-doped NPB, the total number of nanoclusters in Fig. 2b was 4500 from the fitted log-normal distribution curve. The number of the clusters was proportional to the thickness of the films, eliminating the possibility of underestimation due to the overlapping of dopant clusters in the TEM images. Secondly, the number of dopants molecules in the doped films was calculated from the known doping concentration, molecular weight (588 g/mol) and the density (1.2 g/cm^3) of the doped films. The number of ReO_3 molecules (10 mol%) in Fig. 2b ($320 \times 320 \times 50\ nm^3$) is 7.2×10^5 based on the calculation. Comparison of the number of the clusters and the number of the dopant molecules results in the dispersion efficiency of 0.62% for the 10 mol% ReO_3 doped NPB films. The low dispersion efficiency of metal oxide dopants limits their charge generation efficiency in doped organic semiconductors. The charge generation efficiency of 10 mol% ReO_3-doped NPB was calculated to be 0.7% from the carrier density of $9.5 \times 10^{17}\ cm^{-3}$ which was measured for a MIS device containing the doped film [7] if each nanocluster can accept one electron from a host molecule due to the charging effect of nanoclusters. For 2 mol% ReO_3-doped NPB, the dispersion and charge generation efficiencies increased slightly to 1.3% and 1.1%, respectively. The similarity between the dispersion efficiency and charge generation efficiency leads to the conclusion that the formation of nanoclusters by metal complex dopants is an origin of the low charge generation efficiency in doped organic semiconductors. Even though the different surface characteristics between ITO and TEM grid substrate might adjust the diffusion and nucleation formation of dopant molecules in host molecules on the surface of substrate, we consider that the dispersion characteristics of dopants in the films could be similar on the different substrate, based on the results of AFM analysis (data are not shown).

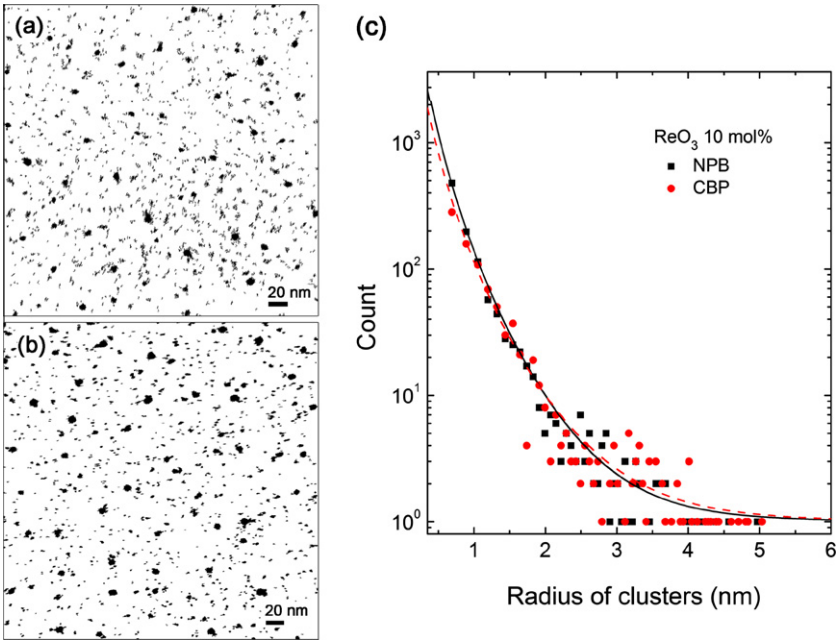

Fig. 4. Binary-treated, inverted HAADF images of 10 mol% ReO_3-doped (a) NPB and (b) CBP films (20 nm). (c) Histogram of the cluster size and fitted log-normal distribution curve for 10 mol% ReO_3-doped NPB (squares, solid line) and CBP (circles, dashed line).

The relationship between the dispersion characteristics and charge generation efficiency for different dopants was investigated using the current density–voltage (J–V) characteristics of hole-only devices consisting of indium tin oxide (ITO)/MoO_3- or ReO_3-doped NPB (50 nm)/Ag (50 nm), as shown in Fig. 3. When a forward bias was applied to each device, hole injection through the interface between ITO and doped NPB dominates over electron injection from the Ag electrode due to the large difference in charge injection barriers. The ReO_3-doped NPB layer possessed a higher current density and electrical conductivity due to higher carrier concentration than the MoO_3-doped NPB layer, even though MoO_3 has larger dispersion efficiency (0.77%) than ReO_3 (0.62%) at a doping concentration of 10 mol%. This fact suggests that the charge generation efficiency can be affected by other factors such as the energy difference (ΔE) between the acceptor level of the dopant and the donor level of the host, as we noted previously [7,9]. The ReO_3-NPB system has larger ΔE values than the MoO_3-NPB system. Further evidence of the ΔE dependence can be obtained by doping the same dopant in two hosts with different highest occupied molecular orbital (HOMO) levels.

Fig. 4a and b shows binary-treated, inverted HAADF TEM images of 10 mol% ReO_3-doped NPB and *N*,*N*′-dicarbazolyl-4,4′-biphenyl (CBP) films with a thickness of 20 nm. To fabricate devices with the same doping concentration in different hosts, the evaporation speed of the dopant was fixed and the evaporation speed of the host was varied to avoid monomer flux dependence such as that shown in Fig. 2c. As shown in Fig. 4c, ReO_3 shows nearly identical dispersion characteristics in the two hosts, because these hosts have similar molecular structures based on triphenylamine groups [23]. However, the ReO_3 doped NPB film had the 2.5 times higher carrier density than ReO_3 doped CBP film [7]. This behavior can be interpreted based on the respective ΔE of the films. NPB has a higher HOMO level than CBP (−5.4 versus −6.0 eV), resulting in a larger ΔE value in the ReO_3-doped NPB system than in ReO_3-doped CBP. The larger ΔE value facilitates charge generation from NPB to ReO_3 [7].

4. Conclusion

In summary, TEM analysis revealed that the formation of dopant nanoclusters is an origin of the low charge generation efficiencies of metal oxides in organic semiconductors. Dopant nanoclusters of ReO_3 and MoO_3 possess cluster sizes with a log-normal distribution and average size of 0.7–1.4 nm, depending on the dopant and their concentration. The low dispersion efficiency of ReO_3 of 0.62% dictates its charge generation efficiency in the organic host of 0.7% in 10 mol% ReO_3-doped NPB. This work demonstrates that the charge generation efficiencies of dopants are predominantly controlled by the dispersion characteristics of the dopant in the host organic semiconductor and also the energy differences (ΔE) between acceptor levels of the dopant and donor levels of organic hosts. It is expected that our findings will be valuable for indentifying efficient dopants for various organic semiconductors.

inorganic layer, with the constraint that it has to be processed at low temperature to remain compatible with a flexible plastic foil. Many methods have been investigated to process high quality oxide at low temperatures [9–11]. However, few of them can be process at room temperature at low cost. In this paper, we show that anodization is able to generate high-quality, dense and thin oxide layer at room temperature. In addition to other studies that show anodized metal oxide as the dielectric in OTFTs [12,13], we also present a method for patterning gate and anodized gate dielectric compatible with bottom-contact transistor geometries. Moreover, it should be noted that anodization is compatible with flexible substrate and has potential for roll-to-roll processing.

2. Material and methods

Bottom gate, bottom contact pentacene transistors with a thin dielectric layer consisting of aluminum oxide were prepared as follows. First, a continuous (non-patterned) aluminum layer was thermally evaporated on a glass or foil substrate. This layer was partly anodized into (50 nm thickness) aluminum oxide which forms the gate dielectric. The electrochemical anodization of aluminum was realized in a mixture of citrates containing potassium phosphate dibasic trihydrate and potassium citrate tribasic monohydrate, using a two electrode cell configuration consisting of the aluminum working electrode and a platinum mesh counter electrode. Aluminum was anodized at the anode into Al_2O_3 according to Eq. 2 [14]:

$$2Al + 3H_2O \rightarrow Al_2O_3 + 6H^+ + 6e^- \quad (2)$$

In order to form a high quality barrier-type oxide layer [15], the oxidation was carried out by a two stages process, consisting of a galvanostatic step determining the thickness of the anodized layer, and a potentiostatic step improving the quality of the oxide layer. In the first stage, a constant current density ($+0.07$ mA/cm^2) was applied to the aluminum working electrode until the voltage difference between this electrode and the Pt mesh reached +30 V, corresponding in our case to 50 nm oxide formation. In the second (potentiostatic) stage remaining defects (pinholes) were repaired by maintaining the applied voltage (+30 V) until the current density dropped to 0.006 mA/cm^2.

The roughness of the dielectric layer has been proven very important to the organic semiconductor growth and therefore carrier mobility in the materials [16,17]. We found that anodized Al_2O_3 is conformal to the underlying Al, and that therefore the smoothness and surface quality of the original Al layer is the key factor for obtaining a high-quality Al_2O_3 surface. Fig. 1 shows atomic force microscopy (AFM) images of evaporated aluminum before anodization (on the left of each picture) and the anodized aluminum oxide (on the right of each picture). Nine different aluminum layers were thermally evaporated at various

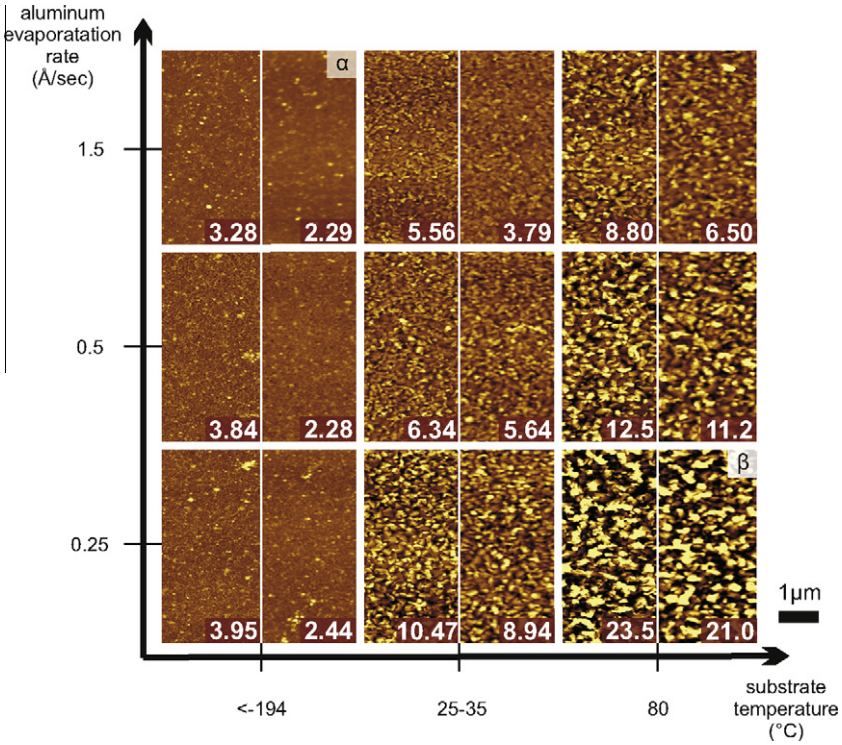

Fig. 1. Atomic force microscopy (AFM) images of thermally evaporated aluminum on glass (on the left of each picture) and after anodization (on the right of each picture). Nine samples were prepared at different evaporation rates and substrate temperatures. The roughness of each surface (nm) is indicated in the corner of each picture. The similarity between before and after anodization illustrates anodized aluminum oxide is conformal to the original surface. The smoothest sample after anodization (α) and the roughest sample (β) were characterized by XRD (Fig. 2).

evaporation rates and substrate temperatures, giving rise to large variation in surface roughness. Smooth layers with roughness as small as 3 nm can be achieved at high rate and low substrate temperature. After anodization (under identical conditions for all samples), the surfaces of the anodized film have almost identical morphology as the original metal layer. In short, the anodized aluminum oxide is conformal to the aluminum layer, and anodization does not generate extra roughness compare to the original aluminum.

The smoothest sample (α) and the roughest sample (β) in Fig. 1 are examined by X-ray diffraction measurement (XRD), and the results are shown in Fig. 2. XRD spectra presents only an Al (111) signal, and no signal from aluminium oxide, indicating that the aluminium oxide is amorphous. We have verified the uniformity of the growth of Al_2O_3 using cross-sectional transmission electron microscopy (TEM) (Fig. 3), confirming that there are no obvious defects or pinholes. From the electric measurement shown in Fig. 4, we infer that a 50 nm thick film of anodized aluminium oxide withstands an electric field as high as 6 MV/cm. This is comparable with 100 nm sputtered aluminium oxide. In addition, the capacitance is around 160 nF/cm^2 and the correspondence dielectric constant is around 9.

We conclude that smooth and dense films of Al_2O_3 with excellent electrical leakage and breakdown characteristics can be prepared at room temperature, and this should have a potential for application in thin-film electronics [18]. In particular, the underlying Al layer can be envisioned as the gate metal, and the anodized Al_2O_3 as the gate dielectric. There remains, however, the problem of patterning the gate/dielectric stack. Indeed, the oxide cannot be formed by anodization of isolated Al islands on a substrate, since electrical current has to be applied to the area to be anodized. Because of the small size of the individual gate electrodes and the large number of gates in electronic circuits, it is impractical to contact each individual gate electrode to anodize it. The only option is to anodize a uniformly deposited layer of Al over the complete area of the substrate, and pattern islands of gate (Al) and gate dielectric (Al_2O_3) afterwards. However, the lateral isolation of the patterned Al gate is now problematic, as the exposed

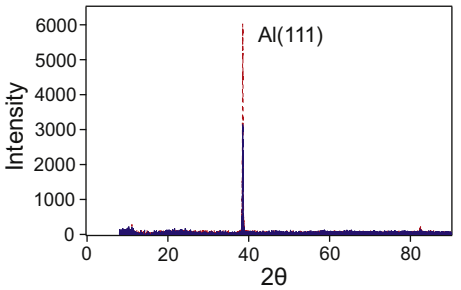

Fig. 2. X-ray diffraction (XRD) spectra of the smoothest (α) (dashed line in red) and roughest (β) (solid line in blue) anodized aluminum layer of Fig. 1. It shows only an Al (111) signal, and no signal from aluminium oxide, indicating that the aluminium oxide is amorphous. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

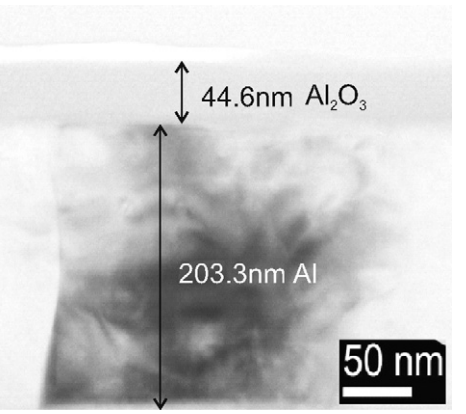

Fig. 3. Cross section transmission electron microscopy (TEM) picture of (α) in Fig. 1 reveals the presence of an amorphous aluminum oxide conformal to the crystalline aluminum surface without obvious defects or pinholes.

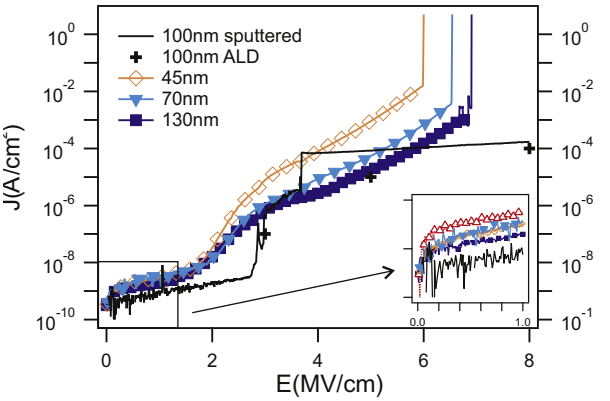

Fig. 4. Leakage current measurement at different fields for different thickness of anodized aluminum oxide compared to sputtered and atomic layer deposit (ALD) aluminum oxide. The anodization voltages are 30 V, 50 V and 100 V, corresponding to 45 nm, 70 nm and 130 nm. The result from 70 nm anodized aluminum oxide is comparable with 100 nm ALD aluminum oxide and sputtered aluminum oxide.

edges of the patterned Al cannot be covered with dielectric during anodization. This problem is the main reason why anodization has not been applied to circuits with large numbers of transistors so far.

We provide a solution that relies on overetching the Al layer in the above process. Our experiments were carried out as shown in Fig. 5. First, a continuous (non-patterned) aluminium layer is deposited by thermal evaporation and anodized to a thickness of 50 nm. Next, a photoresist layer is provided on the metal-insulator stack, and patterned by photolithography, followed by a wet etching step. The wet etchant comprises a mixture of phosphoric acid, nitric acid and acetic acid. The etch rate of Al is higher than that of Al_2O_3, such that the Al layer at the edges is overetched.

Fig. 6 presents an optical micrograph of a top view of this structure, comprising a patterned Al layer with an anodized Al_2O_3 layer and source-drain contacts above. The overetch of the metal oxide layer is in the range be-

tween 2.3 μm and 4.7 μm, much larger than the thickness of the oxide layer, giving a modest bending of the oxide layer without cracks as shown in the cross-section TEM picture in Fig. 7. It indicates the perfect collapse of the Al_2O_3 to cover the edge of the Al pattern. The collapse of the Al_2O_3 can be seen running over the gate edge in Fig. 6, and it ensures complete lateral insulation of the gate

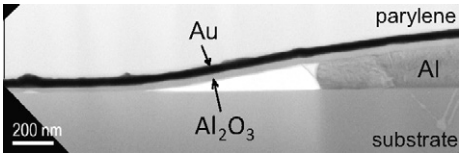

Fig. 7. Cross section TEM picture of overetch aluminum layer demonstrates perfect coverage of the Al edge by the collapsed Al_2O_3, leading to complete lateral insulation of the gate island and preventing short circuits between the gate and the source/drain contacts.

island and prevents short circuits between gate and the drain finger (or source finger). One could argue that the edge line of Fig. 6 is not straight enough for a reliable technology, but this edge is not relevant for the application. The source-drain distance is crucial for correct operation and this is not influenced by this gate patterning technique.

Fig. 8 shows the transfer characteristic of the transistors shown in Fig. 6. Both pentacene and Ga–In–Zn–O are used as a semiconductor layer. After applying self assembled monolayers (pentafluorobenzenethiol and phenethylchlorosilane), pentacene is thermally evaporated at the rate 0.25 Å/sec with substrate temperature 68 °C. Ga–In–Zn–O is sputtered at room temperature and patterned by oxalic acid in room temperature. Both transistors present excellent electrical characteristics with low voltage operation, fairly high charge carrier mobility and close to 0 V onset and threshold voltages: the mobilities for the pentacene transistor on glass, on plastic foil and the Ga–In–Zn–O transistor are 0.47 cm^2/Vs, 0.26 cm^2/Vs, and 0.91 cm^2/Vs; the threshold voltages are 0.51 V, 0.97 V and 0.04 V; the subthreshold swings for these devices are 0.23 V/decade, 0.53 V/decade and 0.21 V/decade. The difference of the off current for these two materials comes from the patterning of the active material. Even though pentacene is unpatterened here, the off current and threshold voltage is low enough for circuit application, and further improvement can be achieved by several methods [19,20]. More importantly, the dashed line in Fig. 8 is the gate to source current showing no current going through between gate and source-drain fingers, confirming that (i) the metal oxide formed by anodization presents an excellent dielectric quality, (ii) the gate electrode is effectively laterally isolated from the source and drain contacts, thanks to the collapsed metal oxide.

In this process, a zero V_{GS} inverter with channel length of 5 μm, channel width of 140 μm for the drive transistors

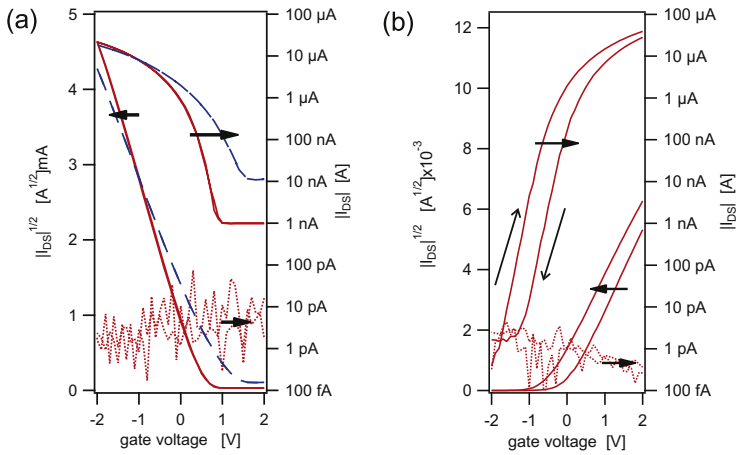

Fig. 8. Transfer characteristics of (a) pentacene (dashed line in blue: on plastic foil substrate, 0.27 cm^2/Vs; solid line in red: on glass substrate, $\mu = 0.47$ cm^2/Vs), (b) Ga–In–Zn–O (on plastic foil substrate, $\mu = 0.91$ cm^2/Vs) transistors (W/L = 1000 µm/10 µm and $V_{DS} = -2V$) prepared according to the process flow of Fig. 5. The low gate to source current (dotted line) confirms an excellent dielectric quality and an effective lateral insulation between gate and source or drain fingers. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

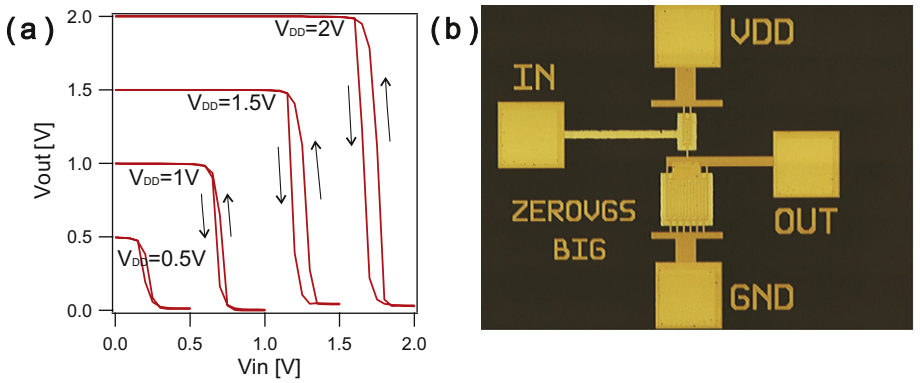

Fig. 9. (a) Voltage transfer curve of a zeroVgs-load inverter, with pentacene as semiconductor, (b) the optical microscopy picture of the inverter. The channel length is 5 µm and the channel width is 140 µm for the drive transistors, 1400 µm for the load transistors.

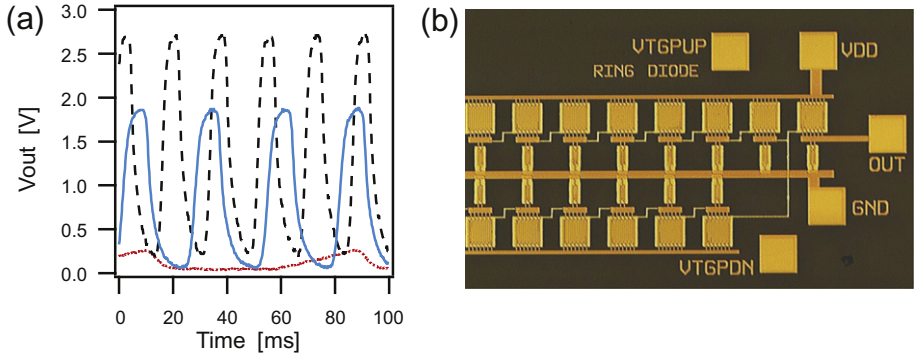

Fig. 10. Ring oscillator consisting of 40 pentacene transistors with channel length 5 µm prepared according the process flow of Fig. 5. Input voltages for dashed line (black), solid line (blue) and dotted line (red) are 3.5V(60Hz), 2.5V(40Hz) and 1V(12Hz). Correct functioning of such ring oscillator made with the above process is shown. It demonstrates the feasibility of the proposed process flow for larger integration. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

and 1400 µm for the load transistors is realized as shown in Fig. 9. In addition, a 19 stage ring oscillator combining 40 transistors (including output buffer transistor) with channel length of 5 µm are also realized and shown in Fig. 10. It demonstrates the feasibility of the proposed process flow for larger integration.

3. Conclusion

We demonstrate a method to make a room-temperature high-k dielectric film, for high-performance organic transistors by anodization of Al to Al_2O_3. An innovative patterning technique circumvents the problem that reliable anodizaton needs to be performed on blank (unpatterned) Al film. It is based on overetching of the Al gate film and collapse of the overlying Al_2O_3 dielectric over the edges to provide efficient and reliable gate edge isolation. Finally, we demonstrate the technique by making and characterising a 19-stage ring oscillator using pentacene.

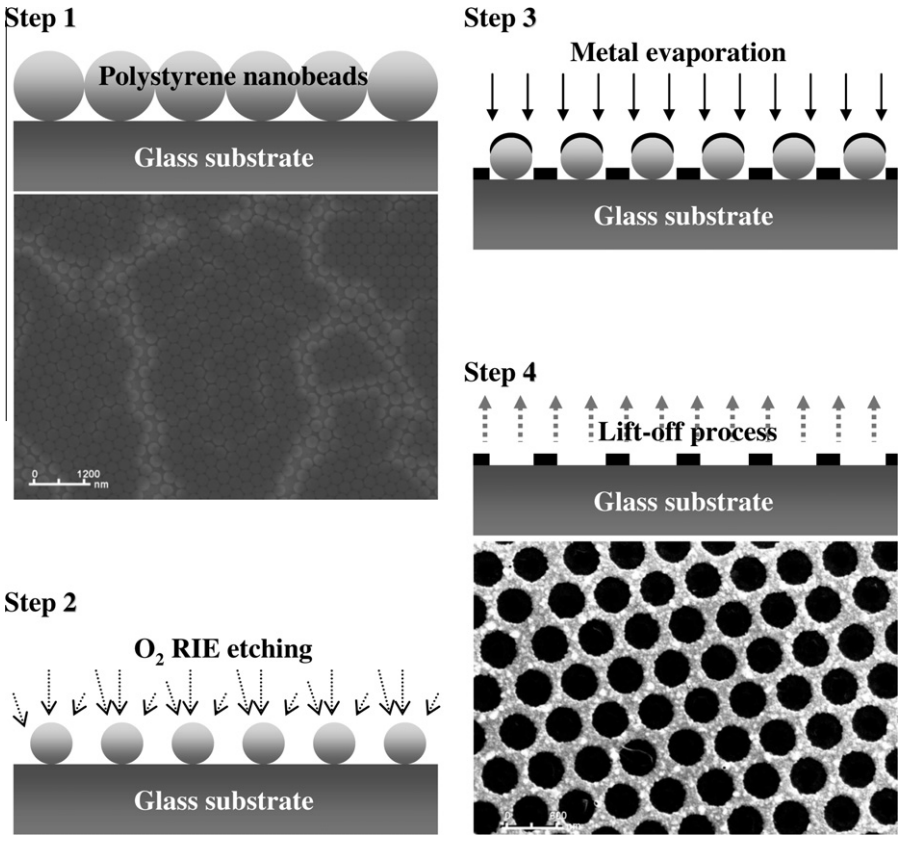

Fig. 1. The diagrams for making metallic nanohole arrays for the anodes of OLED devices.

(H_2SO_4) mixed with hydrogen peroxide (H_2O_2) and then rinsed with deionized water. By controlling the concentration of nanosphere solution and the rotation speed of the spin coater, a single layer of nanospheres was coated on the substrate. After minutes of settling down, the hexagonal close-packed nanostructures were formed. The period of the hexagonal array was determined by the original diameter of the polystyrene spheres. We further reduced the diameter of these spheres by a RIE etcher. In the RIE process, argon ions etched the polystyrene balls isotropically. The periphery of the ball was etched away. It thus reduced the diameter of the polystyrene ball. Subsequently, we used electron-gun evaporation to fill the gap with silver thin film. The sample was then put into dichloromethane (CH_2Cl_2) solution in an ultrasonic cleaner to remove the polystyrene balls. The remained silver film on the substrate formed a periodic nanohole array as shown in Fig. 1 (step 4). For different RIE etching time, the diameter of the polystyrene ball was different. It resulted in different size of holes in the silver film. We defined a parameter, fill-factor, to describe the difference. The fill-factor is defined by the ratio of the area of nanohole array divided by the total area.

The patterned thin film was further treated with an annealing process at 200 °C for 3 h under ultra-high vacuum conditions (<10^{-7} torr) in order to form more compact metal grains. The annealing treatment is crucial to the reduction of the background defects and decrease the grain boundary scattering resistivity [15]. Fig. 2 shows the measured sheet resistance as a function of the fill-factor for different deposition rates of silver film. When the deposition rate changed from 0.2 to 0.6 nm/s, the sheet resistance was greatly reduced, especially for high fill-factors. This implies that the evaporated silver grains construct a more compact structure when the deposition rate is high. After annealing at 250 °C for 3 h, the sheet

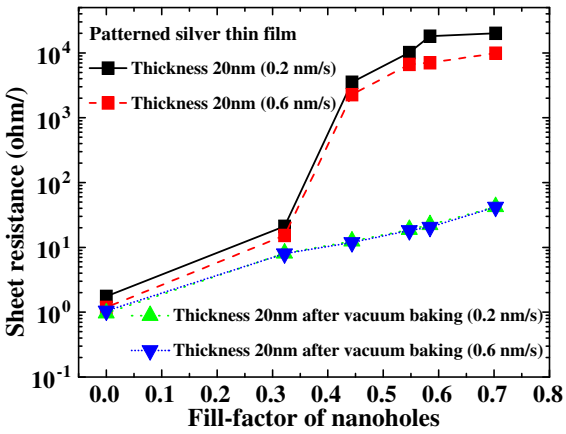

Fig. 2. Sheet resistances of 20-nm-thick silver thin film with different deposition rate and annealing process as a function of the fill-factor. The vacuum baking indicates that the annealing process was done in a high vacuum (<10^{-7} torr) chamber.

resistance decreased greatly. It is noted that the sheet resistances after the annealing process were identical, no matter what the deposition rate was. This was evidence that thermal annealing can reconstruct the silver grains and improve conductance of the nanoscale electrodes.

The averaged visible transmissions for different thicknesses of patterned silver films with different fill-factors were shown in Fig. 3(a). The period of the nanohole array was 590 nm. The flat silver thin film (fill-factor = 0) has a low transmittance. With the nanohole array, it resulted in a great improvement of transparency. For 10 nm thick silver film, the transparency was increased with an increase in fill-factor. However, there was extraordinary increase in transmission for the 20 nm thick Ag film. Fig. 3(b) shows the transmission spectra of 20 nm thick Ag film with different fill-factors. It can be seen that the transmission is increased near the 600 nm wavelength. The wavelength is close to the period. We attribute such transmission enhancement due to the surface plasmon resonant effect in the silver nanohole arrays [16]. The small fill-factor indicates small holes in the silver film. It is known that surface plasmons are generated in these metallic nanoholes. For periodic metallic nanostructures, the surface plasmon resonance can enhance the transmission at wavelengths near the period (590 nm) [17]. This patterned thin film with 0.321 fill-factor had an average transparency of 0.65 for green light. The transparency was smaller than the transparent ITO. Its sheet resistance was only 6.17 Ω/□, lower than the 15 Ω/□ of ITO. A small fill-factor also avoids the problems of the vertical current spreading in optoelectronic devices. Therefore it is more suitable for making light emitting devices.

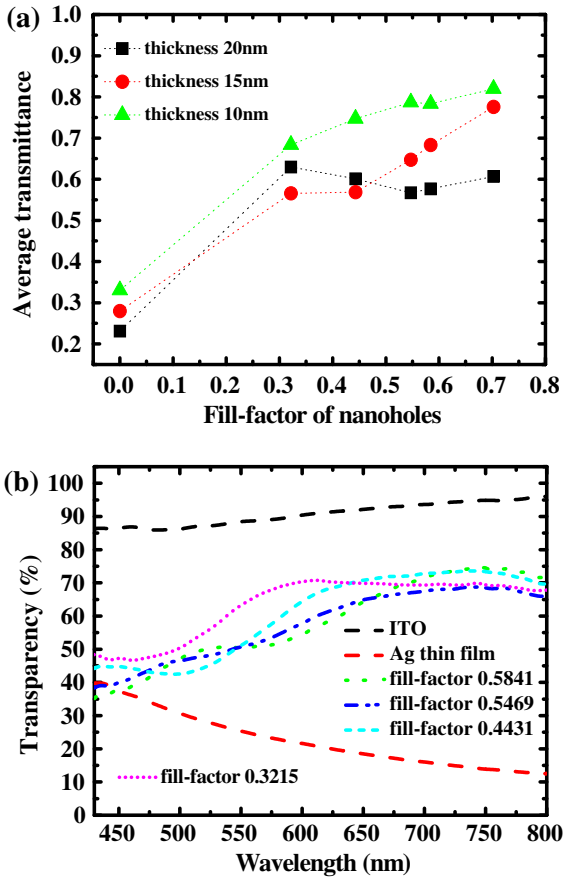

Fig. 3. (a) Transmittance of the patterned Ag films with different fill-factors and film thickness. (b) Transmission spectra of 590-nm-period patterned Ag thin film with 20 nm thickness.

3. OLED with patterned silver thin film

Our OLED fabrication process can be divided into two major parts, including patterned anode smoothing and conventional organic layers evaporation. Because the strong electric field at the sharp point of the patterned anode could result in the penetration of organic layers, the way to smooth the roughness of the patterned anode is a crucial issue to building patterned anode OLEDs. Polymer material spun onto the patterned anode can form a protection layer to smooth its surface and help hole-injection. The PEDOT: RSS (Poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate)) and SAM (self-assemble monolayer) are both suitable polymer materials to be the protection layer. However, the SAM layer also helps increasing the work function of the silver thin film (from 4.68 to 5.6 eV). It provides a better energy level alignment between the work function of the anode and the HOMO level of the NPB [18]. Hence, we used SAM as the protection layer. The PEDOT: RSS was not used in this study. After smoothing the patterned anode, organic layers were deposited in an ultra high vacuum (around 5×10^{-6} torr) thermal evaporator. Hole-transport layer (NPB, *N*, *N*'-di-[(1-naphthalenyl)-*N*, *N*'-diphenyl]-(1,1'-biphenyl)-4,4'-diamine) and electron-transport layer (Alq_3, Tris-(8-quinolinolato) aluminum) were evaporated sequentially on the patterned anode. LiF and Al were set as the opaque cathode of the device. After evaporation, the devices were encapsulated with glass in a glove box chamber. We fabricated OLEDs with conventional ITO anodes, unpatterned and patterned silver thin films with SAM coatings. The fabrication parameters for OLEDs with different kinds of anodes are listed in Table 1.

Fig. 4(a) shows the *I*–*V* curves and the picture of the bottom emission for those devices. The turn-on voltages at the current density of 100 mA/cm^2 were 7.54 V (control device), 5.81 V (unpatterned device) and 6.72 V (patterned device). It is noted that the sheet resistances of the patterned film and the ITO anode are similar (patterned film with SAM modification: 6.17 Ω/□, ITO: 15 Ω/□). However, the hole injection efficiency for the patterned film is much better than the ITO ones due to a better energy alignment for SAM modified silver anodes. Therefore, the patterned silver anode has a turn-on voltage lower than the ITO one. Fig. 4(b) shows the efficiency versus the current density. The saturated current efficiencies were 3.2 cd/A (control device), 4.6 cd/A (unpatterned device), and 5.4 cd/A (patterned device). Even though the current efficiency of the patterned film was depressed by the confinement of the vertical current spreading, it still showed an 84.6% improvement compared to the ITO devices. Such

Table 1
Device structures with different transparent anodes.

Device	Anode	Surface treatment	NPB	Alq_3	LiF	Al
Control	ITO	O_2 plasma	60 nm	60 nm	1 nm	100 nm
Unpatterned	Ag (20 nm)	SAM				
Patterned nanohole array (*FF*: 0.32)	Ag (20 nm)	SAM				

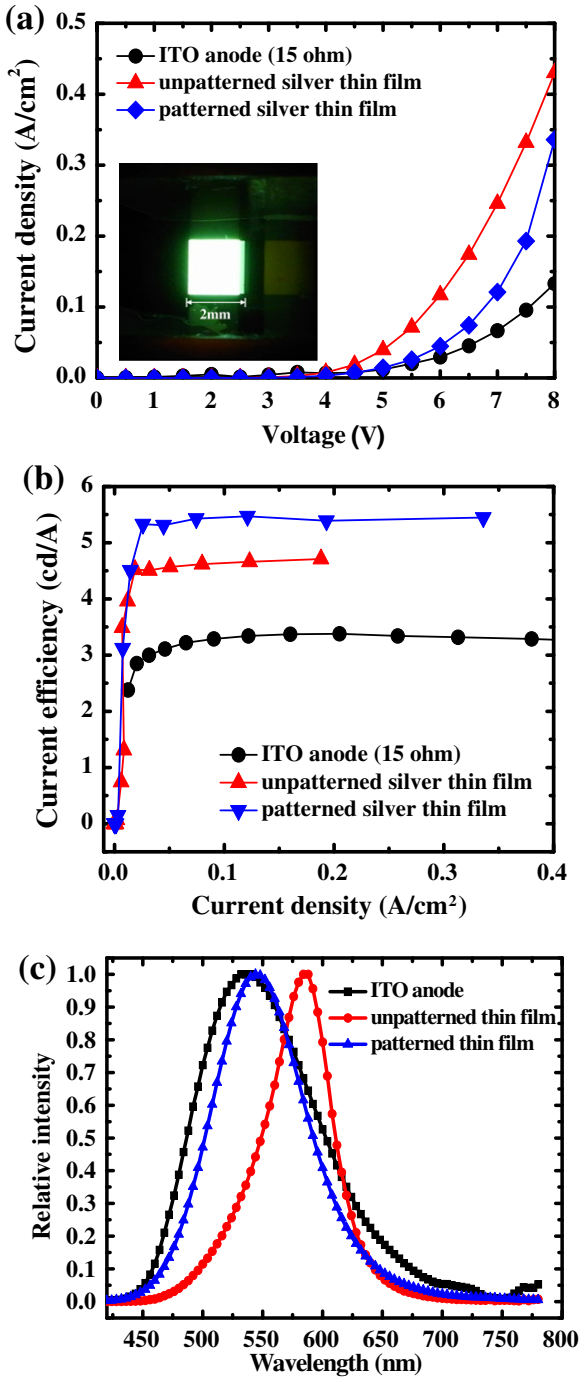

Fig. 4. (a) *I–V* curves, (b) current efficiency versus current density, and (c) normalized EL spectra of OLED devices with different types of anodes.

efficiency enhancement is attributed to the light extraction by the metallic nanostructures. In a typical OLED, less than one third of the generated photons can escape from the emitting devices. One third of these photons are guided in the glass substrate and the others are trapped in the organic layers. The patterned anode was composed of periodic metallic nanostructure. It helps in scattering light out of the organic layer and substrate simultaneously. Therefore, a large improvement of the total quantum efficiency is achieved. Fig. 4(c) shows the diagram of the emission spectra. There is a strong Fabry–Perot effect in the non-patterned silver film device [19]. Such cavity effects narrowed the emission spectrum. For the patterned device, the cavity effect is weaker and the scattering by the silver nanostructures makes the emission spectrum broader and more similar to the ITO ones. If we took the EL (electroluminescence) spectra and calculated the CIE (International Commission on Illumination) coordinate, the resultant emission spectra of the patterned films provided the best color purity (CIE 1931: control device: (0.3529, 0.5337), unpatterned device: (0.4773, 0.502), and patterned device: (0.3484, 0.5953)).

4. Conclusion

We have fabricated an ITO comparable transparent anode using nanosphere lithography. About an 85% transparency and 35 Ω/□ silver anodes were created. The electricity of the anode is better than the ITO anode. The optical transmittance is lower but can be enhanced by the surface plasmon resonance effect. Compared to the traditional ITO based device, the SAM modified patterned silver anode leads to a 0.82 V reduction in turn-on voltage and a 68.8% improvement in current efficiency.

layers. PbPc is a shuttlecock-shaped molecule (Fig. 1a) and a promising material for solar energy conversion at a wavelength that covers the near-infrared region [20]. The mechanism of the structural variation of the PbPc layer with the change of the organic buffer layer was investigated by X-ray diffraction (XRD), synchrotron X-ray diffraction (SR-XRD), and atomic force microscopy (AFM). A clear relationship between the structural, optical, and electrical properties of PbPc-based OSCs with inserted buffer layers was reported.

2. Experimental

PbPc layers and buffer layers were deposited on a polished ITO substrate by organic molecular-beam deposition (OMBD) under a base pressure of 1×10^{-7} Pa. The ITO substrates were chemically treated with a 1:1:4 $NH_4OH/H_2O_2/H_2O$ mixture at 350 K and then dried under a nitrogen flow. We initially deposited poly(3,4-ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) (Bytron 4083, Bayer) on the substrate by spin coating at 4000 rpm to obtain reproducible results on structural and electrical properties of organic layers. The substrate surface was then smoothed by drying it at 100 °C for 10 min. Next, the PbPc layers were deposited onto the PEDOT:PSS layer. Pristine phthalocyanine (H_2Pc), oxovanadium phthalocyanine (VOPc), sexithiophene (6T), and para-sexiphenylene (p-6P), all of which had almost constant hole mobilities ($\sim 10^{-2}$ cm^2/Vs) [13,21–23] were adopted as buffer layers that were inserted between the PEDOT:PSS and PbPc layers. The chemical structure, ionized potential, and electron affinity of PbPc, H_2Pc, VOPc, 6T, and p-6P are shown in Fig. 1a–e, respectively [24–27]. The film thickness was controlled using a crystal oscillator monitor, and the buffer layer and PbPc layer were grown at 0.02 and 0.05 nm/s, respectively. Deposition temperature for all organic materials was kept constant at room temperature (RT).

XRD and SR-XRD analyses were performed using a thin-film X-ray diffractometer (Rigaku RINT2100) with a Cu Kα source ($\lambda = 0.154$ nm) and a Huber six-axis diffractometer at beam line 4C in the KEK photon factory, respectively. The wavelength of the incident synchrotron X-ray for SR-XRD was fixed at $\lambda = 0.1907$ nm, which corresponds to the photon energy of 6.5 keV. Since the intensity of the synchrotron X-rays is much higher than that of the Cu Kα source used in the laboratory system, SR-XRD was used for the structural characterization of the buffer layers, the thicknesses of which were relatively thin. In the out-of-plane XRD analyses, we used the Bragg–Brentano configuration (θ–2θ mode) and the Seemann-Bohlin geometry (incident angle = $\sim 0.15°$) to examine the lattice periodicity perpendicular to the substrate surface [8,28]. The in-plane XRD analysis, on the other hand, is used to examine the lattice periodicity parallel to the substrate surface. Therefore, the three-dimensional crystalline structure can be observed in these measurements. Tapping-mode AFM was performed using a probe system (Seiko Instruments SPI3800) at RT in air. The optical absorption spectra of the films were obtained using a Jasco Ubest V-570 system.

The solar cells (device area: 4 mm^2) were fabricated using a combination of PbPc and C_{60}; the characteristics of these cells were determined using simulated solar light with an air mass of 1.5 (AM 1.5) under 100 mW/cm^2 irradiation in air. The spectrum sensitivity was investigated at RT using a xenon lamp with a 25-cm focal-length single monochromator (Bunko Keiki SM-1700A).

3. Results and discussion

3.1. Structural and electrical properties of PbPc layers

Fig. 2 shows the XRD profiles of 100-nm-thick PbPc layers formed on PEDOT:PSS (a) without a buffer layer and with (b) H_2Pc, (c) VOPc, (d) p-6P, and (e) 6T buffer layers measured in θ–2θ mode. The thickness of the buffer layers was fixed at 5 nm. The structural variation of the PbPc crystal from a monoclinic phase (Fig. 2f; lattice parameter: $a = 2.55$ nm, $b = 2.55$ nm, $c = 0.373$ nm; $\gamma \sim 90°$) [29] to a

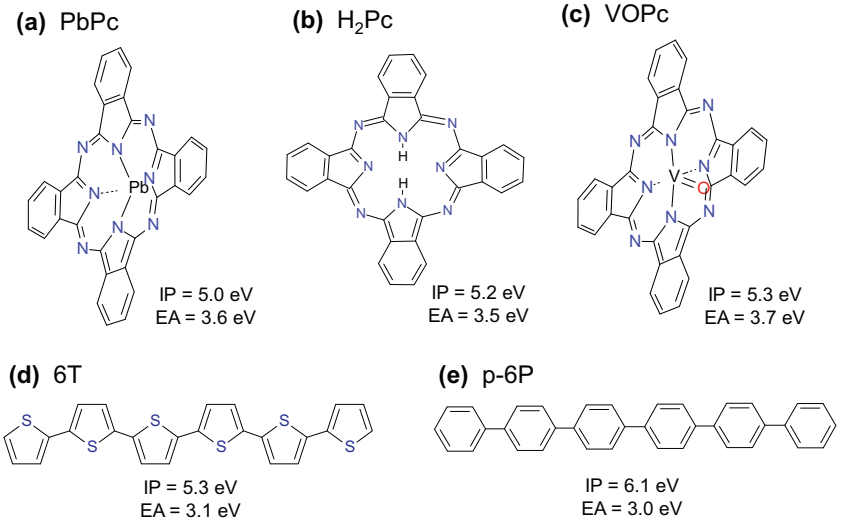

Fig. 1. Chemical structure, ionized potential (IP), and electron affinity (EA) of (a) PbPc, (b) H_2Pc, (c) VOPc, (d) 6T, and (e) p-6P.

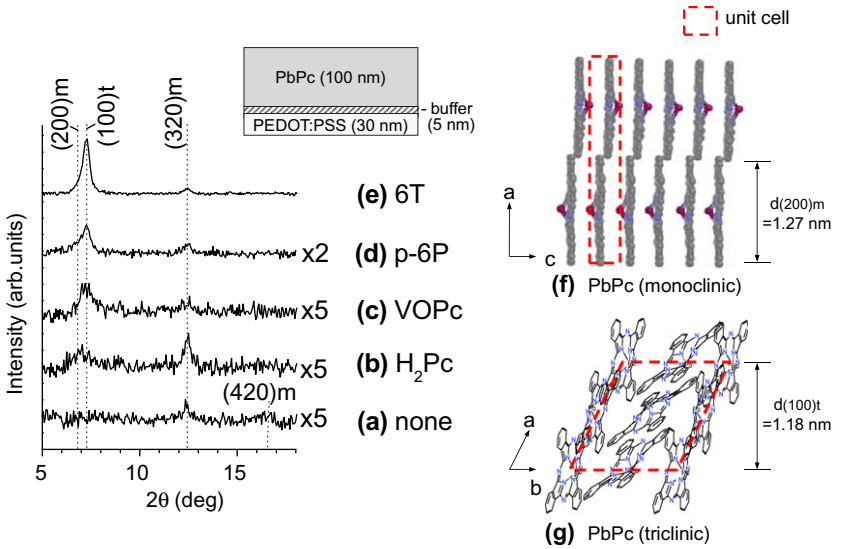

Fig. 2. XRD profiles of 100-nm-thick PbPc layers formed on PEDOT:PSS (a) without a buffer layer and with (b) H_2Pc, (c) VOPc, (d) p-6P, and (e) 6T buffer layers measured in θ–2θ mode. The thickness of buffer layers was fixed at 5 nm. Schematic crystal structures of (f) monoclinic PbPc and (g) triclinic PbPc are also shown in the figure.

triclinic phase (Fig. 2g; $a = 1.31$ nm, $b = 1.61$ nm, and $c = 1.29$ nm; $\alpha = 94.2°$, $\beta = 96.2°$, and $\gamma = 114.2°$) [30] was observed by changing the buffer layers. In the case of the specimen without a buffer layer, diffraction peaks corresponding to monoclinic PbPc (3 2 0), expressed as (3 2 0)m, and (4 2 0)m and were observed at $2\theta = 12.7°$ and 16.5°, respectively [31,32]. The diffraction peaks corresponding to monoclinic PbPc were also observed for the PbPc layer with the H_2Pc buffer layer, whereas a new peak was observed for PbPc (2 0 0)m at $2\theta = 6.9°$. This result indicates that the molecular orientation of PbPc was modified due to the variation in the molecule–substrate interaction resulting from the insertion of the H_2Pc buffer layer, while the weak diffraction peaks suggest that PbPc has a disordered crystalline structure. On the other hand, in the case of the specimens containing VOPc, 6P, and 6T buffer layers, the diffraction peak corresponding to triclinic PbPc (1 0 0), expressed as (1 0 0)t, was newly identified at $2\theta = 7.35°$. In the case of the PbPc/6T and PbPc/p-6P heterostructures, the PbPc (1 0 0)t diffraction peak was observed to have a high intensity and a narrow width, indicating the well-ordered crystalline structure of the PbPc layers. It is known that the crystalline structure of PbPc can be controlled by the variation of the deposition condition (e.g., deposition rate and substrate temperature) [31,32]. The influence of the organic buffer layer on the phase variation of PbPc has not been systematically studied yet.

In order to discuss the variations in the structural properties of PbPc layers grown on buffer layers, we investigated the crystalline structure of the buffer layers using SR-XRD. Fig. 3 shows the out-of-plane and in-plane SR-XRD profiles for (a) VOPc (100 nm), (b) p-6P (50 nm), and (c) 6T (10 nm) layers formed on PEDOT:PSS. The out-of-plane SR-XRD profile was measured using Seemann-Bohlin geometry. The thicknesses of these layers were several times larger than 5 nm, which was applied for the PbPc/buffer layer heterostructures shown in Fig. 2, due to the weak diffraction intensities. The in-plane diffraction profile for the VOPc layer shows no peak probably because of a weak diffraction intensity, while the out-of-plane diffraction peaks were observed at $q = 5.3$, 9.1, 15.5, 17.1, and 19.9 nm^{-1}, where q is the diffraction vector. These peaks correspond to lattice spacings of 1.18, 0.692, 0.405, 0.367, 0.343, and 0.315 nm, respectively, and are in good agreement with the results reported by Pan and co-workers [33]. The monoclinic ($a = 1.35$ nm, $b = 1.33$ nm, and $c = 1.39$ nm; $\beta = 105°$) [34] and triclinic ($a = 1.20$ nm, $b = 1.25$ nm, and $c = 0.869$ nm; $\alpha = 96.0°$, $\beta = 94.8°$, and $\gamma = 68.2°$) [35] phases were observed to coexist in the VOPc layer, as assigned by Miller indices of the planes for each diffraction peak shown in Fig. 3a-i. The crystal structure of triclinic VOPc is shown in Fig. 3a-ii; the out-of-plane diffraction peak related to VOPc (0 1 0)t suggests that the molecular plane of VOPc is perpendicular to the substrate surface, while the VOPc $(2\,1\,\bar{2})$t peak indicates that the stacking direction of the molecular planes of VOPc is parallel to the surface normal [13,36]. Thus, the molecular orientation and crystalline phase in the VOPc layer were disturbed. On the other hand, in the case of the p-6P layer, the out-of-plane diffraction profile shows p-6P (0 0 l) ($l = 2$, 3, 6) diffraction peaks representing the interplanar distance of 2.60 nm at $q = 4.8$, 7.3, and 14.3 nm^{-1}, respectively, and the in-plane diffraction profile shows p-6P $(1\,1\,\bar{1})$ and $(2\,0\,\bar{3})$ related diffraction peaks at $q = 13.7$ and 16.2 nm^{-1}, corresponding to the lattice spacings of 0.458 and 0.388 nm, respectively [37,38]. Considering the crystal structure of p-6P ($a = 0.809$, $b = 0.557$, and $c = 2.62$ nm; $\beta = 98.2°$ (monoclinic)) [37] shown in Fig. 3b-ii, it can be assumed that the molecular plane of p-6P is approximately perpendicular to the substrate surface. A similar trend was observed in the structural properties of the 6T film, the schematic crystal structure of which ($a = 4.47$, $b = 0.785$,

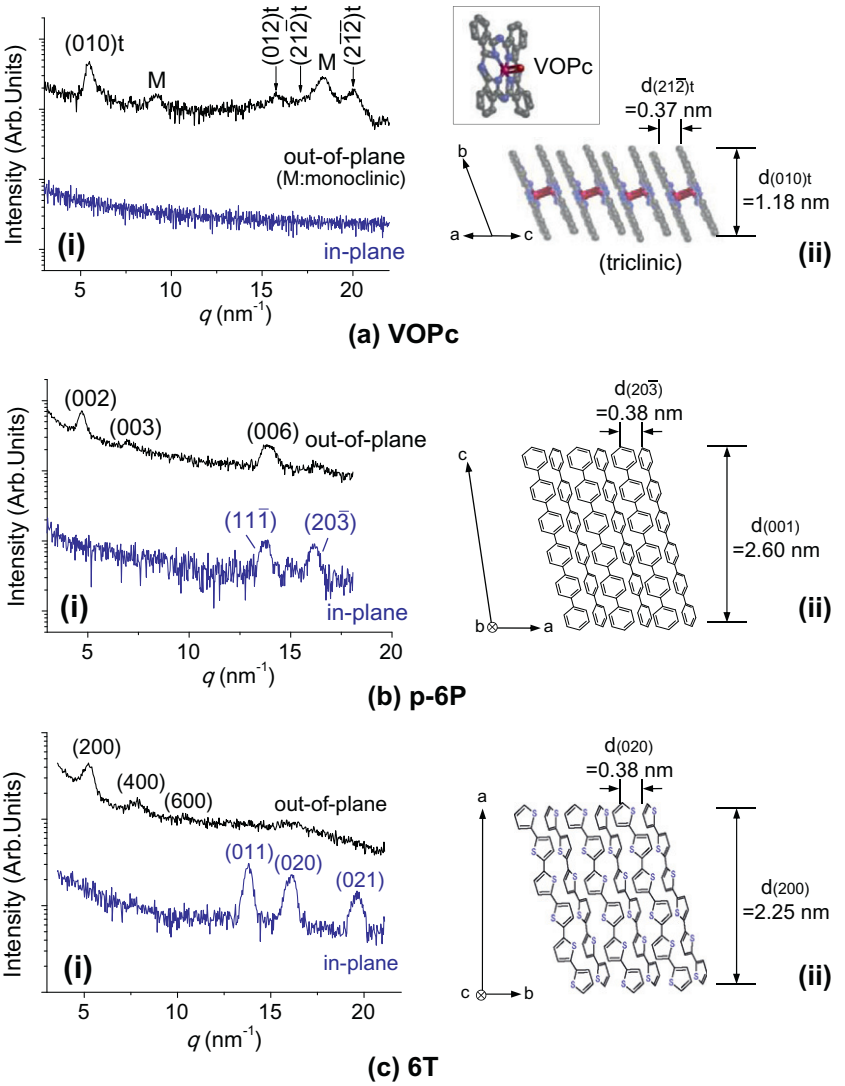

Fig. 3. SR-XRD profiles for (a) VOPc (100 nm), (b) p-6P (50 nm), and (c) 6T (10 nm) layers formed on PEDOT:PSS; (i) out-of-plane and in-plane diffraction profiles, (ii) schematic crystalline structure.

and c = 0.603 nm; β = 90.8° (monoclinic)) [39] is illustrated in Fig. 3c-ii. The out-of-plane diffraction profile for the 6T layer showed 6T (l 0 0) (l = 2, 4, 6) peaks indicating the interplanar distance of 4.48 nm, while the in-plane diffraction profile showed 6T (0 1 1), (0 2 0), and (0 2 1) peaks at q = 13.8, 16.2, and 19.6 nm^{-1}, corresponding to the lattice spacings of 0.455, 0.388, and 0.321 nm, respectively [40]. These results suggest that the molecular plane of 6T is almost perpendicular to the substrate surface since a-axis of 6T observed in the out-of-plane diffraction pattern is perpendicular to both b- and c-axes observed in the in-plane diffraction profiles [39]. Fig. 4 shows an AFM image of the 6T (10 nm) layer formed on PEDOT:PSS. Clear step and terrace structures were observed, and the step height was 2.2 nm, corresponding well with the lattice spacing of 6T (2 0 0). The atomically flat terrace represents the in-plane ordering of 6T in accordance with the in-plane diffraction peaks shown in Fig. 3c-i [40–42]. Our results correspond to the previous reports that suggest that the 6T and p-6P layers tend to grow in a layer-by-layer fashion on inert substrate surfaces such as glass and ITO, while maintaining their standing molecular orientation [12,40–42]. On the basis of these considerations, we assume that the structural properties of the buffer layer are important for the crystal growth of the PbPc layers.

The crystal growth of organic semiconductor layers is dominated by the delicate balance between molecule–molecule and molecule–substrate interactions. The anisotropic van der Waals intermolecular interactions, which arise from the π-orbital in organic semiconductors, stimulate the formation of the specific configuration between two molecules at organic hetero-interfaces [4,8,9,11]. As for the PbPc layer with the VOPc buffer layer, the random orientation of VOPc results in the deterioration of the structural properties of the PbPc layer. In contrast, upright oriented p-6P and 6T molecules appear to promote the

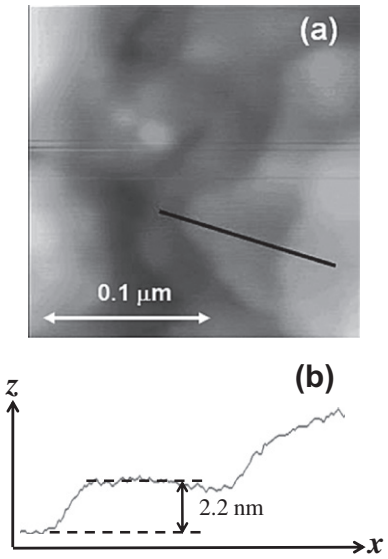

Fig. 4. (a) 0.2 × 0.2 μm^2 AFM images of 10-nm-thick 6T layer grown at room temperature on a PEDOT:PSS/ITO structure. (b) Height profile of black line in (a).

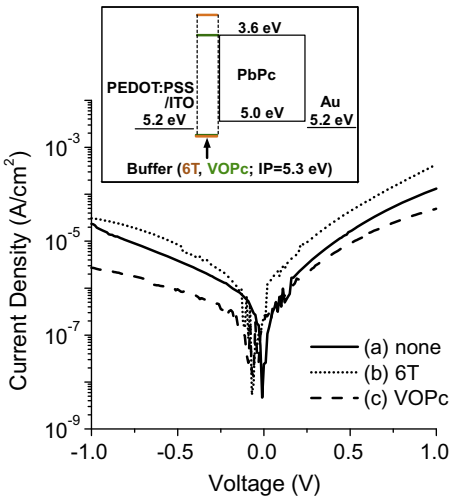

Fig. 5. Current density and bias voltage (*J–V*) characteristics of ITO/PEDOT:PSS/buffer layer (5 nm)/PbPc (200 nm)/Au structures (a) without a buffer layer (solid line) and with (b) 6T (dotted line) and (c) VOPc (dashed line) buffer layers. The inset shows the schematic energy level diagram for ITO/PEDOT:PSS/buffer layer/PbPc/Au structure.

growth of a well-ordered structure of PbPc. Recently, several reports have suggested that atomically flat p-6P and 6T buffer layers with well-ordered in-plane crystalline structures, as in the case of our specimens, promote the heteroepitaxial growth of organic semiconductor layers [12,13,43]. Thus, the control of structural properties of buffer layers is indispensable for obtaining a highly ordered organic heterostructure.

Fig. 5 shows the current density and bias voltage (*J–V*) characteristics of ITO/PEDOT:PSS/buffer layer/PbPc (200 nm)/Au structures (a) without a buffer layer and with (b) 6T and (c) VOPc buffer layers. The thickness of the buffer layers was fixed at 5 nm. The work functions of the electrodes (ITO, PEDOT:PSS, and Au) approximately correspond to the ionized potentials of the organic layers (PbPc, VOPc, and 6T), as illustrated in the energy level diagram shown in the inset of Fig. 5; therefore, these structures can be considered as hole-only single-carrier devices. Since the electrical properties of VOPc (ionized potential and hole mobility) are almost same as those of 6T, the variations in the *J–V* characteristics of these devices suggest the change in the structural properties of the PbPc layers. The electric conductivity of the device with the 6T buffer layer is several times greater than that of the device without a buffer layer. Previous researches have demonstrated that the conductivity of monoclinic PbPc, which corresponds to the device without a buffer layer, is several times higher than that of triclinic PbPc [44–46], which corresponds to the devices with a 6T buffer layer. Considering the analytical result on the structural properties of PbPc layers (Fig. 2), it can be assumed that control of both crystal quality and phase is indispensable for enhancing the electric conductivity of the PbPc film. It was also observed that the degradation of the crystal quality of triclinic PbPc formed on a VOPc buffer layer affected the reduction in the electric conductivity, as shown in Fig. 5c; this was in agreement with the former assumption. Thus, the appropriate buffer layer promotes the crystal growth of the PbPc and improves its electrical properties.

3.2. Performance of PbPc based organic solar cells

Solar cells composed of PbPc and C_{60} were fabricated with and without organic buffer layers. The structure of the cell is given as ITO/PEDOT:PSS/buffer layer(5 nm)/PbPc (30 nm)/C_{60}(30 nm)/bathocuproine(BCP; 6 nm)/Ag. H_2Pc, VOPc, 6T, and p-6P, all of which had almost the same hole mobilities [13,21–23], were used as buffer layers. All the layers were sequentially deposited in an OMBD chamber. The device parameters of the cells are listed in Table 1. The *J–V* characteristics of the cells under light irradiation are shown in Fig. 6a. The cell performance was remarkably enhanced by the insertion of 6T and VOPc buffer layers. The optimum efficiency of 2.1% was obtained for the cell with a 6T buffer layer; this efficiency was 1.6 times higher than that of the cell without a buffer layer. On the other hand, device parameters deteriorated in case of the introduction of H_2Pc and p-6P buffer layers. The degradation of the performance of the cell with a p-6P buffer layer was caused by a large energy level offset for holes of

Table 1
Parameters of PbPc-based solar cells under AM 1.5 illumination at room temperature (~25 °C) for different buffer layers; J_{SC} is a short-circuit current, V_{OC} is an open-circuit voltage, FF is the fill factor, η is the conversion efficiency, and R_S is the series resistance.

Buffer	J_{SC} (mA/cm^2)	V_{OC} (V)	FF	η (%)	R_S (Ω cm^2)
None	6.5	0.51	0.41	1.3	18

VOPc	7.9	0.46	0.43	1.6	16
6T	9.3	0.49	0.46	2.1	6.8
p-6P	5.0	0.43	0.15	0.3	–

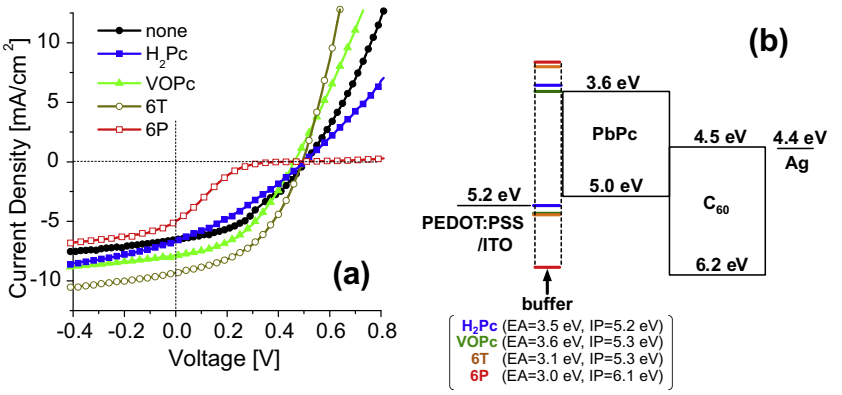

Fig. 6. (a) *J–V* characteristics of the OSCs without a buffer layer (solid circle) and with H_2Pc (solid square), VOPc (solid triangle), 6T (open circle), and p-6P (open square) buffer layers under light irradiation. The structure of OSCs is given as ITO/PEDOT:PSS (30 nm)/buffer layer (5 nm)/PbPc (30 nm)/C_{60} (30 nm)/BCP (6 nm)/Ag. (b) Schematic energy level diagram for OSCs shown in (a).

~1 eV; this offset was present at the p-6P/PbPc (PEDOT:PSS/p-6P) interface, as illustrated in the energy level diagram shown in Fig. 6b. The ionized potentials of H_2Pc, VOPc, and 6T were ~5.3 eV; this value is almost the same as that of PbPc (5.0 eV) and PEDOT:PSS (5.2 eV), indicating the presence of a small energy barrier for holes around the buffer layer. Therefore, in order to understand the variation of the cell performance, other factors apart from the energy level offset should be considered.

Fig. 7 shows the spectral sensitivity of OSCs (a) without a buffer layer and with (b) 6T and (c) VOPc buffer layers. Integration of the external quantum efficiency (EQE) data multiplied by the AM 1.5 solar emission spectrum approximately corresponded with the value of the observed short-circuit current (J_{sc}) shown in Table 1. The OSC without a buffer layer shows a single absorption band at around 750 nm, which corresponds to the Q-band (π–π^* transition) spectrum for monoclinic PbPc [29]. On the other hand, in the case of OSCs with 6T and VOPc buffer layers, both spectra exhibited an absorption shoulder at around 890 nm except for the band at 750 nm, corresponding to the Q-band spectrum for triclinic PbPc [29]. Since the sensitivity data at around 750 nm were not significantly affected by the sort of buffer layers, it can be assumed that absorption at 890 nm enhanced J_{sc}. Consequently, the spectral sensitivity was influenced by the phase of the PbPc layers. The sensitivity data suggests a higher overall efficiency in the case of the OSC with the 6T buffer layer, while the optical absorption spectrum of the 30-nm-thick PbPc layers formed on 6T buffer layer (Fig. 8a), of which spectral profile corresponds to that of the sensitivity data shown in Fig. 7, does not indicate the enhancement of the absorption intensity as compared with the spectrum of PbPc/VOPc heterostructure (Fig. 8b). As can be observed from the structural and electrical properties of the PbPc/6T heterostructure shown in Figs. 2–5, the well-ordered crystalline structure of PbPc formed on 6T enhances the electric conductivity of the PbPc films and reduces the series resistance of the OSC. Such enhancements in the electrical properties of PbPc enhance the spectrum sensitivity of OSC, although further studies, e.g., influence of the PbPc/C_{60} interfaces and the residual monoclinic PbPc domains on EQE, are indispensable to clarify the underlying physics in more detail. Thus, control of both crystal quality and phase of PbPc layers using a proper buffer layer is effective in enhancing the device performance of OSCs.

4. Conclusions

We have investigated the influence of an organic buffer layer on structural properties and performances of PbPc-based solar cells. H_2Pc, VOPc, and 6T, all of which had almost the same ionized potential as PbPc, were used as buffer layers. The device performance of the cells with VOPc and 6T buffer layers was enhanced by about 1.6 times as compared to that of the cells without a buffer layer. On the other hand, no enhancement was observed in the case of the cell with the H_2Pc buffer layer. The crystal structure of the PbPc layer formed on VOPc and 6T buffer layers was different from that of the PbPc layer formed on the H_2Pc layer or that without a buffer layer. The electrical conductivity and spectrum sensitivity of OSCs are directly correlated with their structural parameters determined by X-ray diffraction. From these results, we conclude that structural variation in PbPc layers directly affects the performance of OSCs containing these layers.

studies, the mobilities were determined by the time-of-flight (TOF) technique which generally requires several micron thick films and is highly out of equilibrium, thus it gives different values from other steady techniques [14]. Alternatively, admittance spectroscopy (AS) appears to be a powerful tool for the investigation of mobility in organic materials with the advantage of no specific requirements for the sample thickness [7,15–18]. Moreover, the space-charge-limited current (SCLC) model with exponentially distributed traps is commonly used to describe the current–voltage (*I–V*) characteristics in organic amorphous semiconductors [19]. It yields information on the energy and density of traps. Nevertheless, how the total density of traps will be changed by doping has rarely been reported.

In this paper, we study the effects of trapping and scattering on the hole transport properties of NPB by *I–V* and capacitance–frequency (*C–f*) characteristics. The variations in the mobility and the total density of traps by doping are well determined. Two different charge transport mechanisms caused by trapping and scattering are clearly shown. It can be seen that this also directly affects the performance of the fabricated organic light-emitting devices.

2. Experimental

2.1. Materials

In order to address how dopants affect hole transport in NPB, three molecules were chosen, i.e., 4,4′,4″-tris (*N*-3-methylphenyl-*N*-phenylamine) triphenylamine (*m*-MTDATA), tris-(8-hydroxyquinolinato) aluminum (Alq_3), and 4,4′,4″-tri(*N*-carbazolyl)-triphenylamine (TCTA). The molecular structures and the corresponding HOMO levels are depicted in Fig. 1. The *m*-MTDATA has a higher-lying HOMO level relative to that of NPB. So it is expected to introduce hole traps when doping it into NPB. In contrast, the Alq_3 and TCTA have lower-lying HOMO levels therefore they would act as scattering centers when doping them into NPB [12,13]. All organic materials were purchased from Nichem and used as delivered.

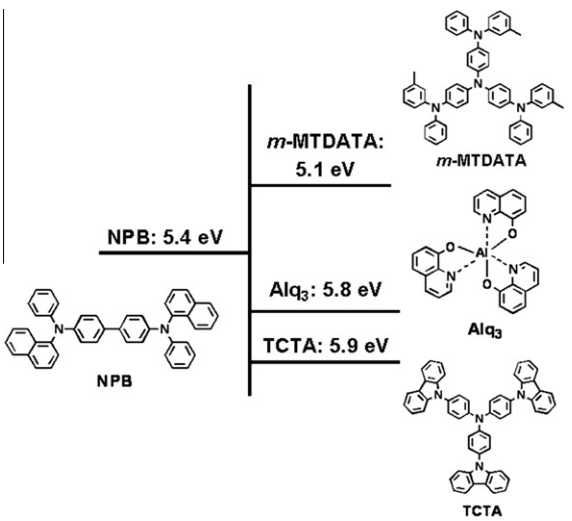

Fig. 1. HOMO energy levels of host material (NPB) and dopants used in this study as well as the corresponding chemical structures.

2.2. Device fabrication

The devices were fabricated by thermal evaporation of the organic materials on indium–tin-oxide (ITO)-coated glass substrates. Prior to deposition, the substrate was thoroughly cleaned in an ultrasonic bath using subsequently detergents and de-ionized water. The surface of ITO substrate was treated with oxygen plasma for 2 min to enhance its work function. Pure and doped NPB films were deposited under a high vacuum (pressure < 10^{-4} Pa). The doped films were deposited by coevaporation process with doping concentration of 4% by weight. In such a low concentration, there are no continuous charge transport channels on the dopant molecules [20]. The thickness was controlled *in situ* by a quarter crystal monitor, and calibrated by Dektak 6M Profiler (Veeco). The aluminum (Al) electrodes were deposited on the organic films through shadow masks. The active area of each device is 16 mm^2.

For the measurements of the temperature dependent *I–V* characteristics, the device had a structure of ITO/molybdenum oxide (MoO_3) (5 nm)/pristine or doped NPB (120 nm)/MoO_3 (5 nm)/Al, where MoO_3 was used to facilitate hole injection from ITO and suppress electron injection from Al [7]. For the AS measurements, the samples had the same structure as mentioned above but the thicknesses were between 120 and 1400 nm for efficiently deriving mobilities in different samples due to the limitation of the maximum frequency in the impedance analyzer [15].

2.3. Measurements

The *I–V* characteristics were carried out using a Keithley 2400 sourcemeter integrated with a vacuum cryostat (Optistat DN-V, Oxford Instruments). The admittance was measured at room temperature by using an Agilent E4980A precision LCR meter in the frequency range of 20 Hz–2 MHz with the oscillation amplitude of the ac voltage kept at 100 mV. The luminance–voltage (*L–V*) characteristics were recorded using a Keithley 2400 sourcemeter and a Keithley 2000 multimeter with a calibrated silicon photodiode.

3. Results and discussion

3.1. I–V and C–f characteristics

Fig. 2a shows the *I–V* characteristics of the hole-only devices based on pristine NPB and doped NPB at room temperature. At a constant current density, the driving voltage increases when dopants are introduced in NPB. In particular, the device based on NPB:*m*-MTDATA shows a pronounced increase in the driving voltage compared with that of NPB: Alq_3 and NPB:TCTA. For example, the high driving voltage is as high as 18.8 V at the current density of 5 mA/cm^2. However, the driving voltages for devices

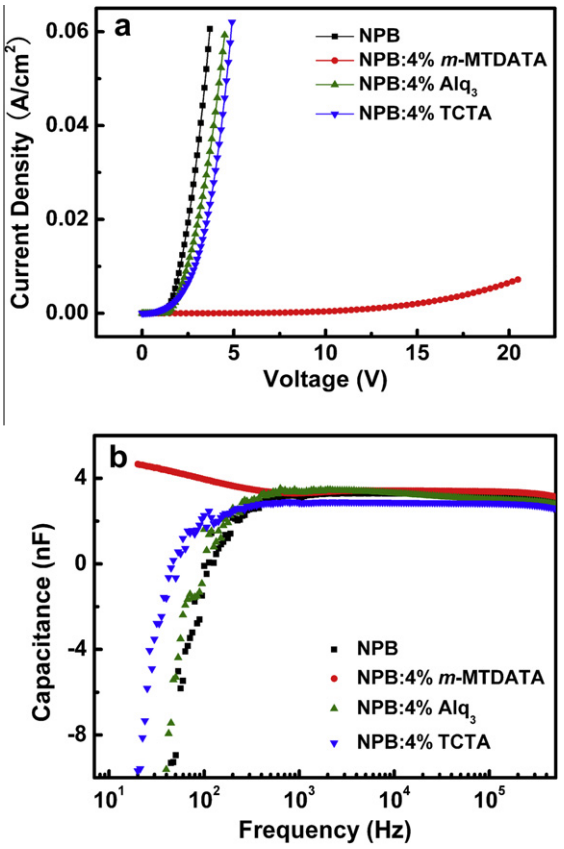

Fig. 2. (a) Current density–voltage characteristics and (b) capacitance–voltage characteristics of undoped and doped devices.

based on NPB, NPB:Alq_3 and NPB:TCTA at 5 mA/cm^2 are 1.6 V, 2.0 V and 2.3 V, respectively. As we know, the mobility and the total trap density play important roles in determining the *I–V* characteristics of organic semiconductor-based devices, which usually obey the SCLC model with exponentially distributed traps [19]. The large differences in *I–V* characteristics in the cases of different dopants should indicate the different roles of traps and scatters in hole transport properties, thus leading to the different changes of the hole mobility and the total trap density in the doping systems.

In order to clearly demonstrate the differences, the capacitance properties of devices based on different doping cases are studied. The frequency dependence of capacitance for different devices at a constant voltage of 3 V is plotted in Fig. 2b. A negative capacitance is observed at lower frequencies for pristine NPB, NPB:Alq_3 and NPB:TCTA, while a positive contribution to capacitance can be seen for NPB:*m*-MTDATA. The negative capacitance stems from the space-charge relaxation transit time [17,21]. When a bias voltage is applied to a device in which SCLC mechanism is dominant, the injected carriers that move into the device will relax to a new equilibrium space-charge distribution, leading to a redistribution of the net charges within a certain transit time. Owing to the finite transit time τ_t for relaxation, the corresponding current lags behind the ac voltage, thus an inductive contribution adds onto the capacitance. For times shorter than τ_t, or frequencies greater than τ_t^{-1}, the injected carriers cannot respond to the frequency within this short duration. Therefore, the negative capacitance disappears. Since the τ_t is directly related with the charge carrier mobility at a constant thickness, it can be concluded that the negative capacitance is prone to appear in a material with high mobility. This fact directly explains the reason why the current densities of NPB:Alq_3- and NPB:TCTA-based devices are higher than that of NPB:*m*-MTDATA-based device, and also implies that the scatterer-doped organic films will show higher mobilities than the trap-doped organic films.

3.2. Mobility determination

In order to gain a deep insight into different effects of trapping and scattering on hole transport properties, admittance spectroscopy (AS) was used to derive the mobilities of different doping cases. In this method, the current response i_{ac} to a small oscillating voltage $v_{ac} = v_o \cdot \cos(\omega t)$ is monitored. The complex admittance Y_{ac} is related to i_{ac} and v_{ac} as follows:

$$Y_{ac} = \frac{i_{ac}}{v_{ac}} = G(\omega) + iB(\omega) = G(\omega) + i\omega C(\omega) \tag{1}$$

where G is the conductance, B is the susceptance, C is the capacitance, and $i^2 = -1$. In addition, the complex admittance Y can be deduced analytically and written by [15]:

$$Y(\Omega) = \frac{\varepsilon\varepsilon_o A}{\tau_{dc} d}\left\{\frac{\Omega^3}{2i[0.75\tilde{\mu}(\Omega)]^2[1-\exp(-\frac{i4\Omega}{3\tilde{\mu}(\Omega)})]+1.5\tilde{\mu}(\Omega)\Omega - i\Omega^2}\right\} \tag{2}$$

where d and A are the thickness and the area of the sample, respectively, ε is the dielectric constant of material, and ε_o is the permittivity of the free space. In the above equation, τ_{dc} is the average hole transit time in the absence of the ac signal, and $\Omega = \omega\tau_{dc}$. The normalized mobility is defined as $\tilde{u}(\Omega) = \mu(\Omega)/\mu_{dc}$, where $\mu_{dc} = d^2/(V\tau_{dc})$ is the *dc* hole mobility in the absence of the *ac* field. To derive the carrier mobility, the imaginary part of *Y*, i.e., the susceptance in frequency domain can be analyzed. Particularly, the negative differential susceptance of the device can be defined as $-\Delta B = -2\pi f(C - C_{geo})$. By plotting $-\Delta B$ as a function of frequency, a characteristic frequency f_{max} at which a maximum of $-\Delta B$ occurs is correlated with the average hole transit time via $f_{max} = 0.56/\tau_{dc}$ [15]. Consequently the carrier mobility can be extracted by the following equation:

$$\mu_{dc} = \frac{f_{max} d^2}{0.56(V - V_{bi})} \tag{3}$$

Fig. 3 presents a series of representative *C–f* and $-\Delta B$–*f* plots for four devices at the given electric field strength. It can be observed that each case shows a minimum capacitance in the intermediate frequency region and then the capacitances tend to their respective geometrical capacitances with increasing frequencies. As shown in insets of Fig. 3, a clear maximum in $-\Delta B$ occurs at a well defined frequency f_{max} for each device. Using Eq. (3), the hole

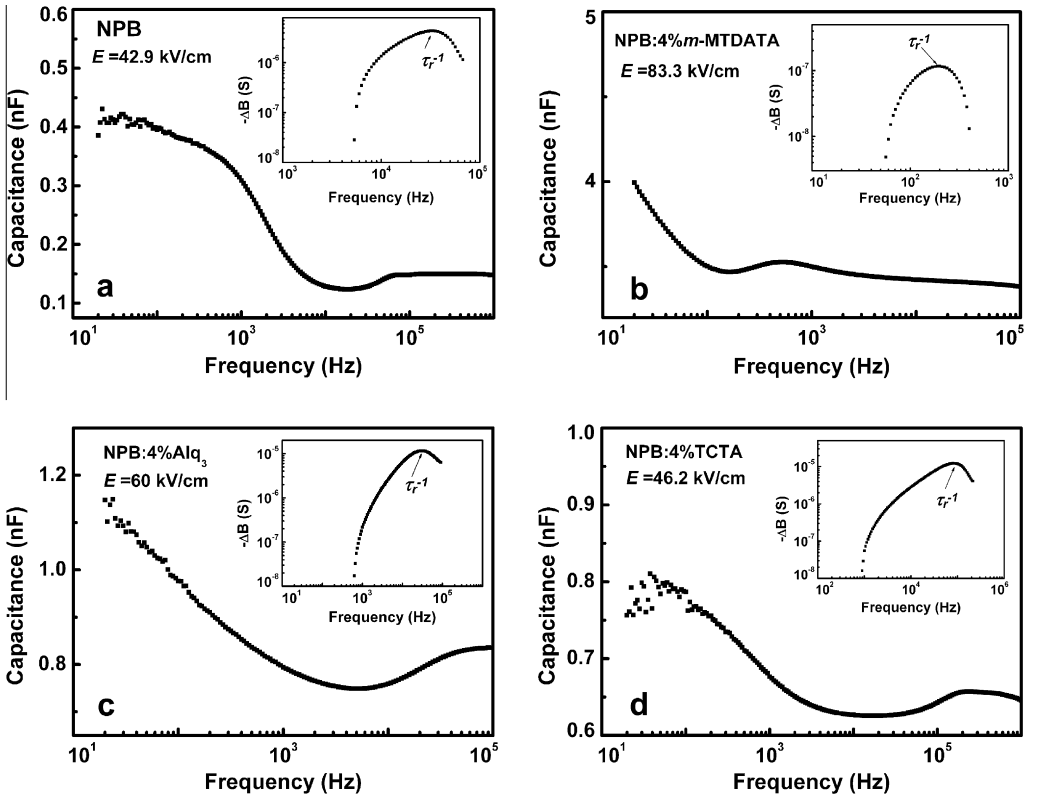

Fig. 3. Capacitances of NPB, NPB:*m*-MTDATA, NPB:Alq_3, NPB:TCTA at room temperature. The insets are the negative differential susceptance $-\Delta B$ versus frequency plots.

mobilities can be evaluated, which are summarized in Fig. 4.

From Fig. 4, it can be clearly seen that the hole mobilities follow the empirical field dependent expression [22]. The hole mobility for the pristine NPB film is in the range of $(2–4) \times 10^{-4}$ $cm^2V^{-1}s^{-1}$ and agrees well with the values reported earlier [16]. In the case of *m*-MTDATA-doped NPB, the hole mobility shows a dramatic decrease of four orders of magnitude. Whereas for NPB doped with Alq_3 and TCTA, the reduction of mobilities is less than one order of magnitude. This phenomenon suggests that trap and scatterer have different effects on hole transport mechanisms [12,13]. In the case of trapping, the mobile holes may be trapped in the generated trap level and detrapped by thermal energy. The processes will lead to the reduction of the mobility due to the additional trap residing times. In the case of scattering, the mobile holes may be hindered by the dopant with a lower-lying HOMO level due to colliding. Although the mobility will lower to a certain degree depending on the difference between the HOMO of NPB and the dopant, holes may transport nearly freely in the film.

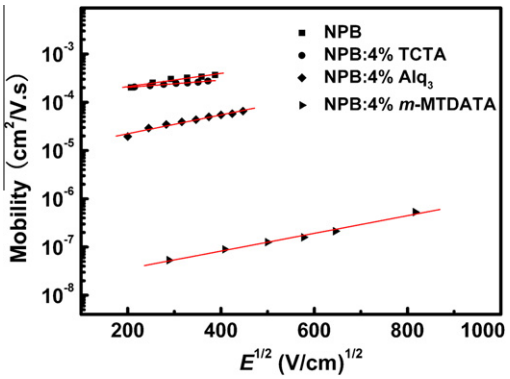

Fig. 4. Hole mobilities of NPB and doped NPB against the square root of the electric field strength. The solid lines are the best linear fits to the data.

3.3. The total density of traps

To further distinguish the different effects of trapping and scattering on the hole transport in NPB, we investigate the temperature dependent *I–V* characteristics of different doping devices. As shown in Fig. 5, the slopes of the *I–V* curves in double logarithmic for each device are greater than 2 at room temperature and increase rapidly with decreasing temperature. This relation leads to the following SCLC model with exponentially distributed traps [19],

$$J = q^{1-l}\mu N_v \left(\frac{2l+1}{l+1}\right)^{l+1} \left(\frac{l}{l+1}\frac{\varepsilon\varepsilon_0}{N_t}\right)^{l} \frac{V^{l+1}}{d^{2l+1}}, \quad (4)$$

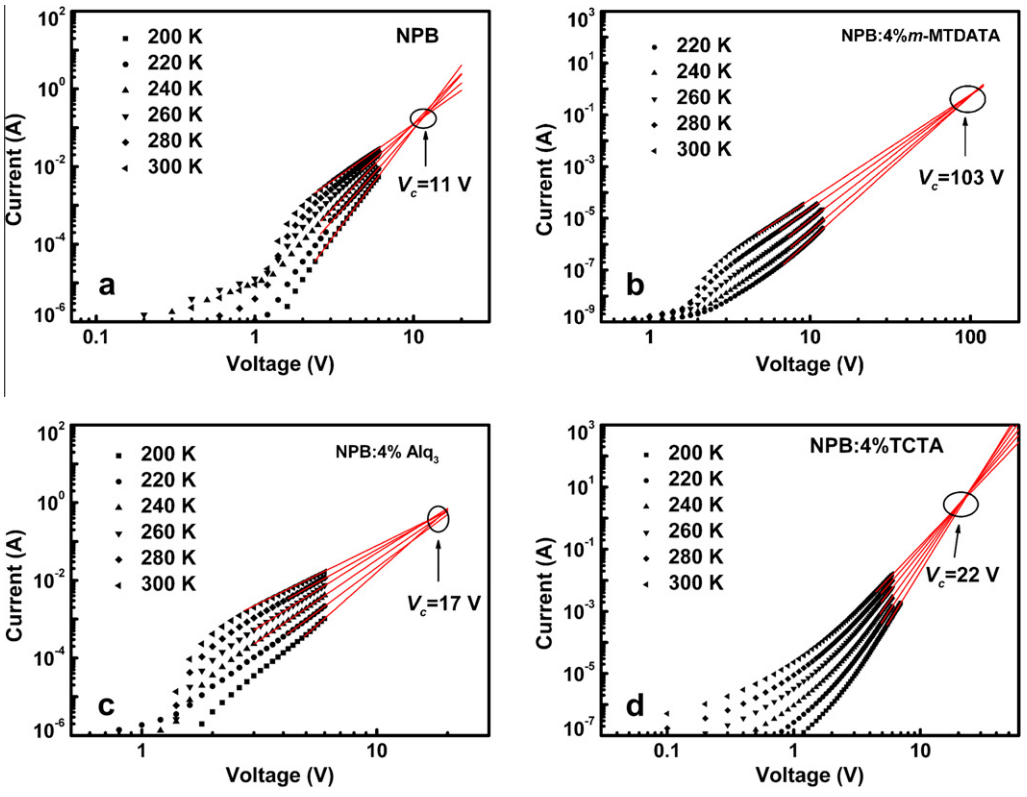

Fig. 5. Extrapolation of the *I*–*V* curves at different temperatures in log–log scale for NPB and doped NPB devices.

where q is the elementary charge, μ is the hole mobility, N_v is the density of states in the valence band, l is an energy parameter given by T_c/T (T_c is characteristic temperature of traps), and N_t is the total density of hole traps. As an analytical method introduced by Kumar et al. [23] to determine N_t, Eq. (4) can be rearranged as follows:

$$J = \frac{q\mu N_v V}{d} f(l) \exp\left[-\frac{T_c}{T} \ln\left(\frac{qd^2 N_t}{2\varepsilon\varepsilon_o V}\right)\right], \tag{5}$$

with

$$f(l) = \left(\frac{2l+1}{l+1}\right)^{l+1} \left(\frac{l}{l+1}\right)^{l} \frac{1}{2^l} \tag{6}$$

For $l > 2$, the value of $f(l)$ is about 0.5, so it can be considered as a constant of 0.5. With this approximation, Eq. (5) becomes a typical Arrhenius form,

$$J = J_o \exp\left(-\frac{E_a}{kT}\right) \tag{7}$$

where

$$E_a = \frac{T_c}{T} \ln\left(\frac{qN_t d^2}{2\varepsilon\varepsilon_o V}\right) \tag{8}$$

For $E_a = 0$, $J = J_o$ and current becomes independent of temperature. The *I*–*V* curves for different temperatures should then converge at a critical voltage,

$$V_c = \frac{qN_t d^2}{2\varepsilon\varepsilon_o} \tag{9}$$

By extrapolating log *I*–log *V* characteristics at various temperatures to higher voltages, V_c can be determined, as shown in Fig. 5. With the obtained V_c and assuming $\varepsilon = 3$, the total density of traps can be calculated as listed in Table 1.

It appears that when *m*-MTDATA is introduced into NPB, the total density of traps increases about one order of magnitude. On the contrary, the total densities of traps for NPB:Alq$_3$ and NPB:TCTA changes a little. This result convinces that the *m*-MTDATA indeed acts as traps in NPB. As a result, the total density of traps is increased and the hole mobility is greatly reduced.

3.4. Electroluminescent device performance

Based on the undoped and doped NPB as the hole-transporting layers (HTL), we also fabricate organic light-emit-

ting diodes with a general configuration of ITO/MoO_3 (5 nm)/NPB or doped NPB layer (60 nm)/NPB (20 nm)/Alq_3: 10-(2-benzothiazolyl)-2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-1H,5H,11H-benzo[*l*]-pyrano-[6,7,8-*ij*]quinolizin-11-one (C545T) (1%, 30 nm)/Alq_3 (30 nm)/LiF (1 nm)/Al. The purpose of inserting a layer of pure NPB between HTL and emitting layer is to block electrons from reaching HTL and make the interfaces between different HTLs and emitting layers the same. It can be observed from Fig. 6a that the current density–voltage (*J*–*V*) and luminance–voltage (*L*–*V*) characteristics differ strongly for OLEDs with trap doped HTL from scatterer doped HTL. The lowest current density in *m*-MTDATA-doped HTL device is obviously consistent with the lowest mobility of *m*-MTDATA-doped NPB film which is in the same order of magnitude as the electron mobility of Alq_3 [24]. Consequently, the *m*-MTDATA-doped HTL device shows the best electroluminescent efficiency due to the balanced electron and hole transport, as shown in Fig. 6b.

4. Conclusions

The effects of trapping and scattering on the hole transport properties of NPB has been well investigated by doping *m*-MTDATA, Alq_3 and TCTA. Temperature dependent current–voltage characteristics, admittance spectroscopy, and luminance–voltage characteristics were used to interpret the roles of trap and scatter played in NPB. It can be seen that doping molecules as trapping increases the density of traps and decreases the hole mobility whereas doping molecules as scattering then does not obviously affect the hole transport, which are attributed to their different roles in hole transporting. This also supplies a method of adjusting charge carrier transport behavior by doping molecules as trapping or scattering, thus optimizing device performance.

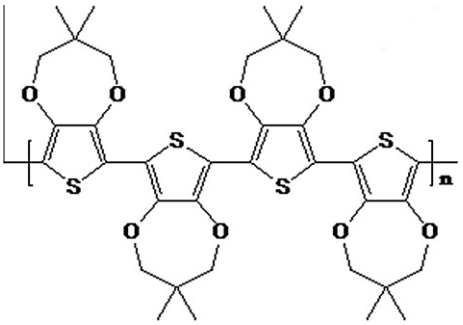

Fig. 1. Structure of PProDOT-Me_2.

decreases, causing the polymer film to become transparent. Slight reduction of the oxidized PProDOT-Me_2 causes the polymer back to its neutral state, resulting in increased the energy band gap and absorption. Further reduction leads the polymer to its deeply colored state. Thus, we can reversibly switch the material's optical properties. We chose this material because of its low oxidation potential, high color-changing and electrochemical stability, ultra fast color-changing speed, and large light transmittance contrast ratio. Furthermore, when exposed to oxygen, moisture, and varying temperatures, it is significantly more stable than other EC polymer candidates [13]. The monomers were electropolymerized in an organic solvent. They underwent oxidation to form radical cations and reacted with other monomers or radical cations to become insoluble polymer chains precipitating on the electrode surface. This easy, inexpensive method can form very thin films (tens of nanometers) [14].

The ECD has a multilayer structural configuration. The EC layer, PProDOT-Me_2 thin film, is electrochemically deposited on indium tin oxide (ITO)-coated polyethylene terephthalate (PET) plastic. The ECD's counter layer, V_2O_5/TiO_2 composite thin film, is also deposited on ITO/PET substrate. The V_2O_5/TiO_2 thin film acts as an ion storage layer that, when paired with the PProDOT-Me_2 thin film, works to maintain the electrical charge balance inside the ECD during color changes. A solution-type electrolyte is sandwiched between the EC and counter layers. This transparent electrolyte layer is a good conductor for small ions, such as ClO_4^- and Li^+, but is an insulator for electrons; inside this layer, ions move quickly during switching.

Our laboratory has developed high-performance ECDs of different sizes and substrates [9–11]. This paper will use both model simulation and experimentation to explore aspects of PProDOT-Me_2: the thin film deposition, its electrochemical and EC properties, its color-changing kinetics, microstructure of the thin film, and charge transport at the polymer/electrolyte interface.

2. Materials and methods

2.1. Materials and reagents

Our lab synthesized ProDOT-Me_2 monomers via an improved method previously reported [2,15]. All starting materials were purchased from Aldrich, except lithium perchlorate ($LiClO_4$, 99% anhydrous, packed under argon), which was purchased from Alfa Aesar. We dried all materials before use and stored them in a glove box filled with argon.

An electrolyte solution was prepared by dissolving 0.1 M of $LiClO_4$ in propylene carbonate (PC). This solution electrolyte was injected into the EC device later using vacuum filling. Special attention must be paid to avoid any contamination from moisture and oxygen. The solution of electrolyte needs to be bubbled by argon gas before use, and all containers should be dried in an oven.

2.2. EC and counter electrodes

PProDOT-Me_2 polymer films were deposited from a 0.01 M monomer in a 0.1 M $LiClO_4$/acetonitrile (ACN) solution. Electrochemical polymerization was carried out on an electrochemical analyzer (CHI 604C, CH Instruments, TX, USA), utilizing the chronoamperometry method [9,16]. We used a three-electrode cell with a silver (Ag) wire as a reference, ITO/PET (purchased from CPFilm, CA, USA, 50 Ω/square surface resistance) as a working electrode and a stainless steel plate as a counter electrode to electrochemically polymerize the film.

In this device design, we adopted vanadium pentoxide and titanium oxide (V_2O_5/TiO_2) composite films. As the ECD's counter film, this composite film exhibits improved performance over the V_2O_5 films used previously. The V_2O_5/TiO_2 composite films were deposited on ITO/PET substrates with the chronoamperometry method [17].

Both of the PProDOT-Me_2 and V_2O_5/TiO_2 composite thin films must be placed into a 0.1 M $LiClO_4$/PC electrolyte solution after deposition. We used the chronocoulometry method to electrochemically condition the films in order to change the inorganic ions in the films, to make them compatible with a $LiClO_4$/PC environment.

2.3. ECD assembly

We placed the V_2O_5/TiO_2-coated ITO/PET on the top of the PProDOT-Me_2-coated ITO/PET so that the active materials faced each other. The electrolyte solution was injected into the space between the two sheets using a vacuum filling system [18]. A UV-curable film sealant (IS 90453, Adhesives Research, Inc., PA, USA) was used as a hermetic barrier to seal the device.

2.4. Characterization methods

We used a surface *profiler* (Dektak 3030, Veeco, NY, USA) and scanning electron microscopy (SEM, FEI Sirion, OR, USA) to study the microstructure of the polymer thin film. We conducted a cyclic voltammetry (CV) study, measured the alternating current (AC) impedance, and conducted an equivalent circuit model simulation using a three-electrode cell on the electrochemical analyzer (CHI 604C) with analysis software (CHI Version 8.13, TX, USA). Optical characterization of the thin film and devices was carried out using a UV–vis–IR spectrophotometer (V-570, JASCO, Tokyo, Japan). The digital photos were recorded

by a high-definition camera (HDR-SR11, Sony, Tokyo, Japan).

3. Results and discussion

3.1. PProDOT-Me_2 film deposition

Generally, ITO substrates must be highly uniform, conductive, and transparent for high-quality optical devices. As the ITO/plastic substrate has greater surface resistance than the ITO/glass substrate, the electric potential drop across the substrate surface is more obvious, resulting in less uniform polymer film. To overcome this disadvantage of the ITO/plastic substrate, we placed an adhesive copper tape electrode (3M, St. Paul, MN, USA) along the edge of the substrate to enhance its electrical conductivity and uniformity. Additionally, we covered the copper tape surface with Teflon tape (Chukoh Chemical Industries, Ltd., Tokyo, Japan) to prevent the polymerization on the copper surface.

Because of the fragility and sensitivity of the PProDOT-Me_2 thin film to experimental conditions, we paid extra attention to electrochemical deposition. We conducted the experiment in inert gas conditions. We achieved a uniform film for the plastic goggle lens that we designed by optimizing the voltage at 1.6 V and using a deposition time of 20 s (Fig. 2). The defect-free deposited film had a vivid blue color. Experimentation demonstrated that films with an approximate thickness of 90–100 nm had the largest light transmittance contrast ratios.

3.2. PProDOT-Me_2 film microstructure and the kinetics of color switching

We performed a color-changing test for the PProDOT-Me_2 film by applying potentials between −1.2 and +1.2 V. The electrochemical process consists of an ion intercalation/deintercalation among the polymer film. In this particular case, anions ClO_4^- in the electrolyte participated in the ion doping/dedoping process [19], as shown in Scheme 1.

We used the cyclic voltammetry (CV) measurement to study the reduction/oxidation of PProDOT-Me_2 thin film. The measurement was recorded at scan rates of 10, 20, 50, and 100 mV/s (see Fig. 3a). The EC polymer film changed from light blue to deep blue, corresponding to a further reduction reaction. When oxidized, the film switched to the transparent state. We found a linear relationship between the square root of the scan rate (X axis) and the cathodic peak current (Y axis), as shown in Fig. 3b. This relationship indicated the color-changing kinetics: the diffusion of ions from the electrolyte into the polymer thin film was the limiting factor for the color-switching speed [20–22].

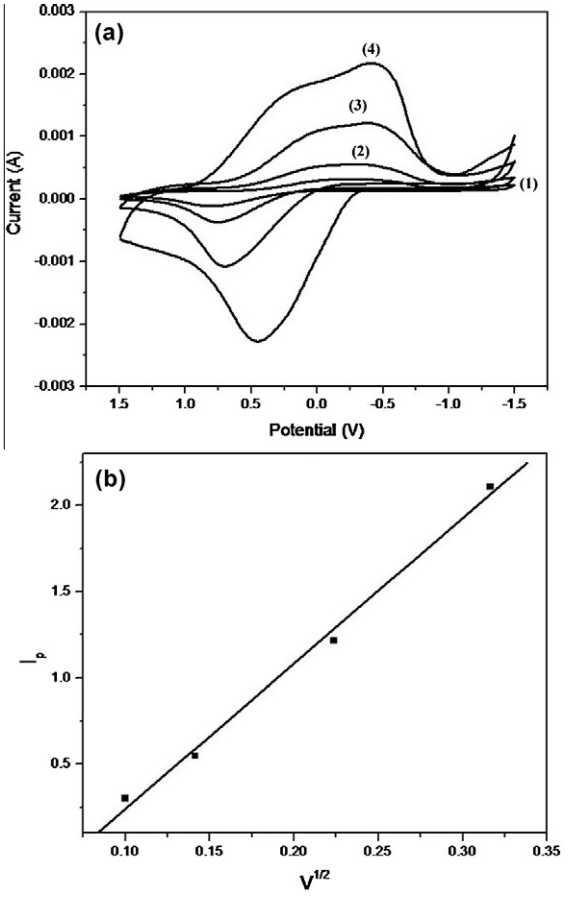

Fig. 3. (a) CV of the PProDOT-Me_2 film at different scan rates (1) 10, (2) 20, (3) 50, (4) 100 mV/s. (b) The linear relationship between the square root of the scan rate (X axis) and the cathodic peak current (Y axis).

The deposited PProDOT-Me_2 thin film had an ultra fast color-changing speed. In a 0.1 M $LiClO_4$/PC electrolyte solution, the film took less than one second to change between its transparent and fully colored states. The EC property of PProDOT-Me_2 arises principally from its redox reaction. During oxidation and reduction of the polymer film, its energy band gap E_g changes, which determines the intrinsic optical/color properties and light transmittance of the material. In order to maintain the charge balance of the polymer film during oxidization (electron removal), counter anions ClO_4^- intercalation is involved. This anion transport through the electrolyte/solid interface to the solid EC polymer film limits the color-changing speed. The

color-changing time is determined by the ion diffusion coefficient [23], as the following equation:

$$T \propto x^2/D \tag{1}$$

where T is the color-changing time, x is the length of ion diffusion path, and D is the ion diffusion coefficient of the polymer film. In this research, the diffusion coefficient D can be calculated using the CV measurement of the polymer film and the Randles–Sevick equation [12]:

$$Ip = (2.6 \times 10^5) n^{3/2} A D^{1/2} C v^{1/2} \tag{2}$$

where Ip is the cathodic peak current from the CV measurement, n is the electron number involved in redox reaction, A is the film area, C is the concentration of electrolyte, v is the scan rate of the CV measurement, and D is the ion diffusion coefficient.

We calculated the ion diffusion coefficient of the PProDOT-Me_2 thin film to be 4.1×10^{-8} cm^2/s, which is comparable to the value of 2.82×10^{-8} cm^2/s obtained from a fast-switching ECD with a color-changing time of 6 ms [24]. This high diffusion coefficient suggests that the film has the potential to change color in milliseconds, an essential advantage for color changeable devices used in intensively light-changing conditions.

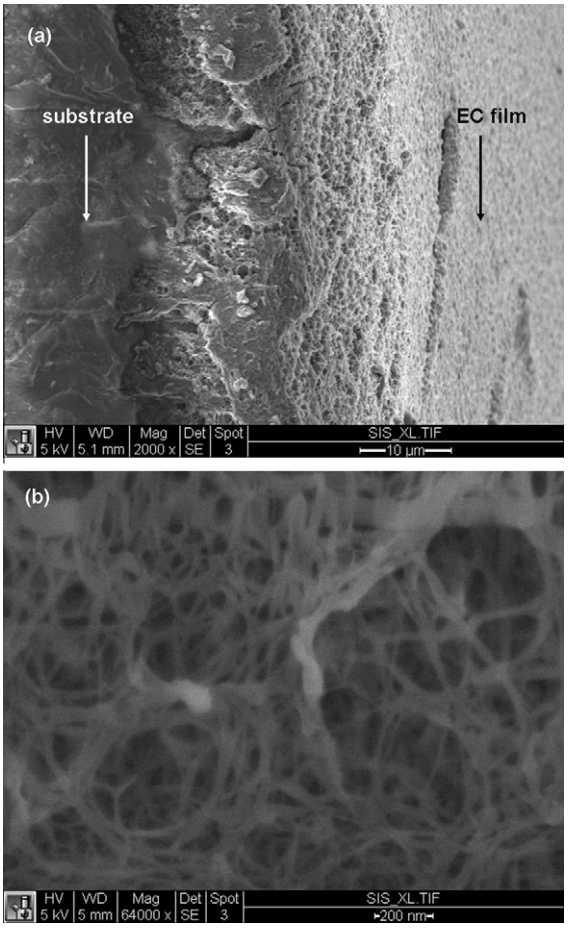

Fig. 4. SEM photos of the PProDOT-Me_2 film (a) cross-section view 2000× and (b) front view 64000×.

We characterized the microstructure of electrochemically deposited PProDOT-Me_2 thin film. Fig. 4 shows the SEM photo of the deposited polymer thin film on ITO/plastic substrate, where (a) is the cross-section view at low magnification and (b) is the front view at high magnification. The rough, porous surface of PProDOT-Me_2 thin film was clearly shown on the substrate. Fig. 4b shows the polymer-wired 3-D network. The polymer wires have diameters of about 30–50 nm, and the holes have diameters of about a hundred nanometers. The porous nanostructure indicates two advantageous EC properties. First, the polymer film has a rich surface area to contact the electrolyte, thus enhancing such EC properties as the light transmittance contrast ratio and coloration efficiency. Second, the nanoscale holes of the film, which fully fill the polymer network, provide good ion diffusion paths that allow ions to migrate easily and smoothly through the "solid" polymer film. Thus, the ions in the EC films are highly mobile.

3.3. Electrochemical AC impedance studies

AC impedance measurements provide important information for charge transfer kinetics [25–30]. Our experiment recorded the electrochemical impedance data using a three-electrode cell setup. To set the redox states of the polymer thin film, we applied a constant base potential, initial E. Negative E signifies the EC film at reduction state, and vice versa. We superimposed a sine waveform onto the base potential. The frequency was scanned from high to low (100 K to 0.01 Hz). The waveform had an amplitude of 5 mV, and we set the initial E to +1.0, +0.1, −0.1, −0.5, and −1.0 V. Fig. 5 shows the measured Nyquist plots : (a) shows the impedance data obtained at +1.0, +0.1, and −0.1 V; (b) shows the enlarged high-frequency region of Fig. 5a; (c) shows the data obtained at −0.5 and −1.0 V with an insert figure showing the enlarged high frequency; (d) shows the simplified and idealized Nyquist plot generalized from the measured AC impedance data of this research. The typical plots can be divided into three regions: the first unfinished semicircle in the high-frequency range, the second semicircle in the middle-frequency range, and a 45° slope Warburg region in the low-frequency range. The tail of the plots curved up, becoming vertical to the real (X) axis at Z'_{low}, because of the pure capacitance response of the polymer thin film. Applying a different initial E set the PProDOT-Me_2 thin film to different redox states, resulting in significant changes to the Nyquist plots. When the applied E changed from positive to negative, the PProDOT-Me_2 thin film transformed from a conductive (transparent) state to an insulative (blue) state. The width of the second semicircle in the Nyquist plots increased with the decreased E. As shown in Fig. 5d, when E became more negative, Z'_{high} stayed constant but Z'_{middle} increased dramatically. This result indicated increased charge transfer impedance at the polymer thin film/electrolyte interface, when the film was reduced. We also noticed that the Warburg region deviated from the ideal 45° angle, which indicated the roughness and non-uniformity of the film surface [31,32]. Meanwhile, the

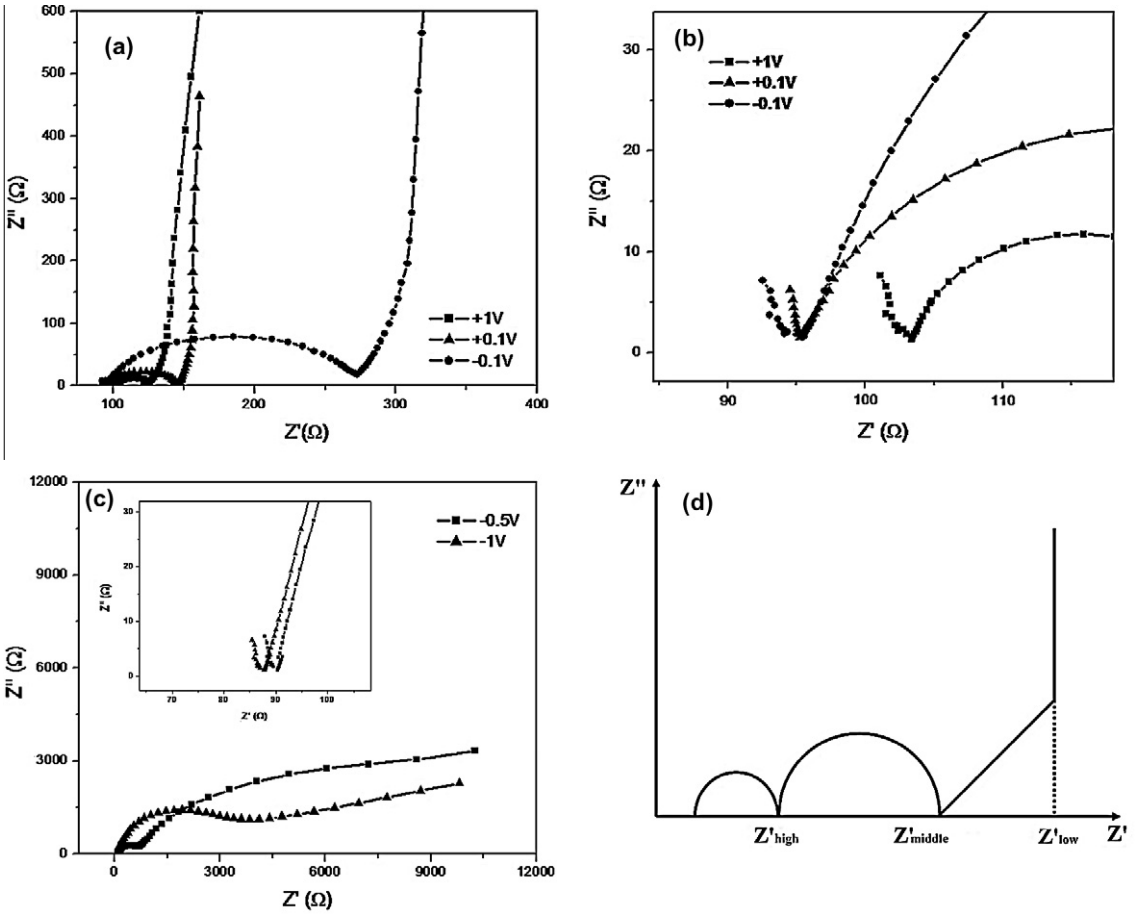

Fig. 5. (a) Nyquist plots of the PProDOT-Me_2 film measured at +1.0, +0.1, and −0.1 V; (b) enlarged high-frequency region of (a); (c) Nyquist plots of the PProDOT-Me_2 film measured at −0.5 and −1.0 V with an insert figure showing the enlarged high-frequency region and (d) simplified and idealized Nyquist plot generalized from the measured AC impedance data.

Warburg region was broadened with the decreased potential, which suggested that the diffusion-controlled impedance was more obvious at negative potentials.

To better understand the charge transfer and color-changing kinetics of the PProDOT-Me_2 thin film, we built an equivalent circuit to describe the behavior of the system at the different redox states, as shown in Fig. 6. In this circuit model, R_0 is the uncompensated resistance related to the solution electrolyte and the polymer thin film/ITO contact; C_g is the geometric capacitance of the electrodes; R_f and C_f are the polymer thin film resistance and capacitance, describing the impedance behavior through the film; R_{ct} is the charge transfer resistance and C_{dl} is the double-layered capacitance at the thin film/electrolyte interface; and W is the Warburg impedance due to the diffusion. The fitting process and estimation of the circuit components were carried out on the electrochemical analyzer (CHI 604C) with preinstalled software. Fig. 7 shows the fitting results; the hollow icons are experimental data, and the solid lines are simulation data. This equivalent circuit provides an accurate fit to the experimental data, especially when the PProDOT-Me_2 thin film is conductive or slightly insulative. As shown in Fig. 7a, the good agreement between experimental data and calculated data continues through the entire measured frequency (insert figure shows the high-frequency range). However, when the polymer thin film was fully reduced at negative potentials, we could observe a deviation from the experimental data at the lower frequency range, as shown in Fig. 7b. The reduction process may be more sensitive to the non-uniform microstructure of the PProDOT-Me_2 thin film, so that the measured Warburg impedance deviated more significantly from the theoretical 45° angle, which was difficult to calculate using the software, resulting in an inaccurate fitting.

3.4. Light transmittance, color-switching speed and repeatability

We monitored the light transmittance of the PProDOT-Me_2 thin film deposited on ITO/PET substrate (shown in Fig. 2) in colored and transparent states in the visible light region (wavelengths from 380 to 800 nm). Fig. 8 shows typical light transmittance data when we applied electric potential of −1.2 and +1.2 V. The flat dashed line shows the light transmittance of the polymer thin film in its

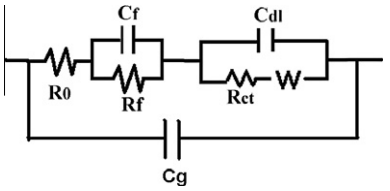

Fig. 6. Equivalent circuit model to describe the impedance behavior of the PProDOT-Me_2 film at different redox states.

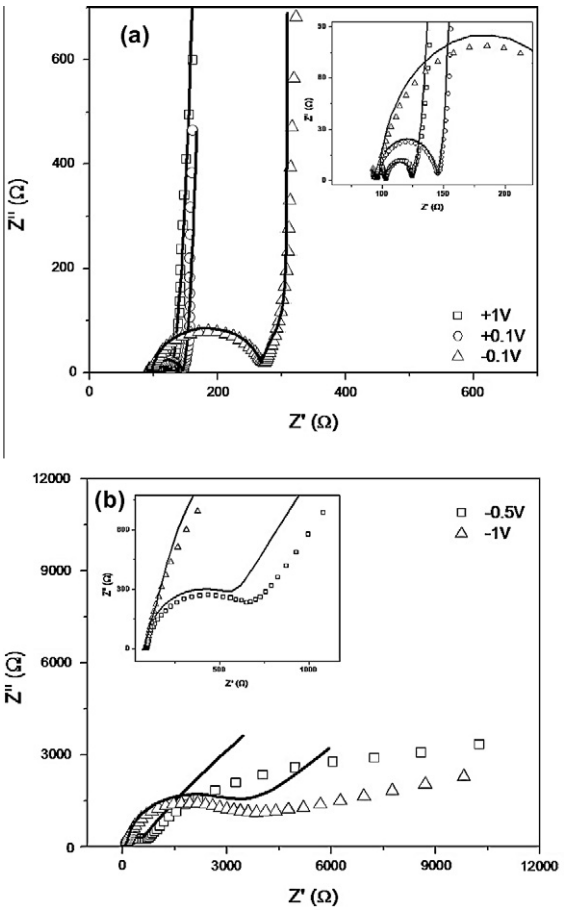

Fig. 7. Fitting of the experimental data at (a) +1.0 V (R_0 = 102.9 Ω, R_f = 1.047e + 10 Ω, C_f = 0.01345F, R_{ct} = 21.5 Ω, C_{dl} = 2.761e-5F, W = 0.05885 Ω $s^{-1/2}$, C_g = 1.269e-9F); +0.1 V (R_0 = 95.97 Ω, R_f = 1.188e + 13 Ω, C_f = 0.03058F, R_{ct} = 48.36 Ω, C_{dl} = 2.79e-5F, W = 0.1151 Ω $s^{-1/2}$, C_g = 1.192e-9F); and −0.1 V (R_0 = 96.85 Ω, R_f = 5.291e + 14 Ω, C_f = 0.02399F, R_{ct} = 156.3 Ω, C_{dl} = 3.274e-5F, W = 0.02538 Ω $s^{-1/2}$, C_g = 1.459e-9F); (b) −0.5 V (R_0 = 92.19 Ω, R_f = 517.8 Ω, C_f = 0.00006605F, R_{ct} = 876.7 Ω, C_{dl} = 0.0007619F, W = 0.0007645 Ω $s^{-1/2}$, C_g = 1.589e-9F) and −1.0 V (R_0 = 89.1 Ω, R_f = 64.34 Ω, C_f = 0.0001377F, R_{ct} = 2890 Ω, C_{dl} = 6.765e-5F, W = 0.0008447 Ω $s^{-1/2}$, C_g = 1.55e-9F).

transparent state, while the "U" shape solid line shows the light transmittance in the colored state. The light transmittance contrast ratio ($\Delta T\%$) is defined in the equation:

$$\Delta T\% = T_t(\lambda) - T_c(\lambda) \quad (3)$$

where $T_t(\lambda)$ and $T_c(\lambda)$ are the light transmittance of certain wave length λ in the transparent state (t) and the colored state (c). Because the absorption peak of the polymer in color state occurred at the 580 nm wavelength, we also calculated the largest contrast ratio at this wavelength. As a result, the transmittance contrast ratio reached 66% (13–79%, shown in Fig. 8). Such a large contrast ratio yields extremely sensitive and effective color changes, as human eyes are most sensitive to light in the 550–600 nm wavelength.

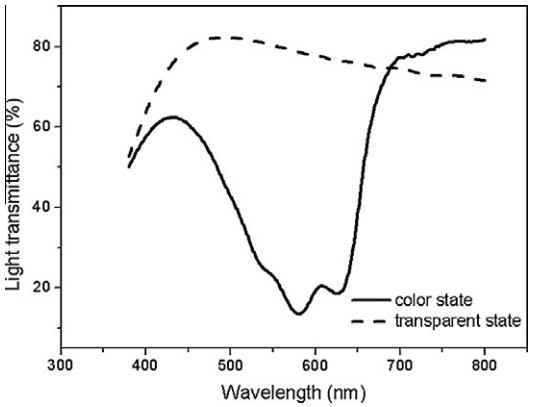

Fig. 8. Light transmittance of the PProDOT-Me_2 film at wavelengths from 380 to 800 nm.

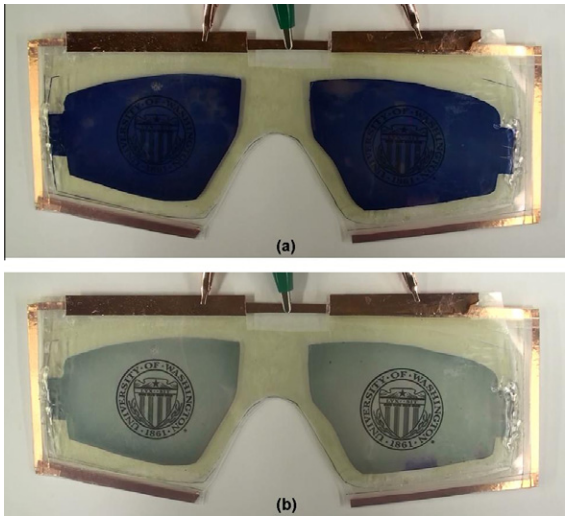

Fig. 9. Assembled goggles lens in (a) colored and (b) transparent states.

The electrolyte was injected into the device by vacuum filling. We describe details of the ECD configuration and assembly elsewhere [10,18]. Fig. 9 shows photos of the assembled goggles lens in the colored and transparent states. We observed fast and vivid color changing of the flexible goggles. We could change the device's color completely using driving electric potentials below 1.2 V. When we subjected the device repeated cyclic changes in the electric potential, the color changed continuously. Fig. 10a shows the repeated cyclic light transmittance data recorded at the 580 nm wavelength. Our apparatus changed the driving electric potential every 2 s to set the every

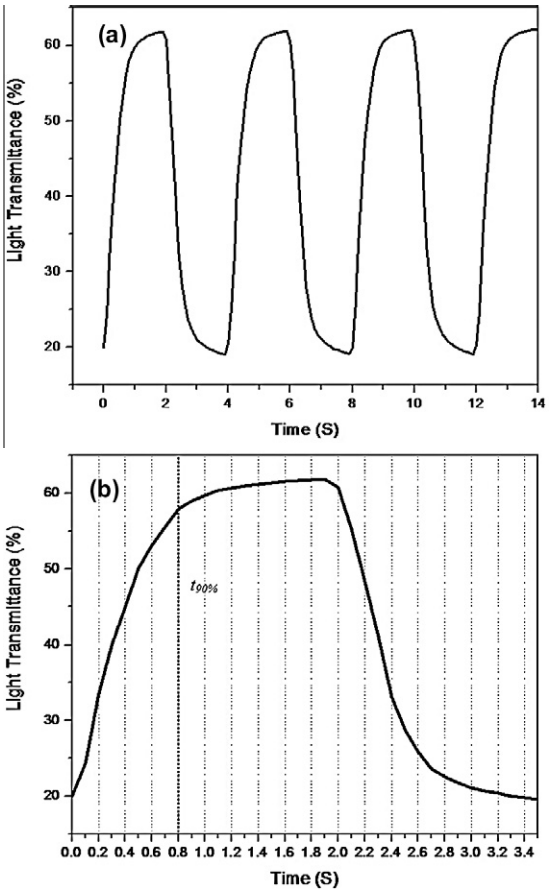

Fig. 10. (a) Cyclic light transmittance data for color switchable goggle lens at 580 nm wavelength. (b) Enlarged 1st cycle.

color-switching period. As the goggles must respond to various lights conditions and perform rapidly during outdoor activities, the color-changing speed of the lens is critical. To determine the switching time, we used the parameter $t_{90\%}$; here, we define $t_{90\%}$ as the time needed for the ECD to reach 90% of a complete color change at the 580 nm wavelength. Fig. 10b shows that $t_{90\%}$ takes about 0.8 s for both bleaching and coloring the lens, as one marked by the thicker dotted line in the bleaching process. This speed, extremely fast for an all-plastic EC device of that size, will suffice for hiking, skiing, motorcycling, and daily driving. The lens also displayed good repeatability and stability. As it continuously changed between the colored and transparent states, the optical spectra curves of different cycles were stable and almost identical to each other. We saw no obvious decay or aging over the 60,000 cycles tested.

4. Conclusions

The calculated high ion diffusion coefficient (4.1×10^{-8} cm^2/s) of the nanoporous PProDOT-Me$_2$ film is consistent with the fast color-changing speed ($t_{90\%}$ 0.8 s) we observed in the device we designed. Our CV study revealed that ion diffusion controls the redox process during color switching. The impedance model, based on the equivalent circuit, fits conductive polymer thin films well but only fits partially for completely reduced films. The goggles we designed and assembled using the film had good dynamic properties and showed promise for military and outdoor activity applications.

we herein report the novel concept of an organic bistable device with thickness control of the insulating layer (LiF) that consists of a new charge trap system (CTS, LiF/Al/LiF) embedded in the organic layer (Alq_3), yielding a device structure of Al/Alq_3/LiF/Al/LiF/Alq_3/Al. The CTS was designed to trap electron carriers, because the insulating layer, LiF, serves as a potential barrier while the Alq_3/LiF structure is a good electron transporting layer (ETL) in an organic light emitting diode (OLED). We reasoned that if the LiF layer was very thin, no electron carriers would accumulate due to easy transport of electron carriers. As the thickness of the LiF layer increases, however, the electrical current would decrease and simultaneously, electron carriers would be trapped. If the LiF layer was sufficiently thick, the electrical current would be expected to decrease sharply with little charge-trapping due to a too high a potential barrier for the charge carriers. Novel devices with thickness control of the insulating layer could potentially be used to exclude subtle filamentary effects in crossbar-type organic memory devices, and guide the development of new prototypes of non-volatile organic memory devices.

2. Experimental

The simple crossbar memory device used for this work was fabricated as follows. All layers were evaporated by thermal evaporation under vacuum (below 2×10^{-6} torr:1 torr $\sim$ 133 Pa). The Al (50 nm) electrode, used as a bottom electrode, was coated on the precleaned glass substrates, followed by Alq3 (50 nm) used as the electron-transporting layer (ETL) in OLED. Then, an LiF layer (2.0, 4.0, or 6.0 nm), a potential barrier of charge carriers, was deposited on the Alq3 to effectively trap electrons from the ETL. The Al layer (3.0 nm), second LiF layer (2.0, 4.0, or 6.0 nm), and second Alq3 (50.0 nm) were sequentially deposited. Finally, the Al (50.0 nm) electrode, as the top electrode, was deposited through a shadow mask defined with an active area of $700 \times 700\ \mu m^2$, resulting in the Al/organic/NT layer/organic/Al structure of memory cells. Current–voltage (I–V) characteristics of the devices were measured using a Keithley 4200 semiconductor characterization system. The I–V curves of the cycle, write–read–erase–read, and stress test were characterized by two Keithley 2400 Series sourcemeters controlled by computer. All electrical measurements were done under ambient conditions.

3. Results and discussion

We fabricated an organic memory device, Al/Alq_3/LiF/Al/LiF/Alq_3/Al, with a CTS consisting of LiF/Al/LiF, located at the center of the Alq_3/Al layer. All layers were evaporated by thermal evaporation under a vacuum. The film thickness of the LiF layer of the CTS was optimimized. The optimized film thickness of the CTS was LiF (4 nm)/Al (3 nm)/LiF (4 nm) and that of the organic-metal layer was Alq_3 (50 nm)/Al (50 nm). Without both Alq3 layers (50.0 nm) served as a buffer layer as well as transporting layer, we used to observe an electrical short problem due to possible diffusion of Al particles even with 6 nm of LiF. Both the top and bottom Al electrodes had a width of 700 μm, giving the device an active area of $700 \times 700\ \mu m^2$. The organic layer consisted of a typical light-emitting material with known organic semiconductor properties (Alq_3) that is commonly used as the ETL in OLEDs. Insertion of a very thin ($\sim$0.5 nm) layer of LiF between the organic layer and the metal cathode has previously resulted in reduced driving voltage of OLEDs [17]. In another report [18], photoelectron emission measurements showed energy-banding and subsequent enhancement of electron carrier injection at the Alq_3/LiF interface. However, thick LiF film ($\sim$ > 4 nm) is a very good insulator with a conductivity of 10^{-10} Scm^{-1} [19], making decomposition of LiF during the evaporation process unlikely. This is consistent with reported photoelectron spectroscopy results [20]. Moreover, even in organic [21] and polymer [22] materials, this buffer layer may isolate the metal impurities in the active medium formed due to diffusion of the metal electrode, which may cause filamentary conduction. Thus, we hypothesized that the use of an adequately thick LiF layer would not only prevent a filamentary conduction mechanism caused by the diffusion of nanoparticles from the metal electrodes, but also provide the advantage of charge trapping in the CTS within the thin-Al layer, yielding a non-volatile organic memory effect.

Typical current–voltage (I–V) characteristics of the device are shown in Fig. 1(a). The device exhibits two states of different electrical conductivity at the same voltage. During the voltage-bias scan, a low current was observed in the bias range from 0 to 4.1 V. A sharp increase in the current took place near 4.1 V, showing the transition of the device from a high-resistance state (OFF state) to a low-resistance state (ON state). As a voltage scan arte increased starting from 100μs, 1, 10 and 100 ms/V, our device showed negligible hysteresis changes [23]. This curve reveals the nonvolatile nature of the memory effect and also indicates that "erasing" is possible; the OFF state can be recovered simply through a reverse voltage scan. To develop a bipolar memory device, we designed the device with structurally and electrically symmetrical structures. Accordingly, regardless of voltage scan direction, the electrical bistable property should be nearly the same, with the exception of the turn-on voltage. A similar phenomenon was observed with Al/Alq_3/Al/Alq_3/Al with a lower turn-on voltage (2.6–3.0 V) [11]. It should be noted that the LiF layer acts as an insulating layer and that this layer is a potential barrier to electron carriers. Because of the LiF insulating layer, the conductivity of the device in the ON state was more than three orders of magnitude larger than that in the OFF state. Electrical switching between the two different states is shown in Fig. 1(b). The voltages for writing, reading, and erasing were 7.0, 2.0, and −0.2 V, respectively. The ON state could be read by a 2.0 V pulse at a current of $\sim 10^{-5}$ A. A negative bias of −0.2 V erased the ON state, producing the OFF state. The OFF state could be detected by a 2.0 V pulse with a current of $\sim 10^{-8}$ A. In addition, the use of a thicker LiF layer to maintain charge trapping resulted in a high write/erase voltage and a slow switching speed. Thus, the device could be controlled by applying an appropriate voltage pulse, resulting in good rewritable characteristics. In addition, we measured the stability of the device under stress using continuous-bias

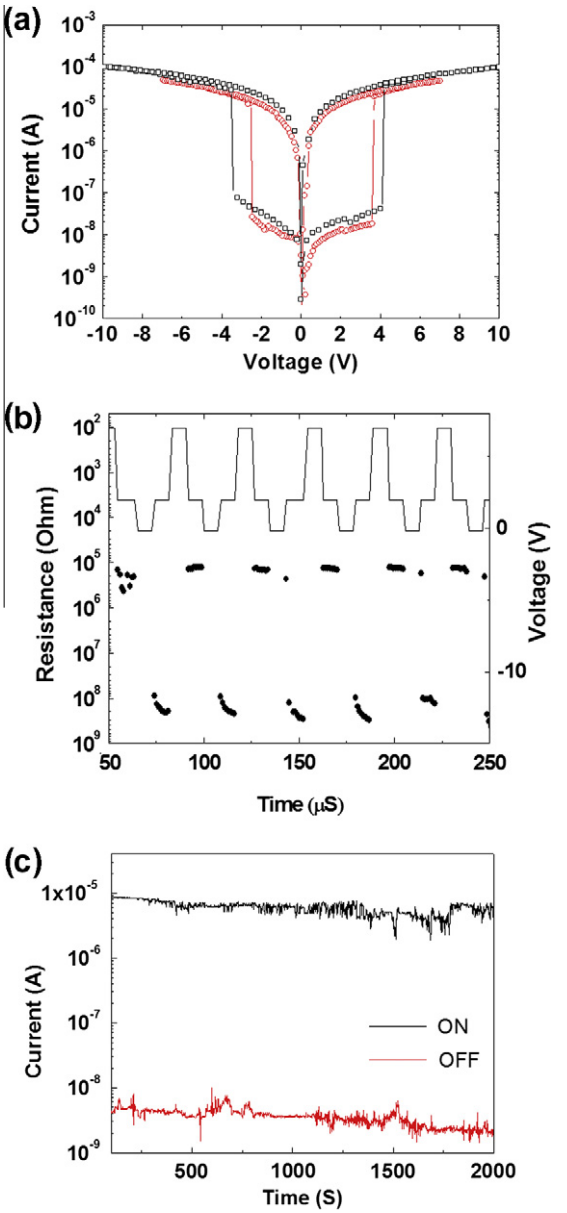

Fig. 1. (a) Current–Voltage characteristics of the Al/Alq3/LiF/Al/LiF/Alq3/Al organic memory device at ±10 V (black rectangle) and ±7 V (red circle). (b) Write–multiple read–erase–multiple read cycles. The top and bottom curves are the applied voltage and the corresponding current response, respectively. (c) Stress tests in both the ON and OFF states. A constant voltage (2.0 V) bias was applied to the device.

conditions; the reuslts are shown in Fig. 1(c). Once the device switched to the other state, it remained in that state for a period of time. Performance under stress is important for practical applications such as binary-information storage. Therefore, we tested the memory retention ability under ambient conditions and evaluated the device under continuous bias conditions. A constant voltage (2.0 V) was applied to the device in the OFF and ON states and each current was recorded at different times. As can be seen from Fig. 1(c), there was little significant degradation of the device in either the ON or OFF state after a continuous stress test. It should be noted that the time scale could not be controlled due to the inherent limitations of the testing equipment and program.

To elucidate the electron transport mechanism of the organic heterostructure device, an energy diagram was used to understand the hysteretic effects shown in Fig. 2(a). When a positive voltage was applied, electrons were injected (1) from the top of the Al (−4.3 eV) electrode into Alq_3 (−3.9 eV). The electrons were further transported through a thick LiF (∼−2.6 eV) [18] layer and then fell into the CTS due to the lower energy levels of Al between the LiF isolating layers. The electrons were trapped in this layer and either accumulated in the thin Al layer or the hetero-interface between the Al and LiF layers beause of the relatively high-energy barrier at a lower bias voltage, until the electrons were filled. However, at the higher bias volt-

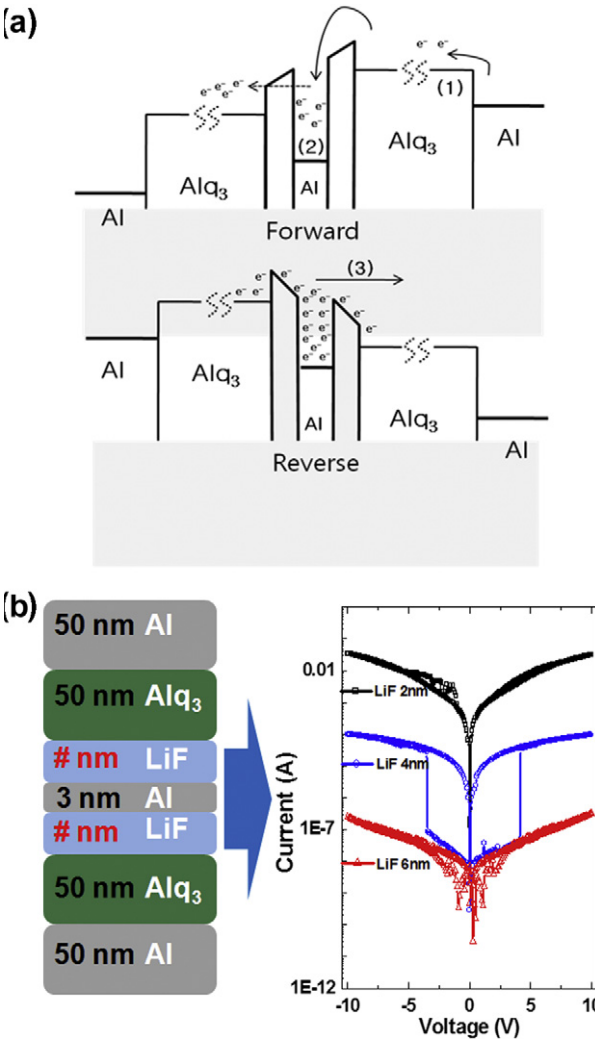

Fig. 2. (a) Schematic diagram of the energy levels of the heterostructure device obtained by applying a bias. (b) Divce structure and current–voltage characteristics of the devices as a function of LiF film thickness (2, 4, and 6 nm).

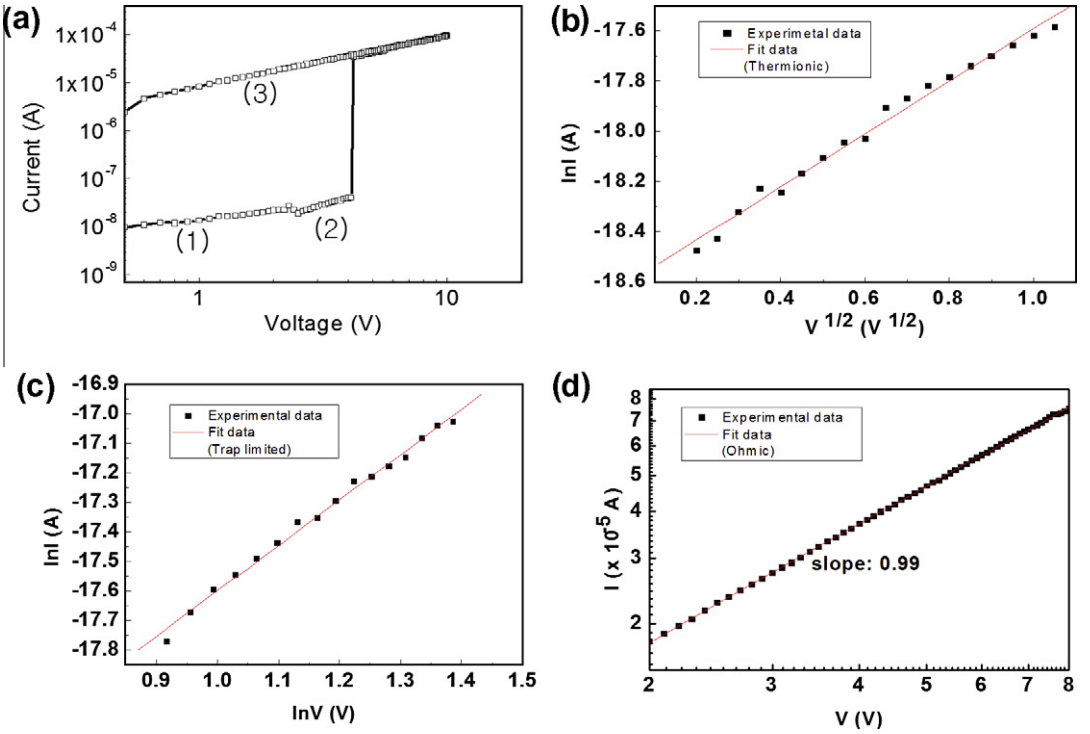

Fig. 3. (a) Current–Voltage characteristics of a heterostructured memory device in a log–log scale. The turn-on voltage is 4.1 with 44 nA and ON current starts from 35 mA at 4.2 V. (b) Thermionic emission fitting on the OFF current (1). (c) Space charge limited current in the CTS layer (2). (d) Ohmic conduction of the turned-on device under high bias conditions.

age, the electrons were able to tunnel (2) through the second LiF blocking layer into the second ETL, causing the device to switch from a high-resistance state to a low-resistance state. At the highest applied voltage, the traps in the CTS are likely to be completely filled, and the electrons kinetically activated by the electrical field could easily run (3) over the potential barrier with preservation of the ON state. As a control experiment, a device with only a thick LiF layer (6.0–11.0 nm) without Al layers between the two LiF layers was evaluated; this device showed no hysteresis.

We suggest that the optimum film thickness for the CTS is 11 nm (LiF (4 nm)/Al (3 nm)/LiF (4 nm)) to observe the hysteresis shown in the middle curve of Fig. 2(b). Due to the chemical reactivity of LiF and Al [24], ultrathin LiF layers have been used to enhance the injection of electrons from metal cathodes. For films with a thickness of 2.0 nm LiF and a fixed Al thickness (3.0 nm), no hysteresis was observed and the electrical current was highest among the three lines depicted in Fig. 2(b). As the thickness of the LiF layer increased to 6.0 nm, however, insulating properties were observed, as shown by the bottom line of Fig. 2(b). Thus, we assumed that a thin LiF layer (<2.0 nm) is not able to trap electrons due to the low potential barrier of the LiF layer, resulting in no hysteresis, while a thick LiF layer (>6.0 nm) does not allow electron transport because of too high a potential barrier, resulting in much less current with little hysteresis. A high built-in field was formed in the CTS under an optimum LiF thickness [25] despite the large dielectric constant of this material ($\varepsilon \sim 9.1$). In summary, control of the thickness of LiF in the CTS enables electron capture across the potential energy barriers of the LiF layers. A combination of potential energy barriers and variations in the thickness of interfacial metal halides in a film could guide the design of nano-scaled, organic hybrid, hetero-structured non-volatile memory devices.

The current–voltage curves have been analyzed to study the mechanism underlying the bistable switching in the memory devices, Fig. 3(a). For the as-fabricated devices under the lower positive bias (step 1 of Fig. 3(a)), the thermionic emission is dominant in the current mechanism as shown in Fig. 3(b). At higher voltages in the intermediate bias region (step 2 of Fig. 3(a)), the dominant current became a space-charged limited current (SCLC) as depicted in Fig. 3(c), indicating that the current was controlled by the trap in the thin Al layer via thermally activated hopping conduction [26,27]. In this regime, the current obeys the Mott-Gurney law as:

$$J = \frac{9\varepsilon\varepsilon_0\mu\Theta V^2}{d^3} \quad (1)$$

where Θ is the trapping fraction, ε is the dielectric constant, and ε_0 is the permittivity of free space. When the voltage was increased further (step 3 of Fig. 3(a)), the traps in the Al metal layer were nearly filled. The current flowed via thermionic emissions and a Fowler–Nordheim conduc-

tion mechanism so that the injected current increased sharply and the electrical state of the device changed simultaneously. After transition from the OFF state to the ON state, most of the traps in the CTS layer were filled and the current flow was free from the influence of traps in the organic heterostructure. When the electrical bias was removed, Fig. 3(d), the current was linearly proportional to the voltage (line slope: 0.99) under the turn-on voltage (4.1 V) as a result of the nonvolatile memory effect. In this regime, the current density J can be described [26,27] as:

$$J = \frac{qn_0\mu V}{d} \quad (2)$$

where n_0 is the density of free carrier, d is the thickness of organic heterostructure, and μ is the carrier mobility. Based on the analysis of the log–log plot of the *I–V* curve, the reversible switching behavior of the organic heterostructure device is due to a release of the stored charge at the middle Al metal layer between the LiF layers. Accordingly, with respect to the above experimental results and discussion, it can be concluded that the electronic transition was attributed to an electrical-field-induced charge transfer between two LiF layers and an Al layer located at the center of the CTS layer through the Alq3 layers.

4. Conclusions

In conclusion, an organic, electrically bistable device with a novel charge trap system (LiF/Al/LiF) was fabricated to develop a vertically oriented crossbar array memory device. Non-volatile memory behavior with a large on/off ratio (more than three orders of magnitude) and writing–reading–erasing–reading cycles were demonstrated. By controlling the thickness of the LiF layer, we were able to determine that the origin of hysteresis was electron charging at the CTS, thereb excluding the possibility of filamentary and metal particle effects. Although the retention time of the devicde still needs to be improved, we anticipate that organic–inorganic heterostructures, such as the one developed in this study, may potentially be applied in nano-scaled organic non-volatile memory devices.

Besides the Suzuki and Stille couplings, Sonogashira coupling is another important way to synthesize conjugated copolymers, which can result into the conjugated polymers with C≡C bonds in the polymer backbone. The C≡C bonds can increase the rigidity and planarity of the conjugated polymers, giving rise to higher charge carrier mobility [25–33]. However, polymerization *via* Sonogashira coupling proceeds quite slowly under a normal heating like oil bath. The molecular weight of the produced polymers is usually low even after polymerization of several days, and the PVs using these polymers as the donor usually exhibit low power conversion efficiency (PCE) [33]. Here, we report the syntheses of copolymers of electron-donating ethynylfluorene and electron-withdrawing 3,6-dithiophen-2-yl-2,5-dihydropyrrolo[3,4-*c*]pyyrole-1,4-dione (DPP) *via* Sonogashira coupling. DPP is used as a unit in the copolymer because it is a very important electron-withdrawing unit in low-band gap copolymers [34–43]. The molecular weight of the copolymers and the photovoltaic performance of the corresponding polymer PVs were significantly improved when the polymers were synthesized under the microwave irradiation.

2. Experimental

2.1. Materials

All reagents were purchased from Sigma–Aldrich and used without further purification unless otherwise noted. All reactions were performed in N_2 unless otherwise noted. 1-Iodo-3,7,11-trimethyldodecane and 3,6-di(thiophen-2-yl)-2,5-dihydropyrrolo[3,4-*c*]pyrrole-1,4-dione were prepared in terms of the literature [38,44].

2.2. Characterization of materials

^{1}H and ^{13}C NMR spectra were measured with a Bruker AC300 spectrometer at 300 and 75 MHz, respectively. Elemental analyses were carried out using a Vario EL elemental analysis instrument (Elementar Co.). Mass spectra were recorded with an EI ionization source and an FAB ionization source using 3-nitrobenzyl alcohol (3-NBA) as the matrix. Absorption spectra were taken with a Varian Cary 5000 ultraviolet–visible spectrometer. Thermogravimetric analyses (TGA) were measured with a Perkin-Elmer TGA-7 at a heating rate of 10 °C min^{-1}. Cyclic voltammetry (CV) was conducted using an Autolab Electrochemical Station. A Pt disk, Pt plate, and Ag/Ag$^+$ electrode were used as working electrode, counter electrode, and reference electrode, respectively. The electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in anhydrous acetonitrile, and the scan rate was 50 mV s^{-1}. Number-average (M_n) and weight-average (M_w) molecular weights were determined by the gel permeation chromatography (GPC) with a Polymer Laboratories PL220 Chromatograph. 1,2,4-Trichlorobenzene and mono-dispersed polystyrenes were used as the solvent and references, respectively. The temperature of the columns was 135 °C during the tests.

2.3. Synthetic procedures

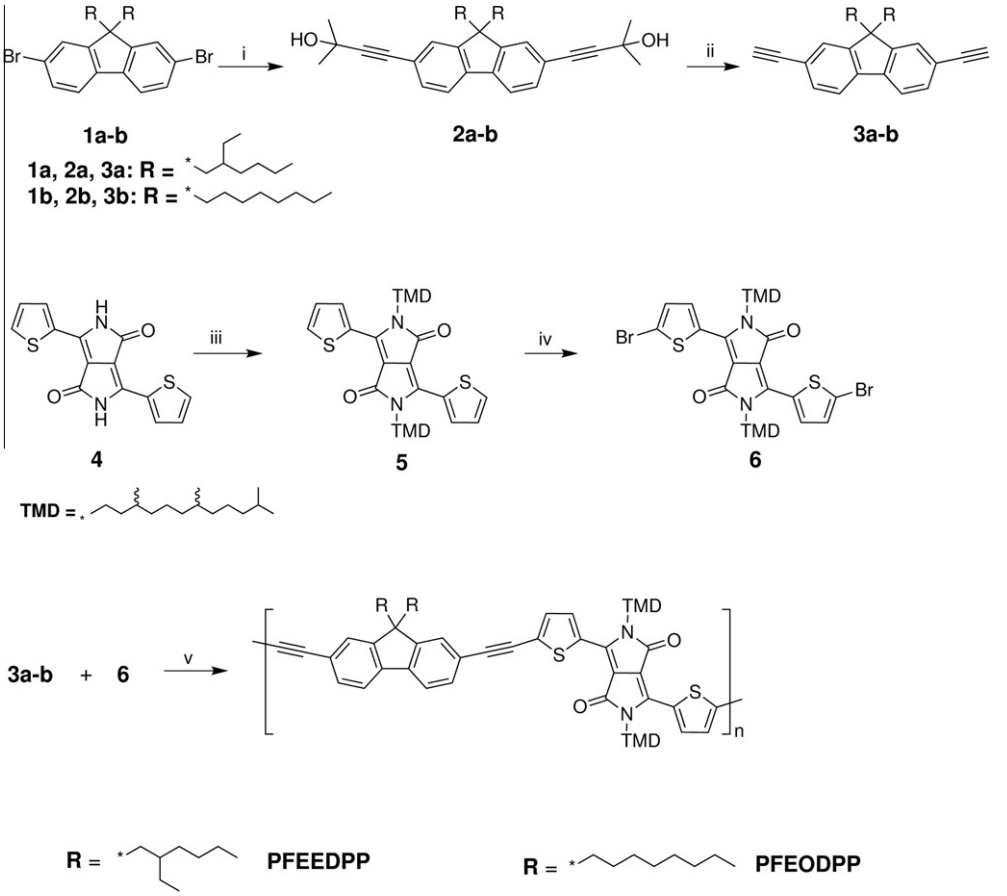
Two copolymers, poly(9,9-bis(2-ethylhexyl)-2,7-diethynylfluorene-*alt*-3,6-dithiophen-2-yl-2,5-dihydropyrrolo[3,4-*c*]pyyrole-1,4-dione) (PFEEDPP) and poly(9,9-dioctyl-2,7-diethynylfluorene-*alt*-3,6-dithiophen-2-yl-2,5-dihydropyrrolo[3,4-*c*]pyyrole-1,4-dione (PFEODPP), were synthesized. The synthetic routes are shown in Scheme 1. The last step, the copolymerization of the two units, was through the Sonogashira coupling, which was carried out in an oil bath or a CEM SP microwave synthesizer.

2.3.1. Synthesis of 9,9-dialkyl-2,7-bis(3-hydroxy-3-methylbutynyl)fluorene (**2a**–**2b**) [45]

2-Methyl-3-butyn-2-ol (1.23 g, 14.6 mmol) was added into a solution of 9,9-dialkyl-2,7-dibromofluorene (**1a** or **1b**) (2 g, 3.65 mmol) in 20 mL of dry THF/diisopropylamine (1:1, v/v). After the solution was degassed with nitrogen for 15 min, $PdCl_2(PPh_3)_2$ (52 mg, 0.07 mmol), PPh_3 (58 mg, 0.22 mmol) and CuI (14 mg, 0.07 mmol) were added. The mixture was then refluxed for 20 h. Then, the reaction mixture was dried by the reduced-pressure evaporation. The title compounds were obtained by purifying the residue with the column chromatography using silica gel (eluent: *n*-hexane/ethyl acetate = 5:1, v/v). **2a**: Pale-yellow powder (1.72 g, 85%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.59 (d, 2H, J = 7.4 Hz), 7.37–7.41 (m, 4H), 2.02–2.04 (m, 2H), 1.94 (d, 4H, J = 5.4 Hz), 1.65 (s, 12H), 0.70–0.98 (m, 22H), 0.52 (t, 6H, J = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 150.82, 150.76, 140.65, 130.66, 127.21, 119.72, 93.64, 82.99, 65.74, 54.81, 44.51, 34.67, 33.37, 33.34, 31.56, 27.94, 27.02, 22.72, 14.07, 10.33. **2b**: Pale-yellow powder (1.78 g, 88%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.59 (dd, 2H, J = 0.5, 7.8 Hz), 7.37–7.41 (m, 4H), 1.87–1.95 (m, 6H), 1.03–1.24 (m, 22H), 0.82 (t, 6H, J = 6.9 Hz), 0.55 (br, 4H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ 150.93, 140.61, 130.74, 126.02, 121.38, 119.79, 93.88, 83.02, 65.75, 55.17, 40.30, 31.77, 31.56, 29.97, 29.21, 23.63, 22.57, 14.05.

2.3.2. Synthesis of 9,9-dialkyl-2,7-diethynylfluorene (**3a**–**3b**) [45]

Compound **2a** or **2b** (1.2 g, 2.16 mmol) was mixed with KOH (0.9 g, 16 mmol) in 2-propanol (20 mL). The solution was refluxed with vigorous stirring for 8 h. Then, the solution was poured into water (50 mL). The organic layer was extracted with diethyl ether, dried over $MgSO_4$, and dried by the evaporation. The title compounds were obtained by purifying the residue with the column chromatography using silica gel (eluent: *n*-hexane). **3a**: Pale-yellow oil (0.88 g, 93%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.63 (dd, 2H, J = 0.7, 7.7 Hz), 7.46–7.52 (m, 4H), 3.12 (s, 2H), 1.96 (d, 4H, J = 5.6 Hz), 0.69–0.90 (m, 22H), 0.44–0.55(m, 6H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 150.79, 140.98, 131.12, 127.76, 120.35, 119.78, 84.44, 76.98, 54.82, 44.35, 34.57, 33.49, 27.94, 26.92, 22.59, 13.87, 10.18. EI-MS: m/z = 438.4 [M]$^+$ (Calcd. 438.3). **3b**: White solid (0.85 g, 90%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.63 (dd, 2H, J = 0.5, 7.8 Hz), 7.46–7.50 (m, 4H), 3.14 (s, 2H), 1.91–1.96 (m, 4H), 0.98–1.26 (m, 20H), 0.80–0.88 (m, 6H), 0.57 (m, 4H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 151.05, 140.98, 131.24, 126.55, 120.85, 119.96,



Scheme 1. Synthetic routes of PFEEDPP and PFEODPP. Reagent and conditions: (i) $PdCl_2(PPh_3)_2$, PPh_3, CuI, diisopropylamine; (ii) KOH, isopropanol; (iii) 1-iodo-3,7,11-trimethyldodecane, DMF, K_2CO_3; (iv) NBS, $CHCl_3$; (v) $Pd(PPh_3)_4$, CuI, toluene, diisopropylamine, oil bath or microwave synthesizer.

84.52, 77.30, 55.21, 40.19, 31.75, 29.92, 29.18, 23.64, 22.57, 14.04. EI-MS: m/z = 438.4 $[M]^+$ (Calcd. 438.3).

2.3.3. Synthesis of 3,6-di(thiophen-2-yl)-2,5-bis(3,7,11-trimethyldodecyl) pyrrolo[3,4-c]pyrrole-1,4-dione (**5**)

Compound **4** (1.0 g, 3.3 mmol) was mixed with K_2CO_3 (1.84 g, 13.3 mmol) in DMF (60 mL). The solution was refluxed at 120 °C for 1 h. Then, 1-iodo-3,7,11-trimethyldodecane (3.94 g, 11.7 mmol) was dropwisely added. The solution was refluxed at 130 °C for 24 h. After cooled down to room temperature, it was poured into water (100 mL). After stirred for 30 min, the water layer was extracted with $CHCl_3$. The $CHCl_3$ phase was combined with the DMF phase. The combined organic phase was dried over $MgSO_4$, and the solvents were removed by the rotary evaporation. The title compound was obtained by purifying the residue with the column chromatography using silica gel (eluent: $CHCl_3$/hexane = 1/1 (v/v) → $CHCl_3$). It was a purple-brown solid (1.6 g, 67%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.90 (dd, 2H, J = 1.1 Hz, 4.0 Hz), 7.63 (dd, 2H, J = 1.1, 5.1 Hz), 7.28 (dd, 2H, J = 4.0, 5.1 Hz), 4.03–4.19 (m, 4H), 0.99–1.77 (m, 40H), 0.82–0.87 (m, 18H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 161.29, 140.01, 135.17, 130.56, 129.72, 128.56, 107.78, 40.83, 39.35, 37.35, 37.26, 37.21, 36.79, 36.71, 32.77, 31.26, 27.95, 24.80, 24.78, 24.33, 22.70, 22.61, 19.71, 19.65, 19.54, 19.47. FAB-MS: m/z = 720.4 $[M]^+$ (Calcd. 720.4).

2.3.4. Synthesis of 3,6-bis(5-bromothiophen-2-yl)-2,5-bis(3,7,11-trimethyldodecyl)pyrrolo[3,4-c]pyrrole-1,4-dione (**6**)

Compound **5** (1.2 g, 1.66 mmol) was dissolved in chloroform in a two-necked round bottom flask covered with aluminum foil. The solution was stirred for 15 min. It was then put in an ice-water bath, and *N*-bromosuccinimide (NBS, 0.622 g, 3.49 mmol) was portionwisely added. The solution was refluxed for 36 h. After the reaction, it was rinsed with water and brine. The organic phase was collected and dried over $MgSO_4$. After the solvent was removed, a dark purple solid was obtained by purifying the residue with the column chromatography using silica gel (eluent: $CHCl_3$) to afford (0.92 g, 63%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.65 (d, 2H, J = 4.1 Hz), 7.22 (d, 2H, J = 4.1 Hz), 3.92–4.09 (m, 4H), 0.99–1.73 (m, 40H), 0.82–0.87 (m, 18H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 160.93, 138.96, 135.26, 131.60, 131.08, 119.08, 107.87, 40.89, 39.36, 37.34, 37.28, 37.18, 37.16, 36.81, 36.73, 32.78,

31.19, 27.97, 24.79, 24.33, 22.71, 22.62, 19.71, 19.65, 19.55, 19.48. FAB-MS: m/z = 878.3 $[M]^+$ (Calcd. 878.3).

2.3.5. Polymerzation

The two copolymers, poly(9,9-bis(2-ethylhexyl)-2,7-diethynylfluorene-*alt*-3,6-dithiophen-2-yl-2,5-dihydropyrrolo[3,4-*c*]pyyrole-1,4-dione) (PFEEDPP) and poly(9,9-dioctyl-2,7-diethynylfluorene-*alt*-3,6-dithiophen-2-yl-2,5-dihydropyrrolo[3,4-*c*]pyyrole-1,4-dione (PFEODPP), were synthesized by the Sonogashira coupling. PFEEDPP-*o* and PFEODPP-*o* were used to denote the two polymers synthesized in a conventional oil bath, respectively. The Sonogashira coupling was performaned by the following procedure. Compound **6** (176 mg, 0.2 mmol), compound **3a** or **3b** (87 mg, 0.2 mmol), $Pd(PPh_3)_4$ (6 mg, 5.2 μmol), and CuI (2 mg, 10.5 μmol) were mixed with anhydrous diisopropylamine (DIPA, 1.4 mL) and anhydrous toluene (4.2 mL) in a 50 mL three-neck flask. The solution was stirred for 30 min at room temperature and then refluxed at 100 °C for 48 h. After the reaction, polymer was precipitated from the solution by adding methanol (250 mL). The precipitate was filtered through a Soxhlet thimble and subsequently purified *via* the Soxhlet extraction for 12 h with methanol, 12 h with *n*-hexane and finally was collected with chloroform. The chloroform solution was concentrated under a reduced pressure. Then, polymer was precipitated by adding methanol again. Solvents were removed by filtration. PFEEDPP-*o*: A blue purple solid (210 mg, 82%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.92 (br, 2H), 7.42–7.69 (br, 8H), 4.12 (br, 4H), 0.55–2.01 (m, 92H). Found: C, 79.20; H, 9.73; N, 2.31; S, 5.59%. Calcd. for $(C_{77}H_{106}N_2O_2S_2)_n$: C, 80.02; H, 9.24; N, 2.42; S, 5.55%. PFEODPP-*o*: A blue purple solid (200 mg, 78%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.94 (br, 2H), 7.39–7.75 (m, 8H), 4.12 (br, 4H), 0.81–2.03 (m, 92H). Found: C, 80.15; H, 9.35; N, 2.44; S, 5.78%. Calcd. for $(C_{77}H_{106}N_2O_2S_2)_n$: C, 80.02; H, 9.24; N, 2.42; S, 5.55%.

The Sonogashira couplings for PFEEDPP and PFEODPP were also carried out in a microwave synthesizer. The polymers obtained with the microwave synthesizer were called PFEEDPP-*m* and PFEODPP-*m*, respectively. Compound **3a** or **3b** (87 mg, 0.2 mmol), compound **6** (176 mg, 0.2 mmol), $Pd(PPh_3)_4$ (6 mg, 5.2 μmol), and CuI (2 mg, 10.5 μmol) were mixed in a 10 mL microwave tube. The tube was subjected to the following reaction conditions in the microwave synthesizer: close vessel, 100 °C for 15 min (hold time), 200 W for power. Then, the polymers were collected and purified through the similar procedure to that for PFEEDPP-*o* and PFEODPP-*o*. PFEEDPP-*m*: A blue purple solid (238 mg, 93%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.93 (br, 2H), 7.43–7.70 (m, 8H), 4.11 (br, 4H), 0.57–2.02 (m, 92H). Found: C, 80.09; H, 9.51; N, 2.21; S, 5.66%. Calcd. for $(C_{77}H_{106}N_2O_2S_2)_n$: C, 80.02; H, 9.24; N, 2.42; S, 5.55%. PFEODPP-*m*: A blue purple solid (246 mg, 96%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.95 (br, 2H), 7.39–7.73 (m, 8H), 4.12 (br, 4H), 0.80–2.01 (m, 92H). Found: C, 80.10; H, 9.45; N, 2.31; S, 5.76%. Calcd. for $(C_{77}H_{106}N_2O_2S_2)_n$: C, 80.02; H, 9.24; N, 2.42; S, 5.55%.

2.4. Fabrication and characterization of polymer PVs

Polymer PVs were fabricated through the conventional process. Patterned indium tin oxide (ITO) glass substrates were sequentially cleaned with detergent, de-ionized (DI) water, acetone, and isopropanol. They were then treated with UV ozone for 15 min. A layer of poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) with a thickness of 30 nm was formed on each ITO glass by spin-coating a PEDOT:PSS aqueous solution (Baytron 4083 from H.C. Starck) and dried at 150 °C for 30 min. The active layer was prepared on the PEDOT:PSS film by spin coating a solution consisting of a polymer synthesized in this research work and [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) in a glove box filled with N_2. The film thickness of the active layer was controlled at about 80 nm, which was measured with a profilometer (Alfa-Step 500, Tencor Instruments). The PVs were completed by thermally depositing a 5 Å-thick LiF layer and subsequently a 100 nm-thick Al layer in a vacuum of 10^{-6} Pa. Each device had an area of 0.11 cm^{-2}.

The polymer PVs were encapsulated with a UV-curable epoxy and glass sheets in the glove box. Then, they were taken out for the electrical tests in air. The photovoltaic performance was measured with a computer-programmed Keithley 2400 source/meter and PVs under the illumination of a Newport's Oriel class A solar simulator, which simulated the AM 1.5G sunlight (100 mW cm^{-2}) and was certified to the JIS C 8912 standard.

Incident photon-to-current conversion efficiencies (IPCE) of the PVs were measured with a 300 W Xenon Lamp (Oriel 6258) as the light source and a Cornerstone 260 Oriel 74125 monochromator that had a resolution of 10 nm. The light intensity was calibrated with a NREL-recommended Si detector (Oriel 71030NS), and the short circuit currents of the PVs were determined with an Oriel 70310 optical power meter.

3. Results and discussion

3.1. Material synthesis and characterization

Two copolymers, PFEEDPP and PFEODPP, were synthesized by Pd-catalyzed Sonogashira coupling. The electron-donating fluorene is connected with the electron-withdrawing DPP unit through the rigid C≡C. Alkyl chains are attached to fluorene and DPP units in order to improve the polymer solubility in organic solvents. The differences in the chemical structure of the two polymers are the side chains connected to the fluorene moiety.

Two heating methods, oil bath and microwave synthesizer, were applied during the Sonogashira coupling of two monomers for PFEEDPP and PFEODPP. Suffices "-*o*" and "-*m*" are attached to PFEEDPP and PFEODPP to indicate the polymerization in the oil bath and the microwave synthesizer, respectively. Applying the microwave synthesizer remarkably lowered the Sonogashira coupling time. The polymerization took 2 days by refluxing in the oil bath at 100 °C, while it was shortened to 15 min in the microwave synthesizer at 100 °C.

Table 1
Number-average molecular weight (M_n), polydispersity index (PDI), and optical parameters of PFEEDPP-*o*, PFEODPP-*o*, PFEEDPP-*m*, and PFEODPP-*m*.

Polymer	M_n (kDa)	PDI	Absorption maxima (nm)		E_g^{opt} [b] (eV)
			Film	Solution[a]	
PFEEDPP-*o*	24	2.2	378, 650	378, 633	1.85
PFEODPP-*o*	20	2.5	391, 648	374, 635	1.86
PFEEDPP-*m*	63	4.4	379, 652	373, 635	1.85
PFEODPP-*m*	89	5.3	372, 668	374, 635	1.85

[a] Chloroform solution.
[b] Optical band gap values obtained from solution spectra.

Besides the polymerization rate, applying the microwave irradiation during the polymerization significantly improved the quality of the polymers as well. The solutions of PFEEDPP-*m* and PFEODPP-*m* were more viscous than that of PFEEDPP-*o* and PFEODPP-*o* at the same weight concentration. This is due to the different molecular weights of the polymers (Table 1). As determined by GPC, PFEEDPP-*m* and PFEODPP-*m* had the number-average molecular weights of 63,000 and 89,000 Da. They were significantly higher than that (24,000 and 20,000 Da) of PFEEDPP-*o* and PFEODPP-*o* (Table 1). All the polymers had good solubility in chloroform and chlorobenzene but a poor solubility in 1,2-dichlorobenzene (DCB) at room temperature. Their solubility in DCB became good at 90 °C.

3.2. Optical properties

The chloroform solutions of these polymers were investigated by UV–vis absorption spectroscopy (Fig. 1a). The optical data are summarized in Table 1. The solution spectra of the four polymers are quite similar. Two absorption bands appear in the range from 480 to 700 nm, which include a shoulder band peaked at *ca.* 590 nm and another peak at *ca.* 635 nm. Both of them can be assigned to intramolecular charge transfer (ICT) of donor–acceptor structures of the polymers [38,42]. In addition, we did not observe any difference in the absorption of these polymers

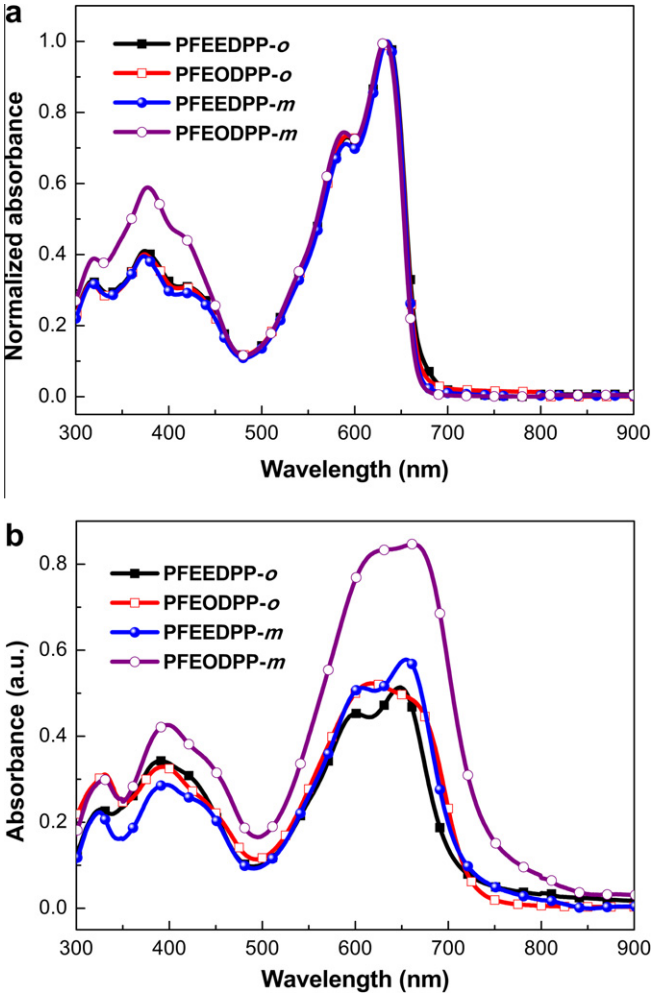


Fig. 1. UV–vis absorption spectra of PFEEDPP and PFEODPP (a) solutions in chloroform and (b) films on quartz. All the polymer films in (b) have the same thickness of 80 nm.

in $CHCl_3$ and DCB. This is different from some DPP copolymers, which exhibits absorption sensitive to the solvent [35,43].

Polymer films formed on quartz by spin coating their chloroform solutions were studied by UV–vis absorption spectroscopy as well (Fig. 1b). Though the PFEEDPP-*m* with PFEEDPP-*o* and PFEODPP-*m* with PFEODPP-*o* films have the same normalized absorption spectrum, PFEEDPP-*m* and PFEODPP-*m* have higher absorption coefficient in the visible range. This may be due to higher interchain interactions in the latter two polymer films [46,47]. The absorptions of PFEEDPP-*o* and PFEEDPP-*m* films shift to red by 17 nm compared with their solution absorptions. More significant change was observed in the absorption of PFEODPP-*o* and PFEODPP-*m* from solution to film. The absorption shifts to red by 33 nm. The red shifts in the absorption from solution to film of the polymers can be attributed to the interchain interactions in the polymer films. It is inferred that the interactions among the PFEODPP chains are stronger than among the PFEEDPP chains. This arises from the different side chains of these two polymers, as a linear side chain can usually cause the polymer chains more compact [13,48]. This may also be the reason for the higher absorption coefficient of the PFEODPP-*m* film than the PFEEDPP-*m* film in the visible range.

3.3. Electrochemical behavior and thermal stability

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the donor materials determine the open-circuit voltage (V_{oc}) and the charge separation of PVs. The HOMO and LUMO levels of PFEEDPP and PFEODPP were studied by CV and calculated in terms of the oxidation (E_{ox}) and reduction (E_{red}) potentials versus Ag/AgCl [49],

$$E_{HOMO} = -e(E_{ox} + 4.71)\ (eV) \quad \text{and}$$
$$E_{LUMO} = -e(E_{ox} + 4.71)\ (eV).$$

Fig. 2 presents the CVs of the four polymers in acetonitrile solutions. E_{ox}, E_{red}, and the calculated HOMO/LUMO levels are listed in Table 2. The band gaps of the polymers by the electrochemical study agree well with the optical absorption spectroscopy.

Thermal stability of these polymers was investigated by TGA (Fig. 3). The TGAs of PFEEDPP-*o* and PFEODPP-*o* coincide with that of PFEEDPP-*m* and PFEODPP-*m*, respectively, so they are not shown. The temperature corresponding to the weight loss of 5% (T_d) is defined as the decomposition temperature. They are higher than 380 °C for these polymers.

3.4. Polymer PVs

The HOMO/LUMO levels, the band gap and the thermal stability of these polymers suggest that they can be used as the donor materials in polymer PVs. Polymer PVs were fabricated using these polymers as donors and PCBM as acceptor. The *J*–*V* curves of the polymer:PCBM PVs with the active layers processed from the DCB solution are presented in Fig. 4. All the polymer PVs exhibited relatively high V_{oc} values, due to the lower HOMO levels of the polymers. These V_{oc} values are comparable to polymer PVs using other fluorene-DPP copolymers [37,38,41].

The device fabrication conditions were optimized, including the donor-to-acceptor ratio, annealing temperature and time, and solvent. The optimal polymer-to-PCBM weight ratio was 1:3, and the optimal thickness of the active layers was 80 nm. These optimal conditions are similar for the PVs with other DPP-based polymer donors

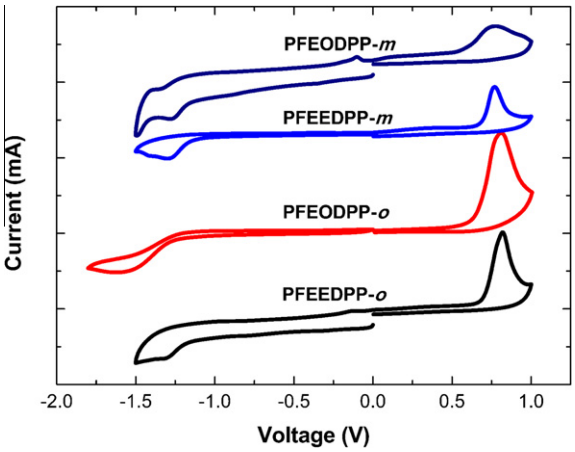

Fig. 2. Cyclic voltammograms of PFEEDPP-*o*, PFEODPP-*o*, PFEEDPP-*m* and PFEEDPP-*m* films.

Table 2
Electrochemical potentials and decomposition temperatures of PFEEDPP-*o*, PFEODPP-*o*, PFEEDPP-*m* and PFEODPP-*m*.

Polymer	E_{ox} (V)	E_{red} (V)	E_{HOMO} (eV)	E_{LUMO} (eV)	T_d (°C)
PFEEDPP-*o*	0.70	−1.17	−5.41	−3.54	388
PFEODPP-*o*	0.63	−1.23	−5.34	−3.48	394
PFEEDPP-*m*	0.68	−1.15	−5.39	−3.56	388
PFEODPP-*m*	0.56	−1.16	−5.27	−3.55	395

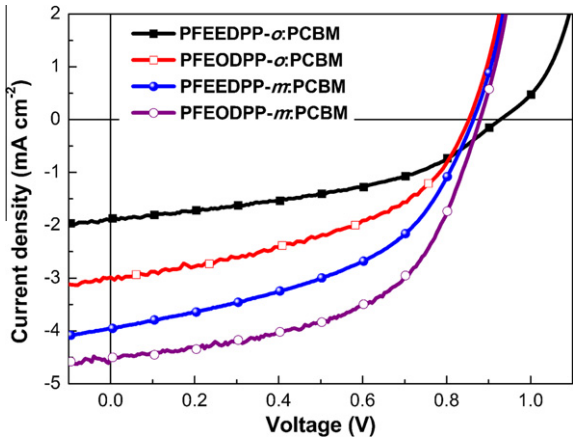

Fig. 4. *J–V* curves of PVs glass/ITO/PEDOT:PSS/polymer:PCBM/LiF/Al with PFEEDPP-*o*, PFEODPP-*o*, PFEEDPP-*m* and PFEODPP-*m* as the donor materials under AM 1.5G illumination. The active films with the polymer-to-PCBM weight ratio of 1:3 were fabricated by spin coating DCB solutions of polymers and DCB. The polymers are indicated in the figure.

Table 3
Short-circuit current (J_{sc}), open-circuit voltage (V_{oc}), fill factor (FF) and PCE of PVs ITO/PEDOT:PSS/polymer:PCBM/LiF/Al under AM 1.5G illumination. Different solvents were used for the fabrication of the polymer:PCBM films.

Polymer	Solvent	J_{sc} (mA cm^{-2})	V_{oc} (V)	FF	PCE (%)
PFEEDPP-*o*	Chloroform	1.76	0.89	0.42	0.66
PFEEDPP-*o*	Cosolvent[a]	2.01	0.92	0.43	0.80
PFEEDPP-*o*	DCB[b]	1.90	0.93	0.44	0.78
PFEODPP-*o*	Chloroform	1.54	0.87	0.48	0.64
PFEODPP-*o*	Cosolvent[a]	2.99	0.85	0.46	1.16
PFEODPP-*o*	DCB[b]	3.28	0.88	0.47	1.34
PFEEDPP-*m*	Chloroform	2.45	0.82	0.48	0.96
PFEEDPP-*m*	Cosolvent[a]	3.41	0.85	0.43	1.25
PFEEDPP-*m*	DCB[b]	3.95	0.86	0.48	1.63
PFEODPP-*m*	Cosolvent[a]	4.24	0.90	0.59	2.25
PFEODPP-*m*	DCB[b]	4.52	0.88	0.55	2.19

[a] Cosolvent of chloroform and 1,2-dichlorobenzene (DCB) with volume ratio of 4:1.
[b] The active layer was spin coated from DCB solution at 90 °C.

[34,38,42]. We studied the effect of annealing the polymer:PCBM films on the photovoltaic performance of the devices. But no remarkable effect was observed.

Chloroform, DCB and their cosolvents were used as the solvent for the polymers and PCBM since polymer PVs using DDP-based polymers usually have photovoltaic performance sensitive to the solvent [34,38]. The PVs fabricated from chloroform solutions exhibited low photovoltaic performance (Table 3). The photovoltaic efficiency was significantly improved when cosolvent of chloroform and DCB was used. In addition, we found that the PVs fabricated from DCB solutions at 90 °C had a photovoltaic efficiency comparable to that from the cosolvent solution. The PFEEDPP-*m*:PCBM PVs fabricated from the DCB solution exhibited the photovoltaic efficiency even higher than from the solution of cosolvent.

Compare the photovoltaic performances of the polymer PVs with the four polymers, we can conclude that the heating method during the Sonogashira coupling

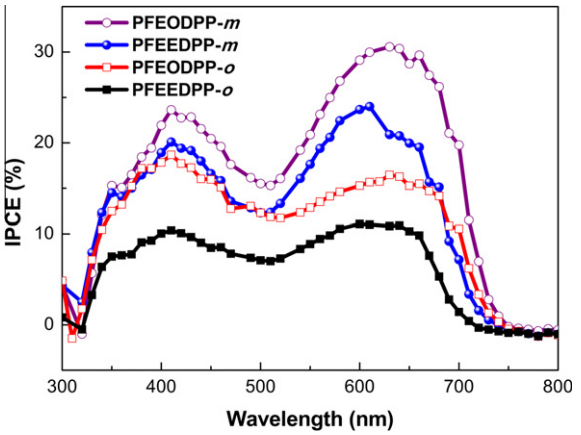

Fig. 5. IPCEs of polymer:PCBM (1:3 w/w) PVs. The active layers were fabricated from DCB solutions.

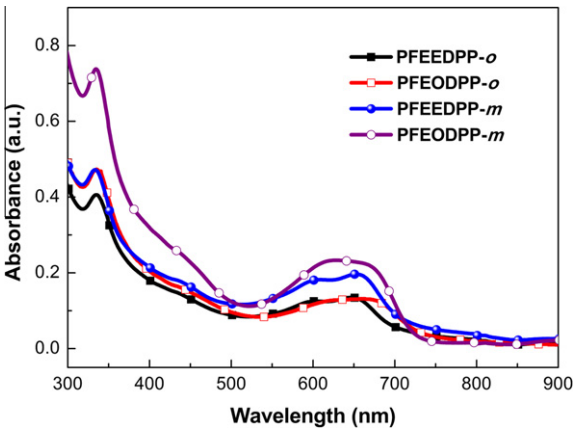

Fig. 6. UV–vis absorption spectra of polymer:PCBM films. All the films had a same thickness of 80 nm.

strongly affects the performance of the polymer PVs. The PFEEDPP-*m*:PCBM and PFEODPP-*m*:PCBM PVs always exhibited higher photovoltaic efficiencies than the PFEEDPP-*o*:PCBM and PFEODPP-*o*:PCBM PVs. The optimal PCE of the PFEEDPP-*m*:PCBM PV was 1.63%, which was twice of that of the PFEEDPP-*o*:PCBM PV. The PFEODPP-*m*:PCBM PV exhibited the highest PCE of 2.25% among the PVs.

In order to understand the different photovoltaic performances of these PVs with the four polymers, we studied the IPCE, absorption, surface morphology and mobility of the active films. Fig. 5 presents the IPCEs of the four PVs in Fig. 4. They are consistent with the UV–vis absorption spectra of the four active films as shown in Fig. 6. The differences can be attributed to the different absorption coefficients of the polymer films.

Besides the optical absorption of the active films, the film morphology can affect the photovoltaic performance of the devices as well [50–52]. The AFM images of the four polymer:PCBM films are presented in Fig. 7. Salient difference in the film morphology was observed. The PFEEDPP-*o*:PCBM and PFEODPP-*o*:PCBM films have remarkably

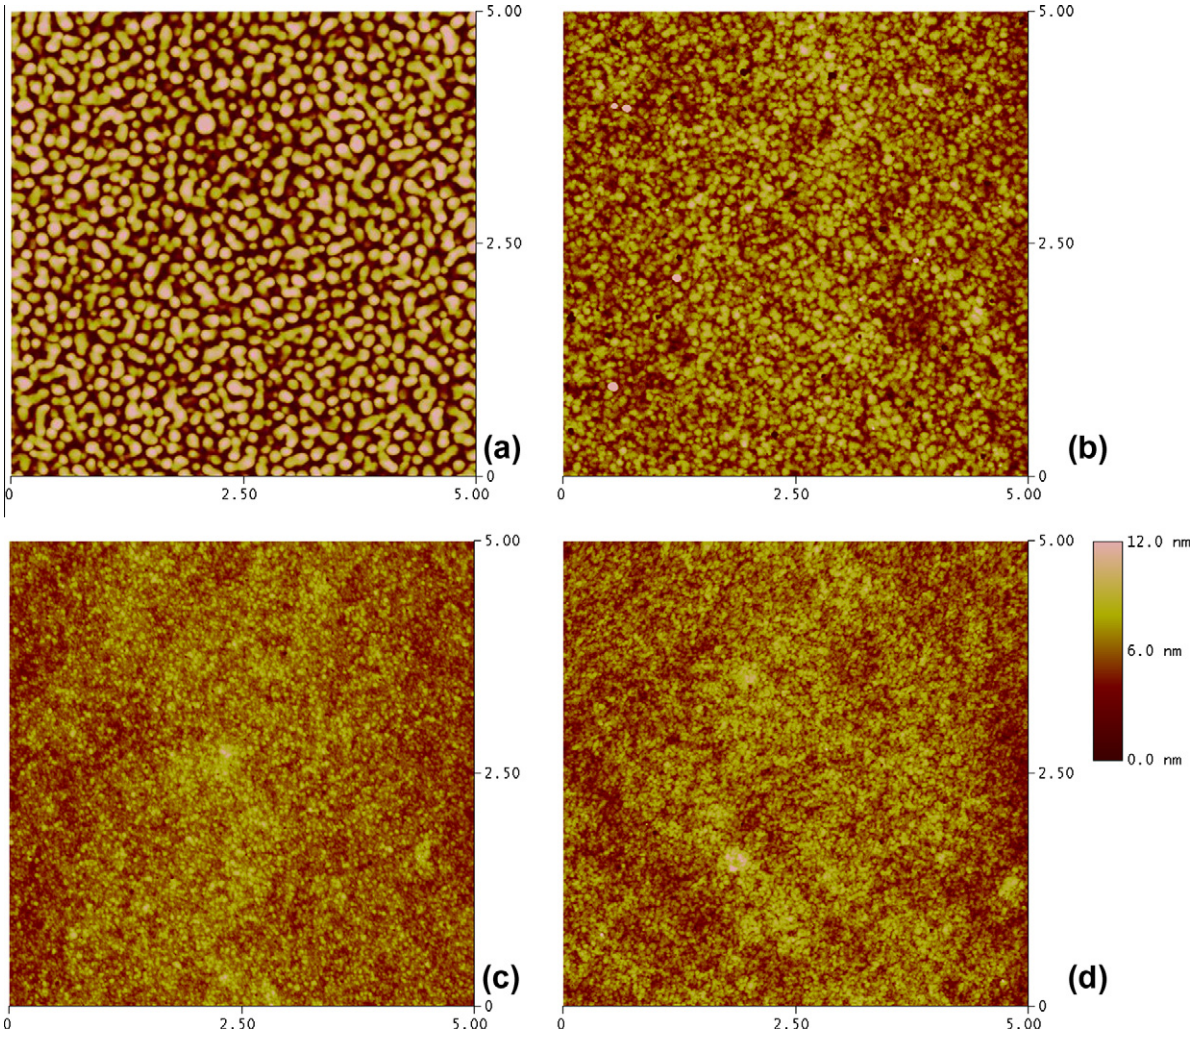

Fig. 7. AFM images of (a) PFEEDPP-*o*:PCBM, (b) PFEODPP-*o*:PCBM, (c) PFEEDPP-*m*:PCBM, and (d) PFEODPP-*m*:PCBM film. The films were prepared by spin coating DCB solutions with the polymer-to-PCBM weight ratio of 1:3. The unit of the AFM images is μm.

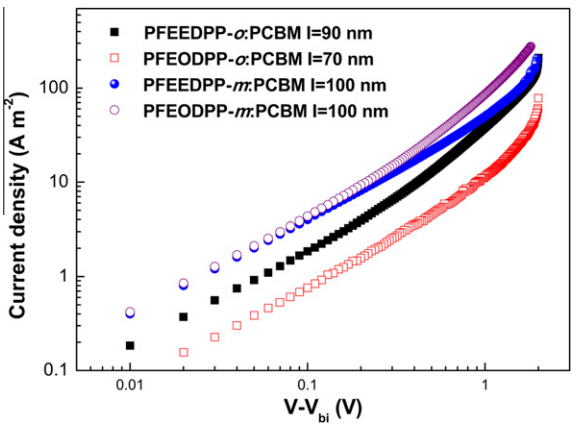

Fig. 8. Current density versus V–V_{bi} curves of polymer:PCBM (1:3, w/w) film. The thicknesses (l) of the films are indicated in the plot.

bigger domains than the PFEEDPP-*m*:PCBM and PFEODPP-*m*:PCBM films. The bigger domains indicate the reduced interface between donor and acceptor, leading to lower photovoltaic performance.

The hole mobilities of the polymer films were estimated in terms of the space charge limited current (SCLC) model,

$$J = \frac{9}{8}\varepsilon_r\varepsilon_0\mu_h\frac{V^2}{L^3},$$

where J is the current density, ε_0 is the permittivity of free space, ε_r is the dielectric constant of the polymer, μ_h is the hole mobility, V is the applied voltage ($V_{applied}$) corrected from the built-in voltage (V_{bi}) arising from difference in the work function of the contacts, and L is the thickness of the organic film [53–55]. The hole mobilities of the polymers:PCBM films (1:3, w/w) were studied by measuring the current through hole-only devices of ITO/PEDOT:PSS/the blend films/Au (Fig. 8). ε_r of 3 was adopted for the estimation of the hole mobilities of all the polymer films [56].

The hole mobilities, estimated by fitting the curves with the SCLC model, were 1.03×10^{-5}, 0.96×10^{-5}, 1.86×10^{-5}, 3.05×10^{-5}, and for the blend films of

PFEEDPP-*o*:PCBM, PFEODPP-*o*:PCBM, PFEEDPP-*m*:PCBM, and PFEODPP-*m*:PCBM, respectively. These hole mobility values are consistent with the PCEs of corresponding PVs.

4. Conclusion

Copolymers of electron-donating ethynylfluorene and electron-withdrawing DPP were synthesized *via* the Pd-catalyzed Sonogashira coupling in an oil bath and a microwave synthesizer. They have low-band gaps and can be used as the donor materials for polymer PVs. Applying the microwave irradiation during the Sonogashira coupling can significantly shorten the polymerization time from several days to a couple of minutes, improve the molecular weight of the copolymers and photovoltaic performances of the polymer PVs using the polymers as the donor material.

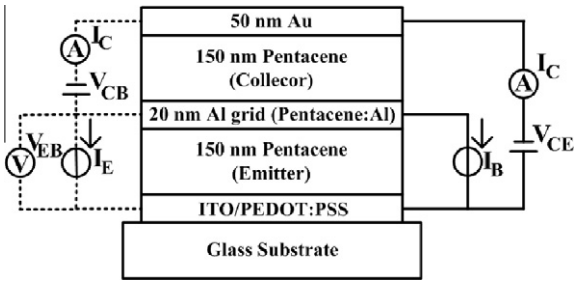

Fig. 1. The schematic diagram of the studied device structure, and the circuits used for transistor characterization in common-base mode (dash line) and common-emitter mode (solid line).

2. Experimental

Fig. 1 shows the schematic diagram of the studied device structure. The patterned ITO/glass substrate is first cleaned and dried. A 40 nm PEDOT:PSS is then deposited on the ITO/glass substrate from its aqueous solution by spin-coating, and the substrate is heated to 120 °C for 30 min in a vacuum oven. In the sequence, a 150 nm pentacene (emitter), 20 nm pentacene:Al (base), 150 nm pentacene (collector) and 50 nm Au are sequentially deposited on the substrate via thermal evaporation under a pressure of 3×10^{-4} Pa in situ. The pentacene:Al base is formed by co-evaporating pentacene and Al, where the deposition rate of pentacene is 0.05, 0.1 and 0.2 nm/s while maintaining 1 nm/s for Al. In

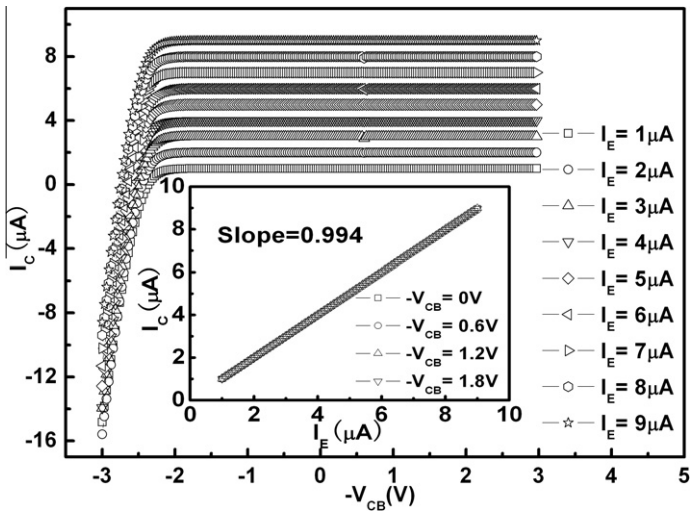

Fig. 2. Common-base characteristics of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.1 nm/s. The inset shows I_C dependence on I_E at different values of $-V_{CB}$ = 0, 0.6, 1.2 and 1.8 V.

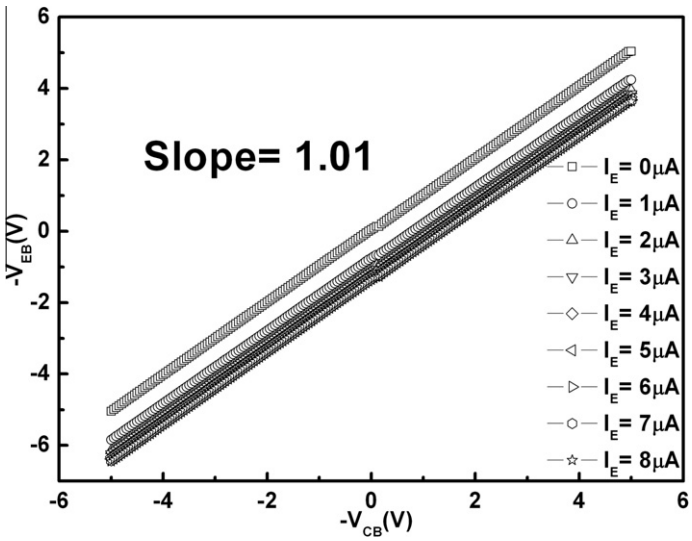

Fig. 3. Dependence of $-V_{EB}$ on $-V_{CB}$ for constant I_E of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.1 nm/s.

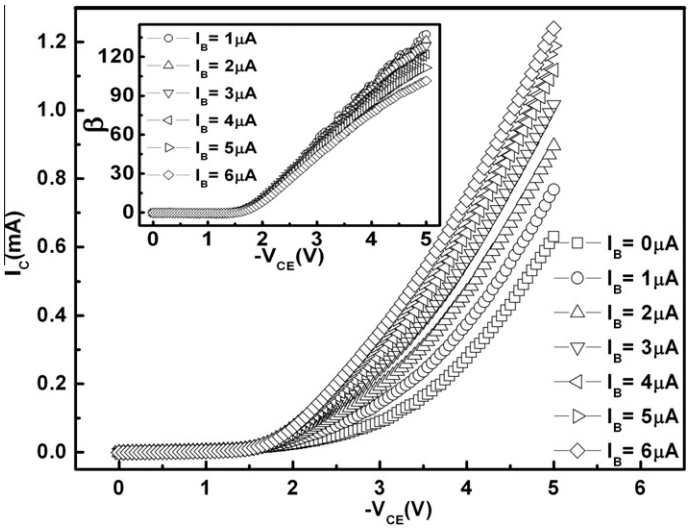

Fig. 4. Common-emitter characteristics of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.1 nm/s. The inset shows β dependence on $-V_{CE}$ at different values of I_B ranging from 1 to 6 μA at steps of 1 μA.

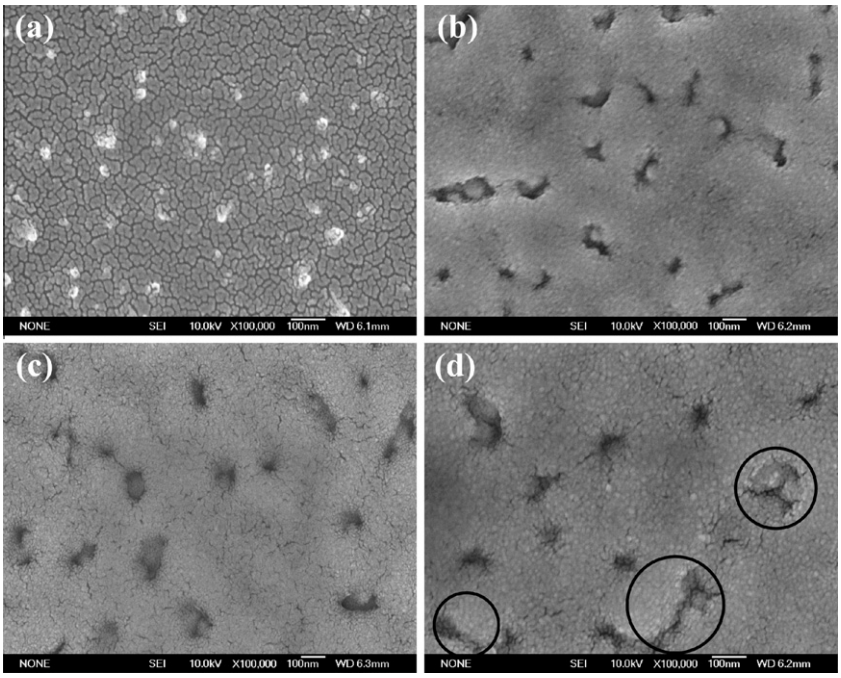

Fig. 5. SEM image of the bare Al metal base (a) and co-evaporated pentacene:Al base with different pentacene evaporation rates of 0.05 nm/s (b), 0.1 nm/s (c) and 0.2 nm/s (d). The circles in (d) indicate the obvious unequal pinhole regions.

addition, the deposition rate of pentacene emitter and collector are 0.05 and 0.1 nm/s for Au electrode. The device area defined as the overlap of three electrodes is 1 mm^2.

Electrical measurements are performed in the dark under argon condition, using three Keithley 2400 Sourcemeters for common-base mode and two for common-emitter mode. The circuits for common-base (dash line) and common-emitter (solid line) characterization are illustrated in Fig. 1.

3. Results and discussion

Fig. 2 shows the common-base characteristics of a ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.1 nm/s. For increasingly negative $-V_{CB}$, large negative I_C can be observed due to the significant hole injection in forward-biased base–collector junction. When $-V_{CB}$ increases to positive values,

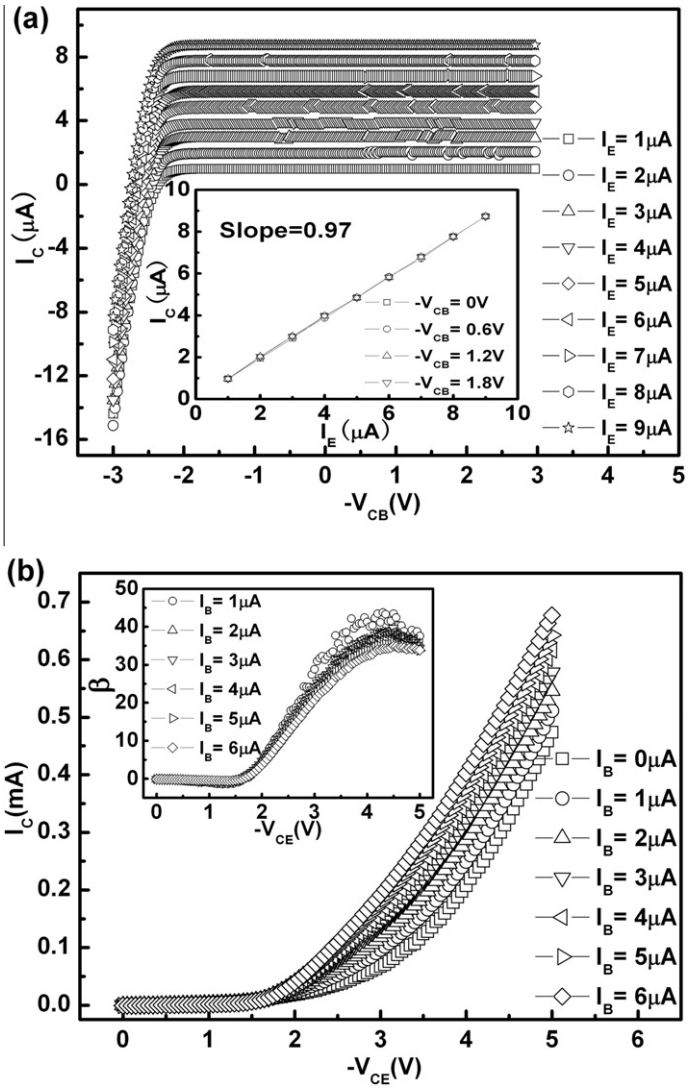

Fig. 6. (a) Common-base characteristics and; (b) common-emitter characteristics of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.05 nm/s. Inset: (a) I_C dependence on I_E at different values of $-V_{CB}$ = 0 V, 0.6 V, 1.2 V and 1.8 V; (b) β dependence on $-V_{CE}$ at different values of I_B ranging from 1 to 6 μA at steps of 1 μA.

a saturation current I_C can be observed for each given constant I_E. The saturation value of I_C can be controlled by I_E, i.e., I_C increases with I_E, which should be the expected common-base characteristics of permeable-base transistor [22]. As shown in the inset of Fig. 2, I_C depends on I_E linearly at a given $-V_{CB}$. For all the four selected $-V_{CB}$, the slopes of the I_C–I_E curves are ~0.994, corresponding to the common-base current gain $\alpha \equiv \partial I_c/\partial I_E$ of the device [22,23]. This high α value, near to ideal value of one, indicates that almost all holes injected from the emitter are able to cross the base area, being collected by the collector, promising well transistor operation. Additionally, the leakage current is negligible, indicating there is no significant minority carrier injection in the Pentacene/Au interface.

The transistor device shows permeable-base characteristics, since at constant I_E, $\partial(-V_{EB})/\partial(-V_{CB}) \cong 1$ [22], as can be seen in Fig. 3. As a result, it is supposed that the observed high α should be attributed to the pinholes existing within the pentacene:Al base area, which results in the emitter not being effectively shielded electrically from the collector.

Fig. 4 presents the common-emitter characteristics of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.1 nm/s. There is a significant high I_C can be observed at I_B = 0, defined as leakage current I_L. On the other hand, I_C increases remarkably after applying a small input I_B. At V_C = 5 V, I_C is increased from 0.63 to 1.24 mA when I_B is changed from 0 to 6 μA. This indicates that the transistor device is capable of current amplification in common-emitter mode. The calculated common-emitter current gain $\beta \equiv (I_C - I_L)/I_B$ [24] reaches ~137 at I_B = 1 μA and $-V_{CE}$ = 5 V.

In order to further investigate the device performance of the proposed permeable-base transistor, device based on bare thermally evaporated Al metal base, and devices

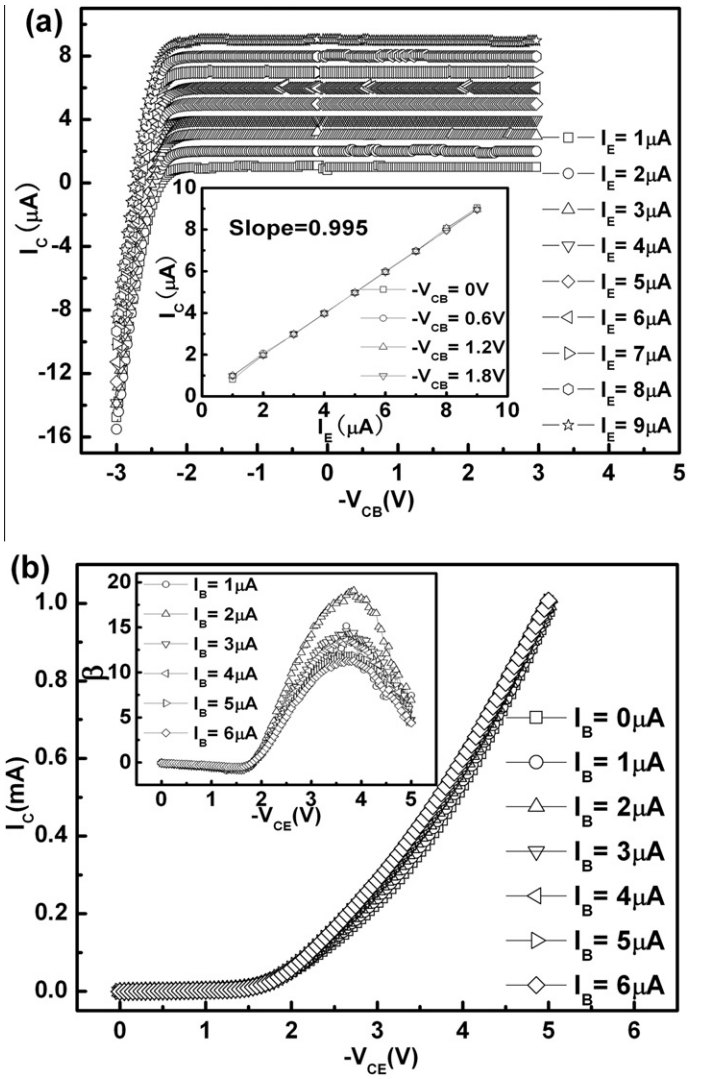

Fig. 7. (a) Common-base characteristics and; (b) common-emitter characteristics of the ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au device, where the evaporation rate of pentacene in the pentacene:Al co-evaporation is 0.2 nm/s. Inset: (a) I_C dependence on I_E at different values of $-V_{CB}$ = 0 V, 0.6 V, 1.2 V and 1.8 V; (b) β dependence on $-V_{CE}$ at different values of I_B ranging from 1 to 6 μA at steps of 1 μA.

based on co-evaporated pentacene:Al base with different evaporation rates for pentacene (0.05, 0.1 and 0.2 nm/s) are prepared. Firstly, it is found that the device based on Al metal base does not demonstrate any common-base and common-emitter characteristics expected for permeable-base transistors. This indicates that doping pentacene in Al deposition plays a relevant role. Fig. 5 shows the SEM image of 20 nm thick bare Al (a), pentacene (0.05 nm/s):Al (b), pentacene (0.1 nm/s):Al (c), pentacene (0.2 nm/s):Al (d) base. It can be clearly seen that adequate pentacene-doping in Al deposition ((b), (c) and (d)) is supposed to cause dispersive pinholes with diameters of several tens to a hundred nanometers, instead of a planar and continuous Al metal base (a). These pinholes promise direct connection between the emitter and collector, resulting in permeable-base operation mode, in accordance with the results shown in Fig. 3. Furthermore, it is found that the evaporation rate of pentacene in the pentacene:Al co-evaporation, i.e., the pentacene doping level are crucial to the base construction and device performance. Figs. 6 and 7 show the common-base and common-emitter characteristics of the devices with 0.05 and 0.1 nm/s evaporated pentacene, respectively. The α (at $-V_{CB}$ = 0 V) and β (at $-V_{CE}$ = 5 V, I_B = 1μA) values of the devices based on co-evaporated pentacene:Al base with different evaporation rates for pentacene (0.05, 0.1 and 0.2 nm/s) are compared in Fig. 8. It can be clearly seen that higher evaporation rate of pentacene causes bigger pinhole diameter [comparing the SEM images b, c and d in Fig. 5], which results in higher α value, indicating that the α value increases with increasing pinhole size [24]. The α value tends to ideal one as the evaporation rate of pentacene increases. On the other hand, β reaches the maximum value of ~137 by controlling the evaporation rate of pentacene at 0.1 nm/s. As a result,

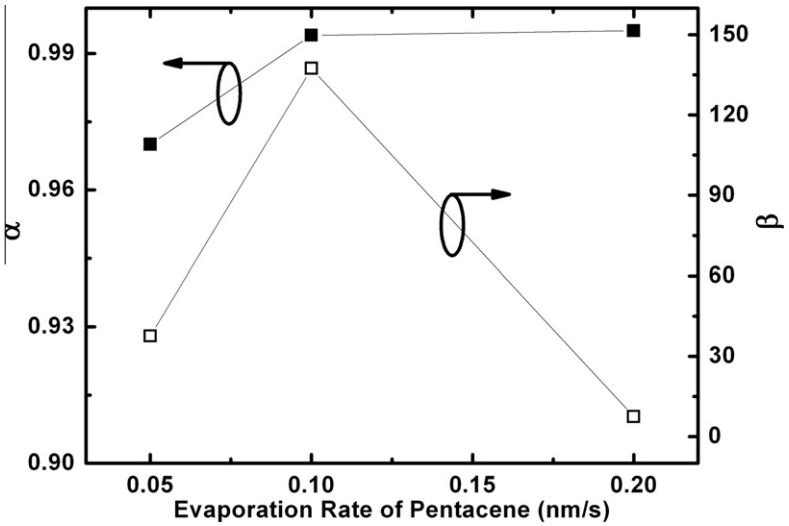

Fig. 8. Comparing the α (at $-V_{CB} = 0$ V) and β (at $-V_{CE} = 5$ V, $I_B = 1$ μA) values of the devices based on co-evaporated pentacene:Al base with different pentacene evaporation rates of 0.05, 0.1 and 0.2 nm/s.

the evaporation rate ratio in the pentacene:Al co-evaporation and the base construction are the key factors for well device operation. The optimal evaporation rate of pentacene in the pentacene:Al co-evaporation falls around 0.1 nm/s, where the transistors operate well in both common-base and common-emitter configurations. It should be noted that the values of α and β, in the case of 0.05 and 0.1 nm/s evaporated pentacene, follow exactly the expected relation $\beta = \alpha/1 - \alpha$ [25], not valid for the case of 0.2 nm/s evaporated pentacene. As shown in the inset of Figs. 4 and 6b, the β values in the case of 0.05 and 0.1 nm/s evaporated pentacene are almost independent on I_B and tend to saturate as $-V_{CE}$ increases, leading to β values that obey $\beta = \alpha/1 - \alpha$ [25]. On the contrary, the strong dependence of β on $-V_{CE}$ and I_B between ~2.5 V and the upper measurements limit, 5 V; and the degradation of β observed above $-V_{CE} = \sim 3.7$ V in the case of 0.05 nm/s evaporated pentacene [inset of Fig. 7b] result in β values that disobey $\beta = \alpha/1 - \alpha$ [25]. Here, we believe that excessive high evaporation rate of pentacene (0.2 nm/s) should bring very unequal pinhole regions [assigned by circles in Fig. 5d] within the base area. In the case, the current flow through the pinholes is difficult to be modulated by potential barrier because the central region of the pinhole is too far from the pinhole edges [14,22], resulting in very low β value (smaller than 20). Moreover, the electrostatic potential of the emitter electrode and the collector electrode with regard to the base electrode are strongly affected by each other via such a base area of large permeability, which results in variable β value. However, the concerning mechanism attributes to this phenomenon is still under investigation. Finally, the methods to quantify the pinhole size and distribution, and the way to achieve equably dispersed pinholes of homogeneous diameter will be the key issues for further study. In addition, developments that lead to suppress the leakage current observed in common-emitter measurements are required.

4. Conclusion

In summary, pentacene-based p-type permeable-base organic transistor ITO/PEDOT:PSS/Pentacene/Pentacene:Al/Pentacene/Au is demonstrated. The permeable pentacene:Al base is formed by co-evaporating pentacene and Al in vacuum. The permeability of the base, consequently the device performance, can be intentionally modulated by controlling the evaporation rate of pentacene in the pentacene:Al co-evaporation. In the case of 0.1 nm/s, the permeable-base transistor operates well in common-base and common-emitter mode, presenting high α value near to ideal 1 and ~137 for β at $I_B = 1$ μA and $-V_{CE} = 5$ V. This opens an effective method to fabricate permeable-base organic transistors.

emission [23]. Of course, a direct transition from the CT state to the ground state has also been confirmed by the experimentally reported near infrared emission from CT states in organic heterojunction devices [24,25]. In the past few years, an unusual phenomenon of "organic spintronics", called as organic magnetoresistance (OMAR), has attracted great attention for both basic research and applications. One of the focused questions is its underlying mechanism. Recently, Wang [26] and Majumdar [27] sequentially investigated such an effect in organic heterojunctions. It is interesting that both of them attributed it to the formation of the CT states.

Thus, the formation of CT states, especially the competition between their dissociation and various types of recombination, determines the different optoelectronic and magnetic applications for the D–A polymer heterojunctions. A crucial parameter affecting the above physical process is the energy offset. For example, for the application of D–A polymer heterojunctions in organic photovoltaic cells, one would like to improve the dissociation probability of a CT state, or suppress its various types of recombination, and in this case, a large energy offset should be expected. However, the energy offset is not as larger as expected, which will reduce the available open-circuit voltage and limit the photovoltaic efficiency [28,29]. So, how to choose the optimalizing energy offset becomes to be a key challenge for the different applications of D–A heterojunctions. Theoretically, Bittner et al. investigated the dependence of the charge transfer (or exciton dissociation) on the energy offset. They speculated that the exciton dissociation requires the energy offset to be greater than the exciton binding energy [6,7]. That is, there exists a critical energy offset for the charge transfer, which numerically equals to the exciton binding energy. However, we have known that this charge transfer does not directly generate free charge carriers, but a CT state. In view of this, we should further modify the critical energy offset by considering the formation of a CT state.

In this paper, a D–A polymer heterojunction consisting of two parallel molecules is modeled, in which we firstly consider the formation of a CT state following a direct transition between the two molecules [16,30,31]. Creation and binding energy of the CT state is sequentially calculated, by which we analyze its stability in a static picture. After that, the dynamic process of the charge transfer and recombination will be focused. Through the discussions, we aim to give a light to choose the optimalizing energy offset in different applications of D–A polymer heterojunctions. The paper is organized as follows. The model and method are presented in Section 2. The results and discussions are shown in Section 3. Finally in Section 4, a summary is given.

2. Model and method

As early as the 1930s, Onsager proposed a phenomenological theory (i.e., Onsager theory) to describe a CT state [32]. Although it has proven to be an effective theory in predicting the experimentally observed variations of charge photogeneration, there remain some restrictions in its application at D–A interfaces [33,34]. In particular, the current modified Onsager theory still can not take into account the effect of the dynamic lattice distortions or relaxations, which have been proven to be crucial for an organic polymer with strong electron-lattice interactions [35]. In this paper, we employ the tight-binding electron-lattice interacting model, i.e., the well-known Su–Schrieffer–Heeger (SSH) model [36]. To constitute an organic heterojunction with a D–A-type characteristic, we consider two coupled parallel poly(*p*-phenylene vinylene) (PPV) molecules with different on-site energy. By a renormalization treatment for the benzene rings, a PPV molecule can be modeled as a one-dimensional chain [11,13]. Thus, the Hamiltonian of the two PPV chains is written as:

$$H = H_1 + H_2 + H_{1-2}, \tag{1}$$

where H_j (j shows the chain index) describes an isolated PPV chain, consisting of two parts

$$H_j = H_{j,e} + H_{j,\text{lattice}}. \tag{2}$$

$H_{j,e}$ is the electronic part,

$$H_{j,e} = \sum_{n,s} \Delta_{j,n} C^+_{j,n,s} C_{j,n,s} - \sum_{n,s} t_{j,n,n+1} \left(C^+_{j,n+1,s} C_{j,n,s} + C^+_{j,n,s} C_{j,n+1,s} \right) + U \sum_n C^+_{j,n,\uparrow} C_{j,n,\uparrow} C^+_{j,n,\downarrow} C_{j,n,\downarrow} + V \sum_{n,s,s'} C^+_{j,n,s} C_{j,n,s} C^+_{j,n+1,s'} C_{j,n+1,s'}. \tag{3}$$

$\Delta_{j,n}$ denotes the on-site energy of electrons on site n, and $C^+_{j,n,s}$ ($C_{j,n,s}$) the creation (annihilation) operator of an electron at site n with spin s ($s = \uparrow, \downarrow$). The second term shows the electron hopping between the nearest neighboring sites, where the transfer integral $t_{j,n,n+1}$ between site n and $n + 1$ is written as:

$$t_{j,n,n+1} = t_0 - \alpha(u_{j,n+1} - u_{j,n}) - t_1 \cos n\pi + t_2 \cos\left(\frac{n+1}{3}\pi\right) \cdot \delta\left(\frac{n+1}{3}, \text{int}\right). \tag{4}$$

Here $\delta(\frac{n+1}{3}, \text{int}) = 1$, if $\frac{n+1}{3} = \text{int}$; and $\delta(\frac{n+1}{3}, \text{int}) = 0$, if $\frac{n+1}{3} \neq \text{int}$. "int" means an integer. t_0 represents the nearest-neighbor transfer integral for a uniform bond structure, α the electron-lattice interaction constant and $u_{j,n}$ the displacement of a unit at site n. t_1 and t_2 are the symmetry-breaking parameters introduced to reflect the lattice feature of a PPV monomer. The last two terms show the e–e interaction, which is treated with the Hartree–Fock approximation for simplicity. U presents the strength of the on-site Coulomb interactions and V the nearest-neighbor interactions:

$$H_{j,\text{lattice}} = \frac{1}{2} K \sum_n (u_{j,n+1} - u_{j,n})^2 + \frac{1}{2} M \sum_n \dot{u}^2_{j,n} \tag{5}$$

describes the classical treatment of the elastic potential and kinetic energy of the sites. K denotes the elastic constant and M the mass of a site.$H_{1,2}$ describes the interactions between the two chains, which consists of two parts,

$$H_{1,2} = -\sum_{n,s} t_\perp (C^+_{1,n,s} C_{2,n,s} + C^+_{2,n,s} C_{1,n,s}) + \sum_{n,s,s'} V_\perp (C^+_{1,n,s} C_{1,n,s} C^+_{2,n,s'} C_{2,n,s'}) \tag{6}$$

$t_\perp$ and $V_\perp$ separately presents the interchain transfer integral and e–e interaction between sites labeled by the same index n on the two chains.

Due to the strong electron-lattice interactions of the organic system, the lattice displacement $u_{j,n}$ is not fixed, and it will change with the electron–hole excitation. The temporal evolution is classically described by the Newtonian equation of motion:

$$M\ddot{u}_{j,n} = -K(2u_{j,n} - u_{j,n+1} - u_{j,n-1}) + 2\alpha(\rho_{j,n,n+1} - \rho_{j,n,n-1}) - \lambda M\dot{u}_{j,n}, \quad (7)$$

where the density matrix ρ is defined as

$$\rho_{j,n,n'} = \sum_s \rho_{j,n,n',s} = \sum_{\mu,s} \Psi_{j,\mu,s}(n,t) f_\mu \Psi^*_{j,\mu,s}(n',t). \quad (8)$$

f_μ is the time-independent distribution function determined by the initial electron occupation. In Eq. (7), a damping term is introduced to describe the energy dissipation into the surrounding medium by a tuning parameter λ [37].

The evolutions of electronic states $\Psi_{j,\mu,s}(n, t)$ are the solutions of the time-dependent Schrödinger equation:

$$i\hbar\frac{\partial}{\partial t}\Psi_{j,\mu,s}(n,t) = -t_{j,n,n+1}\Psi_{j,\mu,s}(n+1,t) - t_{j,n-1,n}\Psi_{j,\mu,s}(n-1,t) + [U\rho_{j,n,n,-s} + V(\rho_{j,n-1,n-1} + \rho_{j,n+1,n+1}) + V_\perp\rho_{j',n,n} + \Delta_{j,n}]\Psi_{j,\mu,s}(n,t) - t_\perp\Psi_{j',\mu,s}(n,t), \quad (9)$$

where j and j' mean different chain.

At beginning or for the static picture, we set $\Psi_{j,\mu,s}(n, t = 0) = Z_{j,\mu,s}|n\rangle$, which is obtained by solving the Schrödinger equation of Hamiltonian H with $u_n = 0$. When the system is photoexcited, electrons will gain energy and $\Psi_{j,\mu,s}(n, t)$ consequently experience an evolution determined by the coupled differential Eqs. (7) and (9), which can be solved by the Runge–Kutta method of order eight with step-size control.

3. Results and discussion

Referring to Refs. [11] and [13], the values of parameters in the Hamiltonian are separately set as $\alpha = 102.9$ eV/nm, $t_0 = 2.66$ eV, $t_1 = 0.02$ eV, $t_2 = -0.2$ eV, $K = 9900$ eV/nm^2, and $M = 1.35 \times 10^5$eV · fs^2/nm^2. For the e–e interactions, the values are fixed to be $U = 2.0$ eV, $V = 1.0$ eV, and $V_\perp = 0.1$ eV. To constitute a D–A-type electronic structure, we set different values to the on-site energy of the two chains: $\Delta_{1,n} = \Delta E$, $\Delta_{2,n} = 0$, where $\Delta E > 0$ is chosen in connection with the results discussed as follows. Then the first chain is a D-type molecule and the second chain an A-type one. Consequently, an energy offset ΔE between LUMO of the D-chain (LUMO^D) and that of the A-chain (LUMO^A) [or HOMO of the D-chain (HOMO^D) and that of the A-chain (HOMO^A)] is obtained, as sketched in Fig. 1.

For such a system, if the photoexcitation takes place only in a single chain, such as in the D-chain, an electron will be excited from HOMO^D to LUMO^D [11], as shown in Fig. 1, which corresponds to the intramolecular transition P_{intra}. After that, we give the net charge distribution $q_n = e(\rho_{n,n} - 1)$ of the two chains with $t_\perp = 0.1$ eV and $\Delta E = 0.2$ eV, as shown by the dashed line in Fig. 2. We can see that it does not appear any charge transfer between the D–A chains. In such a case, an exciton forms and is localized in the D-chain. In addition, the photoexcitation can also take place near the D–A interface, as reported by recent experiments [16,30,31]. It will result in the charge transfer between the chains. To realize such a process, the intermolecular transition P_{inter} is especially considered, as also shown in Fig. 1. After the transition, the net charge distribution of the two chains is presented by the solid line in Fig. 2. Apparently, it is no longer an exciton as there appears a charge transfer. As we know, if an electron transfer between the two chains, a negative polaron and a positive polaron will be formed, separately residing in the D-chain and A-chain. However, as the chains are coupled together, the initial transferred electron and the left hole still exhibit a significant attraction due to the overlapping of the corresponding electronic states. A direct result is that the transferred charges are not the initial one electronic charge (e), but usually fractional electric charges. For example, in present parameters the transferred charges are about 0.5e, which are bound together with the left 0.5h on the D-chain as a CT state.

To compare the two states, we calculate their creation energies. The solid line and the dashed line in Fig. 3 show

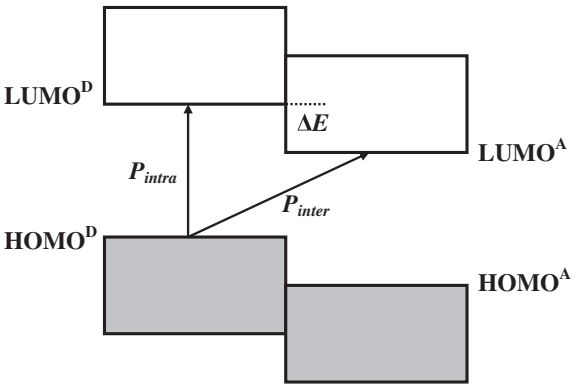

Fig. 1. Schematic diagram of the energy levels of a D–A polymer heterojunction, where ΔE is the energy offset. P_{intra} indicates the intramolecular transition, and P_{inter} the intermolecular one.

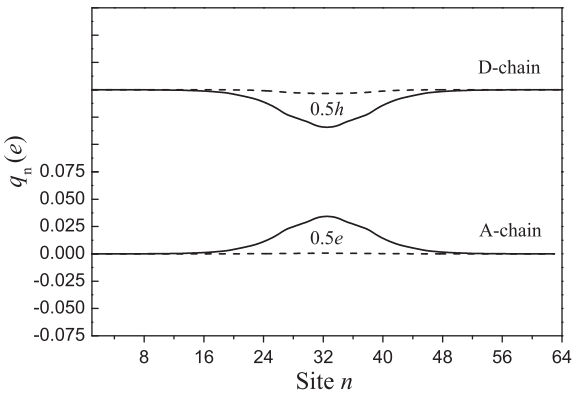

Fig. 2. Two possible states photogenerated in the D–A polymer heterojunction with $t_\perp = 0.1$ eV and $\Delta E = 0.2$ eV, where the dashed line and the solid line separately indicates the result after P_{intra} and P_{inter}.

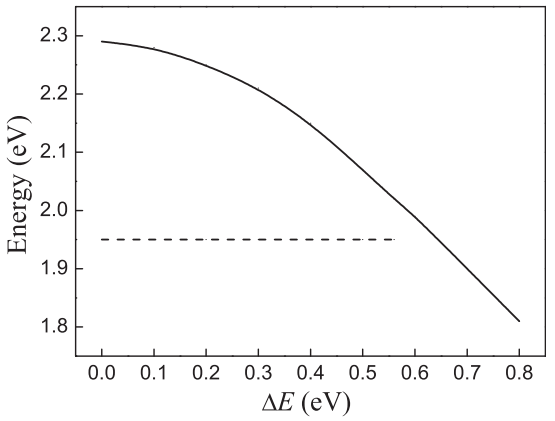

Fig. 3. Dependences of the creation energy of a CT state (solid line) and an exciton (dashed line) on the energy offset.

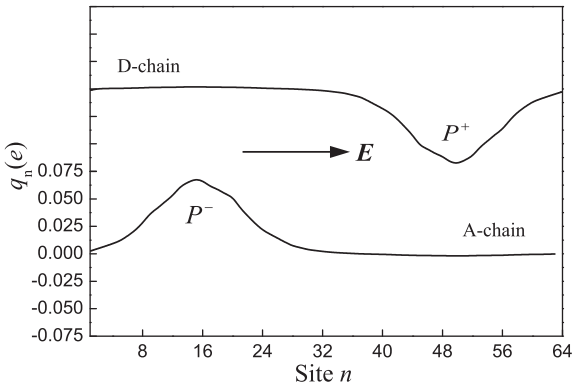

Fig. 4. Dissociation of a CT state in the D–A polymer heterojunction by an external electric field E with the direction from left to right along the chain.

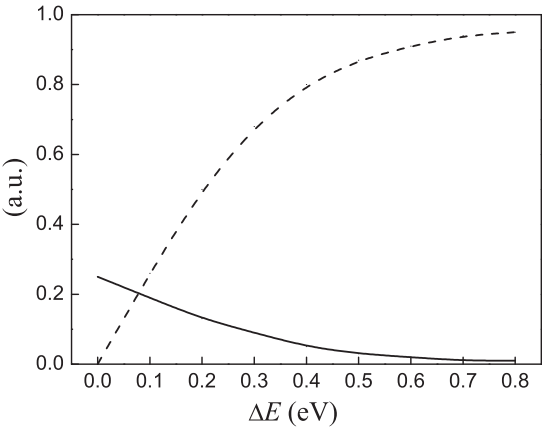

Fig. 5. Dependences of the binding energy (solid line) and the transferred charges (dashed line) of a CT state on the energy offset ΔE in a D–A polymer heterojunction with $t_\perp = 0.1$ eV .

the dependence of the creation energy for a CT state (ΔE_{CT}) and an exciton (ΔE_{exc}) on the energy offset (ΔE), respectively. It is found that there exists a turnover value ΔE_C ($\Delta E_C = 0.56$ eV in present parameters) of the energy offset. When $\Delta E \leqslant \Delta E_C$, not only a CT state but also an exciton can be obtained, and the latter is always energetically favorable to the former. When $\Delta E > \Delta E_C$, we can not obtain an exciton any more. It implies that an exciton is energetically unstable at the D–A interface with $\Delta E > \Delta E_C$. From the speculation of Bittner et al., we know that the critical energy offset ΔE_C is determined by the exciton binding energy E_B^{exc}, and $\Delta E_C = E_B^{exc}$ [6]. Here, we calculate the exciton binding energy referring to [38], and get the value $E_B^{exc} = 0.55$eV in present parameters. The result is approximately consistent with that obtained by Bittner et al., which will be further discussed in the following.

As stated above, the excited electron and hole in a CT state still remain bound across the D–A interface. To dissociate these generated CT states and get the desired free charge carriers, we should consider some external effects, e.g., thermal fluctuation or electric field. Here, we consider the dissociation of a CT state by applying an external electric field E with the form referring to [13]. Compared with the result without considering E, we find that an electric field should help to facilitate the charge transfer. Especially, there exists a critical value of E_C, beyond which the CT state shown in Fig. 2 will be dissociated into a positive polaron (P^+) and a negative polaron (P^-) (see Fig. 4). It indicates that the "energetic barrier" between the CT state and the free charge carriers can be reduced, even eliminated, by an electric field. Of course, such an "energetic barrier" can be quantitatively reflected by the binding energy of a CT state E_B^{CT}, which is defined as the energy difference between the creation energy of free charge carriers shown in Fig. 4 and that of a CT state shown in Fig. 2 ($E_B^{CT} = \Delta E_{P^+P^-} - \Delta E_{CT}$). In present parameters ($t_\perp = 0.1$eV and $\Delta E = 0.2$ eV), we get $E_B^{CT} = 0.13$eV, which is greatly smaller than the exciton binding energy ($E_B^{exc} = 0.55$eV). As we know, the energetics of the dissociation of either a CT state or an exciton is determined by its binding energy. Usually, a larger binding energy means that the state is more stable, and the dissociation is much harder. Therefore, the dissociation of a CT state is much easier than that of an exciton. For example, in present parameters the critical electric field dissociating a CT state is $E_C = 1.9 \times 10^5$ V/cm, while that dissociating an exciton needs a field as high as $E_C = 1.6 \times 10^6$ V/cm.

However, the dissociation of a CT state is found to be dependent upon the energy offset. The solid line in Fig. 5 shows the calculated binding energy of a CT state in different energy offset. It is obtained that the binding energy decreases apparently with the increase of the energy offset. It indicates that a CT state is more easily dissociated in a D–A heterojunction with a large energy offset. Especially, when the energy offset is large enough, the binding energy will fall below the room temperature thermal energy (0.025 eV), which means that the thermal fluctuation at room temperature is sufficient to dissociate a CT state into free charge carriers contributing to the photocurrent. In addition, we check the dependence of the transferred charges between the chains on the energy offset, as shown by the dashed line in Fig. 5. As can be seen, the transferred

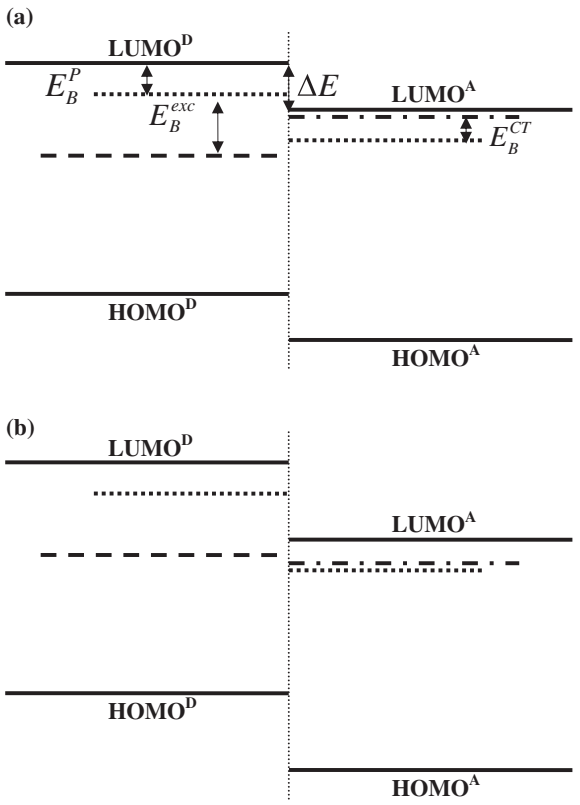

Fig. 6. Energy level diagram of a D–A interface showing a simplified viewpoint of electron transfer and subsequent recombination between the two molecules. The dashed line indicates the energy level of an exciton, the dotted line the energy level of a polaron, and the dash dotted line the energy level of a CT state. E_B^{exc} and E_B^{CT} indicate the binding energy of an exciton and a CT state, respectively, which are both shown relative to the polaron level. E_B^P indicates the binding energy of a polaron.

charges increase with the increase of the energy offset, and finally saturate to one electronic charge (e). It further indicates that, with the increase of the energy offset, the charge separation extent in a CT state will be more complete and approaches the free charge carriers.

On the contrary, if there does not exist any external effects, the weakly bound electron and hole in a CT state are not allowed to separate or drift away from each other, and various types of recombination events may occur [22,23,25]. It has been found to be a major limitation for the efficiency of organic heterojunction solar cells [28]. Here, we consider the recombination of a CT state into an exciton, which can be simply understood by considering the energetics of the D–A interface, as illustrated in Fig. 6. The dashed and dash dotted line present the upper localized energy levels for an exciton and a CT state, respectively. In addition, to obtain their binding energies we give the localized energy level of a polaron (see the dotted line). Thus, the binding energy of an exciton E_B^{exc} and a CT state E_B^{CT} can be simply obtained relative to the polaron level, since we have found that both of them are dissociated into oppositely charged polarons. E_B^P shows the binding energy of a polaron, which is obtained relative to the LUMO [39]. As stated above, with the formation of a CT state, there appears charge transfer from the D-polymer to the A-one, which occupy the CT state level. For the case of a small energy offset ΔE, as shown in Fig. 6a, the energy level of a CT state lies higher in energy than that of an exciton. The initial transferred charges will surely transit from the CT state level to the exciton level due to the energetic downhill, and the CT state consequently recombine into an exciton. With the increase of the energy offset, the exciton binding energy E_B^{exc} and the polaron one E_B^P keep unchanged, while the CT state binding energy E_B^{CT} presents an apparent reduction (see Fig. 5), as shown in Fig. 6b. As a result, the CT state level may lie lower in energy than the exciton level, and the recombination of a CT state into an exciton is energetically unfavorable.

To give a quantitative relation between the recombination and the energy offset, a driving potential P resulting from the energy difference between the exciton energy level and the CT energy level is introduced, which is written as:

$$\begin{aligned} P &= -(\Delta E + E_B^p - E_B^{CT}) - \left[-(E_B^{exc} + E_B^p)\right] \\ &= \left(E_B^{exc} + E_B^p\right) - \left(\Delta E + E_B^p - E_B^{CT}\right). \end{aligned} \tag{10}$$

Fig. 7 shows the dependence of the driving potential P upon the energy offset ΔE. It is apparent that there exists a turnover value ΔE_C (ΔE_C = 0.56 eV in present parameters) of the energy offset. When $\Delta E < \Delta E_C$, the driving potential is positive ($P > 0$). It means that the initially generated CT state at the D–A interface, whether by a photoexcitation here or by electrical injection where else [24,25], should be inclined to recombine into an exciton. Such a situation is desirable for the light emission, and so, the D–A heterojunction is suitable to be used as the functional layer in a light-emitting device. When $\Delta E > \Delta E_C$, the driving potential is negative ($P < 0$). It implies that the initially generated CT state can not recombine into an exciton, however, the reverse process, that is, the dissociation of an exciton into a CT state will surely take place. Therefore, at the D–A interface with $\Delta E > \Delta E_C$, we can only get a CT state, which

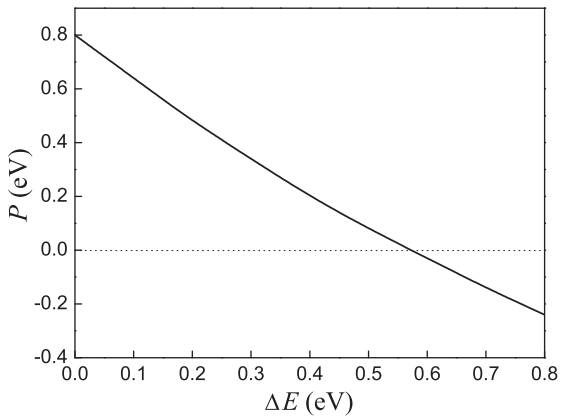

Fig. 7. Dependence of the driving potential P on the energy offset ΔE.

is consistent with the result shown in Fig. 3. Such a situation is desirable for photovoltaic devices, since a CT state is more easily dissociated than an exciton.

In addition, from Fig. 7 we can see that, in the case of $\Delta E < \Delta E_C$, the driving potential P tends to weaken with the increase of the energy offset. It shows that the recombination of a CT state into an exciton will be harder and harder with the energy offset. To give a further confirmation, the dynamic process for the charge transfer and recombination in the D–A polymer heterojunction is addressed. As shown in Fig. 8, at beginning (i.e., $t = 0$), both of the two chains are in their ground state with $q(n) = 0$. When $t > 0$, an electron is excited from $HOMO^D$ to $LUMO^A$, or the case corresponding to transition P_{inter} shown in Fig. 1. We find that there appears net charges in each of the two chains, and $0 < q(n < 64) = -q(n > 64)$. It shows that electrons are transferred from the D-chain to the A-one. Initially, the transferred charges behave in a spread state in respective chain. However, due to the strong electron-lattice interactions in the organic molecules, the spread charges quickly (~10 fs) assemble together to form a localized state. As stated above, the two localized states are not completely separated from each other, but coupled together as a CT state due to the interchain coupling included.

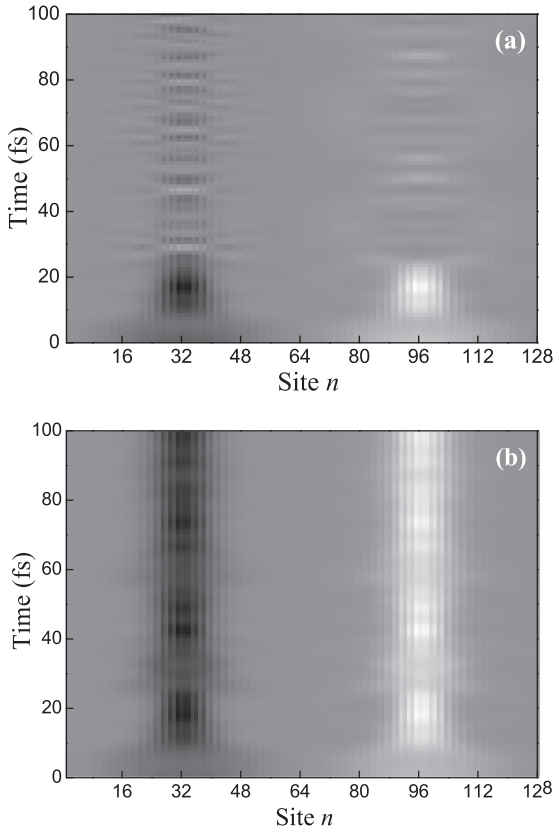

Fig. 8. Time dependence of q_n for the D–A polymer heterojunction with the same interchain coupling $t_\perp = 0.1$ eV and different energy offset $\Delta E = 0.2$ eV (a), $\Delta E = 0.6$ eV (b).

However, after the formation of the CT state, the dynamic evolution of the system is different for different energy offset. Fig. 8a shows the result with $\Delta E = 0.2$ eV. It is found that the initially transferred charges into the A-chain quickly return back to the D-chain, which finally behaves in an exciton, while the A-chain eventually reverts to its ground state. It means that the generated CT state at the D–A interface rapidly recombines into an exciton. For the case of $\Delta E = 0.6$ eV, as shown in Fig. 8b, the transferred charges nearly keep unchanged, and the generated CT state does not recombine into an exciton. Fig. 9 further presents the dependence of the recombination time of the CT state on the energy offset. With the increase of the energy offset, the recombination of the CT state needs a long time. Once the energy offset exceeds the critical value ($\Delta E > \Delta E_C$), the CT state can not recombine any more. The results are consistent with those obtained by the static picture.

Finally, it should be stressed that the critical energy offset ΔE_C for the charge transfer and recombination in the D–A polymer heterojunction is determined not only by the exciton binding energy, but also by the CT state one. By setting $P = 0$ in Eq. (10), we can get the critical energy offset ΔE_C written as:

$$\Delta E_C = E_B^{exc} + E_B^{CT}. \tag{11}$$

However, we note that the CT state binding energy E_B^{CT} is very weak (see Fig. 5) at $\Delta E_C = 0.56$ eV. So, when we consider the exciton dissociation or charge transfer, the critical energy offset is approximately only determined by the exciton binding energy. While in some conditions, e.g., in PPV crystal with strong interchain couplings, the exciton binding energy will be apparently reduced [40]. Consequently, the critical energy offset may also present a reduction. In such a case, the CT state binding energy can not be neglected for the contribution to ΔE_C. In addition, although a large energy offset favors the photogeneration of free charges in a D–A heterojunction. In actual applications of the D–A heterojunctions in photovoltaic devices, a large energy offset will reduce the available open-circuit voltage and fundamentally limit the photovoltaic efficiency [28,29]. Therefore, how to efficiently reduce the critical en-

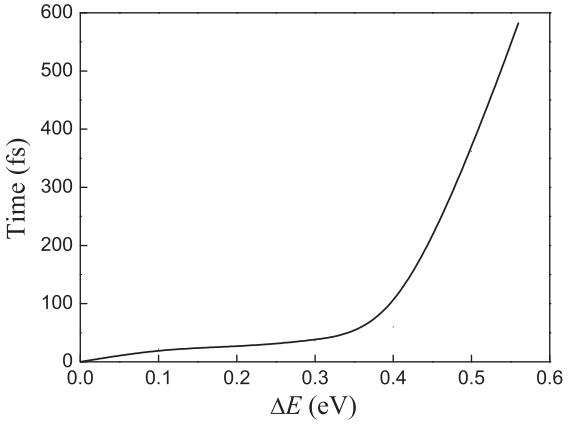

Fig. 9. Dependence of the recombination time of the CT state into an exciton on the energy offset ΔE with the interchain coupling $t_\perp = 0.1$ eV .

ergy offset ΔE_C should be one of the keys to improve the photovoltaic efficiency. So, further investigations should be done in the future that include some physical factors, which can reduce the exciton binding energy or the CT state one, such as the control of the distance between the molecules by applying a hydrostatic pressure [41].

4. Summary

In view of the significant influence of the CT states on the optoelectronic and magnetic applications of D–A polymer heterojunctions, we theoretically investigated the formation and stability of a CT state, and especially the dynamic mechanism of the charge transfer and recombination. It was found that the critical energy offset, which determines the formation and recombination of a CT state, depends on not only the exciton binding energy but also the CT state one. A quantitative relation for them is obtained. When the energy offset is less than the critical value, the electrons in the A-polymer, whether by the intermolecular electron transition or by the electrical injection, will quickly return back to the D-one, and the generated CT state consequently recombine into an exciton. With the increase of the energy offset, the recombination needs a long time. Once the energy offset exceeds the critical value, the generated CT state can not recombine any more.

difficult to do even for a molecular conductor comprising a moderate number of atoms. Another way out was proposed by Büttiker over two decades ago [12,13]. He came up with an elegant idea of incorporating the effect of phase breaking due to inelastic scattering phenomenologically by introducing some fictitious voltage probes into the coherent system. While moving from source to drain electrons get scattered into the fictitious floating voltage probes and then re-emitted into the device by loosing the phase memory. To implement this idea each inelastic scatterer is modeled in terms of electron reservoir (or infinite impedance voltage probe) and coupled to the device. Since the net current flowing through the fictitious probes has to be zero to satisfy the conservation of total number of particles, electro-chemical potentials (μ) of each lead has to be adjusted accordingly. Due to its appealing simplicity Büttiker probe model has been extensively used in studying quantum transport in low-dimensional systems.

The idea of using molecules as active components of a device was suggested by Aviram and Ratner over three decades ago [14]. Since then several ab-initio and model calculations have been performed to investigate molecular transport theoretically [15–23]. But experimental realizations took a little longer time to get feasible. In 1997, Reed et al. studied the current-voltage (I–V) characteristics of a single benzene molecule attached to electrodes via thiol groups [24]. Various other experiments have been reported in literature exploring many interesting features, e.g., ballistic transport, quantized conductance, negative differential resistance (NDR), gate controlled transistor operation to name a few. Effect of dephasing in molecular systems has been studied in few literatures both theoretically [25,26] as well as experimentally. In 1989, D'Amato and Pastawski investigated the effect of inelastic scattering processes on a tight-binding linear disordered chain using Büttiker probe model [6]. In 2007, Datta and co-worker proposed a different phenomenological model which provides the flexibility of adjusting degree of phase and momentum relaxation independently [27]. In 2008, Nozaki et al. obtained transport properties through various molecular junctions by Büttiker model using Extended Hückel theory [28]. In 2009, Guo et al. have reported an ab-initio calculation [29] including the effect of phase breaking in 1,4-benzenedithiol molecule attached to two Al electrodes, gold QPC and a very thin Al(001) nanowire. They have also done a comparative analysis between Büttiker probe model and Datta dephasing model [27]. Though various efforts have already been made to explain the basic features of electron dephasing on molecular transport, but to the best of our knowledge, no rigorous effort has been made so far to unravel the combined effect of quantum interference and electron dephasing on molecular transport. This is the main motivation behind this work.

In our present article we study two terminal electron transport through a single benzene molecule including the effect of dephasing by a discrete tight-binding model. We obtain the transmission probability using Green's function technique within the framework of Landauer–Büttiker formulation. Transmittance–energy and current–voltage characteristics are obtained for three different configurations (*para*, *ortho* and *meta*) of benzene molecule depending on three different positions of the drain with respect to the source. The presence of dephasing provides a significant change in the spectral properties of the molecule and here we essentially focus our results in this aspect. Our model calculation can be extended further for any complicated molecular structure.

In what follows, we present the results. In Section 2, the model and the theoretical formulation are presented. Section 3 describes the results, and finally, we make our conclusions in Section 4.

2. Molecular model and theoretical formulation

We start by describing our model, illustrated in Fig. 1, where a single benzene molecule is connected symmetrically to two one-dimensional, semi-infinite leads, commonly known as source and drain. The leads are characterized by the electrochemical potentials μ_S and μ_D), respectively, under the non-equilibrium condition when an external bias voltage is applied. Both the two leads and the molecule are simulated by a simple tight-binding Hamiltonian within nearest-neighbor hopping approximation. Following Büttiker's idea, the effect of dephasing due to inelastic scattering is incorporated in the model phenomenologically by coupling each spatial sites to a different fictitious electron reservoir or in other words an infinite impedance voltage probe (shown by the pink shaded area in Fig. 1) via perfect leads. The key idea is that *the fictitious floating probes extract electrons from the device to the reservoir, but as the net current flowing through these probes is zero, so they re-inject the electrons into the conductor after phase randomization and thus effectively play the role of phase breaking scatterers.*

The Hamiltonian for the entire system is given by the sum of four terms:

$$H = H_{mol} + H_{leads} + H_{tun} + H_{dephase}. \quad (1)$$

The first term represents the Hamiltonian for the single benzene molecule consisting of six sites ($N = 6$) which is coupled to two electron reservoirs through conducting

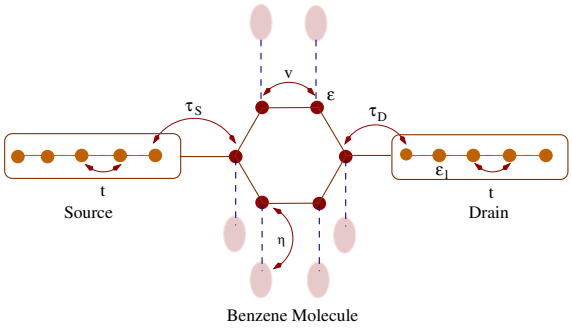

Fig. 1. Schematic diagram of a single benzene molecule attached to two leads, namely, source and drain. Each molecular site is assumed to be coupled to a fictitious electron reservoir, shown by the pink shaded area, which takes into account the effect of phase breaking processes. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

leads, namely, source and drain. The molecule is modeled by the nearest-neighbor tight-binding Hamiltonian which in Wannier basis can be written as,

$$H_{mol} = \sum_i \epsilon d_i^\dagger d_i + \sum_i v[d_{i+1}^\dagger d_i + h.c.], \tag{2}$$

where ϵ refers to the site energy of an electron at the ith site of the molecular system and v represents the isotropic nearest-neighbor coupling strength between the molecular sites. $d_i^\dagger$ and d_i correspond to the creation and annihilation operators, respectively, of an electron at the ith site of the molecule.

Similarly the second and third terms of Eq. (1) denote the Hamiltonians for the one-dimensional semi-infinite leads (source and drain) and molecule-to-lead coupling. In Wannier basis representation they can be written as follows:

$$\begin{aligned} H_{leads} &= H_S + H_D \\ &= \sum_{\alpha=S,D} \left\{ \sum_n \epsilon_l c_n^\dagger c_n + \sum_n t[c_{n+1}^\dagger c_n + h.c.] \right\}, \end{aligned} \tag{3}$$

and,

$$\begin{aligned} H_{tun} &= H_{S,mol} + H_{D,mol} \\ &= \tau_S[d_1^\dagger c_0 + h.c.] + \tau_D[d_p^\dagger c_{N+1} + h.c.]. \end{aligned} \tag{4}$$

Here, ϵ_l and v stand for the site energy and nearest-neighbor hopping between the sites of the two leads. $c_n^\dagger$ and c_n are the creation and annihilation operators, respectively, of an electron at the site n of the leads. The hopping integral between the source and the molecule is τ_S, while it is τ_D between the molecule and the drain. Usually benzene molecules are attached to gold leads via thiol groups (–SH bond) in the chemisorption technique. Here, the effect of such substituent (e.g., thiol group) is included in the parameters τ_S and τ_D. The source is assumed to be connected at the site number 1, while the drain is coupled to the pth site, which is variable, of the molecular system. The integer p becomes 2, 3 and 4 for the *ortho*, *meta* and *para* configurations, respectively.

In order to incorporate the effect of dephasing, external electron reservoirs are phenomenologically introduced and they are connected to all the molecular sites (six) through fictitious probes. The phase breaking probes are identically represented within tight-binding framework like source and drain as given below:

$$H_{dephase} = \sum_{i=1}^{N} \left[H_i^{d,probes} + H_i^{d,tun} \right], \tag{5}$$

where,

$$H_i^{d,probes} = \sum_m \epsilon_d c_m^{Di\dagger} c_m^{Di} + \sum_m t_d[c_{m+1}^{Di\dagger} c_m^{Di} + h.c.], \tag{6}$$

and,

$$H_i^{d,tun} = \eta \left[c_0^{Di\dagger} d_i + h.c. \right]. \tag{7}$$

Here, ϵ_d and t_d being the site energy and the hopping strength between the nearest-neighbor sites of the dephasing probes, respectively. $c_m^{Di\dagger}(c_m^{Di})$ is the creation (annihilation) operator of an electron at the mth site of the ith lead. The dephasing strength is characterized by the coupling parameter η.

To obtain the transmission probability of an electron through such a molecular bridge system, we use Green's function formalism. Within the regime of coherent transport and in the absence of Coulomb interaction this technique is well applied.

The single particle Green's function operator representing the entire system for an electron with energy E is defined as,

$$G = (E - H + i\eta)^{-1} \tag{8}$$

where $\eta \to 0^+$.

Following the matrix form of $\boldsymbol{H}$ and $\boldsymbol{G}$ the problem of finding $\boldsymbol{G}$ in the full Hilbert space $\boldsymbol{H}$ can be mapped exactly to a Green's function $\boldsymbol{G}_{\boldsymbol{mol}}^{\boldsymbol{eff}}$ corresponding to an effective Hamiltonian in the reduced Hilbert space of the molecule itself and we have,

$$\mathscr{G} = \boldsymbol{G}_{\boldsymbol{mol}}^{\boldsymbol{eff}} = \left(\boldsymbol{E} - \boldsymbol{H}_{\boldsymbol{mol}} - \boldsymbol{\Sigma}_{\boldsymbol{S}} - \boldsymbol{\Sigma}_{\boldsymbol{D}} - \sum_{\boldsymbol{k}=1}^{\boldsymbol{N}} \boldsymbol{\Sigma}_{\boldsymbol{k}} \right)^{-1}, \tag{9}$$

where,

$$\begin{aligned} \boldsymbol{\Sigma}_{\boldsymbol{S(D)}} &= \boldsymbol{H}_{\boldsymbol{S,mol(mol,R)}}^{\dagger} \boldsymbol{G}_{\boldsymbol{S(D)}} \boldsymbol{H}_{\boldsymbol{S,mol(mol,R)}}, \\ \boldsymbol{\Sigma}_{\boldsymbol{k}} &= \boldsymbol{H}_{\boldsymbol{k}}^{\boldsymbol{d,tun}\dagger} \boldsymbol{G}_{\boldsymbol{k}} \boldsymbol{H}_{\boldsymbol{k}}^{\boldsymbol{d,tun}}. \end{aligned} \tag{10}$$

These $\boldsymbol{\Sigma}_{\boldsymbol{S(D)}}$ and $\boldsymbol{\Sigma}_{\boldsymbol{k}}$ are the contact self-energies introduced to incorporate the effect of coupling of the molecule to the source (drain) and the fictitious electron reservoirs. It is evident from Eq. (10) that the form of the self-energies are independent of the molecule itself through which transmission is studied. Using Dyson equation the analytic form of the self energies can be evaluated as follows:

$$\Sigma_v = \frac{\tau_v^2}{E - \epsilon_v - \sigma_v}. \tag{11}$$

Here, $\sigma_v = (E - \epsilon_v)/2 - i\sqrt{t_v^2 - (E - \epsilon_v)^2/4}$; and $v = S,\ D,\ 1,\ 2,\ \ldots,\ N$. For source and drain, $v = S(D),\ \tau_v = \tau_{S(D)},\ \epsilon_v = \epsilon$, and $t_v = t$; while considering the dephasing probes, $v = k\ (k = 1,\ 2,\ \ldots,\ N),\ \tau_v = \eta,\ \epsilon_v = \epsilon_l$, and $t_v = t_d$.

Following D'Amato–Pastawski model [6] the effective transmission probability of an electron from source to drain including the partially phase breaking process is given by the following expression:

$$T_{eff} = T_{S,D} + \sum_{i,j=1}^{N} \boldsymbol{T}_{D,i} \boldsymbol{W}_{i,j}^{-1} \boldsymbol{T}_{j,S}. \tag{12}$$

The above expression has a significant physical implication. The first term is the coherent contribution to electron transmission, whereas the second term refers to the incoherent component of tunneling due to electrons suffering phase randomizing scattering at the fictitious dephasing reservoirs. $T_{i,j}$ is the transmission probability between any pair of reservoirs $i,\ j\ (i,\ j = S,\ D,\ 1,\ 2,\ \ldots,\ N)$ and it is expressed as follows:

$$T_{i,j} = \mathrm{Tr}[\boldsymbol{\Gamma}_{\boldsymbol{i}} \mathscr{G}^{\boldsymbol{r}} \boldsymbol{\Gamma}_{\boldsymbol{j}} \mathscr{G}^{\boldsymbol{a}}]. \tag{13}$$

Γ_is are the coupling matrices representing the coupling between the molecule and the leads and they are mathematically defined by the relation:

$$\boldsymbol{\Gamma_i} = i\left[\boldsymbol{\Sigma_i^r} - \boldsymbol{\Sigma_i^a}\right] \tag{14}$$

Here, $\boldsymbol{\Sigma_k^r}$ and $\boldsymbol{\Sigma_k^a}$ are the retarded and advanced self-energies associated with the kth lead, respectively.

In the second term of Eq. (12), $\boldsymbol{W}$ matrix is defined by the following relation:

$$W_{i,j} = [(1 - R_{i,i})\delta_{ij} - T_{i,j}(1 - \delta_{ij})], \tag{15}$$

where,

$$R_{i,i} = 1 - \sum_{j \neq i} T_{i,j}. \tag{16}$$

$R_{i,i}$ is the reflection probability of an electron from ith lead.

It is shown in literature by Datta [3,4] that the self-energy can be expressed as a linear combination of a real and an imaginary part in the form,

$$\boldsymbol{\Sigma_j^r} = \boldsymbol{\Lambda_j} - i\boldsymbol{\Delta_j}. \tag{17}$$

The real part of self-energy describes the shift of the energy levels and the imaginary part corresponds to the broadening of the levels. The finite imaginary part appears due to incorporation of the semi-infinite leads having continuous energy spectrum. Therefore, the coupling matrices can easily be obtained from the self-energy expression and is expressed as,

$$\boldsymbol{\Gamma_i} = -2\,\mathrm{Im}(\boldsymbol{\Sigma_i}). \tag{18}$$

Considering linear transport regime, at absolute zero temperature the linear conductance (g_{eff}) is obtained using two-terminal Landauer conductance formula,

$$g_{eff} = \frac{2e^2}{h} T_{eff}(E_F). \tag{19}$$

With the knowledge of the effective transmission probability we compute the current–voltage (I–V) characteristics by the standard formalism based on quantum scattering theory:

$$I(V) = \frac{2e}{h} \int_{-\infty}^{\infty} T_{eff}[f_S(E) - f_D(E)]dE. \tag{20}$$

Here, $f_{S(D)}(E) = \left[1 + e^{\frac{E-\mu_{S(D)}}{k_B T}}\right]^{-1}$ is the Fermi function corresponding to the source and drain. At absolute zero temperature the above equation boils down to the following expression:

$$I(V) = \frac{2e}{h} \int_{E_F - \frac{eV}{2}}^{E_F + \frac{eV}{2}} T_{eff} dE. \tag{21}$$

In our present work we use the above expression assuming that the potential drop takes place only at the boundary of the molecular system. This assumption is good enough for molecules of smaller size. Throughout our study we choose $c = e = h = 1$ for the sake of simplicity.

3. Numerical results and discussion

In this section we present the results obtained by numerical simulation considering a single benzene molecule sandwiched between source and drain. The orbital energies (ϵ) of the molecule are set to zero and the nearest-neighbor hopping matrix element (t) is fixed at 2.4 eV [17] for an aromatic ring structure of the benzene molecule. The other hopping parameters in the leads (t) and the dephasing probes (t_d) are fixed at 4 eV, while the site energies are chosen to be zero, i.e., $\epsilon_l = \epsilon_d = 0$. The dephasing strength, characterized by the parameter η, is fixed at 1 eV. Throughout our analysis the coupling strengths of the molecule to the source and drain, characterized by the parameters τ_S and τ_D, are set at 1 eV. The molecular coupling to the contacting leads is one of the most important factors which regulates the electronic transmission through a molecular wire and this phenomenon has been extensively studied in our previous works [22,23]. Accordingly, here we describe all the essential features of electron transport for a particular molecular coupling strength. The molecular transport properties are also highly sensitive on the molecule-to-lead interface geometry, and, in the present work we illustrate how they are influenced in the presence of electron dephasing. To reveal these facts first we discuss the behavior of transmittance–energy characteristics and then we describe the nature of current–voltage spectra for three different configurations (*ortho*, *meta* and *para*) of the benzene molecule.

Here, we establish all the results at absolute zero temperature and restrict ourselves within elastic dephasing so that no energy is exchanged between the transported electrons and the external fictitious reservoirs, only the phase informations get lost. This condition allows the incoherent electrons to generate a steady-state current through the sample.

3.1. Transmittance–energy characteristics

3.1.1. Molecule coupled symmetrically

In Fig. 2 we show the variation of transmission probability as a function of injecting electron energy for a benzene molecule, where the molecule is coupled symmetrically to the source and drain, i.e., the upper and

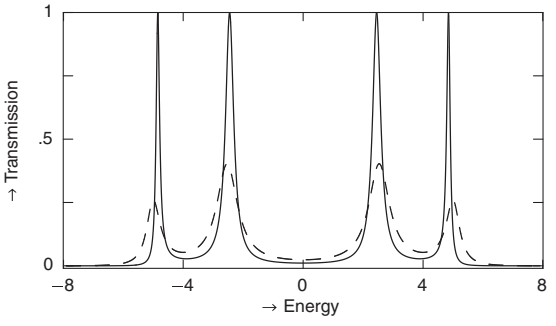

Fig. 2. Variation of transmission probability as a function of energy for a benzene molecule where the drain is connected at the *para* position with respect to the source. The solid and dashed curves correspond to the results in the absence and presence of dephasing, respectively.

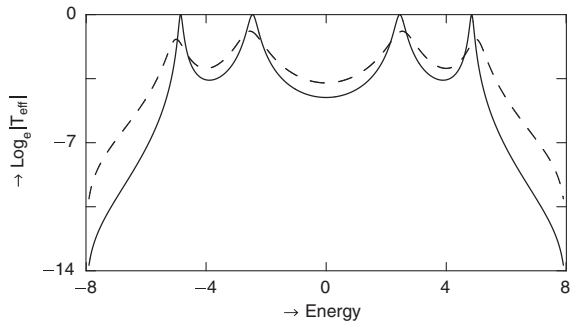

Fig. 3. The results of Fig. 2 are re-plotted in a logarithmic scale to clarify the effect of dephasing more clearly.

lower arms of the molecular ring have identical length. This is the so-called *para* configuration. The solid curve represents the variation of coherent transmission probability, while the dashed curve depicts the result in the presence of electron dephasing. It is observed that, in the absence of dephasing the transmission probability exhibits sharp resonant peaks (see solid line) for some specific energies, whereas it almost vanishes for all other energy values. At these resonances, the transmission probability T_{eff} goes to unity. All the resonant peaks are associated with the energy eigenvalues of the benzene molecule, and therefore, we can say the transmittance spectrum is a fingerprint of the electronic structure of the molecule. The situation becomes much interesting when the effect of dephasing is introduced. It shows that the magnitude of the resonant peaks gets suppressed enormously (dashed line) compared to the coherent transmission (solid line). This is due to the increased rate of scattering in the additional fictitious electron reservoirs. Additionally, we also notice that the widths of the resonant peaks become broadened. This broadening is caused by the dominance of phase randomizing effect over backscattering due to loss of phase coherence of interfering electrons in the presence of dephasing reservoirs. To judge the effect of dephasing more transparently, in Fig. 3 we re-plot the results of Fig. 2 in a logarithmic scale, where the solid and dashed lines represent the identical meaning as above. Since the transmission probability lies within the range 0–1, it

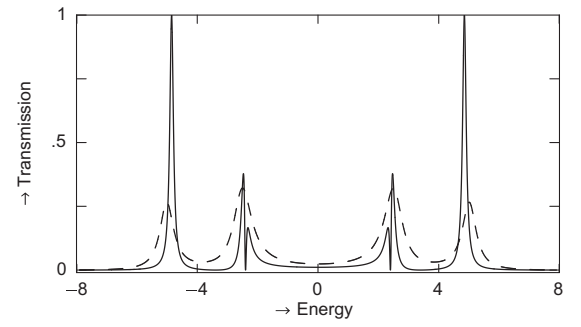

Fig. 4. Transmission probability vs. energy characteristics of a benzene molecule where the drain is connected at the *ortho* position with respect to the source. The solid and dashed lines represent the results in the absence and presence of dephasing, respectively.

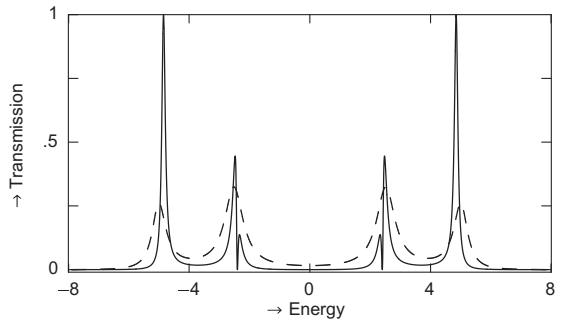

Fig. 5. Transmission probability vs. energy characteristics of a benzene molecule where the drain is coupled to the *meta* position with respect to the source. The solid and dashed curves correspond to the results in the absence and presence of dephasing, respectively.

becomes zero or negative in the logarithmic scale as shown in Fig. 3. It is observed that the variations in the transmission peaks between the two curves (solid and dashed) get suppressed, but the broadening effect in the presence of dephasing can be much clearly observed from the 'log' scale.

3.1.2. Molecule coupled asymmetrically

A significant change in the transmission spectrum is observed when the benzene molecule is coupled asymmetrically to the source and drain, i.e., the upper and lower arms of the molecular ring have unequal lengths. For the *ortho* configuration the results are given in Fig. 4, while in Fig. 5 the results are shown for the *meta* configuration. From the spectra (Figs. 4 and 5) we notice that in the absence of dephasing some resonant peaks do not reach to unity and their amplitudes are significantly reduced compared to the other resonant peaks. This is solely due to the effect of quantum interference between the electronic waves passing through the upper and lower arms of the molecular ring. Quite interestingly we observe that in these asymmetric molecular wires (*ortho* and *meta*) two anti-resonant states appear in the transmittance spectrum where transmission probability drops exactly to zero. These anti-resonant states are specific to the interferometric nature of the molecular system and their positions in the energy scale are independent of the molecule-to-lead coupling strength. A careful observation reveals that a

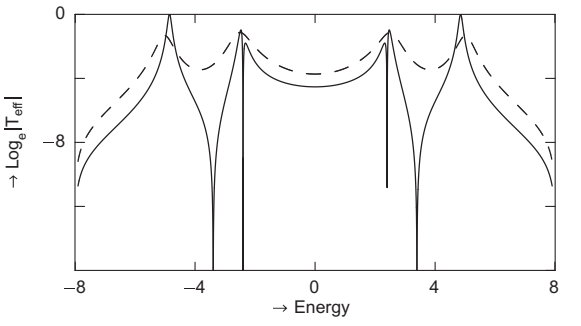

Fig. 6. The results of Fig. 4 are re-plotted in a 'log' scale.

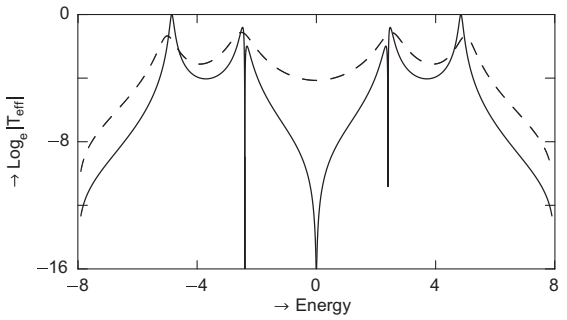

Fig. 7. The results of Fig. 5 are re-plotted in a 'log' scale.

sharp peak is followed by a sharp dip and vice versa across the anti-resonant energy which is quite analogous to a Fano-like line shape. All these anti-resonant states disappear as long as dephasing of electrons is taken into account those are clearly observed from the dashed lines of Figs. 4 and 5. Here also the magnitudes of the resonant peaks get decreased and they become broadened as we describe earlier in the *para* configuration.The results of Figs. 4 and 5 are re-drawn in Figs. 6 and 7, respectively, where the transmission probabilities are determined in the 'log' scale. From these spectra (Figs. 6 and 7) the characteristic features of anti-resonant states in the case of coherent transmission and the broadening of resonant peaks in the presence of electron dephasing are clearly noticed. Our results also predict that in the asymmetric molecular ring the positions of the anti-resonant states are strongly sensitive on the location of measuring electrodes. Broadening of transmission peaks in presence of dephasing is much pronounced in the case where the drain is connected at the *meta* position of the benzene molecule rather than the *ortho* position, and, it can be clearly observed from the Log_eT_{eff} vs. E plot instead of the transmittance–energy spectra.

3.2. Current–voltage characteristics

All the above features of electron transmission become much clear from our study of current-voltage (I–V) characteristics. The current through the molecular system is obtained by integrating the transmission function following Eq. (21). Here we fix the Fermi energy E_F at zero.

3.2.1. Molecule coupled symmetrically

In Fig. 8 we plot the variation of current as a function of applied bias voltage for a benzene molecule where the leads are connected symmetrically. The orange and green lines represent the currents in the absence and presence of electron dephasing. The current varies quite continuously with the applied bias voltage V. Depending on the molecular coupling to the side attached leads, the current shows continuous-like or step-like behavior [22]. Tuning the molecular coupling strength the current amplitude through the molecular wire can be regulated nicely for a fixed bias voltage. This provides an interesting behavior in designing molecular electronic devices. Both in the absence and presence of electron dephasing current shows almost identical variation though a significant change is observed in their conductance spectra. This is due to the fact that the dephasing broadens the transmission peaks, while it also suppresses the magnitude. These two effects nullify each other showing almost identical spectrum in the I–V characteristics.

3.2.2. Molecule coupled asymmetrically

The effect of dephasing becomes much prominent in the current–voltage characteristics when the molecule is coupled asymmetrically to the source and drain. For the *ortho* configuration, the currents are shown in Fig. 9, while in Fig. 10 the results are shown when the molecule is coupled to the leads in the *meta* configuration. Quite similar to the *para* configuration (Fig. 8), in these two cases (*ortho* and *meta* configurations) also the current varies almost continuously with the applied bias voltage V. In these asymmetric configurations, the current amplitude gets enhanced significantly when the phase breaking effect is considered (deep blue curve in Fig. 9 and light blue curve in Fig. 10) compared to the case where the molecule is free from any phase randomizing process (pink line in Fig. 9 and red line in Fig. 10). Such an enhancement in current amplitude takes place because of notable broadening of the transmission peaks due to reduced destructive interfer-

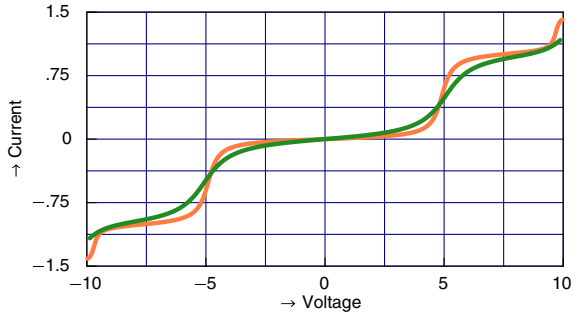

Fig. 8. I–V characteristics of a benzene molecule where the drain is connected at the *para* position with respect to the source. The orange and green curves correspond to the currents in the absence and presence of dephasing, respectively. ence for dominance of phase decoherence over the back-scattering effect.

4. Closing remarks

To summarize, in the present work we have examined electron transport phenomena through a single benzene molecule including the effect of phase breaking using a phenomenological model introduced by Büttiker. Experimentally the benzene molecule is usually coupled to noble metal electrodes (e.g., gold leads) through thiol linking groups. In our theoretical work, we present the entire system (source-molecule-drain) by a discrete lattice model within a simple one-electron, tight-binding framework. We have studied transmission–energy spectrum and current–voltage characteristics considering three different configurations of the system depending on the position of the drain contact (*ortho*, *meta* and *para* positions). We have observed that the sharp transmission peaks are broadened and their magnitude is also suppressed in the presence of dephasing due to loss of phase coherence and thus it provides an enhancement in the current amplitude. But the broadening effect and so as the increase in current amplitude is much pronounced in the case where the drain is connected asymmetrically to the molecule with respect to the source. Another significant feature is that the two anti-resonant states, observed in the transmittance spectrum of an asymmetrically connected benzene molecule, completely disappear in the presence of strong dephasing due to reduced destructive interference. Thus the effect of dephasing can provide a significant change in the current–voltage relation.

In the Büttiker probe model fictitious voltage probes are introduced into the coherent system. These virtual probes introduce additional resistance in the system by relaxing the momentum of the electrons by partially reflecting them, i.e., back-scattering. This model is appropriate for those molecular systems where the dominant scattering source does not conserve electron momentum, for example, electron–phonon scattering which is very important in molecular conductor in finite temperature. However, Büttiker model does not consider the effect of momentum relaxation. In experimental situations dephasing may also arise from electron–electron scattering which destroy phase but not momentum [27,29]. Datta model presents the flexibility of tuning phase and momentum independently of each other and we intend to study this phenomenological model in near future.

Recent experimental progresses have significantly inspired in model calculations and numerical simulations to study vibronic effects on electron transport in molecular junctions [30–33]. Most of the studies of vibronic effects in the resonant tunneling regime (for higher voltages) have illustrated that vibrational motion may affect the current–voltage spectra quite significantly. But, the point is that in the resonant tunneling region vibronic effect becomes significant only when the molecule is coupled to the measuring leads *weakly*. In a very recent work Benesch et al. [34] have studied vibronic effects on conductance in molecular junctions where a benzene ring is coupled *weakly* to two gold electrodes and shown that the vibronic motion affects current–voltage spectra. On the other hand, when the molecule is coupled *strongly* to the electrodes, the vibrational effects in resonant transport are almost negligible. This phenomenon has been clearly justified in the reference [35]. In the present work we have investigated all the essential features of electron transport in the limit of strong molecule-to-electrode coupling, and accordingly, we neglect the vibronic effect.

Throughout our work we have neglected the intra- and inter-site Coulomb interactions as well as the effect of the leads, which we wish to consider in our future studies. Another important assumption is the zero temperature approximation. Although the electron–phonon interaction becomes significant at non-zero temperature, but in our case, we have already considered the dephasing effect phenomenologically at every molecular sites, which takes into account the effect of dephasing of electrons without any exchange of energy between the electron and the external leads. Accordingly, we compute the current–voltage relation at absolute zero temperature. At finite non-zero temperature, the transmission peaks will broaden due to thermal broadening effect, but the basic features will not change significantly as long as the thermal energy (k_BT) is less than the average level spacing of the benzene molecule. Now-a-days various organic compounds and polymers (for example, Tris(8-hydroxyquinolino) aluminum (Alq_3) and 1,2,3,4,5-pentaphenylcyclopentadiene (PPCP)) are used as electroluminescent devices. Knowledge of electronic structure and current–voltage relation is important to elucidate the light emitting mechanism [36]. It may be interesting to see the effect of electron dephasing on this mechanism. Our presented results may be useful in understanding the effect of phase breaking processes on the basic two-terminal molecular transport phenomena.

charge injection from the charge transport layer to the emitting layer. However, more systematic study about the relationship between the chemical structure of the phenylcarbazole based phosphine oxide host material and physical properties of the host material is required to develop better high triplet host materials for deep blue PHOLEDs.

In this work, the effect of the substitution position of the phosphine oxide on the physical properties of the host material and device performances of the deep blue PHOLED were investigated. The diphenylphosphine oxide was attached to the ortho, meta and para position of the phenyl group in the phenylcarbazole unit. It was demonstrated that the para substitution is better than ortho or meta substitution in terms of quantum efficiency. A high quantum efficiency of 20.4% was demonstrated from the deep blue PHOLED with the phenylcarbazole based host substituted at para position of the phenyl group.

2. Experimental

2.1. Materials and measurements

9H-carbazole, *n*-butyllithium, chlorodiphenylphosphine, *N*-bromosuccinimide, and 4-bromobenzene (Aldrich Chem. Co.) and hydrogen peroxide (Duksan Sci. Co.) were used without further purification. Tetrahydrofuran (THF) was distilled over sodium and calcium hydride. Detailed.

The ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were obtained using a Varian 200 (200 MHz) spectrometer. The photoluminescence (PL) spectra were recorded on a fluorescence spectrophotometer (HITACHI, F-7000) and the ultraviolet–visible (UV–vis) spectra were obtained using UV–vis spectrophotometer (Shimadzu, UV-2501PC). Samples were dissolved in THF at a concentration of 1.0×10^{-4} M. Hexane and methanol were also used as the solvents for the PL measurement to confirm solvatochromic effect. Low temperature PL spectra were obtained at 77 K under liquid nitrogen. The differential scanning calorimetry (DSC) measurements were carried out using a Mettler DSC 822 at a heating rate of 10 °C/min under nitrogen atmosphere. The mass spectrometry (MS) was performed using a JEOL, JMS-AX505WA spectrometer in FAB (fast atom bombardment) mode. Cyclic voltametry (CV) measurement was carried out in acetonitrile solution with tetrabutylammonium perchlorate at 0.1 M concentration. Organic materials were coated on indium tin oxide substrate and were immersed in electrolyte for analysis. Scan rate was 0.1 mV/s. Ferrocene was used as the reference material for the CV analysis. Elemental analysis of the materials was carried out using EA1110 (CE instrument). High performance liquid chromatography (HPLC) analysis of the synthesized materials was carried out using HPLC from Youngrin Instrument. A mixed eluent of acetonitrile:methanol (90:10) was used for the analysis.

2.2. Synthesis

Detailed synthesis of the 3-(diphenylphosphoryl)-9-(4-(diphenylphosphoryl)phenyl)-9-carbazole (PPO21) was described in previous work [10].

2.3. Synthesis of 9-(3-bromophenyl)-9H-carbazole (**3**)

A mixture of 9H-carbazole (4.0 g, 23.92 mmol), 1-bromo-3-iodobenzene (8.08 g, 28.70 mmol), Cu-powder (3.04 g, 47.84 mmol), potassium carbonate (13.20 g, 95.68 mmol) and dibenzo-18-crown-6 (0.63 g, 2.39 mmol) in dimethylformamide (DMF, 40 ml) was purged with argon and heated at reflux for 7 h. The mixture was quenched with H_2O and extracted with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane to provided 5.67 g of title compound as white solid (m.p. 69–70 °C; 71% yield).

^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.15–8.12 (d, J = 6.0 Hz, 1H), 7.74–7.68 (m, 2H), 7.58–7.41 (m, 7H), 7.34–7.30 (m, 2H).

2.4. Synthesis of 9-(2-bromophenyl)-9H-carbazole (**5**)

A mixture of 9H-carbazole (3.0 g, 17.94 mmol), 1-bromo-2-iodobenzene (10.15 g, 35.88 mmol), copper iodide (2.39 g, 12.55 mmol) and potassium carbonate (4.95 g, 35.88 mmol) in xylene (40 ml) was purged with argon and heated at reflux for 48 h. The mixture was quenched with H_2O and extracted with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane to provide 2.5 g of title compound as white solid (m.p. 93–94 °C; 56% yield).

^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.17–8.13 (d, J = 8.0 Hz, 1H), 7.90–7.68 (m, 1H), 7.57–7.29 (m, 8H), 7.08–7.02 (t, J = 6.0 Hz, 1H).

2.5. Synthesis of 3-bromo-9-(3-bromophenyl)-9H-carbazole

Compound **3** (2.0 g, 6.20 mmol) was dissolved in dimethylformamide (DMF, 20 ml) under argon atmosphere. The reaction vessel was immersed in a ice bath until the temperature was about −20 °C and then *n*-bromosuccinimide (NBS, 1.32 g, 7.44 mmol) in DMF (5 ml) was added dropwise slowly into and stirred for 12 h. The mixture was allowed to gradually warm to room temperature overnight and then quenched with H_2O followed by extraction with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane to provided 1.8 g of title compound as white solid (m.p. 187 °C; 80% yield).

^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.45 (s, 1H), 8.25–8.08 (t, J = 17.0 Hz, 3H), 7.86–7.66 (m, 3H), 7.55–7.31 (m, 5H).

2.6. Synthesis of 3-(diphenylphosphoryl)-9-(3-(diphenylphosphoryl)phenyl)-9H-carbazole (PPO25)

3-Bromo-9-(3-bromophenyl)-9H-carbazole (4.73 g, 11.79 mmol) was dissolved in tetrahydrofuran (THF, 50 ml) under argon atmosphere. The reaction vessel was immersed in a dry ice/acetone bath until the temperature

was about −78 °C. To this solution 11.32 ml (28.30 mmol) of 2.5 M *n*-BuLi solution in hexane was added dropwise slowly and stirred for 3 h. Chlorodiphenylphosphine (5.22 ml, 28.30 mmol) was then added to the solution and stirred for 3 h in a dry ice/acetone bath. The mixture was allowed to gradually warm to room temperature overnight and then quenched with methanol, extracted with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane/dichloromethane (10:1) to provided 2.2 g of title compound as white solid (32% yield).

The white solid was dissolved in dichloromethane (40 ml) and hydrogen peroxide (8 ml) was stirred overnight at room temperature. The organic layer was separated and washed with dichloromethane and water. The extract was evaporated to dryness affording a white solid, which was further purified by column chromatography to yield 2.2 g of chemically pure PPO25 (purity 99.0% by HPLC).

Tg: 110 °C, ^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.55–8.49 (d, J = 12.0 Hz, 1H), 8.08–8.05 (d, J = 6.0 Hz, 1H), 7.88–7.69 (m, 12H), 7.61–7.50 (m, 14H), 7.37–7.30 (t, J = 7.0 Hz, 3H) ^{13}C NMR (200 MHz, $CDCl_3$): (ppm) 142.2, 140.8, 137.5, 137.1, 136.3, 134.3, 134.0, 132.6, 132.0, 131.4, 130.8, 130.9, 129.2, 129.0, 128.9, 128.2, 128.0, 127.9, 127.4, 126.1, 124.9, 123.9, 123.6, 123.0, 121.9, 121.4, 120.8, 120.2, 110.3, 109.2 MS (FAB) m/z 644 [$(M + H)^+$] Anal. Calcd. for $C_{42}H_{31}NO_2P_2$: C, 78.37; H, 4.85; N, 2.18; O, 4.97. Found: C, 78.12; H, 4.81; N, 2.00; O, 5.04.

2.7. Synthesis of 3-bromo-9-(2-bromophenyl)-9H-carbazole

Compound **5** (5.0 g, 15.51 mmol) was dissolved in dimethylformamide (DMF, 30 ml) under argon atmosphere. The reaction vessel was immersed in a ice bath until the temperature was about −20 °C and then *n*-bromosuccinimide (NBS, 3.0 g, 17.07 mmol) in DMF (15 ml) was added dropwise slowly into and stirred for 12 h. The mixture was allowed to gradually warm to room temperature overnight and then quenched with H_2O followed by extraction with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane to provided 5.54 g of title compound as white solid (m.p. 190–194 °C; 89% yield).

^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.26–8.22 (d, J = 8.0 Hz, 1H), 8.12–8.08 (d, J = 8.0 Hz, 1H), 7.88–7.68 (m, 2H), 7.55–7.30 (m, 5H), 7.07–7.01 (t, J = 6.0 Hz, 1H), 6.96–6.99 (t, J = 3 Hz, 1H).

2.8. Synthesis of 3-(diphenylphosphoryl)-9-(2-(diphenylphosphoryl)phenyl)-9H-carbazole (PPO26)

3-Bromo-9-(2-bromophenyl)-9H-carbazole (5.20 g, 12.96 mmol) was dissolved in tetrahydrofuran (THF, 50 ml) under argon atmosphere. The reaction vessel was immersed in a dry ice/acetone bath until the temperature was about −78 °C. To this solution 15.55 ml (38.89 mmol) of 2.5 M *n*-BuLi solution in hexane was added dropwise slowly and stirred for 3 h. Chlorodiphenylphosphine (7.18 ml, 38.89 mmol) was then added to the solution and stirred for 3 h in a dry ice/acetone bath. The mixture was allowed to gradually warm to room temperature overnight and then quenched with methanol followed by extraction with dichloromethane. The organic fractions were dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The residue was purified by column chromatography on silica gel using hexane/dichloromethane (10:1) to provided 2.6 g of title compound as white solid (33% yield).

The white solid was dissolved in dichloromethane (40 ml) and hydrogen peroxide (8 ml) was stirred overnight at room temperature. The organic layer was separated and washed with dichloromethane and water. The extract was evaporated to dryness affording a white solid, which was further purified by column chromatography to yield 2.8 g of chemically pure PPO26 (purity 99.1% by HPLC).

Tg: 110 °C, ^{1}H NMR (200 MHz, $CDCl_3$): (ppm) 8.33–8.27 (d, J = 12.0 Hz, 1H), 7.96–7.64 (m, 7H), 7.58–7.43 (m, 6H), 7.39–7.29 (m, 8H), 7.18–7.09 (t, J = 9.0 Hz, 3H), 7.01–6.94 (m, 6H) ^{13}C NMR (200 MHz, $CDCl_3$): (ppm) 143.7, 142.6, 139.6, 136.4, 135.6, 134.6, 133.6, 132.9, 132.5, 132.1, 131.8, 130.4, 129.9, 129.2, 128.9, 128.1, 127.9, 127.5, 126.8, 123.0, 122.7, 121.2, 120.8, 120.5, 120.2, 119.6, 111.8, 110.8 MS (FAB) m/z 644 [$(M + H)^+$] Anal. Calcd. for $C_{42}H_{31}NO_2P_2$: C, 78.37; H, 4.85; N, 2.18; O, 4.97. Found: C, 78.21: H, 4.84; N, 2.18; O, 4.99.

2.9. Device fabrication

A basic device configuration of indium tin oxide(ITO, 150 nm)/*N*,*N*′-diphenyl-*N*,*N*′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/*N*,*N*′-di(1-naphthyl)-*N*,*N*′-diphenylbenzidine (NPB, 5 nm)/*N*,*N*′-dicarbazolyl-3,5-benzene (mCP, 10 nm)/PPO21 or PPO25 or PPO26: tris((3,5-difluoro-4-cyanophenyl)pyridine) iridium (FCNIr) (30 nm, 15%)/diphenylphosphine oxide-4-(triphenylsilyl)phenyl (TSPO1, 15 nm)/LiF (1 nm)/Al (200 nm) was used for the device fabrication. Hole only and electron only devices had device configurations of ITO/DNTPD (60 nm)/NPB (5 nm)/mCP (10 nm)/host (30 nm)/Au and ITO/TSPO1 (10 nm)/host (30 nm)/TSPO1 (25 nm)/LiF (1 nm)/Al (100 nm), respectively. The evaporation rate of the organic materials was 0.1 nm/s and the deposition rate of the dopant was controlled according to the doping concentration of the dopant. Al was deposited at a deposition rate of 0.5 nm/s, while LiF deposition rate was 0.01 nm/s. The devices were encapsulated with a CaO getter and a glass rid after the device fabrication. The device performances of the blue PHOLEDs were measured with Keithley 2400 source measurement unit and CS1000 spectroradiometer.

3. Results and discussion

Three host materials based on a phenylcarbazole core and a diphenylphosphine oxide substituent were synthesized. Three host materials had two diphenylphosphine

oxide groups. One diphenylphosphine oxide group was attached to the phenyl unit of the phenylcarbazole, while the other diphenylphosphine oxide group was attached to the 3 position of the carbazole unit. The position of the diphenylphosphine oxide group attached to the phenyl unit was changed to study the effect of substitution position on the physical properties of the host material. All materials were synthesized by the reaction of the chlorodiphenylphosphine with brominated *N*-phenylcarbazole moiety followed by oxidation with hydrogen peroxide. Synthetic scheme of all materials is shown in Scheme 1. All materials were purified by column chromatography and a high purity level over 99% was obtained in all materials.

The energy level of the host material is critical to device performances of the PHOLED and is closely related with the molecular orbital distribution. Therefore, density functional theory (DFT) calculation of the host materials was carried out using a suite of Gaussian 03 program. The nonlocal density functional of Becke's 3-parameters employing Lee–Yang-Parr functional (B3LYP) with 6–31G* basis sets was used for the calculation [25]. Fig. 1 shows the HOMO and the lowest unoccupied molecular orbital (LUMO) orbital distribution of host materials synthesized in this work. The HOMO was mostly distributed over the carbazole unit of the phenylcarbazole core, while the LUMO was dispersed over the phenyl unit of the phenylcarbazole core and diphenylphosphine oxide in all host materials [15]. The carbazole unit is an electron donating group and the HOMO was localized in the carbazole group. The diphenylphosphine oxide is a strong electron withdrawing group and the LUMO was dispersed over the phenyl and diphenylphosphine oxide groups. There was little difference of the molecular orbital distribution between the three materials. The calculated HOMO levels of the PPO21, PPO25 and PPO26 were 5.56, 5.66 and 5.74 eV, while the LUMO levels were 1.12, 1.17 and 1.07 eV. Although the molecular orbital distribution of the three host materials was similar, the HOMO level was increased in the PPO26 with the diphenylphosphine oxide at ortho position. This indicates the

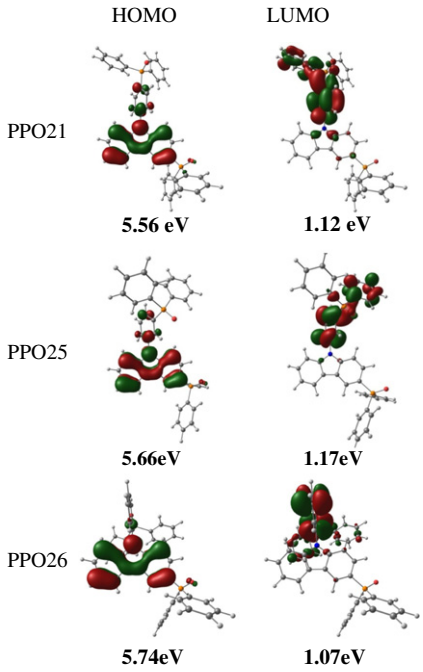

Fig. 1. Molecular simulation results of PPO21, PPO25 and PPO26. HOMO and LUMO orbital distribution is shown in this figure.

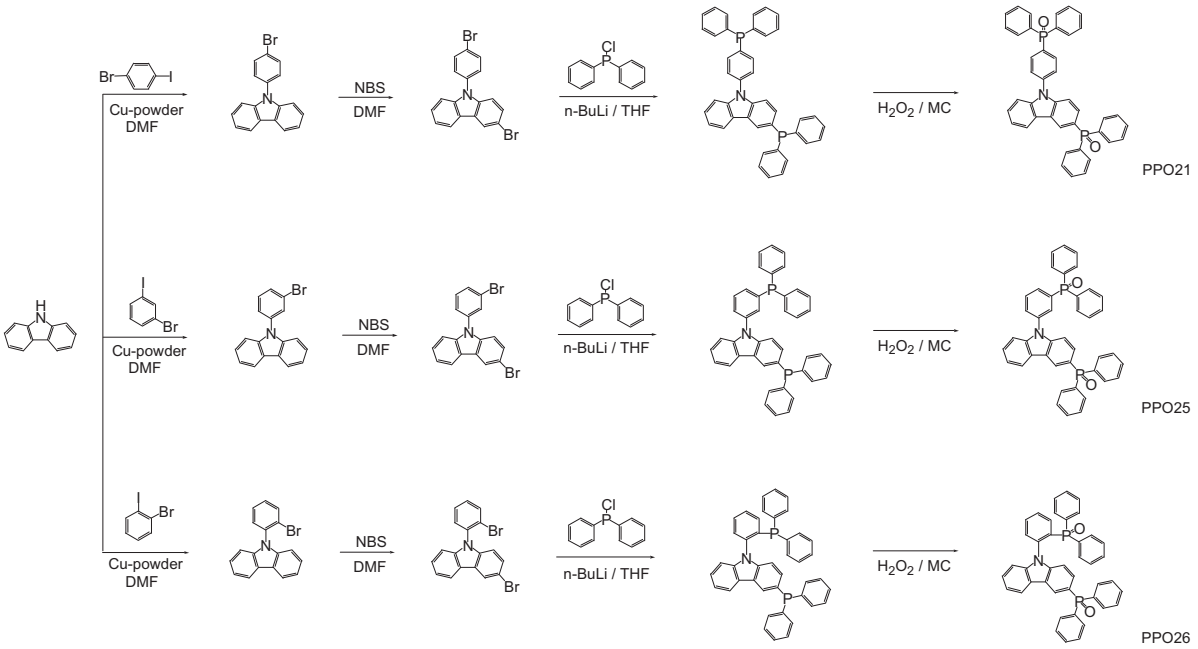

Scheme 1. Synthetic scheme of PPO21, PPO25 and PPO26.

reduction of the electron density in the carbazole group of the PPO26.

Photophysical properties of the host materials were analyzed with ultraviolet–visible (UV–vis) and photoluminescence (PL) measurements. UV–vis and PL spectra of the host materials are shown in Fig. 2. UV–vis absorption of the three host materials was similar and there was little shift of the UV–vis absorption peak. The main absorption of the three host materials is $\pi-\pi$ transition of the phenylcarbazole core at 338 nm, resulting in similar absorption spectra. However, the PL spectra were different depending on the substitution position of the diphenylphosphine oxide. In particular, the PL spectrum of the PPO26 with the diphenylphosphine oxide at ortho position of the phenyl group was red-shifted and broadened compared with that of other host materials. The peak maximum of the PPO26 was 375 nm compared with 361 nm of the PPO25. The electron is partially transferred from the carbazole unit to the phosphine oxide unit, resulting in intramolecular charge transfer complex formation. The bandgap is reduced by the charge transfer complex formation, and the PL emission is red-shifted and broadened.

Solid PL spectra of the evaporated host materials are shown in Fig. 3. The solid PL spectra of the host materials were red-shifted and the full width at half maximum was also increased due to intermolecular interaction in solid state. In particular, the PPO26 with a phosphine oxide at ortho position showed two PL emission peaks at 367 and 450 nm. The PL emission peak at 367 nm is assigned to the PL emission of the phenylcarbazole core, while the PL emission at 450 nm is assigned to the emission of the intramolecular charge transfer complex. The intramolecular charge transfer emission was strong in the solid state by the solvent effect of polar PPO26 molecules. The UV–vis absorption spectrum of the dopant material is also shown in Fig. 3. The PL emission of host materials was well overlapped with the UV–vis absorption of the FCNIr dopant, indicating efficient energy transfer from the host to dopant in solid state.

The intramolecular charge complex formation was confirmed from solution PL of host material using various solvents with different polarity. It is well known that strong solvatochromic effect is observed in the organic material

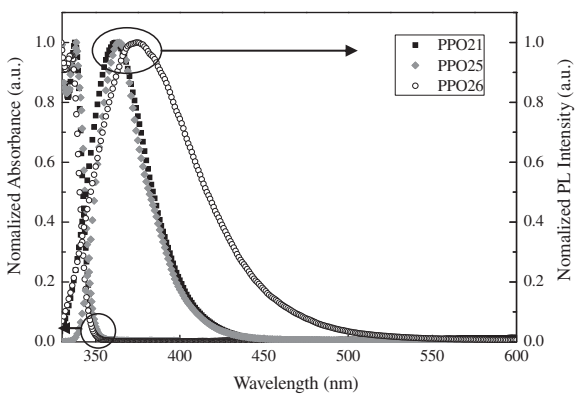

Fig. 2. UV–vis and solution PL spectra of PPO21, PPO25 and PPO26.

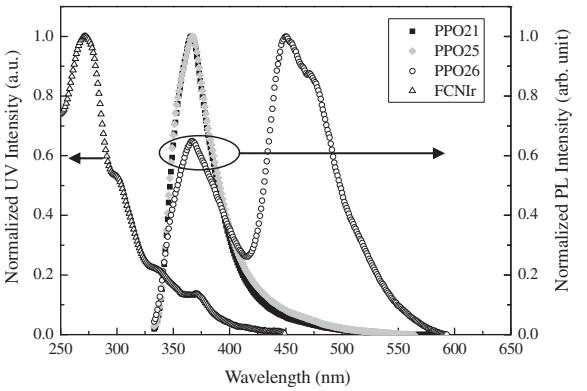

Fig. 3. Solid PL spectra of PPO21, PPO25 and PPO26. UV–vis spectrum of the FCNIr dopant was also added.

with charge transfer complex formation [26]. Fig. 4 shows the solution PL spectra of PPO25 and PPO26 at different solvents. Hexane, THF and methanol (MeOH) were used as the solvents. In the case of PPO25 with little intramolecular charge transfer complex formation, the PL emission was shifted only by 3–5 nm in highly polar MeOH solvent. However, the PL emission of PPO26 was red-shifted by more than 40 nm in highly polar solvent, proving the intramolecular charge transfer complex formation. Therefore, the solid PL emission of the PPO26 at long wavelength is originated from intramolecular charge transfer complex formation. The PPO26 is surrounded by higly polar PPO26 molecule and red-shifted PL emission of PPO26 by intramolecular charge transfer complex formation is observed.

The HOMO levels of three host materials were measured from the oxidation potential of the cyclic voltametry and the bandgap from UV–vis spectra. Energy levels of the host materials are summarized in Table 1. There was little difference of the HOMO and LUMO levels between the host materials. The HOMO was dispersed over the phenylcarbazole core in all host materials and similar HOMO levels were obtained. The LUMO was also distributed over the phenyl group substituted with diphenylphosphine oxide in all materials, resulting in similar LUMO levels. This can be further understood by analyzing the HOMO and LUMO distribution of 3-(diphenylphosphoryl)-9-phenyl-9H-carbazole (PPO1) without the diphenylphosphine oxide unit attached to the phenyl unit of the 9-phenylcarbazole [11]. The HOMO (6.16 eV) and LUMO (2.60 eV) of the PPO1 were localized in the carbazole unit with little dispersion over the phenyl unit. This indicates that the HOMO and LUMO of PPO1 are not greatly affected by substitution of electron withdrawing or donating moiety to the phenyl unit (less than 0.1 eV). Therefore, the substitution of the diphenylphosphine oxide group to the phenyl unit did not significantly change the HOMO and LUMO levels of host materials. In our previous work, the substitution of the diphenylphosphine oxide at the carbazole unit change the energy level by about 0.3 eV [11]. Therefore, the substitution of the diphenylphosphine oxide at the phenyl unit showed less significant effect on the energy level than the substitution of the diphenylphosphine oxide at the carbazole unit. Although the calculated HOMO level from

Table 1
Physical properties of PPO21, PPO25 and PPO26.

	Optical analysis				Electrical analysis		
	UV absorption (nm)	PL solution (nm)	PL solid (nm)	HOMO (eV)	LUMO (eV)	Bandgap (eV)	E_T (eV)
PPO21	337	362	366	6.25	2.68	3.57	3.01
PPO25	338	364	367	6.25	2.70	3.55	2.99
PPO26	335	375	367 450	6.25	2.67	3.58	3.01

molecular simulation was shifted in the three host materials, experimental HOMO levels were the same in the three organic materials.

The triplet energy of the host materials was measured from low temperature PL emission peak and the triplet energy was 2.99–3.01 eV. All host materials showed a high triplet energy about 3.00 eV irrespective of the substitution position of the diphenylphosphine oxide. The triplet energy of the phenylcarbazole core was 3.01 eV and the diphenylphosphine oxide did not change the triplet energy of the phenylcarbazole core. As reported earlier, the diphenylphosphine oxide unit does not extend the conjugation of the core structure and did not reduce the triplet energy of the core [8]. Therefore, all host materials synthesized in this work can be effective as host materials for deep blue phosphorescent device.

Deep blue PHOLEDs were fabricated using three host materials doped with deep blue emitting FCNIr dopant. Fig. 5 shows the current density–voltage–luminance curves of the deep blue PHOLEDs doped with FCNIr at a doping concentration of 20%. The current density was high in the PPO26 with the diphenylphosphine oxide at ortho position, while it was low in the PPO21 with the diphenylphosphine oxide at para position. The current density generally depends on the hole and electron density in the device. Therefore, hole and electron current density of three host materials was compared.

Current density–voltage curves of hole only and electron only devices of three host materials are shown in Fig. 6. The PPO26 showed the highest hole current density and lowest electron current density. The hole and electron current density depends on the energy barrier for charge

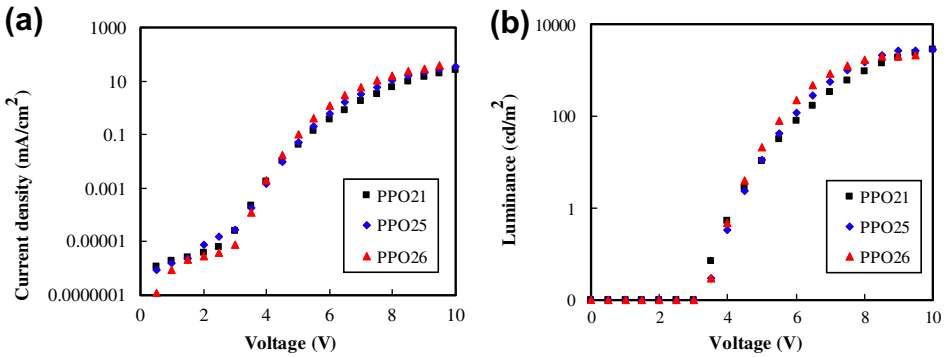

Fig. 5. Current density–voltage (a) and luminance–voltage and (b) curves of the deep blue PHOLEDs with the PPO21, PPO25 and PPO26.

injection and charge transport properties. Considering the HOMO level for hole injection, there should be no difference of the hole current density. Therefore, the increased hole current density of the PPO26 is due to improved hole transport properties of the PPO26. The origin for the improved hole transport properties of the PPO26 can be found in the intramolecular charge transfer complex formation in the PPO26. The carbazole unit donates electrons to the partially positive P atom in the phosphine oxide unit. This can give rise to weak p type doping effect in the carbazole unit, enhancing the hole transport properties of the PPO26. Similar increase of the hole current density by the weak p-type doping effect was reported in other work [27]. On the contrary, the electron donating effect of the carbazole to the P atom in the phosphine oxide has negative effect on the electron transport properties, leading to the low electron current density. The high hole and electron current density of the PPO25 compared with PPO21 may be due to small molecular size of the PPO25 for good hole and electron hopping. The HOMO and LUMO of the host materials were localized in the molecular structure and large molecule size hinders the charge transport through hopping.

Considering the hole and electron current density of the device, the high current density of the PPO26 device is due to high hole current density [28]. Both hole and electron current density of the PPO21 was lower than that of the PPO25, leading to low current density in the PPO21 device. The luminance followed the same relationship as the current density.

The quantum efficiency–luminance curves of the deep blue PHOLEDs are shown in Fig. 7. The PPO21 showed the highest maximum quantum efficiency of 20.4%, while the PPO25 and PPO26 showed the same maximum quantum efficiency of 17.1%. The maximum quantum efficiency of the PPO21 device is one of the best quantum efficiency value reported in the literature. Comparing the quantum efficiency at 1000 cd/m^2, the PPO21 and PPO25 showed better quantum efficiency than PPO26. The quantum efficiency is generally affected by the charge balance in the emitting layer. As shown in the hole only and electron only device data, the PPO26 showed the highest hole current density and lowest electron current density. Therefore, the charge balance is worse than other host materials, which decreased the quantum efficiency of the PPO26 device. PPO25 was better than PPO21 in terms of efficiency roll-off. Balanced charge injection and balanced hole/electron density at low and high voltage improved the quantum efficiency at high luminance. Device data of the host materials are summarized in Table 2.

Table 2
Device performances of PPO21, PPO25 and PPO26 blue devices.

	Turn on voltage (V)	Driving voltage (V)[a]	Maximum quantum efficiency (%)	Quantum efficiency (%)[a]	Maximum power efficiency (lm/W)	Power efficiency (lm/W)[a]	Color coordinate[a]
PPO21	3.5	8.2	20.4 ± 1.7	11.9 ± 1.1	26.1 ± 2.4	6.6 ± 0.9	(0.14, 0.19)
PPO25	3.5	7.6	17.1 ± 1.3	12.3 ± 1.4	21.2 ± 1.9	7.3 ± 1.0	(0.15, 0.19)
PPO26	3.5	7.2	17.1 ± 1.2	10.4 ± 1.3	20.6 ± 2.1	6.4 ± 0.8	(0.15, 0.18)

[a] Data were measured at 1000 cd/m^2.

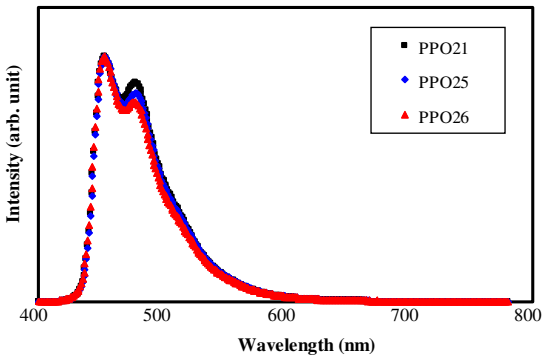

Fig. 8. Electroluminescence spectra of the deep blue PHOLEDs with the PPO21, PPO25 and PPO26 hosts.

Electroluminescence (EL) spectra of the deep blue PHOLEDs are shown in Fig. 8. Three blue PHOLEDs showed similar EL spectra with a peak maximum at 454 nm. The color coordinate of the deep blue PHOLEDs was (0.14, 0.18) in all host materials. Therefore, high efficiency deep blue PHOLEDs with a *y* color coordinate less than 0.20 could be developed using the phenylcarbazole based phosphine oxide compounds.

4. Conclusions

The photophysical properties and device performances of phenylcarbazole based phosphine oxide host materials were correlated with the substitution position of the phosphine oxide. The substitution at ortho position of the phenyl group induced an intramolecular charge transfer complex formation, while meta or para substitution did not significantly change the physical properties of the core structure. The ortho substitution enhanced the current density through intramolecular charge transfer, while the meta and para substitution enhanced the quantum efficiency of the deep blue PHOLEDs. A high quantum efficiency of 20.4% could be achieved using the high triplet energy host materials in deep blue PHOLEDs.

tens of volts and poor subthreshold slopes on the order of several volts/decade, both of which depend on the dielectric capacitance. Such characteristics would render these devices unusable in practical O-CMOS circuits.

Gundlach et al. [6] discuss the large threshold voltage of PTCDI devices. They note that although a relatively small threshold voltage hysteresis of only a few volts occurs between successive off–on and on–off sweeps, which they refer to as the reversible threshold voltage shift (TVS), a very large, irreversible (on the timescale of the measurement) threshold voltage shift of several 10 s of volts occurs when the devices are first biased in the on state (positive V_{gs}). The large initial shift most likely indicates a large density of deep electron traps in either the bulk or at the semiconductor/dielectric interface that are populated when the device is initially operated. As will be discussed later, great care must be taken when calculating carrier mobilities from such initial sweeps, as the threshold voltage continues to shift to more positive values throughout the duration of the measurement, leading to large errors in the extracted mobility.

Recently, Walser et al. [8] have reported that PTCDI-C_{13} devices fabricated using a Cytop® CTL-809M fluoropolymer single-layer dielectric show negligible threshold voltage shift (including the initial, irreversible component), and have near-zero, slightly positive threshold voltages and excellent subthreshold swings. Even with a lower-capacitance, bilayer SiO_2 (260 nm)/Cytop® (7–9 nm) dielectric, these devices exhibit excellent subthreshold swings of 0.6 V/decade and relatively small threshold voltages of 7 V [10]. We note, however, that the low dielectric constant ($\varepsilon_r = 2.1$) and dielectric strength (900 kV/cm) [11] reported by the manufacturer of Cytop® are disadvantageous properties for a transistor gate dielectric, although there are reports of significantly higher dielectric strengths in the literature [8]. In addition, the non-wetting nature of the fluoropolymer surface makes subsequent processing, such as patterning using photoresists or solution deposition of organic semiconductor materials, problematic.

To investigate these effects, and to try to find more suitable, stable and hysteresis-free dielectrics, we have performed a systematic study of PTCDI-C_{13} transistors fabricated using several dielectrics: Cytop®, bare SiO_2, alkyl-phosphonic acid self-assembled monolayer (SAM) terminated SiO_2, and poly(chloro-*p*-xylylene), or parylene-c, which has a dielectric strength three times that of Cytop® and a relative permittivity of 3.1. Although parylene-c has previously been demonstrated as a suitable gate dielectric material for p-channel devices [12], we believe this is the first investigation of its use in n-channel OTFTs.

2. Experimental

PTCDI-C_{13} transistors were fabricated on heavily doped Si wafers (p-type; boron; <0.005 Ω cm) with 100 nm thermal SiO_2. The Si wafer served as a common gate electrode for all transistors, and the thermal oxide plus various overlayers (SAMs, Cytop®, parylene) as the gate dielectric. Si coupons were sonicated in methanol, immediately blown dry with dry compressed air, followed by oxygen plasma cleaning in a parallel plate reactive ion etcher (Trion Technologies Phantom) at 250 W rf power, 200 mTorr, 20 sccm O_2 for 1 min. After removal from the plasma, each coupon underwent further processing, depending on the dielectric to be studied.

For phosphonic acid SAMs, the coupons were immediately immersed in 0.5 mmol solutions of n-alkyl phosphonic acids (Strem Chemical) in 2-propanol, where the alkyl chain length was one of C_6–C_{18}, in steps of 2 carbon atoms. After immersion for 24 h, the coupons were removed from the solution, annealed under rough vacuum at 145 °C for 10 min, rinsed in clean 2-propanol and immediately blown dry with compressed air.

Cytop® dielectrics were prepared by spin coating 3 parts Cytop® CTL-809 M dissolved in 14 parts CTSolv-180 at 500 rpm for 30 s, resulting in a Cytop® film 110 nm thick on top of the 100 nm SiO_2 film. Capacitors of 0.5, 1 and 2 mm diameters were fabricated by deposition of metal electrodes through a stencil mask. The specific capacitance was determined at frequencies from 100 Hz to 100 kHz, and was found to be 11 nF/cm^2, independent of frequency within experimental uncertainty. This corresponds to a relative permittivity of 2.1 for Cytop®, in close agreement with the values given by the manufacturer [11].

Parylene dielectrics were prepared in a Specialty Coating Systems Labcoater 2 parylene deposition system. Film thickness is determined by the amount of di-(chloro-*p*-xylylene) dimer processed, and measured post-deposition using a Dektak 150 Surface Profiler. Specific capacitance was determined as above, and was found to be 15 nF/cm^2, independent of frequency, for the compound dielectric with a 101 nm-thick film. This corresponds to a relative permittivity of 3.1 for parylene-c, in close agreement with accepted values.

Following dielectric preparation, the samples were transferred to a vacuum deposition system (base pressure 1×10^{-6} Torr; pressure during deposition $<8 \times 10^{-6}$ Torr). 50 nm of PTCDI-C_{13} (Sigma Aldrich PN 3837783; as-received) was deposited through a stencil mask at 0.05–0.1 nm/s onto the coupons held at 90 °C. The samples were allowed to cool to <40 °C before vacuum was broken (briefly exposing the samples to air), and a source-drain stencil mask was aligned with the active semiconductor. Aluminum source-drain contacts were deposited at a rate of 0.1 nm/s to a thickness of between 50 and 60 nm with the samples nominally held at room temperature. Each coupon contained an array of 24 transistors with channel lengths ranging from 25 μm to 250 μm and widths between 0.5 mm and 1.5 mm. After metal deposition, the samples were again exposed to air for a few minutes before transferring to a N_2 glove box for testing (MBraun Unilab; <1 ppm H_2O, O_2). All testing, unless otherwise noted, was performed under N_2.

Electrical characteristics of the PTCDI-C_{13} OTFTs were measured using two Keithley 236 source-measure units – one to control the source-drain voltage and measure the drain current, and one to control the source-gate voltage and measure the gate leakage current. The saturation and linear transfer curves were measured by applying +50 V and +1 V, respectively, to the drain and sweeping the gate from −5 V to +50 V and back for the off-to-on and on-to-off

scans, respectively. In all cases, an initial off-to-on scan is performed prior to an on-to-off scan to determine threshold voltage shifts/hysteresis due to electron trapping. The sweep rate is dependent on the integration time of the Keithley 236 SMUs, which is dynamically adjusted, depending on the magnitude of the current being measured. For most of the sweep, an effective rate of 2 V/s was used, although it was as low as 0.5 V/s in the "off" region, where the currents are very small. Device parameters were not studied as functions of sweep rate. The saturation and linear threshold voltages and electron mobilities were extracted from the transfer curves from the intercept and slope, respectively, of the linear portion of the square root of the drain current (for saturation) or drain current (for linear) as a function of gate voltage, assuming the ideal n-channel FET equations to hold:

$$I_{\mathrm{Dsat}} = \mu_n C_{\mathrm{ox}} \frac{W}{2L}(V_{\mathrm{gs}} - V_{\mathrm{t}})^2, \quad V_{\mathrm{ds}} \geqslant V_{\mathrm{gs}} - V_{\mathrm{t}} \tag{1}$$

$$\sqrt{I_{\mathrm{Dsat}}} = \sqrt{\mu C_{\mathrm{ox}} \frac{W}{2L}}(V_{\mathrm{gs}} - V_{\mathrm{t}}) \tag{2}$$

$$I_{\mathrm{Dlin}} = \mu_n C_{\mathrm{ox}} \frac{W}{L}\left[(V_{\mathrm{gs}} - V_{\mathrm{t}})V_{\mathrm{ds}} - \frac{V_{\mathrm{ds}}^2}{2}\right], \quad V_{\mathrm{ds}} \leqslant V_{\mathrm{gs}} - V_{\mathrm{t}} \tag{3}$$

Device stability was investigated by repeating the above off–on–off cycle one hundred times, and device parameters were extracted as functions of cycle number. One hundred such cycles corresponds to a total stress time of approximately two and a half hours.

3. Results

3.1. SiO_2 control

A typical first cycle of a control PTCDI-C_{13} transistor on bare SiO_2 is shown in Fig. 1a. We note the large degree of hysteresis between the off–on and on–off scans. Such shifts are typical of PTCDI/SiO_2 devices, and have been noted before [6]. Gundlach et al. refer to these large initial shifts as the irreversible threshold voltage shift, as the threshold voltage does not recover to its initial value on the timescale of the experiment. Indeed, they note that while some devices do seem to recover after several days, others never return to the initial, near-zero threshold voltage seen in the first off–on scan. We have made the same observation. We will refer to this effect simply as the threshold voltage shift. A much smaller shift, seen between subsequent off–on and on–off sweeps, that recovers on the timescale of a single cycle, will be referred to as the threshold voltage hysteresis.

It is important to be aware of these large initial threshold voltage shifts when extracting parameters from the device transfer curves. For instance, referring to Eq. (2), the saturation mobility is typically extracted from the slope of the square root of the drain current plotted against the gate-source voltage, V_{gs}. In such analysis, it is implicitly assumed that the threshold voltage, V_{t} is a constant. In the case of the devices described here, however, V_{t} is not a constant, and further more, it is not simply dependent on the value of V_{gs}. It is dependent of the past history of V_{gs}. Considering the first sweep, as performed above from the off state to the on state, the threshold voltage is shifting to more positive voltages during the measurement. This causes the drain current to increase more slowly that it would if V_{t} were constant, and the electron mobility extracted assuming constant V_{t} greatly underestimates the true mobility (which we define as the value that would be extracted in the absence of dynamic filling/emptying of traps during a gate voltage sweep). For the data shown in Fig. 1a, the true electron mobility is approximately 0.23 cm^2/Vs, while the mobility extracted from the initial off–on sweep, assuming constant V_{t}, is only 0.05 cm^2/Vs. The converse is also true. If we had chosen our initial sweep to be from the on state to the off state, the threshold voltage would still have shifted to more positive values as the sweep progressed, and the current would have decreased more sharply than it would if V_{t} were constant, resulting in an overestimate of the electron mobility. By using initial sweeps from on to off (not shown) we have extracted erroneous electron mobilities as high as 2 cm^2/Vs. Obviously, great care must be taken when analyzing data from devices exhibiting such threshold voltage shifts.

By repeated cycling of these devices between the off, on and off states, we have studied the evolution of the threshold voltage as a function of cycle number. A selection of saturation transfer curves from one such experiment is presented in Fig. 1b. We note that both the threshold voltage shift and hysteresis appear to asymptotically approach steady-state values. The overall threshold voltage shift is approximately 35 V and the steady-state threshold voltage hysteresis between off–on and on–off sweeps is approximately 1.5 V. We also note that the mobility appears to approach a steady-state value of 0.23 cm^2/Vs for the off–on sweep, and 0.26 cm^2/Vs for the on–off sweep. A summary of the evolution of device parameters with cycle number is presented in Fig. 2.

3.2. Alkyl phosphonic acid SAMs

Devices were fabricated and tested using alkyl phosphonic acid modified SiO_2 dielectrics with chain lengths of 6–18 carbon atom in steps of two. Our previous work found that pentacene devices had superior performance when chain lengths of 8 and 10 carbon atoms were used [13]. In the case of PTCDI-C_{13} devices, however, the performance was found to improve monotonically with increasing chain length. The results that follow will therefore focus on PTCDI-C_{13} films deposited on octadecyl phosphonic acid modified SiO_2.

The first cycle (off–on–off) of a device fabricated using octadecyl phosphonic acid is presented in Fig. 3a. The appearance of the hysteresis loop is similar to that of the SiO_2 control devices with two important differences. First, the threshold voltage shift, while still large, appears to be significantly smaller than that of the control devices, and second, there appears to be an inflection point in the on–off sweep, well below threshold, at a V_{gs} of approximately 12–14 V. Gundlach et al. noted a similar feature in the second sweep of similar devices fabricated on untreated SiO_2, and attributed it to a discrete trap level [6]. Here, while we have found evidence of such a state on some untreated

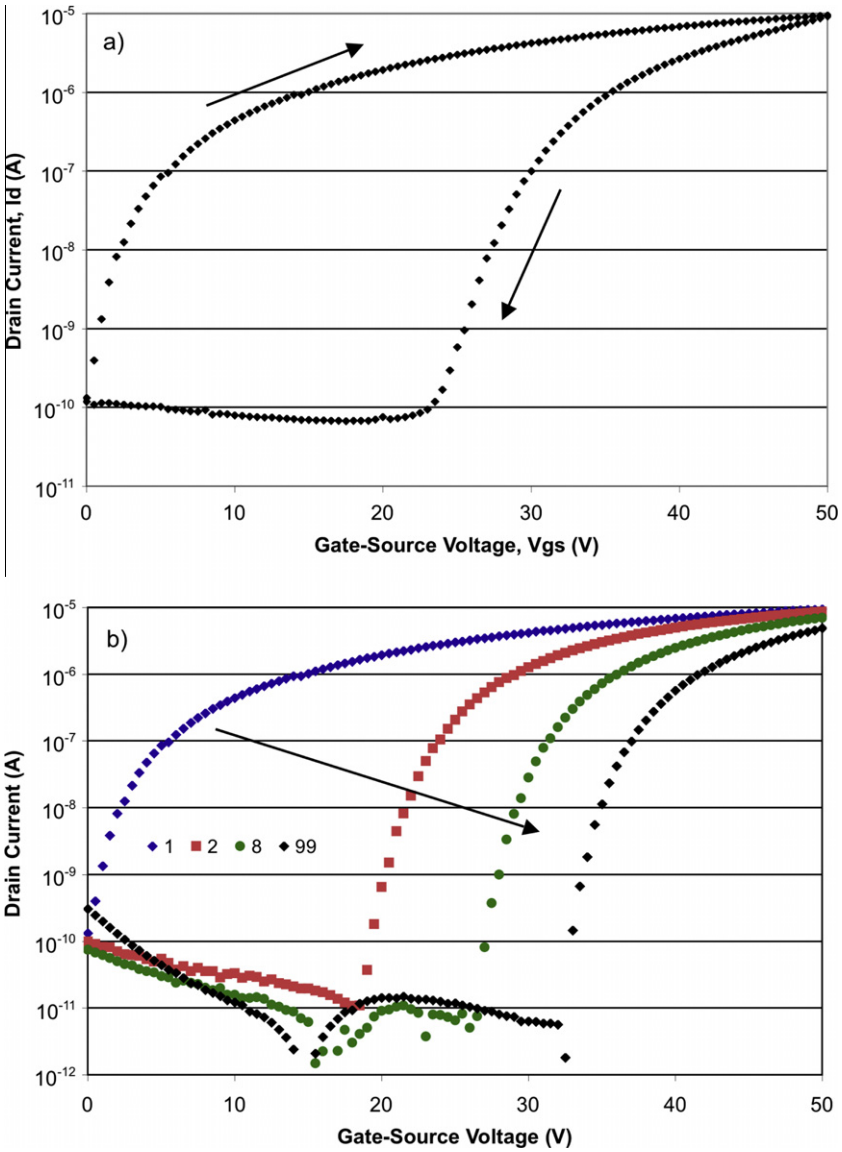

Fig. 1. PTCDI-C_{13}/SiO_2 (a) first off–on–off sweep indicating the large initial, irreversible threshold voltage shift (b) off–on sweeps from repeated cycling tests. Cycle numbers indicated.

SiO_2 devices, we have found much more pronounced and consistent evidence of a significant density of trap states induced by the presence of the alkyl-PA monolayer at all chain lengths. When the devices are cycled (Fig. 3b), we find the threshold voltage continues to shift to more positive values, approaching a steady state value. The evolution of device parameters versus scan number is presented in Fig. 2. Note the erroneously high electron mobility of almost 0.9 cm^2/Vs extracted from the first on–off sweep caused by the positive shift of the threshold voltage during the sweep as discussed above.

3.3. Cytop®

In Fig. 4a we present the first off–on–off cycle of the saturation transfer curve for a typical PTCDI-C_{13} device fabricated on a Cytop® dielectric. We note that virtually no hysteresis between the initial off–on and on–off scans is evident, as previously reported [8,10]. Additionally, the trap state evident in the alkyl-PA devices that resulted in the inflection point below threshold is completely absent in the Cytop® devices, clearly indicating that the origin of this feature is related to the dielectric or the semiconductor/dielectric interface, and not to the bulk semiconductor material. Off–on scans for a selection of cycle numbers are presented in Fig. 4b, with an inset on an expanded *x*-scale to illustrate the small degree of shift observed. The evolution of device metrics is presented in Fig. 5. We note an initial threshold voltage shift of *negative* 0.1–0.15 V during the first few sweeps, after which the threshold voltage begins to increase slowly with increasing cycle number. A small hysteresis of −50 mV is observed between initial

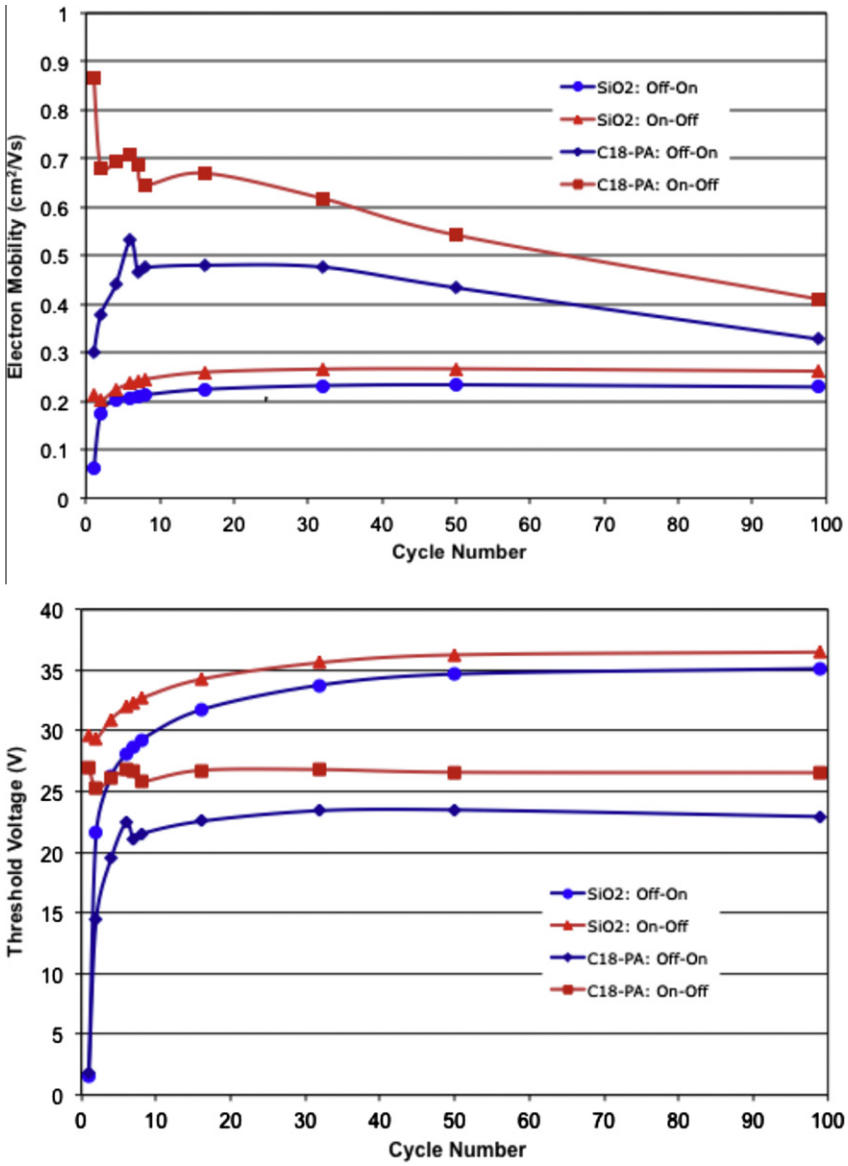

Fig. 2. Parameters extracted from repeated cycling of PTCDI-C_{13}/SiO_2 and PTCDI-C_{13}/octadecyl phosphonic acid/SiO_2 devices.

off–on and on–off sweeps, and is almost completely absent in later cycles. Negative (counter clockwise) hysteresis in n-channel devices can be attributed to the slow drift of ions or the reorientation of dipolar species within the polymer dielectric. Similar effects have been seen in p-channel pentacene transistors that exhibit positive (clockwise) hysteresis [14,15]. We also note a slight but consistent decrease in the electron mobility over time.

3.4. Parylene-C

The initial off–on–off cycle and a subset of the repeated sweep data for PTCDI-C_{13} devices fabricated with a parylene-c dielectric are presented in Fig. 6a and b, respectively. As in the case of Cytop® dielectrics, we find almost no visible hysteresis between off–on and off–on sweeps. Upon closer inspection (Fig. 6a, inset) we find an off–on/on–off hysteresis of −50 mV, similar to that of the Cytop® devices. Also, in contrast to all other devices reported here, the threshold voltage tends to shift to more negative values with repeated cycling (Figs. 6b and 5). After 100 cycles, the threshold voltage has shifted by ∼−1 V, significantly larger than the shift observed for Cytop® devices, but much smaller than the shift observed for SiO_2 or alkyl-PA devices. As in the case of Cytop®, we attribute the counter clockwise hysteresis and negative threshold voltage shift to the drift of ions and slow reorientation of dipoles within the polymeric dielectric [14,15]. Furthermore, we note that the shift has a much longer time constant, continuing to shift throughout the 100-cycle experiment. In contrast with Cytop® devices, we find that the measured mobility tends to *increase* slightly with increased cycling. Note the

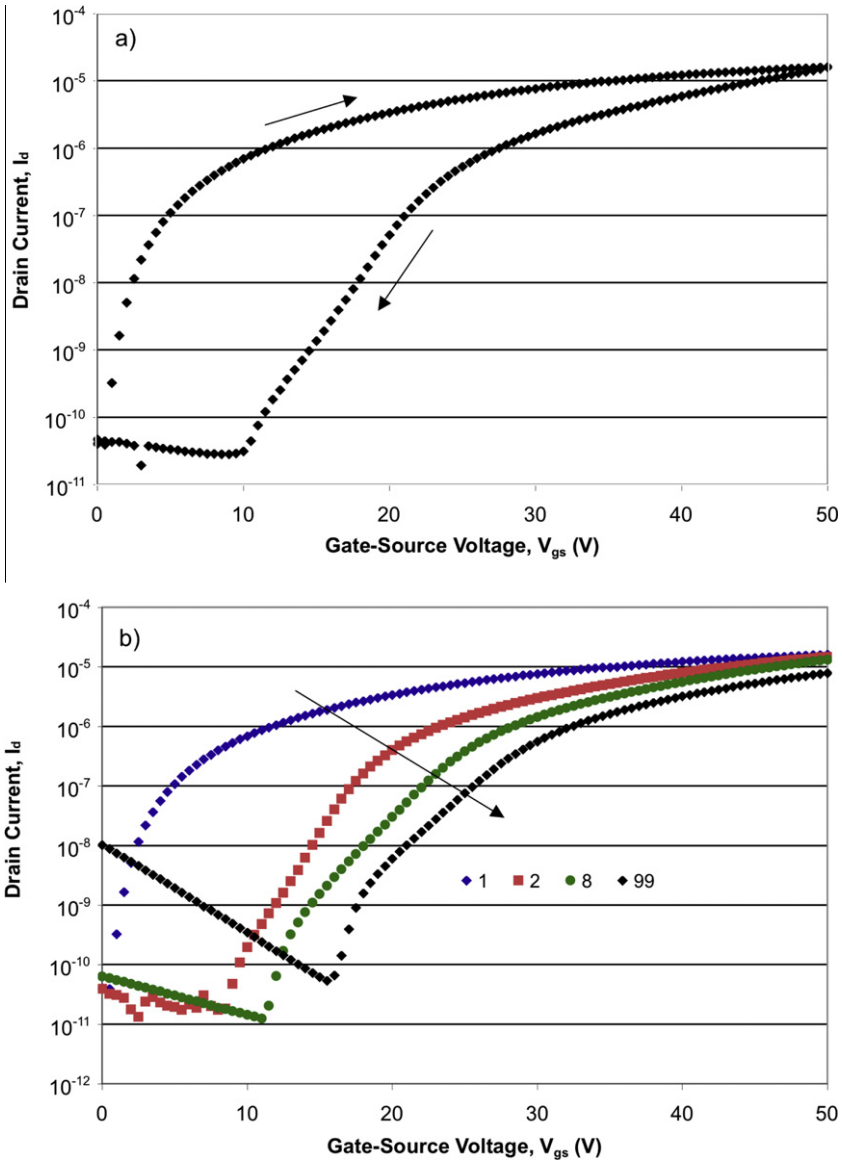

Fig. 3. PTCDI-C_{13}/octadecyl phosphonic acid/SiO_2 devices (a) initial off–on–off cycle, (b) repeated cycling (cycle numbers indicated).

apparent contradiction between the voltage hysteresis of 50 mV from Fig. 6a, and the almost 0.4 V threshold voltage hysteresis reported in Fig. 5. The mobility measured from the on–off sweep is consistently lower than that of the off–on sweep. Thus, the slope of the $\sqrt{I_d}$ plots will be lower for the on–off sweep than the off–on sweep. The horizontal distance (voltage) between points of equal current must therefore decreases as we approach the common point at V_{gs} = 50 V.

4. Discussion

The large degree of hysteresis, irreversible threshold voltage instability, and high operating voltages of PTCDI-C_{13} devices fabricated on SiO_2 dielectrics and alkyl-PA treated SiO_2 render these OTFTs unsuitable for use in electronic devices, including O-CMOS digital logic circuits. We attribute these undesirable characteristics to a large density of electron trapping sites at the semiconductor/dielectric interface, most likely due to hydroxyl groups present on the SiO_2 interface [16]. While the phosphonic acid monolayer does displace a large number of these groups, they are not completely eliminated. We therefore observe improved transistor characteristics when the monolayers are introduced, including smaller irreversible threshold voltage shifts, lower threshold voltages and less hysteresis between off–on and off–on sweeps, but the influence of the remaining traps is still too large for a feasible technology. Furthermore, we stress again the care that must be taken when extracting mobilities from the transfer curves of such devices during the first few sweeps, while the

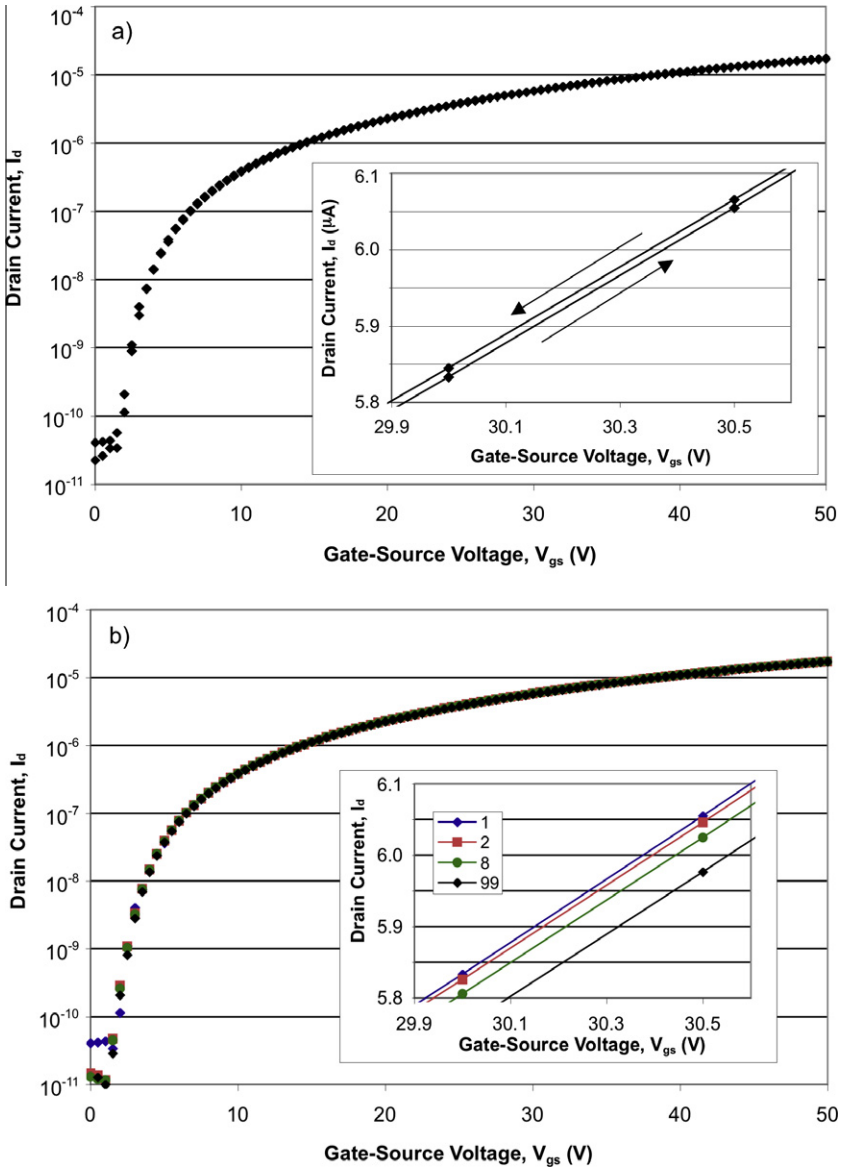

Fig. 4. PTCDI-C_{13}/Cytop devices (a) initial off–on–off cycle, (b) repeated cycling (cycle numbers indicated). Insets are included so that the small hysteresis (a) and threshold shift (b) are visible.

threshold voltage is continually shifting to larger positive voltage. If extracted from the initial off–on sweeps, the resulting mobility will be lower than the true value and if extracted from the initial on–off sweep (especially if this is the first sweep of a fresh device), the reported mobility can be nearly an order of magnitude larger than the true value. Surprisingly, we note almost no difference between the mobility extracted from the steady-state sweeps on devices with large densities of electron trapping states, and those measured on Cytop® and parylene-c devices, which appear to have much lower trap densities. This would seem to indicate that the dominant trap states associated with the semiconductor/dielectric interface are energetically deep, with detrapping times that are long compared to the length of the experiment. We would expect the elimination of shallow traps (such as those described in a multiple trap and release model) to increase the macroscopically observed electron mobility, while populating deep, long-lived traps will result in electrostatic shifting of the threshold voltage, as observed here. It is most likely that a continuum of electron trap states exists below the conduction band edge, with a corresponding distribution of detrapping times, as evidenced by the very long-lived irreversible threshold voltage shift, and the smaller off–on/on–off hysteresis observed between subsequent sweeps. We cannot rule out the existence of shallow electron traps in the bulk of the PTCDI-C_{13} film, or traps at the semiconductor/dielectric interface that are insensitive to the choice of dielectrics we have presented here (although this seems unlikely, given the very different physical and

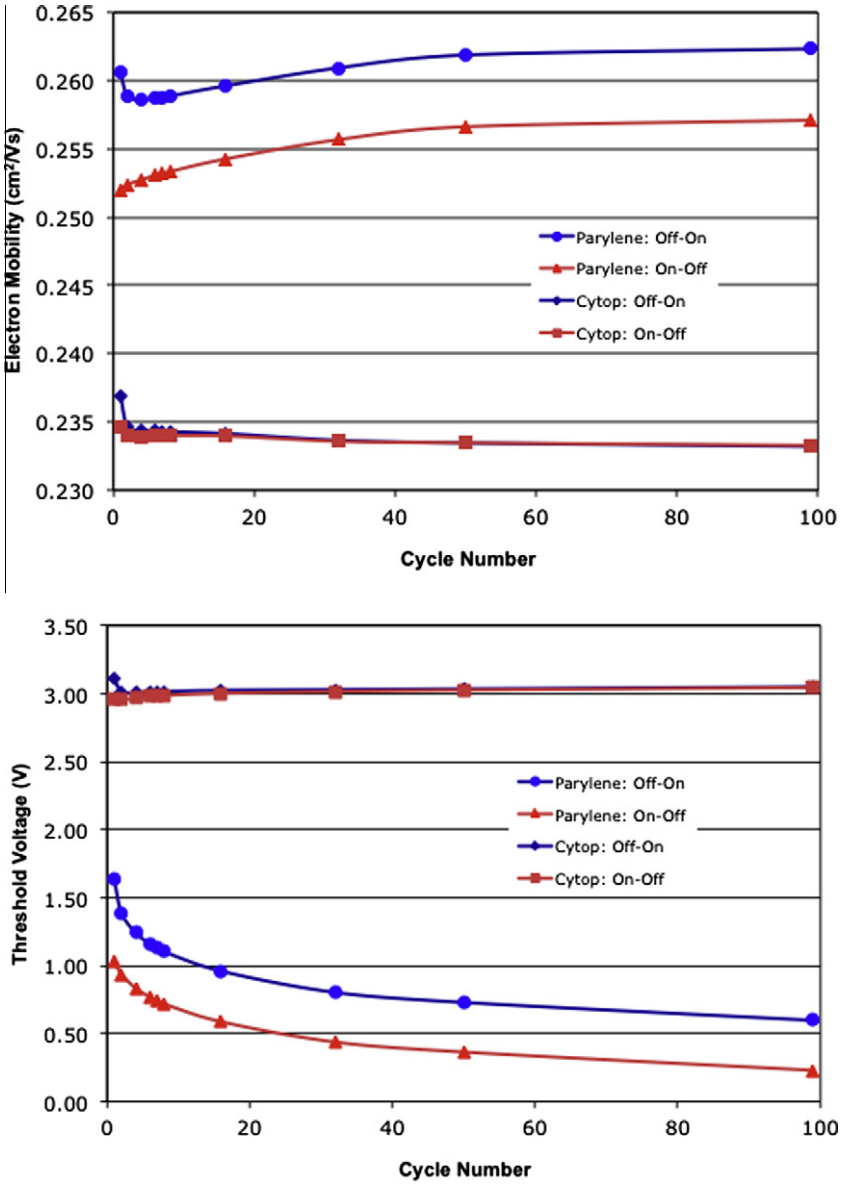

Fig. 5. Evolution of parameters extracted from repeated cycles of PTCDI-C_{13}/Cytop and PTCDI-C_{13}/parylene-c devices. Note vertical scales.

chemical properties of the materials studied). The results clearly show, however, that the electron traps associated with the SiO_2 surface that are attributed to hydroxyl groups are energetically very deep, as their elimination does not strongly influence the macroscopically observed electron mobility.

Both Cytop® and parylene-c are suitable dielectrics for PTCDI-C_{13}. Both result in devices with stable, positive, near-zero threshold voltages. Both have vanishingly small off–on/on–off hysteresis. These properties indicate that the deep electron trapping states, present on SiO_2 and SAM-treated SiO_2 are largely absent on these dielectrics, consistent with the absence of hydroxyl groups. We also note advantages and disadvantages of each material. Many of the device metrics for Cytop®-based devices are superior to those constructed using parylene-c. Threshold voltage shifts and hysteresis are smaller, stability appears to be better, and drain currents at $V_{gs} = 0$ are 1–2 orders of magnitude smaller than parylene-c devices. On the other hand, parylene-c has a higher relative permittivity, easily forms uniform, conformal pinhole-free coatings, and has a dielectric breakdown strength three times that of Cytop® – all desirable qualities for a gate dielectric.

It should be noted that although we have chosen to use thick, bilayer dielectrics for ease of fabrication and to ensure high yields, extremely thin films of both Cytop® and parylene can be formed. Walser et al. [8] have demonstrated that Cytop® films <20 nm thick can be successfully used as gate dielectrics. Increases in specific capacitance on the order of 10 times can therefore be realized. By increasing the specific capacitance of the gate dielectric, many of the stability metrics, including threshold voltage shift and

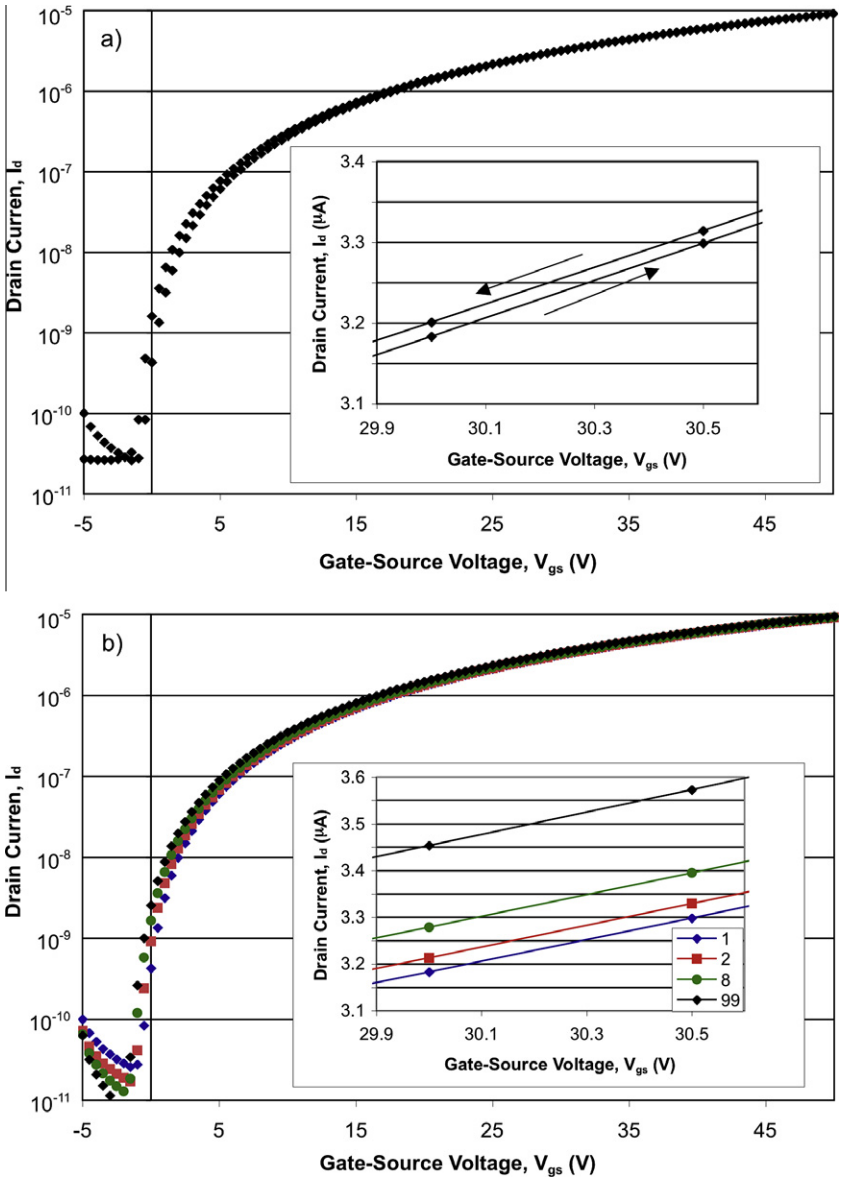

Fig. 6. PTCDI-C_{13}/parylene-c devices (a) initial off–on–off cycle, (b) repeated cycling (cycle numbers indicated). Insets are included so that the small hysteresis (a) and threshold shift (b) are visible.

hysteresis, as well as the operating voltages, will decrease by the same factor.

5. Conclusion

N-channel PTCDI-C_{13} OTFTs fabricated using Cytop® and parylene-c have excellent device performance and stability. Both exhibit high, stable, electron mobilities, very small threshold voltage shifts and hysteresis under repeated cycling. While the performance of Cytop® devices is slightly better than those fabricated using parylene-c, parylene-c possesses better dielectric properties, is inexpensive, and can more easily form uniform, pinhole-free films. Furthermore, parylene-c is easily wet by organic solvents, such as those used in solution deposition of organic semiconductor materials and those used in photoresists, making it an attractive gate dielectric material for organic thin-film transistors.

In contrast, both phosphonic acid SAM-modified SiO_2 and bare SiO_2 gate dielectrics have been shown to be unacceptable for use in n-channel PTCDI-C_{13} OTFTs. Large densities of electron trapping states result in large positive threshold voltage shifts, on–off hysteresis, and threshold voltage instability with repeated cycling.

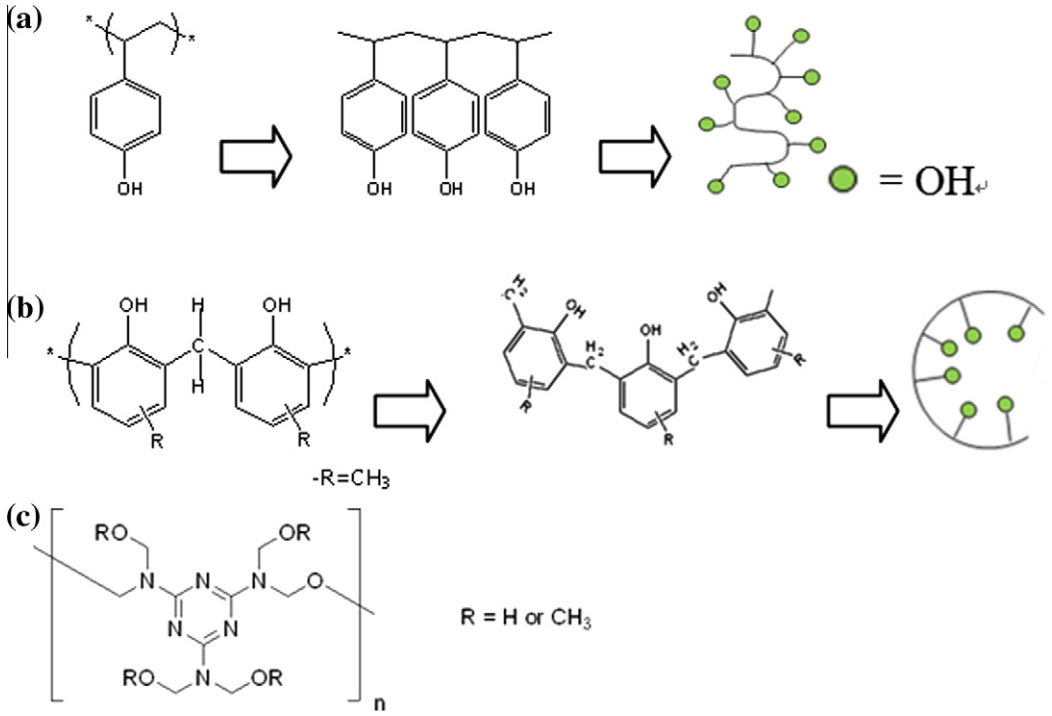

Fig. 1. Chemical structures of polymeric dielectric as (a) conventional PVP resin and (b) phenolic resin as alternative PVP and (c) low molecule melamine as cross-linker.

outside from the backbone chain. However, the alternative PVP resin has a backbone with hydroxyl phenol, which takes the shape of the micellar structure with 6–12 pieces of hydroxyl phenol after cross-linking as shown in Fig. 1b; the phenolic resin has identical structure with Bismethylol Para-Substituted Phenol that has calixarene like structure [14,15]. All of PVP resins were prepared from solution with low molecule melamine as a cross-linker in propylene glycol monomethyl ether acetate (PGMEA) as a solvent.

Initially, to evaluate the functions of the PVP films as dielectric materials, electrical properties were analyzed: the *I–V* characteristic by making an element-OTFT and *C–V* and *C–F* by applying elements MIM and MISM, respectively. Furthermore, the film properties of the chemical bonding structures were analyzed through FTIR.

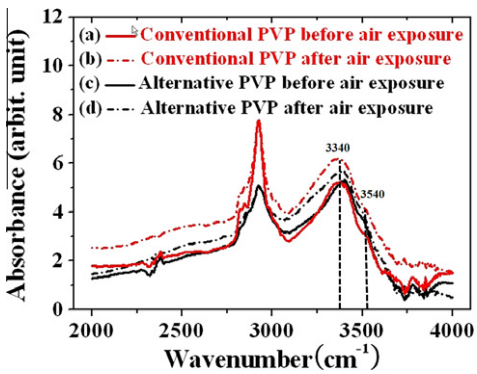

Fig. 2. FT-IR spectra of the polymer dielectrics absorption spectra of conventional PVP and alternative PVP films, used to examine the existence of hydroxyl (O–H) bonds.

For fabrication of the OTFT test devices, after the PVP–OGI solution was prepared, chrome gate electrode was patterned on the glass substrate by the conventional photo-lithography process. PVP–OGI solution was spun on the patterned Cr gate electrode and subsequently, cross-linked at 200 °C for 1 h in the vacuum oven. The PVP–OGI layer was approximately 400 nm thick after cross-linking as measured by the surface profiler (Alpha-step). The gold source–drain electrodes were patterned by the conventional photolithography and wet etching method; nominal channel width (*W*) and length (*L*) of OTFTs were 200 and 10 μm, respectively. Pentacene were deposited by thermal evaporation with the base pressure of 10^{-7} Torr and the deposition rate of 0.02 nm/s at room-temperature, and the final thickness was 40 nm.

3. Results and discussion

Fig. 2 presents the FTIR analysis data of the conventional and the alternative PVP films. Both resins have the O–H stretching bonds, which are affected by polar molecule showing peaks at 3340 cm^{-1} and 3540 cm^{-1} as the non-hydrogen bonded O–H group and the hydrogen bonded O–H group, respectively; the non-hydrogen bonded O–H group are easily responded with the polar molecule and induce slow polarization by attracting charge carriers [16,17]. Both the conventional and the alternative PVP films show 3340 cm^{-1} peak and non-hydrogen bonded hydroxyl group, for the same content volume under 5%.

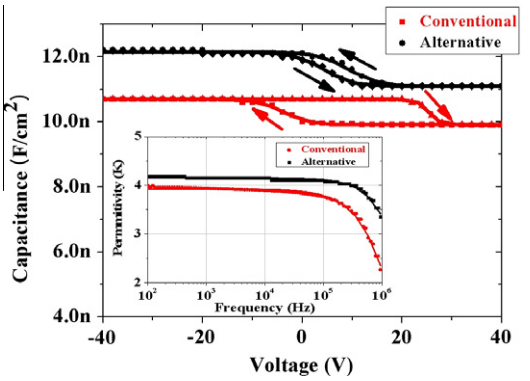

Fig. 3. Voltage dependent capacitance plot for conventional and alternative PVP films with MISM structures; (inset) frequency dependent permittivity plot with MIM structure.

With equal thickness of conventional and alternative PVP films, FTIR analysis was started after exposing them in the air for 200 h. Both films confirmed that the content proportion of the non-hydrogen bonded OH group (3340 cm^{-1}) had been increased.

If slow polarization was induced by the polar molecules, where absorption of moisture is the primary factor as an example, the dielectric material applied by two resins might be seen to have equal or similar form of hysteresis phenomenon by the slow polarization. In order to confirm this result, the dielectric constant and hysteresis of a thin film were analyzed with metal–insulator–metal (MIM) and metal–insulator–semiconductor–metal (MISM) test devices.

Fig. 3 shows the voltage dependent capacitance plot for conventional and alternative PVP films with MISM structure which shows conflicting hysteresis phenomenon each other, while Fig. 3 inset shows the frequency dependent permittivity plot for conventional PVP (k_{con} = 3.89) and alternative PVP (k_{alt} = 4.16) films with MIM structure. The permittivities of both resins were not much different from each other. The conventional PVP film shows a typical hysteresis, which is fundamentally caused by the slow

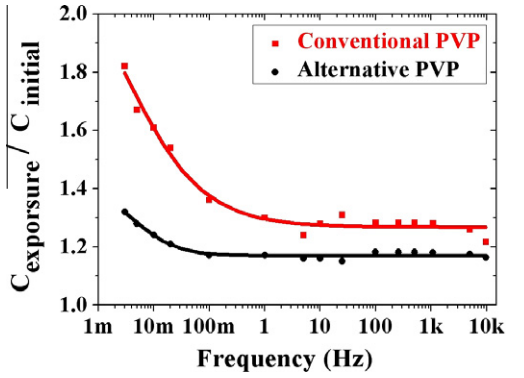

Fig. 4. Frequency dependent capacitance scans using MIM devices with various dielectrics. (In the axis of C_{expo}/C_{ini}, indicating a numerical value of the ratio of capacitance of thin film after exposure in the ambient air and the capacitance of thin film in the initial state.)

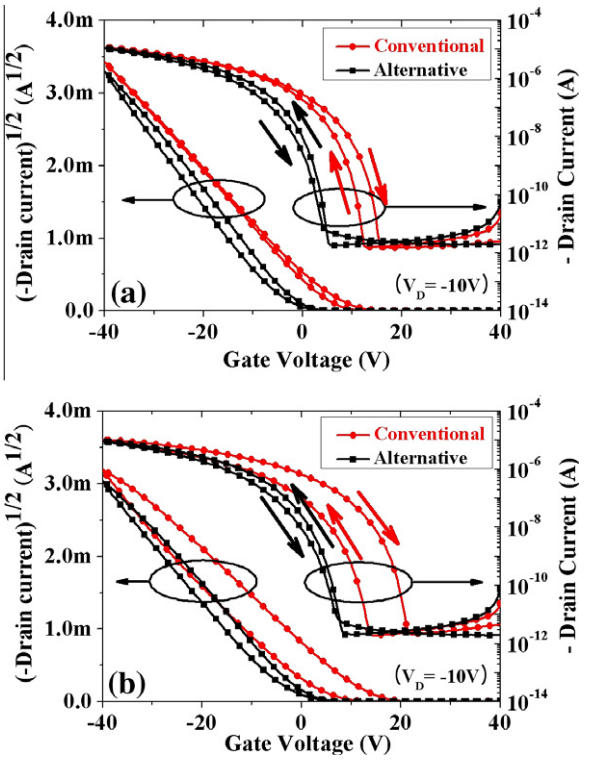

Fig. 5. Transfer (I_D–V_G) characteristics of pentacene based OTFTs with V_{DS} = −10 V, swept in both directions, of device with length (L = 10 μm) and width (W = 200 μm). (a) Without air exposure, (b) air exposure (60 h).

polarization in the PVP–OGI [18,20]. However, the alternative PVP film shows the opposite direction of the hysteresis loop, which means that the alternative PVP film was nearly free of hysteresis mainly caused by PVP–OGI itself. The slow polarization induced hysteresis should be dependent on the amount of dipolar groups in the dielectric [21]. In other words, dielectric films containing a small number of OH groups, may show reduced hysteresis [22]. However, two species of PVP–OGI films showed a similar proportion of non-bonded OH-group peak formation in the FTIR as shown in Fig. 2. That is contradicting result.

To clarify this phenomenon, we investigated the frequency dependent capacitance measurement including very low frequency range (below 100 milli Hz) with the MIM device.

Slow polarization can be analyzed by capacitance variation of MIM device through C–F measurement in the section at low frequency [26]. Provided that a polymer dielectric absorbs the water molecule, capacitance at low frequency is rapidly increased. As a result, it caused surface screening on interface between semiconductor and polymer dielectric as memory effect and obtained voltage is not permitted to respond rapidly so that induces hysteresis. Simply, an increase in capacitance at low frequency causes the dielectric material to show a large hysteresis effect.

In Fig. 4, instead of capacitance value in the initial state, the ratio of capacitance of thin film after exposure in the air is inscribed. In the result of Fig. 4, it is confirmed that

Table 1
Electrical characteristics of the pentacene OTFTs.

Performance parameter	Device configurations [W/L = 200/10]			
	Without air exposure		Ail exposure (60 h)	
	Conventional	Alternatives	Conventional	Alternative
*V*th (V)	5.3	−1.4	3.6	0.5
Hysteresis (V)	0.79	−2.5	8.87	−3.3
Mobility (cm^2/V s)	0.179	0.17	0.14	0.12
S-slope (V/Dec)	1.86	1.67	2.5	1.99

the ratio of capacitance for conventional PVP was 1.82 times higher (40% increasing), while that of alternative PVP was just 1.3 times higher (10% increasing) in the rate of increasing at low frequency (3 milli Hz); so to figure it out that the capacitance of conventional PVP in the rate of increasing was relatively higher than the other one. According to the result from Figs. 2 and 3, both PVP thin films showed no large difference of the content volume of the non-hydrogen bonded OH group and the absorption volume of water molecule; this means that the capacitance of the conventional PVP is relatively much higher in the rate of increasing, which is not only due to the effect of water absorption but also due to other factors that affect slow polarization as one of root cause of hysteresis in OTFT.

We assumed that the backbone structure of PVP is effective suppressing hysteresis, and planned an experiment. The result above was in agreement with the result from our hypothesis. In order to confirm the hysteresis of the OTFT based on the result, the changes of hysteresis before and after OTFT exposure to air were measured with pentacene based OTFT using two dielectric materials as mentioned in previous section.

Fig. 5a shows the comparative current dependent voltage (*I*–*V*) curves obtained from our pentacene OTFTs with initial state dielectrics, conventional and alternative PVP films, and Table 1 summarizes the transistor parameters extracted from the measurement. Conventional PVP based OTFT shows typical hysteresis with clockwise direction of the hysteresis loop, which is caused by slow polarization in OGI, however, the alternative PVP based OTFT shows totally different hysteresis with a counter-clockwise loop direction which is caused by mainly electronic traps in semiconductor [18–27]. Fig. 5b shows the *I*–*V* characteristic of the OTFT after exposure in the air. Although hysteresis does not change with the element that uses the alternative PVP, large hysteresis was observed with the element that uses the conventional PVP.

According to our modeling, the conventional PVP–OGI is shown to be the effect of slow polarization by the ambient air, but there was not any change of hysteresis after exposure in the air though alternative PVP–OGI contained OH-phenol with the same way of the conventional PVP. This result that all of OH group and water molecule cannot be revealed to slow polarization even though they can be combined in dielectric bulk by analogy. It can be found the reason to distinguish differences of hysteresis between both dielectric materials from the backbone structure which resin has.

With this kind of difference of fusion, the absorption and the arrangement between the dielectric material and water molecule make a difference. Therefore, the approach, in which the fusion structure such as phenolic alternative PVP film with the shape of partially micelle structure induces the localization of the dipoles by O–H group, can be suggested as one method to suppress hysteresis.

4. Summary

We suggested that the amelioration of PVP backbone structure as a method to constrain hysteresis is caused by O–H group which OGIs consisting of OH-phenol has in the nature of the case and analyzed a difference between two kinds of OGIs, the conventional PVP and the phenolic alternative PVP through various analysis methods. Both of the two PVP–OGIs seem to have a similar chemical behavior of what caused by the absorption of water molecules from O–H group but show totally different hysteresis characteristics, and OTFT, which we had designed and ameliorated by applying resin was shown to have stable characteristic in the side hysteresis. The result of hysteresis is the conclusion induced by the amelioration of backbone structure of PVP as OGI to be localization of O–H group and hysteresis caused by the dipole which was formed by combining with the O–H group and the water molecule is possible to be eliminated.

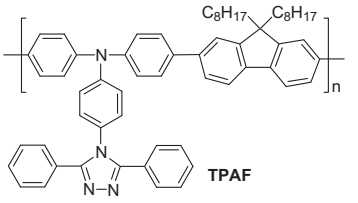
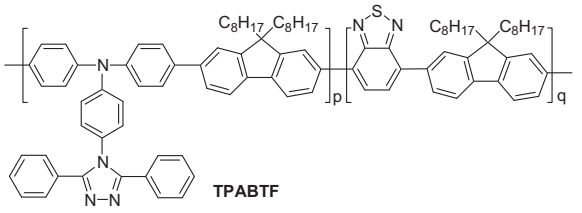
electron-deficient moieties into the polymer backbone [4,25,26].

Aromatic 1,2,4-triazole shows good electron affinity and hole-blocking properties. However, its high rigidity may lead to low solubility in common organic solvents [4,20,27,28]. On the other hand, triphenylamine exhibits good hole affinity and solubility properties [25,26,29–31]. These complementary properties make 1,2,4-triazole and triphenylamine couple well, and they have been incorporated as electron- and hole-transporting moieties in organic- and polymeric-emitting materials. The incorporation of electron-rich and electron-deficient components into a single polymer is expected to enhance the hole-transporting and electron-transporting properties of that polymer. Barriers to charge injection from both electrodes into the polymer matrix would therefore be reduced. Moreover, the bulky pendant side chain substituent triphenylamine is also expected to prevent the polymer from aggregating. Self-quenching would therefore be reduced, and the light-emitting efficiency would be enhanced.

Some studies [26,29,30] had reported that polymers containing donor–acceptor main chains show a reduction in the band gap of the polymers due to the backbone charge transfer from the donor to the acceptor. Based on the aforementioned considerations, our research group previously reported the synthesis and electroluminescent properties of donor–acceptor conjugated polymers **TPAF** and **TPABTF** with triphenylamine main chains and 1,2,4-triazole side chains [4]. The presence of the bipolar moiety significantly improves charge injection and charge transport in the polymer matrix.

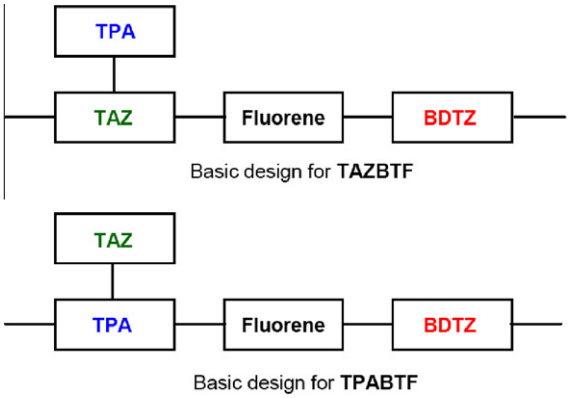


TPAF



TPABTF

It is well-known that the molecular architectures importantly affect physical properties of polymers, such as molecular skeleton, side chains, functional groups, bond connections and stereo structures. Therefore, it is interesting to study the relationship between the physical properties and chemical structure of polymers as shown below. The LUMO and HOMO of the polymers will be significantly different due to the different moiety connection; and the physical properties such as solubility, thermal, photophysical properties and emitting properties as an emitting material will be different.



In this paper, contrary to the previous donor–acceptor main chain-pendant design, we report the synthesis and light-emitting properties of a series of copolymers containing electron-deficient main chains with electron-rich pendant groups. The electron-deficient main chains contain 1,2,4-triazole and 2,1,3-benzothiadiazole as their major components. The electron-rich side chains are mainly composed of triphenylamine groups. The thermal, PL, and EL properties of the polymers are discussed.

2. Experimental

2.1. Materials

N-Bromosuccinimide (Acros), 4-bromobenzoyl chloride (Fluka), phosphorus pentachloride (Riedel-de Haën), 4-nitrofluorobenzene (Acros), tin (II) chloride anhydrous (Showa), hydrazine monohydrate (Alfa Aesar), heptanoyl chloride (Acros), tetrakis(triphenylphosphine)palladium (0) (Acros), aluminum chloride (Acros), and 9,9-dioctylfluorene-2,7-diboronic acid bis(1,3-propanediol) ester (Aldrich) were used as received. *N*-Methyl-2-pyrrolidinone (NMP), *N,N*-dimethylacetamide (DMAc) and dimethyl sulfoxide (DMSO) were purchased from TEDIA, and tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF) were purchased from ECHO. These solvents were distilled after drying with appropriate agents and stored over 4 Å molecular sieves. The surfactant trioctylmethylammonium chloride (Aliquat336®) was purchased from TCI and used as received.

2.2. Measurements

Infrared (IR) spectra were recorded on a PerkinElmer GX FT-IR spectrometer. NMR spectra were recorded using a BRUKER DRX-500 NMR (^{1}H at 500 MHz and ^{13}C at 125 MHz). Elemental analyses were made using a Perkin-Elmer 2400 instrument. Weight-average (M_w) and number-average (M_n) molecular weight were determined by gel permeation chromatography (GPC). Five Waters (Ultrastyragel) columns 300 × 7.7 mm (guard, 500, 10^3, 10^4, 10^5 in a series) were chained with a refractive index detector (RI 2000), using tetrahydrofuran (THF) (1 mL min^{-1}) as the eluent and polystyrene as the standard for GPC analysis. Thermogravimetric data were obtained

with a PerkinElmer Pyris 6 TGA under nitrogen flow at a rate of 20 cm^3 min^{-1} and a heating rate of 20 °C min^{-1}. Differential scanning calorimetric analysis was performed using a PerkinElmer Pyris DSC 6 under nitrogen flow at a rate of 20 cm^3 min^{-1} and a heating rate of 10 °C min^{-1}. Absorption spectra were recorded with a UV–Visible spectrometer (UV 500) at room temperature in air. Photoluminescence (PL) spectra were performed using a PerkinElmer LS 55 Luminescence spectrometer. Cyclic voltammetry (CHI model 619A) was conducted with the use of a three-electrode cell in which ITO was used as the working electrode, a platinum wire was used as the auxiliary electrode, and an Ag/AgCl couple was used as the reference electrode. Ferrocene was used as the internal standard for potential calibration.

2.3. EL device fabrication and characterization

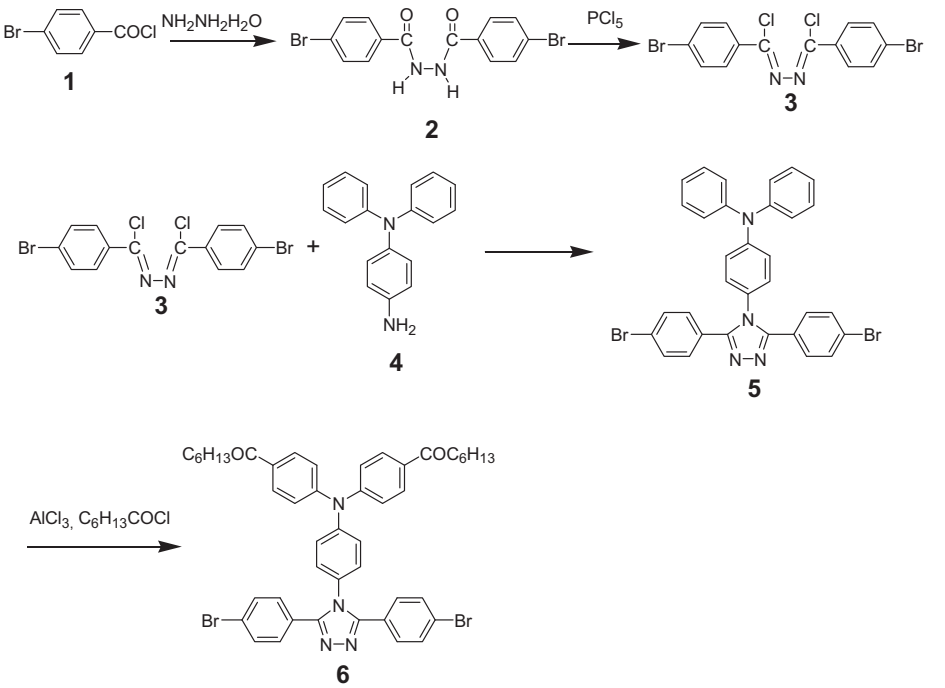
PLEDs were fabricated into an ITO glass/PEDOT:PSS/polymer/LiF/Al structure. ITO-coated glass, with a sheet resistance of 15 Ω/sq, was purchased from Applied Film Corp. Glass substrates with patterned ITO electrodes were washed well and cleaned by an oxygen plasma treatment. A thin film (850 Å) of hole-transporting material poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS; Bayton PVPAI 8000) was spin-cast on the ITO glass, followed by spin-coating of the polymer film from the filtered (0.45-μm filter) dioxane solution (20 mg/mL). The films were dried at 80 °C for 1 h in a glove box. Subsequently, the metallic cathode was thermally deposited in a high-vacuum chamber (5×10^{-6} torr). Then, the PLED was transferred from the evaporation chamber to a glove box under nitrogen atmosphere (oxygen and moisture <1 ppm), inside which the device was then encapsulated with glass covers using UV-cured epoxy glue. Current–voltage characteristics were measured on a programmable source-meter (Keithley 2400). Luminance was recorded with a BM-8 luminance meter (Topcon).

2.4. Synthesis of monomers

The synthetic pathways are summarized in Scheme 1. Compounds **2**, **3**, **4**, and **8** were prepared and characterized as described in the literatures [3,4,32]. The syntheses of **5**, **6**, and the polymers **TAZF1**, **TAZF2**, and **TAZBTF** are summarized as follows.

2.4.1. 3,5-Bis-(4-bromophenyl)4-([4-(N,N-di(phenyl)amino)]phen-1-yl)-1,2,4-triazole (**5**)

Compounds **3** (2.70 g, 6.2 mmol) and **4** (3.40 g, 13 mmol) and xylene (80 mL) were added to a three-necked flask fitted with a stirrer. The mixture was refluxed with stirring at 160 °C for 72 h. After cooling, the solvent was evaporated to collect the crude product, which was further washed with hot ethanol and recrystallized from a cosolvent of ethanol and tetrahydrofuran (1:1) to yield **5** as gray–white crystals (65%): mp 294 °C (by DSC); FT-IR (KBr, cm^{-1}): 1072 (C–Br); 1509 (C=N). ^{1}H NMR ($CDCl_3$, ppm): δ 6.94–6.96 (d, 2H, Ar–H, *J* = 9.04 Hz), 7.00–7.02 (d, 2H, Ar–H, *J* = 8.82 Hz), 7.11–7.14 (m, 6H, Ar–H), 7.31–7.34 (t, 4H, Ar–H, *J* = 7.84 Hz), 7.38–7.40 (d, 2H, Ar–H, *J* = 8.41 Hz), 7.48–7.50 (d, 2H, Ar–H, *J* = 8.49 Hz). ^{13}C NMR ($CDCl_3$, ppm): δ 121.5, 124.6, 124.7, 125.2, 125.6, 126.2, 128.2, 129.7, 130.2, 131.7, 146.3, 149.4, 154.0. Anal. Calcd.



Scheme 1. Synthetic route for dipolar dibromo monomers.

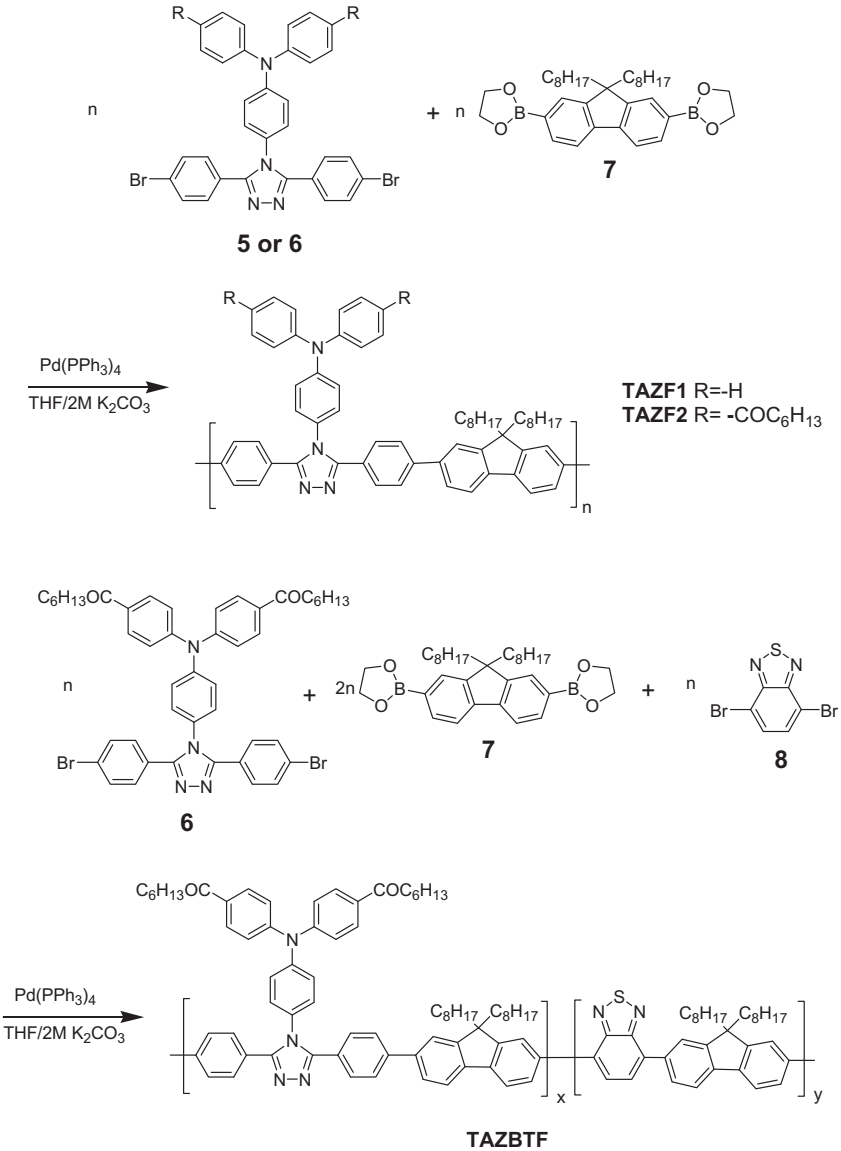
for $C_{32}H_{22}Br_2N_4$: C, 61.76; N, 9.00; H, 3.56; found: C, 61.59; N, 8.90; H, 3.61.

*2.4.2. 3,5-Bis-(4-bromophenyl)4-([4-(N,N-di(4-heptanoylphen-1-yl)amino)]phen-1-yl)-1,2,4-triazole (**6**)*

$AlCl_3$ (1.41 g, 11 mmol), **5** (1.00 g, 1.6 mmol), and CH_2Cl_2 (50 mL) were added to a three-necked flask fitted with a stirrer. The mixture was stirred in an ice bath for 5 min under nitrogen atmosphere. A solution of heptanoyl chloride (1.8 mL, 12 mmol) in CH_2Cl_2 was added drop-wise into the mixture. The mixture was then allowed to further react for 4 h. The resulting mixture was quenched by pouring into water. The product was extracted into CH_2Cl_2 and washed with water several times. The extracts were then dried over anhydrous $MgSO_4$, concentrated, and purified with liquid column chromatography (silica gel, ethyl acetate/hexane (1/1) as eluent) to yield **6** (0.80 g, 59%) as a yellowish solid: mp 167 °C (by DSC); FT-IR (KBr, cm^{-1}): 1074 (C–Br); 1506 (C=N); 1685 (C=O); 2852, 2930 (alkyl group). ^1H NMR ($CDCl_3$, ppm): δ 0.84–0.89 (m, 6H, aliphatic H), 1.22–1.36 (m, 12H, aliphatic H), 1.67–1.73 (m, 4H, aliphatic H), 2.88–2.91 (t, 4H, aliphatic H, J = 7.38 Hz), 7.09–7.17 (m, 8H, Ar–H), δ 7.31–7.32 (d, 4H, Ar–H, J = 8.34 Hz), 7.45–7.46 (d, 4H, Ar–H, J = 8.24 Hz), 7.90–7.91 (d, 4H, Ar–H, J = 8.55 Hz). ^{13}C NMR ($CDCl_3$, ppm): δ 13.9, 22.4, 24.2, 28.9, 31.5, 38.3, 123.5, 124.5, 125.3, 125.4, 128.9, 129.7, 129.8, 130.0, 131.6, 132.7, 147.5, 149.8, 153.9, 198.8. Anal. Calcd. for $C_{46}H_{46}Br_2N_4O_2$: C, 65.25; N, 6.62; H, 5.48; found: C, 65.49; N, 6.52; H, 5.56.

*2.4.3. Preparation of **TAZF1**, **TAZF2** and **TAZBTF***

The polymers were prepared *via* the facile Suzuki coupling reaction (Scheme 2). The standard procedure for **TAZF2** is described below.



Scheme 2. Preparation of conjugated polymers.

To a mixture of **6** (1 g, 1.61 mmol) and 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (**7**) (0.68 g, 1.22 mmol), several drops of Aliquat336® and $Pd(PPh_3)_4$ (0.027 g, 23 mmol) and aqueous K_2CO_3 (2 M, 6.7 mL) and toluene (20 mL) were added under argon. The mixture was heated to 110 °C and stirred for 96 h and then quenched by pouring into a mixture of deionized water and methanol (1:10). The precipitate was collected by filtration and dried. The precipitate was further purified by dissolving in $CHCl_3$ and re-precipitated into a mixture of deionized water and methanol several times. The polymer was further washed by Soxhlet extraction with methanol for 24 h. The polymer (**TAZF2**) was obtained after drying under vacuum at 60 °C overnight (0.708 g, 56%). FT-IR (KBr, cm^{-1}): 1507 (C=N); 1677 (C=O); 2852, 2924 (alkyl group). ^1H NMR ($CDCl_3$, ppm): δ 0.76–0.80 (m, 10H), 0.87–0.89 (t, 6H), 1.08–1.17 (m, 20H), 1.25–1.37 (m, 12H), 1.71–1.74 (t, 4H), 2.08 (s, 4H), 2.89–2.92 (m, 4H), 7.05–7.25 (m, 8H), 7.59–7.85 (m, 14H), 7.85–7.95 (m, 4H). Anal. Calcd. for $C_{75}H_{88}N_4O_2$: C, 83.60; N, 5.20; H, 8.23; found: C, 83.53; N, 5.06; H, 8.14.

The yield of **TAZF1** was 53%. Because **TAZF1** is highly insoluble in organic solvents, a good quality NMR is difficult to obtain. Therefore, **TAZF1** was characterized by FT-IR and elemental analysis. FT-IR (KBr, cm^{-1}): 1508 (C=N); 1676 (C=O); 2852, 2925 (alkyl group). Anal. Calcd. for $C_{61}H_{62}N_4$: C, 86.08; N, 6.58; H, 7.34; found: C, 86.56; N, 6.44; H, 7.16.

TAZBTF copolymer (98% yield) was prepared by reacting equal moles of **6** and **8**. FT-IR (KBr, cm^{-1}): 1507 (C=N); 1678 (C=O); 2853, 2925 (alkyl group). $^{1H\ NMR}$ ($CDCl_3$, ppm): δ 0.75–0.88 (m, 25H), 1.12–1.16 (m, 41H), 1.25–1.38 (m, 14H), 1.73 (t, 5H), 2.10 (d, 5H), 2.92 (s, 4H), 7.19–7.25 (m, 10H), 7.63–8.09 (m, 24H). Anal. Calcd. for $C_{110}H_{130}N_6O_2S$: C, 82.56; N, 5.25; H, 8.19; found: C, 81.56; N, 5.44; H, 8.16.

3. Results and discussion

Monomers **5** and **6** containing the electron-donating triphenylamine and the electron-accepting 1,2,4-triazole moieties were prepared as shown in Scheme 1. Bromobenzoyl chloride (**1**) was reacted with hydrazine hydrate to give hydrazide **2**, which was further chlorinated in the presence of PCl_5 to give chlorinated azine **3**. Cyclocondensation of compounds **3** and **4** gave compound **5**, which was further acetylated through Friedel–Crafts acylation to give **6**. Formation of the 1,2,4-triazole ring on **5** could be monitored by the change of a characteristic band in the FT-IR spectra; the characteristic band of the chlorinated azine **3** at 1571 cm^{-1} gradually disappeared as a new characteristic band of the 1,2,4-triazole ring appeared at 1509 cm^{-1}. Formation of **6** was evidenced by the appearance of a band at 1685 cm^{-1} for the carbonyl group in the IR spectrum. The NMR spectra and 2D C–H COSY of **5** are shown in the supplementary material (Fig. S1). Fig. 1 shows the ^1H NMR and ^{13}C NMR spectra of **6** in $CDCl_3$. In the ^1H NMR spectrum of **6**, the H_g shifted to δ 7.90 ppm due to incorporation of the electron-withdrawing carbonyl groups at the *para*-positions. The peaks appearing at δ 0.8–2.9 ppm with correct integral ratios for the aliphatic protons indicated that the acylation was completely carried out as proposed. In the ^{13}C NMR spectrum, observation of 6 peaks of the aliphatic carbons, 13 peaks of the aromatic carbons, and 1 peak of carbonyl carbon at 198.8 ppm again supported the proposed structure.

Fluorene-based conjugated polymers were readily prepared by facile Suzuki cross-coupling of **7** with **5/6** and **8** as shown in Scheme 2. The polymerization was carried out in a mixture of aqueous $NaHCO_3$ and THF with freshly prepared $Pd(PPh_3)_4$ as the catalyst. Unfortunately, the solubility of **TAZF1** obtained by this approach was so poor that **TAZF1** could only be identified by FT-IR and elemental analysis, which supported the proposed structure. In contrast, **TAZF2** and **TAZBTF** are soluble in several different organic solvents and, therefore, could be further identified by NMR. In the FT-IR spectra, the observation of the characteristic bands of 1,2,4-triazole at 1507 cm^{-1} and of the alkyl chains at 2852 and 2925 cm^{-1} strongly suggested polymeric structures. Moreover, disappearance of the characteristic stretching C–Br band of the dibromo monomers at 1074 cm^{-1} is consistent with the assumption of condensation polymerization. The ^1H NMR spectra of **TAZF2** and **TAZBTF** are illustrated in Fig. 2. The spectra are assigned by matching the chemical-shift data with those of the corresponding dibromo and fluorene monomers. For **TAZBTF**, the copolymerized segment ratio (x/y) of 5/6 was determined (Fig. 2B) on the basis of the peak integrals of H_e (α-protons adjacent to the C=O groups) against the total aliphatic protons attached to triphenylamine and fluorene moieties.

The molecular weights and thermal properties of the conjugated polymers are summarized in Table 1. The weight-average molecular weights (M_w) of the polymers were 1.28×10^4 and 2.56×10^4 for **TAZF2** and **TAZBTF**, respectively, as measured by gel permeation chromatography (GPC) relative to the polystyrene standards. The thermal properties of the conjugated polymers were evaluated by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). The glass transition temperatures (T_g) of the polymers were found to be 153–185 °C, which are much higher than that of poly(9,9-dioctylfluorene) (**POF**; T_g = 75 °C) [28]. The thermal properties reported in the literature [4] for polymers **TPAF** and **TPABTF** containing triphenylamine main chains and 1,2,4-triazole pendant groups were collected in the table for comparison. It is evident that incorporation of the rigid 1,2,4-triazole and triphenylamine subunits into the polymer enhances the rigidity of the chain and increases T_g. Obviously, **TAZF1** and **TAZF2**, with their 1,2,4-triazole main chains, show much higher T_g than previously reported for **TPAF** (135 °C) [4], in which the triphenylamine is in the main chain. However, **TPABTF** and **TAZBTF** containing 2,1,3-benzothiadiazole (**BTDZ**) moiety have similar T_gs. In contrast, the thermal properties of these polymers with 1,2,4-triazole main chains exhibit slightly lower degradation temperatures than the reported polymers with triphenylamine main chains due to the lower molecular weight and higher content of aliphatic segments.

The results of the qualitative solubility test (1 mg/10 mL) of the polymers are summarized in Table 2. The

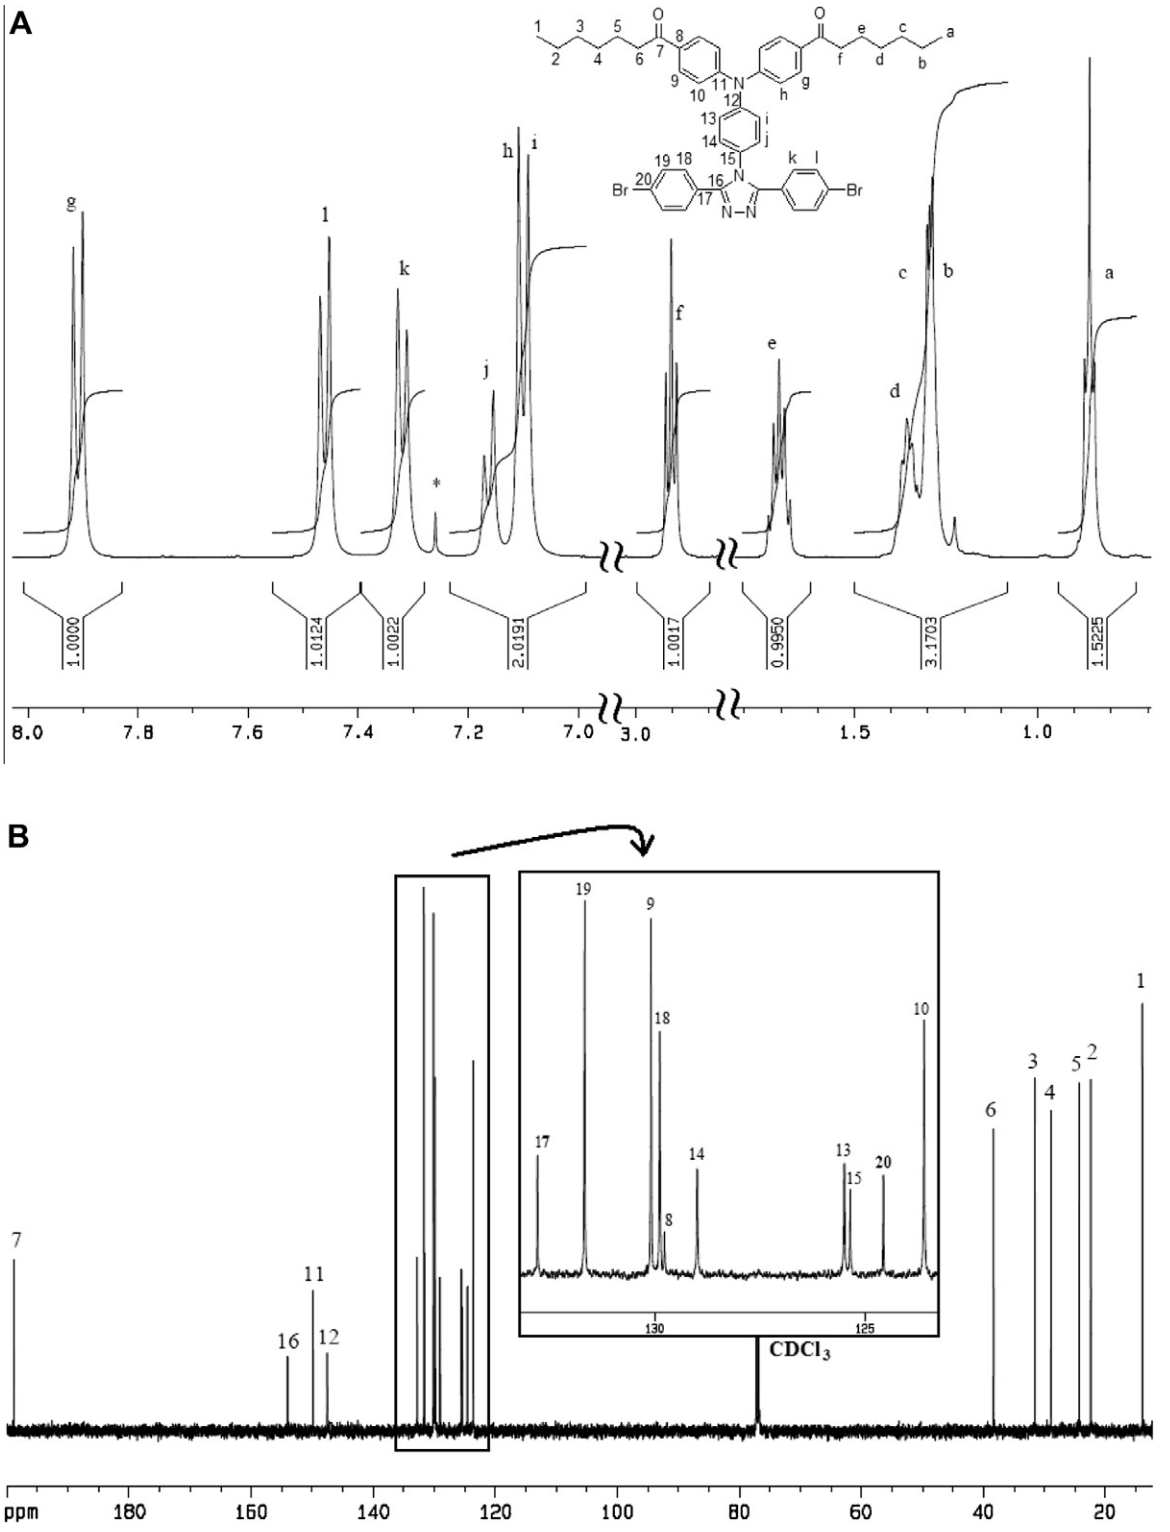


Fig. 1. (A) ^{1}H NMR, (B) ^{13}C NMR spectra of the dibromo monomer **6.**

previously reported **TPAF** exhibited good solubility due to the propeller triphenylamine structure in the main chain [4]. However, **TAZF1** has much lower solubility in comparison to **TPAF** due to its relatively rigid 1,2,4-triazole main chain structure. However, **TAZF2** was reasonably soluble or partially soluble in some organic solvents; the aliphatic

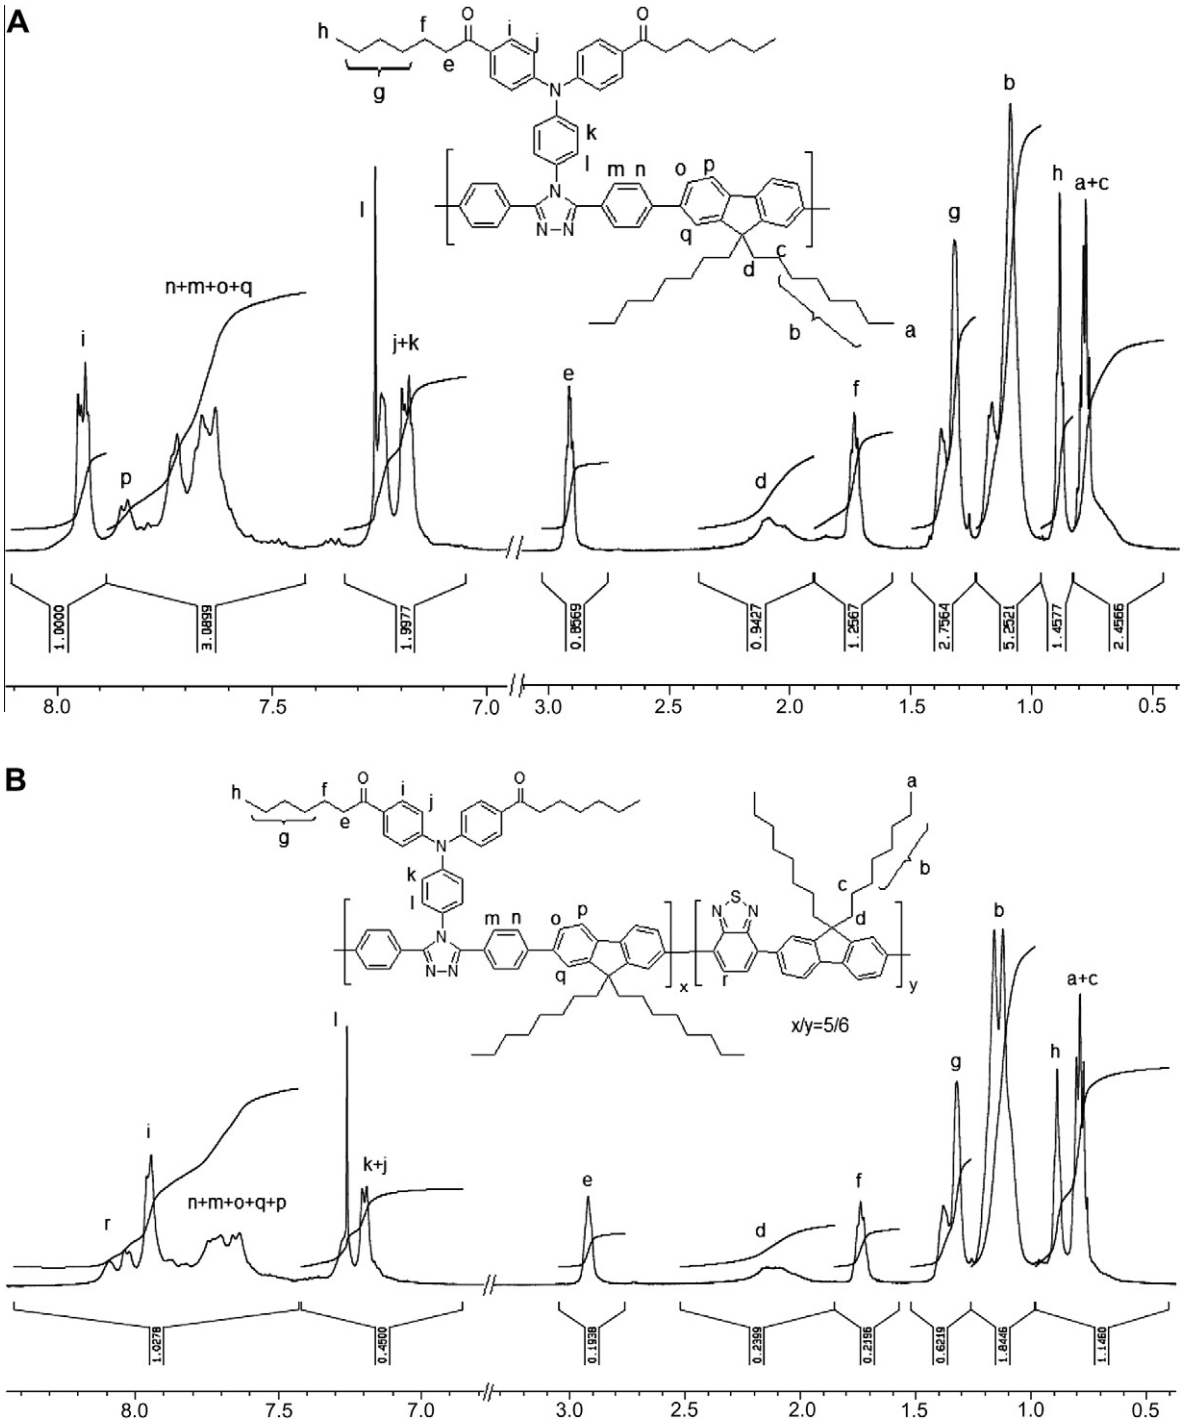

Fig. 2. ^{1}H NMR spectrum of conjugated polymers: (A) **TAZF2** and (B) **TAZBTF**.

side chains attached on the triphenylamine help **TAZF2** to increase the solubility. The **TAZBTF** shows much better solubility due to the higher flexible aliphatic contents.

The optical properties of the conjugated polymers are summarized in Table 3. The optical properties of the polymers were investigated by UV–Vis and photoluminescence spectroscopy in the solid state and in chloroform (1 mg/10 mL). The UV–Vis and photoluminescence spectroscopy of the polymers are shown in Fig. 3. In chloroform, **TAZF2** exhibits absorption with λ_{max}^{UV} at 355 nm (Fig. 3A). By comparing this spectrum with the absorption spectra of poly(9,9-dioctylfluorene) (**POF**), one might ascribe the

absorption at 355 nm to a π–π* transition derived from the conjugated polymer backbone. However, a blue shift by 36 nm relative to that observed for **POF** (at 391 nm) [33] is due to the twist (31–35°) between 1,2,4-triazole and adjacent phenyl in the main chain (see below), which shortens the conjugated length of the polymer. Thin-film **TAZF2** shows an absorption peak at 356 nm, which is close to that in solution. The cut-off for absorption was 404 nm for the film state, and the optical energy band gap (E_g) was calculated to be 3.1 eV. **TAZF2** emits blue fluorescence with λ_{max}^{PL} at 425 nm in chloroform, while in solid film the emission is slightly blue-shifted and exhibits λ_{max}^{PL} at 413 nm (Fig. 3A). The charge-transfer properties in the excited-state emission in chloroform are apparently significant so that a broad and red-shifted emission band was observed. Low PL quantum yield (Φ_f) of 0.29 in chloroform and 0.08 in the film state for **TAZF2**, as excited at 355 nm, were recorded by comparing against the fluorescence standard 9,10-diphenylanthrancene (Φ_f = 0.9).

For **TAZBTF**, two major bands are observed at 435 and 345 nm in chloroform (Fig. 3B). The first absorption band at 435 nm is attributed to the π–π* transitions of the benzothiadiazole–fluorene component of the main chain. The second absorption band at 345 nm might arise from the π–π* transition of the conjugated polymer backbone. However, a red shift by 10 nm relative to that was observed for **TAZF2**. **TAZBTF** fluoresces at λ_{max}^{PL} of 538 nm in chloroform. Because the emission from the **TAZ** subunit at 425 nm has a good overlap with the spectral absorption of the **BTDZ** subunit at 435 nm, Förster energy transfer [34] from **TAZ** to **BTDZ** is expected so that light emission at 425 nm is quenched and transferred to the emission at 538 nm. Similarly, emission with λ_{max}^{PL} at 541 nm was found in solid film. The emission is red-shifted by 113 and 128 nm in comparison to the spectra observed for **TAZF2** in solution and in the film state, respectively (Table 3). The high quantum yield of **TAZBTF** is over 0.9 in solution [35] indicating that the Förster energy transfer from the **TAZ** to **BTDZ** unit is efficient. Although the quantum yield of 0.4 in the film state is higher than that of 0.08 for **TAZF2** in solid film, this value is relatively low in comparison to that in solution as well as to other **BTDZ**-based polymers reported in the literature [35], indicating that fluorescence quenching would occur in solid films.

Careful study of the PL spectra of **TAZBTF** in $CHCl_3$ revealed that some residue emission from the **TAZ** component exists at 425 nm. Although this detectable emission was concentration-dependent, the corresponding PL intensity was very weak even under high dilution (<2%) (Fig. 4). Because the ratio of the integrated intensities of 550 nm peaks to 425 nm peaks can be considered a measure of internal energy transfer efficiency from **TAZ** subunits to **BTDZ** subunits [35], this result indicates that the internal Föster energy transfer is efficient and may play a major role in the energy transfer process. However, the energy transfer might still operate intermolecularly at high concentration or in the condensed phase and cannot be simply

excluded [36,37]. The Stokes shifts for polymer films are greater than 57 nm (Table 3), indicating that the spectral overlap between PL and UV spectra is not significant. Therefore, the interference in the emissive spectral properties of **TAZF2** and **TAZBTF** in the solid phase through self-absorption in luminescence should be insignificant.

Theoretical studies provide insights into polymers and have been making a great contribution to support experimental results [38–40]. To better understand the absorption behavior of the polymers, we used density functional theory (DFT) and semiempirical ZINDO calculation to study the electronic and optical properties of the polymers. All theoretical calculations in this study are carried out using quantum mechanical package Gaussian 03. The electronic states for the polymers are determined using DFT calculation with the B3LYP functional and the 6-31G* basis set. The calculated excitation energies with the largest oscillator strength (f) are compared to the maximum absorption in UV–Vis spectrum. The simulated results with two repeating units ($n = 2$) are shown in Fig. 5. Fig. 5A shows that the $S_0 \rightarrow S_5$ electronic transition has the largest oscillator strength for **TAZF2** with maximum absorption at

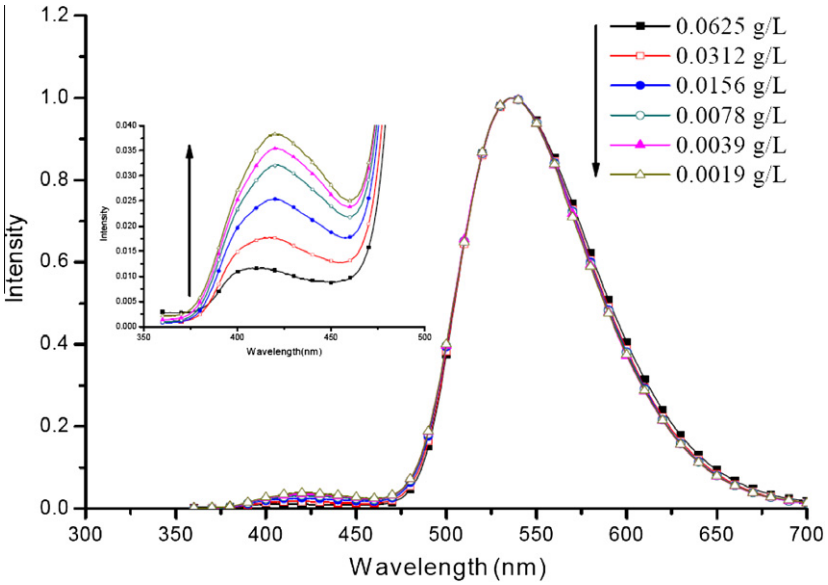

Fig. 4. Emission spectra of the polymer **TAZBTF** in chloroform solution at different concentrations.

357 nm, which corresponds to the maximum absorption at 355 nm in the UV–Vis spectrum. The HOMO → LUMO+2 transition mainly dominates the $S_0 \rightarrow S_1$ transition, and the absorption is mainly distributed by the charge transfer from the conjugated main chain to the triphenylamine side chain. For **TAZBTF** polymer (Fig. 5B), the $S_0 \rightarrow S_1$, $S_0 \rightarrow S_7$ and $S_0 \rightarrow S_9$ electronic transitions have the larger oscillator strengths with maximum absorption at 499, 360 and 352 nm, respectively. The HOMO−1 → LUMO transition mainly dominates the $S_0 \rightarrow S_1$ transition, and the absorption is mainly distributed by the charge transfer from the conjugated main chain to the 2,1,3-benzothiadiazole (**BTDZ**) moiety. The HOMO → LUMO+6 and HOMO-3 → LUMO+1 transitions mainly dominate, respectively, the $S_0 \rightarrow S_7$ and $S_0 \rightarrow S_9$ transitions, and the absorptions are mainly distributed by the combination of π–π^* transitions in the main chain. The UV–Vis spectra for the polymers are also calculated based on the electronic states as shown in Fig. 6. The calculated results are comparative to the experimental results in Fig. 3, especially for **TAZF2**. For **TAZBTF**, the $S_0 \rightarrow S_7$ and $S_0 \rightarrow S_9$ electronic transitions with maximum absorption at 360 and 352 nm, respectively, are converse to an absorption peak corresponding to the actual absorption at 345 nm. The $S_0 \rightarrow S_1$ electronic transition with maximum absorption at 499 nm corresponds to the actual absorption at 435 nm.

The electrochemical behavior of the polymers was investigated by cyclic voltammetry (CV) (Fig. 7). From the oxidation potential relative to ferrocene/ferrocenenium, which refers to an energy level of −4.8 eV below the vacuum level, we can estimate the HOMO energy level of the conjugated polymers, although the LUMO level of the polymers could, in principle, be estimated according to the equation: LUMO = HOMO + E_g, where E_g is the value of the optical band gap. The HOMO and LUMO values of the polymers are summarized in Table 4. The HOMO and LUMO values of **TAZF2** and **TAZBTF** were found to be −5.72 and −2.62 eV, and −5.78 and −3.40 eV, respectively. According to the above results, we first conclude that the HOMO and LUMO levels of **TAZF2** and **TAZBTF**, with 1,2,4-triazole main chains and triphenylamine pendant groups, are much lower than those of **TPAF** and **TPABTF** with triphenylamine main chains and 1,2,4-triazole pendant groups. However, the energy gaps for the similar polymer pairs (**TAZF2** *vs* **TPAF** and **TAZBTF** *vs* **TPABTF**) are almost the same. As simulated results shown in Fig. 5, the HOMOs and LUMOs were controlled by the conjugated backbone. Therefore, the polymers with triazole acceptor moieties in the main chain will lower the HOMOs and LUMOs comparing to those polymers with triphenylamine donor moieties in the main chain. Because the similar polymers have the same functional moieties in the polymer structure, the HOMOs and LUMOs decrease in the similar values that makes the band gaps are almost the same for the polymer pairs. The polymers with **BTDZ** in the main chain (**TAZBTF** and **TPABTF**) have lower HOMOs and LUMOs than those (**TAZF2** and **TPAF**) without **BTDZ** due to the same reason. The second conclusion from the experimental results is that the polymers with **BTDZ** in the main chain (**TAZBTF** and **TPABTF**) have lower energy gaps than those (**TAZF2** and **TPAF**) without **BTDZ** moieties. As sown in the simulation, the **BTDZ** involves in the main chain conjugation. Therefore, the **BTDZ** increases the conjugation lengths and results in smaller energy gaps of the polymers (**TAZBTF** and **TPABTF**).

To further understand the optoelectronic properties of the polymers, electroluminescence (EL) devices were fabricated with the configuration ITO/HTL/polymer/cathode, in which poly(3,4-ethylenedioxythiophene):poly(styrene sulfonic acid) (PEDOT:PSS) or poly(vinyl carbazole) (**PVK**) was used as the hole-injection layer. The hole-transporting **PVK** was blended with the emissive polymer due to good solu-

bility in chloroform; it is likely that the interface between the **PVK** and polymer layer is diffused rather than being flat and well defined. Two layers of Mg or Ca followed by Ag (150 nm) were used as the cathode. The EL performance of all devices obtained from the current density (J)–voltage (V)–luminance (L) characteristics is summarized in Table 5. The relative energy level diagrams for the devices are sketched in Fig. 8.

Among the devices we fabricated, the EL devices of **TAZF2** are non-emissive. However, devices I and II, using **TAZBTF** as the emissive layer, exhibit green–yellow emission with λ_{max} (EL) at 534–542 nm, similar to the PL emission. This result suggests that the **BTDZ** subunit functions as the major core of light emission; all excitons formed within the polymer matrix will have their energy transferred to the **BTDZ** subunit to emit. It should be noted that the devices using the same PEDOT:PSS as the hole-injection layer but using different metallic cathodes of Mg and Ca show the same switch-on voltage at 8 V. This result implies that the electron-injection could not be improved even using a metal with a lower work function. This phe-

nomenon can be rationalized by the low-lying LUMO level of −3.40 eV for **TPABTF**; electron injection either from Mg or Ca cathode into the LUMO of the polymer matrix should be energetically favorable (Fig. 8C). Nevertheless, the switch-on voltage of 8 V is relatively high in comparison to the devices of **TPABTF**. We attribute this to the lower-lying HOMO level of the triphenylamine units on **TAZBTF**. The large energy gap of 0.58 eV between the PEDOT:PSS and **TAZBTF** (Fig. 8D) might become a major factor in causing a high Fowler–Nordheim barrier for tunneling injection. Furthermore, the presence of the barrier may also prevent high current injection into the device, limiting the value of the highest brightness. Nevertheless, the luminance efficiencies of the EL devices are as high as 2.07 and 2.60 cd/A, indicating a good balance of charge carriers within the device.

Jen has recently found that conjugated polymers having electron-deficient benzothiadiazole main chains show very poor electron-injection ability compared to polymers with electron-rich polyfluorene main chains [41]. This phenomenon is quite different from that obtained from conventional designs of electron-injection materials. Similar to Jen's observations, the low brightness with high efficiency strongly indicates in our EL devices the difficulty of charge injection through both electrodes, which limits the carrier density inside the polymer matrix.

The reasons for the failure of the EL devices using **TAZF2** are still unclear. In our device, the triphenylamine group is also the major hole-transport component, which is oxidized to form a radical cation under applied electrical potentials. Luminescence quenching can be by two basic mechanisms: (1) normal diffusional or dynamic quenching of Stern–Volmer type and (2) associational or static quenching where the donor and quencher form a nonluminescent association pair which reduces the amount of excitation energy absorbed by potentially luminescent donors [42]. Brudvig et al. reported that oxidized chlorophyll (a redox-active site) is a potent quencher of chlorophyll fluorescence with 15% of oxidized chlorophyll sufficient to quench 70% of the fluorescence intensity, which involves electron donation to the electron donor [43]. The situation is not the same but similar to this system. Therefore, we suppose that formation of the triphenylaminyl radical cation during hole-injection may lead to a quenching effect that prohibits its electroluminescence in the **TAZ** group.

Blending 10% hole-transporting **PVK** with a **TAZBTF** emissive layer, device III exhibits electroluminescence with higher brightness but much lower efficiency. Because the introduction of **PVK** in the blending approach plays a role in reducing the hole-injection barrier (Fig. 8E), higher current density is allowed, which leads to higher brightness. Because **PVK** is unable to function effectively as an electron block, charge recombination within the **PVK** matrix may cause the low efficiency.

Comparing the structural designs of **TPABTF** and **TAZBTF**, the electron-deficient **TAZ** group was incorporated into the main chain while the electron-rich **TPA** group was grafted as the pendant group in **TAZBTF**. The re-

ported EL performance of devices fabricated from **TPABTF** is also shown in Table 5 for comparison. Under this configuration, the HOMO and LUMO of the polymers were significantly altered by exchanging the structures in main chain and pendant group. These changes are reflected in the HOMO–LUMO values of **TAZBTF**, which are approximately 0.4 eV lower than those of **TPABTF** (Table 4). However, similar photophysical properties are maintained. These provide us an opportunity to tune the HOMO–LUMO levels of the polymers.

4. Conclusion

Conjugated polymers containing electron-deficient 1,2,4-triazole-fluorene main chains and electron-rich triphenylamine pendant groups were successfully synthesized *via* the Suzuki coupling reaction. The thermal stability of the conjugated polymers was enhanced due to introduction of the rigid bipolar component. The incorporation of 2,1,3-benzothiadiazole structure further reduced the coplanarity of the conjugated polymer. Intramolecular and intermolecular energy transfers were clearly evidenced, leading to a shift of PL and EL to the yellow–green region. The connection of functional moiety in the polymer strongly is an approach to tune the HOMO and LUMO energy levels of the polymers.

the hole transporting layer (HTL). In addition, TCTA has a high triplet energy level (2.7 eV), which can play the role of an exciton blocking layer (ExBL) in phosphorescent OLEDs [13]. In addition, TCTA has good solubility and film forming properties, as well as good adhesion to the next organic layer. In order to study the effect of the printing process on the device performance, an emitting layer (EML) was processed by contact printing and spin-coating onto a small molecule layer. Although thermal evaporation was used after formation of an EML, this is needed as an assured method for measurement and analysis of a completed device utilizing the printing process. These results would be a possibility of the layer transfer process for high-performance OLED in low-cost process, and next step is working in progress for all-printing process. Finally, the enhanced performance of OLEDs fabricated without intermixing problems by using contact printing was studied, which demonstrates a suitable process that can fabricate high-performance OLEDs based on solution-processes with a low-cost method.

This contact printing technique utilizes a planar poly(dimethylsiloxane) (PDMS) elastomer. The PDMS stamps are suitable for a repeatable process since they are characterized by their low adhesion, durability, and elasticity. When the next layer is printed onto the preceding layers mounted on a substrate, the intermixing problem between the layers does not occur since the organic solvents are completely dried before the transfer.

2. Experiment

In order to fabricate the stamps, PDMS (Sylgard 184, Dow Corning Co.) was poured onto a plain silicon wafer substrate. The PDMS was then cured in an oven at 70 °C for over 3 h. The PDMS stamp can then be easily peeled-off from the master since the PDMS has a good elasticity and a low surface energy.

In order to fabricate the OLED devices, indium-tin-oxide (ITO) coated glass was sonicated in acetone, methanol and deionized water; and then cleaned in an oxygen plasma. Poly(ethylenedioxythiophene):poly(stylenesulfonate) (PEDOT:PSS) as a hole injection layer (HIL) was then spin-coated onto the ITO substrates to a thickness of 30 nm and annealed at 115 °C for 10 min on a hot plate in order to remove the solvent. Subsequently, TCTA as a HTL with a 0.5 wt.% in toluene was spin-coated at 2500 rpm to obtain a thickness of 25 nm, then annealed at 150 °C for 30 min on a hot plate. Next, the prepared plain PDMS stamps were treated using oxygen plasma in order to enhance their surface energy for a better wetting of the EML on the PDMS. Poly(N-vinylcarbazole) (PVK) based green emitting material was used for the EML (Fig. 1d). After a few drops of the EML solution suspended in chlorobenzene were applied to the surface of the PDMS stamps, the stamps were spin-coated at 3000 rpm in order to obtain a thickness of 30 nm, and then dried. Fig. 1 shows the schematic illustration of the contact printing process. The EML coated PDMS stamp was then brought into contact with the TCTA coated substrate at 80 °C for 20 s. The PDMS stamp was then carefully peeled-off, leaving the EML on the substrate. After releasing the layer, the substrate was annealed at 150 °C for 30 min on a hot plate.

We compared our device to spin-coated EMLs on TCTA coated devices in order to define the effect of the EML printing process has on the device.

Reference device 1: ITO/PEDOT:PSS (25 nm)/EML (30 nm, spin-coated).
Reference device 2: ITO/PEDOT:PSS (25 nm)/TCTA (25 nm)/EML (30 nm, spin-coated).
Reference device 3: ITO/PEDOT:PSS (25 nm)/TCTA (50 nm)/EML (30 nm, spin-coated).
Contact printing: ITO/PEDOT:PSS (25 nm)/TCTA (25 nm)/EML (30 nm, contact-printed).

In order to examine the dissolution problems of the EML solvent on the TCTA layer, the TCTA was spin-coated at 2500 and 800 rpm to obtain thicknesses of 25 and 50 nm, respectively, and then annealed. Subsequently, the EML was spin-coated to a thickness of 30 nm on the TCTA layer. Finally, in order to study the effect on the electroluminescence (EL) efficiencies of the spin-coated and contact-printed devices, we deposited layers of 10 nm 4,4′-di(triphenylsilyl)-biphenyl (BSB) as a hole blocking layer (HBL), 45 nm 4,7-diphenyl-1,10-phenanthroline (Bphen) as an electron transport layer (ETL), 0.8 nm lithium-fluoride (LiF) as an electron injection layer (EIL), and 100 nm aluminum as a cathode using thermal evaporation. The emission area of the devices was 5 mm × 5 mm. The current–voltage characteristics were measured using a Keithley 237 High-Voltage Source-Measure Unit (Keithley Instruments, Inc.), the EL efficiency was measured using a PR-670 SpectraScan Spectroradiometer (Photo Research, Inc.) in a dark box.

3. Results and discussion

Fig. 2 shows the current density and the luminance as a function of the applied voltage. The multilayered OLEDs using spin-coating were fabricated as reference devices with the same organic layers and metal layers under the same conditions. The turn-on voltage of the contact-printed device was lower than the spin-coated devices: 5.1 and 6.2 V, respectively. The luminance of the contact-printed device was also enhanced compared to the spin-coated devices at the same voltage, since the contact-printed device has a higher current density than the spin-coated devices. The spin-coated devices have the interlayer dissolution issue when the EML solvent chlorobenzene is spin-coated onto the top of the TCTA interlayer. The dissolution test was examined by measuring the thickness of the remaining TCTA layer after the spin-coating of the chlorobenzene on the 25 and 50 nm TCTA layers. As a result, only the thickness of the PEDOT:PSS layer was measured without the TCTA layer. Fig. 2 shows that the *I–V* curves of Refs. [2,3] are almost the same as Ref. [1]'s without TCTA layer. This interlayer dissolution by the organic solvent affects the current–voltage characteristics, since the thickness of the TCTA is insufficient to play the role of the HTL. However,

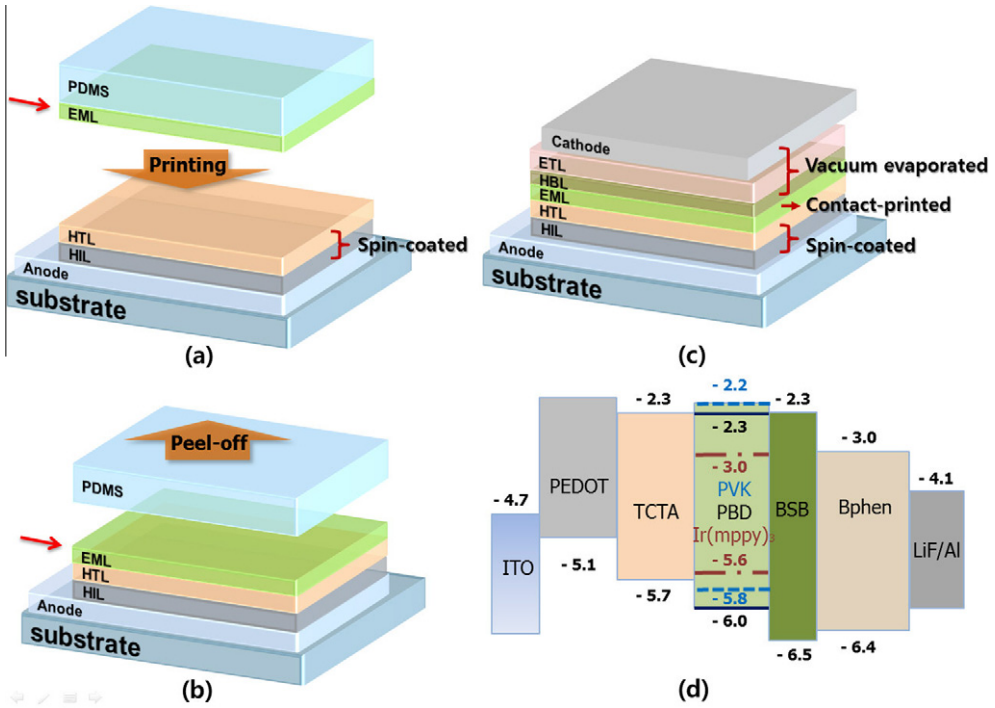

Fig. 1. The schematic illustration for the contact printing technique and the structure of the multilayered OLED. The EML spin-coated PDMS stamp is applied to the HIL and HTL coated substrate (a). The PDMS stamp is then carefully peeled-off leaving the EML on the substrate (b). The HBL, ETL, and cathode are thermal evaporated, sequentially (c). Fig. 3. The current efficiency and power efficiency characteristics as a function of the luminance.

the device using contact printing with the dried EML allows a well formed TCTA interlayer on the PEDOT:PSS; it is a good HTL. Therefore, the hole injection efficiency of the contact-printed device is higher than the spin-coated device. In addition, Joo et al. demonstrated that the transfer printing process was better than the spin-coating process in terms of current density, because the interfacial contact was improved by the pressure and heat applied during the transfer printing process [14].

Fig. 3 shows the current efficiency and power efficiency characteristics as a function of the luminance. The contact-printed device shows an enhanced performance compared to the spin-coated devices in terms of both the current efficiency and the power efficiency. In this multilayered OLED, the TCTA interlayer plays desirable roles in hole transportation, electron blocking, and in preventing exciton quenching caused by the PEDOT:PSS [15]. Refs. [1–3] also show a significant tendency for a short device life time,

due to the exciton quenching between the PEDOT:PSS and the EML. The contact printing process improves the maximum device current efficiency on the multilayered OLEDs from 10.82 to 28.93 cd/A; it also improves the power efficiency from 2.45 to 7.88 lm/W.

The contact printing technique improves not only the availability of multilayered structures without any damage but also lends itself to the compatibility of the organic materials, since it is solvent-free when the layer is printed onto the substrate. This enables the organic materials to be free from the limitations of having to be selected for compatibility and crosslinkability in a multilayered OLED. The solution based multilayered OLEDs employing contact printing allow the use of any suitable material in order to enhance the OLED performance. Fig. 4 shows the images of the stacked layers and the patterned layers using contact printing on various substrates. Fig. 4a and b show capability of stacking organic multi-layers on glasses. Fig. 4c and d show that the contact printing process is suitable for the formation of organic layers and patterns on the flexible substrate. Also, Fig. 4e and f show uniformity of fabricated OLEDs utilizing the contact printing process. The light-emission images of the OLEDs were taken at 6 and 8 V, respectively, at the same exposure time. Only one cell was contact-printed for visual emphasis. In addition, Fig. 5 shows the voltage dependence of electroluminescence spectra for the contact-printed device and the spin-coated device to demonstrate the color stability. The contact-printed device revealed that the peak wavelength is same as the spin-coated device under continuous operation which means the contact printing process does not affect the color stability.

Even though OLEDs have advantages in display devices compared to LCDs, they are still limited by the expensive processes necessary to create commercial displays. Solution based processes, such as ink-jet, spin-coating, and microcontact printing have been developed in order to achieve a low cost process, however, these are restricted to the deposition of only a couple of layers because of the intermixing problem. The contact printing technique outlined in this paper is a good method to solve this problem in solution-based small molecule multilayered OLEDs since this process allows the next layer not to damage the preceding layer due to the organic solution. In addition, contact printing is available for patterning on large sized substrates using the roll-to-roll process with a low cost and a high processing speed, and does not need expensive

vacuum equipment, high temperature processes, or UV exposure for the patterning. Therefore, our contact printing is a very simple and low cost process that needs to be considered as a candidate for the next generation printing processes.

4. Conclusions

In summary, efficient multilayered OLEDs have been demonstrated using the contact printing process with PDMS stamps. Unlike the conventional solution processes, this contact printing process does not damage the preceding layer. Therefore, this technique is suitable for solution-based small molecule multilayered OLEDs, which allow a high performance and a low cost process. In this study, the performance of the multilayered OLEDs made by contact printing significantly outperforms devices using spin-coating. As a result, efficient multilayered OLEDs have been developed by contact printing, which allows for the replacement of the thermal evaporation needed for the deposition of the organic layers and metal electrodes for future display devices.

In previously studies, we have demonstrated that a carbazole-substituted aromatic enyne derivative (*E*)-CPEY [5], which are easily prepared by catalytic dimerization of a terminal alkyne [6] and shows wonderful blue fluorescence in dilute solution, can act as an excellent single-emitting-component for WOLEDs, as a result of combination of the blue emission from an isolated molecule with the longer-wavelength emissions (green and orange-red) from eximers. Herein, we report series of blue fluorescent OLEDs based on the emitting layer of (*E*)-CPEY doped in the CBP (4, 4′-*N*, *N*′-dicarbazolylbiphenyl) host with the easily controlled doping concentrations, where the host matrix widens the intermolecular distance between the dopant molecules and eliminates the possibility of forming excimer in the emitting layer. The resulting EL devices based on (*E*)-CPEY with the pure and stable blue light (0.15, 0.10 ± 0.01) not only show relatively insensitive EL performances to the doping concentration changing in a high and wide range of 10–20 wt%, but also exhibit the highest EL efficiency ever reported for the saturated deep-blue OLEDs up to now.

2. Experimental section

2.1. Instrumentation

Photoluminescence spectra were recorded on a Perkin–Elmer LS 55 spectrophotometer, whereas UV–visible spectra were recorded on a Shimadzu UV-2550 PC spectrometer. The PL quantum yields were measured by use of quinine sulfate in 1 M sulfuric acid as a standard ($\Phi = 0.546$) [7]. Electrochemical measurements were performed in anhydrous CH_2Cl_2 with a BAS 100 W bioanalytical electrochemical work station, using Pt as the working electrode, platinum wire as the auxiliary electrode, and a porous glass wick Ag/Ag^+ as the reference electrode. It was standardized against a ferrocene/ferrocenium couple with a scan rate of 100 mV s^{-1}. Elemental analyses were performed on a Flash EA 1112 spectrometer. The EL spectra, brightness, CIE coordinates, and current–luminance–voltage characteristics of the devices were measured with a rapid scan system using a Photo Research PR650 spectrophotometer combined with a computer-controlled, programmable direct-current (DC) source (Keithley 2400).

2.2. Materials and OLED fabrication

The chemical structures and proposed energy diagram of the materials used in OLEDs are shown in Fig. 1. Prior to deposition, all organic materials were purified by sublimation. The devices were grown on a glass substrate precoated with an indium tin oxide (ITO) anode having a sheet resistance of 20 Ω^{-2}. The ITO substrate was routinely cleaned via ultrasonic treatment in detergent solutions, followed by rinsing with acetone, boiling in isopropanol, rinsing in methanol, and finally rinsing in de-ionized water. The substrate was dried in a vacuum oven between each cleaning step. The devices were fabricated by successive vacuum deposition of organic materials onto the substrate. A very thin layer of LiF can enhance electron injection from the aluminum cathode. A shadow mask with 2×3 mm^2 openings was used to define the cathodes.

3. Results and discussion

3.1. Absorption and photoluminescent (PL) properties

To investigate the PL emission properties of (*E*)-CPEY, a series of evaporated-film samples based on CBP and (*E*)-CPEY were prepared on quartz substrates, and their PL spectra are shown in Fig. 2. The PL spectra of the neat (*E*)-CPEY film and the thin film of (*E*)-CPEY doped in CBP with the high concentration of 30 wt% show extra broad emissions at 510–520 nm and tailed to 600 nm in addition to the strong emission at about 460 nm, because of formation of excimers based on (*E*)-CPEY molecules [5]. However, the PL curves of the doped film with the low concentration of 20 wt% and 10 wt% are similar to that of the solution except the dominant emission with a peak at 455 nm is slight blue-shifted by about 5 nm, which reveals that the excimer emission has been eliminated in such doped-concentration level and the emission of 455 nm band comes from the isolated (*E*)-CPEY molecules. It is consistent with the quantum yield alignment of the doping films (0.33 for 10 wt%, 0.29 for 20 wt% and 0.18 for 30 wt%). In addition, the similarly secondary PL emission band located at 390–420 nm in 10, 20 and 30 wt% doped solid films are observed, which should be the PL contribution from the host CBP. The fluorescence of CBP not being quenched effectively in spite of the doping concentration up to 30 wt% indicates that no or incomplete energy transfer from the host to the dopant. This result is supported by the characteristics of almost no overlap between the UV absorption spectrum of (*E*)-CPEY and PL spectrum of CBP in their solid films.

3.2. EL properties

To check the EL properties of (*E*)-CPEY as a blue emitter, a series of OLEDs (device I–III) with the device configuration of [ITO/NPB (50 nm)/emitting layer (40 nm)/TPBI (20 nm)/LiF (1 nm)/Al] were fabricated, where NPB (4,4′-bis(*N*-(1-naphthyl)-*N*-phenylamino)biphenyl) was hole-transporting layer (HTL) and TPBI (1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene) was employed as electron-transporting layer (ETL) and hole-blocking layer (HBL) [8]. The films of (*E*)-CPEY doped in CBP were adopted as the emitting layers (EML) with the doping concentrations of 5 wt% (device I), 10 wt% (device II) and 20 wt% (device III).

Fig. 3 shows the normalized EL spectra of device I, II and III and all of them have similar emission peak at around 450 nm. Device II and III show narrow spectral shape with the half-maximum width ranging from 60 to 70 nm, which present very saturated blue light with CIE (Commission Internationale de l'É clairage) coordinates of (0.15, 0.09) and (0.15, 0.11) detected at the brightness of 5000 cd m^{-2}, respectively. The CIE and EL spectral curves of device II and III remain almost unchanged in the driving voltage range of 4–9 V. When the brightness of device II with the doping

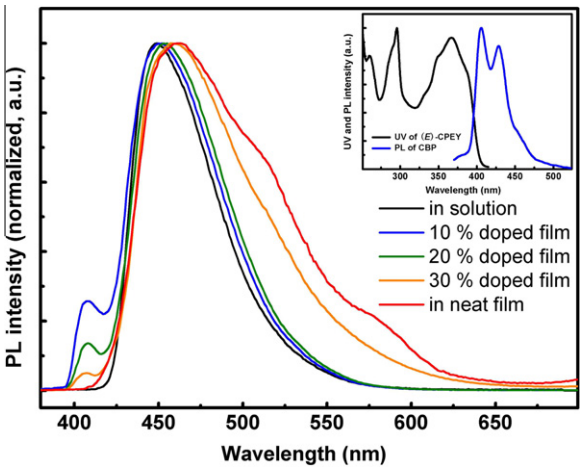

Fig. 2. PL spectra of (*E*)-CPEY in the dilute CH_2Cl_2 solution and in the neat evaporated film. PL spectra of (*E*)-CPEY doped in CBP with different concentrations in the evaporated films. Inset: UV absorption spectrum of (*E*)-CPEY and PL spectrum of CBP in the evaporated films.

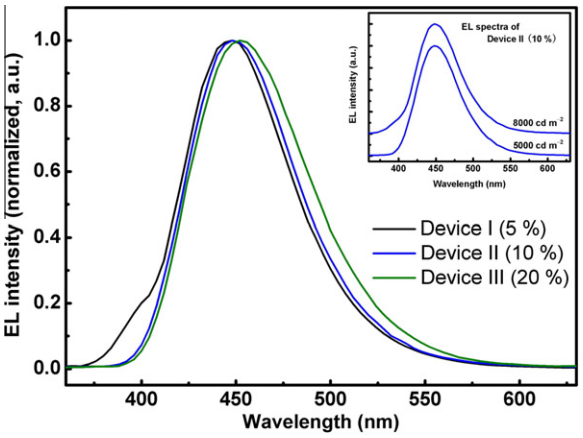

Fig. 3. Normalized EL spectra of device I, II and III at the brightness of 5000 cd m^{-2}. Inset: EL spectra of device II at the brightness of 5000 and 8000 cd m^{-2}, respectively.

concentration of 10 wt% increases above 8000 cd m^{-2}, a slight shoulder emission in the wavelength region of about 400 nm from CBP is observed (Fig. 3, inset), which appears more obviously in the EL spectrum of device I with the low doping concentration (5 wt%) during its whole driving process.

The current density–brightness–voltage characteristics of device II and III are plotted in Fig. 4. Device II and device III exhibited similar turn-on voltage of 2.9 V and 2.8 V (recorded at 1 cd m^{-2}) and the maximum brightness of 11,020 and 9120 cd m^{-2} are reached at 10 V, respectively. In both devices, brightness increased linearly with current density, indicating that they are highly efficient blue OLEDs. Compared with device II, device III shows faster rise of the EL intensity and the current density after the onset voltages and up to about the brightness of 1000 cd m^{-2}. For this case in particular, the reduction in driving voltage of device III should result from the higher HOMO (The highest occupied molecular orbital) of (*E*)-CPEY than that of CBP [9], which leads to that more holes can easily and directly inject from the HTL into the EML in device III with relatively high doping concentration (20 wt%) and it can be understood in terms of the proposed energy diagram

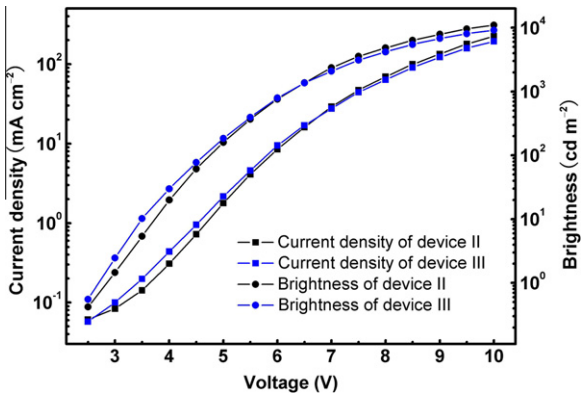

Fig. 4. Current density–brightness–voltage characteristics of device II and III.

(Fig. 1). In contrast, when the brightness is over 1000 cd m^{-2}, the slightly rapid increase of the EL intensity and the current density showed in device II, which should partly due to the better charge-transporting ability of CBP than that of (*E*)-CPEY and indicates also that the concentration quenching of (*E*)-CPEY molecules might still occur in device III, specially at the high current density.

Fig. 5 plots the LE (luminous efficiency), PE (power efficiency) and EQE (external quantum efficiency) of the devices as functions of the current density and the corresponding values of the EL efficiencies based on different brightness level are listed in Table 1. Device II and III exhibit the exciting peak EL efficiencies of 9.1 cd A^{-1} (7.1%) and 5.9 lm W^{-1}, 8.6 cd A^{-1} (6.0%) and 5.6 lm W^{-1} at the reliable brightness of 370 and 60 cd m^{-2}, 395 and 75 cd m^{-2}, respectively. Notably, the EL efficiencies of both devices at the brightness of 100 cd m^{-2} and 1000 cd m^{-2}, which are the practical level used in the fields of display and lighting, remain as high as 8 cd A^{-1}, 4 lm W^{-1} and 5%. The values mentioned above are the highest EL efficiencies ever reported for a saturated deep-blue OLED to the best of our knowledge, even including the devices utilizing doped [4] and non-doped emitting systems [10]. In addition, both devices keep the EL efficiency over 6 cd A^{-1}, 2 lm W^{-1} and 4% in very wide current density range (0.2–100 mA cm^{-2}) and brightness range (20–5000 cd m^{-2}), indicating the good operational stability of the devices.

Clearly, the observed EL efficiencies in the blue OLEDs are remarkably high, and the measured high EQE value is larger than the apparent limit of ca. 5% EQE for fluorescence-based OLEDs [11]. The 5% theoretical limit is based on the two assumptions of a statistical singlet/triplet formation ratio of 1:3 and a light outcoupling efficiency η_c of ca. 20% ($\eta_c < 0.5/n^2$, n being the refractive index of the emitter, typically about 1.6–1.8). However, the validity of both these assumptions is currently debatable [10a]. High η_c values of 30–50% have been estimated depending on the choice and optimization of device parameters such as the refractive index and the thickness of ITO glass and organic thin films, position of the emission zone in the device, and a combination of other factors [11,12].

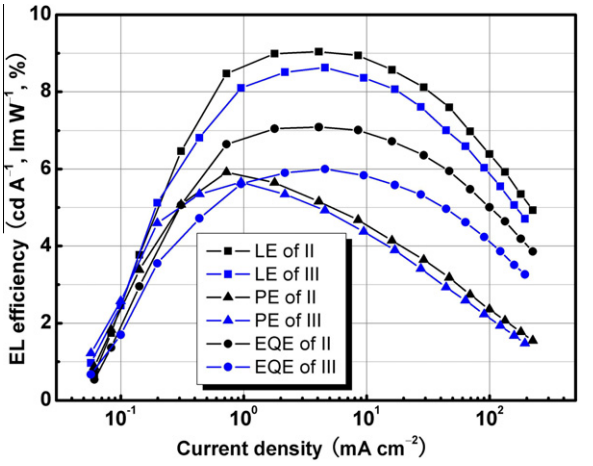

Fig. 5. EL efficiency of the device II and III as functions of the current density.

Table 1
Corresponding values of driving voltage, LE, PE and EQE based on different brightness level of device II and III.

Device		Max. efficiency	10 cd m^{-2}	100 cd m^{-2}	1000 cd m^{-2}	5000 cd m^{-2}
II	V (V)		3.7	4.7	6.2	8.1
	LE (cd A^{-1})	9.1 (5.5, 370)[a]	5.2	8.6	8.7	6.8
	PE (lm W^{-1})	5.9 (4.5, 60)[a]	4.3	5.8	4.4	2.6
	EQE (%)	7.1 (5.5, 370)[a]	4.1	6.6	6.7	5.2
III	V (V)		3.5	4.6	6.2	8.3
	LE (cd A^{-1})	8.6 (5.5, 395)[a]	5.1	8.2	8.2	6.1
	PE (lm W^{-1})	5.6 (4.5, 75)[a]	4.6	5.5	4.1	2.3
	EQE (%)	6.0 (5.5, 395)[a]	3.6	5.7	5.7	4.4

[a] Numbers in parentheses are the corresponding voltages (*V*) and brightness (cd m^{-2}), respectively.

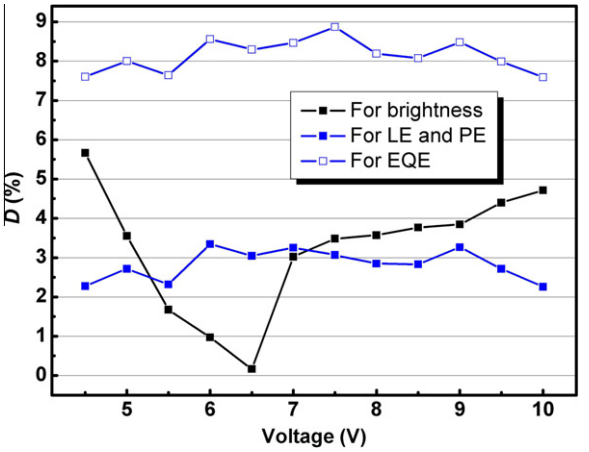

Fig. 6. Deviation (*D*,%) for the brightness and the EL efficiency between device II and III with respect to the driving voltages.

Additionally, EQE values greater than the apparent limit have been previously reported for fluorescence-based OLEDs, including the EQE of 5–7% for a blue OLED [4b,10,13] and 7–10% for green OLEDs [14]. Thus, there is evidence in the literature that the apparent 5% limit on EQE and the underlying assumptions are questionable.

More importantly, it is clear that device II and III present very similar EL performance such as the similar values of the EL efficiency and brightness upon the same current density and driving voltage level, as shown in Figs. 4 and 5, respectively. Fig. 6 shows intuitively the deviation (*D*,%) for the brightness (*B*) and the EL efficiency (*E*) between device II and III with respect to the driving voltages. The corresponding deviation is defined by the formula of D_B (for brightness) = ½Δ*B* (II and III)/½Σ*B* (II and III) and D_E (for EL efficiency) = ½Δ*E* (II and III)/½Σ*E* (II and III), respectively, and the values of brightness or efficiency using in one formula should base on same driving voltage. Obviously, although the doping concentration changes such large span as between device II (10 wt%) and device III (20 wt%), the deviation for both the brightness and the EL efficiency always keep within a small range of 9%, especially, the deviations for LE and PE even remain as low as 4%. This result reveals the high EL performance of the blue devices based on (*E*)-CPEY are relatively insensitive to the doping concentration changing in such high and wide

range as 10–20 wt%, which is one gratifying property suggesting the easy and reproducible fabrication process of mass production and not provided by all the blue guest emitters previously reported up to now [4]. The excellent EL performance (*E*)-CPEY-based devices should be attributed to the pronounced photoelectric properties of (*E*)-CPEY, which is demonstrated by being acted successfully as a single-emitting-component for highly efficient white OLED [5]. On the other hand, the morphological likeness and the well-matched energy levels between CBP and (*E*)-CPEY lead to that CBP is a favorable host for this blue dopant, is another possible reason.

4. Conclusions

In summary, highly efficient deep-blue OLEDs employing the emitting layer based on an aromatic enyne derivative (*E*)-CPEY doped in the CBP with the easily controlled doping concentrations have been developed. The series of OLEDs show high peak EL efficiencies (>8.5 cd A^{-1}, >5.5 lm W^{-1} and $\geqslant$6.0%) with pure and stable blue emission (0.15, 0.10 ± 0.01), which are the highest EL efficiencies ever reported up to now for the saturated deep-blue OLEDs. More importantly, both the EL efficiency and the brightness of these blue OLEDs just present very small deviation within such a high and wide range of doping concentration (10–20 wt%), which should lead to the easy and reproducible fabrication process of high performance EL devices. The easily controlled doping concentrations together with high EL efficiency and pure blue emission, are the unique gratifying properties provided by the OLEDs based on (*E*)-CPEY, which suggest that the blue OLEDs have high potential for the applications in large flat panel displays and solid-state lighting in future.

[12,13]. Such high temperatures are not compatible with the use of plastic substrates and prohibit the full integration of inorganic materials with organic electronics. To this end, low temperature atomic layer deposition (ALD) has also been used to make TiO_2 films [14,15]. However, a room temperature solution process would be the ultimate solution from the point of view of large-scale, cost-effective manufacture of electronic devices.

In this letter, we report the synthesis of TiO_2 nanoparticles via a sol–gel process, and the deposition of transparent TiO_2 thin films by spin-coating from an aqueous dispersion at room temperature, without any further heat treatment. We show that these films are suitable for applications in polymer optoelectronic devices (photovoltaic cells and light emitting diodes). The developed process yields TiO_2 thin films that are suitable for large-area deposition on practically any substrate, and thus it makes low cost, large-scale manufacturing of organic electronics possible in the not-so-distant future.

2. Experimental

2.1. Nanoparticle synthesis

TiO_2 was synthesized by hydrolysis of $TiCl_4$ (Fluka, 99.0%) at 40 °C in an aqueous solution containing hydrochloric acid (HCl, Fishersci.) and 2-propanol (Mallinckrodt) [16]. $TiCl_4$ (1 mol/L) aqueous solution was prepared by dissolving $TiCl_4$ in a mixture of deionized (DI) water (18.2 MΩ Barnstead EASYpure® RoDI) and HCl (volume ratio of 19:1, H_2O:36–38% HCl). Because the reaction was highly exothermic and produced high quantities of fumes, $TiCl_4$ was added dropwise into the ice cooled HCl solution with vigorous stirring, and the reaction had to be carried out inside a fume hood. The $TiCl_4$ solution (4 mL) was filtered (syringe filter; 0.2 μm, Nylon, Millipore) and then added into a 2-propanol solution (32 mL of 2-propanol mixed with 4 mL of DI water). The obtained reaction mixtures were incubated at 40 °C in a water bath (Fishersci.) for 12 h, which led to the formation of white TiO_2 particles. The particles were separated by centrifugation, washed with ethanol, and then dried at 40 °C overnight.

Particle size and morphology were investigated by transmission electron microscopy (TEM, FEI Tecnai G2 T12, field emission gun, 120 kV), and thin film sections were examined by field emission scanning electron microscopy (FESEM, Hitachi S4500, 10 kV) after being sputter-coated with Au/Pd. The crystal phase of the particles was determined by powder X-ray diffraction (XRD) in θ–2θ scan mode from 15° to 80° (Scintag Inc., Theta–Theta Diffractometer; Radiation: Cu Kα1; Scan rate: 0.012°/min; Step: 0.02°). The surface morphology of the films was examined with an atomic force microscope (AFM, DI 3100 Dimension microscope) using tapping mode. UV/Vis absorption spectra were obtained using a Shimadzu UV-3101PC UV/Vis/Near-IR Spectrophotometer; thin films to be measured were spin-coated on quartz slides to obtain accurate UV/Vis absorption spectra. The chemical states of titanium and oxygen were analyzed by X-ray photoelectron spectroscopy (XPS, Surface Science Instruments SSX-100, monochromatic Al Kα; 1486.6 eV) at a take-off angle of 90°.

2.2. Device fabrication

Devices were fabricated on pre-patterned indium tin oxide (ITO)-coated soda lime glass substrates (<20 Ω/sq, Kintec, Hong Kong). Before thin film deposition, these substrates were cleaned by sonication in non-ionic detergent and DI water, and then treated with a 10-min UV-ozone (Jelight) exposure.

The photovoltaic cells had a structure of glass/ITO/TiO_2 (15 nm)/P3HT (40 nm)/Au (50 nm). Before the TiO_2 thin film deposition, the TiO_2 nanoparticles were dissolved in DI water (5–10 mg/mL) to form a clear dispersion. TiO_2 thin films were deposited on top of cleaned ITO glass substrates by spin-coating. Prior to the deposition of P3HT (poly-3-hexylthiophene), the as-deposited TiO_2 thin films were treated in UV-ozone for 10 min. P3HT (American Dye Source) was dissolved in chlorobenzene to a concentration of 10 mg/mL before it was spin-coated at 1500 rpm in air on top of the TiO_2 layer. After P3HT deposition, the films were annealed on a hot-plate at 230 °C in N_2 atmosphere for 15 s and then cooled down slowly (~40 min) to improve the crystallinity of P3HT. Finally, 50 nm of Au was thermally evaporated at 0.05 nm/s under high vacuum (~10^{-6} Torr) to form the anode of the devices.

The light emitting diodes had an inverted structure of glass/ITO/TiO_2 (10 nm)/Al_2O_3 (5 nm)/F8BT copolymer (75 nm)/WO_3 (20 nm)/Au (40 nm). Similar to photovoltaic cell fabrication, TiO_2 dispersed in DI water was spin-coated onto cleaned ITO glass substrates in air to yield films with thickness of about 10 nm. A 10-min UV-ozone treatment of these films was followed by the deposition of 5 nm of Al, which was then oxidized under UV-ozone for 15 min. Subsequently, the F8BT light-emitting copolymer, namely poly[(9,9-dioctylfluorenyl-2,7-diyl)-co-(1,4-benzo-{2,1′,3}-thiadiazole)], with 10% benzothiadiazole was spin coated. The F8BT copolymer had a molecular weight of 15,000 and a polydispersity of 3.0. It was dissolved in p-xylene to yield a solution of 15 mg/mL and was spin-coated at 1000 rpm in a N_2 environment. Finally a top contact of WO_3 (20 nm)/Au (40 nm) was thermally evaporated at 0.1 and 0.05 nm/s, respectively.

3. Results and discussion

TiO_2 nanoparticles were prepared by hydrolysis of $TiCl_4$ at 40 °C in an isopropanol based sol–gel environment. TEM images show that nanoparticles, which did not aggregate, were obtained with an average particle size of 2 ± 0.4 nm (Fig. 1a). Fig. 1d shows the XRD pattern of as-prepared TiO_2 nanoparticles. From the XRD analysis, it is evident that both anatase and rutile structures exist in the sample, with anatase as the major phase. The XRD pattern of the formed phases is consistent with the data recorded in JCPDS file no. 21-1272 (anatase) and 21-1276 (rutile). The broad width of the diffraction peaks is attributed to the small crystallite size of the TiO_2 nanoparticles. The

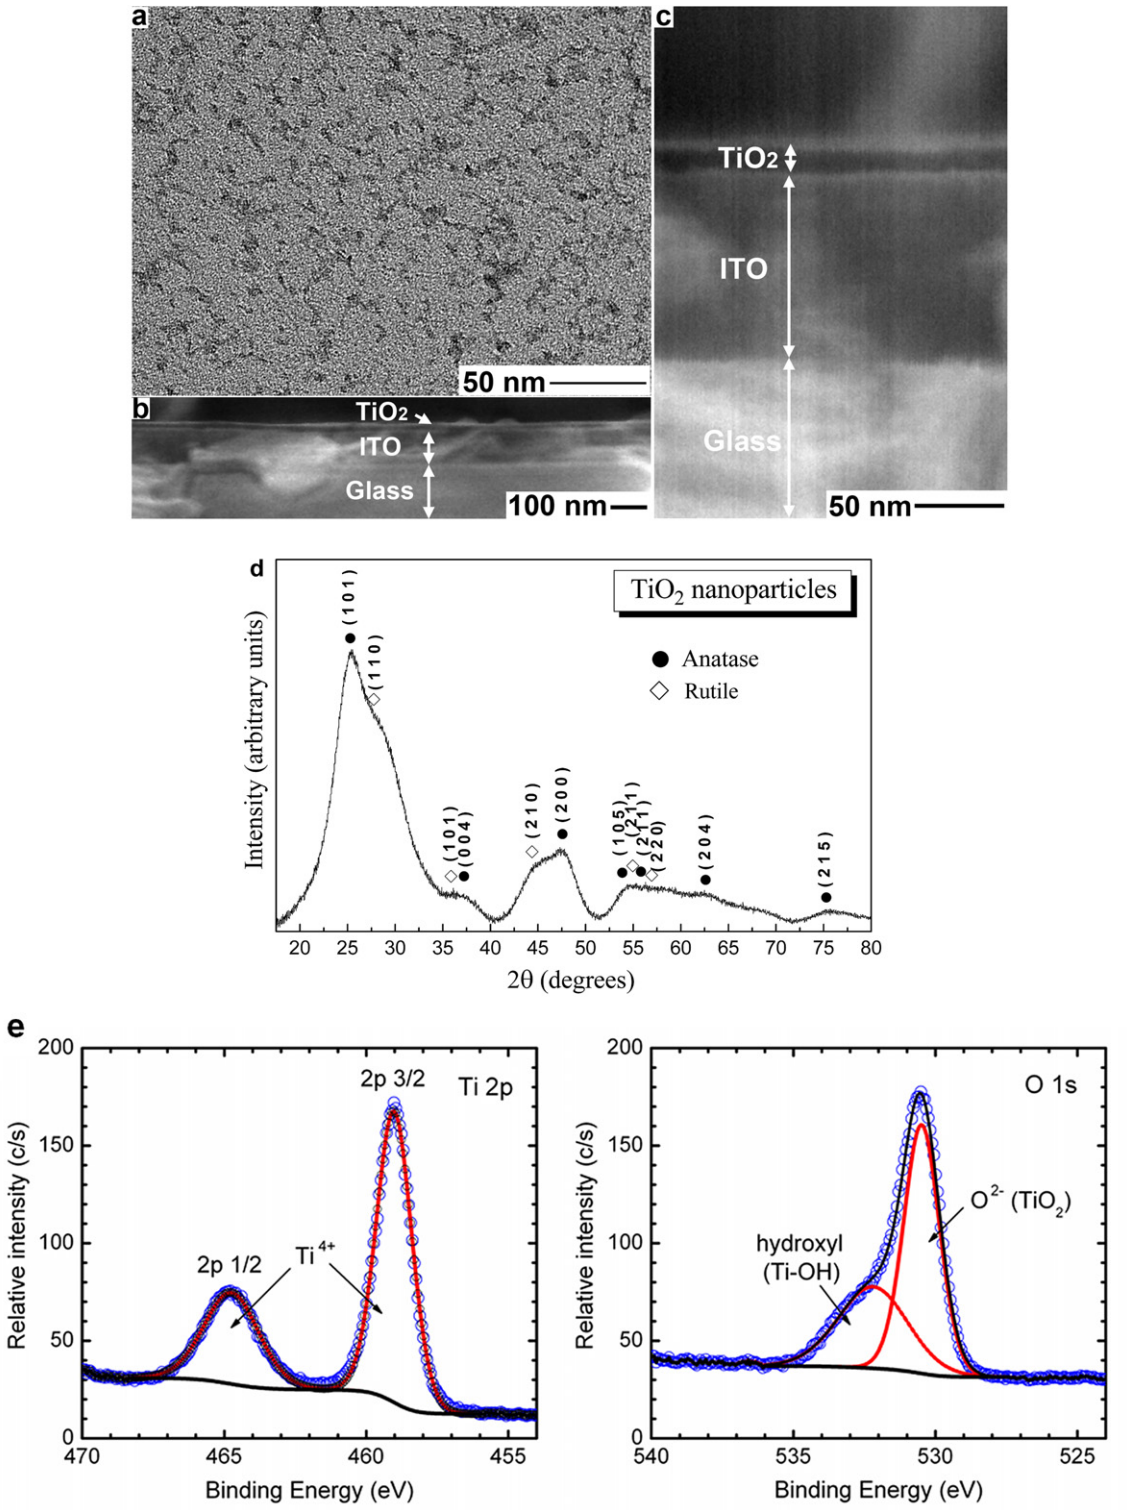

Fig. 1. (a) TEM image of the TiO_2 nanoparticles. (b and c) FESEM image of a TiO_2 thin film deposited on ITO-coated glass substrate. (d) XRD pattern of the TiO_2 nanoparticles. (e) XPS spectra (Ti 2p and O1s) of the deposited TiO_2 thin film after treated with UV-ozone exposure.

crystallite size of as-prepared TiO_2 nanoparticles could be calculated from the full width at half maximum of the (1 0 1) peak for anatase and (1 1 0) peak for rutile by the Debye–Scherrer formula (the distribution of these two partially overlapping peaks was analyzed with Pearson 7 waveform). It was found to be about 2 nm, which

is consistent with the particle-size measured from TEM images. Fig. 1e shows the high-resolution XPS spectra of the Ti 2p and the O1s peaks taken on the surface of deposited TiO_2 thin film after UV-ozone exposure. The shape of the Ti 2p 3/2 peak at 459.0 eV is symmetric, which proves Ti^{4+} to be the only oxidation state in our TiO_2 material. This reinforces the distinction between our TiO_2 thin films and amorphous TiO_x films, which contain a substantial amount of coordinatively unsaturated Ti species (e.g. Ti^{3+}) in the films [3,17]. The O1s peak is deconvoluted into two individual subpeaks: metal oxide (O^{2-}) and hydroxyl group (OH^-). The resulting peak positions for the O^{2-} and OH^- peaks are in good agreement with values reported by other studies [18,19]. The observed O^{2-} is assigned to the Ti–O bonding in bulk TiO_2 while the hydroxyl group is ascribed to the Ti–OH bonding on the surface of TiO_2 nanoparticles. The hydroxyl content of our TiO_2 materials is greater than other TiO_2 nanoparticles (e.g. P25 [20]) owing to the much larger surface area of the characteristically small nanoparticles (~2 nm).

One advantage of these nanoparticles is that they are easily dispersed in water and form a clear dispersion [21], which enables low-cost and environmental-friendly thin-film processing by means of spin-coating. No further annealing was needed to make our process more amenable to the fabrication of TiO_2/polymer hybrid devices, as compared to previously reported high-temperature processes [22–24]. A section of a typical TiO_2 thin film spin-coated on ITO coated soda-lime-glass substrate was examined by FESEM. The FESEM images show that the TiO_2 thin film is uniform in thickness along the section (Fig. 1b) which was measured to be around 15 nm in the high-magnification image (Fig. 1c). By adjusting the conditions of spin-coating, the thickness of TiO_2 films could be varied from several nanometers to the sub-micrometer scale.

The morphology of the as-prepared TiO_2 thin films on ITO glass substrate was investigated by AFM and it was found that it can be adjusted by changing the concentration of dispersion and the deposition conditions. Under specific conditions (high TiO_2 concentration and low spin speed, e.g. 10 mg/mL and 1000 rpm), rougher films with an RMS roughness (over a scan area of 10 μm × 10 μm) of 1.33 nm were obtained (Fig. 2a and b). These TiO_2 films with a typical thickness around 15 nm were used for photovoltaics. In the case of TiO_2 thin films for use in LED fabrication (typical thickness around 6 nm), the surface roughness could be significantly reduced by coating lower concentration dispersions with higher spin speeds (e.g. 5 mg/mL, 9000 rpm). The RMS roughness of these smoother films (over a scan area of 10 μm × 10 μm) was only 0.6 nm (Fig. 2c and d), similar to the surface roughness of the ITO coated glass substrate.

Photovoltaic cells were designed using room temperature deposited TiO_2 thin films as the electron extraction layer, while P3HT was spin-coated on top as the hole transporting layer. Annealing was applied after the deposition of P3HT on TiO_2 to improve the crystallinity of P3HT. In order to test the light absorption behavior of TiO_2 and P3HT, UV/

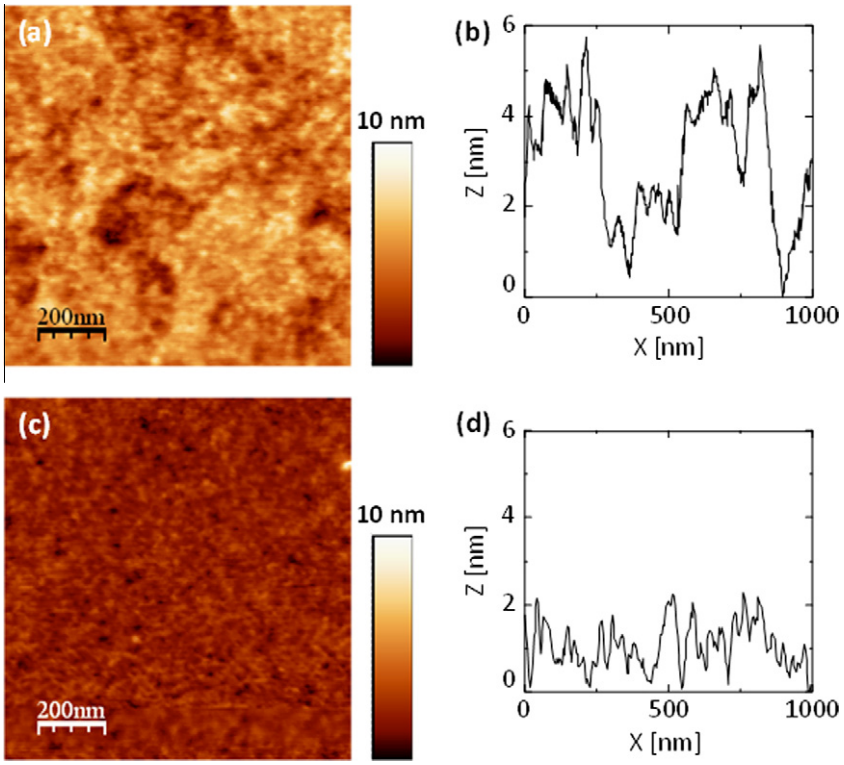

Fig. 2. (a and b) AFM images (left) and 1D profiles (right) for TiO_2 coated on ITO-coated glass for applications in photovoltaics. (c and d) AFM images (left) and 1D profiles (right) for TiO_2 coated on ITO-coated glass for applications in polymer LEDs.

Vis absorption spectra of these films were measured (Fig. 3a). The UV/Vis absorption spectrum of the TiO_2 thin film exhibits an absorption peak at 257 nm with the band-gap of about 3.5 eV estimated from the absorption onset (350 nm). The absorption onset is found to be blue-shifted as compared both to bulk rutile (~413 nm) and anatase (~387 nm) TiO_2, and this phenomenon is attributed to the quantum-size effects since the size of nanocrystals

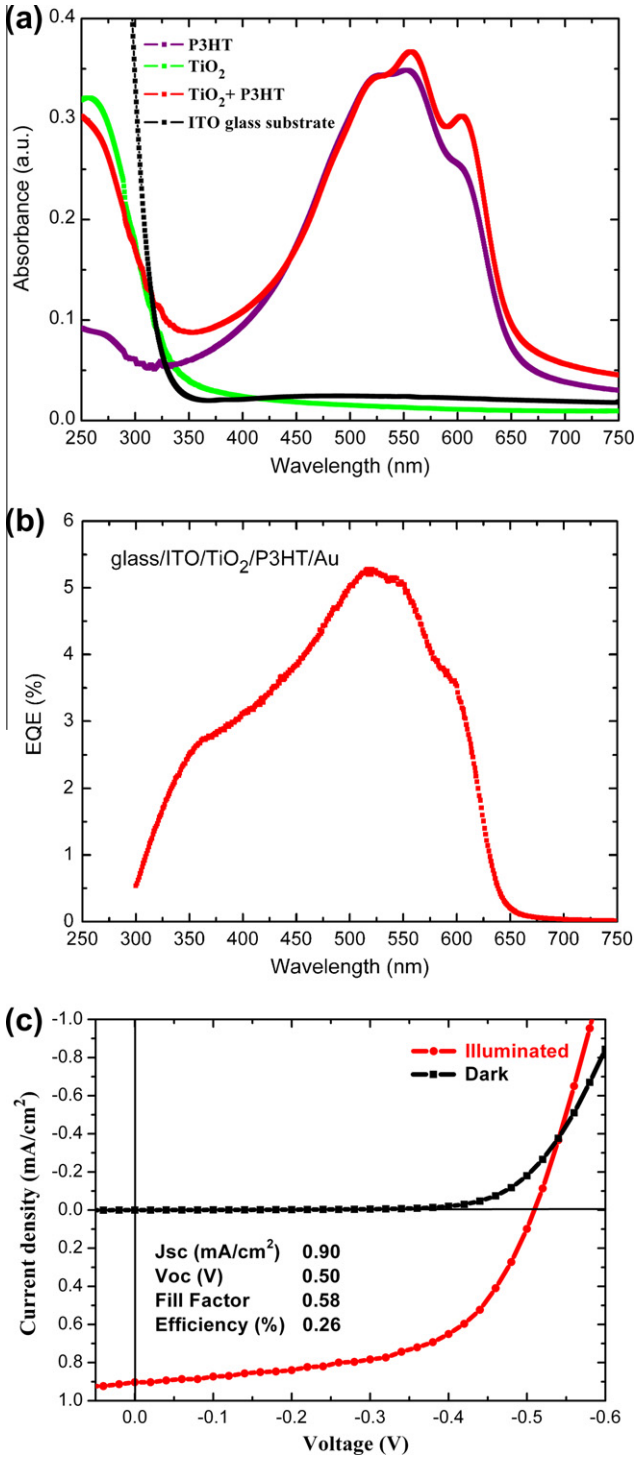

Fig. 3. (a) UV/Vis absorption for thin films of TiO_2, P3HT, a bilayer of the two (all on quartz), and the glass substrate used for device fabrication. (b) External quantum efficiency scan from an ITO/TiO_2/P3HT/Au device. (c) *I–V* curves of the photovoltaic cell.

comprising the TiO_2 thin films is only 2 nm on average (Fig. 1a) [21,25,26]. TiO_2 absorbs in the UV range, while P3HT absorbs from about 350 to 650 nm, thus the TiO_2 layer has the potential to extend the spectral response of P3HT-based solar cells. Moreover, the TiO_2 layer can protect the polymer overlayer from photo-bleaching by absorbing UV light. Fig. 3a also shows the enhanced vibronic transitions in the UV/Vis spectrum of TiO_2/P3HT films. P3HT on TiO_2 thin film displays two discernible intrachain π–π^* absorption peaks at 560 and 610 nm, which is associated with stronger interchain interactions in more ordered polymers. This phenomenon was due to the slow cooling process after annealing, which increased the degree of order in P3HT on TiO_2. Similar behavior was also observed as P3HT deposited on ZnO layer with similar annealing/cooling treatment after [7].

The relationship between light absorption and photocurrent was examined by external quantum efficiency (EQE) measurements. Gold was chosen as top electrode of the device due to its appropriate work function (~5.1 eV). Fig. 3b shows the EQE values for the hybrid photovoltaic device. The glass/ITO/TiO_2 (15 nm)/P3HT (40 nm)/Au (50 nm) device achieved an EQE of 5% in the 500–550 nm spectral region. A shoulder in the 300–350 nm spectral region shows that the device also generates current in the UV region, which could be attributed to the contribution of the TiO_2 layer. The open circuit voltage (V_{oc}), short circuit current (J_{sc}), fill factor (FF) and power conversion efficiency (PCE) of the hybrid photovoltaic cell under AM 1.5 100 mW/cm^2 illumination were calculated from the *I*–*V* curves. As shown in Fig. 3c, the hybrid photovoltaic cell achieved a V_{oc} of 0.50 V, a J_{sc} of 0.90 mA/cm^2, a FF of 0.58 and a PCE of 0.26%. The efficiency of our photovoltaic cell is comparable to the efficiency (0.28% PCE) reported by Shen et al. of a photovoltaic cell with similar combination of materials (ITO/TiO_2/P3HT/Au) [27]. However, in that report, the TiO_2 thin films were deposited from a sol–gel precursor and required post annealing at 450 °C, which is significantly higher than the process temperature reported here. In comparison to inverted devices based on ZnO layer, the performance of TiO_2/P3HT photovoltaic cell reported here is better than the performance of bi-layer ZnO/P3HT devices [5], and is comparable to the ZnO nanorod/P3HT composite devices (0.20–0.28% PCE) [5,7]. However, the performance of ZnO/P3HT photovoltaic devices reported by Olson et al. shows an improved efficiency (0.53% PCE)

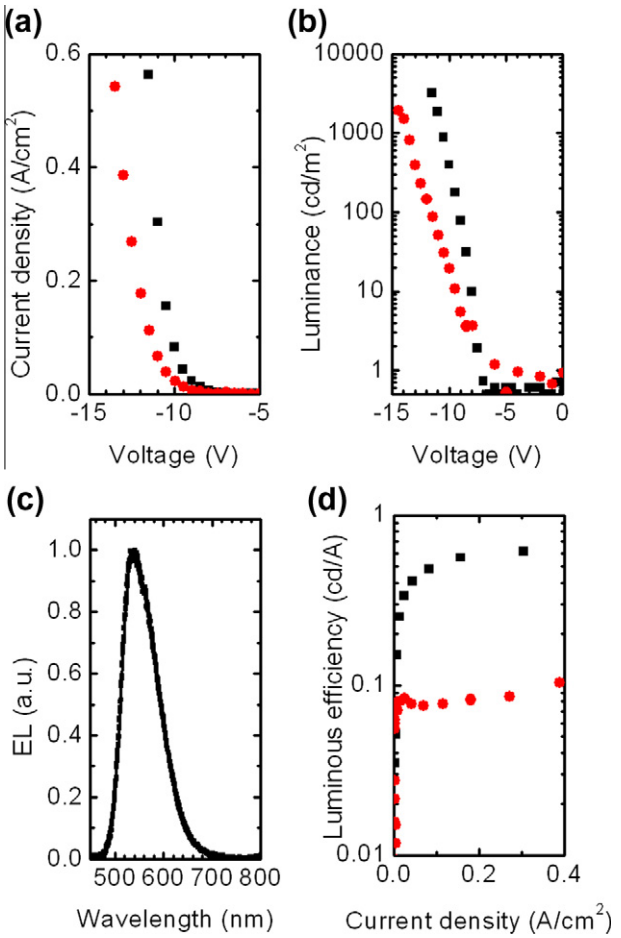

Fig. 4. (a) Current vs. voltage (*J*–*V*), (b) luminance vs. voltage (*L*–*V*) characteristics, (c) EL spectrum, and (d) luminous efficiency of a TiO_2/polymer hybrid LED. Data from two devices are shown: ITO/TiO_2/Al_2O_3/F8BT copolymer/WO_3/Au (squares ■) and one with a similar structure but utilizing only ITO as the cathode (circles ●).

due to a mesoporous structure of ZnO nanofibers that were grown via a hydrothermal process [6].

We found that if we spin-coat TiO_2 thin films with suspensions dispersing larger size TiO_2 nanoparticles (e.g. P25 with the average particle size of about 21 nm, a generous gift from Degussa Corporation), the photovoltaic devices fabricated with the similar process as this study often suffer from large current leakage and poor photovoltaic response. This result is due to the rough surface of as-deposited TiO_2 layer with large nanoparticle clusters (~100 nm) "sprinkled" on the surface. A strong point of the process described in this letter is that smooth and homogeneous TiO_2 thin films with very small roughness can be prepared readily at room-temperature via a liquid phase process. The good dispersibility and the good film forming properties can be attributed to the small and uniform size of the TiO_2 nanoparticles.

Fig. 4a and b show the current vs. voltage and luminance vs. voltage characteristics of the TiO_2/polymer hybrid light emitting diode with a structure of ITO/TiO_2 (10 nm)/Al_2O_3 (5 nm)/F8BT copolymer (75 nm)/WO_3 (20 nm)/Au (40 nm). The electroluminescence spectrum shows an emission peak at 536 nm (Fig. 4c). This hybrid LED turns on at ~7 V and reaches 100 cd/m^2 at ~8.5 V. The maximum brightness approaches ~4000 cd/m^2 at 12 V. The corresponding luminous efficiency at 100 mA/cm^2 is ~0.6 cd/A (Fig. 4d). This value is six times higher than that of a reference inverted device (~0.1 cd/A) utilizing only ITO as the cathode (Fig. 4a, b, and d, circle symbols), and comparable to that of a reference typical bottom anode device (ITO/PEDOT:PSS (AI4083) (60 nm)/F8BT copolymer (75 nm)/CsF (1 nm)/Al (40 nm)), in which the turn-on voltage was ~4.5 V, and the maximum brightness was ~4500 cd/m^2 at 9 V.

Previous reports attempted to incorporate either dense or porous TiO_2 into inverted polymer LEDs by following different schemes. For example, by means of spray-pyrolysis using a titanium organic precursor on heated substrates and then annealing at 520 °C, to obtain dense TiO_2 films [13]. The corresponding hybrid light emitting diodes showed an efficiency of about 0.6 cd/A. In a second example, spin-coating of a TiO_2 colloidal suspension of nanoparticles, followed with sintering at 450 °C, yielded a mesoporous film structure [28]. This method was used to prepare a TiO_2 layer for hybrid light emitting diodes, which showed a substantially lower current efficiency [28,29] than the one we report here. Therefore, the devices reported here show comparable or better performance than light emitting diodes employing TiO_2 films prepared and sintered at higher temperatures. To the best of our knowledge, the data described here constitute the first demonstration of a room-temperature processed TiO_2 film for hybrid light emitting diodes.

4. Conclusions

In conclusion, we show that TiO_2 thin films suitable for polymer optoelectronic device fabrication can be prepared at room temperature via a properly designed liquid phase deposition process. TiO_2/P3HT photovoltaic cells show comparable performance to devices utilizing TiO_2 layers sintered at high temperatures. TiO_2/F8BT hybrid light emitting diodes show an efficiency of 0.65 cd/A. These results show that it is now possible to apply TiO_2 films to the fabrication of low cost organic devices.

experimental and theoretical investigations in order to understand the factors affecting its molecular rectification. Some theoretical studies examined the rectification properties of diblock diode, [16,18–22] but very little addressed the issue of the effect of structural factors [16,20]. A good reported example of single diblock molecular diode is the dipyrimidinyl-diphenyl dithiol (**DPDPh1**), Fig. 1. Experiment demonstrated that the electronic structure of this molecule allows the current to pass preferably in one direction [11]. Consequently, recent theoretical studies were interested in studying the effect of some structural factors on the electrical behavior of the **DPDPh1** molecule [16,20,22]. These studies indicated that the anchoring group [16] and molecular length [20] have obvious effects on the molecular rectification. It was also found that the asymmetric feature in the calculated current–voltage curve increases with increasing the molecular length [20]. On the experimental side, the rectification of current by diblock diode is enhanced by increasing the dipole moment of the molecule [11,14].

In this work, the authors investigated the effect of two new structural factors on the rectification properties of the **DPDPh1** molecule within a range of applied voltages: the constitutional and conformational isomery. It is worth mentioning that the isomery effect on the electron transport through two different molecular wires has been studied [23,24]. It was apparent that the relative position of nitrogen atoms in the molecular rings can significantly affect the transport characteristics due to changes in the electronic structures. The effect of constitutional isomery on the electrical properties of molecular diode was studied through four isomers: **DPDPh1**, **DPDPh2**, **DPDPh3** and **DPDPh4**. Fig. 1 illustrates these isomers in sandwiched form between two equatorial triangles of Au atoms. On the other hand, the conformational isomery effect was examined by varying the mid torsion angle between the donor and acceptor subunits of the **DPDPh1** molecule. To achieve these objectives, geometrical and electronic structures of all isomers were investigated using density functional theory (DFT) for the calculations of the intrinsic properties of all isomers. Moreover, the effect of electric field on the electronic properties of constitutional isomers was considered. The current–voltage (I–V) curves for the promising isomers were calculated to support our interpretations.

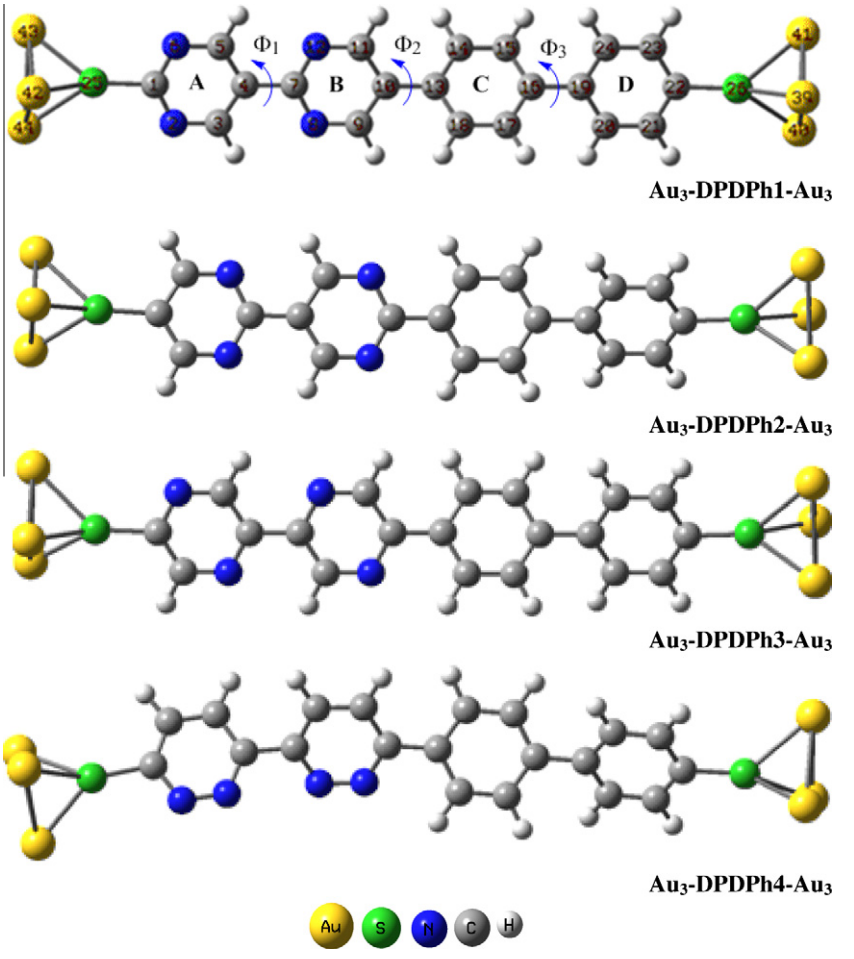

Fig. 1. B3LYP-optimized structures of the studied diblock molecular systems. The numbering and label scheme is presented on the structure of **Au_3–DPDPh1–Au_3** as a representative for all isomers. Φ_1, Φ_2 and Φ_3 are the torsion angles between each two adjacent rings.

In general, the electrical properties of molecules could be calculated by quantum chemical method, electron transport method, or both of them. The former deals with studying of molecular electronic structures in the absence [1–3] or presence of electric field [22,25–31]. Many authors prefer to use the electric field on isolated molecules without taking into account the effect of electrodes because they consider electrical properties of a given molecular device is an intrinsic character of the molecule itself [22,25–24,31] Others simulate the effect of electrodes by connecting the molecule with two small clusters representing the metal as semi-infinite electrodes [18,9,32]. On the other hand, the electron transport method uses two-probe configuration to calculate experimentally observable quantities like current or conductivity [20,33–35], see Fig. 2. This configuration is divided into three regions, two electrodes and the central region. The latter involves the molecule and the surface atoms of electrodes on each side. Some recent studies tried to combine them to validate their interpretations [18,23,35].

2. Background and methodology

In order to link the chemical properties of the molecular diode with its physics, we try to examine the response of some chemical parameters to the effect of electric field. When a single molecular diode is placed between two electrodes, electrons flow from the source to the drain through the molecule [3,18]. Thus, we can consider the molecule as an electrophile with respect to the source electrode. Accordingly, some electronic parameters such the global electrophilicity index "ω" were calculated in the framework of DFT approach [36]. The electrophilicity index measures the electrophilic power of a given system and is defined as follows:

$$\omega = \frac{\mu^2}{2\eta} \tag{1}$$

where μ and η are the chemical potential and global hardness, respectively. They could be calculated using the following mathematical expressions:

$$\eta = I - A \text{ and } \mu = -(I + A)/2 \tag{2}$$

where I and A represent the vertical ionization potential and electron affinity of a chemical species. Another related quantity, ΔN_{max}, [36] is the maximum amount of electronic charge that an electrophile may accept from its environment (i.e., the source electrode in this case),

$$\Delta N_{max} = -\mu/\eta \tag{3}$$

We preformed the calculations as follows:

2.1. The isolated molecules

Geometry optimization of all isomers were performed using the hybrid B3LYP functional [37–39] with the 6-31+G(d,p) basis set as implemented in the Gaussian 03 suite [40]. Single point energy calculations of the cationic and anionic species at B3LYP/6-31+G(d,p) using the optimized geometries of the neutrals. Then the vertical I and A were calculated from subtracting the energies of the cations and anions, respectively, from that of the neutral systems.

2.2. Effect of electric field

To simulate the connection of a molecular device to electrodes, the two anchoring sulfur atoms of the fully optimized structure of the isolated molecules were fixed in the space and then allowed to be optimized again under the effect of a uniform electric field [22] ranges from 0 to 5.00×10^{-3} a.u. in its strength. This corresponds to a range of bias voltage from 0 to 4.90 volt (V). The field was aligned along and against the z-molecular axis (dihetrocyclic-diphenyl direction).

2.3. Au_3–molecule–Au_3

It is well known that the thiol group losses its hydrogen atom when attached to the metal surface, thus forming a strong covalent bond that provides a good electrical contact between the molecule and the electrodes [41–44]. Each optimized molecular fragment is sandwiched between two equatorial triangles of Au atoms, with an Au–Au bond length of 2.88 Å as shown in Fig. 1 [41,42]. Each sulfur atom is attached at the hallow site on Au clusters with vertical distance 1.90 Å, where the attachment by this way give local energy minimum [41–44]. In such configuration, the small Au clusters were used to simulate the attachment of the Au(1 1 1) surfaces. The relative positions of the Au atoms were frozen in each triangle, but the distance between the clusters were relaxed during the

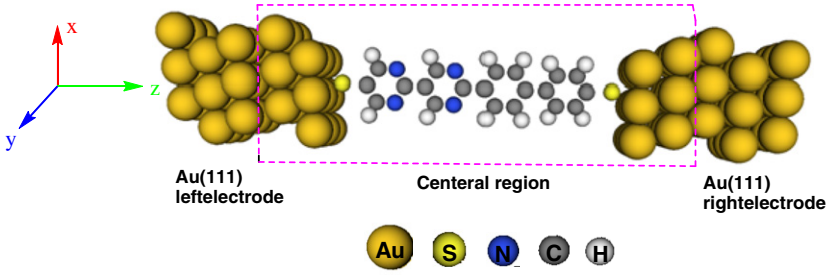

Fig. 2. Schematic illustration of the two-probe configuration for computing the I–V curve of the molecule coupled to pair of (3×3) gold electrodes. The central region includes the molecule between two surface layers.

geometric optimization. Geometry optimizations have been conducted using B3LYP/mixed basis sets: Los Alamos National Laboratory Double Zeta basis set (LANL2DZ) [45] for the gold atoms and 6-31+G(d,p) basis sets for the rest of atoms.

2.4. Calculation of I–V curve

The current (I) is calculated through two-probe system as a function of steadily increasing bias in both directions. The applied bias ranges from −2.0 to 2.0 V similar to the range of the experimental measurement [11]. The two-probe system is built by sandwiching the optimized isolated molecules from step (i), without the two terminal hydrogen atoms, between two gold electrodes through sulfur atoms. The non-equilibrium Green's function (NEGF) combined with exchange correlation DFT functional (LDA/PZ, the local density approximation with the Perdew–Zunger parameterization) [46] to compute the current using Atomistix ToolKit computer code (ATK 2.0) [47–48]. Double-zeta plus polarization (DZP) basis set was chosen for all atoms except gold for which single-zeta plus polarization (SZP) was used. Fig. 2 shows a representative example for the two-probe systems which divides into three regions: left electrode (L), central region, and the right electrode (R). Each electrode Au(1 1 1) surface is simulated by a (3×3) cell with the periodic boundary conditions. The central region includes the molecular fragment between couple of two surface layers.

3. Results and discussion

3.1. Diblock diode versus AR diode

It has been demonstrated that the diblock and AR diodes are able to rectify the alternating current [1–22]. The diblock diode (***A–D***) consists of donor (***D***) and acceptor (***A***) parts covalently connected, while the AR-diode (***A–S–D***) includes a spacer group (***S***) such as CH_2 between ***A*** and ***D***. Experiment proved that the **DPDPh1** junction has an ability to rectify alternating current [11]. However, what is the effect of turning this diblock molecule into AR-like model by inserting a spacer group between the diphenyl and dipyrimidinyl moieties? Both models were fully optimized to investigate the effect of spacer on the geometrical and electronic structures of the **DPDPh1** molecule. The results are given in Table 1. It is clear that the insertion of a CH_2 group induces bending ($<C_A–C–C_D = 114°$). The HOMO and LUMO are delocalized over the **DPDPh1** molecule with high weight on ***D*** and ***A*** subunits, respectively. Apparently, inserting CH_2-spacer produces AR-diode character [1–3]; where HOMO and LUMO are entirely localized at D and A subunits. Moreover, the inserted CH_2 group raises the dipole moment and increases the HOMO–LUMO energy gap due to interruption of conjugation, introduced by bending, and impedes electron-flow through the molecule.

3.2. Constitutional isomery

The diblock diode consists of donor and acceptor parts, where the donor part is the same in all isomers while the type of acceptor part depends on the relative positions of nitrogen atoms, see Fig. 1. To clearly understand the effect of constitutional isomery, the acceptor and donor units which constitute the ***A–D*** molecules were optimized separately. The HOMO and LUMO energies and HOMO–LUMO energy gaps for ***A*** and ***D*** are collected in Table 2. Evidently, the LUMO energy of the acceptor molecules decreases dramatically upon insertion of the nitrogen atoms, which can be ascribed to reducing electron density on the aromatic rings. Therefore, the diphenyl block can act as n-type molecular device, while insertion of nitrogen atoms gives it a p-type character. The potential drop was estimated to examine the effect of relative positions of nitrogen atoms on the accepting ability of p-type device and then the extent of coupling between it and the other individual n-type when they are chemically connected. As an approximation, the potential drop is defined as the energy difference between the LUMO energies of individual n-type and p-type [1]. According to the results given in Table 2, the accepting ability of 2,2′-dipyrazinyl molecule is higher than that of

Table 1
The energies of HOMO, LUMO and E_g (eV) and the dipole moment (Debye) as well as spatial orientations of HOMO and LUMO of **DPDPh1** molecule (***A–D***) and its acceptor–spacer–donor analogue (***A–S–D***) calculated at B3LYP/6-31+G(d,p) level.

Parameter	***A–D*** (**DPDPh1**)	***A–S–D***
ε_{LUMO}	−2.35	−2.12
ε_{HOMO}	−6.13	−6.08
E_g	3.78	3.97
Dipole moment	5.62	6.01
LUMO		HOMO		
Table 2
The energies of HOMO, LUMO, E_g and the potential drop (ΔE_{LUMO}) (eV) of the diphenyl and its isoelectronic constitutional isomers calculated at B3LYP/6-31+G(d,p) level.

Constituent	ε_{HOMO}	ε_{LUMO}	E_g	ΔE_{LUMO}
 diphenyl	−6.93	−0.72	6.21	–
 [2,5′]dipyrimidinyl	−7.09	−2.26	4.82	1.54
 [2,2′]dipyrazinyl	−6.97	−2.43	4.54	1.71
 [3,3′]dipyridazinyl	−6.75	−2.24	4.51	1.52

2,5′-dipyrimidinyl or 3,3′-dipyridazinyl molecule. This would affect the HOMO–LUMO energy gap of the combined ***A–D*** molecules.

Fig. 3 displays the molecular orbital energy levels of the donor and acceptor molecules compared to their combination in the **DPDPh1** molecule. It is apparent that the insertion of nitrogen atoms in biphenyl block has a similar effect as the electron-withdrawing substituent in AR-model, where both HOMO and LUMO energies are decreased [1]. It is also clear that the LUMO level of ***A–D*** is close to that of the acceptor molecule. This may be attributed to the relatively high-weight localization of LUMO on the acceptor moiety of ***A–D***. On contrary, the HOMO of the donor molecule is far away from the HOMO of ***A–D***, but the degeneracy of HOMO and HOMO-1 of the donor may cause relatively high-weight localization of HOMO on the donor moiety of ***A–D*** species.

The optimized geometries of all isomers in between two equatorial triangles of gold atoms are shown in Fig. 1. The calculations shows that the effect of connecting gold clusters on the geometry of the molecules is little where average deviation of bond lengths and bond angles for the common fragment between the isolated and **Au3–molecule–Au3** species hovers around 0.001 Å and 0.03°, respectively. Thus it suffices here to discuss the geometrical parameters of the isolated molecules. Further details about the geometries of the isomers and the comparison between some selected geometrical parameters of the isolated molecules and **Au3–molecule–Au3** species are given in the supporting information, Tables S1 and S2. The torsion angles Φ_1, Φ_2 and Φ_3 between each two adjacent rings and the bond lengths located on the molecular axis are given in Table 3. All isomers adopt twisted structures. The extent of twisting depends on the relative positions of nitrogen atoms. For example, rings ***A***, ***B***, and ***C*** of the **DPDPh2** isomer are almost coplanar. The shift of two nitrogen atoms from positions 9 and 11 to 8 and 12, increases Φ_1 and Φ_2 to 1.5 and 37°, respectively, leading to a high twist between ***B*** and ***C*** rings. Also, the **DPDPh4** molecule is the most twisted isomer giving a simple concave shape where all adjacent rings are twisted with respect to each other. However, the angle between the two phenyl rings, Φ_3, and most of bond lengths of all isomers are independent on the position of the nitrogen atoms. The angle Φ_2 between the donor and acceptor parts of the molecule is correlated to a great extent with the dipole moment; larger Φ_2 the higher the dipole moment. Furthermore, the constitutional isomery has a remarkable effect on the anchor atoms, especially S25, and the binding properties with metallic electrodes, Table 3. For example, the Mulliken atomic charge on S25 is dramatically reduced (from 0.258 to 0.004 e). The effect of isomery on the charge on S25 atom follows the order: **DPDPh1** > **DPDPh4** > **DPDPh3** > **DPDPh2**, while that of S26 atom shows the order: **DPDPh3** ≈ **DPDPh2** > **DPDPh1** ≈ **DPDPh4**.

Conjugated systems provide channels for electrons to transfer from a part to another part within the molecule, where π-electron cloud extends over the fully delocalized molecular orbitals [15,49,50].Table 4 shows the surfaces of four molecular orbitals of the **Au3–molecule–Au3** systems. These systems are considered extended molecules, where the molecule is attached to the nearest three gold atoms in each side. The depicted orbitals of the **Au3–molecule–Au3** species correspond to LUMO, HOMO, HOMO-1 and HOMO-2 of the isolated molecule. Although we used a different DFT methodology compared to that used by Gasyna et al. [18], we got very similar results for the spatial distribution of frontier molecular orbitals (FMOs) of the **Au3–DPDPh1–Au3** molecule. An inspection of Table 4 also indicates that the LUMO surface is almost delocalized over

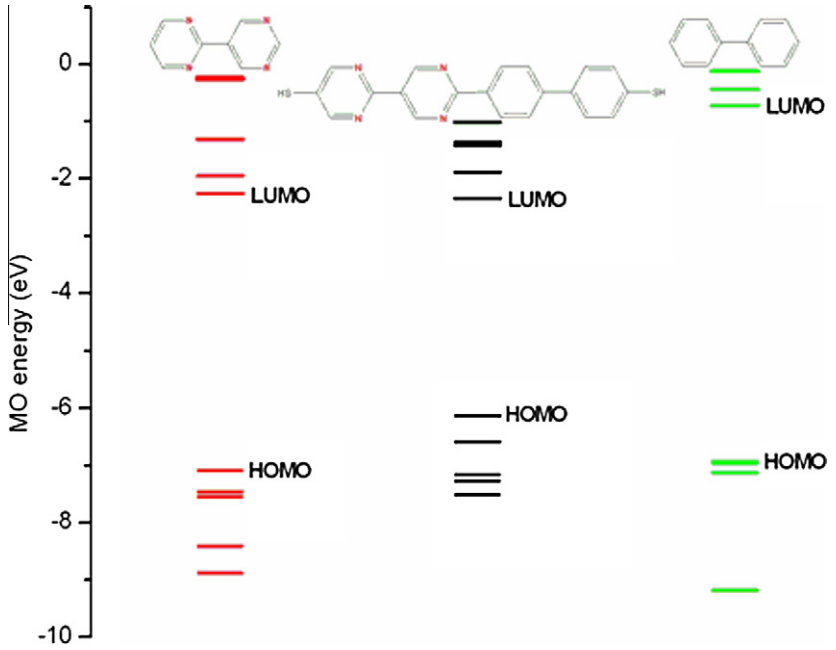

Fig. 3. the molecular orbital diagram of the five highest occupied and five lowest unoccupied orbital energy levels for 2,5′-dipyrimidinyl, **DPDPh1**, and diphenyl molecules calculated at B3LYP/6-31+G(d,p) level.

Table 3

the molecular skeleton and does not change by isomerisation. The HOMO state tends to be mainly localized at biphenyl subunit while HOMO-1 and HOMO-2 states are localized on the pyrimidinyl ring. The orbital overlap between the π-electrons of the subunits looks weak which resembles *p–n* semiconductor junction [18]. Accordingly, applying electric field in the direction of the molecular axis (from acceptor to donor) will direct the free π-electrons to move from the source-side to the drain-side. This process creates a potential barrier in the inter-subunit region. Upon reversing the direction of electric field, the potential barrier becomes higher than in the case of forward one [18].

Upon applying positive bias voltages, electrons move from source to drain overcoming tunneling potential barrier between the donor and acceptor subunits. With reversing the bias, the potential barrier becomes higher and thus electrons are difficult to flow. It is known that the transport property depends mainly on the alignment of molecular orbital to the Fermi level, i.e. the molecular orbital whose energy lies closer to the Fermi level [18,51,52]. If a gold metal is used as an electrode, the equilibrium Fermi level is assumed to be −5.31 eV for single crystal Au (1 1 1) electrode [11]. Therefore; one can expect that HOMO would be used in the electron tunneling process due to the closeness of HOMO of the molecule to the Fermi level compared to LUMO. This agrees with other previous studies [14,16,18,22].

Some electronic structure parameters from quantum chemical calculations are collected in Table 5. Most of these parameters are comparable for all isomers reflecting the similarity in their electronic structures, which may rectify the alternating current like **DPDPh1**. For example, the tunnelling process of rectification of **DPDPh1** depends on the alignment of the HOMO with the Fermi energy level of the gold electrode (−5.31 eV). Compared to that of the **DPDPh1** molecule, the HOMO energy levels of the other three isomers are slightly closer to the Fermi level. The effect of electric field on the FMOs of the **DPDPh1** molecule has been reported in previous studies [18,22]. They found that the energy of HOMO is closer to Fermi level than does the LUMO which implies that the electron tunnelling occurs mainly through HOMO. On contrary, LUMO of substituted oligophenylene ethynylenes is the closest orbital to Fermi level [10]. Here we try to extend these studies by correlating some chemical properties with the physics of

Table 4
The spatial orientations of the FMOs of the **Au3–molecule–Au3** molecular systems calculated at B3LYP/mixed basis set level.

LUMO				HOMO				HOMO-1				HOMO-2				
the device. These chemical properties include the global electrophilicity and the maximum propensity of the systems to acquire electronic charges from the source electrode as described in Section 2. These parameters follow the order: **DPDPh3** > **DPDPh2** > **DPDPh1** > **DPDPh4** in the absence of electric field.

However, we could follow the maximum propensity of the system to acquire electronic charge from the circuit under application of electric field. This was performed by plotting ΔN_{max} against bias voltage as displayed in Fig. 4a. The plots for all isomers have nearly *I–V*-like shape. By sweeping negative bias, ΔN_{max} shows a limited increase, if any. On the other hand, raising of positive indicated a slight increase in the ΔN_{max} until 0.98 V and then a rapid increase by further moving toward more positive bias. This result agrees with the observed rectifying character of the **DPDPh1** junction, where the current flows easily under positive voltage and is impeded under negative voltage [11]. Therefore, one could expect that junctions of **DPDPh2**, **DPDPh3** and **DPDPh4** may able to rectify alternating current. This promising rectification ability of the new isomers can also be confirmed from the plot of global electrophilicity index ω against bias voltage which shows an *I–V*-like shape as given in Fig. 4b. These plots can be utilized to examine the response of the intrinsic electrical properties of the isolated molecule under the effect of applied bias.

The asymmetrical response of the ΔN_{max} and ω parameters of the promising isomers to the applied voltage bias in the positive direction relative to the negative one can be proved by computing the electrical current using NFEG-DFT as described in Section 2. The prediction of the rectification efficiency of a given molecular junction can be judged by computing the *I–V* curve. Fortunately, the *I–V* curve of **DPDPh1** molecular junction has been measured experimentally using a.c.-assisted STM break-junction method [11]. Therefore, calculations of the *I–V* curve of the **DPDPh1** junction and its isomers will help in giving clear evidence about the unknown rectification ability of the new isomers. The current was computed for the experimentally measured voltage (from −2 to +2 V) [11] and the results are depicted in Fig. 5. At first glance, it is apparent that the transport ability is dependent on the constitutional isomery of the molecular junctions. For example, the current at 2 V is about 6.0, 6.3, 8.9 and 1.9 μA for the **DPDPh1**, **DPDPh2**, **DPDPh3** and **DPDPh4** junctions, respectively. Another important observation is that the **DPDPh1**, **DPDPh2** and **DPDPh3** junctions show clear asymmetric features in the computed *I–V* curves. This means that the transport ability under positive bias is significantly stronger than that at the negative bias. On contrary, the **DPDPh4** junction almost shows slightly asymmetric feature. By inspection Fig. 4 again in the bias windows from −2 to 2 V, we find the order of ΔN_{max} is **DPDPh3** > **DPDPh2** > **DPDPh1** > **DPDPh4** (or for ω **DPDPh3** > **DPDPh2** ≈ **DPDPh1** > **DPDPh4**) which agrees qualitatively to a great extent with that of *I–V* curves. Therefore, we could link the chemistry of the molecules with the physics of the molecular junctions.

To quantify the asymmetric response of the molecular junctions under positive and negative biases, we have

determined the rectification ratio, $R(V)$, which is defined as $R(V) = |I(V)/I(-V)|$. If $R(V)$ approaches 1, the molecular junction does not rectify the alternating current. The obtained rectification ratio of the molecular junctions as a function of the applied voltage is shown in Fig. 6. In general, the **DPDPh3** junction exhibits relatively significant rectification within the whole applied voltage especially at higher voltage, while the **DPDPh4** junction exhibits relatively weak rectification especially at high voltages. However, the effect of isomery on the rectification depends on the applied voltage. For instance, at voltage less than 1 V, the $R(V)$ values of the investigated molecular diodes are very close to each other (ca. 1.5). After 1 V, the isomers behave differently with respect to the rectification where the **DPDPh3** junction exhibits an enhancement, while the **DPDPh4** junction shows a weakness. At 2 V, the order of $R(V)$ is **DPDPh3** > **DPDPh2** > **DPDPh1** > **DPDPh4**. Therefore, we propose the **DPDPh3** junction as a better rectifier than the **DPDPh1** isomer especially at relatively higher voltages and it is worthy to be tested experimentally. However, the **DPDPh4** junction has a relatively slight rectification character. The difference between the **DPDPh2** and **DPDPh1** junctions depends on the applied voltage.

As the investigated diblock molecules and substituted oligophenylene ethylenes [10] represent two models for current rectification from the molecular wire, comparing

the calculated molecular rectification between them is worthy. There are three differences between rectification plots of both classes. NEGF calculation indicated that the diblock oligomers exhibit higher $R(V)$ than the other class. The average values of $R(V)$ of the diblock oligomers equal about 1.5 compared to less than 0.2 for phenylene ethylene oligomers. However, the plots of rectification ratio of phenylene ethylene oligomers have a curvature while those of the diblock oligomers show a quasi-linear feature. Other difference between them appears at higher bias voltages, the $R(V)$ of diblock junction has high values while that of oligophenylene ethylenes.drops down to negative values [10].

3.3. Conformational isomery

To study the effect of conformational isomery on the electrical properties of molecular diode **DPDPh1**, the torsion angle between the donor and the acceptor segments was fixed at a given value while optimizing other geometrical parameters. Fig. 7 displays the relaxed potential energy surface and the corresponding HOMO energies. The graph shows that the potential energy is symmetrical around 90° with two minima at low twist angle of ca. 45 and 135°. This rotation is similar to the rotation of the phenyl ring in the biphenyl molecule which shows a double well energy diagram [53] with a twist angle of 44.4° from electron diffraction studies [54]. These preferred configurations results from a competition between the repulsion between ortho hydrogens and π-electron delocalization [55]. The latter factor favors fully planar structures while the former prefers the perpendicular position. The energy barrier of rotation for the **DPDPh1** molecule is small (∼2 kcal/mol). The energy of the HOMO decreases with twisting. This means it becomes far from the Fermi energy

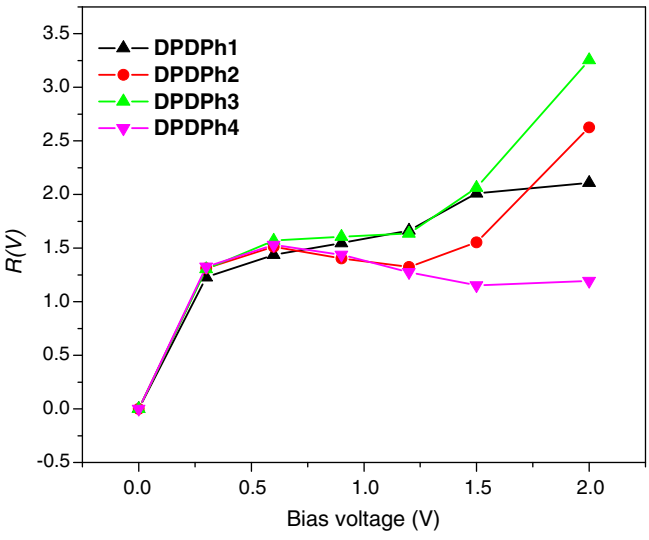

Fig. 6. The rectification ratio, $R(V)$ as a function of the applied voltage.

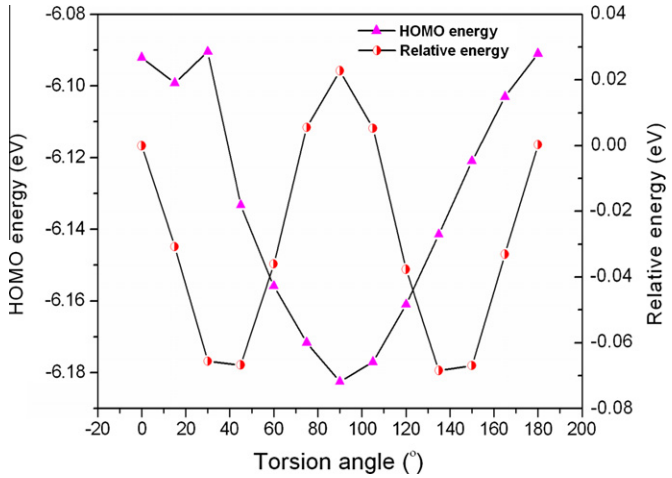

Fig. 7. The relative energy and the corresponding HOMO energy of **DPDPh1** molecule as a function of torsion angle between the donor and acceptor subunits calculated at B3LYP/6-31+G(d,p) level.

level and then the tunneling process through the HOMO, decreases. However, the HOMO–LUMO energy gap increases due to the interruption of the π-electron delocalization upon twisting.

Table 6 displays spatial orientations of FMOs of the **DPDPh1** molecule with planar and perpendicular conformations. The HOMO and LUMO are entirely delocalized over the whole molecule in the planar configuration, while they totally shrink towards the donor and acceptor parts, respectively in the case of perpendicular configuration, reflecting an AR-diode behavior [1–3].

It has been reported that the rectification of diblock diode depends, to somewhat extent, on its dipole moment [14,15]. For example, it was observed that rectification ra-

tio of the **DPDPh1** diblock diode is larger than that of dithiophene–dithiazole one because the former has a stronger intrinsic polarization [11,19]. In this context, one could expect that varying the torsion angle between the donor and acceptor units of the **DPDPh1** molecule will have a direct impact on its dipole moment, see Fig. 8. Indeed, the dipole moment decreases with increasing the twist angle; the maximum value of dipole moment of the **DPDPh1** molecule was reached when both subunits are coplanar. This result could be taken into account as a guide for designing new diblock diodes.

Because the electric current corresponds to an experimentally observable quantity, it has been calculated to support our interpretations. The two-probe configuration is built by sandwiching a B3LYP-optimized fragment at each angle between two electrodes, Fig. 2. The current passed through **DPDPh1** junction as a function of the mid torsion angle was calculated under selected applied voltages of 1 and −1 V, Fig. 9. The asymmetric feature of the **DPDPh1** junction remains prominent whatever the change in Φ_2, where the electric current under 1 V is nearly twice than that under −1 V. Under the effect of voltage 1 V, increasing the torsion angle, decreases the forward current until the torsion angle reaches 90°, hence the current becomes at its minimum limit, just with very small leakage current (0.0055 μA). Further increase of the torsion angle leads to gradual increase in the current. The opposite behaviour is observed under −1 V. The rectification ratio

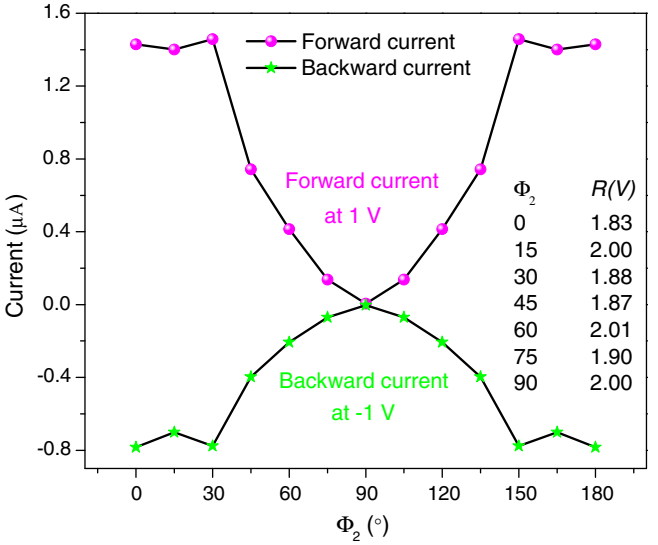

Fig. 9. The calculated current through **DPDPh1** junction as function of mid torsion angle (Φ_2) under voltages 1 and −1 V. The rectification ratio, $R(V)$ versus Φ_2 is inset in the figure. Notice the forward current (0.0055 μA) at angle 90° is not coincided with the backward current (0.0028 μA) in the figure giving rectification ratio of 2.

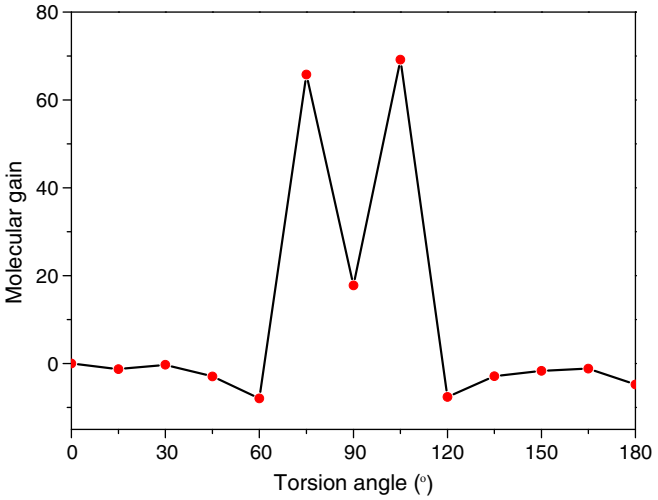

Fig. 10. The gain of molecular diode, **DPDPh1**, as a function of torsion angle (Φ_2) between the donor and acceptor subunits calculated at B3LYP/6-31+G(d,p).

as a function of Φ_2 is inset in Fig. 9. It is clear that the value of $R(V)$ hovers around 2. This may be ascribed to the size of molecular polarization which does not affected greatly by changing the mid torsion angle where the dipole moment ranges between 5.12 and 5.72 D (Fig. 8). The synthetic tailorability can be used to increase the molecular polarization and enhance the rectifying property.

The molecular gain is defined as the quotient of the differences between the HOMO–LUMO energy gaps of two isomers and the difference in their corresponding total energies [56,57]. The molecular gain of the **DPDPh1** molecule was plotted against twist angle in Fig. 10. It is apparent that the gain reaches its maximum value close to perpendicular conformations (75°, 90° and 105°). It is expected that, if **DPDPh1** molecule is subjected to electric field the output voltage signals would be larger than the input ones which requires twisting the mid angle by 75°, 90° and 105°. The relation between the molecular gain of diblock molecular diode and the torsion angle between the donor and acceptor moieties could be used to guide organic chemists to synthesize a specific molecular system with low or high molecular gain through controlling torsion angle *via* chemical substituents.

4. Conclusions

Density Functional Theory (DFT) and Green's function approach combined with DFT (NEGF-DFT)) have been used to study the effect of constitutional and conformational isomery on the electrical properties of **DPDPh1** molecular diode. The results obtained can be summarized as follows:

1. The qualitative agreement between the effect of electric field on the maximum propensity of the molecular system to acquire electronic charge from the circuit, ΔN_{max} or index ω (electrophilicity), and I–V curve could link the chemistry of molecules with the physics of molecular junctions. The plot of ΔN_{max} or ω *vs* voltage may be beneficial for examining the rectifying property of other systems.
2. The effect of variation of the twist angle between the donor and acceptor subunits of the **DPDPh1** molecular diode on its electrical properties such as dipole moment, HOMO energy, relative energy, electrical current, rectification ratio and molecular gain has been studied. The results indicated that the increase in the twist slightly decreases the dipole moment while the HOMO energy becomes gradually far away from the Fermi level of electrode leading to a decrease in the passing current. However, the net rectification ratio does not greatly affected because the change in the value of molecular polarization is limited. For this reason, the asymmetric feature of the current remains prominent whatever the change in the mid torsion angle.
3. Introducing a spacer or twisting the mid torsion angle by 90° produces AR-like diode.
4. The constitutional and conformational isomery could be a guide for modifying the electrical properties of molecular diodes through the synthetic tailorability.
5. Based on the calculations, we propose the **DPDPh3** molecule as a better rectifier than the **DPDPh1** isomer particularly at higher voltages and it is worthy to be tested experimentally. The **DPDPh2** junction does not show a big advantage over the **DPDPh1** one. However, the **DPDPh4** junction has relatively a slight rectification character.
6. This study could provide basic knowledge for the design of new molecular devices.

their 4-(dialkylamino) aryl analogues [8]. Moreover, the incorporating diarylamino–heteroaryl donors were able to achieve an improvement of almost one order of magnitude in r_{33} over alkylamino chromophores [9]. Despite the advantages of increasing β by using these donors, very little experimental research is known due to the synthetic difficulty of diarylamino aromatic units using unstable starting materials.

In this study, we developed a novel donor modification approach by attaching a benzyloxy group as an additional electron-donating part on 2-dicyanomethylen-3-cyano-4-{2-[E-(4-N,N-di(2-acetoxyethyl)-amino)-phenylene-(3,4-dibutyl)thien-5]-E-vinyl}-5,5-dimethyl-2,5-dihydrofuran (denoted as FTC) type donor-π-acceptor molecules. The motivation of this study is to improve the EO response by a simple donor-strengthening method for mature FTC chromophores. If this strategy takes effect on NLO activities of FTC series micro- and macro-scopically, it may also be utilized for other known chromophore systems to further enhance the r_{33} for the EO device application.

The structures of new chromophores are depicted as A1–A3 in Fig. 1, along with the FTC series (B1–B3) references are included for comparison. The synthesis of given chromophores is carried out by the modified procedures according to the literature [4] and [10]. As an example, a typical preparation route for chromphore A3 is depicted as Scheme 1, and the details of these are discussed elsewhere. The new synthesized chromphores contain the same key thiophene bridge and TCF acceptor as the FTC. Acceptor TCF, stronger CF_3–TCF, and CF_3–Ph–TCF are used to investigate the impact of the new donor on different acceptors. As the synthesis run differs only in the step of donor moiety, there is almost no extra synthesis cost associated with the new chromophores, and the total yields of A1, A2, and A3 are 33.8%, 53.2%, and 53.6%, respectively, which are comparable to those of the FTC series. Thermal properties of A1–A3 explored by differential scanning calorimetry and thermal gravity analysis revealed that the additional donor had no negative impact for actual applications, having a range of decomposition temperature of 253 °C, 194 °C, and 220 °C, respectively (Table 1).

All of the chromophores are well dissolved in either chloroform ($\varepsilon = 4.81$) or 1,4-dioxane ($\varepsilon = 2.21$) and the absorption spectra in both solvents are recorded to determine the wavelength of the maximum absorption (λ_{max}) of the charge-transfer band as depicted in Fig. 2. For the FTC benchmark (B1), the λ_{max} shows up at 685 nm in $CHCl_3$ (Table 1). With an additional benzyloxy group attached on the dialkyamino aryl group, the λ_{max} of A1 red-shifted to 714 nm, implying that the benzyloxy group effectively provides an extra electron-donating strength to the π-conjugated bridge. Such a trend becomes more evident for chromophore A2 and A3 with stronger acceptors, rendering a larger red-shift of 40 nm relative to their counterparts B2 and B3. The comparison of UV–visible absorption spectra in $CHCl_3$ with those in less polar 1,4-dioxane enable us to examine the solvatochromic behavior of the chromophores, and the results are also listed in Table 1. Based on the following two facts: (1) the solvatochromic effects are indicative of the product ($\mu\beta$) of dipole moment (μ) and first hyperpolarizability (β) of a NLO chromophore [11] and (2) the difference of series A and B lies only in the auxiliary benzyloxy group, it can be asserted that the donor strengthening route is favorable to improve the nonlinear optical property of chromophores.

Fig. 1. Structure of the NLO chromophores A1–3 and B1–3 investigated in this study.

The β values of chromophore series are measured in diluted $CHCl_3$ solution (5 μmol/L) by the hyper-Rayleigh scattering (HRS) technique at the wavelength of 1.9 μm and the results are tabulated (Table 1). Series A show a systematic improvement of β values over B analogous: A1 (3161×10^{-30} esu), A2 (9491×10^{-30} esu), and A3 (10,203 $\times 10^{-30}$ esu). As the strong solvatochromic effect discussed above, the resonance contribution for series A is reasonably more significant. The intrinsic β_0 is roughly estimated according to the two-level model [12], and the results reveal that the β_0 of the series A are still significantly enhanced over the B analogues, which confirms the effective strengthening effect of the additional donor. In addition, a semiempirical quantum simulation for gaseous model is performed by the software package MOPAC 09 [13] and the results are also included in Table 1 for comparison. The discrepancy of absolute magnitudes of calculated and measured β values is owing to resonant effect in the diluted $CHCl_3$ solution [2], whereas the quantum calculation is carried out for the gaseous model. Although some deviation exists, the increasing trend that experimentally observed on β by the auxiliary donor is consistent with the prediction made on the basis of semiempirical calculations.

To investigate the influence of an extra donor on the macroscopic nonlinearity, the r_{33} is measured in poly (methyl methacrylate) (PMMA) host, and the number density of all chromophores are fixed as 2.1×10^{20} molecules/cm^3 which results in weight percentage in chromphore/PMMA composite ranging from 17% to 26%. The real time r_{33} measurement is performed (Teng-Mann reflection method [14,15]) under an electric filed: $V(t) = V_{dc} + V_{ac} \sin \omega t$ in order to observe the EO activity during the poling process, where V_{dc} is the applied voltage and $V_{ac} \sin \omega t$ is modulating voltage. According to the given calculation equation in Ref. [16], the r_{33} is in proportion to I_m/I_c, where I_m is the amplitude of EO modulation and I_c is the intensity of incident light when phase retardation is 90° between the TE and TM mode. Fig. 3a–d shows a typical poling

process recording r_{33} and flowing current against temperature and applied voltage of A2/PMMA composite.

Apparently, the additional donor on the chromophore results in not only a great strengthening effect on microscopic molecular hyperpolarizabiliy, but also some remarkable characteristics during the poling process. The first of these characteristics is the large r_{33} with the applying electric field. With the increase of temperature and poling voltage, the r_{33} maximizes at about 250 pm/V, a level that has rarely been reported previously in conventional guest/host systems. Whereas only 70 pm/V is detected for B2/PMMA even at a poling field of 130 V/μm. The high r_{33} of A2/PMMA reflects the significant enhancement of $\mu\beta$ value on macroscopic scale. At an external field of 50 V/μm, the r_{33} stabilized and saturated at a certain level, even the electrical field is raised up to 55 V/μm (Fig. 3b). Actually, the electrode area is very close to the threshold of dielectric breakdown though the poling is processed under such a moderate external field.

Second, the flowing current reaches its maximum simultaneously with the r_{33} and sustains its intensity until

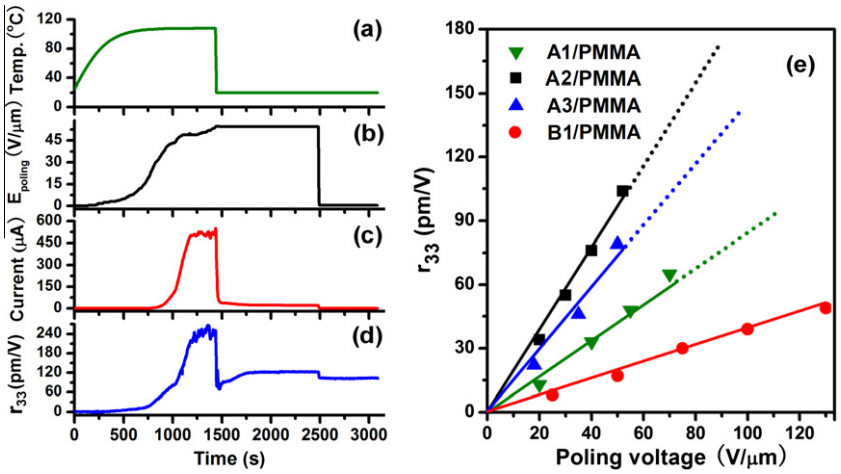

Fig. 3. Time-dependent temperature (a), flowing current (b), applied voltage (c), and r_{33} (d) of A2/PMMA, together with the poling efficiencies (e) of A1, A2, A3, and B1 in PMMA.

the cooling process begins. In this case, the flowing current reaches 550 μA (Fig. 3c) and it is more than 10 times of that in the B2/PMMA counterpart. The origin of flow current is temporarily ascribed to the charge hopping mechanism which increases the conductivity of molecularly doped polymer [16]. Generally, the hopping occurs in a distribution of states, the width of which is determined by the variation in spacing between the individual dopant molecules [17]. The additional benzyloxy donor on the chromophore A2, in effect, increases the effective volume and shortens the intermolecular distance between two A2 chromophores in PMMA host, which undoubtedly facilitates charge hopping from one chromophore to another. Considering the uniform number density (2.1×10^{20} molecules/cm^3) of A2 and B2 in PMMA, it is the shortening of intermolecular distance that leads to a ten times higher current flow. More importantly, such a hopping procedure in the disordered system is thermally activated [18]. Higher temperature improves the charge transport by providing the energy required to overcome the barriers created by the energetic disorder. The relationship has been often fitted to an Arrhenius-like law [18]: $M \propto \exp(-\Delta/k_B T)$, where M is the mobility, Δ, k_B, and T are activation energy, Boltzmann constant, and temperature, respectively. Conversely, it is also responsible for the decrement of current from 550 μA to 30 μA during the rapid cooling process, which accompanying with a significant drop of r_{33} as shown in Fig. 3d. Currently, we have not come to an exact ascertainment for the reason of this large decay and it is still under investigation. There are, however, two factors that should be taken into account which potentially have contributions: (1) Reversion of host to the rigid state. Though the initial orientation of chromophore is much high ($r_{33} \sim 250$ pm/V) at the temperature around T_g of the composite, the rubber-like composite will return to the rigid state in a rapid cooling process. This process may eventually leads to enhance the degree of disorder and decrease the r_{33}. The additional electron-donating group also brings unfortunately a considerable trade-off electrostatic effect. This large decay is quite related to the strong molecular electrostatic interaction between the chromphores with a low activation energy for dipolar relaxation [19]. The sum of above two contributions eventually accounts for the dramatic reduction of final macroscopic nonlinearity. Even so, the r_{33} above 100 pm/V maintains eventually with the electrical field removed.

Eventually, it is worth noting the increased poling efficiency (PE) of the new chromophores, which is plotted as the slope of r_{33} *vs.* poling voltage in Fig. 3e. For A1/PMMA, the PE is about 0.87 (nm/V)^2, which is more than twice of that for B1/PMMA [0.33 (nm/V)^2], and further gains are realized for A2 and A3 analogues. These results are consistent with the stronger electron-withdrawing ability of the CF_3–TCF and CF_3–Ph–TCF moieties. Though a higher intrinsic β_0 is observed for the chromophore B3 bearing stronger electro-drawing group CF_3–Ph–TCF, the large volume of phenyl group somewhat hinders the electrical alignment. Thus, A2/PMMA achieves the highest PE of 1.84 (nm/V)^2, and this value is comparable to that of the phenyltertraene-type (CLD) analogue [3].

As the molecular dipole–dipole interaction plays an important role for the alignment of the NLO chromophore under the external field and it increase the flow current which influence the poling efficiency, the dependence of r_{33} and current on the dopant concentration for A2/PMMA is investigated as Fig. 4. With increasing of chromophore introducing concentration, the r_{33} experiences firstly a linear climb up to the maximum of about 100 pm/V, then a considerable drop is followed ascribing to the strong electrostatic effect at high concentration region. For the flow current observed during the poling process, it ascends steeply with increasing concentration and the value exceeds 1 mA at the concentration of 35 wt.%. Such a high flow current limits the poling by the occurrence of dielectric breakdown. This obstacle is expected to be overcome by exploiting other three-dimensional network polymers with sterical hindering or by using a TiO_2 buffer layer on ITO substrate [5,20]. Thus, an r_{33} of about 200 pm/V is

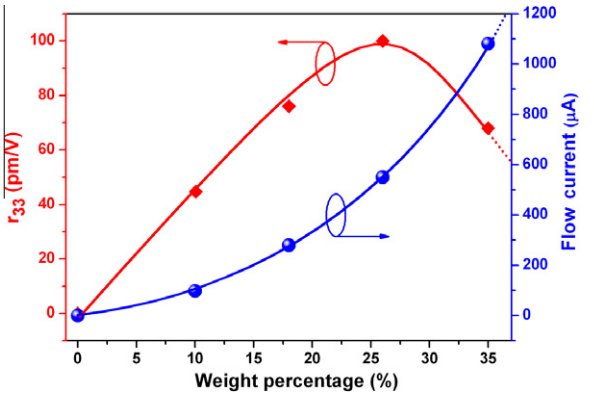

Fig. 4. Dependence of r_{33} and flow current on the chromophore concentration for A2/PMMA.

achievable for this NLO chromophore if an electrical field of 100 V/μm is exerted. Additionally, due to the distinct drawbacks of guest–host system, more suitable strategies, such as side-chain, cross-linking or dendrimer methods are urgently required to delay the intermolecular interaction to higher dopant concentration scale. Currently, we adopted the side-chain route to enhance the doping concentration of B3 up to 40 wt.% at which the r_{33} about 150 pm/V was obtained without causing severe aggregation. Furthermore, the T_g of such side-chain polymer is also much enhanced up to 140 °C to meet the device applications. These subsequent works will be reported in detail elsewhere [21].

In summary, we synthesized and characterized the NLO chromophores by using a donor modified strategy. The electro-optic coefficient (r_{33}) was remarkably enhanced by simply introducing a benzyloxy group as an additional donor part. Comparing with the traditional FTC benchmark, the first hyperpolarizability was improved by increasing the electron donating strength, which was confirmed by the absorption spectral analysis and HRS measurement. An in situ poling was performed by controlling the temperature and external field, and an r_{33} above 100 pm/V was eventually achieved for the A2/PMMA with a poling efficiency of 1.84 (nm/V). A simple and effective donor strengthening route was proposed for further electro-optic materials and applications.

purchased from Sigma–Aldrich Company and used as received. The light-emitting conjugated polymer polyfluorene (PFO, purchased from H.W. Sand Company) and Super-Yellow (purchased from Merck Company) were used as received. The electrophosphorescent material Iridium (III) tris(2-(4-totyl)pyridinato-N,C^2) [Ir(mppy)$_3$] was purchased from American Dye Source Inc. In order to investigate the role of SWNTs on the performance of the OLEDs, three types of device architecture were fabricated. The first type of devices have the structure of ITO/PEDOT:SWNT (*x* wt.%, 40 nm)/PFO (80 nm)/Ca (20 nm)/Al (80 nm), where *x* is 0, 0.001, 0.01, and 0.02, relative to solid PEDOT content. The second one is ITO/PEDOT:SWNT (0.01 wt.% relative to solid PEDOT content, 40 nm)/PVK:PBD:Ir(mppy)$_3$ (69 wt.%:30 wt.%:1 wt.%, 60 nm)/Ca (20 nm)/Al (80 nm), which use Ir(mppy)$_3$ as a phosphorescent emissive material. The third one has a structure of ITO/PEDOT (40 nm)/Super-Yellow:SWNTs (*x* wt.%, 80 nm)/Ca (20 nm)/Al (80 nm), where *x* is 0 and 0.005.

To get the uniform dispersion of SWNTs in PEDOT, we suspended the SWNTs functionalized by with crown ether, making them dispersible in deionized water [11]. They were then ultrasonicated the SWNTs solution 30 min, and then we mixed the SWNT solution with PEDOT solution and deionized water to form the composites at designed doping concentration. For the Super-Yellow:SWNTs composite preparation, SWNTs dispersed in chloroform were added into Super-Yellow chloroform solution to give the desired doping concentrations. The PEDOT:SWNTs composites were spin-coated onto ITO-coated glass substrate and the thickness of the film was 40 nm. The light-emitting layers for the three types of devices were all formed by spin coating from their chloroform solutions. Finally, the calcium (Ca) and aluminum (Al) electrode were deposited sequentially by thermal evaporation under the vacuum of 2×10^{-6} Torr, and the deposition rate was typically about 1 Å/s. The thicknesses and the morphology of the films and were measured by a Veeco atomic force microscopy (AFM) using a tapping mode. The resistivity and conductivity of PEDOT:SWNTs composite films on glass substrates were measured by a four-probe method with a Keithley source meter. The current and voltage characteristics of the OLEDs were measured with Keithley 2400 source meter. The EL spectra of OLEDs were recorded by a HORIBA Jobin Yvon spectrometer. The luminance and efficiency of OLEDs were measured by an OLED testing system calibrated by the National Institute of Standards and Technology.

3. Results and discussion

We investigated the roles of SWNTs in a hole conducting layer on the performance of OLEDs at first. Fig. 1a shows the current density–voltage (*J*–*V*) characteristics of OLEDs employing PEDOT:SWNTs composites with various doping concentrations under a forward bias. With increasing the SWNTs concentration in PEDOT, the current density of devices becomes higher under the same voltage, which means the hole injection and/or transport are improved by introducing SWNTs in the PEDOT layer of devices. However, the EL intensity did not show a monotonous increase when increasing the SWNTs concentration in PEDOT under the same current density. From Fig. 1b we can see that when the SWNTs concentration in PEDOT is no higher than 0.01 wt.%, then the higher the doping concentration, the stronger the EL intensity. But when the doping concentration of SWNTs reaches 0.02 wt.%, the EL performance of the devices deteriorates, and the EL intensity becomes lower than that of the device without SWNTs doping. Our results have some differences compared to those reported by Woo et al. [8]. In their case, the doping concentration of SWNTs in PEDOT is no less than 0.05 wt.%. Although they also observed the enhancement of current density when increasing the SWNTs doping concentration in PEDOT, they only found that EL brightness in devices employing PEDOT:SWNTs composites was reduced relative to the device without using SWNTs. As a result, their explanation of SWNTs as hole traps in PEDOT film should be reconsidered, since there would be no EL intensity enhancement in our case if the injected holes were initially trapped by SWNTs in PEDOT film.

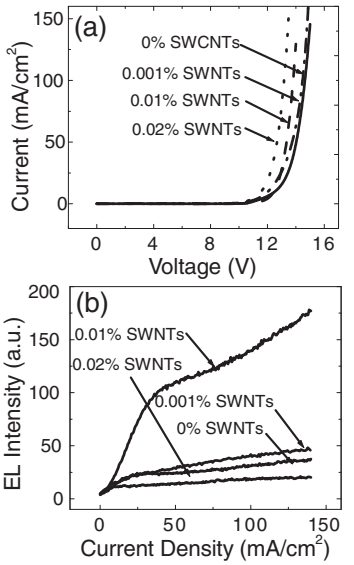

Fig. 1. The *J*–*V* curves (a) and the EL intensity–current density curves (b) of devices with the structure of ITO/PEDOT:SWNTs (*x* wt.%, 40 nm)/PFO (80 nm)/Ca (20 nm)/Al (80 nm).

We investigated the conductivity of PEDOT:SWNTs composite films with different doping concentration of SWNTs. It is shown in Table 1 that when the SWNTs

Table 1
The resistivity (ρ) and conductivity (C) of PEDOT:SWNT composite films with various SWNT concentration.

SWNT concentration (%)	ρ (Ω cm)	C (S/cm)
0	44,902	2.23×10^{-5}
0.0004	40,778	2.45×10^{-5}
0.0042	31,709	3.15×10^{-5}
0.0010	29,775	3.36×10^{-5}
0.6622	23,666	4.23×10^{-5}

concentration changed from 0 wt.% to a high value of 0.66 wt.%, the conductivity of the composite film increased monotonously. This can be ascribed to the increase in partial conductive paths when introducing SWNTs into the polymer film [12], since the metallic components in SWNTs have a better conductivity than PEDOT. As a result, the enhancement of EL intensity shown in Fig. 1b when increasing the SWNTs concentration in PEDOT from 0.001 to 0.01 wt.% can be ascribed to the increase of the conductivity in PEDOT film with SWNTs doping, and thus leading to the improvement of hole transport in devices. It should be noted that although SWNTs can be beneficial in improving the carrier transport, they also can act as trap sites for quenching the excitons [13,14]. It is well known that when excitons are formed in the emissive layer, they can migrate during their lifetime and the singlet excitons usually have a migration distance of ~20 nm [15]. Thus if the excitons are formed near the interface of PEDOT:SWNTs/PFO interface, they can easily migrate to the SWNTs trapping sites and thus be quenched provided that the SWNTs concentration is high enough near the interface.

We notice that PEDOT has a highest occupied molecular orbital (HOMO) energy level of −5.2 eV while PFO has a HOMO energy level of −5.8 eV [16], so there is an energy barrier of 0.6 eV for holes to overcome. In our devices with the structure of ITO/PEDOT:SWNTs/PFO/Ca/Al, the lowest unoccupied molecular orbital (LUMO) energy level of the light-emitting material PFO aligns with the Fermi level of the Ca cathode. Consequently, the electron transport from the cathode into the light-emitting layer is not hindered. However, since an energy barrier between the HOMO levels prevents holes from entering the light emitting layer, the exciton recombination zone in the PFO layer must be close to the interface of PEDOT:SWNTs/PFO interface. As a result, the excitons formed in the PFO layer can migrate to the PEDOT:SWNTs layer and be quenched by the SWNTs if the SWNTs concentration is high enough in the PEDOT:SWNTs film. That is the reason why we see reduced EL intensity in OLEDs when the SWNTs concentration is as high as 0.02 wt.% in the PEDOT:SWNTs film compared with pure PEDOT film.

Fig. 2a shows the luminance–voltage curves of OLEDs using pure PEDOT and PEDOT:SWNTs (0.01 wt.%) composite. The maximum luminance of the device with SWNTs in PEDOT is 2150 cd/m^2, which is as 1.4 times high as the one without SWNTs. Fig. 2b and c illustrate the EL efficiency vs. current density curves of device with and without SWNTs doping. We can see the maximum luminous efficiency and

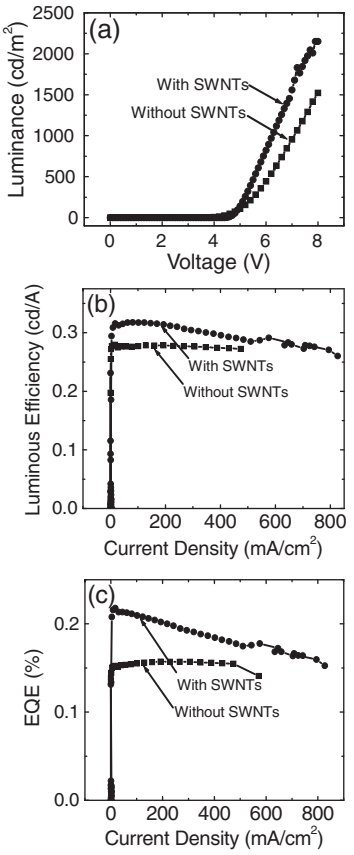

Fig. 2. The *L–V* curves (a), the luminous efficiency (b), and the external quantum efficiency (c) characteristics of devices without and with SWNTs doping. The device structure is ITO/PEDOT (40 nm)/PFO (80 nm)/Ca (20 nm)/Al (80 nm) and ITO/PEDOT:SWNTs (0.01 wt.%, 40 nm)/PFO (80 nm)/Ca (20 nm)/Al (80 nm), respectively.

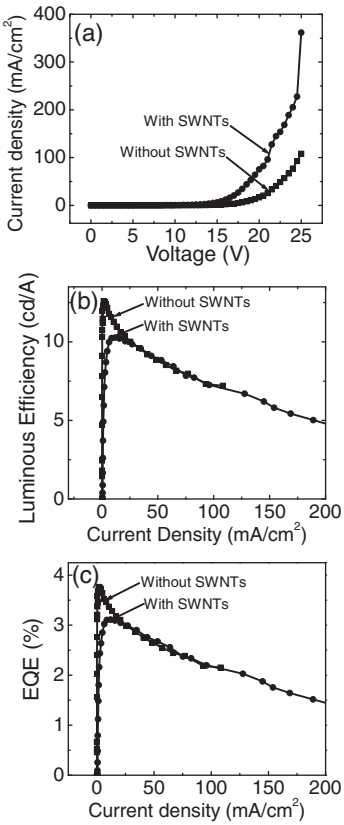

Fig. 3. The *J–V* curves (a), the luminous efficiency (b), and the external quantum efficiency (c) characteristics of the electrophosphorescent devices without and with SWNT doping. The device structure is ITO/PEDOT (40 nm)/PVK:PBD:Ir(mppy)$_3$ (69 wt.%:30 wt.%:1 wt.%, 60 nm)/Ca (20 nm)/Al (80 nm) and ITO/PEDOT:SWNTs (0.01 wt.%, 40 nm)/PVK:PBD:Ir(mppy)$_3$ (69 wt.%:30 wt.%:1 wt.%, 60 nm)/Ca (20 nm)/Al (80 nm), respectively.

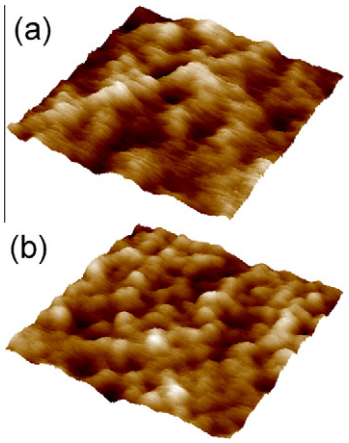

Fig. 4. The AFM images of the pure PEDOT film (a) and the PEDOT:SWNTs (0.01 wt.%) composite film (b), measured by tapping mode.

the maximum external quantum efficiency (EQE) of the device with SWNTs in PEDOT are 0.32 cd/A (1.2 times than that without SWNTs) and 0.22% (1.4 times than that without SWNTs), respectively. The enhancement of EL efficiency in devices employing SWNTs in PEDOT can be ascribed to the improvement of hole transport, thus leading to more balanced holes and electrons in the light-emitting layer.

As we mentioned above, the improvement of EL performance in devices with the SWNTs concentration no higher than 0.01 wt.% lies in their role of increasing hole transport in the conducting PEDOT film. Consequently, for OLEDs with holes as the minor carriers in the light-emitting layer (such as our PFO case), the EL performance can be improved by doping a very low amount of SWNTs into the hole conducting polymer. To investigate the impact of the mixture of the hole conducting polymer and SWNTs on the EL performance of OLEDs with balanced electrons and holes in the light-emitting layer, we have fabricated devices with the structure of ITO/PEDOT:SWNT (0.01 wt.%)/PVK:PBD:Ir(mppy)$_3$/Ca/Al. It has been reported that when the mixture of PVK, PBD and Ir(mppy)$_3$ is used as a light-emitting layer in OLEDs, highly efficient electrophosphorescence is achieved due to balanced electrons and holes in the light-emitting layer [17].

Fig. 3a shows the *J–V* curves of the electrophosphorescent devices with and without SWNTs doped in the PEDOT films. As can be seen from the figure, the *J–V* curve of the device with PEDOT:SWNTs composite shifts to a lower voltage compared with the one without SWNTs, which is similar with the PFO case. However, the maximum EL efficiency in the device with SWNTs is reduced relative to the one without SWNTs (shown in Fig. 3a and b). As we

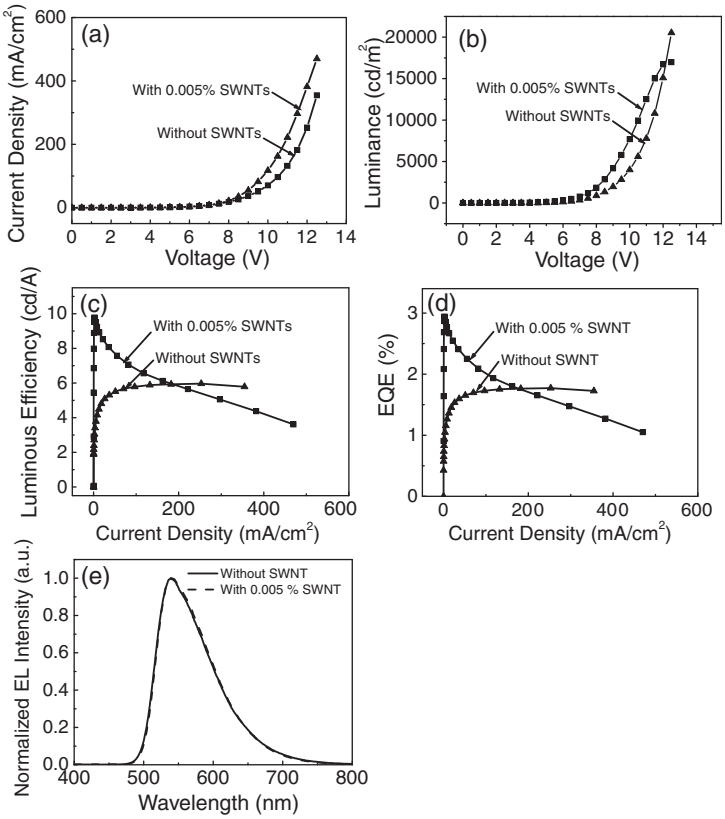

Fig. 5. The *J–V* curves (a), the *L–V* curves (b), the luminous efficiency (c), the external quantum efficiency (d), and EL spectra (e) of devices without and with SWNT doping. The device structure is ITO/PEDOT (40 nm)/Super-Yellow (80 nm)/Ca (20 nm)/Al (80 nm) and ITO/PEDOT (40 nm)/Super-Yellow:SWNTs (0.005 wt.%, 80 nm)/Ca (20 nm)/Al (80 nm), respectively.

expected, a low concentration of SWNTs in PEDOT film will enhance the hole transport in devices and shift the *J–V* curve to a lower voltage. Nevertheless, in OLEDs with balanced holes and electrons, introducing more holes to the light-emitting layer will upset the balance thus reducing the EL efficiency. Fig. 4 shows AFM images of the PEDOT film with and without SWNT dopants. In the case of pure PEDOT film, the islands have big sizes. But in the PEDOT:SWNTs (0.01 wt.%) composite film, the islands have small sizes, which means the contact at the interface between the PEDOT:SWNTs and the light-emitting layers will be improved. This morphological result suggests that using SWNTs in PEDOT layer can enhance hole injection into the light-emitting layer in the ITO/PEDOT:SWNTs/PFO/Ca OLED.

Besides acting as dopants in a hole conducting polymer in OLEDs, SWNTs can also be used in the light-emitting polymer layer. To investigate the SWNT's effect on the EL performance when it is in the light-emitting layer, we have fabricated devices with the structure of ITO/PEDOT/Super-Yellow:SWNTs/Ca/Al. Fig. 5a shows the *J–V* characters of devices with and without SWNTs in the light-emitting layer. Introducing SWNTs into the Super-Yellow layer shifts the *J–V* curve to the lower voltage compared with the pure Super-Yellow layer. Since Super-Yellow is a poly(*p*-phenylene vinylene) (PPV) derivate and it can transport holes more easily than electrons [18], OLEDs based on Super-Yellow are hole-dominated devices and electrons are minority carriers. It is well known that SWNTs have an electron-withdrawing ability [19,20], so they can act as an n-type material to improve the electron transport when doped into a polymer host, and can improve charge injection at interfaces [21]. Consequently, the *J–V* curve of the device with the Super-Yellow:SWNTs composite shifts to a lower voltage due to improved electron transport in the Super-Yellow layer. It can also be seen in Fig. 5b that the Super-Yellow:SWNTs OLED exhibits a lower threshold voltage in electroluminescence as compared to Super-Yellow only OLED. This result further suggests that the minority charge carrier (electron) transport is enhanced in Super-Yellow:SWNTs OLED. As can be seen from Fig. 5c and d, the EL efficiency has also been improved in devices with the Super-Yellow:SWNTs composite. The maximum luminous efficiency and maximum EQE reaches 9.8 cd/A and 2.9%, which is 1.6 times and 1.7 times than the one with pure Super-Yellow layer, respectively. Such enhancement in EL efficiency is also the result of the improvement of electron transport in the Super-Yellow layer due to the SWNTs acting as n-type dopants, thus leading to more balanced electrons and holes in the light-emitting layer. Fig. 5e shows the EL spectra of devices with and without SWNTs in the light-emitting layer and we can see that mixing the Super-Yellow with SWNTs does not change the EL emission spectra.

4. Conclusion

Here we elucidate that SWNTs play different roles when used as polymer:SWNTs composites in OLEDs. When SWNTs are mixed in a hole-conducting layer, they can have a helpful or a hurtful influence on the EL performance of OLEDs, which depends on the SWNTs concentration. If the SWNTs concentration is low enough (in our case $\leqslant$0.01 wt.%), they can play a role in improving the conductivity thus enhancing the hole transport in the hole-conducting layer. Also, they improve contact at interfaces by inducing much smaller surface islands than the ones on the surface of purely hole-conducting layers. But if the SWNTs concentration is too high (in our case higher than 0.02 wt.%), they can act as centers to quench the excitons that have migrated to the interface between the hole-conducting layer and the light-emitting layer. When SWNTs are incorporated into an emitting polymer layer, they improve the electron transport since SWNTs can act as n-type dopants in the light-emitting layer, which profits from the electron-withdrawing nature of SWNTs.

p–n diode and the gate electrodes of TFTs were patterned with ITO etchant solution (LCE-12K) through conventional photolithography method. Then, 40 nm-thick ZnO n-type layer for p–n diode was deposited at room temperature (RT) by 100 W rf magnetron sputtering of a ZnO target (99.999%) in the 10 mtorr Ar/O_2 (6:1) gas mixture, through the first shadow mask for patterning. Then, 100 nm-thick AlO_x layer was deposited by rf magnetron sputtering of an Al_2O_3 target (99.99%) in a 20 mtorr Ar gas, through the 2nd shadow mask. A 150 nm-thick pentacene (Aldrich Chem. Co., 99% purity, with no other purification) was deposited as the p-type layer on n-ZnO through the 3rd shadow mask by thermal evaporation at RT and then, 50 nm-thin pentacene was also deposited as p-channels of TFTs on AlO_x through 4th mask. Pentacene deposition rate was fixed to 1 Å/s. For a semi-transparent anode of p–n diode and source/drain electrode of pentacene TFTs (W/L = ~500/90 μm), 100 nm-thick NiO_x ($E_g \sim 4.0$ eV, transmittance ~30%, sheet resistance ~100 Ω/□, anode pattern area ≃1.4 × 1.4 (= 1.96) mm^2) was deposited on the pentacene layer by the thermal evaporation of NiO powder (99.97% purity), [11] through the last shadow mask. As the final process for our semitransparent photo-detector, the NiO_x drain electrode of pentacene TFT was serially connected to the ITO cathode of p–n diode by the same thermally-evaporated NiO_x. In order to improve the transparency of our p–n diodes and pentacene TFTs, we also attempted sequential double deposition of 30 nm-thin NiO_x buffer (by thermal evaporation on pentacene) and 70 nm-thick indium zinc oxide (IZO) layer (by sputter deposition on NiO_x). The first two photographs in Fig. 1(a) display optical microscope images of photo-detector cells (photodiode and TFT) with semitransparent NiO_x and transparency-improved NiO_x/IZO top electrodes, respectively; Arabic numbers typed on a paper were seen through our p–n diodes. All current–voltage (I–V) properties of our p–n diodes were measured with a semiconductor parameter analyzer (HP 4155C, Agilent Technologies) in an air ambient (relative humidity ~40%) at RT. Photoresponse measurements were performed with a light source unit consisting of a 500 W Hg–Xe arc lamp and a monochromator covering the range of 250–1000 nm (Oriel optical system). The optical power was measured by a Si-based optical power meter (TQ8210, ADVANTEST) and the photons were delivered through an optical fiber that plays as an optical probe. All transmittance measurements of p–n diode structures were carried out with a spectrophotometer (Varian Cary 5G).

3. Results and discussion

Fig. 1(b) displays the transmittance spectra of our thin-film p–n diodes (inset) fabricated on ITO glass with two different kinds of top electrode: 100 nm-thick NiO_x (black line) and 67 nm IZO/30 nm NiO_x (red line). In both cases, the pentacene layer-induced optical absorption was clearly shown in the visible range of 710–410 nm (1.75–3.0 eV) while ZnO-induced absorption was observed at over 3.2 eV, although the diode with the double layer electrode appeared slightly more transparent as expected. It is

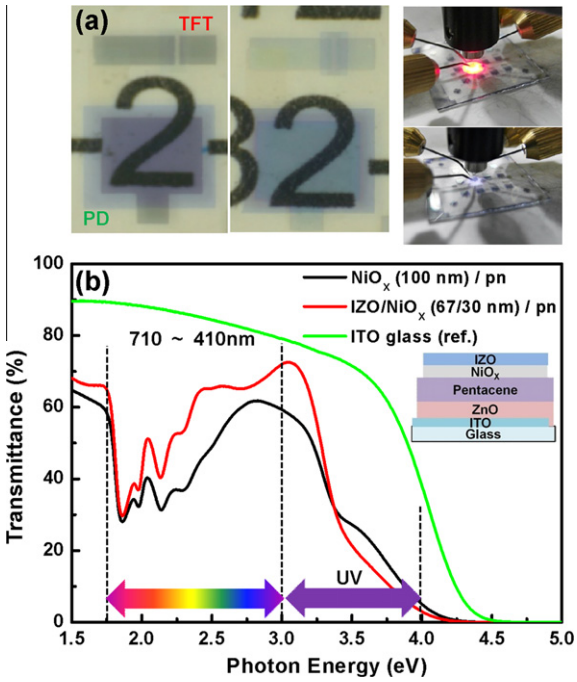

Fig. 1. (a) Photographs of our semitransparent photo-detector cells (composed of pentacene-TFT and pentacene/ZnO p–n diode) with NiO_x (1st left) and IZO/NiO_x (2nd left) top electrodes. Right-side photos show photoresponse measurement under red (640 nm: up)) and UV (364 nm: down) light. (b) Transmittance spectra of our p–n diodes with the two types of top electrodes. The inset is a schematic device structure of p–n diode with IZO/NiO_x top electrode. Reference ITO glass shows a high transmittance of more than 80% in visible range. known that thermally-evaporated Ni-rich conducting NiO_x has a limited transmittance but is well matched with pentacene for a good ohmic contact (having a large work function of more than 5.1 eV) [12]. In the present study, we could divide the photo-detection ranges of our photo-detector into two by photon energy as indicated in Fig. 1(b): 1.75–3.0 eV (visible) and 3.0–4.0 eV (UV). These detection ranges were determined by considering the respective energy gaps of pentacene and ZnO materials; the up and down photos located in the right-side of Fig. 1(a) demonstrate our photo-detection measurements by visible and UV photons.

The photoresponse of our p–n diodes with the two types of top electrodes was measured as shown in the dark/photo I–V curves of Fig. 2(a and b), where the dark curves displayed rectifying behavior (the ideality factor of our hybrid diode was as high as ~7.9 and its schematic band diagram is shown in the inset of Fig. 2(c)). Dark leakage current appears to be ~1 nA at −3 V reverse bias while it increases to 20 nA under blue light with 440 nm wavelength. According to the figures, the current minimum is not observed at zero volt but at a negative bias side near −0.6 V in the dark. It is because our pentacene/ZnO is a heterojunction diode containing interface trap charges; under a large reverse bias those trap charges are released and transported to play as the source of junction leakage but the leakage current would be minimized at a certain

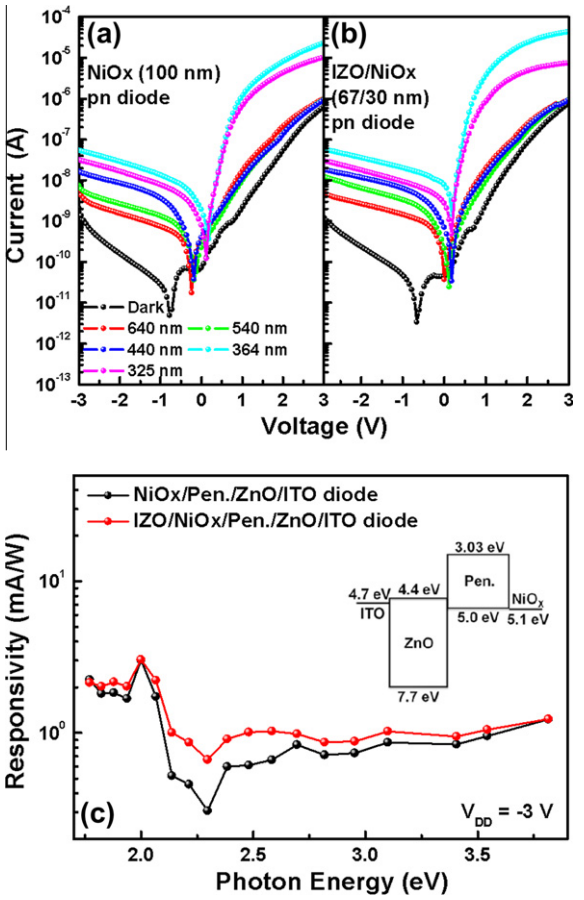

Fig. 2. Dark and photo *I–V* curves of our p–n diodes with two semitransparent electrodes of (a) NiO_x (100 nm) and (b) IZO (67 nm)/NiO_x (30 nm). (c) Spectral responsivity curves of our pentacene/ZnO photodiode with the two electrodes. The inset is the band diagram of the hybrid p–n diode with NiO_x and ITO electrodes.

small reverse bias which may make a flat p–n band condition. Such photoresponse was spectrally analyzed in the visible photon energy range of 1.75–3 eV, as shown in Fig. 2(c). Main mechanism of the photo-current generation under a reverse bias might be involved with the following serial events: photo-absorption and exciton generation in pentacene, exciton diffusion and dissociation into electron–hole carrier, and carrier transport to ZnO or ITO electrode under electric field. The responsivity spectra in the range between 1.75 and 2.5 eV almost follow that of the pentacene Schottky photodiode which was previously shown by our group, [10] now showing its peak responsivity of ~2 mA/W at 1.97 eV at −3 V (the respective optical power of all monochromatic lights could not be normalized for the spectral responsivity measurements: 640 nm–0.11 mW/cm^2, 540 nm–0.92 mW/cm^2, 440 nm–1.08 mW/cm^2, 364 nm–3.28 mW/cm^2, 325 nm–1.29 mW/cm^2). However, from 2.5 to 3 eV the responsivity does not vary much, unlike the behavior of the Schottky diode, where the responsivity monotonically decreases after 2.5 eV. It is likely that the present p–n diode with n-ZnO layer displays additional responses due to the deep level defects of transparent ZnO in the high photon energy regime [13,14]. Another point to note is that somewhat higher photoresponse is achieved from the diode with IZO/NiO_x double electrode than the other one with thick NiO_x single electrode (Fig. 2(c)). It is because slightly higher density of photons was received by the pentacene/ZnO diode through the IZO/NiO_x double electrode than through the 100 nm-thick NiO_x (see the transmittance data in Fig. 1(b)).

Fig. 3(a) displays the transfer curves of the pentacene TFT as obtained through several times of repeated gate voltage (V_G) sweeps while green illumination was applied only on the photodiode by an optical probe. At the both applied drain voltages (V_D) of −5 V and −0.5 V, the original dark transfer curve was hardly changed regardless of any scattered illumination and sweep number. (Our pentacene TFT with thin channel is known to be quite photo-stable unlike the photodiode with thick pentacene layer) [4]. The saturation mobility of our pentacene TFT was

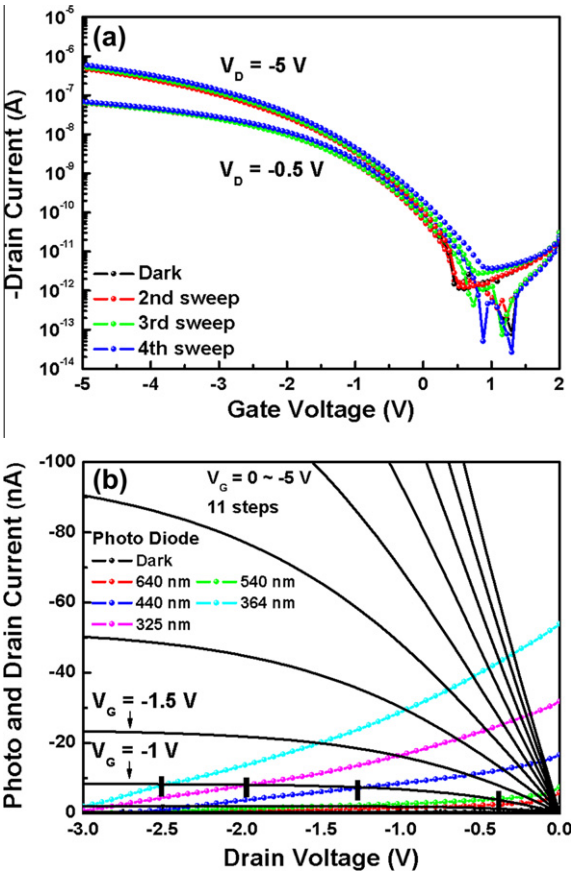

Fig. 3. (a) Transfer curves of our pentacene TFT at $V_D = -0.5$ V (linear regime) and −5 V (saturation regime). Green illumination was collimated only on the photodiode, and any scattered light could hardly change the dark original transfer characteristics during several sweeps. (b) A load-line analysis for our photo-detector cell. The cross points between the output curves of pentacene TFT and photo *I–V* curves of reverse-biased p–n diode were obtained as photo-induced V_{out}. $V_G = -1$ V appears an optimum condition for the photo V_{out} signals. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

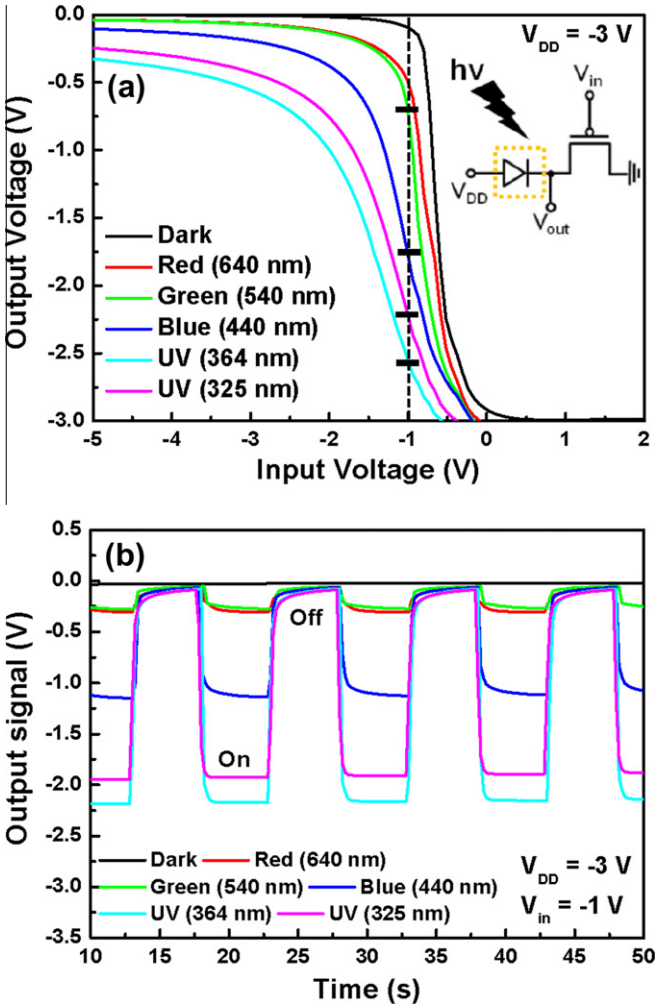

Fig. 4. (a) Photo-induced VTC curves of our detector cell (TFT + illuminated photodiode). The inset illustrates the photo-detection measurement. The dashed line indicates an optimum V_{in} (−1 V) and the cross points indicate the photo-induced V_{out} as signals. (b) Dynamic response of our photo-detector cell under the illuminations, that were repetitively turned on and off for the measurements. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

0.21 cm^2/Vs (at $V_D = -5$ V) while the linear mobility was 0.11 cm^2/Vs (at $V_D = -0.5$ V) as estimated from the transfer curves. As a load-line analysis of Fig. 3(b) was implemented between the output curves (drain current I_D vs. V_D) of the TFT and photo I–V curves of our reverse-biased p–n diode, an optimum V_G was turned out to be −1 V. Clear V_D values were obtained at $V_G = -1$ V as indicated by cross points between two types of curves: TFT output and photodiode I–V curves. This analysis is, however, more efficiently expressed by voltage transfer characteristics (VTC) as shown in Fig. 4(a), where V_G is now input voltage (V_{in}) for sweep, V_{DD} is supply voltage, and V_{out} is output voltage to be obtained at the node between TFT and serially connected p–n diode. (Note that V_{out} signals are now about the same as the cross points V_D values of Fig. 3(b)). Inset circuit illustrates our photo-detection measurements, and according to our VTC curves the most effective photo-induced V_{out} signals may come from the V_{in} of −1 V under V_{DD} of −3 V as expected from the load-line analysis of Fig. 3(b).

Dynamic photo-induced V_{out} response was also measured under the optimum voltage condition: $V_{in} = -1$ V at $V_{DD} = -3$ V. According to Fig. 4(b), less than 1 s (minimum ~300 ms) was nicely observed as response time when visible and UV illuminations were turned on and off. The V_{out} for dynamic turn-on was not exactly the same as that of VTC in Fig. 3(b), but very much approaches to: for 364 nm UV, 2.6 V in VTC and 2.2 V in dynamics. (Reason for such slight deviations is not clearly understood, yet). A slight delay was observed in our detector particularly under UV-off situations. It is primarily because our photodetector cell has relatively a large diode area to receive more light, but then the diode may possess more junction traps where photo-induced trapped charges can not be easily transported. However, despite such delays we regard our detector still worthy and promising since its spectral

response in static VTC characteristics quite well matches with the response in voltage dynamics.

4. Conclusion

In summary, we have fabricated semi-transparent organic–inorganic hybrid photo-detector cells, composed of pentacene/ZnO photodiodes and serially connected pentacene TFTs. Our photodiode well demonstrated the detection of visible and UV photons utilizing pentacene and ZnO, respectively, although its responsivity was not high. Our photo-detector cell thus exhibited good photo-induced V_{out} in VTC and in dynamic response behavior as well at -1 V input and -3 V supply voltage. We thus conclude that our semitransparent pentacene/ZnO hybrid cell is quite promising as a visible/UV detector fabricated on glass for a host of applications.

current under constant bias stress [10–13]. On the other hand, dipolar groups such as hydroxyl groups (OH) in the bulk of the gate dielectric, and/or gate charge injection cause clockwise hysteresis in *p*-channel (anticlockwise for *n*-channel) transistors and increase the drain current under prolonged bias stress [10,11,13–16]. The stability of FETs can in general be rationalized by one, or a combination of these mechanisms. In a recent study, we proposed the concept of compensation of some of these degradation effects and demonstrated OFETs on rigid substrates, with excellent operational stability. Such transistors were comprised of a bi-layer top-gate insulator of CYTOP followed by a high-*k* Al_2O_3 layer grown by atomic layer deposition (ALD), and a hole-transporting semiconductor composed of a 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) and poly(triarylamine) (PTAA) blend fabricated on rigid glass substrates [17].

Here, we report on solution-processed TIPS-pentacene and PTAA blend OFETs fabricated on a flexible polyethersulfone (PES) substrate. Changing from a glass substrate to a flexible one can be a challenging task as differences in surface energy and roughness of the substrate are likely to affect the properties of the semiconductor layer and consequently the performance of the transistor and its stability. Furthermore, the temperature of all processing steps during the device fabrication must be compatible with the temperature load that the flexible polymeric substrate can sustain. These flexible OFETs exhibit degradation compensation mechanisms due to the use of a CYTOP/Al_2O_3 top gate dielectric bi-layer that are similar to those observed previously in devices on glass substrates. Good electrical stability under constant dc bias stress for 2 h could be achieved without significant changes of mobility (μ) or threshold voltage (V_{th}). Furthermore, we verify the potential of these OFETs to form circuit components by connecting them to external load resistors (R_L), thereby creating a resistive-load inverter. We demonstrate that in such inverters the switching threshold voltage (V_M) remained almost unchanged after a constant dc bias stress for 2 h due to the excellent electrical stability of the transistor. Besides the operational stability, environmental and mechanical stabilities are also challenging issues to achieve when OFETs are transition from glass to flexible substrates. These OFETs and inverters showed negligible changes on μ, V_{th}, and V_M after 4 months of air exposure and mechanical bending tests for 30 min.

2. Device fabrication and electrical characterization

OFETs with a bottom-contact and top-gate structure were fabricated on a flexible PES substrate. Poly-4-vinylphenol (PVP) buffer layers were prepared from 2 wt.% solutions of PVP ($M_w \sim 20{,}000$) and poly (melamine-co-formaldehyde), as a cross-linking agent, in propylene glycol monomethyl ether acetate (PGMEA), which were deposited by spin coating at 3000 rpm for 40 s and subsequently cross-linked at 175 °C on a hot plate for 1 h in a N_2-filled glove box. Au (50 nm) bottom contact source/drain electrodes were deposited by thermal evaporation through a shadow mask. To improve contact at the metal and organic semiconductor interface, a self-assembled monolayer of pentafluorobenzenethiol (PFBT) was formed on the Au electrodes by immersion in a 10 mM PFBT solution in ethanol for 15 min in a N_2-filled dry box, rinsed with pure ethanol, and dried. The TIPS-pentacene and PTAA blend solution was prepared as follows: TIPS-pentacene and PTAA were individually dissolved in 1,2,3,4-tetrahydronaphthalene anhydrous, 99%, (Sigma–Aldrich) for a concentration of 30 mg/mL and the two individual solutions were mixed to yield a weight ratio of 1:1. Blends of TIPS-pentacene and PTAA were deposited by spin coating at 500 rpm for 10 s and at 2000 rpm for 20 s. Then, samples were annealed at 100 °C for 15 min in a N_2-filled dry box. A CYTOP (40 nm)/Al_2O_3 (50 nm) bi-layer was used as the top-gate dielectric. A CYTOP solution (CTL-809 M) was purchased from Asahi Glass with a concentration of 9 wt.%. To deposit the 40 nm-thick CYTOP layers, the original solution was diluted with a solvent (CT-solv.180) to have a 2 wt.% of CYTOP. The 40 nm-thick CYTOP layers were deposited by spin coating at 3000 rpm for 60 s. The CYTOP (40 nm) films were annealed at 100 °C for 20 min. All spin coating and annealing processes were carried out in a N_2-filled dry box. Then, the Al_2O_3 dielectric films were deposited on top of the CYTOP layer using a Savannah 100 ALD system from Cambridge Nanotech Inc. Films were grown at 110 °C using alternating exposures of trimethyl aluminum [$Al(CH_3)_3$] and H_2O vapor at a deposition rate of approximately 0.1 nm per cycle. Details about the Al_2O_3 films grown by ALD are described elsewhere [18]. Finally, Al (150 nm) gate electrodes were deposited by thermal evaporation through a shadow mask. Fig. 1(a) and (b) shows a schematic cross-sectional view of the OFET and a photograph of an OFET array on a flexible PES substrate.

The electrical characterization of the OFETs was carried out in a N_2-filled glove box (O_2, $H_2O < 0.1$ ppm). Current–voltage (*I–V*) characteristics of OFETs and voltage transfer characteristics (*VTC*) of resistive-load inverter were measured with an Agilent E5272A source/monitor unit. Field-effect mobility in the saturation regime was calculated from the slope of the |drain current (I_{DS})|$^{1/2}$ versus V_{GS} plot by the standard thin-film transistor equation:

$$\sqrt{I_{DS}} = \sqrt{\frac{W}{2L} C_{in} \mu_{sat}}\ (V_{GS} - V_{th}) \quad (1)$$

where C_{in} is the capacitance per unit area of the gate dielectric [F/cm^2], and W (width) and L (length) are the dimensions of the semiconductor channel defined by the source/drain electrodes of the transistor. Resistive-load inverters consisted of an OFET and an external R_L of 5, 10, and 20 MΩ.

3. Results and discussion

Fig. 2(a) and (b) show hysteresis-free transfer and output characteristics of OFETs (W/L = 2550 μm/180 μm) with the CYTOP (40 nm)/Al_2O_3 (50 nm) bi-layer dielectric. OFETs operated below 8 V due to the high capacitance density of the bi-layer dielectric (34.8 nF/cm^2) and showed an average (over 4 devices) saturation μ of 0.24 ± 0.08 cm^2/Vs and an averaged V_{th} of −1.3 ± 0.1. In comparison with previous OFETs on a glass substrate (μ = 0.46 ± 0.08 cm^2/Vs), the average μ value slightly degrades but is still reasonably

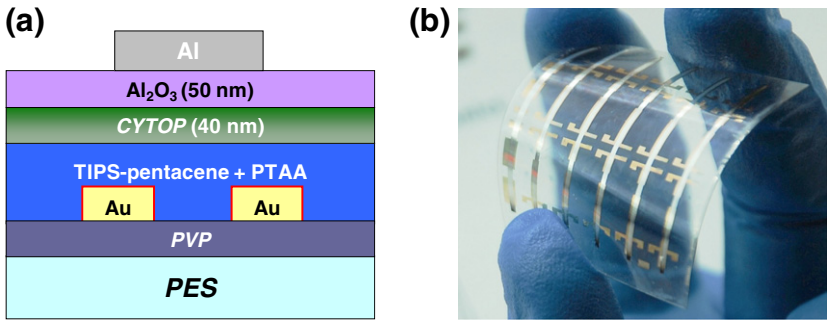

Fig. 1. (a) Schematic cross-sectional view and (b) a photograph of the OFET array fabricated on a flexible PES substrate.

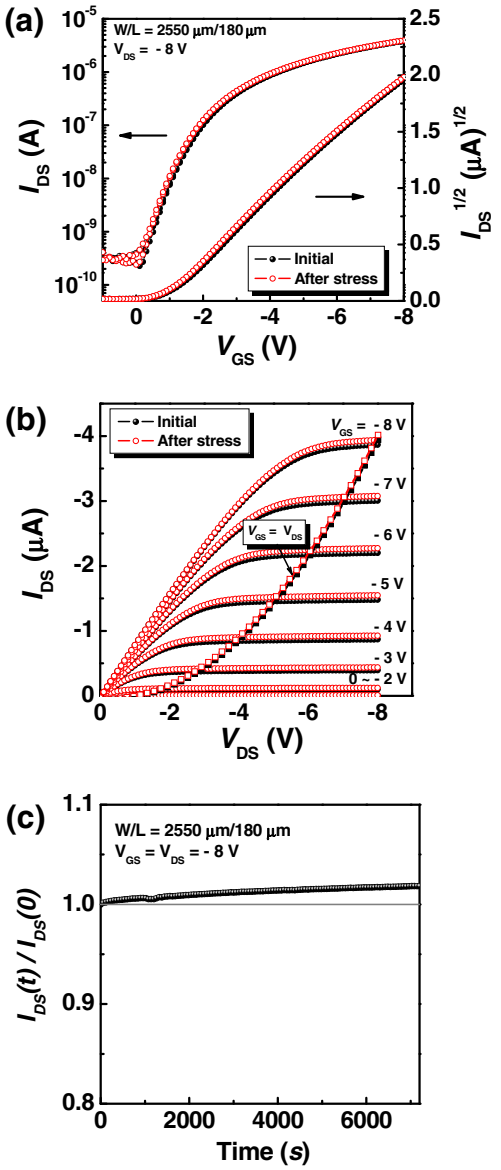

Fig. 2. Representative hysteresis-free (a) transfer and (b) output characteristics of OFETs (W/L = 2550 μm/180 μm) before and after bias stress test. (c) Temporal evolution of the normalized drain current for the stress condition of $V_{GS} = V_{DS} = -8$ V.

high. The operational stability of these OFETs was evaluated through a constant direct current (dc) bias stress test. Fig. 2(c) shows the temporal evolution of the I_{DS} measured in all OFETs normalized to the initial value for the bias stress condition of $V_{GS} = V_{DS} = -8$ V. It is noted that the I_{DS} slightly increases, reaching a value of 1.02 after 2 h, similar to results we have previously obtained in similar OFETs on rigid glass substrates [17]. This behavior is different from the conventional decay of I_{DS} during bias stress. As mentioned above, the high stability of these OFETs can be explained by compensating effects arising from filling of deep traps at the semiconductor/gate dielectric interface and, simultaneously, field-induced dipolar orientation at the CYTOP/Al_2O_3 interface and/or charge injection from the gate electrode [17]. After the bias stress tests, we re-measured the transfer and output characteristics to confirm that neither μ nor V_{th} underwent significant changes, which is clearly shown by the open symbols in Fig. 2(a) and (b).

To evaluate the real potential of these OFETs, towards their application as circuit components in electronic applications, we implemented a resistive-load inverter by connecting an external R_L to an OFET. An important parameter in the static performance of an inverter is V_M which is defined as the voltage when the input voltage (V_{IN}) equals the output voltage (V_{OUT}). This parameter can be directly extracted from the inverter voltage transfer characteristics (*VTCs*). High and balanced noise margins are found when the ideal condition $V_M = 0.5V_D$ is met, hence when $V_M = V_{IN} = 0.5V_D = V_{OUT}$. For reliable circuit operations, V_M should be constant during operation. In a previous study, we developed a technique to calculate V_M which does not require any fitting parameters such as μ and V_{th} [19]. The transistor can be modeled as a voltage dependent variable resistor (*p*-channel resistance, $R_P = -V_{IN}/-I_{DS}$ at $V_{GS} = V_{DS}$), which can be directly interpolated from the measured output characteristics, as shown in Fig. 2(b). The voltage distribution simply follows the difference between two series resistances. Hence, the value of V_M is determined at $R_P = R_L$. Fig. 3(a) shows R_P and R_L before and after bias stress. At $R_P = R_L$, the calculated V_M values were 5.48 V for R_L = 20 MΩ, 4.85 V for R_L = 10 MΩ, and 4.08 V for R_L = 5 MΩ, respectively, before bias stress. After bias stress, those values were 5.58 V for R_L = 20 MΩ, 4.95 V for R_L = 10 MΩ, and 4.16 V for R_L = 5 MΩ, respectively. Fig. 3(b) and (c) show the *VTCs* and static circuit gain

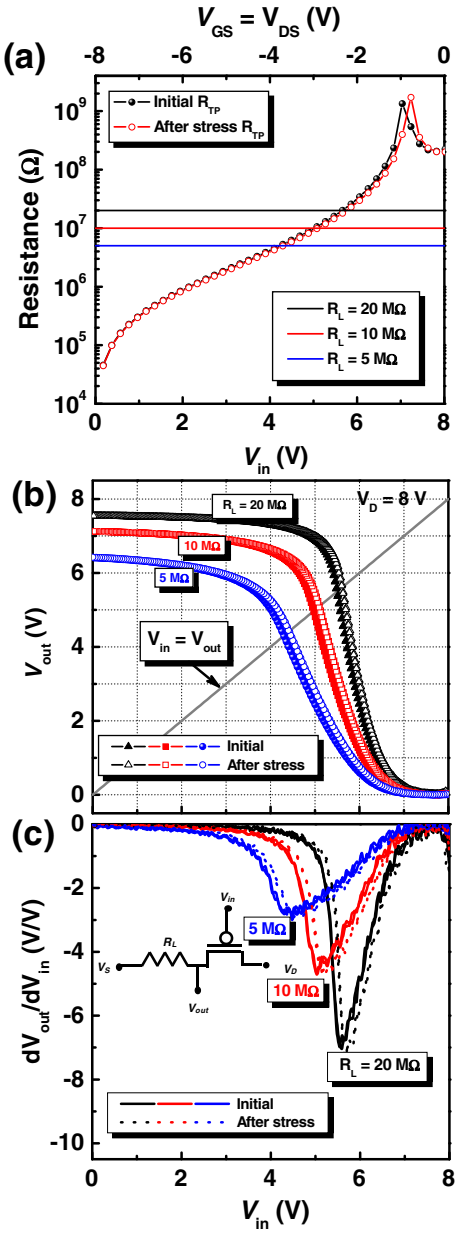

Fig. 3. (a) Resistance of *p*-channel TIPS-pentacene and PTAA blend OFET at $V_{GS} = V_{DS}$ by sweeping V_{GS} from 0 V to −8 V. (b) Voltage transfer characteristics and (c) static gain of the resistive-load inverter.

of these resistive-load inverters. As expected from the hysteresis-free transistor current–voltage characteristics, the resistive-load inverters showed negligible hysteresis. After a constant bias stress for 2 h, negligible changes in *VTCs* were observed. Hysteresis-free *VTCs* and negligible changes of V_M before and after bias stress are attributed to the excellent operational stability of the individual transistor, which allows reliable circuit operations. As shown in Fig. 3(b), the measured V_M values from *VTCs* were 5.50 V for R_L = 20 MΩ, 4.98 V for R_L = 10 MΩ, and 4.31 V for R_L = 5 MΩ, respectively, before bias stress. After bias stress, those values were 5.62 V for R_L = 20 MΩ, 5.10 V for R_L = 10 MΩ, and 4.42 V for R_L = 5 MΩ, respectively. Measured and calculated values of V_M are comparable with negligible variations of circuit gains before and after bias stress, as shown in Fig. 3(c). The maximum static gain value of 7 was obtained from R_L = 20 MΩ. The static gain value of the resistive-load inverter is low but it can be improved by fabricating complementary inverters combining *p*-channel FET with *n*-channel FET.

After the operational stability tests, the environmental and mechanical properties were also studied. These OFETs were exposed to normal ambient conditions with a relative humidity between 30 and 50% for 4 months. Fig. 4(a) and (b) show hysteresis-free transfer and output characteristics of OFETs before and after air exposure. While no significant degradation was observed in μ and V_{th} before and after air exposure, the on/off current ratio slightly decreased due to an increase in the off current. This can be explained by the diffusion of oxygen, and probably water, into the semiconductor layer. A similar behavior was observed on OFETs fabricated on glass substrates [17]. On the other hand, Fig. 4(a) and (b) also shows the hysteresis-free transfer and output characteristics of these OFETs after they were subjected to bending for 30 min under tensile stress. As shown in Fig. 4(c), for the bending test, the sample (with the OFETs located on the top surface) was bent at a radius of curvature (R_c) of 13.5 ± 0.5 mm. Considering that the substrate thickness (D) was measured to be 0.2 mm, a strain (ε) of 0.74% can be calculated from the equation, $\varepsilon = D/2R_c$ [6]. Even after this bending test, the electrical characteristics of the OFETs remained practically unchanged. Hence, as expected, the resistive-load inverter also showed hysteresis-free *VTCs* and negligible changes of V_M after undergoing air exposure and mechanical deformation as shown in Fig. 4(d). The electrical performance parameters of the inverter after bias stress, air exposure, and mechanical bending tests are summarized in Table 1.

4. Conclusion

In summary, we demonstrated electrically stable TIPS-pentacene and PTAA blend OFETs with a top-gate geometry on a flexible PES substrate. A CYTOP/Al_2O_3 bi-layer was employed as a top gate dielectric with a high capacitance density to realize OFETs with excellent electrical stability. TIPs-pentacene and PTAA blend OFETs with the CYTOP/Al_2O_3 bi-layer gate dielectric showed an average saturation mobility value of 0.24 ± 0.08 cm^2/Vs without hysteresis at operation voltages below 8 V. Under a dc bias stress at $V_{GS} = V_{DS} = -8$ V for 2 h, the change in I_{DS} was less than 2%. Neither serious μ degradation nor significant V_{th} shift was observed. As expected from the excellent electrical stability of this transistors, resistive-load inverters showed hysteresis-free voltage transfer characteristics as well as negligible changes of switching threshold voltage after a dc bias stress test. In addition, after exposure to air for 4 months and mechanical deformation for 30 min, no significant changes in performance were observed in either a single transistor device or in a resistive-load inverter. Therefore, OFETs comprised of a CYTOP/Al_2O_3 bi-layer gate dielectric can be a promising building block to realize stable electronic circuits.

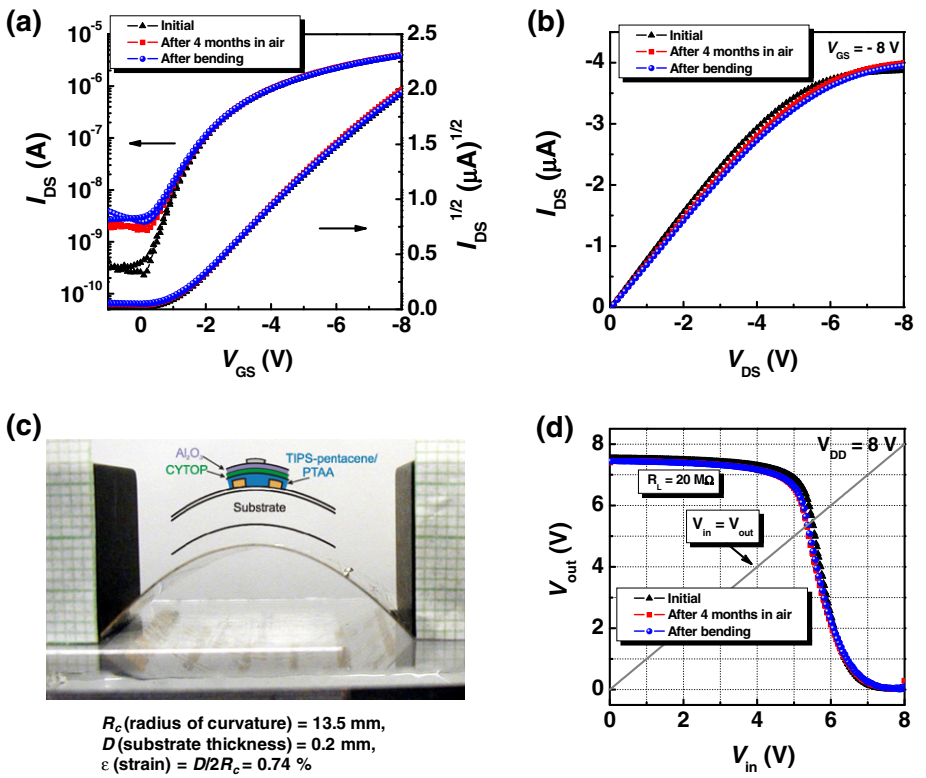

Fig. 4. Hysteresis-free (a) transfer and (b) output characteristics of OFETs (W/L = 2550 μm/180 μm); (c) photograph of the mechanical bending experiment; and (d) voltage transfer characteristics of the resistive-load inverter before and after air exposure and mechanical deformation.

Table 1
Performance of resistive-load inverters after undergoing different tests.

Condition	V_D (V)	R_L (MΩ)	dV_{out}/dV_{in} (V/V)	V_M (calculated) (V)	V_M (measured) (V)
Initial	8	20	−7	5.48	5.50

molecules in order to maintain a high E_T results in a reduction of the carrier transporting properties [6]. Particularly, most of the host materials with high E_T, i.e. carbazole-containing compounds or aromatic phosphine oxides, are unipolar in nature. As charge balance plays an important role in determining the device efficiency, this ultimately limits the device efficiency and leads to a detrimental efficiency roll-off at high current densities owing to triplet–triplet annihilation [10].

Until very recently, Lee et al. reported an effective approach to increase the charge transporting property in EML [11,12]. Through the incorporation of hole-transporting host material into the electron-transporting EML to form a mixed triplet host system, the EQE of blue PHOLEDs can be dramatically increased up to 20.5%, doubling that of single host device (8.96%) [12]. The enhanced EQE is mainly due to the improvement on charge carrier transport balance as well as a broader recombination zone within the EML. This finding opens up the possibility to further improve the performance of PHOLEDs where the doping approach might be applicable for other commonly used host materials.

In this letter, we present the utilization of mixed triplet host systems to improve device performance and reduce the power consumption of blue PHOLEDs; particularly, either an electron-transporting or a hole-transporting triplet host material was intentionally doped into the commonly used *N*,*N*′-dicarbazolyl-3,5-benzene (mCP) host to form mixed triplet host system. We found that the device efficiency is very sensitive to the energy levels and the relative composition of the host materials in the EML, in which a superior device performance with high current and power efficiencies of 47.4 cd/A and 37.3 lm/W, respectively, can be obtained for an optimized device. Particularly, device efficiencies are strongly dependent on the choice of triplet host materials, as suggested by time-resolved phosphorescence decay studies for different mixed host thin films.

2. Experimental

Patterned indium-tin-oxide (ITO)-coated glass substrates (30 Ω/square) were cleaned with Decon 90, rinsed in deionized water, then dried in an oven, and finally treated in an ultraviolet-ozone chamber. PHOLEDs were fabricated with a hole-transporting α-naphthylphenylbiphenyl diamine (NPB) layer, a carrier confinement 4,4′,4″-tris(*N*-carbazolyl)triphenylamine (TCTA) layer, and an electron-transporting bis(2-methyl-8-quinolinato)-4-phenylphenolate aluminum(III) (BAlq) layer. Devices with the configuration of ITO/NPB (70 nm)/TCTA (5 nm) (30 nm)/EML (30 nm)/BAlq (30 nm)/LiF (0.8 nm)/Al (200 nm) were fabricated, in which either TCTA or 3-(4-biphenyl)-4-phenyl-5-(4-*tert*-butylphenyl)-1,2,4-triazole (TAZ) was doped into mCP to form mixed host system as EML. Six percent of bis [2-(4′,6′-difluorophenyl)pyridinato-*N*,$C^{2'}$]iridium(III) (FIrpic) was doped into EML as phosphorescent guest. In particular, TCTA and TAZ are well-known hole-transporting and electron-transporting materials, respectively; while mCP is hole-transporting triplet host material. For comparison, a standard device with 6% FIrpic:mCP as EML was also made as reference. Fig. 1 shows the proposed energy level diagram for the devices, in which HOMO, LUMO levels, and E_T of the organic materials are taken from the literature [1,13,14]. All organic materials were used as purchased and the films are sequentially deposited by thermal evaporation in high vacuum chamber without vacuum break. A shadow mask was used to define the cathode and to make four 0.1 cm^2 devices on each substrate. The deposition rates were controlled by a quartz oscillating thickness monitor to be 1–2 Å/s for the organic materials and metals. The current density–voltage–luminance (*J*–*V*–*L*) characteristics and electroluminescence (EL) spectra were measured simultaneously with a programmable Keithley model 2420 power source and a Photoresearch PR655 colorimeter. All measurements were carried out in air at room temperature.

Time-resolved photoluminescence decay measurements were performed using a conventional laser system. The excitation source used was a 355-nm output (third harmonic) of a Spectra-Physics Quanta-Ray Q-switched GCR-150-10 pulsed Nd-YAG laser. Luminescence decay signals were detected by a Hamamatsu R928 PMT and recorded on a Tektronix Model TDS-620A (500 MHz, 2 GS/s) digital oscilloscope and analyzed using a program for exponential fits.

3. Results and discussion

Fig. 2(a) depicts the EL spectra for devices doped with various TAZ concentrations to form mixed hosts. Apparently, for the reference device (i.e. 0% TAZ), it exhibits a characteristic FIrpic emission peaking at 472 and 496 nm in the absence of any undesirable emission from adjacent hole- or electron-transporting layers. This confirms that

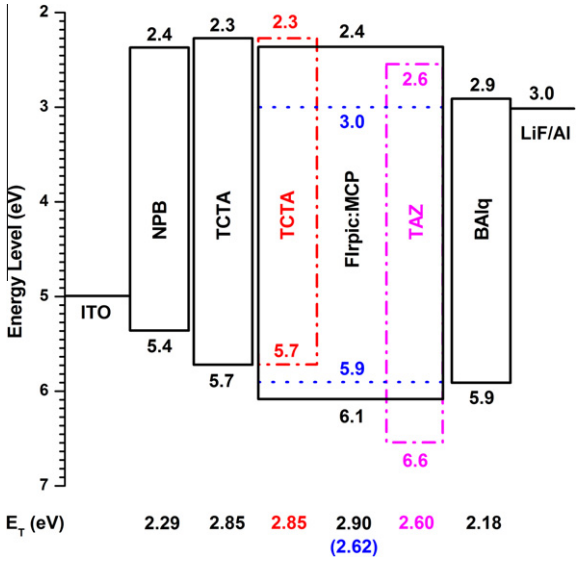

Fig. 1. Proposed energy level diagram for the devices. Note that numbers indicate the respective HOMO and LUMO energies relative to the vacuum as well as the E_T in eV. HOMO and LUMO energies of FIrpic are also indicated with dotted lines; while E_T of FIrpic is shown in parentheses.

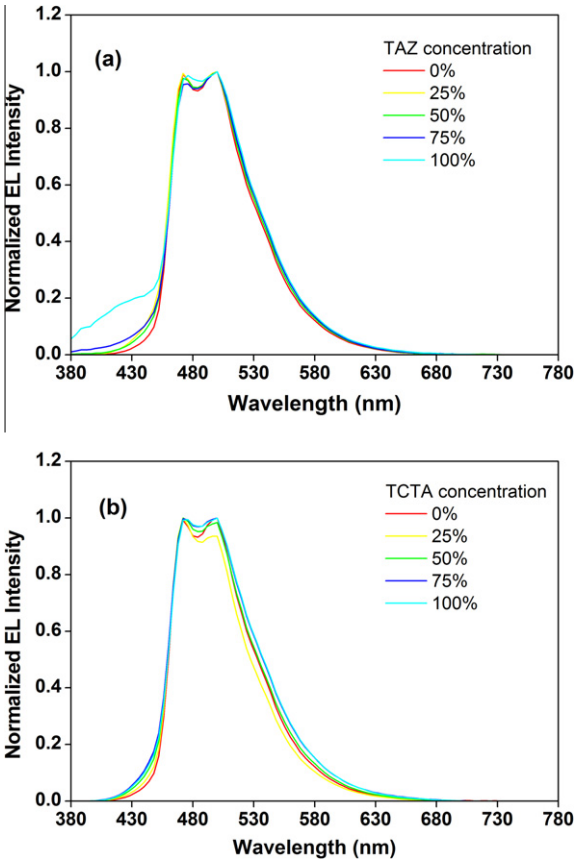

Fig. 2. EL spectra for devices doped with various concentrations of (a) TAZ and (b) TCTA to form mixed hosts.

efficient energy transfer between mCP and FIrpic takes place due to effective confinements of both charge carriers and triplet excitons. On the other hand, as TAZ concentration increases up to 100%, a new EL peak at ~400 nm is also noticed, which is tentatively assigned to the fluorescence of the carrier confinement layer of TCTA. This observation suggests that a portion of excitons may be formed within the TCTA charge confinement layer, perhaps due to the mismatch of HOMO levels between TCTA and TAZ. As shown in Fig. 1, we infer a large hole injection barrier at TCTA/TAZ interface of 0.9 eV, much larger than that at the TCTA/mCP contact (0.4 eV), impeding hole injection from TCTA into the EML. Thus, holes are expected to be accumulated at the TCTA/TAZ interface, leading to the formation of excitons within TCTA layer. On the other hand, it is not the case for the TCTA-doped devices (see Fig. 2(b)).

Fig. 3 shows the *J–V–L* characteristics and efficiencies of the TAZ-doped devices with different TAZ concentrations. With increasing TAZ concentration, both *J–V* and *L–V* curves shift to a higher driving voltage. For instance, to generate a luminance of 1000 cd/m^2, the driving voltage increases from 7.1 V (for 0% TAZ device) to 13.0 V (for 100% TAZ device). In addition, the incorporation of TAZ would result in poor device performance with device efficiencies dropped by an order of magnitude. For the reference device, high current, power efficiencies, and EQE of 21.9 cd/A, 14.8 lm/W, and 9.7%, respectively, can be obtained at current density of 0.1 mA/cm^2, which are in good agreement with other previous studies for the 6% FIrpic-doped mCP devices [1,6,15]. As TAZ concentration increases, the efficiencies drop sharply to 3.2 cd/A, 1.8 lm/W, and 1.4% for 100% TAZ-doped device. The poor performance can be explained in terms of the mismatch of both

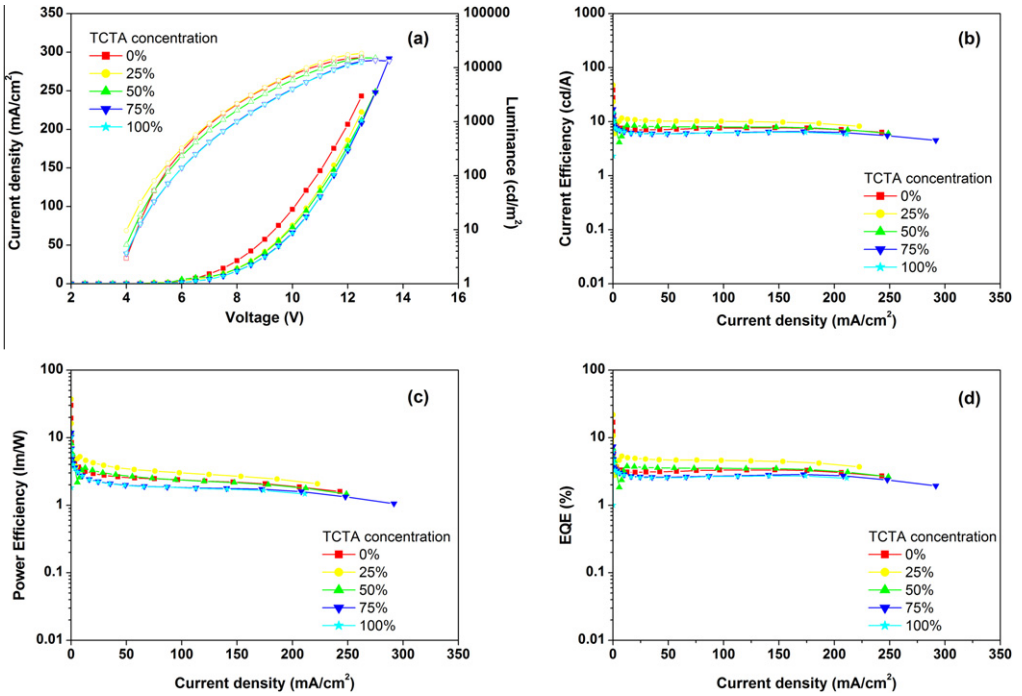

Fig. 4. *J–V–L* characteristics and efficiencies of the TCTA-doped devices with different TCTA concentrations.

Table 1
Characteristics of the TAZ-doped and TCTA-doped devices. η_c, η_P, η_{EQE} are the maximum current, power, and external quantum efficiencies.

	η_L (cd/A)	η_P (lm/W)	η_{EQE} (%)
TAZ concentration (%)			
0	32.2	24.1	14.2
25	19.4	15.0	8.4
50	34.4	24.1	14.2
75	13.9	9.8	6.5
100	4.3	2.3	2.0
TCTA concentration (%)			
0	32.2	24.1	14.2
25	47.4	37.3	21.9
50	15.4	12.1	6.9
75	16.9	11.8	7.4
100	14.6	10.2	6.3

HOMO levels and E_T of TAZ and mCP. As aforementioned, the relatively large HOMO level of TAZ restricts the hole injection into the EML, leading to a higher driving voltage and a lower EL efficiency. Meanwhile, the endothermic energy transfer from the excited state of the TAZ host to the phosphor FIrpic with higher E_T of 2.62 eV results in a further reduction in device efficiency. Similar to the case of FIrpic:CBP system [15,16], the relatively low E_T of TAZ (2.60 eV) will provide a non-radiative path for exciton quenching and thus reduces the phosphorescent light emission from FIrpic. Particularly, a pronounced efficiency roll-off is observed for all the TAZ-doped devices. Notably, the EQE for 25% TAZ-doped device dramatically drops from 6.1% at a current density of 0.1 mA/cm^2 to 3.1% at current density of 200 mA/cm^2. This detrimental efficiency roll-off is indicative of the sensitivity of backward energy transfer to the presence of energy dissipative pathways via triplet–triplet annihilation (see discussion below).

On the contrary, it is not the case for the TCTA-doped devices. Fig. 4 depicts the *J–V–L* characteristics and efficiencies of the TCTA-doped devices with different TCTA concentrations. As TCTA concentration increases, both *J–V* and *L–V* curves slightly shift to a higher driving voltage. For example, the driving voltage for generating a luminance of 1000 cd/m^2 slightly increases from 7.1 V (for 0% TCTA) to 8.1 V (for 100% TCTA). Meanwhile, both current and power efficiencies increase with increasing TCTA concentrations. At an optimal TCTA concentration of 25%, the device achieves excellent performance with current efficiency of 26.2 cd/A and power efficiency of 18.5 lm/W at a current density of 0.1 mA/cm^2, about 25% higher than those of the reference device. It is worth noting that, at a current density of 0.02 mA/cm^2, peak current and power efficiencies of 47.4 cd/A and 37.3 lm/W can be obtained. This corresponds to an extremely high EQE of 21.9%, reaching the theoretical limit of phosphorescent OLEDs. Table 1 summarizes the characteristics of the TAZ-doped and the TCTA-doped devices. The reason for the performance improvement may be attributed to a relatively lower hole mobility in TCTA. In particular, under an electric field of 6.4×10^3 V/cm, hole mobility in TCTA is $\sim 4.0 \times 10^{-4}$ cm^2 V^{-1} s^{-1} [17]; while that in mCP is $\sim 9.0 \times 10^{-4}$ cm^2 V^{-1} s^{-1} [18]. The doping of TCTA with a relatively lower hole mobility would definitely decrease the hole transporting ability in EML, leading to a better carrier balance and thus an improved device efficiency. On the other hand, with a further increase in the TCTA concentrations, the device efficiencies are found to show a slight drop due to an inefficient Förster energy transfer. In order to

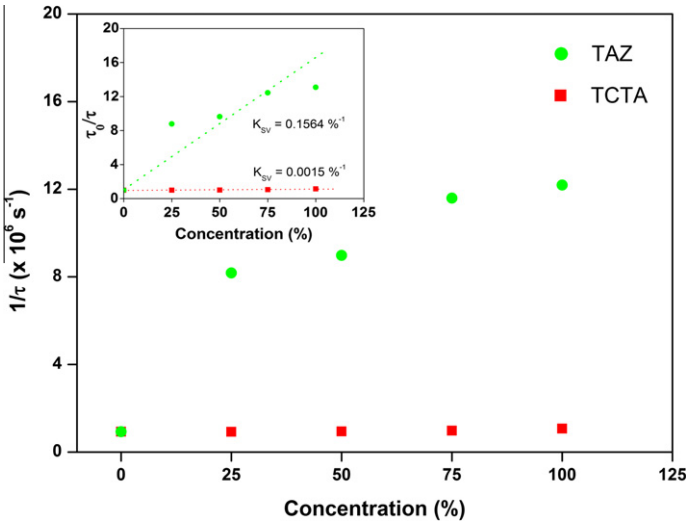

Fig. 5. A plot of the reciprocal of the lifetimes of FIrpic obtained as a function of TAZ or TCTA concentration. Inset: the Stern–Volmer plot of the TAZ- and TCTA-doped FIrpic:mCP films.

achieve 100% internal quantum efficiency, harvesting of both singlet and triplet excitons are important. Taking into the account the fact that the HOMO level of FIrpic is 0.2 eV lower-lying than that of TCTA, the mismatching of spectral overlap between the absorption spectrum of the FIrpic and the fluorescence spectrum of TCTA would definitely inhibit the energy transfer from singlet excitons of TCTA to those of FIrpic via long-range Förster transfer, reducing the EL efficiency. Nevertheless, the present results suggest that, in addition to the well-known effect of charge balance within the EML, both energy levels and E_T of mixed host materials play crucial roles in determining the device performance of PHOLEDs.

In order to confirm the mechanism for energy loss, time-resolved photoluminescence decay properties were measured by means of a direct excitation of thermally evaporated thin films, in which either TAZ or TCTA was doped into 6% FIrpic:mCP layer to form mixed host systems. Fig. 5 plots the reciprocal of the phosphorescence lifetimes (τ) of FIrpic obtained as a function of TAZ or TCTA concentration. For the reference film (i.e. 100% mCP), the phosphorescence decay of FIrpic consists of a single component with a time constant of ~1.06 μs, consistent with other previous studies (~1 μs at room temperature in neat film) [15,16,19]. No longer-lived phosphorescence was observed, which indicates that the triplet excitons are efficiently trapped within FIrpic. As TCTA concentration increases, the phosphorescent behavior of FIrpic is almost identical to that in mCP host. On the other hand, the lifetime is found to decrease steadily with increasing concentration of TAZ. It is interesting to note that the phosphorescence lifetime of FIrpic obeys the Stern–Volmer quenching equation, i.e. $\tau_0/\tau = 1 + K_{SV}[Q]$, where τ_0 is the lifetime of FIrpic in the absence of either TAZ or TCTA, K_{SV} is the Stern–Volmer constant, and Q is the concentration of TAZ or TCTA. As shown in the inset of Fig. 5, the Stern–Volmer constants of the TCTA- and TAZ-doped films derived from the slope of linear fits are estimated to be $0.0015\%^{-1}$ and $0.1564\%^{-1}$ (corresponding to the quenching constants of $\sim 1415\%^{-1}\,s^{-1}$ and $\sim 147{,}545\%^{-1}\,s^{-1}$). The higher K_{SV} for the TAZ-doped films confirms that the FIrpic blue dopant is quenched by the presence of TAZ [20]. Both shorter lifetime and higher K_{SV} values are further indications of endothermic energy transfer from TAZ to FIrpic and the presence of significant dissipative non-radiative transitions. As the phosphorescence efficiency is approximately proportional to the lifetime of triplet excitons [21,22], the shorter lifetime in TAZ is consistent with the lower EL efficiencies of the TAZ-doped devices.

4. Conclusion

In conclusion, the influences of different host materials on the performance of FIrpic-based blue phosphorescent OLEDs have been systematically studied. In addition to the well-known effect of charge balance, both energy levels and E_T of mixed host materials play crucial roles in determining the device performance. Particularly, a theoretical limit on EQE of 21.9% can be achieved by using hole-transporting TCTA to form mixed host. It is found that the lifetime of FIrpic is strongly dependent on the composition of triplet host materials, in which a shorter lifetime with a higher K_{SV} of $0.1564\%^{-1}$ (corresponding to the quenching constant of $\sim 147{,}545\%^{-1}\,s^{-1}$) is observed for all the FIrpic:TAZ systems. This observation clearly explains the poor performance of all TAZ-doped devices.

Acknowledgments

The work described in this paper was fully supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. HKU 700409P). Infrastructural and facility support from the Strategic Research Theme on Molecular Materials, the University Development Fund of The University of Hong Kong,

surface tension. While there have been demonstrations of femtoliter and attoliter inkjet heads using electrohydrodynamic techniques, scaling of the complex patterns necessary to realize circuits has remained elusive due to the difficulty in controlling the landing and positioning of such small drops [7,8]. Thus, to achieve highly scaled and high performance printed transistors using a low-cost approach has remained tremendously challenging. Therefore, in this work, we have demonstrated a novel hybrid-printing technique to realize printed features as narrow as 5 μm using a state-of-the-art printer. Using this technique, we have demonstrated all printed highly scaled transistors and inverters. Due to the substantially reduced capacitance and reduced linewidth, the fully printed inverter has a propagation delay as low as 15 μs, in contrast to the typical value of ~0.01 s obtained by previously reported all-printed processes [9–11]. We thus demonstrate orders of magnitude improvement in performance relative to other reported fully printed circuits.

2. PND technique

The novel hybrid-printing technique used in this work was inspired by dip-pen nanolithography, in which molecules are delivered from an atomic force microscope tip to a solid substrate of interest via capillary transport [12]. Here, we implemented the technique in a low-cost manner by merging a multi-nozzle inkjet head with a mechanical probe system to provide both the high throughput of inkjet and the feature scalability of a mechanical pen. The process consists of two steps – print-and-drag (PND) as illustrated in Fig. 1a. First, large pads and other large features were printed on a conventional Dimatix DMP-2800 inkjet printer equipped with a 10 pL piezoelectric head, using silver nanoparticle ink (Suntronic U5603). The silver ink solvent evaporated slowly and thus allowed the pads to act as ink reservoirs for the subsequent process. Next, a micron-scale mechanically controlled tungsten probe was used as a pen to drag through the pad to create a highly scaled feature. Note that the ink flow is facilitated by the meniscus formed between the tip and the pad; therefore actual contact of the probe tip to the surface is not necessary. Thus the PND technique is also expected to be applicable to surfaces such as soft plastic substrates. The technique combines high-throughput low resolution printing (via inkjet) with high-resolution critical feature patterning (via pen printing), and since the pen can address multi-nozzle inkjetted patterns, high throughput is achievable. The printed lines become conductive with a resistance of ~100 Ω for a 195 μm long line with a cross-section of 9 μm by 73 nm after a 150 °C and 20 min sintering.

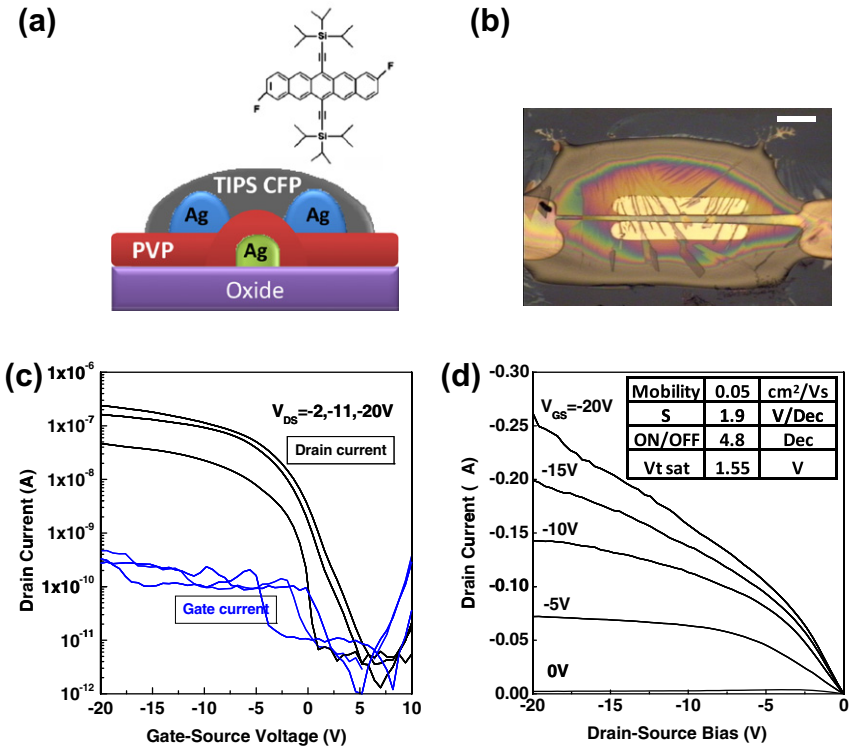

Fig. 2. (a) Cross-sectional view of a fully printed transistor. Chemical structure of TIPS CFP is also shown. The transistors and inverters were fabricated on 1 μm oxide wafers. (b) The optical micrograph of the fully printed transistor. The scale bar represents 100 μm. (c) Transfer characteristics with the gate current. (d) Output characteristics of the transistor. The channel length of the transistor is 14 μm.

Fig. 1b shows the optical micrograph of a typical dragged line. The length (L), line-tip width (W_T) and line-base width (W_B) defined in Fig. 1b were measured using an optical microscope, and the average and standard deviation from 20 measured lines were used for the following discussions. It is noted that W_B was measured right at the junction of the line and the pad. The line geometry as a function of dragging speed, probe tip radius and ink concentration was then studied. Since the PND performed in this work involved a direct physical contact, the printed lines are expected to strongly correlate with the probing method and the probe tip radius. The probe tip was probed on the surface with a constant tilt angle and probing depth by controlling a vertical stepping motor with one micron resolution. In our initial system used here, feedback control was not implemented into the system to adjust the probing depth and angle in a real-time basis; hence W_B was checked afterward to confirm the consistency of the probing because W_B is expected to be directly proportional to the probing depth and angle. Probe tips with three different point radii were used in the study (see Section 5.1). Fig. 1c shows the L and W_T as a function of W_B and the corresponding probe tip radius at a fixed dragging speed of 1000 μm/s. It is clear that the linewidth can be scaled down by using a smaller tip radius. Dragged lines as narrow as 5 μm can be consistently formed using a probe tip of 0.3 μm radius as shown in the inset of Fig. 1c.

The dragging speed was controlled by setting up the probe tip on a stage with programmable moving velocity. As shown in Fig. 1d, increasing dragging speed reduces the length of the feature, as well as both W_B and W_L (Fig. 1d). From the previous discussion, the reduction of W_B indicated a change in the probing depth and angle. However, those changes were not clearly observed under a microscope with a 45× magnification. Therefore it is possible that when dragging at a higher speed, the ink from the pads does not have sufficient time to form the meniscus on the tip, resulting in a relatively smaller amount of ink being transferred and thus a smaller L, W_B and W_L. Note the fact that line-base being wider and thicker than the line-tip is not ideal for gate electrode applications. Fortunately, the difference in thickness should not affect the insulator thickness atop if a conformal layer such as PVP is used. The difference in linewidth, however, could result in a non-uniform channel length if a self-aligned S/D is applied [6]. This can be mitigated by producing a longer line, where the transition from W_B to W_T takes place over a longer distance, resulting in a more uniform linewidth. Moreover, the gate lines can be dragged from two ink pads and merged in the middle. Using this method, the PND lines become more uniform and symmetric in the middle for gate electrode applications.

The ink concentration also affects the dragged line feature. The ink concentration was diluted by adding water to the aqueous silver ink, which is a common method to adjust the viscosity of this ink. Three different concentrations and the corresponding viscosities were then obtained as listed in the inset table of Fig. 1e. Square pads were printed

with three different inks and the lines were then produced using the PND technique. The dragging speed was fixed at 500 μm/s and the probing conditions were kept constant. The W_B and W_T were then verified to be independent of ink concentration, indicating the probing condition was consistent. Higher ink concentration results in longer dragged lines as shown in Fig. 1e. Note that the measured viscosities do not account for changes in ink concentration occurring prior to and during the PND process due to evaporation. More studies on the feature formation will be done in the future to completely understand the PND process. It is important to note that no limitation on further scaling of linewidth using this technique has been observed to date; further scaling should be possible by using a smaller probe tip.

3. Fully printed transistors and inverters

Fully printed, highly-scaled, p-type bottom-gate bottom-contact transistors were then demonstrated using the PND gate electrodes. The printing process flow (See Section 5.2) is similar to our previous work [13] except that the downscaled gate lines are now produced by the PND technique. Poly(4-vinylphenol) (PVP) was printed as the insulator and the silver S/D were then printed to align the gate. The S/D electrodes were then treated with PFBT (pentafluorobenzenethiol) to form good contacts with the semiconductor; TIPS CFP (triisoprophylsilylethynyl catafluoro-pentacene) with two Fluorine atoms added in the regular TIPS molecule to improve its chemical interaction with PFBT was used in this work [14]. The semiconductor was inkjet printed using an ink consisting of TIPS CFP dissolved in a cosolvent of dichlorobenzene:dodecane (3:1 vol. ratio) to cover the S/D. The cosolvent has been reported to suppress the coffee ring effect and thus allow the deposition of a more uniform film [15]. The printing of TIPS CFP was done at a substrate temperature of 60 °C to facilitate drop pinning and the simultaneous crystallization. The cross-sectional structure of a single printed transistor is shown in Fig. 2a and the optical micrograph of the transistor is shown in Fig. 2b. The transistor shown has a mobility of 0.05 $cm^2 V^{-1} s^{-1}$ and an on/off ratio of almost 10^5 as outlined in the inset table of Fig. 2d (see Supplementary information Fig. S1 for statistical data). The mobility obtained in this work is similar to previous work using TIPS CFP [14]. This indicates that TIPS CFP also forms good contacts with PFBT treated silver electrodes. The on/off ratio is not as high as devices fabricated using thermal oxide gate insulators due to increased gate leakage current through the printed PVP film; however, in general, the obtained electrical characteristics are consistent with other reported results using PVP. The threshold voltage of 1.55 V and the average sub-threshold swing of 1.1 V/Dec are also similar to previous work using a full solution process [16], indicating the combination of TIPS-based pentacene and PVP can yield a good channel interface. The channel length and width are 14 μm and 243 μm respectively. Note that the channel width was measured from the effective coverage of the printed TIPS CFP on the channel. Fig. 2c and d shows the transfer and output characteristics of the printed transistor, attesting to the well-behaved nature of this highly-scaled device produced by the novel PND technique.

Fully printed inverters consisting of one drive transistor and one diode-connected load transistor were then demonstrated. The gate electrodes were produced by the PND technique with a dragging speed of 100 μm/s. PVP (Poly-4-vinylphenol) dielectric was printed to cover both gate lines and cross-linked as the insulator. Dewetting of the printed PVP film was observed between the PND electrodes as shown in Fig. 3a, due to some point defects on the oxide surface and the preferential wetting of PVP on

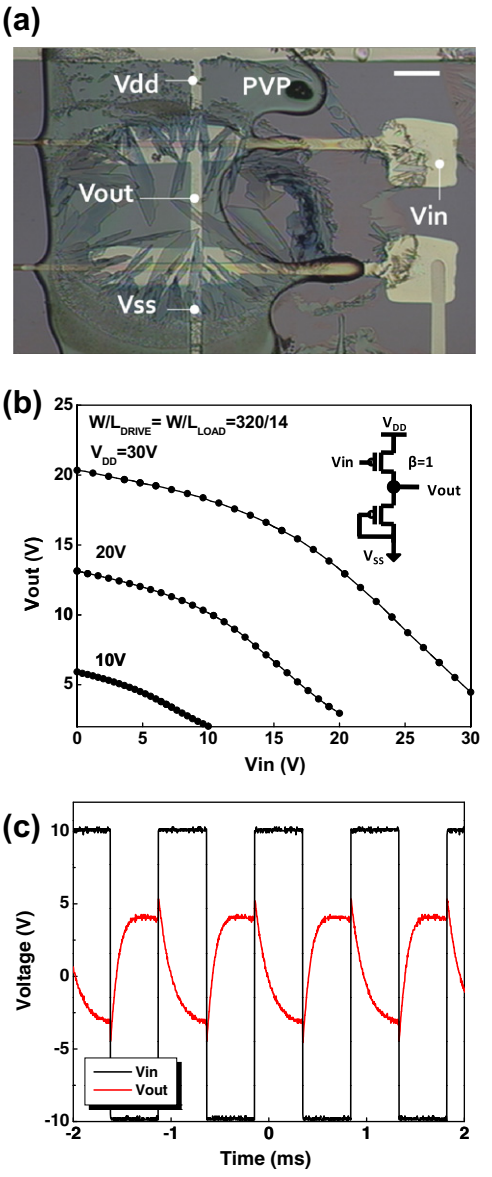

Fig. 3. (a) Optical micrograph of a fully printed inverter. TIPS CFP was printed in the form of a big drop to cover both transistor channels. The scale bar represents 100 μm. (b) Voltage transfer characteristics of the printed inverter. Inset shows the equivalent circuit of the inverter. (c) Transient characteristics of the printed inverter showing a 1 kHz and 20 V_{P-P} square wave input. The inverted output waveform was measured at a fan-out of 6.

silver lines. Nevertheless, the overall printed PVP film is smooth and conformal (See Supplementary information Fig. S2 for measured profile of the PVP). The S/D electrode and the interconnection were then printed to align to the gate, followed by a sintering step. The S/D was then treated with PFBT to form a good contact to TIPS CFP. Finally, TIPS CFP was inkjet printed with the drop size controlled to cover the two transistors. As shown in Fig. 3a, higher evaporation at the drop edge causes the TIPS CFP to crystallize from the perimeter towards the center, resulting in symmetric coverage of both transistors. The printed TIPS film showed a large crystallize size, which is beneficial for obtaining high mobility, but also resulted in device-to-device variation. Fortunately, the uniformity can be improved in the future by using a polymer-small molecule blend while also maintaining high performance [17]. Fig. 3b shows the voltage transfer characteristics and the equivalent circuit of the inverter with a W_{DRIVE}/W_{LOAD} ratio of one. Fig. 3c shows the transient characteristics of the inverter (See Section 5.3). Due to the extra parasitic capacitance from the bottom silicon wafer, the inverter has a fan-out of six ($C_{OUT}/C_{IN} = 6$). The average propagation delay from Fig. 3c is 90 μs, indicating that the inverter at a fan-out of one will has a propagation delay as low as 15 μs. The propagation delay corresponds to an operation frequency of 66 kHz, which is in good agreement with the calculated value (see Supplementary information Fig. S3 for statistical data and details of the calculations). This high speed operation is achieving despite the relatively low mobility of the semiconductor used here, attesting to the beneficial impact of PND-based scaling. The benefits of the scaling in terms of the speed enhancement are clear across all devices.

4. Conclusions

We have developed and demonstrated a new technique that provides an alternative low-cost solution to create highly-scaled printed features. Using a combination of inkjet printing and mechanical pen dragging, we demonstrate features as small as 5 μm while exploiting the benefits of multi-nozzle inkjet printing. Using this technique, we have successfully demonstrated highly scaled transistors and inverters with sufficient performance for the realization of the low-cost electronics.

5. Experimental

5.1. Probe tips

Probe Tips with three different point radii were used in this study. (1) Cascade PTT-120-25, point radius 12 μm (2) Cascade PTT-24-25, point radius 2.4 μm (3) Micromanipulator model 7s, point radius 0.35 μm, Tungsten tip, Nickel shank.

5.2. Transistor printing process

An N-type silicon wafer with thermally grown oxide of 1 μm was used as underlying mechanical substrate. Silver nanoparticle ink (Suntronic U5603) was used to print the large pads for PND process. The silver pads were then dragged by a tungsten tip with 2.4 μm point radius at 100 μm/s to create a long gate line. The gate electrode was then sintered at 150 °C for 20 min. 7.6 wt.% of Poly(4-vinylphenol) (PVP) dissolved in hexanol with 0.6 vol.% of cross linker poly(melamine-co-formaldehyde) was printed atop the gate and cross-linked at 200 °C for 10 min. Five nozzles were used simultaneously to print the PVP layer with a drop spacing of 30 μm, resulting in a dielectric thickness of 110 nm. Silver ink was then printed to form source and drain electrodes with a drop spacing of 20 μm. This was followed by a sintering step identical to that used for the gate electrode. The S/D electrodes were then treated with PFBT (pentafluorobenzenethiol) to form good contacts with the TIPS CFP (triisoprophylsilylethynyl cata-fluoro-pentacene). PFBT was deposited in an ethanol solution with 10 mM concentration, followed by an ethanol wash step. The transistor was then completed by inkjet printed TIPS CFP dissolved in a cosolvent of dichlorobenzene:dodecane (3:1 vol. ratio) to cover the S/D. All inkjetting was performed using a Dimatix DMP-2800 printer with a jetting frequency of 2 kHz except the TIPS CFP, which was inkjet printed using a custom-built printer with a Microfab nozzle (60 μm orifice).

5.3. Transient behavior of the inverter

To measure the inverter transient output, an Agilent 4156C was used to provide Vdd at 20 V and ground. The input square wave of 1 k Hz was provided by an Interstate Electronics Corporation F34 function generator. The output was buffered by an operational amplifier Burr Brown OPA602BP and the waveform was measured using an Acute DS-1202 Oscilloscope.

Herein, we present the use of a soluble QA precursor for the fabrication of organic solar cells via solution processing. As one of the most important low-cost industrial pigments with exceptional color and weather fastness, QA has been used extensively in a variety of applications, e.g., automobile coatings, artist's paints, and ink for printers [16]. Recently, the application of QA in electronic devices, i.e., organic light emitting diodes, solar transistors and solar cells, has gained a great deal of attention [17–24]. Most of these QA based devices have been fabricated via high vacuum vapor deposition due to its low solubility. More recently, a few soluble QA derivatives have been developed, affording solution processed QA based devices with high performance [5,24]. For instance, the organic field effect transistors (OFETs) fabricated by *t*-BOC QA have been found to exhibit nearly equivalent device characteristics to vacuum deposited devices. The objective of our present investigation is to evaluate the performance of QA based organic solar cells prepared via solution processing and thermal treatment of *t*-BOC QA.

2. Experimental

2.1. Materials and equipments

Pre-patterned ITO-coated glass substrates ($R = 20\ \Omega/sq$) were purchased from Thin Film Devices, Inc. Phenyl-C61-butyric acid methyl ester ($PC_{60}BM$) was purchased from Nano-C Inc. Poly(3,4-ethylenedioxythiophene) poly (styrenesulfonate) (PEDOT:PSS) (Baytron PH) was purchased from H.C. Starck. Pristine QA was purchased from Aldrich. *t*-BOC QA was prepared according to the procedures described in literature, i.e., stirring the pigment in tetrahydrofuran (THF) at room temperature with two equivalents of di-(*t*-butyl)-dicarbonate and *N,N′*-dimethylaminopyridine as a catalyst for 24 h, producing *t*-BOC QA at a yield of ~65%.

TGA was carried out on Thermogravimetric Analyzer (TGA) Q5000 IR (TA instruments). UV–Vis data were obtained using CARY 5000 UV–Vis-NIR spectrophotometer with film samples spin-coated on glass substrates. Film thickness was measured with a Veeco Dektak 150 surface profilometer. Tapping-mode atomic force microscopy (AFM) was carried out on a Veeco Nanoscope V scanning probe microscope. SEM was performed on Zeiss Gemini Ultra-55 Analytical Scanning Electron Microscope.

2.2. Device fabrication and testing

Organic solar cells with three device architectures, bilayer, bulk heterojunction, and p-i-n structure, were fabricated. The pre-patterned ITO-coated glass substrates were cleaned using the following procedure: sonication in soap solution, rinsing in deionized water, sonication in acetone and isopropanol, respectively, for 15 min, and UV ozone cleaning for 10 min. A thin-layer (~30 nm) of PEDOT:PSS (Baytron PH) was spin-coated onto the ITO glass substrate at 4000 RPM for 40 s and then baked at 140 °C for 15 min in air.

For p-n devices, *t*-BOC QA solutions with concentrations varying from 2 to 14 mg/mL (thickness 15–70 nm) and $PC_{60}BM$ with concentrations of 8–14 mg/mL (thickness 30–70 nm) were used. The optimal condition was found to be 10 mg/mL of *t*-BOC QA (57 nm) and 12 mg/mL of $PC_{60}BM$ (60 nm) both in chloroform. The *t*-BOC QA film was baked at 170 °C for 15 min on the hot plate prior to spin casting of the $PC_{60}BM$ layer.

For i devices, the photoactive layers were prepared by spin casting a blend *t*-BOC QA and $PC_{60}BM$ chloroform solution with varying weight ratios and concentrations of 6–20 mg/mL (40–110 nm thick). The optimal *t*-BOC QA:$PC_{60}BM$ weight ratio was found to be 1:1.5 with a concentration of 16 mg/mL (87 nm). The blend film was then baked at 170 °C for 15 min on the hot plate.

For p-i-n devices, *t*-BOC QA (p), *t*-BOC QA:$PC_{60}BM$ (i), and $PC_{60}BM$ (n) were varied from 2 to 4 mg/mL (17–32 nm), 10 to 20 mg/mL (55–117 nm), and 6 to 20 mg/mL (22–41 nm), respectively, to find the optimal conditions. The optimal condition was found to be 2 mg/mL (18 nm) in chloroform for *t*-BOC QA, 15 mg/mL (80 nm) in chloroform for *t*-BOC QA:$PC_{60}BM$, and 16 mg/mL (33 nm) in chlorobenzene for $PC_{60}BM$. The p and i layer were each baked at 170 °C for 15 min on the hot plate prior to deposition of the subsequent layer. All active layers were cast at 2000 rpm and passed through a 0.2 μm polytetrafluoroethylene filter prior to spin casting.

After the depositions of organic layers, an Al cathode (100 nm) was thermally evaporated under high vacuum (~10^{-7} Torr) through a shadow mask defining an active device area of ~0.03 cm^2. The current density–voltage (*J–V*) curves were measured using a Keithley 236 source-measure unit under AM 1.5 G solar illumination at 100 mW cm^{-2} (1 sun) using a Thermal-Oriel 300 W solar simulator. External Quantum Efficiencies (EQEs) were obtained with a monochromator and calibrated with a silicon photodiode.

3. Results and discussion

Soluble *t*-BOC QA precursor is prepared by replacing the H atom of the NH group of QA with a *t*-butoxycarbonyl (*t*-BOC) group in high yield. The soluble precursor can be converted into insoluble parent pigment QA in high purity and quantitative yield by thermal treatment, as shown in Fig. 1a. This process has been well characterized by UV–Vis spectroscopy, TGA and SEM. (See Supplementary data) Spin casting of *t*-BOC QA solutions in chloroform allowed for the formation of uniform thin yellow colored films. Thermal treatment of those films at 170 °C for 15 min resulted in the generation of polycrystalline red colored films of QA pigment, as evidenced by absorption spectra (Fig. 1b) and SEM (Fig. 1c and d). The change of photophysical and morphological properties is attributed to the NH···O hydrogen-bonding effect of QA. The field effect mobility of the regenerated QA film was previously reported to be p-type with a value of ~8×10^{-6} $cm^2\ V^{-1}\ s^{-1}$ [24]. The optical and electronic properties of QA suggest that it can act as an electron donor for organic solar cells.

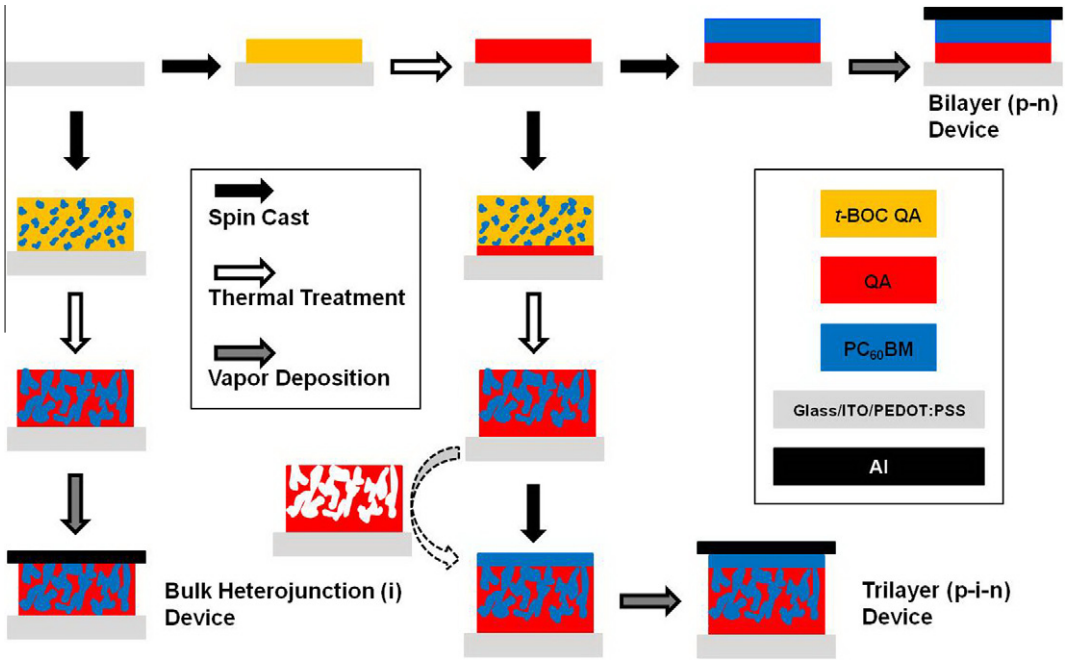

Fig. 2. Solution processing of organic solar cells with three different device architectures: bilayer (p-n) device, bulk heterojunction (i) device, and trilayer (p-i-n) device. The fabrication processes involve spin coating, thermal treatment and vapor deposition of Al cathode.

The thermal transformation of solution processed thin films into insoluble ones allows for solution processing of multilayer structures. As illustrated in Fig. 2, bilayer organic solar cells were fabricated by depositing the acceptor layer of $PC_{60}BM$ from solution on the top of the regenerated QA layer. Fig. 3a shows the current density–voltage (*J*–*V*) characteristics of the optimized p-n device with a structure of ITO/PEDOT:PSS(30 nm)/QA(57 nm)/$PC_{60}BM$

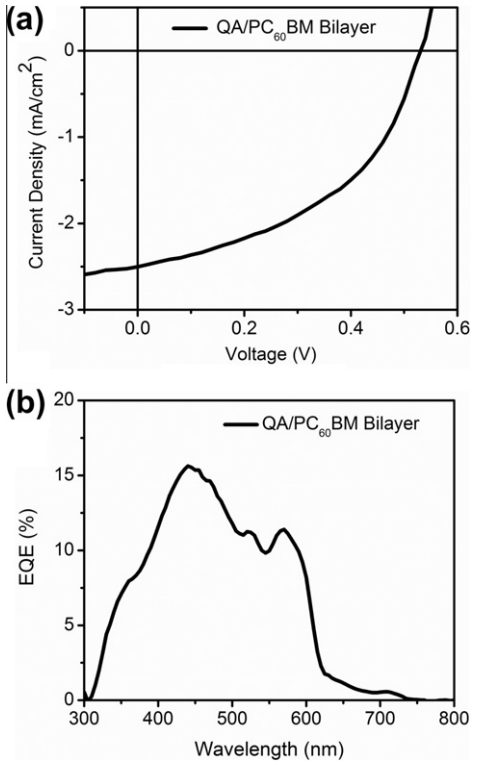

Fig. 3. (a) The *J–V* curve under 1 sun illumination for the optimized p-n device that shows a PCE of 0.61%; (b) The EQE curve of the p-n device.

(60 nm)/Al. The device showed a modest PCE of 0.61% with V_{oc} = 0.53 V, J_{sc} = 2.50 mA/cm^2, and FF = 0.46 (Table 1). Fig. 3b shows the external quantum efficiency of this device, with photocurrent generation in a broad range from 300 nm to 750 nm. An EQE of 10–15% is very typical for planar heterojunction devices. The photocurrent at short wavelengths (300–500 nm) and long wavelengths beyond 610 nm is mainly contributed by $PC_{60}BM$. The contribution from QA is mainly in the region of 500–600 nm, where QA exhibits high absorption intensity as shown in Fig. 1b.

To further improve the device performance, we have adapted a more advanced device architecture, i.e., trilayer p-i-n structure, which contains an additional mixing layer (i) sandwiched between the pure donor (p) and acceptor (n) layers. The fabrication process for p-i-n device is shown in Fig. 2. As control, a single layer (i) device was also fabricated. The i layer was prepared by spin casting of blends of *t*-BOC QA and $PC_{60}BM$ followed by thermal treatment to convert soluble *t*-BOC QA into insoluble QA. We have investigated various ratios of *t*-BOC QA to $PC_{60}BM$ and different thicknesses of i layer to obtain optimized device performance. Spin casting of pure $PC_{60}BM$ solution on the top of the regenerated QA:$PC_{60}BM$ mixing layer might dissolve the existing $PC_{60}BM$ component, creating porous structures while filling the pores at the same time. Nevertheless, a neat film of $PC_{60}BM$ can be generated with careful control of the concentration of the $PC_{60}BM$ solution.

The device characteristics of i and p-i-n devices are shown in Fig. 4. A PCE of 0.83% has been achieved for the p-i-n device with V_{oc} = 0.79 V, J_{sc} = 2.34 mA/cm^2, and FF = 0.44 (Table 1). In contract, the i device exhibited a much lower PCE of 0.57%. The improvements in open circuit voltage and fill factor account for the enhanced device performance of p-i-n over i device. As demonstrated in a number of systems, high open circuit voltage can be achieved by reducing the electron leakage current though the introduction of carrier blocking layers between the organic layers and the electrodes [25–29]. As shown in Fig. 4b, reduced dark current was observed for the p-i-n device, indicating the blocking effects induced by the neat film layers of QA and $PC_{60}BM$. Moreover, the improved organic/electrode interface properties is likely to lower the series resistance affording a higher fill factor, as evidence by the higher current density under forward bias of >1 V.

Interestingly, the EQEs for both i and p-i-n devices showed little-to-no change as compared to the p-n device, which are significantly lower than typical values of 40–60% for typical bulk heterojunction devices with nanophase separations [30]. This is likely due to the morphology of the blends of QA and $PC_{60}BM$, i.e., micron sized phase separation is formed in the i layer, similar to what has been observed in the blends of diethylhexyl functionalized QA and $PC_{70}BM$ [5]. This suggests that further improvement of device performance can be realized with better control of the phase separation between QA and acceptor materials. In addition, the p-i-n device has a slightly lower EQE than the i device. Provided that both devices have very similar absorption spectra (See Supplementary data), this can be explained by that a portion of light was harvested by the neat films to generate excitons, which were not able to reach the donor/acceptor interfaces to produce the photocurrent. Another interesting finding is that both i and p-i-n devices exhibited much higher V_{oc} than the p-n device (See Supplementary data for the dark current curves as well). This might be attributed to the different nature of the donor/acceptor interfaces for the devices. For the p-n device, the interfaces consist of QA that was regenerated from the neat film of *t*-BOC QA and solution processed $PC_{60}BM$. While for the devices with an i layer, the interfaces consist of QA regenerated from the blends of *t*-BOC QA and $PC_{60}BM$, and solution processed and/or leftover thermally annealed $PC_{60}BM$. Thermal treatment of the blends likely produces QA domains with less crystallinity and encourages the phase separation between QA and

Table 1
Device parameters for OSCs in three device structures.

Devices	Structures	V_{oc} (V)	J_{sc} (mA/cm^2)	FF	PCE (%)
Bilayer (p-n)	QA (57 nm)/$PC_{60}BM$(60 nm)	0.53	2.50	0.46	0.61
BHJ (i)	QA:$PC_{60}BM$ (1:1.5, 87 nm)	0.70	2.54	0.32	0.57
Trilayer (p-i-n)	QA(18 nm)/QA:$PC_{60}BM$ (1:1.5, 80 nm)/$PC_{60}BM$(33 nm)	0.79	2.34	0.44	0.83

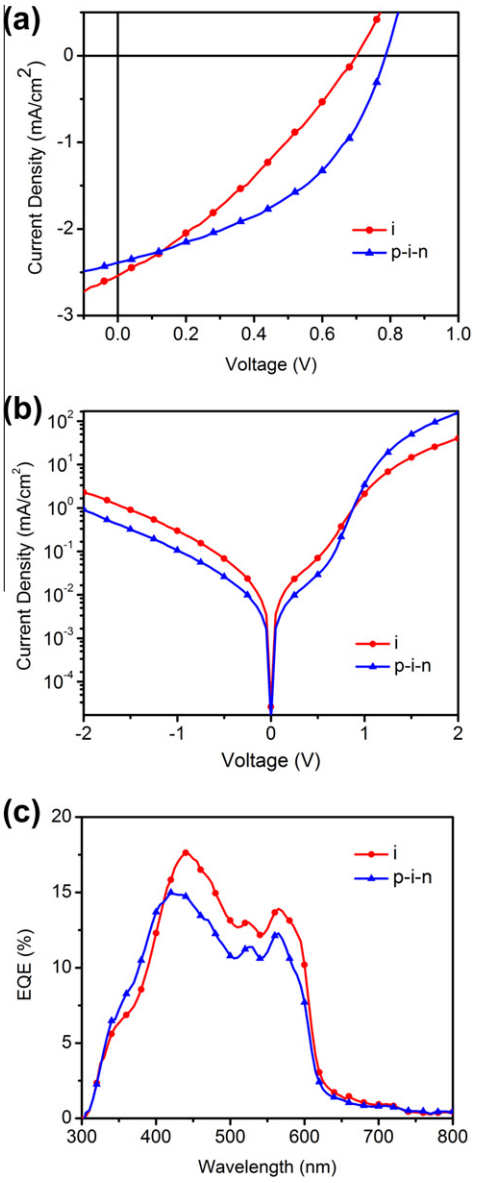

Fig. 4. (a) The *J–V* curves under 1 Sun illumination for the optimized p-i-n and i devices that exhibit PCE of 0.83% and 0.57% respectively; (b) The dark current characteristics of the optimized p-i-n and i devices; (c) The EQE curves of the i and p-i-n device.

$PC_{60}BM$, which would lead to weaker donor/acceptor interactions and subsequently higher open circuit voltages [31].

4. Conclusions

In summary, we have demonstrated a simple device fabrication approach for p-i-n junction organic solar cells based on an "old" industrial pigment, quinacridone. The pristine insoluble quincridone molecule was easily functionalized with solubilizing *t*-BOC groups, yielding a solution processable material with suitable properties for photovoltaic application. Although the overall power conversion efficiencies of these cells of up to 0.83% are still below those of state-of-the-art, our work is a proof-of-concept for the great potential of solution processing of highly stable industrial pigments for solar cells. On-going research is to develop effective approaches to realizing controlled nanophase separation within the blends of pigment donors and fullerene acceptors.

amorphous InGaZnO (*a*-IGZO) and a vacuum deposited pentacene TFTs as channel semiconductors, respectively. The inverters yielded high DC gain values of 61 V/V with high and balanced noise margins at a low supply voltage of 5 V [9]. However, to reduce the cost of such inverters, it would be desirable to demonstrate that such structures can also be implemented using solution-processed semiconductors.

A challenge to implement vertically stacked TFTs and consequently inverters with vertical geometries and solution-processed semiconductors, is to find gate dielectric materials and processing methods that do not damage the organic semiconductor layers during deposition. An amorphous fluoropolymer, CYTOP, has recently provided a particularly attractive way to realize TFTs with a top-gate geometry. This is because CYTOP dissolves in fluorinated solvents that are orthogonal to most organic semiconductor materials, has an excellent chemical stability and is highly hydrophobic [10,11]. Furthermore, we recently demonstrated 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) and poly(triarylamine) (PTAA) blended *p*-channel TFTs using a top-gate bi-layer gate insulator which operated at low voltages with remarkable long-term environmental and operational stabilities [12]. The bi-layer was comprised of a spin-coated CYTOP layer and a high-*k* metal-oxide layer, fabricated by atomic layer deposition (ALD).

Here, we combine this *p*-channel TFTs with a solution-processed [6,6]-phenyl c_{61} butyric acid methyl ester (PCBM) *n*-channel TFT in a vertically stacked complementary inverter geometry. In this geometry, a bottom-gate *n*-channel TFT is fabricated on top of a top-gate *p*-channel TFTs with a shared common gate electrode positioned between two dielectric layers. The *p*- and *n*-channel TFTs showed saturation mobility values of 0.25 and 0.004 cm^2/V s, respectively. We demonstrate a complementary inverter that shows a DC gain value of −24 V/V with a switching threshold voltage value of 3.3 V, close to half of the supply voltage, and NM_L and NM_H values of 2.5 and 2.1 V, respectively.

2. Device fabrication and electrical characterization

Fig. 1(a) shows the geometry of the complementary inverter in which a bottom-gate top-contact *n*-channel TFT was fabricated on top of a top-gate bottom-contact *p*-channel TFT with a shared gate electrode. The inverter was fabricated on a glass substrate by first depositing at room temperature 60 nm-thick Au source and drain electrodes through a shadow mask using a thermal evaporator. A self-assembled layer of pentafluorobenzenethiol (PFBT) was deposited on the Au electrodes to improve the contact between the metal and the organic semiconductor interface and to increase the work function of Au. The PFBT layer was deposited by immersing the substrates in a 10 mM PFBT solution in ethanol for 15 min inside a N_2-filled dry box, were the substrates were also rinsed with pure ethanol, and dried. The TIPS-pentacene and PTAA blend solution was prepared as follows: TIPS-pentacene and PTAA were individually dissolved in 1,2,3,4-tetrahydronaphthalene anhydrous, 99%, (Sigma Aldrich) with a concentration of 30 mg/mL, then, the two individual solutions were mixed to yield a weight ratio of 1:1. Blends of TIPS-pentacene and PTAA were deposited by following a two-step spin coating process comprising of a first cycle at 500 rpm for 10 s and followed by a second cycle at 2000 rpm for 20 s. Then, the samples were annealed at 100 °C for 15 min in a N_2-filled dry box. A CYTOP/Al_2O_3 bi-layer was then fabricated as top-gate dielectric for the *p*-channel TFTs. A CYTOP solution (CTL-809M) was purchased from Asahi Glass with a concentration of 9 wt.% and diluted with a solvent (CT-solv.180) to reduce the concentration to 2 wt.%. This diluted solution was used to deposit 40 nm-thick CYTOP layers by spin casting at 3000 rpm for 60 s. The CYTOP film was then annealed at 100 °C for 20 min. All spin-coating and annealing processes were carried out in a N_2-filled dry box. After that, a Savannah100 ALD system from Cambridge Nanotech Inc. was used to deposit 50 nm-thick Al_2O_3 layers at 110 °C by using alternating exposures of tri-methyl-aluminum ($Al(CH_3)_3$) and H_2O vapor at a deposition rate of approximately

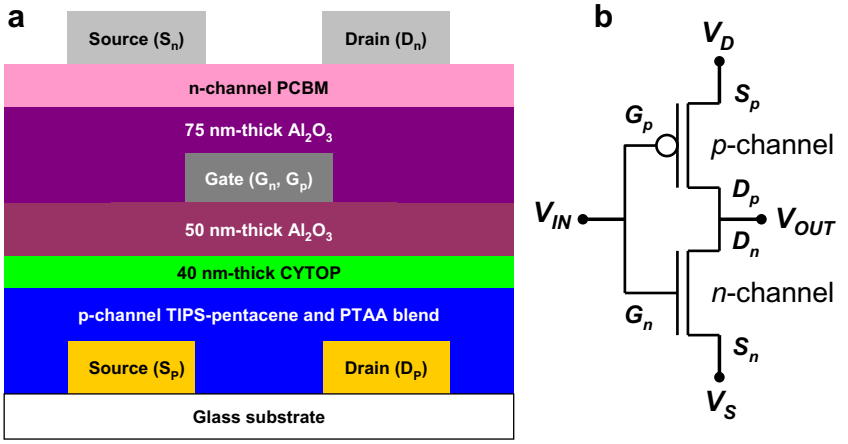

Fig. 1. (a) Schematics of vertically stacked *n*-channel (PCBM) transistor on the top of an *p*-channel (TIPS-pentacene and PTAA blend) transistor on a glass substrate. (b) Complementary inverter circuit diagram.

0.1 nm per cycle. A 50 nm-thick Al electrode was then deposited by thermal evaporation through a shadow mask to serve as a common gate electrode. Then, a 75 nm-thick Al_2O_3 was deposited by ALD as previously described. A thin layer of PCBM (Solenne B.V., 99.5%) was then deposited by spin-coating from a 10 mg/mL chlorobenzene solution at 1000 rpm for 60 s in a N_2-filled dry box. Hence, PCBM was never exposed to normal ambient during the fabrication process. Finally, Au (100 nm) source/drain electrodes were deposited through a shadow mask over the PCBM channel. After fabrication, the electrical properties of the samples were measured in a N_2-filled glove box (O_2, $H_2O < 0.1$ ppm).

The dielectric properties of the gate dielectrics used in both transistors were measured in parallel plate capacitors fabricated using the same procedures previously described but on independent substrates with the following geometries, glass/Au/CYTOP (40 nm)/Al_2O_3 (50 nm)/Al and glass/Au/Al_2O_3 (75 nm)/Al, with areas ranging from 1 to 5 mm^2. Capacitance densities of 35 ± 1 and 114 ± 2 nF/cm^2 were measured for the CYTOP/Al_2O_3 bi-layer and the Al_2O_3 single layer, respectively. The properties of these Al_2O_3 and CYTOP/Al_2O_3 layers are consistent with our previous reports [9,12,13]. The current–voltage characteristics of the vertically stacked, bottom-gate *p*-channel and top-gate *n*-channel TFTs with channel widths of $W_P = W_N = 2550$ μm and lengths of $L_P = L_N = 180$ μm are shown in Fig. 2(a) and (d). The output characteristics (drain current I_{DS} vs. drain–source voltage V_{DS} at multiple constant gate–source voltages V_{GS}) and transfer characteristics (I_{DS} vs. V_{GS} at fixed V_{DS}) of the TFTs were measured using an Agilent E5272A medium-power source/monitor unit connected to a probe station. Transfer and output curves are shown in Fig. 2(a) and (b) (*p*-channel) and Fig. 2(c) and (d) (*n*-channel). Saturation mobility values of 0.25 and 0.004 $cm^2/V\,s$ and threshold voltage values of −3.9, and 0.3 V were obtained for the *p*-channel and *n*-channel TFTs, respectively. The relatively high contact resistance and threshold voltage observed in the *p*-channel TFTs could be attributed to an incomplete Au surface

Table 1
Performance of a complementary inverter using vertically stacked *n*-channel ([60] PCBM) TFT on top of a *p*-channel (TIPS-pentacene and PTAA blend) TFT.

$W_P = W_N$ [μm]	$L_P = L_N$ [μm]	V_{IN} [V]	V_D [V]	*Maximum* dV_{OUT}/dV_{IN}	V_M [V]	NM_L [V]	NM_H [V]	ΔV_{IN} [V]
2550	180	0 to +6	+6	−22	2.8	2.10	1.99	0.98
		0 to +7	+7	−24	3.3	2.51	2.09	1.16
		0 to +8	+8	−26	4.1	3.10	2.17	1.27

modification by the PFBT and the negative shifts of threshold voltage introduced by the unintended vacuum annealing during the second ALD deposition [12]. Further optimization of the processing conditions of TFTs with this geometry could reduce these effects. For instance exposing this *p*-channel TFT to air has been found to cause positive shifts of the threshold voltage, bringing it closer to zero. Hence, a longer air exposure prior to the second ALD deposition could reduce the threshold voltage of the *p*-channel TFT. The low mobility values obtained in the PCBM TFTs compared with previous reports [14,15] is attributed to the unpassivated gate dielectric interface.

3. Vertically stacked complementary inverters with solution-processed organic semiconductors

The static performance of an inverter is evaluated by its static gain and noise margin values, both extracted from the measured voltage transfer characteristics (*VTC*s) [16,17]. Achieving high and balanced noise margin values is necessary for reliable circuit operation in complex logic circuits such as ring oscillators. Noise margin values are defined by the noise margin low ($N_{ML} = V_{IL} - V_{OL}$) and noise margin high ($N_{MH} = V_{OH} - V_{IH}$), where V_{IH}, V_{IL}, V_{OH}, and V_{OL} are input (V_{IN}) and output (V_{OUT}) voltages at high and low levels of a given inverter *VTC*s. The noise margin is limited by the steepness ($\Delta V_{IN} = V_{IH} - V_{IL}$) of the transition and by the position of the switching threshold voltage ($V_M = V_{IN} = -V_{OUT}$). High and balanced noise margins are found when the ideal condition $V_M = 0.5V_D$ is met, hence when $V_M = V_{IN} = 0.5V_D = V_{OUT}$. However, the value of V_{IN} at which this transition occurs is generally not $0.5V_D$. In complementary inverters with a vertically stacked geometry the control of thicknesses of the top- and bottom-gate transistors with the use of different dielectric materials is used to compensate for: (1) differences in hole (μ_h) and electron mobility (μ_e) in the TIPS-pentacene and PTAA blend and PCBM transistors; and (2) differences in the threshold voltages of the two transistors. To test the inverter characteristics of these vertically stacked TFTs, the drain electrodes of the top and bottom TFTs were connected by using a single probe at the region of electrode overlap. The common gate electrode for both *n*- and *p*-channel TFTs served as the input voltage (V_{IN}) of the inverter circuit. Fig. 3 shows the corresponding hysteresis *VTC*s and static gain (dV_{OUT}/dV_{IN}) values of the inverters for V_D = 6, 7, and 8 V. The maximum static gain value at V_D = 7 V was −24 V/V with V_M = 3.3 V. The corresponding value of NM_L and NM_H are 2.51 and 2.09 V with the steepness of ΔV_{IN} = 1.27 V (18% of max. V_{IN}). The performance of this complementary inverter at different V_D is summarized in Table 1. We note that further optimization of the inverter performance could be achieved by passivating the *n*-channel dielectric interface, and by selecting *n*-channel materials with better air stability than PCBM, which here has been selected for its ease of processing and reproducible behavior. The geometry demonstrated in this study shows many degrees of freedom that allow for the optimization of inverters as illustrated by the use of two un-patterned solution-processed materials with very different charge mobilities. Hence, the proposed geometry allows the use of solution-processed semiconductors in vertically stacked complementary inverter geometries, which is a step forward towards the development of low-cost complementary electronics.

4. Conclusion

In summary, we have demonstrated a vertically stacked complementary inverter geometry using solution-processed PCBM *n*-channel and TIPS-pentacene/PTAA blend *p*-channel TFTs. The *p*- and *n*-channel TFTs showed saturation mobility values of 0.25 and 0.004 $cm^2/V\,s$ and threshold voltages of −3.9 and 0.3 V, respectively. The complementary inverters yielded a maximum gain value of −24 V/V with high and balanced noise margins at a low voltage of 7 V. The use of vertically stacked *p*- and *n*-channel TFTs in complementary circuits is a promising way to realize higher packing density and higher interconnectivity with low power by the reduction of the interconnection lengths and parasitic resistances. Balanced "*on*-currents" during inverter operation were achieved because this geometry allows for the independent control of the channel widths, the *n*- to *p*-channel ratios, as well as separate control of the thickness of the gate dielectric layers. Furthermore, the low processing temperature (<110 °C) used in this work would make possible the implementation of the complementary circuits on flexible substrates.

ITO/Ag/ITO (IMI) structure with higher conductivity [24]. Recently, Lewis et al. reported flexible OLEDs based on IMI stacks which fabricated onto polyethylene terephthalate (PET) by sputtering deposition process [22]. In addition, multilayer InZnSnOx/Ag/InZnSnOx, ZnS/Ag/ZnS, WO_3/Ag/WO_3, and ITO/Ag/WO_3 were also reported as electrodes for OLEDs [25–28]. But all the reported multilayer electrodes above were almost used in monochrome OLEDs, having no white light emission devices reported.

In this article, we reported a warm and high color-rendering TEWOLED with MoO_3/Ag/MoO_3 (MAM) multilayer used as a cathode. We prepared conductive transparent MAM coating on PET substrates by vacuum thermal evaporation and measured the optical transmittance. The TEWOLED we fabricated had a comparable efficiency but superior CRI relative to bottom-emitting OLED.

2. Experimental details

The device A consisted of PET substrate/Al (100 nm)/MoO_3 (1.5 nm)/4, 4′, 4″-tris(3-methylphenyl–phenylamino)-tripheny-lamine (m-MTDATA, 30 nm)/N, N′-bis-(1-naphthyl)-N, N'diphenyl-1, 1-biphenyl-4, 4′diamine (NPB, 10 nm)/4, 4′-bis(2, 2′-diphenylvinyl)-1, 1′-biphenyl (DPVBi, 15 nm)/4, 4-N, N- dicarbazole-biphenyl (CBP, 3 nm)/CBP: bis(2-(2-fluorphenyl)-1, 3-benzothiozolato-N, C2′)iridium(acetylacetonate) [(F–BT)2Ir(acac)] (7 nm)/4, 7-diphenyl -1, 10-phenanthroline (Bphen, 30 nm)/LiF (1 nm)/Al (1 nm)/Ag (1 nm)/MoO_3 (40 nm)/Ag (17 nm)/MoO_3 (40 nm). In this device, Al/MoO_3, m-MTDATA, NPB, DPVBi, CBP: $(F–BT)_2Ir(acac)$, Bphen, and LiF/Al/Ag/M/A/M were used as the anode, hole injection layer, hole transporting layer, blue emitting layer, orange emitting layer, electron transporting layer and cathode, respectively. Here, we use metal Al as the anode replacing the common metal Ag because Al film has larger phase shift on reflection than that of metal Ag. The neat CBP is introduced to separate blue and orange emitting layers to avoid the Dexter energy transfer between the two emitters. For comparison, the bottom-emitting device (ITO glass substrate) with the same organic layers (device B) was fabricated, which consisted of glass coated with ITO /m-MTDATA (30 nm)/NPB (10 nm)/DPVBi (15 nm)/CBP (3 nm)/CBP: $(F–BT)_2Ir(acac)$ (7 nm)/Bphen (30 nm)/LiF (1 nm)/Al (200 nm). All films were deposited at pressure below 4×10^{-6} Torr. The deposition of each layer and the measure of devices characteristics were described before [20].

3. Results and discussion

Ryu et al. reported that the Ag thin film was the dominant factor of the sheet resistance in a dielectric/Ag/dielectric multilayer [28]. Consequently, a low resistance of multilayer cathode will be obtained by adjusting the thickness of Ag layer in MAM electrode. We measured the sheet resistance of the prepared MAM multilayer by four-point probe and a low resistance of 11 Ω/□ was obtained. If the film boundary effects are negligible, the sheet resistance of the multilayer is the sheet resistance of MoO_3, Ag, MoO_3 layer coupled in parallel: [28].

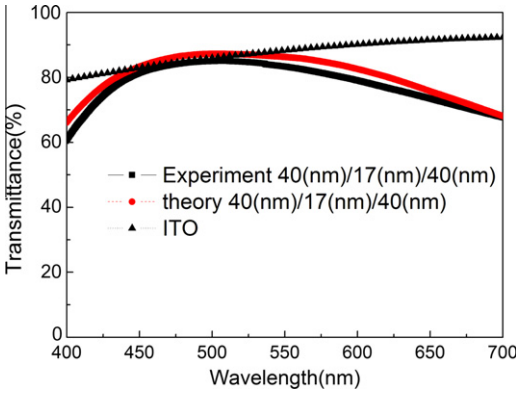

Fig. 1. The measured optical transmittance curves of MAM and ITO, the calculated optical transmittance of MAM is also plotted.

$$\frac{1}{R_{total}} = \frac{1}{R_{MoO3}} + \frac{1}{R_{Ag}} + \frac{1}{R_{MoO3}}.$$

R_{total}, R_{Ag}, R_{MoO3} is the sheet resistance of MAM, Ag, MoO_3 layer, respectively. Fig. 1 shows the measured and calculated optical transmittance curves of multilayer MAM as a function of the wavelength. The optical transmittance is calculated by the transfer-matrix method [29]. The measured optical transmittance curve of ITO was also plotted in Fig. 1. It can be seen that a high average transmittance of over 84% is obtained for the MAM-based transparent multilayer, which is comparable with the conventional ITO. Here, we also calculated the transmittance of MoO_3 (y nm)/Ag (17 nm)/MoO_3 (y nm) for different y value (the data was not shown) and found that the MAM multilayer had the highest transmittance when $y = 40$. Considering the electric and optical properties, we choose a 17 nm Ag layer for MAM coating. One should note that the MAM multilayer with superior features is obtained by simple thermal evaporation without subjecting to substrate heating and post-annealing, which is especially favorable for flexible OLEDs and top-emitting OLEDs.

Fig. 2a shows the normalized EL spectra of device A and B at operating voltage of 6, 8, and 10 V. It can be seen that the narrowness of the full width at half maximum (FWHM) of the DPVBi and $(F\text{-}BT)_2Ir(acac)$ emission in device A is not observed at all. Insert is the normal spectra normalized to blue emission. We can see that the devices have the same blue emission spectral profile. However, the spectra have large difference in long wavelength region. In order to explain this, we calculated the phase shift characteristics of the TEWOLED by the transfer-matrix method [29], as shown in Fig. 2b, the calculated round-trip phase changes for organic layers sandwiched between two reflection electrodes [i.e., $\varphi_1(\lambda) = \sum_i \frac{4\pi d_i n_i(\lambda)}{\lambda}$], and the phase changes at two reflective electrodes [i.e., $\varphi_2(\lambda) = \varphi_{cathode} + \varphi_{anode}$]. In our calculation, the multilayer MoO_3 (40 nm)/Ag (17 nm)/MoO_3 (40 nm) was considered the cathode. The point of intersection is the resonant wavelength (RW). It can be seen that a RW at 635 nm is observed. Insert is the absorptance and reflectance of multilayer MAM. The absorptance is almost the same over the visible range, which will not affect the distribution of the spectrum intensity. High reflectance (>25%) at longer wavelength (>600 nm) will benefit

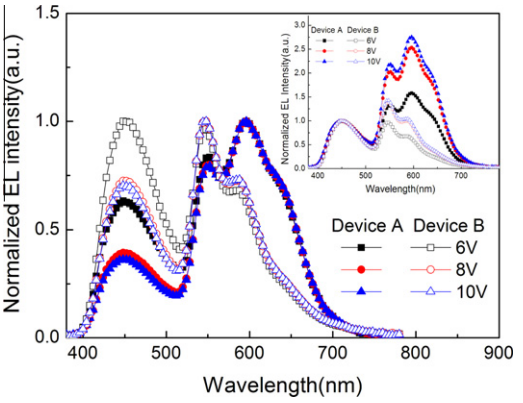

Fig. 2a. The normalized EL spectra of devices A and B at different voltage of 6, 8, and 10 V; Insert is the EL spectra of devices A and B normalized to blue emission.

to the light emission near 635 nm due to constructive interference. High reflectance at shorter wavelength would attenuate the blue emission intensity near 439 nm where the destructive interference arises. In order to clarify the microcavity effect in the device, we calculated the cavity emission by considering wavelength-independment instrsinc luminescence spectra of the emitters [30], as shown in Fig. 2c. The calculated resonant wavelength of the device is 638 nm, which is agreement with the calculated result for the phase shift. We can see that the cavity emission is varied with wavelength, which will result in a different enhanced emission st different wavelength for device A. Thus, device A shows a more enhanced orange emission and less enhanced blue emission. The spectrum of device B is also shown in Fig. 2c. As can be seen from the power distribution of the spectrum of device B and the trend of the cavity emission, we can deduce the spectrum of device A. In Fig. 2c, we also calculated the normal emisson of the device, which is excellent agreement with the experiment results. All of the descriptions above result in the difference of the spectra between devices A and B.

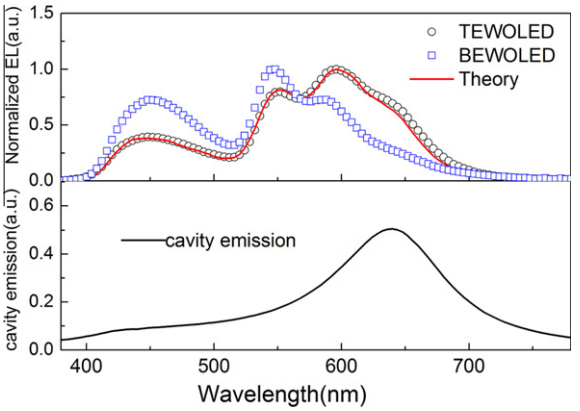

Fig. 2c. The normalized EL spectra by calculating and measuring of the devices (top) and the calculated forward directed cavity emission of device A (down).

Fig. 3 shows the CIE coordinates of devices A and B operated from 5 to 10 V. The CIE coordinates of device A change from (0.3532, 0.3270) to (0.4277, 0.3894) and that of device B change from (0.2562, 0.2689) to (0.323, 0.3533) over all the range of operation voltages. We can see that the CIE coordinates are fairly stable at high operation voltages for the two devices. Besides, the device A has a higher color rendering index (CRI) of 84 at correlated color temperature (CCT) of T_c = 3736 K (Ideal CCT values for warm white is 2500–4500 K [2]) than that of device B (CRI = 75 at T_c = 8224 K), which is an important parameter for lighting sources. This TEWOLED satisfies the CRI need for future solid-state lighting applications (with a CRI > 80) [31].

Fig. 4a shows the current density–voltage–luminance characteristics of the devices, revealing a luminance of 6398 and 6435 cd/m^2 at 9 V for devices A, and B, respectively. When the operating voltage is below 8 V, device A has a lower current density than that of device B. Fig. 4b shows the voltage-efficiency characteristics of the devices. The maximum current efficiency can reach 8.66 and 9.10 cd/A for devices A and B, respectively. We can also see that the MAM-based device has a lower roll-off of efficiency than that of ITO-based one due to the microcavity effect. The microcavity effect increases the optical mode density and consequently increases the radiation rate,

which reduces the possibility of triplet–triplet annihilation [32,33]. However, the TEWOLED exhibits a lower efficiency than that of the ITO-based device. The poor contact and high energy barrier at MAM/organic interface may be two important factors which influenced the performance of MAM-based device. In addition, the thick MoO_3 layer will increase the operating voltage of the devices, as described in Ref. [34], in which thick (>10 nm) MoO_3-doped NPD hole injection layer increased the operating voltage of the device.

4. Conclusions

In summary, we have successfully obtained a warm-white top-emitting organic light-emitting device with MAM multilayer transparent cathode. A high average transmittance of 84% and low resistance of 11 Ω/□ for MAM coatings was obtained. Therefore, the MAM-based electrode structure can be used as a low resistance transparent cathode and anode for transparent or top-emitting OLEDs, especially for flexible devices, in practical applications. Comparing to ITO-based device, MAM-based TEWOLED exhibits some superior performance, such as high CRI and low CCT, which are the key factors to estimating the performance of lighting sources. Most important, the MAM multilayer can be prepared by vacuum thermal evaporation, which is compatible with OLEDs fabrication process.

adjustable slit with the right side of the stripe always maintained in the edge of the sample. The photoluminescence (PL) emission was collected from the edge and focused into an Ocean Optics USB4000 Miniature Spectrometer. The pump intensity I is measured very near the sample, after the laser beam had been shaped into a stripe. In our experimental procedure the edge emission spectra were obtained for constant lengths L of the excitation laser stripe. At each L the laser intensity was varied from a relatively small value up to the well established ASE peak.

3. Results and discussions

In order to fit the experimental results we followed the method developed in Ref. [20], where the ASE output integrated PL intensity I_{out} from the sample edge is given by,

$$I_{out}(I,L) = \left[\frac{\alpha I_{max}}{(1+Ce^{-I/I_0})}\right]\left\{\int_0^L e^{-Ibwz^2}dz\right\}e^{IbwL^2}, \quad (1)$$

where α is a constant related to the cross section for spontaneous emission, I_0 is a threshold pump intensity, establishing the crossing from spontaneous emission (SE) to ASE regime. The value of the parameter C corresponds to how fast the system reaches an intensity higher than the threshold pump intensity. I_{max} is the maximum value of the pump intensity when $I \gg I_0$, in the saturation region of the Arrhenius expression inside brackets in Eq. (1). The integrand expression $Ibwz^2$, comes as a result of the intermediary integration process [20] where the expression $g(z) = 2Ibzw$ was assumed for the net gain. The dependence of the b parameter on the excitation length is obtained experimentally from the fits of each different $I_{out} \times I$ curve.

The experimental curves $I_{out} \times I$ (symbols) and the corresponding fits (full lines) are shown in Fig. 1 for 5 representative excitation lengths, considering the complete integration of the emitted spectra. The parameters αI_{max}, I_0, C and b used in the fitting process are displayed in Table 1. The experimental threshold intensities were determined by the method shown in Ref. [10]. The theoretical threshold intensities in Fig. 2 are found to be underestimated in comparison to the experimental ones for $L \leqslant 0.06$ cm. Although the $I_{out}(I,L)$ expression (Eq. (1)) presents this limitation it enabled us to fit quantitatively well the experimental $I_{out} \times I$ data (Fig. 1) and provided the same trend for both experimental and theoretical I_0 behavior (Fig. 2). The qualitative agreement shown in Fig. 2 also gives a further support that the interpretation of the ASE effect should take into account the excitation length dependence.

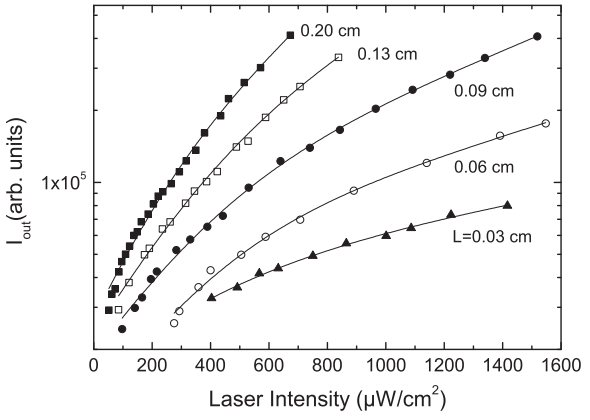

Fig. 1. Integrated I_{out} intensity as a function of pump intensity I for the excitation lengths $L = 0.03$, 0.06, 0.09, 0.13 and 0.20 cm at room temperature. The full lines are the fits obtained from Eq. (1).

The same increase of the threshold intensity with decreasing excitation length has been observed in $In_xGa_{1-x}N$ inorganic multiple quantum well waveguides [1] at room and low temperatures. In Ref. [1] it was observed that two modes competed for the gain. The mode at higher energy, even though suffering a higher self-absorption effect, possessed a higher gain in order to overcome the total losses and attain the minimum threshold intensity more easily for a relatively lower excitation length. The threshold intensity would then vary little for a further increase of the excitation length. In our case, the decrease of the threshold intensity reaching a more stable behavior at longer excitation length, has been observed experimentally. The lower the losses the smaller the variation of the threshold intensity with the excitation length.

The net gain as a function of the excitation length has been shown and discussed in the literature for different materials [2,12,14,20]. In inorganic materials it initially increases rapidly, reaching a maximum and then decreases up to a stabilized value [2,12]. For erbium-doped fiber amplifiers [14] the gain increases monotonically to a saturation regime. In this work the net gain, for excitation lengths longer than 0.03 cm, decreases slowly to a broad minimum at around 0.15 cm and then increases slightly for higher excitation lengths (Fig. 3). For excitation lengths shorter than 0.03 cm, the net gain curve (dashed line in Fig. 3) was estimated by considering the extrapolation of the b parameter, which was based on its growing trend with decreasing excitation length, as derived from the experimental data (see Table 1). We have also considered that $g(0) = 0$ (i.e. for the zero excitation length the gain should be zero). In comparison with the net gain curve in Ref. [20], the maximum in our case (Fig. 3) occurs at a shorter length around $L = 0.03$ cm, which would be expected due to the relatively higher PL quantum yield of PFO. Thus, the model used here points out that the smaller the L required for maximum gain, the better the material gain characteristic of the polymer.

In a general way the net gain curve as a function of the excitation length follows some common trends for these different materials, which does not agree with a constant g assumed to analyse the ASE intensity [3,6,10]. The gL function considering the net gain g as obtained here and a constant net gain $g = 420\ \text{cm}^{-1}$ (inset of Fig. 3) shows a match between the curves only at smaller excitation lengths. In addition, by assuming a net gain independent of the excitation length, only dependent on the laser intensity($g \propto I$), we find a final ASE intensity expression given by a simple exponential function $I_{out} \propto (e^{\sigma IL} - 1)$ (σ being a

Table 1
Fit parameters for the $I_{out} \times I$ curves at different lengths of the excitation laser stripe L. The error of the excitation length L corresponds to a maximum 0.005 cm. The errors of the other parameters are given by the standard deviation coming from the fitting method. The column I_{0exp} depicts the values of the experimental threshold intensities.

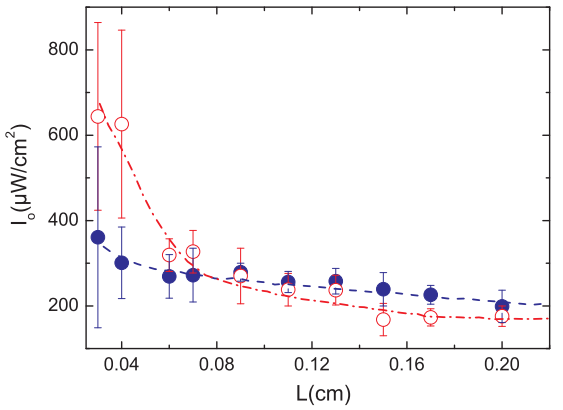

Fig. 2. The theoretical (full circles) and experimental (open circles) threshold intensity I_0 as a function of the excitation length L. The dashed and dot-dashed lines in the respective curves are guides for the eyes.

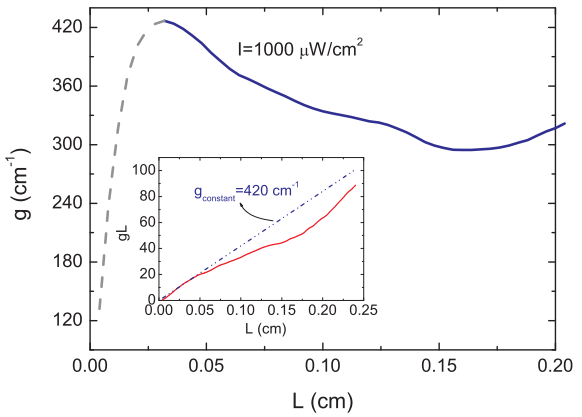

Fig. 3. The net gain curve as a function of the excitation length L with $I = 1000$ μW/cm^2. The net gain curve was obtained from the expression $g(z) = 2Ib(z)zw$ given in Ref. [20]. The dashed part of the gain curve is an estimate of the net gain in the range $0 < L < 0.03$ cm obtained by extrapolation (see text). The full line part is obtained by interpolation of the b data from Table 1. In the inset we compare the gL expression as a function of L for the net gain considered in this work (full line) and for a constant net gain $g = 420$ cm^{-1} (dashed dot dot line), which corresponds to the maximum value of the gain curve.

constant), which does not allow us to perform the fitting of all $I_{out} \times I$ experimental curves.

4. Conclusions

In summary, the theoretical method whereby the net gain depends on the excitation length L [20], was successfully employed to fit the experimental ASE intensity behavior of PFO thin film waveguides, as well as to provide the same qualitative behavior for the threshold intensity as a function of L. The experimental threshold intensity was observed to increase about 3-fold with decreasing excitation length in comparison to the work of Silvestre et al. [22], where an increase of about 6 times has been observed. This is a direct consequence of the higher PL quantum yield [PLQY = (21 ± 2) %] of the PFO film used here [23], which also presented a threshold intensity three orders of magnitude lower. The variation of the threshold intensity with the excitation length depends on the quantum efficiency characteristic of the luminescent material and gives further support to the gain dependence on the excitation length. The enhancement of the ASE intensity at different excitation lengths, however, represents a more general characteristic of the conjugated polymer waveguided systems, being independent if it is a low or high gain material, and can only be explained assuming the gain dependence on the excitation length.

(p-type) semiconductor film by using PVA as the dielectric layer and PLGA as the substrate of a biodegradable p-type thin-film transistor [27]. These previous accomplishments point to the importance of combining organic electronics and synthetic organic biodegradable materials to take a first step towards biodegradable and environmentally sustainable electronic devices.

Very recently silk fibroin was used as dielectric in a p-type pentacene transistor with a high mobility value [28], which confirms the feasibility of using silk as gate dielectrics in OFETs. Here, we show that silk-fibroin can be integrated as an efficient dielectric also in n-type and light-emitting field-effect organic transistors. These results open the way towards the development of multifunctional optoelectronic devices, which in perspective can be made fully biocompatible, and eventually bioresorbable, if used in combination with biocompatible substrates and active materials.

2. Experimental

Fig. 1 shows the schematic of the fabricated n- and p-type silk organic thin film transistors. A 400 nm thick film of silk fibroin is spin coated from aqueous solution onto an optically transparent glass/ITO substrate, patterned 150 nm-thick ITO acting as a gate contact. The silk film is rendered water insoluble by inducing beta sheet formation (i.e. crosslinking) as previously described [18]. A 15 nm thick film of N,N′-ditridecylperylene-3,4,9,10-tetracarboxylic diimide (P13) is vacuum deposited at a sublimation rate of 0.1 Å/s as a n-type organic semiconductor for electron conduction on top of the silk film. A 50 nm thick source and drain gold contacts are vacuum thermo-deposited through a metal mask thus completing a 70 μm and 15 mm channel length and width top-contact organic field-

effect transistor (OFET) configuration. With the same protocol and parameters, a p-type semiconductor, namely the α,ω-dihexyl-quaterthiophene (DH4T) has been grown for hole conduction. It is worth nothing that the semiconductor compounds were not modified or manipulated from their commercially available from namely, P13 by Sigma–Aldrich, and DH4T (ActivInk P0400) by Polyera Corporation. The molecular structure of the grown moieties and the output curves of the respective n- and p-type silk organic FET are shown as well in Fig. 1. Both P13 and DH4T are well known and extensively researched materials for electron (n-type) and hole (p-type) transport organic thin film transistors [6,29,30]. As such, they provide an ideal system to benchmark the silk-based OFETs and OLETs. Indeed, reference P13 and DH4T based devices were fabricated implementing different dielectric and gate electrode materials. In particular, the substrates consisted of heavily doped n^{+2} silicon with a 300 nm thick-layer of thermal oxide (SiO_2) and of glass/ITO with 450 nm-thick polymethylmethacrylate (PMMA). The electrical characterization of the fabricated silk-organic transistors has been performed by probe station equipped with a parametric analyzer both in atmosphere controlled dry-box systems and in air-room temperature. Is worth noting how the *I–V* characteristics of OFETs can be adequately described by standard models [31,32] and the mobility of the n- and p-type silk based transistors were derived from the saturation curves. For electroluminescence measurements the probe station was equipped with a planar S1337 Hamamatsu photodiode for collecting light through the ITO/PMMA/substrate. The elec-

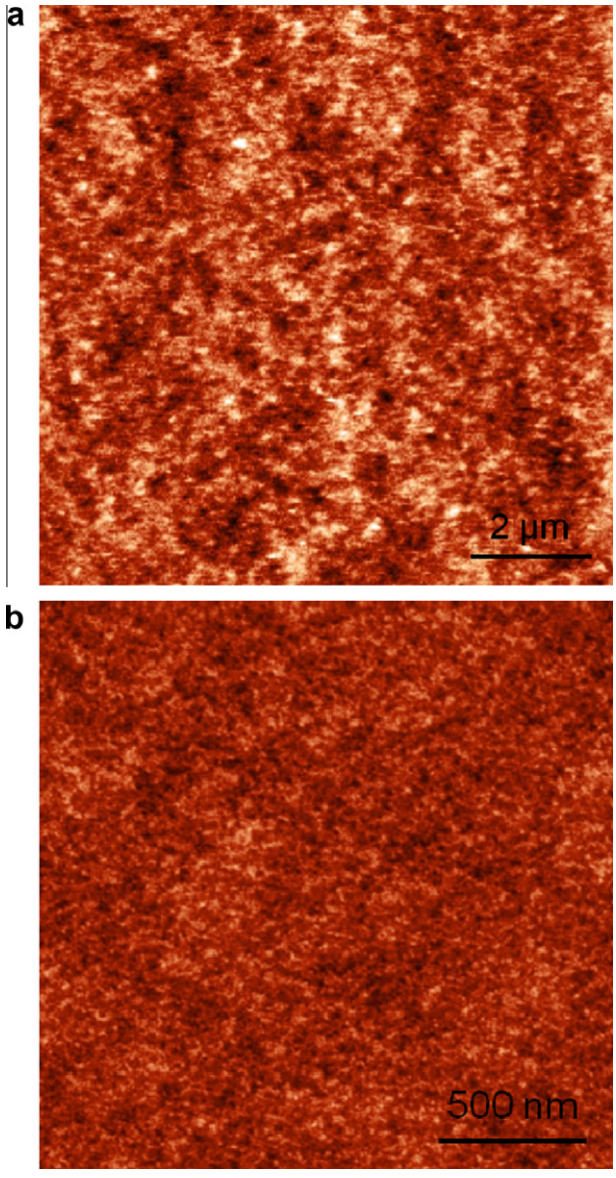

Fig. 2. Topographic AFM image of (a) the silk dielectric layer deposited onto glass/ITO and (b) of the PMMA layer deposited onto glass/ITO.

troluminescent signal was corrected for the photosensitivity of the photodiode considering the P13 photoluminescence spectrum.

Atomic Force Microscope (AFM) topographical images were collected using an NT-MDT Solver Scanning Probe Microscope in tapping mode with the samples kept in air.

3. Results and discussion

The saturation curves measured at $V_{d-s} = \pm 90$ V, where V_{d-s} is the voltage between drain–source contacts depending on the n- or p-type semiconducting material, are reported in Fig. 1. The two nearly overlapping lines are for forward and backward scanning of the gate–source voltage while V_{d-s} is kept constant. This indicates the near absence of hysteresis and consequently low charge trapping in the silk dielectric layer in particular for electron transport, i.e. the silk–P13 device.

Indeed, as it can be seen from Fig. 2a the AFM investigation on silk dielectric layer reveals a smooth and homogeneous morphology with a root-mean-square roughness value similar to that of PMMA (Fig. 2b) which is around 0.5 nm. This feature can explain the almost complete absence of hysteresis in the electrical characteristics of silk based OFETs and OLETs.

Table 1
Comparison of the mobility, threshold values and on/off ratio for silk p and n-type OFETs and respective standard PMMA and SiO_2 devices. The measured silk dielectric constant in the device configuration $\varepsilon_s = 6$. The channel length and width are 70 μm and 15 mm, respectively for both silk and PMMA devices. For SiO_2 the channel length is 300 μm and width 10 mm.

	DH4T p-type			P13 n-type		
	Mobility (μm)	Threshold (V_T)	On/off ratio	Mobility (μm)	Threshold (V_T)	On/off ratio
SiO_2	4×10^{-2} cm^2/V s	−3 V	10^3	0.13 cm^2/V s	21 V	10^3
PMMA	9×10^{-2} cm^2/V s	−20 V	10^2	0.3 cm^2/V s	18 V	10^4
Silk	1.3×10^{-2} cm^2/V s	−17 V	10^4	4×10^{-2} cm^2/V s	2 V	10^4

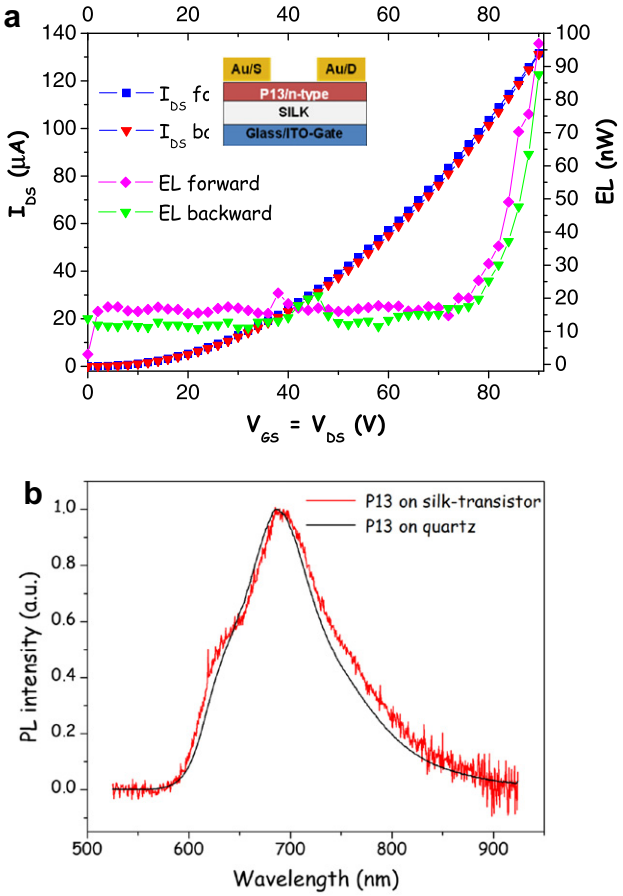

Fig. 3. (a) Electroluminescence collected from a glass/ITO/silk/P13/Au top contact unipolar silk-OLET device. The device is biased in the locus mode. The double experimental points are for forward and backward cycle. (b) Comparison of the photoluminescence spectra from P13 deposited on quartz and from P13 in silk-based OLET.

The charge mobility values associated to the measurement are $\mu_n = 4 \times 10^{-2}$ cm^2/V s for the silk–P13 and $\mu_p = 1.3 \times 10^{-2}$ cm^2/V s for the silk–DH4T. A comparison of the parameters of the silk-based devices and PMMA and SiO_2-based devices are reported in Table 1. We note that the measurements are comparable to efficient charge mobility values (n- and p-type) of thin film OFET reported in the literature [29–31] and with our results from standard SiO_2–PMMA gated OFETs [29]. Moreover, we should underline how the measured voltage threshold for the silk–P13 transistor is one order of magnitude lower, namely 2.0 V at 20 V, than the respective standard OFET. The other defining parameter to assess the performance of an OFET is the on/off switch ratio. Which we also include in the comparisons of Table 1. In this case, the switching rate of 10^4 matches the highest values reported for thin film organic transistor based on P13 and DHFT organic semiconductors.

To explore optical utility in these devices, organic light emitting transistors have been also studied, These recently designed structures [6–11] have the ability to combine in a single device the advantages and functions of a transistor and of electroemission. Moreover, electroemission efficiency and nanoscale localization of the light emission make OLETs a breakthrough multifunctional device concept. The first evidence of OLETs emission has been demonstrated for a unipolar emitting device [6,7].

To study these results in silk, we have leveraged the best-performing silk-transistor, (the silk–P13), and operated the device in the locus mode. The emission was collected by using a calibrated photodiode. The obtained results are shown in Fig. 3. When $V_{g-s} = V_{d-s}$ of 75 V, a nonlinear intensity of the emitted light is observed. The measured relevant operation parameters assessing the performance of the unipolar silk-OLET device are: V_{th} = 1.4 V; n-mobility = 0.013 cm^2/V s; light emission intensity = 100 nW at $V_{g-s} = V_{d-s}$ = 90 V. This clearly demonstrates the first observation of electroluminescence emission from OFET devices employing silk as gate dielectric. In order to check possible effects on the optical properties of P13 due to the interaction with the silk layer, we compared the photoluminescence spectrum of P13 layer measured directly in the OLET device with the photoluminescence spectrum of an optically inert quartz substrate (Fig. 3b). It is shown that silk does not affect the optical properties of the P13 layer and that P13 is the only emitting species in the OLET device.

A systematic and quantitative comparison of the optoelectronic characteristics of the silk-based OLET with those of the conventional ones [8] is beyond the scope of present paper.

4. Conclusions

The present results demonstrate how natural silk fibroin can be successfully used as a dielectric material for fabrication of advanced n- type silk-based organic transistors and light emitting transistors. The combined use of silk in electronics as presented here in combination with previous work on silk-based photonics, thin-film and conformal electronics sets the stage for a powerful approach towards the fabrication of eco-sustainable and multifunctional bioactive devices. The favorable substrate properties of this all natural biopolymeric substrate [33,34] can be also exploited in the future as an alternative to the rigid substrates used here enabling fully degradable devices and opening a path for sustainable high-tech manufacturing.

the need for masks used in vapor deposition and is often chosen over nozzle based methods when higher viscosity inks are required or the unreliable characteristic of nozzle clogging must be avoided. In addition, the entire LIFT process is conducted in ambient conditions making it a cost effective and convenient technique for the rapid prototyping of novel devices.

When dealing with organic molecules, LIFT presents a number of challenges. For instance, special care must be taken when the material of interest is particularly susceptible to thermal, optical, or mechanical damage [11]. Conversely, when the ink material does not strongly absorb incident laser energy, transmitted radiation inevitably interacts with the receiver substrate and can cause undesired vaporization of the transparent conducting oxide. The addition of foreign materials in the ink to absorb the laser can enable transfer in these cases but can also quench electroluminescence and hinder device operation.

To avoid these drawbacks we incorporate a polymer film absorbing layer (thickness = 2–8 μm) between the glass substrate and ink material on the donor [11,18,19]. Upon laser irradiation, a small volume of polymer nearest the polymer/glass interface absorbs the energy, forming an enclosed high pressure vapor that deforms the remaining polymer film into the adjacent ink and induces its transfer. This modified LIFT technique is termed blister-actuated laser-induced forward transfer (BA-LIFT) because the ink transfer is a consequence of laser-generated blister motion (Fig. 1a). BA-LIFT eliminates possible contamination issues associated with laser-absorbing additives or thinner laser absorbing layers by tuning the process for the absorption of laser energy solely in the polymer film and by selecting a thick enough polymer layer that will not fully decompose. In addition, BA-LIFT has been shown to successfully deposit weak laser-absorbing organic and biological materials, including systems that are optically and thermally sensitive [11,19].

In this work we use ambient laser direct-write techniques for fabricating patterned $[Ru(dtb\text{-}bpy)_3]^{2+}(PF_6^-)_2$ (Complex **1**) electroluminescent devices. To confirm the viability of the BA-LIFT process for printing damage-free luminophore molecules, nuclear magnetic resonance (NMR) spectroscopy is employed. Our devices are characterized by acquiring emission spectra and measuring luminous efficiencies and lifetimes, which are similar to literature values of devices fabricated in nitrogen environments. Finally we demonstrate the versatility of BA-LIFT, by printing multi-color luminophore patterns for future use in high-resolution device fabrication.

2. Experimental

The two employed iTMC examples are tris(4,4′-di-tert-butyl-2,2′-bipyridyl)ruthenium, $[Ru(dtb\text{-}bpy)_3](PF_6)$ [20] (Complex **1**), and bis(5-trifluoromethyl,2-(2′,4′-difluorophenyl)pyridyl), (4,4′-di-tert-butyl-2,2′-bipyridyl)iridium, $[Ir(F_5\text{-}mppy)_2(dtb\text{-}bpy)](PF_6)$ [21] (Complex **2**), both of which are prepared as previously described [20,21]. In the absence of a blue-emitting iTMC, 9-anthracenemethanol (Aldrich, 97%, Complex **3**) is selected as a surrogate, and used without further purification.

Donor substrates are produced by soaking glass slides in a solution of NOCHROMIX and sulfuric acid to remove oils and loosen debris. Slides are subsequently washed in deionized water, rinsed with acetone and ethanol, and blow dried with nitrogen. Slides are then spin coated with commercially available polyimide (HD Microsystems PI2525) at different spin speeds (3000 and 6000 RPM), and cured as in previous work to produce final film thicknesses of approximately 7 μm and 4 μm, respectively [19]. Luminophore solution is subsequently spread onto donor substrates with a wirecoater, or an aliquot of solution is drop cast onto donor substrates and spun at 1000 rpm

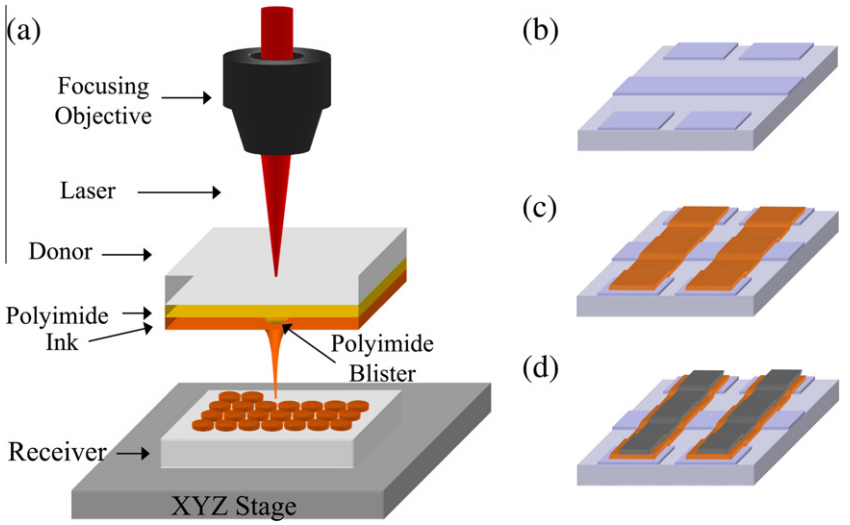

Fig. 1. (a) Illustration of the BA-LIFT process depicting ink transfer in the form of a coherent jet. Device fabrication begins with (b) laser micromachined indium tin oxide coated glass followed by (c) BA-LIFT printing of the organic ink in ambient conditions defining two $3.5 \times 12.5\ mm^2$ pads. (d) Vapor deposition of the aluminum bottom electrode completes the fabrication process.

for 20 s. Wirecoating produces a donor film thickness of 10 μm and is used to print luminophore material for the device and for the NMR measurements. Spin coating decreases the donor film thickness (1 μm) and is used to print multi-color luminophore patterns. For NMR spectroscopy and multi-color patterning experiments, solutions are created for each complex by adding 38 mg of the complex into a solution of acetonitrile/*N*-methyl-2-pyrrolidone (NMP, 1/1 v/v, 1 mL). This is heated to 50 °C for 5 min to dissolve the solute. For electroluminescent device fabrication Complex **1** (38 mg) is added to the same solvent (1 mL) with an addition of poly(methyl methacrylate) (PMMA, 6 mg).

Device fabrication begins by laser micromachining the electrically isolated Indium Tin Oxide (ITO) patterns in Fig. 1b. This is accomplished with a Nd:YVO_4 laser (λ = 355 nm, τ = 20 ns) at a laser fluence of 0.5 J/cm^2. Polyimide donor substrates and ITO receiver substrates are cleaned in acetonitrile prior to the deposition of the organo-metallic layer. Complex **1** luminophore solution is subsequently wirecoated onto a donor substrate and held at a 100 μm distance from the ITO receiver. Transfer is with the same laser focused to a 10 μm diameter at the glass/polyimide interface (fluence = 2.5 J/cm^2). The BA-LIFT process produces arrays of overlapping voxels that form two uniform pads as shown in Fig. 1c. The receiver is then dried in vacuum for 1 h to evaporate the remaining solvent. The aluminum bottom electrode is vapor deposited through a shadow mask to a final thickness of 50 nm at a rate of 1–2 Å/s. This produces two pixels located at the intersection of the top and bottom electrode (2.5 × 2.5 mm^2 each, Fig. 1d).

Photoluminescence measurements are carried out using an Hg lamp equipped with an optical filter centered at 370 nm. The devices are pre-biased to 4 V for 3 min to assist the drift of PF_6^- counterions to the ITO electrode, followed by a quick ramp to a higher voltage (~6 V) to ensure the device turns on. All emission spectra are recorded with a colorimeter and are later normalized by peak intensity. Time-dependent electroluminescent measurements are conducted from pristine devices without a pre-bias. For NMR measurements ½ mL of deuterated acetone is used to rinse the luminophore material off the ITO acceptor slides. For droplet characterization printed arrays are illuminated and images are captured with a fluorescent microscope equipped with a standard CCD camera.

3. Results and discussion

An image of the working device is shown in Fig. 2a. Under room light illumination, two bands of printed luminophore (orange–red hue) are visibly wider than the aluminum electrode, eliminating the possibility of shorting between the top and bottom electrodes. Under forward bias (ITO+, Al−), bright electroluminescence is visible from the pixels (Fig. 2b). The uniformity of the electroluminescence suggests that the ITO electrode remains undamaged during the BA-LIFT process, since damage would impede uniform charge transfer across the electrode and into the active material.

Charge injection in this organo-metallic molecule differs from typical small molecule organics due to the presence of mobile counterions. In forward bias, PF_6^- counterions migrate towards the ITO electrode [5], creating high electric fields in its vicinity, aiding the injection of holes to the highest occupied molecular orbital of the $[Ru(dtb\text{-}bpy)_3]^{2+}$ metal center [6,7]. This depletes the region near the aluminum electrode of PF_6^- ions, enhancing the injection of electrons to the lowest unoccupied molecular orbit of the $[Ru(dtb\text{-}bpy)_3]^{2+}$ ligand. This implies that for a given voltage, device current and light emission are time dependent quantities that depend on the extent of counterion migration. To mitigate this behavior, turn-on time can either be reduced by the addition of an ionic solvent containing PF_6^- counterions [5,21] or through prebiasing the device [22], the later of which is done in this work according to the prior literature [5,23].

We characterize the emission spectrum of the printed Complex **1** film via photoluminescence (PL) as shown in Fig. 2c. The PL spectrum of the printed luminophore matches the non-printed control solution, with a peak wavelength (630 nm) analogous to literature values [20,22,24]. This ensures that the photoluminescent properties of the molecule are not altered during the BA-LIFT process. Similarly, a direct match in peak wavelength (630 nm) and shape is present between the electroluminescence (EL) and PL spectra in Fig. 2c, indicating undamaged electroluminescent properties. Similar results are available for devices fabricated in nitrogen environments from a spin coated solution of Complex **1** [20,22]. This implies that the presence of air and moisture during the fabrication and testing of our device does not alter its

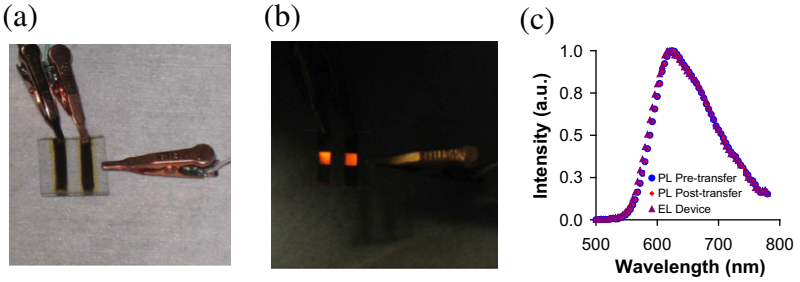

Fig. 2. (a) Image of the device (12.5 × 12.5 mm^2) under room light illumination. (b) Device operation under ambient conditions depicting two 2.5 × 2.5 mm^2 orange–red pixels. emission spectrum and verifies the air tolerance of this complex.

Molecular damage, which can limit device performance, cannot always be properly detected via PL and EL spectroscopy. To ensure the printing of non-damage molecules, NMR spectra are acquired using a procedure described in our earlier work [11]. Fig. 3 depicts the NMR results for the green and red molecules featured in this manuscript. The NMR spectra for the blue molecule are given in earlier work [11] and reproduced here for comparison. Spectra of samples printed via BA-LIFT are depicted in (d–f), and corresponding control samples are in (a–c). As seen, samples printed via BA-LIFT produce identical NMR spectra to control samples, indicating the absence of molecular damage during the printing process. This ensures that device performance, as in the case of the $[Ru(dtb\text{-}bpy)_3](PF_6)_2$ molecule depicted in (c and f), will not be hindered by molecular damage created during device processing.

To verify that a continuous luminophore pad is printed using BA-LIFT and not a pinhole structure often characteristic of drop-on-demand techniques, we further examine the electrical performance of the device. Current density (J) versus applied voltage (V) (Fig. 4a) is seen to exhibit the expected trend of a proper light-emitting diode. The smooth nature of the curve and absence of spikes is indicative of a device that is free of short circuits. Likewise, the linearity of luminance (EL) versus current density (Fig. 4b) is also indicative of a properly functioning device. A luminance

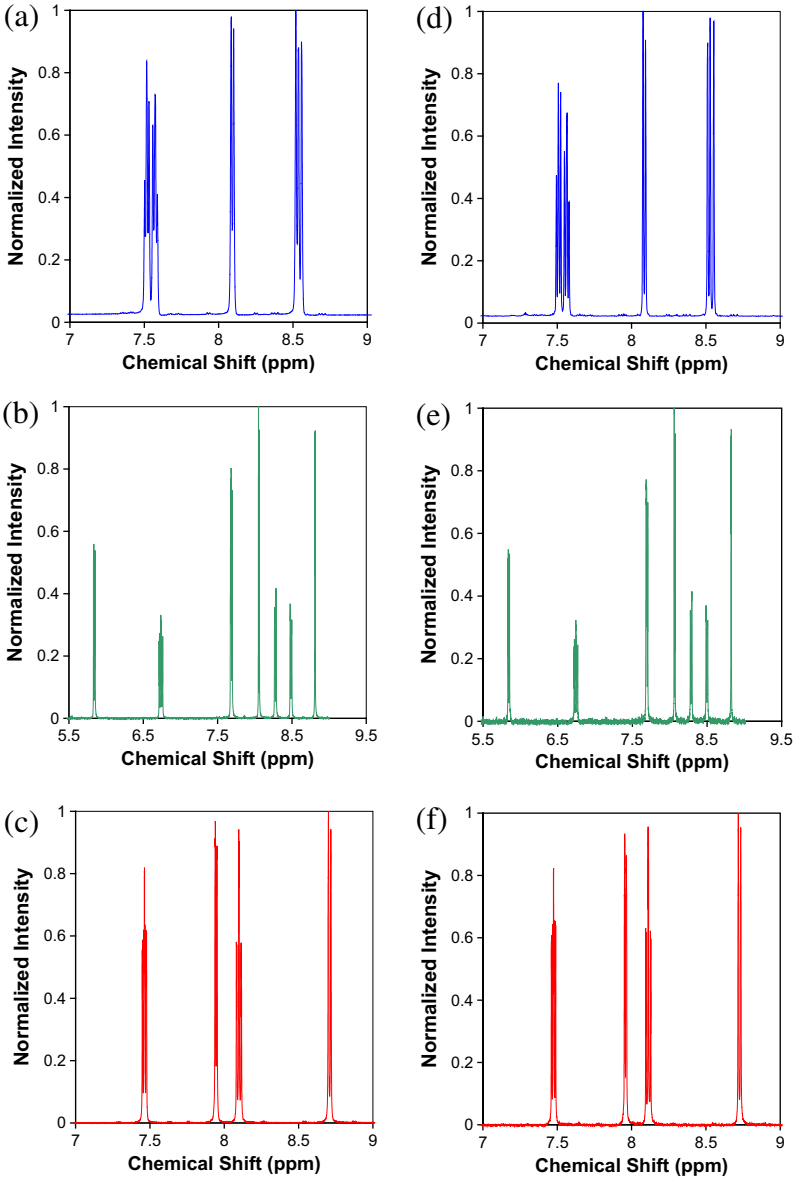

Fig. 3. Control sample NMR spectra for the (a) blue, (b) green, and (c) red molecule. BA-LIFT printed samples for the (d) blue, (e) green, and (f) red molecule display identical spectra to the control samples. The spectra from the blue molecule are reproduced from [11] for comparison. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

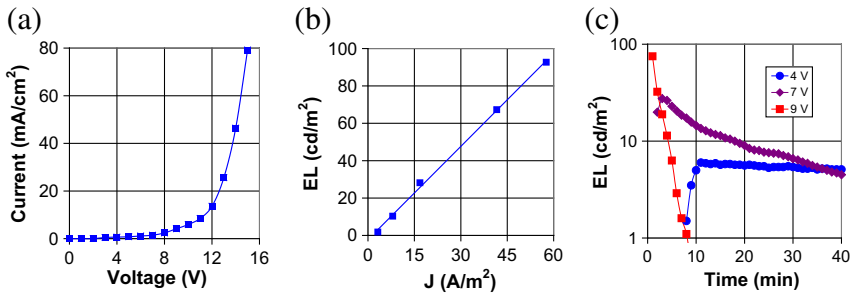

Fig. 4. (a) *I–V* and (b) EL-J measurements, and (c) time dependent EL of pristine devices for 3 bias voltages under ambient conditions.

of 93 cd/m^2 is measured at 11 V (Fig. 4b) with a device luminous efficiencies of roughly 0.39 ± 0.03 Lm/W at 3 V. This is comparable to literature values of 0.3 Lm/W given for devices fabricated by spin coating $[Ru(bpy)_3]^{2+}(PF_6^-)_2$, a molecule similar to ours, and vapor depositing a gold bottom electrode [25].

To probe the air stability of Complex **1** devices, time-dependent EL at different voltages is acquired from pristine, non-packaged and non-pre-biased devices (Fig. 4c). As expected, a reduction in turn on time and an increase in luminance is evident at higher voltages. However in accordance with literature observations, the benefits of higher voltage are outweighed by a reduction in device lifetime [5,22]. For example, at 9 V, (75 cd/m^2) peak luminance rapidly decays to its half life within two minutes of operation. The expected decrease in radiant flux is attributed to irreversible degradation of the molecule [20,22]. In contrast, a balance can be struck between peak luminance and device lifetime, through the application of a lower bias (7 V). Although device degradation rate is lower, it is still too high for practical purposes. A further decrease in applied voltage to 4 V can stabilize the device to a constant 6 cd/m^2 over 40 min. This measured lifetime increase is comparable to that reported in the literature [20] and is attributed to a combination of added poly(methyl methacrylate) and applied voltage close to the redox potential (2.5–3.0 V) [23]. We attribute the lower intensity relative to the literature to a thicker than optimal luminophore film. However, device intensity can be improved through optimized luminophore concentration, better solvent selection, or through deliberate ligand modification [26].

While our results demonstrate the ability to print millimeter sized electroluminescent devices, higher-resolution patterning is desirable in many applications. In order to demonstrate the applicability of BA-LIFT as a technique capable of creating novel architectures, micron-sized arrays of ink voxels are printed from spin coated donor substrates. The ability to handle arbitrary inks is demonstrated by laser transferring an additional green fluorescing $[Ir(F_5\text{-mppy})_2(dtb\text{-bpy})]^+(PF_6^-)$ (Complex **2**) molecule from a second donor substrate. Fig. 5a shows a phosphor array printed (fluence = 1.8 J/cm^2) from 7 μm polymer-film-coated donor substrates with an average voxel diameter of 80 μm. The irregularity in green versus red voxels is explained by a change in the overall solvent/solute surface tension which alters the voxels interaction with the receiver substrate and modifies the solute transport mechanism during solvent evaporation. More uniform voxels may be achieved by independently fine tuning each solvent for the particular molecule at hand, either through the selection of a different solvent or through the judicious combination of many. Nevertheless, the direct-write nature of BA-LIFT enables high-resolution luminophore patterning, through independent motion control of the receiver substrate, without the need for additional patterning steps. High throughput for large area coverage can be readily accomplished by high-speed laser scanning, splitting single beams into multiple beams, using patterned masks [27] or

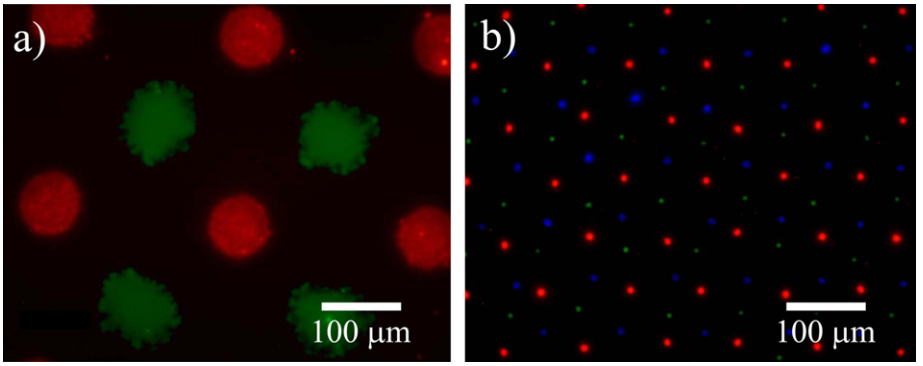

Fig. 5. (a) Fluorescent microscopy images of a typical luminophore array depicting voxel dimensions of approximately 80 μm. Ink/receiver surface tension sets the circumferential geometry. (b) Red, green, and blue voxel size is reduced to approximately 10 μm through BA-LIFT processing parameter optimization. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

using arrays of glass microspheres [28,29] to generate high-resolution patterns.

Another attractive capability of BA-LIFT is the easy miniaturization of voxel size through processing parameter optimization. As a demonstration, a thinner polymer film thickness (4 μm) and lower fluence (0.7 J/cm^2) is selected based on previous knowledge that both quantities affect voxel size [18]. These processing parameters enable us to print multi-color voxel diameters of approximately 10 μm (Fig. 5b). Here an additional blue emitting 9-anthracenemethanol molecule (Complex **3**) is laser transferred to further demonstrate the technique's ability at printing the three colors found in standard organic light-emitting diode (OLED) display technologies. Transfers are conducted in a sequential manner from three luminophore-coated donor substrates to obtain multi-color printed arrays. Since all transfers are conducted at the same fluence, the small scatter in diameter size between colors is attributed to the variation in each of the inks fluid/substrate surface tension [30]. This can be easily controlled by altering the ink properties through small additions of different solvents to the host solution or by modulating the laser energy. Deviation in voxel diameter and position for a given color is primarily affected by statistical variations in the transferred droplet size due to the detailed fluid mechanics of the transfer process [18]. Size effects can be mitigated in a number of ways, for instance, by creating isolated wells in the donor substrate prior to transfer to pre-define the volume of transferred liquid [31], whereas positioning accuracy can be improved by reducing the spacing between the donor and receiving substrates. Nevertheless, resting voxel diameters of 10 μm are an appropriate size for future organic electronic technologies, and serve as a staring point to begin the study of structure–function relationships in these iTMCs.

4. Conclusion

This work presents a novel approach to printing light-emitting diodes from organo-metallic luminophore compounds. By employing air and moisture tolerant molecules, devices are fabricated in ambient conditions using a laser-based process termed BA-LIFT. The direct-write nature of this approach enables printing of the active organo-metallic luminophore with resolution down to 10 μm, without damage and without the need for masks, molds, etching, or vacuum processes. Devices are tested and shown to exhibit electroluminescence emission, diode behavior, and lifetimes in agreement with literature results for spin-coated devices fabricated in nitrogen environments. Our laser-based approach is compatible with rapid-prototyping and large-area electronics yet at the same time, the high printing resolution opens the door to novel experiments characterizing the structure–property relations for this important class of materials.

areas and to prevent the formation of shorts during the top electrode contact soldering, the ITO layers were patterned by a photolithographical process. Four kinds of ITO/PEDOT/PF6/Al OLEDs – denoted as *A*, *B*, *C* and *D* – were manufactured employing four commercial PEDOT dispersions: Clevios™ P CH 8000 (previously known as Baytron® P 8000), a dispersion with PEDOT:PSS ratio 1:20 (w/w) for the *A* device; Clevios™ P AI 4083 (previously known as Baytron® P 4083), a dispersion with PEDOT:PSS ratio 1:6 (w/w) for the *B* device; a poly(3,4-ethylenedioxythiophene)-*block*-poly(ethylene glycol) – PEDOT–PEG – dispersion with *p*-toluenesulfonate (PTS) as dopant for the *C* device; a PEDOT–PEG dispersion with perchlorate (PC) as dopant for the *D* device. The dispersions characteristics and the deposition parameters are summarised in Table 1. For all the devices the PEDOT layer is 70 nm thick. After the PEDOT coating, the devices were completed with the same following steps: the obtained films were backed under nitrogen flow at 120 °C for 15 min and then PF6 was spun over the PEDOT layer at 1500 rpm from a 1.0% (w/w) chlorobenzene solution obtaining a thickness of 90 nm. After the deposition the samples were backed in vacuum at 50 °C for 3 h. Finally, the OLED structure was completed with a 200 nm thick Al layer deposited by thermal evaporation with a base pressure of 10^{-7} mbar. The active device area is 12.6 mm^2 and the final realized structure is shown into the inset of Fig. 1. Electrical analysis was performed by the means of a HP 4192A impedance analyzer and a Keithley 4200 semiconductor parameter analyzer under ambient condition.

3. Results and discussion

In Fig. 1 typical current density–voltage characteristics are shown; both the devices realized using PEDOT–PEG (C and D) are more conductive than those realized using PEDOT:PSS, and the most conductive one is that realized with a layer doped with perchlorate (D device). Comparing the results shown in Fig. 1 and Table 2 an anomalous behaviour can be observed: the device current increases with the anode potential barrier. In fact, as shown into the inset of Fig. 1, since the ITO work function is 4.8 eV and the PF6 HOMO level is 5.8 eV, reducing the PEDOT work function from 5.2 to 4.2 eV an increase of the PEDOT/PF6 hole barrier is awaited, with the effect of a reduction of the number of injected holes and therefore a reduction of the device current. Instead, the experimental results show an opposite behaviour suggesting the presence of other dominant phenomena into the device about the charge injection and transport. Capacitance-frequency and conductance-frequency measurements have been performed at various biases for all the devices and, as shown in Fig. 2 (for simplicity only for device A), these spectra don't vary with the applied voltage below the optical threshold. The bias independent capacitance is a known result tuned by charge phenomena, and it is well analyzed in literature [23]. In order to analyze the device in the under-threshold regime, we have performed all the admittance spectra at 0 V bias.

The spectra reported in Fig. 3 show capacitances having decreasing monotonic behaviour with low frequency unitary value of about 21 nF/cm^2 for the first three kinds of device and 48 nF/cm^2 for the D one. The Fig. 4 show the loss (L) spectra defined as

$$L = \frac{G}{\omega} \tag{1}$$

where G is the electrical conductance and ω the angular frequency of the applied signal: the devices A, B and C have one loss-peak while the D device shows two peaks. The loss-peak specifies the relaxation time constant (τ): 220 ns, 290 ns and 2.31 μs for A, B, C, respectively, while the device D has a low frequency peak with a time constant of 160 μs and a high frequency one of 140 ns. In literature [24] it is reported an experiment similar to ours where the authors study OLED devices with a similar structure, ITO/PEDOT:PSS/PF8/cathode, but with different PF8 layer thicknesses. The results of their measurements show an unexplained thickness dependence of the relaxation time. Our spectral results can be interpreted by a physical key shown in literature [25–31]: it is known that a semiconductor junction shows peaks in Loss vs. Frequency diagram when a trap distribution is at the semiconductor interface. In the case of a single energy level, Nicollian and Brews [32] proved that the device conductance and capacitance are described by the following equations

$$\frac{G}{\omega} = \frac{qD_S\omega\tau}{1+(\omega\tau)^2} \tag{2}$$

$$C_S = \frac{qD_S}{1+(\omega\tau)^2} \tag{3}$$

where C_S is the capacitance, q is the electron charge, D_S is the interface state density and τ is the time constant. For a distribution of more close energy trap levels [32], the device admittance is described by

$$\frac{G}{\omega} = \frac{qD_S}{2\omega\tau}\ln\left[1+(\omega\tau)^2\right] \tag{4}$$

$$C_S = \frac{qD_S}{\omega\tau}tan^{-1}(\omega\tau) \tag{5}$$

Table 1
Technological parameters of the PEDOT layers.

	PEDOT dispersion	Constituent ratio	Solution	Dopant	Deposition rate and time
A	PEDOT:PSS	1:20	3 wt.% in water	None	2000 rpm for 30 s
B	PEDOT:PSS	1:6	1.7 wt.% in water	None	2000 rpm for 20 s
C	PEDOT–PEG	1:1	1 wt.% in nitromethane	p-toluenesulfonate (PTS)	1000 rpm for 30 s
D	PEDOT–PEG	1:1	1 wt.% in perchlorate	Perchlorate (PC)	1000 rpm for 30 s

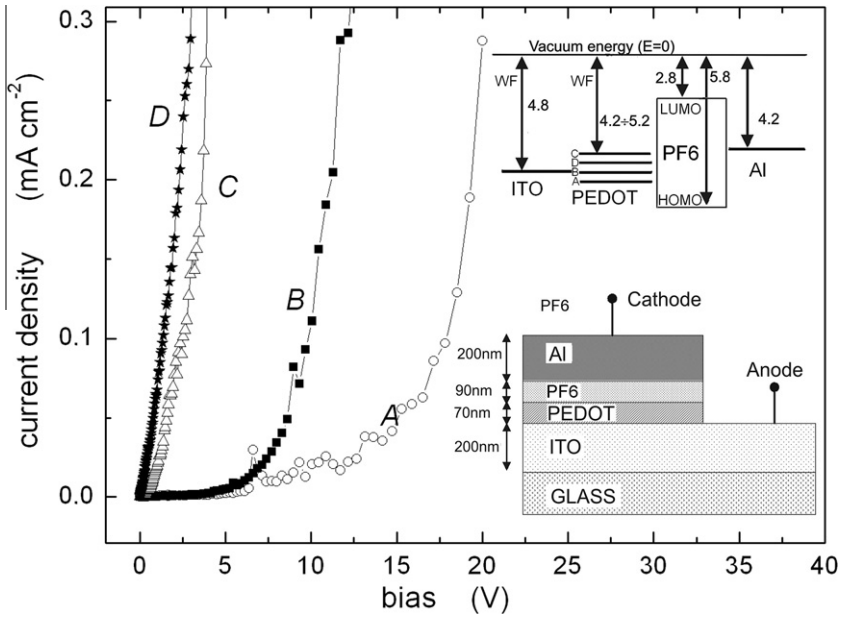

Fig. 1. Current–voltage characteristics of the polymeric OLEDs realized at different PEDOT dispersions. In the upper inset the energetic diagram of the realized samples where the PF6 HOMO and LUMO, and the ITO, PEDOT and Al work functions are drawn: the devices differ only for the kind of PEDOT dispersion with a variation in work function between 4.2 and 5.2 eV. In the lower inset the devices structure (the figure is not in scale).

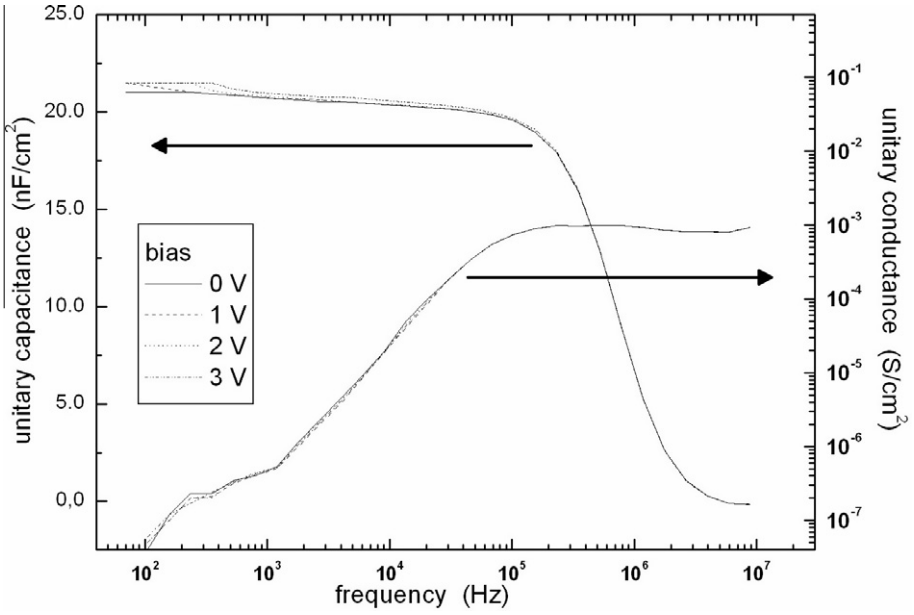

Fig. 2. Typical unitary capacitance and conductance spectra at different biases (for simplicity only the A device measurements are shown). For all A, B, C, D devices the spectra do not change with bias.

The Nicollian and Brews model was developed to study the trap effect in MOS Field Effect Transistor, but it has also been used in the analysis of the interface state distribution in MIS structure (Metal/Insulator/Semiconductor) and in particular for organic and inorganic diodes [33–36].

For each device, besides the time constant τ, we have extracted the interface state density D_S from the peaks in Fig. 4, as reported in Table 2. In Figs. 3 and 4 the continuous lines represent the Eqs. 2,3,4,5, drawn using the experimental estimation of D_S and τ. As it can be seen, a good agreement between the experimental data and the single energy level model (Eqs. 2 and 3) is obtained for the devices A, B, C and the high frequency peak of D (denoted with *c* in Figs. 3 and 4). The low frequency peak of device

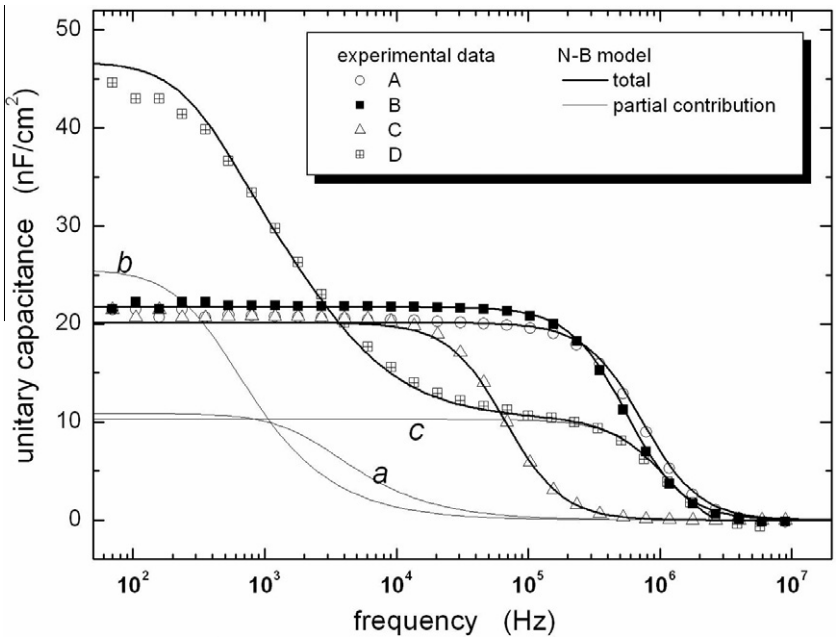

Fig. 3. Unitary capacitance spectra of the polymeric OLEDs. Decays with single time constant are visible in the figure for the A, B, C devices while a decay with a double time constant is evident for the D device.

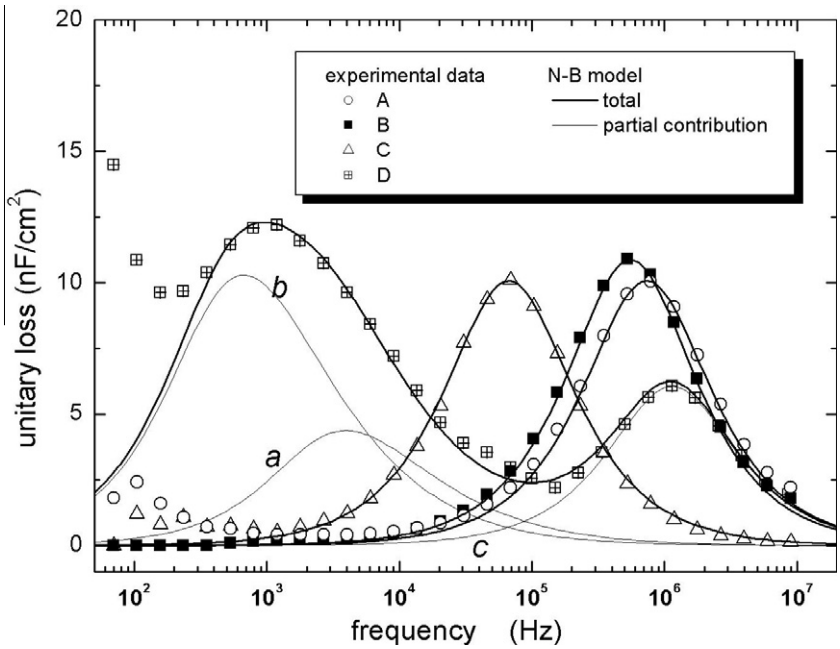

Fig. 4. Unitary loss spectra (G/ω) of the devices. A single peak spectra are visible in the figure for A, B, C devices while a double peak spectrum is evident for the D device.

D results to be the sum of two multiple-level distributions (denoted with *a* and *b* in Figs. 3 and 4) modelled by Eqs. 4, 5. The results confirm the model applicability in our case. Because the devices vary exclusively for the kind of PEDOT, the differences in admittance measurements are only imputable to this layer: in other words, the found variability between the four interface trap distributions is only ascribable to the four different PEDOT dispersions. As proposed in [41], the curves shown in Fig. 4 can be interpreted also as the effect of both interface and bulk trap distributions: in fact the low frequency peak can be ascribed to interface phenomena while the high frequency one is

usually due to bulk traps. Considering the Brunson interpretation [41] only in *D* device the bulk traps have a prominent effect. However, as pointed out by Lang [42], the capacitance measurements experience mainly the interface states, being their spatial sensitivity higher at the interface and decreasing towards bulk material [25].

As indicated above, A and B devices differ only for the PEDOT:PSS ratio determining two similar interface state distributions. The C device differs from the D only for the dopant (both are PEDOT–PEG block-copolymers), resulting in different defect state distribution; the time constant of the C device is similar to those of the A and B ones, while, for the D device, the higher frequency time constant is lower than those of the A and B devices, the two lower frequency time constants cannot be compared the other ones. As described in [25,26] the relaxation time τ can be described by the following energetic law (Arrhenius)

$$\omega_R = \frac{1}{\tau} = A_t e^{-\Delta E/k_B T} \tag{6}$$

where A_t is a material constant, ΔE is the energy deep of the state respect the band edge, k_B is the Boltzmann constant and T the absolute temperature. The hole anode barrier φ_i (for the *i*-device) can be indicated respect to one of the four kinds of device. Choosing A device as reference, we can write

$$\varphi_i = \varphi_A + \Delta\varphi_i \tag{7}$$

The total current density in every point of the device is constant. The current density at the PEDOT/PF6 junction, neglecting the electron current, can be written as the product between the holes concentration (p) and the probability of the barrier crossing (Boltzmann law), obtaining

$$J(V_{app}) = Kqp\mu_{PEDOT_i} e^{\gamma V_{app}} e^{\beta\varphi_i} = K\sigma_{PEDOT_i} e^{\gamma V_{app}} e^{\beta\varphi_i} \tag{8}$$

similar to the classical p–n junction equation. The constant K collects all the effects not ascribable to the PEDOT, μ_{PEDOT_i} is the hole mobility of the PEDOT layer, V_{app} is the applied bias, γ and β are the exponential factors related to the anode hole barrier, considered independent from the particular kind of device and finally, σ_{PEDOT_i} is the bulk conductivity of the *i* PEDOT layer.

In order to remove the effect of the PEDOT conductivity, we can divide Eq. 8 for σ_{PEDOTi}

$$\frac{J(V_{app})}{\sigma_{PEDOT_i}} = Ke^{\gamma V_{app}} e^{\beta\varphi_i} \tag{9}$$

obtaining the curves J/σ shown in Fig. 5 as function of the hole anode barrier variation $\Delta\varphi_i$ (respect to the A device) at various biases. This values follow linear behaviours for many bias voltages in a semi-log plot (except for C device which values are out of liner trend): this result suggests that the exponential dependence (at fixed temperature) on φ_i described in Eq. 8 is verified. Moreover, the slopes in Fig. 5 are different for each bias value: this result suggests that the β factor is bias dependent, but the purpose of this work is only to point out that the experimental points of Fig. 5 follows linear trends. In order to explain why the values extracted from the current–voltage characteristic of the C device do not follow the behaviour predict by Eq. 8 or Eq. 9, other phenomena have to be taken into account. The exception of the *C* device can be justified considering the different trap time constants and in particular the lower τ of the device (dominant τ). As described in [25,26] the time constant is related to the carrier capture rate c_c

$$\tau = \frac{2\pi}{c_c} \tag{10}$$

When the applied signal frequency ω is less than $1/\tau$, the traps can follow the voltage variations by the means of the emission and capture processes. Instead, for $\omega > 1/\tau$, only the untrapped charge can respond to the voltage variations giving rise to a decrement of the device capacitance and the slope of the conductance. This implies that the maximum of the normalized conductance (loss) is at $\omega = 1/\tau$, in other words at the resonance pulsation of the trapping phenomenon. From Eqs. 6 and 10 the increment of τ gives rise to a decrement of the capture rate resulting in a higher fraction of untrapped carriers available for the conduction. From Table 2, the devices A, B and D show a similar dominant τ ($140 \div 290$ ns) and so they have trap distributions with similar energetic depth. Instead the C device shows a greater dominant τ (2.31 μs), then a deeper trap distribution (a higher energy gap), that allows an higher fraction of carriers available for the conduction, for this reason the J/σ values for the device C are higher then for the other devices. The plot of Fig. 5 help us to understand also the previous reported anomaly about the current increment with the hole anode barrier (see Fig. 1 and Table 2): in fact, in Fig. 5 we can see how the current density normalized through the conductivity decreases increasing the anode hole barrier, as expected. Considering Fig. 1, where the current–voltage characterises are reported, we have to take account of the effects of the different PEDOT conductivities that have a fundamental role in the device electrical behaviour.

Table 2
Electrical and energetical properties of the PEDOT layers and interfaces.

Device/ distribution	Energy distribution	PEDOT work function (eV)	PEDOT conductivity σ $(\Omega\,\mathrm{cm})^{-1}$	State density D_S $(\mathrm{eV}^{-1}\,\mathrm{cm}^2) \times 10^{11}$	Time constant τ $(\mathrm{s}) \times 10^{-6}$
A	Single level	5.15 [20]	5×10^{-6} [40]	1.26	0.22
B	Single level	4.85 [20]	2×10^{-4} [37]	1.36	0.29
C	Single level	4.19 [38]	1×10^{-3} [39]	1.26	2.31
D (a)	Multiple levels	4.33 [38]	0.4 [39]	0.68	80.4
D (b)	Multiple levels			1.62	4.71
D (c)	Single level			0.76	0.14

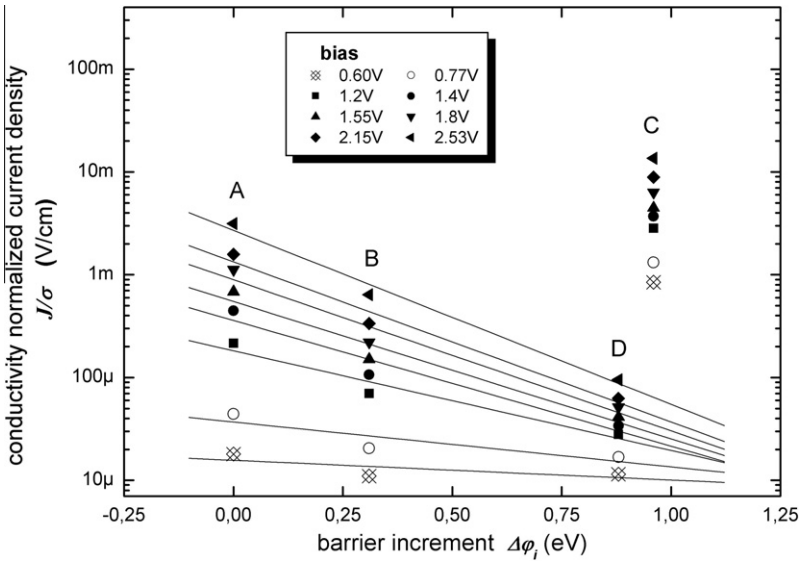

Fig. 5. Normalized current densities (J/ω) as function of the anode hole barrier increment (respect to the PEDOT work function of the A device) at different voltage biases. Only the C device does not follow the linear trend in the semi-log plot.

4. Conclusions

The analysis of polymeric OLEDs varying only for the kind of PEDOT dispersion has allowed to ascribe the variations of the admittance spectra to the effects of interface trap distribution: a good agreement between the experimental data and the Nicollian–Brews model has been found. The exponential dependence of the current on the hole barrier height has been verified only for three kinds of devices; the exception of the fourth has been explained in terms of trapping rate that tunes the increment of the number of carriers available for the conduction. The study of the normalized current has allow to evidence the importance of the PEDOT conductivity of the layer, often forgotten to advantage of consideration about the energetic levels of the layers work functions.

an independent colour conversion layer on top of the transistor. The colour conversion is achieved by the mixture of the transmitted light from the transistor channel and the reemitted light after photoexcitation from the conversion layer at longer wavelength due to a material specific Stokes shift. Since the colour conversion layer is deposited subsequently onto the completed transistor, the electrical properties of the transistor are not altered. The semiconductor and the conversion layer do not need to match electronically and thus, an optimized ambipolar transistor setup with an efficient bipolar and light emitting material can be chosen without risking a destructive interaction with the colour conversion layer.

2. Experimental section

We used a bottom-contact top-gate ambipolar transistor with F8BT (poly(9,9-di-*n*-octyl-fluorene-alt-benzothiadiazole)) as bipolar semiconductor, PMMA (poly (methylmethacrylate)) as gate insulator and Au as source and drain metal. This OLET was first introduced by Zaumseil et al. [4] and emits efficiently in the green region of the visible spectrum with an external quantum efficiency of up to 0.85% [9]. On float glass 50 nm thick Au source and drain contacts were deposited via physical vapour deposition (PVD) at a base pressure of 2×10^{-7} mbar. Subsequently, F8BT and PMMA were spin cast from toluene and butyl acetate solution, respectively. The semiconductor and PMMA layers were dried for 15 min at 280 and 110 °C, respectively, resulting in 50 and 430 nm thick layers. Finally, a semitransparent 15 nm thick Au gate was deposited on the PMMA layer. An approximately 350 nm thick rubrene colour conversion layer was evaporated on the gate. Utilizing a parallax technique [10], a conversion layer that covered the transistor channel only partially was obtained. Rubrene was deposited at a base pressure of $<10^{-6}$ mbar and a deposition rate of about 1 Å s^{-1} at room temperature. Fig. 1d points out the evaporation process using the displacement between substrate and material source.

The transistors were electrically characterised by a HP4155A semiconductor parameter analyzer in nitrogen atmosphere, the emitted light was measured by a calibrated photodiode S1227-1010BR from Hamamatsu. The electroluminescence spectra were recorded in parallel with a PI-MAX ICCD camera from Roper Scientific and an Acton 2300i monochromator. The absorption and photoluminescence measurements were carried out with a Lambda 900 spectrometer (Perkin Elmar) and a Cary Eclipse spectrometer (Varian), respectively. The layer topographies were measured with a Profilometer Dektak IIA from VECCO.

3. Results and discussion

In Fig. 1a the drain current I_{Drain} and the corresponding electroluminescence (EL) intensity versus gate bias V_{Gate} demonstrate the ambipolar character of the F8BT transistor, whereby the electron and hole mobility were measured to be 1.2×10^{-4} and 4.8×10^{-4} $cm^2 V^{-1} s^{-1}$,

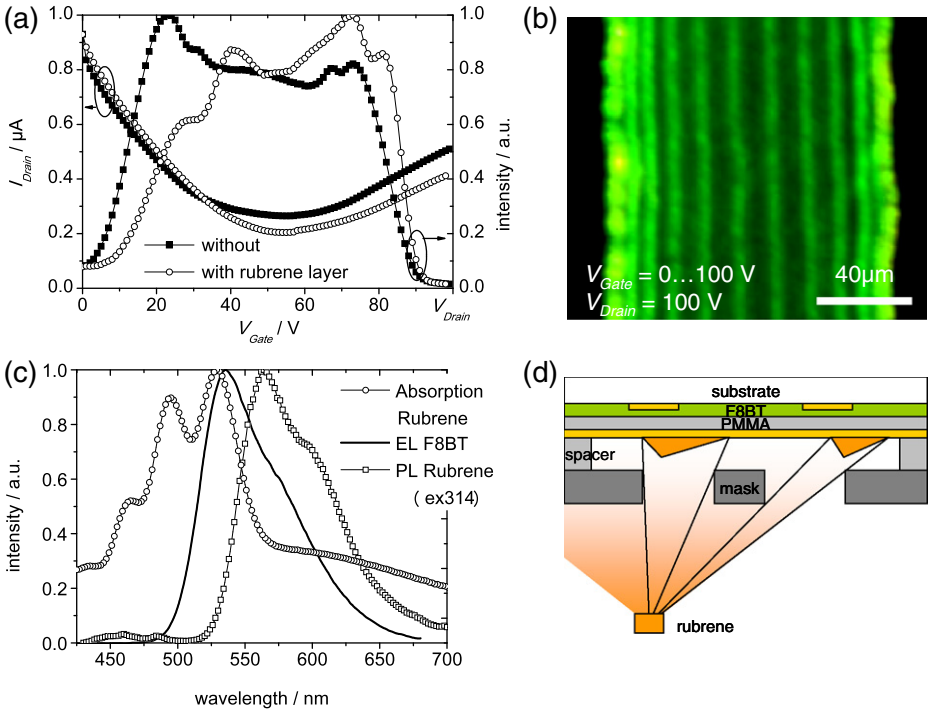

Fig. 1. (a) I_{Drain} and electroluminescence intensity versus V_{Gate} of a F8BT transistor without and with rubrene layer covering half of the channel. (b) Micrograph of the channel of a pure F8BT transistor at gate voltage increased from 0 to 100 V in 5 V steps and at V_{Drain} = 100 V. The micrograph is taken with long exposure time. (c) Normalized absorption and photoluminescence spectrum (excitation wavelength 314 nm) of rubrene and the electroluminescence spectrum of F8BT and (d) principle of rubrene deposition utilizing parallactic displacement.

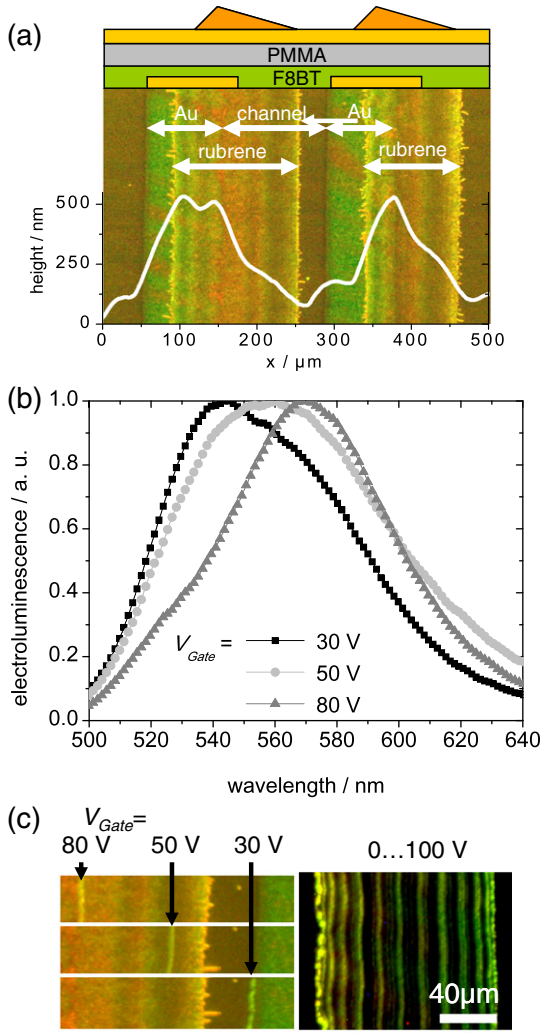

Fig. 2. (a) Setup of the F8BT/rubrene transistor and micrograph of the transistor with profile. (b) Electroluminescence spectra of a F8BT/rubrene transistor at different gate voltages at V_{Drain} = 100 V. (c) Respective micrographs of the transistor channel at different gate voltages V_{Drain} = 100 V. The position of the emission region appears as bright but narrow vertical strip in the transistor channel highlighted by the arrows. Micrograph of the channel at gate voltage increased from 0 to 100 V in 5 V steps and at V_{Drain} = 100 V. The micrograph is taken with long exposure time.

respectively. The photograph in Fig. 1b displays an EL map at increasing V_{Gate} in 5 V steps at constant source-drain voltage V_{Drain} of 100 V. The position of charge carrier recombination x_R within the transistor channel can be changed by V_{Gate} in the ambipolar regime [3,4,11]. The green emitted light has a maximum at 535 nm as shown by the EL spectrum in Fig. 1c and exhibits CIE coordinates (calculated for a 2° standard observer) of x = 0.394 and y = 0.565. The external electroluminescence quantum efficiency (EQE) was estimated to 0.56% being in the same range as reported by Zaumseil et al. [4]. To estimate the EQE we did not introduce any corrections related to the device geometry, but calculated the efficiency directly as the ratio between the emitted photons per time and the flowing charge per time given by the drain current. The emitted photons per time are proportional to the current of the calibrated photo diode and the proportionality factor is determined by the emission spectrum and the wavelength dependent sensitivity of the calibrated photodiode. To achieve a colour shift of the emitted light, rubrene often used as single-crystalline semiconductor in organic transistors [12] was evaporated on the semitransparent top-gate contact of the F8BT transistor. Fig. 1c shows that the absorption spectrum of an amorphous rubrene layer prepared by PVD matches the emission spectrum of F8BT. Thus the emitted light from F8BT can be used to excite the rubrene layer. The photoluminescence spectrum of rubrene, excited at 314 nm, is also displayed in Fig. 1c. The photoluminescence maximum is located at 565 nm in the yellow range of the visible spectrum and hence, a colour change can be expected once the rubrene layer is excited via the F8BT emission.

To realize a voltage dependent colour change the rubrene layer is supposed to cover only a part of the channel region of the F8BT transistor. Fig. 2a shows a micrograph of the transistor channel comprising the confined rubrene layer covering only half of the channel. Thus depending on the position of charge carrier recombination, emission occurs either underneath the rubrene layer or at regions of undisturbed light extraction path.

Fig. 1a proves that the transfer characteristic and the EL intensity versus V_{Gate} dependence of the F8BT/rubrene transistor compares to a transistor without rubrene layer. This demonstrates the advantage of the selected colour conversion concept leaving electrical properties of the transistor unchanged.

To investigate the impact of x_R on the emission colour, V_{Gate} was set to 30, 50 and 80 V at V_{Drain} of 100 V and the EL spectra were recorded. The normalized spectra are displayed in Fig. 2b and the respective micrographs of the channel region are depicted in Fig. 2c. At V_{Gate} = 30 V a green light emission with a peak emission at 540 nm is observed from a narrow recombination zone positioned in a channel region where no rubrene layer exists. In the contrary, the micrograph at V_{Gate} = 50 V shows the charge carrier recombination under the additional rubrene layer. The respective spectrum in Fig. 2b has a maximum at about 560 nm, 20 nm shifted to the red range compared to the pure F8BT spectrum. This shift is based on a partial wavelength conversion by rubrene. In Fig. 2a the transistor cross section along the transistor channel shows that the rubrene strip does not have a constant thickness but a decreased thickness towards the centre of the transistor channel. At V_{Gate} = 50 V the position of charge carrier recombination is located at the edge of the rubrene strip and therefore, the colour change is weak. At V_{Gate} = 80 V the emission zone reaches the region where the rubrene layer has its full thickness of 350 nm being thick enough for a full colour conversion as the yellow emission colour of the recombination zone in the micrographs of Fig. 2c already indicates. The maximum of the respective spectra in Fig. 2b is with 570 nm indeed close to the maximum of the photoluminescence spectra of pure rubrene films leading to a change of the emission wavelength maximum of about 30 nm. The bias controlled colour switch changes the CIE

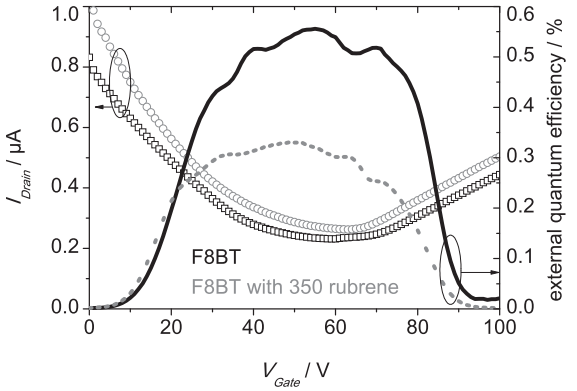

Fig. 3. Transfer characteristic and efficiency of a pure F8BT transistor and a F8BT transistor with 350 nm rubrene deposited across the entire channel.

coordinates from $x = 0.384$, $y = 0.590$ at $V_{Gate} = 30$ V to $x = 0.450$, $y = 0.537$ at $V_{Gate} = 80$ V. This colour shift is summarized in Fig. 2c where a micrograph is depicted which was taken at long exposure times while at constant $V_{Drain} = 100$ V V_{Gate} was increased stepwise. The EQE of a transistor including a rubrene layer over the entire channel reached 0.33%. Fig. 3 shows the transfer characteristic and the respective EQE for a pure F8BT transistor and a F8BT transistor with an additional rubrene layer covering the whole channel, whereby the EQE shows constant values in the ambipolar window. Even though the EQE was reduced by losses during the absorption-reemission process in rubrene 59% of the EQE of the pure F8BT transistor was obtained after all which demonstrates that the spatial separation of the colour conversion layer from the transistor conserves the good device performance of the employed OLET.

4. Summary

In summary, we demonstrated an ambipolar OLET with colour-tuneable light emission. The emission colour is controlled by the position of the recombination zone within the transistor channel and achieved by colour conversion in a layer on top of the transistor covering partially the transistor channel. The advantage of the employed concept can be seen in the decoupling of electronic processes of the OLET from the colour conversion in the optical active organic layer. This appears to be crucial, since the fragile balance of complementary charge carrier injection and transport should not be disturbed by the conversion process in order to retain full control over the emission position along the transistor channel.

it is important to analyze the movement of the molecules inside a droplet during drying. We set up a system to collect images of the movement of the particles inside a droplet using a CCD camera and laser beam [15]. A droplet containing fluorescence particles with 1 μm diameter was dropped onto a glass substrate, and then images of the flow of the particles were taken at 10 shots per second to analyze the velocity vector of the movement of the particles. The measurement was carried out on a droplet dried in air and also under the influence of Ar gas which was injected toward the droplet in order to change the movement of the particles. The velocity vectors within the droplet subjected to Ar gas injection were compared with those within the droplet dried in air in order to analyze the effects of Ar gas on particle movement. The solution comprising the droplet was pure water with a volume of 1.8 μl and the diameter of the droplet was 1.98 mm.

The OTFTS employed a bottom contact structure whose source and drain electrodes were located below the semiconductor layer as shown in Fig. 1. The fabrication process was as follows. An aluminum layer with 1000 Å thickness was evaporated on a glass substrate and patterned by photolithography for gate electrodes. Polyvinylphenol (PVP) was spin coated on the gate electrode to deposit a gate dielectric layer. The detailed process for the PVP layer can be found in the literature [16,17]. Subsequently, for the source and drain (S/D) electrodes, Au was evaporated on the PVP layer and patterned by a lift-off process. Finally, the TIPS-pentacene solution was jetted onto the S/D electrodes by an ink jet. Three types of OTFTs were fabricated and were dried in different environments. The first group of OTFTs was dried in air (air-OTFT), and the other OTFTs were dried in a quartz tube under the influence of Ar gas injection as described below. The second group of OTFTs was dried under Ar gas whose injection direction was parallel to the current flow between the S/D electrodes (par-OTFT). The third group of OTFTs was subjected to Ar gas injection perpendicular to the current (per-OTFT). The effects of Ar gas injection were analyzed by comparing the morphology of the grains and the performance of the OTFTs.

The OTFTs with ink-jetted TIPS-pentacene droplets were placed in a quartz tube with a diameter of 10 cm as shown in Fig. 1. Ar gas was then injected into the quartz tube in order to alter the movement of the molecules and also to push back the front contact line, which directly faces the Ar gas, of the droplet, and thus obtain grains with

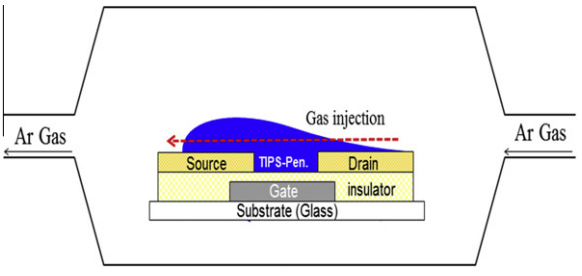

Fig. 1. The structure of OTFTs using TIPS-pentacene semiconductor droplet which was dried under Ar gas injection in a quartz tube.

uniform thickness and morphology. The droplet of TIPS-pentacene was comprised of 2 wt.% of TIPS-pentacene mixed with anisole solvent. The flow rate of the Ar gas was adjusted to be laminar. However, turbulence reflected from the quartz wall could not be avoided near the wall, and consequently some devices near the wall did not reflect the influence of the Ar gas injection. The flow rate was varied from 300 to 1000 sccm to examine the effects of the flow rate on the morphology of TIPS-pentacene grains.

The morphology of the grains was analyzed via a microscope, 3D profiler, AFM, and XRD. The electrical characteristics of the OTFTs were measured by a Kithley 4200.

3. Results and discussion

The movement of particles in a droplet on a glass substrate heated at 30 °C was analyzed during drying in air. Since the contact point P is pinned on the hydrophilic substrate, a convective flow of solvent from the center surface to the contact point was generated as shown in Fig. 2 in order to provide a certain volume of solvent to the contact point, which was necessary to keep the contact point pinned. Thus, the molecules in the droplet also moved together with the solvent convective flow and accumulated at the contact point resulting in a so-called "coffee stain". Therefore, the final crystal of the TIPS-pentacene droplet, which was dried in air, typically had a thick coffee stain at the contact point and thin grains in the middle area with a random size and shape and location as shown in the inset of Fig. 2.

When Ar gas was injected into the droplet as shown in Figs. 1 and 3, the solvent flow changed to move from the contact point to the center surface inversely as shown in Fig. 3. Furthermore, the contact point itself also moved back along the gas direction instead of being pinned while it dried because the solvent near the front contact point was compulsorily dried by the Ar gas injection.

The velocity vectors of the solvent flow were obtained by taking the images of the particle movement at 10 shots per second and then calculating the particle velocity with the PIV (Particle Image Velocimetry) method. As the gas flow rate was varied from 300 to 500 to 1000 sccm, the velocity increased from 0.41 to 0.68 to 1.41 mm/s, respectively. It was clearly seen that the particles on the droplet surface moved backward from the front contact line to the back contact line as shown in Fig. 3.

Depending on the Ar gas flow rate, the shape and the morphology of the crystal grains changed. At 1000 sccm it was clearly seen that the crystal grains grew along the direction of the gas injection as shown in Fig. 4c. Meanwhile, at 300 sccm there was no clear correlation between the grain morphology and the gas flow direction as shown in Fig. 4a. The correlation started to appear at 500 sccm as shown in Fig. 4b. The correlation was maximized at 1000 sccm where slender and longish grains started to grow at the front contact line and elongated up to the back contact line of the droplet. As the flow rate was increased, the length of the grain increased while the width decreased.

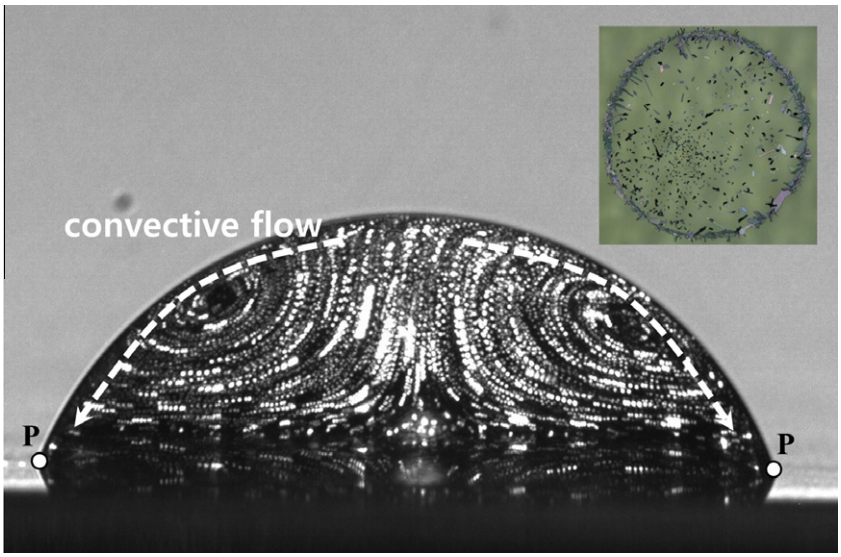

Fig. 2. Convective movement of fluorescent particles inside a water droplet during drying in air; P represents the contact point of the droplet with the substrate, and this point was pinned during drying; the inset show crystals of TIPS-pentacene dried in air where a large coffee stain is formed on the contact line and the small crystals are randomly distributed in the middle region.

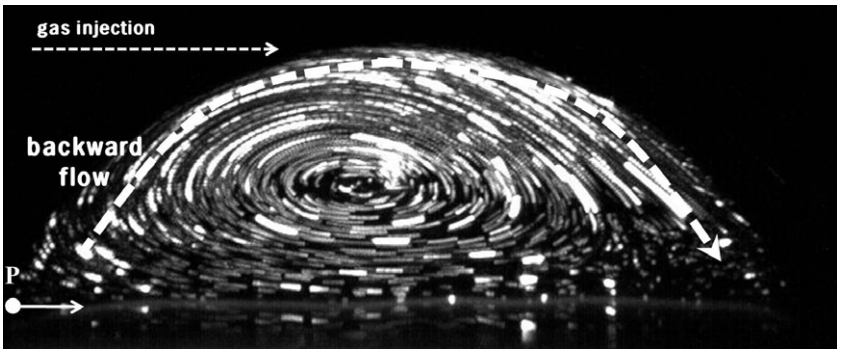

Fig. 3. Due to Ar gas injection the convective flow was perturbed and thus the particles moved backward from the front contact point to the back contact point. Additionally, at an appropriate Ar gas injection rate the contact point P itself moved along the direction of gas injection during drying.

At a small flow rate the backward flow created by the gas was not sufficient to perturb the ordinary convective flow, and the final grains were consequently similar to those without the gas flow. A large flow, such as 1000 sccm, generated a strong backward flow, causing the grains to grow along the direction of the backward flow. Additionally, the front contact line also moved backward toward the back contact line, and the grains grew along the movement of the front contact line. Above 1000 sccm, crystals did not form because of the very strong perturbation.

This gas effect was also found in the uniformity of grain thickness. The thickness was relatively uniform all over the crystal in a range of 90–110 nm at 1000 sccm as shown in Fig. 5c. The surface roughness was also very small, at 1.2 nm. However, at 300 sccm and at 500 sccm the thickness varied extensively in the range of 120–190 nm and 110–150 nm, respectively, and the surface roughness was 6.3 nm at 300 sccm and 7.5 nm at 500 sccm as shown in Fig. 5a and b.

A coffee stain was created for all gas flow rates because the droplets were dropped before being placed into the quartz tube, and thus the grains started to grow before the Ar gas was injected. Due to the backward flow the coffee stain at the back contact line was larger than that at the front. If we can develop a way to apply Ar gas simultaneously to dropping the droplet, crystal grains without coffee stain could be obtained.

In the XRD data the signature peak of the pentacene crystal at $2\theta = 5.7^\circ$ was also stronger for 1000 sccm than for 300 sccm or 500 sccm as shown in insets of Fig. 5, reflecting a strong crystallinity for 1000 sccm.

By comparing the enlarged crystal grains produced at 1000 sccm in the inset of Fig. 4c with the schematic of TIPS-pentacene crystal planes of the referenced article [9] the crystal grains appear to grow in the direction of (1 2 0). Several 1000 μm long grains with a few 100 μm narrow width grains were found oriented toward (1 2 0).

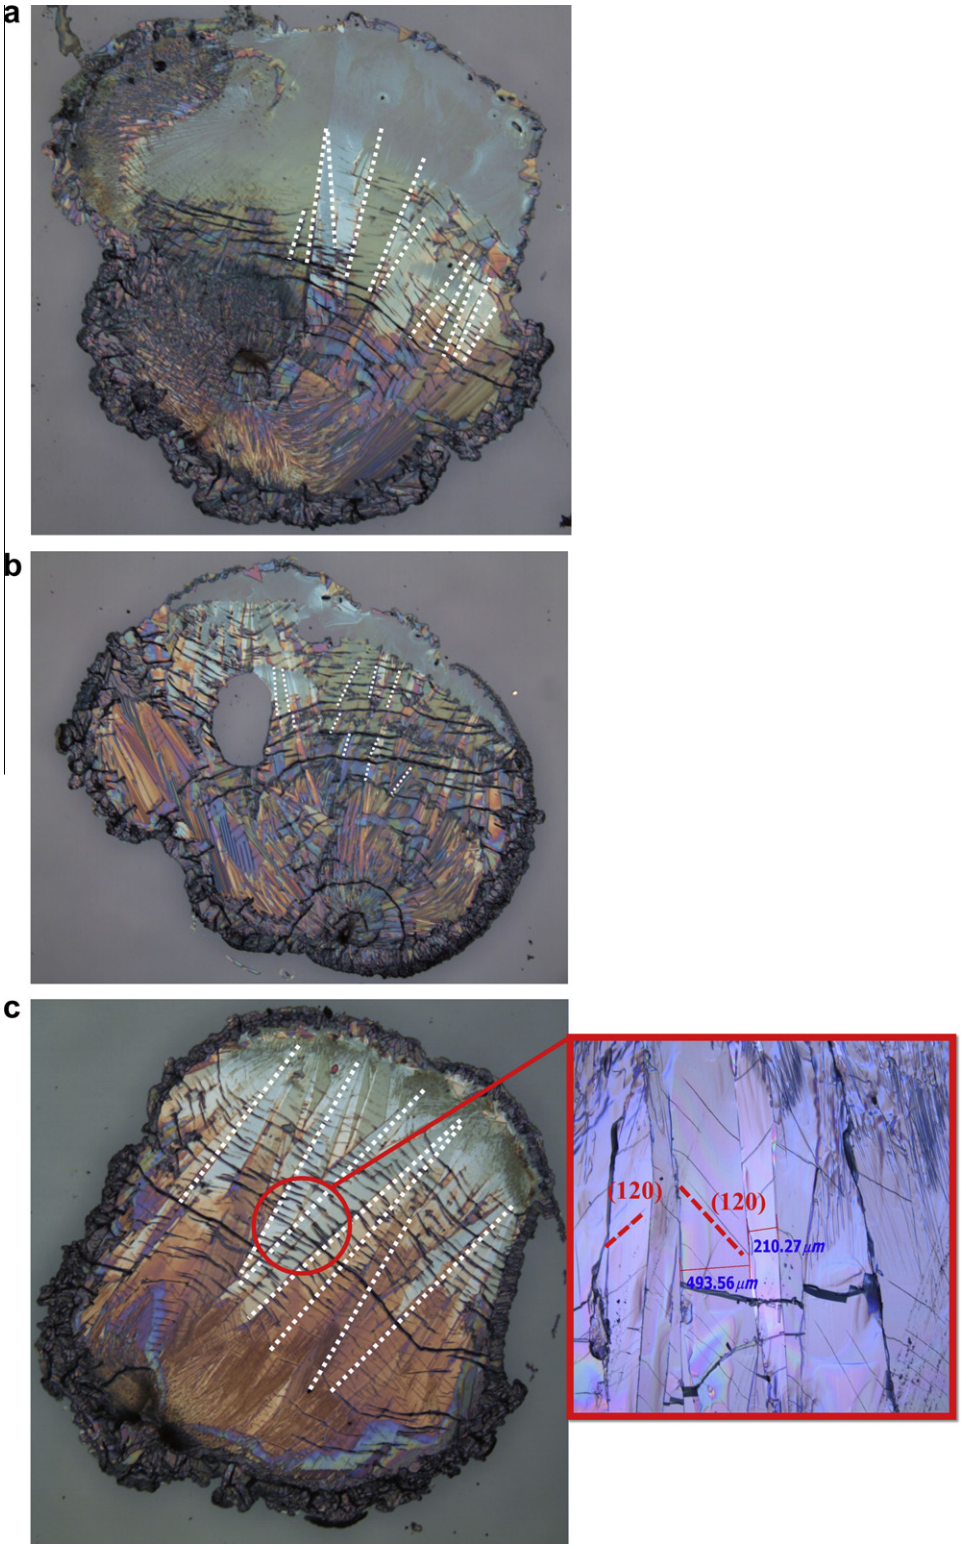

Fig. 4. Depending on the Ar gas flow rate the shape of TIPS-pentacene grains on the PVP dielectric layer was changed, (a) at 300 sccm the shape did not show a clear correlation with the flow rate, (b) at 500 sccm the correlation started to appear, (c) at 1000 sccm the grains became slender and longish along the direction of Ar gas injection.

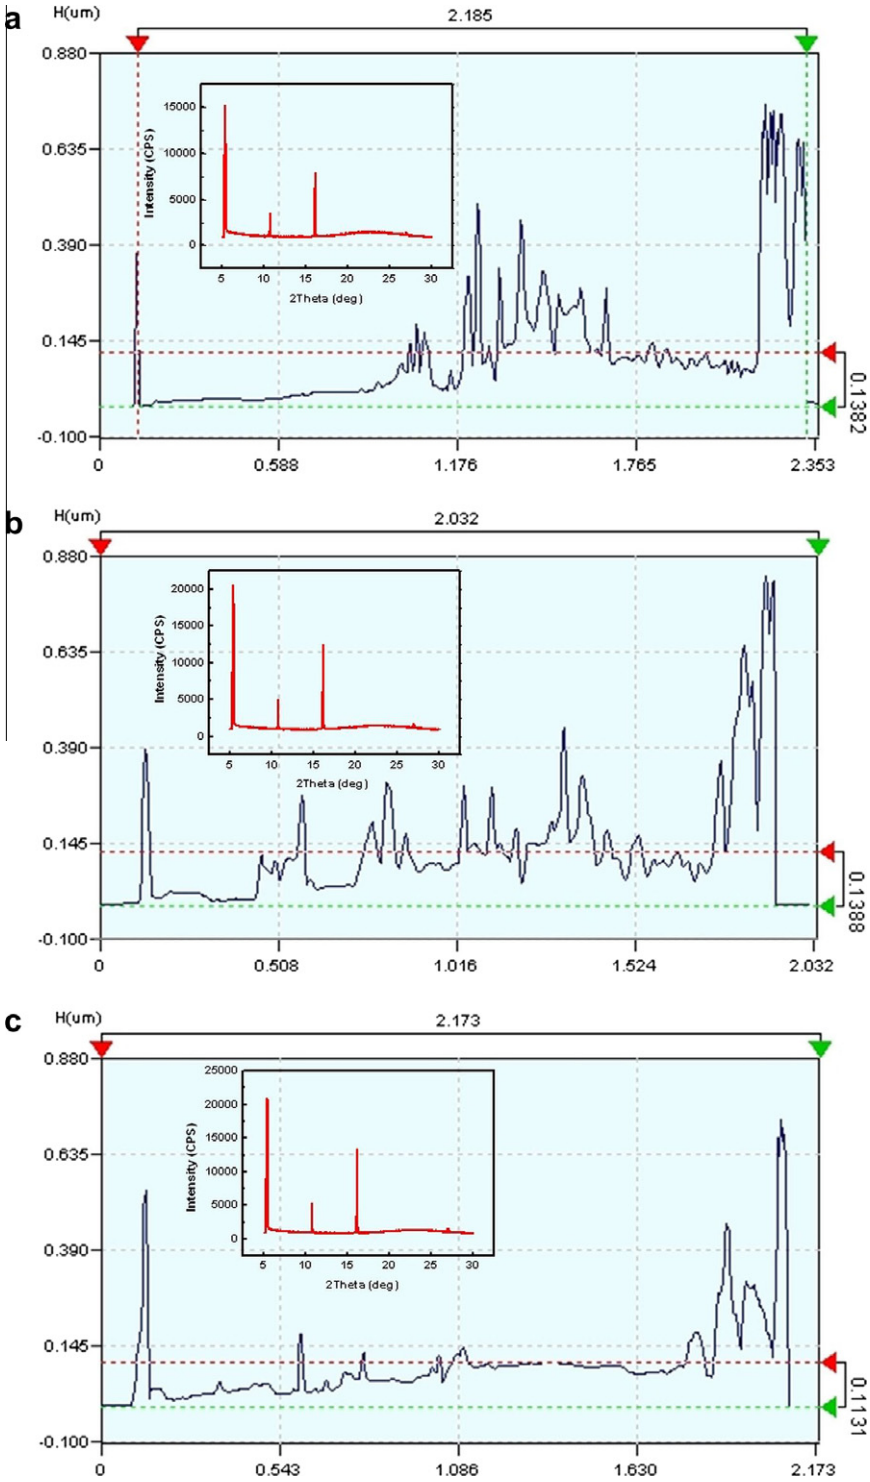

Fig. 5. Depending on the Ar gas flow rate the thickness of the TIPS-pentacene grains changed, (a) at 300 sccm the thickness was not uniform and the surface roughness was also quite large, (b) at 500 sccm the thickness became relatively uniform but the surface was still rough, (c) at 1000 sccm the best results were exhibited in terms of thickness uniformity and surface roughness; the enlarged grain of TIPS-pentacene clearly exhibited crystal direction of (1 2 0).

To investigate the effects of the direction of Ar gas injection on electrical performance, three types of OTFTs were prepared. Microscope pictures of the channel area of the OTFTs are presented in Fig. 6. In the air-OTFTs the grains have random size and shape. The par-OTFTs display grain boundaries parallel to the Ar gas direction and thus parallel

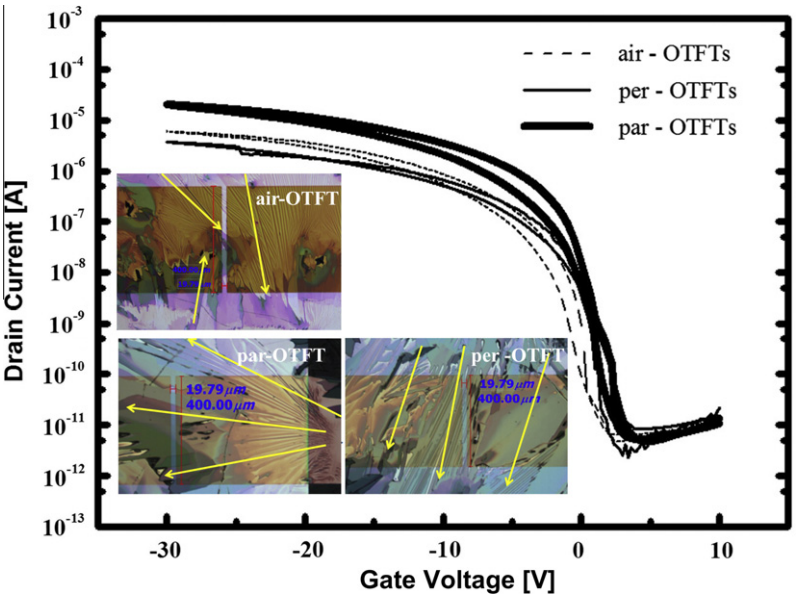

Fig. 6. The transfer characteristics of three type of OTFTs, air-OTFTs, per-OTFTs, and per-OTFTs; the insets show microscope images of the channel area of the OTFTs.

Table 1
The performance parameters of three types of OTFTs using TIPS-pentacene as a semiconductor dried under different environments.

Device type	Channel (W/L)	Mobility (cm^2/V s)	I_{on}/I_{off}	V_{th} (V)	SS (V/dec)	Off state current (pA/μm)
Air-OTFTs	400/20	0.12 ± 0.05	2.23×10^5	−0.8	0.5	0.016
Par OTFTs	400/20	0.53 ± 0.02	4.45×10^6	0.97	0.6	0.011
Per-OTFTs	400/20	0.06 ± 0.02	1.34×10^6	1.03	1.0	0.007

to the current direction. The per-OTFTs produced grain boundaries perpendicular to the gas direction as well as to the current flow.

The electrical characteristics strongly depended on the direction of the grain boundaries as shown in Fig. 6. The performance parameters were averaged from 36 devices of each type of OTFT, and are presented in Table 1. The par-OTFTs produced the largest mobility among the devices; 0.53 ± 0.02 cm^2/V s with the smallest standard deviation less than 10%, while the per-OTFTs exhibited the smallest mobility at 0.06 ± 0.02 cm^2/V s, and the air-OTFTs lied between them with 0.12 ± 0.05 cm^2/V s and a large deviation of 42%. These results clearly present the relationship of performance with the grain boundary direction. The parallel grains of par-OTFTs easily directed the current along the grain direction because the grain boundaries were located parallel to the current and thus rarely interrupted the current flow. However, in the per-OTFTs, the grain boundaries vertically directed to the current appeared to severely block the current flow. In the air-OTFTs, the above two effects appeared together and thus produced the intermediate performance. The off-state current also exhibited similar results: the smallest was obtained for the per-OTFTs, with a value of 0.007 pA/μm, while a value of 0.016 pA/μm was derived for the air-OTFTs, and the largest value, 0.011 pA/μm, was obtained for the par-OTFTs. Meanwhile the on-state current at $V_{GS} = -30$ V was the largest for the par-OTFTs, with a value of 20.5 μA, and the smallest for the per-OTFTs, with a value of 3.7 μA, thus reflecting the same gas direction effect as described above.

4. Conclusion

In this study Ar gas was injected to the droplets of TIPS-pentacene of OTFTs while drying the droplets in a quartz tube in order to change the flow of the molecules inside the droplet and also move backward the front contact line which faced the Ar gas during drying. As a result, we could control the morphology and the growth direction of the grain boundaries and thus improve the performance of the TIP-pentacene OTFTs. The OTFTs with the growth direction of grain boundaries parallel to the current flow between the source and drain electrodes displayed the best results with mobility of 0.53 ± 0.02 cm^2/V s, as compared to 0.06 ± 0.02 cm^2/V s for the OTFTs where the grain boundaries were perpendicular to the current flow.

2. Experimental

2.1. Buckling fabrication

The fabrication process of buckling and OLED devices was almost the same as in our previous studies [12,13]. Standard commercial PDMS materials (Wacker ELASTOSIL RT 601) were spincoated and cured at 100 °C for 1 h on glass substrates. 5-, 10-, 15- and 20-nm-thick Al layers were deposited on PDMS by thermal evaporation without external heating. After cooling to ambient temperature, the difference in thermal expansion coefficients between the Al film and PDMS generates a buckling structure [9–11]. For shorter periodicity of buckles, the UVO treatment was conducted on the cured PDMS before a 10-nm-thick Al layer. Finally, the buckled PDMS templates with the peak wavelengths (periodicities) ranging from 300 to 800 nm were fabricated. PDMS replicas were replicated by pouring and curing the PDMS materials at 60 °C for 2 h.

2.2. Device fabrication and measurement

For the fabrication of devices with gratings of different periodicities, glass substrates were coated with UV curable resin (Norland Optical Adhesive 81) by spincoating. After curing by UV irradiation for 10 min, a drop of resin was placed on the resin-coated substrates. Then the buckling patterns of the PDMS replicas with various periodicities were transferred to UV-curable resin layers by imprinting technique. After UV curing of the resin layers for 10 min, each buckled resin layer was produced on the glass substrates. After UV/ozone treatment on the cured resin layers for 5 min, a 120-nm-thick ITO anode layer was formed by DC sputtering at room temperature. The following layers were then thermally evaporated on the ITO-coated substrate: 40-nm-thick TPD (*N*,*N*′-bis(3-methylphenyl)-*N*,*N*′-diphenylbenzidine) layer for hole transport, 30-nm-thick Alq_3 (tris-(8-hydroxyquinoline) aluminium) layer for light emission and electron transport, 1.5-nm-thick LiF layer for electron injection, and 100-nm-thick Al cathode layer. The devices with the emitting area of 3 mm × 3 mm were encapsulated with glass and UV curable resin in a glove box under Ar atmosphere.

Electroluminescence (EL) spectra were recorded with a source meter (Keithley 2400) and a spectrometer (Ocean Optics USB 2000). The angular emission patterns were measured by integrating the EL spectra of devices according to emission angles.

2.3. Attenuated total reflection Fourier transform infrared (ATR-FTIR)

The PDMS was spincoated on bare silicon wafer and cured at 100 °C for 1 h, and the UVO treatment was conducted on the cured PDMS for 5 min. In order to eliminate an effect of a corrugated structure in measurements, 5-nm-thick Al layer that shows no buckling structure was deposited on PDMS. FTIR spectra were recorded by the attenuated total reflection (ATR) technique, using a Jeol-SPX 200 spectrometer. For each sample, 1837 scans were collected using a Ge-crystal detector with a resolution of 4 cm^{-1}.

3. Results and discussion

AFM images of buckles formed on PDMS under different conditions are shown in Fig. 1(a–d). All the AFM images with inserted fast Fourier transform (FFT) patterns with symmetric rings clearly indicate that these buckles have characteristic wavelengths with wide distributions and without preferred orientation. Fig. 1(e) presents the power spectra of various buckles, plotted against wavelength (periodicity). It is known that the wavelength of the buckles λ depends on the film thickness t and the elastic modulus of the film and the substrate E_f and E_s by the equation $\lambda \sim t(E_f/E_s)^{1/3}$ [14]. Buckles produced by depositing 20- and 10-nm-thick Al layers are shown in Fig. 1(a) and (b), where controllability due to the above equation is qualitatively shown. This is more quantitatively shown in Fig. 1(e); i.e., the characteristic wavelengths for 10-, 15- and 20-nm-thick Al layers are ~460, 650 and 800 nm, respectively. In order to have shorter periodicity, we tried a 5-nm-thick Al layer. However, no buckles were formed on the surface, indicating that it is difficult to decrease the periodicity of buckles anymore by the Al layer thickness. Since the pitch of periodic grating applied to OLED should be below 400 nm for efficient outcoupling of waveguide mode into normal direction, we introduced ultraviolet/ozone (UVO) treatment on PDMS to control the periodicity of the buckles.

Fig. 1(c and d) shows the buckled structure by 10-nm-thick Al layer on the PDMS treated by UVO for 1 and 2 min. As the exposure time increases, the periodicity decreases and the diffuse FFT ring pattern becomes larger, indicating a shorter characteristic wavelength. The power spectra in Fig. 1(e) represent that the peak wavelength are ~400, ~315, and ~300 nm for 1, 2, and 3 min UVO treatment. It is well known that UVO treatment of PDMS converts its surface into silica-like structure, and particularly at short treatment time of a few minutes the modification extends to 10–20 nm below the surface, converting the density of the top surface to below ~10% of that of silica [15]. These modified layers by UV or UVO are considered as a composite layer with metal films deposited on them. The increased thickness $t_{composite}$ and elastic modulus $E_{composite}$ of the composite layer have been believed to increase the characteristic wavelength of buckles λ due to the relation $\lambda \sim t_{composite}(E_{composite}/E_s)^{1/3}$. Actually this relation was confirmed using buckles formed by a noble gold film of 50 nm; i.e., λ increases with a UV exposure time because of increasing $t_{composite}$ and $E_{composite}$ [11]. However, the situation was completely opposite, as shown in Fig. 1(c–e), if a reactive metal film such as Al was deposited on UVO-treated PDMS with very thin thickness of 10 nm; the periodicity of buckles decreases with increasing UV exposure time. We will describe why such opposite situation resulted in the following.

Kovacs and Vincett have shown that a metal subsurface is formed beneath a polymer surface when a metal is thermally evaporated onto a polymer substrate above its glass transition temperature [16–18]. The formation of

(a) Buckle by 20-nm-thick Al layer without the UVO treatment (Dimensions, 10 × 10 μm). (b) Buckle by 10-nm-thick Al layer with 0 min, (c) 1 min, and (d) 2 min UVO treatment (Dimensions, 5 × 5 μm). Inset: The FFT pattern of each image. (e) The power spectra from FFTs as a function of wavelength for the buckling patterns by 20-nm-thick (–), 15-nm-thick (- - -) and 10-nm-thick (.....) Al layer without the UVO treatment, and by 10-nm-thick Al layer with UVO treatment for 1 min (▬), 2 min (▬) and 3 min (▬).

sub-surface structures is thermodynamically favorable because the surface energies of inorganic evaporants γ_1, organic polymer γ_2, and interface γ_{12} generally satisfy $\gamma_1 > \gamma_2 + \gamma_{12}$. The deposited sub-surface consists of spherical clusters, embedded with a deeper distribution of several tens of nanometers below the surface, instead of the nominal film thickness. Considering the low surface energy (15–20 mJ/m^2) and the low glass transition temperature (∼−125 °C) of PDMS, it is expected that evaporated Al adatoms sink and coalesce beneath the PDMS surface, being oxidized by chemical reaction with PDMS, rather than showing the surface nucleation and growth on PDMS, when thermally evaporated. However, the stiffer and activated silica-like surface formed by UVO treatment on PDMS may prevent the Al adatoms from being sank beneath surface and induce three- or two-dimensional growth mode above the surface [19]. We found that this is actually the case, as will be shown in the following.

The magnified AFM images (500 nm × 500 nm) of an Al layer on silica glass, bare PDMS and 30-min-UVO-treated PDMS are shown in Fig. 2. Although an Al-deposited layer emerged as a typical granular surface morphology on silica glass (Fig. 2(a)), a smooth and buckled (large bump) surface morphology was obtained on bare PDMS

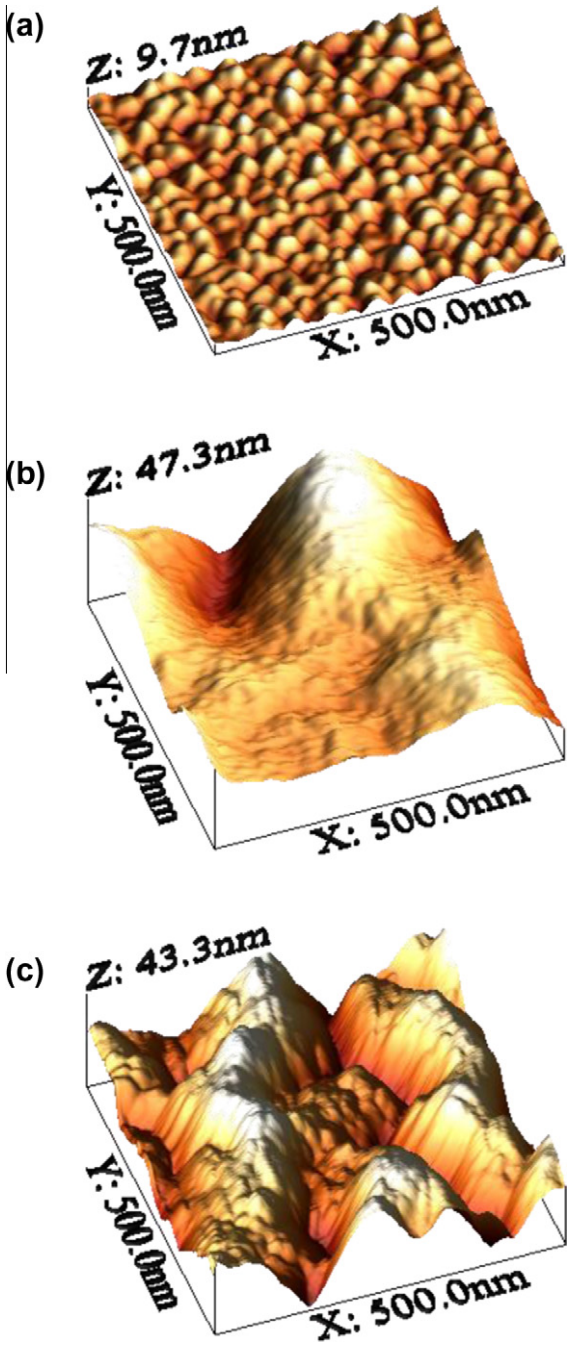

Fig. 2. Magnified three-dimensional AFM analysis of 10-nm-thick Al layer (Dimensions, 500 nm × 500 nm). (a) Granular surface morphology of Al layer on glass substrate. (b) Smooth morphology in the buckled structure of Al layer on bare PDMS (a–c). (c) Granular-like surface morphology in the buckled structure of Al layer on 30-min-UVO-treated PDMS.

(Fig. 2(b)), indicating the sub-surface nucleation and growth. In a 30-min-UVO-treated PDMS (Fig. 2(c)), in which the surface is converted to a more dense material (~50% density of pure silica) [15], the granular-like surface morphology, similar to the granular structure of Fig 2(a), is formed in the buckles.

To examine the oxidation condition of these films, Fourier transform infrared spectroscopy was conducted in the attenuated total reflection mode (FTIR–ATR). Fig. 3 shows the spectra of pristine PDMS (a), Al-deposited PDMS without (b) and with (c) UVO pretreatment. Characteristic peaks showing oxidation of the Al layer were observed over a broad range of 650–1000 cm^{-1} [20–22], in addition to the peaks of pristine PDMS [15]; the O–Al–O bending mode (650–700 cm^{-1}), the Al–O stretching mode (750–1000 cm^{-1}), and the Al–OH bending mode (850–1000 cm^{-1}). The absorption intensities of these characteristic IR bands particularly of O–Al–O bending peak are stronger for the Al layer on the bare PDMS (b) than on the UVO-treated PDMS (c), indicating that the silica-like surface of the PDMS treated by UVO restrains the Al adatoms from being sank and oxidized. Another difference can be also seen in their appearance; i.e., the 50-nm-thick Al layer on the PDMS without UVO treatment is optically transparent by naked eye, whereas that on the 10-min-UVO-treated PDMS is opaque (Supporting Figure). Therefore, the Al layer on the UVO-treated PDMS forms a thinner composite layer with less oxidized conditions. Considering the elastic modulus of bulk alumina (~370 GPa) and Al (~69 GPa) [23], the elastic modulus in UVO-treated case becomes smaller than that without UVO treatment. Because the characteristic wavelength of the buckles is strongly dependent on the thickness and the elastic modulus of the composite layer, the reduced thickness and elastic modulus by the UVO treatment are responsible for the decreased characteristic wavelength of the buckles, as experimentally obtained (Fig. 1(c–e)).

The depth of a buckling structure D generally depends on the buckling periodicity λ and the imposed compressive strain (stress) Δ; $D \sim \lambda \bullet \Delta^{1/2}$ [24]. The decreased periodicity of the buckles by the UVO treatment reduces the depth of buckle to 55–65, 50–60, 40–50, and 35–45 nm for the treatment of 0, 1, 2, and 3 min, respectively. The buckle by 3 min treatment in Fig. 1(e) has a large fraction in the periodicity

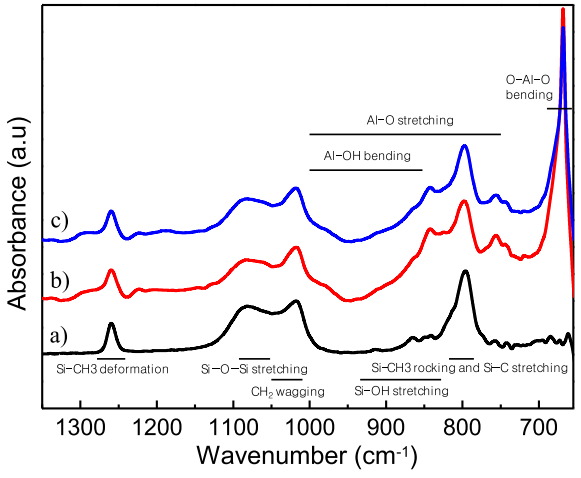

Fig. 3. FTIR–ATR spectra of (a) pristine PDMS (–), (b) PDMS deposited by 5-nm-thick Al layer without (▬), and (c) with the UVO pretreatment for 5 min (▬). The PDMS shows no buckling structure by 5-nm-thick Al layer, so the effect of the corrugated structure on the measurement was excluded. The bars represent the characteristic IR bands corresponding to various chemical functionalities.

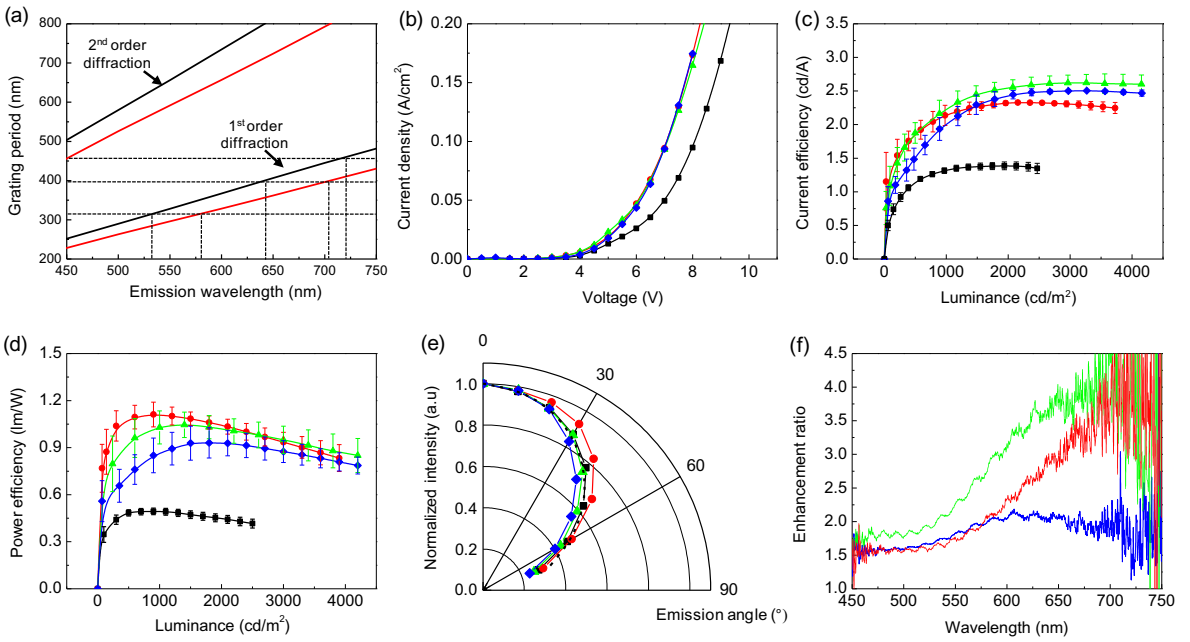

Fig. 4. (a) Relation between the outcoupled emission wavelength in the normal direction and the grating period for the TE_0 (–), and TM_0 (▬) modes. The first- and second-order diffractions were considered. The dotted horizontal lines correspond to the peak wavelengths of the buckles by 0 (λ_{peak} = 460 nm), 1 (λ_{peak} = 400 nm), and 2 min (λ_{peak} = 315 nm) UVO treatment. (b) Current density of the devices without (■) and with the buckles by 0 (●), 1 (—●—), and 2 min (—●—) UVO treatment. (c) Current efficiency, (d) Power efficiency, and (e) Angular depedence of normalized light intensity for the devices with the same information as (b). The dashed line (- - -) represents the Lambertian emission pattern. (f) Light enhancement ratio of the devices as a function of wavelength for the devices with the buckles by 0 (▬), 1 (▬), and 2 min (▬) UVO treatment. The data were obtained by dividing the EL spectra of each device with buckles by that without buckles.

below ~250 nm, which is too short to diffract the waveguiding light of ~520 nm into normal direction. Moreover, the higher depth of the buckle by 2 min treatment than that by 3 min treatment is more suitable for effective diffraction. Therefore, we fabricated the OLED devices with the buckle by 2 min treatment, in addition to those by 0 and 1 min treatment for comparison. The pattern of the buckled PDMS mold was transferred to UV-curable resin by an imprinting technique [12], on which we fabricated OLED devices.

To characterize the waveguide modes existing in this structure, we calculated their in-plain propagation vector, k_{wg}, for the emission wavelength by using a transfer matrix method [12,25–27]. One transverse-electric (TE_0) and one transverse-magnetic (TM_0, surface plasmon) modes were calculated. Based on the Bragg grating equation of $k_{||} = k_0 \sin\theta = k_{wg} \pm mk_g$ (k_0, the absolute values (wavenumbers) of the wave vectors in free space; $k_{||}$, its in-plain component; k_G, grating (buckling); θ, polar angle of emitted light with respect to the surface normal; and m, an integer), the grating period satisfying the Bragg equation for the first- and second-order diffractions in the normal direction (m = 1 and 2, θ = 0) is plotted in Fig. 4(a) as a function of wavelength of the outcoupled light. The buckles by 0, 1, and 2 min UVO treatment with the peak wavelength of ~460, 400, and 315 nm are expected to mainly outcouple the TE_0 mode at ~720, 640, and 530 nm and the TM_0 mode at ~800, 705, and 580 nm, respectively. However, the broad distribution of the buckles in periodicity allows the waveguide modes to be extracted over the broad emission wavelength ranges through even the second-order diffraction as well as the first-order diffraction. Moreover, the diffractions toward off-normal directions occur in all azimuthal directions because of random orientation of buckles.

The current densities for the devices with and without buckles are plotted as a function of applied voltage in Fig. 4(b). The devices with buckles show higher current density than the reference device, irrespective of the UVO treatment time. This larger current density in the corrugated device due to a partial reduction of the organic layer thickness is a well-known phenomenon [6,12][28]. The current efficiencies at a luminance of 2000 cd/m^2 were 1.38 cd/A for the reference device and 2.32, 2.55, and 2.43 cd/A for the devices with the buckles by 0, 1, and 2 min UVO treatment, respectively (Fig. 4(c)). Although the periodicity of the buckle by 2 min treatment is most suitable to outcouple the waveguide modes at the main emission peak of ~520 nm into normal direction, its relatively low depth may limit the effective diffraction. For the devices with buckles on non-treated PDMS, in contrast, the peak wavelength of the periodicity distribution is too long (~460 nm) to effectively outcouple the main emission peak (Fig. 4(a)) despite of its highest depth of the buckles. Therefore, the device with the buckle by 1 min treatment shows the highest current efficiency of the enhancement ratio 1.85.

The power efficiencies at a luminance of 2000 cd/m^2 were 0.45 lm/W for the reference device, and 1.04, 1.02, and 0.93 lm/W for the devices with the buckles by 0, 1,

and 2 min treatment, respectively, as shown in Fig. 4(d). The device with the non-UVO-treated buckle shows the highest power efficiency, being enhanced by a factor of 2.3. This result is related to the angular distribution of emitted light from the devices in Fig. 4(e). While the reference device shows a nearly Lambertian emission pattern, the device with the buckle by 0 min treatment shows a broader distribution and that by 1 and 2 min treatment a narrower distribution compared with the Lambertian emission pattern. According to the Bragg grating equation, the TE_0 and TM_0 modes at 520 nm are diffracted to the polar angle of 35–50°, 25–35°, and 0–13° by grating with the periodicity of 460, 400, and 315 nm, respectively. However, because of wide distribution of grating vectors and periodicities of buckles, the outcoupled light concentrates into normal direction, resulting in the Lambertian-like emission pattern without any particular angle dependence [12], although the tendency of the stronger diffraction toward off-normal directions by the longer periodicity is maintained.

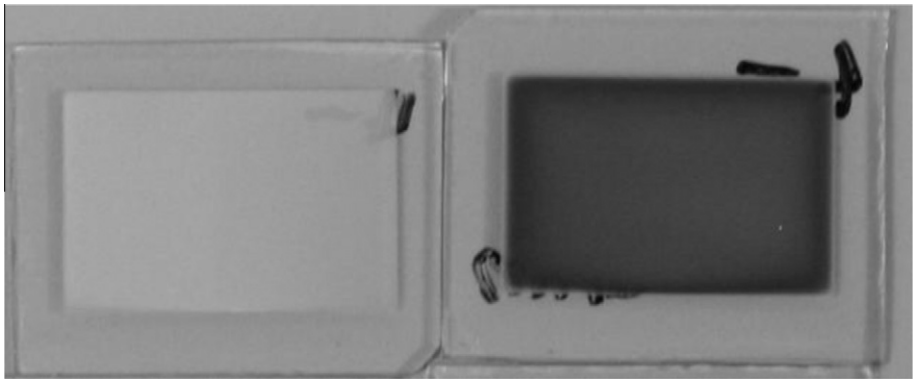
In order to examine the relationship between the buckling periodicity and the wavelength with highest enhancement, we evaluate the enhancement ratio as a function of wavelength in Fig. 4(f), where electroluminescence (EL) spectra of 0, 1 and 2 min UVO-treated devices normalized by that of the reference device for normal direction are displayed. With increasing the treatment time, the peak wavelength showing the highest enhancement shifts toward shorter wavelength according to the shortened periodicity, as expected. For instance, the expected peak wavelengths of the outcoupled TE_0 and TM_0 modes by the buckles without UVO treatment (0 min) with the periodicity of 460 nm are about 790 and 740 nm, respectively (Fig. 4(a)). Actually, the observed highest enhancement ratio is located above 700 nm, although exact peak cannot be estimated because of weak EL intensity. Good agreement was obtained for the buckles by 1 min UVO treatment, i.e., highest enhancement ratio at 680 nm (experiment) is quite close to the expected wavelength 710 (TE_0) and 640 nm (TM_0) for 400 nm periodicity. Thus, although the main outcoupled peak wavelengths through the buckles by 0 and 1 min treatment are far from the main emission wavelength of ~520 nm, overall enhancement for entire emission wavelength ranges was observed because of the broad periodicity and the second-order diffraction as well as the first-order diffraction. The agreement is not so good for the buckle with the periodicity of 315 nm by 2 min treatment compared with previous two examples (buckles by 0 and 1 min treatments). This device is expected to show the highest enhancement ratio at the emission wavelength of 530 and 580 nm for the TE_0 and TM_0 modes, but the highest intensity shown in Fig. 4(f) is located at around 600 nm. The disagreement can be attributed to the asymmetric power spectrum shown in Fig. 1(e) (green line). Namely the power spectrum has wider distribution and longer tail in longer wavelength side, which make the enhancement ratio at longer wavelengths high. Thus, we succeeded in getting high enhancement ratio in a visible wavelength region, although the low depth of the buckles limits the effective diffraction. If a multiple deposition process of Al layer, as demonstrated in our previous study [12], is applied to the buckles by 2 min treatment, a better outcoupling efficiency through the higher depth of the buckle is expected.

4. Conclusions

The spontaneously formed buckling patterns were able to be controlled by the UVO treatment time. Both the periodicity and depth of the buckle decreased with increasing UVO treatment time. The controllability for the periodicity from 300 to 400 nm is particularly important, since the periodicity in those ranges determines the wavelength of enhanced outcoupling for visible EL light. Actually we succeeded in obtaining the device with buckles of 315 nm periodicity by 2 min UVO treatment, and in shifting the wavelength showing the highest enhancement ratio toward the shorter wavelengths with this device. With the simple controllability of the periodicity by the UVO treatment, the advantages of buckles such as broad distribution in periodicity and directional randomness supply a practical solution for all kind of display and lighting applications suffering from power loss by waveguide modes.

Appendix A

Photographs of the buckled PDMS layers on glass substrates by depositing a 50-nm-thick-Al layer on the PDMS layer without (Left) and with 10-min-UVO-treatment (Right). The Al layer on the buckled PDMS without UVO treatment looks optically transparent but white by diffuse scattering, indicating the Al layer is fully oxidized by a chemical reaction with the PDMS layer during deposition.



However, the Al layer on the buckled PDMS with 10-min-UVO-treatment looks opaque, indicating that the silica-like surface of the PDMS by the UVO treatment restrains the Al adatoms from being sank and oxidized.

polymers with structural units containing in the side-chains both photoconductive and electro-optic functionalities, such as poly{(4-nitrophenyl)-[3-[*N*-[2-(methacryloyloxy)ethyl]-carbazolyl]]diazene} [poly(CARBA)], it is possible to observe photorefractive and non-linear optical (NLO) properties as well as photoinduced molecular reorientation and the formation of surface relief gratings [38,39].

In this context, we have recently shown [40] how the photorefractive properties of non-poled azo-polymers containing carbazole moieties in the side-chain can be observed at more than 100 °C below their glass transition temperatures. The chemical structures of the four materials (**1–4**) used in that study are shown in Fig. 1. In these particular materials, although light activated conformational mobility is a necessary requirement at such temperatures, a photogenerated electric field is also necessary in order to encode a phase-shifted hologram, via the reorientation of polar chromophores. Such photogenerated field is directly dependent on the photoconductive properties of the polymers, which have not yet been studied in detail.

In the present work, in order to fully investigate the charge photogeneration and transport mechanisms of this class of multifunctional polymers, we have considered compounds **1**–**9**, including five homopolymers without azochromophores (**5–9**). The chemical structures of all the materials used in this study are shown in Fig. 1. The reason for studying also polymers not containing azochromophores relates to the necessity of simplifying structures, reducing the possibility of interferences of the azo-groups over the measured properties. In addition, this allows a comparison between the properties of similar polymers, with and without azochromophores.

2. Experimental

2.1. Polymers

Structures, molecular weight distributions, glass transition (T_g) and decomposition (T_d) temperatures of the studied polymers, obtained by AIBN initiated radical polymerization, are shown in Fig. 1 and Table 1. Poly[(*S*)-(4-cyanophenyl)-[3-[9-[2-(2-methacryloyloxypropanoyloxy) ethyl]carbazolyl]]diazene] {poly[(*S*)-MLECA]} (**1**) was synthesized as previously described [41]. It bears three distinct functional groups (i.e., the azoaromatic, carbazole, and chiral groups of one single configuration) directly linked to a single side chain. Poly[(*S*)-(−)-3-methacryloyloxy-*N*-[3-(9-ethylcarbazolyl)]pyrrolidine-*co*-(*S*)-3-methacryloyloxy-1-(4′-nitro-4-azobenzene)pyrrolidine] 50/50 {poly[(*S*)-(−)-MECP-co-(*S*)-MAP-N] 50/50} (**2**) was synthesized as previously described [40]. Copolymers poly [(*S*)-(+)-2-methacryloyloxy-*N*-[3-(9-ethylcarbazolyl)]succinimide-*co*-(*S*)-(+)-2-methacryloyloxy-*N*-(4-azobenzene)-succinimide] 24/76 {poly[(*S*)-(+)-MECSI-co-(*S*)-(+)-MOSI] 24/76} (**3**) and poly[(*S*)-(+)-2-methacryloyloxy-N-[3-(9-ethylcarbazolyl)]succinimide-*co*-(*S*)-(+)-2-methacryloyloxy-N-(4-azobenzene)succinimide] 76/24 {poly [(*S*)-(+)-MECSI-co-(*S*)-(+)-MOSI] 76/24} (**4**) were synthesized as previously described [42]. Copolymeric compounds **2–4** have two different side-chains: one comonomer with either a (*S*)-3-hydroxy pyrrolidinyl (**2**) or a (*S*)-2-hydroxy succinimide (**3**,**4**) ring as a chiral moiety, covalently linked to a photochromic azoaromatic group, substituted (**2**) or not (**3**,**4**) in the 4-position with a nitro (electron withdrawing) residue. In the side-chain of the second kind of comonomer, the same chiral rings are linked to photoconductive carbazole chromophores. In **2–4**, the conformationally rigid pyrrolidine or succinimide rings increase the stiffness of the macromolecules and induce high T_g values (see Table 1). The presence of a strong electron-withdrawing or donating group such as the five membered cyclic succinimide moiety or the pyrrolidine residue, respectively, within a highly conjugated carbazolyl systems, can potentially modify the charge photogeneration and transport properties. In addition, strongly electron-withdrawing cyano or nitro groups are present in **1** and **2**, respectively, inducing considerable permanent dipole moments. Poly[(*S*)-(+)-2-methacryloyloxy-*N*-[3-(9-ethylcarbazolyl)]succinimide] {poly[(*S*)-(+)-MECSI]} (**5**) and poly[(*S*)-(−)-3-methacryloyloxy-*N*-[3-(9-ethylcarbazolyl)]-pyrrolidine] {poly[(*S*)-(−)-MECP]} (**6**) were synthesized as previously described [43]. The three homopolymers containing 9-phenylcarbazolyl moieties, poly[(*S*)-(+)-3-methacryloyloxy-*N*-[4-(9-carbazolyl) phenyl]-pyrrolidine] {poly[(*S*)-(+)-MCPP]} (**7**), poly[*N*-(2-methacryloyloxyethyl)-*N*-[4-(9-carbazolyl)phenyl]ethylamine] {poly-[MCPE]} (**8**) and poly[(*S*)-(+)-2-methacryloyl oxy-*N*-[4-(9-carbazolyl)phenyl]succinimide] {poly[(*S*)-(+)-MCPS]} (**9**), were synthesized as previously described [44]. The macromolecular compounds **5** and **6** are the corresponding homopolymers of **3/4** and **2**, respectively. Homopolymeric derivatives **7** and **9** contain instead in the side chain a 9-phenylcarbazole moiety linked either to the (*S*)-3-hydroxy pyrrolidinyl (**7**) or to the (*S*)-2-hydroxy succinimide (**9**) ring. The replacement of the alkyl substituent usually bound to the N atom of carbazole by a phenyl group, is expected to expand the electronic conjugation in the chromophores, while at the same time increasing their rigidity. In this respect, polyacrylates and polymethacrylates with pendant 9-phenylcarbazolyl moiety have been largely studied in order to correlate the architecture of the chromophores to the photochemical and photophysical properties [45].

The glass transition temperatures of the investigated polymers are listed in Table 1. All the polymeric derivatives exhibit by differential scanning calorimetry (DSC) measurements only a second order thermal transition attributed to the glass transition (T_g). No endothermic melting peaks, attributable to crystalline domains, were detected. This is in accordance with a substantially amorphous character of the macromolecules in the solid state, expected when, as in this case, side-chain polymers are obtained via free radical polymerization.

2.2. Electrochemistry

HOMO (Highest Occupied Molecular Orbital) and LUMO (Lowest Unoccupied Molecular Orbital) energy levels of the polymers were estimated by cyclic voltammetry, in some cases through a correlation with UV–Vis absorption spectroscopy. Cyclic voltammetry data were performed in dry

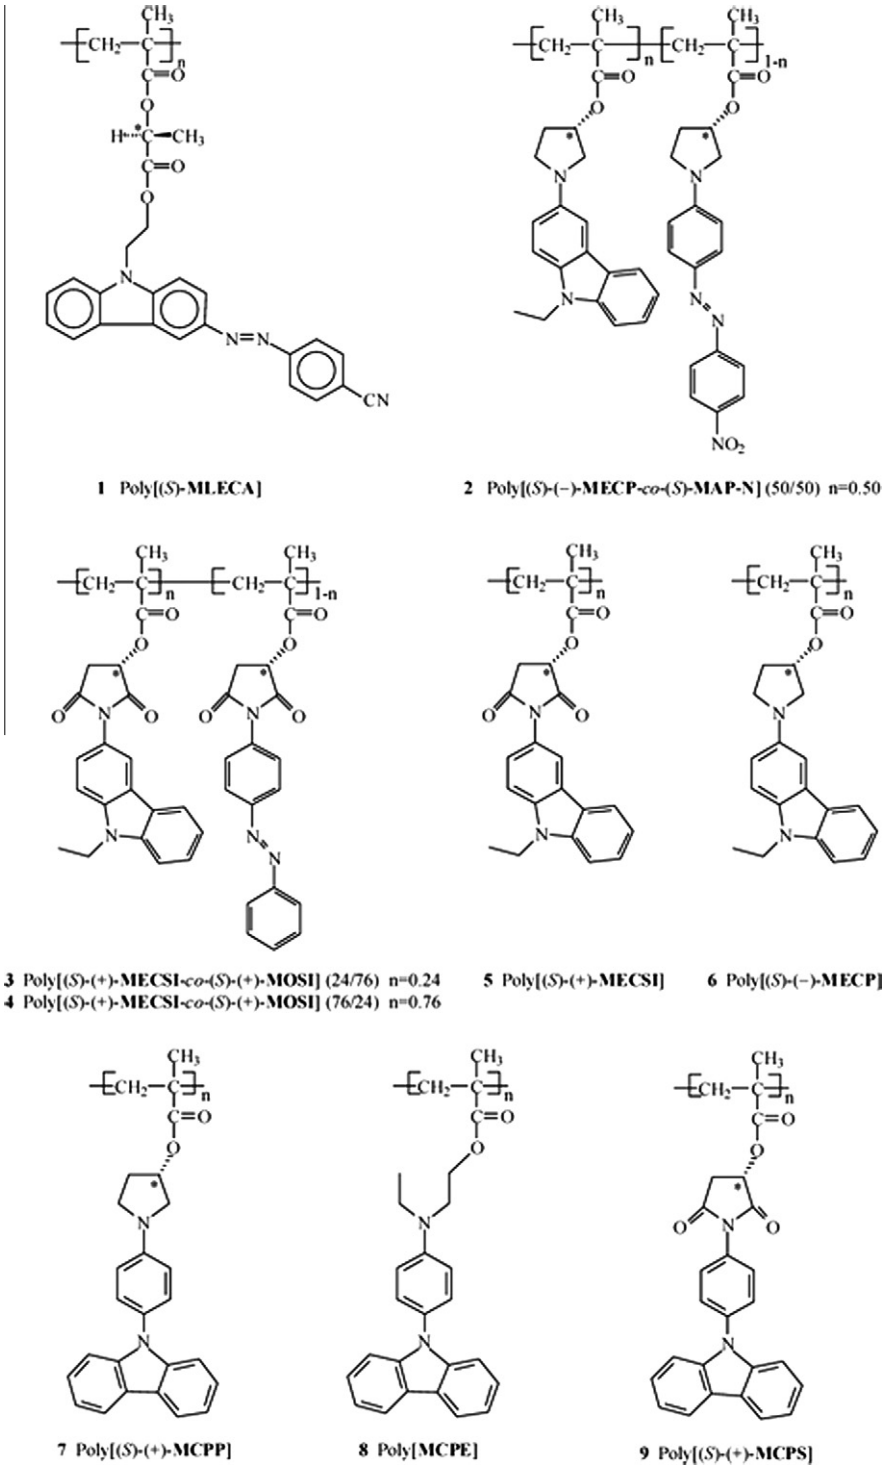

Fig. 1. Chemical structures of the investigated polymers.

dichloromethane solutions using tetrabutylammonium hexafluorophosphate (0.1 M) as an electrolyte, a Pt disk working electrode, a Pt wire counter electrode and an Ag/AgCl reference electrode at a scan rate of 100 mV s^{-1}. An equimolar amount of ferrocene was added to the solution for internal reference. For irreversible (Irr) oxidation or reduction waves, values of the irreversible peak were considered, while for Quasi Reversible (QR) redox waves, the average value (Epc + Epa)/2 was taken into account. Energy values were calculated by comparing the polymer

oxidation/reduction potentials to the ferrocene/ferrocenium oxidation potential, taking the value of −4.8 eV for the HOMO of ferrocene [46]. With the exception of **1**, all analyzed polymers have shown two oxidative waves, as shown in Fig. 2 in the case of **6** and **7**. HOMO levels were evaluated considering the first oxidation potential. Polymers **1** and **2** showed irreversible oxidation waves and irreversible (**1**) and quasi-reversible (**2**) reductions waves. For all other compounds no reduction was detected within the solvent potential window, while a quasi-reversible behaviour was observed for oxidation. When reduction waves were not observed, the highest wavelength band observed in the absorption spectrum was considered in order to estimate the HOMO/LUMO band gap.

2.3. Photoconductivity

Samples were prepared by sandwiching materials between two glass slides, each one covered with five 1 mm wide strips of conducting Indium Tin Oxide (ITO). Substrates were obtained by acid etching of conducting glass slides uniformly covered with ITO (110 nm, from Unaxis). Sample preparation starts by placing a proper amount of polymer on one substrate and heating above its glass transition temperature (T_g) on a hot plate. When the material is soft enough, it is covered and pressed with another hot glass and finally the sample is quickly cooled to room temperature. The thickness of the polymeric film was controlled by glass spacers and measured by interferometry.

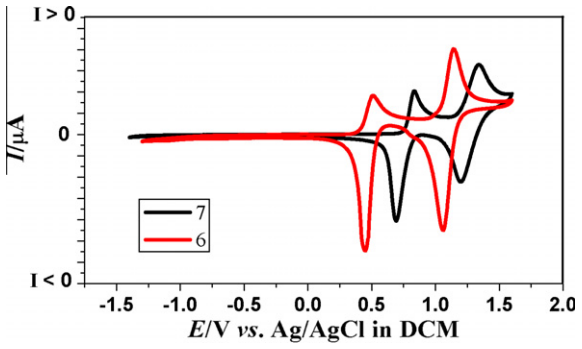

Fig. 2. Cyclic voltammograms of 6 and 7 in dry dichloromethane, using a Pt working electrode, a Pt wire as counter electrode, an Ag/AgCl reference electrode and tetrabutylammonium hexafluorophosphate as an electrolyte (0.1 M). Scan rate: 100 mV s^{-1}.

Photoconductivity measurements were performed by applying an electric field $E = 18$ V/m to the sample and measuring the electric current through the sample, both in the dark and under illumination. The current was measured by a 6517A Keithley electrometer, while the light was provided by a DPSS laser at $\lambda = 532$ nm. For polymers **1**, **2** and **4**, where absorption at such wavelength is too high, measurements were carried out using a He–Ne laser at $\lambda = 633$ nm. In order to take into account the different absorption properties of the investigated compounds, photoconductivity was always normalized with respect to the absorption coefficient.

2.4. Hole mobility

A layer of the material was deposited on an ITO covered glass by spin coating tetrahydrofuran solutions (30 mg/ml) at 800 rpm. The thickness of the resulting films (between 0.4 and 1.4 m) was measured using a Veeco Dektak 8 stylus profilometer. A gold electrode was then deposited on the films by high vacuum thermal evaporation. Considering their HOMO energy levels, polymers **1** and **9** cannot have ohmic contacts with gold and therefore they were not considered for hole mobility measurements via the Space-Charge Limited Current (SCLC) technique described below. In addition, the quality of films obtained from **2**, **4** and **7** was poor, so that measurements was restricted to **3**, **5, 6** and **8**. Measurements were performed by recording I-V curves using a 6517A Keithley electrometer. At low applied voltages, the current is a linear function of voltage and the resistive behaviour is ohmic:

$$J = ne\mu\frac{V}{d} \quad (1)$$

where J is the current density, n is the charge carrier density, e is the elementary charge, μ is the charge carrier drift mobility, V is the applied voltage and d is the sample thickness. At higher voltages and charge densities, the electric field in the material is determined not only by the applied voltage but also by the space-charges. In such case, the

voltage dependence of the current can be approximated by the Mott-Gurney equation [47]:

$$J = \frac{9}{8}\varepsilon\varepsilon_0\mu\frac{V^2}{d^3} \quad (2)$$

where ε_0 is the free space permittivity and ε is the relative dielectric constant of the material. Therefore, from a measurement of cell thickness and dielectric constant, it is possible to obtain the mobility from the *I–V* curves, assuming an ohmic contact from the injecting electrode. The dielectric constants of the materials were obtained via capacitance measurements by using an Agilent B905A precision bridge.

A reliability check of the mobility measurement can be carried out considering that, according to Eqs. (1), (2), the voltage V_T at which the slope of the *I–V* curves change from linear to quadratic is:

$$V_T = \frac{8}{9}en\frac{d^2}{\varepsilon\varepsilon_0} \quad (3)$$

The measured value of the mobility can be used in Eq. (1) to obtain n which, in turn, can be used in Eq. (3) to obtain V_T. A good matching between such calculated value of V_T and the experimental value extracted from *I–V* curves is an indicator of reliable measurements.

3. Results and discussion

3.1. Frontier orbitals

Table 2 shows the values of the HOMO and LUMO energy levels of the investigated polymers, as determined by Cyclic Voltammetry. A clear trend can be highlighted when the energy of the HOMO's, which are directly involved in hole transport, are considered in relation with molecular structure. Not surprisingly, the highest energy HOMO's are found for **2** and **6**, where an electron-donating pyrrolidine–nitrogen is directly linked to the 3-position of carbazole. Note that the HOMO levels of the homopolymer **6** and of the copolymer **2** are the same, a result pointing out the importance of the carbazolyl moiety in determining HOMO's, with the azo side-chain being irrelevant in this respect. The same can be said comparing the HOMO's of **3**/**4** and **5**. However, in these last compounds the presence of an electron-withdrawing succinimide-nitrogen in the 3-position of the carbazolyl group lowers their HOMO's, if they are compared with **2** and **6**. A similar, although less marked, effect was found when the amino or succinimide groups were linked to the nitrogen atom of carbazole through a phenyl bridge (compare **7**/**8** with **9**). Comparing instead the effect of a given substituent on different positions, results show relevant differences for amino substituents (compare **2**/**6** with **7**/**8**) but not for succinimide (compare **3**/**4**/**5** with **9**). Polymer **1** is the only compound of the series with an azo-group directly linked to the carbazolyl moiety. Its HOMO is by far the most stable, probably as a consequence of the presence of a strongly electron-withdrawing cyano moiety directly connected with the conjugated carbazole.

Table 2
HOMO and LUMO energies of polymers **1–9.** All the LUMO energies (except those for **1** and **2**, obtained by CV) were estimated by using UV–Vis data.

Polymer	LUMO (eV)	HOMO (eV)
1	−3.1	−5.7
2	−3.4	−4.8
3	−2.5	−5.3
4	−2.5	−5.3
5	−1.9	−5.3
6	−1.8	−4.8
7	−1.5	−5.1
8	−1.55	−5.1
9	−1.8	−5.4

3.2. Hole mobility

Being the HOMO levels of all polymers (with the exception of **1** and possibly of **9**) within 0.3 eV from the work function of gold, the Space Charge Limited Current method in samples with one Au electrode could be used in order to measure hole mobility. As explained in the experimental section, samples suitable for hole mobility (μ) measurements could be obtained only for **3**, **5**, **6** and **8**. A typical current voltage plot is illustrated in Fig. 3.

The resulting mobilities for the four compounds are listed in Table 3. The striking result is that in **5** and **6** the mobility is several orders of magnitude lower than in **3** and **8**. Mobility thus depends neither on the chemical nature of the linking group nor on the HOMO energy level. The only trend that can be found is that homopolymers in which the carbazolyl group is linked to the main-chain through a conformationally stiff linker (**5** and **6**) have a much lower mobility than copolymers (**3**) or homopolymers with a more mobile linker (**8**). Although the number of investigated polymers is not high enough to allow the drawing of a final conclusion, our data indicate that a higher degree of conformational freedom of the carbazole-containing side-chains favours charge mobility, probably via a more favourable arrangement in space of the carbazolyl

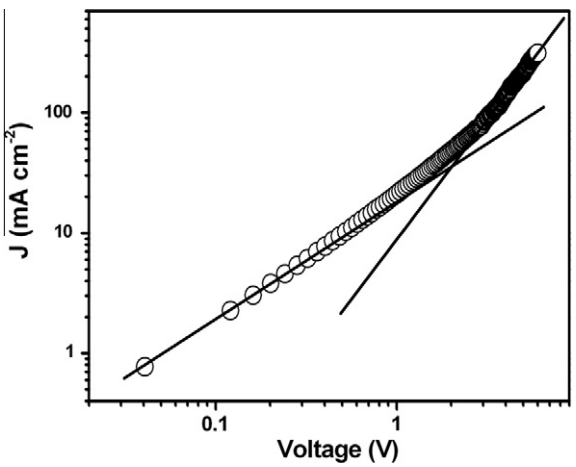

Fig. 3. Voltage dependence of the current in a sample of polymer **8**. The thickness of the spin-coated polymer layer was $d = 400$ nm. The two straight lines have slopes 1 and 2.

Table 3
Absorption coefficient (α), hole mobility (μ), photogenerated charge carrier density (n_D), number of carriers per watt of absorbed power (η) and photogeneration efficiency (ϕ) for polymers 3, 5, 6 and 8.

Polymer	α (λ = 532 nm) (cm−1)	μ ($cm^2\ V^{-1}\ s^{-1}$)	n_D (cm^{-3})	η (W^{-1})	ϕ
3	358	2.2×10^{-3}	$<8.5 \times 10^{+5}$	$<1.0 \times 10^{+4}$	$<3.3 \times 10^{-9}$
5	987	2.6×10^{-7}	$2.6 \times 10^{+10}$	$1.3 \times 10^{+8}$	1.5×10^{-9}
6	1267	1.3×10^{-8}	$5.1 \times 10^{+15}$	$2.8 \times 10^{+13}$	1.6×10^{-5}
8	78	2.1×10^{-3}	$1.9 \times 10^{+10}$	$5.6 \times 10^{+8}$	5.0×10^{-5}

moieties. This result is in agreement with previous observations [1] on carbazole side-chain polymers, in which a higher charge mobility was tied to a lower density of charge traps: in our case, the conformational freedom of the side-chains should contribute to a decrease of trap-forming structural defects.

Considering the absolute values of the measured hole mobilities, the low values obtained for both **5** and **6** are in line with what measured in most carbazole polymers. But while the high mobility in **8** can be accounted for by the higher conformational freedom, the equally high mobility measured in **3** is surprising. In fact, for **3** one would expect a mobility even lower than for **5**, on account of the fact that the density of carbazole charge carriers is decreased. The only possible explanation of such experimental evidence is an involvement of the azo-containing side-chain in charge transport. Studies are in progress to verify such hypothesis.

It should be underlined that, as usual in side-chain polymers obtained via radical polymerization, the polymers under investigation are amorphous, as confirmed by the absence of melting peaks in DSC curves. As a consequence, in contrast to what observed in many main-chain polymers, the differences in molecular weight (see Table 1) do not affect the degree of crystallization and the morphology of the polymeric films. In other words, the effect of molecular weight on charge mobility can safely be neglected.

3.3. Photoconductivity

Charge photogeneration in carbazole-containing polymers is often studied in blends with electron acceptors, because such composites find application in photovoltaic devices [48,49]. In this work instead, charge photogeneration and photoconductivity is studied in pure, undoped samples. The photoresponsivity (photoconductivity per watt of incident power I) of the investigated polymers is listed in Table 4. In order to better compare the different materials, data were normalized with respect to the absorption coefficient α. Photoresponsivities span a range of more than 5 orders of magnitude. In the best performing compounds, **2** and **8**, photoconductivity measured at an applied field E = 18 V/μm is two orders of magnitude lower than in poly(vinylcarbazole) photorefractive composites [50], where however it was measured at E = 80 V/m and in samples doped in order to increase absorption.

Hole photoconductivity in organics is often found to decrease with increasing stability of the HOMO's, and this is usually attributed to a decrease in photogeneration efficiency due to the lower tendency of the donor (in our case the carbazolyl moiety) to ionize [51]. The photoresponsivity dependence on the HOMO energy level for the investigated polymers is shown in Fig. 4. The correlation is good, with the notable exceptions of **3**, **5** and **8**. Note that in the case of **3** (E_{HOMO} = 5.3 eV), photoconductivity was below the detection limit of the instrumentation used, so that its photoresponsivity would be found in Fig. 4 somewhere below the point corresponding to compound **5**.

An attempt towards the rationalization of such a behaviour is instructive and, to some extent, even enlightening. Photoconductivity (σ) depends on two factors: the density of photogenerated charge carriers and their mobility:

Table 4
Photoresponsivity of polymers **1**–**9** measured at an applied electric filed E = 18 V/m.

Polymer (% DPP)	$\sigma/\alpha I$ ($cm^2\ \Omega^{-1}\ W^{-1}$) λ = 532 nm	$\sigma/\alpha I$ ($cm^2\ \Omega^{-1}\ W^{-1}$) λ = 633 nm
1		1.7×10^{-16}
2 (20%)		1.7×10^{-13}
3	$<10^{-15}$	
4		4.9×10^{-15}
5 (20%)	2.3×10^{-18}	
6 (20%)	2.0×10^{-14}	
7	5.3×10^{-15}	
8 (15%)	1.6×10^{-13}	
9 (15%)	3.0×10^{-15}	

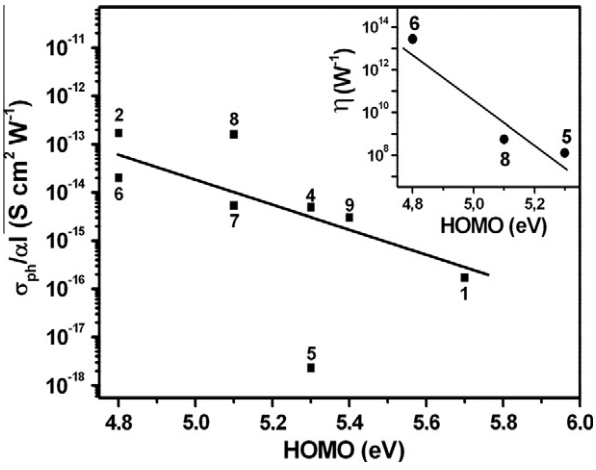

Fig. 4. Photoresponsivity as a function of the HOMO energy level measured at an applied electric filed E = 18 V/m for **1**–**9**. The inset shows the estimated number of carriers per watt of absorbed power for the three polymers for which this parameter could be obtained. Lines are guides to the eye.

$$J_{Ph} = en_D\mu E = \sigma E \quad (4)$$

where J_{Ph} is the photocurrent density, e is the electron charge, n_D is the photogenerated charge carrier density and E is the applied electric field. Mobility was independently measured for four of the polymers. The density of photogenerated charges is instead a direct consequence of the photogeneration efficiency ϕ, defined as the ratio between the number of photogenerated carriers and the number of absorbed photons. If we write the intensity of light absorbed through the volume of a sample of thickness d as

$$I_{abs} = I(1 - e^{-\alpha d}) \quad (5)$$

where I is the incident power per unit surface, the photogeneration efficiency can be written as:

$$\phi = \frac{\sigma E \hbar\omega}{eI_{abs}} \quad (6)$$

where ħ is the energy of a single photon of the incident light. However, Eq. (6) neglects trapping and recombination and it does not allow a discrimination between the contributions of the density of carriers and of their mobility. Since mobility data are available, even if not for the whole series of polymers, it seems more appropriate to discuss the results in terms of the density of carriers n_D, that can be obtained from Eq. (4), and to compare the properties of the different polymers by taking, as an indicator of photogeneration efficiency, the following ratio:

$$\eta = \frac{dn_D}{I_{abs}} \quad (7)$$

i.e. the number of carriers per watt of absorbed power. Such parameter is listed in Table 3 for the four polymers for which mobility was measured. Polymer **3** shows the lowest η, with less than 10^4 carriers per Watt, while for polymers **5** and **8** this figure increases by at least four orders of magnitude. In polymer **6**, we see a further increase by five orders of magnitude. These data clearly indicate how the succinimide linker depresses photogeneration efficiency when compared to an amino linker (**5** vs. **6**). In addition, when the amino linker is in position 3 of the carbazole (**6**), it enhances photogeneration much more than when it is further removed (**8**). Note that when the "real" photogeneration efficiency is calculated by using Eq. (6), a completely different scale of relative efficiency among the different polymers is obtained. Values of are also listed in Table 3. This discrepancy is due to the fact that in Eq. (6), charge mobility (included in σ) is seen as a factor directly influencing photogeneration efficiency. We believe instead that, if charge mobility values are available, the η ratio obtained using Eqs. (4,7) is a better indicator of charge photogeneration efficiency. The inset of Fig. 4 shows the dependence of on the HOMO energy, in the case of the three materials for which n_D could be obtained. Although it consists of only three points, such dependence follows the expected trend, in contrast with the results illustrated in the main Figure for the photoconductivity of the same three polymers. This shows that if mobility and photogeneration efficiency of a series of compounds are not independently determined, the simple consideration of the photoconductivity (which depends on both properties) may be misleading when attempting the rationalization of structure/property relationships.

This is also evident, for example, if we compare the results for polymers **3**, **4** and **5,** with a gradually increasing content of the carbazole-containing side-chain. One would expect a regularly varying trend of photoconductivity in the series, but instead **4**, the compound with an intermediate composition, shows the highest σ. This result is understandable only by considering the mobility and η figures of Table 3. Charge mobility in **3** is four orders of magnitude higher than in **5**. However, its photoconductivity is lower, due to a much lower density of carbazole-containing side-chains, which is reflected in a lower efficiency of photogeneration. However, both **3** and **5** show a photoconductivity which is orders of magnitude lower than in **4**. Although mobility data for **4** are not available, these results suggest that compound **4** shares the high mobility of **3** and the higher carrier density of **5**. As it was already mentioned, the higher mobility of **3** and **4** can be attributed to the higher conformational freedom present in a co-polymer. Notice that the lower content of carbazole bearing side-chains of **3** does not seem to affect mobility, but it greatly reduces the carrier density. A possible explanation of this observation is an involvement of the azo-group in the hole transport process but not in the photogeneration. Further studies are needed in order to clarify this point.

It is also interesting to compare in Fig. 4 the photoresponsivities of **7**–**9**, three compounds with a very similar structure. Polymer **8** shows the highest value, which is more than one order of magnitude higher than what measured for **7** and **9**. This could again be tied with the higher conformational freedom of the side-chains in **8**, inducing a higher charge mobility, while the effects of the different groups on photogeneration efficiency should be leveled by the interposition of a phenyl ring between the carbazole and the amino/succinimide bridging group. The observation that the carrier density in **8** is much lower than in **6** (see Table 3) confirms this lower influence on charge photogeneration of a group far removed from the carbazole unit.

4. Conclusions

The described experimental studies of the charge photogeneration and transport properties of a series of carbazole side-chain polymers underline several structure-related properties. The comparison between homo- and co-polymers clearly points out that in carbazole/azo copolymers the HOMO energy level is only determined by the carbazole containing side-chain, a relevant result when considering the charge transport and other HOMO related properties in multifunctional polymers. In addition, different electron-withdrawing or donating substituents on the 3-position of carbazole have a large influence on the HOMO energy, while their effect is much reduced if they are further removed from the carbazole moiety. In turn, the HOMO energy level is one of the important factors determining photoconductivity, via the control of photogeneration efficiency: in general, a lower photogeneration

efficiency is found for compounds with a more stable HOMO. This is an extremely relevant effect, as we found that the density of charge carriers per Watt of absorbed power can span a 10 orders of magnitude range, with more carriers being generated when (a) the density of carbazole moieties is higher and (b) the HOMO is less stable due to the presence of electron-donating groups linked to the 3-positions of carbazole. Charge mobility seems instead not to depend on the HOMO energy but rather on the conformational freedom of the side chains. The very high value of hole mobility, of the order of 10^{-3} cm^2 V^{-1} s^{-1}, obtained for two of the investigated polymers, should be highlighted. In addition, a possible contribution of the azo-moieties to charge transport was observed.

This study shows how it is necessary to separately measure and consider the different contributions of charge photogeneration and charge transport in order to rationalize the relationship between photoconductivity and chemical structure. The picture that emerges is that photoconductivity in azo/carbazole co-polymers depends on the contribution of several factors affecting charge photogeneration and transport, that can be controlled by carefully selecting the nature of the linker between the carbazole unit and the main chain and the position on the carbazole where this linker is attached.

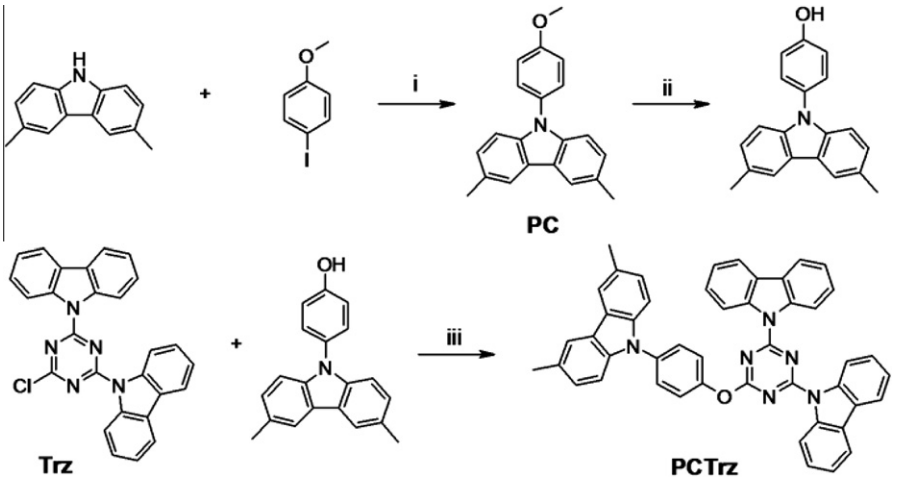

Scheme 1. Synthesis of 2-(4-(3,6-dimethylcarbazol-9-yl)-phenoxy)-bis-4,6-biscarbazolyl-1,3,5-triazine PCTrz: (i) CuI, K_3PO_4, trans-1,2-diamino-cyclohexane, dioxane, 120 °C, 18 h, 68%; (ii) BBr_3, CH_2Cl_2, −78 °C, 12 h, 92%; (iii) NaOH, H_2O, dioxane, 100 °C, 6 h, 80%.

of those triazines were limited and yielded a recombination zone close to the HTL/EML interface. Thus enhanced hole injection properties are desirable and supposed to improve the charge carrier balance and the OLED performance.

In this work we present 2-(4-(3,6-dimethylcarbazol-9-yl)-phenoxy)-bis-4,6-biscarbazolyl-1,3,5-triazine PCTrz as a new bipolar host material for blue phosphorescent OLEDs. PCTrz comprises one hole conducting phenoxy-carbazole and one electron deficient biscarbazolyl-triazine moiety, which are connected by an ether bond, that breaks the conjugation between the two parts of the molecule. This was proved by cyclic voltammetry and density functional theory calculations. The separation of the oxidation- and reduction-site results in a "monodisperse molecular mixed host" which combines good transport properties for both types of charges. PCTrz has a triplet energy of 2.91eV, which makes it suitable as host material for blue phosphorescent emitters. The material exhibits high thermal stability and good sublimation properties. The glass transition temperature of 148 °C ensures morphological stability of the host–guest emission layer during the operation of the device. An organic light emitting diode with PCTrz as host for FIrpic were fabricated. They exhibited a high current efficiency of 13.5 cd/A at a luminance of 1000 cd/m^2 combined with a maximum luminance of 29,000 cd/m^2.

2. Experimental

2.1. Synthesis of the host material

The synthesis of PCTrz is outlined in Scheme 1. The donor part is prepared by a modified *Goldberg* reaction [13] of 3,6-dimethylcarbazole and 4-iodoanisole followed by methyl ether cleavage with boron tribromide to yield 9-(4-hydroxyphenyl)-3,6-dimethylcarbazole in 62% yield. The synthesis of 2-chloro-4,6-biscarbazolyl-1,3,5-triazine (Trz) is described elsewhere [12]. Finally, PCTrz is prepared by a nucleophilic substitution at the triazine core in 80% yield.

2.1.1. Materials

All commercially available reagents were purchased from Aldrich and used without further purification. The synthesis of 2,4-biscarbazolyl-6-chloro-1,3,5-triazine [12], tris[(3-phenyl-1H-benzimidazol-1-yl-2(3H)-ylidene)-1,2-phenylene]-Iridium (DPBIC) [14] and 2,8-bis(triphenylsilyl)-dibenzofuran (DBFSi) [15] is described in the literature.

2.1.2. 9-(4-Methoxyphenyl)-3,6-dimethylcarbazole (PC)

3,6-Dimethylcarbazole (3.90 g, 20 mmol), 4-iodanisole (5.15 g, 22 mmol), copper(I)-iodide (0.38 g, 2 mmol), potassium phosphate (4.24 g, 20 mmol) and (trans)-1,2-diaminocyclohexane (0.23 g, 2 mmol) were dissolved in 80 ml dry dioxane before the reaction mixture was refluxed for 14 h in an argon atmosphere. After cooling to room temperature the mixture was filtered to remove all inorganic salts and the solvent was removed under reduced pressure. The crude product was purified with column chromatography using a hexane/THF (10/1; V/V) eluent to yield 9-(4-methoxyphenyl)-3,6-dimethylcarbazol (4.01 g, 13.6 mmol) as white solid. (Yield: 68%). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 7.90.(s, 2H), 7.44 (d, 2H), 7.21 (m, 4H), 7.10 (d, 2H), 3.91 (s, 3H), 2.54 (s, 6H); ^{13}C NMR (75 MHz, $CDCl_3$, δ): 158.6, 139.8, 130.8, 128.7, 128.3, 126.9, 123.1, 120.1, 114.9, 109.3, 55.6, 21.4; EI-MS (m/z (%)): 301 (100) [M$^+$], 286 (25).

2.1.3. 9-(4-Hydroxyphenyl)-3,6-dimethylcarbazole

9-(4-Methoxyphenyl)-3,6-dimethyl-carbazole (3.45 g, 11.5 mmol) was dissolved in dry dichloromethane (60 ml) under argon and cooled to −78 °C before boron tribromide (8.80 ml of a 1 M solution in dichloromethane, 12.6 mmol) was added dropwise. The mixture was allowed to warm to room temperature under stirring. After the addition of water (20 ml) the organic phase was collected and the solvent was

removed under reduced pressure. The crude product was purified with column chromatography using a hexane/THF (7/1; V/V) eluent to yield 9-(4-hydroxyphenyl)-3,6-dimethylcarbazol (3.03 g, 10.6 mmol) as white solid. (Yield: 92%) ^{1}H NMR (300 MHz, $CDCl_3$, δ): 7.89 (s, 2H), 7.39–7.37 (d, 2H), 7.20 (m, 4H), 7.03–7.00 (d, 2H), 5.03 (s, 1H), 2.54 (s, 6H); ^{13}C NMR (75 MHz, $CDCl_3$, δ): 154.6, 139.8, 130.9, 128.8, 128.6, 127.0, 123.1, 120.1, 116.4, 109.3, 21.4;EI-MS (m/z (%)): 286 (100) [M^+].

2.1.4. 2,4-Biscarbazolyl-6-(4-(3,6-dimethylcarbazol-9-yl)phenoxy)-1,3,5-triazine (PCTrz)

4-Hydroxyphenyl-3,6-dimethylcarbazole (0.77 g, 2.67 mmol) and sodium hydroxide (0.10 g, 2.5 mmol) were dissolved in a water/dioxane mixture (20 ml, 1/1 (V/V)) at room temperature and stirred for 10 min until the solution was added to a solution of 2,4-biscarbazolyl-6-chloro-1,3,5-triazine (0.99 g, 2.23 mmol) in dioxane (40 ml). The mixture is stirred for 8 h at 70 °C. After cooling to room temperature and addition of water (20 ml) the solid is filtered and washed with water and ethanol. The crude product is further purified by recrystallisation from a hexane/THF mixture and sublimation to yield 2,4-biscarbazolyl-6-(4-(3,6-dimethylcarbazol-9-yl)phenoxy)-1,3,5-triazine (PCTrz) (1.24 g, 80%) as white crystalline solid. ^{1}H NMR (300 MHz, $CDCl_3{}^-F_3CCOOD$, δ): 8.73–8.70 (m, 4H), 8.08–8.05 (m, 4H), 7.96 (s, 2H), 7.78 (d, 2H), 7.64 (d, 2H), 7.44–7.40 (m, 10H), 7.28–7.25 (m, 2H), 2.59 (s, 6H); ^{13}C NMR (75 MHz, $CDCl_3{}^-F_3CCOOD$, δ): 171.5, 164.9, 150.4, 139.2, 138.5, 136.6, 129.6, 128.2, 127.3, 127.2, 126.8, 124.0, 123.7, 123.6, 120.3, 119.8, 117.4, 109.4, 21.3; EI-MS (m/z (%)): 696 (100) [M^+], 530 (30) [$M^+-C_{12}H_8N$], 348 (30) [M^{2+}], 166 (30) [$C_{12}H_8N$ (carbazole)]; T_m: 301 °C; T_g: 148 °C; T_d^1: 425 °C.

2.2. Characterization of the host material

2.2.1. Characterization

1H NMR spectra were recorded on a Bruker AC-300 at 300 MHz. All NMR-data given are given as chemical shifts δ (ppm) downfield from $Si(CH_3)_4$. MS spectra were obtained on a Finnigan Mat 8500, MAT 112 S Varian machine using EI-ionization. Melting points and glass transition temperature determination was carried out on a Perkin Elmer Diamond DSC at a heating/cooling rate of 10 K/min under nitrogen atmosphere. Thermogravimetric analysis (TGA) was performed on a Mettler Toledo TGA/SDTA851e machine at a heating rate of 10 K/min under nitrogen atmosphere. UV–vis absorption spectra were recorded on a Hitachi U-3000 instrument. Photoluminescence spectra were obtained using a Shimadzu Spectrofluorophotometer RF-5301PC. UVASOL solvents purchased from Merck were used to prepare solutions and films for optical characterization. Cyclic voltammetry measurements were carried out in absolute solvents measuring at a platinum working electrode vs. a $Ag/AgNO_3$ reference electrode. Each measurement was calibrated against an internal standard (ferrocene/ferrocenium redox system).

2.2.2. Single carrier device and OLED fabrication

The organic layers were deposited by thermal evaporation in high vacuum (<10^{-6} mbar) onto indium-tin-oxide (ITO, 10 ohm/square) precoated glass substrates. Prior to use the ITO glass was degreased using organic solvents and cleaned using an UV-ozon treatment for 30 min. The organic layers and the metal cathode were evaporated without breaking the vacuum.

2.2.3. Computational calculations

The transport levels of the materials used were determined via density functional calculations. For the ionization potential and the electron affinity first the geometry of the neutral as well as the charged states were optimized using the BP86-functional [16,17] in combination with a split-valence basis set (SV(P)) including polarization functions on all heavy atoms [18]. For the energetics single point calculations at the optimized geometries using the same functional in combination with a valence triple zeta basis set (TZVP) [19] were conducted. To account for dielectric solid state effects a UPS/IEPS-calibrated version of the conductor like screening model (COSMO) [20] was used in conjunction with the single point calculations. All calculations were carried out with the turbomole program package [21].

3. Results and discussion

3.1. Thermal properties of the host material

The thermal properties of PCTrz were investigated using thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The TGA curve in Fig. 1 (left) illustrates thermal stability up to 400 °C. A weight loss of 1% (T_D^1) is observed at 425 °C while T_D^5 is reached at a temperature of 453 °C. This value is more than 150 °C above the sublimation temperature of PCTrz and therefore substantiates its very high thermal stability. The morphological stability of an amorphous film strongly depends on the glass transition temperature (T_g) of the material. The T_g should exceed the operational temperature by 50 °C to guarantee morphological stability [22,23]. Regarding the temperature requirements of potential technological applications for OLEDs [24] a T_g of more than 110 °C should be high enough to prevent the crystallization of an amorphous film during operation. In the inset in Fig. 1 (left) the second DSC heating scan of PCTrz is shown. The T_g is observed at 148 °C followed by an exothermic peak at 201 °C which is assigned to the crystallization of the material. The endothermic peak at 301 °C corresponds to the melting of the sample. These thermal properties, especially the high T_g, fit very well into the profile of requirements for a host material.

3.2. Optical properties of the host material

The absorption and fluorescence spectra measured in cyclohexane solution are given in Fig. 1 (right). The absorption spectrum of PCTrz is an almost perfect addition of the absorption of its two parts 2-chloro-4,6-biscarbazolyl-1,3,5-triazine (Trz) and 9-(4-methoxyphenyl)-carbazole (PC) (gray line and gray dotted line in Fig. 1 (right)). Therefore the low energy maximum at 349 nm is attributed to the phenoxy-carbazole moiety. The maximum at 327 nm

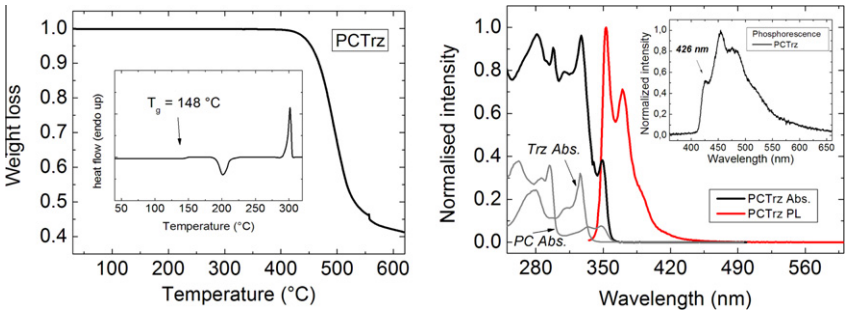

Fig. 1. Left: Thermal characterization of PCTrz:TGA curve (10 K/min; N_2); inset: second DSC scan (10 K/min; N_2; after; fast cooling of the melt at 40 K/min); right: absorption of PCTrz (black line), PC (gray line) and Trz (gray line) as well as fluorescence (red line) in cyclohexane solution at room temperature. Inset: phosphorescence of PCTrz at 10 K. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

is attributed to the π–π^* transition of the carbazole moiety of the carbazolyl-triazine. The optical bandgap of 3.45 eV was estimated from the absorption edge at 359 nm. On excitation the fluorescence of PCTrz is detected. It consists of two maxima at 353 and 370 nm as well as a shoulder at 390 nm. This fluorescence behavior is identical to phenylcarbazole with a small hypsochromic shift due to the strong electron accepting character of the triazine which is located para to the carbazole. However, the influence of the triazine is only weak due to the non-conjugated ether bond.

In contrast to that the two carbazoles which are directly bound to the triazine are strongly influenced and possess a more electron deficient character. It can be supposed that the energy which is absorbed by the carbazolyltriazine part undergoes intramolecular transfer to the phenoxy-carbazole part. Therefore, only the fluorescence of this moiety is detected. To determine the triplet energy of PCTrz a phosphorescence spectrum (see inset in Fig. 1 (right)) of a film (120 nm) consisting of 10% PCTrz and 90% PMMA was measured at a temperature of 10 K. The triplet energy is obtained from the first vibronic transition of the phosphorescence spectrum. PCTrz shows a 0–0 phosphorescence transition at 426 nm (2.91 eV) and a maximum centered at 472 nm which correspond to the 0–1 transition. From this high triplet energy value it can be assumed that exothermic energy transfer to most blue phosphorescent emitters is possible.

3.3. Electrochemical properties and single carrier devices of the host material

In order to demonstrate the improved hole injection properties of PCTrz compared to other carbazole substituted triazines [12], cyclic voltammetry (CV) and single carrier device (SCD) measurements were carried out. The electrochemical behavior upon oxidation and reduction was studied in CH_2Cl_2 and THF solution, respectively (see Fig. 2 (middle)). Both oxidation and reduction processes of PCTrz exhibit reversible behavior in multi-scan experiments. The oxidation is observed at a half-wave potential of 0.68 V (vs. Fc/Fc^+). This result is in contrast to the irreversible oxidation of donor-substituted triazines without phenoxy-carbazole moiety like TRZ2 (see Fig. 2). Furthermore, the oxidation of TRZ2 was observed at distinctly higher potential (1.16 V vs. Fc/Fc^+). Therefore the oxidation wave of PCTrz at 0.68 V is attributed to the oxidation of the phenoxy-carbazole moiety. This is supported by the similar oxidation behavior of 9-(4-methoxyphenyl)-3,6-dimethylcarbazole (PC; E_{ox} = 0.69 V). The perfectly reversible oxidation behavior can be explained by the blocking of the reactive 3- and 6-position of the phenoxy-carbazole, since it is known that unprotected carbazoles undergo side-reactions upon oxidation [25]. The reduction of PCTrz is observed at a half wave potential of −2.61 V (vs. Fc/Fc^+). Due to the similarity to the reduction of TRZ2 it is attributed to the reduction of the triazine moiety. Furthermore these results are invigorated by computational calculations of the electron density distribution of the HOMO and LUMO (see Fig. 2). It was found that the electron density is centered on the HOMO of the phenoxy-carbazole moiety, while the LUMO is mainly confined on the triazine ring. These results substantiate the successful separation of electron accepting and donating counterparts. The oxidation and reduction potentials of PCTrz can be translated to an ionization potential (IP) of 5.48 eV and an electron affinity (EA) of 2.20 eV, respectively. The decreased HOMO of PCTrz compared to TRZ2 should yield improved hole injection properties. The *I*–*V*-characteristics of hole- and electron-only devices are presented in Fig. 2 (left).

The charge transport properties of PCTrz were investigated with single carrier devices with the following configuration: hole-only-device: ITO/HIL (80 nm)/NPD (p-doped, 35 nm)/NPD (10 nm)/PCTrz (30 nm)/NPD (10 nm)/NPD (p-doped, 35 nm)/Al; electron-only-device: ITO/BCP (n-doped, 70 nm)/BCP (10 nm)/PCTrz (30 nm)/BCP (10 nm)/BCP (n-doped, 30 nm)/Al. For the electron-only devices the n-doped BCP (HOMO = 6.5 eV) effectively prevented the injection of holes from the ITO anode (4.8 eV) and enhances the electron injection and transport. In a similar way the p-doped NPD prevents the injection of electrons from the cathode in case of the hole-only devices and enhances the hole injection and transport. In Fig. 2 (left) the current density–voltage (*I*–*V*)-characteristics of hole- and electron-only-devices of PCTrz and TRZ2 are compared. From the hole-only-device characteristics it can be seen that the turn on voltage of the PCTrz device is about 2.5 V lower compared to that of TRZ2. Also at current-densities of 100 mA cm^{-2} the

Fig. 2. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

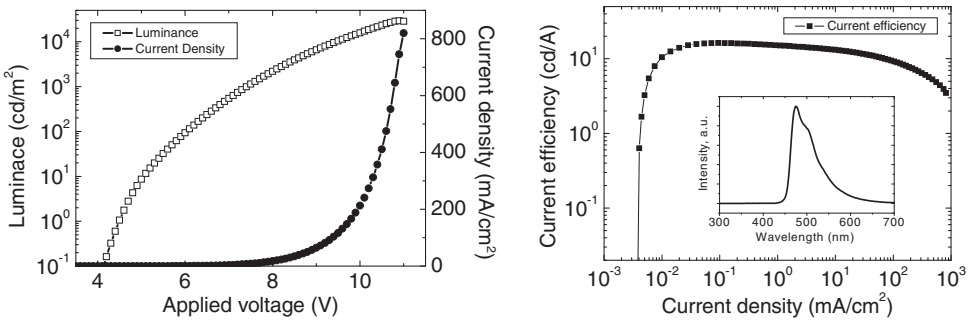

Fig. 3. Left: Luminance–voltage–current density characteristics and right: current efficiency–voltage characteristics of the blue phosphorescent OLED (for details see text) inset: electroluminescence spectrum of the device.

difference in driving voltage is about 2.5 V. This behavior can be understood with respect to the higher IP of PCTrz which facilitates the hole injection from the hole transporting NPD layer. From the *I–V* curves of the electron-only devices it can be seen that the device with PCTrz exhibits a much lower threshold voltage. At current densities of 100 mA cm^{-2} the difference in voltage is as high as 7 V. This behavior cannot be explained by a restrained injection as the LUMO levels are very similar for both materials. Therefore we speculate that a different packing behavior (morphology) might favor electron transport in PCTrz.

3.4. Phosphorescent organic light emitting diodes

In order to demonstrate the potential of PCTrz as host material for blue phosphorescent emitters an OLED with the following configuration was fabricated. On top of indium-tin-oxide (ITO) poly(thiophene-3-[2-(2-methoxyethoxy)ethoxy]-2,5-diyl) was used as hole-injection layer followed by 35 nm of DPBIC p-doped with molybdenum(VI) oxide as hole-transporting layer. An additional 10 nm thick layer of DPBIC followed as exciton and electron blocker. The 20 nm thick emission layer consisted of PCTrz doped with 16% FIrpic. The hole-blocking and electron-conduction layers consisted of 5 nm DBFSi and 40 nm BCP. The devices were finalized by deposition of a LiF (0.7 nm)/Al (100 nm) cathode.

Fig. 3 displays the current density–voltage–luminance (left) and current efficiency–voltage characteristics (right) of the device. The inset in Fig. 3 (right) shows the electroluminescence spectrum of the devices at a current density of 10 mA cm^2. The spectrum shows the pure emission of FIrpic with a maximum at 473 nm and CIE coordinates of $x = 0.17$ and $y = 0.33$. The device exhibits a maximum current efficiency of 16.2 cd/A at a luminance of 20 cd/m^2. The maximum values of external quantum efficiency and power efficiency are 7.8% and 10.1 lm/W, respectively. The maximum luminance of 29,000 cd/m^2 is reached at 10.9 V. At a luminance of 1000 cd/m^2 the current efficiency of 13.5 cd/A was measured. These results demonstrate the potential of PCTrz as host material for blue phosphorescent OLEDs.

In summary we have designed a new bipolar host material, which contains a phenoxy-carbazole that is separated from the biscarbazolyl-triazine by a non-conjugated ether bond. PCTrz exhibits a very high thermal stability and its glass forming properties are excellent. The T_g of 148 °C is high enough to ensure morphological stability in OLED applications. Results from cyclic voltammetry and computational calculations proved the separation of the oxidation- and reduction-site. The charge carrier injection and

transport properties were significantly improved compared to donor-substituted triazines like TRZ2. A phosphorescent OLED with PCTrz as host and FIrpic as blue emitter yielded high current efficiencies of up to 16.2 cd/A.

Acknowledgments

We thank C. Bonsignore for his support during the preparation and characterization of the single carrier devices and organic light emitting diodes. We also like to thank S. Hoffmann for recording the phosphorescence spectrum. We are grateful to the BMBF for financial support through the project OPAL 2008 (Grant No. 13N8992).

a variety of intermolecular interactions such as van der waals (vdw) interactions, weak hydrogen bondings, π...π stacking, and sulfur...sulfur interactions [14,15]. In contrast to linear oligomer, a new family of oligothiophenes, namely, the macrocyclic oligothiophenes, has been synthesized by Bäuerle and co-workers [16–18]. Several papers which characterize these novel molecules and investigate their physical properties by X-ray and scanning tunneling microscopy (STM) coupled with semiempirical theoretical calculations have been reported by the same group [19–21]. Due to the novel structures of these macrocycles, some groups investigated their ring strain, the geometry of cyclic oligomers, optical spectra, Raman spectra, ionization energy, and the factors influencing the band gap, etc. and showed that these materials probably possessed excellent electronic properties [22–24], but so far, their carrier mobility have not been quantitatively obtained by neither experimental nor theoretical investigation. Many groups systemically investigated charge transport properties of linear oligothiophenes and the factors influencing these properties, such as the relative orientations, intermolecular separations, solid-state packing of these molecules, reorganization energies, and substituent effects, etc. [25–32]. But the investigation of these properties of cyclic oligothiophenes is only at the initial stage. So this work mainly predicted theoretically their carrier mobility, and investigated the factors influencing the mobility and some intrinsic reasons that gave rise to the differences in charge transport properties between linear and cyclic oligothiophenes studied (Fig. 1). The theoretical investigations may be useful to find new leading materials and likely to provide important information for improving transport efficiency (enhancing device response), reducing power, and finding new applications of the promising materials.

2. Theoretical and computational methodology

There are mainly two types of carrier transport mechanisms in organic electronic materials: (1) the coherent

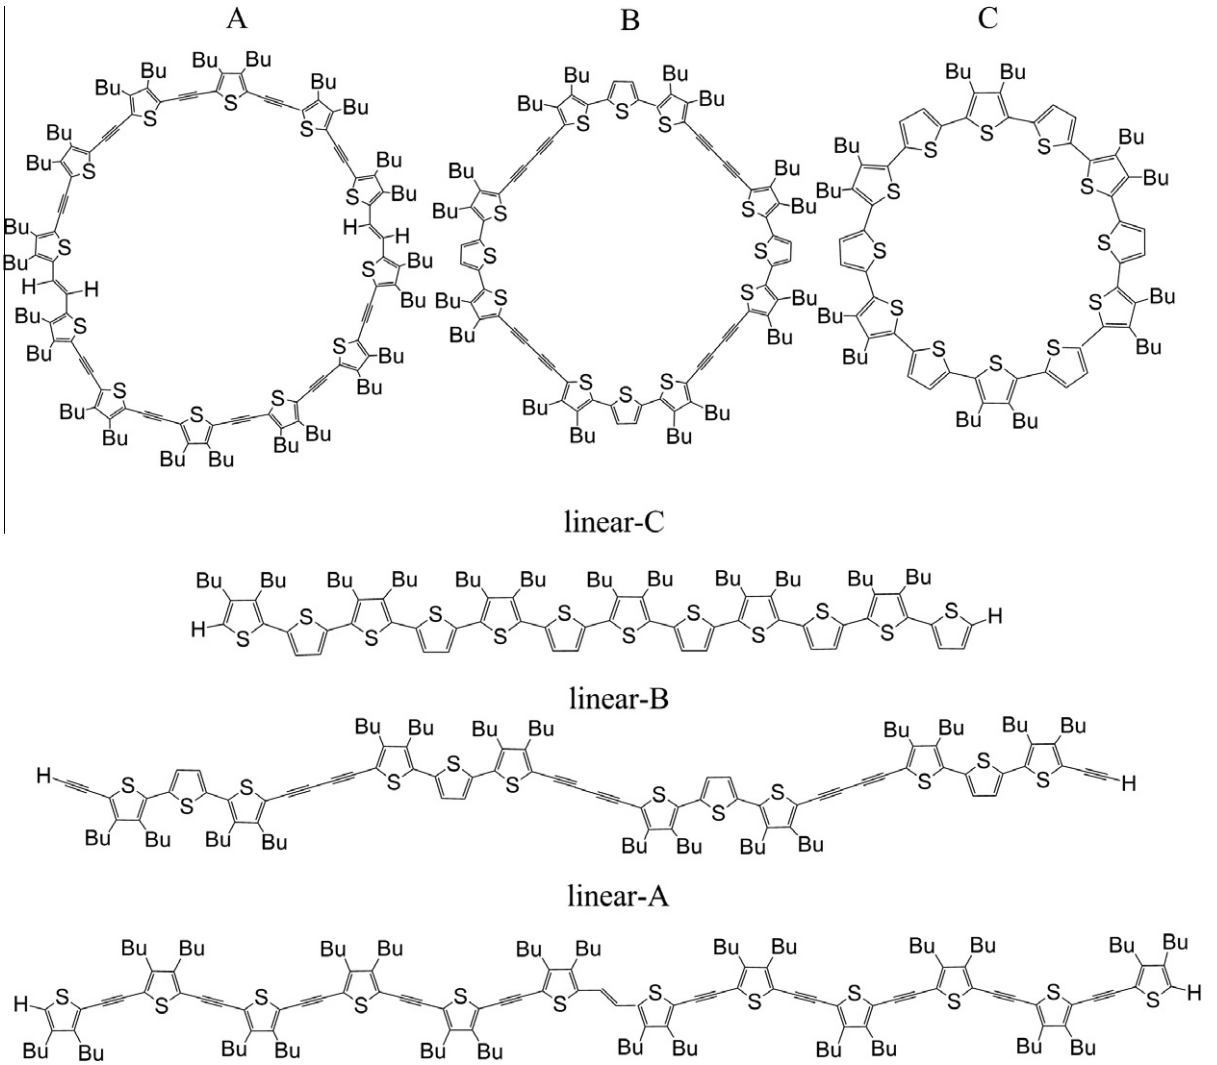

Fig. 1. Chemical structures of the compounds studied.

band mechanism and (2) the incoherent hopping mechanism. In low temperature, the band mechanism dominates for organic materials. The carrier moves as a highly delocalized plane wave in an energy band. The interaction between the nearest-neighbor sites is large compared with dynamic structural disorder, for instance, the reorganization energies resulting from charge transfer process from one molecule to another. At high temperature (are probably at room temperature), the band mechanism may be invalid, because charge carriers are expected to be localized over a single molecule (due to the strong electron–phonon coupling, which is a major nature of π-conjugated materials). The motion of the carrier can be described as the sequential jumps of the relaxed charges between adjacent molecules, that is, the mechanism can be referred to as hopping mechanism. Extensive experimental evidences, particularly the observed thermal signatures and optical spectra are consistent with this assumption [33–36].

Here, each hopping event is viewed as a nonadiabatic charge transfer reaction: $M+M^{+/-} = M^{+/-}+M$, which is a self-exchange reaction. Charge transfer rate between neighboring molecules can be expressed by standard Marcus theory by the following equation: [37–40]

$$k_{ct} = \frac{4\pi^2}{h}\frac{V^2}{\sqrt{4\pi\lambda k_B T}}\exp\left\{-\frac{(\Delta G^0+\lambda)^2}{4\lambda k_B T}\right\} \quad (1)$$

where ΔG^0 is the free energy difference between the initial and final states, λ is the reorganization energy, and V is the electronic coupling matrix element between the two species M and $M^{+/-}$. For our case, where charge transfer reaction is the self-exchange reaction, ΔG^0 is zero. Thus the rate is mainly determined by two important parameters: the intermolecular electronic coupling matrix element (V) and reorganization energy (λ) (see Fig. 2(a)). For the hopping approximation to be valid, the system needs to be strongly localized in one of the two states in Fig. 2(a), that is, the coupling between neighboring molecules are small. The reaction coordinate Q in Fig. 2(a) is an ensemble of geometric modifications of the dimer system. The reorganization energy (λ) contains the internal reorganization energy (λ_{int}) and external reorganization energy (λ_{ext}). λ_{int} reflects the geometric relaxation associated with going from the neutral to the ionized state, and vice versa. λ_{ext} describes the relaxation of the surrounding medium. λ_{ext} is commonly neglected. The internal reorganization energies (λ_{int}) are evaluated directly from the adiabatic potential-energy surfaces of neutral/cation or neutral/anion species (see Fig. 2(b)). λ for hole can be defined as follows

$$\lambda_h = \lambda_+ + \lambda_1 = [E^+(M) - E^+(M^+)] + [E(M^+) - E(M)] = IP(v) - HEP \quad (2)$$

As illustrated in Fig. 2(b), $E^+(M^+)$ and $E(M)$ represent the energies of the cation and neutral species in their lowest energy geometries, respectively, while $E^+(M)$ and $E(M^+)$ represent the energies of cation and neutral species with the geometries of neutral and cation respectively. In this way, λ for electron can be expressed as follow

$$\lambda_e = \lambda_- + \lambda_2 = [E^-(M) - E^-(M^-)] + [E(M^-) - E(M)] = EEP - EA(v) \quad (3)$$

The obove quantities were calculated at density functional theory (DFT) level, using the B3LYP functional and 6-31g(d) basis set. All calculations on open shell (ionized) states used the unstricted formalism (UB3LYP).

To calculate the electronic coupling matrix element, V, all the possible nearest-neighbor intermolecular hopping pathways are shown in Fig. 3. Within the framework of the Marcus–Hush two-state model, we calculated the coupling matrix element between adjacent molecules using the "energy splitting in dimer" (ESD) method [41,42], as sketched in Fig. 4. V for hole/electron in this scheme can be obtained by the following equation [43,44].

$$V = \frac{1}{2}\sqrt{(E_{HOMO/LUMO+1} - E_{HOMO-1/LUMO})^2 - (e_2 - e_1)^2} \quad (4)$$

where $E_{HOMO/LUMO+1}$ and $E_{HOMO-1/LUMO}$ are the energies of the HOMO and HOMO − 1(LUMO and LUMO + 1) levels

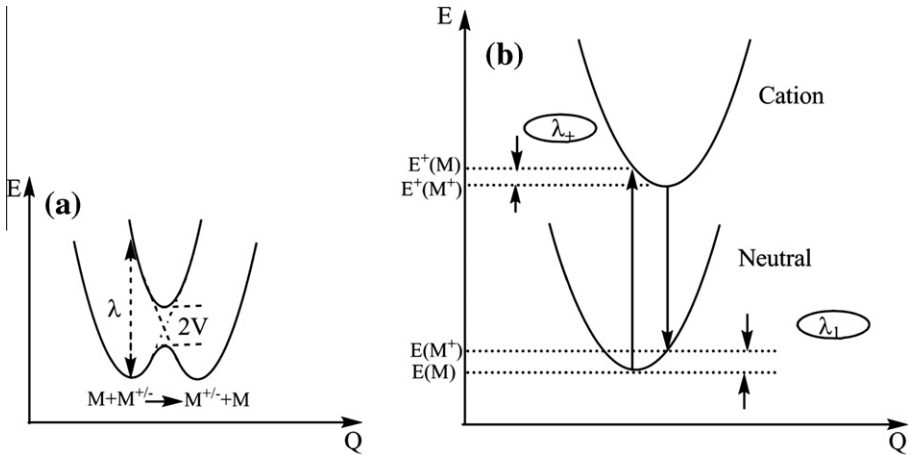

Fig. 2. (a) Schematic representation of a charge exchange reaction pathway for hole transfer through a transition state by weak (nonadiabatic) coupling. The solid curves are the adiabatic surfaces, while the dashed lines refer to diabatic surfaces. (b) Schematic description of internal reorganization energy for hole transfer.

taken from the closed-shell configuration of the neutral dimer, respectively; e_1 and e_2 is the site energy of the isolated molecule in the dimer, respectively. As sketched in Eq. (4), the electronic coupling matrix element can be

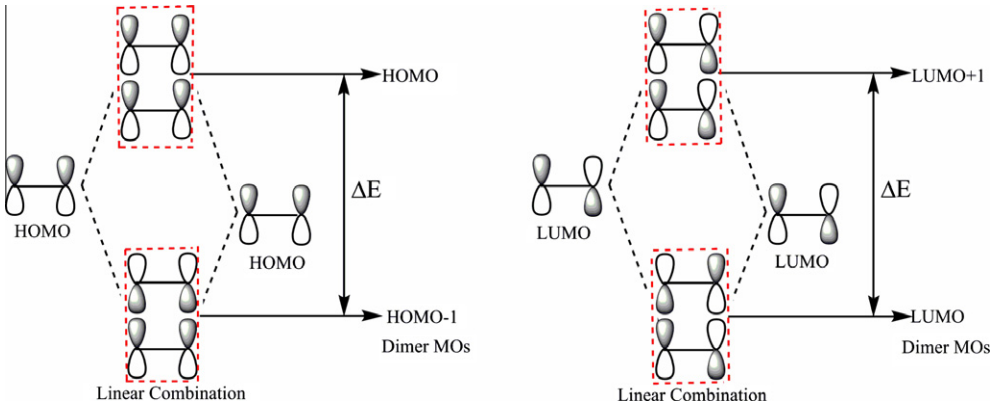

Fig. 4. Diagram for the estimate of coupling matrix element in the neutral dimer.

strongly affected by the site energies. In our case, the molecules stack symmetrically (see Fig. 3), that is, the isolated molecules are in equivalent sites in the crystal, so the site energy difference Δe_{12} ($= e_2 - e_1$) is zero, so Eq. 4 can be written as

$$V = \frac{E_{\mathrm{HOMO/LUMO+1}} - E_{\mathrm{HOMO-1/LUMO}}}{2} \tag{5}$$

The electronic coupling matrix elements for all the hopping pathways were calculated by employing the pw91pw91/6-31g(d) method. The study of Huang et al. showed that the functional gave the best description for the bandwidth of organic solid [45] and Shuai et al. also investigated many conjugated molecules and obtained very good results using the pw91pw91 functional [28,46,47]. Many groups investigated the effects of the basis sets on the *V* values, such as 6-31g, 6-31g(d) and 6-311g(d,p). The results indicated that the *V* values were largely independent of the above base sets [26,48]. To clarify the effects of the diffuse function on electronic coupling matrix elements for our systems studied, these V values for molecule B were calculated and compared by using the two basis sets: 6-31g(d) and 6-31+g(d). (the results calculated by using 6-31+g(d) are listed in Table S2 of Supporting Information). We found that for most of the hopping pathways, these values and their variation trend possess small change, in result that the lack of the diffuse function can not largely affect the *V* values for the dominant transfer pathways and hence the final mobility. In addition, many investigations have obtained the reliable results for the different systems by employing 6-31 g(d) basis set [26,42,46–50]. So for our systems studied, it should be reliable that these electronic coupling matrix elements for all the hopping pathways were predicted by using 6-31 g(d) basis set.

In this context, the charge transport is modeled as a Brownian motion process, as described by a particular diffusion process. The mobility can be obtained by the Einstein equation [51]

$$\mu = \frac{e}{k_B T} D \tag{6}$$

where μ is the carrier mobility, D is the isotropic charge diffusion coefficient, T is the temperature, K_B is the Boltzmann constant and e is the electronic charge. Given the hopping rate between the nearest-neighbor molecules, the diffusion coefficient can be evaluated from the hopping rates as

$$D = \frac{1}{2n} \sum_i r_i^2 k_i P_i \tag{7}$$

where n is the dimensionality (when n is equal to 3, the average mobility of all the hopping pathways can be evaluated), k_i is the hopping rate due to charge carrier to the ith neighbor, r_i is the distance to neighbor i, P is the relative probability for charge carrier to a particular ith neighbor,

$$P_i = k_i \Big/ \sum_i k_i \tag{8}$$

Summing over all possible hops leads to the diffusion coefficient in Eq. (7). All the calculations were performed with the GAUSSIAN 03 package [52].

3. Results and discussions

The geometrical structures for the neutral and ionized states of compounds studied were optimized by employing the B3LYP/6-31g(d) method, presenting their geometrical parameters in Table S1 (Supporting Information), and then calculated the ionization potentials (*IP*s), electron affinities (*EA*s) and reorganization energies (λs) on the base of their equilibrium geometries for comprehensive understanding the charge injection and transport properties of organic electronic materials. The ionization potential (*IP*) and electron affinity (*EA*) are well-defined properties that can be calculated by DFT to estimate the charge injection barrier. And for improving the ability of electron and hole injection of electronic devices, the achievement of high *EA* and low *IP* is crucial. According to Eq. 1, lower λ value leads to bigger charge transport rate according to Eq. 1, so one of the aims of material design is the obtainment of low λ value. Table 1 contains the ionization potentials (*IP*s), electron affinities (*EA*s), both vertical (*v*; at the geometry of the neutral molecule) and adiabatic (*a*; optimized structures for both the neutral and charged molecules), and the extraction potentials (*HEP* and *EEP* for the hole and electron,

Table 1
*IP*s, *EA*s, extraction potentials, reorganization energies and the HOMO and LUMO energies for each molecule (eV).

Species	$IP(v)$	HEP	λ_h	$IP(a)$	$EA(v)$	EEP	λ_e	$EA(a)$	HOMO	LUMO	ΔE_{H-L}
A	5.06	4.93	0.13	4.99	1.71	1.85	0.14	1.79	−4.54	−2.24	2.30
B	5.29	5.18	0.11	5.22	1.62	1.78	0.16	1.69	−4.74	−2.18	2.56
C	5.43	5.15	0.28	5.30	1.00	1.33	0.33	1.16	−4.73	−1.71	3.02
Linear-A	5.02	4.87	0.15	4.94	1.85	2.01	0.16	1.93	−4.48	−2.40	2.08
Linear-B	5.38	5.08	0.30	5.09	1.67	1.95	0.28	1.93	−4.84	−2.22	2.62
Linear-C	5.46	4.98	0.48	5.18	1.13	1.58	0.45	1.39	−4.76	−1.84	2.92

respectively) that refer to the geometries of the ions, the reorganization energies for both hole and electron transport.

The charge injection and transport properties of these materials studied are discussed from the following several points.

3.1. Charge injection properties

Good charge injection and transport properties of organic semiconductors as electron/hole transport layer (ETL/HTL) are crucial to improve the performance of OLED. In terms of the energy difference between the Fermi level (E_F) of electrodes and the highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) of organic semiconductor materials, the hole/electron injection barrier can be understood to measure the ability of the charge injection. IP and EA values of organic materials are the most important parameters that characterize the reduction and oxidation performance of the materials, respectively. So the decrease of the charge injection barrier, the achievement of high EA for ETL materials and low IP for HTL materials playing an important in improving the electroluminescence (EL) efficiency of OLED. For the comparison of the ability of charge injection for these organic materials studied, Fig. 5 shows their energy levels alignment.

From Table 1, cyclic oligomers mostly possess lower $IP(v)$ and $EA(v)$ values compared with their corresponding linear molecules. For molecules linear-A, better planarity decreases its energy gap (ΔE_{H-L}), which leads to higher

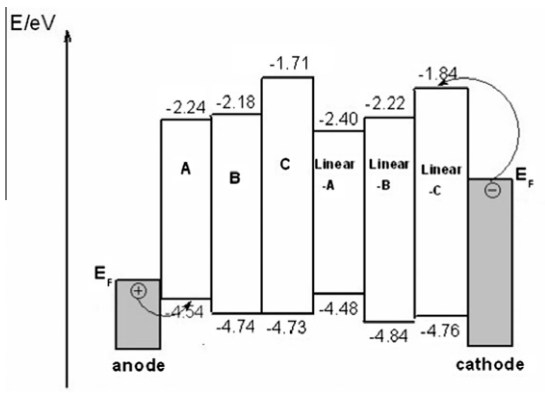

Fig. 5. Schematic drawing of the energy levels alignment of the molecules studied.

HOMO level and thus lower $IP(v)$ value. The fact can be found that cyclic oligomers mostly possess stronger reduction ability, whereas the linear ones show better oxidation performance. From Fig. 5, hole injection barriers of cyclic oligothiophenes are almost lower than those of the corresponding linear ones, while the electron injection from cathode into linear molecules is easier.

Due to their low charge injection barriers and small λ values for molecules A, B and linear-A, they can be excellent charge transport layer materials. From the investigation of the following section, high carrier mobility of molecular materials A and B also demonstrates their fine charge transport properties.

3.2. Charge transport properties

3.2.1. Reorganization energy: A. Molecular geometrical structures

From Table S1, it can be found that the bond lengths and bond angles have little change between the neutral and corresponding ions geometries for all the compounds and these changes are very close among different compounds, while the changes of the torsion angles of two adjacent thiophene rings have greatly difference among different compounds. For compound A, the maximal change value of the torsion angles between the neutral one and cation(anion) is 14.1° (13.5°). The changes of the torsion angles for molecule B are similar to that for molecule A. But for molecule C, the changes of the torsion angles resulting from hole (electron) transfer are within a wide range from 7.1° (3.3°) to 13.1° (32.1°), and most of torsion angle changes for the molecule C are larger than those for both molecules A and B. These facts are the indication of the intrinsic difference of the relaxation processes occurring in these systems: small differences between the neutral and ion geometries lead to low reorganization energy, and vice versa. Due to larger torsion angle changes for molecule C compared with both molecules A and B, it possesses larger internal reorganization energies for both the hole and electron. The introduction of the alkynyl relieves the strain of the macrocycles composed of twelve thiophene rings for molecules A and B, which make their structures more stable. But for molecule A, C–C double bond improves the flexibility of the whole macrocycle, so their introduction gives rise to a "ring flip" of the thiophene adjacent to double bond and large changes of the torsion angles between the thiophene rings adjacent to double bonds in charge transfer process.

To reveal the effects of the closed ring structure on transport properties of these molecules, cyclic oligothioph-

enes are compared with their corresponding linear ones. Through the comparisons, we find that the geometric deformations in charge transfer process are no greatly different between compounds A and linear-A. But for molecule linear-B, the changes of the torsion angles accompanying with hole (electron) transfer are within a wide range from 18.6° (11.5°) to 60.6° (63.8°), while for cyclic molecule B, these changes are within a narrow range from 4.7° (3.2°) to 9.8° (9.8°). For molecules C and linear-C, the changes of the torsion angles have a similar situation (see Table S1). These facts show that the closed ring structure effectively suppresses the rotation of the thiophene rings and reduce the geometrical deformation accompanying with charge transfer, so it leads to low reorganization energy and consequently improves charge transport properties of these macrocycles.

B. Frontier molecular orbitals, ionization potentials and electron affinities. From the perspective of electronic structure, charge injection and transport properties of these compounds can be fundamentally understood. It is useful to examine HOMOs and LUMOs of these compounds because their relative ordering can provide a reasonable qualitative indication of the ability of charge injection and transport. We have plotted the contour plots of HOMO and LUMO of the linear oligothiophenes and cyclic oligothiophenes in Figs. 6 and 7, respectively.

As sketched in Figs. 6 and 7, the electronic cloud of the frontier orbitals of all compounds spread over the whole π-conjugated backbone, although dense electronic cloud distributes on the different parts of chromophores. For molecule C, the HOMO shows antibonding character between two adjacent thiophene rings, while the LUMO shows a bonding character. So the variation of torsion angles between the adjacent thiophene rings should have larger effects on the LUMO. Indeed, for molecule C, the torsion angles are mostly larger than those for both molecules A and B. Large torsion angles decrease the bonding character between two adjacent thiophene units for LUMO level and thus destabilize it, so it weakens the abilities of electron injection and transport, and hence leads to low EA and large electronic reorganization energy. It may be the reason that two neighboring thiophene rings show the cis-conformation, namely, two sulfur atoms in the two rings are in the same side, and the sulfur atom in every thiophene ring possesses a lone electron pair which gives rise to very strong coulomb repulsion between sulfur atoms in adjacent thiophene rings. But for molecules A and B, the introduction of the alkynyl and double bond increases the separation between the thiophene rings, which are beneficial to weakening this repulsion and steric effects. To present the frontier orbitals more quantitatively, the sum of the square of the LCAO coefficients for HOMOs and LUMOs of all the molecules studied was analyzed in Fig. S1 (Supporting Information); a large value on a atom reflects large electronic density on the atom, and the results are presented in Fig. S1 (Supporting Information). For cyclic oligothiophenes, as the introduction of the alkynyl and double bonds increases their conjugation extent, this gives rise to lower electronic density of π-conjugated backbone of both molecules A and B compared with that of molecule C. So the geometric deformation in charge transfer process for molecules A and B is less remarkable, which leads to smaller reorganization energies.

The fashion of the introduction of the alkynyl largely influences the torsion angle between two neighboring thiophene rings. Each alkynyl is located in the middle of neighboring thiophene rings for molecule A, which weakens efficiently the repulsion and the steric effects, and hence leads to small torsion angles. But for molecule B, it can not largely lower those interactions, because of its molecular fragments similar to that of molecule C and larger torsion angles between adjacent thiophene rings. Compared with molecules B and C, the increase of the conjugation extent and smaller torsion angles for molecule A give rise to higher HOMO and lower LUMO levels, in result to lead to lower IP, higher EA values and smaller

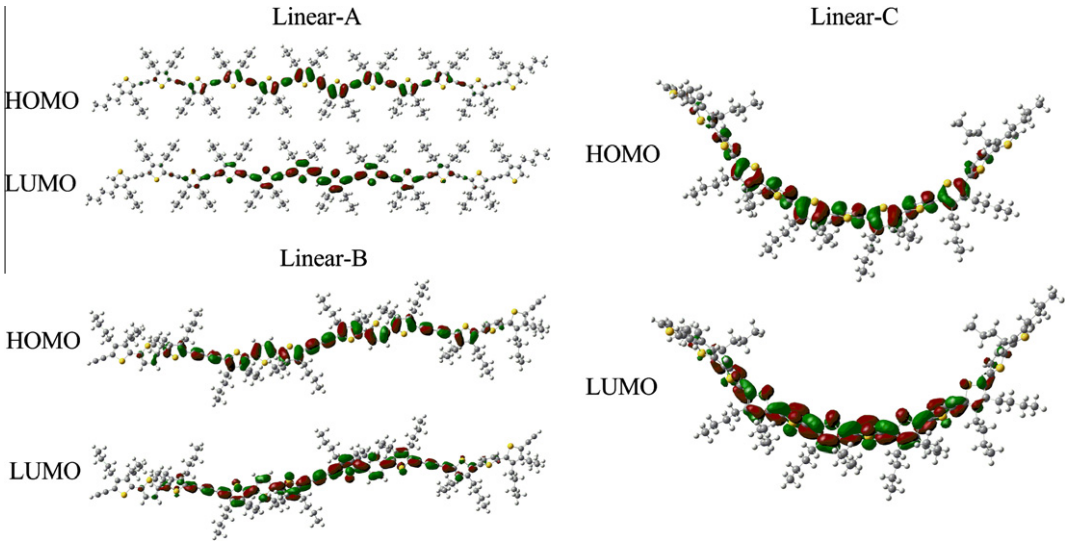

Fig. 6. The contour plots of the frontier orbitals for molecules linear-A, linear-B and linear-C.

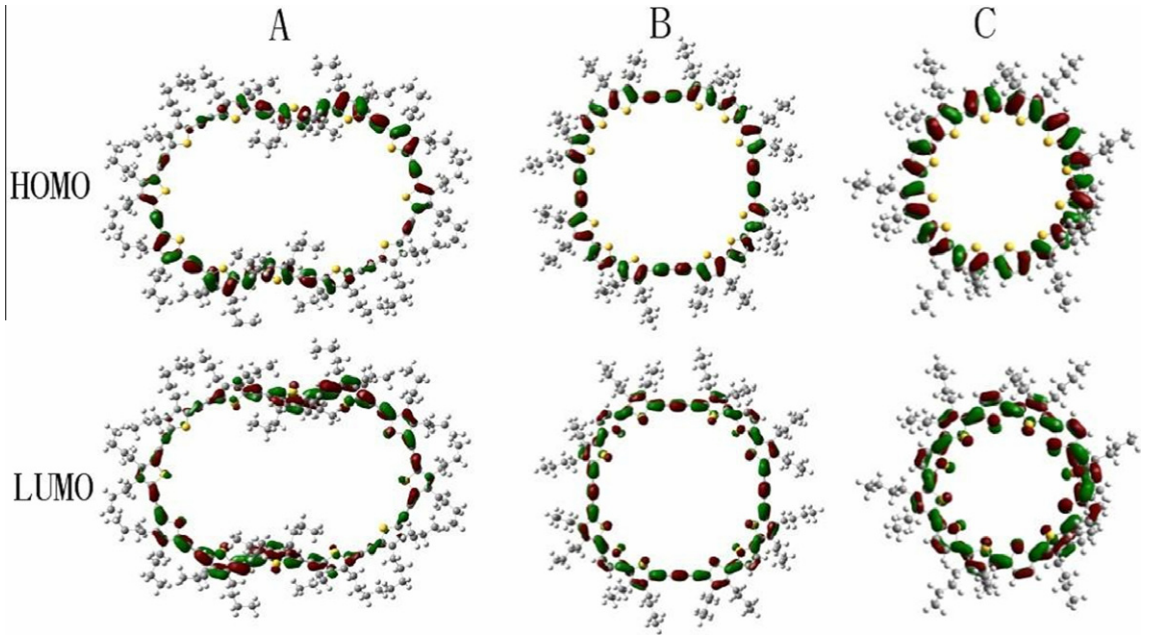

Fig. 7. The contour plots of the frontier orbitals for cyclic oligthiophenes A, B and C.

reorganization energies, and hence improve its charge injection and transport properties. Compared with the macrocycles, except for molecule linear-A, the torsion angles of other corresponding linear molecules do not possess large change in charge transfer progress. This is fully understandable: the fashion of the introduction of the alkynyl does not change and the steric effects resulting from the butyls still are obvious. For molecule linear-A, the breakage of one of double bonds and favorable position of the alkynyl give rise to the best planarity comparing with other molecules. It leads to high HOMO level and low LUMO level, so it possesses good properties of hole/electron injection ($IP(v) = 5.02$ eV, $EA(v) = 1.85$ eV) and transport. ($\lambda_h = 0.15$ eV, $\lambda_e = 0.16$ eV).

3.2.2. Electronic coupling matrix element

According to Eq. 1, it is obvious that for the achievement of high charge transport rate, the materials not only possess λ value, but also large V value. To calculate V, we identified 13 distinct nearest-neighbor hopping pathways (see Fig. 3) based on the crystal structures of molecules A and B, and hence calculated the corresponding V values for all the pathways using Eq. (5) (these results were presented in Table 2, (a) for A, while, (b) for B). The crystal structures of the two molecules belong to the triclinic system with space group $P\bar{1}$ and lattice constants: $a = 12.69$ Å, $b = 16.13$ Å, $c = 20.02$ Å, $\alpha = 93.98°$, $\beta = 96.60°$, $\gamma = 107.50°$ (for A) and $a = 11.91$ Å, $b = 16.44$ Å, $c = 17.75$ Å, $\alpha = 113.17°$, $\beta = 98.40°$, $\gamma = 104.63°$ (for B) [16,53]. From Table 2, it is interesting to note following points:

(i) For molecule A, most coupling matrix elements for the electron are close to those for the hole. The dominant transfer pathways are pathways 2 ($V_h = 62.586 \times 10^{-4}$ eV, $V_e = 176.874 \times 10^{-4}$ eV), 6 ($V_h = 142.862 \times 10^{-4}$ eV, $V_e = 58.504 \times 10^{-4}$ eV), and 8 ($V_h = 168.711 \times 10^{-4}$ eV) (Fig. 8(a)). According to Eq. 1, the maximal k_{ct}s for the hole and electron should occur in pathway 8 and pathway 2, respectively and should be very close, because the reorganization energy for the hole is only 0.01 eV smaller than that for the electron. In Table 2, The mass center distance (D_1) of two adjacent molecules in pathway 1 is close to that in pathway 2, but their V values for both the hole and electron make notably difference. The phenomena can be rationalized by examining the crystal structure and major interactions taking place between two adjacent molecules. For the crystal structure of molecule A, although the D_1 of the dimer in pathway 1 is 3.44 Å smaller than that in pathway 2, the perpendicular distance (D_2) of the dimer in pathway 1 is 9.65 Å larger than that in pathway 2. Large perpendicular distance leads to a poor overlap of HOMOs and LUMOs of two interacting molecules and consequently small V_h and V_e values, such as pathways 3, 4, 5, 7, 9, 11, 13. Small perpendicular distance leads to good overlap of orbitals of two interacting molecules, because of much intermolecular interaction in these systems, such as sulfur...sulfur and π...π interaction. For pathways 2, 6 and 8, the nearest sulfur...sulfur distances are within 4.15, 4.37, and 3.88 Å and the nearest π...π distances are within 3.74, 4.08, and 4.05 Å, respectively, which is promising to lead to significant intermolecular electronic coupling. From the HOMO and LUMO plots of molecule A in Fig. 7, the HOMO and LUMO wave functions are mainly localized on around the flipping thiophene ring and C–C double bonds. The major interactions of the dimers in the three dominant pathways occur in

Table 2
The mass center distance (D_1) (Å), the perpendicular distance (D_2) (Å), electronic coupling matrix elements V_h and V_e (eV) for all pathways, and the carrier mobility μ_h and μ_e ($cm^2\ V^{-1}\ s^{-1}$) at room temperature (298 K), (a) and (b) for molecules A and B, respectively.

the region, so a good overlap of orbitals of two interacting molecules gives rise to large V_h and V_e values. It is interesting to note the pathways 10 and 12. The D_1 and D_2 values of the dimer in pathway 10 are close to those in pathway 8, but the V values make a great difference between them. From the crystal structures of molecule A in Fig. 8(b), the region of the major interactions of the two molecules in pathway 10 occurs in the two thiophene rings. Due to little electronic density on one of the two thiophene rings (see Figs. 7 and S1), this gives rise to a poor overlap of HOMOs and LUMOs of two interacting molecules and consequently small the coupling matrix elements. For pathway 12, although the perpendicular distance of the dimer is zero, the mass center distance is very large (30.52 Å), and the reduced contact in the colinear dimer induces interaction only between the p_z atomic orbitals located on the terminal atoms. This largely reduces the overlap of orbitals and consequently leads to small V_h and V_e values.

(ii) It is well known that most unsubstituted π-conjugated organic semiconductors are *p*-type. Shuai et al. systemically studied the hole transport properties of unsubstituted linear oligothiophene [28]. Our study indicates that not only hole mobility of molecule A is largely similar to unsubstituted linear oligothiophene, but also the electronic mobility is large, which makes it probably become the promising charge transport layer materials in application to OLED. Large electronic mobility of the annular molecule firstly is due to smaller electronic reorganization energy. Secondly, the good overlap between LUMOs of the interacting molecules occurs in transport pathways, such as pathway 2. There, V_e is much larger than V_h. This can be explained by different degree of bonding versus antibonding interactions in the overlapping region and the charge distributions of the corresponding frontier orbital. It can be seen that its interring interactions give rises to fully constructive or destructive interring overlap of LUMOs from the overlapping region of the two interacting molecules in Fig. 8(b) and the charge distributions of the region in Figs. 7 and S1. In contrast, the mixing of bonding and antibonding interring overlap of HOMOs leads to a cancelation of the interring interaction, and from the HOMO and LUMO plots of molecule A and Fig. S1, the electronic density on all the sulfur atoms is very small in the HOMO level, while it is larger in the LUMO level. These facts give rise to more significant energetic splitting between LUMO and LUMO + 1 of the dimer in pathway 2 and hence larger coupling matrix element for the electron than that for the hole. For the hole, the maximal k_{ct} should occur in pathway 8 (Fig. 8(b)) and the splitting energy between HOMO and HOMO−1 of the dimer in pathway 8 is much larger than that between LUMO and LUMO+1. The overlap of LUMOs is very large mixing of bonding and antibonding interring overlap, which leads to cancelation of interring interaction. This fact results in a better overlap of HOMOs and consequently much larger V_h value. In a word, the coupling matrix element is increased if both are bonding or antibonding π-orbital interactions and decreased when there occurs a cancelation between bonding and antibonding overlaps.

For molecule B, its transport properties including transfer pathways, electronic coupling matrix elements and charge transfer rate are similar to those for molecule A and these properties are rationalized with the similar reasons. It is particularly pointed out that although the mass center distance of the dimer in the pathway 10 is very close to those in these dominant transfer pathways such as pathways 2, 6 and 8 and the perpendicular distance is even smaller than those in dominant pathways, the V values in pathway 10 are great different from them. We find that the nearest sulfur...sulfur and π...π distances are within 7.06 and 7.58 Å in pathway 10, respectively, while for the pathways 2, 6 and 8, the nearest sulfur...sulfur distances are within 3.81, 3.67 and 3.51 Å and π...π distances are within 4.03, 3.75 and 5.21 Å, respectively. So such large s...s and π...π distances weaken the intermolecular interaction of the dimer in pathway 10 and hence lead to a poor overlap of orbitals.

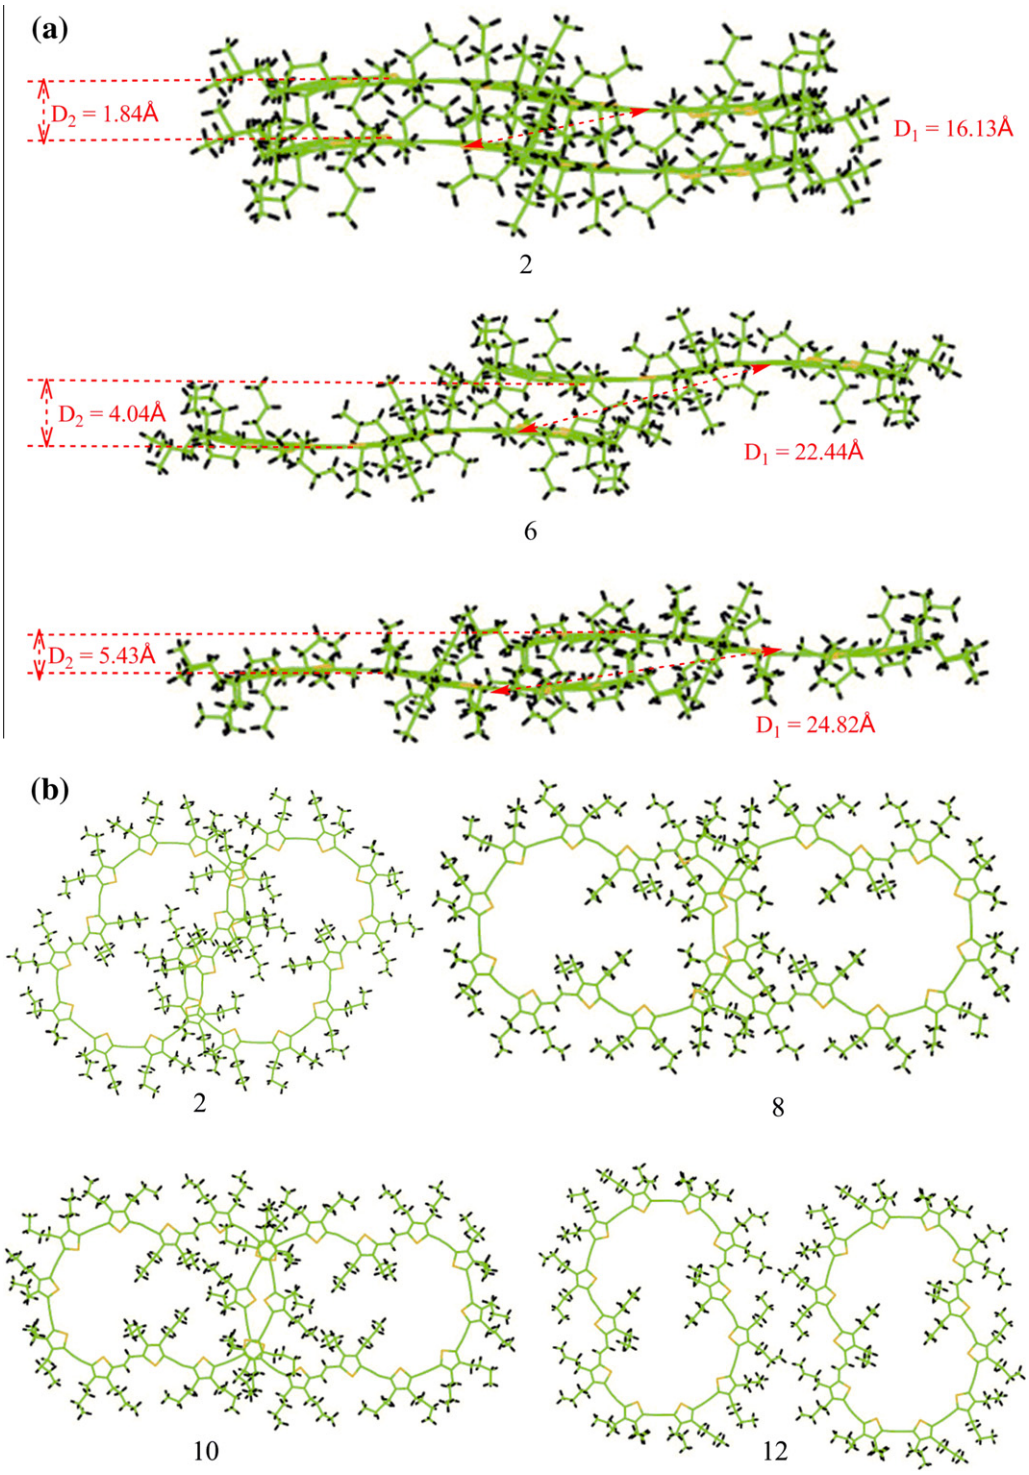

Fig. 8. (a) Schematic representation (side-view) of dominant charge transfer pathways (2, 6 and 8). (b) Schematic representation (top-view) of pathways (2, 8, 10 and 12) of charge transfer for molecule A.

3.2.3. Carrier mobility and temperature dependences of carrier mobility

On the basis of the above discussions, we estimated the carrier mobility of molecules A and B according to the Eqs. (1), (6), (7), and (8), because X-ray structures of other molecules have not been reported. To have a rough estimate on the intermolecular charge transfer rate and the carrier mobility, it is assumed that the external reorganization

energy (λ_{ext}) is within the range 0.2–0.6 eV [54]. λ_{ext} is chose as 0.4 eV to estimate the carrier mobility at T = 298 K, listing the results in Table 2. It can be seen that large carrier mobility of both molecules A and B makes them become the promising bipolar charge transport materials, $\mu_h = 1.164 \times 10^{-2}$ cm^2 V^{-1} s^{-1}and $\mu_e = 5.814 \times 10^{-3}$ cm^2 V^{-1} s^{-1} for molecule A, while, $\mu_h = 4.720 \times 10^{-2}$ cm^2 V^{-1} s^{-1} and $\mu_e = 1.227 \times 10^{-3}$ cm^2 V^{-1} s^{-1} for molecule B. It should be noticed that the relative ordering of the carrier mobility is consistent with that of their reorganization energies for the two cyclic molecules. It should be ascribed to the dominating role of λ in the exponential term of Eq. (1) in the charge transfer rate. The fact indicates that for these studied macrocycles possessing similar crystal structures, the magnitude of the reorganization energy can qualitatively predict that of the mobility. So the relative ordering of hole carrier mobility should be B > A > C; that of electron carrier mobility should be A > B > C.

The hole carrier mobility of molecules A and B is close to those of the traditional unsubstituted linear oligthiophenes [28], while they also possess very good electron transport properties. It maybe the major reason that the closed ring structure suppresses the rotation of the thiophene units in charge transfer process, and the introduction of the alkynyl and double bonds weakens the repulsion and steric effects between two adjacent thiophene rings to stabilize the LUMO level, in result to decrease the electronic reorganization energy (λ_e) and thus improve their electron transport ability. For the studied linear and cyclic oligothiophenes with the butyl, so large substituent should lead to loose molecular packing, in result to weaken the intermolecular interaction and largely decrease the electronic coupling matrix element. So their charge transfer rate should be dominated by the corresponding reorganization energies in the exponential term of Eq. (1). For our case, the small difference of λ values between cyclic and linear oligothiophenes probably gives rise to the difference of one order of magnitude for the calculated mobility, which is similar to that case reported in the literature [47]. So smaller λ values for these macrocycles probably give rise to better charge transport properties than their corresponding linear molecules. To further enhance these macrocycles' ability of charge transport, ones can tune their crystal structures to decrease the separation between the neighboring molecules in the charge transfer pathways by varying their substituents.

As we mentioned in Section 2, the charge transfer mechanism and carrier mobility are closely related to temperature (T), so the temperature dependence of the carrier mobility was examined. Huang–Rhys factor, S_j characters the electron–phonon coupling strength. In the case of weak local electron–phonon coupling, the mobility is dominated by tunneling and displays band-like temperature dependence in the whole range of temperature. For strong local coupling ($\sum_j S_j \gg 1$), (i) at low temperature, the mobility is band-like, that is, it is decreased with the increase of

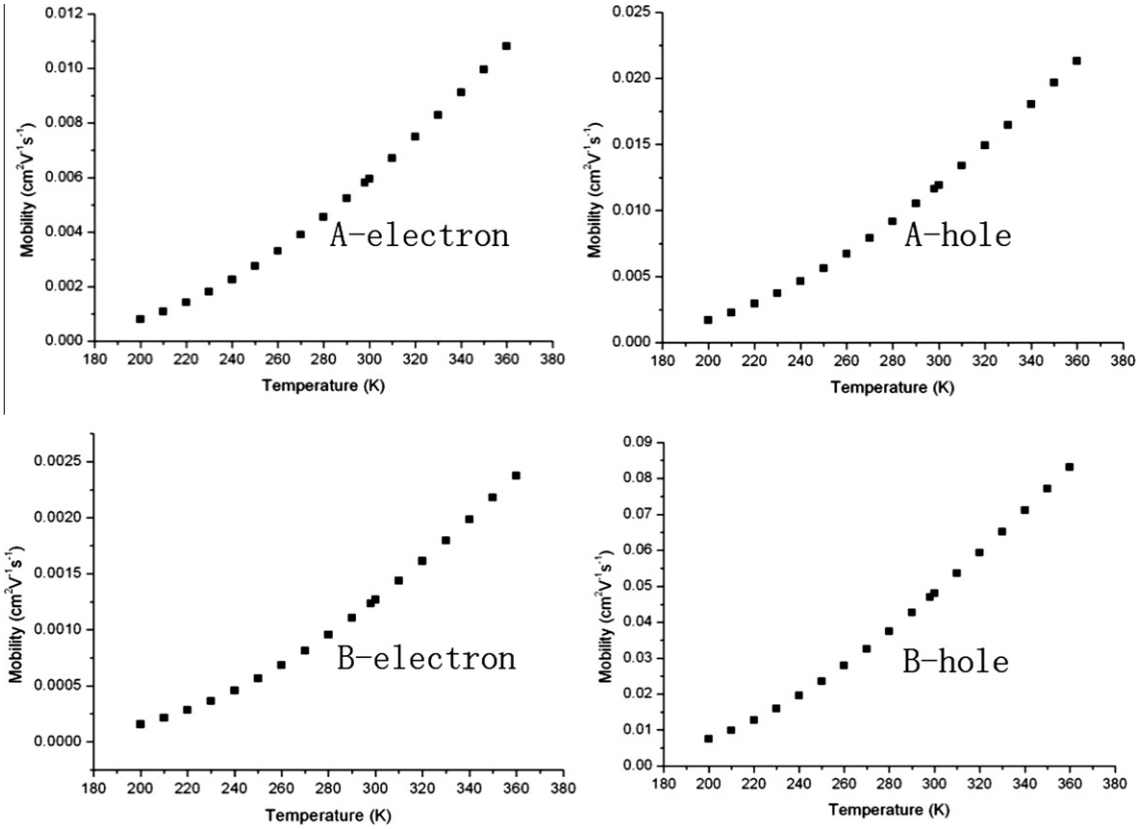

Fig. 9. The predicted temperature dependences of hole and electron carrier mobility for molecular materials A and B.

temperature; (ii) as the temperature increases, the hopping mechanism starts to dominate for organic electronic materials from coherent transport to an incoherent temperature-activated transport; (iii) at very high temperature, at which the thermal energy becomes large enough to dissociate the polaron, the residual charge is scattered by thermal phonons, and as a result the mobility decreases again with increasing the temperature [41]. Because of large separation between the neighboring molecules in the pathways of charge transfer for our case, the magnitudes of Vs are about one to several orders of magnitude less than the λ values. So the hopping mechanism and standard Marcus theory are applicable for our systems. It is firstly assumed that the reorganization energies and the electronic coupling matrix elements are temperature independent. The hopping mechanism predicts the mobility to follow a temperature dependence of $T^{-3/2}\exp(-\lambda/4k_BT)$ according to the Eqs. (1), (6), (7), and (8). Many groups also successfully obtained some reliable results in terms of the hopping mechanism and the above temperature dependence of the mobility [41,47,55]. Due to the decomposition temperature of the two molecules (about 370 K) [56]. We only plot the curves of the temperature dependences of the mobility within a temperature range from 200 to 360 K (Fig. 9). The exponential law dominates within the temperature range, so one can enhance their carrier mobility by increasing the temperature.

4. Conclusion

The work shows that the closed ring structure and the introduction of the alkynyl and double bond are beneficial to decreasing the internal reorganization energy for thiophene-based materials. A rationale based on molecular geometric structure and molecule-orbital arguments is provided: the closed ring structure restricts the rotation of the thiophene units in charge transfer reaction and the introduction of the alkynyl and double bonds weakens the coulomb repulsion between lone electron pairs of sulfur atoms and the steric effects resulting from the butyls, in result to decrease the reorganization energy (λ_e) and hence improve their ability of charge transport. In two-state model, by employing the "energy splitting in dimer" (ESD) method, we estimate the electronic coupling matrix element (V) values for all pathways for molecules A and B. The results indicate that the amplitude of the coupling matrix element is highly sensitive to various aspects of molecular packing. By assuming localized charge hopping described be the Marcus electron transfer model and the Brownian diffusion process, we theoretically predicted the carrier mobility at room temperature for molecules A and B, and investigated the temperature dependence of the mobility. The hole carrier mobility for the two molecular materials is large and close to unsubstituted linear oligthiophenes, more importantly, their ability of electron transport is very outstanding, which mainly results from small reorganization energy for the electron. According to the temperature dependence of the mobility, we predicted that their carrier mobility should be enhanced by increasing the temperature within a temperature range from 200 to 360 K. As the internal reorganization energy and electronic coupling matrix element are the important properties of these molecules, the insights gained from this study will benefit to the design of other organic electronic devices such as OLED.

that the optimal band gap of a donor polymer is in the range of 1.2–1.7 eV [3].

Recent research efforts on developing low-band-gap polymers and device processing techniques are fruitful, and some BHJ solar cells based on new low-band-gap polymers have demonstrated efficiencies well above 5% [14–18]. In many of these works, processing additives have been used to tune the nano-scale morphology [16–18]. A selective solubility to fullerene and a higher boiling point than the host solvent have been identified as two criteria for effective processing additives [17]. One of the most commonly used additives is 1,8-diiodooctane (DIO) that has been reported to improve both the short-circuit current density (J_{sc}) and fill factor (*FF*) in several types of polymer: fullerene BHJ systems [17,18].

More recently, a new class of low-bandgap polymers have shown a PCE above 7% when blended with $PC_{71}BM$ [19,20]. The backbones of these polymers consist of alternating ester or ketone substituted thieno[3,4-*b*]thiophene and dialkyloxy substituted benzodithiophene units. In this design, the thieno[3,4-*b*]thiophene in each repeating unit is used to stabilize the quinoidal structure that not only narrows the energy gap but also enhances the planarity of the backbone. In addition, the planarity as well as the rigidity of the backbone offered by the benzodithiophene units ensures a high hole mobility in this type of polymers. In this paper, we report a new low-band-gap polymer based on ketone substituted thieno[3,4-*b*]thiophene and dioctylbenzodithiophene units, PTTBDT-C8, for high-performance polymer solar cells (Fig. 1a). As compared with the materials reported in literature, PTTBDT-C8 contains two linear octyl groups on the benzodithiophene unit instead of two 2-ethylhexyloxy side chains, with an attempt to enhance the interchain interaction. The resulting polymer is soluble in a wide range of organic solvents, such as chlororform, chlorobenzene, and dichlorobenzene. By introducing the processing additive, DIO, to the host solvent of chloroform, the efficiency of the BHJ solar cells based on PTTBDT-C8 and $PC_{71}BM$ (1:2 by weight) has been dramatically improved from 1.45% to 4.83%. The correlation between the film morphology, charge mobility, and overall device performance has been investigated in detail.

2. Experimental

The BHJ solar cells prepared in this study have a structure of ITO/PEDOT:PSS (30 nm)/PTTBDT-C8:$PC_{71}BM$ (110–115 nm)/BCP (bathocuproine) (3 nm)/LiF (1 nm)/Al (100 nm). The indium tin oxide (ITO) coated glass substrate was cleaned stepwise by ultrasonic bath in acetone and isopropanol before UV-ozone treatment. The PEDOT:PSS and the active layers were successively deposited by solution spin casting, and the BCP, LiF, and Al layers were deposited by thermal evaporation. Chloroform or a mixture of chloroform with DIO was used as the solvent for the active layer. The BCP layer sandwiched between active layer and LiF/Al cathode was used to block pinholes and suppress micro short-circuits. The resulting devices have an active area of 0.49 cm^2. The current density–voltage (*J–V*) characteristics were measured under simulated air mass 1.5 global (AM 1.5G) irradiation of 100 mW/cm^2. The charge mobility data were obtained from field effect transistor (FET) measurements with a bottom contact structure and calculated from the saturation regime.

The new polymer, PTTBDT-C8, was synthesized via Stille coupling reaction of 1-(4,6-dibromothieno[3,4-*b*]thiophen-2-yl)-2-ethylhexan-1-one with 2,6-bis(trimethylstannyl)-4,8-dioctylbenzo[1,2-*b*:4,5-*b*′]dithiophene in refluxing toluene under Ar using $Pd(PPh_3)_4$ as the catalyst. After purification by Soxhlet extraction, the obtained polymer has a number averaged molecular weight of 37.6 kDa and weight averaged molecular weight of 100.9 kDa with a polydispersity of 2.68. The branched ketone substituent on the thieno[3,4-b]thiophene unit renders the resulting polymer good solubility in organic solvents, while the linear octyl groups on the benzodithiophenethe unit allow intimate Π–Π stacking and thus offer high hole mobility. DSC measurement showed that this polymer is an amorphous material with a glass transition temperature around 122 °C. The hole mobility is 2×10^{-4} cm^2/Vs as measured from the OFETs. The LUMO and HOMO energy levels are at −3.41 eV and −5.10 eV respectively, as determined by cyclic voltammetry (CV), corresponding to an electrochemical band gap of 1.69 eV.

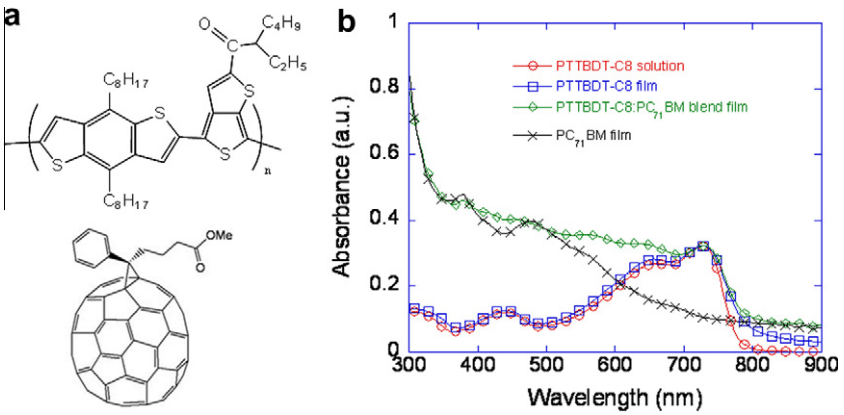

Fig. 1. (a) Structure of PTTBDT-C8 (top) and $PC_{71}BM$ (bottom). (b) Absorption spectra of PTTBDT-C8 solution in chloroform, PTTBDT-C8 film, $PC_{71}BM$ film, and PTTBDT-C8:$PC_{71}BM$ blend film. The absorption spectra of PTTBDT-C8 solution and PTTBDT-C8 film are normalized at 730 nm with reference to that of the blend film. The ratio of the blend film is PTTBDT-C8:$PC_{71}BM$ = 1:2 by weight.

3. Results and discussion

The UV–vis absorption spectra of PTTBDT-C8 solution and solid films overlap quite well and both show a double peak at 650 nm and 730 nm. The absorption onset of the solid film at 800 nm translates into an optical band gap of 1.55 eV which agrees well with CV results. The strong absorption in the wavelength region between 550 and 760 nm coincides with the maximum photon flux region of the solar spectrum (~700 nm), which ensures an efficient harvest to long-wavelength photons. $PC_{71}BM$ was used as the electron acceptor to harvest short-wavelength (300–500 nm) photons (Fig. 1b).

Fig. 2a shows the *J–V* curves of BHJ solar cells prepared using chloroform with various amounts of DIO under 1 sun of simulated air mass 1.5 global (AM 1.5G) irradiation. We chose chloroform as the processing solvent because it readily dissolves PTTBDT-C8 even at room temperature. Upon heating, this polymer is also soluble in toluene and chlorobenzene, but it will precipitate out when cooling down. The photovoltaic parameters, including open circuit voltage (V_{oc}), J_{sc}, *FF*, PCE, series resistance (R_s), and shunt resistance (R_{sh}), are extracted from these *J–V* curves and summarized in Table 1. The solar cell made without DIO additive exhibited a high V_{oc} of 0.75 V and *FF* of 0.57. But the J_{sc} of this cell was surprisingly low, only about 3.20 mA/cm^2, resulting in a low PCE of 1.39%. After adding 1% (by volume) DIO to the host solvent of chloroform, the resulting J_{sc} increased more than 3 folds reaching 12.74 mA/cm^2, with a slight drop in V_{oc} and *FF*. The PCE was thus improved by more than three times, reaching 4.79%. But the device performance remained nearly unchanged at this level when further increasing the amount of DIO to 3% and 6%. As DIO content increased from 1% to 3%, and to 6%, the V_{oc} showed no change, being about 0.71 V all the time. The *FF* showed a tiny drop from 0.53 to 0.52, and the J_{sc} decreased less than 3%. As a result, the overall change in PCE was less than 4%. The short-circuit current densities measured from the *J–V* curves were compared with the J_{sc} calculated from the integration of the corresponding external quantum efficiency (EQE) curve and solar spectrum. These two values were found in excellent agreement with an error less than 2%. Fig. 2b and c show the EQE and reflectance spectra of the same solar cells referred to in Fig. 2a. Both EQE and reflectance spectra of all these four devices show a similar broad response covering a spectral range from 300 to 800 nm. Without DIO additive, the resulting EQE is averaged at about 10–15%. With a few volume percentages (1–6%) of DIO additive, the EQE spectra are lifted up to an average of 40–50%.

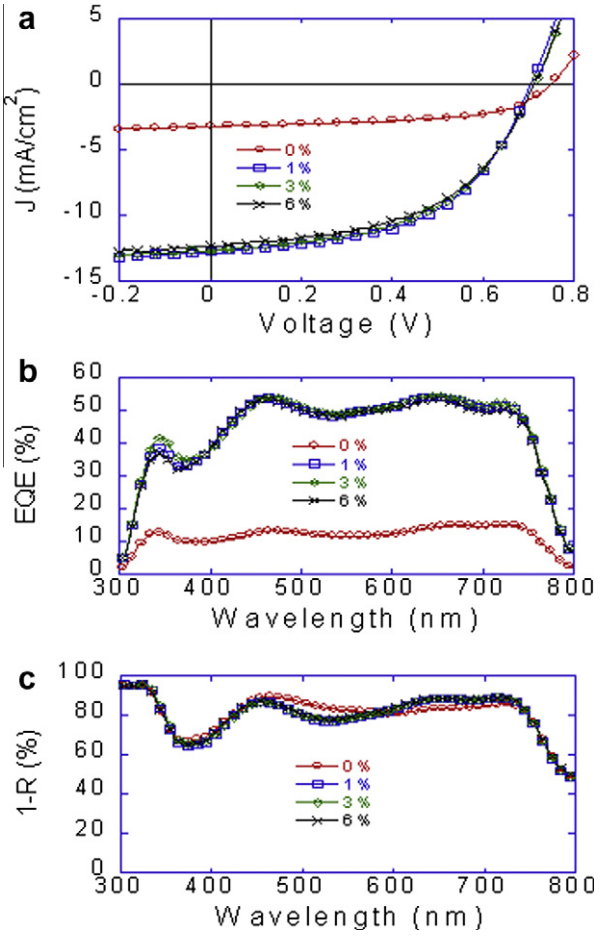

Fig. 2. (a) Current density–voltage (*J–V*) characteristics, (b) External Quantum Efficiency (EQE) spectrum, and (c) Reflectance spectrum of the PTTBDT-C8-$PC_{71}BM$ BHJ solar cells prepared with various volume percents of DIO additive in the host solvent of chloroform. The DIO percentages are 0% (no DIO additive), 1%, 3%, and 6%.

Table 1
Photovoltaic performance of the BHJ solar cells prepared with various amounts of DIO additive. The data were extracted from the *J–V* curves shown in Fig. 2a. Values in parentheses are the J_{sc} calculated from EQE spectra and PCE calibrated from the calculated J_{sc}.

DIO content (%)	V_{oc}	J_{sc} (mA/cm^2)	*FF*	PCE (%)	R_s (Ωcm^2)	R_{sh} (Ωcm^2)
0	0.75	3.20 (3.35)	0.58	1.39 (1.45)	14	1070
1	0.71	12.74 (12.87)	0.53	4.79 (4.83)	6	441
3	0.71	12.72 (12.74)	0.52	4.68 (4.69)	7	425
6	0.71	12.32 (12.60)	0.52	4.56 (4.66)	7	388

The dramatic improvement in J_{sc} must be related to the changes in nano-scale morphology since DIO does not react with the polymer or fullerene and there is no DIO present in the completely dried films. Fig. 3 shows the surface topography of BHJ films as directly measured from the same solar cell devices referred to in Fig. 2 by atomic force microscopy (AFM) and two Auger electron spectroscopy (AES) sulfur mapping images. The BHJ film prepared with no DIO additive has a separated-islands like structure (Fig. 3a); the brown phase forms round islands (about 200 nm in diameter), and the yellow phase fills the gaps between islands. The yellow phase in the gaps consists of well interconnected bulky domains (about 40 nm in diameter) and obviously shows good continuity. AES sulfur mapping experiment unambiguously shows that the separated islands are composed primarily of $PC_{71}BM$ since this phase has a very low S content (Fig. 3b, shown as dark area), and the yellow phase mainly consists of the polymer because PTTBDT-C8 contains rich S element in the polymer

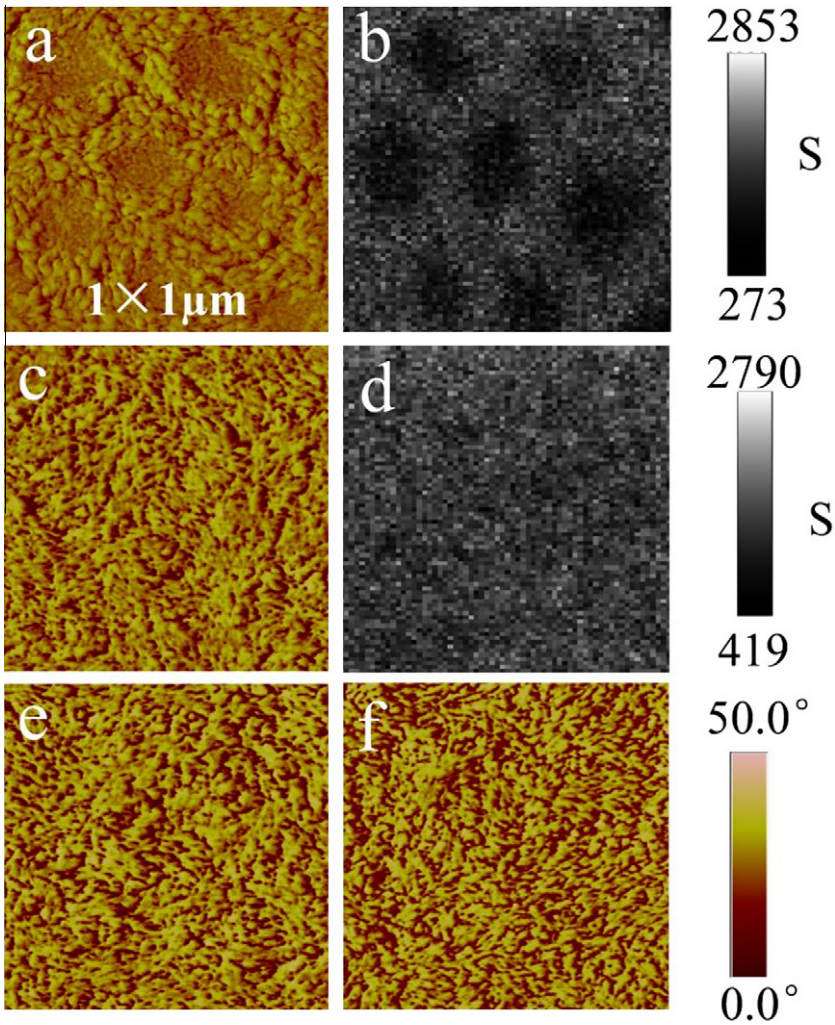

Fig. 3. AFM phase images and AES sulfur mapping images of films with various amounts of DIO additive as directly measured from the same solar cells referred in Fig. 2. The DIO percentages corresponding to AFM images (a, c, e) and (f) are 0%, 1%, 3%, and 6%, respectively. The AES sulfur mapping image (b) was measured on the same sample as (a), and (d) was measured on the same sample as (c). All images have a scan range of 1×1 μm2.

Table 2
FET mobility of films with various amounts of DIO additive.

DIO content (%)	μ_h (10^{-7} cm^2/Vs)	μ_e (10^{-7} cm^2/Vs)
0	1122	0.55
1	30	35497
3	16	19017
6	14	14713

backbone. The assignment of the polymer to the yellow phase is also well consistent with the FET mobility data. The continuous polymer network contributes to a high hole mobility of 1.12×10^{-4} cm^2/Vs while the separated fullerene islands only give an electron mobility on the order of 5.50×10^{-8} cm^2/Vs (Table 2). Note that the hole mobility of this film is very close to that of neat polymer film (2.09×10^{-4}), confirming a good continuity of polymer phase in the mixture. The morphology of large separated fullerene islands embedded in polymer matrix not only hampers exciton diffusion to the donor/acceptor interface and is highly unfavorable for exciton dissociation, but also significantly impedes electron transport in the BHJ film, leading to an extremely low electron mobility. As a result, although the device absorbs about 80% of the incident photons as indicated by the device reflectance spectrum (Fig. 2c), the J_{sc} of this device is rather low.

The use of DIO additive when preparing BHJ films eliminated the island pattern and changed the bulky polymer domains into branched ones, resulting in greatly increased donor–acceptor interface. As seen in films prepared with 1%, 3%, and 6% of DIO (Fig. 3c,e, and f), the two phases are well interpenetrating and the films look much more uniform. AES sulfur mapping experiment also demonstrates the disappearance of the large isolated $PC_{71}BM$ islands (Fig. 3d). As a result of the enhanced continuity in fullerene phase, the electron mobility was improved by more than four orders of magnitude, with the highest value of 3.55×10^{-3} cm^2/Vs achieved from the BHJ film processed with 1% DIO. On the other hand, the continuity of the polymer phase was affected by the addition of DIO,

and thus the hole mobility decreased to the order of 10^{-6} cm^2/vs. The drop in hole mobility might be caused by the vertical phase separation during the film forming process, it would leave a very thin, slightly $PC_{71}BM$ rich region on the substrate, and will inevitably affect the hole mobility data; by the same token, the measured electron mobility could also be slightly higher due to this $PC_{71}BM$ rich region on the FET substrate. Nevertheless, the overall device performance was greatly improved by the use of DIO, regardless of the drop in hole mobility. It is safe to say that both the electron mobility and the exciton dissociation efficiency were greatly improved by this processing technique.

The difference in the morphology of the polymer-$PC_{71}BM$ BHJ films prepared with and without DIO additive is very pronounced. However, when the DIO content was increased from 1% to 6%, the change in morphology is quite small, so are the changes in the hole and electron mobilities as well as the device performance. The observed DIO effects on morphology may be related to the selective solubility of DIO to fullerene. The host solvent of chloroform is a good solvent for polymers but a poor one for fullerene. In the case of chloroform-only solvent (0% DIO), fullerene precipitates out first from the solution during a spin casting process and crystallizes to form big islands, and polymer comes out after, filling the gaps between islands. If the solvent is a mixture of DIO and chloroform (1–6% DIO), chloroform vaporizes first due to its high vapor pressure relative to that of DIO. Some portion of fullerene is pushed to DIO phase in the film-forming process so that chloroform phase has less fullerene left. In other words, DIO additive is tuning the relative content of polymer and fullerene in chloroform phase towards an ideal case in which the two materials come out at the same time during a spin casting process. Of course, the tuning ability of DIO and thus the morphology of the resulting film depend on the DIO percentage. With an optimal DIO content, a simultaneous precipitation may be realized giving rise to an interpenetrating network of polymer and fullerene.

4. Conclusions

In conclusion, we have investigated the morphology and device performance relation of BHJ solar cells based on a new low-bandgap polymer with a backbone of alternating thieno[3,4-*b*]thiophene and benzodithiophene. By adding a suitable amount of DIO additive to the host solvent (chlorofoorm in this study), the PCE was improved by a factor of more than 3 from 1.45% to 4.83%. The enhancement in PCE is attributed to the improvement in the nano-scale morphology of the BHJ film. A dynamic picture of film-forming process has been proposed.

2. Experimental details

2.1. General

All chemicals and reagents used in this paper, unless otherwise specified, were purchased from Aldrich, Aladdin, Alfa Aesar and TCI Chemical Co. and used as received. All the solvents were further purified before use. All important compounds synthesized were characterized by ^{1}H NMR, ^{13}C NMR. ^{1}H NMR spectra were measured on a Bruker AV 300 (300 MHz) spectrometer at the ambient temperature with tetramethylsilane (TMS) as an internal standard. ^{13}C NMR spectra were recorded on Bruker AV 300 (75 MHz) spectrometer at the ambient temperature and chemical shifts were recorded in ppm from the solvent resonance employed as the internal standard. Atmospheric pressure chemical ionization mass spectra were obtained on a Bruker HCT Mass Spectrometer. Melting points were determined by differential scanning calorimetry (TAQ 100) at a heating rate of 10 °C/min under Ar atmosphere. Infrared spectroscopic measurements were performed in the range of 4000–400 cm^{-1} on a Bruker Tensor 27 FTIR Spectrometer. UV spectra were performed on a Unico UV-4802H UV–visible spectrophotometer connected to a computer. Cyclic

voltammetry was carried out on CHI 650B electrochemical workstation using three-electrode system. All solid ECD were fabricated, sealed and tested at room temperature.

2.2. Synthesis of (1,3,5-tri(1-methyl-4,4′-bipyridinium bromide)-2,4,6-trimethyl- benzene) (TBTB)

1,3,5-Tri(bromomethyl)-2,4,6-triethylbenzene [23] (0.8 g, 2.0 mmol) in CH_2Cl_2 (300 mL) was added dropwise to a stirred solution containing a 1.5 times excess of 4,4′-bipyridine in CH_2Cl_2 (500 mL) over a period of 24 h. The desired product was isolated as a pale yellow solid by filtration of the resulting mixture. Then the crude product was further purified by washing with diethyl ether and then recrystallising from methanol (Scheme 1). Yield: 1.5 g, 1.73 mmol, 87%. m.p. – decomposed by about 250 °C. ^{1}H NMR (D_2O, 300 M, δ/ppm): 8.85 (m, 6H, bipy), 8.73 (m, 6H, bipy), 8.41 (m, 6H, bipy), 7.87 (m, 6H, bipy), 6.16 (s, 6H, CH_2N^+), 2.36 (s, 9H, Me). ^{13}C NMR (D_2O, 300M, δ/ppm): 153.9, 149.7, 144.5, 142.7, 128.6, 127.6, 126.4, 122.7, 59.0, 16.4. APCI-MS (m/z): 785 $[M{\cdot}Br_2]^+$. FT-IR (KBr, cm^{-1}): 3145 (m, Ar C—H)$_s$, 3108 (m, Ar C-H)$_s$, 2991 (m, CH_2/CH_3)$_s$, 2919 (m, CH_2/CH_3)$_s$, 1634 (s, Ar C═C)$_s$, 1562 (s, Ar C═C)$_s$, 1508 (m, Ar C═C)$_s$, 1442 (m, CH_2/CH_3)$_\delta$, 1375 (m, CH_2/CH_3)$_\delta$, 1203, 1110, 1007, 786, 570.

3. Results and discussion

3.1. Electrochemical properties

Electrochemical measurements were performed by using cyclic voltammetry at room temperature in a conventional three-electrode system using platinum disk (0.02 cm^2) as working electrodes, platinum wire as counter electrodes and Ag/AgCl in 3 M NaCl (aq) solution as a reference. In order to investigate the electrochemical properties exactly, TBTB was tested in different electrolyte solution ((a) KCl/H_2O; (b) $LiClO_4/H_2O$; (c) TBAP (tetrabutylammonium perchlorate)/MeOH; (d) TBAF (tetrabutylammonium hexafluorophosphate)/MeOH) at a scan rate of 100 mV s^{-1}. As shown in Fig. 1, the redox behavior of TBTB in the electrolyte solution above was quite similar, which showed three reversible redox couples at similar potentials. Based on this fact, the possible redox mechanism and states of TBTB were proposed. As shown in Scheme 2, four redox states and accepting–donating e^- process of TBTB were presented.

Taking Fig. 1c for example, there were three coupled redox peaks ($a_3 - a_3'$, $b_3 - b_3'$, $c_3 - c_3'$) in electrolyte solution of TBAP/MeOH for TBTB. The first redox couple at ca. 1.31 V (a_3) and ca. 0.67 V (a_3') was correlated with the redox reaction between the colorless tri-cationic species,

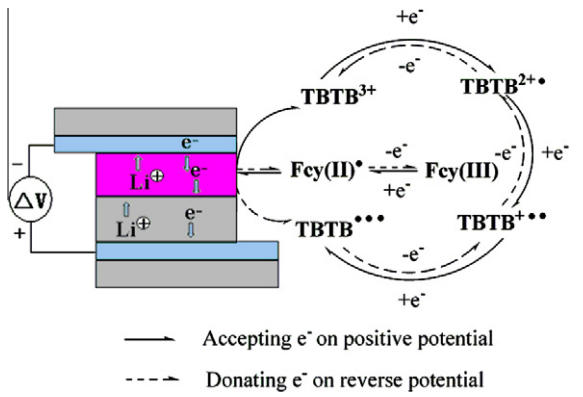

Fig. 3. The accepting–donating electron mechanism of TBTB monocation-Fcy(II) complex in ECD.

$TBTB^{3+}$, and blue di-radical-cation, $TBTB^{2+}$, respectively. The second redox couple at ca. 0.09 V (b_3) and −0.82 V ca. (b_3') was assigned to the blue di-radical-cation, $TBTB^{+\cdot}$·and the violet–blue radical-cation, $TBTB^{+\cdot\cdot}$, respectively. The third redox couple at ca. −0.87 V (c_3) and ca.−1.20 V (c_3') was related to the violet–blue radical–cation, $TBTB^{+\cdot\cdot}$ and the violet–red tri-reduced species, $TBTB^{\cdot\cdot\cdot}$, respectively.

3.2. Electrochromic devices construction

Electrochromic devices were assembled in sandwich configuration with electrochromic materials (TBTB) deposited on ITO glass electrodes and a polymer gel electrolyte. TBTB, potassium ferrocyanide (abbreviated as Fcy(II)) and polyvinyl acetate (PVA) were dissolved in water and thinly spread onto the ITO glass (50 Ω/sq, 3 cm × 5 cm) and then dried to form thin films as electrochromic layer (Scheme 3). P(MMA-VAc)/$LiClO_4$ polymer gel electrolyte [28] and propylene carbonate (PC) were dissolved in THF and thinly spread onto the ITO glass and then dried to form thin films as ionic conductive layer. All the edges of the ECD were sealed with an insulating epoxy resin. The structure of the ECD is shown in Fig. 2, including conductive ITO glass||TBTB + potassium Fcy(II)||polymer gel electrolyte||conductive ITO glass.

3.3. Electrochromic mechanism and behavior study

In order to further investigate their electrochromic behavior, a serial of environmentally friendly (no organic solvents) solid ECD (3 cm × 4 cm) were assembled and the accepting–donating electron mechanism of electrochromic materials contained in the ECD was proposed (Fig. 2 and Fig. 3) and discussed. The migration movement of the cations and anions between the polymer gel electrolyte layer and electrochromic layer during electrochemical redox process had already been studied. The rate of mobility of the cations and anions, their respective sizes, and their interaction would determine the extent of ion exchange in electrochromic layer [29]. When the positive potential was charged (the reduction process of TBTB), counter ions, usually lithium ions (Li^+) with small size and fast mobility, intercalated into the electrochromic layer because the system wanted to be electrically neutral [14]. Then the electrostatic interaction between Li^+ and Fcy(II) anions would be an obstacle for Li^+ to move further. So Fcy(II) anions in the electrochromic layer played a role of counter electrode layer which were helpful for the

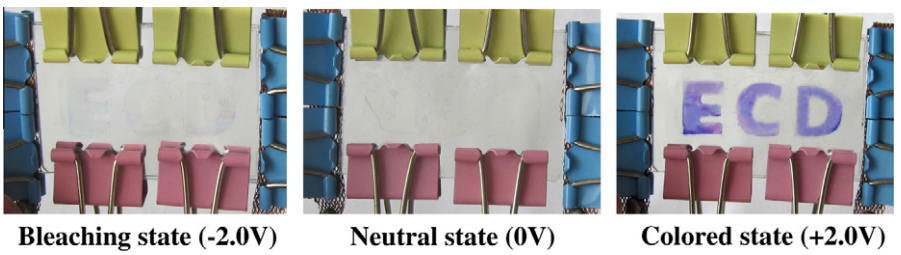

Fig. 4. The electrochromic behavior of characters in ECD (3 cm × 4 cm).

storage of Li^+. While the reverse potential (the oxidation process of TBTB) was charged, Li^+ were ejected from the electrochromic layer and injected into the polymer gel electrolyte layer again.

It was reported that viologen dication and Fcy(II) could form viologen dication-Fcy(II) complex. And complex formation was an important aspect of viologen electrochemistry [13]. The viologen dication-Fcy(II) complex, as a popular choice of electron mediators [13,30–33] could improve the write–erase (coloring–bleaching) efficiency of the ECD. In this paper, TBTB monocation-Fcy(II) complex formation promoted the conversion among the four redox states (Scheme 2 and Fig. 3).

Because of the multi-electrochromic feature of the electrochromic material TBTB, it was necessary to choose an appropriate operating range of potential for the ECD from the viewpoint of complementary color-matching considerations. Furthermore, to avoid unnecessary formation of peroxide and other byproducts (which could decrease and even destroy the performance of the ECD) in the devices, two proper potential points (between −2.0 V and 2.0 V) were chosen to monitor and investigated the electrochromic behavior of characters in ECD. As shown in Fig. 4, when the potential of +2.0 V was charged to the ECD, the color of characters shifted from colorless to violet–blue. While the reverse potential (−2.0 V) was charged, the color of characters changed from violet–blue to almost transparent (light blue). The corresponding electrochromic mechanism (from violet to blue to light blue) was also discussed and given. In addition to the conversion

$$TBTB^{2+\cdot} \underset{-e}{\overset{+e^-}{\rightleftharpoons}} TBTB^{+\cdot} \quad (1)$$

when the potential was charged, the other possible process for the conversion of $TBTB^{2+\cdot}$ to $TBTB^{+\cdot}$ between −2.0 V and 2.0 V in ECD was given by the reaction with the oxidized or reduced form of the anodic compound [34].

$$TBTB^{2+\cdot} + Fcy(II)^{\cdot} \rightleftharpoons TBTB^{+\cdot} + Fcy(III) \quad (2)$$

Herein, in TBTB monocation-Fcy complex, as counter ions of TBTB monocation, the anodic compounds Fcy(II) and Fcy(III) promoted the conversion between $TBTB^{2+\cdot}$ and $TBTB^{+\cdot}$, which further improved the performance of color change between light blue and violet–blue.

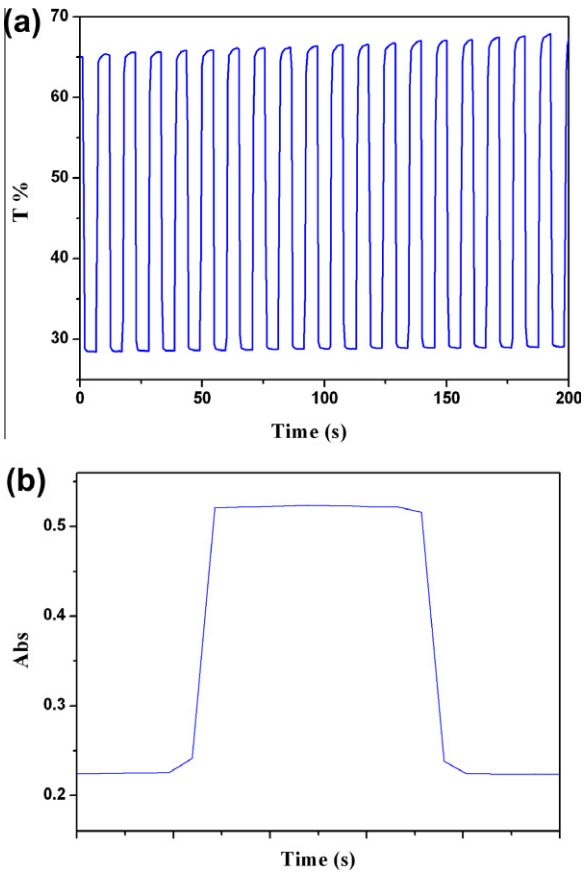

Fig. 6A. (a) Optical transmittance changes and (b) optical switching studies for ECD based on TBTB was monitored at 530 nm while the ECD was switched between −2.0 V and +2.0 V with a switch time of 5 s.

3.4. Spectroelectrochemistry study

Spectroelectrochemical study on ECD (3 cm × 4 cm) based on TBTB was carried out by varying the voltage between +3.0 V and −2.0 V. For monitoring the electrochromic process of the ECD, four potential points were chosen and corresponding electrochromic photos were taken and recorded. The ECD revealed multicolor electrochromism exhibiting several colored states between 0 V (colorless), +1.5 V (blue), +2.0 V (violet–blue) and +3.0 V (violet–red) (Fig. 5A). The optical contrast is given as the transmittance difference between the reduced and oxidized states and is reported as ΔT% which is monitored as a function of time at the specified wavelength. The ECD exhibited high contrast between +2.0 V and −2.0 V at 530 nm and the ΔT% was observed up to 55% (Fig. 5B).

3.5. Switching and stability

Switching and stability are two important properties of an electrochromic material and its corresponding ECD. In order to exactly investigate these properties, the ECD (3 cm × 4 cm) based on TBTB, fabricated as shown in Fig. 2, were switched under ambient conditions by repeated potential steps (500 electrochromic cycles) between the oxidized (−2.0 V) and reduction states (+2.0 V) with a residence time of 5 s. Quantification of switching time is performed by defining a change in 95% of the total absorbance span, since the naked eye can not distinguish the color change after this point.

In order to further testify the mechanism proposed in Section 3.3, as a reference, the ECD in which Fcy(II) was not contained were also assembled and monitored. As shown in Fig. 6A(a) and (b), the ECD which contained Fcy(II) had a switching time of ~0.3 s for coloring and a bleaching time of ~0.5 s at switching voltages of +2.0 V to −2.0 V and the optical switching was for the color change from violet to blue to transparent light blue. The difference in coloring and bleaching time of the devices is due to the different time constants for ejection/insertion of ions from/to electrochromic layer [35–36].

However, the reference ones (Fcy(II) was not added) showed an obvious degradation on ΔT% and longer switching time (Fig. 6B(c) and (d)). This result showed that TBTB monocation-Fcy(II) complex formation could remarkably improve the write–erase (coloring–bleaching) efficiency and stability of the ECD.

Furthermore, the optical contrast of the ECD, measured as ΔT%, ranged from 25% (after the 500th cycle) to 40% (the 1st cycle) at 530 nm between −2.0 V and 2.0 V (Fig. 7(a)). To compare with this result, cyclic voltammetry was employed to monitor the stability of the devices. Non-stop

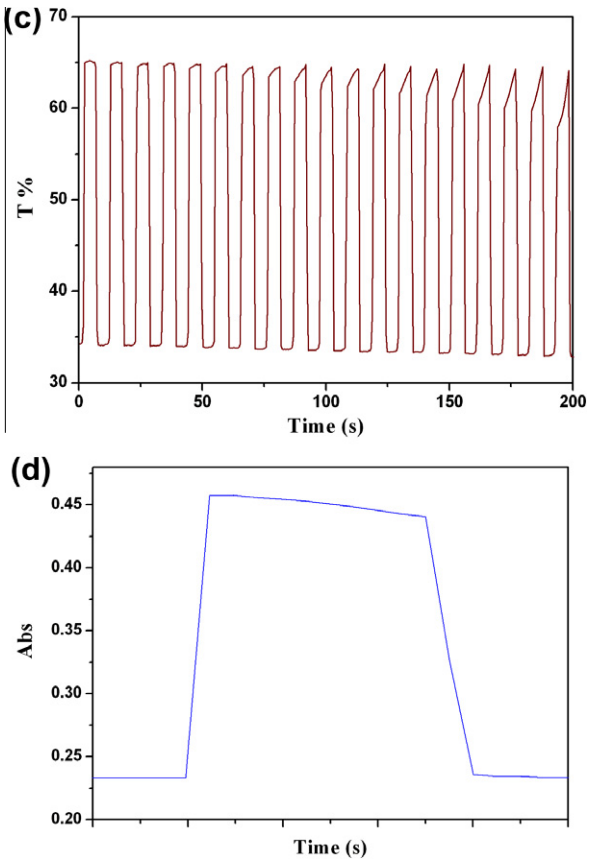

Fig. 6B. (c) Optical transmittance changes and (d) optical switching studies for the reference ECD (Fcy(II) was not added) based on TBTB was monitored at 530 nm while the ECD was switched between −2.0 V and +2.0 V with a switch time of 5 s.

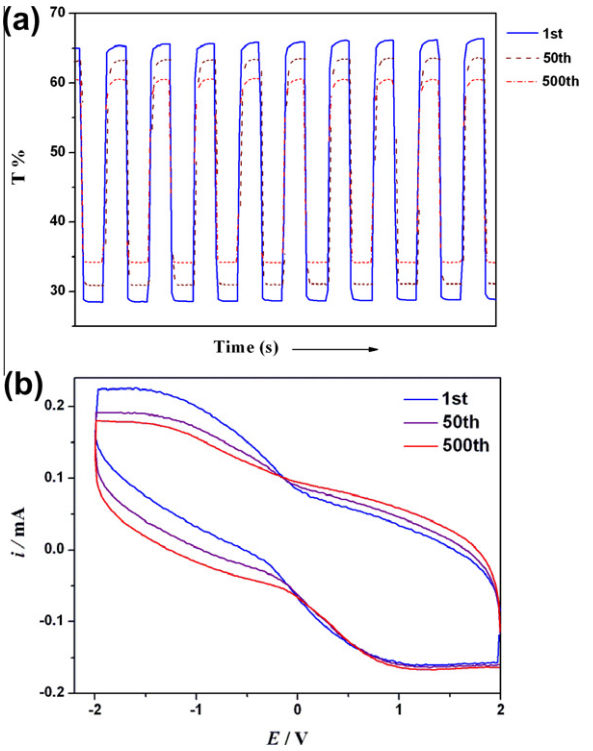

Fig. 7. (a) Optical switching changes for ECD at 530 nm between −2.0 V and +2.0 V with a switch time of 5 s and (b) Cyclic voltammogram of ECD as a function of repeated scans at 500 mV s^{-1}; 1st, the 50th and after the 500th cycle.

cycling between −2.0 V and +2.0 V for the ECD with 500 mV s^{-1} was performed to analyze the stability of devices. Fig. 7(b) presented the change in the anodic and cathodic peak currents as a function of the potential. The ECD showed only a slight decrease in electroactivity after 500 cycles. This result, which was consistent with the previous one, revealed that the ECD had reasonable environmental and redox stability. Therefore, the devices could be operated with applied potentials between −2.0 V and +2.0 V for future applications. Furthermore, the optical density (ΔOD) and coloration efficiency (CE) are two key parameters in order to compare electrochromic materials and devices. The ΔOD and CE between −2.0 V and +2.0 V at 530 nm of the ECD can be calculated using the following equations [37],

$$\Delta OD = \log \frac{T_{bleached}}{T_{colored}} \text{ and } CE \frac{\Delta OD}{Q_d}$$

where Q_d is the injected/ejected charge during a redox step of the ECD; $T_{colored}$ and $T_{bleached}$ are the transmittance in the colored and bleached states of the ECD, respectively. On the basis of these equations, the ΔOD and CE were calculated to be 0.39 cm^2 C^{-1} and 279 cm^2 C^{-1}, respectively.

4. Conclusions

In conclusion, a new kind of star-shaped monosubstitute 4,4′-bipyridine derivative TBTB was successfully synthesized and characterized. The environmentally friendly solid ECD based on TBTB were assembled and their corresponding electrochromic mechanism was investigated. As a popular choice of electron mediators, TBTB monocation-Fcy(II) complex played an important role in improving the electrochromic performance of the ECD. The solid ECD presented a stable as well as multicolor electrochromic change from blue to violet–blue and then to violet–red. Their environmental friendliness, easy preparation, abundant color, fairly fast electrochromic switching at low voltages, along with their stability under atmospheric conditions, made the ECD good candidates for electrochromic display.

2. Experimental

The photovoltaic device has a structure of ITO/nc-TiO_2/RR-P3HT: PCBM/V_2O_5/Ag/V_2O_5, as shown schematically in Fig. 1. The ITO-conducting glass substrate (a sheet resistance of 15Ω/□ was precleaned by acetone, ethanol, and de-ionized water, respectively, for 15 min. Anatase TiO_2 thin films were prepared as described in our previous papers [18,19]. The thickness of TiO_2 is 25 nm. P3HT (Lumtec Corp., used as received) was dissolved in 1,2-dichlorobenzene to produce 18 mg/ml solution, followed by blending with PCBM (Lumtec Corp, used as received) in 1:1 weight ratio [20]. The blend was stirred for 72 h in the air before spin coating on top of TiO_2 film surface. Then the samples were baked in low vacuum (vacuum oven) at ~160°C or 20 min. The typical film thickness of P3HT: PCBM is about 200 nm. Finally 10 nm V_2O_5, 13 nm Ag, and x (x = 20, 40, 60, 80 nm) V_2O_5 were thermally evaporated in sequence under a high vacuum (5×10^{-4} Pa) without disrupting the vacuum. The deposition rate was about 0.02 nm/s, which was monitored with a quartz-oscillating thickness monitor (ULVAC, CRTM-9000). The active area of the device was about 6.4 mm^2.

Current density–voltage (J–V) characteristics were measured with a computer-programmed Keithley 2400 source/meter under AM1.5G solar illuminations with an Oriel 300 W solar simulator. The intensity of the solar simulator was 100 mW/cm^2. The light intensity was measured with a photometer (International light, IL1400) which was corrected by a standard silicon solar cell. The transmission spectra and the reflection spectra were measured by means of ultraviolet/visible spectrometer (UV 1700, Shimadzu).

3. Results and discussion

Fig. 2a shows the J–V characteristics of semitransparent inverted polymer solar cells with outer 40 nm (device II) and without V_2O_5 (device I) under AM1.5G illumination of 100 mW/cm^2. The incidence light irradiate from the ITO side (Bottom). The detailed results are given in Table 1. Device I shows short circuit current density (J_{sc}) of

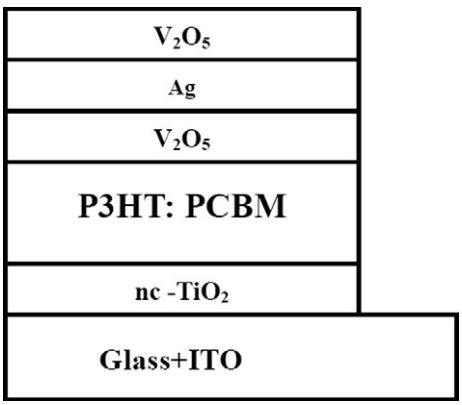

Fig. 1. The schematic structure drawing of the semitransparent inverted polymer solar cells.

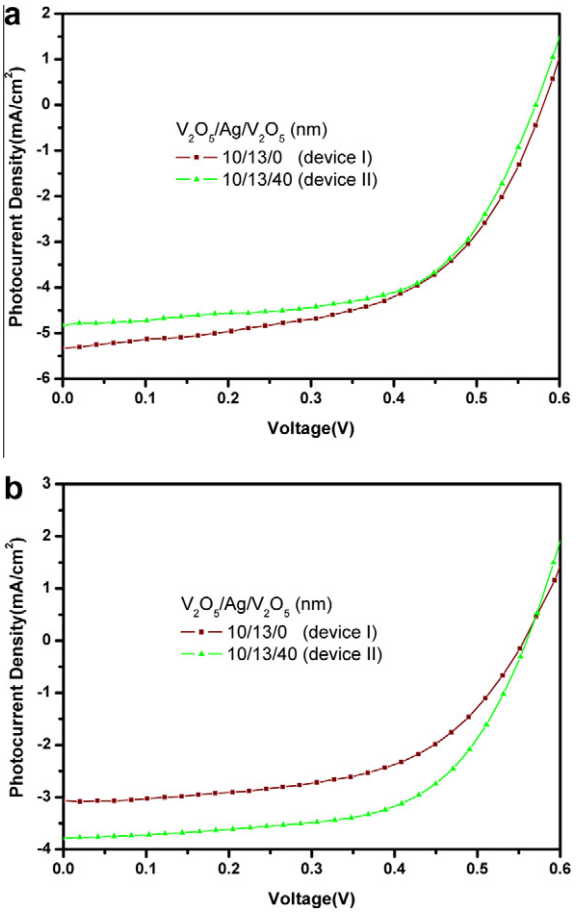

Fig. 2. The J–V characteristics of device ITO/nc-TiO_2/P3HT: PCBM/V_2O_5 (10 nm)/Ag (13 nm)/V_2O_5 (x = 0, 40 nm) when illuminated from (a) ITO side and (b) V_2O_5/Ag/V_2O_5 side.

Table 1
Characteristic data of semitransparent inverted polymer solar cells with different thickness of the V_2O_5 capping layer illuminated from ITO (bottom) and V_2O_5/Ag/V_2O_5 (top) side.

Device (nm)	Illumination	J_{sc} (mA/cm^2)	V_{oc} (V)	*FF* (%)	*PCE* (%)
20	Bottom	5.09	0.585	60.3	1.79
20	Top	3.44	0.561	60.2	1.16
40	Bottom	4.83	0.581	60.6	1.70
40	Top	3.79	0.565	60.6	1.30
60	Bottom	5.36	0.592	59.9	1.91
60	Top	2.99	0.553	59.8	0.99
80	Bottom	5.96	0.594	59.8	2.12
80	Top	2.67	0.551	59.8	0.88

5.31 mA/cm^2, open circuit voltage (V_{oc}) of 0.590 V, fill factor (*FF*) of 0.540, and power conversion efficiency (*PCE*) of 1.69. Device Π shows J_{sc} of 4.83 mA/cm^2, V_{oc} of 0.581 V, *FF* of 0.606, *PCE* of 1.70. It can be seen that the *PCE* of device I is almost same as that of device II. The J_{sc} of device Π decreases, but *FF* increases dramatically compared to that of device I. We attribute the decrease of J_{sc} to lower reflectance of V_2O_5/Ag/V_2O_5 from 400 to 650 nm, which is shown in Fig. 3b. It is evident that the resistivity of the thin

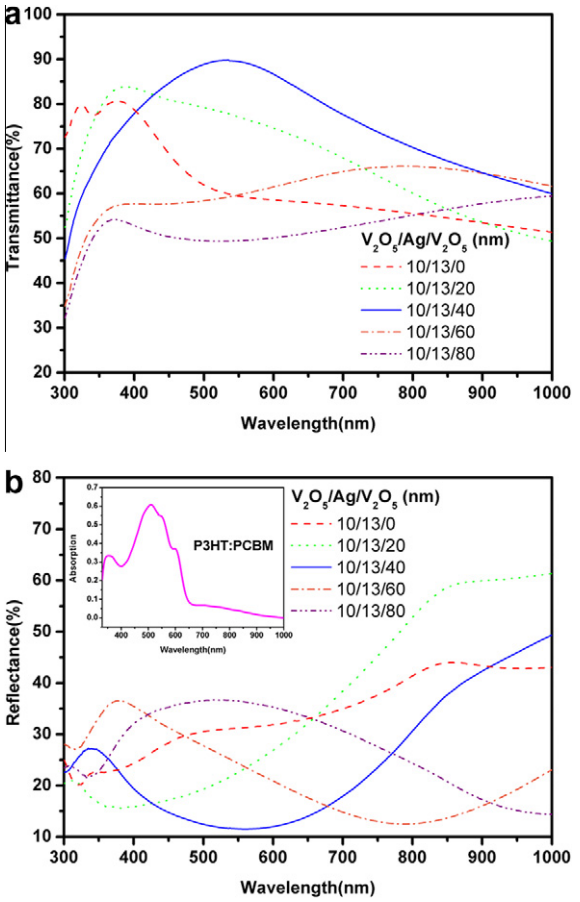

Fig. 3. (a) The transmittance spectra of the transparent electrode V_2O_5 (10 nm)/Ag (13 nm)/V_2O_5 (x = 0, 20, 40, 60, 80 nm) (b) the reflectance spectra of the transparent electrode V_2O_5 (10 nm)/Ag (13 nm)/V_2O_5 (x = 0, 20, 40, 60, 80 nm).

metal film (13 nm Ag here) is higher than that of the bulk metal due to the scattering of the electrons from the surface of the discontinuous film. The outer V_2O_5 decreases the series resistance (R_{sc}), which is defined by the slope of the J–V curve at J = 0 mA/cm^2. The series resistance is estimated to be 33.6Ω for device I and 23.3Ω for device Π. The decrease of R_{sc} results in the increase of *FF* from 0.540 to 0.606. Fig. 2b shows the J–V characteristics of semitransparent inverted polymer solar cells (device I and Π) under AM1.5G illumination of 100 mW/cm^2 when illuminated from V_2O_5/Ag/V_2O_5 side (Bottom). Here, the mixture of P3HT and PCBM, which has main absorption spectrum from 400 to 650 nm, is chosen as active layers. The photocurrent density is in direct proportion to light absorption of the active layer. Since device Π has higher transmittance from 400 to 650 nm, as shown in Fig. 3a, it has bigger J_{sc} than device I.

Fig. 3a shows the transmittance spectra of the V_2O_5/Ag/V_2O_5 from 300 to 1000 nm. It can be seen that the transmittance becomes week with the increase of wavelength, and high transmittance of 80% appears in short wavelength range when the thickness of V_2O_5 is zero. When introducing outer V_2O_5 (capping layer), the transmittance is changed dramatically. With the increase of the thickness of V_2O_5 capping layer, the transmittance peaks are redshifted. The maximum transmittance of 90%, which appears from 400 to 700 nm, is obtained when the thickness of V_2O_5 is 40 nm. To continue increasing the thickness of V_2O_5, the transmittance gradually descends. It is evident that transmission can vary with the thickness of the V_2O_5 capping layer.

Fig. 3b shows the reflectance spectra of the V_2O_5/Ag/V_2O_5 from 300 to 1000 nm. Since the absorption is little, the reflectance spectrum is nearly one to one complement with the transmittance spectrum. It can be seen that reflectance peaks are redshifted gradually and would match better to the absorption spectra of the active layer (400–650 nm) when the thickness of the V_2O_5 capping layer increases.

Fig. 4a shows the the J–V characteristics of semitransparent inverted polymer solar cells under AM1.5G illumination of 100 mW/cm^2 when illuminated from ITO side (Bottom). The detailed results are given in Table 1. When the thickness of V_2O_5 is 40 nm, the J_{sc} is 4.83 mA/cm^2, the V_{oc} is 0.581 V, the *FF* is 60.6%, and the PCE is 1.70%. When

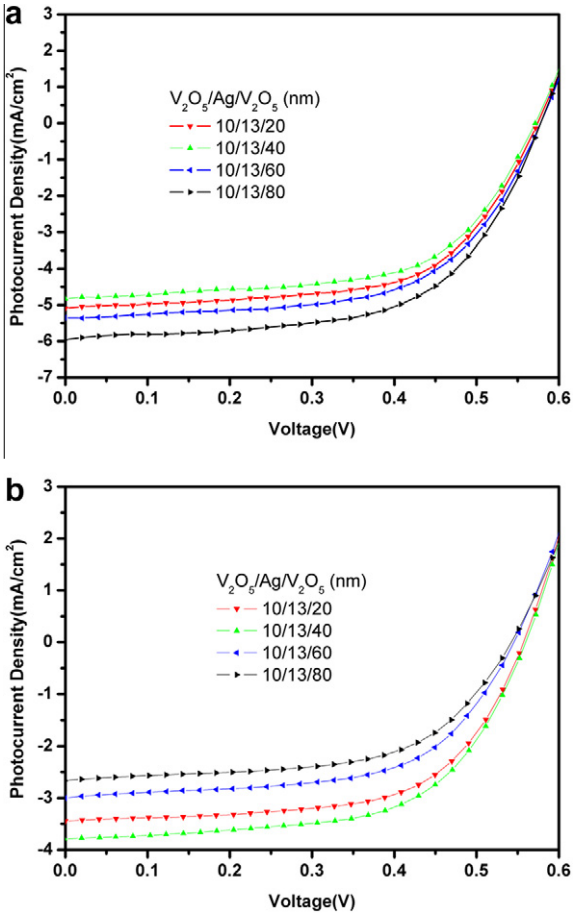

Fig. 4. The J–V characteristics of device ITO/nc-TiO_2/P3HT: PCBM/V_2O_5 (10 nm)/Ag (13 nm)/V_2O_5 (x = 20, 40, 60, 80 nm) dependent on the thickness of the V_2O_5 capping layer when illuminated from (a) ITO side and (b) from V_2O_5/Ag/V_2O_5 side.

the thickness of V_2O_5 is 80 nm, the photovoltaic device has a J_{sc} of 5.96 mA/cm^2, V_{oc} of 0.594 V, *FF* of 59.8%, and *PCE* of 2.12%. The J_{sc} of the device with 40 nm V_2O_5 is the smallest; and the J_{sc} of the device with 80 nm V_2O_5 is the biggest. It is known that the reflectance of the top electrode plays an important role in trapping light for the active layer to reabsorb. The reflectance of V_2O_5/Ag/V_2O_5 (80 nm) from 400 to 650 nm is the strongest, but the reflectance of V_2O_5/Ag/V_2O_5 (40 nm) is poorest in Fig. 3b.

Fig. 4b shows the the *J–V* characteristics of semitransparent inverted polymer solar cells under AM1.5G illumination of 100 mW/cm^2 when illuminated from V_2O_5/Ag/V_2O_5 side (Top). The detailed results are given in Table 1. When the thickness of V_2O_5 is 40 nm, the J_{sc} is 3.79 mA/cm^2, the V_{oc} is 0.565 V, the *FF* is 60.6%, and the PCE is 1.30%. When the thickness of V_2O_5 is 80 nm, the photovoltaic device has a J_{sc} of 2.67 mA/cm^2, V_{oc} of 0.551 V, *FF* of 59.8%, and *PCE* of 0.88%. The J_{sc} of the device with 40 nm V_2O_5 is the biggest, and that for the device with 80 nm V_2O_5 is the smallest. This is because the transmittance of V_2O_5/Ag/V_2O_5 (40 nm) is the highest, and the absorption of active layer material is directly proportional to the transmittance of the incidence electrode. When illuminated from V_2O_5/Ag/V_2O_5 side, the V_{oc} becomes smaller compared with that illuminated from the ITO side. The dependence of the V_{oc} and the photocurrent (I_{ph}) can be generally expressed as follows [21]:

$$V_{oc} = \frac{kT}{q} Log\left(\frac{I_{ph}}{I_s} + 1\right) \quad (1)$$

Where I_s is reverse saturation current, k is Boltzman constant, T is the temperature, and q is charge. Under Eq. (1), the V_{oc} is directly proportional to I_{ph}. The I_{ph} from ITO side is much bigger than that from V_2O_5/Ag/V_2O_5 side, which is shown in Table 1.

4. Conclusion

In summary, we present efficient semi-transparent inverted polymer solar cells with highly transparent V_2O_5/Ag/V_2O_5 anodes. The inner V_2O_5 layer was introduced as a buffer layer to improve holes collection, while the outer V_2O_5 served as a light coupling layer to enhance optical transmittance. The incident light transmittance changed with the thickness of V_2O_5.When the thickness of V_2O_5 is 40 nm, the highest transmittance is obtained. The reflectance peaks are redshifted gradually and would match better to the absorption spectra of the P3HT: PCBM layer when the thickness of the V_2O_5 capping layer increases.

"any design or process improvements specifically directed at a reduction of the contact resistance in organic TFTs should be regarded as equally important to improving the performance of organic electronic devices as improvements directed at increasing the intrinsic carrier mobility of the organic semiconductor material" [16].

So far, gold has proven to be the most successful material for the fabrication of source and drain (S/D) electrodes of bottom gate (BG) bottom contact (BC) transistors (Fig. 1a) used as building blocks of high speed organic circuits. This can be attributed to its manifold benefits such as: (i) high chemical inertness (no spontaneous oxidation in air) allowing easy cleaning after photolithographic patterning (for example by solvents, strong chemical oxidizers or ultraviolet–ozone (UV/O_3)), (ii) simple deposition by evaporation or sputtering, (iii) good electrical conductivity, and (iv) the ability to fix self-assembled monolayers (SAMs) that improves charge injection into the organic semiconductor, enabling ohmic contacts, an asset for successful transistor downscaling. All these properties together lead to well-behaved pentacene transistors based on gold S/D BC exhibiting low contact resistance and high extrinsic hole saturation mobilities (μ_{sat}) of up to 0.5–1 $cm^2/(V\,s)$ even for short channel lengths ($L \leqslant 10\,\mu m$) [17]. Further on, gold has proven to be the material of choice to successfully scale-down transistor dimensions, thus boosting circuit speeds. Current high-speed state-of-the art organic circuits such as full-wave rectifier circuits operating at 13.56 MHz [18] and 64-bit and 128-bit plastic transponder chips for RFID-tags [6] are based on pentacene transistors with gold S/D BCs. On the other hand, the high cost of the gold layer (typical thickness of around 30 nm [8]) precludes commercialization in low-cost applications such as RFID-tags. Indeed, for a 1 cm^2 area RFID-tag [6] the cost of such a gold layer (based on the current gold price of 44 USD per gram) would already reach 25% of the target price of 0.01 USD, to which additional costs of the antenna, the substrate, the dielectric, the organic semiconductor, solvents and chemicals, yields below 100%, and the processing have to be added.

During the past years a huge number of alternative BC materials for pentacene transistors have been investigated, such as metals [19–24], metal oxides [22,24], ionic salts [25–27], carbon (including carbon nanotubes and graphene [28–35]) and conductive polymers [36–39]. For some of the non metallic materials, pentacene BG BC transistors with mobilities in the range of 0.1–1 $cm^2/(V\,s)$ could be achieved with *large* channel lengths [24–26,28,29,32,37,39]. However, this does not imply that such high carrier mobility could be reached for similar transistors with short channel lengths, a requirement for high speed organic circuits. Academic research has proven that mobilities within the 10^{-2} $cm^2/(V\,s)$ range can be reached with organic semiconductors and metallic or conductive polymer based BCs of sub-micrometer channel length [36,40–42], where the channels were defined by innovative processes such as nanoscratching and self-aligned printing. Although such developments are highly valuable for future generations of organic electronic circuits, additional research will likely be required for reaching sufficient high yield of operational transistors and low spread of their electrical parameters required for circuits involving several hundred organic transistors [6], which can currently be obtained with photolithography based patterning of S/D BCs.

In this paper, we propose a different approach towards cost-effective while high performing S/D electrodes. These consist of metallic bilayers: a thick layer of an inexpensive first metal, Ti or Al, directly deposited onto the substrate, assuring good adhesion and high electrical conductivity, and a second, thin layer – deposited above the first one – of a noble metal, Au or Pd, providing good charge injection into pentacene. Using these metallic bilayer structures, we demonstrate the feasibility of low cost, short channel ($L \leqslant 5\,\mu m$) BG BC pentacene transistors, yielding performances that favorably compare to equivalent reference transistors based on 30 nm thick Au-only S/D electrodes, and this for metal costs down to 5% of those of the traditional route.

2. Experimental

Transistors were processed on a highly doped Si wafer (200 mm diameter, IMEC production line) with aluminum backside, acting respectively as the substrate and the gate electrode. A uniform, about 140 nm thick thermally grown SiO_2 provides the gate dielectric; the exact thickness of which is evaluated by ellipsometry. Source and drain electrodes made with various metallizations (see below) were patterned by double layer photoresist (AZ6612 and LOR™ 1A (MicroChem)) lithography and lift-off. The use of a double layer resist permits a negative slope that ensures the absence of spikes after resist lift-off. Subsequently, the substrates were thoroughly cleaned by ultrasonication in acetone (10 min.) and isopropylalcohol (10 min), blown dry with nitrogen, and cleaned by a UV/O_3 step (15 min). A self-assembled monolayer of pentafluorobenzenethiol (PFBT) was then deposited from a 5 mM solution in ethanol

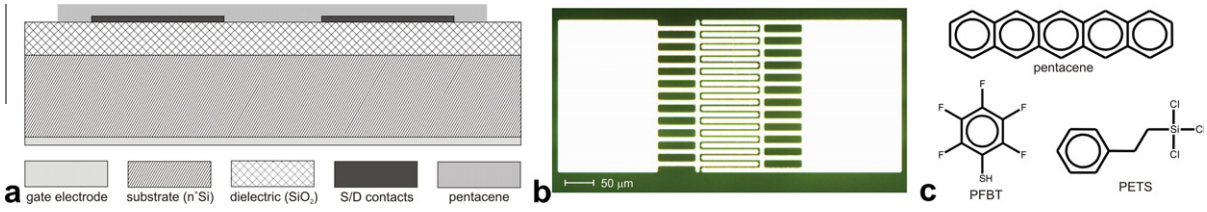

Fig. 1. (a) Schematic view of a BG BC pentacene transistor (optional surface modification layer on the dielectric and the S/D bottom contacts are omitted for clarity); (b) Optical micrograph of a bottom S/D contacts (W/L = 2500/5 µm/µm) on SiO_2; and (c) Chemical structure of pentacene, PFBT and PETS.

(30 min) onto the Au containing S/D contacts; this step was omitted for Pd metallizations. Then a silane based self-assembled monolayer was deposited onto the SiO_2 dielectric by exposure of the substrates to vapors of phenylethyltrichlorosilane (PETS, 60 °C, reduced pressure) during 30 min. Pentacene, purified by gradient sublimation, was evaporated onto the substrates in an ultrahigh vacuum chamber (10^{-8} Torr) at 0.25 Å/s, while the substrate was kept at 68 °C. After pentacene evaporation, the samples were directly transferred from the vacuum chamber into a nitrogen filled glovebox ($[O_2] < 1$ ppm, $[H_2O] < 1$ ppm), where transistors were measured using an Agilent 4156C parameter analyzer. All indicated mobilities were evaluated in saturation mode. Transistor structures had nominal channel width/length (W/L) of 2500 μm/5 μm. Exact channel lengths (typically around 3.7–4.5 μm), measured by optical microscopy (Olympus AX70) were used for the computation of the saturation mobility and are reported in the corresponding figures. BC substrates were characterized by scanning electron microscopy (SEM, Philips XL30) and the morphology of the organic polycrystalline film by atomic force microscopy (AFM, Agilent 5100), operated in tapping mode.

3. Results and discussion

In order to replace the 30 nm thick (sputtered) Au layer used in our standard process BCs, we investigated alternative BC metallizations consisting of thin (5 nm) Au and Pd layers formed on a thicker (25 nm) evaporated Al layer. Although preliminary experiments revealed that Ti (25 nm) is also suitable for this lower layer, the entire study reported within this paper is performed with Al. Indeed, this metal – in addition to lower cost – has a significant lower electrical resistivity as compared to that of Ti (Table 1) [43].

A simple calculation, based on resistivity values indicated in Table 1 and the formula of two resistors connected in parallel, reveals that the resistance of the BC consisting of 5 nm Au on 25 nm Al, and 5 nm Pd on 25 nm Al, are respectively only 15% and 35% higher to that of a 30 nm thick pure Au layer. This slight increase in resistivity is fully acceptable for the envisaged circuit applications.

Since Al adheres very well to SiO_2 it was also possible to investigate a thin *evaporated* Au layer on top of Al, in addition to the thin *sputtered* Au layer on Al. As will be shown later, this processing detail leads to a significant difference in electrical performance of the corresponding pentacene transistors.

Table 1
Electrical resistivity of metals at 20 °C. The value for Cu is given for comparison.

Metal (Symbol)	Electrical resistivity μΩ cm at 20 °C [43]
Gold (Au)	2.24
Palladium (Pd)	10.54
Aluminum (Al)	2.6548
Titanium (Ti)	42.0
Copper (Cu)	1.678

3.1. Characterization of bottom contacts with different metallizations schemes

After the patterning of the BCs, it is important to ascertain that transistors BCs and channels are free of contaminants (as for example remaining photoresist). Indeed, the presence of insulating particles could hinder current flow into the channel and/or act as injection barrier at the BC/semiconductor interface. For this reason substrates were investigated by SEM directly after the UV/O_3 cleaning step that follows the BC layer patterning. Corresponding micrographs, depicted in Fig. 2, confirm the absence of photoresist for all different BC metallizations. In addition, we observe a difference between 5 nm thick sputtered Au and 5 nm thick evaporated Au, both on 25 nm thick evaporated Al (Fig. 2b and c). In the case of evaporated Au (Fig. 2c) the border between the metal and the dielectric is sharp – similar to the case of evaporated Pd (Fig. 2d) – whereas in the case of sputtered Au on Al, an additional intermediate zone is present, as depicted in the inset of Fig. 2b. This discrepancy is related to differences in mass transport in the two considered metallization methods: lower pressures in evaporation ensure a straight ballistic transport (Fig. 3a), whereas sputtering occurs at higher pressure, resulting in a more random angled delivery of the metal (Fig. 3b). As a consequence, when using a negative resist for lift-off, sputtered Au provides a good step coverage on the thick evaporated Al, resulting in a slightly larger finger width of the S/D contacts (Fig. 3c).

3.2. Pentacene growth on bottom contact transistor substrates with different metallization schemes

Morphology of the polycrystalline pentacene layer (30 nm thickness) on BC structures after PFBT (only Au based substrates) and PETS treatment (all substrates) is investigated by AFM. Being interested in injection properties of the BCs, this investigation focuses on the contact/channel region. The left column on Fig. 4 shows AFM topographical images of transistors with a 5 μm long channel (nominal length). The right column displays a closer view of the contact/channel area (right). As expected, on the dielectric (PETS treated SiO_2) in the channel, pentacene growth is independent of the BC metallization scheme (Fig. 4a–d). In this region, pentacene forms large dendritic and terraced grains, with here and there, higher 3-dimensionnal grains, a growth that is typical for this type of substrate and processing conditions. When growing pentacene on thiol-treated sputtered Au, no morphological difference can be observed between the thick 30 nm Au (Fig. 4a) and the bilayer 25 nm Al/5 nm Au substrates (Fig. 4b). On the other hand, pentacene growth on top of S/D contacts appears to be influenced by the upper metallization layer. Firstly, pentacene on thiol treated Au reveals larger grains and rougher layers on the sputtered (Fig. 4b) than on the evaporated metal (Fig. 4c). This is related to a smoothness difference between evaporated and sputtered Au. Secondly, pentacene on evaporated Pd (Fig. 4d) surprisingly shows small dendritic grains, a growth that is similar to that of pentacene in the channel, and this *without* any thiol treatment of the Pd.

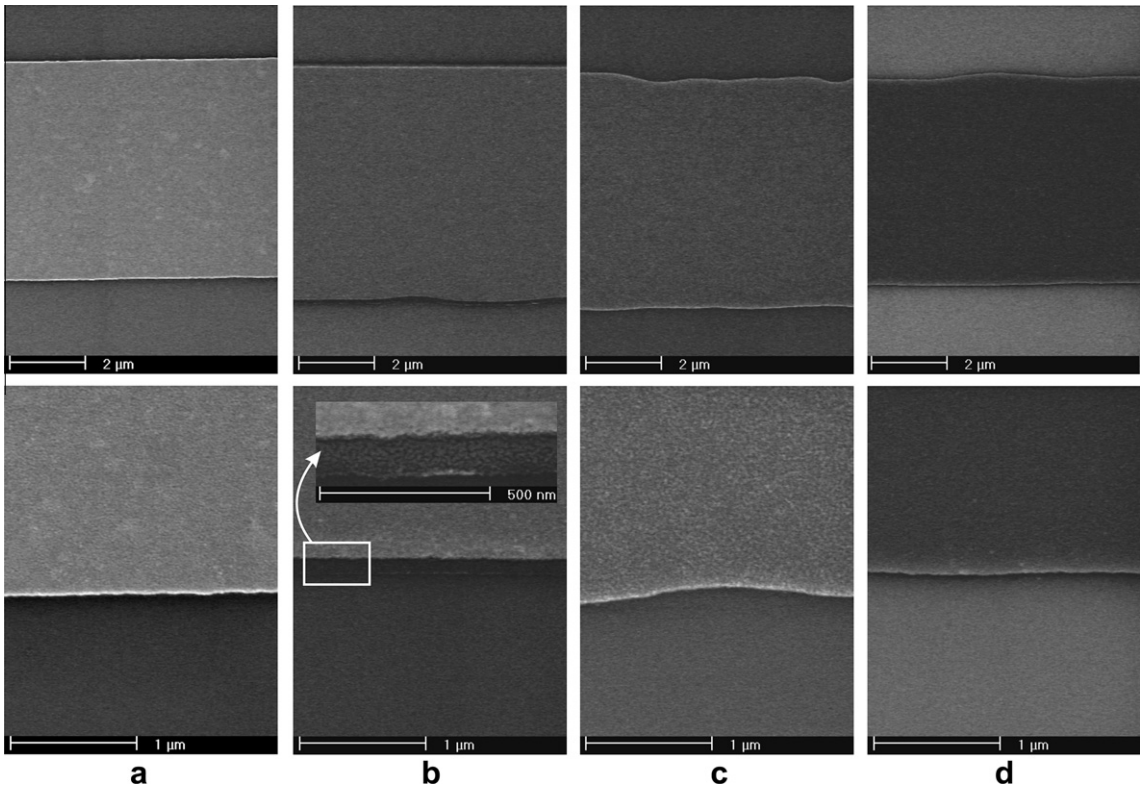

Fig. 2. Scanning electron micrographs (top view) of BC metallizations on SiO_2: (a) 30 nm sputtered Au, (b) 5 nm sputtered Au on 25 nm evaporated Al, (c) 5 nm evaporated Au on 25 nm evaporated Al, and (d) 5 nm evaporated Pd on 25 nm evaporated Al.

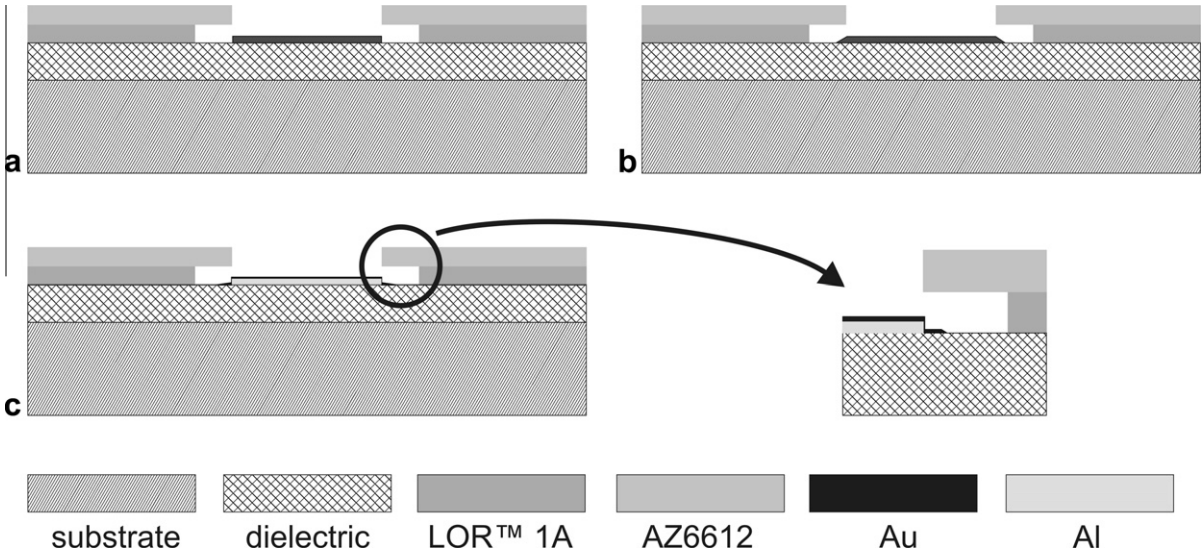

Fig. 3. Schematic representation of the BC metallization process: (a) evaporated metal (Au), (b) sputtered metal (Au), (c) thin layer of sputtered metal (Au) on top of a thicker layer evaporated metal (Al).

In the closer view of the contact/channel interface (right column of Fig. 4), it appears that, in all cases, pentacene two dimensional grains nucleate along the metal wall and subsequently grow inside the channel by step flow. This leaves a pattern of superimposed terraces all stemming from the same nucleation point and propagating inside the channel. In the case of the thin sputtered Au layer on Al, the small grained morphology that is typical of pentacene growth on top of thiol treated Au slightly extends to the right of the thick contact region (Fig. 4b,

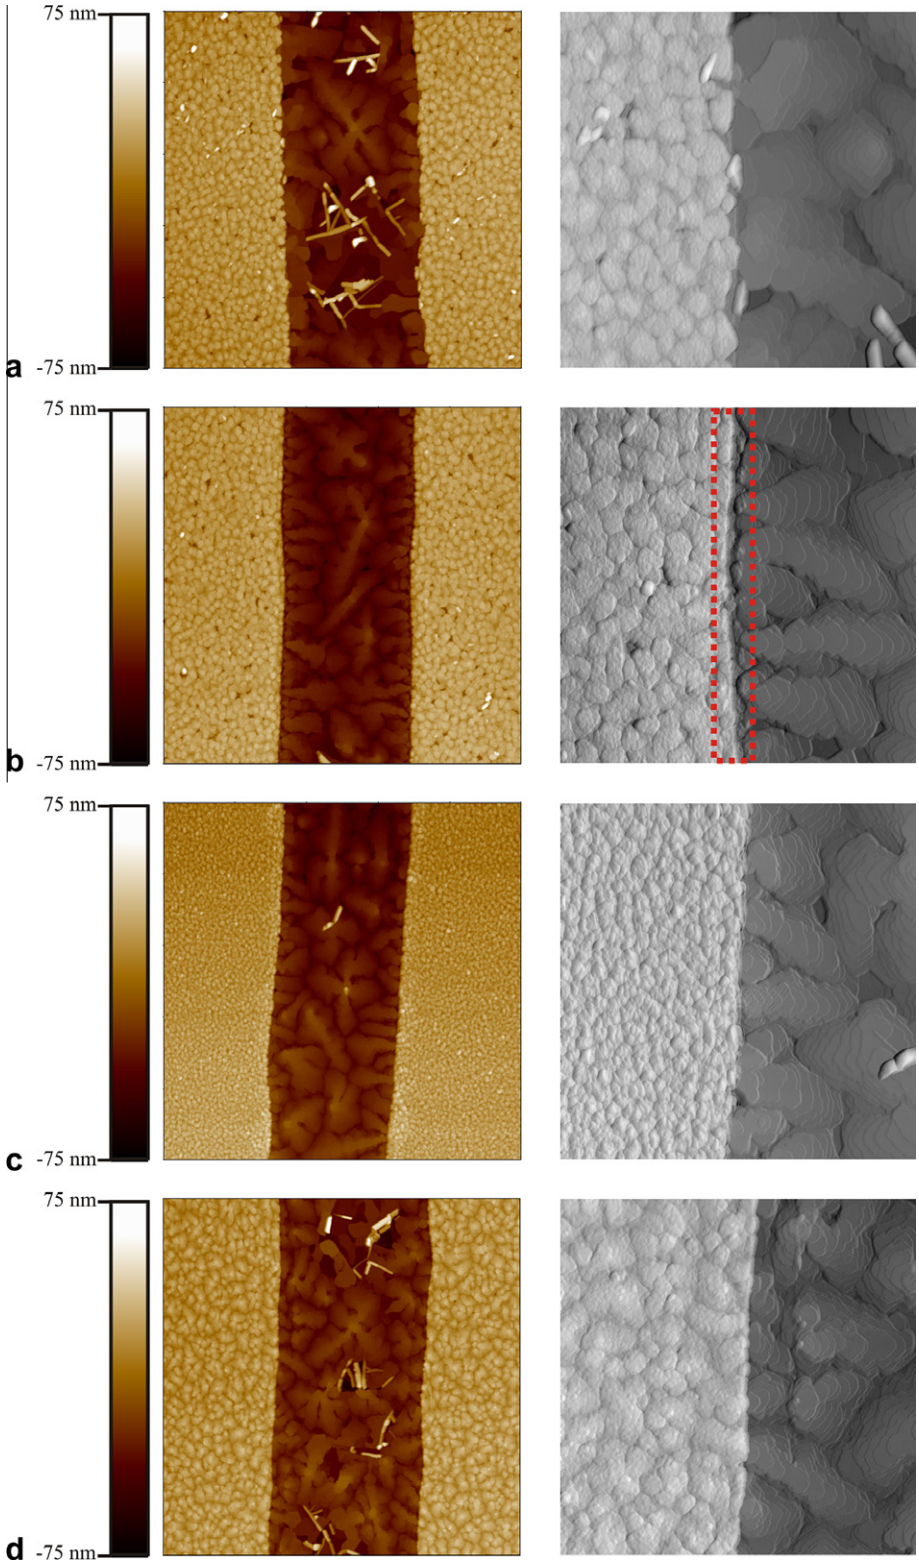

Fig. 4. AFM pictures of the source/drain BCs and the channel region for (a) 30 nm Au (sputtered) BC, (b) 5 nm Au sputtered onto 25 nm Al, (c) 5 nm Au evaporated onto 25 nm Al, (d) 5 nm Pd evaporated onto 25 nm Al. SiO_2 dielectric was treated with a silane (PETS) and Au containing substrates with a thiol (PFBT). Left pictures: 10 μm by 10 μm scan of the channel between source and drain contacts; right pictures with shaded contrast enhancement: 3 μm by 3 μm scan of the contact/channel interface.

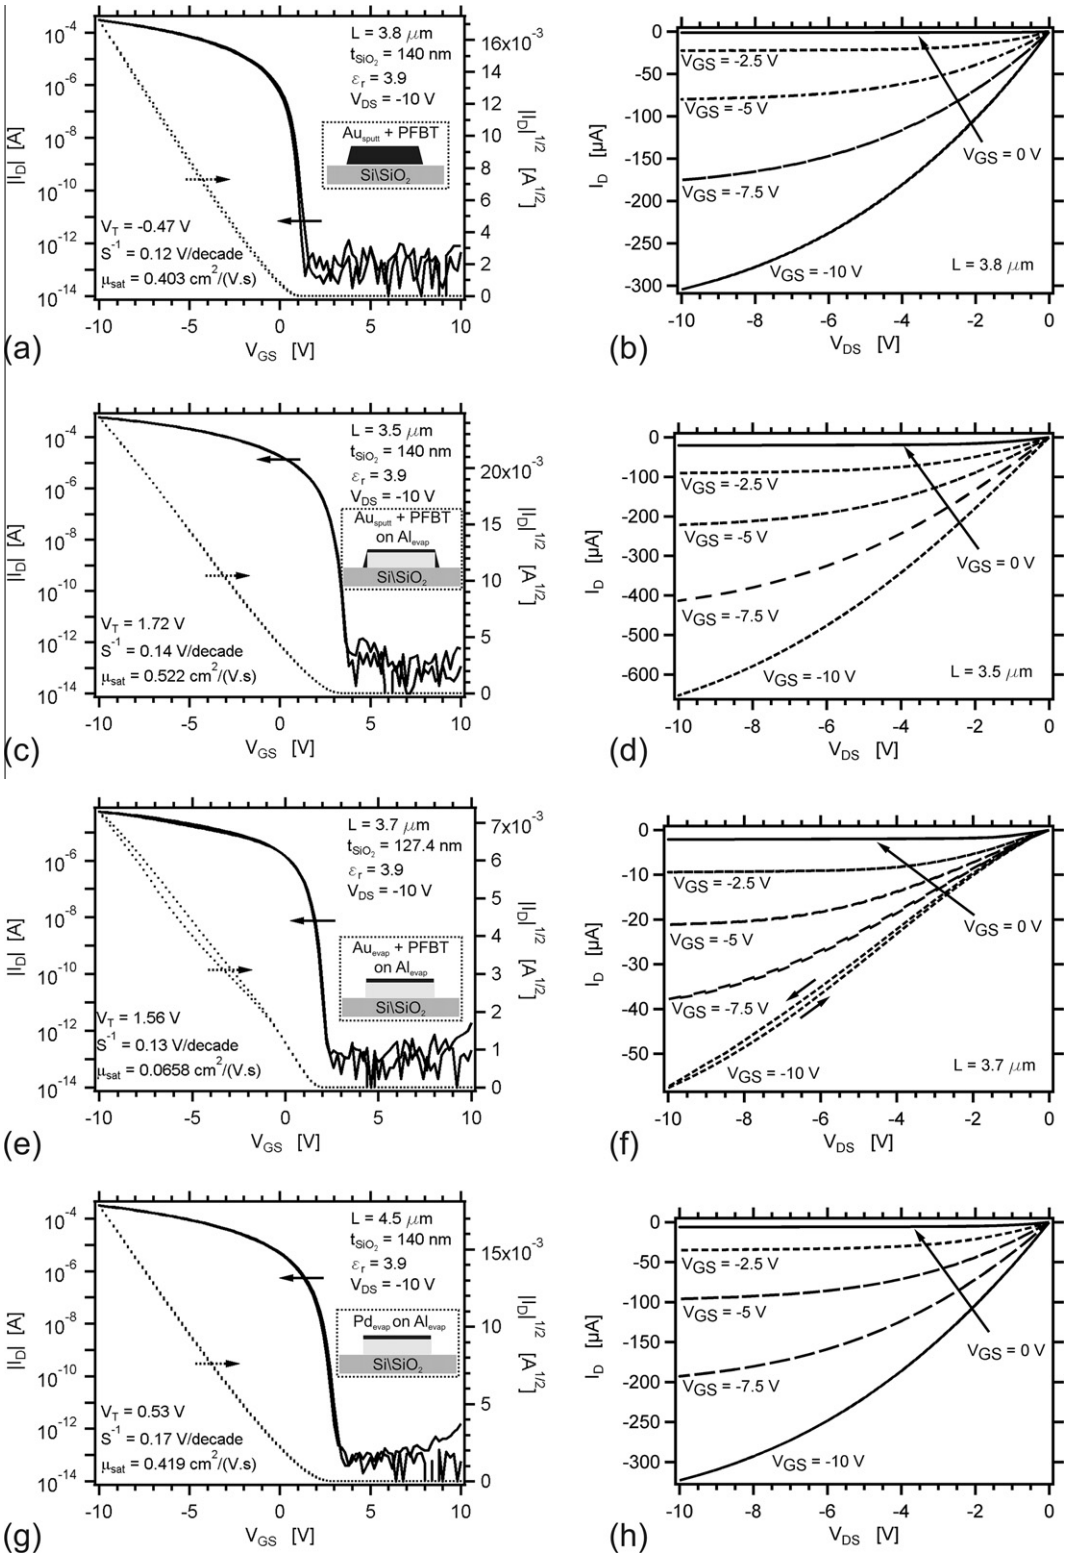

Fig. 5. Electrical transfer (a,c,e, and g) and output (b,d,f, and h) characteristics of pentacene transistors (nominal W/L = 2500/5 μm/μm) with various BC metallization schemes: (a,b) 30 nm sputtered Au, (c and d) 5 nm sputtered Au on 25 nm evaporated Al, (e and f) 5 nm evaporated Au on 25 nm evaporated Al, and (g and h) 5 nm evaporated Pd on 25 nm evaporated Al (L: measured channel length, t_{SiO2}: thickness of SiO_2 dielectric, ε_R: dielectric constant of the gate dielectric, V_T: threshold voltage, S^{-1}: subthreshold slope). SiO_2 dielectric was treated with a silane (PETS) and Au containing substrates with a thiol (PFBT).

dashed rectangle). This confirms the earlier observation that the thin sputtered Au layer extends beyond the width of the evaporated Al (inset in Fig. 2b).

Previously reported SEM micrographs published by Bock et al. [20] for pentacene growth on 25 nm thick Pd and Au bottom contacts (both on 1 nm thick Ti adhesion layer and without thiol treatment) showed a film morphology similar in the channel and on the Pd electrode, but not on the Au electrode. Our results indicate that the metallic bilayer structure is not detrimental for pentacene growth. In all studied cases, homogeneous pentacene films can be obtained.

3.3. Effect of bottom contact metallization on transistor characteristics

Electrical performances of the investigated S/D metallization schemes for pentacene BG BC transistors with nominal W/L = 2500 μm/5 μm are shown in Fig. 5, with transfer and output curves respectively in the left and in the right column. The reference transistor with 30 nm thick Au BC displays well-behaved characteristics. From the transfer curve, a saturation mobility μ of 0.4 $cm^2/(V\,s)$ and a threshold voltage V_T close to 0 V are extracted (Fig. 5a). The output curve displays a good saturation behavior with no evidence of injection problem at the contacts. Such characteristics are fully representative of a stable and optimized pentacene BG BC transistor technology. We observe comparable characteristics for pentacene transistors with 5 nm sputtered Au on 25 nm evaporated Al (Fig. 5c and d) and with 5 nm evaporated Pd on 25 nm evaporated Al (Fig. 5g and h). Both metallic bilayer BC architectures deliver excellent transistors, with μ in the range of 0.4–0.5 $cm^2/(V\,s)$, low V_T and no evidence of injection problems at the contacts. On the other hand, in the case of the 5 nm evaporated Au on 25 evaporated Al BC architecture, the S-shaped output curves in Fig. 5f clearly exhibit signs of non-ohmic contacts [44]. This adversely affects the source/drain current flowing through the device whose μ decreases by almost one order of magnitude (Fig. 5e).This unexpected difference between a thin sputtered (Fig. 5c and d) and evaporated (Fig. 5e and f) Au film on Al finds its explanation in the earlier evidences from the SEM and AFM device characterizations that sputtered Au extends beyond the width of the evaporated Al film whereas the evaporated Au has the same width as the Al film underneath. Indeed, experiments reported for BG BC pentacene transistors with 50 nm thick Au layers on 0.5–10 nm thick Ti adhesion layers revealed that good charge injection into the pentacene could only be achieved for Ti layer thicknesses *below* 3 nm, which is about the thickness of the accumulation layer in a pentacene channel [12]. The requirement to have a direct contact between the noble metal and the pentacene in the transistor channel region explains why the BC metallization with evaporated Au on Al led to poor charge injection (Fig. 5e and f) whereas injection from the sides of the sputtered Au on Al led to excellent transistor properties (Fig. 5c and d).

Considering this advantage of sputtering over evaporation for the thin Au layer, it is surprising that we obtain such good transistors for the 5 nm evaporated Pd on 25 nm Al BC architecture (Fig. 5g and h) who favorably compare to those reported in the pioneering work by Klauk et al. on pentacene transistors based on ion-beam sputtered Pd BC [10]. Moreover the absence of any specific contact treatment besides the UV/O_3 exposure constitutes an advantage of Pd over the for Au obligatory thiol treatment, leading to potentially air sensitive Au-thiolates [45]. The reason for not encountering similar injection problems with the thin evaporated Pd as with the thin evaporated Au is not clear. It could find its origin in the improved continuity of the pentacene film formed on top of the Pd contact and on top of the dielectric in the channel, as hinted by the similar dendritic morphologies in Fig. 4d.

3.4. Metal cost reduction for S/D bottom contacts

Since noble metals like gold and palladium are significantly more expensive than aluminum, simple calculations – neglecting the cost of the aluminum layer – have been made in order to estimate the material cost reduction by using a 5 nm thin Au or Pd layer as metallization for BC instead of a 30 nm thick pure Au layer. In this way, metallization cost of the thin Au layer was only 1/6th of the standard Au metallization, and this with similar performance of the short-channel pentacene transistors (Fig. 5a–d).

The relative metallization cost of a 5 nm thick Pd layer with respect to 30 nm thick Au layer was calculated using the following formula, in which C_M, d_M, A_M, ρ_M and P_M respectively represent the metallization cost, the layer thickness, the metallization area, the density, and the prize/weight of the metal M:

$$C_M = d_M \times A_M \times \rho_M \times P_M$$

From this formula, the ratio of C_{Au}/C_{Pd} was computed as follows:

$$\frac{C_{Au}}{C_{Pd}} = \frac{d_{Au}}{d_{Pd}} \times \frac{A_{Au}}{A_{Pd}} \times \frac{\rho_{Au}}{\rho_{Pd}} \times \frac{P_{Au}}{P_{Pd}}$$

Knowing (i) that the metallization areas are identical for Au and Pd, (ii) d_{Au} = 30 nm and d_{Pd} = 5 nm, (iii) ρ_{Au} = 19.30 and ρ_{Pd} = 12.0 g/cm^3 at 20 °C [46] and (iii) the current ratio of the gold prize with respect to the palladium prize $P_{Au}/P_{Pd} \approx 2.1$, the metallization cost ratio is $C_{Au}/C_{Pd} \sim 19.8$.

This indicates that the material cost of a 5 nm thin Pd layer (on 25 nm thick Al) is only about 5% of the cost of the traditional metallization consisting of 30 nm Au.

4. Conclusions

The issue addressed in this paper can be wrapped up in the three following facts: (i) organic circuits require high mobility short channel pentacene transistors to reach sufficient speeds, (ii) up to now, such high mobilities in short channel devices could only be achieved with Au S/D contacts, (iii) in mass production, the gold cost amounts for a significant fraction of the final device price. In this work, we prove the concept of using metallic bilayers (5 nm thin sputtered Au or evaporated Pd on 25 nm thick evaporated Al) as replacement of traditional plain Au (30 nm thick) S/D

contacts in short channel ($L \leqslant 5$ μm) pentacene BG BC transistors. Using this new BC architecture, transistors achieve similar saturation hole mobilities to those of reference transistors with pure Au contacts, and this with at metal costs of respectively 17% and 5% of the reference transistor. With its equivalent performance at a significantly lower cost, the bilayer approach presented here represents the only credible alternative to plain Au electrodes and can be considered as significant step towards the commercialization of low-cost high quality organic electronic circuits. The achievement of good electrical performance with bilayers consisting of evaporated metals is furthermore promising for future cost reductions since the metal bilayer profile can be expected to be similar to the one obtained by etching processes, which typically gives higher yields than lift-off processes and are therefore used in industrial processes of the display industry.

Acknowledgments

Erwin Vandenplas (IMEC) is acknowledged for metal deposition on the substrates. This work was performed in a collaboration between IMEC and TNO in the frame of the HOLST Centre. The authors acknowledge financial support of EC-funded project Polaric (FP7-247978).

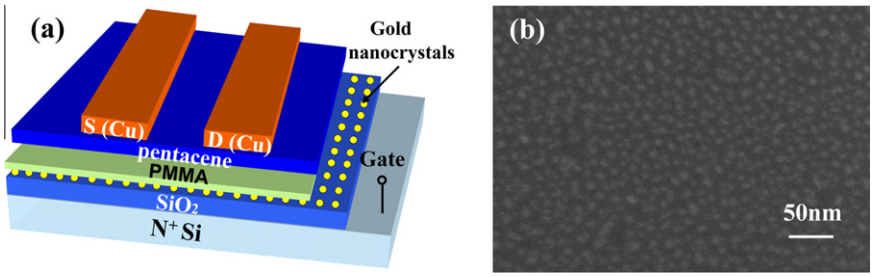

Fig. 1. (a) Schematic illustration of the fabricated organic memory devices. (b) SEM image of the Au nanocrystals used as the charge trapping elements.

memory devices were fabricated on heavily doped n-type Si wafers with a 300 nm thermal oxides SiO_2 as the gate electrode and the blocking layer. Au nanocrystals were obtained by e-beam evaporating a 1.5 nm thick Au layer at a deposition rate of 0.3 Å/s. The polymethylmethacrylate (PMMA) tunneling layer was then prepared from a PMMA solution in *O*-xylene by spin-coating on the surface of Au nanocrystals and then baked in the oven at 180 °C for 30 min to remove the solvent. The thickness of the PMMA film was 60 nm. The pentacene film with a thickness of 50 nm was deposited by vacuum thermally evaporated at a deposition rate of 0.3 Å/s with a typical background pressure of 4×10^{-4} Pa and the substrates were kept at 60 °C. Finally, 50-nm-thick copper (Cu) top source/drain electrodes were deposited by e-beam evaporation through a shadow mask, the defined channel lengths (L) and channel widths (W) were 500 μm and 60 μm, respectively. Cu top contacts were employed because of their smaller contact resistance compared with conventional gold contacts [19]. The electrical characteristics of the transistors were measured with a Keithley 4200 semiconductor characterization system at room temperature in air. No illumination was applied during all the measurements of output and transfer characteristics. The morphologies of the Au nanocrystals were observed by scanning electron microscope (SEM).

3. Results and discussion

Fig. 1(b) shows the SEM image of uniform Au nanocrystals on SiO_2 dielectric layer. The average diameter of the Au nanocrystals is 10 ± 2 nm and the density was 6.9×10^{11} cm^{-2}. Devices with this configuration exhibit excellent transistor performance, which is comparable to those reported elsewhere. Shown in Fig. 2 are the typical output and bidirectional transfer characteristics of the OFET memory device. A hysteresis window of 5 V was observed in the transfer curve and the calculated saturation mobility, V_T, and on/off current ratio (I_{on}/I_{off}) from the forward curve were 0.5 cm^2 V^{-1} s^{-1}, 1 V, and 10^7, respectively.

To study programmable characteristics of fabricated memory devices, the transfer curves under programming/erasing bias pulses of ±80 V both in dark and with light-assisted program were measured. As shown in Fig. 3(a), the shift in the transfer characteristics of the fabricated memory devices at $V_{DS} = -60$ V, under programming and erasing operations were observed where bias pulses of 80 and −80 V were applied to the gate for 1 ms in dark. Hysteresis was observed in transfer curves for both states and the hysteresis window for the programmed state was slightly larger than that of erased state. However, comparing with the memory window, the hysteresis under both states was negligible. The programmed and erased V_T extracted from forward transfer curves were found to be −1 V and −19 V, respectively. The memory window was defined as the change of V_T with respect to the applied program/erase bias pulses. The memory window of our device was 18 V with program/erase operation in dark. In addition, the on/off memory ratio with a reading voltage of $V_{DS} = -60$ V, $V_{GS} = 0$ V was 10^2. Fig. 3(b) shows the programmable memory characteristics of the memory devices with light assisted program. When using a program with top light irradiation (white light with a power density of 1.33 mW/cm^2 from a lighting emitting diode lamp) and gate bias pulses of 80 V for 1 ms, the programmed V_T was found to be 43 V. Meanwhile, erased state with V_T of

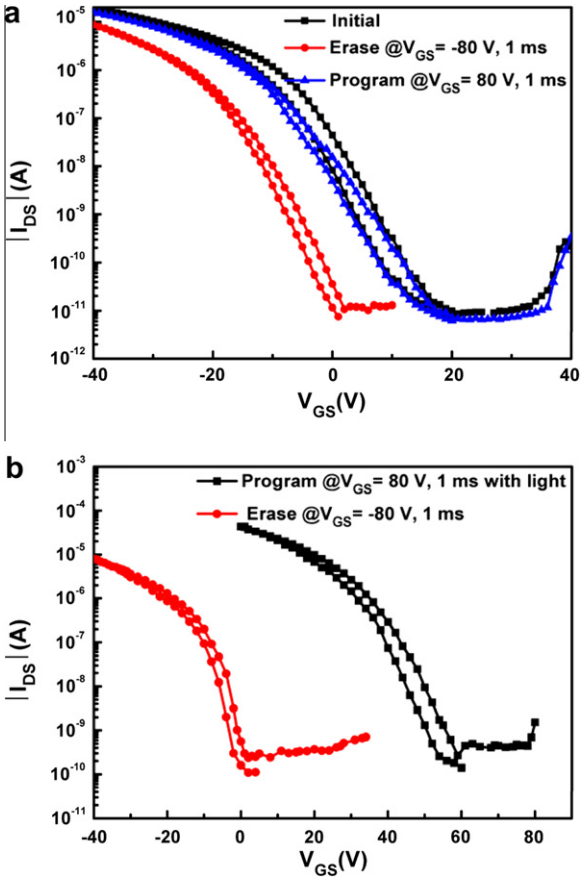

Fig. 3. (a) Bidirectional transfer curves of the organic memory devices according to the programming/erasing bias pulses of ±80 V for 1 ms in dark. (b) Bidirectional transfer curves of the organic memory devices under V_{GS} = 80 V, 1 ms with light assisted program and V_{GS} = −80 V, 1 ms erase conditions.

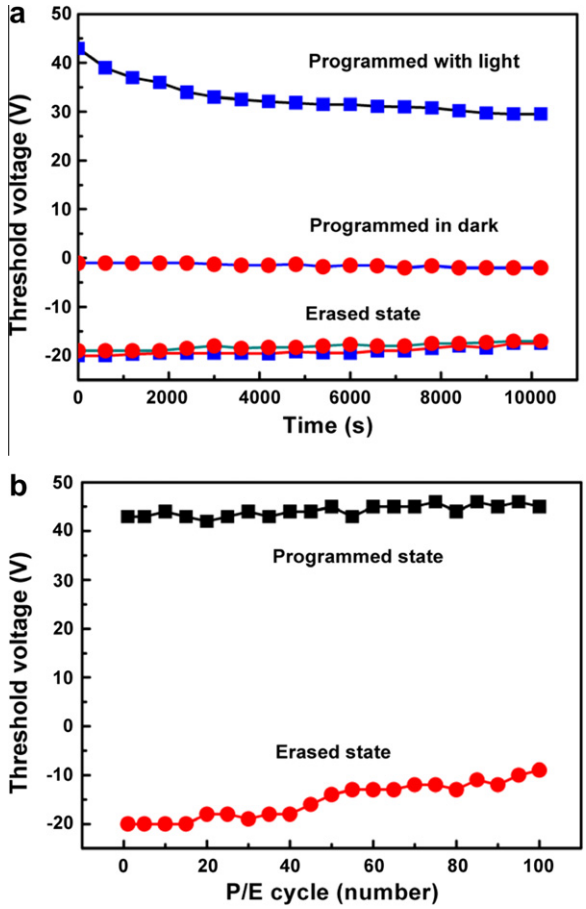

Fig. 4. (a) Data retention characteristics in terms of the threshold voltage for the memory device in the programmed/erased states. (b) Endurance characteristics of the memory device with light assisted program.

−20 V could be obtained when a bias pulse of −80 V applied to gate for 1 ms in dark. It should be indicated that the hysteresis characteristics were similar to that of programmed in dark and V_T were also extracted from forward transfer curves. Therefore, the memory window of 63 V and on/off memory ratio of 10^5 with a reading voltage of V_{DS} = −60 V, V_{GS} = 0 V were obtained. It is noted that the memory window and on/off memory ratio can be significantly increased through light assisted program.

The reliable operations of the memory devices are very important in nonvolatile memory devices. Fig. 4(a) shows the data retention properties that were measured as a function of time using the memory devices in the programmed/erased states at room temperature. The same bias pulses were applied to set the programmed/erased states as shown in Fig. 3. The initial memory windows were approximately 63 V and 18 V for light assisted program and conventional program, respectively. The memory window of the devices under the two kinds of states showed little degradation and memory windows of 47 V and 15 V can be preserved after 10^4 s. The retention time was estimated from the measured data to be more than 10^7 s for the devices with light assisted program. Also, endurance properties were measured by consecutive applications of program/erase bias pulses to the memory devices. After certain endurance cycles the reading operations were done to verify the change of the V_T, as shown in Fig. 4(b). The programmed states have no obvious change of V_T over 100 program/erase cycles. For erased state, there is some fluctuation of V_T and V_T has a slight shift to the positive direction over 100 program/erase cycles. But overall, the V_T did not change much as the number of endurance cycles varied.

The OFETs without Au nanocrystals were also proposed to determine the charging effects of Au nanocrystals in the transistor devices. Comparing with the memory devices, the only difference was the absence of the Au nanocrystals in the gate dielectric layer. All of the devices used in our experiment were fabricated under the same processing conditions. The device exhibited almost no hysteresis in the transfer curves, as shown in Fig. 5(a). We further investigated the charging effect by the application of programming/erasing bias pulses to the gate which were the same as used for memory device operations. There was no obvious V_T shift after application of programming/erasing bias pulses in dark. However, a memory window of 35 V was observed with light assisted program, and

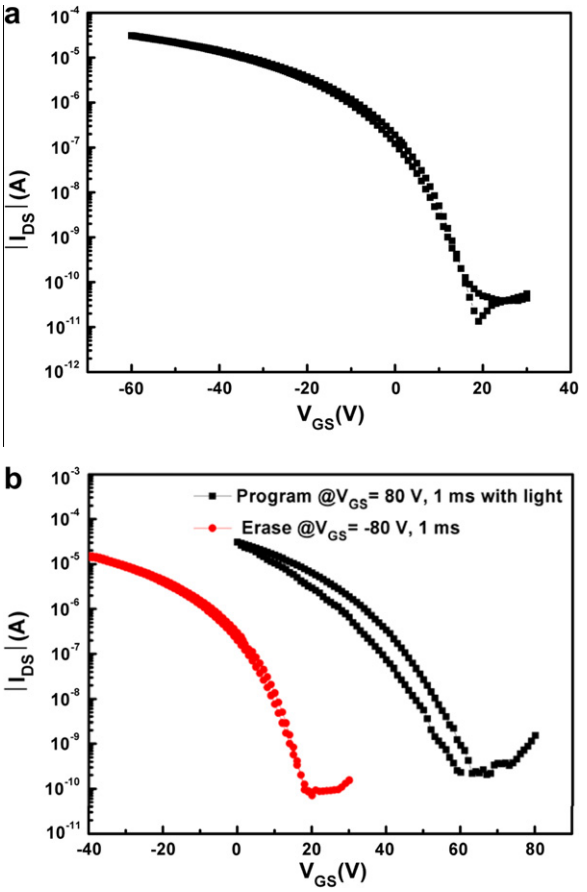

Fig. 5. (a) Bidirectional transfer characteristics of the devices without Au nanocrystals. (b) Bidirectional transfer curves of the devices without Au nanocrystals under V_{GS} = 80 V, 1 ms with light assisted program and V_{GS} = −80 V, 1 ms erase conditions.

a hysteresis window of 9 V for the programmed state was observed (Fig. 5(b)). In addition, the retention time was only 10^3 s for the devices. The results indicated that the memory performances of the device are strongly depending on the existence of Au nanocrystals.

The memory performances of the device with light assisted program are much better than that of with conventional program. To clarify the reason for this improvement, the charge storage mechanism of memory device was studied. Due to the low carrier mobility of the organic semiconductor, Fowler–Nordheim (FN) tunnelling should dominate the transfer mechanism for the organic memory devices [20]. Under dark conditions, holes charging/discharging from the pentacene to the Au nanocrystals and vice versa play a dominant role in the programming/erasing processes because pentacene is a p-type semiconductor. When a large negative voltage is applied to the gate electrode, holes are injected from the channel into the Au nanocrystals through the FN tunnelling process and of being captured in the Au nanocrystals. The trapped holes in Au nanocrystals perturbed and modulated a subsequently applied gate field, resulting in substantial shifts in V_T by the amount of Eq. (1) [6].

$$\Delta V_T = -\frac{Q}{C_i} \tag{1}$$

Where C_i is the dielectric capacitance of total dielectrics and ΔV_T is the memory window. From Eq. (1), we calculated the total number of trapped holes at Au nanocrystals to be 1.1×10^{12} cm^{-2} at a bias pulse of −80 V applied to gate for 1 ms. When a relatively large positive voltage is applied to the gate electrode, the holes stored in the Au nanocrystals are ejected back into the pentacene channel through FN tunnelling. Thus, the programmed state is thought to be an empty state and the erased state is regarded as a state that holes are trapped in the Au nanocrystals. When the OFET is illuminated by light, excitons are photogenerated in the bulk of pentacene film through absorption of photons with higher energy than the band gap energy of pentacene [17]. When a positive gate bias is applied, excitons are separated into electrons and holes, and the separated electrons are injected and stored into the Au nanocrystals. From Eq. (1) we can conclude that the stored electrons in the Au nanocrystals resulting in a positive directional V_T shift. In addition, the calculated total number of trapped electrons in the Au nanocrystals is 2.3×10^{12} cm^{-2} at a program with top light irradiation and gate bias pulses of 80 V for 1 ms. It should be noted when the program process is finished, there is no illumination applied. When a negative gate bias is applied, the electrons stored in the Au nanocrystals will be released back to the pentacene film and recombined with those photogenerated holes in the channel; with the increase of the negative bias, holes are injected into the Au nanocrystals and of being captured in the Au nanocrystals, the same as described above. The number of trapped holes is 1.16×10^{12} cm^{-2}. Thus, the programmed state is regarded as a state that electrons are trapped in the Au nanocrystals with number of 2.3×10^{12} cm^{-2} and the erased state is regarded as a state that holes are trapped in the Au nanocrystals with number of 1.16×10^{12} cm^{-2}. So the memory performances were significantly improved with light assisted program.

4. Conclusions

In summary, OFETs based nonvolatile nano-crystal floating gate memory devices with light assisted program were studied. The memory performances could be significantly enhanced with light assisted program compared with conventional program. The memory window of 63 V and on/off memory ratio of 10^5 were obtained. In addition, the data retention and programming/erasing operation cycles measurements suggested that the memory devices have good reliability. Therefore, this method has a great potential for OFETs nano-crystal floating gate memory devices in the near future.

process the stamp has to be a commodity and it has to be on the centimeter scale. However, stamps are typically fabricated using e-beam lithography which makes these two requirements contradicting.

The goal of this paper is to show that it is possible to use NIL as part of an optimization procedure and specifically to explore the dependency between features depth/height and the power conversion efficiency of imprinted bi-layer organic solar cells. To this end, we first report a robust and parallel method to produce master stamps with nanometer resolution and centimeter scale area which is based on solution casting of block co-polymers. This is then followed by a report of systematic enhancement of the power conversion efficiency of double layer organic solar cells demonstrating that a twofold enhancement can already be reached using relatively low resolution (~80 nm) patterns and not very deep (~35 nm) features.

2. Results and discussion

2.1. Stamp fabrication and nanoimprinting

The fabrication process allowing the production of multiple centimeter scale master stamps in parallel (see also Supplementary Information) is shown schematically in Fig. 1.

Master stamps were prepared on at least ~1 cm × 1 cm highly hydrophilic silicon samples onto which a solution of the diblock copolymer poly(styrene-*block*-methyl methacrylate) (PS-*b*-PMMA) was spin coated resulting in ~90 nm thick film.

Spin coated samples were transferred to a solvent annealing chamber [21] where they were exposed to chloroform vapor under controlled conditions. We have found that controlling the solvent annealing conditions, such as temperature and vapor pressure, is crucial to obtain uniform patterns over the entire sample with negligible number of defects resulting from incipient dewetting. The resulting BCP film (Fig. 2A) exhibits 80–100 nm wide phase separated domains in a "worm" like morphology over the entire sample. Replicating the pattern into the silicon substrate begins with exposing the films to 254 nm light, exploiting the different response of the two blocks to UV light exposure: [22,23] the PMMA degrades while the PS is cross-linked and becomes insoluble. The relatively thick film used dictated morphology of PS cylinders lying parallel to the surface with a thin PMMA layer separating them from the substrate (see inset in Fig. 2A). In this case, rinsing out the PMMA would result in deformation of the PS and to defects which are noticeable on cm scale samples. To ensure defect free master stamps, we did not remove the PMMA but relied on differences in the resistance to etching between the degraded PMMA blocks and the cross-linked PS blocks. This naturally had a penalty in the maximum achievable feature depth which could be ~50% deeper. Alternatively, one could use the morphology of vertically oriented PS cylinders and remove the PMMA without inducing defects [24]. However, such morphology is achieved only for thinner films thus making no difference

in the final features depth. Etching of the silicon was carried out using SF_6 as the etchant gas. By optimizing the etching time it was possible to transfer the pattern into the silicon with aspect ratio (height:width) of 1.2:1 (Fig. 2B). Master stamps were completed with the deposition of a self assembled monolayer that serves as an anti-stiction layer. In all the above steps we would typically produce in parallel about 10 stamps.

Although the fabricated master stamps can be used directly in a NIL process we chose to use elastomeric stamps as their flexibility permits their use even on non planar surfaces. Following a process adopted from Ref. [16], elastomeric stamps based on polydimethylsiloxane (PDMS) were molded from the master stamps. As can be seen in Fig. 2C, pattern resolution was maintained but feature height decreased by roughly 30%.

The NIL process was carried out in a home-built nanoimprinting setup. Imprinting was done using an elastomeric stamp and the feature height could be adjusted by controlling the imprinting pressure. Fig. 2D shows an AFM image of imprinted P3HT film. The depth of the features shown was 35–40 nm in an initially 80 nm thick film.

2.2. Device fabrication

The availability of multiple stamps through the above process enabled us to integrate the imprinting procedure with the fabrication and optimization of organic solar cells (see Supplementary Information). We found that in order to achieve reliable and reproducible imprinted features the stamp has to be of a relatively large size and that the nano-scale features should extend over the entire area. As this was enabled by the procedure described above we could test the effect due to enhancement of junction area by fabricating organic solar cells with controlled interpenetrating heterojunction and comparing these devices to simple bi-layer devices. For this comparison we chose the layers thicknesses through optimization of the efficiency measured for the non-imprinted bi-layer structure. We used P3HT as the donor and PCBM as the acceptor, a materials combination that was found to produce relatively high efficiency solar cells in both bi-layer [8] and BHJ [25] structures. Devices were fabricated with the following layered structure: patterned indium-doped tin oxide (ITO)/45 nm of poly(ethylenedioxythiophene):poly(styrenesulfonic acid) (PEDOT:PSS)/80 nm P3HT/60 nm PCBM/0.6 nm LiF/Aluminum. NIL was performed on some of the devices, prior to PCBM deposition, using PDMS elastomeric stamps prepared by the process described above. As stamps were much larger than the defined pixels area (2.7 mm^2) we could emboss all pixels simultaneously and avoid the need for any alignment. By varying the applied pressure we have fabricated imprinted devices with average features height of ~10, ~20, and ~35 nm. In order to avoid damage to

the patterned P3HT during PCBM deposition we have used dichloromethane (DCM) as the PCBM solvent. We have verified that DCM does not affect the P3HT layer or the pattern created in it using AFM and absorption measurements. The AFM features of an imprinted P3HT film before PCBM casting are as described in Fig. 2D. The films after PCBM removal were essentially similar but careful examination revealed that in small fraction of the sample there was a slight (~10%) decrease in features height. Absorption measurements (Fig. 3A) support this conclusion as almost no change is observed between the samples.

Recently it was shown that PCBM can substantially interdiffuse into P3HT even when the two materials are deposited from orthogonal solvents or even stamp transferred [26–28]. However, critical reading of the papers indicates that PCBM interdiffusion into P3HT requires that either the P3HT is not fully dry and/or that post heating is applied. Namely, interdiffusion of PCBM into P3HT is dependent on the processing conditions. In the current study we made sure the P3HT films are fully dry (110 °C for 3 h in a vacuum oven) before depositing PCBM and we did not apply any post-heating (post annealing). While we do not provide depth-profiling to indicate that PCBM did not penetrate into the films we do report that by simply spin coating pure DCM on the P3HT/PCBM stack the PCBM was removed to the point it had none to negligible effect on the photoluminescence (PL) efficiency Fig. 3B shows PL measurements confirming that almost no change is observable between samples before PCBM deposition and after it was removed. As the PL of P3HT is highly sensitive to minute amounts of the PCBM quencher and since a spin coating procedure would not suck the PCBM out from the bulk of the film, we are led to conclude that PCBM never penetrated the bulk of the P3HT film.

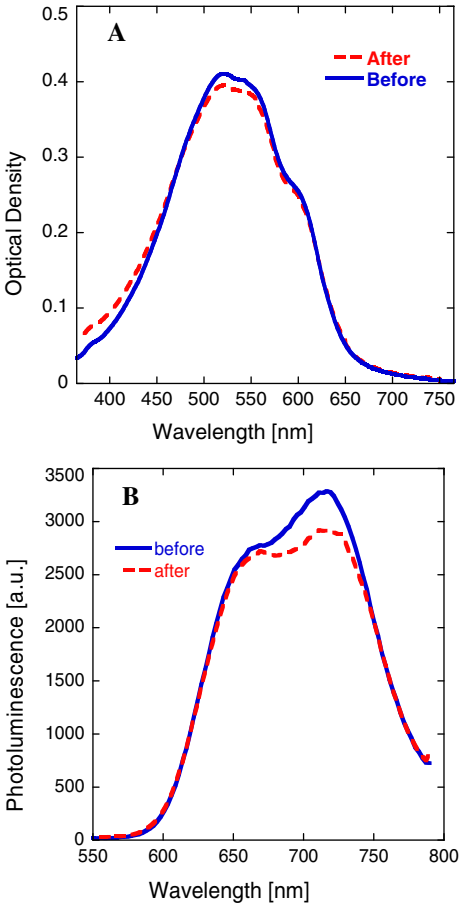

Fig. 3. The absorption (A) and photoluminescence (B) spectra of imprinted P3HT film before PCBM deposition (full line) and after PCBM removal (dashed line).

2.3. Device characterization

The photovoltaic response of our devices was examined by measuring their external quantum efficiency (EQE) as a function of incident photon wavelength and by measuring their current versus voltage (*I–V*) response under a 100 mW/cm^2, A.M 1.5 G illumination. All measurements were performed under nitrogen atmosphere. The EQE spectra of our devices, i.e. the ratio between the number of carriers collected and the number of photons arriving to the device at a given wavelength, is presented in Fig. 4. The EQE of the devices is clearly increased with imprinted feature height up to about 40–53% in the device with ~35 nm features height compared to the bi-layer, not imprinted, device. In the imprinted devices we expect to have an increased interface area due to the sidewalls of the imprinted features. Using image processing of the AFM images we were able to estimate the surface area in the imprinted devices. For the 35 nm deep imprint, the surface area is 1.75 times larger than that in the flat, non-imprinted device. But, accounting for up to 10 nm exciton diffusion length will reduce the ratio between the junction volumes to a factor of 1.55. Hence, while it may seem that the imprinted devices do not exploit the full potential-offered (55%) by the increased interface area/junction volume, the value is almost within experimental error

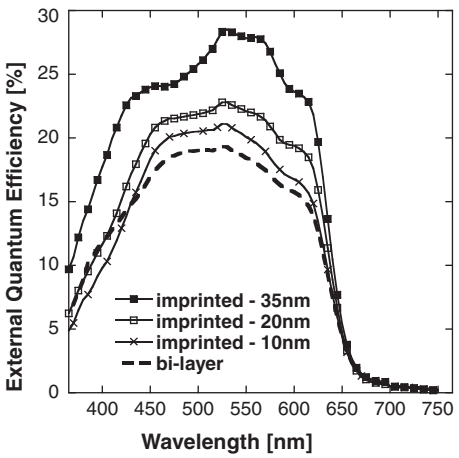

Fig. 4. External quantum efficiency (EQE) spectra of the fabricated devices. The bi-layer device is the non-imprinted control device (dashed line) and imprinted devices are with features height of approximately 10, 20, and 35 nm.

Table 1
Summary of average values obtained for the different type of devices. At least 3 separate devices from each type were measured and the values in brackets indicate the standard deviation between the different independent measurements. The bi-layer device is the non-imprinted control device and imprinted devices are with approximately 10, 20, and 35 nm features height. J_{sc} is the short circuit current, V_{oc} the open circuit voltage, FF the fill factor, r_s the serial resistance, EQE the external quantum efficiency (measured at 525 nm wavelength), and PCE is the power conversion efficiency under 100 mW/cm^2, A.M 1.5 G illumination.

Average values obtained for the different types of devices						
Device type	J_{sc} (mA/cm^2)	V_{oc} (V)	FF (%)	r_s (Ω)	EQE (%)	PCE (%)
Bi-layer (not imprinted)	−3.28 (±0.27)	0.51 (±0.01)	42 (±2)	55.3 (±6.3)	20 (±1)	0.69 (±0.05)
Imprinted (10 nm)	−2.47 (±0.72)	0.52 (±0.02)	44 (±2)	59.5 (±21.3)	18 (±2)	0.57 (±0.21)
Imprinted (20 nm)	−3.86 (±0.17)	0.55 (±0.01)	50 (±2)	29.2 (±3.0)	23 (±1)	1.07 (±0.06)
Imprinted (35 nm)	−4.58 (±0.10)	0.54 (±0.01)	57 (±2)	17.5 (±1.2)	28 (±1)	1.41 (±0.03)

mentioned above of 40–53% (see also Table 1). We note that accounting for the 10 nm diffusion length is also consistent with the observation that the differences between the 10 nm deep features device and the non embossed device are within experimental error (see also Table 1). It is also interesting to note that the above dependence of the EQE on the embossing depth provides another indirect evidence that the PCBM diffusion into P3HT is negligible under the processing conditions used here (i.e. fully dry P3HT film and no post heating). The argument regarding the junction area made using the exciton diffusion could be interchanged with PCBM diffusion into the P3HT film and hence indicates that PCBM did not diffuse more than 10 nm into the P3HT.

Typical *I–V* curves of the different devices measured under illumination are presented in Fig. 5. The statistical averages and standard deviations of the different figures of merit extracted from the measurements of all devices are presented in Table 1.

Two pronounced differences between imprinted and non-imprinted devices can be observed. First, with the exception of the shallowest imprinted device (imprinted – 10 nm), there is an increase in the short-circuit current (J_{sc}) with increased features height. The magnitude of this increase corresponds to the observed increase in the EQE measured at low (μW/cm^2) intensities, indicating that this

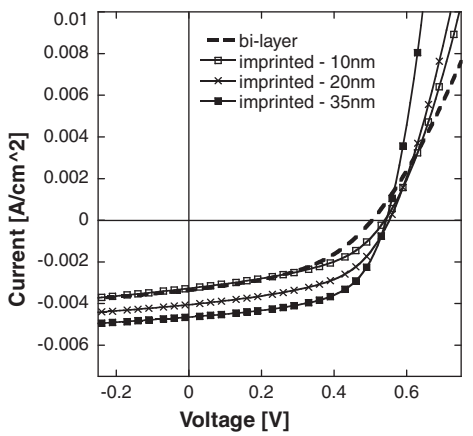

Fig. 5. Current–voltage (*I–V*) characteristics of the fabricated devices under 100 mW/cm^2, A.M 1.5 G illumination. The bi-layer device is the non-imprinted control device (dashed line) and imprinted devices are with features height of approximately 10, 20, and 35 nm.

is due to the larger junction volume. Secondly, the imprinted devices exhibit reduced serial resistance (r_s) combined with an improved open circuit voltage (V_{oc}). The origin of this second effect could be due to shorter minimal film thickness associated with the embossed features. An alternative explanation could be related to the potential contribution from pressure induced changes as was suggested by Shih et al. [29], yet, the fact that the 10 nm imprinted device do not exhibit improvement suggest that pressure does not play a significant role here.

The increased J_{sc} and FF in the imprinted devices manifested in improved power conversion efficiency (PCE) of those devices (Table 1). The device exhibiting the deepest features (imprinted – 35 nm), displays on average more than a twofold improvement in PCE compared to the simple bi-layer device.

3. Conclusion

We have demonstrated that it is possible to use nanoimprinting to systematically enhance the charge generation and extraction efficiency in bi-layer solar cells. This optimization was enabled by the development of large area and low cost process which is based on solution processed block copolymer. An added value of using block copolymer lithography is that it should be possible to scale down the lateral feature size even below 30 nm and approach the resolution dictated by excitons diffusion lengths. The linear relation found between the enhancement in charge generation efficiency (EQE) and the junction area together with the relatively low resolution of the current stamp, suggest that the efficiency enhancement could be made even higher.

In the present study, counter electrode containing NCS groups were prepared, and connected with the NCS groups of the dye molecules by CuI. A highly efficient all solid state DSSC have been prepared by the specific interaction of CuI with the NCS groups of the dye molecules and those of the counter electrode. The specific interaction of CuI with NCS groups could facilitate the hole injection from the CuI into the NCS groups of the counter electrode. The PEG containing NCS groups/FTO heterojunction device was modified by inserting a PEDOT interlayer. PEDOT interlayer has been widely used to modify the electronic devices [31,32]. The resulting all solid state DSSC were stable (the decrease of the conversion efficiency were lower than 5% for 1000 h) and exhibited remarkably high conversion efficiency (4.2%). The solid state DSSC are manufactured with inexpensive and low quality materials. A lot of DSSC have been prepared for the past 20 years, however, most of them were not so stable, and the conversion efficiencies were relatively low. This is the first DSSC which can be applied for practical use.

2. Experimental

2.1. Preparation of the samples of XPS

The CuI film was prepared by coating the CuI–acetonitrile solution(0.15 M) onto nanostructured TiO_2 covered on the FTO (AGC type U TCO glass). The CuI film was soaked in 0.05 mM ethanol solution of Ru(dcbpyH$_2$)$_2$(NCS)$_2$ (N3 dye, kojima chemicals co.) for 10 min, followed by rinsing in ethanol. FTO covered with a TiO_2 was soaked for 30 min in 0.5 mM ethanol solution of N3 dye. The CuI film was soaked in the ethanol solution containing 0.5 mM lithium thiocyanate and equivalent amount of poly(ethylene glycol) (PEG20000) for 10 min, followed by rinses in ethanol. The ethanol solution of 0.5 M lithium thiocyanate and PEG20000 (1:1) was coated on the substrate layers of TiO_2 on FTO conducting glass.

2.2. Fabrication of DSSC

A compact TiO_2 layer was deposited onto FTO by spray pyrolysis. The TiO_2 paste was prepared [33] and coated onto the FTO using squeeze printing technique (film area = 0.5 cm^2), and then the electrode was heated at 450 °C for 30 min in air. The post-treatment with $TiCl_4$ aqueous solution was applied to the prepared films by soaking in 0.2 M aqueous $TiCl_4$ at 70 °C for 30 min, followed by a water rinse and fired at 450 °C for 30 min. The thickness of porous TiO_2 film was about 7 μm. The porous TiO_2 film was immersed into 0.5 mM ethanol solution of N3 dye for 12 h at room temperature. The coating of CuI onto dyed electrodes was performed in N_2-atmosphere in a glove box. The CuI–acetonitrile solution(0.15 M) was lightly coated over the dyed electrode. After coating, the electrode was heated to 80 °C to evaporate the solvent. This process was repeated several times. The amount of CuI solution is about 0.06 mL cm^{-2}. The counter electrode was prepared by coating the solution of PEG containing NCS groups onto the FTO modified by PEDOT. The PEDOT modified FTO was prepared by spin coating of PEDOT:PSS aqueous dispersion (Clevios PH) on FTO and dried at 100 °C for 30 min in vacuum. The PEG containing NCS groups was prepared by dissolving PEG20000 and lithium thiocyanate (or guanidium thiocyante) (1:1) in acetonitrile and heated to 80 °C to evaporate the solvent. The CuI/dye/TiO_2 glass plate was fixed together with the counter electrode. The resulting cells had an active area of 0.25 cm^2.

2.3. Characterization

X-ray photoelectron spectroscopy (XPS) measurement was performed using SSX-100 instrument using a monochromatized Al Kα X-rays at hν = 1487 eV. IR spectra of the samples were measured with the spectrometer Perkin Elmer BX-FT-IR for disks diluted with KBr. The photoelectrochemical properties of the DSSC were studied by recording the current–voltage (*I–V*) characteristics under illumination of AM 1.5 (1 Sun; 100 mW cm^{-2}) by using a solar simulator (Yamashita Denso). Stability tests on DSSC were conducted with Xe lamp at an intensity of 40 mW cm^{-2} at room temperature. The electrochemical impedance spectroscopy (EIS) of the DSSC was measured with an impedance analyzer (Solartron Analytical, 1260) connected with a potentiostat (Solartron Analytical, 1287) under illumination of AM1.5 by using a solar simulator. The EIS was recorded over frequency range of 0.1–10^6 Hz. The AC amplitude and the applied voltage were 10 mV and set at Voc of the cells, respectively.

3. Results and discussion

3.1. The specific interaction between the NCS groups of dye molecules with CuI

Possible interaction between the NCS groups of the dye molecules and the CuI was investigated by the N 1s and S 2p core level spectra. The N 1s core level spectra for the dye-sensitized CuI surface and for nonbonded dye molecules are shown in Fig. 1a. In the spectrum of the nonbonded dye molecules two clearly resolved peaks were observed representing the bipyridine nitrogen (the peak at higher binding energy) and the NCS nitrogen (the peak at lower binding energy). The structure of N 1s spectrum measured for the dye-sensitized CuI surface is similar expect for a clear shift of the peak originating from NCS. This peak shift about +0.6 eV, showing a strong interaction between the NCS groups with the surface. This presumption is further supported by the S 2p spectra in Fig. 1b. A shift of +0.9 eV is obtained for the position of the S 2p signal for the nonbonded dye molecules compared with that obtained from the dye-sensitized CuI.

3.2. Preparation of the counter electrode containing NCS groups

A mixture of lithium thiocyanate and PEG were dissolved in acetonitrile. The solution was coated on FTO glass modified by PEDOT. The IR spectra of PEG containing NCS groups were shown in Fig. 2.

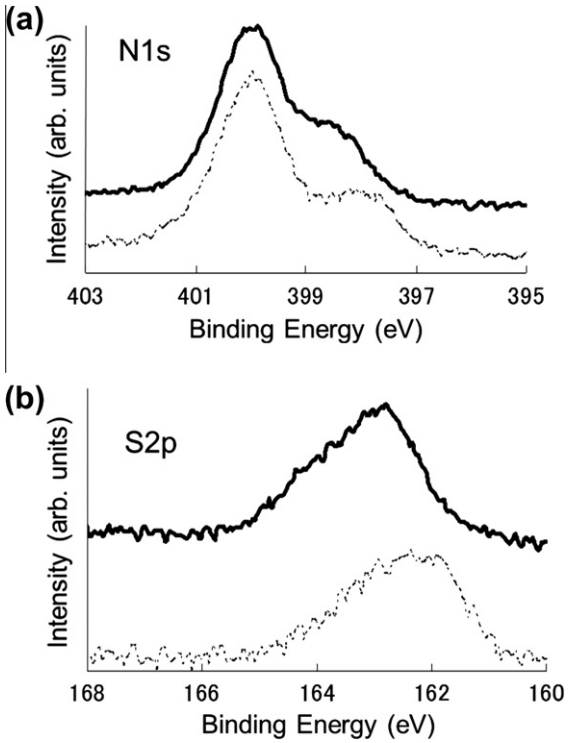

Fig. 1. (a) N 1s core level spectra of nonbonded dye molecules (dotted curve) and dye-sensitized CuI surface (solid curve). (b) S 2p core level spectra of nonbonded dye molecules (dotted curve) and dye-sensitized CuI surface (solid curve).

3.3. The interaction between the NCS groups of the counter electrode with CuI

The interaction of the NCS groups of the counter electrode with CuI was investigated by the N 1s core level spectrum, which is shown in Fig. 3a. The peak shift about +0.8 eV, showing a strong interaction with the CuI surface. This conclusion is also supported by the S 2p spectrum, a shift of +1.0 eV, as shown in Fig. 3b.

3.4. Fabrication of all solid state DSSC

A highly efficient all solid state DSSC were fabricated by the specific interaction of CuI with the NCS groups of the dye molecules and that of the counter electrode. The counter electrodes of DSSC A, DSSC B and DSSC C were prepared by coating the solution of PEG + guanidium thiocyanate, PEG + lithium thiocyanate and PEG on FTO glass modified by PEDOT, respectively. Fig. 4 shows the photocurrent–voltage characteristics of the series of all solid state DSSC.

DSSC A and DSSC B were fabricated by connecting the NCS groups of the dye molecules and that of the counter electrode by CuI. The DSSC A and DSSC B exhibited much higher performance compared with DSSC C. DSSC C is the conventional solid state DSSC.

The interaction was investigated by impedance spectroscopy. Fig. 5 shows the impedance spectra of the specific

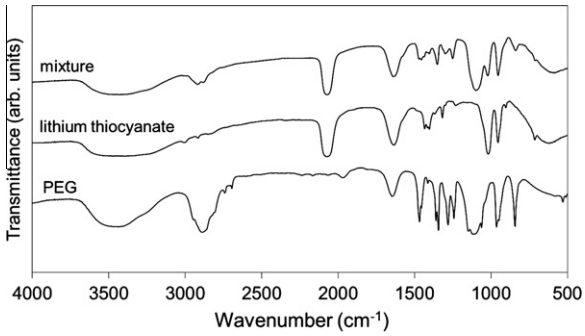

Fig. 2. IR spectra of PEG containing NCS groups.

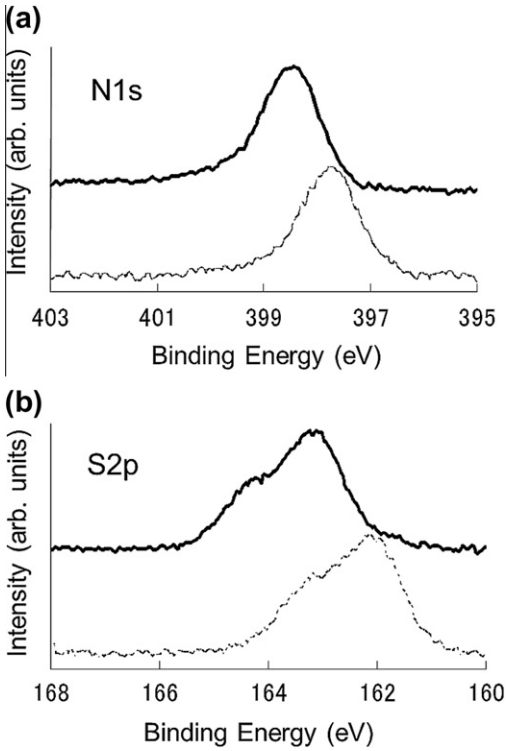

Fig. 3. (a) N 1s core level spectra of nonbonded PEG containing NCS groups (dotted curve) and PEG containing NCS groups coated CuI surface(solid curve). (b) S 2p core level spectra of nonbonded PEG containing NCS groups (dotted curve) and PEG containing NCS groups coated CuI surface (solid curve).

interaction of CuI with PEG and the PEG containing NCS groups. The interaction of CuI with PEG containing NCS groups gave small impedance, compared with the PEG not containing NCS groups. This is attributed to the specific interaction of CuI with NCS groups.

3.5. The impedance of the all solid state DSSC

Fig. 5 shows the electrochemical impedance spectra recorded over frequency range of 0.1–10^6 Hz of DSSC B and DSSC C (without NCS groups) under open circuit condi-

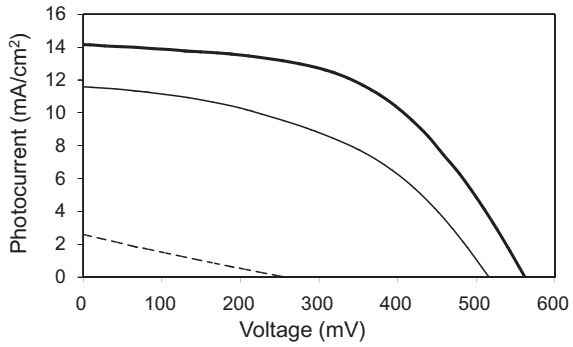

Fig. 4. Photocurrent–voltage curves of all solid state DSSC fabricated from different counter electrodes: PEG + guanidium thiocyanate (bold curve), PEG + lithium thiocyanate (solid curve), PEG (dash curve).

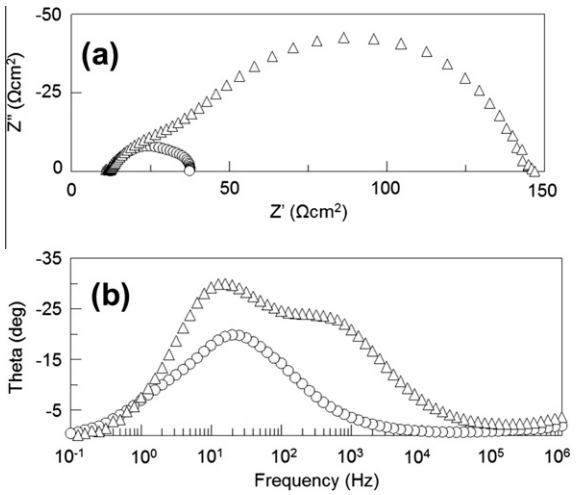

Fig. 5. Nyquist (a) and Bode (b) diagrams of impedance spectra obtained under illumination for the cell with the PEG containing NCS groups (DSSC B:○) and the cell with PEG without NCS group (DSSC C:△).

tions. The equivalent circuits of these DSSC which contain at least three RC parallel circuits can be proposed in the above frequency region as shown in Fig. 6. Based on previous studies [12,13,34–36], we assumed that R_1C_1, R_2C_2 and R_3C_3 correspond to a charge-transfer resistance and an electrochemical capacitance formed by TiO_2 dye/CuI, CuI/polymer and polymer/substrate interface, respectively. R_0 indicates the sheet resistance of DSSC [34–36]. Constant Phase Elements (CPE), with an electrical impedance written as $Z_{CPE} = 1/T(j\omega)^{\alpha}$, were used instead of pure capacitances for a better fit. Those values of R, C and α were obtained by fitting with Z-view software are shown in Table 1.

The counter electrode of DSSC B was prepared by coating the solution of PEG containing NCS groups on FTO glass modified by PEDOT, and that of DSSC C was prepared by coating the solution of PEG without the NCS group on the modified FTO glass. R_1 is attributed to the resistance of TiO_2 dye/CuI interface. DSSC B and C exhibited nearly same R_1 value. Concerning R_2, DSSC B exhibited much smaller value than DSSC C. That can be explained by the strong interaction between the NCS group of the polymer and CuI, which facilitate the hole injection from CuI into NCS groups of counter electrode.

3.6. Enhancement of photovoltaic characteristics using a PEDOT interlayer

PEDOT has been widely used to modify the anodes of electronic devices, including those of organic light emitting diodes [32] and thin-film transistors [37]. In the present study, the basic structure of FTO and the PEG containing NCS groups was modified by inserting a PEDOT interlayer between the FTO and the PEG containing NCS groups. The counter electrode of DSSC D was prepared by coating the solution of PEG containing NCS groups on FTO glass. Fig. 7 shows the electrochemical impedance spectra of DSSC B and DSSC D under open circuit conditions. DSSC B containing the interlayer exhibited much smaller value of R_3 compared with that of DSSC D.

The insertion of PEDOT interlayer between the FTO and PEG containing NCS groups enhanced photovoltaic properties.

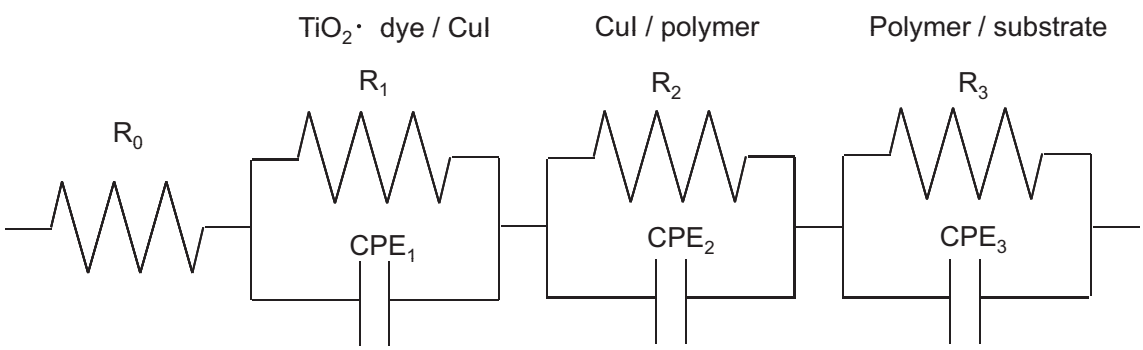

Fig. 6. Equivalent circuit of all solid state DSSC.

Table 1
Parameters obtained by fitting the impedance spectra of DSSC containing different counter electrode, using the equivalent circuit (Fig. 6).

	R_0 (Ω cm^2)	R_1(Ω cm^2)	C_1(F cm^{-2})	α	R_2(Ω cm^2)	C_2(F cm^{-2})	α	R_3(Ω cm^2)	C_3(F cm^{-2})	α
DSSC B	12.4	6.8	12.4×10^{-3}	1	9.3	2.0×10^{-3}	0.74	9.4	16.2×10^{-4}	0.98

DSSC D (without PEDOT)	12.2	7.1	14.4×10^{-3}	1	9.7	2.6×10^{-3}	0.71	106.9	2.8×10^{-5}	0.93

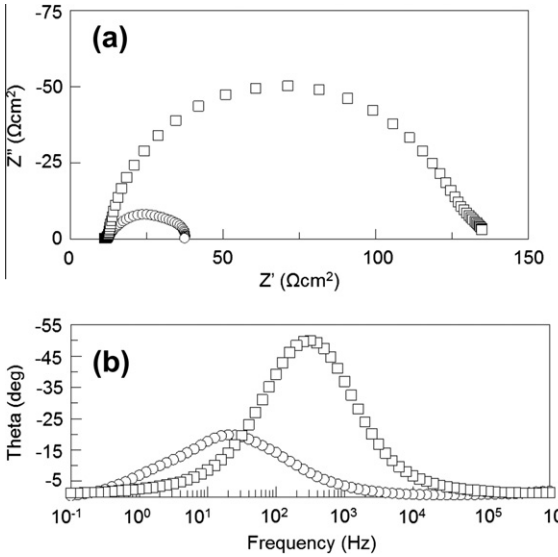

Fig. 7. Nyquist (a) and Bode (b) diagrams of impedance spectra obtained under illumination for cells with PEDOT interlayer (DSSC B: ○) and cell without PEDOT inter layer (DSSC D: □).

3.7. The properties of the all solid state DSSC

DSSC A and DSSC B were fabricated utilizing the specific interaction of CuI with the NCS groups of counter electrode modified by the insertion of PEDOT layer, while no NCS groups was contained in the counter electrode of DSSC C. The properties of the DSSC were summarized in Table 2. Fig. 8 shows the normalized efficiency of DSSC containing different counter electrode. DSSC A and DSSC B were stable and exhibited high efficiency but DSSC C was unstable and the performance was lost in short time. The DSSC A and DSSC B were stable in longer time, and the decrease of the conversion efficiency of DSSC A was smaller than 5% for 1000 h under filtering UV region quasi-sunlight (λ < 435 nm).

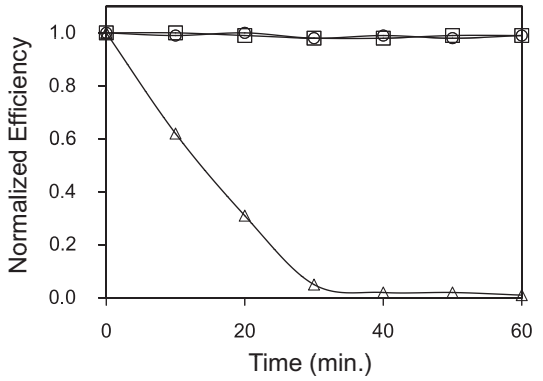

Fig. 8. Changes of the normalized energy conversion efficiency of DSSC A(□), DSSC B(○) and DSSC C(△) under one-sun condition(100 mW cm^{-2}), with the lapse of time after fabrication.

4. Conclusion

A highly efficient all solid state dye-sensitized solar cells (DSSC) have been prepared by the specific interaction of CuI with the NCS groups of the dye molecules and the NCS groups of the counter electrode. The resulting all solid state DSSC were stable, and exhibited high conversion efficiency.

The specific interaction of the CuI with the NCS groups of the working electrode and the counter electrode was investigated by X-ray photoelectron spectroscopy. The structure of the N 1s spectrum measured for the dye-sensitized CuI surface is similar except for a clear sift of the originating from NCS group. The peak shifts about +0.6 eV, showing a strong interaction between the NCS groups with the surface CuI.

In the present study, the counter electrodes containing NCS groups were prepared, and the NCS groups were connected with the NCS groups of the dye molecule by CuI. The specific interaction of CuI with the NCS groups of both electrodes could lower the impedances of the interfaces and facilitate the flow of the hole into the electrodes, which resulted in the high efficiency of the resulting DSSC. The performance was improved by introducing PEDOT

Table 2
Comparison of the performance parameters of the solid state DSSC.

	Jsc (mA cm^{-2})	Voc (mv)	FF	η (%)
DSSC A (guanidium thiocyanate)	14.2	562.0	0.52	4.19
DSSC B (lithium thiocyanate)	11.6	516.1	0.45	2.72
DSSC C (without NCS)	2.59	256.6	0.24	0.15

layer between the FTO and the PEG containing NCS groups. These improvements are due to the reduction of the junction resistance across the interface in the presence of PEDOT interlayer. The resulting all solid state DSSC were stable (the decrease of the conversion efficiency were lower than 5% for 1000 h) and exhibited high conversion efficiency (4.2%). The solid state DSSC could be manufactured with inexpensive and low quality materials, and the practical use is promising.

operation include cross-linked polymers [16], self-assembled monolayers [17,18] and the use of electrolytes [19,20]. The latter can achieve very low voltage ranges due to the very high electric field generated at the interface between the electrolyte and the organic semiconductor. Mobile ions inside the electrolyte move to form an electric double layer (EDL) at the interface, with a capacitance that can reach several hundreds of $\mu F/cm^2$ [19,21,22]. These devices typically operate below 1 V. Furthermore, increasing the capacitance leads to an increase of the charge carrier mobility for polymer semiconductors and the subsequent increase in the output current [23].

In a previous work [24], we successfully used pure water to isolate the gate from the semiconductor. We managed to show that within the water stability potential range, our devices run in the field-effect mode with negligible electrochemical reactions, which is usually the main issue for electrolyte-gated OFETs [25].

Here, we investigate the use of semiconductor/insulator blends as active layer in water-gated OFETs in order to improve the performance of the device.

2. Experimental

2.1. Materials

Poly(3-hexylthiophene) (P3HT) (MW = 37,000 g mol^{-1}, 98% regioregular) and poly(methyl methacrylate) (PMMA MW = 120,000 g mol^{-1}) were purchased to Sigma–Aldrich and used without further purification. Chlorobenzene was purified by distillation.

Solutions of P3HT/PMMA (1 wt.%) blends with different ratios were prepared as followed. First PMMA was dissolved in chlorobenzene by stirring overnight. Then P3HT was added to the PMMA solution and stirred until the P3HT is totally dissolved. Finally, solutions were filtered with a 200 nm polytetrafluoroethylene (PTFE) filter.

2.2. OFETs preparation

A general view of the device is sketched in Fig. 1 together with the chemical structure of P3HT and PMMA. The transistors were built in a bottom contacts and top gate configuration. The substrate consisted of a silicon wafer with 300 nm thermally grown oxide. Contacts were made of evaporated gold patterned by conventional micro-lithography. P3HT/PMMA solutions were spin-coated onto the substrates at 1500 rpm for 30 s in ambient conditions. The devices were then kept overnight in an oven at 110 °C under a pressure of 50 mbar to remove the residual solvent.

A water droplet was generated with a calibrated microsyringe and deposited onto the semiconductor. The water used was obtained from a Elgastat UHQ II purification system with a resistivity of 18 MΩ cm. In ambient conditions, the main contaminant of water is dissolved carbon dioxide, which forms carbonic acid that dissociates in turn into hydrogenocarbonate and hydronium ions with a concentration of about 10^{-6} mol/L. The concentrations of other species in solution are negligible. The gate electrode consisted of a platinum wire dipped into the droplet.

2.3. Electrical characterization and thin-films morphological study

Electrical measurements were realized using a semiconductor parameter analyzer (Keithley 4200-SCS) in a humid environment to prevent the water droplet from drying. Before measuring each blend, the platinum wire was cleaned in an ultrasonic bath for 10 min in deionized water and 10 min in acetone then put in a UV surface decontamination system (Novascan PSD-UV) for 15 min to get rid of any trace of organic contamination.

Three different channel lengths (3, 10 and 40 μm) were used and for each length, six transistors were tested. The reported data correspond to the mean of these six measurements.

Atomic force microscopy was realized on a multimode SPM with Nanoscope III controller (Digital Instruments) in tapping mode on thin-films deposited on silicon wafers with thermally grown oxide (300 nm).

3. Results and discussion

Fig. 2 shows AFM 10 × 10 μm^2 topographic images of the P3HT/PMMA films with various weight ratios. Blends with PMMA concentrations up to 30% (Fig. 2a and b) do not show any clear phase separation at this scale. However,

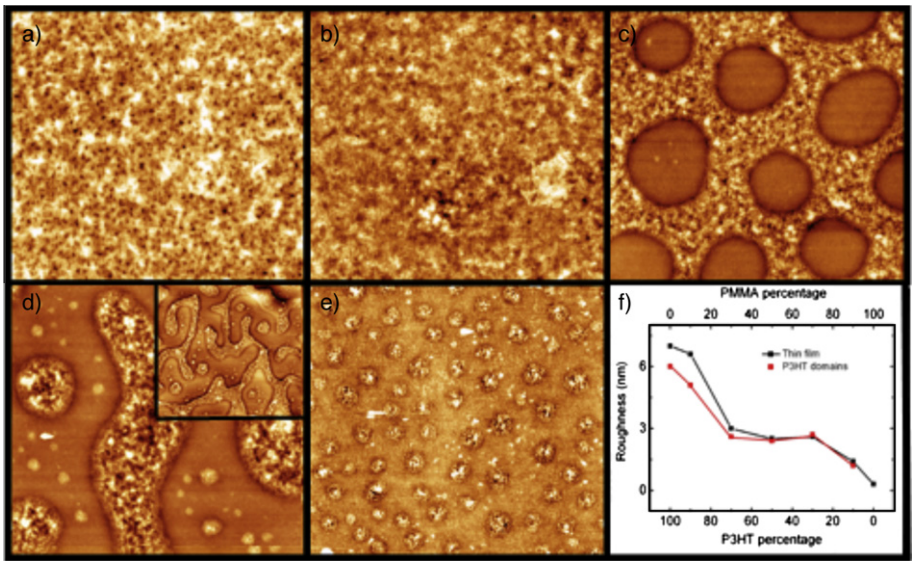

Fig. 2. AFM topographic images ($10 \times 10\ \mu m^2$) of (a) 100%, (b) 70%, (c) 50%, (d) 30% (the inset shows the topography of a $30 \times 30\ \mu m^2$ image) and (e) 10% of P3HT/PMMA blend thin films. (f) RMS roughness as a function of P3HT percentage. The RMS was estimated over the whole image or over the P3HT domains only.

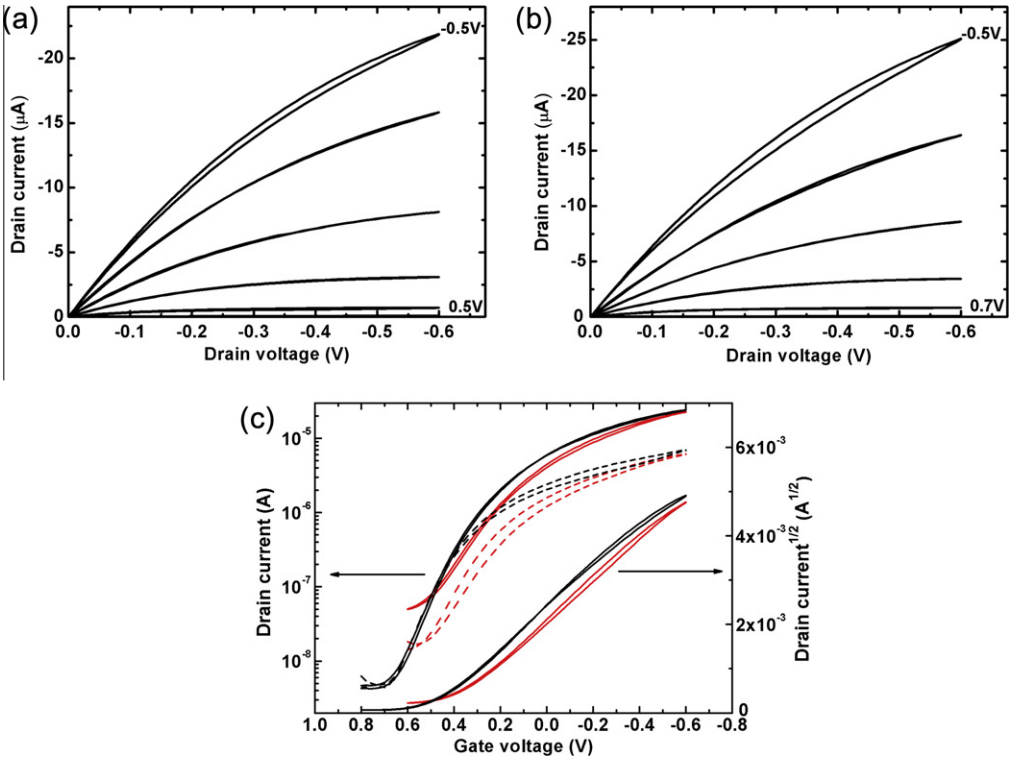

Fig. 3. Output curves of OFETs with (a) pure P3HT and (b) P3HT:PMMA 3:7 blend. (c) Transfer curves of homo-P3HT (red line) and P3HT:PMMA 3:7 blend (black line) plotted in a semi-log scale (left scale) for $V_d = -0.1$ V (dashed line) and $V_d = -0.5$ V (full line) and in a square root scale (right scale) for $V_d = -0.5$ V. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

an abrupt decrease of the RMS roughness (Fig. 2f) occurs, indicating an enhancement of the homogeneity due to the increase of PMMA content (RMS roughness of pure PMMA was found to be below 0.5 nm). For a ratio of P3HT/PMMA of 1:1 (Fig. 2c), lateral phase separation clearly occurs as indicated by the dark nanospheres of PMMA into a matrix of P3HT. With 70% of PMMA (Fig. 2d), the two phases tend to form two continuous net-

works that extend all over the film, as indicated by the $30 \times 30\ \mu m^2$ image given in the inset. Increasing the PMMA weight ratio to 90% (Fig. 2e) results in isolated nanospheres of P3HT. Furthermore, above this amount of PMMA, the roughness decreases to reach a plateau that extends up to 70% of PMMA, resulting in a smoother film. A further decrease of the roughness occurs for PMMA concentrations above 70%. This trend is also observed when measuring the roughness of the domains composed of P3HT only. We note that a similar behavior has been recently reported on P3HT/PMMA blends [26].

All OFETs made of polymer blends show a typical p-channel behavior. Output characteristics of pure-P3HT and blend with 70% of PMMA are presented in Fig. 3.

The field-effect mobility of holes was extracted from the transfer characteristics in the saturation regime (Fig. 3c). The mobility is estimated from the slope of the $I_d^{1/2}$ vs. V_g curve and the capacitance used is that measured in a previous work [24]; data for various blend ratios are gathered in Fig. 4a. Three different channel lengths have been used. Increasing the channel length from 3 to 40 μm improves the effective mobility by almost one order of magnitude. This phenomenon is well documented and is a consequence of contact resistance [27,28]. For small channels, the contact resistance considerably reduces the effective mobility. This lowering is less pronounced as the channel length increases.

For pure-P3HT spin-coated from a chlorobenzene solution, the highest mobility with a 3 μm channel length is 0.03 $cm^2/V\,s$, which is higher than what reported in our previous work where the film was deposited from a chloroform solution [24]. We attribute this increase to the highest boiling point of chlorobenzene. Chloroform is widely used as solvent for P3HT. However, due to its low boiling point (62 °C) and fast evaporation rate, the corresponding films have a lesser degree of crystallinity. It has been shown that the use of a higher boiling point solvent such as chlorobenzene (132 °C) leads to an improvement of the mobility due to a higher crystallinity consecutive to a slower evaporation speed [29].

Of interest is that in blends, the mobility remains practically constant within a broad range of PMMA concentration (up to 70%). As the phase separation is lateral, one would expect a variation of the mobility due to a decrease of the P3HT area at the interface. Instead, it seems that the percolation paths observed on the AFM pictures suffices to warrant a good charge carrier transport through the blend. However, above 70% of PMMA, P3HT domains change into isolated islands, leading to discontinuous conducting paths and a subsequent lowering of the hole mobility.

Blends with 90% of PMMA show a clear (although substantially reduced) field-effect behavior. The presence of a thin P3HT film on top of the blend (vertical phase separation) is unlikely because it is at variance with the observed decrease of the RMS roughness. Instead, we attribute this reduced charge transport capability to a partial dilution of P3HT into the PMMA matrix; although this hypothesis

would deserve further investigations, evidence for it can already be found in the literature [26].

Fig. 3c shows the transfer curves, in the saturation regime, for pure-P3HT and P3HT:PMMA 3:7 blend. The on current is almost identical in both cases, while the off current is lowered by one order of magnitude for the blend, thus resulting in a significant increase of the on/off ratio. The dependence of the on/off ratio with the composition of the blend is shown in Fig. 4b; it increases up to 5000 when decreasing the P3HT concentration down to 30%. Below this value, the on/off ratio drops down to the value of pure-P3HT, because of the drop of the on current, while the off current still decreases. Several explanations can be put forward. One is the fact that the formation of insulating domains decreases the leakage current. An alternative explanation would be the decrease of the charge density at the semiconductor/water interface resulting of the lowering of the P3HT concentration in the film, because the off current is known to be inversely proportional to the charge density [30,31]. Of interest is the fact that for high PMMA concentrations (above 50%), the off current measured on the transfer curves does not depend on the drain voltage (Fig. 3c).

Finally, Fig. 4c shows the variation of the threshold voltage as a function of the concentration of PMMA. A threshold voltage close to 0 V is desired for low-voltage applications. In the blends, this voltage shifts towards more positive values for PMMA concentration above 50%, yet remaining at a low level (<1 V).

4. Conclusion

Used in a water-gated configuration, P3HT/PMMA blends can lead to transistors with reasonably high mobility (up to 0.15 $cm^2/V\,s$) working at very low voltage (below 1 V). The mobility is not affected when increasing the proportion of PMMA up to 70%, while the off current is significantly lowered, thus resulting in an enhancement in the on/off ratio. AFM images showed that up to 70% of PMMA, a percolation path exists, thus allowing an efficient charge transport through the channel, in good agreement with the electrical measurements.

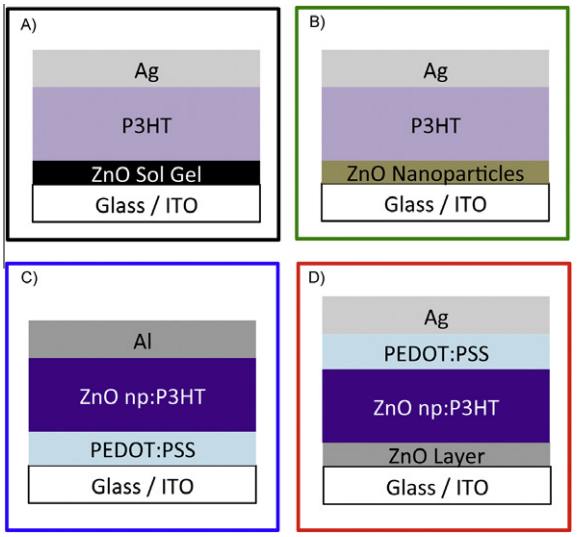

Fig. 1. Schematic representation of device architectures for (A) sol–gel bilayer, (B) nanoparticle bilayer, (C) conventional blend and (D) inverted blend devices.

Blended devices may be constructed in either a conventional or an inverted architecture. In a conventional architecture, holes are collected through the ITO by first applying poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) to increase the ITO work function and using a low work function metal top contact, e.g. Ca or Al, to collect the electron (Fig. 1C). In the inverted architecture, electrons are collected through ITO by first applying ZnO to decrease its work function and using a hole transport layer, e.g. PEDOT:PSS, and a high work function metal to collect holes (Fig. 1D). One obstacle to viable ZnO np blended devices is a sharp decline in the solar cell performance with exposure to even low amounts of UV [18,19]. While blended all-organic P3HT:PCBM bulk heterojunction devices have been shown to benefit from an inverted architecture [20–22] in terms of device stability, [20–26] an inverted architecture has not been widely investigated in devices with other active layers. When ZnO is used as the acceptor, the deposition of commercial acid PEDOT:PSS layer on top of the active layer results in removal/damage of the active layer. Krebs et al. demonstrated the ZnO np hybrid cells blended with poly-(3-carboxydithiophene) [27] using commercial PEDOT:PSS as the hole transport layer, but the very poor performance of the device indicates that the ZnO in the active layer might have been damaged. Here, we report the first demonstration of inverted ZnO np:P3HT blended devices using a neutral pH PEDOT:PSS [28–30]. The device performance and UV stability of ZnO:P3HT bilayer and blend devices in conventional and inverted architectures are compared.

2. Experimental methods

ZnO np were synthesized in methanol (Fisher Chemical, ACS grade) following a published procedure [18]. The ZnO np were rinsed three times in methanol by settling under gravity to a final concentration of 350 mg/ml. The nanoparticles were diluted with a solution of chlorobenzene and 10% 1-propanol to a final concentration of 50 mg/ml, with approximately 10% methanol in the final solution, or diluted to 7 mg/ml in butanol (ACS certified, Fisher Chemical) with a trace amount of methanol in the final solution.

The devices are prepared on patterned ITO substrates ($R \leqslant 15\ \Omega\ cm^2$) (Thin Film Devices, Anaheim, CA), which are sonicated in soapy water and isopropyl alcohol (ACS grade, Fisher Chemical) for 10 min each and then dried under flowing nitrogen, followed by a 20 min UV ozone treatment. For the sol–gel bilayer device (Fig. 1A), a 35 nm ZnO film is prepared by spin coating a 0.75 M zinc acetate solution with 0.045 ml ethanolamine/ml in 2-methoxyethanol onto the ITO at 1000 rpm and annealing in air on a hotplate at 300 °C for 10 min. P3HT films of 100 nm are then spun from a 24 g/L solution of P3HT (electronics grade regioregular P3HT 4002-E, Rieke Metals) dissolved in chlorobenzene (Sigma Aldrich, 99.8%) at 1000 rpm for 1 min in air. In the ZnO np bilayer (Fig. 1B), the ZnO np layer is prepared by spinning four layers of the ZnO np in butanol solution at 1000 rpm to form a 50 nm thick film, and a P3HT layer spun on top as in sol–gel bilayer devices.

For conventional blend devices (Fig. 1C), a 50 nm PEDOT:PSS (H.C. Starck, Clevios) layer was deposited on the ITO by spinning at 2000 rpm for 1 min followed by heating at 120 °C for 10 min in air to remove water. In inverted blend devices (Fig. 1D), a ZnO sol–gel layer or ZnO np layer is spun on ITO as described above. The active layer in either architecture uses a ZnO np:P3HT blended suspension with 15 wt.% ZnO and 10 mg/ml P3HT prepared in a solution of 10% 1-propanol (certified normal, Fisher Chemical):90% chlorobenzene (99+%, ACROS). A 100 nm blended active layer is spun at 500 rpm for 1 min in air. For inverted blend devices, a PEDOT:PSS solution was spun at 2000 rpm for 1 min. The PEDOT:PSS has 1% by weight surfactant (Aldrich, Zonyl 100) added to aid wetting, and is adjusted to pH 7.5 with 1 M NaOH to prevent etching of the ZnO np in the active layer [31]. The PEDOT:PSS film was dried on a hotplate at 120 °C for 10 min. Conventional blend devices were likewise heated to 120 °C for 10 min in a nitrogen box after spinning to ensure the same heat treatment of the active layer in both blend architectures. The top aluminum (99.999%, Kurt J. Lesker Co.) (conventional) or silver (99.999%, Williams Advanced Materials) (inverted) contacts are prepared by thermal evaporation of 100 nm of metal on top of the devices in vacuum.

The device performance was then measured under simulated one-sun illumination, using a KG5 filtered tungsten–halogen lamp adjusted with an NREL calibrated Si photodiode to 100 mW/cm^2. Devices were stored and tested under ambient condition, and humidity was not controlled. No UV filter was used. Conventional devices were tested immediately after Al deposition while inverted devices were aged in the dark for three days before testing. Ag is used as the hole-collecting electrode for the inverted device. It has been documented that the work function of the Ag increases over time with air exposure, resulting in improved device performance [25,32]. In contrast, conventional devices degrades quickly with air exposure. Hence, the initial measurements of the two kinds of devices are offset by 3 days, and represent the best possible values

for each. Each of the six individual devices per sample was tested upon initial exposure to light, and the results averaged to get the initial current–voltage characteristics. Subsequently, the devices were tested at regular increments for 70 min under continuous white light illumination in the solar simulator. The device cross-section was prepared by focused ion beam (FIB), and was imaged using a Philips CM30 TEM at an operating voltage of 300 kV.

3. Results and discussion

Fig. 2A depicts the *I–V* response for the four types of photovoltaic devices shown in Fig. 1. The device parameters are summarized in Table 1. The average and standard deviation in the device parameters in Table 1 are determined from six devices measured from each substrate. Bilayer devices have an open circuit voltage (V_{oc}) of ~400 mV when the ZnO layer is made from sol–gel (Fig. 1A), while they have a V_{oc} of ~600 mV when using ZnO np (Fig. 1B). The increase in V_{oc} in the ZnO np bilayer solar cells originates from an increased ZnO bandgap, resulting in an larger band offset between the highest occupied molecular orbital of the P3HT and the conduction band of ZnO [31]. While there is an increased V_{oc} in the nanoparticle bilayer device, this device suffers from a decreased short circuit current (J_{sc}) and fill factor compared with the sol–gel bilayer, resulting in an efficiency of 0.08%, similar to the sol–gel based bilayer device which has $\eta = 0.10\%$ (Table 1).

Conventional blended ZnO np:P3HT devices (Fig. 1C) work when excitons are generated in the P3HT, and electrons collected by the ZnO np and transported up to the Al electrode, while holes are carried through the P3HT to the PEDOT:PSS and down to the ITO. Not only do conventional blend devices have an increased V_{oc} above sol–gel bilayer devices due to the larger bandgap in the ZnO np, as in the np bilayer device, they also have a greatly increased J_{sc}, resulting from a much larger interfacial surface area. These blended devices have an average resulting efficiency of 0.62%; 7.75 times the efficiency of the ZnO np bilayer (Table 1). Our best single conventional blend device achieved a η of 0.75% with $J_{sc} = 2.64$ mA/cm^2, $V_{oc} = 510$ mV, and FF = 55%. However, even this device has not achieved as high efficiency as previous published result by Beek et al., of 0.9% [1].

Optimizing blend morphology between the electron donor and acceptor is critical for achieving high efficiency [17]. By spin coating the blend from a single solution, control over this final morphology is a significant challenge. A representative TEM of the cross-section of a conventional blend device is shown in Fig. 2B, revealing large agglomerations of ZnO np in the blend layer. There are areas of P3HT devoid of ZnO np (light regions) and dark regions of ZnO np aggregates. In addition, pure P3HT regions are found preferentially near the bottom PEDOT:PSS hole transport layer while ZnO np are at the top electrode interface. A higher efficiency can be expected if less aggregation in the blend morphology can be produced with optimized processing conditions.

Inverted ZnO np:P3HT blend devices have not been previously reported in the literature due to the acidity of the commercially available PEDOT:PSS. However, an inverted device structure is made possible by adjusting PEDOT:PSS from being highly acidic to neutral pH to prevent ZnO np in the active layer from being etched out when PEDOT:PSS is deposited on top. Neutral PEDOT:PSS has been used in the literature to make tandem solar cells, [28–30] but has not been utilized in making inverted ZnO np blend solar cells. The inverted blend structure (Fig. 1D) using a sol–gel derived bottom ZnO electron transport layer demonstrates an $\eta = 0.47\%$; 5.9 times that of the bilayer analog, though not quite as high as the conventional architecture. The increases in efficiency come primarily from the increased J_{sc}; 2.9 mA/cm^2 for the conventional blend device, and 2.0 mA/cm^2 in the inverted blend, compared with 0.45 mA/cm^2 for the sol–gel bilayer device (Fig. 2A and Table 1). The TEM micrograph of an inverted device (Fig. 2C) reveals similar ZnO np aggregations as in the conventional device (Fig. 2B). In addition, pure P3HT regions are found near the bottom ZnO np electron transport layer and ZnO np aggregates are in contact with the PEDOT:PSS hole transport layer. Since both kinds of devices have been annealed at 120 °C for 10 min, it is not surprising that the distributions of ZnO and P3HT in the blend are similar in both. In conventional devices, the high concentration of ZnO np at the top surface of the active layer may act as an electron

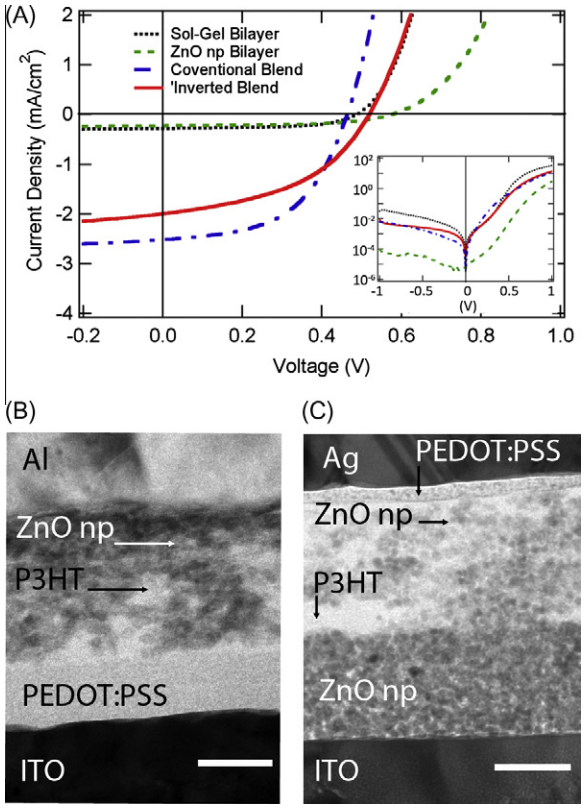

Fig. 2. (A) Current density–voltage response of each of the four device architectures measured under white light illumination at 100 mA/cm^2. Inset: current density–voltage dark response for each device. Cross-sectional TEM micrograph of (B) a conventional blend device and (C) an inverted device.

Table 1
Photovoltaic device characteristics for each hybrid device architecture are averaged over six devices with standard deviations. Characteristics include open circuit voltage (V_{oc}), current density (J_{sc}), fill factor (FF), efficiency (η), and series resistance (R_s).

Sample	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF (%)	η (%)	R_s (Ω cm^2)
Sol–gel bilayer	394 ± 7	0.45 ± 0.01	58.1 ± 3.78	0.10 ± 0.00	14 ± 1.4
Nanoparticle bilayer	579 ± 11	0.23 ± 0.01	56.2 ± 0.05	0.08 ± 0.01	35 ± 2.8
Conventional blend	468 ± 48	2.52 ± 0.11	52.3 ± 0.02	0.62 ± 0.11	9 ± 0.23
Inverted blend	520 ± 24	2.00 ± 0.09	45.2 ± 2.58	0.47 ± 0.05	18 ± 0.5

transport layer, readily transporting the electrons accepted by the ZnO throughout the blend to the Al electrode. In contrast, having the donor material adjacent to the electron transport layer and acceptor material in contact with the hole transport layer in the inverted devices are not ideal. Therefore, the blend morphology could explain the difference in device performance for the two architectures, where a lower J_{sc} is observed in the inverted device as compared to the conventional device.

Under white light exposure, we observe degradation behavior, with decreases in current, voltage, as well as fill factor, for all nanoparticle based hybrid devices, albeit with different rates (Fig. 3). Each of the data plots in Fig. 3 are taken from one device, however, they are representative of the white-light-exposure degradation behavior for each architecture observed across numerous devices. While the sol–gel bilayer device has a relatively low $\eta = 0.1$, it has superior stability in light (Fig. 3). By contrast, the nanoparticle bilayer degrades moderately over the 70 min testing time to 60% of its original efficiency, primarily through a decline in the short circuit current density (Fig. 3A). Since both bilayer devices have the same architectures, this difference in light-exposure stability indicates the difference in the microstructure in the ZnO acceptor layer. The sol–gel derived ZnO layer consists of nanometer-sized crystallites that are sintered and connected during the thermal pyrolysis. The nanoparticle ZnO film is not further heated, leaving behind a close packed layer of individual nanoparticles, presumably with acetate groups on the surfaces. These differences in surface chemistry and structure of the ZnO nanocrystallites are most likely responsible for the differences in light-exposure stability. If the ZnO np film is annealed to 300 °C, i.e., the same heat treatment as the sol–gel ZnO film, the device performance would be similar to that of devices containing sol–gel ZnO.

In the conventional blend devices, as noted previously in the literature, [19] there is a significant loss of performance with white light exposure due to the UV components. We observe sharp drops in J_{sc} (Fig. 3A), V_{oc} (Fig. 3B) and fill factor (Fig. 3C), resulting in a loss of 60% of device efficiency in 70 min of white light exposure (Fig. 3D). Quist et al. explain the degradation in performance originating from electrons generated by the UV illumination, causing filled electron traps in the ZnO. Once electron traps are filled, free electrons are formed leading to the ZnO acting as a conductor, leading to loss of photovoltaic behavior [19]. Since the inverted device shown in Fig. 3 uses an unannealed ZnO np film as the electron transport layer, it exhibits similar J_{sc} and V_{oc} degradation behavior as the ZnO np bilayer device with white light exposure. Although the inverted blend devices have the

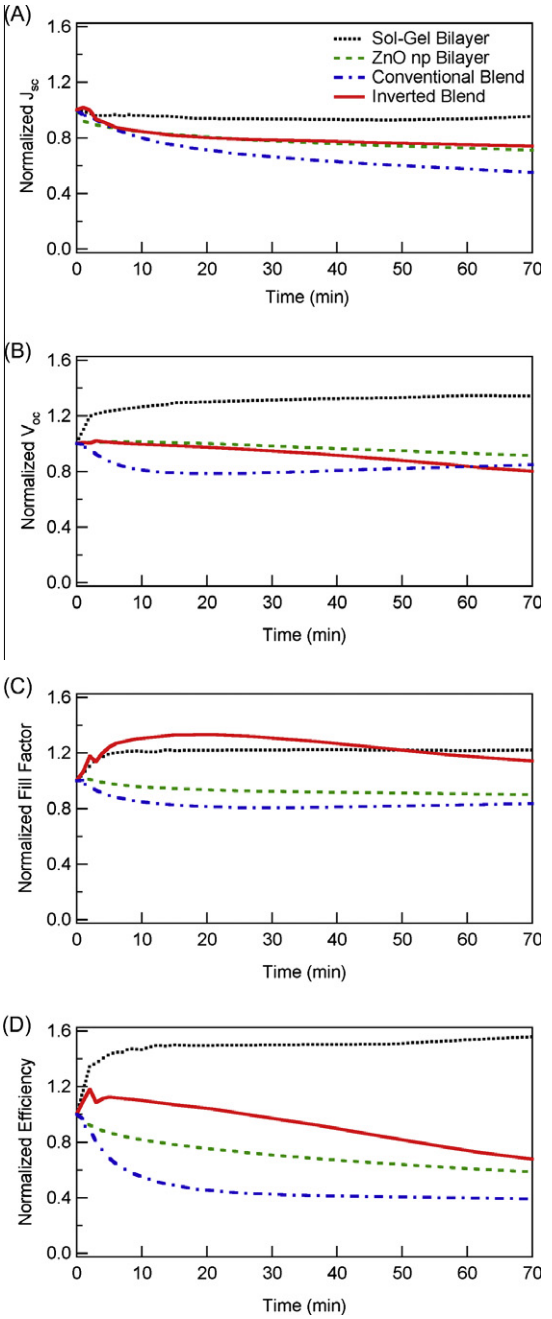

Fig. 3. Plots of normalized (A) current density (J_{sc}), (B) open circuit voltage (V_{oc}), (C) fill factor, and (D) efficiency for each hybrid device as a function of white light exposure time in minute. Dotted lines included to guide the eye.

same active layer as the conventional blend devices, they exhibit enhanced stability, dropping only to 60% of its initial efficiency compared to 40% of the initial efficiency in the conventional blend devices.

The improved stability observed in inverted architecture over conventional, similar to P3HT:PCBM devices, indicates that the relationship between device stability and architecture might be more broadly applicable. It points out that the change in the Al electrode, rather than changes in the active layer, might be the culprit for the degradation of conventional devices, as water and oxygen can transport through the Al grain boundaries [33,34]. A question arises about whether conventional devices using Ag, a more inert metal than Al, would exhibit better stability. As shown previously on P3HT:PCBM BHJ devices, conventional devices with Ag electrodes have lower efficiency [35] and actually degrade faster than ones with low work function electrodes [25,36]. The origin of the faster degradation using Ag as the cathode arises from a work function increase of Ag, which makes Ag ineffective in collecting electrons. We wanted to compare the degradation behavior for the highest efficiency cells of the two architectures. Thus, we chose Al as the electron-collecting electrode for the conventional cell and Ag as the hole-collecting electrode for the inverted cell.

4. Conclusions

We have shown that in bilayer hybrid devices, by using ZnO np in the acceptor layer, the V_{oc} is increased by 200 mV above sol–gel based ZnO devices due to the increase in the ZnO bandgap in the nanoparticles. For the first time, an inverted ZnO np:P3HT blend solar cell is demonstrated. Blend devices have a 6–8 times higher efficiency over bilayer devices due to the increased interfacial area between electron donor and acceptor when both are intimately mixed, leading to higher J_{sc}. However, we find that devices employing ZnO np are more susceptible to light-exposure degradation when compared to those employing ZnO sol–gel films. Similar to previous publications, we observe rapid device degradation as a result of white light exposure in conventional ZnO np:P3HT blended devices. We find that when the device architecture is changed from a conventional to an inverted blend structure, the response to light exposure is dramatically altered, and the devices show significant improvement in stability. If ZnO np hybrid devices can be designed with light-exposure stability, their performance is promising for future applications. Determining the origin of improved light-exposure stability in inverted and bilayer nanoparticle devices may benefit future work in these hybrid devices.

In inorganic semiconductor devices, there is an extensive literature already dealing with the effects of spin–orbit interaction on transport and spin filtering. As early as 1990, Datta and Das predicted that the spin–orbit coupling in a semiconductor results in spin precession that can be used to tune a spin valve effect in spin transistor devices [23]. Since then, there have been many theoretical and experimental studies on that topic [24–28]. In recent years, some theoretical investigations were carried out on the effect of spin-flip scattering in organic devices [21,29,30]. For instance, when the spin-flip effect caused by Co penetration in the organic layer is considered in a Co/OSC/LSMO device, the magnetoresistance obtained theoretically is consistent with experimental data [21]. Also, in one study the effect of spin-flip on spin injection into a DNA chain led to some valuable conclusions [30]. Therefore, an improvement of the two-current model is necessary to include the spin-flip scattering during the transport in an organic spin device.

Recently, there have also been several studies on inorganic spin filters, such as Europium-based spin filters [4], mutiferroic spin filters [31], and graphene spin filters [32], however, the investigations of organic spin filters are relatively few. In this paper, we modify the two-current model to include the spin flip of carriers and then investigate the spin-polarized current in an organic spin filter. A schematic diagram of the device is shown in Fig. 1, the interlayer is an organic ferromagnet poly-BIPO [1,4-bis(2,2,6,6-tetramethyl-4-piperidyl-oxyl)] [33], which can be described using a simple quasi-one dimensional model. To demonstrate the effect of spin flip on the spin polarized current through the device, we compare our result to that of the two-current model. The paper is organized as follows: the model and formulation are presented in Section 2. In Section 3, we provide the numerical calculations and analyze the results. Finally in Section 4, we summarize our main results. In particular, the spin filter effect is found to exist even when spin-flip scattering is included; thus it is a robust effect.

2. Model and method

We have investigated a metal/organic ferromagnet/metal (M/OF/M) device with a two-current approach and predicted that such a device can serve as a spin filter, which means that only one kind of spin can tunnel through the device, that is, the current through the device will be fully spin polarized [13]. To confirm the spin filter effect when the spin-flip scattering is included, we adopt the device model used in Ref. [13]. The modeling scheme is shown in Fig. 1. An organic ferromagnetic polymer poly-BIPO [1,4-bis(2,2,6,6,-tetramethyl-4-piperidyl-1-oxyl)] is connected with two semi-infinite metallic electrodes. The Hamiltonian is written as,

$$H = H_{OF} + H_{sf} + H_{l(r)} + H_{coup}, \tag{1}$$

where the first term is the Hamiltonian of the organic ferromagnetic polymer without spin-flip. The polymer has a main chain composed of carbon atoms. The side radicals are connected with odd (or even) sites and each radical has an unpaired electron which can offer a residual spin. A theoretical model has been well established to obtain the ferromagnetic ground state of this molecule [34].

$$H_{OF} = -\sum_{n,s} t_{n,n+1}(c^{+}_{n,s}c_{n+1,s} + c^{+}_{n+1,s}c_{n,s}) + \frac{K}{2}\sum_{n}(u_{n+1} - u_n)^2 + J_f \sum_{n} \delta_{n,odd}\,\vec{S}_{nR}\cdot\vec{S}_n. \tag{2}$$

Here $t_{n,n+1} = t_0 - \alpha(u_{n+1} - u_n)$, t_0 is the hopping integral of π electrons along the main chain with a uniform lattice; α stands for the electron–lattice coupling parameter and u_n the lattice displacement at site$n$; K is the elastic constant between the two lattice atoms; $c^{+}_{n,s}(c_{n,s})$ denotes the creation (annihilation) operator of an electron at site n with spin s; J_f denotes the spin coupling strength between the conduction electron (π-electron) spins $\vec{S}_n$ and the side radical spins $\vec{S}_{nR}$. It is assumed that the radicals (R) connect with the odd sites in the chain which is written as $\delta_{n,odd}$. We take the mean-field approach for $\vec{S}_{nR}$ and set $\vec{S}_{nR}\cdot\vec{S}_n = -\frac{1}{4}\left(c^{+}_{n,\uparrow}c_{n,\uparrow} - c^{+}_{n,\downarrow}c_{n,\downarrow}\right)$.

H_{sf} describes the spin-flip effect in the organic magnetic polymer of the interlayer, which may be caused by spin–orbit coupling, magnetic environment, temperature, etc.,

$$H_{sf} = -\sum_{n} t_{sf}(c^{+}_{n,\uparrow}c_{n,\downarrow} + c^{+}_{n,\downarrow}c_{n,\uparrow}), \tag{3}$$

with t_{sf} denoting spin-flip transfer integral. It is not easy to give an exact value of the spin-flip parameter t_{sf}. In a recent work, Wohlgenannt et al. studied the spin–orbit interaction in a conjugated polymer based on a simple model. They obtained t_{sf} values of the magnitude of about 10 μeV and pointed out that the spin–orbit value is structure dependent [35]. Here we assume that the spin flip contribution arises from both the spin–orbit coupling and other factors, such as magnetic environment and temperature.

$H_{l(r)}$ is the Hamiltonian of the left (right) electrode, which is supposed to be a simple metal chain,

$$H_{l(r)} = \sum_{m,s} \varepsilon_{l(r)} a^{+}_{m,s}a_{m,s} - \sum_{m,s} t_{l(r)}(a^{+}_{m,s}a_{m+1,s} + h.c.), \tag{4}$$

where $\varepsilon_{l(r)}$ is the on-site energy of a metal atom compared to that of a carbon atom, $t_{l(r)}$ is the transfer integral of adja-

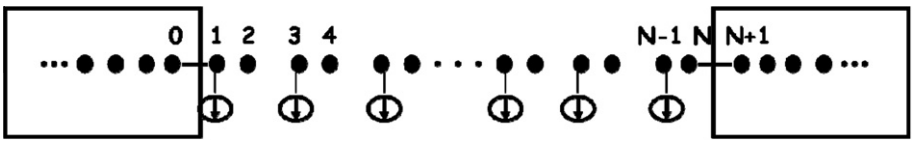

Fig. 1. One-dimensional scheme for a poly-BIPO based device, the arrows indicate the localized spin direction of side radicals.

cent sites, $a^+_{m,s}(a_{m,s})$ is the creation (annihilation) operator of an electron in the electrodes.

The coupling between the electrodes and the polymer is assumed to take place only at the nearest connecting atoms at the interfaces.

$$H_{coup} = -\sum_s t_{lM}(a^+_{0,s}c_{1,s} + h.c.) - \sum_s t_{rM}(c^+_{N,s}a_{N+1,s} + h.c.), \quad (5)$$

where $t_{l(r)M}$ is the interfacial coupling, which is simplified by neglecting the spin-dependent scattering at the interfaces. N is the total number of carbon sites in the organic ferromagnetic polymer.

For an M/OF/M device, the current is spin-dependent due to the ferromagnetic polymer interlayer. If there is no spin-flip process in the transport, we may consider the spin up and spin down current separately, i.e. the two-current model. If the spin-flip scattering is included during the transport, the spin up current measured at the acceptor electrode is contributed not only from the transmission of spin up electrons but also from the spin down electrons. Similar is the case for the current of spin down electrons. Therefore, to estimate the spin-dependent current measured at the acceptor side, we have to extend the Landauer–Büttiker formula [36] to include the possible spin flip transmission,

$$I_s(V) = \frac{e}{h}\int_{-\infty}^{+\infty}[T_{ss}(E,V) + T_{-ss}(E,V)][f(E-\mu_l) - f(E-\mu_r)]dE, \quad (6)$$

where $f(E-\mu_{l(r)}) = 1/\{1+\exp[(E-\mu_{l(r)})/k_BT]\}$ is the Fermi distribution function and $\mu_{l(r)} = E_F \pm eV/2$ is the chemical potential of the left (right) electrode with Fermi energy E_F. If the spin-flip transmission coefficient $T_{-ss} = 0$, then the two-current model is recovered. In order to discuss the spin-polarized transport in the M/OF/M device, the spin polarization of the current is defined as,

$$P(V) = \frac{I_\uparrow(V) - I_\downarrow(V)}{I_\uparrow(V) + I_\downarrow(V)}, \quad (7)$$

which is voltage (V) dependent. The zero-bias spin polarization of the device is given by $P_0 = \lim_{V\to 0} P(V)$.

The spin-dependent transmission coefficient is calculated using the transfer matrix method. The wavefunction on the μ th orbital with spin s is written as $\psi_{\mu,s} = \sum_n Z_{n,\mu,s}|n\rangle$, where $Z_{n,\mu,s}$ expresses the amplitude of the wavefunction on site n. From the relevant Schrödinger equation, we obtain the transfer relation,

$$\begin{pmatrix} Z_{N+2,\mu,\uparrow} \\ Z_{N+1,\mu,\uparrow} \\ Z_{N+2,\mu,\downarrow} \\ Z_{N+1,\mu,\downarrow} \end{pmatrix} = M_r \prod_{n=1}^{N} P^{(n)} M_l \begin{pmatrix} Z_{0,\mu,\uparrow} \\ Z_{-1,\mu,\uparrow} \\ Z_{0,\mu,\downarrow} \\ Z_{-1,\mu,\downarrow} \end{pmatrix}, \quad (8)$$

where M_l, M_r and $P^{(n)}$ are written as,

$$M_l = \begin{pmatrix} \frac{t_l}{t_{lM}}e^{ik_la} & 0 & 0 & 0 \\ 0 & e^{ik_la} & 0 & 0 \\ 0 & 0 & \frac{t_l}{t_{lM}}e^{ik_la} & 0 \\ 0 & 0 & 0 & e^{ik_la} \end{pmatrix} M_r = \begin{pmatrix} e^{ik_ra} & 0 & 0 & 0 \\ 0 & \frac{t_{rM}}{t_r}e^{ik_ra} & 0 & 0 \\ 0 & 0 & e^{ik_ra} & 0 \\ 0 & 0 & 0 & \frac{t_{rM}}{t_r}e^{ik_ra} \end{pmatrix}, \quad (9)$$

$$P^{(n)} = \begin{pmatrix} \frac{(E-\varepsilon^\uparrow_n+\frac{J_f}{4}\delta_{n,o})}{t^\uparrow_{n,n+1}} & -\frac{t^\uparrow_{n-1,n}}{t^\uparrow_{n,n+1}} & \frac{t_{sf}}{t^\uparrow_{n,n+1}} & 0 \\ 1 & 0 & 0 & 0 \\ \frac{t_{sf}}{t^\downarrow_{n,n+1}} & 0 & \frac{(E-\varepsilon^\downarrow_n-\frac{J_f}{4}\delta_{n,o})}{t^\downarrow_{n,n+1}} & -\frac{t^\downarrow_{n-1,n}}{t^\downarrow_{n,n+1}} \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad (10)$$

and $\cos(k_{l(r)}a) = \frac{E-\varepsilon_{l(r)}}{2t_{l(r)}}$.

Within the left electrode ($n \leqslant 0$) and the right electrode ($n \geqslant N+1$), we suppose that the electronic state is a simple plane wave. For a spin up electron, it is written as,

$$\begin{aligned} Z_{-1,\mu,\uparrow} &= e^{-ik_la} + \rho^{\uparrow\uparrow}e^{ik_la}, Z_{-1,\mu,\downarrow} = \rho^{\uparrow\downarrow}e^{ik_la}, \\ &\times Z_{0,\mu,\uparrow} = 1 + \rho^{\uparrow\uparrow}, Z_{0,\mu,\downarrow} = \rho^{\uparrow\downarrow}, Z_{N+1,\mu,\uparrow} = \tau^{\uparrow\uparrow}e^{i(N+1)k_ra}, \\ &\times Z_{N+1,\mu,\downarrow} = \tau^{\uparrow\downarrow}e^{i(N+1)k_ra}, Z_{N+2,\mu,\uparrow} = \tau^{\uparrow\uparrow}e^{i(N+2)k_ra}, \\ &\times Z_{N+2,\mu,\downarrow} = \tau^{\uparrow\downarrow}e^{i(N+2)k_ra}, \end{aligned} \quad (11)$$

where $\rho^{\uparrow\uparrow(\uparrow\downarrow)}$ and $\tau^{\uparrow\uparrow(\uparrow\downarrow)}$ are the amplitudes of the reflected and transmitted electron wavefunctions with spin up, which include spin-conserving parts $\rho^{\uparrow\uparrow}, \tau^{\uparrow\uparrow}$ as well as spin-flipping parts $\rho^{\uparrow\downarrow}, \tau^{\uparrow\downarrow}$. A similar form can be written down for the spin down state. Then, the spin-dependent transmission coefficients T_{ss} and T_{-ss}, which are defined as the ratio of the transmitted flux to the incident flux are obtained as,

$$T_{ss} = \frac{t_r\sin(k_ra)}{t_l\sin(k_la)}|\tau^{ss}|^2, \; T_{-ss} = \frac{t_r\sin(k_ra)}{t_l\sin(k_la)}|\tau^{-ss}|^2. \quad (12)$$

We carry out numerical calculations by taking the parameters as follows: for the organic ferromagnet [13,34], $t_0 = 2.5$ eV, $\alpha = 4.1$ eV/Å, $K = 21$ eV/Å^2, which appropriately describe the properties of poly-BIPO. For the electrodes, we take $\varepsilon_{l(r)} = 0$, $t_l = t_r = 2.5$ eV, $E_F = 0.5$ eV. The interfacial coupling is taken as $t_{lM} = t_{rM} = 0.5$ eV. We choose a low temperature of $T = 11$ K.

3. Results and discussion

First, we consider an isolated organic ferromagnetic polymer with half-filled occupation of electrons (one itinerant π-electron for each carbon site in the main chain). When the spin-flip scattering is absent, it is known that the polymer described with Hamiltonian (2) has a dimerization structure along the main chain. The polymer has a ferromagnetic ground state and exhibits a semiconducting behavior. There is an oscillatory variation of the spin amplitude from site to site along the main carbon chain, and the amplitude is mainly determined by the Heisenberg spin coupling between the side radical and the main carbon chain.

When the spin-flip scattering is included, we find that the polymer still has a ferromagnetic state. The amplitude of the spin oscillation is enhanced compared to that without the spin-flip. In this case, the electronic state is a spin mixed state, i.e. $\psi_\mu = a_\mu|\uparrow\rangle + b_\mu|\downarrow\rangle$, where $|a_\mu|^2$ and $|b_\mu|^2$ reflect the probability of electron spin direction (up or down). The spin-flip affects the electronic density of the ferromagnetic polymer and thus affects the lattice distortion due to the strong electron–lattice interaction of the or-

ganic polymer, which results in a redistribution of the Peierls distortion of the polymer chain. This effect is reflected in the energy level structure. As shown in Fig. 2, with increasing spin-flip parameter t_{sf}, the energy gap decreases gradually. It means that the Peierls gap in the organic molecule is reduced due to the spin-flip effect, which is a peculiar property of the organic ferromagnetic polymer.

To understand the conduction properties of the organic device, in the following, the electronic states near the Fermi level are checked. As shown in Fig. 3(a and b), where there is no spin-flip scattering, i.e. $t_{sf} = 0$, the orbitals are spin separated. The LUMO (lowest unoccupied molecular orbital) of the organic ferromagnetic polymer is the eigenstate of spin up Hamiltonian, while the LUMO + 1 is the spin down eigenstate. If a bias is applied, the spin up transport occurs first and the current is 100% spin polarized. With increasing bias, the LUMO + 1 goes into the conduction region. As LUMO + 1 has an opposite spin state to LUMO, the spin polarization decreases.

When the spin-flip scattering is included (i.e. nonzero t_{sf}), the electronic state of each orbital becomes a mixed state of different spins, as shown in Figs. 3(c and d). (To emphasize the effect of spin-flip scattering, for illustrative purposes hereafter a much larger value of t_{sf} is taken). In this case, the LUMO has a probability of $|a_{\mathrm{LUMO}}|^2$ for spin up electrons and $|b_{\mathrm{LUMO}}|^2$ for spin down electrons, as stated above. Therefore, even at low applied bias so that only one orbital (LUMO in the present case) enters the conduction region, a fully spin polarized current could not be realized. However, as $|a_\mu|^2 \neq |b_\mu|^2$, it is expected that the current is still spin polarized. The polarization of current will depend on the spin-flip scattering.

Next we study the effect of spin-flip scattering on the current spin polarization in an M/OF/M device at a fixed bias of $V = 0.8$ V (just above the turn-on voltage). The interlayer polymer has 20 carbon sites and each site provides one π-electron. The result is shown in Fig. 4, In the case of $t_{sf} = 0$, the current is fully polarized with $P = 100\%$. When the spin-flip scattering is considered, it is found that the spin polarization decreases gradually. But the current still keeps a good spin polarization even for a significant value of t_{sf}. For example, if we consider that the spin flip is caused only by the spin–orbit interaction in the organic semiconductor interlayer, which is of the order of tens of μeV [35], then from the calculation it is found that the current spin polarization remains nearly unchanged for these vaules of t_{sf}. Of course here we only consider a very short chain, $N = 20$ or the length of the 'interlayer' $L \approx 3$ nm, which is much shorter than the interlayer thickness of an actual device.

Further, if we include the spin flip contribution from all possible factors in addition to the spin–orbit interaction, such as the leakage field of the ferromagnet, the magnetic effect of the radical, temperature and doped ions the effective value of t_{sf} may be considerably large. We take $t_{sf} = 0.2$ eV, which is much larger than the room-temperature thermal energy ($k_BT \sim 0.026$ eV) and the Zeeman energy corresponding to one Tesla magnetic field ($g\mu_B\vec{S}\cdot\vec{B} \sim 10^{-5}$ eV). It is found that the current has a spin polarization of about 75%. We note that an organic semiconductor has a long spin relaxation time (much longer than that in an inorganic semiconductor), which means that the spin-flip scattering should be very weak in organic semiconductors (the real value of t_{sf} should be much smaller than 0.2 eV used here). Therefore, our calculation shows that even when a spin-flip scattering is included, such an organic device still keeps a high spin polarization. The device can still serve as a spin filter.

In the following, we study the effect of Heisenberg coupling J_f on the spin polarization by setting $t_{sf} = 0.25$ eV at a fixed bias of $V = 0.8$ V. As shown in Fig. 5, we find that the spin polarization of the current increases with J_f rapidly. Combined with the above result, we note that the spin-flip scattering and the side radical's Heisenberg coupling are

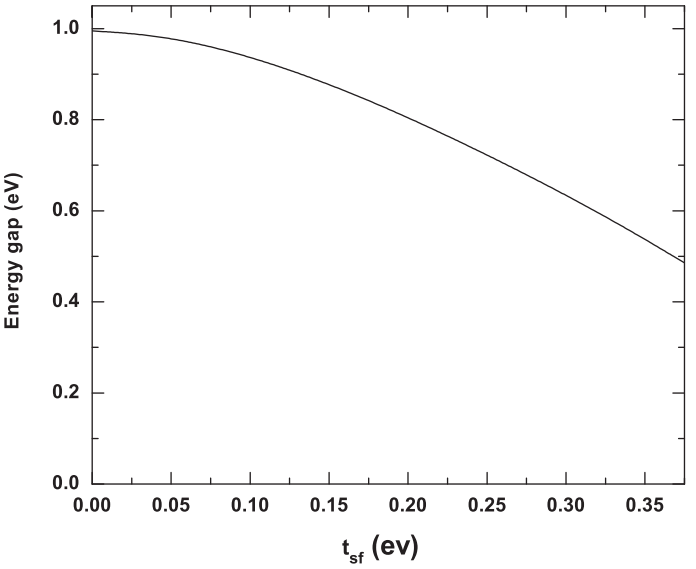

Fig. 2. Dependence of the energy gap on the spin-flip parameter t_{sf}.

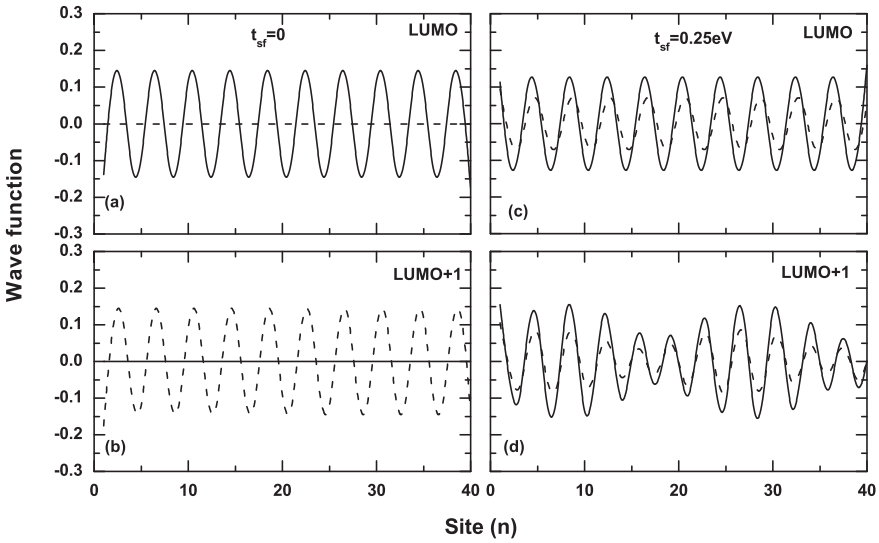

Fig. 3. Wave functions near the Fermi level: LUMO and LUMO + 1 states. (a) and (b) $t_{sf} = 0$; (c and d) $t_{sf} = 0.25$ eV. A large value of t_{sf} is chosen for illustrative purposes. (Spin up: solid line and spin down: dashed line).

competing effects for the spin polarization. To obtain a good spin filter, one hopes to adopt an organic ferromagnetic polymer with a strong side radical spin coupling and a weak spin-flip scattering. Comparatively, the effect of the side radical spin coupling on the spin filter is more sensitive than that of the spin-flip scattering. This conclusion is helpful in designing an organic spin filter.

To understand the current polarization mechanism with the spin-flip scattering included, we calculate the spin-dependent transmission coefficient at a fixed bias. When the spin-flip scattering is considered, the incident electrons from the left electrode have four channels to get to the right electrode. The transmission coefficients include spin-conserving parts $T_{\uparrow\uparrow}, T_{\downarrow\downarrow}$ and spin-flip ones $T_{\uparrow\downarrow}, T_{\downarrow\uparrow}$. The total transmission coefficient of spin up electrons is $T_{\uparrow} = T_{\uparrow\uparrow} + T_{\downarrow\uparrow}$, and that of spin down electrons is $T_{\downarrow} = T_{\downarrow\downarrow} + T_{\uparrow\downarrow}$. When spin-flip parameter $t_{sf} = 0$, the transmissions $T_{\uparrow\downarrow}$ and $T_{\downarrow\uparrow}$ are absent, i.e. the spin remains conserved during the transport process. As shown in Fig. 6(a), the peaks of $T_{\uparrow}$ and $T_{\downarrow}$ appear independently. In this case, we can treat the transport with the two-current model. Under a low bias, the peak of $T_{\uparrow} = T_{\uparrow\uparrow}$ appears first, which corresponds to the transport of only spin up LUMO state and a 100% spin polarized current can be obtained. When the spin-flip scattering is included during the transport process, as shown in Fig. 6(b), the transmissions $T_{\uparrow\downarrow}$

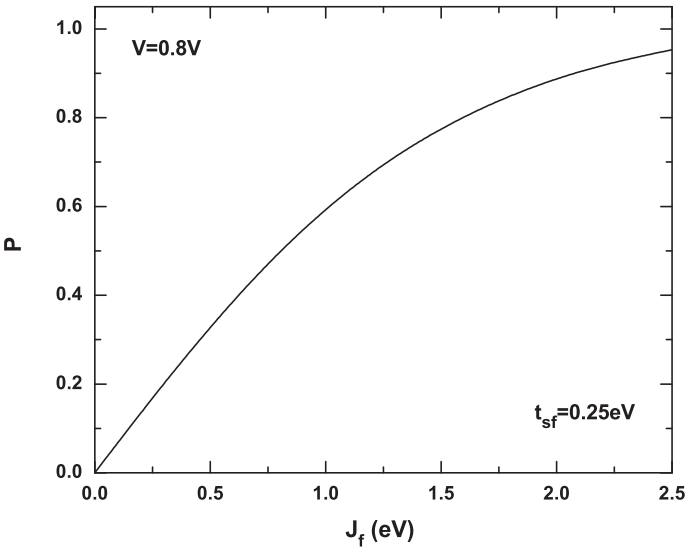

Fig. 5. Dependence of current polarization on the Heisenberg coupling J_f at $V = 0.8$ V.

and $T_{\downarrow\uparrow}$ will take place and the peaks of $T_\uparrow$ and $T_\downarrow$ appear simultaneously, which destroy the full polarization of the current. For example, the couple of peaks of $T_\uparrow$ and $T_\downarrow$ near $E - E_F \approx 0.1eV$ (as shown in Fig. 6) correspond to the LUMO. As this state contains both the component of spin up and spin down with a probability of $|a_{\mathrm{LUMO}}|^2$ and $|b_{\mathrm{LUMO}}|^2$, respectively, the current contributed from this state will become partly spin polarized. Since $|a_{\mathrm{LUMO}}|^2$ is much larger than $|b_{\mathrm{LUMO}}|^2$ in the present case, the spin polarization of the current still keeps a high value at a positive low bias when the LUMO enters the conducting window.

4. Summary

In conclusion, we considered the possible spin flip of an electron when it passes through an organic device and calculated the effect of spin-flip scattering on the current spin polarization. It is known that Datta and Das first indicated the spin precession of electrons through the Rashba spin orbit coupling effect in narrow-gap inorganic semiconductors [23]. The Rashba spin orbit coupling describes spin flip from one site to another due to the motion of electrons. Here in our model, the spin flip takes place at the same site, which may be contributed from the leakage field of the ferromagnet, the magnetic effect of the radical, temperature and doped ions. We did not study the details of spin precession here, instead we considered the measurable spin current polarization and investigated the effect of spin-flip coupling.

First, we studied the basic properties of an organic ferromagnetic polymer in the presence of spin-flip scattering. We found that the π-electronic orbital becomes a spin mixed state. Due to the strong electron–lattice interaction

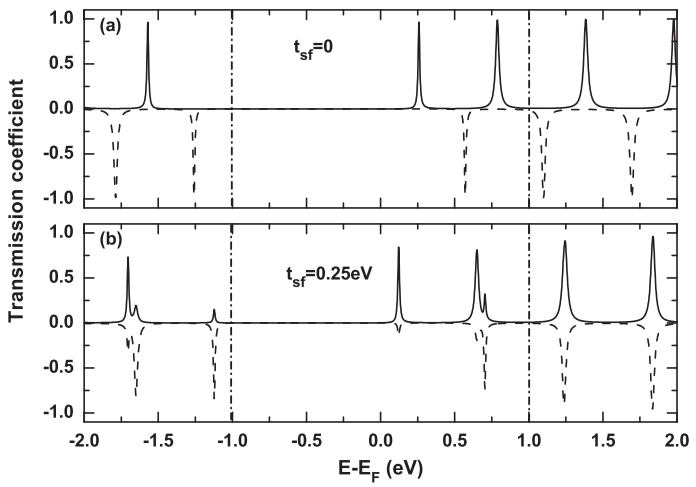

Fig. 6. Spin-dependent transmission coefficient at (a) $t_{sf} = 0$ and (b) $t_{sf} = 0.25$ eV. ($T_\uparrow$: solid line and $T_\downarrow$: dashed line).

in an organic polymer, the spin-mixing of the orbital results in a decrease of the LUMO–HOMO gap or the Peierls energy gap. This kind of spin-induced change in the Peierls gap is a peculiar property of an organic ferromagnetic polymer. Then, we extended the Landauer–Büttiker formula to include spin dependence and calculated the current spin polarization in an organic spin filter. We found that, although the spin polarization of the current through the device decreases due to the spin-flip scattering, the device still functions well as a spin filter even with a considerable spin-flip scattering. We also considered the competing effects of the spin-flip scattering and the ferromagnetism of the organic interlayer on the spin filter and found that it is more sensitive to the latter. These findings are important for designing an optimal organic spin filter.

of 5–6 nm, and are coated with *n*-butylamine ligands. The ZnO nanoparticle layer is prepared by spin-coating from chloroform solution, followed by annealing at 250 °C in air. Here the ZnO nanoparticle layer is a hole-blocking layer, which can dramatically reduce the switching current density [5]. Fig. 1 also shows *JV* curves of three different devices with different ZnO nanoparticle layer thickness, scanning from 0 V to 3 V to 0 V. The three curves are very similar, indicating that the current is determined largely by the properties of the PEDOT:PSS layer and its interfaces. Scanning towards +3 V (Al positive), the current density has a peak at ~1.3 V at a value of less than 1 mA cm^{-2}. The device current is about 2–3 orders of magnitude lower when the voltage is swept back to below 2 V. The device conductivity cannot be recovered, indicating a permanent change. There is no significant recovery observed after 6 months storage.

3. WORM device operation mechanism

To investigate the mechanism responsible for the conductance switching, Raman spectra (633 nm excitation) have been measured before and after switching (Fig. 2A). Before switching, the spectrum shows broad peaks in the region around 1420 cm^{-1}, whereas after switching the spectrum shows sharp peaks in this region, with clear peaks at 1422 and 1516 cm^{-1} corresponding to symmetric and antisymmetric C=C stretching modes respectively. This change in spectrum is consistent with a change from *p*-doped to undoped PEDOT [10,11]. Further evidence for the dedoping of PEDOT can be obtained from the UV–visible absorbance of the devices, obtained by measuring the change in intensity of light incident through the glass substrate, passing through the PEDOT:PSS layer, and reflected at the Al electrode. Fig. 2B shows the change in reflectance between 375 and 750 nm while sweeping the bias from 0 to 3.3 V. In the conducting, *p*-doped state the PEDOT is highly transparent, leading to high reflectivity across the spectral range. As the bias increases, the reflectance decreases, corresponding to the formation of undoped PEDOT, which is much more absorbing [10,12]. The change in reflectance peaks at 510 nm, and the observed behavior is consistent with the color change seen in electrochromic cells based on doping and dedoping of PEDOT [13]. Fig. 2C shows the reflectance change at 510 nm together with the current flowing in the device. It can clearly be seen that the reflectance change is associated with the reduction in current. The maximum reflectance change is over 80%, which, considering the other reflection losses present in the structure, corresponds to a very significant change in absorbance of the PEDOT. The combination of in situ Raman and reflectance measurements therefore provides unambiguous evidence that the change in conductivity is due to dedoping of the PEDOT.

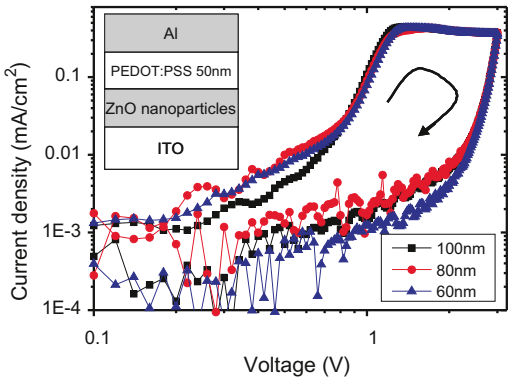

Fig. 1. Device structure and log–log current–voltage curves for ITO/ZnO/PEDOT:PSS/Al devices using different ZnO layer thickness (as indicated in the figure). The measurement was performed using the pulse mode of an Agilent 4155B Semiconductor Parameter Analyzer. The pulse period was 20 ms, and the pulse duration was 10 ms. The voltage step was 0.02 V.

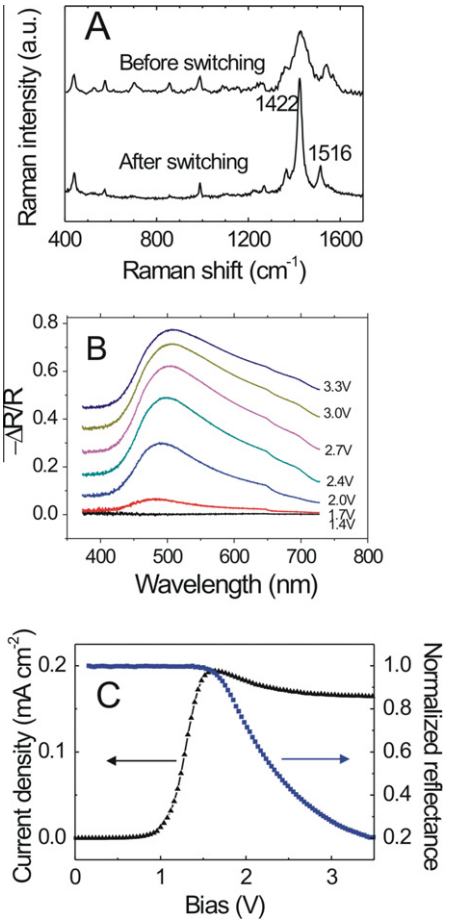

Fig. 2. (A) Raman spectra (633 nm excitation) before and after switching. (B) Reflectance spectrum (fractional reduction in reflectance relative to unswitched device) as a function of bias voltage. (C) Normalized reflectance at 510 nm and current density as a function of bias voltage. Voltage scan rate for (C) 0.2 V/s.

Dedoping of the PEDOT requires injected electrons to be captured by the PEDOT. We can estimate the amount of transient electrochemical current related to this dedoping process. Taking a rough estimate of the doping density in PEDOT:PSS as 10^{19} cm^{-3} [7], for a 50 nm film 5×10^{13} electrons/cm^2 are required to completely dedope the

PEDOT layer. From our previous work [5], we know that timescale of switching is typically about 20 ms. To completely dedope the PEDOT within this time requires a current of about 0.4 mA cm^2, which is close to our device switching current, indicating that the switching process in our device is very efficient. In reality, the electrochemical current could be less than this value because even a thin dedoped interfacial layer might be sufficient to reduce device conductivity dramatically, however the spectroscopic data presented above suggest that the bulk of the film is indeed dedoped.

We have confirmed that the change in device conductivity is caused by dedoping of the PEDOT. The electrochemical doping and dedoping of PEDOT usually is a reversible process [10–13]. However, when it is followed by electrolysis of water to form stable neutral PSSH, then the PEDOT doping level is irreversibly changed [2,8,9], which results in a permanent change of the device conductivity, as we suggested in our previous work [5].

We note that electrical switching behavior has also been observed in ZnO nanoparticles [14,15]. We believe that the switching mechanism in our device is not due to a change in conductivity of ZnO layer. Besides the spectroscopic investigations described above, we also found that the device performance is independent of the ZnO layer thickness (Fig. 1). In our device, the role of the ZnO layer is to block holes and inject electrons, which results in a dramatic reduction in device operation current.

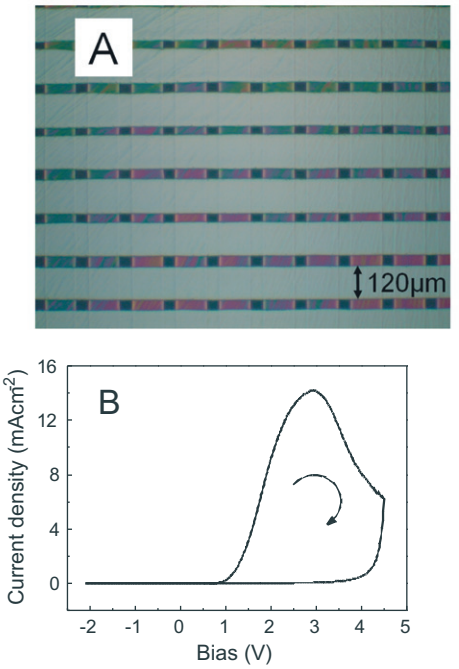

Fig. 3. (A) Optical micrograph of inkjet-printed memory array. (B) Current–voltage characteristic of an Au/ZnO/PEDOT:PSS/ZnO/Ag device. The measurements were performed using an Agilent 4155B Semiconductor Parameter Analyzer (SPA) in pulse mode, in air. The pulse period was 20 ms, and the duration was 10 ms. The voltage step is 0.015 V.

4. Towards entirely solution-processed WORM

In order to obtain low-cost PEDOT:PSS WORM memories, it is useful to fabricate arrays of devices without lithographic substrate patterning or high-vacuum processing. However, it is difficult to print metals directly on top of the PEDOT:PSS layer in the structure described above without forming short-circuits. To solve this problem, we use an additional ZnO nanoparticle layer on top of the PEDOT:PSS to prevent shorting, while still maintaining the electron-only device structure. This allows arrays to be fabricated entirely by solution processing. Bottom electrodes were formed by inkjet printing of 120 μm wide lines of gold nanoparticle ink (NPG-J, Harima Chemicals), followed by annealing at 250 °C for 1 h. ZnO nanoparticle and PEDOT:PSS films were deposited as before, followed by spin-coating of a further ZnO nanoparticle layer of 200 nm thickness. The device was then annealed at 200 °C for 30 min under nitrogen. Top electrodes were deposited by inkjet printing 120 μm wide lines of a silver complex ink (InkTec TEC-IJ-010 or InkTec TEC-IJ-050) perpendicular to the bottom electrode lines, followed by annealing at 130 °C for 5 min. The possibility to realize a highly conductive second level of printed metallization thanks to a low sintering temperature silver complex based ink was first demonstrated by Caironi et al. [16]. Fig. 3A shows an optical micrograph of the array, and Fig. 3B shows a typical current–voltage curve of a single device (gold electrode positive, −2 V to 4.5 V to −2 V). Rectifying behavior is again observed due to the difference in electrode properties. Switching occurs at 3–4 V, and the conductance in the range 1–3 V is reduced by a factor of approximately 500 after switching. We note that the current density of this printed structure WORM device is higher than the spin-coated structure device (Fig. 1). This is probably due to the different amount of water contained in the PEDOT:PSS layers of this two devices. The importance of water in the dedoping process has been discussed in our previous work [5]. In the printed structure device, the extra annealing process after deposition of the top ZnO nanoparticle layer can also dry the PEDOT:PSS layer, making it more difficult to permanently reduce the device conductivity. This 120 μm × 120 μm size printed WORM device can thus be programmed with powers of only 10 μW. Low programming power is essential for low-cost printed RFID tags where the total power is limited. We note the inkjet printed line width can be easily downscaled to 10–50 μm, so it is possible that the programming power of the WORM device can be further reduced to below 1 μW. Using simple pulses rather than voltage pulse ramps the required power can be higher, depending on the programming time required, as we found in Ref. [5].

5. Conclusions

In summary, by spectroscopic investigation, we have shown direct evidence that the switching in low-power WORM devices based on PEDOT:PSS is due to dedoping of the PEDOT. Based on this understanding, we have demonstrated an entirely solution-processed WORM

device, which is promising for application in low-cost RFID tags.

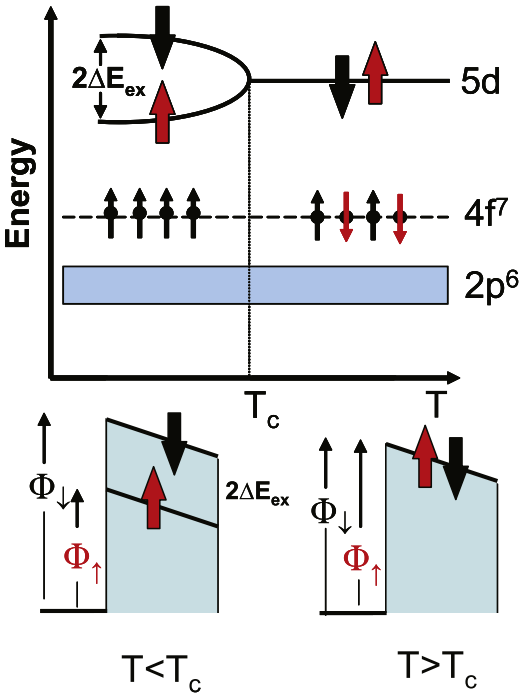

Fig. 1. Energy levels of EuS showing the splitting in the 5d conduction band below T_c (16.6 K) by the exchange energy, $2\Delta E_{ex}$ ($\sim$ 0.36 eV in bulk). When used as a tunnel barrier, it leads to lowering of the barrier height for spin-up electrons ($\Phi_\uparrow$) relative to the spin-down electrons ($\Phi_\downarrow$).

to serve as a good source for injecting spin-polarized electrons into an OS. There has been a recent report of utilizing a spin filter (EuO) for spin injection into rubrene [13]. However, in this preliminary study the interface and device stability was a significant issue. In the present work, we show that the use of SF barrier does not only provide spin injection, but also leads to enhanced spin injection at high applied voltage biases. Recently, chemically synthesized organic ferromagnetic semiconductor, $V(TCNE)_x$, has also been used to inject spins in OS. However, its stability especially in thin film form and high resistance as an electrode need to be addressed.

In the current study, the quasi-magnetic junction (QMJ) devices were fabricated using an *in situ* shadow mask technique in a vacuum chamber with a base pressure of 7×10^{-8} Torr. The geometry of the device (junction area: $200 \times 200\ \mu m^2$) is shown in Fig. 2. A thin film of EuS (2 nm) was grown at room temperature over Al, followed by the deposition of rubrene. Different thicknesses of the rubrene layer were grown ranging from 5 to 12 nm. A thin film of Fe (12 nm) was used as the top FM electrode and the whole structure was subsequently protected by 8 nm of Al_2O_3. The growth of rubrene, as seen in previous studies, has been shown to be influenced by the local surface electronic properties of the bottom seed layer [7,14]]. The insulating property of EuS can be expected to lead to azimuthal growth of rubrene at the interface, as in the case with alumina seed layer. Such interface ordering has been reported to improve the spin injection efficiency in rubrene [7].

MR measurements were performed at 1 K to achieve full exchange splitting of the conduction band in EuS, below its T_c, for higher spin filtering efficiency. MR was measured for different rubrene film thicknesses ranging from 5 to 12 nm. For 5 nm thick rubrene, the bulk of the junction resistance was coming from EuS and the anti-parallel state of the magnetization between EuS and Fe layer was not observed, whereas for 7 nm rubrene, although there was magnetic coupling between EuS and Fe, independent switching of EuS and Fe magnetizations could be seen (see Fig. 2a). Here, the large background non-saturating MR signal observed might be attributed to the magnetic field dependent resistance of the EuS barrier. With increasing rubrene thickness, the device showed a transition from a EuS dominated to a rubrene barrier dominated junction resistance. For 9 nm rubrene, higher MR was seen with a well-defined parallel and anti-parallel magnetization state of the EuS and Fe layer (see Fig. 2b). In these devices, the resistance was observed to increase at zero fields before reaching the anti-parallel state of the two FM electrodes. This could be caused by the dipolar coupling of EuS and Fe layer. The coercivity of bottom EuS layer was confirmed to be $\sim$90 Oe by SQUID measurements. A MR of 6% was

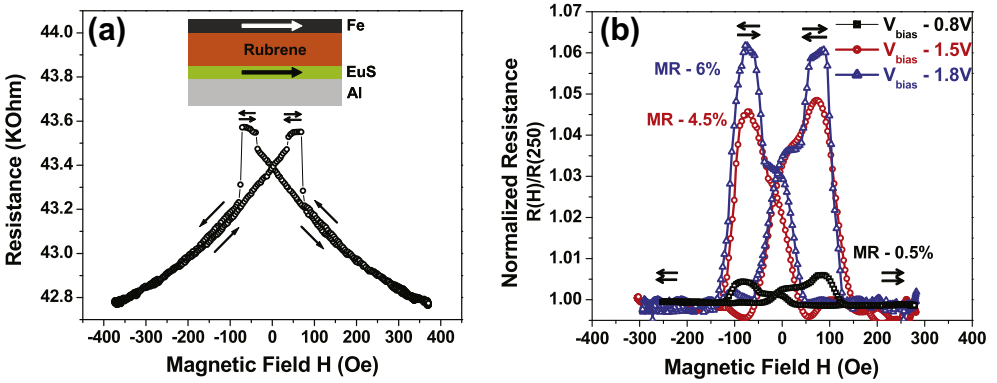

Fig. 2. (a) MR measured for rubrene barrier thickness of 7 nm at 1 K in a quasi-magnetic junction (schematically shown in the inset) having the layer structure: Al (8 nm)/EuS (2 nm)/Rub (x nm)/Fe (12 nm). (b) Increase in MR with applied voltage bias, for a junction with 9 nm rubrene barrier, measured at 1 K. The DC resistance of the device reduced from $\sim$12 MΩ at 0.8 V to $\sim$300 KΩ at 1.8 V.

observed in this device for an applied bias of 1.8 V. The increase in MR at high bias is interesting and will be discussed later.

The current–voltage (I–V) characteristics and the junction resistance of the 9 nm rubrene device as a function of temperature measured at different voltage bias are shown in Fig. 3a. Junctions, where the OS barrier dominated the resistance, showed stronger temperature dependence. The decrease in the junction resistance below ~12 K is attributed to the exchange splitting of EuS below its T_c and the accompanying decrease in the barrier height [11]. These results show good tunneling behavior as well as spin filtering to be occurring, as expected in these junctions. I–V plot shows non-linear behavior with some asymmetry: higher current in the negative bias implying lower injection barrier for electrons coming from the top Fe electrode. This is expected due to the large rubrene molecules that introduce roughness and defect states at the top interface. This can also create magnetic dipolar coupling between Fe and EuS, as observed in Fig. 2b, with magnetic switching starting even before zero field is reached. On increasing the thickness of rubrene to 11 nm, the dipolar coupling between EuS and the top Fe is considerably weakened (see Fig. 3b). As a result, magnetic switching of Fe was sharper and the device resistance only marginally increased near zero field (showing near independent switching of Fe and EuS), improving the device response. In this case, MR ~1.8% peaked at around 1.6 V.

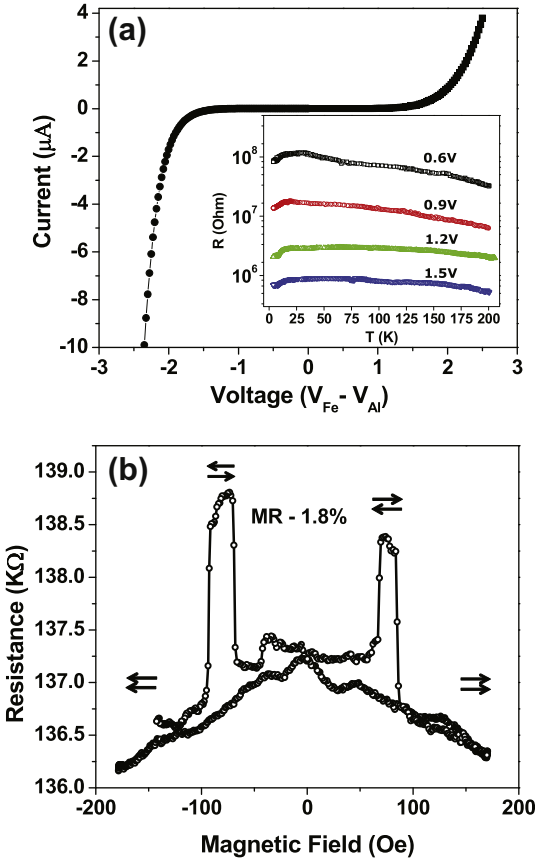

Fig. 3. (a) Non-linear I–V characteristics of the device Al/EuS/Rub (9 nm)/Fe measured at 1 K. Inset: temperature dependence of the junction resistance (semi-log scale) measured at different biases – the slight drop in the resistance at low temperatures shows EuS becoming ferromagnetic below ~12 K. (b) MR measured at 1 K with a bias voltage of 1.6 V for the device: Al/EuS/Rub (11 nm)/Fe.

These junctions showed unconventional dependence of MR with voltage bias (see Fig. 4). In contrast to MTJs having typical FM electrodes, QMJs showed a monotonic decrease in MR with increase in bias-voltage, which can be attributed to excitations of magnons, phonons and band effects [15]. However, in the present case, MR increased from 2% to 6% on increasing the voltage bias from 0.8 to 1.8 V and thereafter it decreased. The bias dependence of the MR was extracted from the I–V measurements in the parallel (300 Oe) and the anti-parallel (80 Oe) magnetization configurations of the junction, using the expression $\mathrm{MR}(V) = [(I_{\mathrm{parallel}}(V) - I_{\mathrm{anti\text{-}parallel}}(V))/I_{\mathrm{anti\text{-}parallel}}(V)] * 100$ and is shown in Fig. 4. The noise at low voltage bias resulted from very high impedances, where the measured currents were extremely small (~ tens of pA). Five sets of samples were measured and three of the devices showed similar bias dependence of MR. However, the peak value of MR varied from 3% to 6% and the position of the maximum MR changed between 1.3 and 1.8 V.

Earlier studies on a quasi-magnetic tunnel junction device without an OS barrier such as Al/EuS/Al_2O_3/Co/CoO have shown similar bias dependence of MR [16]. This MR vs bias behavior has been attributed to Fowler–Nordheim (FN) tunneling mechanism. However, the conduction process in these earlier devices is slightly different to the one reported in the present work. In the earlier study, a thin Al_2O_3 layer (1.2 nm) was used as an insulator spacer layer to magnetically decouple the two FM electrodes, with direct tunneling as the main conduction process. In the present study, a thicker OS (>7 nm) film served as the spacer layer. As a result, multi-step tunneling involving the energy levels in the OS barrier is the expected conduction process. The process of FN tunneling in these QMJs can be understood schematically from the energy diagram shown in Fig. 4. When bias is applied to the junction, voltage drops across rubrene as well as EuS barrier: the voltage drop across the EuS barrier causes its spin-split conduction band to bend. As the bias increases, the band bends sufficiently (with spin-up barrier of EuS falling below the electrode Fermi level) to cause the onset of FN tunneling, resulting in preferential tunneling of spin-up electrons into the organic electronic levels. This leads to enhanced spin-polarized tunneling injection into the organic barrier leading to higher MR signals. Occurrence of the MR peak at higher bias (~1.8 V) compared to the previous report of 1.2 V for the non-OS barrier junctions mentioned before confirm that considerable voltage drops across the rubrene barrier as well. As the applied bias increased further, the spin-down band bends sufficiently to contribute to tunneling and thus reducing the MR. At higher thicknesses of rubrene (>12 nm), the MR was reduced and the signal became weaker and noisier.

In conclusion, our study has shown an alternate method to inject spin-polarized carriers into rubrene, using SF materials. In addition to the observation of MR, it was interesting to find the increase in MR at higher voltage

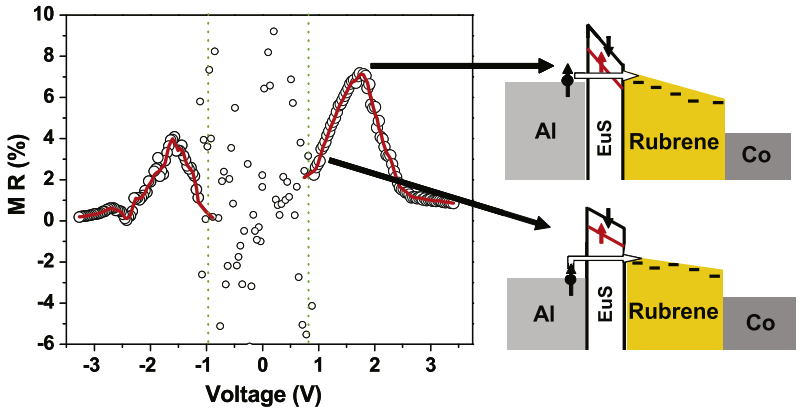

Fig. 4. Left: unconventional bias dependence of MR in a QMJ device with 9 nm rubrene barrier, measured at 1 K. Line through the data is guide to the eye. Data points in between the dotted lines have large fluctuations due to the difficulty in data extraction from *I–V* curves at these low bias regions (current ~100 pA). Tunneling mechanism at low and high bias regions are shown schematically on the right: direct Fowler–Nordheim tunneling at high bias (top) compared to the indirect tunneling at low bias (bottom) of the spin-up electrons into the organic layer.

bias. This could prove important for injecting spin-polarized carriers into organic light emitting diodes close to the device turn-on voltage and in-turn investigate spin-excitonic recombination processes by electroluminescence studies. At present, due to the low T_c of EuS, the observations are confined to low temperature studies. There have been studies on oxide-based ferrites where the possibility of spin filtering at room temperature is shown [17]. It might be worth extending the above investigation to these ferrite materials for achieving the room-temperature operation. Also, if organic molecules having SF properties close to room temperature could be synthesized, it could lead to major advance in organic spintronics.

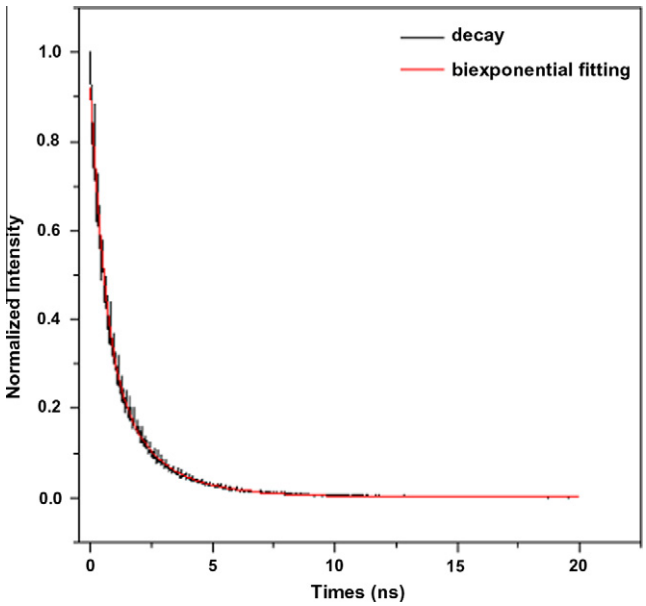

Fig. 3. Time resolved PL decay of Ag–SiO_2–Rb hybrid NPs.

Subsequently, 1.25 mL of 10 mM tetraethyl orthosilicate (TEOS) ethanol solution was added into silver NPs solution every half an hour, and totally 20 mL TEOS solution has been added within 8 h period. The mixture was kept for another 24 h before separation. Finally the silver–silica core–shell NPs were obtained by centrifugation at 3500 rpm for 30 min, washed with ethanol three times and dried in an oven (insert in Fig. 1). The silver–silica core–shell NPs were dispersed into 50 mL anhydrous toluene, 2 mmol silanized rhdoamine B, synthesized in the way reported by Nedelcev et al. [12] and 314 mL (1 mmol) triethoxy(octyl)silane were added into the NPs solution. The obtained mixture was refluxed at 110 °C for 12 h under dry nitrogen. The functionalized NPs were separated from solution by centrifugation, washed with toluene three times and dried in oven overnight. The dark red NPs powder indicates that rhodamine dye was successfully bound to the silver–silica core–shell nanostructure.

The OLED containing hybrid NPs was fabricated as follows (Fig. 2). PEDOT was spin coated on pre-cleaned ITO glass at the speed of 4000 rpm for 40 s. The spin coating method was attempted for hybrid NPs deposition, but only little amount of NPs could be deposited on the slice due to the low viscosity. Therefore a spray method was developed to deposit hybrid NPs. 6 nm bathocuproine (BCP) was sublimated on hybrid NPs by thermal vacuum deposition. Here BCP serves as a hole blocking layer. We did not employ Tris(8-hydroxyquinolinato)aluminium (Alq_3) as electron transport layer in our diodes because the EL of Alq_3 would overlap with the EL of hybrid NPs. Finally, 200 nm aluminum was deposited as cathode.

The absorption spectra were taken with a Lambda 20 UV/Vis spectrometer, and the PL spectra were measured by USB2000-Ocean Optics spectrometer. Atomic force microscope (AFM) image was captured with an Ambios multimode microscope. Current–voltage curves were measured on Keithley semiconductor characterization system. OLED luminance intensity was obtained by a calibrated silicon photodiode (S2281 series, Hamamatsu Photonics).

3. Results and discussion

Fig. 1 shows the UV–Vis spectra measured at each functionalization step, from the bare silver NPs to the final product. The pure silver NPs dispersed in ethanol shows an absorption peak at around 440 nm, which represents

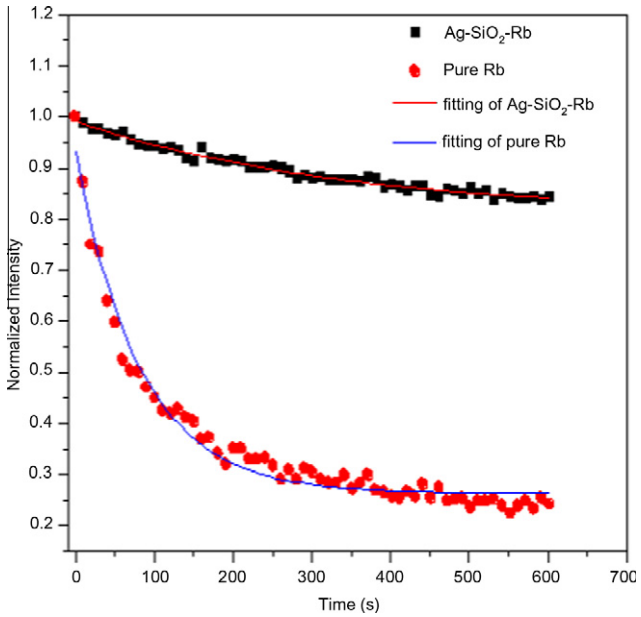

Fig. 4. Photobleaching dynamics of pure rhodamine B and hybrid NPs on glass substrate. Samples were irradiated under 200 mW/cm^2 Nd-YAG laser light at 532 nm.

the typical resonance peak of metallic silver. When the silver NPs are coated by silica, the absorption peak red shifts to 480 nm, this can be attributed to the refractive index change according to Mie theory [13]. With the binding of rhodamine onto silver–silica NPs, the absorption spectrum evolves into a broad hump with absorption maximum around 550 nm which is identical to that of pure rhodamine B. It may result from the superposition between silver NP plasmon and rhodamine B absorption.

We have measured the luminescence lifetime of hybrid NPs, The time-correlated single photon counting PL intensity decay curve shown in Fig. 3 can be fitted with a bi-exponential decay. Two lifetime components 0.58 and 1.96 ns are obtained, while the lifetime of rhodamine B in solution is around 7 ns [14]. The much shorter lifetime component from hybrid NPs can be attributed to metal enhanced fluorescence (MEF) [10]. As known to us the collective oscillation of electrons on the surface of metal results in a localized evanescent electric field (E-field) [15]. According to Fermi's golden rule, the transition probability from one state to another is proportional to the square of the E-field strength which molecule experiences. Thus the surface plasmon induced localized E-field increases the radiative decay rate of the exciton, it means that the electrons in the excited state have larger probability to relax back to ground state via the photoluminescence channel instead of phonon relaxation which is a nonradiative decay. As a result, the photoluminescence quantum efficiency is improved due to surface plasmon effect and consequently fluorescent lifetime is shortened. We attribute the longer lifetime component to the part of the rhodamine molecules which are away from the silver NPs, they thus experience lower E-field enhancement. The 1.07 ns average lifetime implies that hybrid NPs may have better photostability than pure rhodamine B molecules for which degradation channels have larger probability.

We have investigated the photostability of hybrid NPs by recording the PL intensity evolution under the irradia-

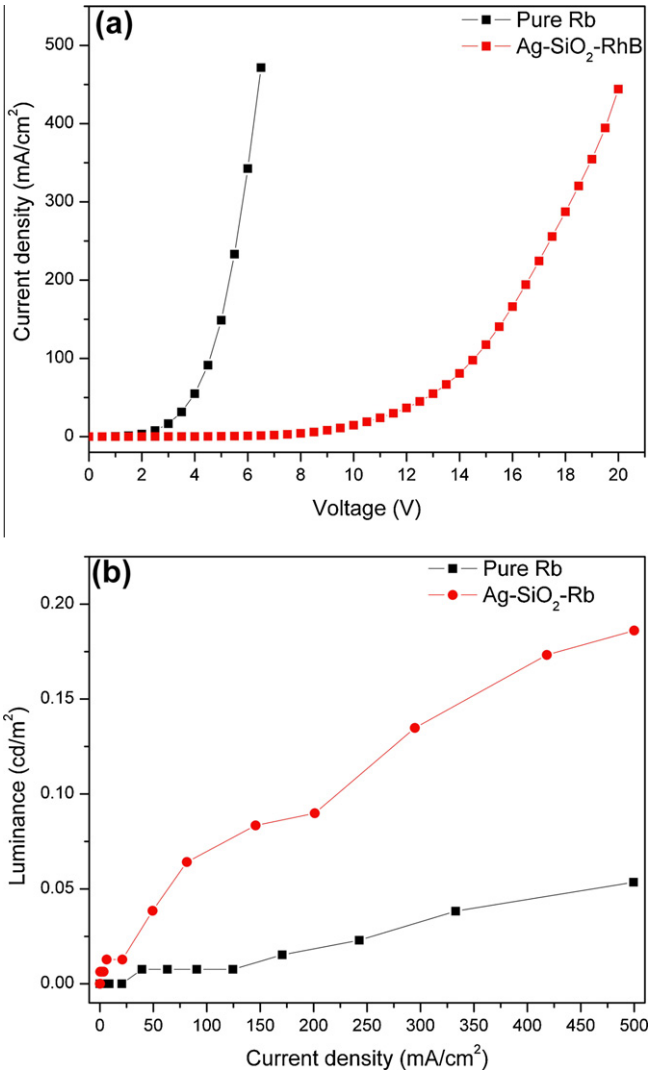

Fig. 6. (a) Current density–voltage curves of OLEDs with pure rhodamine B and hybrid nanoparticles as emitting layer respectively; (b) corresponding luminance–current density curves.

tion with 532 nm laser light (Nd-YAG, 200 mW/cm^2). As shown in Fig. 4 the PL intensity of hybrid NPs degrades to 85% of its original intensity after 600s exposure. While it only takes 10 s for rhodamine B to reach the same intensity decay. This remarkable improvement of photostability indicates that hybrid NPs are a much stable luminescence source which might find potential application in single photon emitting devices.

The AFM profile of spray deposited hybrid NPs on the substrate is shown in Fig. 5. The hybrid NPs have quite even distribution with diameter around 65 nm, and it is clearly observed that the emission layer consists of NPs multilayer, this stacked NPs structure ensures enough thickness for the emission layer and thus prevents the device from current leakage and short circuit.

We have investigated the performance of OLEDs with hybrid NPs and pure rhodamine B as emission layers. Fig. 6a shows the *J*–*V* curves of the diodes, and both of them present very good rectification characteristic. However, the hybrid NPs diode has higher turn-on voltage compared with the pure rhodamine B diode, which can be attributed to deep charge trapping in the hybrid NPs layer. The luminance–current density curves of both diodes are shown in Fig. 6b. We see that the hybrid NPs diode presents much higher luminance intensity compared to pure rhodamine B diode under the same current density, the maximum luminance efficiency of the hybrid NP diode is about 6.8 times larger than that of the rhodamine B diode. This benefits from the surface plasmon enhanced luminescence.

Fig. 7 presents the EL from the hybrid NP OLED. The EL spectrum shows remarkable broadening compared with its PL spectrum. Because the spectral broadening only occurs in the EL experiment, it rules out dimer formation induced spectral broadening that should also be observed in the PL. It is most likely that the spectral broadening originates from charge recombination at an interface. As commonly known, the excitation by an external light source on a bulk material will not induce charge accumulation at an interface since the exciton decay occurs on a nanosecond time scale. However, charge carriers tend to gather at an interface in the EL process due to massive charge injection from electrodes and low mobility in hybrid materials, which offers a considerable probability to form exciplexes [16]. It is also expected that owing to disorder, interface exciplexes will display broad emission spectra. In order to validate that hypothesis, we fabricated another OELD with the same structure except that the hybrid NPs were replaced by concentrated rhodamine B dye, but we failed to observe the spectral broadening. This indicates that the surface plasmon of silver NPs plays an important role in facilitating exciplex recombination at the interface. Indeed, surface plasmons induce an enhanced evanescent E-field which in turn favors exciplex recombination. Direct exciplex luminescence from the LUMO level of rhodamine at −3.5 eV to the depleted HOMO level of PEDOT at −5.1 eV is thus temptatively assigned to the broad emission spectrum in Fig. 7.

In order to investigate charge transport behavior in our OLED structure, we measured time resolved EL as shown in Fig. 8. Electric pulse width was 100 μs, the duty cycle 50%, and both rise and fall time were 1 μs. The bias voltage was set to 15 V and the EL signal was collected by an avalanche single photon detector (APD). There is no obvious delay time t_d observed in the present OLED, which usually corresponds to the charge carrier (holes or electrons) transport time in a diode with thicker organic film. In the present diode structure, holes should reach the NPs layer within a very short time interval since PEDOT is a conductor, meanwhile electrons are injected into the NPs by means of tunneling through the BCP, which is also a fast process. Thus it is understandable that we do not observe any delay time.

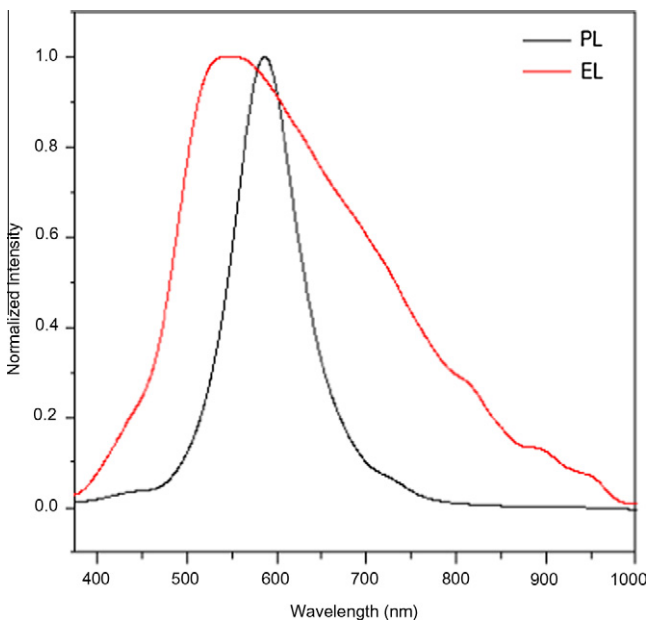

Fig. 7. The PL and EL spectra of OLED with Ag–SiO_2–Rb hybrid NPs.

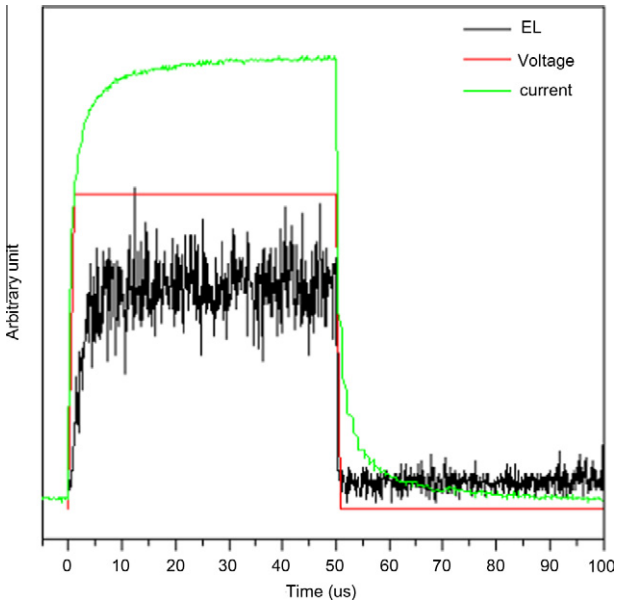

Fig. 8. Time resolved EL of OLED with hybrid NPs.

However, we clearly observe that EL signal takes about 5–6 μs to reach saturation, which is limited by charge carrier dynamics. With the increase of EL signal, the current density also increases. That cannot be explained by the classic capacitor model, in which the current density should decrease along with the accumulation of charge at the interface of organic layers. We interpret our charge transport process as follows: the holes can easily pass through the PEDOT layer and accumulate into the NPs layer due to the BCP hole blocking layer. A space charge induced electrical field builds up, expediting electron tunneling from the aluminum cathode into the NPs layer. As a result, both the current and EL intensity increase. When charge distribution comes to equilibrium, i.e. the minimum hole concentration is established in the hybrid NPs layer, both the current and EL intensity saturate. Finally when the bias voltage is turned off, we can still observe a current decay due to relaxation of the trapped charges inside the diode [17]. However, we do not observe a corresponding EL decay, because the bias voltage falls below the threshold (turn-on) voltage, and no EL can be generated although current flows through the diode.

4. Conclusion

A novel rhodamine dye functionalized Ag–SiO_2 core–shell NPs has been synthesized and applied into OLED as an emitting layer. The EL of hybrid NPs shows much broader spectrum than its PL spectrum. It is observed that the presence of surface plasmon enhanced E-field favors the spectral broadening. This will inspire us to tune OLED electroluminescence, to design and optimize white light OLED from a novel point of view. In addition, much more stable luminescence benefiting from surface plasmon also makes the hybrid NPs a good light source for the study of single photon emission.

broadening and enable the electroluminescence (EL) even in the planar geometry of electrodes [23,24]. Recently we have demonstrated that the LE-OFET based on a polyfluorene (PFO)–ZnO nanoparticles film exhibits very high FET mobility values at high concentration of the ZnO nanoparticles in a unipolar regime [25]. However, the ambipolar regime of the PFO:ZnO LE-OFET was not demonstrated so far. We have focused our attention on the PFO, which is a most promising stable conjugated polymer semiconductor for OLEDs and OFETs active layers and ZnO nanoparticles which is a relatively nontoxic n-type, solution processible inorganic semiconductor. ZnO has extremely high electron mobility (up to ~20 cm^2/Vs [26]), excellent environmental stability, and high transparency [27]. Most recently, solution-processed ZnO FETs were presented with a high electron mobility up to ~5.25 cm^2/Vs [28] and ~7.2 cm^2/Vs [29] and with a high on/off ratio. To reach the ambipolar LE-OFET regime we have decided to use a hybrid structure of composite film consists of n-ZnO and p-PFO semiconductors. The main problem for ambipolar LE-OFETs is the injection of both: electron and holes from the electrodes [7], due to the mismatch in the energy levels of the electrodes and the semiconductors. Injection of holes into the HOMO level of p-type polymer semiconductors can be achieved by using gold electrodes because the HOMO level of many conjugated polymers (~4.8–5.3 eV) and the work function of gold (~5.1 eV) are very close. However, gold electrodes are not appropriate for electron injection into the LUMO level of conjugated polymers due to very high injection barrier of ~2–3 eV [18]. This problem was solved in our present work by using two different metal electrodes (gold and aluminum) with high and low work functions values.

In this article we report on a solution-processed PFO–ZnO nanoparticles composite ambipolar LE-OFET. We have analyzed the behavior of absorption, PL spectra and EL intensity of the PFO:ZnO hybrid films with different ZnO concentration. It was found that by changing the PFO/ZnO nanoparticles concentration ratio the PFO:ZnO LE-OFET shows either unipolar or ambipolar behavior of current–voltage characteristics (I–Vs) and operates in the hole/electron accumulation mode with current saturation behavior. The transistor shows transfer characteristics with a small reversible hysteresis. We have found that for the ambipolar PFO:ZnO LE-OFET with the modest PFO/ZnO nanoparticles ratio (1:0.2) well balanced electron and hole mobility values at 300 K are ~0021 and ~0029 cm^2/Vs respectively, whereas for films with high ZnO nanoparticles concentration (1:1) the mobility (~2 cm^2/Vs) is close to that of polycrystalline ZnO. It was observed that the ambipolar PFO:ZnO LE-OFET emits light at both positive and negative gate bias. The working mechanism of the PFO:ZnO LE-OFET is discussed.

2. Experimental

Fig. 1a and b provides chemical structure of the conjugated polymer poly[9,9-bis-(2-ethylhexyl)-9*H*-fluorene-2,7-diyl] (PFO), used in our experiments and schematic illustration of the polymer–inorganic nanoparticles hybrid FET, which comprise a n-Si/SiO_2/Au/PFO:ZnO/Al structure. An n+ silicon substrate was used with 200 nm thermally grown SiO_2 as gate dielectric with thermally evaporated gold and aluminum electrodes on top. The distance between the electrodes was ~7 μm and the width of the electrode ~1 mm. The conjugated polymer, PFO, and ZnO nanoparticles (diameter ~ 50–70 nm) used in our study were purchased from Sigma–Aldrich and used as received. PFO polymer and ZnO nanoparticles were dissolved and dispersed in chloroform respectively, and then they were mixed together and subjected to ultrasonic treatment for 10 min ($f \sim 22$ kHz). The mixtures with different concentration ratios of components were drop-cast or spin-coated onto a Si substrate. The thickness of the composite films was about ~0.6 μm according to Atomic Force Microscopy (AFM) results. The composite films were dried and heated at 80 °C in N_2 atmosphere for 15 min. The samples for absorption measurements were drop cast onto quartz substrates (the film thickness ~1 μm) and studied by using a Cary-50 (Varian) spectrometer. The detailed microstructure of these films was studied by AFM using P47-Solver NT-MDT. A LGI-21 pulse laser (λ = 337, 1 nm, E_i >10^{-4} J/cm^2, $\tau \sim 10^{-8}$ s) was used to excite the PL. The laser beam was focused onto the sample using the quartz lens (The diameter of the focused beam was ~2–3 mm). The PL spectra and the EL intensity at 300 K were analyzed using a SPM-2 spectrometer (spectral resolution ~2 nm) and a photomultiplier with a spectral sensitivity range 300–850 nm. The PL/EL light collection was about ~100% owing to the use of a special mirror. The I–V characteristics of OFETs were measured in vacuum (3×10^{-3} torr) in the dark at 300 K using a liquid N_2 cryostat holder and a dc electronic computer controlled measuring system with a Keithley 6487 picoammeter/voltage source and AKIP-1124 programmable voltage source. The source – drain and gate voltages were varied between – 40 and +40 V in variable steps. Field-effect hole/electron mobility, μ_{FET}, was calculated using the following equations for the saturation and low field regimes respectively [2]:

$$I_{DS} = (W/2L)\mu_{FET}C_I(V_G - V_{th})^2 \quad (1)$$

$$I_{DS} = (W/L)\mu_{FET}C_I(V_G - V_{th})V_{DS} \quad (2)$$

Here W is the channel width, L is the channel length, C_I is the capacitance per unit area of the SiO_2 layer (for SiO_2 layer thickness of about 200 nm, $C_I \sim 7$–10 nF/cm^2). V_G is the gate voltage, and V_{th} is the threshold voltage, which corresponds to the onset of the strong accumulation regime.

3. Results and discussion

Fig. 2 shows the absorption and PL spectra of the PFO pristine and the PFO:ZnO composite (ZnO concentration ~17 wt.%, 1:0.2) films. It is evident from Fig. 2, the absorption spectra of both: pristine PFO and PFO:ZnO films have maxima at ~380 nm, however in the case of hybrid film this maximum is lower that confirms the presence of weak interaction between the polymer molecules and inorganic nanoparticles. As regards the PL spectra, Fig. 2 shows that

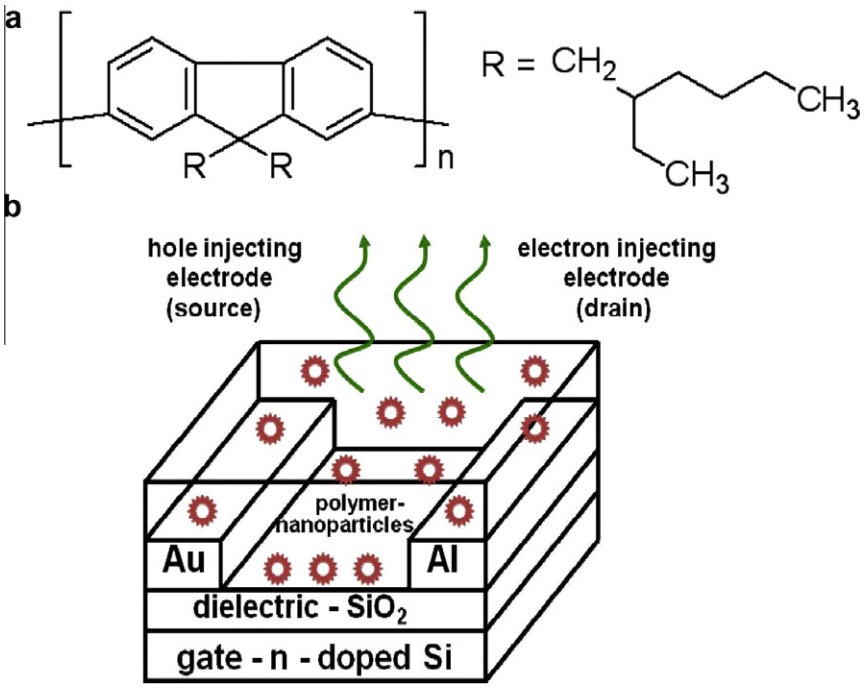

Fig. 1. Chemical structure of the PFO polymer (a) and schematic device structure of PFO:ZnO OFET (b).

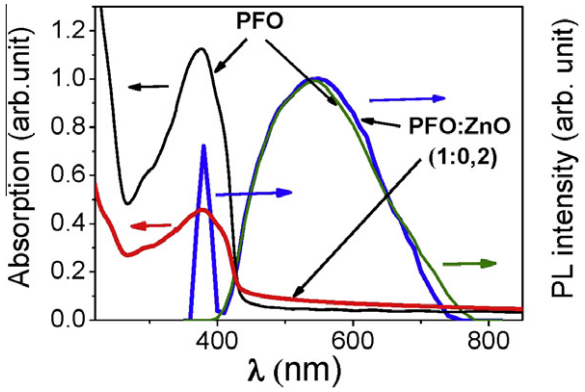

Fig. 2. Absorption and PL spectra of PFO (thin solid lines) and PFO:ZnO (thick solid lines) films. Concentration of the ZnO nanoparticles for PFO:ZnO ~17 wt.% (1:0.2). Film thickness ~0.6 μm.

an introduction of the ZnO nanoparticles results in shifting of the PL maximum from ~580 nm (pristine PFO) toward the ultraviolet (hybrid PFO:ZnO) spectral region. The increase of the ZnO nanoparticles concentration leads to an increase of intensity of the PL peak at 380 nm related to the emission of the ZnO nanoparticles. There are no distinct signs of complexes formation in visible spectral region that can be explained by high values of the ionization potential I_D of PFO (I_D >8.2 eV), which results in relatively weak interaction between the PFO molecules and ZnO nanoparticles.

Fig. 3a–c shows the AFM micrographs of pure PFO and PFO:ZnO (1:0.2) films between Au and Al electrodes on a n-Si/SiO_2 substrate. It is worth noting that the channel length of ~7 μm is much larger with respect to the diameter of the ZnO nanoparticles ~50–70 nm. As can be seen from Fig. 3a, detailed AFM surface examination indicates rather smooth pure PFO film structure. Introduction of the ZnO nanoparticles into the PFO matrix results in very rough composite film structure with few pinholes throughout the film between Au–Al electrodes (Fig. 3b and c). There are a number of the ZnO nanoparticles aggregates with a diameter of about several hundreds nm despite the PFO–ZnO solution was subjected to ultrasonic treatment before deposition. The presence of the ZnO nanoparticles aggregates can affect the I–Vs of OFETs and therefore they can influence the μ_{FET} (300 K) values as will be shown below.

Typical output I–V characteristics of the LE-OFET based on PFO:ZnO nanoparticles film (1:0.2) with a channel length of ~7 μm and a channel width of ~1 mm operated at different gate voltages in vacuum are displayed in Fig. 4a and b. It is evident from Fig. 4a, the PFO:ZnO OFET exhibits the output I–V characteristics for the hole-enhancement mode of a OFET with nearly saturation behavior. As can be seen from Fig. 4b, the output characteristics for the electron-enhancement mode at positive gate voltages are rather similar to those of the hole-enhancement mode. Fig. 4a and b, demonstrate that the saturated drain currents of I–Vs are not flat completely due to probably leakage currents between source and gate electrodes at high gate-to-source voltage (V_G). Moreover, there is a sharp increase of the source-drain current, I_{DS}, in the output characteristics at rather high V_{DS} >25 V at modest V_G for the PFO:ZnO LE-OFET structures (see inset to Fig. 4a) similar to that found for other LE-OFETs [13,18]. This indicates the onset of electron (negative V_G) or hole (positive

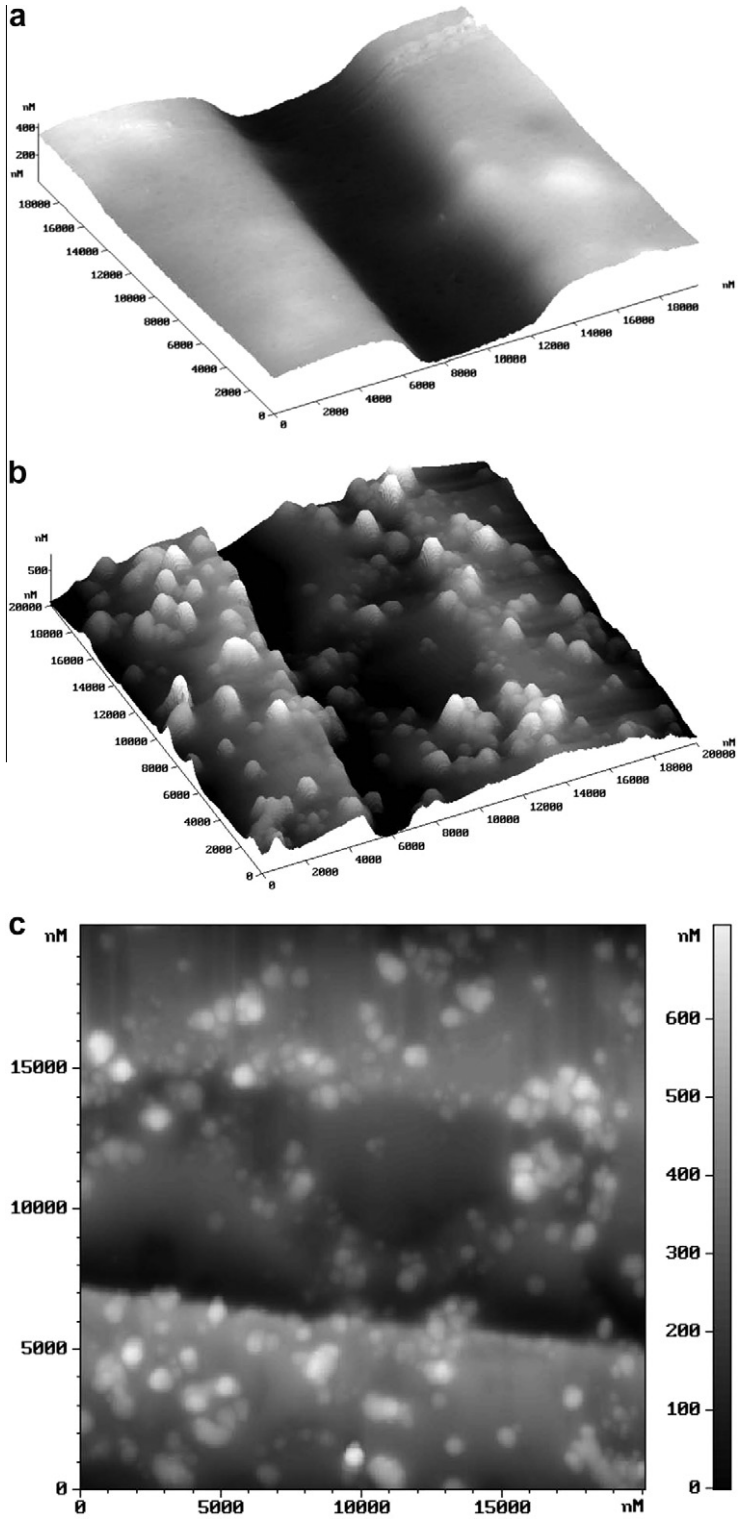

Fig. 3. AFM micrographs of PFO (a) and PFO:ZnO (b and c) films between Au–Al electrodes. Concentration of the ZnO nanoparticles ~17 wt.%.

V_G) transport. Such a behavior correlates well with numerical modeling results which predict an indication of the ambipolar regime by a superlinear current increase on top of a significant saturation current [30]. The transfer characteristic for the same device in the saturation regime for positive and negative gate voltage is shown in Fig. 4c.

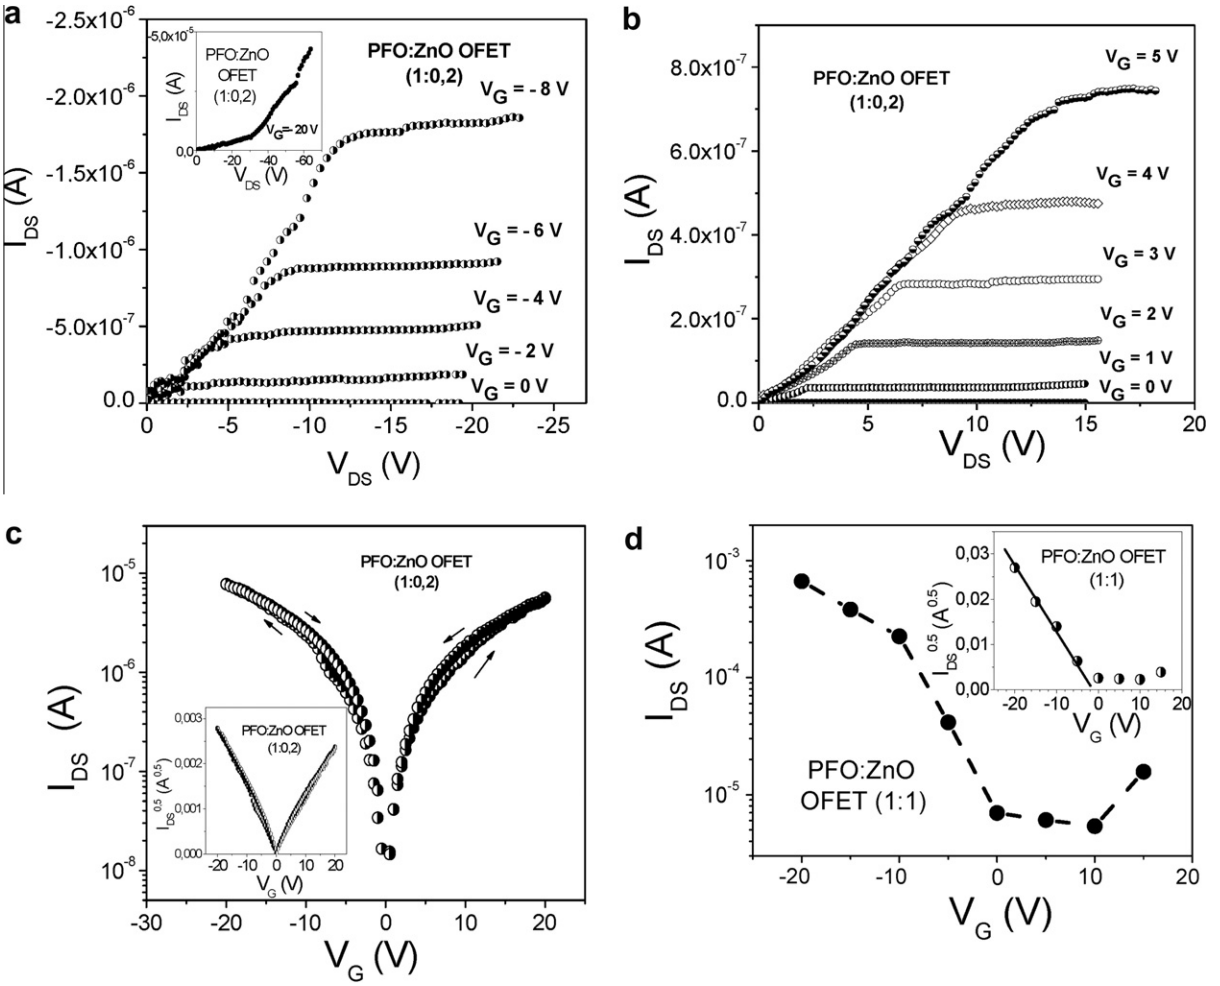

Fig. 4. (a) Output I–V characteristics of the PFO:ZnO OFET (1:0.2) at 300 K for different negative V_G; (inset) output I–V characteristics for the same sample at high V_{DS} >20 V and $V_G = -20$ V; (b) output I–V characteristics of the PFO:ZnO OFET (1:0.2) at 300 K for different positive V_G; (c) Transfer characteristic of the PFO:ZnO OFET (1:0.2) at 300 K for $V_{DS} = -10$ V; (inset) $I_{DS}^{0.5}$ versus V_G for the same sample; (d) transfer characteristic of the PFO:ZnO OFET (1:1) at 300 K for $V_{DS} = -10$ V; (inset) $I_{DS}^{0.5}$ versus V_G for the same sample.

The gate-to-source voltage was swept between +20 V to −20 V at 0.5 V step with a constant drain voltage $V_{DS} = -10$ V. Fig. 4c clearly shows both electron and hole accumulation regimes for the PFO:ZnO OFET with relatively low ZnO nanoparticles concentration (1:0.2). The PFO:ZnO OFET shows the transfer characteristics with a small reversible hysteresis. Electron and hole field-effect hole mobility, μ_{FET}, was calculated for the saturation and low field regimes according to Eqs. (1) and (2). For the PFO:ZnO OFET (1:0.2) shown in Fig. 4a and b, the threshold voltages V_{th} estimated from the slope of the $I_{DS}^{0.5}$ versus V_G plot at $V_{DS} = -10$ V were found to be about ∼−0.2 and ∼+0.2 V for negative and positive V_G, respectively (Fig. 4c). Therefore electron and hole mobility values at 300 K for this OFET estimated according to Eq. (1) were found to be ∼0021 and ∼0029 cm^2/Vs, respectively. The μ_{FET} (300 K) values estimated for the same sample using Eq. (2) are of the same order of magnitude. On/off ratio determined for this device from the transfer characteristics was found to be in the range of $\sim 10^3$ for $V_G \sim -20$ V, but it is obviously higher for higher V_G values. As the concentration of the ZnO nanoparticles increases the transfer plot of the PFO:ZnO OFET becomes asymmetric that indicates the transition to the unipolar regime (Fig. 4d). For such PFO:ZnO OFET (1:1), shown in Fig. 4d, we observed the $V_{th} \sim -1$ V and on/off ratio $\sim 10^2$ for $V_G = -20$ V. The μ_{FET} (300 K) values calculated for this PFO:ZnO OFET (1:1) using Eq. (1) at $V_G = -20$ V and $V_{DS} = -10$ V were found to be unusually high and reached the value of ∼2 cm^2/vs. These results demonstrate that on/off ratio decreases whereas the μ_{FET} (300 K) value increases significantly with increase of concentration of the ZnO nanoparticles. The observed rather low threshold voltages and on/off ratios indicate a low concentration of trap states as well as low injection barriers at the contacts. The obtained mobility values for PFO:ZnO OFET (1:0.2 and 1:1) are much higher than those observed in our experiments and reported in the literature for pure PFO OFETs (∼4×10^{-4} cm^2/Vs [12]). We have suggested that the μ_{FET} (300 K) values obtained in our experiments for PFO:ZnO OFET with modest ZnO nanoparticles

concentration (~17 wt.%) reflects the contribution to charge transport from both p- and n-components of the PFO:ZnO film. The μ_{FET} (300 K) at high ZnO nanoparticles concentration is mostly related to the mobility of ZnO nanoparticles, which may form some bridges or thin ZnO layers between Al–Au electrodes, according to our AFM data (Fig. 3b and c). This suggestion correlates well the μ_{FET} (300 K) values obtained by other authors for the polycrystalline ZnO (~20 cm^2/Vs [26]) and for the ZnO FETs (up to ~7.2 cm^2/Vs [29]).

The optical output characteristics (EL intensity versus V_{DS}) at different negative and positive gate voltages of the ambipolar PFO:ZnO LE-OFET (1:0.2) are shown in Fig. 5. We found that the EL intensity at 300 K is increasing with increasing of source – drain, V_{DS}, and both: negative and positive gate voltages, V_G, at nearly saturated drain currents. It is worth noting that the EL intensity measured at the same conditions of the PFO:ZnO LE-OFET with high ZnO nanoparticles concentration (1:1) is higher by factor of 3 with respect to that of the PFO:ZnO LE-OFET (1:0.2), but it has been observed at negative values of V_{DS} and V_G only. That correlates well with an increase of the ZnO nanoparticles concentration that affects strongly the EL intensity. There is the almost fixed onset of the light EL emission at $V_{DS} \sim -5$ V independent of the ZnO nanoparticles concentration and the gate voltage polarity. This onset have been observed even for gate voltages up to −60 V, where the only intensity of the emitted light changes after application of V_G (Fig. 5). This behavior is similar to that observed earlier for tetracene and pure PFO LE-OFETs [11,12], but in our case of the PFO:ZnO LE-OFET the onset of the V_{DS} values is lower significantly. Inset to Fig. 5 presents the EL intensity vs electric field for the PFO:ZnO LE-OFET (1:0.2) at different spectral regions: I_0 – integral; I_1 – 600–830 nm; I_2 – 450–620 nm; I_3 – 300–400 nm. It is evident from these data that the EL emission of the PFO:ZnO LE-OFET (1:0.2) takes place mainly in the green spectral region. In particular, for the PFO:ZnO LE-OFET (1:0.2) it reaches ~40% of the integral EL intensity, whereas the EL emission intensity in the blue region reaches ~20% of the integral EL that correlates with the PL spectra of such composite films (Fig. 2). The same result was obtained for the PFO:ZnO LE-OFET (1:1). The mechanism for the formation of the excited states in the PFO:ZnO composite films implies the presence of a LUMO–HOMO recombination channel in the PFO polymer as well as the contribution of UV excitonic emission (at ~380 nm) from radiative recombination in the ZnO nanoparticles. The latter channel can be suppressed by changing the concentration of ZnO nanoparticles [24]. The PL line observed at 550 nm (Fig. 2) corresponds to the excimer emission from the original polymer aromatic (fluorene) fragments.

Our results demonstrate that the light output of the PFO:ZnO LE-OFET is controlled by the ZnO nanoparticles concentration and the gate voltage. To determine the charge carrier injection mechanism one can consider the energy band diagram of the Au–PFO:ZnO–Al structure shown in Fig. 6. It is evident from this band diagram that the work functions for Au and Al are ~5.1 and ~4.3 eV, respectively, compared with the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels of PFO of ~5.8 and ~2.1, respectively [31]. Therefore the injection barrier for holes in Au–PFO is ~0.7 eV and for electrons in Al–PFO is ~2.1 eV. From another side the conduction and valence bands energy levels of ZnO are ~7.5 and ~4.2 eV, respectively. That makes the injection barrier for electrons in Al–ZnO of about ~0.1 eV. It is clear evident from these values that the structure Au–PFO:ZnO–Al should work as ambipolar LE-OFET, that is in good agreement with our experimental results for PFO:ZnO LE-OFET with modest concentration of the ZnO nanoparticles (1:0.2). It is worth noting that some signs of ambipolar transport manifest themselves even for high mobility unipolar PFO:ZnO LE-OFETs (1:1) but at relatively high values of positive V_G only (see Fig. 4d). The reason why the hole accumulation mode still dominates in the unipolar regime of the PFO:ZnO LE-OFET with high concentration of ZnO nanoparticles is not clear completely. One may suggest that this behavior

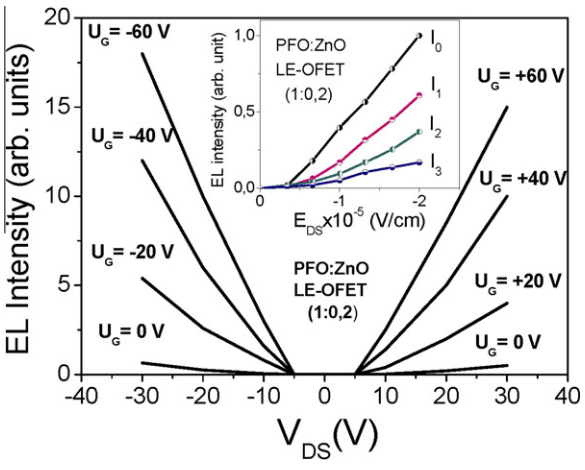

Fig. 5. Optical output characteristics of the PFO:ZnO LE-OFET (1:0.2): EL intensity versus V_{DS} at different V_G at 300 K. (Inset): EL intensity vs electric field for the PFO:ZnO LE-OFET (1:0.2) at different spectral regions: I_0 – integral; I_1 – 600–830 nm; I_2 – 450–620 nm; I_3 – 300–400 nm.

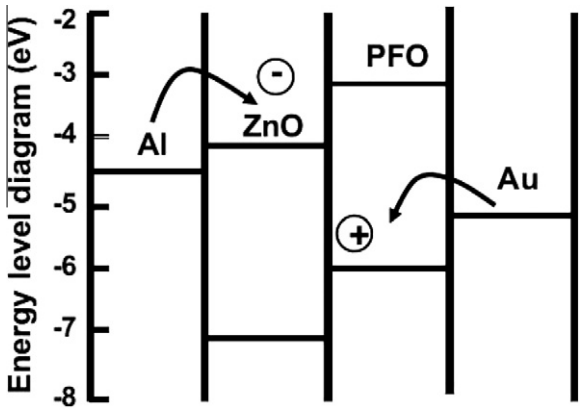

Fig. 6. Band diagram of the Au–PFO:ZnO–Al composite structure.

is due to absence of the robust electrical contact between ZnO nanoparticles and Al/Au electrodes.

As regards the model for the light emission mechanism for the composite active layer LE-OFET, it has been developed recently by Schidleja et al. [21,32]. Follow this model we suggest that for the PFO:ZnO LE-OFET the light emission in the unipolar p-type regime is due to a stable reservoir of electrons established in the PFO in the vicinity of the Al contact. Since the work function of Al and PFO differ, a charge transfer occurs after contact formation and a constant electrochemical potential across the contact is the consequence. The diffusion of electrons from the metal into the organic semiconductor is stopped by the self-induced electric field of the transferred charge. Thus, a reservoir of excess electrons establishes close to the Al contact. In the unipolar p-type regime accumulated holes flow from the Au electrode to the Al electrode. At the Al contact they can either be ejected in the metal or recombine with the electrons of the reservoir. Therefore light emission can be observed even in the unipolar p-type regime of the LE-OFET. Switching from the unipolar to the ambipolar transport regime the position of the charge carrier recombination zone can be moved through the channel from one contact to the other [16,18,21,32]. In the ambipolar regime the charge carrier recombination takes rather place at the polymer/dielectric and polymer/ZnO nanoparticle interfaces than at the contacts. Consequently, the position of the recombination zone is moved from the metal/polymer interface to the polymer/dielectric and polymer/ZnO nanoparticle interfaces by changing the transport regime from unipolar to ambipolar. One may suggest that the spatial heterogeneity of the PFO:ZnO LE-OFET channel affects strongly the EL emission and the electrons and holes injections from different electrodes (Al and Au) is not completely balanced especially at high concentration of the ZnO nanoparticles. The results demonstrate that LE-OFETs based on solution processible polymers such as PFO and semiconducting nanoparticles such as ZnO provide a good example of the multifunctional devices obtained by the deposition technique compatible with up-to-date printed organic electronic technology.

4. Conclusions

We have investigated the solution-processed PFO–ZnO nanoparticles composite light-emitting organic field-effect transistor. We have analyzed the behavior of absorption, PL spectra, EL intensity and I–Vs of the PFO:ZnO hybrid films with different ZnO nanoparticles concentration. The field effect mobility of charge carriers depends on ZnO concentration. It was found that by changing the PFO/ZnO nanoparticles concentration ratio the PFO:ZnO OFET shows either unipolar or ambipolar behavior of I–Vs (at high and low ZnO nanoparticles concentration, respectively) and operates in the hole/electron accumulation mode with nearly current saturation behavior. The FET mobility of charge carriers in PFO:ZnO films depends on ZnO concentration and at high concentration of the ZnO nanoparticles it is close to the mobility of polycrystalline ZnO. The observed ambipolar regime for the PFO:ZnO LE-OFET with relatively low ZnO nanoparticles concentration makes these devices useful for applications in complementary logic circuits.

PHOLEDs. A previous report showed that high triplet energy electron transport material improves the quantum efficiency of vacuum-deposited blue PHOLEDs by exciton and charge confinement [16]. The high triplet energy material can also confine excitons and charges inside the emitting layer and enhance the quantum efficiency of soluble blue PHOLEDs.

In this study, a high triplet energy exciton blocking material, diphenylphosphine oxide-4-(triphenylsilyl)phenyl (TSPO1), was deposited on a PVK:FIrpic blue emitting layer and the device performance was investigated. A high quantum efficiency of 19.4% at 20 cd/m^2 was achieved in the soluble blue PHOLEDs using TSPO1 as the electron transport type exciton blocking material. In addition, solution processed three-color white PHOLEDs were also fabricated and a quantum efficiency of 12.3% at 119 cd/m^2 was demonstrated. This study revealed that the solution-processed blue PHOLEDs can show the same quantum efficiency as vacuum deposited blue PHOLEDs by confining the triplet excitons and blocking holes, which could not be realized in other studies. This is the first demonstration of ~20% external quantum efficiency in solution-processed blue PHOLEDs.

2. Experimental

The basic device configuration of indium thin oxide (ITO)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate (PEDOT:PSS, 60 nm)/PVK: iridium(III) bis(4,6-(di-fluorophenyl)-pyridinato-*N*,C′) picolinate (FIrpic) (66 nm, 15%)/TSPO1(x nm)/LiF (1 nm)/Al (100 nm) was used to evaluate the TSPO1 as the exciton blocking material for solution processed blue PHOLEDs. The thicknesses of the TSPO1 were 25, 30, 35 and 40 nm. The device structure of the white PHOLEDs was ITO/PEDOT:PSS (60 nm)/PVK:FIrpic: tris[2-(p-tolyl)pridine]iridium(III)(Ir(mppy)$_3$): iridium(III) bis(2-phenylquinoline) acetylacetonate (Ir(pq)$_2$acac) (70 nm, 15%, *x*%, 0.5%)/TSPO1 (30 nm)/LiF (1 nm)/Al (100 nm). The doping concentrations of the Ir(mppy)$_3$ in the white PHOLEDs were 1% and 0.3%. Fig. 1 shows the chemical structure of TSPO1 and the device structures of blue and white PHOLEDs. The PVK emitting layer was spin coated from toluene solution at a concentration of 1.5 wt%. The spin coated PVK layer was baked at 80 °C from 20 min to remove the residual solvent. TSPO1 was deposited by vacuum evaporation. The current density (*J*)–voltage (*V*)–luminance (*L*) characteristics and electroluminescence (EL) spectra of the devices were measured using a Keithley 2400 source measurement unit and a Minolta CS 1000 A spectroradiometer. The Lambertian distribution of light emission was observed in all devices and the quantum efficiency was calculated based on the Lambertian distribution of light emission.

3. Results and discussion

A high triplet energy and deep highest occupied molecular orbital (HOMO) level of the electron transport materials are important for confining the holes and triplet excitons inside the emitting layer. The TSPO1 has a high triplet energy of 3.36 eV and a HOMO level of 6.79 eV [16]. The triplet energy of the TSPO1 was much higher than

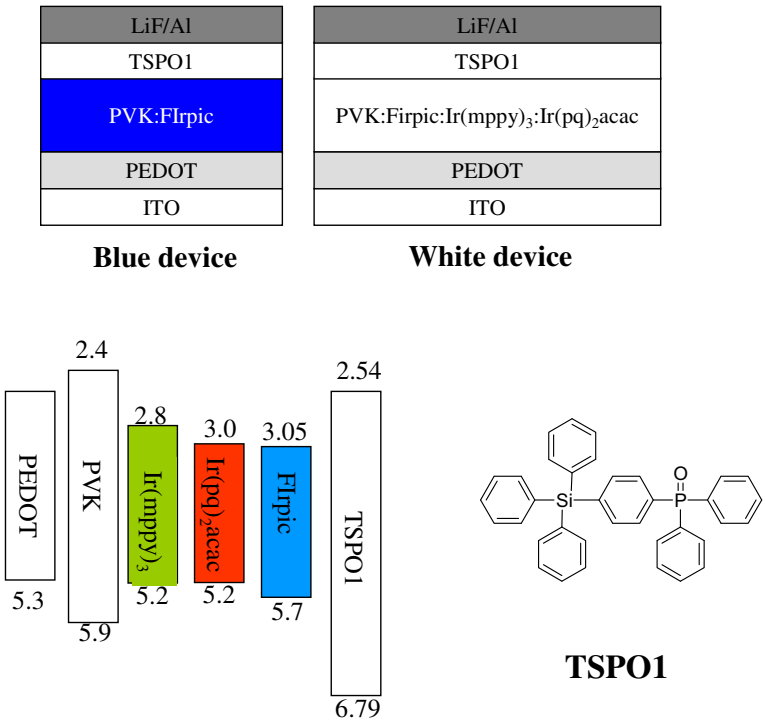

Fig. 1. Device structures of the blue and white PHOLEDs. Energy level diagram of the PHOLEDs is also shown in this figure.

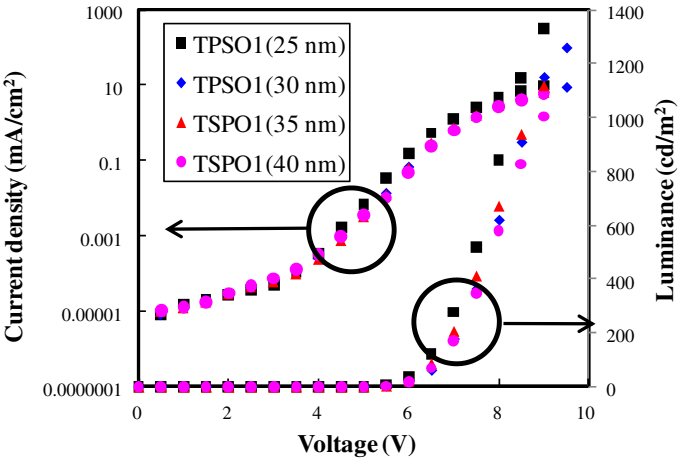

Fig. 2. Current density–voltage–luminance curves of the blue PHOLEDs with TSPO1 exciton blocking layer according to TSPO1 thickness.

that of the common blue phosphorescent dopant and the HOMO level was deep enough to block hole injection from the common host materials. Therefore, TSPO1 was efficient as an electron transport type exciton blocking material in blue PHOLEDs. As the TSPO1 was effective as an electron transport layer, it can also improve the quantum efficiency of the solution processed blue PHOLEDs by blocking the holes and confining the triplet excitons.

The TSPO1 was applied as the electron transport type exciton blocking material in PVK based blue PHOLEDs. Fig. 2 shows the current density–voltage–luminance curves of the PVK based blue PHOLEDs. The thickness of the TSPO1 exciton blocking layer was changed from 25 to 40 nm to optimize the device performance. The current density was high in the PVK blue PHOLEDs with 25 nm TSPO1 exciton blocking layer and decreased with increasing TSPO1 thickness. The luminance was also high in the PVK blue PHOLED with a 25 nm thick TSPO1 layer but the luminance of the blue PHOLED with a 30 nm thick TSPO1 layer was lower than that of the blue PHOLED with a 35 nm thick TSPO1 layer. This suggests that the recombination efficiency of the blue PHOLED with a 35 nm TSPO1 layer is better than that of the blue PHOLED with a 30 nm TSPO1 layer.

Fig. 3 shows the quantum efficiency–luminance curves of the blue PHOLEDs. The quantum efficiency of the PVK devices increased with increasing thickness of the TSPO1 layer. The maximum quantum efficiency of the blue PHOLEDs with 35 nm thick TSPO1 layer was 19.4% at 20 cd/m^2 and the quantum efficiency at 1000 cd/m^2 was 11.2%. This quantum efficiency is one of the best efficiency values reported in solution-processed blue PHOLEDs (15.5%) [11]. The high quantum efficiency of the blue PHOLEDs can be explained by the hole and triplet exciton blocking properties of TSPO1. TSPO1 has a high triplet energy of 3.36 eV for triplet exciton blocking and a HOMO level of 6.79 eV for hole blocking. The triplet energy of the FIrpic dopant in PVK layer is 2.65 eV and the triplet exciton quenching of the FIrpic by the TSPO1 layer is suppressed. Hole leakage from the PVK emitting layer to the TSPO1 layer is also blocked by the TSPO1 layer because of the high energy barrier for hole injection from the HOMO of PVK (5.9 eV) to the HOMO of TSPO1. Fig. 1 shows the energy level

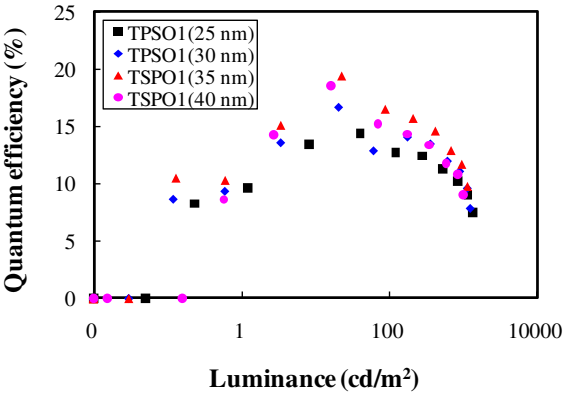

Fig. 3. Quantum efficiency–luminance curves of the blue PHOLEDs with TSPO1 exciton blocking layer according to TSPO1 thickness.

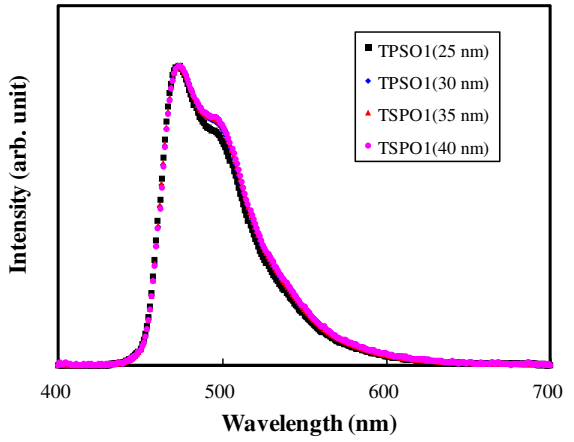

Fig. 4. Electroluminescence spectra of the blue PHOLEDs with TSPO1 exciton blocking layer according to TSPO1 thickness.

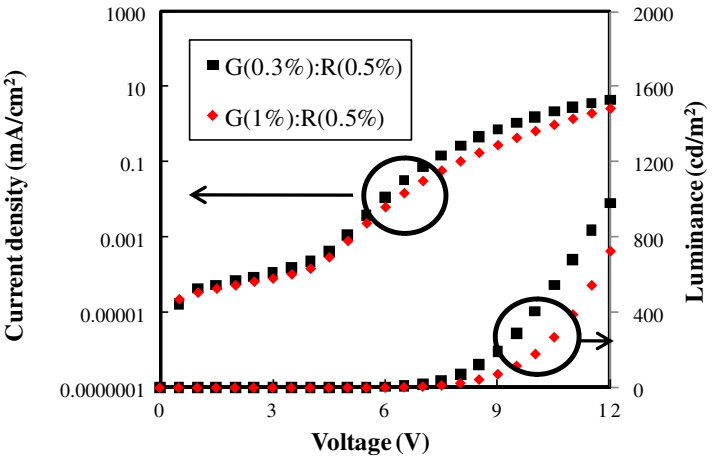

Fig. 5. Current density–voltage–luminance curves of the white PHOLEDs with TSPO1 exciton blocking layer.

diagram of the blue PHOLEDs. In addition to the hole and triplet exciton blocking effect, efficient electron injection from the TSPO1 layer to the PVK emitting layer contributes to the high quantum efficiency of the blue PHOLEDs. The LUMO level of PVK is 2.4 eV, whereas the LUMO level of TSPO1 is 2.54 eV. The energy barrier for electron injection is between PVK and TSPO1 only 0.14 eV, which facilitates electron injection from TSPO1 to PVK. The LUMO level of common electron transport materials is in the range, 2.8–3.2 eV, and the energy barrier for electron injection is 0.4–0.8 eV [13]. Therefore, the reduced energy barrier for electron injection improved the electron injection, enhancing the quantum efficiency of blue PHOLEDs. The maximum current efficiency of the blue PHOLEDs with a 35 nm thick TSPO1 layer was 35.9 cd/A at 20 cd/m^2 and the current efficiency at 1000 cd/m^2 was 20.4 cd/A. The color coordinates of the blue PHOLEDs were (0.15, 0.34). The efficiency of the solution processed PVK:FIrpic device was improved by more than 50% using the TSPO1 exciton blocking layer [14].

Fig. 4 shows the electroluminescence (EL) spectra of the blue PHOLEDs with TSPO1 exciton blocking layer. All devices showed similar EL spectra, even though the vibrational peak of the blue PHOLEDs with the 30, 35 and 40 nm thick TSPO1 layer was intensified slightly by the optical effect. The maximum emission wavelength of the blue PHOLEDs was 472 nm and no emission peak from the electron transport layer was observed. The color coordinates of the solution processed blue PHOLEDs were (0.15, 0.34).

As the TSPO1 was effective as an electron transport type exciton blocking layer in blue PHOLEDs, it was applied as an exciton blocking layer in PVK-based white PHOLEDs. Three color PHOLEDs with red, green and blue phosphorescent dopants were fabricated. The doping concentration of the blue dopant was fixed to 10% and the doping concentration of the red dopant was 0.5%. The doping concentrations of the green dopant were 0.3% and 1.0%. Fig. 5 shows the device performance of the white PHOLEDs. The current density and luminance of the white PHOLED with a 1% Ir(mppy)$_3$ doping concentration were lower than those of

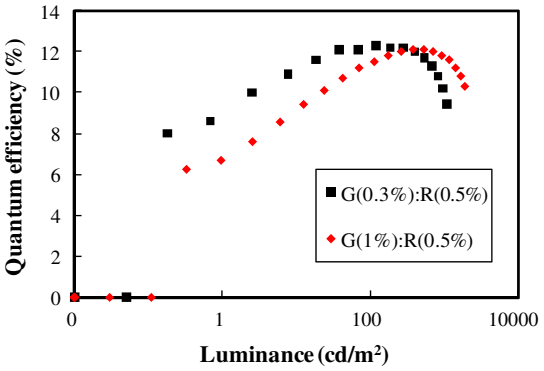

Fig. 6. Quantum efficiency–luminance curves of the white PHOLEDs with TSPO1 exciton blocking layer.

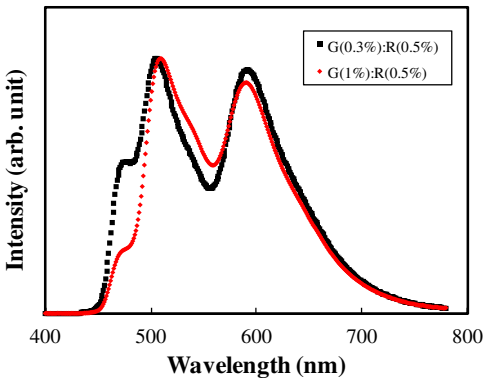

Fig. 7. Electroluminescence spectra of the white PHOLEDs with TSPO1 exciton blocking layer.

the white PHOLED with a 0.3% Ir(mppy)$_3$ doping concentration because of the charge trapping effect by the green dopant. The green dopant traps both holes and electrons, reducing the current density of the white PHOLED at a 1% doping concentration. The current density and

luminance of the white PHOLEDs were lower than those of the blue PHOLEDs due to charge trapping by the green and red dopants.

Fig. 6 presents the quantum efficiency–luminance curves. The maximum quantum efficiency of the white PHOLEDs with 0.3% Ir(mppy)$_3$ and 0.5% Ir(pq)$_2$acac was 12.3% at 119 cd/m^2 and the quantum efficiency at 1000 cd/m^2 was 10.0%. The color coordinates of the white PHOLED were (0.39, 0.45). Similar quantum efficiency was observed in the white PHOLEDs with 1.0% Ir(mppy)$_3$ and 0.5% Ir(pq)$_2$acac. The TSPO1 exciton blocking layer improved electron injection and enhanced the charge balance of the emitting layer, resulting in high efficiency white PHOLEDs. The current efficiency was slightly high in the white PHOLEDs with 1% Ir(mppy)$_3$ because of the stronger green emission, as shown in the electroluminescence spectra (Fig. 7). The maximum current efficiency of the white PHOLEDs was 28.2 cd/A at 544 cd/m^2 and a high current efficiency was kept at 1,000 cd/m^2. The current efficiency at 1000 cd/m^2 was 27.4 cd/A. The color coordinates of the white PHOLEDs with 1% and 0.3% Ir(mppy)$_3$ doping concentration were (0.40, 0.49) and (0.37, 0.44), respectively. The green and red emission was intensified at high Ir(mppy)$_3$ concentrations due to more energy transfer from the blue emitting FIrpic to the green dopant, resulting in a color shift at a 1% Ir(mppy)$_3$ doping concentration.

4. Conclusions

The TSPO1 exciton blocking layer was effective in improving the quantum efficiency of the solution processed blue and white PHOLEDs. A high quantum efficiency of 19.4% and a high current efficiency of 35.9 cd/A were achieved in the solution processed blue PHOLEDs with a PVK:FIrpic emitting layer. The efficiency was one of the best efficiencies reported in the solution-processed blue emitting layer. In addition, high efficiency solution-processed white PHOLEDs with a quantum efficiency of 12.3% were also fabricated using the TSPO1 exciton blocking layer. Therefore, TSPO1 is promising as an electron transport type exciton blocking layer in solution-processed PHOLEDs.

fields were extracted using the nucleation-limited-switching (NLS) model [15]. We found that for the electric field range evaluated, the activation field increases faster for higher electrical field stress. Only a small frequency dependence on the activation field is observed. The suppression of switchable polarization after fatigue (1 million switching cycles) remains at approximately 10% of the total initial switching polarization. There is little dependence on the stress voltage or frequency of the electric field used for fatigue characterization.

2. Experimental

The films were prepared using P(VDF-TrFE) copolymer powder with a 70/30 M ratio (Hisense Electronics Co., China) without further purification. The copolymer powder was dissolved in 2-butanone at a concentration of 2.5 wt.%. The solution was then spin-coated on photo-lithographically patterned Cr/Au contacts. The films were dried and annealed at 120 °C for 2 h in vacuum (approximately 20 Torr). The resulting films showed an RMS roughness of 1.8 nm, as measured using atomic force microscopy (AFM, DM09 Veeco), and a thickness of approximately 100 nm (measured by a Dektak profilometer). Next, gold is thermally evaporated as the top contact. Both the copolymer film and top contact are patterned using photolithography. Details of the fabrication process can be found in [16].

The hysteresis loop of the MFM capacitor is measured using a 1 Hz triangular wave. The switching and nonswitching polarization (P_{sw} and P_{ns}), as well as the switching kinetics are measured using the Positive Up Negative Down (PUND) method [17,18]. The time delay between each pulse is set to 1 s. All measurements use a virtual ground circuit (RT66B, Radiant Technology).

3. Results and discussions

In an FeRAM memory circuit, the two states (“0” and “1”) are read and differentiated by using the switching and nonswitching polarization (P_{sw} and P_{ns}). Therefore, it is important to study the effects of repeated switching between P_{sw} and P_{ns}. MFM capacitors with a size of 5×10^{-4} cm^{-2} were first stressed by using square wave pulses with a frequency of 500 Hz at a voltage of 14 V. Fig. 1a shows the results using the PUND method to characterize the P_{sw} and P_{ns} in both positive and negative directions. Voltage pulses used for the PUND characterization were the same as those used for stressing the devices [19]. P_{sw} begins to decrease after 10^4 switching cycles. After 10^6 switching cycles, P_{sw} is at 87% of its initial value whereas P_{ns} remains unchanged. The symmetric results of P_{sw} and P_{ns} indicate that the devices evaluated show no preference in polarization direction. The hysteresis loop was also measured at 1 Hz and 14 V before and after fatigue (Fig. 1b). The switching polarization is approximately 88% of its initial value, in agreement with the PUND measurements shown in Fig. 1a. The coercive voltage increases from 5.3 to 8.9 V (corresponding to coercive fields of 0.53 MV/cm and 0.89 MV/cm, respectively).

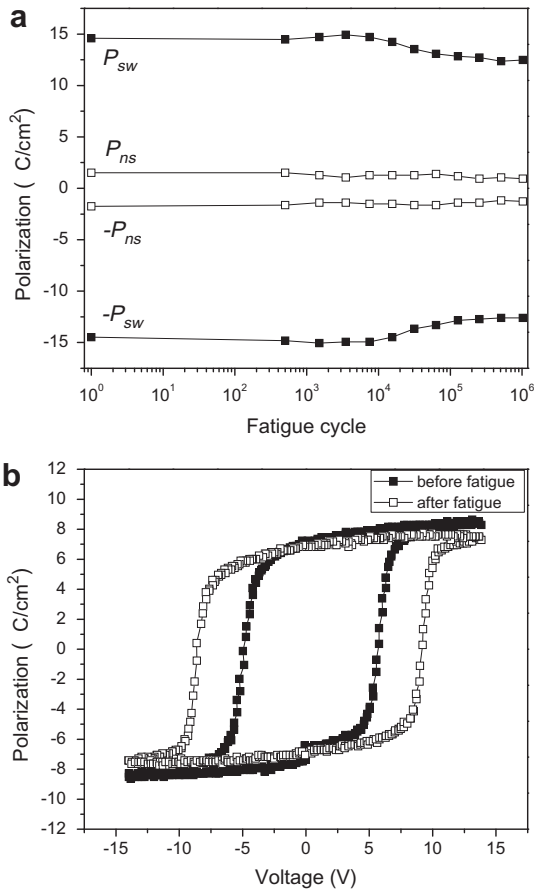

Fig. 1. The degradation of switching and nonswitching polarizations in positive and negative directions as a function of stress cycle at 14 V and 500 Hz (a), and the hysteresis loop measured at 14 V and 1 Hz before and after one million switching cycles (b). The P(VDF-TrFE) film thickness is 100 nm.

The effects of fatigue on the polarization switching kinetics are presented in Fig. 2. Fig. 2a corresponds to the study of P_{sw} and P_{ns} measured with pulse widths swept from 0.1 ms to 1 s. Plots A and B represent the measurements using 14 V pulses before and after fatigue, respectively. After fatigue, no switching is observed for films measured at pulse widths of 0.1 ms, and a decrease of approximately 10% of the initial maximum switching polarization is observed for all other pulse widths. Plot C in Fig. 2a shows that by increasing the PUND voltage pulse to 16 V for characterizing the P_{sw} and P_{ns} after fatigue, P_{sw} partially recovers. The observed increases in P_{sw} and P_{ns} at pulse widths >100 ms are likely due to the large D.C. conductance for high voltage and low frequency [20]. Fig. 2b shows the P_{sw} and P_{ns} measured by sweeping the pulse voltage from 4 to 14 V. Plots A and B were obtained using 500 Hz (1 ms pulse width) pulses before and after fatigue, respectively. After fatigue, the voltage needed to initialize the switching polarization increases from 8 to 12 V. Increasing the pulse width to 10 ms after fatigue results in a lower switching voltage, approximately 11 V (plot C).

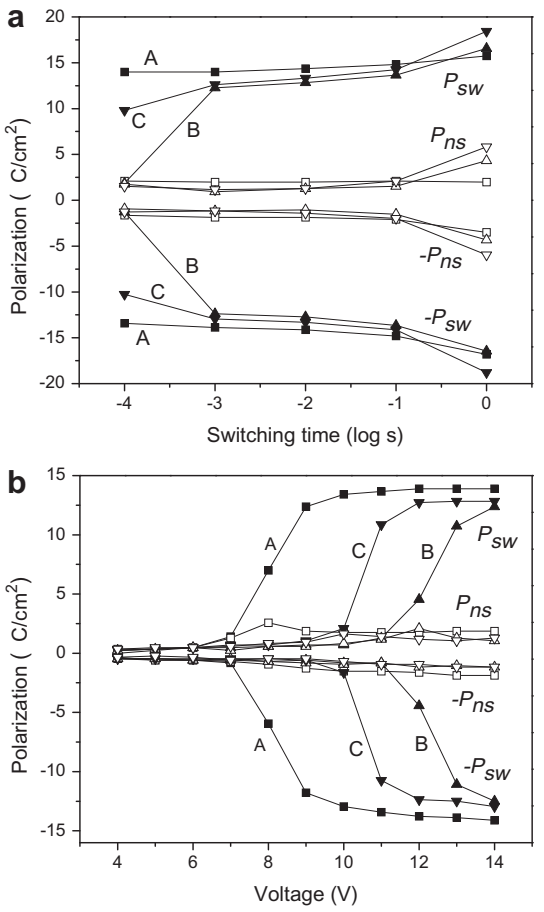

Fig. 2. The switching and nonswitching polarizations in positive and negative directions as a function of applied pulse width (a) and voltage (b) before and after fatigue. In (a), plot A and B are measured at 14 V before and after fatigue, and plot C is measured at 16 V after fatigue. In (b), plot A and B are measured at 1 ms pulse width before and after fatigue, and plot C is measured at 10 ms pulse width.

The results shown in Fig. 2a and b demonstrate that repeated switching of the MFM capacitors during stress induces an increase in both switching time and voltage. The activation fields were extracted by using the nucleation-limited-switching (NLS) model [15]. The activation field increases from 10.6 MV/cm for a new MFM capacitor to 15.6 MV/cm after 10^6 switching cycles at 14 V and 500 Hz. It is important to mention that the decrease in saturation polarization (10%) observed in both the hysteresis loop and PUND measurements does not recover with increasing voltage or pulse width. This is defined as the suppression of switchable polarization [21].

Fatigue properties as a function of stress voltage and frequency for P_{sw} and P_{ns} in both the positive and negative directions were also studied using identical MFM capacitors with a size of 3.0×10^{-4} cm^2. In Fig. 3, which shows the voltage dependence, all the plots correspond to MFM capacitors stressed and characterized at 1000 Hz with different voltages. Plots A and B represent the MFM capacitors stressed at 12 and 10 V pulses, respectively, with both characterized at 10 V. For $<10^4$ switching cycles, the P_{sw} for both conditions reach saturation. However, as the number of stress cycles increases, plot A decreases first, indicating a larger induced degradation compared to plot B. The recovery of the P_{sw} from plot A to D as the characterization voltage increases to 12 V indicates that this portion of the degradation of P_{sw} is due to an increase in the switching activation field leading to incomplete switching at lower voltage after fatigue. For devices characterized at 12 V, the one stressed at 14 V (plot C) shows faster degradation compared to the one stressed at 12 V (plot D). As the characterization voltage increases to 14 V, the results move from plot C to plot E. These results indicate that a higher stress voltage causes a larger increase in the activation field.

In order to determine the frequency dependence, all the devices were stressed and characterized at 12 V. The P_{sw} and P_{ns} of devices stressed at 1000 and 5000 Hz, with both characterized using 5000 Hz, are plotted in Fig. 4 as plot A and B, respectively. A larger induced P_{sw} degradation was observed for plot A, indicating a larger induced fatigue effect for lower frequency stressing. However, when the characterization frequency is decreased to 1000 Hz, P_{sw} increases from plot A to D, indicating that this loss of P_{sw} is also mainly due to the increase in the switching activation field. For plot C and D, MFM capacitors stressed at 200 Hz show a slightly larger degradation of P_{sw} compared to the one stressed at 1000 Hz, but the capacitors partially recover when they are measured at a lower frequency (200 Hz), as shown in plot E.

In order to study the increase of the activation field and the suppression of switchable polarization at different fatigue voltages and frequencies, the switching kinetics of the MFM devices before and after fatigue in each condition were characterized. P_{sw} was measured as a function of pulse width, and the activation field for each set of stress conditions was extracted from the data using the NLS model. The stress voltage and frequency dependence of the activation field are shown in Tables 1 and 2, respectively. It is found that as the stress voltage increased from 10 to 14 V for 1000 Hz pulses, after 1 million switching cycles, the activation field increased from the initial value of 10.6 to 13.6 MV/cm and 15.6 MV/cm, respectively. The activation field is less dependent on the stress frequency.

The suppression of switchable polarization was extracted using the PUND technique using 100 ms pulses with the same stress voltages as were used for each fatigue condition. The mean values of P_{sw} in both positive and negative directions as a ratio of the initial P_{sw} are plotted vs. fatigue voltage and frequency in Fig. 5. It is found that, after one million switching cycles, the suppression of switchable polarization for all characterized fatigue conditions reaches a constant value, which is approximately 10% of the initial switching polarization value.

Fang et al. reported that for 68/32 P(VDF-TrFE) copolymer film (not stretched) based MFM capacitors, electrical stress increases the degree of the film crystallinity [13]. This is because the electromechanical coupling from the repeated rotation of the H–F dipoles within the copolymer chain along the *c* axis in the A.C. electric field results in a higher oriented chain morphology, creating a longer range ordering of β phase. Therefore, the energy barrier required

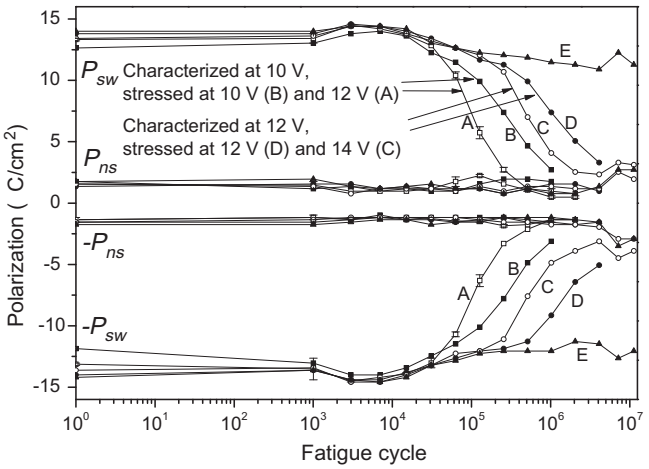

Fig. 3. The voltage dependence of the switching and nonswitching polarizations vs. electrical stress cycles at 1 kHz. Plot A and B are for the devices characterized at 10 V, and electrical stressed at 12 and 10 V, respectively. Plot C and D are for the devices characterized at 12 V, and electrical stressed at 14 and 12 V, respectively. Plot E represents the device characterized and stressed at 14 V.

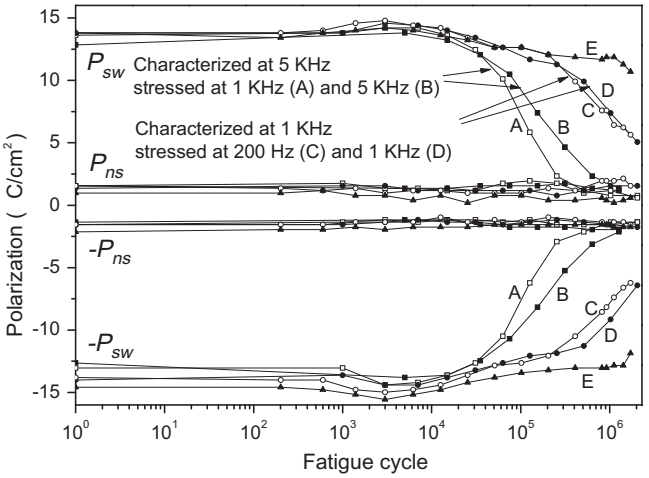

Fig. 4. The frequency dependence of the switching and nonswitching polarizations vs. electrical stress cycles at 12 V. Plot A and B are for the devices characterized at 5 kHz, and electric stressed at 1 and 5 kHz, respectively. Plot C and D are for the devices characterized at 1 kHz, and electrical stressed at 200 Hz and 1 kHz, respectively. Plot E represents the device characterized and stressed at 200 Hz.

Table 1
The increase of the activation field for fatigue at different voltages.

Fatigue voltage (V)	Fatigue frequency (Hz)	Activation field before fatigue (MV/cm)	Activation field after fatigue (MV/cm)	Number of fatigue cycle (Million)
10	1000	10.6	13.6	~1.0
12			14.8	
14			15.6	

Table 2
The increase of the activation field for fatigue at different frequencies.

Fatigue frequency (Hz)	Fatigue voltage (V)	Activation field before fatigue (MV/cm)	Activation field after fatigue (MV/cm)	Number of fatigue cycle (Million)
5000	12	10.6	14.6	~1.2
1000			14.8	~1.0
200			15.2	~1.7

for switching the dipole and the coercive field increase due to the stronger interchain coupling. The increased degree of crystallinity corresponds to a higher activation field [15]. This agrees with our data and explains the increased activation field after fatigue. In addition, a higher stress electric field induces a larger increase of the crystallinity [22], explaining the voltage dependence of the activation field in our data.

For the suppression of switchable polarization after fatigue, Warren et al. reported that in a PZT thin film system with Pt electrodes, it is due to electronic charge trapping or ionic defects. The relative roles of electronic or ionic charge

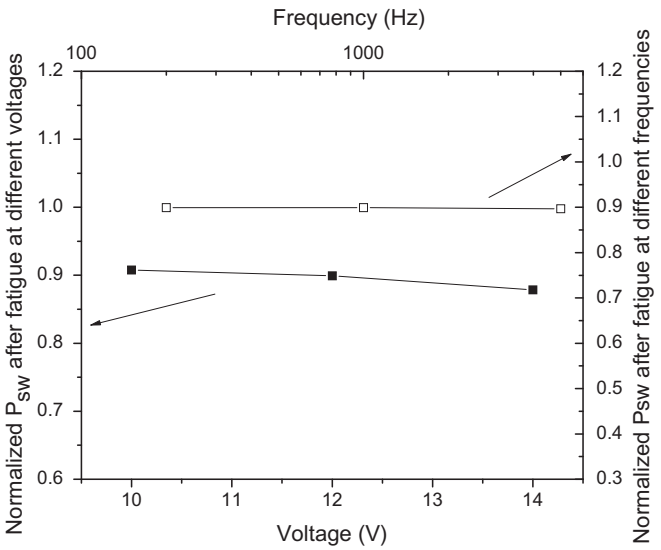

Fig. 5. The normalized switching polarization after approximately one million switching cycles at different stressed voltage and frequency conditions. The devices are characterized using 100 ms pulses in each fatigue condition. The loss of switching polarization represents the suppression of switchable polarization.

defects depend on the material [21]. As an external electric field is applied between the two contacts on the ferroelectric film, charges are injected into the film and localized on trap sites (impurities, vacancies, domain boundaries, etc.). In the repeated polarization switching process, due to the strong interaction between the dipoles and the trapped charges in the film, the trapped charges tend to redistribute through the ferroelectric film and lock the domain walls, and eventually prevent the domains from switching. The inhibition or locking of the opposite polarization at the electrode-ferroelectric interfaces also corresponds to a decrease of the switching dipoles [9,13]. Therefore, the number of switchable dipoles decreases during repeated switching, corresponding to a decrease of switchable P_{sw}. This charge injection could be one of the major contributions to the origin of the suppression of switchable polarization after fatigue in our data.

4. Conclusion

We have studied the electrical fatigue effects of P(VDF-TrFE) copolymer based MFM capacitors using different stress voltages and frequencies. The switching kinetics was studied before and after fatigue. The increase of the activation field of the switching polarization can be explained by an increase in the degree of film crystallinity. The suppression of switchable polarization is possibly caused by trapped charges. A higher stress electric field causes a larger increase of the activation field. The activation field is less dependent on the stress frequency. The nonswitching polarization stays low throughout the characterization range. The amount of suppression of switchable polarization after approximately 1 million stress cycles for the characterized voltage and frequency ranges is approximately 10% of the initial switching polarization. It is demonstrated that in certain working conditions, our optimized MFM capacitors can switch with limited polarization degradation, which is compatible with flexible electronics.

its many advantages, this approach is widely used to fabricate low voltage, high performance organic FETs [14,17].

To make useful devices, the electrical stability/reliability of organic FETs is another important parameter, which has not yet reached the stage of the practical use. After a much dedicated research, it has been found that employing a FET structure with dual dielectric is an efficient way to enhance the device stability, where they would compensate both dielectrics' drawbacks, for example, the buffer dielectric forms few defects at the interface but has a low electrical strength/dielectric constant, while high-k gate insulator uses low voltage but has poor interface [14]. A proper buffer dielectric also can depress the absorption of moisture at the dielectric interface and the penetration of oxygen into OSCs, thus further retarding device characteristics decay throughout its shelf-life and operating life. In order to characterize its significance, application of a gate bias is normally utilized. Zhang et al. [19] showed that FET devices of polycrystalline pentacene with polystyrene (PS) buffer dielectric and Al_2O_3 gate insulator exhibited a steady current output ($I_{ds}(t)/I_{ds0} > 95\%$) and little threshold voltage shift ($\Delta V_{th} < 0.1$ V) upon gate-bias stress at $V_{gs} = V_{ds} = -10$ V for 1 h in a N_2-filled glovebox (O_2, $H_2O <$ 1 ppm). It is comparable to or even better than that of a-Si FETs, ascribing to the excellent interface of PS and its lack of dipole moments. Good device stability now can be achieved, but not to the point of having no degradation for a more prolonged period of time, e.g. more than a year. Usually, the shift of the threshold voltage is one of manifestations of device degradation, which was proposed to arise from the following factors: (i) charging/polarization of gate dielectric and changes in dielectric constant over time; (ii) the presence of oxygen, moisture, chemical impurities and light irradiation etc.; and (iii) intrinsic structural and energetic disorder of organic semiconductors (OSCs) and/or specific structural defects [20–29]. Despite the wide range of possible dielectric-dielectric combinations, it should be pointed out that trapping states at the surface of gate insulator actually still exist but are simply shielded from carriers' access, when a polymeric buffer dielectric is used for surface passivation. Previously, Ng et al. [29] investigated the influence of different gate insulators by the charge injection from the gate electrode, and water ion movement on the stability of PQT-based FETs with pMSSQ buffer dielectric. However, the effect of buried trapping states on the device stability, especially under applied extrinsic stimulus, is still lack of in-depth study.

In this work, we studied the electrical stability of both p- and n-channel FET devices, in which the gate insulator SiO_2 is modified by poly(methyl methacrylate) (PMMA). The bottom layer of the bilayer dielectrics investigated in this study is thermally oxidized SiO_2 grown on n^{++}-Si due to the material's high chemical stability and excellent insulating properties with extremely low current leakage, which would minimize the effect of charge injection from the gate electrode. More importantly, a large amount of Si–OH silanol groups tend to be present on the SiO_2 surface, leading to electrochemical trapping of electrons, when thermal SiO_2 is grown at 800–1000 °C [15]. On the other hand, the selection of trap-free PMMA buffer dielectric is motivated by its hydrophobic methyl radical groups that can serve as moisture inhibitors and the absence of hydroxyl groups, providing a defect-free high-quality interface [14,17,30]. In the present study, both electrical and optical signals are utilized to trigger the response of these buried trapping states in ambient condition, which can be manifested by the shift of threshold voltage. It was reported that although moisture causes charge trapping, trap formation was only observed after negative bias stress in pentacene flip-crystal FETs [27], and thus had little impact on studying how these buried traps were approached by minority carriers in our devices shown below.

2. Experimental

Organic FET devices were fabricated with a top-contact configuration. A heavily doped n-type silicon wafer and 500 (or 200)-nm thermally oxidized SiO_2 were used as a gate electrode and gate dielectric layer, respectively. Before being processed, the substrates were cleaned by acetone and IPA in an ultrasonic bath and rinsed in deionized-water. The substrates were then dried using a nitrogen gun. The PMMA buffer dielectric was spin-coated from the solution in anisole and the thickness was evaluated by a Dektak surface profilometer. Pentacene and C_{60} were deposited onto the PMMA/SiO_2 surface by high-vacuum thermal evaporation at room temperature and deposition rates were controlled at 0.5 Å s^{-1} and 1 Å s^{-1}, respectively. The gold (Au) and aluminum (Al) used as the source–drain contacts for pentacene and C_{60} FETs, respectively, were thermally evaporated through a shadow mask. The channel length (L) and width (W) were 0.1 and 2 mm, respectively.

In the bilayer insulators, PMMA buffer dielectric acts as part of the dielectric layer during the device operation. The capacitance (C_i) of the devices can be calculated using the following equation:

$$\frac{1}{C_i} = \frac{1}{C_3} + \frac{1}{C_P} = \frac{t_3}{\varepsilon_0 \varepsilon_3} \frac{t_P}{\varepsilon_0 \varepsilon_P}, \quad (1)$$

where t_s and t_P are the thickness of SiO_2 dielectric layer and PMMA buffer dielectric, respectively; ε_s and ε_P are the dielectric constants of SiO_2 dielectric layer and PMMA buffer dielectric, respectively.

The electrical characterization of the devices was measured using a Keithley 4200 SCS semiconductor parameter analyzer under ambient condition at room temperature on a standard probe station with or without light illumination. The visible light illumination was used for the study of photo-induced charge transfer, shining at the top surface of the device from a halogen lamp and focused to a spot size approximately equal to the area of the device to cover the entire channel with an estimated light intensity of 1 mW cm^{-2}. AFM images were obtained using a Nanoscope IIIa AFM (digital instrument) in tapping mode.

3. Results and discussion

3.1. Electrical characteristics in dark condition

The pentacene FET with 10 nm PMMA buffer dielectric (see Fig. 1a) exhibits unipolar p-channel field-effect

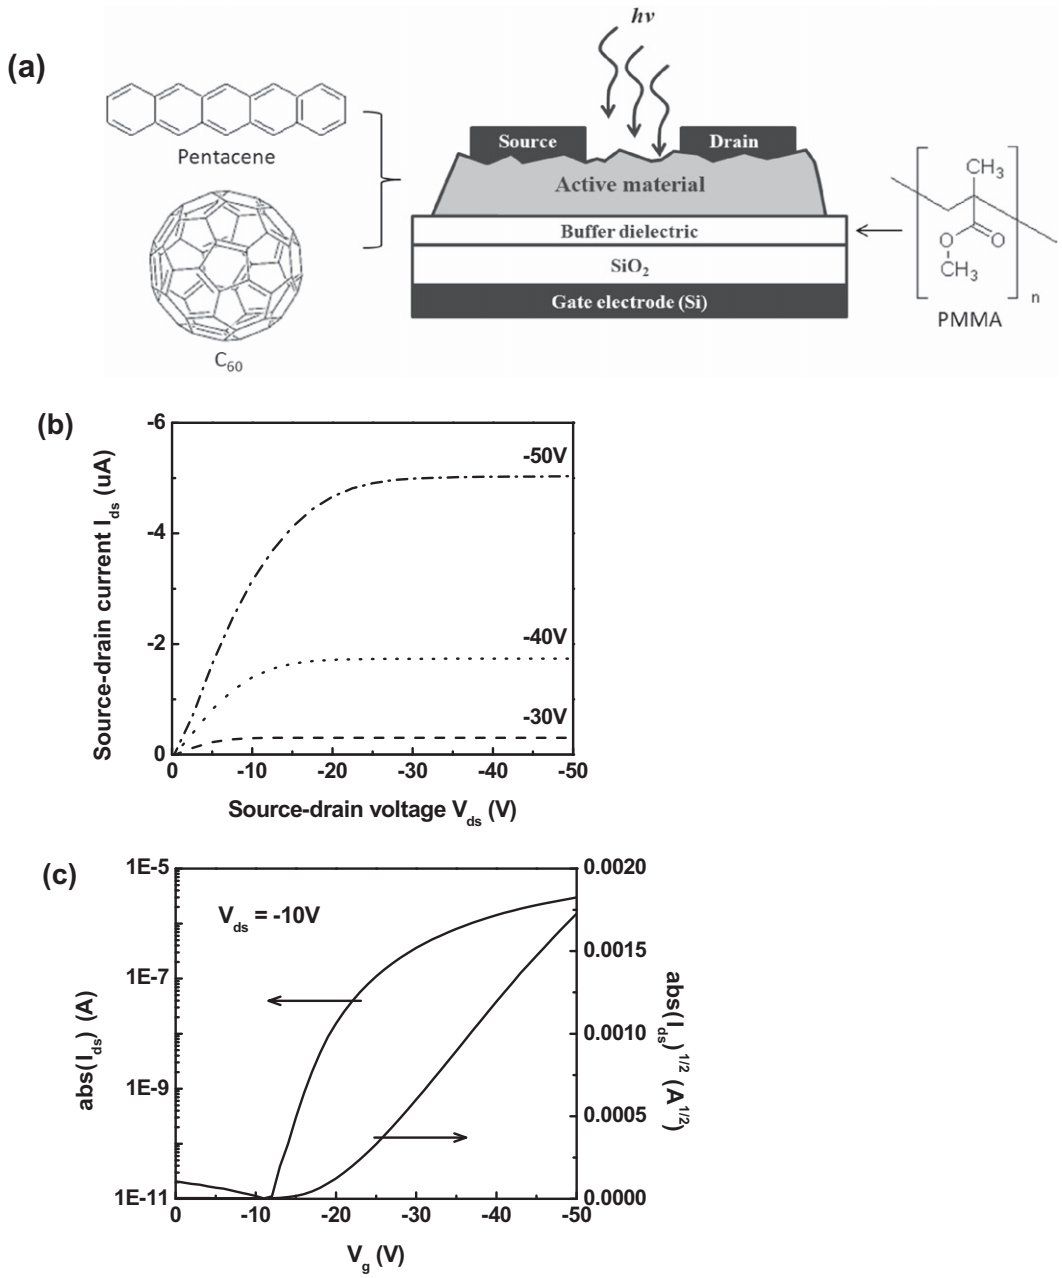

Fig. 1. (a) A schematic cross-section of the organic FET presented in this study, (b) the output and (c) transfer characteristics of pentacene FETs with PMMA buffer dielectric.

behavior, i.e. hole accumulation in the channel, as seen from the output characteristics in Fig. 1b. The output characteristics show two distinct regions of device operation: linear and saturation. In the linear region (also known as the ohmic mode), the FETs operate like a resistor, controlled by the gate voltage related to both the source and drain voltage. The source–drain current is modeled as:

$$I_{ds} = \frac{W}{L}\mu C_i\left[(V_g - V_{th})V_{ds} - \frac{V_{ds}^2}{2}\right], \tag{2}$$

where W and L are the channel width and length, μ is the charge carrier mobility, C_i is the gate dielectric capacitance per unit area, V_g is the applied gate-to-source bias, V_{ds} is the applied drain-to-source bias, and V_{th} is the threshold voltage described as follows [31]:

$$V_{th} = V_{fb} + 2\psi_b + \frac{\sqrt{2\epsilon_s q N_a(2\psi_b)}}{C_i}, \tag{3}$$

$$V_{fb} = \phi_{ms} - \frac{Q_f}{C_i}, \tag{4}$$

where ψ_b is the potential difference between the Fermi level E_f and the intrinsic Fermi level E_i of the semiconductor, ϵ_s is the permittivity of the semiconductor, q is the charge

of electron, N_a is the density of the acceptor, ϕ_{ms} is the potential difference the metal gate and semiconductor bulk at zero gate bias, and Q_f is the interface charge. When $V_g > V_{th}$ and $V_{ds} > (V_g - V_{th})$, the accumulated layer in the channel is pinched off, as indicated by the lack of channel region near the drain. The drain current is now weakly dependent on drain voltage and controlled primarily by V_g, and modeled approximately as:

$$I_{ds} = \frac{W}{2L}\mu C_i (V_g - V_{th})^2. \quad (5)$$

Using the above equations, several key parameters of FET devices can be extracted from transfer and output characteristics, as summarized in Table 1.

It is known that V_{th} can be shifted through the change in the density of charge at the interface. In order to investigate this effect, the device characteristics were measured after programing with a gate bias at $V_{ds} = 0$ V for various durations. When a negative bias was applied to the gate, the shift in transfer curves increased with increasing bias time, as shown in Fig. 2a. A shift in V_{th} as large as 8 V was obtained after programing with a gate bias of $V_g = -200$ V for 500 ms, indicating that a great number of field-induced holes were trapped. It suggested that device failure would occur when the device operates successively at "ON" state. This phenomenon is generally observed when SiO_2 is employed as the gate dielectric, which is proposed to result from structural defects present in polycrystalline pentacene film and/or hole trapping states due to absorbed water molecules on the SiO_2 surface [26,32]. When the device was programed with positive gate bias, the shift in transfer curves was hardly observed as shown in Fig. 2b and the inset of Fig. 4b. Compared with the devices with bare SiO_2 [15,33], our devices appeared to be more immune to V_{th} shift caused by positive bias, which actually is a preferred feature for practical application of organic integrated circuits (ICs). It can be proposed that such a feature results from: (i) the charge injection barrier provided by the 10 nm-thick PMMA layer, which hinders the field-induced minority carriers (electrons) from being captured by the surface silanol groups; (ii) the large electron injection barrier between Au and pentacene; (iii) the low electron carrier density in the p-type pentacene active layer. The above hypotheses were also applicable for the n-channel FETs with C_{60} as active layer, but these devices exhibited the opposite trend as compared to that of pentacene FETs, as shown in Fig. 3. The inset in Fig. 3b showed that the drain current I_{ds} began to decrease due to the oxygen molecules acting as electron traps [34], when V_{ds} swept to the saturation region. The trapping of electrons appeared even more significant at higher gate voltage, e.g. with threshold voltage shift $\Delta V_{th} = 18$ V for biasing at $V_g = 200$ V and $V_{ds} = 0$ V for 1 s. The I_{ds}–V_g curve would return to the initial state when the device was left unbiased for around 1 h due to the release of trapped electrons (data not shown here). The trapping of holes was hardly observed, i.e. almost no shift in the subsequent I_{ds}–V_g curves, although a gate bias of −200 V for 1 s was applied.

The above results indicated that the silanol group-related electron traps for p-channel devices and the water-related hole traps for n-channel devices at the interface of SiO_2 almost cannot be accessed, which was primarily attributed to the charge injection barriers, originating from the large mismatch between the work functions of source/drain contacts and LUMO/HOMO levels of used active layers, and from the additional buffer dielectric. Given that $\Phi_{Au} = -5.1$ eV and $LUMO_{Pen} = -3.2$ eV and $HOMO_{Pen} = -5$ eV, $\Phi_{Al} = -4.2$ eV and $LUMO_{Ful} = -3.8$ eV and $HOMO_{Ful} = -7.1$ eV, the charge injection barrier of electrons (holes) for pentacene (C_{60}) FETs is as large as 1.9 (2.9) eV, without taking PMMA into account, which is already too large to be surmounted [35,36]. This is slightly different from that of memory devices based on the FET structure employing floating gate (FG) and/or the metal–nitride-oxide-silicon (MNOS) transistor [31,37,38]. In the case of devices with FG, electrons are easily induced and injected through a thin insulator at high transverse electrical field, even though high work-function metal is used as the source–drain contact in p-channel FETs. The average electrical field during writing/erasing in flash memory is about 10 MV cm^{-1}, we might need to increase the applied voltage to verify our results. But due to the voltage limitation of our equipment, a thinner gate insulator shall be employed. The exact mechanism for preventing charge carriers from being captured in

pentacene (C_{60}) FETs would be investigated in future. On the other hands, the trapping of majority carriers occurred in pentacene (C_{60}) FETs when devices operated under working state. We assumed that the amount of trapped charge Q_{trap} at their initial state was zero. When negative (positive) gate bias was applied, the amount of trapped charges, Q_{trap}, can be evaluated through the following equation:

$$Q_{trap} = \pm C_i \Delta V_{th}. \quad (6)$$

By applying a gate bias of ±200 V with 1 (0.5) s bias time for C_{60} (pentacene) FETs, respectively, the calculated value of Q_{trap} was around ±1 (0.5) × 10^{-7} C cm^{-2}. Obviously, Q_{trap} increases when the bias time was extended and long time biasing would completely turn the device off leading to the failure of switching function. A similar phenomenon was also observed in the devices using SAMs as buffer dielectric when these devices were repeatedly stressed by measuring transfer characteristics in the saturation regime, because surface silanol groups cannot be fully passivated by SAMs [15,39].

3.2. Under illumination

It is important to understand light illumination effects on electrical performance of these devices, as well as the underlying physics of these effects in applications such as switches for flat panel displays (FPDs). Light absorption generates electrons and holes, and these electrons and holes may be paired in form of excitons that diffuse like neutral particles. The bound electron–hole pairs can be dissociated by applying an appropriate gate-to-source bias in the FET devices, and the separated electrons (holes) begin to move under the influence of the electrical field. It was expected that the shift of V_{th} toward the positive (negative) side in pentacene (C_{60}) FETs would be brought out due to the involvement of non-equilibrium charge carriers, when a positive (negative) gate bias was applied under illumination [40]. When investigating the effect of steady-state broadband illumination on the electrical performance of our devices, the illumination power was controlled at a low level to minimize the degradation of OSCs under light irradiation and the programing time was not more than 30 s to minimize the charge trapping in the grain boundaries of our polycrystalline films. Before programing by a gate bias, the incident light was stabilized for 5 s. This was done by shining the top of the entire channel region.

As expected, the entire transfer curve of pentacene FETs with 10 nm PMMA buffer dielectric was greatly shifted toward the positive direction by applying a gate bias of 200 V for 20 s under illumination, as shown in Fig. 4a. As a result,

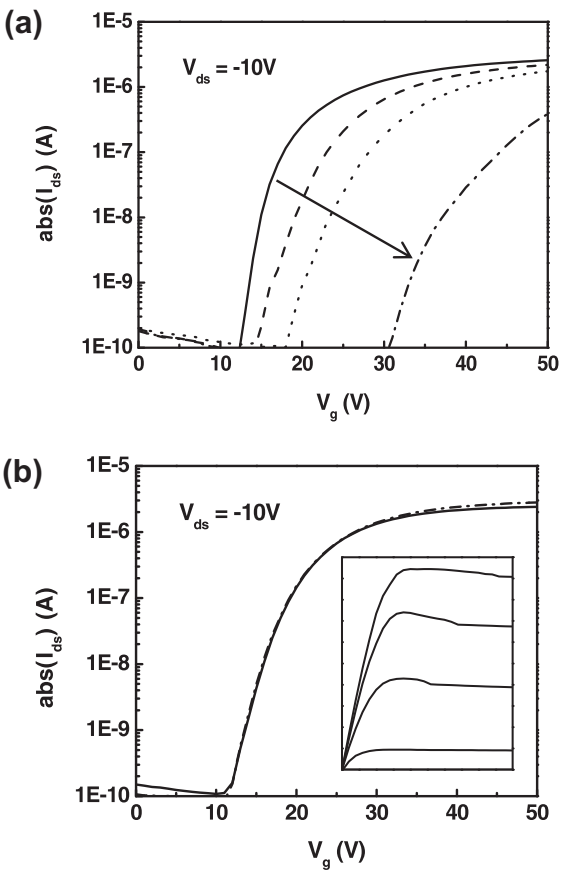

Fig. 3. Transfer curves of C_{60} FETs with 10 nm PMMA buffer dielectric with V_{ds} = 10 V before (solid line) and after programing with a gate bias of (a) 200 V and (b) −200 V at V_{ds} = 0 V for 10 ms (dash line), 100 ms (dot line) and 1 s (dash dot line). The inset shows its output characteristics.

the value of V_{th} was changed by more than 125 V, as seen from Fig. 4b. In contrast, there was little change in V_{th} when the device was merely illuminated for 20 s without gate bias, shown by the solid circle in Fig. 4b, or programed by a positive gate bias without illumination, shown in the inset of Fig. 4b. Usually, the drain current in the "OFF" state is slightly affected, which is attributed to the enhancement of carrier density in the channel of the device and thus the conductivity. The change in V_{th} was attributed to the generation of non-equilibrium charge carriers, which were transferred under the electrical field and trapped by buried trapping states at the PMMA–SiO_2 interface. It showed a good agreement with published results observed in p-channel FETs with 10 nm PS (or PMMA) buffer dielectric [41]. However, the time of positive gate bias needed for inducing the shift in V_{th} was much shorter than ours, which might result from the variation of conductivity of polymers because of different processing conditions, e.g. the effect of solvent [42]. The charge transport can either tunnel between localized states, depending on the density of defect states in polymers, or hop via extended electronic states, though clearly one mechanism would dominate. In the case of transport via extended states, carrier motion is repeatedly interrupted by trapping of carriers in localized states and then re-emission into the extended states. The drift mobility in such situations in greatly reduced from the free carrier mobility due to the time the carriers spend in traps. Although it is still far away from the well understanding of the exact mechanism in OFET memory devices, a potential mechanism was proposed, in which the charge transfer was greatly related with the applied electrical field [41,42]. An electrical field F of ca. 4.6 MV cm^{-1} (according to $F = \frac{V_g}{t_P + t_3(\varepsilon_P/\varepsilon_3)}$), much larger than the dielectric strength of PMMA (ca. 0.2 MV cm^{-1}), was applied to facilitate the charge injection. Fig. 4b shows the resulting shift in V_{th} of our pentacene FETs as a function of bias time. Clearly, there was a turning point. For $t < 1$ s, the change in threshold voltage ΔV_{th} was less than 4 V. For $1 \leqslant t \leqslant 20$ s, the value of ΔV_{th} increased sharply. This was ascribed to a response time τ, which the photogenerated electrons needed to be transferred through PMMA and trapped at the interface of SiO_2. It seemed that this was a slow process, as a long bias time was indispensable to achieve the considerable shift in V_{th} under a constant transverse electrical field F. Given that the mobility of PMMA at room temperature is ca. 1.0×10^{-11} cm^2 V^{-1} s^{-1} [43], it took nearly 0.02 s for electrons to transport through 10 nm PMMA), which was reasonable compared to the observed response time τ. It is believed that the observed photoinduced shift in V_{th} is caused by the charging of the bilayer gate dielectric with non-equilibrium carriers that are photogenerated in pentacene near the interface and transferred/trapped in these buried trapping states at the interface of SiO_2, schematically shown in Fig. 4d. The variation of the surface density of charges transferred/trapped at the PMMA–SiO_2 interface, $\Delta n = Q_{trap}/q$, is related to the observed shift of threshold voltage V_{th} according to Eq. (6). The charge transfer rate can be roughly estimated from the shift ΔV_{th} after applying a V_g at V_{ds} = 0 V for a (short) time interval Δt under illumination:

$$dn/dt = \frac{C_i \Delta V_{th}}{q \Delta t}. \tag{7}$$

Interestingly, the electron transfer rate decreased quickly ($t < 1$ s) and gradually reached a constant level ($1 \leqslant t \leqslant 20$ s), as shown in Fig. 4c. This indicated that the average charge transfer rate across 10 nm PMMA under illumination was ca. 1.6×10^{11} cm^{-2} s^{-1}. It was because a surface potential created by charge trapped in the buried states decelerated the injecting electrons and reduced the electron penetration range, resulting in a saturation of trapped charges. An electron transfer rate of ca. 5×10^9 cm^{-2} s^{-1} under short wavelength light illumination ($400 < \lambda < 500$ nm) was reported in the single crystal rubrene FETs with parylene as the gate dielectric, which was much smaller than our results [40]. This was mainly ascribed to (i) the different flux of photons, (ii) the injection barrier provided by the bulk material of parylene, and (iii) the transverse electrical field F, which determined the extent of the charge injection and transport.

When a charge is injected and trapped, the de-trapping also occurs simultaneously to restore the neutral state by transferring the excessive charges to the ground, which was characterized by the retention time in dark condition.

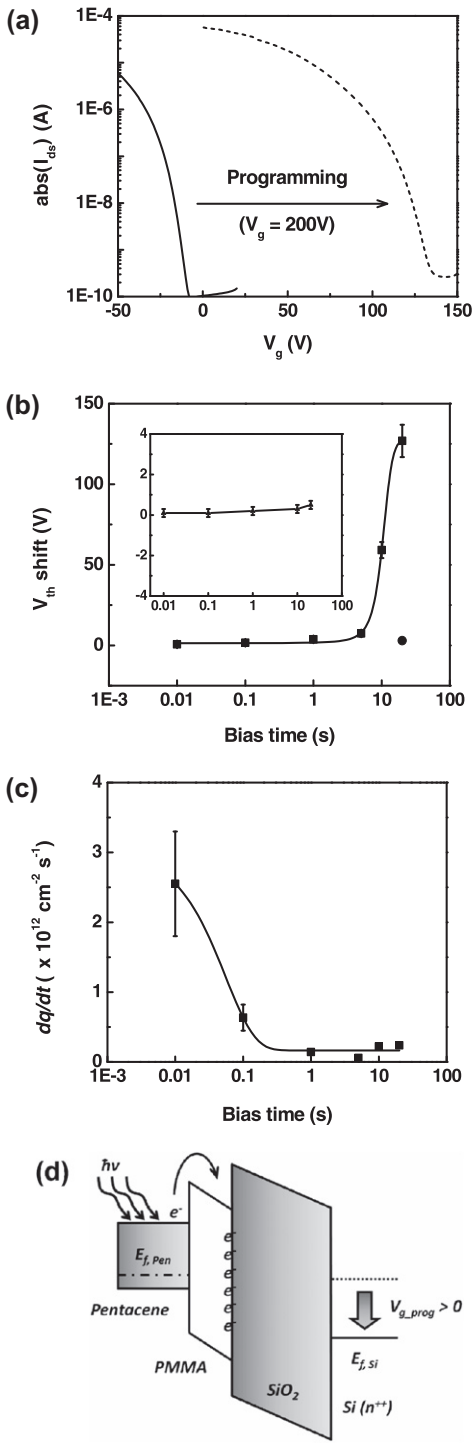

Fig. 4. (a) Transfer curves of pentacene FETs with 10 nm PMMA buffer dielectric at $V_{ds} = -50$ V before and after programing with a gate bias of 200 V for 20 s at $V_{ds} = 0$ V under illumination; (b) V_{th} shift versus programing duration under illumination (solid square) and in dark condition (solid triangle, shown in the inset), and solid circle represents the V_{th} shift was induced by the illumination for 20 s without application of gate bias; (c) the transfer rate of electrons versus programing time; (d) schematic illustration of electron generation under illumination, transfer across PMMA barrier, and trapping at the PMMA/SiO_2 interface, where $E_{f,Si}$ and $E_{f,Pen}$ are the Fermi energy of pentacene and silicon, respectively.

After programing, a decay process of I_{ds} (measured at $V_{ds} = -50$ V and $V_g = 0$ V) in the "ON" state in dark condition was recorded and plotted in Fig. 5b, where the time required for the "ON" state current to decrease to 10% of its initial value was estimated to be around 10^4 s. In Fig. 5a, it was more obvious that the shift in V_{th} toward

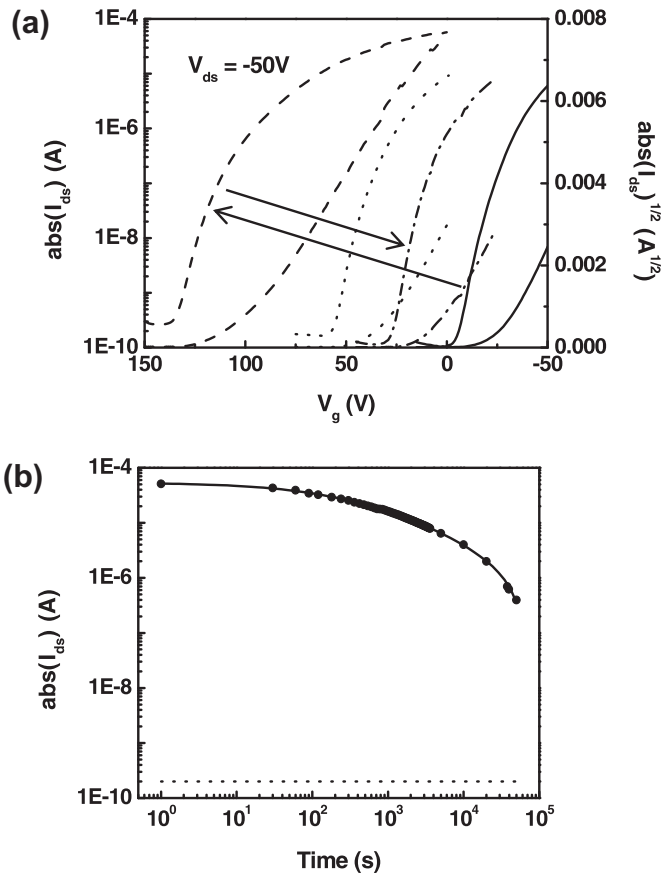

Fig. 5. (a) Transfer curves of pentacene FETs with 10 nm PMMA buffer dielectric at $V_{ds} = -50$ V: initial characteristics (solid line), measured in the dark after programing ($V_g = 200$ V, $V_{ds} = 0$ V for 20 s under illumination) immediately (dash line), 1 h later (dot line), and 10.5 h later (dash dot line); (b) Time evolution of I_d measured in the dark at $V_{ds} = -50$ V and $V_g = 0$ V after programing ($V_g = 200$ V, $V_{ds} = 0$ V, for 20 s under illumination). The off current (dot line) is shown for reference.

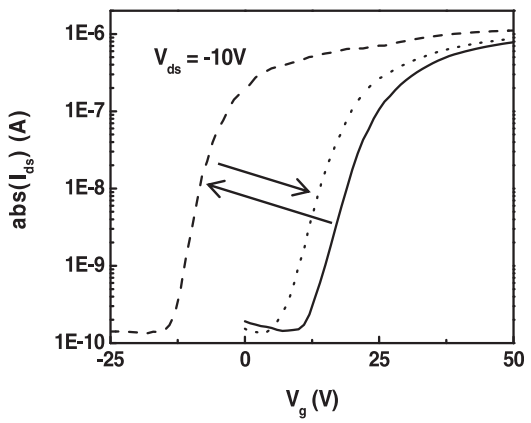

Fig. 6. Transfer curves of C_{60} FETs with 10 nm PMMA buffer dielectric at $V_{ds} = 10$ V: initial characteristics (solid line), measured in the dark after programing ($V_g = -200$ V, $V_{ds} = 0$ V for 1 s under illumination) immediately (dash line) and 1 min later (dot line).

negative side was very fast in the first hour and became very slow in the next 10 h, indicating that there were two distinguishable decay rates: (i) an initial rapid relaxation due to the recombination of closely packed holes and electrons and (ii) a subsequent slower relaxation that originated from deeply trapped carriers, depending on the quality and conductivity of the PMMA buffer dielectric. Our results indicated that a charge storage lifetime in the dark can be estimated to be several days long. On the other hand, based upon our discussion in section 3.1, the trapped electrons can also be swept out and/or recombined with field-induced holes by applying a negative gate bias in the dark. Consequently, the shifted transfer curve can restore to its initial state, completing a cycle of turning "ON" and "OFF".

The photo-induced charge transfer was also studied in the n-channel FETs. However, when programing the device, only a short time period of gate bias was used in order to minimize the degradation of C_{60} due to the exposure to the ambient air and light irradiation [34,44,45]. Two mechanisms of degradation had been described as following: (i) the absorbed oxygen molecule acts as electron traps within the lattice of C_{60} molecule and epoxidation reaction might take place on C_{60} [34], and (ii) the fragmentation of C_{60} caused by ultraviolet (UV) light [44–46]. When a gate bias of -200 V with a period of 1 s was applied, the transfer curve was greatly shifted toward the negative direction, as shown in Fig. 6a. However, it quickly went back to the

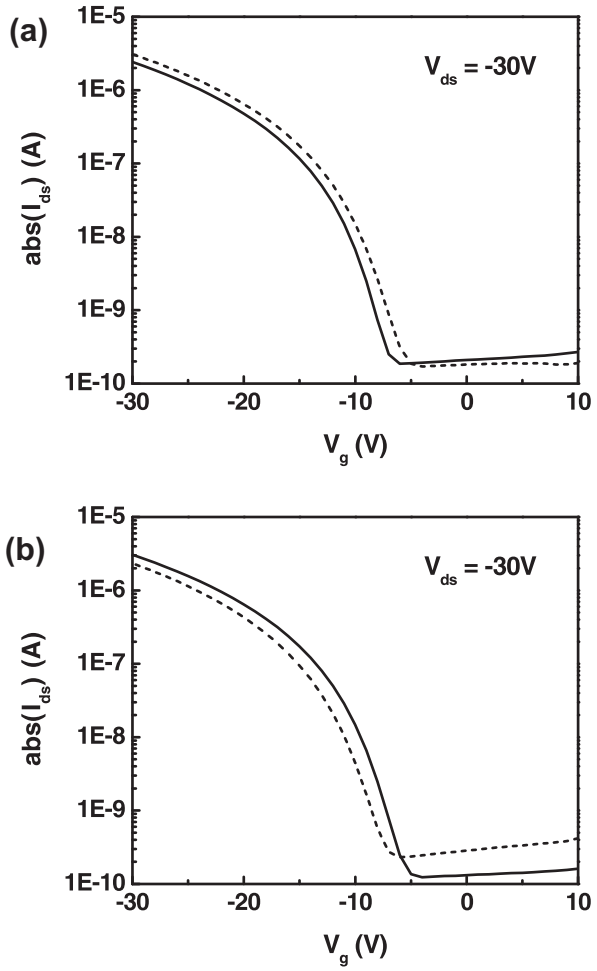

Fig. 7. Transfer curves of pentacene FETs with 45 nm PMMA buffer dielectric with $V_{ds} = -30$ V before (solid line) and after (dash line) programing, where a programing gate bias of (a) 100 V and (b) −100 V for 30 s at $V_{ds} = 0$ V was applied under illumination.

original state within a few minutes in the dark, attributing to the rapid release of trapped holes. This suggested that the trapping of electrons was much more supportive in this device due to the presence of oxygen dopants and accessible hydroxyl groups, as compared to that of holes.

To further verify our previous hypothesis that the charge trapping primarily took place at the dielectric–dielectric interface, 45 nm-thick PMMA was used as the buffer dielectric to minimize the pinhole defects and increase the barrier width, and 200 nm-thick SiO_2 was used as the gate insulator. To compare with the previous results, the effect of light illumination on inducing the shift in V_{th} was carried out by applying a gate bias of ±100 V in order to equalize the value of F (ca. 4.7 MV cm^{-1}) across the dual-dielectric. When programed by a gate bias of 100 V with a period of 30 s under illumination, the transfer curve only shifted slightly toward the positive direction (see Fig. 7a), giving rise to a ΔV_{th} of less than 2 V. This was ascribed to a small quantity of electrons trapped in the structural defects of polycrystalline pentacene thin films, i.e. grain boundaries, and at the interface between pentacene and PMMA. The transfer of electrons from the active layer into these buried trapping states at SiO_2 surface was greatly depressed as the thick PMMA film effectively shielded the underneath hydroxyl groups. At the same time, a gate bias of −100 V with a period of 30 s was also applied under illumination, the shifted transfer curves due to the application of the positive gate bias was almost restored to the initial state (see Fig. 7b), showing only a little shift (ca. 0.5 V) to the negative direction. This indicated that the trapping of holes was suppressed because the reduction of absorbed water molecules thanking to the hydrophobic surface of PMMA. By utilizing the thickness-optimized PMMA, our devices were very resistive to the high transverse electric field and light illumination, resulting in excellent device stability. This differed from that of devices with $\geqslant$60 nm styrenic polymers (or PMMA), who exhibited considerable shift in V_{th} after programing [22,41]. To further improve the device stability, the purification of active materials as well as the buffer dielectrics is needed to cut down the unintentional doping acting as the charge trapping centers.

4. Conclusions

In conclusion, the shift of threshold voltage due to the charge trapping (both electron and hole) in the buried states between PMMA and SiO_2 was evaluated in p- and n-channel OFETs, respectively. The trapping of electrons (compared to holes) in p-channel devices and the trapping of holes (compared to electrons) in n-channel devices are more difficult in the dark condition due to the large injection barrier between the contact and the active layer. Although the 10 nm-thick PMMA layer also provides an additional charge injection barrier, when the device is programed under illumination, the photo-generated non-equilibrium charge carriers in the active layer can be easily injected through 10 nm PMMA into these buried states and trapped under the high electrical field. The trapped electrons in p-channel FETs can retain for several days while the release of trapped holes in n-channel FETs is much faster. However, such photo-induced charge transfer can be effectively suppressed by an optimized thickness of buffer dielectric (45 nm) at the same characterization condition, and thus stabilize the threshold voltage. Besides the device encapsulation and the development of new OSC combining high mobility with excellent stability, data presented in this work brings out an alternative approach to enhance the stability and reliability of organic transistors using bi-layer gate dielectric. In order to selecting a proper buffer dielectric, attention must be paid to the following: (i) non-polar buffer dielectrics with excellent film-forming and low surface/bulk states are preferred, such as low-k polymeric dielectric BCB and Cytop [15,47], and (ii) its thickness should also be optimized when it is applied in FET structures (both bottom- and top-gate architectures). Our findings should also be relevant to other cases, for example, in an OFET-based memory device where the charge dissociation/trapping process under light irradiation is involved.

Acknowledgements

We would like to thank Dr. Q.L. Song for the fabrication of C_{60} thin film. This work is supported by the Ministry of Education, Singapore (Research Grant No. RG 13/06).

PO1 and SO1. The computed electronic properties of PO1 and SO1 are consistent with the available experimental data (discussed below). The vertical triplet energies evaluated at the TDDFT level (Table 1) are identical, 3.14 eV; they are significantly higher than that of FIrpic (2.70 eV at the same level of theory) and only 0.17 eV lower than that of the unsubstituted biphenyl core. The adiabatic triplet energies computed at the ΔSCF level (computed as the difference in the SCF energies at the optimized S_0 and T_1 geometries) are nearly identical, being 2.87 and 2.88 eV for PO1 and SO1, respectively. The dominant excitation giving rise to the triplet state is localized on the biphenyl moiety and corresponds in both cases to a HOMO-to-LUMO transition. The very similar nature of the HOMO and LUMO orbitals of PO1 and SO1 is evident from the isosurface plots displayed in Fig. 1. The stronger, predominantly inductive, electron-withdrawing character of the sulfonyl moiety relative to that of the phosphoryl substituent can be seen from the trends in the computed HOMO/LUMO energies and electron affinities (EAs). In general, the values for PO1 are calculated to lie between those of SO1 and biphenyl. Thus, the computational results are consistent with a largely inductive effect for the sulfonyl substitution and predict that the high triplet energy of PO1 should be maintained in SO1.

Compound SO1 is reversibly reduced at −2.06 V vs. $FeCp_2^{+/0}$ in 0.1 Bu_4NPF_6/*N*,*N*-dimethylformamide, i.e. somewhat more readily than PO1 under the same conditions (−2.4 V) [12], consistent with the trend in computed EAs. Its absorption and fluorescence maxima in dichloromethane (277 and 331 nm, respectively) are very similar to those reported for PO1 in the same solvent [12]. The adiabatic triplet energy for SO1 is estimated to be 2.72 eV from the phosphorescence spectrum acquired in a 2-methyltetrahydrofuran glass at 77 K. As in the case of the TDDFT values, the value for SO1 is indistinguishable within experimental uncertainty from the value for PO1 (2.72 eV) [12] and is higher than the value of 2.65 eV reported for FIrpic [20], suggesting that SO1 might also be an effective host for this phosphor. As expected, the experimental adiabatic triplet energies (based on the highest energy emission at the relaxed triplet geometry) are smaller than the computed vertical triplet energies (calculated at the singlet geometry), while the computed adiabatic triplet energies (ΔSCF level) provide energies that are only slightly higher than those measured from the phosphorescence spectra.

Small-molecule derivatives of the 3,6-bis(carbazol-9-yl)carbazole ("tricarbazole") moiety have been used as hole-transport components for OLEDs [21,22]. In order to simplify the fabrication process of our OLEDs we were

Table 1
Computed HOMO and LUMO energies, adiabatic ionization potentials and electron affinities, vertical TDDFT transition energies from the ground state to the lowest singlet (S0-S1*) and triplet (S0-T1*) excited states, and the ΔSCF adiabatic triplet energies ($S_0 - T_1$).[a]

	HOMO	LUMO	IP	EA	$S_0 - S_1^*$	$S_0 - T_1^*$	$S_0 - T_1$
PO1	−6.42	−1.51	7.40	0.65	4.47	3.14	2.87
SO1	−6.85	−2.02	7.96	1.04	4.39	3.14	2.88
Biphenyl	−6.06	−0.69	7.61	−0.70	5.02	3.31	3.04

[a] All values are in eV and computed at the DFT B3LYP/6-31G** level. EAs are defined as the negative of the free-energy change for the process M + e → M^-.

interested in using a solution-processible tricarbazole-based material as a hole-transport layer (HTL), since this would reduce the number of layers requiring vacuum deposition. As earlier work on poly(norbornene) polymers functionalized with charge-transport side groups has shown that the backbone of the polymer does not adversely affect the energy levels of the moiety [23,24], polymer P-TCz, a poly(norbornene) with pendant tricarbazole moieties, was synthesized (M_w = 49,000; PDI = 1.9 according to GPC in chloroform vs. polystyrene standards) [25]. For comparison to devices incorporating P-TCz, analogous devices were also fabricated using the widely used hole-transport polymer, poly(*N*-vinylcarbazole) (PVK, M_w = 81,800; PDI = 1.68) as a solution-processible HTL with good hole-transport properties, as reported, for example, by Kido et al. [26].

Devices were fabricated on glass substrates precoated with indium tin oxide (ITO) with a sheet resistance of 20 Ω/□ (Colorado Concept Coatings, L.L.C.). The substrates were first cleaned in an ultrasonic bath using a dilute solution of Triton-X (Aldrich) in deionized (DI) water (20 min) followed by successive ultrasonication in DI water, acetone, and finally ethanol (20 min each). Washed ITO substrates were then dried in a vacuum oven at 70 °C under

vacuum (1×10^{-2} Torr) for 1 h. Films of PVK and polymer P-TCz with a thickness of 35 nm were spin-coated from toluene onto air-plasma treated ITO coated substrates in a nitrogen inert atmosphere. The substrates were then loaded into a Kurt J. Lesker Spectros vacuum system without being exposed to atmosphere. For all subsequent organic layers, materials were first purified using gradient zone sublimation, and were then thermally evaporated at a pressure below 1×10^{-7} Torr. The OLED devices have the following architecture: ITO/spin-coated carbazole-based polymer (35 nm) – either PVK (device **I**) or polymer P-TCz (device **II**) – as a HTL/compound SO1 layer doped with 6 or 10 wt% FIrpic (20 nm) as an emitting layer/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) (40 nm) as a hole-blocking layer. The cathode consisted of a thin layer of lithium fluoride (LiF) (with an effective thickness of 2.4 nm based on the deposition rate and time) followed by a 200-nm thick layer of aluminum (Al). The thickness of the different layers was selected based on our experience with the optimization of electrophosphorescent devices with comparable geometry. The chemical structures of the materials used are shown in Fig. 2 and the estimated ionization potentials (IPs) and electron affinities (EAs) [27] of the materials used are shown in Fig. 3. Luminance–current density–voltage (*L*–*J*–*V*) characteristics of the devices were measured using a Keithley 2400 source meter for current–voltage measurements. The devices were tested inside a nitrogen-filled glovebox with O_2 and H_2O levels <20 and <1 ppm, respectively.

The current density–voltage (*J*–*V*) characteristics of the two device architectures, with PVK (device **I**) or polymer P-TCz (device **II**) as a HTL, are shown in Fig. 4. It is noted that the operation voltage of devices of type **I** are greater than that for devices of type **II**; for instance, the operation voltage at 2 mA/cm^2 is 9.3 V for device **I** with 6 wt% doping of the FIrpic phosphor and 9.7 V for device **I** with 10 wt% doping, whereas for device **II** the operation voltage is 7.1 V at 6 wt% doping and 6.4 V at 10 wt%. At a luminance of 100 cd/m^2, device **II** shows maximum external quantum efficiencies (EQE) of 6.9% and a current efficiency of 12.9 cd/A, while device **I** shows efficiencies of 6.4% and 11.3 cd/A, respectively. The luminance–voltage (*L*–*V*) and EQE curves of the OLED devices are compared in Fig. 5 and show that the luminances for SO1-based blue-green OLEDs incorporating polymer P-TCz are higher than for those incorporating PVK. Furthermore, the turn-on voltages (defined as the voltage required to obtain a brightness of 10 cd/m^2) of the P-TCz-based devices **II** (4.4 and 4.3 V for devices with 6 and 10 wt% FIrpic, respectively) are clearly lower than those of the PVK-based devices **I** (6.4 and 6.0 V for 6 and 10 wt%).

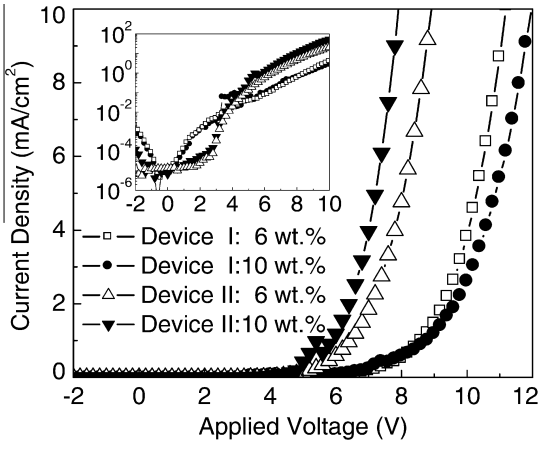

Fig. 4. *J*–*V* characteristics for devices using PVK (device **I**) and polymer P-TCz (device **II**) as a HTL. (Inset) Log scale *J*–*V* plot.

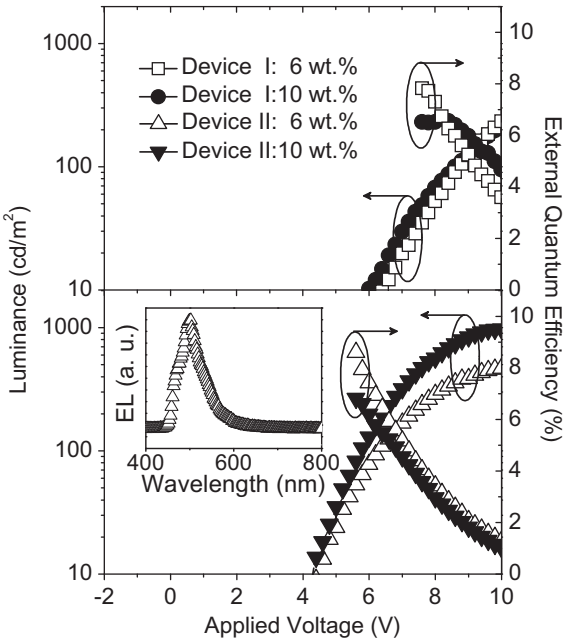

Fig. 5. Luminance and external quantum efficiency as a function of applied voltage for devices. (Inset) EL spectrum of device **II** (6 wt%).

The EQE, current efficiencies, and electroluminescence (EL) spectra demonstrate that compound SO1 is a good host material for FIrpic in electrophosphorescent OLEDs. Indeed, the performance of the current hybrid (mixed solution/vacuum-deposited) devices approaches that of fully vacuum-deposited devices in which its phosphine-oxide analog, PO1, was used as a host for FIrpic (EQE up to 7.8%) [28].

Carrier injection and transport efficiency may be crucial issues affecting the charge balance and quantum efficiency of OLEDs. The differences between devices of types **I** and **II** may be attributable either to different hole mobility values and/or injection efficiencies in the two polymers. Although the electrochemically estimated ionization potential of P-TCz is a little lower than that of PVK, this apparent difference should be treated with caution due to the irreversible oxidation of the latter material. Moreover, the increased chemical stability of charge carriers in P-TCz relative to PVK, which is reflected by the more reversible electrochemistry of the former, may play a role. The hole mobility of P-TCz will be investigated as part of our continuing study of this polymer.

In summary, we have demonstrated that a bis-sulfone host (SO1) can act as a high-triplet-energy host suitable for the fabrication of highly efficient blue-green phosphorescent OLEDs. We believe that the synthetic flexibility of sulfone chemistry opens the possibility for a range of useful organic electronic materials based upon bis-sulfones. Devices employing the new tricarbazole-functionalized polymer P-TCz as a HTL showed that the current density was increased by 20 times and that the operation voltage was also significantly lowered as compared to that of PVK devices.

Acknowledgments

This material is based upon work supported by Solvay SA and in part by the STC Program of the National Science Foundation under Agreement No. DMR-0120967. We are grateful to Jean-Pierre Catinat and Véronique Mathieu for measuring the adiabatic triplet energy of SO1.

[27] The EA of SO1 was estimated from the electrochemical reduction potential vs. ferrocene according to $EA = eE^{red}_{1/2} + 4.8$ eV and the IP from the EA estimate and the absorption onset, as previously described for PO1 in Ref. [12]. The IP of P-TCz was estimated from the oxidation potential of the corresponding monomer vs. ferrocene according to $IP = eE^{ox}_{1/2} + 4.8$ eV and its EA from the IP estimate and the absorption onset. Accordingly the IP of SO1 and the EA of P-TCz are likely to be under- and overestimated, respectively, due to the neglect of exciton binding energy. The values for FIrpic and BCP were taken from V.I. usage and a simpler process for device integration [15]. The challenge is to print well-defined structures from dilute inks. By blending the molecular semiconductor with a polymer, the viscosity of the printing solution can be varied. Blending, however, is also expected to impact the electrical performance of the final deposited transistor. This interplay is in fact the topic of this paper.

Two different approaches of ink-jet printing small-molecule semiconductors have been used: printing multiple droplets which coagulate into a film covering a relatively large area on the substrate, or single-droplet printing where each droplet forms an individual functional deposit. The former was adopted in a recent study by Madec et al. [16]. They ink-jet printed multiple droplets of inks containing TIPS-PEN and an amorphous and electrically insulating polymer, polystyrene (PS), at a blending ratio of 1/1 (w/w). By printing from a specific binary solvent mixture and/or using a multilayer printing method, a continuous layer with improved morphology was achieved, and they found an increased mobility of up to 10^{-2} cm^2/Vs (±71–80% variance) in bottom-gate/top-contact transistors. These mobilities are however much lower than the values of 0.12 cm^2/Vs reported by Lim et al. [17] for single-droplet printing of pure TIPS-PEN from a solvent mixture, making it thus far unclear if blending with an insulating polymer can result in a further improvement in high-performance ink-jet printed transistors.

In this paper, we investigate single-droplet ink-jet printing of TIPS-PEN/PS blends, with each printed single droplet being an individual transistor [6,18]. This eliminates the need for additional patterning steps. As in the previous work of Lim [17], we use a bottom-gate/bottom-contact device geometry. This device architecture offers a straightforward route for downscaling of the transistor channel length to a few micrometers. In contrast to Lim's work, we did not rely on the unusual concentric ring arrangement of source and drain electrodes, because that configuration does not allow simple device integration. Here, we use conventional interdigitated comb structure for the source and drain electrodes.

To gain insight into the charge-transport properties of our devices, we study the differences between the transistors based on pure TIPS-PEN and TIPS-PEN/PS blends with respect to macroscopic device operation and local charge-transport properties, by using channel scaling studies and surface potential profilometry, respectively, and relate them to the morphology of the devices. The fundamental understanding of device operation obtained for our blend transistors provides valuable guidelines to the development of next generation transistors based on small-molecule semiconductor and insulating polymer blends.

2. Experimental

6,13-Bis(triisopropyl-silylethynyl)pentacene (TIPS-PEN) was synthesized according to literature [19]. Polystyrene (PS), Mw = 9.58 kDa (Mn = 9.32 kDa, PDI = 1.03), was purchased from Fluka. 1,2,3,4-tetrahydronaphtalene (tetralin, purchased from Merck) was used as the solvent.

An ink-jet printing setup with a high-precision vertical translation stage and a Microfab glass nozzle (type MJ-ATP-01-50-DLC, 50 μm orifice diameter) was used to print inks with a constant TIPS-PEN concentration of 20 mg/ml and varied PS concentrations according to their blending weight ratios. Each droplet with a typical volume of 50 pL was jetted on demand and aligned to the transistor channel region to form an individual device, on substrates that were kept at 70 or 20 °C. All printing experiments were performed in ambient cleanroom conditions.

Bottom-contact/bottom-gate transistors were printed on Si (n++)/SiO_2 substrates with an oxide thickness of 140 nm and photolithographically patterned Au as source and drain electrodes. A pentafluorobenzenethiol monolayer was deposited on Au electrodes [20]. The SiO_2 was treated with trichlorophenylsilane. The transistor channel length was varied between 2 and 40 μm. Device characteristics were measured at room temperature in inert atmosphere using an Agilent 4155C semiconductor parameter analyser. The field-effect mobilities of our transistors in linear (μ_{lin}) and saturation (μ_{sat}) regime were calculated from the two equations as follows, with $V_{DS} = -1$ V and -10 V, respectively [21]:

$$\mu_{lin}(V_G) = \frac{L}{W \cdot C_i} \frac{1}{V_{DS}} \left(\frac{\partial I_{SD}}{\partial V_G} \right) \quad (1)$$

$$\mu_{sat}(V_G) = \frac{2L}{W \cdot C_i} \left(\frac{\partial \sqrt{I_{SD}(V_G)}}{\partial V_G} \right)^2 \quad (2)$$

where C_i is the capacitance per unit area of the gate dielectric layer, and L and W are channel length and width, respectively. The threshold voltage (V_{th}) of our devices is extracted by extrapolating the square root (SQRT) of $|I_{SD,sat}|$ vs. V_G plot to $I_{SD,sat} = 0$ (as depicted in the plots in Fig. 1a). The sub-threshold slope (SS) value was calculated from the measured I_{SD} values over more than two decades above noise level, using the following equation:

$$SS = \frac{V_{G_1} - V_{G_2}}{\log_{10}\left(\frac{I_{SD_1}}{I_{SD_2}}\right)} \quad (3)$$

Optical micrographs were taken on a Leica DM2500M Microscope with cross-polarizers. SKPM was performed using a Veeco Dimension 3100 with a NanoScope IVa controller operating in the lift mode. For the comparison of contact resistance in the pure and blend transistors, a maximized scan size of 80 × 80 μm^2 was used here to span over three active channels in the transistors to rule out any local effects. To avoid any effect of morphological anisotropy due to the direction of crystal growth from periphery towards centre of the droplets, the scanning regions of SKPM on two groups of devices (pure vs. blend) were chosen at the same location relative to the exact centre of the droplets, and with the same scanning direction with respect to the orientation of interdigitated electrodes of the devices. First, the height profile was recorded with tapping-mode atomic force microscopy (AFM). In the second pass the tip is lifted at a fixed height of 50 nm above the surface, and a voltage is applied to the tip, to record the local surface potentials. Several effects can influence the accuracy of SKPM measurements, e.g. the distance between SKPM tip and the sample surface, the geometry of the tip and cantilever, and the relative in-plane positioning of the cantilever with respect to the interdigitated electrodes of transistors

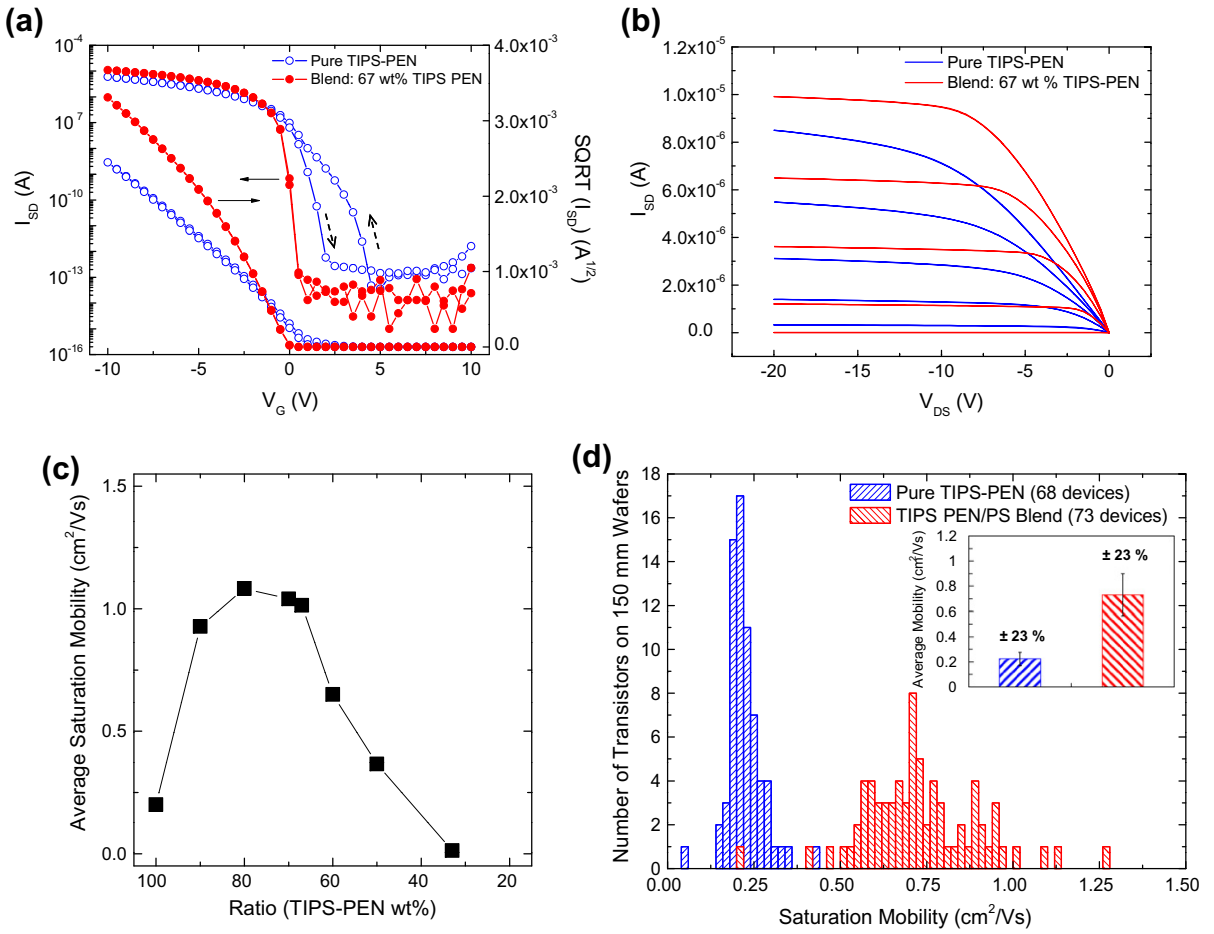

Fig. 1. (a) Transfer characteristics in saturation regime (V_{DS} = −10 V) for two representative transistors with pure TIPS-PEN channel (open circles in blue) and blend channel of 67 wt.% TIPS-PEN and 33 wt.% PS (solid circles in red). Channel length and width are 10 and 200 μm, respectively. The two dashed arrows indicate the counter-clockwise hysteresis for the pure device (gate swept from +10 V → −10 V → + 10 V). The plot of the square root (SQRT) of I_{SD} vs. V_G was used to extract mobility as well as the threshold voltage (V_{th}): the blend device shows a mobility of 1.04 cm^2/Vs and a near-zero V_{th}, while the pure one has a mobility of 0.29 cm^2/Vs and a V_{th} of 2.5 V. (b) Output characteristics of the same two transistors as shown in (a). V_G was varied between 0 and −10 V at a step of −2.5 V. (c) Average saturation mobilities as a function of TIPS-PEN weight ratios in TIPS-PEN/PS blend transistors (averaged from >10 devices for each ratio). All devices were printed on 15 mm × 15 mm square substrates at 70 °C. (d) Histograms of saturation mobilities for 68 pure TIPS-PEN transistors and 73 blend (67 wt.% TIPS-PEN) transistors printed on 150 mm wafers. The inset shows their average mobility values. The relative variance (standard deviation divided by the average value) is 23% for pure TIPS-PEN as well as the blend devices. Transistors were printed at 70 °C. Channel length and width are 5 and 1400 μm, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

[22–24]. The accuracy of our SKPM measurements is comparable to earlier reports on working organic transistors [22,25,26], with observed voltage drop from source to drain electrodes slightly lower than the actual bias applied (V_{DS}). Here we tend to attribute this smaller measured potential drops to the effect of non-local coupling between the entire cantilever/tip and the microscopic device surface, and/or a relatively high tip-sample distance of 50 nm in our measurements [23,24,27,28].

3. Results and discussion

3.1. Effect of insulating polymer (PS) on transistor device performance

Our transistors were independently processed over a period of 14 months on substrates that were prepared under identical conditions. Over time no significant drift in transistor parameters was observed. Representative transfer characteristics in saturation (V_{DS} = −10 V) for pure TIPS-PEN transistors printed at 70 °C are shown in Fig. 1a (open circles in blue). Non-ideal sub-threshold behavior was observed in the form of 'shoulder-like' I_{SD}, with an obvious hysteresis between the forward and backward sweeps. This phenomenon was also reported by Lee et al. [29]. The average saturation mobility of pure TIPS-PEN transistors is 0.20 cm^2/Vs, comparable with earlier reports of ink-jet printing pure TIPS-PEN [6,17]. Adding a polymer binder to the pure TIPS-PEN ink dramatically improves the device characteristics (solid circles in red, Fig. 1a): the transistors switch on sharply at ~0 V, the on-current and mobility are higher than the pure TIPS-PEN devices and no hysteresis is observed. The sharp turn-on is a desirable device property for a switching transistor as it allows

high-speed and low-power operation. Typical output characteristics for pure TIPS-PEN and blend (67% TIPS-PEN) transistors are compared in Fig. 1b. No notable non-linearity of I_{SD} is observed for the pure or blend transistor; not even when the output characteristics are plotted in the form of $\Delta I_{SD}/\Delta V_{DS}$ vs. V_{DS} (graphs not shown). Next, we found that the device mobility is a function of relative weight ratio of TIPS-PEN/PS (Fig. 1c). For blends with 90–67 wt.% of TIPS-PEN, the average mobility has increased up to ~1 cm^2/Vs, a factor of 5 higher than the pure TIPS-PEN (0.20 cm^2/Vs). At lower concentration of TIPS-PEN (e.g. 60 wt.%) the mobility decreases. The average value and standard deviation of mobility (μ) in linear and saturation regime, on-current (I_{on}), and on/off ratio (I_{on}/I_{off}) for transistors (channel length: 10 μm, on 15 mm × 15 mm square substrates) printed at 70 °C with different blending ratios are summarized in Table 1. At a processing temperature of 20 °C we obtain typically lower device performance (Table 2). To further study large area uniformity, we printed 68 pure TIPS-PEN and 73 blend (67 wt.% TIPS-PEN) transistors with a channel length of 5 μm on 150 mm diameter wafers at 70 °C. The histograms in Fig. 1d clearly demonstrate enhanced mobilities of our blend transistors over the entire wafer, with the relative variance (standard deviation divided by the average value) at the same level as the pure TIPS-PEN devices (±23% in the inset of Fig. 1d). This demonstrates the potential of our blend inks for applications in large-area and low-cost organic electronics.

The observation that the mobility is increased by the presence of an insulator up to a critical blending ratio demonstrates that introducing an insulating polymer does not negatively affect the charge transporting layer in the device. This implies that in particular the composition and morphology of the first few nanometers of our TIPS-PEN/PS blend are similar to that of pure TIPS-PEN, as charge transport takes place at this zone in the semiconductor layer [30]. Similar behavior was recently reported for spin-cast blends of TIPS-PEN with poly(α-methylstyrene) [8,9], and blends of TIPS-PEN or fluorinated 5,11-bis(triethylsilylethynyl) anthradithiophene (diF TES-ADT) with a semiconducting polymer, polytriarylamine [7,12]. The results were explained by the occurrence of vertical stratification upon casting and solvent evaporation. During solvent drying TIPS-PEN is predominantly expelled to both top and bottom interfaces of the deposited films [8,9,12]. As long as phase separation leads to almost pure phase of TIPS-PEN at the two interfaces, it should be possible to realize transistors with good performance. This hypothesis can explain why the mobility decreases at too high weight fraction of the polymer in our blends: phase separation is incomplete and no continuous film of TIPS-PEN is formed at the bottom interface of our devices. It can however not explain why the maximum mobility of the blends is higher than that of the pure TIPS-PEN transistors. At least two explanations have been proposed for the improved charge transport in the blend transistors. Ohe et al. suggested that the addition of polymer binder leads to slower drying and hence to a different morphology of the TIPS-PEN film [9]. Yoon et al. proposed that the polymer binder influences the film formation process of the small-molecule organic semiconductors and acts indirectly as a purification method [31].

Typical optical micrographs (cross-polarized reflection mode) in Fig. 2a present the morphology evolution of TIPS-PEN/PS blends printed at 70 °C, with TIPS-PEN weight ratios ranging from 100% to 50%. Pure TIPS-PEN devices have irregular shaped crystalline deposit attributed to the de-pinning of the contact line during solvent drying (image of 100 wt.%), leading to limited crystal coverage on transistor channels. The addition of PS up to ~40% gives circular deposits with large crystals of TIPS-PEN that cover the whole device area with an improved crystal morphology (images of 80 and 67 wt.% of TIPS-PEN). Devices with this type of morphology have high mobility. At further higher concentration of PS, small and isolated TIPS-PEN crystals in a matrix of amorphous materials are observed (images of 50 wt.%). The lack of crystalline TIPS-PEN in this deposit explains the lower transistor performance and large parameter spread (Table 1). Corresponding transfer characteristics for the four transistors of Fig. 2a are compared in

Table 2
Summary of transistor parameters for TIPS-PEN/PS transistors with different blending ratios printed on 15 mm × 15 mm square substrates at 20 °C, under the same processing conditions. Field-effect mobilities were extracted in linear (μ_{lin}) and saturation (μ_{sat}) regime, on-current (I_{on}) was measured at $V_G = -10$ V, with $V_{DS} = -10$ V. Data was obtained for >10 transistors of each ratio.

Ratio (TIPS-PEN wt.%)	μ_{lin} (cm^2/Vs)	μ_{sat} (cm^2/Vs)	I_{on} (μA)
100	0.17 ± 0.03	0.15 ± 0.05	4.4 ± 0.9
67	0.53 ± 0.13	0.55 ± 0.14	7.8 ± 1.7
50	0.58 ± 0.47	0.65 ± 0.51	8.3 ± 6.6
33	0.02 ± 0.02	0.04 ± 0.04	0.3 ± 0.3

Table 1
Summary of transistor parameters for TIPS-PEN/PS transistors with different blending ratios printed on 15 mm × 15 mm square substrates at 70 °C, under the same processing conditions. Field-effect mobilities were extracted in linear (μ_{lin}) and saturation (μ_{sat}) regime, on-current (I_{on}) and off-current were measured at $V_G = -10$ V and +10 V, respectively, with $V_{DS} = -10$ V. Data was obtained for >10 transistors of each ratio.

Ratio (TIPS-PEN wt.%)	μ_{lin} (cm^2/Vs)	μ_{sat} (cm^2/Vs)	I_{on} (μA)	On/off ratio
100	0.23 ± 0.06	0.20 ± 0.07	4.5 ± 1.1	$4.9 \times 10^6 \pm 3.0 \times 10^6$
90	0.72 ± 0.14	0.93 ± 0.23	8.6 ± 1.7	$1.2 \times 10^7 \pm 1.0 \times 10^7$
80	0.90 ± 0.14	1.08 ± 0.16	9.4 ± 1.7	$3.0 \times 10^7 \pm 1.8 \times 10^7$
70	0.83 ± 0.22	1.04 ± 0.26	9.7 ± 2.8	$2.9 \times 10^7 \pm 1.7 \times 10^7$
67	0.85 ± 0.09	1.01 ± 0.12	10.8 ± 1.3	$4.9 \times 10^7 \pm 2.3 \times 10^7$
60	0.53 ± 0.24	0.66 ± 0.30	5.7 ± 2.5	$3.8 \times 10^7 \pm 6.6 \times 10^7$
50	0.30 ± 0.27	0.37 ± 0.33	3.6 ± 3.4	$2.2 \times 10^7 \pm 3.1 \times 10^7$
33	0.005 ± 0.003	0.01 ± 0.009	0.06 ± 0.04	$2.1 \times 10^5 \pm 1.6 \times 10^5$

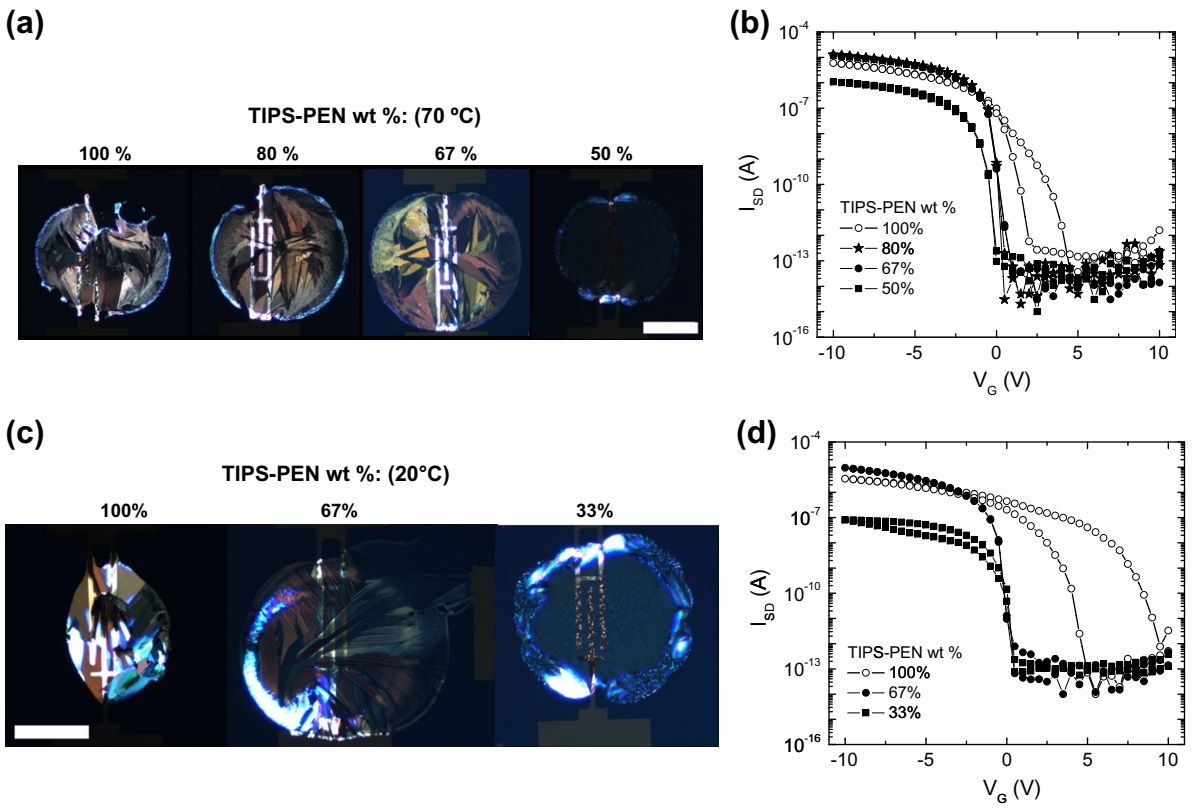

Fig. 2. (a) Representative cross-polarized optical micrographs showing the morphology transition of TIPS-PEN/PS blends with different TIPS-PEN concentrations printed at 70 °C. The scale bar indicates 100 μm. (b) Transfer characteristics in saturation regime ($V_{DS} = -10$ V) for transistors corresponding to the optical micrographs in (a). (c) Representative cross-polarized optical micrographs showing the morphology transition of TIPS-PEN/PS blends printed at 20 °C with decreased TIPS-PEN weight ratio from 100% to 33%. The scale bar indicates 100 μm. (d) Transfer characteristics in saturation regime ($V_{DS} = -10$ V) for the three transistors corresponding to the optical micrographs in (c).

Fig. 2b. Similar trends in contact-line pinning, transition of crystal morphology, and transistor performance as a function of polymer content were also observed when printing at a lower substrate temperature of 20 °C (Fig. 2c and d). The de-pinning effect, however, is more dominant for 20 °C: the lack of positioning control with ill-defined crystal coverage on transistor channels results in their lower device performance and larger spread (Table 2).

3.2. Channel scaling studies

In relation to the phase separation mentioned above, the steep on-switch of current (I_{SD}) of the blend devices is also informative. Steep sub-threshold slopes are observed for all blend transistors, i.e. independent of the TIPS-PEN/PS ratios and process temperatures. Steep sub-threshold slope and low threshold voltage (V_{th}) are usually taken as evidence of a high quality gate dielectric–semiconductor interface with few charge trapping centers [32,33]. This suggests that the polymer binder modifies the interface either directly, for instance, by forming a very thin wetting layer between the silane-treated dielectric and the molecular semiconductor, or indirectly, by influencing the molecular packing of the semiconductor leading to fewer grain boundaries. Meanwhile, reduced charging effects at the top surface of the semiconductor channel ('backchannel effect') by the passivation/encapsulation of phase-separated insulating polymer can also explain the improved characteristics [29]. Although these explanations can play a role also in our blend devices, we propose a third explanation below.

The sub-threshold slope in most blend transistors is very close to the theoretical minimum of 60 mV/decade ($= kT/q \times ln10$) for an Ohmic charge injection from a metal into a semiconductor at room temperature [34,35]. Fig. 3 shows a representative sub-threshold slope as steep as 67 mV/decade in saturation regime for a blend transistor, calculated over more than 2 decades of I_{SD}. This points towards the existence of a tunneling barrier at the metal contacts, which is characterized by a highly non-linear I–V behavior in transfer characteristics [35–38].

We measured the channel length (L) dependence of the total resistance ($R_t = V_{DS}/I_{SD}$) at different gate biases (V_G) in linear regime ($V_{DS} = -1$ V) for two groups of transistors: pure TIPS-PEN vs. blend (67 wt.% TIPS-PEN) (Fig. 4). For the sake of comparison we choose the device series to have similar extracted mobilities. This implies that this group of blend transistors has below-average mobilities. As compared in Fig. 4, R_t decreases linearly with L for the pure transistors, down to a channel length of 2 μm. In contrast,

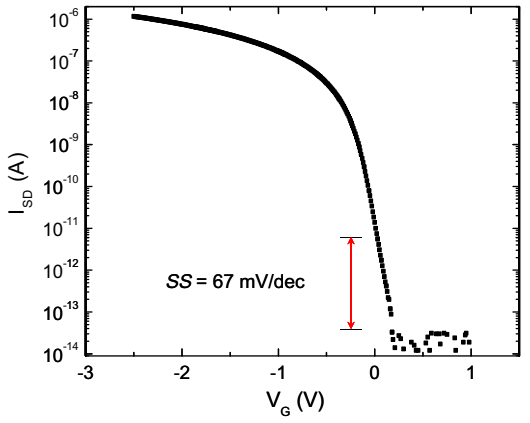

Fig. 3. A representative TIPS-PEN/PS blend (67 wt.% TIPS-PEN) transistor showing the extremely steep sub-threshold slope (*SS*) of 67 mV/decade in saturation regime ($V_{DS} = -10$ V). The *SS* value was calculated from the measured I_{SD} values over more than two decades above noise level, as indicated by the red arrows. The *I–V* curve was measured with 0.01 V increment per step of V_G. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

for the blend transistors, R_t does not decrease further if we decrease L below 10 μm, illustrating the importance of a parasitic contact resistance, R_{sd}, in series with the channel resistance. Apparently the influence of R_{sd} for the extraction of intrinsic channel mobility is substantial for the blend but relatively small for the pure TIPS-PEN transistors. From similar analysis for other blend device series, we know that in all cases the blend transistors are influenced by contact resistance (contact limited) and that the variation in R_{sd} is one of the major causes for the variation in mobility reported in Table 1. This makes it particularly relevant to study the origin of the parasitic contact resistance.

3.3. Contact resistance identified by SKPM

To study the origin of parasitic contact resistance in our devices and correlate it to local charge-transport properties, scanning Kelvin probe microscopy (SKPM) measurements were performed during device operation [39]. As shown in the potential image of Fig. 5a, the pure TIPS-PEN transistors show typical parabolic potential profiles from source to drain electrodes when devices were operated in saturation regime, with a small voltage drop at the source electrode, <15% relative to the voltage drop across the channel. Some negligible potential steps along the channel can be discerned and attributed to the grain boundary effects (see corresponding topography image in Fig. 5a), in line with previous studies [25]. In contrast, the potential profiles of the blend (67 wt.% TIPS-PEN) transistors show significant voltage drops at the electrodes (Fig. 5b). Because >80% of the voltage drastically drops at the source electrodes, the profile inside the channel is absent of details.

This high-Ohmic spatial zone close to the source electrodes of blend devices suggests a substantial barrier for charge injection from the contacts into the channels. Based on the potential profiles in Fig. 5, we can quantitatively compare the contact resistance (R_{sd}) for pure and blend devices operated at the 'on-state' (bias conditions: $V_{DS} = -10$ V and $V_G = -10$ V [22,40]) using [22,39]:

$$R_{sd} = \frac{\Delta V_S + \Delta V_D}{I_{on}} \tag{4}$$

where ΔV_S and ΔV_D are the voltages drops at the source and drain electrodes (in Fig. 5), respectively, and I_{on} is the measured 'on-state' source-drain current I_{SD}. With such calculations we found R_{sd} for pure (~0.13 MΩ) and blend (~0.51 MΩ) devices, respectively, much higher in the blend.

3.4. Charge-trapping at the edges of Au electrodes in blend transistors

Recently electric force microscopy (EFM) was adopted to study charge trapping in TIPS-PEN transistors by Jaquith et al. [41]. Clear evidence of long-lived charge trapping was observed. In their study the films were prepared using different processing conditions, leading to different mobilities (10^{-4}–10^{-3} cm^2/Vs). In that work frequency-shift EFM images were recorded to reflect the variations in local trap density. Here, we use SKPM to directly monitor the possi-

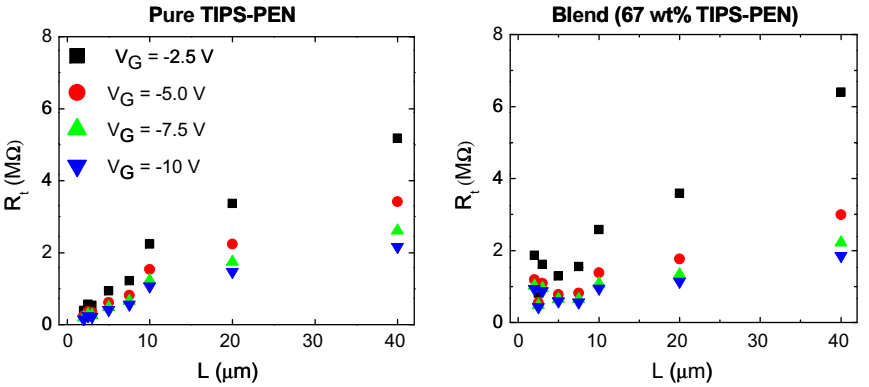

Fig. 4. Channel length dependence of total resistance (R_t) in linear regime ($V_{DS} = -1$ V) at different gate biases (V_G) for pure TIPS-PEN and blend (67 wt.% TIPS-PEN) transistors.

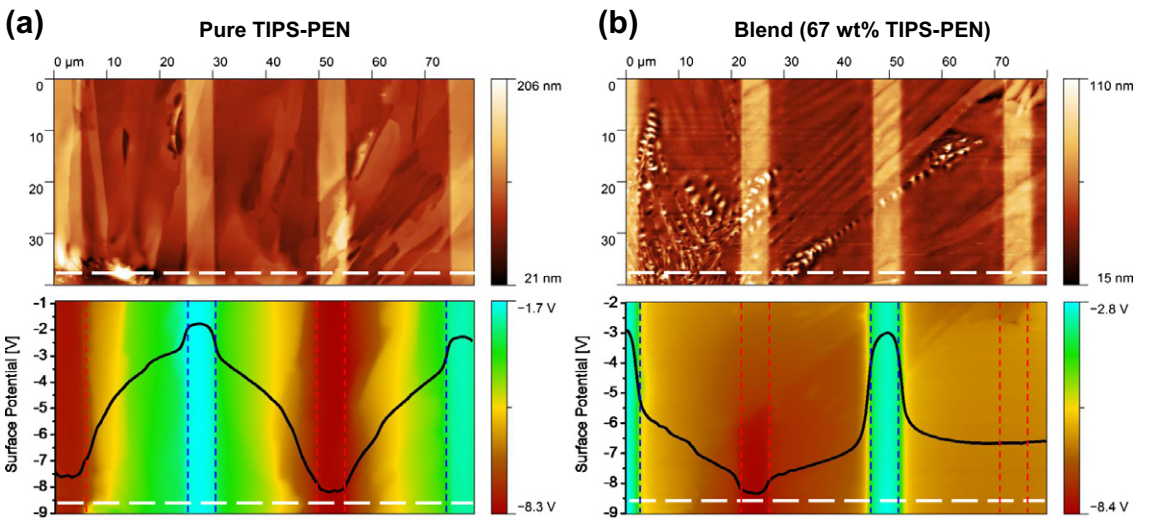

Fig. 5. 2D topography and corresponding surface potential images measured with SKPM of pure TIPS-PEN (a) and blend (67 wt.% TIPS-PEN) transistors (b), as shown in the upper and lower panels, respectively. White dashed lines indicate the positions where the potential cross-sections were taken. Solid black lines denote the cross-section potential profiles along the positions indicated by the dashed white lines. In the potential images, parallel dotted lines in the vertical direction indicate the positions of the edges of source (in blue) and drain (in red) electrodes. Channel length is 20 µm. The transistors were biased in saturation regime ($V_{DS} = -10$ V and $V_G = -10$ V). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

bly trapped charges by measuring their local surface potentials with time. To (possibly) create long-lived trapped charges in our samples, a gate bias of $V_G = -10$ V was applied for ~10 min. During this time, some of the mobile charges may become trapped. The biases were then set to zero in order to extract the mobile charges from the transistor channel, and the local electrostatic potential was measured immediately. Recorded potential images of a pure TIPS-PEN and a blend (67 wt.% TIPS-PEN) transistor are compared. As shown in Fig. 6a (middle image: $t = 0$), only few spots with slightly higher potentials are identified in pure TIPS-PEN channels. These can be correlated to grain boundaries or material voids from the corresponding topography image. The potential differences at these spots disappear on a time scale of ~1 h (bottom image in Fig. 6a: $t = 68$ min). In comparison, in the blend device we observed noticeable local surface potential variations (middle image in Fig. 6b: $t = 0$). If we attribute the contrast in these potential images to trapped positive charges (holes), then we observe substantial hole trapping at the edges of Au electrodes in the blend devices. These trapped holes in the blend films are very long-lived (bottom image in Fig. 6b: $t = 612$ min). For more than 10 h we observed no significant decrease of trapped charges as evidenced by the essentially unchanged potential image.

It has recently been shown that insulating polymer such as poly(α-methylstyrene) can trap charges (holes) in pentacene-based organic transistors [42], and these holes remain trapped in the insulating polymer until sufficient counter charges (electrons) can tunnel into the polymer from the channel [43]. Based on the clear differences of trapped charges in terms of locations, areal densities and life-times between our pure TIPS-PEN and blend devices, we argue that the hole trapping in our blend films is related to the local presence of insulating polymer (PS). The potential variations in the blend films (Fig. 6b) are explained by a lateral phase-separation between TIPS-PEN enriched crystal grains and PS enriched regions. In particular, our SKPM results reveal obvious hole trapping effects exactly at the edges of the source/drain Au electrodes with no apparent correlation with its local crystal morphology. This strongly suggests the presence of a thin film of PS (or PS enriched phase) at the Au electrodes. Such an insulating barrier can explain the differences in sub-threshold slope of the I–V characteristics, contact resistance observed in channel scaling measurements, potential drops and hole trapping at the electrodes observed by SKPM, between our pure TIPS-PEN and blend devices.

3.5. Discussion on the relation between charge-trapping, threshold voltage and channel conductivity

If charges are trapped (de-trapped), or fixed space charges are distributed in the transistor channel on a timescale comparable to the typical duration of the I–V measurement, it can be observed as a hysteresis during the forward and backward sweeps in transfer characteristics. We typically swept the voltages at a rate of 1 V/s, meaning a total measurement time of ~1 min.

In the case of pure TIPS-PEN transistors, non-ideal subthreshold behavior was observed in the form of 'shoulder-like' I_{SD}, with an obvious hysteresis during gate sweeps (Fig. 1a). The (counter-clockwise) hysteresis was independent of the sweep direction, i.e. it was the same when sweeping the gate biases (V_G) in the opposite direction (from -10 V → + 10 V → -10 V, graphs not shown). This hysteresis occurs in the depletion regime, i.e. when the bulk of the semiconductor is (partly) depleted of unintentional charges. We attribute it to charging effects at the top surface of the semiconductor channel (the so-called 'backchannel effect'),

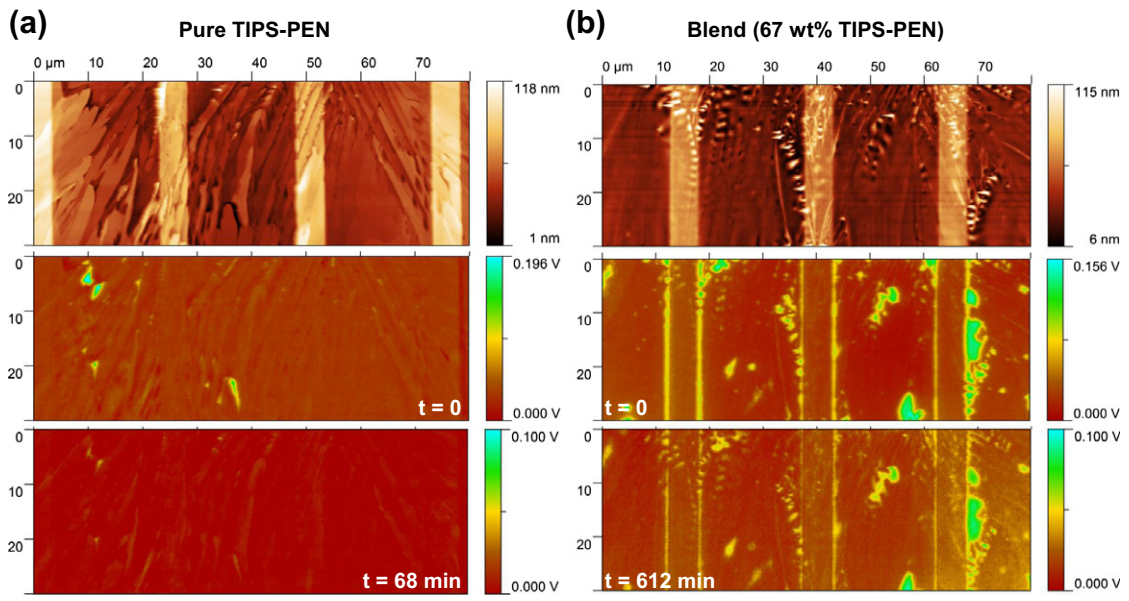

Fig. 6. Time-dependent surface potential images and corresponding 2D topographies recorded by SKPM, for pure TIPS-PEN (a) and blend (67 wt.% TIPS-PEN) transistors (b). The potential images in the middle row ($t = 0$) were measured by grounding all electrodes immediately after a gate bias of −10 V was applied for 10 min. The potential images at the bottom row were measured at $t = 68$ and 612 min after three electrodes were grounded for the pure and blend device, respectively.

as previously reported by Lee et al. [29]. The transfer characteristics of our blend transistors (with different TIPS-PEN/PS ratios) are essentially hysteresis-free, independent of the direction or range of the gate sweeps. Apparently, the 'back-channel effect' is absent in these blend devices. This points to an additional advantage of the insulating polymer binder. It passivates the charge transport layer.

Trapped channel charges can result in shifts of transistor threshold voltages. Furthermore, deep and shallow trapping can also influence the charge transport negatively. We found that in our blend devices that (1) the existence of insulating polymer causes long-term trapping of holes, and (2) the existence of insulating polymer increases the field-effect mobility and has only a marginal influence on the threshold voltage. We attribute this seeming contradiction to the fact that charge-trapping takes place almost exclusively at the contact edges and to a far lesser extent in the channel region of our blend transistors. Less than 1.6% [44] of the initially accumulated mobile charges induced by the gate bias can be trapped at only a few locations inside the channel (Fig. 6b). This explains why we do not observe threshold voltage shifts in our blend transistors. Whether and how much the trapped charges will mitigate charge transport in the channel cannot be determined or quantified. If any, it is expected to result in a decrease in channel conductivity, but in fact we observe the opposite. The net positive effect of polymer blending indicates that a complex interplay between different mechanisms is taking place here.

4. Conclusions

To conclude, we have presented a systematic study of the influence of material composition and ink-jet processing conditions on the charge transport in bottom-gate field-effect transistors based on single droplets of TIPS-PEN/PS blends. Under optimal conditions the field-effect mobility of the blends is significantly higher than that of the pure TIPS-PEN. In addition, blending results in much better sub-threshold characteristics. These results represent an important step towards the application of ink-jet printing for controlled deposition of high-performance transistors in large-area organic electronics. Using channel scaling measurements and SKPM measurements, we show that the sharp turn-on in current in the blends is the result of a contact resistance that originates from a thin insulating PS layer between the injecting contacts and the semiconductor channel. This insight suggests that reducing the contact resistance is the best way forward to improve the transistor characteristics even further.

[44] The ratio (Y) of trapped holes to the gate-induced charges by accumulation at this location is estimated by using the following equation (Ref. [41]): $Y = \Delta\varphi\ /|(V_G - V_{th})|$, where $\Delta\varphi$ is the surface potential difference within the transistor channel region, as determined from SKPM (Fig. 6b ($t = 0$)), a maximum of +0.156 V, under the charging gate bias of $V_G = -10$ V. Y is calculated to be a maximum of ~1.6% for the blend device.

This scalable, fully hierarchical library is well suited to simulate the accurate static and dynamic behavior of the functional blocks present in a RFID system based on organic processes. The SPICE CAD environment [5] has been chosen as the most suitable tool for time domain simulations, while the Agilent ADS suite has instead been adopted for its system-level environment, robust optimization, layouting, and routing capabilities. As a case study, the design of a complete organic RFID chip using the developed libraries is presented and discussed.

The paper is organized as follows: Section 2 presents the major organic technology issues, focusing on the OFET modeling strategy and implementation into commercial CAD tools. Section 3 describes the two basic architectures considered, a simplified memoriless RFID, and a full RFID with memory. The building blocks of the memoriless RFID are described in Section 4, where a full simulation of the RFID is also presented. Section 5 reports the analysis of the additional building blocks needed for the full RFID, in particular, the asynchronous counter. Finally, some conclusions are drawn in Section 6.

2. The OFET model

The core element of the library is the OFET active large-signal model, on which the design of all digital and analog circuits discussed is based. As a case study, the selected OFET refers to a specific public-domain process [6], based on pentacene organic semiconductors, although the proposed approach can be also applied in principle to other OFET technologies. The choice of a pentacene OFET is at present justified by the fact that, among organic semiconductors, this material allows for the development of OFETs with good performances and process stability, both being key issues in the development of organic integrated RF circuits [7]. In fact, among *p*-type materials that are today the most promising candidates for OFET implementation (see e.g. [8]) pentacene reaches comparatively high mobilities: the reported state-of-the-art mobility for the small-molecule pentacene, processed in different ways, are 1.8 cm^2/Vs for a solution processed pentacene, and 5.5 cm^2/Vs for an evaporated pentacene.

The use of a model expressly conceived for Organic Thin Film Transistors, instead of a general-purpose MOS model for digital applications [3], allows a more flexible (e.g. scalable) library to be implemented, also suitable for analog subsystems, such as for example the RF-receiver/harvesting block. The adopted OFET equivalent circuit, shown in Fig. 1, is generated by combining a literature nonlinear DC model with nonlinear, MOS-like capacitances. The DC model, taken from Marinov et al. [9], permits a systematic and accurate fitting [10] of *IV* experimental characteristic, in a wide range of values. Moreover, the model correctly works on all four quadrants of the output characteristics, i.e. for both negative and positive values of the drain-source voltage and drain current. This model feature, consistent with the OFET electrical and structural symmetry, is essential to simulate transistors operating in diode mode, as required in the energy harvesting section, see Section 4.1. A simulated example, showing the diode like

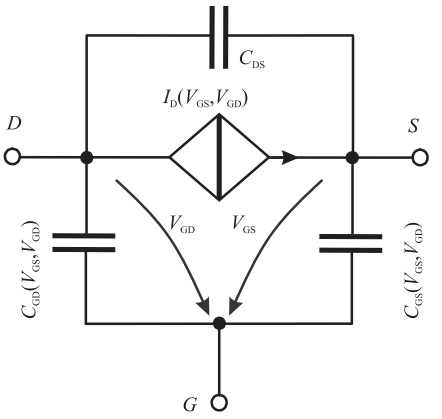

Fig. 1. SPICE and ADS equivalent circuit model of the OFET.

behavior of the direct and inverse output characteristics for zero gate-source voltage is reported in Fig. 2.

The model process (geometrical and physical) and fitting parameters are listed in Table 1 and Table 2 with their short description. The drain current generator I_D (see Fig. 1) is modeled as:

$$I_D = \frac{W\mu_0 C_{OX}}{L(1-\alpha_L)} \frac{V_{DEODR}^{2+\gamma} - V_{SEODR}^{2+\gamma}}{(2+\gamma)V_\gamma^\gamma}, \tag{1}$$

where the so-called source (V_{SEODR}) and drain (V_{DEODR}) effective overdrive voltages [9] are:

$$\begin{aligned} V_{SEODR} &= V_{SS} \ln\left\{1+\exp\left[\frac{V_T - V_{GSI}(1+\delta_{VT})}{V_{SS}}\right]\right\}, \\ V_{DEODR} &= V_{SS} \ln\left\{1+\exp\left[\frac{V_T - V_{GDI}(1+\delta_{VT})}{V_{SS}}\right]\right\}, \end{aligned} \tag{2}$$

where V_{GSI} and V_{GDI} are related to the gate-source V_{GS}, gate-drain V_{GD}, and drain to source current I_D by the following expressions:

$$\begin{aligned} V_{GSI} &= V_{GS} - \frac{R_T}{2}(I_D - |I_D|), \\ V_{GDI} &= V_{GD} + \frac{R_T}{2}(I_D + |I_D|). \end{aligned} \tag{3}$$

Second-order effects such as channel modulation, and bias sensitivity of the threshold voltage, have been included through:

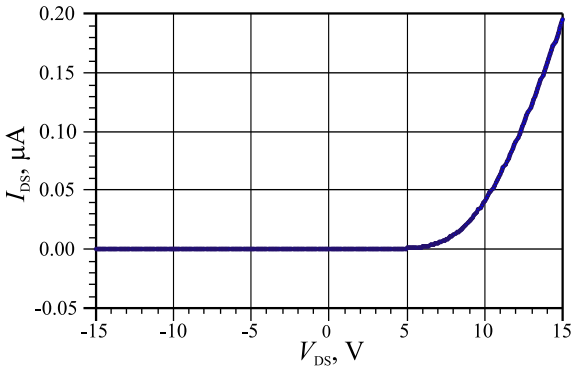

Fig. 2. Philips OFET direct and inverse output characteristic for V_{GS} = 0 V.

Table 1
Process (physical) parameters of the model.

Model parameter	Notation	Value
Channel width	W	300 μm
Channel length	L	4 μm
Gate capacitance per unit area	C_{OX}	345 μF/m^2
Threshold voltage	V_T	1.87 V
Fermi potential	ϕ_N	1 V
Low-field mobility	μ_0 (10^{-9})	54.4 m^2/Vs
Drain-source capacitance	C_{DS}	0.01 pF

Table 2
Fitted parameters of the model.

Model parameter	Notation	Value
Voltage overdrive	V_γ	5 V
Mobility enhancement	γ	1.58
Channel modulation	λ	0.067/V
Subthreshold voltage	V_{SS}	0.9078 V
Sensitivity of V_T to bias	δ_{VT}	−0.0084
Min. (contact) resistance	R_C	26 kΩ
Max. (contact) resistance	R_{Cmax}	88 kΩ
Max. current (R_{Cmax})	I_{Cmax}	1.62 nA
Reduction exp. (R_{Cmax})	N_{IC}	1.58

$$\alpha_L = \lambda|V_{GS}-V_{GD}|\frac{|V_{GS}-V_{GD}|+V_{GT\Delta L}}{2|V_{GS}-V_{GD}|+V_{GT\Delta L}} \qquad (4)$$
$$V_{GT\Delta L} = \max[(V_{GS}-V_T),\ 10\text{ mV}].$$

Eq. (3) shows that V_{GSI} and V_{GDI}, controlling I_D (see Eq. (1)), are the effective intrinsic gate-source and gate-drain voltages respectively, derived from the external ones (V_{GS} and V_{GD}) by deembedding the voltage drop on the contact resistance R_T. This resistance is fairly large in OFETs and has a non linear behavior approximated as a function of the drain current according to:

$$R_T = R_C + R_{Cmax}\left[\frac{I_{Cmax}}{I_{Cmax}+|I_D|}\right]^{N_{IC}}. \qquad (5)$$

The implementation of R_T, embedded in the non linear drain current generator of Fig. 1, preserves the symmetry of the OFET model with respect to an exchange of the drain and source terminals. This property can be verified from the previous reported model equations where, see Eq. (3), the R_T effects are moved from source to drain when the voltage $V_{DS} = V_{GS} - V_{GD}$, and thus the drain current I_D changes sign.

The static OFET model proposed by [9] has been coupled to a set of nonlinear capacitances, to account for dynamic effects that are essential in the design of some components, see for example the case of the oscillator of Section 4.3. We adopted the well-known Meyer's capacitance model, already successfully exploited for pentacene-based OFET [11]. The gate-source and gate-drain capacitances were implemented according to the piecewise analytical expressions in [12], that depend on the controlling voltages V_{GS} and V_{GD}, on the gate dielectric specific capacitance C_{OX}, and on the OFET gate width and length, W and L respectively. The Fermi potential ϕ_N, used within the subthreshold capacitance expressions, has a well defined meaning in p-channel MOS devices; however it can be considered here as a fitting parameter. For a p-channel MOS ϕ_N is of the order of one half of the semiconductor energy gap; taking into account that the pentacene gap is around 2.2 eV [13], this parameter has been set to 1 V. The expressions of C_{GS} and C_{GD} (the gate-source and gate-drain capacitances, respectively) used for $V_{GS} > V_{GD}$ ($V_{DS} > 0$), are:

$$V_{GS} < V_T - 2\phi_N \Rightarrow \begin{cases} C_{GS} = 0 \\ C_{GD} = 0 \end{cases},$$
$$V_T - 2\phi_N < V_{GS} < V_T \Rightarrow \begin{cases} C_{GS} = C_{OX}WL\frac{V_{GS}-V_T+2\phi_N}{3\phi_N} \\ C_{GD} = 0 \end{cases},$$
$$V_{GD} < V_T < V_{GS} \Rightarrow \begin{cases} C_{GS} = \frac{2}{3}C_{OX}WL \\ C_{GD} = 0 \end{cases}, \qquad (6)$$
$$V_{GD} > V_T \Rightarrow \begin{cases} C_{GS} = \frac{2C_{OX}WL}{3}\left[1-\frac{(V_{GD}-V_T)^2}{(V_{GS}+V_{GD}-2V_T)^2}\right] \\ C_{GD} = \frac{2C_{OX}WL}{3}\left[1-\frac{(V_{GS}-V_T)^2}{(V_{GS}+V_{GD}-2V_T)^2}\right] \end{cases},$$

where the last formula implies, since the previous relationships apply for $V_{DS} > 0$, that $V_{GS} > V_{GD} > V_T$. As already done for the drain current, the above relationships have been formulated so as to emphasize the electrical and topological OFET symmetry, thus making their derivation for $V_{GS} < V_{GD}$ ($V_{DS} < 0$) straightforward. In this case, the source and drain roles are exchanged, which is obtained by replacing in the previous expressions V_{GS} with V_{GD}, and viceversa. Although the effect of drain charge storage is negligible at the operating frequency considered, a drain-source constant capacitance C_{DS} has been added to the model, see Table 1.

The model includes 16 parameters that can be divided into two classes, 7 process (physical) parameters listed in Table 1, and 9 fitting parameters listed in Table 2. Process parameters were directly identified following [6], while the other parameters were fitted on the DC output and transimpedance characteristics of different devices of various periphery, using the Agilent ADS suite optimization tool. The model has been then tailored on the Philips process [6], and the fitted OFET model parameters are listed in Tables 1 and 2. As an example, Fig. 3 reports a comparison between the measured (data from [6]), and the simulated device transcharacteristic obtained using a simple MOS like model, already presented in [3], and the advanced OFET model before introduced. The results, relative to $V_{DS} = -1$ V, and -20 V, show the MOS loss of accuracy for higher V_{DS}, where instead the OFET model maintains its effectiveness to follow the measured behavior.

3. RFID architectures

To demonstrate the potential of the proposed library, we consider as a case study two RFID designs: a simplified, memoriless RFID (Fig. 4), and a more complex RFID system with an on-board memory (Fig. 5). From now on, the two schemes will be referred to as the memoriless and full RFID, respectively. In both schemes, the transponder link from and to the reader is represented by the antenna block, although, due to the low operating frequency (a few MHz), near-field coupling should be more correctly represented

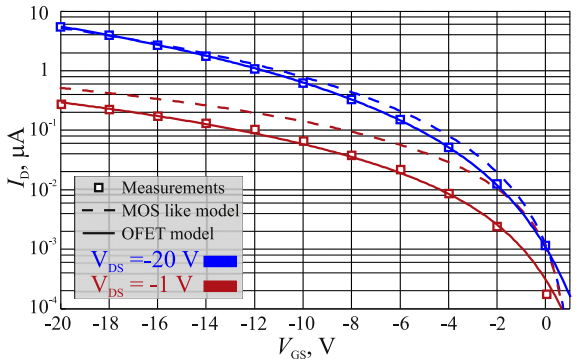

Fig. 3. Philips OFET DC transcharacteristic: comparison between experimental data (markers only) [6], and simulation with a MOS like model [3] (dashed traces), and with the OFET advanced model here described (continuous traces). Results are for $V_{DS} = -1$ V (red traces), and -20 V (blue traces). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

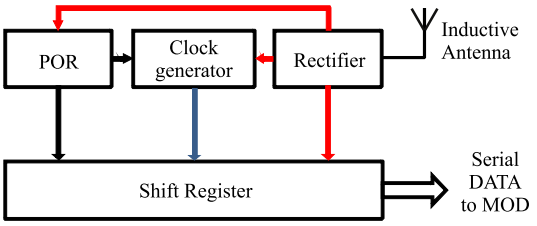

Fig. 4. Simplified RFID TAG system architecture (memoriless RFID).

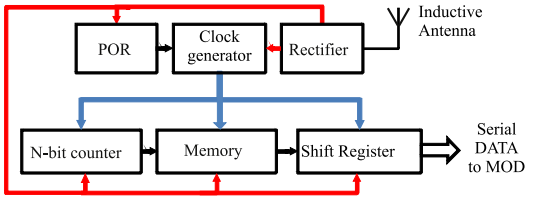

Fig. 5. General purpose RFID TAG system architecture with ROM memory (full RFID).

through in-air coupled coils, as sketched in Fig. 6. In the memoriless RFID (Fig. 4), the synchronous counter scans the data memory, and transfers the data read to the shift register for their serialization. A *n*-bit shift-register (8-bits in our case study), with preset/reset control, replaces the counter, memory and shift register blocks of the full RFID, see Fig. 5.

The memoriless RFID architecture is convenient when the number of bits written on the TAG is low (not exceeding a few tens), since it allows the circuit size and complexity to be reduced. This feature is particularly interesting if we consider the relative immaturity of presently available OFET processes, and the large device areas involved. All blocks of the simplified RFID will be analyzed in detail in Section 4, while some specific comments on the simulation of the full architecture will be presented in Section 5.

The data reading procedure, as exemplified in Fig. 6, is rather straightforward at the TAG side, and shall not be

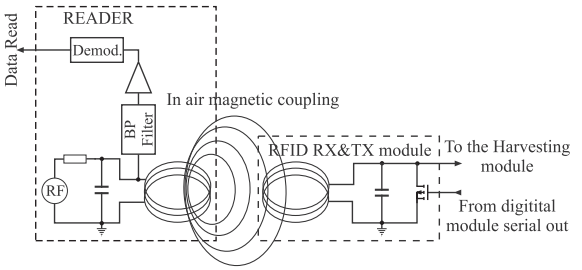

Fig. 6. Circuit exemplifying the implementation of the reader harvesting and data recovery functionalities.

dealt with in the paper: the RF CW signal generated and transmitted by the reader section (Fig. 6, left) energizes the RFID TAG (Fig. 6, right), and triggers the serialized binary data flow with a bit rate imposed by the TAG clock frequency. This data stream, that embeds the TAG code, drives the drain-source resistance of an OFET placed before the rectifier of the harvesting block, forcing an amplitude modulation of the RF inquiring carrier at the primary coil, that can be detected by the reader unit.[2]

4. Simplified architecture (memoriless RFID) analysis and simulation

In this section we will consider the simulation of the individual building blocks of the memoriless RFID (Fig. 4) and the simulation of the whole system.

4.1. Rectifier

The rectifier, i.e. the energy harvester unit, converts the RF CW input signal into DC power. Standard implementations are based on diodes (see e.g. [14]), but this strategy implies increased complexity in terms of process steps. As a more convenient alternative, the same OFET used for the logic gates was used, but in a diode configuration, exploiting the direct and inverse strongly different OFET channel resistance for $V_{GS} = 0$ (see Fig. 2). A limitation of the presently available OFET technology consists in the rather large drain bias voltages needed to properly drive the device (typically $|V_{DS}| \geqslant 10$ V in the process considered); therefore, a voltage booster is typically required within the harvesting unit. The architecture adopted is the classical three stage Cockcroft–Walton multiplier [15], whose circuit is reported in Fig. 7. This approach is modular and the number of stages can be tailored and optimized according to the required DC voltage. A SPICE simulation, assuming an input RF signal consistent with typical "on the field" conditions [16], is reported in Fig. 8, demonstrating the effectiveness of the proposed approach to generate voltage levels consistent with the required bias.

[2] More complex operations are required at the reader side where, before binary data recovery, filtering and amplification are needed. In fact, due to the low in-air coupling, the signal sidebands have small amplitude with respect to the carrier; therefore, analog or digital filtering is needed to separate them from the CW signal, before amplification and demodulation.

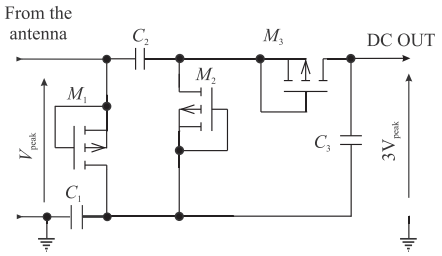

Fig. 7. Circuit of the rectifier/harvester module.

4.2. Digital logic blocks

Since *p*-type organic semiconductors only are practically available at present, the two choices considered in the literature (see e.g. [6]) for logical implementations are (1) logic gates with zero-V_{GS} load, and (2) logic gates with diode load and level shifters. Solution (1) is simpler but requires a larger aspect ratio between the drive and load device (M_1) and M_2 in Fig. 9, respectively) to optimize the inverter transfer curve (Fig. 9). Approach (2), instead, despite requiring a larger number of devices and higher routing complexity, ensures better performances in terms of the transfer characteristic. In our study, we focused on the technologically simpler solution (1). The aspect ratio between M_2, working with $V_{GS} = 0$, and acting as a non linear pull-down resistance, and M_1, has been optimized using SPICE and the Monte Carlo analysis available in the Agilent ADS suite to obtain the best trade-off between noise margins and port gain, thus maximizing the area of the square in Fig. 9 [6]. The final optimized aspect ratio of 25 between M_2 and M_1 ensures a noise margin of the order of 4 V, suitable for the digital blocks. The direct and inverse (mirrored) input–output inverter transfer characteristic with $V_{DD} = -15$ V are shown in Fig. 9.

Following a hierarchical approach, the NAND ports needed to implement logic functions were realized by direct connection of inverters [17], re-optimizing the device geometries in order to maximize the port performances. The values of the pull-down and pull-up device aspect ratio, optimized for the best noise margins, have been found to be 15 and 25, respectively, for the 2 and 3 input NAND.

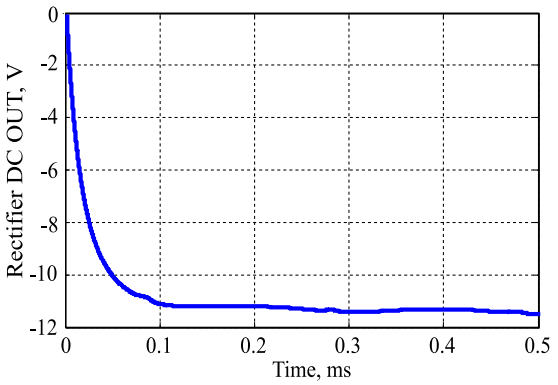

Fig. 8. Rectifier output voltage vs. time, with RF input frequency of 13.56 MHz.

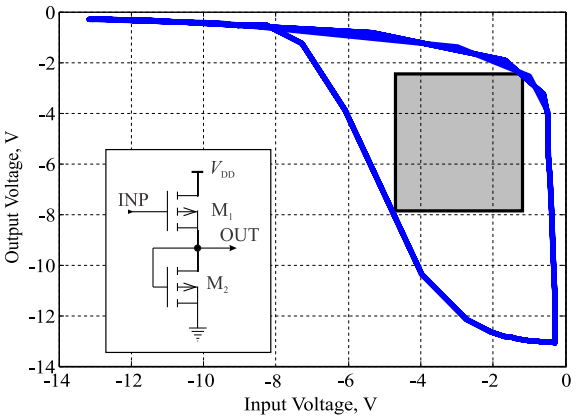

Fig. 9. Inverter (NOT) direct and inverse transfer curve. The inset reports the NOT schematic implementation.

To complete the analysis of the logical building blocks, the sequential basic cell structure, i.e. the elementary 1-bit memory unit, was considered. Among the several flip-flop NAND based architectures, the Delay (D) memory cell with preset and clear hardwiring, reported in Fig. 10, was adopted. The asynchronous preset and clear inputs are used to independently load each D flip-flop, accordingly to the preassigned values, when the POR (power on reset) block (see Section 4.4) generates the enable control signal. In Fig. 11 the correct master–slave D flip-flop simulated response in presence of a clock falling edge is shown; consistent with a master–slave behavior, the flip-flop inputs are sampled during the rising clock edges, then transferred at the outputs at the falling edges (Fig. 11).

4.3. Clock generator

The clock generator provides the timing and synchronization of all functional blocks. Oscillators realized on organic materials running up to 220 kHz have already been demonstrated, see [18]. However, increasing the operating frequency is not an issue, since, to be compatible with the logical gate time constraints in terms of setup and holding time, this has to be limited to a few kHz. The most stringent limitation is related instead to the small current driving capabilities of OFETs. To overcome this drawback, an output driver, made of a multistage (four stages in our case) progressive, exponential, buffer taper has been implemented and optimized. Agilent ADS has been exploited to find the best trade-off among output current level, time delay, power consumption [19], and reduce the oscillation

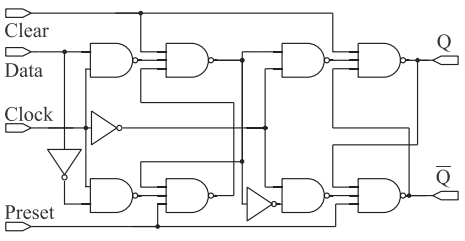

Fig. 10. D-flip flop NAND and NOT based implementation (from [3]).

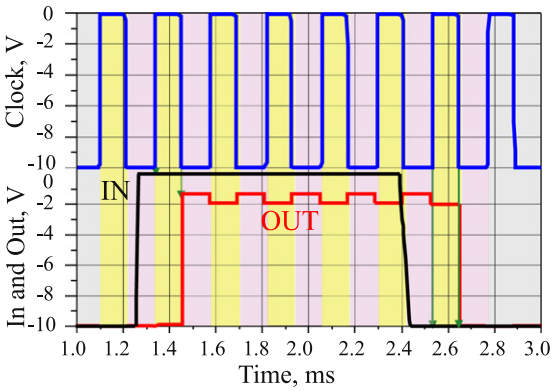

Fig. 11. Master–slave D flip-flop response. Clock at 4.2 kHz (blue curve, top plot), D input (black, bottom plot), output (red curve, bottom plot). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

frequency dependence on the load termination. The implemented topology relies on the classical *ring oscillator* odd stage cascade architecture, with enhanced oscillation frequency stability through interstage *RC* filter cells (see Fig. 12). The obtained results are summarized in Fig. 14, showing the simulation of the overall circuit: an oscillation frequency of 4.2 kHz, well compatible with the flip-flop timing requirements, has been obtained adjusting the capacitance *C* value. Further details can be found in [3].

4.4. Power-on-reset unit

The last block considered is the power-on-reset (POR). At the onset of the incoming RF signal, the system must be activated with proper timing, thus preventing flip-flop metastable behavior, and other spurious effects, such as shift register incorrect reading/loading due to preset activation while flip-flops are in non stable supply condition. The POR signal, generated when the voltage on a capacitor reaches a proper threshold (see Fig. 13), is initially used to drive the hardwired flip-flop preset and clear, and then, to initialize the system clock.

4.5. Complete system simulation

A complete system simulation of the 8-bit demonstrator of Fig. 4 is shown in Fig. 14. In the first ms in Fig. 14 the TAG identification data are loaded into the shift register then, when the POR signal (green curve, center plot of Fig. 14) becomes high, the serial transmission starts. The timing of the system (blue curve, top plot of Fig. 14) shows that the rising and falling edges of the signal were fast enough to avoid unwanted transitions and flip-flop metastates. The ripple exhibited by the serialized output data (red curve, bottom plot of Fig. 14) depends mainly on the voltage drop on the contact resistance R_T (not considered in [3]), that reduces the swing of the output voltage. It is worth noticing that, to test the system behavior in "low voltage" conditions, operation of all RFID components have been demonstrated with a supply voltage of 10 V, that is reduced with respect to the value used in [3]. This allows to significantly decrease the number of cascade stages needed to boost the RF signal in the energy harvesting block, thus reducing the circuit area.

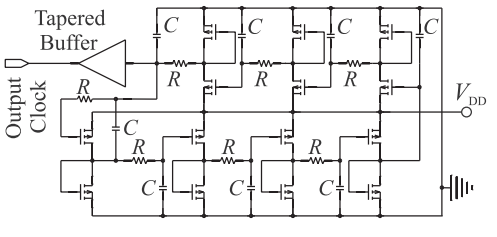

Fig. 12. Ring oscillator (from [3]).

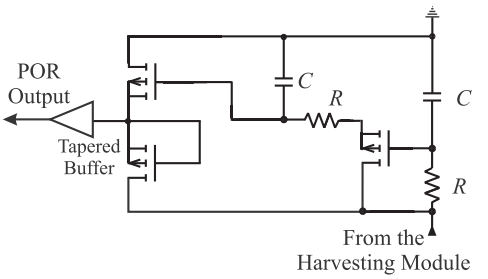

Fig. 13. Power-on-reset (POR) electrical scheme implementation.

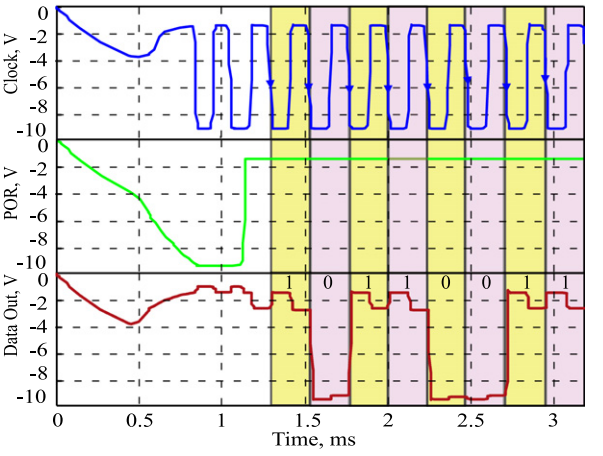

Fig. 14. Simulation result of the complete system. The stored bit code "10110011" is correctly serialized as the red trace shown by the red trace corresponding to the TAG data. The blue curve is the clock, at 4.2 kHz (valid falling edge are with arrows). The green trace is the POR enable signal. Sampling starts at the first clock falling edge after POR signal becomes high. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

5. Standard architecture (full RFID) analysis and simulation

To demonstrate the validity of the library in the design of high-capacity, full RFIDs (Fig. 5) including a memory block, we consider here additional building blocks; in particular, an asynchronous 4-bit counter has been also designed and tested. Larger counters can be derived from the 4-bit architecture by cascading more cells, thanks to the modular structure of asynchronous dividers [20].

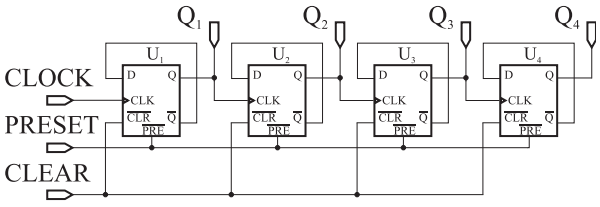

Fig. 15. Asynchronous counter implementation (from [17]).

Concerning the memory, this can be implemented through OFETs via a mask-programmed ROM approach [21], i.e. inserting transistors in a grid of row/column array of metallizations; despite the simplicity of the architecture, even a small-size memory requires a very large number of active devices, leading to computationally intensive circuit-level simulations. For this reason, the memory blocks, that can be more effectively handled through a system level approach, are not explicitly addressed here.

5.1. Asynchronous counter

An asynchronous 4-bit counter, able to completely scan a memory with 16-cells, was designed and simulated. To minimize the OFET number we exploited an asynchronous approach based on toggle T flip-flops. The basic cell of such "ripple counter" architecture (the T flip-flop) is obtained by connecting the input and negated output of a D flip-flop. The single-input, single-output T flip-flop divides by two the input signal and can be used to implement a n-bit counter, i.e. a 2^n binary divider, by simply chaining n T cells. The architecture is intrinsically modular, i.e. it can be tailored to scan memories of arbitrary size, even if there are limitations related to the propagation time along the chain. The implemented 4-bit asynchronous counter scheme is shown in Fig. 15, while simulation results, demonstrating the correct behavior of the block, are reported in Fig. 16.

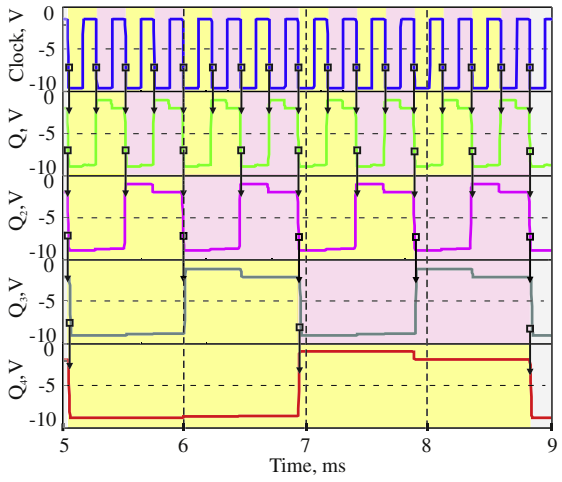

Fig. 16. Simulated behavior of the asynchronous counter. From top to bottom plot: clock at 4.2 kHz, Q_1 = clock/2, Q_2 = clock/4, Q_3 = clock/8, Q_4 = clock/16.

6. Conclusions

A SPICE and ADS analog/digital pentacene OFET library for the simulation and design of organic RFIDs has been presented. Starting from a nonlinear dynamic OFET model, the analog and digital functional blocks of a complete memoriless RFID demonstrator, including a rectifier, a 8-bit shift-register with preset/reset, a ring oscillator, a power on reset block have been discussed and tested. The simulation of the complete system has been shown, demonstrating the suitability of the developed CAD library for the design and optimization of a passive 8-bit RFID TAG operating at 10 V bias voltage. Further results concerning the asynchronous counter block of a full RFID were also presented.

Acknowledgment

The research was supported by the NAMATECH project of Regione Piemonte, Italy.

For this purpose, Capelli et al. have proposed adapting multilayered structures (MLS) as the channel layers of ambipolar FETs. A major advantage of multilayered structures is that various materials can be selected and combined as required to improve device performance, such as carrier injection, transport, and luminescent efficiency. For example, trilayer FETs, in which each layer acts independently for hole transport, light emission and electron transport, have been investigated as LE-FETs with the aim of enhancing luminous efficiency [2]. Even though their report demonstrates that multilayered structures are capable of high luminous efficiency, there is still room for progress in the interfacial morphology, molecular packing and orientation of the layer structures. A rough interface and random molecular packing cause a loss of carrier mobility. The field effect mobility observed in the multilayered FETs is, in fact, somewhat lower than that in single-component FETs. Well-defined film structures are therefore crucial for improving the device properties of multilayered FETs.

To overcome these problems, we have proposed a heteromolecular FET with well-ordered interfacial morphology and molecular orientation. A fine growth method based on an ultra-slow deposition technique has already been established that forms highly ordered molecular layers [6–9]. This method allows layer-by-layer growth and the precise preparation of a molecular superlattice combined with a very high degree of controllability of the monolayer (ML) level [10,11]. In this paper, we discuss a mechanism for ambipolar carrier transport in the thus prepared heteromolecular FET.

2. Experimental

PTCDI-C_8 and QT thin films were employed as channel layers of a heteromolecular FET. These molecules are expected to work as n-type and p-type semiconductors, respectively. Their chemical structures are shown in Fig. 1a and b. PTCDI-C_8/QT layers were formed on SiO_2 (200 nm)/Si substrates under a high vacuum of 10^{-8} Torr. The thicknesses of both the PTCDI-C_8 and QT layers were fixed at 2 MLs. Details of the growth conditions are reported in our previous studies [10,11]. The Al electrodes are deposited on the top of the PTCDI-C_8/QT heterolayers by electron beam deposition to form top-contact heteromolecular FETs. Channel length and width are 50 μm and 400 μm, respectively. The molecular orientation, roughness and density of the heteromolecular layers were confirmed by the X-ray reflection method (not described here) as illustrated in Fig. 2. Surface morphologies were examined by atomic force microscopy (AFM; Seiko Instruments Inc., SPI-4000 E-sweep) in dynamic force mode. FET characteristics were measured in a vacuum chamber ($\sim 10^{-4}$ Torr) using a semiconductor device analyzer (Agilent, B1500A). All experimental processes were carried out under vacuum, without exposure to air.

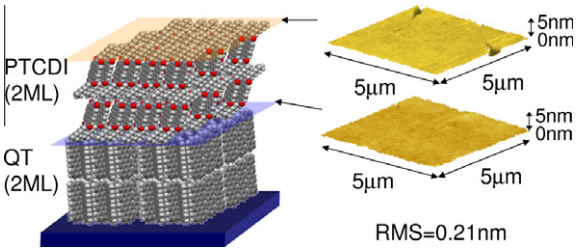

Fig. 2. Schematic illustration of PTCDI-C_8/QT heteromolecular layers and AFM images of surface morphologies of each layer.

3. Results and discussion

The AFM images in Fig. 2 show the surface morphologies of the first QT layer and overlying upper PTCDI-C_8 layer. The root mean square (RMS) roughness values of each layer were estimated to be 0.29 and 0.21 nm in 5×5 μm areas, almost identical to that of the SiO_2 surface (RMS = 0.19 nm): evidence of the perfect surface flatness of the PTCDI-C_8 and QT layers.

The transistor characteristics of the PTCDI-C_8/QT heteromolecular layer were examined under vacuum without exposure to air, since air exposure is known to cause deactivation of the n-type characteristics and debasement of field effect mobility [12]. Fig. 3a and b show the source-drain voltage (V_{DS})–source-drain current (I_{DS}) characteristics of PTCDI-C_8 (2 ML)/QT (2 ML) heteromolecular FETs. A typical p-channel operation was confirmed in the range of negative gate voltage as shown in Fig. 3a. In contrast, Fig. 3b exhibited a monotonic increase of I_{DS} with V_{SD}, even without gate bias voltage (V_G = 0 V), which decreased with increasing V_G up to 40 V. To switch the polarity of the FET operation from the p- to the n-channel, a V_G above 40 V was required, as can be seen in Fig. 3b. Ambipolar operation [13] was thus clearly demonstrated, in which the QT

and the PTCDI-C_8 layer worked as a p-channel and n-channel. Here, holes (electrons) were accumulated in the QT (PTCDI-C_8) layers, according to the polarity and magnitude of the applied V_G as shown in Fig. 3c.

The threshold voltage (Vth) was estimated using liner region data ($V_{SD} \sim 0$ V) by the following equation;

$$dI_{SD} = \mu \frac{CW}{L}(V_G - V\text{th})dV_{SD}$$

where L and W represent the channel length and width, C is the capacitance of the insulator per unit area, and I_{SD}, V_G are the drain current in the saturation region, gate voltage, and threshold voltage, respectively. The Vth values for holes and electrons were estimated to be 6.6 and 61.6 V, respectively. These values are reasonable for the ambipolar transport characteristics as mentioned above.

The carrier mobilities (μ) were calculated using the Eq. (1) to investigate the carrier transport in the FETs. The μ for holes and electrons was estimated to be 3.6×10^{-3} and 2.7×10^{-2} cm^2 V^{-1} s^{-1}, respectively. For comparison, the transistor characteristics of the respective neat layers of PTCDI (2 ML) and QT (2 ML) FETs are summarized in Table 1 [9,14]. It is noteworthy that the μ values for both carriers in the PTCDI-C_8/QT heterolayer FET were comparable to those of the individual FETs of PTCDI (2 ML) and QT (2 ML) neat layers. This fact indicates that the injected holes and electrons were transported independently through the QT and PTCDI-C_8 layers, and were not disturbed, even in the multilayered structure. We thus conclude that the formation of a perfect heteromolecular interface improves carrier transport. In the following section, our discussion is focused only on the electron transport in the PTCDI-C_8 layer. This is because the Vth values for the hole transport in the single-component and the heteromolecular QT FET cannot be compared due to the difference in the metal contacts (Au for QT single-component FET in Ref. [3] and Al for heteromolecular FET in this manuscript).

Another crucial finding is that the Vth for electron transport in PTCDI-C_8/QT heteromolecular FET shifted markedly compared with that of the PTCDI-C_8 single-component FET. The Vth for electron transport was estimated to be 61.6 V, whereas the value was calculated to be 5.0 V in the PTCDI (2 ML) FET [9]. Chemical treatments using self-assembling monolayers on the gate insulator surface have proved to be effective for fine control of Vth [15]. However, the drastic shifts in Vth observed in our study have not been reported elsewhere. Thus, elucidation of this mechanism should lead to control of the operation voltages in ambipolar FETs.

In many situations, this mechanism has been explained in terms of the interfacial dipole and/or charge transfer at the heteromolecular interface. Hence, the shift in the Vth needs to be considered in the context of energy-level alignment. We previously evaluated the energy levels of the PTCDI-C_8/QT heteromolecular layers by photoemission

Table 1
Transistor properties: field effect nobilities (μ) and threshold voltage (Vth) in single-component QT, PTCDI-C_8 and PTCDI-C_8/QT heteromolecular FETs. The mobility of QT 2 ML was estimated from the relation between thickness and mobility as described in Ref. [3], which were estimated from following equation;

$$\mu = \mu_{sat}\left[1 - \exp\left\{-\left(\frac{\theta}{\theta_c}\right)^{\alpha}\right\}\right]$$

where μ_{sat}, θc, and α are the saturated carrier mobility, crossover thickness, and exponent, respectively. The μ_{sat} = 0.015 cm ^{2}/V s, θc = 2.5 ML, and α = 5.0 were used for the mobility estimation of QT 2 ML. (*)Vth of QT FET with Au electrode.

	QT [3]	PTCDI [9]	(p) QT/PTCDI	(n) QT/PTCDI
μ (cm^2/V s)	4.3×10^{-3}	4.8×10^{-2}	3.6×10^{3}	2.7×10^{-2}
V_{th} (V)	58.5*	5.0	6.6	61.6

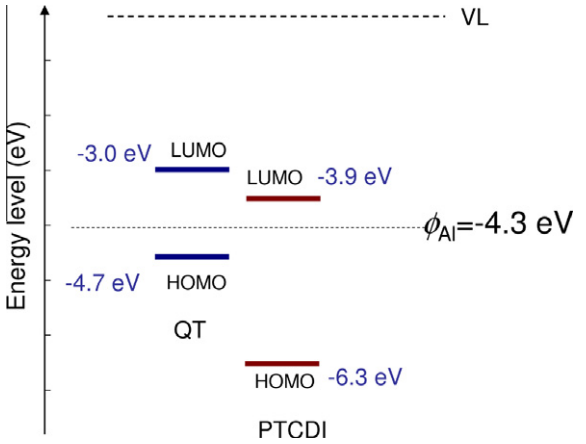

Fig. 4. The energy-level diagram of the PTCDI-C_8/QT heteromolecular layers.

spectroscopy and optical absorption measurements [11]. The energy-level diagram at the heterointerface, together with the work function of the Al electrode (Φ = –4.3 eV) is illustrated in Fig. 4. Here, the HOMO–LUMO levels were modified from those in our previous report by taking into account the effect of exciton binding energy [16–18]. The energy levels at the heteromolecular interface are known to be rearranged by certain effects: for instance, interfacial dipole and charge transfer between interlayers. These phenomena can be explained in terms of charge neutrality level [19,20]. However, no rearrangement of the energy levels was observed in our experiments, as can be seen in Fig. 4. We assume that rearrangement of the energy levels is not induced at well-established heteromolecular interfaces: this is consistent with recent observations by another group [21]. This is because the direct intermolecular interaction of π-electrons is restricted due to the upright orientations of the molecules at the heteromolecular interface, as illustrated in Fig. 2. We can thus rule out any causal link between the interfacial dipole and charge transfer at the heteromolecular interface and the observed shift in Vth.

Another possible reason is that charged carriers are intrinsically present in the films. Similar shifts in Vth have often been reported in other ambipolar FETs [22]. In fact, the heteromolecular FET exhibited a hole transport in

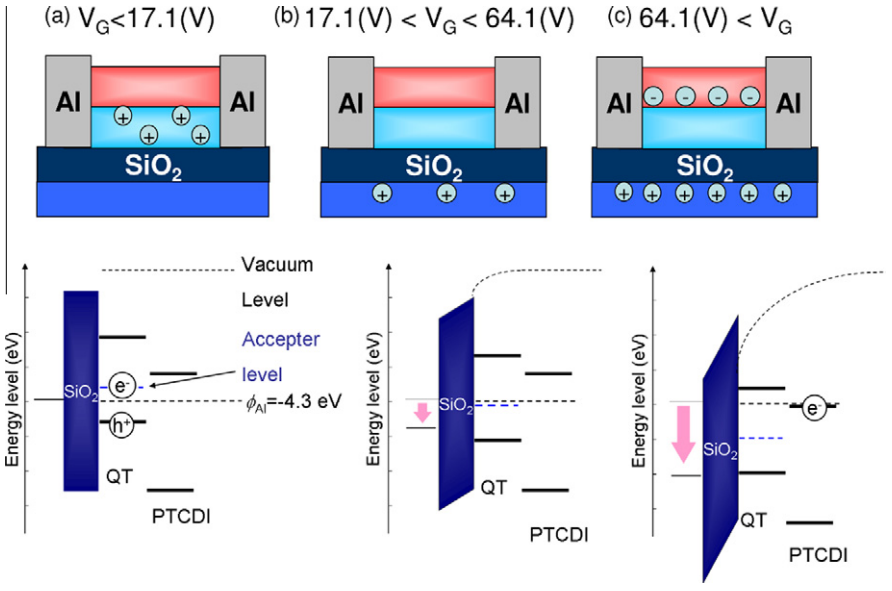

Fig. 5. Schematic illustration of hole and electron accumulation in the PTCDI-C_8/QT heteromolecular FET and respective energy-level diagrams in the range of (a) V_G < 6.6 V, (b) 6.6 V < V_G < 61.6 V, and (c) V_G > 61.6 V.

V_G = 0 V, as shown in Fig. 3, proving that hole carriers were intrinsically doped into the QT layer. Based on these results, we conclude that the observed shift in *V*th for n-channel operation was caused by the presence of hole carriers in the QT layer. The mechanism of this shift in *V*th is illustrated in Fig. 5. In the V_G range below 6.6 V, hole carriers remain in the QT layer (Fig. 5a, V_G < 6.6 V) that hinder the downward shift of the energy level of the PTCDI-C_8 layer. A gate voltage of more than 6.6 V is necessary to deplete the holes from the QT layer (Fig. 5b, 6.6 V < V_G < 61.6 V). A further increase in V_G above 64.1 V is needed to accumulate electrons in the PTCDI-C_8 layer (Fig. 5c, V_G > 61.6 V).

There are several possible reasons for the origin of the hole carriers being in the QT layers. One possibility is structural defects in the films, as proposed by Hayakawa et al. [14], which agree with the transport characteristics of QT FETs formed on SiO_2 substrate. Another is that the carriers are involuntarily doped into the QT layer. Maruyama et al. report that oxygen doping of the organic layer occurs even under high vacuum of below 10^{-4} Pa [23]. In this case, the doping level of oxygen is located at 4.1 eV to form acceptor levels (see the energy-level diagram in Fig. 5a), a picture which closely coincides with our model. By this mechanism, a certain amount of oxygen could be doped into the QT layer, although all experimental processes were carried out under vacuum to avoid air exposure. In either case, the electronic states of the QT layer contribute to the considerable shift of *V*th in PTCDI-C_8/QT heteromolecular FETs. This finding suggests there is potential to control *V*th by carrier doping into molecular layers in ambipolar transistors, without any loss of carrier transport.

In conclusion, this is the first report on the device performance of an ultra-thin heteromolecular FET consisting of well-defined PTCDI-C_8 and QT layers. Ambipolar behavior was clearly demonstrated in the PTCDI-C_8 (2 ML)/QT (2 ML) heterolayer FET. The carrier mobilities were comparable to those of the respective single-component FETs. We conclude that a well-defined multilayered structure is essential to exclude the influence of the hetero-layer interface and to sustain the device performance of the individual FETs. On the other hand, the heterolayer was observed to accumulate carriers in the PTCDI-C_8 layer with a considerable shift in *V*th. We attribute this phenomenon to the presence of hole carriers in the QT layer. Our findings suggest a potential method for radical control of *V*th according to the electronic state of the underlying layer in ambipolar transistors, without disturbing carrier transport.

roughness of the [84]PCBM:PMMA composite layer. Current–voltage (*I–V*) and switching measurements were performed to investigate the memory performance of the fabricated devices. Retention measurements and current analyses of randomly selected cells were carried out to investigate the stability and the reproducibility of the devices. The memory mechanisms for the fabricated devices are described on the basis of the current density–voltage (*J–V*) results.

2. Experimental

The memory devices were fabricated on indium–tin-oxide (ITO)-coated glass substrates. The ITO-coated glass substrates were alternately cleaned ultrasonically in acetone and methanol at 27 °C for 10 min each and rinsed in de-ionized water thoroughly. The chemically-cleaned ITO-coated glass substrates were then dried by using N_2 gas with a purity of 99.99%. Then, 100 mg of PMMA (ALDRICH, M_W = 15000) was dissolved in 10 ml of chlorobenzene solvent, and 2 mg of [84]PCBM (ALDRICH, a mixture of isomers) was mixed with a PMMA/chlorobenzene solution. The chlorobenzene solution dissolved with the [84]PCBM and PMMA polymer was treated by using ultrasonics. The [84]PCBM:PMMA layer with a thickness of 50 nm was coated on the ITO-coated glass substrate at 300 rpm for 5 s, 3000 rpm for 25 s, and 300 rpm for 3 s at room temperature by using spin-coating method. The [84]PCBM:PMMA layers with thickness of 31 and 63 nm were also formed on the ITO-coated glass substrates. After the spin-coating of the mixed solution, the solvents existing on the samples were removed by putting the samples on a hot-plate at 135 °C for 30 min; then, the samples were cooled at room temperature for 1 h. Finally, the top Al electrodes with a thickness of 200 nm and a diameter of 500 μm were thermally deposited through a metal mask at a system pressure of 1×10^{-6} Torr. A schematic diagram of the OBDs fabricated with a [84]PCBM:PMMA composite is shown in Fig. 1. The *I–V*, retention, and reproducibility measurements were performed by using a HP 4140B pA meter and DC voltage source at 300 K.

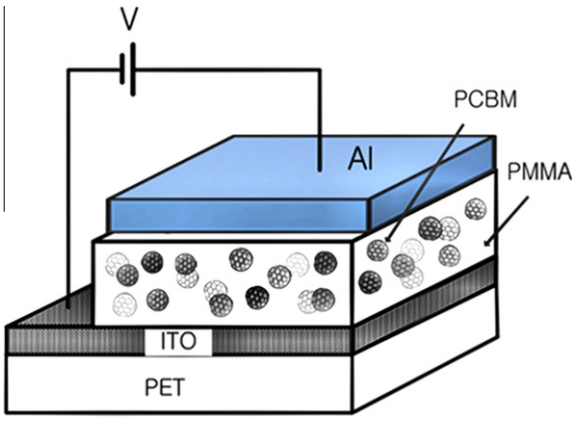

Fig. 1. Schematic diagram of the fabricated OBDs containing [84]PCBM:PMMA.

3. Results and discussion

Figure 2 shows an AFM image of the PMMA polymer layer containing [84]PCBM with a PCBM:PMMA layer thickness of 50 nm on an ITO-coated glass substrate. The AFM image shows that the surface of the PMMA layer containing the [84]PCBM is very uniform. The root-mean-square value of the surface roughness, approximately 0.5 nm, indicates a very good surface roughness, resulting in the fabrication of reliable and reproducible devices.

Figure 3(a) shows the *J–V* curves for the Al/[84]PCBM:PMMA/ITO/glass devices with a PCBM:PMMA layer thickness of 50 nm for voltage from −7 to 0, 0 to 7, 7 to 0, and 0 to −7 V. The *J–V* curves for the memory devices clearly show current hystereses, indicative of a memory effect in the nonvolatile memory device. The device currents abruptly increase at approximately −3.5 V, resulting in a conductivity transition from low to high values. The high conductivity state and the low conductivity state are defined as the ON state and the OFF state, respectively. The state variations from the OFF state to the ON state and from the ON state to the OFF state are equivalent to the writing and the erasing processes of a digital memory cell, respectively. The ON state of the device is achieved by applying a voltage above −3.5 V to the device. The ON state current at −7 V has a maximum value, and the ON state is maintained as the voltage is swept from −7 to 7 V. The state transition into the OFF state is achieved by applying an erase voltage of about 7 V. The *J–V* characteristics of the device did not change significantly, regardless of the number of voltage sweeps, as shown in Fig. 3(a), indicating good stability of the device fabricated with [84]PCBM. The maximum ON/OFF current ratio of the OBDs at 2 V was approximately 1×10^3.

Figure 3(b) shows the *J–V* curves for the OBDs with different PCBM:PMMA thicknesses of 31, 50, and 63 nm. The *J–V* curves for the OBDs are affected by the thickness of the PCBM:PMMA layer. While the *J–V* curves for the device with a thickness of 31 nm shows the largest ON and OFF current densities, the ON/OFF ratio of the device is smaller than that of the device with a thickness of 50 nm. The *J–V* curves for the device with a thickness of 63 nm exhibits the smallest ON/OFF ratio. The *J–V* curves for the device with a thickness of 50 nm shows the highest ON/OFF ratio among three devices. Because the electron injection probability at the electrodes decreases with increasing PCBM:PMMA layer thickness due to a lower interface electric field [20], the

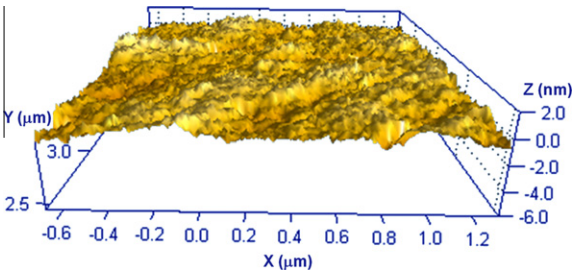

Fig. 2. AFM image of the PMMA polymer layer containing [84]PCBM with a PCBM:PMMA layer thickness of 50 nm on an ITO-coated glass substrate.

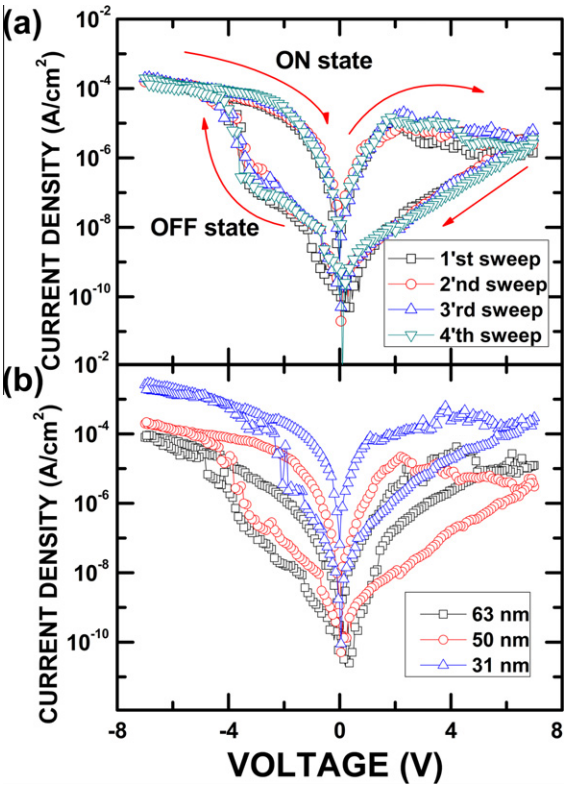

Fig. 3. (a) Current density–voltage (J–V) curves for the Al/[84]PCBM:PMMA/ITO/glass devices with a PCBM:PMMA layer thickness of 50 nm at different voltage sweeps, and (b) J–V curves for the devices with PCBM:PMMA layer thicknesses of 31, 50, and 63 nm.

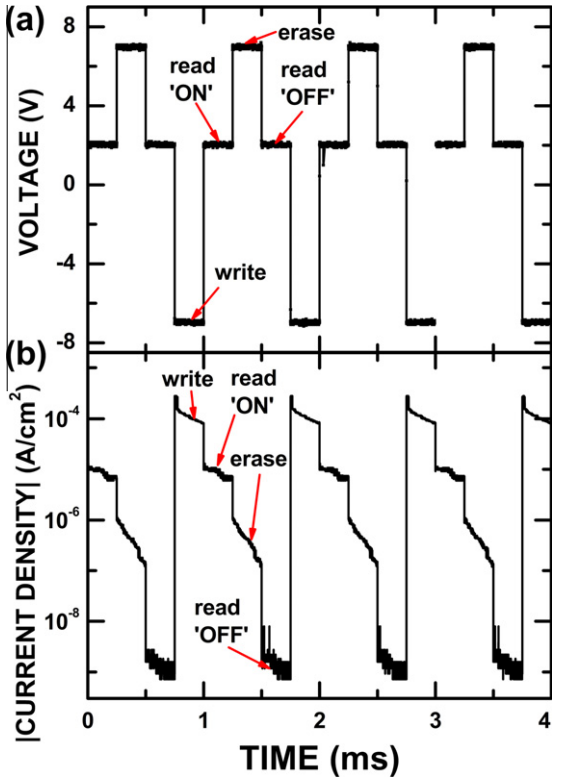

Fig. 4. Switching results for the (a) input voltage pulse and the (b) output current density for the OBDs with a PCBM:PMMA layer thickness of 50 nm in the atmosphere.

current density decreases with increasing layer thickness, as shown in Fig. 3(b). Because carrier trap sites increase with increasing layer thickness, the conductivity transition from the OFF to the ON states for the device with a thickness of 63 nm is not easily occurred due to a large number of trap sites. However, the traps of the PCBM:PMMA layer in the device with a layer thickness of 31 nm are not enough to occupy carriers for achieving the large ON/OFF ratio. Therefore, the OBDs with a thickness of 50 nm show the best electrical performance with the largest ON/OFF ratio.

Figure 4 shows the switching characteristics of the memory devices with a PCBM:PMMA layer thickness of 50 nm. The input voltage pulses of the write, read, and erase voltages for measuring the switching characteristics shown in Fig. 4(a) were set as −7, 2, and 7 V, respectively. A voltage pulse with a cycle of 0.001 s is applied to the memory device. The erase voltage pulse is applied to change the current state of the device to the OFF state. Then, the current densities at a read voltage pulse are approximately 8×10^{-9} A/cm^2, as shown in Fig. 4(b). Sequentially, the writing voltage pulse is applied to turn the device to the ON state. Then, the current densities at a read voltage pulse are approximately 1×10^{-5} A/cm^2, as shown in Fig. 4(b). The switching characteristics of the devices are sensitive to the electrodes due to the different work functions of the electrodes [21]. The J–V results of Fig. 3 and the switching results of Fig. 4(b) show excellent memory performance. These results offer opportunities for promising applications in next-generation nonvolatile memory devices.

Figure 5 shows the retention performances of the ON state and the OFF state current densities for the OBDs with a PCBM:PMMA layer thickness of 50 nm in the atmosphere. The ON state and the OFF state currents are monitored by applying the read voltage after applying the write

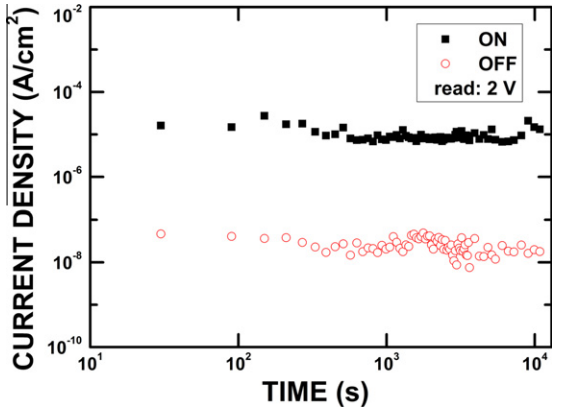

Fig. 5. Retention characteristics of the current densities of the ON state and the OFF state for the OBDs with a PCBM:PMMA layer thickness of 50 nm in the atmosphere.

voltage and the after applying the erase voltage, respectively. A read voltage of 2 V is applied to the ON state and the OFF state of the devices. A slight degradation of the ON state and the OFF state currents occurred, as shown in Fig. 5. No significant degradations of the devices were observed in the ON state and the OFF state until 10^4 s, indicative of the excellent memory retention performance of the memory devices.

Figure 6 shows the reproducibility results for the fabricated devices with a PCBM:PMMA layer thickness of 50 nm. The ON state and the OFF state currents are measured in 20 randomly selected cells. The ON/OFF ratios of the 20 cells for the memory devices are approximately 1×10^3, as shown in Fig. 6. The currents density of the ON state and the OFF state for the 20 cells were in the range of about 10^{-5} and 10^{-8} A/cm^2, respectively, indicative of the high reproducibility of the fabricated devices. The difference between the minimum current density of the ON state for the 17th cell and the maximum current density of the OFF state for the 2nd cell is above 10^2, indicative of a high memory margin. The high reproducibility of the OBDs originates from the stable material characteristics of [84]PCBM and from the uniform surface roughness of the [84]PCBM:PMMA composite. When the surface roughness of the [84]PCBM:PMMA composite layer is rough, the interface characteristics corresponding to carrier injection at the two electrodes are different from each other. The surface uniformity of the [84]PCBM:PMMA composite layer enhances the reproducibility of the memory devices.

The memory mechanism in the Al/[84]PCBM:PMMA/ITO/glass devices can be explained in terms of trapping and detrapping of electrons in defect sites in the organic layer [22]. *J–V* fittings were performed to investigate the carrier transport characteristics. The thermionic emission (TE) current of the OFF state at low voltages is dominant from 0 to −1 V. In the voltage range from −1 to −3.5 V, the TE current and the space-charge-limited current (SCLC) with a slope of 2 appear together, indicative of the existence of charge trapping sites. The current of the device abruptly increases at a threshold voltage of −3.5 V. When the traps in the organic materials are fully occupied by carriers, an abrupt increase in the current typically appears at a specific voltage [23]. After the abrupt increase in the current, the ON current of the device follows the trap-filled SCLC with a slope of 2. Because the device without [84]PCBM does not show any current hysteresis, the memory effect of the device with [84]PCBM originates from the [84]PCBM in the PMMA layer. The [84]PCBM in the device provides charge trapping sites; thus, the trap-filled SCLC in the ON state is attributed to the electrons trapped in the [84]PCBM, which is in reasonable agreement with another reported result [22]. A negative differential resistance (NDR) behavior of the ON current at positive voltages appears in the voltage range between 2 and 7 V. The electron tunneling between nearby [84]PCBM molecules can occur in a high electric field with the opposite polarity, resulting in a appearance of the NDR behavior [24]. When the [84]PCBM molecules are emptied by the electron tunneling, the device returns to the OFF state.

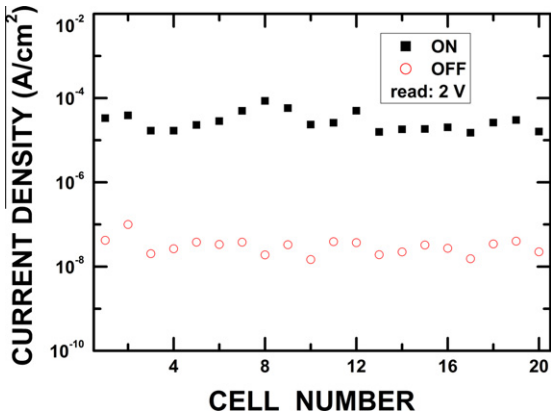

Fig. 6. Reproducibility results of 20 randomly selected cells for the OBDs with a PCBM:PMMA layer thickness of 50 nm.

4. Conclusions

AFM images of nonvolatile memory devices based on [84]PCBM embedded in a PMMA layer showed that the surface of the [84]PCBM:PMMA composite layer was uniform. The *J–V* curves for the OBDs clearly showed current hystereses, indicative of a memory effect in the nonvolatile memory device. The maximum ON/OFF ratio at 2 V for OBDs with a PCBM:PMMA layer thickness of 50 nm was approximately 1×10^3. The switching characteristics showed that the OBDs with a PCBM:PMMA layer thickness of 50 nm had a rewriteable characteristic and a retention time of about 10^4 s. The current densities of the ON state and the OFF state for 20 randomly-chosen cells with a PCBM:PMMA layer thickness of 50 nm were in the range of about 10^{-5} and 10^{-8} A/cm^2, respectively, indicative of the high reproducibility of the fabricated OBDs. The memory mechanisms for the fabricated device were described on the basis of the *J–V* results. The present results indicate that [84]PCBM:PMMA composites hold promise for potential applications in next-generation nonvolatile memory devices.

and OSL based on the high performance host/guest system BN-PFO doped with the stilbene dye 1,4-bis(2-(4-(*N*,*N*-di(*p*-tolyl)amino)phenyl)vinylbenzene (DPAVB) [4]. First we studied the laser emission of second order distributed feedback (DFB) lasers under excitation with repetition rates up to 5 MHz. In the second experiment we pumped an BN-PFO/DPAVB based laser with a laser diode and studied the spectro-temporal behavior of the organic laser emission. By measuring the material gain and the triplet absorption spectra we could explain the substantially different behavior, of a quasi cw emission found for BN-PFO on the one hand and a termination of the laser emission in the doped system on the other hand. We attribute the latter phenomenon to the spectral overlap of the triplet induced absorption and the optical gain, leading to an increase of the laser threshold due to piled-up triplet excitons. For the pure BN-PFO we evidence spectrally separated material gain and triplet absorption spectra, which excludes absorption and quenching of the laser emission and leads to a quasi-cw operation.

2. Experimental

All organic layers were spin-cast from toluene solution with a layer thickness of 180–190 nm on silicon dioxide substrates. The layer thickness was controlled by a Veeco Dektak 8 surface profiler. As substrates for our second order DFB lasers we used structured silicon dioxide with a grating period of 270 nm for BN-PFO and 300–310 nm for BN-PFO/DPAVB. The gratings had a modulation depth of 50 nm and a duty cycle of 80:20 (hill:valley). The gain and triplet absorption measurements were carried out on silicon substrates covered with 2 μm silicon dioxide.

During all optical measurements the samples were mounted in a nitrogen purged sample chamber. The laser- and photoluminescence emission of the organic layers are detected with spectral and temporal resolution using a streak camera (Hamamatsu C4334).

The experiments with variable repetition rate (shown in Figs. 1 and 2) were carried out using a mode-locked, frequency-tripled, diode pumped solid state (DPSS) laser emitting at $\lambda = 355$ nm (Spectra-Physics, Vanguard) as a pumping source. The pulse width and repetition rate were 12 ps and 80 MHz, respectively. For the variation of repetition rate between 1 kHz and 5 MHz, an acousto–optical modulator was employed as pulse picker. Speed limitations of the modulator allowed only to pick a packet of approximately 8–10 of the mode-locked pulses at one time rather than individual pulses. The pump laser has additionally been chopped to deliver pulse trains of 400 μs duration which fits into the temporal window of the streak camera. The pump light was focused to a spot of $250 \times 250\ \mu m^2$ on the sample. Further details concerning the measurement setup have been published before [16].

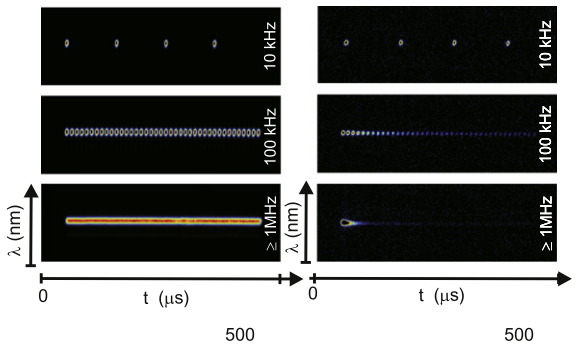

Fig. 1. Spectro-temporal images of the laser emission of pure BN-PFO excited at $1.4 \times E_{th}$ (left) and BN-PFO doped with 5 wt.% DPAVB excited at $1.9 \times E_{th}$ (right) for varied repetition rates. The displayed spectral windows are 440–451 nm for BN-PFO and 480–491 nm for BN-PFO/DPAVB, respectively.

To achieve diode pumped lasing in BN-PFO/DPAVB (Fig. 3) we used a GaN based laser diode emitting at $\lambda = 405$ nm, provided by Nichia Chemical (NDHV2200A-PAE1). The multimode output of the diode was focused to spot of approximately $200 \times 120\ \mu m^2$. By optimizing the grating period, the organic layer thickness and the doping concentration we were able to achieve a laser threshold of 0.75 $\mu J/cm^2$, which is sufficiently low to allow pumping with the limited output power of the inorganic laser diode. A grating period of 320 nm, a film thickness of 180 nm and a doping concentration of 4 wt.% was used. Further details can be found elsewhere [4].

As sources for optical pumping in the photo-induced absorption measurements (Figs. 5 and 7) the laser diode and a DPSS laser (AOT) emitting at $\lambda = 355$ nm were used as pump and probe excitation sources, respectively. The pulse width and the repetition rate of the DPSS laser were 700 ps and 2 kHz. The absorption was measured in a waveguide structure build up by the organic layer on top of the silicon dioxide substrate. A long laser diode pump pulse is used to generate triplet states via intersystem crossing in a defined area of the waveguide (pulse length 10 μs, spot size $0.77 \times 0.18\ mm^2$, pulse energy density 600 $\mu J/cm^2$). A probe pulse (DPSS) follows the pump pulse (laser diode) with a fixed time delay of 200 ns for the triplet absorption measurement and a variable time delay of 200 ns to 488 μs for triplet lifetime determination. The minimal delay of 200 ns between the pump and the probe pulse assures that all photoluminescence (PL) is decayed. The probe pulse is focused on a spatially separated area on the sample (spot size 27 μm × 0.5 mm). The waveguided emission generated by the probe pulse has to pass the region where the excitation by the pump pulse has led to the creation of triplet excitons. Therefore, the intensity of the edge emission, detected for different delay times between pump and probe pulse is directly related to the absorption due to triplet excitons in this region of the waveguide. Further details about the measurement technique have been reported previously [14,18].

The material gain was measured using the variable stripe length method (VSL) [19]. Here a Triax 320 monochromator (grating 300 lines/mm, Jobin Yvon) combined with an liquid nitrogen cooled charge couple device camera was used for signal detection. The DPSS laser (AOT) was used as optical pumping source. For further details see [20].

3. Results

3.1. High repetition rate excitation of BN-PFO and BN-PFO/DPAVB OSLs

Initially, we studied the output power of the OSL depending on the repetition rate of the pulsed optical excitation. We compared the laser emission of BN-PFO and BN-PFO/DPAVB based lasers at varied repetition rates between 1 kHz and 5 MHz. Fig. 1 shows streak camera images of the laser output for both laser devices at an excitation slightly above the laser threshold energy density (E_{th}). Here, the BN-PFO device is excited at $1.4 \times E_{th}$ which corresponds to 3.5 μJ/cm^2 and the doped device is excited with 3.2 μJ/cm^2 which equals to $1.9 \times E_{th}$. As reported before [16], the undoped device shows no influence of the repetition rate on the laser output. On contrary, in the doped system the laser emission terminates within the first μs from the beginning of the excitation at a repetition rate of 1 MHz. For lower repetition rates, the decrease of the laser emission becomes less severe. It is important to note, that the temporal decrease of the emission is not due to degradation of the organic material. For each individual pulse-train we repeatedly measured the same behavior on the same spot of the sample.

The OSL intensity, corresponding to the streak camera images shown in Fig. 1, is displayed in Fig. 2(a) and (c). At a high excitation energy density of $3.1 \times E_{th}$ the laser emission of the doped device persists during the excitation pulse even at 1 MHz (Fig. 2b). Nevertheless, also in this case a significant decrease of 80% of the emission (at 1 MHz) from the beginning of the excitation is observed. Subsequently, the OSL emission remains constant at a substantially lower level. Additionally, we determined the la-

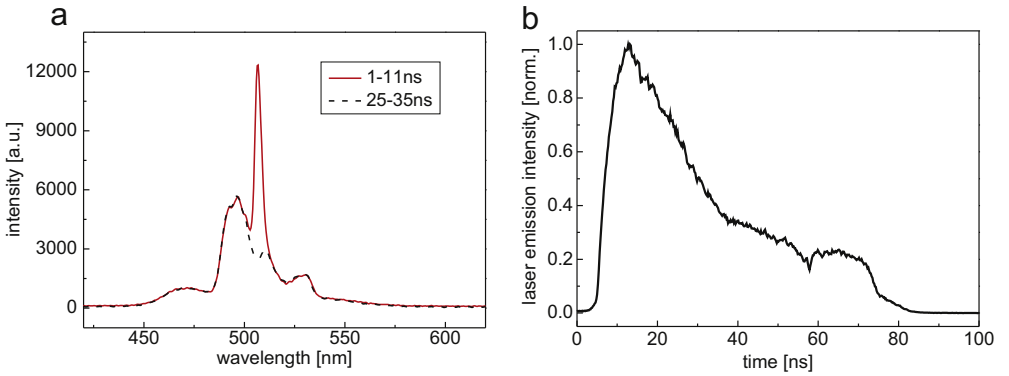

Fig. 4. (a) Emission spectra of a laser diode pumped BN-PFO/DPAVB laser excited at 1.2 × E_{th} (Fig. 3(c)). The average emission is displayed in a time region from 1 ns to 11 ns and 25 ns to 35 ns after the beginning of the excitation pulse. ser threshold E'_{th} in a steady region, 250 μs after the beginning of the excitation pulse (shaded region in Fig. 2(b)). The results are shown in Fig. 2(d). In case of pure BN-PFO we determined a constant laser threshold for all repetition rates. In the doped system E'_{th} is increasing with repetition rate by a factor of 2 at 1 MHz.

3.2. Laser diode pumping of BN-PFO/DPAVB

In the second experiment we studied the spectro-temporal behavior of an OSL based on BN-PFO/DPAVB pumped with an inorganic laser diode. Aside from the relevance of diode pumping for many applications, this allows to adjust the pump pulse length as desired. Specifically, a longer pump pulse duration as opposed to the DPSS laser is possible. Here, the inorganic laser diode was driven with a rectangular pulse of 70 ns length. As it can be seen from the photoluminescence in Fig. 3(a), the optical output of the la-

ser diode reproduces the rectangular electrical excitation pulse. Furthermore, the time resolved evolution of the organic laser emission is shown for different pump energy densities. Below lasing threshold (Fig. 3(a)), only photoluminescence is observed. At the lasing threshold a short laser emission peak appears immediately after the beginning of the excitation pulse (see Fig. 3(b) in the red circle[1]). With increasing pump power density, the laser emission becomes stronger but terminates after 25 ns at $1.2 \times E_{th}$ (Fig. 3(c)). Only at $1.8 \times E_{th}$ the laser emission persists during the all the excitation pulse (Fig. 3(d)). Even though, the output power decreases to 20% in comparison to the maximum laser emission at the beginning of the excitation pulse (Fig. 4(b)). Fig. 4(a) shows the average emission spectra for an excitation energy density of $1.2 \times E_{th,}$ in a time window of 1–11 ns following the start of the excitation pulse and in a time region of 25–35 ns, respectively. Obviously, the clearly visible laser line disappears after 25 ns.

Due to the higher laser threshold of undoped lasers and the very limited output power of inorganic laser diodes, similar experiments for pure BN-PFO lasers were not successful in our case. Nevertheless, the experiments, where we pump our laser with a variable repetition rate, presented in Section 3.1, offer an excellent alternative.

3.3. Gain and triplet absorption in BN-PFO and BN-PFO/DPAVB

In order to explain the temporal behavior of the laser emission at quasi-cw excitation, we studied the spectra of the optical gain and the triplet induced absorption in pure and doped BN-PFO. The material gain spectra of BN-PFO/DPAVB and BN-PFO are shown in Fig. 5(a) and (b). Compared to the undoped BN-PFO, the maximum gain is shifted from 450 nm to 505 nm in BN-PFO/DPAVB. As expected from the lower lasing threshold, the doped material system reaches a positive gain at lower energy densities than the pure BN-PFO. Furthermore, the doped system offers a broader gain spectrum. The material gain vs. energy density is shown in Fig. 5 for low excitation energy densities. Using a linear fit we can derive a gain slope of 24 $(cm^{-1})/(\mu J/cm^2)$ for BN-PFO/DPAVB and 21 $(cm^{-1})/(\mu J/cm^2)$ for BN-PFO.

In addition to the gain spectra the photo-induced absorption spectra are displayed in Fig. 5. The photo-induced absorption spectra of the doped and the undoped BN-PFO show similar spectral characteristics. We observed an increasing absorption for wavelengths longer than 480 nm in both cases. For a wavelength shorter than 480 nm the photo-induced absorption is less than 1 cm^{-1}. In case of BN-PFO/DPAVB the gain spectrum strongly overlaps with the photo-induced absorption spectrum, whereas both spectra are well separated in the undoped BN-PFO film.

By increasing the time delay between the pump and the probe pulse from 200 ns up to 488 μs we determined the lifetime of the photo-induced absorption. Our results for BN-PFO, BN-PFO/DPAVB and pristine DPAVB are displayed in Fig. 7. For the pristine materials a monoexponential fit is used. The doped system shows a biexponential behavior, which could be fitted well using the time constants of the pristine materials. The photo-induced absorption in BN-PFO and BN-PFO/DPAVB persists for several 100 μs, whereas in pristine DPAVB the absorption disappears after 10 μs.

4. Discussion

Our experimental results have shown very different dynamics of the OSL based on the neat- and the doped organic gain media pumped at high repetition rates. The organic laser emission of pure BN-PFO based lasers was unaffected by an increase of the repetition rate, whereas the DPAVB doped gain medium led to a dramatic decrease of laser emission at quasi-cw excitation (high repetition rates or long excitation pulses). In the doped system, Förster energy transfer [21] from the host to the guest molecules leads to a shift of the maximum gain by 55 nm. Our photo-induced absorption measurements evidenced a persisting absorption (several 100 μs) in both systems, which had a similar spectral behavior. Only in case of the doped system the measured photo-induced absorption overlaps with the material gain spectrum.

Previous reports have investigated the photophysical properties of PFO derivates. Particularly, triplet excitons with corresponding lifetimes on the order of 100 μs to 1 ms [22,23] would be a candidate to explain the above findings. The photo-induced absorption due to triplet states has a spectral maximum at around 750 nm in solution with a short wavelength tail extending well into the spectral region of the stimulated emission in our BN-PFO/DPAVB system [22–24]. Similar T_1-T_n absorption spectra have been reported in spin-cast PFO thin films [24].

Triplet formation occurs either by intersystem crossing from singlet state or through the recombination of polarons. Cadby et al. have reported that in glassy phase PFO intersystem crossing is the dominant mechanism for triplet generation [22]. They estimated a triplet quantum yield of 5%. Additionally to triplets, absorption due to polarons has been observed in PFO after optical excitation [22,24]. β-phase PFO has been shown to facilitate the formation of polaron pairs [22,24]. It is worth to note that polaron absorption observed in β-phase PFO peaks around 1.9 eV and could also contribute to our measured photo-induced absorption [22,24].

Our modified BN-PFO has been shown to suppress the formation of β-phase in spin coated films [16], which reduces the formation of polaron pairs [22,24]. In pure glassy phase PFO Hayer et al. did not observe any polaron absorption feature [24]. Therefore, we assume that the majority of the detected photo-induced absorption is attributed to triplets.

In the host/guest system triplet states can occur either on the guest or on the host. Regarding the triplet decay dynamics shown in Fig. 7 a similar decay is observed in BN-PFO and BN-PFO/DPAVB for delay times longer than 10 μs. For shorter delays, the decay in the host/guest sys-

[1] For interpretation of reference to color in this figure, the reader is referred to the web version of this article.

tem is alike to the decay in pristine DPAVB. Previous reports have reported on a stabilization of triplet excitons in host/guest systems on guest molecules for different material systems [18]. This effect is not observed in the host/guest system studied here. Due to the decay dynamics, we assume that triplets are located on the guest and on the host. An allocation of the triplets via the spectral characteristics of the triplet induced absorption is not possible due to the relatively small spectral window of our experiments (Fig. 5). Here, the doped and the undoped laser material show similar absorption spectra.

Regarding the laser threshold of the BN-PFO/DPAVB devices and the material gain slope shown in Fig. 6 we can derive a resonator loss in the order of 10 cm^{-1}. Here, the intrinsic absorption of the gain material and the scattering losses of the waveguide (DFB grating) contribute to the resonator losses. At an excitation pulse repetition rate of 1 MHz we measured a doubled laser threshold, comparing to the excitation at 1 kHz (Fig. 2(d)), where piled-up photo-induced absorption is negligible. In comparison, the measured photo-induced absorption of 10 cm^{-1} at the lasing wavelength (Fig. 4) is in the same order of magnitude. Here, an additional waveguide absorption around 10 cm^{-1} could favorably explain the doubled laser threshold. Nevertheless, an exact analysis of the quantitative influence of the absorption on the laser threshold is difficult, due to the different excitation sources used in the experiments described above. In Fig. 2(a) the laser emission stops within 30 μs at 1 MHz, whereas in Fig. 2(b) a constant emission is achieved after 20 μs. Summing up the energy of the excitation pulses within these time periods an energy density of 970 $\mu J/cm^2$ and 1050 $\mu J/cm^2$ was supplied to the samples. This is comparable to the energy density used in the experiments to determine the triplet absorption. Therefore we assume that a similar triplet density is generated in both experiments, leading to a comparable absorption. The constant laser emission shown in Fig. 2(b) suggests a saturation of the triplet density, preventing any further triplet absorption. This is in good accordance with the triplet absorption experiments, where we observed a saturation of the triplet absorption for excitation pulses longer than 10 μs (not shown here).

Aside from the additional waveguide absorption, the triplet states can also affect the laser emission by quenching. Carrying out photoluminescence (PL) quenching measurement in PFO (not shown here, for measurement details see [14]) under similar conditions to the photo-induced absorption measurement and to the laser devices presented above, we observed a PL decrease of about 12% at a wavelength of 505 nm and around 1–3% at 450 nm. This indicates that quenching is also taking place in our laser devices. However, due to the relatively small quenching effect we conclude that triplet absorption is mainly responsible for the increase of the laser threshold in the BN-PFO/DPAVB laser device under our experimental conditions.

5. Conclusion

In summary we studied the laser dynamics of organic thin film lasers at quasi-cw excitation conditions. We observed a constant laser output power in BN-PFO laser, whereas in devices based on BN-PFO/DPAVB the laser emission decreases dramatically towards longer pump pulses. We attributed this phenomenon to an accumulation of triplet excitons during the excitation pulse. By measuring the gain and the persistant photo-induced absorption we evidenced that gain and photo-induced absorption spectra are spectrally separated in BN-PFO. On the contrary, the gain spectrum is red shifted and overlaps with the photo-induced absorption spectrum in BN-PFO/DPAVB, which enables quenching and absorption at the lasing wavelength. The separation of gain and triplet absorption in BN-PFO seeds the prospect of simple organic thin film lasers operating under cw conditions. Furthermore, the high conversion efficiency at long pumping pulses greatly extends the number of appropriate pumping sources (e.g. laser diodes with a cheap driving unit). Regarding organic laser diodes triplet accumulation is supposed to be a major obstacle to prevent electrical driven lasing, which would be substantially relaxed in case of BN-PFO, due to the separated spectra.

reported by Sen and Chakrabarti [24] in a fused thiophene trimer. In their quantum chemical study, the NDR feature was ascribed to the shift of the transmission resonance peak across the bias window as the bias voltage varied. Through the analysis of MPSH (Molecular projected self-consistent Hamiltonian) states contributing to the bias window at different bias voltages, they provided an explanation of the origin of the NDR character in this system.

It should be mentioned that in the above *ab initio* calculations, the molecular structure was first exactly described, and then the charge transportation process in the device was simulated using the NEGF method. However, the combination of the NEGF and the *ab initio* theory does not work well when electron–lattice (*e–l*) interactions are considered. The reason stems from the fact that the molecule was assumed to be rigid and lattice vibrations were ignored. Structural changes which are believed to contribute to NDR during the charge transport process can therefore not be accurately described [25]. Organic molecules, however, are characterized by strong *e–l* interactions, and the lattice structure is easily affected by additional charges and/or applied electric fields. Consequently, it could be expected that the origin of the NDR phenomenon in polythiophene goes beyond the redistribution of the conducting states or the shift of the transmission resonance peak under gate bias. Organic NDR involves strong *e–l* coupling that induces a structural change in the OSE. As a result, to get a comprehensive understanding of the above issues, it is necessary to capture the strong *e–l* coupling effect explicitly.

Based on these considerations, we have adopted the Su–Schrieffer–Heeger (SSH) model which well describes the *e–l* interactions in organic/molecular systems, combined with the NEGF (SSH + NEGF) to investigate the transport process in a metal/thiophene/metal structure and elucidate a possible mechanism for NDR in thiophene oligomers. The paper is organized as follows: in the following section, the model is described and the nonequilibrium quantum transport method is presented. The results are discussed in Section 3 where we show how a change in the structural conformation can induce NDR. Finally, a summary is given in Section 4.

2. Model and method

The Su–Schrieffer–Heeger (SSH) model [26], which captures the essential characteristics of the *e–l* coupling of organic materials, has been remarkably successful in the study of electronic conductivity and optical phenomena in π-conjugated molecules. Here we have extended the SSH model to describe the thiophene oligomer. The thiophene oligomer can be regarded as a quasi-one-dimensional chain of sp^2 hybridized carbon atoms analogous to that of *cis*-polyacetylene but also including the influence of a sulfur heteroatom on the π electrons [27]. As a consequence, the extended SSH Hamiltonian proposed to describe a molecule containing several thiophene units such as shown in Fig. 1 can be explicitly written as

$$H_{PTh} = \sum_{n,\sigma}\left[\varepsilon_0 c^{\dagger}_{n,\sigma}c_{n,\sigma} - \left(t_0 - \alpha y_n - t_e\cos\frac{n\pi}{2}\right)\left(c^{\dagger}_{n+1,\sigma}c_{n,\sigma} + h.c.\right)\right] - \sum_{n,\sigma}\left[t^{s}_{\triangle}\left(c^{\dagger}_{4n-3,\sigma}c_{4n,\sigma} + h.c.\right) + \varepsilon^{s}_{\triangle}\left(c^{\dagger}_{4n,\sigma}c_{4n,\sigma} + c^{\dagger}_{4n-3,\sigma}c_{4n-3,\sigma}\right)\right] + \frac{1}{2}K\sum_{n} y_n^2. \quad (1)$$

Here, the first term describes the electrons along a carbon chain, with a nondegeneracy parameter t_e to preserve the four-period structure [26]. The operator $c^{\dagger}_{n,\sigma}(c_{n,\sigma})$ denotes the creation (annihilation) operator of an electron at nth thiophene unit with spin σ, while ε_0 and t_0 are the electronic on-site energy and zero-displacement hopping integral between the nth and $n+1$th atoms, respectively. The lattice distortion is treated classically in terms of the bond distance $\{y_n = u_{n+1} - u_n\}$, where u_n is the displacement of the nth atom from its energy-minimum values determined via the Hellmann–Feynman theorem with the spring constant K and the *e–l* coupling constant α. The second term in Eq. (1) denotes the effects of the heteroatom sulfur, including the electron hopping integral $t^{s}_{\triangle}$ between lattice sites $4n-3$ and $4n$ via the sulfur atom and the effective confinement $\varepsilon^{s}_{\triangle}$ energy of π electrons from the sulfur atom (see Fig. 1). The last term represents the lattice elastic energy.

For the electrode, we chose two symmetric identical nonmagnetic metals, each of them described by a one-dimensional single band tight-binding Hamiltonian

$$H_M = \sum_{n,\sigma}\left[\varepsilon_f d^{\dagger}_{n,\sigma}d_{n,\sigma} + t_f\left(d^{\dagger}_{n+1,\sigma}d_{n,\sigma} + h.c.\right)\right]. \quad (2)$$

Here, $d^{\dagger}_{n,\sigma}(d_{n,\sigma})$ denotes the creation (annihilation) operator of an electron with spin σ at the nth site in the metal electrode, ε_f is the on-site energy of a metal atom, and t_f is the nearest neighbor transfer integral. The couplings between the thiophene and each of the metal electrodes were described by a tight-binding hopping integral

$$t_{ML} = t_{MR} = \beta(t_f + t_0), \quad (3)$$

where β denotes the OSE-metal binding parameter.

At the mean-field level for taking correlations into account, one can evaluate the current based on the NEGF formalism [28,29]

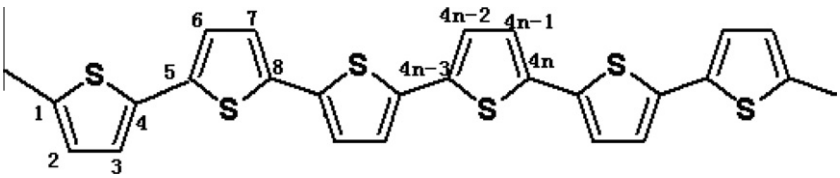

Fig. 1. Schematic structure of a polythiophene molecular.

$$I = \frac{2e}{h}\int_{-\infty}^{+\infty} T(E)[f(E,\mu_L) - f(E,\mu_R)]dE, \quad (4)$$

Here, $T(E)$ is the transmission coefficient function at a finite bias, which can be read as

$$T(E) = Tr\left(\Gamma_L G^r \Gamma_R G^\alpha\right). \quad (5)$$

The term involving $\Gamma_{L/R}$ denotes the lead reservoir-induced broadening matrix, while $G^r(E)$ and $G^\alpha = (G^r)^\dagger$ are the retarded and advanced single-particle Green's functions for the central scattering region (S region) which consists of the thiophene oligomer together with a number of metal atoms attached to each of its ends. $f(E,\mu_{L/R})$ is the Fermi distribution function with the lead chemical potential $\mu_{L/R}$. For an open quantum system, both the charging effect from the electrodes and the external potential from the bias voltage are contained in the nonequilibrium reduced density matrix of the coupled e–l system

$$\rho = \frac{1}{2\pi}\Sigma_{\alpha=L/R}\int_{-\infty}^{+\infty} G^r \Gamma_\alpha G^\alpha \Gamma_R f(E,\mu_\alpha)dE, \quad (6)$$

which should be evaluated self-consistently together with Poisson's equation and the Hellman–Feynman variation theorem for lattice distortion: $\partial[Tr(H_{s\rho})]/\partial u_n = 0$. The NEGF also determines the density of states, $D(E)$, through $D(E) = \frac{i}{2\pi}Tr[G^r(E) - G^\alpha(E)]$. The detailed self-consistent procedure can be found in Ref. [25].

In this study, the SSH parameters for the thiophene molecular were chosen as: $t_0 = 2.5$ eV, $t_e = 0.27$, $t_0 = 0.675$ eV, $\alpha = 4.4$ eV/Å, $K = 21.0$ eV/Å^2, $\varepsilon_0 = -4.9$ eV, and $t^s_\triangle = \varepsilon^s_\triangle = 0.05t_0 = 0.125$ eV. These parameters can reproduce the band gap (~2.0 eV) of polythiophene [30–32]. The tight binding parameters for fitting the Au band structure of the electrode metal in Eq. (2) are $t_f = 3.0$ eV and $\varepsilon_f = -4.9$ eV. The thiophene–Au metal binding parameter β represents the coupling strength, which affects the magnitude of current sensitively. In the calculations, one can adjust it, so the calculated I–V curve is the same amplitude as the measured one. We find that $\beta = 0.25$ for the molecular junction will produce the current in the magnitude of μA, which is comparable with the results for the same nanosize molecules reported in the Refs. [23,24]. These parameters can properly represent the bulk properties at the boundary and in the absence of applied bias, both the scattering region and the molecular segment are charge neutral.

3. Results and discussions

We are now in the position to calculate the I–V characteristics, especially the NDR behavior, of the model Au/PTh/Au structure at low temperature. For the sake of definiteness, we have chosen a temperature of $T = 11$ K. For a self-consistent evaluation of quantum transport based on the NEGF formalism, the central scattering region is chosen such that its Green's function can properly represent the bulk properties at the boundary. For the coupling parameters given above, we selected the S-region to consist of $20 + N + 20$ sites; i.e., 20-sites of Au atoms attached to each terminal of the polythiophene molecule which had N carbon sites. Due to the four-period structure of the thiophene, N is a multiple of 4. Numerical calculations show the NDR feature in the I–V curves of the device. At certain molecular lengths (3–5 thiophene units) the NDR effects are prominent. As an example, in Fig. 2, we show the I–V curve for a molecule with four thiophene units. For clarity, the inset also shows the differential resistance, dI/dV, as a function of V. From the figure, one can see that under the applied bias, the current increases markedly at $V \sim 1.05$ V (35 μA) (threshold voltage) and reaches a value of about 70 μA at $V \sim 1.5$ V. After the initial increase, the current drops abruptly from 70 to 1.2 μA at 1.55 V. The reduction in current with an increase in the external bias voltage indicates the presence of NDR. The NDR is prominent up to a bias voltage of 1.55 V. The peak-to-valley current ratio is as high as 70. The current then remains at a low level (about 1 μA) over the bias range from 1.55 to 1.75 V. Subsequently, the current again rapidly increases to about 70 μA as the voltage is raised above 1.75 V, and subsequently, the molecule remains in high conductance states.

To elaborate what happens across the NDR region, we also examined other nonequilibrium properties. Fig. 3a shows the representative results for the voltage-dependent transmission probabilities $T(E)$ at bias voltages of $0, 1.5, 1.55$ and 1.8 V. In this figure, E_f represents the energy of the Fermi level and the dashed lines indicate the bias window $\mu_R - \mu_L$. Consider first the case of the zero bias transmission spectra. We can see that no transmission resonance peaks exist near the Fermi energy. The current remains nearly zero until several transmission resonance peaks enter into the bias window at 1.05 V. As a consequence, current through the molecule increases and the molecule enters the conducting state. Subsequently, transmission spectra contributing to the bias window gradually increase with increasing external bias voltage (not represent in the figure). However, the existing resonance peaks disappear abruptly at 1.55 V, which induces an abrupt decline in the current. This is an indication of the appearance of the NDR feature, which is apparent in Fig. 2. In the bias range from 1.55 to 1.75 V, the structures of the

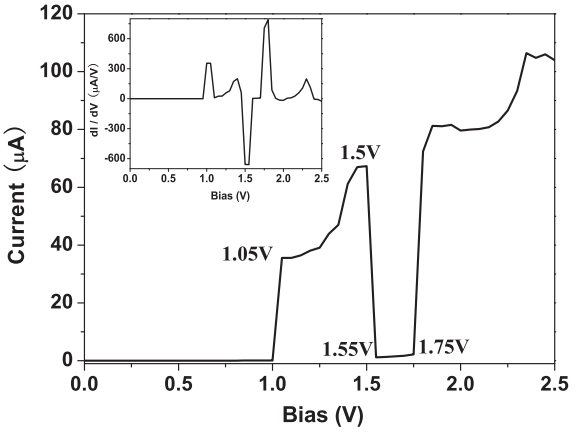

Fig. 2. The current–voltage characteristic of the Au–thiophene oligomer–Au system studied in the present paper. The inset shows the differential conductance (dI/dV) against the bias (V).

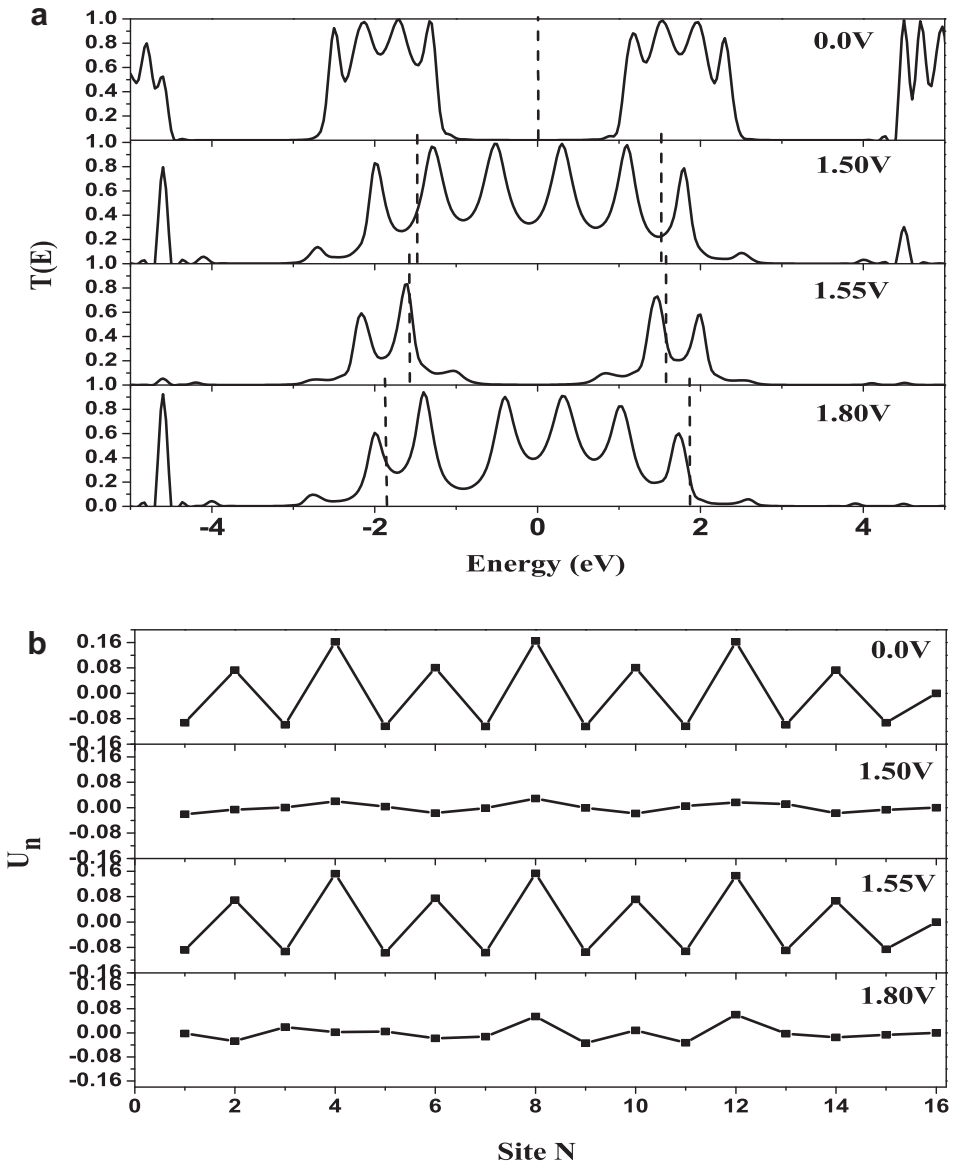

Fig. 3. (a) Energy-dependent transmission coefficient $T(E)$ near the Fermi energy at $V = 0, 1.5, 1.55$ and 1.8 V. The long dotted lines indicate the bias window, and the Fermi level is set to be the origin of energy. (b) Lattice distortion $\{y_n = u_{n+1} - u_n\}$ of the OSE substructure at $V = 0, 1.5, 1.55$ and 1.8 V.

transmission spectra are quite analogous and the currents of the system remain at a very low value, which corresponds to the insulating state. When the bias is greater than 1.75 V, some transmission resonance peaks enter into the bias window and the current through the molecular system again starts to increase.

In order to understand the conducting insulating states distinguished in the transmission spectrum, it is important to determine the underlying mechanism. This can be done by checking the lattice distortion of the molecule. Fig. 3b shows the changes of the lattice distortion at the representative biases $0, 1.5, 1.55$ and 1.8 V. Note that in Fig. 3b, the lattice distortions are reported in terms of the *e–l* coupling induced bond length variation $\{y_n = u_{n+1} - u_n\}$ between nearest neighbors. The zero bias curve has the dimerized lattice configuration in the Peierls phase. In contrast, the distinct reduction in the lattice distortion or single-double bond alteration at 1.5 V suggests a diminishing of the Peierls phase. In this condition, the atoms take on a uniform distribution and the molecule enters a conducting state. When the bias continues to increase, the lattice distortion re-appears and complete dimerization appears at 1.55 V. It is obvious that the lattice configuration is the same as in the equilibrium lattice distortion $(V = 0)$, which gives the largest contribution to the insulating state and results in a large band gap and small current. As a consequence, the NDR effect appears in Fig. 2. From 1.55 to 1.75 V, the lattice configuration is characterized by dimerization, so the conductance of the molecular remains at low values over this range. With increasing bias, the dimerization of

the lattice diminishes and when the voltage reaches 1.8 V the Peierls gap disappears. The molecule then starts to conduct again. The above analysis leads us to conclude that the external bias leads to important changes in the conformation of the molecule which in turn induces the NDR phenomenon.

In the following, we calculate the reduced eigenvalues of the bias-dependent Hamiltonian of the molecule to provide more information regarding the NDR phenomenon. The Hamiltonian is shown in Eq. (1), and the nonequilibrium lattice parameters are evaluated in a self-consistent manner. The Hamiltonian also contains the electric potential variation in the molecule, which was also determined self-consistently. The information contained in this Hamiltonian was shown in the discussion above to be able to reflect the bias-induced intrinsic changes of the organic molecule in the device. The resulting energy levels from the aforementioned self-consistent Hamiltonian, as they vary with the bias voltage, are shown in Fig. 4, where the dashed lines indicate the conducting window determined by the space between μ_L and μ_R. From the figure, we can see that at about 1.05 V, the LUMO enters the conducting window between μ_L and μ_R and induces a rapid increase in the current. However, at 1.55 V, the LUMO moves outside the conducting window. No available orbitals contributing to the conductance can then be found in the conducting window, so the current decreases abruptly, which constitutes the emergence of the NDR feature. Over the bias range 1.5—1.75 V, the molecular orbitals are always outside the bias window and the Peierls phase of the molecular substructure is recovered. The conductance of the molecule remains at a very low value. This is corresponds to the insulating state. Eventually, at 1.8 V, LUMO−1, a new orbital contributing to the conductance appears between the bias windows, and the current begins to increase again.

In most of the calculations based on the first principle combining with the NEGF method, the molecule is assumed rigid and its vibrations are ignored in the transport process. At last, we freeze the motion of the atoms when the bias is applied in order to compare the transport characteristics with that of the rigid molecule. Fig. 5 is the current–voltage characteristic of the Au–thiophene oligomer–Au system when the lattice is frozen. Due to the structure of the thiophene is dimerized throughout the transport process the current is weaker than that in Fig. 2. Furthermore, the NDR phenomenon is unobserved when the motion of the atoms is frozen, which manifests that the structural change in the organic molecule plays a key role in the NDR phenomenon.

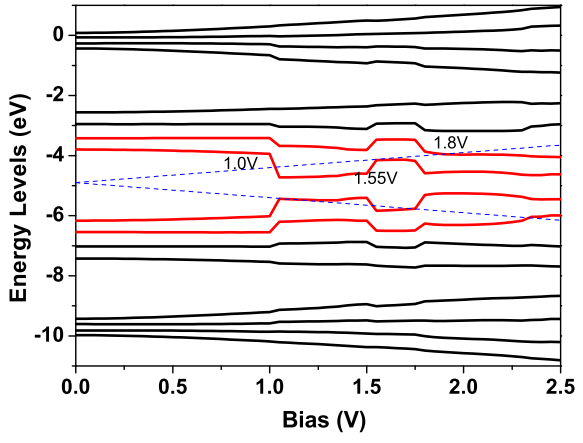

Fig. 4. Evolution with voltage of the energy levels of the thiophene molecule. The dashed lines indicate the conducting window determined by the space between μ_L and μ_R. The nearest four energy levels to the Fermi levels, LUMO, HOMO, LUMO+1, HOMO−1, are represented by red lines. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

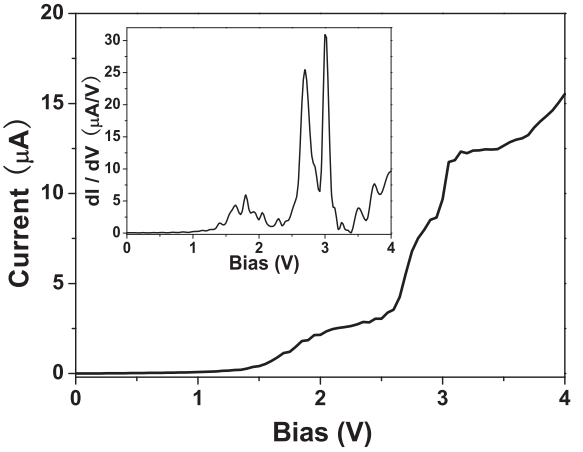

Fig. 5. The current–voltage characteristic of the Au–thiophene oligomer–Au system, the motion of the lattice is frozen when the bias applied. The inset shows the differential conductance (dI/dV) against the bias (V).

4. Summary

In summary, to study electron transport in an organic device, electron–lattice coupling effects in the organic material should be emphasized. In this article, by combining the SSH model and the Green's function method, we have calculated electron transport through thiophene oligomer molecular devices and have given an explanation of the negative differential resistance (NDR). The results of this model were found to capture the essential physics of the process. The NDR was found to be a result of conformation changes, induced by the external bias, between a dimerized state (low conductance) and a uniform (high conductance) state of the molecular structure of the lattice. These results provide further insight into the origin of NDR behavior in the I–V characteristic in organic molecular devices.

WEG films can approach the same magnitude of their single crystal film counterparts [21]. One of the promising candidate materials is vanadyl phthalocyanine (VOPc), which is a non-planar phthalocyanine with high mobility, as well as good air and electrical stability [27–29]. However, investigations on VOPc are less common than those on pentacene and rubrene. Wang et al. fabricated VOPc films consisting of lamellar crystals on a *p*-6P inducing layer and the mobility based on the VOPc/*p*-6P is up to 1.0 $cm^2 V^{-1} s^{-1}$ [30]. The lamellar crystals on the *p*-6P inducing layer are different from those of planar phthalocyanine films. They facilitate the in-plane transport of charge carriers by applying the WEG technique. However, at the contact surfaces between the VOPc and the *p*-6P, large lattice mismatching occurs, resulting in incommensurate epitaxy. The domain size of VOPc polycrystalline films is smaller than 1 μm, resulting in many domain boundaries that act as trap sites in VOPc films, thereby limiting the performance improvement of VOPc-based devices. Therefore, new inducing layer materials that have better lattice-matching relationship with VOPc and form smooth, continuous, large-size crystal domains are required to improve VOPc OTFT performance further.

In this paper, we report the inducing layer material 5,5‴-bis(4-fluorophenyl)-2,2′:5′,2″:5″,2‴-quaterthiophene (F2-P4T), which can form smooth, continuous bilayer films at an optimized substrate temperature, on which VOPc grows following a WEG pattern. A commensurate epitaxial relationship is formed between the F2-P4T and the VOPc films, leading to highly ordered VOPc films with grain size larger than 1 μm. Simultaneously, the crystal domains were extensively connected to each other, resulting in a decrease in the density of the grain boundary. This film morphology enhanced in-plane carrier transport; hence, a higher mobility was obtained. The organic field-effect transistors with VOPc/F2-P4T films active layers exhibited a high mobility of 2.6 $cm^2 V^{-1} s^{-1}$ with relatively good stability under ambient conditions.

2. Experimental

2.1. Materials and device fabrication

The VOPc samples were purchased from Aldrich Company (USA), and 5,5‴-bis(4-fluorophenyl)-2,2′:5′,2″:5″,2‴-quaterthiophene (F2-P4T) was synthesized according to Ref. [31] as a red solid with a yield of 60% after purified by vacuum sublimation twice, using 1-bromo-4-fluorobenzene instead of 4-bromotoluene. F2-P4T: Anal. Calcd for $C_{28}H_{16}F_2S_4$: C, 66.84; H, 3.11; Found: C, 66.65; H, 3.01. M.p. = 342 °C (from DSC measurement). T_d = 415 °C (corresponding to 5% weight loss). All the materials were purified twice by thermal sublimation prior to experiments. A heavily doped *n*-type silicon wafer with a 300 nm thermal oxidation SiO_2 layer (dielectric capacitance C = 10 nF/cm^2) was used as the substrate. The substrate was subjected to cleaning by acetone, alcohol, and deionized water. The cleaned substrates were dried at 100 °C for 30 min in the roast to eliminate the influence of the moisture. First, F2-P4T film with thickness of 6 nm was deposited on SiO_2, forming continuous bilayer films. Second, VOPc films with different thicknesses were deposited on the F2-P4T thin films. The organic thin films were deposited at 10^{-4}–10^{-5} Pa at a rate of about 1 nm/min, and the substrate temperatures were kept at 170 °C. Finally, the samples were rapidly transferred to another vacuum chamber to define the source and drain contacts by thermally evaporating Au with a mask shadow in vacuum at 10^{-4} Pa to complete the fabrication of organic field-effect transistors.

2.2. Characterization of organic film and OTFT measurements

Atomic force microscopy (AFM) measurements of film morphology were imaged by a SPI 3800/SPA 300HV (Seiko Instruments Inc., Japan) with tapping mode. The out-of-plane X-ray diffraction (XRD) patterns were taken from a D8 discovery thin-film diffractometer with Cu Kα radiation (λ = 1.54056 Å). The selected voltage and current were 40 kV and 40 mA, respectively. The selected area electron diffraction (SAED) was imaged with a JEOL JEM-1011 transmission electron microscope operated at 100 kV. The fabrication of samples was according to Ref. [32] Current–voltage measurements of OTFT were performed at room temperature in air with two Keithley 236 source-measurement units. Field-effect mobility (μ) was estimated from the saturation regime ($V_{GS} = V_{DS} = -50$ V) using the following equation:

$$I_{DS} = \frac{W}{2L}\mu C_i (V_{GS} - V_T)^2$$

in which L (180 μm) is the channel length, W (6000 μm) is the channel width, C_i (10 nF/cm^2) is the capacitance (per unit area) of the insulator, V_{GS} is the gate voltage, V_T is the threshold voltage, and I_{DS} is the drain-source current.

3. Results and discussion

3.1. Films morphology and properties

The molecular structures of F2-P4T and VOPc are shown in Fig. 1a. The morphology of the 6 nm (nearly two molecular layer) F2-P4T films deposited onto the SiO_2 substrate at 170 °C is shown in Fig. 1b. The first layer of F2-P4T has completely formed and the second layer has covered the surface of 98%, which indicated that the F2-P4T presents a layer-by-layer growth behavior in the first two layers. This growth behavior leads to large, continuous double-layer thin films with ultra-flat surfaces which show a root-mean-square (RMS) roughness of 0.5 nm. This is different from that of *p*-6P, which only shows layer-by-layer growth mode in the monolayer [33]. Furthermore the SAED pattern (Fig. 1c and d) of a single grain present a regular rectangular lattice, evidenced the highly crystalline of the F2-P4T layer and its similar packing to *p*-6P. The highly ordered smooth bilayer films of F2-P4T favored the nucleation and growth of VOPc. It is well known that carrier transport mainly in the several molecular layers of active layers at the interface between active layers and insulator [34]. So the morphology of initial several molecular layers of VOPc is essential for the organic thin film transistor. Fig. 1e shows the AFM morphology of the 6 nm VOPc

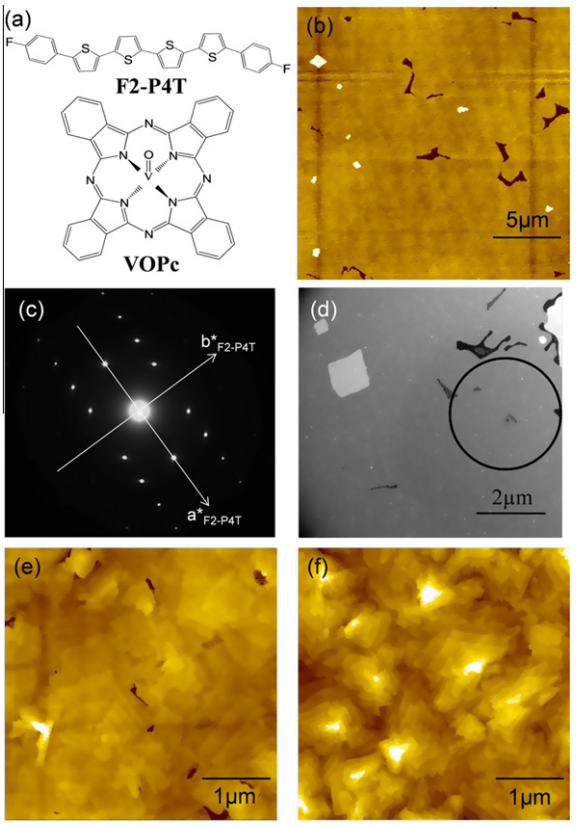

Fig. 1. (a) The molecular structures of 5,5‴-bis(4-fluorophenyl)-2,2′:5′,2″:5″,2‴-quaterthiophene (F2-P4T) and vanadyl phthalocyanine (VOPc), respectively. (b) 20 μm × 20 μm AFM image of the F2-P4T (6 nm) bilayer grown on SiO_2 at 170 °C, RMS = 0.5 nm. (c) and (d) The SAED pattern and corresponding electron micrograph of bilayer F2-P4T films. (e) 4 μm × 4 μm AFM image of the VOPc (6 nm) on the F2-P4T (6 nm) films at 170 °C. (f) 4 μm × 4 μm AFM image of the VOPc (30 nm) on the F2-P4T (6 nm) films at 170 °C.

deposited onto the F2-P4T bilayer. The VOPc films present layered crystal grains similar to that on *p*-6P films, however, the domain size of the VOPc is larger than 1 μm, which is larger than that on *p*-6P films [30]. In addition, although adjacent grains present different orientations, the crystal domains intimately coalesced with each other, resulting in a continuous film with less dense grain boundary which favors the in-plane charge carrier transport. Fig. 1f shows the AFM morphology of the 30 nm VOPc deposited onto the F2-P4T bilayer. With the increasing of the thickness of VOPc films, the lamellar shape of VOPc grains can be observed obviously, but the films still maintained good continuity and integrity. The quality of VOPc films on F2-P4T has been improved significantly compared with that on *p*-6P [30]. X-ray diffraction pattern of VOPc/F2-P4T films was shown in Fig. 2, which indicates the highly order of VOPc films. The intensity diffraction peak at 7.5° corresponds to the (0 1 0) lattice plane of VOPc films in phase II [35]. Simultaneously, the exclusive appearance of (0 *k* 0) peak indicated VOPc molecules preferentially stand on F2-P4T films. In other words, the π–π stacking direction is parallel to the substrate, which is favorable to carriers transporting in film plane.

also contains a symmetry orientation with an angle of −37.5°. As inferred from the diffraction pattern of VOPc, a coincidence of $(\bar{2}\,1\,2)$VOPc with the underlying $(2\,0\,0)_{F2\text{-}P4T}$ layer is observed which is indicative of commensurate epitaxy between the VOPc and the F2-P4T. This implies better lattice matching between the VOPc and the F2-P4T compared with that on *p*-6P wherein no coincidence was observed. Based on the lattice parameters of F2-P4T and *p*-6P (Table 1), the lattice spacing of $(2\,0\,0)_{F2\text{-}P4T}$ is much shorter than that of *p*-6P but close to the *d* spacing of $(\bar{2}\,1\,2)_{VOPc}$, thus leading to highly ordered VOPc films with continuous, large grain sizes. The epitaxial relationship of VOPc and F2-P4T are $(0\,1\,0)_{VOPc}$ || $(0\,0\,2)_{F2\text{-}P4T}$ and $[1\,0\,1]_{VOPc}$ || $[1\,0\,0]_{F2\text{-}P4T}$. Fig. 3b displays the corresponding packing diagram of this orientation, in which the molecular plane of VOPc is parallel to the lattice direction of [1 0 0] of F2-P4T. This packing diagram is favorable to the diffusion and growth of VOPc. The electron diffraction pattern and corresponding morphology, proved large-gain, low-defect, continuous VOPc epitaxial films on an F2-P4T inducing layer are formed by WEG. Such high quality organic thin films are desired for organic thin film transistors.

3.2. Device performance and air stability

The VOPc/F2-P4T transistor was fabricated on the SiO_2 insulator. The device configuration is shown in Fig. 4a. The output (I_{DS}–V_{DS}) characteristics at V_{GS} from 0 V to −50 V is shown in Fig. 4c. It can be seen that the device exhibits the p-channel accumulation operation mode. With the increasing of source-drain voltage (V_{DS}), the linear region and saturation region are observed obviously from output curve. Typical transfer (I_{DS}–V_{GS}) characteristics and plots of ($I_{DS}^{1/2}$) vs. V_{GS} at a fixed V_{DS} of −50 V are shown in Fig. 4d. The device exhibited high field-effect mobility (μ) of 2.4 $cm^2\,V^{-1}\,s^{-1}$ extracted from the saturation region of the transfer curve at a V_{DS} of −50 V, a low threshold voltage (V_T) of −2.7 V, and a high on–off current ratio (I_{on}/I_{off}) of 10^6. During device operation, F2-P4T served as the dielectric layer because of its low conductivity. OTFTs based on single 50 nm F2-P4T film active layers measured under both vacuum and ambient conditions at room temperature didn't present field effect property. Hence, carrier transport is mainly in the VOPc films. In addition, the F2-P4T layer is too thin to have a significant effect on capacitance. The curves of gate leak current vs. gate voltage were showed in Fig. 4b, the leak currents level were almost at 10^{-10} A. The performance of the F2-P4T/VOPc device under multiple optimized conditions is summarized in Table 2, which is much better than that of *p*-6P/VOPc. The improvement in the performance of the device is mainly due to the

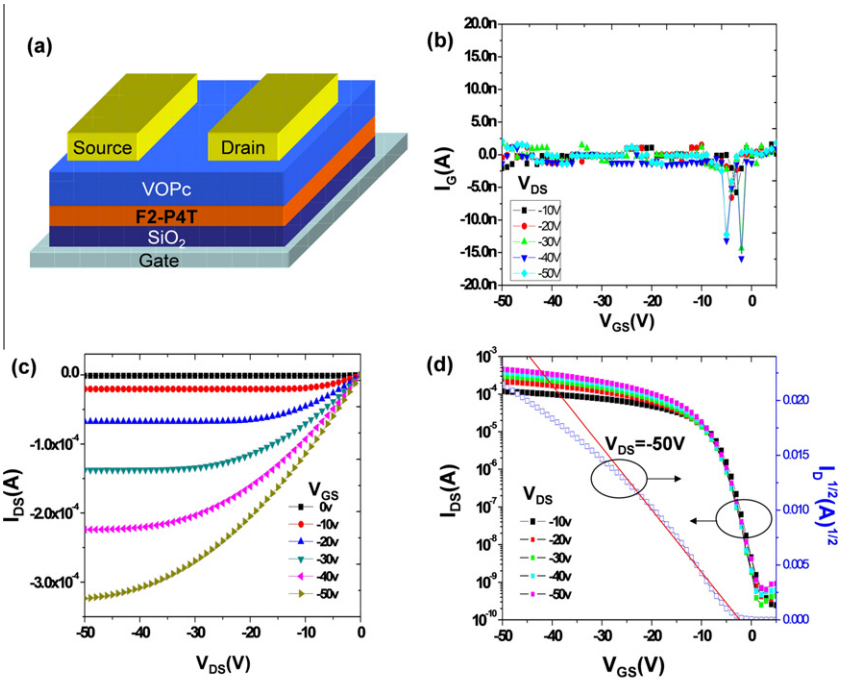

Fig. 4. (a) The device configuration of the VOPc (30 nm)/F2-P4T (6 nm). (b) The I_G–V_G curves of VOPc OTFT with F2-P4T/SiO_2 dielectrics at drain voltage (V_D) from −10 V to −50 V. (c) The output characteristics (I_{DS}–V_{DS}) of VOPc (30 nm)/F2-P4T (6 nm) OTFT at different V_{GS} from 0 V to −50 V. (d) The transfer characteristics (I_{DS}–V_{GS}) of VOPc (30 nm)/F2-P4T (6 nm) OTFT at different V_{DS} from −10 V to −50 V and the typical $I_{DS}^{1/2}$ vs. V_{GS} plot ($I_{DS}^{1/2}$–V_{GS}) at V_{DS} = −50 V.

Table 2
Summary of the performances for VOPc OTFTs based on the *p*-6P and the F2-P4T inducing layer.

Device structure	μ ($cm^2 V^{-1} s^{-1}$)	V_T (V)	I_{on}/I_{off}	
p-6P/VOPc	0.6–1.5	−9 to −15	10^6	Ref. [30]
F2-P4T/VOPc	1.2–2.6	−1 to −5	10^6–10^7	

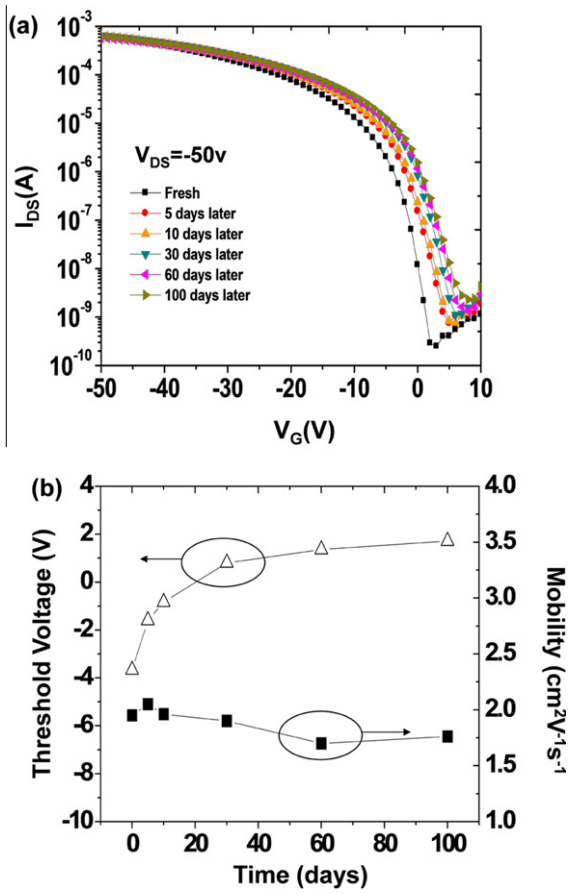

Fig. 5. (a) The air stability measurements of the VOPc (30 nm)/F2-P4T (6 nm) device: drain current (I_{DS}) vs. gate voltage (V_{GS}) at V_{DS} = −50 V as a function of time. (b) The field-effect mobility (μ) and the threshold voltage (V_T) of the VOPc (30 nm)/F2-P4T (6 nm) device as a function of time that exposed in air at room temperature.

improvement in the quality of the VOPc films. Larger grain size and fewer defects in the VOPc films led to a more continuous carrier transport channel formed near the interface between the F2-P4T and the VOPc layers, which facilitate higher mobility and lower threshold voltage. In addition, because the fluorine (F) groups introduced in the F2-P4T inducing layer formed F atomic arrangement surface, there might be a built-in electric field in the interface between the F2-P4T and the VOPc layers, leading to holes accumulating in the VOPc films. Thus, the threshold voltage is shifted to the positive side [36,37].

The F2-P4T/VOPc OTFTs also showed good air stability. The transfer curves obtained at different times are shown in Fig. 5a. After 100 days of storage under ambient conditions, the mobility of the F2-P4T/VOPc device slightly decreased from 1.99 to 1.76 $cm^2 V^{-1} s^{-1}$, the threshold voltage shifted from −3.6 V to 1.7 V, and on–off current ratio maintained a magnitude of 10^6. Fig. 5b shows the mobility (μ) and threshold voltage (V_T) as a function of exposure time to ambient conditions. The good stability of the F2-P4T/VOPc device is related to the large ionization potential of the VOPc (HOMO 5.5 eV) [38], which is against oxidation [39–41]. Furthermore, the closed packing of the F2-P4T/VOPc films with few defects prevents the physical absorption of the environmental gases that deteriorate the performance of device [42,43].

4. Conclusions

In summary, a new fluorinated inducing layer material called F2-P4T was introduced. It can form smooth and continuous bilayer films on which VOPc films exhibited weak epitaxial growth behavior. A commensurate epitaxial relationship was observed, which implied perfect lattice matching between the VOPc and the F2-P4T. The epitaxial VOPc films with highly oriented order, large domain size, and few defects were obtained on the F2-P4T inducing layer. The thin-film transistors based on such high quality films as active layers exhibited high performance. The field-effect mobility reached up to 2.6 $cm^2 V^{-1} s^{-1}$, the threshold voltage was lower than −5 V, the on–off current ratio was at a magnitude of 10^6, and it exhibited relatively good air stability. Such high performance OTFTs is a great impetus for realizing large-area, low-cost and flexible displays.

[9]. Although the hole mobility in the $Ir(ppy)_3$-doped CBP thin films can be determined, the hole mobility of undoped CBP thin films was not evaluated because the hole injection barrier between ITO electrode and the undoped CBP thin film is 0.9 eV. The results indicate that holes are directly injected from the injecting electrode to $Ir(ppy)_3$ in $Ir(ppy)_3$-doped CBP thin films because the injection barrier between the injection electrode and the $Ir(ppy)_3$ is less than 0.2 eV.

The insertion of an injection layer between an injection electrode and an organic thin film reduces the injection barrier, and allows us to measure the charge carrier mobility of the organic thin film. Indeed, Hoping et al. have determined hole mobility of CBP thin films by inserting an injection layer of WO_3 between ITO and CBP [6].

Tris(8-hydroxy-quinolinato) aluminum (Alq_3) has shown to be one of the most promising material for an electron transport layer and/or a light emissive layer. Both electrons and holes are injected and transported in the Alq_3 layer and thus the Alq_3 layer is used as a light emissive layer. Notably, it is well known that the cationic Alq_3 is unstable [12] and understanding the hole transport of Alq_3 is useful for determining the degradation mechanism of OLEDs with the Alq_3 thin film as an emissive layer. The determination of the hole mobility in Alq_3 is therefore of fundamental importance.

Although the drift mobilities of the Alq_3 thin films obtained by means of TOF transient photocurrent measurements have been reported [13,14], the thickness of the Alq_3 thin film was between 0.4 and 13 μm and is much thicker than that of Alq_3 layer in OLEDs. Transient EL measurements are another method for determining a charge carrier mobility. However, it is difficult to determine the hole mobility in Alq_3 by them because the higher carrier mobility can be determined from the delay time of the EL signal; the electron mobility in the case of Alq_3. It is therefore important to measure the hole drift mobility in Alq_3 layer with thickness comparable to that in OLED application. However, IS measurements for hole mobility determination have not been carried out yet. To do this, an injection layer for hole injection is necessary because the hole injection barrier between ITO and Alq_3 is too high to measure hole drift mobility using IS. A candidate of the injection layer is 4,4′-bis[N-(1-naphthyl)-N-phenyl-amino]-biphenyl (NPB). A NPB/Alq_3 double layer is a prototypical OLED structure and hence IS measurements for the device structure is essential to understanding of drift-mobility measurements in double layer or multilayer OLEDs.

In this paper, we report on the IS measurement of Alq_3 hole-only devices (HODs) with NPB injection layers, and show that the hole mobility in Alq_3 thin films can be determined from IS measurements. The hole transit in Alq_3 thin films is also observed even in NPB/Alq_3 double layers where the thickness of NPB is comparable to that of Alq_3. The observation is a key information for the understanding of the charge carrier transit in double layer or multilayer OLEDs.

2. Experimental

Fig. 1 shows the device structure of the NPB/Alq_3 HODs, which consists of indium-tin oxide (ITO)/NPB/Alq_3/Au. A

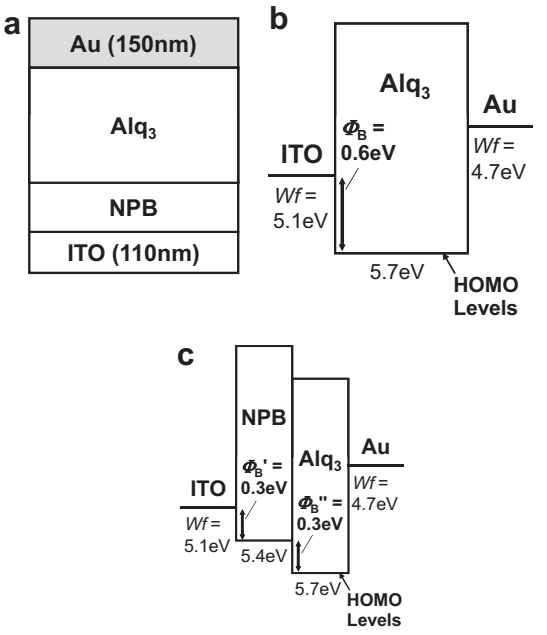

Fig. 1. (a) Cross-sectional view of a NPB/Alq_3 double layer hole-only device (HOD), which consists of ITO/NPB/Alq_3/Au. (b) Energy diagram of an Alq_3 HOD, which consists of ITO/Alq_3/Au. (c) Energy diagram of the NPB/Alq_3 HOD, which consists of ITO/NPB/Alq_3/Au. *Wf* is a work function, and Φ_B is the injection barrier between the *Wf* of ITO and the HOMO energy level of Alq_3. Φ'_B is the injection barrier between the *Wf* of ITO and the HOMO energy level of NPB and Φ''_B is the injection barrier between the HOMO energy level of NPB and the HOMO energy level of Alq_3.

vacuum deposition method was used to fabricate the NPB and Alq_3 thin films in series on a glass substrate with patterned ITO electrodes (pressure $\sim 5 \times 10^{-5}$ Pa). The glass substrate with the ITO electrodes was cleaned ultrasonically in deionized water and by an UV-ozone treatment before vacuum deposition of the organic thin films. The thickness of the NPB thin films were 0, 5, 125, and 310 nm. The film thickness of the Alq_3 was 110 and 180 nm. Au electrodes (150-nm-thick) were deposited on the organic thin films. The structures of samples 1–4 are ITO/NPB(5 nm)/Alq_3(180 nm)/Au, ITO/NPB(5 nm)/Alq_3(110 nm)/Au, ITO/NPB(310 nm)/Alq_3(180 nm)/Au, ITO/NPB(125 nm)/Alq_3(180 nm)/Au, respectively. The samples were then carried in a glove box (with less than 1 ppm water) without exposure to the laboratory atmosphere and sealed by a cap-glass with epoxy resin adhesives. The measurement area was 1×1 mm^2.

The IS was measured with a Solartron 1260 impedance analyser connected to a 1296 dielectric interface. The frequency range was from 10 mHz to 1 MHz, and the measurements were made at room temperature.

3. Results and discussion

3.1. Determination of hole mobility in Alq_3 with a thin NPB layer

The hole charge carrier mobility of Alq_3 thin films was determined from the transit-time, which was estimated

from the frequency dependence of the capacitance (C); the method for measuring charge carrier mobility has been known as $-\Delta B$ method, where $-\Delta B$ is a negative differential susceptance [1–9].

Fig. 2a shows the frequency dependence of capacitance in sample 1. The frequency response curves of capacitance at V = 3–7 V exhibit a minimum value, which is caused by the transit-time effect [1–8]. A transit-frequency which is proportional to the reciprocal of the transit-time is in the vicinity of the frequency at the minimum value of the C–f curve. In the frequency range higher than the transit-frequency, the capacitance reaches the geometrical capacitance C_0 because the period of the applied AC field is too short to redistribute the space charges in the device. Meanwhile, in the frequency range lower than the transit-frequency, the capacitance reaches $3/4C_0$ in the trap-free device because the space charges were redistributed in the device (the dashed line shown in the data at V = 7 V in Fig. 2a) [7,8]. In practice, the capacitance is increased with decreasing frequency in the low frequency range shown in Fig. 2a. The increase in capacitance is due to trapping of injected charge carriers in distributed localised states [8]. However, the increase in capacitance does not affect the determination of charge carrier mobility because the increase in the capacitance is observed below the transit-frequency [8]. The slight decrease in capacitance toward higher frequency is due to the series resistances of the device.

Fig. 2b shows the frequency dependence of $-\Delta B = -\omega\cdot(C-C_0)$ in sample 1. The frequency at the maximum value of $-\Delta B$, f_{max}, is indicated by arrows in Fig. 2b and is related to the transit-time, t_t, $f_{max} \approx 0.72 t_t^{-1}$ [7,8]. Charge carrier mobility μ is then determined by Eq. (1) from the transit-time, t_t [7,8]:

$$\mu = \frac{4}{3}\frac{L^2}{V_0}\frac{1}{t_t} \tag{1}$$

where L is the thickness of the organic thin film between the injecting electrode and the counter electrode, and V_0 is the applied voltage. In the Alq_3 HOD with the NPB injection layer, L is the thickness of the Alq_3 thin film because the thickness of the Alq_3 thin film is much thicker than that of the NPB injection layer. The hole mobility of the Alq_3

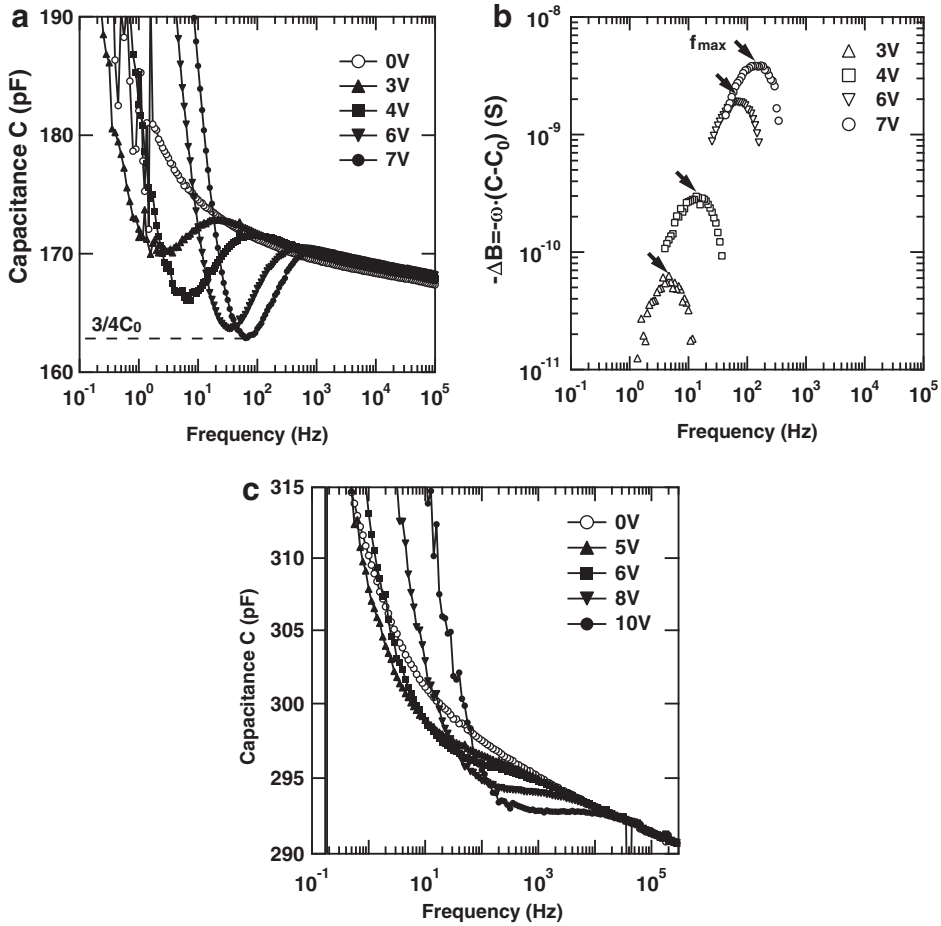

Fig. 2. (a) Frequency dependence of capacitance in sample 1 at DC bias voltages of 0, 3, 4, 6, and 7 V; sample 1 consists of ITO/NPB(5 nm)/Alq_3(180 nm)/Au. (b) Frequency dependence of $-\Delta B = -\omega\cdot(C-C_0)$ in sample 1 at DC bias voltages of 3, 4, 6, and 7 V. (c) Frequency dependence of capacitance in the Alq_3 HOD without the NPB injection layer at DC bias voltages of 0, 5, 6, 8, and 10 V. $-\Delta B$ is a negative differential susceptance, ω is an angular frequency, and C_0 is a geometrical capacitance. f_{max} is the frequency of the maximum value at the $-\Delta B$-frequency curves.

thin film is 9.3×10^{-10}–1.2×10^{-8} $cm^2 V^{-1} s^{-1}$ at $V = 3$–7 V (the data will be shown in Fig. 3).

Fig. 2c shows the frequency dependence of the capacitance in an Alq_3 HOD without a NPB injection layer. Since the minimum value of the C–f curves is not observed at $V = 5$–10 V, the transit-time is not estimated from the $-\Delta B$–f curves. We note that the hole mobility of the Alq_3 thin films is not determined in the Alq_3 HOD without the NPB injection layer.

Fig. 1b shows the energy diagram of the Alq_3 HOD without the NPB injection layer (ITO/Alq_3/Au). Holes are injected from the ITO electrode into the Alq_3 thin films; the hole injection barrier Φ_B is estimated to be 0.6 eV because the work function of ITO W_f is 5.1 eV and the energy level of the highest occupied molecular orbital (HOMO) of Alq_3 is 5.7 eV. As mentioned above, our simulation results show that the transit-time effect is observable using the $-\Delta B$ method when the injection barrier is less than 0.2 eV [7,8]. This explains why the transit-time effect was not observed in the Alq_3 HOD without the NPB injection layer. On the other hand, the transit-time effect can be observed in the Alq_3 HOD with the NPB injection layer (ITO/NPB/Alq_3/Au). Fig. 1c shows the energy diagram of the Alq_3 HOD with the NPB injection layer. The hole injection barrier Φ'_B between the Wf of ITO and the HOMO energy level of the NPB thin film and the hole injection barrier Φ''_B between the HOMO energy levels of the NPB thin film and of the Alq_3 thin film are estimated to be 0.3 eV and 0.3 eV, respectively because the HOMO energy level of NPB is 5.4 eV. The injection barriers, Φ'_B and Φ''_B are slightly higher than the threshold value of the injection barrier, 0.2 eV [7–8]: the criterion of the barrier heights, Φ'_B and Φ''_B, for the observation of the charge carrier mobility is that both barrier heights are less than 0.2 eV. The threshold value was estimated on the assumption that the HOMO energy level of an organic thin film is constant. However, the HOMO energy level in an amorphous organic thin film is, in practice, distributed in energy [13]. The increase in capacitance in the low frequency range shown in Fig. 2a supports the energy distribution of HOMO level in Alq_3 thin film. The transit-time is therefore observed at the injection barriers Φ'_B and Φ''_B, which are slightly larger than the threshold value.

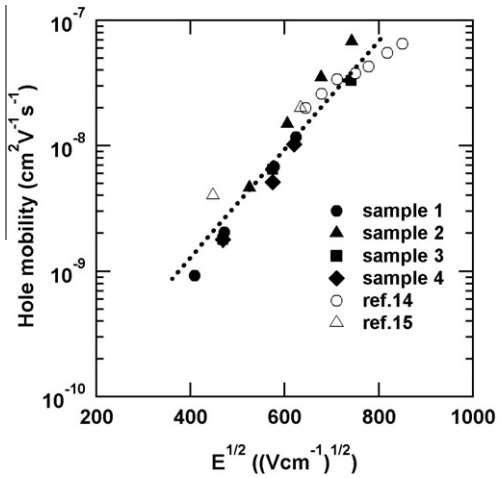

Fig. 3. Electric field dependence of hole mobility in the Alq_3 HODs using the 5-nm-thick NPB injection layer and the NPB/Alq_3 HODs; the structures of sample 1–4 are ITO/NPB(5 nm)/Alq_3(180 nm)/Au, ITO/NPB(5 nm)/Alq_3(110 nm)/Au, ITO/NPB(310 nm)/Alq_3(180 nm) /Au, and ITO/NPB(125 nm)/Alq_3(180 nm)/Au, respectively. As reference data, the hole mobility in Alq_3 films is shown [14–15]; these data were measured by the TOF method.

Fig. 3 shows the electric field dependence of hole mobilities in Alq_3 thin films estimated from the IS measurements of sample 1 and sample 2. For comparison, the hole mobilities of Alq_3 thin films measured using the TOF method are shown in Fig. 3 [14,15]. The hole mobility determined from the IS measurements of the Alq_3 HODs using the NPB injection layers is almost the same as the results of the TOF measurements. It is reasonable that both measurements give the same mobilities because drift mobilities can be measured by the IS and the TOF measurements [8] if the hole transport properties in the Alq_3 thin films are independent of film thickness; the thickness of the Alq_3 thin films measured by the TOF method was between 0.4 and 13 μm, whereas that measured by the IS method was 110 and 180 nm. We stress here that IS can determine the drift mobility of organic semiconductors with a thickness of about 100 nm (the TOF method is not applicable to such thin samples because we can not identify hole transit and electron transit separately). We have determined the hole mobility of Alq_3 thin films using the IS measurements with the 5-nm-thick NPB injection layer.

It was difficult to determine the carrier mobility of organic materials using IS measurements when the injection barrier between the injecting electrode and the organic thin films is high. We also stress that the injection layer, which reduces the injection barrier, allows us to determine the carrier mobility of the organic thin film.

3.2. Determination of hole mobility in NPB/Alq_3 double layers

We examine here IS of NPB/Alq_3 double layers. Fig. 4a shows the C–f curves of sample 3. In the frequency range higher than 10^4 Hz, the capacitance, approximately 60 pF, corresponds to the thickness of the sum of the NPB layer and the Alq_3 layer (the relative permittivity of both NPB and Alq_3 are assumed to be 3.5). The capacitance is increased with decreasing frequency below 10^4 Hz and then is constant in the frequency range between 10 and 10^3 Hz at $V = 0$ V. The capacitance in the frequency range between 10 and 10^3 Hz, approximately 160 pF, corresponds to that of Alq_3 layer. The minimum value of the capacitance, which is caused by a transit-time effect, is observed at $V = 4$, 6, and 7 V in the frequency range between 1 and 100 Hz in Fig. 4a. Fig. 4b shows the $-\Delta B$–f curves of sample 3 at $V = 4$, 6, and 7 V. The $-\Delta B$–f curves have the peaks and the frequency at the maximum value of $-\Delta B$, f_{max}, is indicated by arrows in Fig. 4b. The $-\Delta B$–f curves are similar to the $-\Delta B$–f curves for the Alq_3 HOD with the 5-nm-thick NPB layer shown in Fig. 2b and the transit-time effect was observed in sample 3. The hole mobility of the NPB/Alq_3 double layer is 1.8×10^{-9}–1.0×10^{-8} $cm^2 V^{-1} s^{-1}$ at $V = 4$–7 V, when we assume that L in Eq. (1) is equal to the thickness of the Alq_3 layer even in the double layer devices.

The transit-time can also be obtained from the $-\Delta B$–f curves of sample 4, and the hole drift mobilities calculated

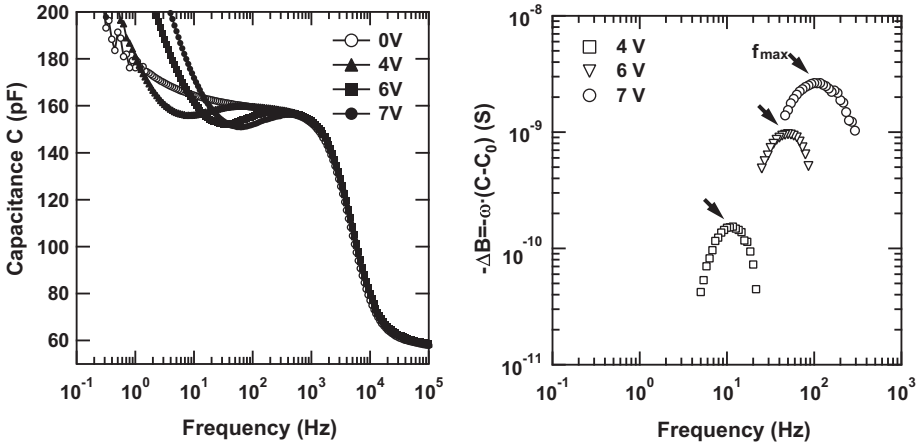

Fig. 4. (a) Frequency dependence of capacitance at DC bias voltages of 0, 4, 6, and 7 V in sample 3; sample 3 consists of ITO/NPB(310 nm)/Alq_3(180 nm)/Au. (b) Frequency dependence of $-\Delta B$ in sample 3 at DC bias voltages of 4, 6, and 7 V.

from the transit-time are shown in Fig. 3. It can be seen that the electric field dependence of the hole drift mobilities of sample 3 and sample 4 is in excellent agreement with those of Alq_3 layers with thin NPB injection layers and with those in literature measured by time-of-flight transient photocurrent technique [14,15]. Our assumption (L in Eq. (1) is equal to the thickness of the Alq_3 layer in sample 3 and sample 4) is reasonable.

We have performed device simulation based on the standard transport equations for HODs using a device simulator (ATLAS, Silvaco) to confirm that the observed transit-time effects results from the hole transit in the Alq_3 layers of sample 3 and sample 4. LUMO and HOMO levels, hole drift mobilities and dielectric constants of NPB and Alq_3 layers were the input parameters for the device simulation. The thicknesses of NPB and Alq_3 layers were set to be the same as those in sample 3 and sample 4.

At lower applied electric field, holes are injected into the NPB layer of the HOD, and injected holes are accumulated at the NPB/Alq_3 interface (Externally applied electric field is applied to the Alq_3 layer). The accumulated holes are injected into the Alq_3 layer at higher applied electric field whose strength is in the same range that we have observed the transit-time effects in Fig. 4. The energy band diagrams obtained from the simulation are consistent with those depicted in Fig. 4 in Ref [16]. The device simulation reproduced the transit-time effects in C–f curves and the values of hole drift mobility obtained from C–f curves using $-\Delta B$ method in sample 3 and sample 4 are in agreement with Alq_3 hole drift mobility. The simulation results are consistent with the experimental results.

The results presented here are the demonstration of the measurement of charge carrier mobilities in double layer OLEDs. Further device simulation and IS studies would be necessary for establishing the criteria for observing charge carrier transit in multilayer OLEDs.

4. Conclusions

The charge carrier mobility of Alq_3 thin films has been determined using IS measurements of the Alq_3 hole-only device with the NPB injection layer, which reduces the hole injection barrier between an injecting electrode and the Alq_3 thin film. The hole mobilities of Alq_3 thin films measured using IS are the same as those measured by TOF transient photocurrent technique. IS method can determine the drift mobility of organic semiconductors with a thickness of ~100 nm. An injection layer is useful for determining the charge carrier mobility of organic thin films when the injection barrier between an injecting electrode and the organic layer is high.

The charge carrier mobility of Alq_3 thin films has also been determined using IS measurements of NPB/Alq_3 double layer hole-only devices in which the thickness of NPB is comparable to that of Alq_3. This indicates that the external electric field is mostly applied to Alq_3 layer in the NPB/Alq_3 double layer hole-only devices. The information would be valuable for interpreting the transit-time effects in multilayer OLEDs.

with the mobilities previously reported for low-voltage DNTT TFTs [23]. Compared with the previous report [23] the thickness of the DNTT layer has been reduced from 30 to 25 nm, which is expected to reduce the parasitic potential drop associated with the vertical current path between the source/drain contacts (located on top of the semiconductor) and the carrier channel (located at the bottom of the semiconductor) and hence is expected to increase the transconductance and effective mobility of the TFTs [24].

The TFTs and circuits were fabricated on glass (Corning Eagle 2000) or flexible polyethylene naphthalate (Teonex® Q65 PEN; kindly provided by William A. MacDonald, DuPont Teijin Films, Wilton, UK). Aluminum with a thickness of 20 nm was evaporated directly onto the substrate through a polyimide shadow mask (CADiLAC Laser, Hilpoltstein, Germany) to define the gate electrodes. The aluminum was briefly exposed to an oxygen plasma to create a 3.6 nm thick AlO_x film, followed by immersion of the substrate in a 2-propanol solution of *n*-tetradecylphosphonic acid to form a 1.7 nm thick self-assembled monolayer (SAM) on the surface of the oxidized gates. This results in an AlO_x/SAM gate dielectric with a thickness of 5.3 nm and a capacitance of 800 nF/cm^2 [25–27]. A 25 nm thick DNTT layer was vacuum-deposited through a shadow mask, followed by the deposition of 30 nm thick gold through another shadow mask to define the source/drain contacts. The channel length is between 10 and 50 μm and the channel width is 100 μm or 200 μm. The maximum process temperature is 60 °C (the substrate temperature during the DNTT deposition). Fig. 1. shows the chemical structure of the semiconductor DNTT, a schematic cross-section of the TFTs, and photographs of a TFT with a channel length of 10 μm. All electrical measurements, including the shelf-life and bias–stress measurements, were performed in ambient air at room temperature.

The static performance of the flexible DNTT TFTs measured shortly after fabrication is summarized in Fig. 2. The TFTs have an on/off ratio of 10^8 and a subthreshold swing of 100 mV/decade. For the shortest channel length (L = 10 μm), the transconductance (normalized to the channel width) reaches 0.12 S/m. This is a factor of three larger than the transconductance of pentacene TFTs based on the same fabrication process and the same channel length fabricated on glass substrates [20] and similar to the transconductance of photolithographically patterned bottom-contact pentacene TFTs with a channel length of 5 μm on flexible polymeric substrates recently reported by the IMEC group [10]. The field-effect mobility extracted from the transfer characteristics of our DNTT TFTs in the saturation regime ranges from 1.2 cm^2/V s (L = 10 μm) to 2.1 cm^2/V s (L = 50 μm). The observation that the mobility extracted from the transfer characteristics decreases with decreasing channel length indicates that the relative contribution of the contact resistance to the total device resistance increases with decreasing channel length. This effect has been analyzed in detail for pentacene TFTs [28] and is expected to be even more pronounced for DNTT TFTs, since the larger ionization potential of DNTT (5.4 eV) compared with pentacene (5.0 eV) [18] is expected to produce a larger energy barrier at the interface between the semiconductor and the Au source and drain contacts (Fermi energy about 5 eV), and hence a larger contact resistance.

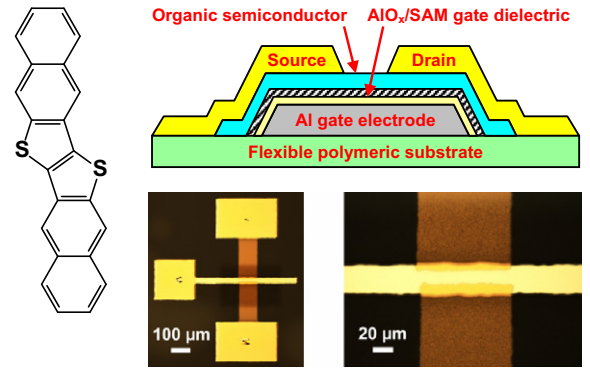

Fig. 1. Chemical structure of the conjugated organic semiconductor dinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]thiophene (DNTT), schematic TFT cross-section, and photographs of a DNTT TFT with a channel length of 10 μm and a channel width of 100 μm patterned using polyimide shadow masks.

Fig. 3a. shows how the saturation mobility of a flexible DNTT TFT with a channel length of 50 μm evolves over time when the substrate is kept in ambient air with a humidity of 40–70% under weak yellow light (laboratory conditions). The mobility decreases from initially 2.1 to 2.0 cm^2/V s after three months and then to 1.5 cm^2/V s after a total of eight months in air. For comparison, Fig. 3a. also shows that the DNTT TFTs have substantially better air stability than pentacene TFTs fabricated with the same technology (i.e., same type of substrate, same gate dielectric, same contacts).

Although the air stability of the DNTT transistors is better than that of the pentacene devices, there is a slight drop in the mobility of the DNTT TFTs, from initially 2.1 to 1.5 cm^2/V s after eight months in air. The mechanism for this slow degradation is unknown. Although oxidation of the DNTT molecules cannot be completely ruled out, it is unlikely given the molecular structure of DNTT. An alternative explanation for the observed mobility degradation is that air-borne molecules (e.g., H_2O, O_2, O_3) penetrate into the grain boundaries of the polycrystalline DNTT film and then interact with the mobile charge carriers or with the DNTT molecules at or near the grain boundaries in a way that is detrimental for the field-effect mobility [29,30].

In addition to the shelf-life stability we have also investigated the bias–stress stability. Fig. 3b illustrates the time-dependent decrease in drain current and the associated shift in threshold voltage of DNTT TFTs fabricated on a glass substrate during prolonged gate–bias stress. As in the case of TFTs based on hydrogenated amorphous silicon [31,32] and pentacene [33] the drain current decays faster when the applied gate–source voltage is larger. The reason is that a larger gate–source voltage results in a larger carrier density in the channel and hence in a larger trapping rate. The carrier density accumulated in the transistor channel at a certain gate–source voltage can be estimated as follows:

$$n = \frac{1}{q} C_{\mathrm{diel}} |V_{\mathrm{GS}} - V_{\mathrm{th}}| \qquad (1)$$

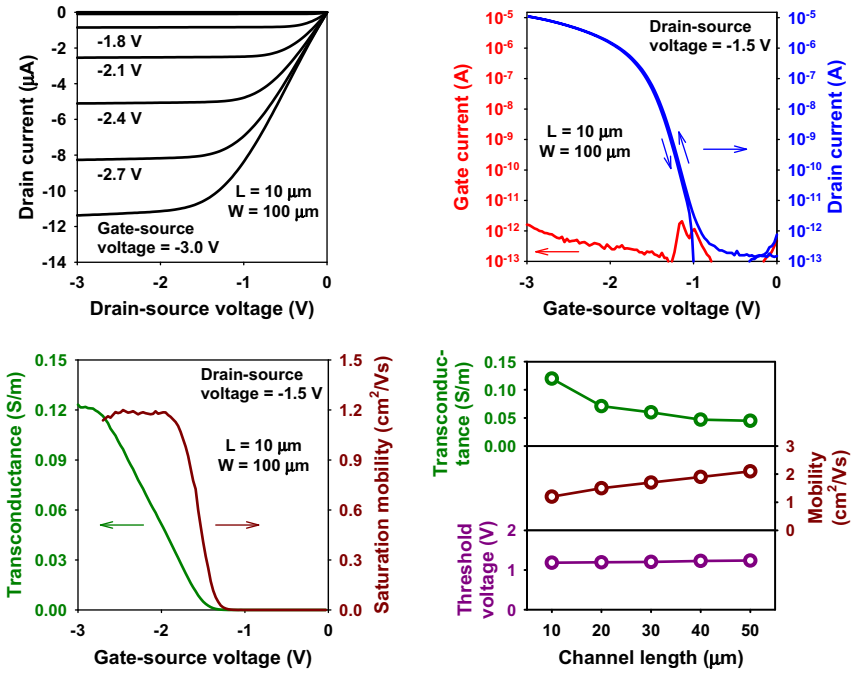

Fig. 2. Electrical characteristics of a DNTT TFT with a channel length of 10 μm. The transconductance has been normalized to the channel width (W = 100 μm). The influence of the channel length on the transconductance, the saturation mobility extracted from transfer characteristics and the threshold voltage is also shown.

where q is the elementary charge (1.6×10^{-19} C), C_{diel} is the capacitance of the gate dielectric per unit area, and V_{th} is the threshold voltage. According to Eq. (1), the carrier density in our DNTT TFTs (C_{diel} = 800 nF/cm^2, V_{th} = −1.4 V) is about 8×10^{12} cm^{-2} at a gate–source voltage of −3 V and 3×10^{12} cm^{-2} at a gate–source voltage of −2 V. In addition to the carrier density it is also useful to estimate the sheet resistance of the transistor channel, as suggested by the Princeton group [32]:

$$R_{sheet} = \frac{V_{DS}}{I_D}\frac{W}{L} \qquad (2)$$

where V_{DS} is the drain–source voltage, I_D is the drain current, W is the channel width, and L is the channel length. According to Eq. (2), the sheet resistance of the DNTT TFT in Fig. 3b. (W=100 μm, L = 30 μm) in the linear regime (V_{DS} = −0.1 V) is about 1 MΩ/sq at a gate-source voltage of −3 V and 2.5 MΩ/sq at a gate–source voltage of −2 V. When the DNTT TFTs are stressed with a gate-source voltage of −3 V it takes 10^4 s for the drain current to decay by 10%, whereas at a gate-source voltage of −2 V the lifetime for a 10% decay is 10^5 s. These lifetimes are similar to those reported by the Princeton group for a-Si:H TFTs fabricated at a temperature of 285 °C [31,32] despite the fact that the DNTT TFTs were fabricated at a more flexible-substrate-friendly temperature of 60 °C.

A direct comparison between the bias stress-induced drain-current decay of DNTT and pentacene TFTs is more difficult, since the drain current of pentacene TFTs decays in part simply due to the rapid oxidation of the pentacene molecules. In order to decouple the bias stress-induced threshold-voltage shift from the oxidation-induced degradation, the MIT group has performed bias–stress measurements on the pentacene TFTs in nitrogen [33]. However, since their pentacene TFTs utilized a different gate dielectric (parylene–N), a direct comparison with our DNTT TFTs is not possible.

To assess the dynamic performance of the TFTs we have fabricated unipolar ring oscillators based on inverters with saturated load [20,23]. The drive TFTs have a channel length of 10 μm and a gate overlap of 15 μm, from which a gate capacitance of 0.3 pF/μm (normalized to the channel width) can be estimated. Fig. 4 shows the signal delay per stage of a 5-stage ring oscillator on a glass substrate measured as a function of supply voltage. At a supply voltage of −5 V, the stage delay is 7 μsec. This is the shortest signal delay reported for an organic ring oscillator at this supply voltage (5 V), and it is within a factor of 20 of the fastest organic ring oscillators reported to date [10], despite the smaller supply voltage (5 V instead of 10 V) and the more relaxed channel length (10 μm instead of 2 μm).

Although functional active-matrix displays based on organic light-emitting diodes (LEDs) and organic TFTs have been demonstrated [1,3,4], there is some uncertainty about whether organic TFTs are capable of driving organic LEDs to the brightness required for practical display applications [34]. Fig. 5 shows photographs of a blue organic LED controlled by a DNTT TFT for five different gate–source voltages. The TFT has a channel width (W) of 200 μm and a channel length (L) of 10 μm (W/L = 20). The LED is a bottom-emitting fluorescent low-voltage device manufactured by Novaled [35,36] and has an active area of 0.067 cm^2. This area is about 1000 times larger than the pixel area in a notebook computer display (e.g., the area

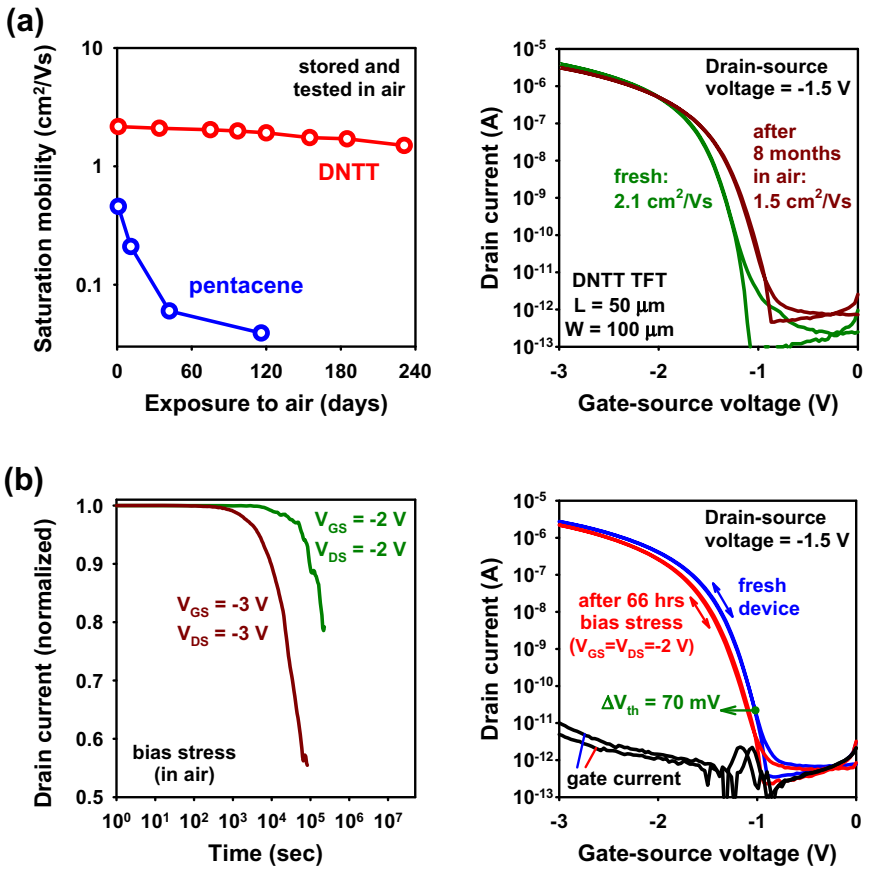

Fig. 3. (a) Shelf-life stability of a DNTT TFT (channel length 50 µm) in comparison to that of a pentacene TFT based on the same technology. (b) Bias–stress stability of DNTT TFTs (channel length 30 µm).

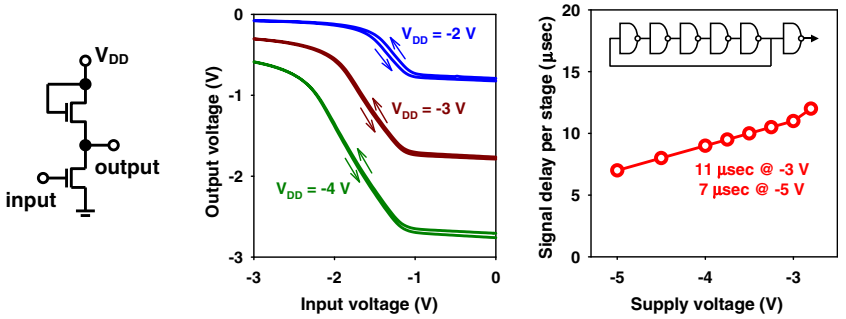

Fig. 4. Circuit schematic and transfer characteristics of a unipolar inverter with saturated load, and signal delay per stage as a function of supply voltage for a unipolar five-stage ring oscillator based on DNTT TFTs (channel length 10 µm, gate overlap 15 µm).

of an RGB subpixel in a display with a 17-inch diagonal and SXGA resolution is about 7×10^{-5} cm^2). The LED has a luminous efficiency of 7 cd/A and CIE color coordinates of 0.14/0.25. The LED and the TFT were connected using a BNC cable. When a gate–source voltage of −3.5 V is applied to the TFT and a potential of −5 V to the cathode of the LED, the TFT drives a current of 67 µA through the LED. At this current, the potential difference between source and drain of the TFT is 2.2 V and the potential difference between anode and cathode of the LED is 2.8 V. The current of 67 µA produces a luminance of 70 cd/m^2, which is within an order of magnitude of the maximum brightness of most commercially available computer monitors (typical display brightness: ~500 cd/m^2; typical subpixel brightness: 600–1500 cd/m^2). Assuming the luminance is approximately proportional to the current density, a TFT with $W/L = 1$ would be able to drive an LED with the same efficiency (7 cd/A), but with a typical display subpixel area of 10^{-4} cm^2 to a brightness of 2500 cd/m^2, which is well above the maximum brightness required for most display

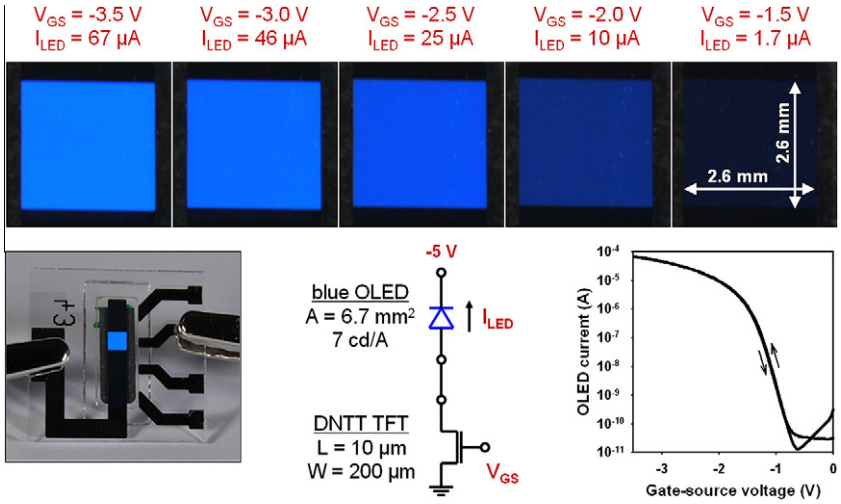

Fig. 5. Photographs of a blue organic light-emitting diode (LED) with an area of 6.7 mm^2 controlled by a DNTT TFT with a channel width of 200 µm and a channel length of 10 µm. At the maximum gate–source voltage (−3.5 V), the luminance of the organic LED reaches 70 cd/m^2. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

applications. Organic LEDs based on phosphorescent emitter materials, which typically have luminous efficiencies between 30 and 70 cd/A, depending on color [35–37], would reach a brightness of 10,000–20,000 cd/m^2 when controlled by a DNTT TFT with $W/L = 1$. This clearly shows that organic TFTs even with the smallest possible footprint ($W/L = 1$) are fully capable of providing the electrical current required to drive organic LEDs in active-matrix displays.

In summary we have evaluated the current–voltage characteristics, the air stability, the bias–stress stability, the dynamic performance, and the OLED-drive capability of low-voltage TFTs based on the organic semiconductor dinaphtho-thieno-thiophene (DNTT), a fused heteroarene with large ionization potential. We have found that DNTT TFTs have larger mobility, better air stability, better bias–stress stability, and better dynamic performance than pentacene TFTs fabricated with the same technology, suggesting that DNTT has great potential for organic electronics, including flexible active-matrix OLED displays.

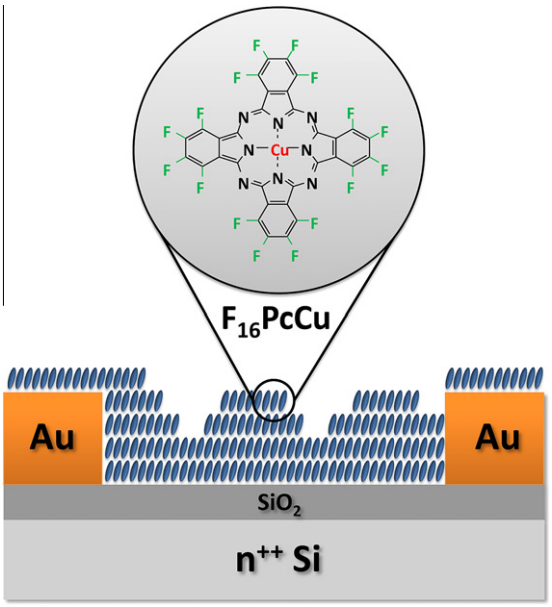

Scheme 1. Schematic drawing of the OFET device structure with F_{16}PcCu as organic semiconductor thin film.

particular of ultrathin films [14,20] it is hard to study the thickness-dependence of a quantity which is as sensitive as μ_{FET} in a comparison of different films prepared in parallel with different thickness because of large scatter in the results.

The general electrical characteristics of OFET are well described within the model of MOSFET theory [21] since the electrical properties of the semiconductor layer in OFET depend on the interface between the gate dielectric and the organic layer. However, the characteristics of OFET often deviate substantially from the expected linear increase of the drain-source current (I_{SD}) on the drain-source voltage in the output characteristics and develop a sigmoidal ("*S*-") shape [22]. Such characteristics were argued to arise from the field-effect mobility of charge carriers to depend on the applied bias [23], the density of charge carriers in the conductive channel [24] or injection barriers to/from the contact metals [23,25–27]. Such complications in modeling hampered the safe identification of μ_{FET} of a given material. The mobility μ_{FET}, however, plays a crucial role in the understanding of charge carrier transport and its control is critical for the success of many applications using OFET.

Charge transport at the interface with the gate dielectric of an OFET involves an accumulation layer thickness on the order of only several times the spacing between molecule layers. Estimates based on classic continuum electrostatics give thicknesses of only a few nanometers [28]. F_{16}Pc showed the formation of ultrathin conductive films already in the regime of one or few monolayers [14,29]. The structure of such ultrathin F_{16}Pc films has been analyzed *in situ* during growth by electron diffraction [30], optical spectroscopy [31,32], and very detailed *in situ* X-ray diffraction analysis [33–35]. A detailed control of the films in the ultrathin regime in the very interface with the gate dielectric as explicitly accessible for F_{16}PcCu is the key to optimize devices.

In the present work we studied films of F_{16}PcCu from the monolayer regime to films of about 40 nm thickness. Further, full transfer characteristics for varied gate voltages were measured as needed to safely determine the threshold gate voltage and the on/off ratio as technically relevant parameters and as quantities that clearly indicate the degree of interfacial charge transfer to the conductive channel. We determined the output characteristics for gate voltages between 1 and 50 V during deposition of F_{16}PcCu (*in situ*) at subsequently growing film thickness. Thickness-dependent changes were therefore safely determined and scattering of results among samples was thereby avoided. Applied electric fields above 1000–2500 kV m^{-1} during deposition can have an influence on the growth of organic semiconductor films [36,37]. Our experiments were therefore performed at significantly lower electric field strength. The formation of an active channel of F_{16}PcCu was studied in bottom gate, bottom contact field-effect transistors in a setup that allowed electrical characterization in real time, fast compared to typical growth rates of vapor-deposited organic semiconductor thin films. Since metal adhesion layers beneath the desired contact metal had led to difficulties in the interpretation of contact formation in particular for organic films in the monolayer range [19] we used pure metal contacts of either silver or gold without any adhesion layer in the present study. The evolution of the apparent charge carrier mobility and the development of the threshold voltage as well as the on/off ratio were studied in dependence on the formation of conductive layers in real time as opposed to preceding and subsequent island formation and an optimum accumulation layer crucial for device operation is explicitly discussed.

2. Experimental details

Highly n-doped silicon [1 1 1] wafers with a 300 nm thermally grown oxide layer were used as substrate. The wafers were cleaned with acetone (Roth, 99.8%) and ethanol (Roth, 99.8%) in an ultrasonic bath and dried with nitrogen (Air Liquide, 99.999%). Optical UV lithography has been used to structure inter digital source drain contacts with channel length of 40 and 20 μm, respectively. Therefore, positive resist ma-P1215 (MicroResist) was spun onto the wafer, exposed to UV-light through a shadow mask and resist removed from the illuminated areas by rinsing in a ma-D331 (MicroResist) developer solution. A 50 nm thick film of Ag or Au was deposited in a Leybold-Heraeus Z400 sputter machine (10^{-4} mbar Ar, Air Liquide, 99.999%). The interdigitated electrode arrays were achieved by lift-off in acetone within an ultrasonic bath. Such structures with the silicon wafer as gate electrode were mounted onto a ceramic sample holder and contacted with spring loaded pins.

Perfluoro copper phthalocyanine (F_{16}PcCu) was obtained from D. Wöhrle's group at the University of Bremen, purified by 3-zone sublimation (Lindbergh) in vacuum (5×10^{6} mbar) and then used as organic semiconductor and thermally evaporated under high vacuum conditions

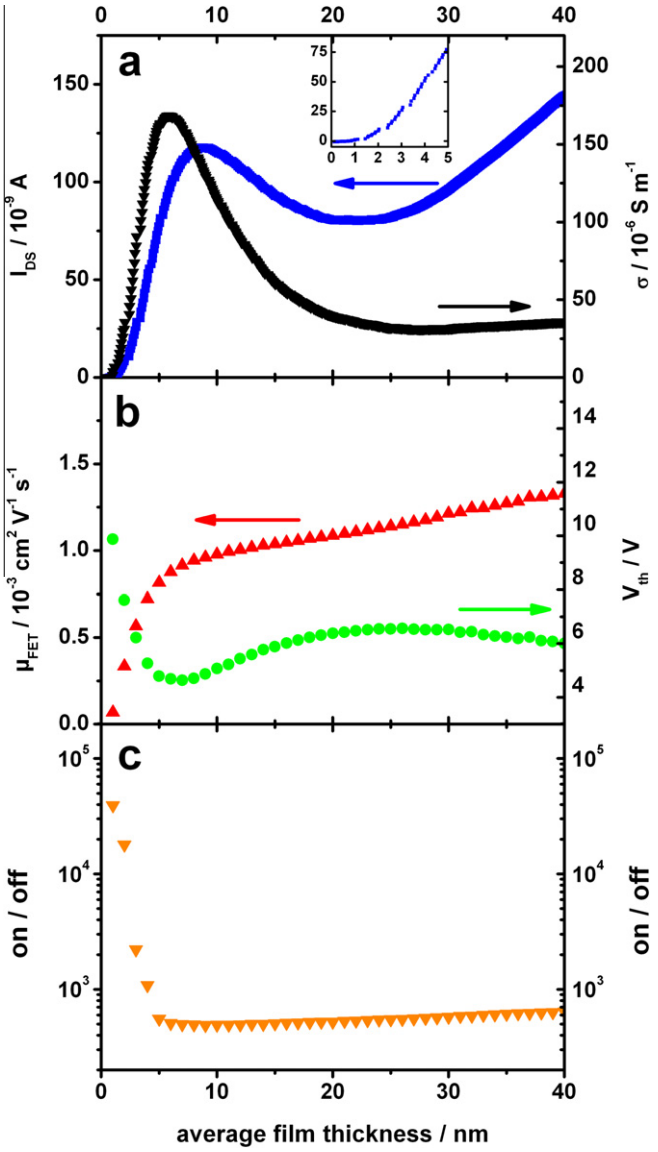

Fig. 1. Development of current I_{DS} (■) and the specific conductivity σ (▼) across a channel length of L = 40 μm between the source and drain gold electrodes at a constant source-drain-voltage of 10 V (a), charge carrier mobility μ_{FET} (▲) and threshold voltage V_{th} (●) calculated from the output and transfer characteristics determined by voltage sweeps (b) and the maximum on/off-ratio of the transistor (c) during deposition of F_{16}PcCu. The inset in (a) depicts initial percolation towards a conductive channel.

(10^{-7} mbar) from resistively heated BN crucibles (Lesker) leading to a deposition rate of 0.5 nm per minute as monitored by a calibrated quartz crystal microbalance. The substrate temperature increased from 22 to 43 °C during deposition and subsequently decreased again to 22 °C as monitored by a Pt100. For electrical measurements a Keithley 6430 digital multimeter and a Keithley 487 Picoamperemeter were used.

These structures with bottom gate and bottom contact enabled us to investigate electrical properties during film growth from the earliest stage of material deposition in the range of mono layer formation up to the final film thickness of typically 40 nm. Every 10 s the formation of conductive pathways within the transistor structure was monitored by measurements of the source-drain current at a constant voltage of 10 V. At each nm of deposited material (about every 2 min) during the organic layer deposition full output and transfer characteristics were measured to determine the charge carrier mobility μ_{FET} in the saturation regime of the output characteristics and the threshold voltage V_{th} from the linear fit to the square root of the drain current as a function of gate voltage according to MOSFET theory [21] for the transistor in a range of typically 1–30 V of applied voltages which took about 20 s. The corresponding electric field strength in our experiments of less than 250 kV m^{-1} was therefore chosen to avoid a significant influence on film growth. Further, the very same preparation procedure was used for the discussed films.

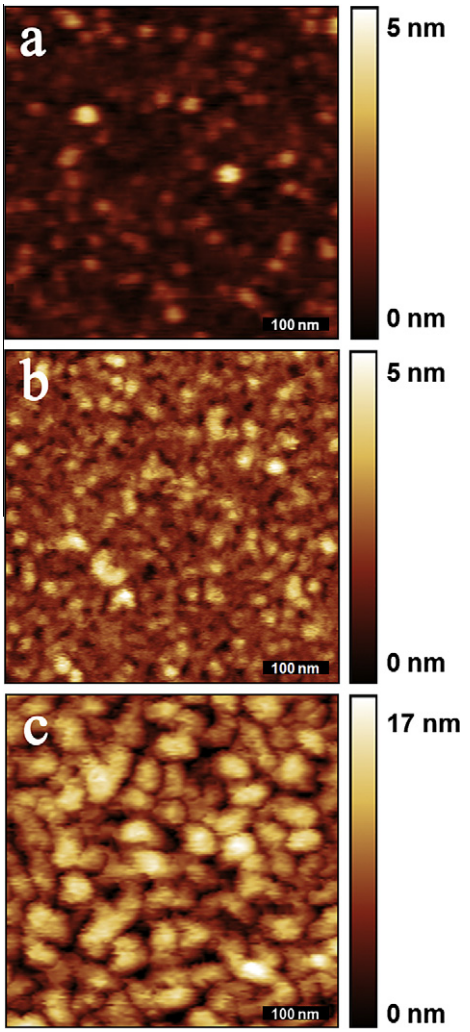

Fig. 2. Atomic force microscopy (AFM) images and calculated root means square roughness (rms) of the SiO_2 gate dielectric substrate (a, rms = 0.49 nm), a $F_{16}PcCu$ film of 3 nm average film thickness deposited on SiO_2 (b, rms = 0.62 nm) and a 40 nm $F_{16}PcCu$ film on SiO_2 (c, rms = 3.16 nm) showing 0.5 × 0.5 μm sections with a height range as indicated in the figure (black to white).

Stabilization of the transistor characteristics was studied following these experiments in vacuum without any thermal annealing procedures and by venting with synthetic air (20.5% O_2 in N_2, Air Liquide, 99.999% each). In order to provide optimum consistency of the different methods we discuss in this work the properties of only two separate films in different growth states although similar characteristics were reproduced for other films also. Subsequent to the electrical studies, atomic force microscopy (AFM) was performed with a smart SPM 1000 by AIST-NT in the resonant mode using N1A cantilevers.

3. Results and discussion

$F_{16}PcCu$ was deposited onto silicon oxide with bottom contact electrodes at room temperature. The conductivity

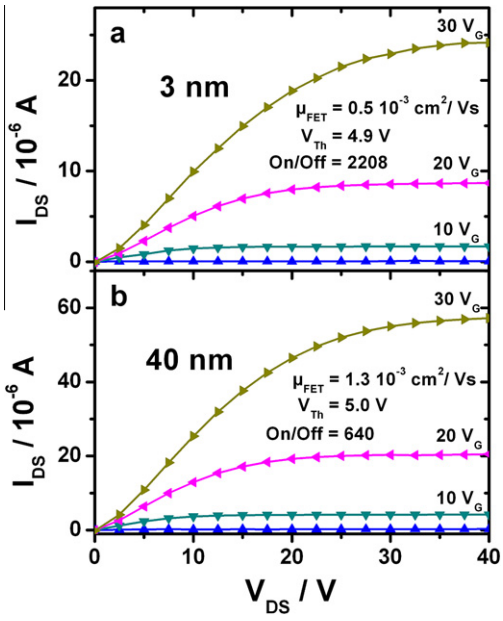

Fig. 3. Output characteristics of a thin film $F_{16}PcCu$ transistor at 3 nm (a) and 40 nm (b) average film thickness measured subsequently during one deposition.

during the film growth was measured every 10 s corresponding to 0.1 Å average film thickness during deposition. In Fig. 1a the current distribution over increasing film thickness is shown for a structure with Au interdigitated source and drain electrodes. The background current of about 10^{-11} A increased with the deposited amount of $F_{16}PcCu$ from the very beginning showing the geometric percolation of the semiconductor material on the gate insulator. From earlier experiments it is known that $F_{16}PcCu$ grows in layers of upright standing molecules (~1.5 nm height) with the molecular plane almost parallel to the surface normal on oxide surfaces after treatments similar to the present one [38,39]. Such layered growth continues up to an average film thickness of about 8 nm. This increase in current is also reflected in an increase of the specific conductivity as also shown in Fig. 1a. A maximum conductivity of 1.7×10^{-4} Sm^{-1} was reached at about 6 nm average film thickness. Deposition beyond a monolayer (~1.5 nm) obviously led to the formation of additional conductive layers of up to about four monolayers contributing efficiently to the electrical charge transport by adding parallel conduction paths. This growth mode changed for deposition beyond an average film thickness of four monolayers. Additional $F_{16}PcCu$ contributed less efficiently to the conduction presumably by growth on top of islands for which the layers were not completed shown by a decreasing conductivity and an only slightly increasing current before the current also even decreased beyond about 8 nm. Such decrease in both, conductivity and current could either be caused by a decrease of μ_{FET} at widely constant diameter of the conductive path or by a decrease of the diameter of the conductive path by a rearrangement of molecules from already formed layers toward presumably more stable

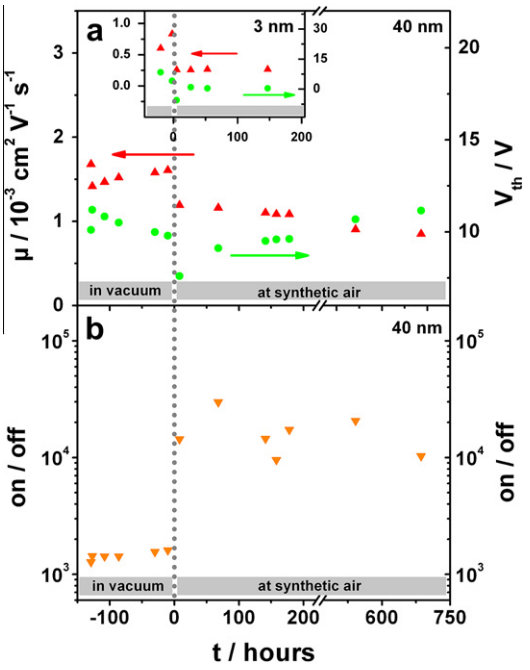

Fig. 4. Charge carrier mobility μ_{FET} and threshold voltage V_{th} over elapsed time t after deposition of a 40 nm $F_{16}PcCu$ film with the dotted line indicating the ventilation with synthetic air and an ultra thin film transistor with 3 nm $F_{16}PcCu$ shown as inset in the same units (a) and the maximum on/off-ratio of the 40 nm transistor (b).

three-dimensional isolated islands on top of it. These characteristics continued up to an average film thickness of 20–30 nm. Upon further deposition these islands started to percolate forming additional conductive pathways. The current increased at almost constant conductivity as shown in Fig. 1a. The AFM image of such $F_{16}PcCu$ film with 40 nm average film thickness was measured (Fig. 2c) and was compared to the SiO_2 surface of an uncovered substrate (Fig. 2a). The film growth had led to a significant increase of the roughness from rms = 0.49 nm for the uncovered SiO_2 to rms = 3.16 nm indicating the island characteristics of film growth. Compared with the film thickness of 40 nm, however, such little roughness showed a widely percolated structure of the islands.

The electronic properties of transistors in such structures with Au electrodes were measured for every nm of average film thickness (Fig. 1b). The field-effect-mobility μ_{FET} determined from the saturation of the output characteristics sharply rose from the formation of the first pathways to the maximum in current and conductivity. Such characteristics were explained by the presence of only a few conductive pathways, a large number of grain boundaries or defects in monolayer islands and hence a large influence of hopping barriers and a low value of μ_{FET} in the beginning. In this regime the threshold voltage V_{th} determined from the transfer characteristics started out with a rather high value of 10 V and decreased to 5 V. An initially high positive threshold in the gate voltage arose from a large density of electron traps in grain boundaries or defects in the monolayers that had to be filled before additional electrons could participate in charge transport [21]. At increased average film thickness beyond about 8 nm the increase of μ_{FET} leveled off and V_{th} reached a minimum indicating a minimum trap density. The growing films showed a lower number of grain boundaries leading to less trap density. The increasing film thickness obviously led to a stabilization of the first mono layers where the active transistor channel was formed [38]. V_{th} increased beyond 8 nm speaking for a less efficient utilization of electrons in the conductive channel of $F_{16}PcCu$. At a simultaneously increasing μ_{FET} such characteristics indicate charge diffusion from the interface region into additional islands on top of the conductive channel as also detected in the decreasing current and conductivity in Fig. 1a. Percolation of these islands on top of the conductive channel was observed by an increasing current and a constant conductivity at about 22 nm film thickness. Beyond this range percolation of the islands and healing of grain boundaries that led to increasing current and conductivity, also led to more efficient participation of injected electrons in the conduction and hence a decrease in V_{th}. Very similar development of the electrical characteristics during film growth of $F_{16}PcCu$ speaking for similar percolation and growth characteristics were observed also for the growth between Ag contacts (Supplemental Information). Almost identical values of μ_{FET} were observed at, however, an increased electron injection from the Ag contacts as reflected in an increased conductivity and decreased V_{th}.

As expected, all transistors prepared in this study showed accumulation mode n-channel field-effect transistor characteristics. In Fig. 3b typical output characteristics of a 40 nm thin film between Au electrodes on SiO_2 are shown with an increasing drain current for positive gate voltages. A charge carrier mobility $\mu_{FET} = 1.3 \times 10^{-3}$ cm^2/Vs and a threshold voltage of $V_{th} = 5.0$ V was determined. These compare favorably with known values from the literature for thin films of $F_{16}PcCu$ on untreated SiO_2 where $\mu_{FET} = 2.0 \times 10^{-3}$ cm^2/Vs for bottom contacts [18] and $\mu_{FET} = 5.6 \times 10^{-3}$ cm^2/Vs for top contacts were typically determined for films deposited at room temperature as in the present case [13]. A maximum on/off = 640 ratio of the drain current was reached in this structure within the present range of gate voltages from 0 to 30 V and drain voltages from 0 to 50 V. In Fig. 1, however, it was seen that thinner films already showed similar characteristics. The output characteristics of such transistor with an ultra-thin semiconductor layer of only 3 nm was analyzed and plotted in Fig. 3a. At slightly smaller $\mu_{FET} = 0.5 \times 10^{-3}$ cm^2/Vs, a comparable $V_{th} = 4.9$ V and an even increased on/off = 2208 was determined. Such clear competitiveness of the device constructed with the thinner film was confirmed by a plot of the on/off ratio determined during the growth of the film (Fig. 1c). The maximum values above 10.000 were reached for the initial stage of monolayer percolation for which all electrons in the interface of $F_{16}PcCu$ with the dielectric efficiently participated in the drain current. As expected from the discussion of the development of the electrical characteristics with film thickness (Fig. 1) the surface roughness of a (separately prepared) 3 nm thin $F_{16}PcCu$ semiconductor layer of rms = 0.62 nm (Fig. 2b) was found just slightly increased relative to rms = 0.49 nm for the uncovered SiO_2 (Fig. 2a) confirming

the layered growth in the percolation range leading to such smooth films.

Since structural studies at $F_{16}PcCu$ films on SiO_2 reported a detailed dependence of the film structure on film thickness [33] widely independent of the preparation conditions, the present results serve to discuss the mobility within these different structures. Since a $\beta_{bilayer}$ structure of $F_{16}PcCu$ was found within the first two monolayers of $F_{16}PcCu$ on SiO_2 which carried almost completely the drain current in the present study a rather high charge carrier mobility typically used in devices can be assigned to $F_{16}PcCu$ in the $\beta_{bilayer}$ structure. The β structure found for further increased film thickness proved to be of almost negligible mobility in the present study.

The storage of transistors in vacuum led to an increased μ_{FET} and decreased V_{th} as shown in Fig. 4 a for the 40 nm thin film ($t < 0$ s). The field effect mobility increased from $\mu_{FET} = 1.4- \times 10^{-3}$ cm^2/Vs. to $\mu_{FET} = 1.6 \times 10^{-3}$ cm^2/Vs. Since this was studied for the very same film, this could be explained by some healing of structural defects in the organic semiconductor, specifically within the first layers at the semiconductor–insulator interface. Simultaneously the threshold voltage therefore decreased from $V_{th} = 11.2$ to $V_{th} = 9.8$ V because of a smaller number of trapped electrons at a given total concentration in the interface of $F_{16}PcCu$ with SiO_2.

The stability of $F_{16}PcCu$ field-effect transistors at air was reported in various earlier reports [13,18,40] and was also confirmed in the present study. Of particular interest, however, is the change of decisive parameters and differences between ultrathin films and films of the usual thickness. In Fig. 4a, a small decrease was observed for the 40 nm thick film as discussed above from $\mu_{FET} = 1.6 \times 10^{-3}$ cm^2/Vs in vacuum to $\mu_{FET} = 1.2 \times 10^{-3}$ cm^2/Vs following exposure to synthetic air. Oxygen diffused into the organic layer and led to an increased concentration of deep traps and structural defects which resulted in further decreasing electron mobility towards $\mu_{FET} = 0.9 \times 10^{-3}$ cm^2/Vs within 5 weeks and an increase of the threshold voltage from $V_{th} = 7.6$ V to $V_{th} = 11.2$ V. After such elongated period of exposure almost constant characteristics were observed. Stability of the organic field-effect transistor over more than 4 weeks at air was proven. The performance of the device even improved under air as seen in an increased on/off-ratio by an order of magnitude (Fig. 4b). For optimized devices with an ultrathin conductive channel of some monolayers of $F_{16}PcCu$ (3 nm) only, the time-dependent analysis in vacuum and air showed clearly shorter response times (inset of Fig. 4a). Upon storage in vacuum the mobility increased from $\mu_{FET} = 0.7 \times 10^{-3}$ cm^2/Vs to $\mu_{FET} = 0.8 \times 10^{-3}$ cm^2/Vs within one day. Upon exposure to air this organic field-effect transistor showed a fast stabilization of the charge carrier mobility at $\mu_{FET} = 0.3 \times 10^{-3}$ cm^2/Vs and a stable value of the threshold voltage at $V_{th} = 0.4$ V after less than a day compared to weeks for the thicker films.

4. Conclusions

It was reproducibly confirmed that a thin conductive channel of $F_{16}PcCu$ was formed already in the beginning of deposition within a few monolayers. The formation started in the interface region at about 2 nm average film thickness. Once the threshold thickness of about 8 nm was reached for this conductive channel, $F_{16}PcCu$ showed a constant charge carrier mobility and threshold voltage independent of further increasing the film thickness. The threshold voltage increased with the metal work function. A decreased electron density in the conductive channel of $F_{16}PcCu$ is thereby indicated, well in line with decreased electron injection into the organic semiconductor. Upon ventilation with air the threshold voltage also increased also speaking for a decreased electron concentration in the conductive channel in this case caused by electron transfer from $F_{16}PcCu$ (or the electrode metal) to oxygen.

Additional islands of $F_{16}PcCu$ deposited on top of the initially formed conductive channel showed only minor increase of μ_{FET}, presumably only caused by healing of defects within the underlying channel. No separate contribution to charge transport from the source to the drain electrodes was found, in good agreement with earlier reports of conductivity measurements in similar structures for (per)fluorinated zinc phthalocyanines [14]. The threshold voltage, however, reacted quite sensibly on the formation of such additional islands on top of the conductive channel by a positive shift indicating a decreased electron concentration within the channel caused by charge diffusion from the interface region into the additional islands and by a subsequent negative shift upon percolation of these additional islands.

It was confirmed that field effect transistors of $F_{16}PcCu$ showed a mobility widely stable in air. However, the detailed present investigation showed a decrease of the mobility by about 50%, reproducibly observed for thin as well as 40 nm thick films. The stabilization was considerably faster for thinner films and reached a stable value proving long time stability of $F_{16}PcCu$ conductive channels at air. An increased on/off-ratio at air showed an overcompensation of the decreased mobility by a strongly decreased charge carrier concentration and off-current following interaction with air.

We conclude that a film limited in thickness to the fully developed conductive channel in the interface with SiO_2 of about 8 nm average film thickness without additional parasitic island formation represents the optimum film thickness for device applications in OFET. Further increase of the film thickness did not improve the mobility, but decreased the device performance by an increased threshold voltage up to about 22 nm and by an increased off-current caused by an increased bulk transport beyond about 22 nm. This led to a decreased on/off ratio.

Field-effect measurements for different film thicknesses of the organic semiconductor layer can serve to discuss in detail the development of a conductive channel. It was shown before for spin-coated polymeric semiconductors that the charge carrier mobility changed with the thickness of the organic film thickness which was explained by poor ordering in thin films and improved ordering at about 50 nm [19]. The present *in situ* measurements performed during film preparation by PVD and starting at considerably smaller channel thickness showed the most significant changes already far below such reordering threshold

and showed the strong influence of direct interaction in the interface of gate dielectric as substrate and a growing organic film. To clearly assign such influence it is mandatory to study the channel formation in real time during growth to exclude any subsequent influence of external parameters. Such measurements led us to a clear optimization of the organic semiconductor film thickness for device performance and we assume that such approach can serve to efficiently optimize OFET structures beyond the present films of F_{16}PcCu.

Acknowledgments

electrode. We find that the light-emitting efficiency of top or bottom side emissions as well as bottom/top emitting ratio is greatly influenced by the top metal cathode thickness. We also investigate the radiation distribution pattern of the transparent OLEDs with increasing top metal cathode thickness by a separate examination of the top and bottom side emissions with spectrogoniometer measurements. We find significant deviations from the Lambertian characteristics on emission direction. Moreover, we analyze our transparent OLEDs with an OLED numerical optical model software calculating the flux of outcoupled photons [18–21], and then compare theoretical predictions with our experimental results.

2. Experimental

A series of seven different red emitting phosphorescent semi-transparent OLEDs based on *p–i–n* doped structures [18–23] are fabricated as shown in Fig. 1. The organic layers are sandwiched between a 90 nm thick indium tin oxide (ITO) anode and a thin Ag metal cathode. The effect of varying the thickness of the Ag cathode layer from 15 to 45 nm on the device performance of the TOLEDs is investigated. All samples are deposited by thermal evaporation onto ITO-coated structured glass substrates in an ultra-high vacuum (UHV) chamber (Kurt J. Lesker Co.) in ultrahigh vacuum at a base pressure around 10^{-8} mbar. The devices are encapsulated immediately after preparation under nitrogen atmosphere using epoxy glue and glass lids.

As *p*-type hole injection and transport layer, we use 60 nm thick films of N,N,N,N′-tetrakis(4-methoxyphenyl)-benzidine (Meo-TPD) which is doped with 4 wt% of the Novaled dopant *p*-type 2 (NDP-2, Novaled AG, Dresden).

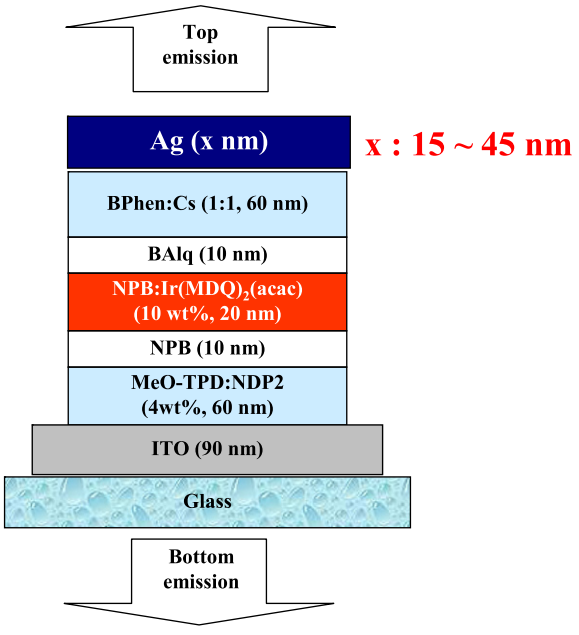

Fig. 1. Device structures of the transparent OLEDs tested in this study.

This *p*-type dopant has similar electric properties to 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) and exhibits a conductivity of around 10^{-5} S cm^{-1} [18–23]. As *n*-type electron injection and transport layer, we use 60 nm of cesium (Cs) doped 4,7-diphenyl-1,10-phenanthroline (BPhen) with a conductivity comparable to the *p*-side. The *p* and *n* layer thicknesses of these structures have been optimized in terms of constructive interference for maximal outcoupled photon flux using optical simulations based on classical electrodynamics [21]. Optimization of OLED transport layer will not alter the electrical properties of the OLED since the electrical conductivity of the *p* and *n* sides is almost independent of the thickness due to electrical doping [18–23]. N,N′-di (naphthalene-1-yl)N,N′-diphenyl-benzidine (NPB, 10 nm) and bis(2-methyl-8-quinolinolato)-4-(phenyl-phenolato) aluminum-(III) (Balq2, 10 nm) are used as electron and hole blocking layers, respectively, to confine not only holes but also electrons in the emitting layer (EML). The 20 nm thick red EML consists of NPB doped with 10% of the triplet red emitter iridium (III)bis [2-methyldibenzo-(f,h) quinoxaline](acetylacetonate) (Ir(MDQ)2(acac)). The overall active area of a single OLED device is 6.7 mm^2.

The devices emit bright red light from both sides when a positive voltage is applied to the ITO anode; no light is observed in reverse bias. For OLED characterization we utilize a Keithley Source Measure Unit 2400 to obtain the current–voltage data, while an INSTRUMENT SYSTEMS GmbH CAS140 spectrometer is used to measure luminance and spectral radiant intensity in the forward direction at the same time. Afterward, the spatial emission of the OLED is evaluated with a spectrogoniometer setup to estimate external quantum efficiency and luminous efficacy [18–21,24]. These data can be directly determined from the integration of the azimuthal angle θ resolved radiant intensity over the solid angle, assuming the emission to the invariant with respect to the polar angle φ because of the planar geometry of the samples.

3. Results and discussion

The current density–voltage–luminance (*J–V–L*) curves of the semi transparent OLEDs are shown in Fig. 2((a) bottom side, (b) top side) according to the thickness of the top Ag cathode. Both Fig. 2(a) and (b) clearly show that the *J–V* curves as well as the EL onset voltages of the OLEDs at the luminance region are almost identical, i.e. the thickness variation of the top Ag electrode does not alter the electrical characteristics of our transparent OLEDs. However, significant differences in *L–V* curves depending on the thickness variation of the top Ag electrode can be observed. The luminance of the bottom direction increases gradually with increasing Ag thickness in the transparent OLEDs, while in the top direction it gradually decreases. For example, luminance values of 2143, 3112, 3950, and 4084 cd/m^2, respectively, are measured in the bottom direction at a driving voltage of 3.5 V with an Ag thickness of 15, 25, 35 and 45 nm, respectively (whereas luminance of 444, 216, 128, 47 cd/m^2 were observed in the top direction). This luminance behavior can be easily understood

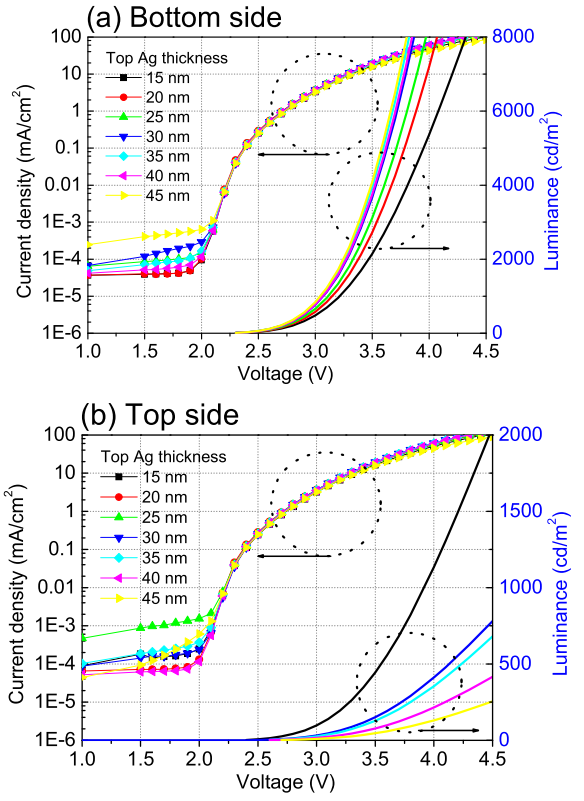

Fig. 2. Current density versus voltage (I–V) and voltage versus luminance (V–L) characteristics of (a) bottom side emission and (b) top side emission.

by transmittance and reflectance changes of the top Ag electrode with increasing thickness. With increasing the thickness of the top Ag electrode, the reflectance also increased while the transmittance decreased. Therefore, light emission toward the bottom side was highly enhanced, but that toward the top side was gradually reduced.

To examine the transmittance change depending on the top Ag electrode thickness, we measure the transmittance of all TOLEDs in this study with air reference. As shown in Fig. 3, the overall transmittance of devices is reduced gradually by increasing the thickness of the top Ag layer. For a

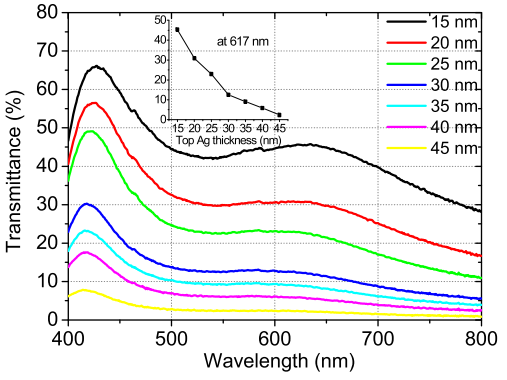

Fig. 3. Transmittance characteristics of the transparent OLEDs tested in this study with air reference (inset: transmittance at 617 nm).

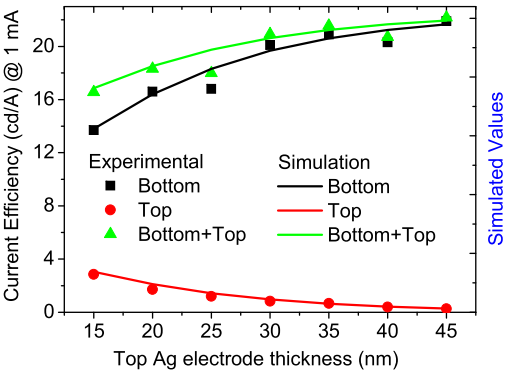

Fig. 4. Current efficiency and bottom to top ratio characteristics of the transparent OLED at a driving current density of 1 mA/cm^2.

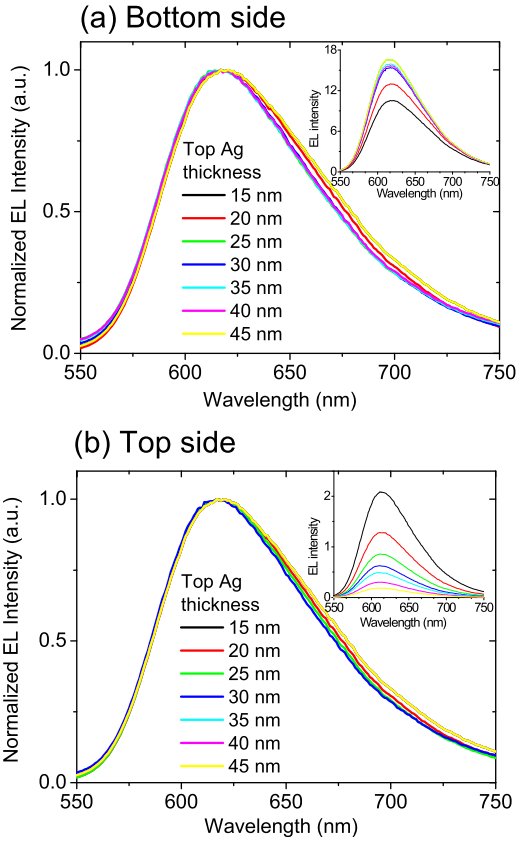

Fig. 5. Normalized electroluminescence (EL) intensity of (a) bottom side and (b) top side (inset: EL intensity at a driving current density of 15 mA/cm^2).

15 nm thick Ag layer the transmittance is over 45% at 617 nm which is the maximum wavelength of devices in this study. However, the transmittance of devices with over 35 nm thick Ag is less than 10%. From these results, we can easily confirm that the luminance behavior which shows a gradual increase in the bottom direction while a decrease in the top direction with increasing top Ag thickness is originated by the thickness dependent optical property change of the Ag layer.

As shown in Fig. 4, the dependence of the luminance behaviors with the top Ag electrode thickness is also reflected in the behavior of the current efficiency. With the 15 nm thick top Ag electrode a current efficiency of 13.7 cd/A is obtained in the bottom side at a driving current of 1 mA/cm^2. These values at a driving current density of 1 mA/cm^2 are chosen to compare to simulation results because the simulation does not consider an additional *roll-off* effect at a higher current density caused by triplet quenching processes such as triplet–triplet annihilation or triplet–polaron annihilation. With increasing Ag thickness the current efficiency is enhanced 1.6 times, up to 21.9 cd/A. On the other hand, the current efficiency of the top side decreases from 2.85 to 0.26 cd/A with increasing Ag thickness. Interestingly, the overall current efficiency by gathering both the bottom and top side emissions is also enhanced by 34%, from 16.55 to 22.16 cd/A at a driving current density of 1 mA/cm^2. The current efficiency for both the bottom and top sides also is compared with simulation results [18–21]. Quantum physical effects such as the Purcell effect are not taken into account in this study and we assume that the recombination zone is positioned at the EML/ETL interface because the host material (NPB) of EML is a strong *p*-type material. As described in Fig. 4, the trend of the current efficiency agrees well with that from simulation even though there are slight variations between them.

One of the interesting aspects of transparent OLEDs is the bottom to top ratio. As the luminance behavior of the bottom and top sides changes, the bottom to top ratio of our transparent OLEDs is also dramatically changed. With a 15 nm thick Ag electrode, the bottom side emission is 4.8 times higher than that of the top side. In case of a 45 nm thick Ag contact, the bottom to top ratio is larger than 84. Therefore, the variation in the thickness of the top Ag electrode can be considered as a powerful method to control the bottom to top ratio.

Fig. 5 shows normalized electroluminescence (EL) spectra of our transparent OLEDs for the (a) bottom and (b) top sides. All devices exhibit similar EL spectra with maximum luminescence wavelength near 617 nm originated from the triplet emission of Ir(MDQ)2(acac) emitter. However, we observe that the light emission for both the bottom and top sides is slightly broadened in the region from 650 to 700 nm. This slight EL spectra change depending on the top Ag thickness might be understood by optical property changes such as reflectance as well as transmittance of the Ag layer.

To examine the optical effect of a variation of the top Ag thickness in detail, and also to obtain accurate power and quantum efficiencies, we characterize the fabricated devices with a spectrogoniometer again. Generally, BEOLEDs can be described well by the Lambertian emitters, while TEOLEDs are assumed to be a non-Lambertian emitter

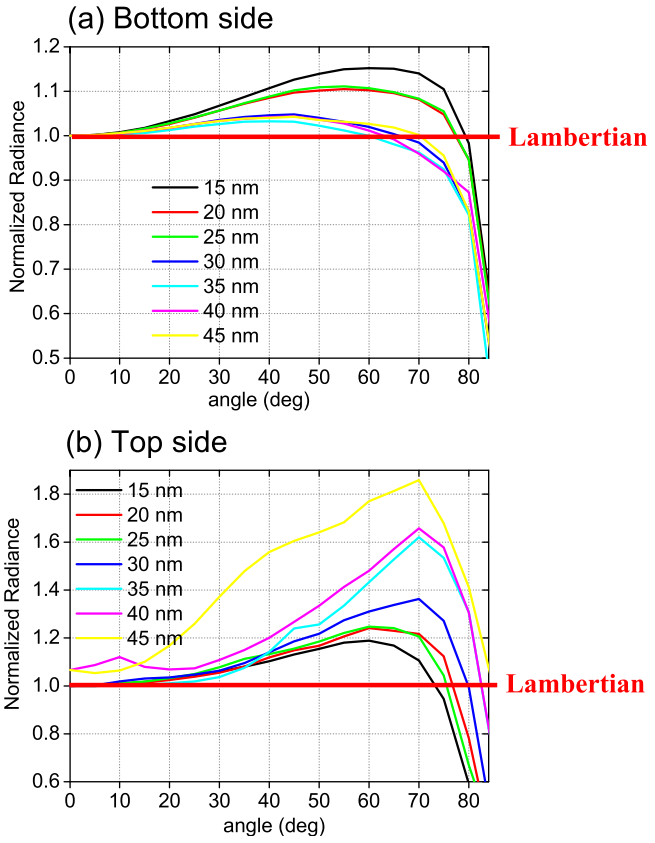

Fig. 6. Normalized radiance versus viewing angle characteristics of (a) bottom side and (b) top side at a driving current density of 15 mA/cm^2.

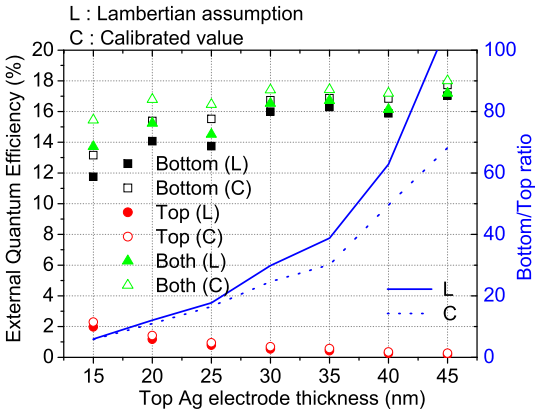

Fig. 7. External quantum efficiency and bottom to top ratio characteristics with calibration (open symbol, line) and with a Lambertian assumption (closed symbol, dot) at a driving current density of 15 mA/cm^2.

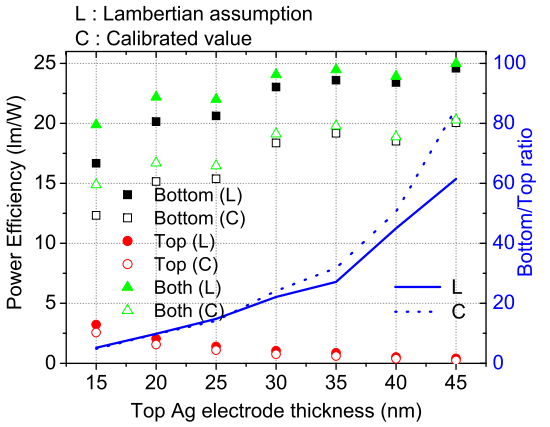

Fig. 8. Power efficiency and bottom to top ratio characteristics with calibration (open symbol, line) and with a Lambertian assumption (closed symbol, dot) at a driving current density of 15 mA/cm^2.

due to the microcavity effect. In case of transparent OLEDs with both bottom and top emissions, therefore, it is difficult to tell a priori whether the device is a Lambertian emitter or not, and there has been no report which relates to these aspects up to date. Here, we evaluate the distribution patterns of transparent OLEDs for both the bottom and top sides, and we further compare them to a Lambertian assumption.

Fig. 6 shows the normalized radiance versus viewing angle of the transparent OLEDs. Even with a 15 nm thick top Ag electrode, both bottom and top side emission patterns are far different from a Lambertian distribution. This might be attributed to the weak microcavity effect caused by a thin Ag layer as similar to TEOLED. Note that the normalized radiance trends as increasing the top Ag thickness are different depending on the bottom or top side. In case of bottom emission, the emission distribution is getting closer to Lambertian distribution with increasing top Ag thickness, i.e. the overall emission pattern is approaching common BEOLEDs. On the other hand, the emission distribution for the top side deviates from a Lambertian distribution with increasing top Ag thickness.

Based on these results from spectrogoniometer measurements, we evaluate the power (PE) and external quantum efficiencies (EQE) by considering the angular and spectrally resolved emissions over the whole forward emission hemisphere [18–21,24,25]. The calibrated (open symbols) EQE and PE at a driving current density of 15 mA/cm^2 are plotted together with those for a Lambertian (closed symbols) in Figs. 7 and 8. The EQE and PE characteristics show similar trends with the current efficiency, i.e. they are enhanced in the bottom side but reduced in the top side with increasing Ag thickness. The overall EQE and PE obtained by summing both the bottom and top emissions are enhanced to 17%, and 26%, respectively, at a driving current density of 15 mA/cm^2 (EQE: from 15.45% to 18.0%, PE: from 19.89 to 24.99 lm/W).

Note that the calibrated values for both the bottom and top sides do not agree with those from a Lambertian assumption as we expect from the angular dependent radiance results in Fig. 6. For example, the device with a 15 nm thick Ag electrode shows a calibrated external quantum efficiency of 13.16% (bottom side) and 2.29% (top side), respectively, however, the Lambertian assumption leads to slightly lower values (11.75% for the bottom side and 1.97% for the top side). We also find that the discrepancy between the values from calibration and a Lambertian assumption is much larger for PE than for EQE as shown in Fig. 8.

Finally, we compared the scale of difference between calibration and a Lambertian assumption as plotting Fig. 9. Interestingly, we found that the discrepancy of

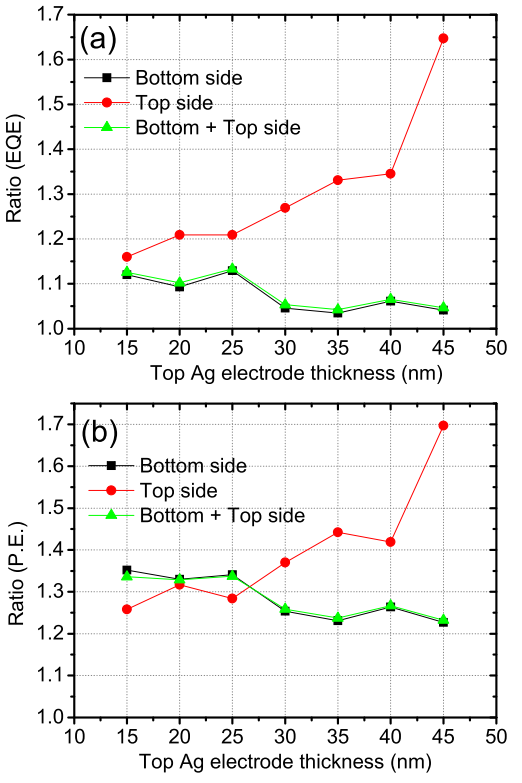

Fig. 9. Discrepancy ratio of values between a calibration and a Lambertian assumption. (a) External quantum efficiency, (b) power efficiency.

values between calibration and a Lambertian assumption decreases for the bottom side while it increases for the top side with increasing top Ag thickness. For a 15 nm thick Ag electrode, the EQE ratio between calibration and a Lambertian assumption is almost 1.12, and is gradually reduced for increasing top Ag thickness, resulting in only 1.04 with the 45 nm thick Ag electrode. On the contrary, the ratio increases from 1.16 to 1.63 for the top side with increasing top Ag thickness. These results show that the assumption of a Lambertian emitter is not valid for transparent OLEDs. Therefore, more careful measurement systems such as a spectrogoniometer or an integrating sphere are required to provide meaningful values for the EQE and PE of TOLEDs. Additionally, we find that there is an efficiency/transmittance trade-off depending on the thickness of the transparent top electrode and devices with a thicker top Ag electrode show enhanced overall efficiency.

4. Conclusion

We have studied the dependence of phosphorescent red emitting transparent OLEDs on the thickness of the top metal electrode. We find that the bottom or top emission shows different optical characteristics depending on the top Ag electrode thickness. The overall efficiency can be enhanced by varying the thickness of the top electrode, with an efficiency/transmittance trade-off. Moreover, we investigate the light-emitting distribution of transparent OLEDs for bottom and top side emissions separately, and find that the emission pattern does not agree with a Lambertian assumption.

degradation of the basic materials used within the device [18–20]. Those new works describe in detail the action of ozone attack as well as of direct photo-oxidation occurring in conjugated polymers.

The correlation of nanostructure and (macroscale) device performance is still far from being fully understood, even though this issue is of outstanding relevance: while the basic physical processes determining photoelectric energy conversion occur at the nanoscale, technologically relevant devices – in particular solar cells – are macroscopic in size. We note that increased lifetime is at the present stage a goal as important as the efficiency improvement [12]. In this article we report a study on P3OT thin films with special focus on the effect of UV irradiation – and therefore ozone exposure – on nanoscale morphology and electronic behavior, as well as on optical properties of the material. We will present correlations between these properties and point out interesting effects that should improve the understanding of the degradation mechanisms of the poly-alkyl-thiophenes, one of the most promising families of conjugated polymers for the fabrication of organic solar cells.

2. Experimental

Regioregular P3OT was purchased from Sigma–Aldrich, with 98.5% head to tail couplings, molecular weight $M_n = 54000$, polydispersity index $D = 2.6$ and density $\rho = 1.05\ g/cm^3$ [21]. We recall that a monomer of the P3OT chain has a molecular weight of $m_{Mol} = 194$ g/Mol (P3OT linear formula $C_{12}H_{18}S$), therefore a number density $n_{P3OT} = \rho \cdot N_A / m_{Mol} \approx 3.26 \times 10^{27}$ monomers/m^3 is obtained, corresponding to a volume of $(0.67\ nm)^3$ per monomer. Glass cover slips have been used in this study as substrates. P3OT thin films of approximately 110 nm thickness were prepared by spin-coating a 10 mg/ml solution in toluene at 2500 rpm for 90 s in air and at room temperature.

UV/O_3 exposure was performed using a commercial 50 W UV/ozone cleaning system from Novascan Technologies (Ames, IA, USA). According to manufacturer specifications this system delivers most of its energy (about 50%) into the 254 nm peak and about 5% into the more energetic 185 nm peak. The lamp has a tube diameter of approximately 0.5 cm and a total length of 100 cm. The tube is bent and folded so that the light is emitted from 10 parallel segments that are about 10 cm long and separated 1 cm. A simple calculation shows that this geometry illuminates the sample homogeneously when the distance between the light and the sample is larger than the tube separation, which was the case in our experimental set-up (distance light-sample: 2 cm, tube separation: 1 cm). We therefore estimate an irradiance of $G_0 \approx 25\ W/(0.1\ m)^2 = 2.5\ kW/m^2$ for the main wavelength of $\lambda_0 = 254$ nm, which is about 3 orders of magnitude more UV energy than that delivered by sunlight at AM 1.5G standard conditions. We note that at this high UV irradiation the expected ozone generation in the cleaning system is quite high. The ozone concentration was higher than the standard measurement range of commercial ozone instrumentation (of the order of 1 ppm); we estimate the ozone concentration in our experiments to be of the order of 100 ppm. The corresponding photon flux is $j_{ph} = I_0/(h\nu_0) = I_0\,\lambda/(hc) \approx 3.2 \times 10^{21}$ photons/(m^2 s). In the experiments to be discussed an important quantity will be the photon flux per conjugated electronic bond. Since each P3OT monomer has two conjugated electronic bonds, the corresponding number density is $2\ n_{P3OT.}$ In a $d = 110$ nm thick film, each bond is therefore illuminated by $j_{ph}/(2\ n_{P3OT}\ d) = 4.5$ photons per second.

A Nanotec Electronica SFM system with a phase locked loop (PLL)/dynamic measurement board [22] was used with Olympus OMCL-AC-type cantilevers (nominal force constant: 2 N/m; resonance frequency: 70 kHz). This SFM system uses red laser light ($\lambda = 665$ nm) focused on the free end of the cantilever to detect the bending of the cantilever using the optical beam deflection technique. We have confirmed that neither the red light, nor the laboratory illumination degrades the sample or modifies its electrostatic properties. Topographic imaging was performed in non-contact dynamic SFM (NC-DSFM) using the oscillation amplitude as feedback channel to maintain a constant tip-sample interaction, and thus a constant tip-sample distance. A small reduction of oscillation amplitude ($A_{set} \approx 0.95\ A_{free}$) was chosen for feedback in order to maintain the tip-sample system in the "attractive" part of the interaction and avoid tip-sample contact. In addition to topography images, also the electrostatic interaction – so called Electrostatic Force Microscopy (ESFM) [23,24] – was measured in order to determine the electronic properties of the sample. In particular, Kelvin Probe Microscopy (KPM) and capacitance images were acquired working in non-contact dynamic mode with Platinum coated silicon tips ($\nu_0 = 70$ kHz). An external lock-in board was employed for the ESFM and KPM measurements using modulation V_{ac} voltages as low as 500 mV at a (electrical) modulation frequency $\nu_{elec} = 7$ kHz. The ESFM technique and the details of how it is implemented in our group are described elsewhere [25,26]. Essentially, we use the frequency shift induced by the modulation voltage V_{ac} in order to determine the local contact potential as well as the tip sample capacitance [27].

We have developed a new micron-precision sample holder integrated in the Nanotec SFM system for these investigations [28]. This experimental set-up allows ex-situ manipulation of the sample and SFM imaging of the same region with a very accurate re-positioning of about 5 μm. We can therefore attribute changes of morphology or other properties to a particular effect of UV radiation and/or ozone, which are monitored for the same exact location on the sample. Without this precise re-allocation, that is, if only the approximate position of the sample is recovered as in most SFM experiments, only statistical variations of surface properties can be determined. The SFM experiments were performed in air and with the standard illumination conditions of a laboratory.

In order to characterize the variations of optical properties, an inverted optical microscope was used (Nikon Eclipse TE2000-E). In this case large scale optical transmission images were acquired in order to observe variations of the absorption of the thin films as they were exposed to UV radiation. Images were digitally acquired with a Cannon

EOS 400D camera and analyzed with standard image processing software.

3. Results and discussion

3.1. Evolution of surface morphology

We will first discuss the large scale morphological variations of the sample as it is irradiated with UV-light. Fig. 1 shows a series of images ($60 \times 60\ \mu m^2$) taken for the pristine sample and for 3, 7, 10, 15 and 30 min of irradiation. As discussed above, our SFM system allows removal of the sample, external manipulation (here UV-irradiation) and precise re-allocation at the same position. Therefore the evolution of the same individual features can be studied in detail. During the first 7 min of irradiation no significant changes of surface morphology are observed on this large scale. The surface is covered by round structures with a diameter of either about 0.5 μm, or 1–2 μm. We think that these round features are polymer aggregates which have not been well dissolved or air bubbles inside the film formed during the preparation method. The smaller structures tend to have a ring (donut-) like shape and are about 50 nm high, while the larger structures are mostly disk-like, some seem to have a protrusion in the center and are about 200 nm high. The largest structure, however, is also donut-shaped, as the smaller ones. After 7 and 10 min of irradiation, the disk-like larger structures start to develop a center hole. In addition, the hole of the smaller structures becomes more pronounced. In the case of the largest structure, this hole reaches all the way down to the glass substrate (depth about 100 nm, see below). After 15 min, a characteristic ring of small spherical particles – satellites – develops around the circular structures that were present from the beginning. These rings have a diameter of 5–10 μm while the satellites have a diameter of 0.5–1 μm. Interestingly, the region between the initial center particle and the satellites has a lower roughness than the rest of the surface. The rings are also seen after 30 min of irradiation, even though then the surface looks more blurred and the surface roughness has significantly increased.

In addition to the large scale images, a series of small scale images ($5 \times 5\ \mu m^2$) were acquired on the flat areas seen in the large scale images; that is, between the disk and the donut-shaped structures. As for the large scale images, during the first 5 min the surface morphology does not vary significantly, see Fig. 2. We recall that the images show always the same region of the sample, in particular, the arrow points to the same feature in all images. After 7 min of irradiation, small granular structures (50 nm diameter) grow over the whole surface. These grains become denser after 10 min of irradiation. After 15 min, the surface morphology has completely changed: the grains have merged into clusters containing several grains, separated by rather smooth areas in-between. And, finally, after 30 min the surface morphology has changed again: the grains are larger (100–200 nm) and the overall RMS roughness has increased significantly (14 nm), as it is observed in Fig. 3, where within the experimental error the roughness is constant in first 10 min of UV/ozone exposure and increases after 15 min.

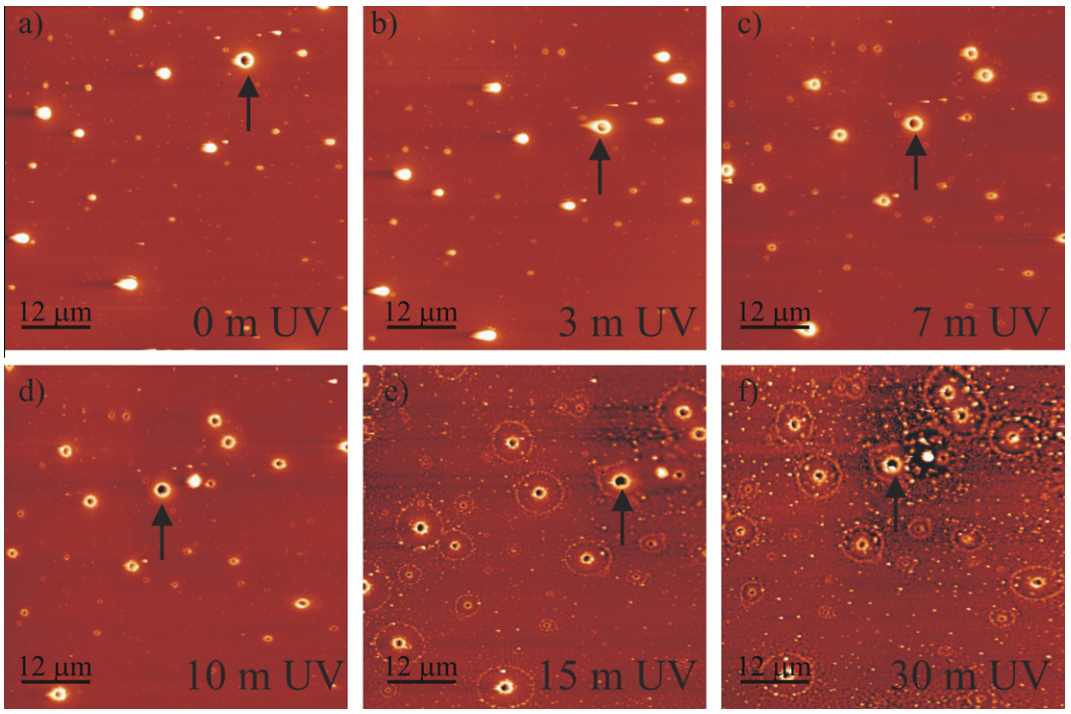

Fig. 1. A series of large area ($60 \times 60\ \mu m^2$) SFM topographic images showing the morphology of the P3OT thin film (a) pristine sample, (b) after 3 min, (c) 7 min, (d) 10 min, (e) 15 min and (f) 30 min of UV/ozone exposure. In all images $\Delta z = 200$ nm. An arrow indicates the same feature in all images.

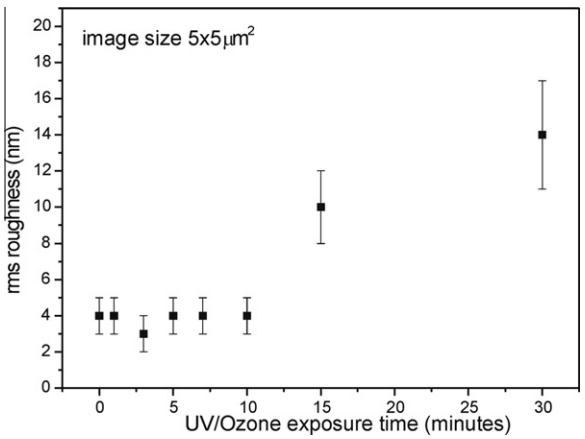

Fig. 3. RMS roughness, from the images of Fig. 2, as function of the UV irradiation.

In order to analyze more quantitatively the effect of irradiation on the surface morphology of the samples, the power spectral density of surface roughness (PSD) has been computed (see Fig. 4a) for each of the images shown in Fig. 1. The PSD-curves corresponding to the early stages of irradiation show that the morphology does not vary significantly: all curves can be described by an approximately linear decrease of surface roughness with an excess roughness at about $\log(1/\lambda) = -3.5 \pm 0.4$ corresponding to a wavelength of about 3 μm, which is in good agreement with the 0.5–2 μm size of the disk and donut shaped structures discussed above. For larger irradiation times (7 and 10 min), however, this peak becomes much less pronounced and finally for large irradiation times a new peak appears around $\log(1/\lambda) = -3$, which corresponds to the size of the satellites around the larger donut-shaped structures. The PSD curves calculated for the small scale images in Fig. 2 (see Fig. 4b) show a similar behavior in the sense that at the beginning of the irradiation (0–5 min) the curves are similar and approximately linear in the region $-3 \leqslant \log 1/\lambda \leqslant -2$. Note that the peak at $\log 1/\lambda = -3.5$ observed in PSD-curves corresponding to the large scale images is not observed in these PSD-curves since it would be at the very left of the graph, where data is filtered by the FFT-algorithm used to compute the PSD curves. The PSD-curves obtained from the images after 7 and 10 min of irradiation show a peak around $\log 1/\lambda = -2$, which corresponds to the small granular structure in the 50–100 nm range observed in the small scale images. For the final stages of irradiation process the PSD curves show a significant increase of surface roughness for $\log 1/\lambda = -3$, which hides the initial peak at $\log 1/\lambda = -2$. We note that while the increased surface roughness at $\log 1/\lambda = -3$ is also observed in the large scale images, the small peak at $\log 1/\lambda = -2$ is not detected in these images, since it is at the limit of their resolution.

Figs. 1 and 2 show how the surface morphology of the films varies as they are irradiated. From this data, however, we cannot deduce information on how the film thickness varies and in particular on possible removal of material. In order to solve this issue, SFM has been used to measure the film thickness as the films are irradiated. Since the

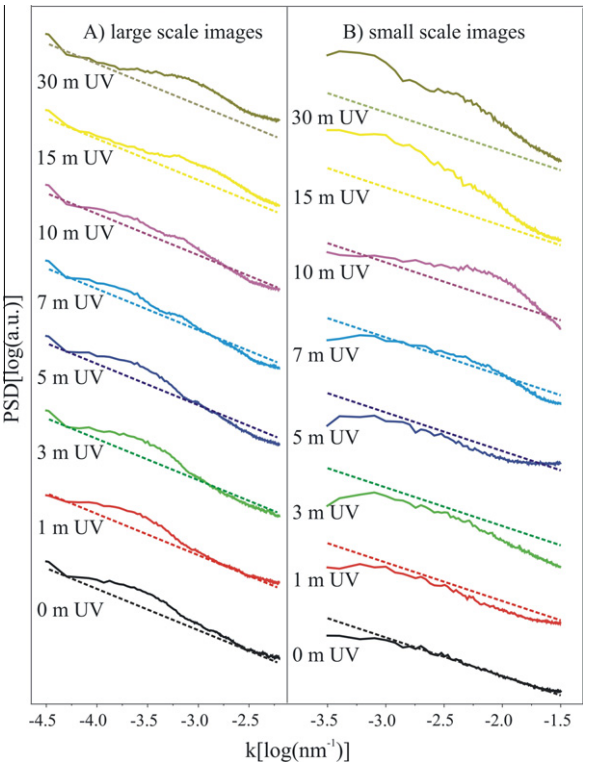

Fig. 4. Power spectral density of surface roughness (PSD) from (a) large scale images of Fig. 1 and (b) small scale images of Fig. 2. The dotted straight lines correspond to lines which approximate the PDS curves at the beginning of the irradiation process (lowest curves). For each irradiation time this line is then shifted with respect to the initial line by the same amount as the corresponding PSD curve, therefore these lines serve as reference in order to visualize the variation of the PSD curves as the sample is irradiated.

P3OT films are mechanically much softer than glass these films can be carefully scratched in order to expose the glass substrate. The depth of the corresponding trenches has been measured by SFM and gives a faithful average value for the film thickness at different stages of the irradiation process. Figs. 5 and 6 shows images of the trenches, as well as a graph of the film thickness as a function of UV-exposure. Data are shown for different films, and the results

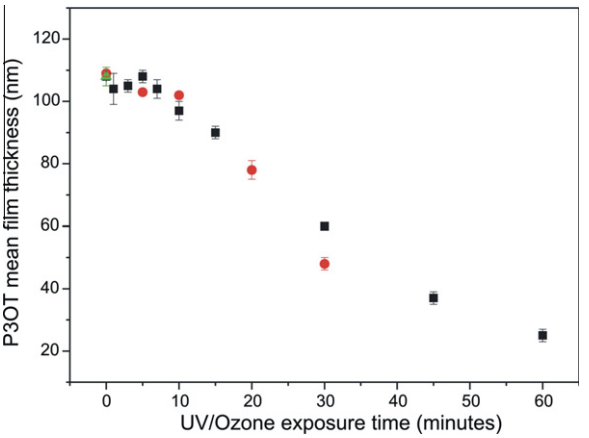

Fig. 6. Mean P3OT film thickness as function of the UV/ozone exposure. Squares, circles and triangle correspond to different P3OT samples.

of these experiments agree quite well. During the first 5 min, the film thickness stays essentially constant. Then, between 5 and about 30 min, the thickness decreases at a constant rate of about 2 nm/min. Finally, after 30 min the film still decreases, but at a slower rate. The evolution of surface morphology and film thickness are clearly related: during the first 5 min, neither thickness nor the morphology vary appreciably. Then, the film thickness starts to decrease at a constant rate while the surface roughness increases. In this regime the film thickness is considerably larger than the surface roughness and the film predominantly covers the glass substrate. After about 30 min of irradiation, the film is so thin and so rough that the mean film thickness and the surface roughness are of the same order of magnitude. At this stage, significant portions of the glass substrate will start to be uncovered by the thinning P3OT-film (see, in particular, the surface after 30 min in Fig. 1) and after 60 min most of the glass substrate has been exposed (see Fig. 5c). When this occurs, it is reasonable that the rate of thinning decreases: now the UV light does not shine only on the P3OT film, but also on the exposed glass substrate; therefore the UV-light is less effective in the film removal process, which is precisely the behavior observed in our experiment. The loss of material in thin films of poly(3-hexythiophene) P3HT,

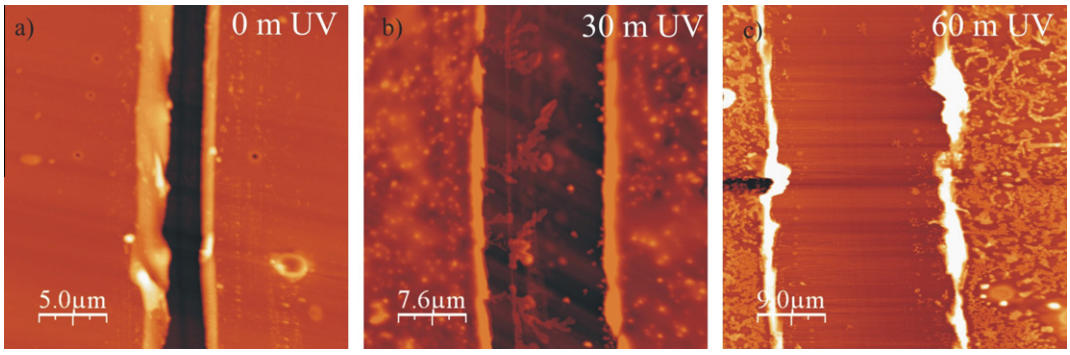

Fig. 5. SFM images of different trenches in P3OT thin films (a) pristine sample, (b) after 30 min and (c) after 60 min of UV/ozone exposure. In all images $\Delta z = 400$ nm.

which is a very similar chemical compound to the polymer P3OT used in the present study during the illumination under oxygen has been also observed by Hintz et al. [18]. They report the appearance of the X-ray photoelectron spectroscopy signal of Indium, which is part of the substrate material ITO, at later stages of degradation.

3.2. Nanoscale electronic properties

In addition to the topography, also the electrostatic properties of the sample have been measured. Using ESFM techniques the nanoscale contact potential and capacitance (more precisely, the second derivative of the tip-sample capacitance, see [27]) have been determined. Fig. 7 shows high resolution images of the topography, the contact potential and the capacitance signal measured on (approximately) the same location. Images are shown for a pristine sample, and for 3 and 5 min of UV irradiation. In agreement with the topographic results discussed above, during the first 5 min of irradiation the morphology of the sample does not change significantly. The electrostatic properties, however, do show important variations. On the one hand, although no nanoscale structure is observed, the overall contact potential difference between tip and sample decreases already after 3 min of irradiation. On the other hand, after about 5 min of irradiation the capacitance signal shows a marked contrast (darker spots in Fig. 7c) with rounded structures of 20–40 nm. We associate these regions of lower tip-sample capacitance with a locally lower electrical conductivity of the sample. These regions of lower conductivity are correlated with grains in the topography image. Similar grains were observed in the previous experiment (Fig. 2), where after 7 min of irradiation a grain like structure started to become visible,

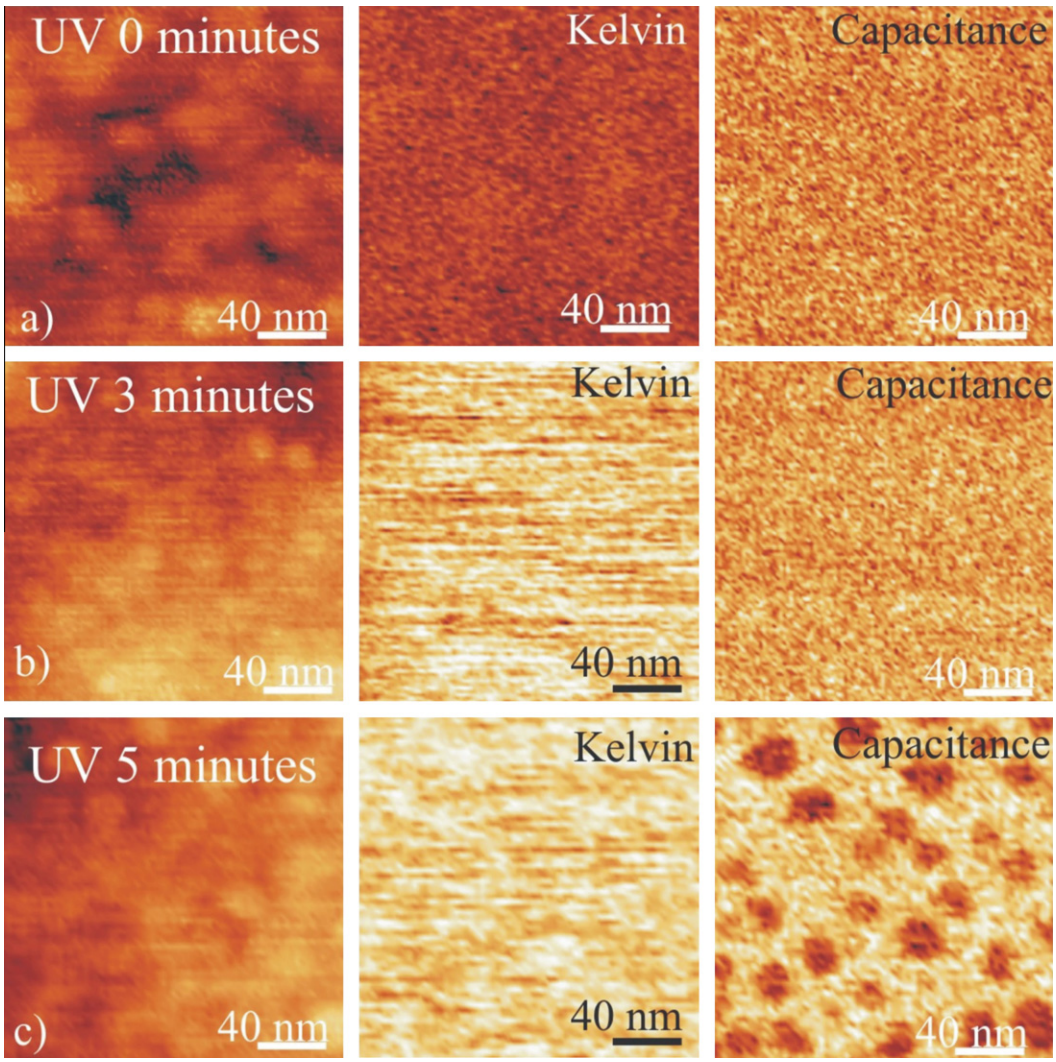

Fig. 7. Topography (left column), contact potential (central column) and capacitance images (right column) acquired on similar topographic regions of a thin film P3OT sample. Top row (a) was measured on the pristine sample, the middle row (b) after 3 min and the lower row after (c) 5 min of UV irradiation. For all topographic images the gray scale corresponds to $\Delta z = 5$ nm, for the contact potential the gray scale is $\Delta CP = 600$ mV, while the capacitance images are shown in arbitrary units, corresponding to a signal output of $\Delta U = 200$ mV of our lock-in amplifier.

increasing in density and size as the sample was further irradiated. From a series of topographic and contact potential images acquired for the first 15 min of UV irradiation, the evolution of the contact potential difference between tip and sample was monitored. As shown in Fig. 8, this contact potential difference is largest for the pristine sample and rapidly varies from about 0.5 V to about 0.1 V during the first 5 min of irradiation. After this initial variation, the contact potential remains constant. From the evolution of surface morphology and electronic data we conclude that the first variation of surface properties is observed for the contact potential, which starts to change as soon as the sample is irradiated. Then, after 3–5 min of irradiation the local conductivity of the sample changes and becomes inhomogeneous with regions of lower conductivity (lower tip-sample capacitance) corresponding to small grains (20–40 nm) in the topography. During this initial stage of irradiation, neither the surface morphology nor the film thickness varies appreciably. Only after 5–7 min small grains appear that are correlated with regions of lower conductivity, and after about 10 min the roughness increases and the film thickness starts to decrease.

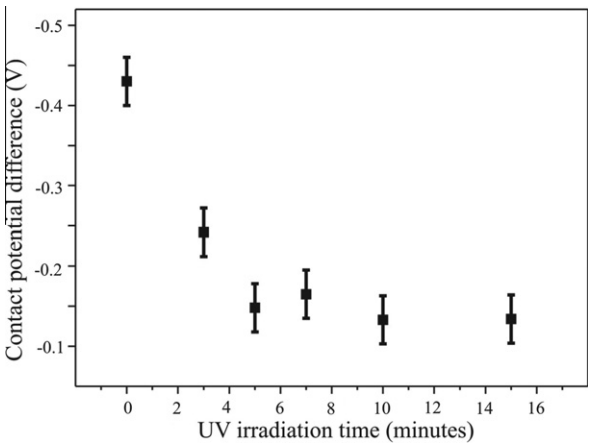

Fig. 8. Evolution of the tip-sample contact potential difference as function of the UV/ozone irradiation time.

3.3. Optical Measurements

In addition to the nanoscale SFM measurements we have performed simple optical experiments in order to study how the optical absorption of the P3OT films varies with UV irradiation. Fig. 9 shows a set of optical images taken with an inverted microscope in white light transmission mode. These images show a scratch in the P3OT film in addition to some much smaller circular inhomogeneities which we associate to the round structures observed in the previous SFM images. All images were taken with the same illumination intensity and the same acquisition parameters (in particular speed) of the camera. Clearly, the P3OT film becomes brighter as the film is irradiated by UV-light, therefore the absorption of the film decreases. Since the scratch observed in the images is free of P3OT, it allows

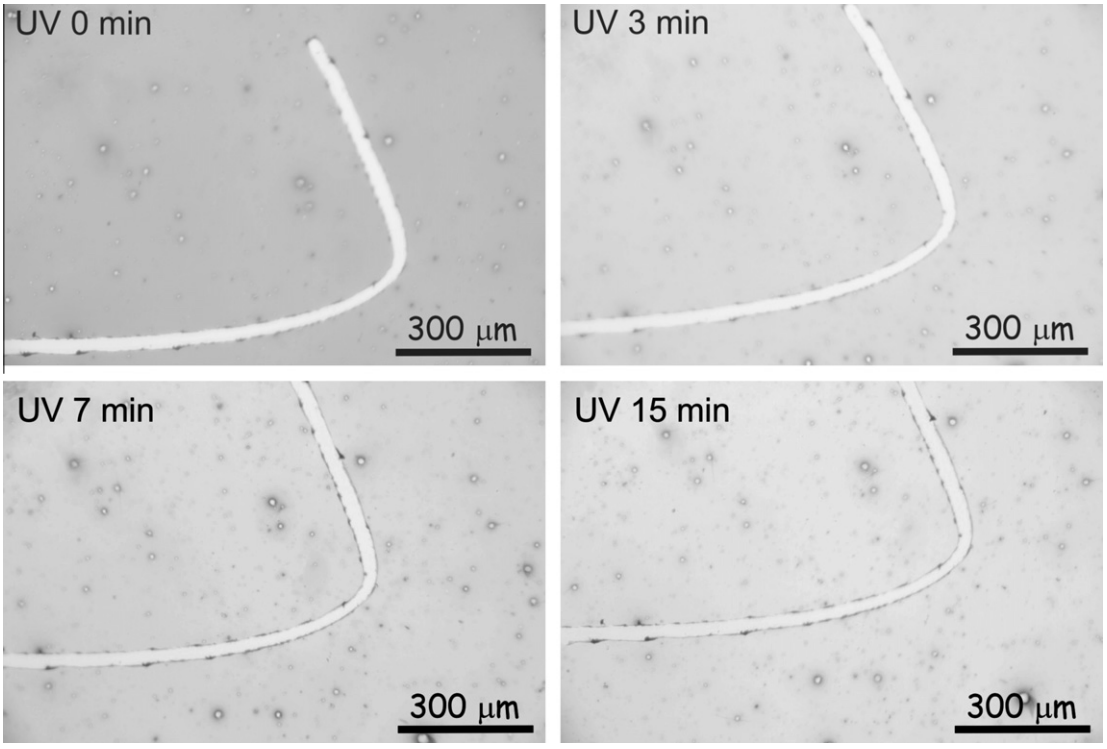

Fig. 9. A series of optical images showing a scratched P3OT thin film (a) pristine sample, (b) after 3 min, (c) 7 min, and (d) 15 min of UV/ozone exposure. The streak has been performed to compare the color contrast between the polymer film and the substrate.

calibrating the light passing through the bare glass substrate which is used as a reference for the calculation of the absorption of the P3OT film. The main differences found between the images are the loss of contrast between the polymer film and the glass substrate. After 15 min of UV/ozone exposure the contrast is almost lost and the polymer thin film turns colorless. The evolution of light absorption as a function of UV-irradiation is shown in Fig. 10. During the first 5 min, we observe a very fast decrease of absorption, followed by a transition regime between 5–15 min and a much slower reduction after 30 min. These results are in agreement with those obtained by Hintz et al. [18] and Rivaton et al. [20] for P3HT films, where the illumination under oxygen leads to the loss of the optical absorption in the range between 330 and 650 nm. In order to quantitatively discuss the measured light absorption, we will first assume that the material properties of the film stay constant during the experiments. Then the transmitted light intensity $T(d)$ should follow the well known relation:

$$T(d) = I_0 e^{-d/\kappa} \quad (1)$$

where I_0 is the light intensity without film (measured in the scratch), d is the film thickness and κ the absorption length (often, the absorption coefficient $\alpha = 1\kappa$ is used instead of κ). Since the light attenuation A and transmittance T are related through $A(d) + T(d) = I_0$, we may rewrite (1) as

$$A(d(t)) = I_0 - T(d(t)) = I_0(1 - e^{-d(t)/\kappa}) \quad (2)$$

where we have explicitly taken into account that in our experiments the film thickness $d(t)$ varies with time. As will be discussed in more detail below, our data does not follow this behavior, but we will nevertheless use it at starting point for our analysis. From Eq. (2) we define the (relative) light attenuation $a(d(t))$ as $1-(T(d(t))/I_0)$. In the inset of Fig. 10 this relative light attenuation across the polymer film is plotted as a function of the UV/ozone exposure time. It shows a very pronounced decrease during the first few minutes of exposure, a slower decrease between about 5 and 15 min. After 30 min the absorbance is essentially zero, since the color of the film is very similar to that of the scratch used as reference for I_0 (image not shown, but see for example Fig. 9 after 15 min, were the contrast between the scratch and the film is already quite low).

Since not only the optical absorption, but also the film thickness has been measured as a function of irradiation time, the absorption can be plotted as a function of the film thickness (Fig. 10). As a function of film thickness the decrease of adsorption is even more pronounced than when plotted as a function of time. Comparing the data of light absorption with the SFM data we directly find an apparent contradiction: the strong variation of light absorption during the first minutes of UV exposure corresponds to the time period were essentially no variation of surface morphology or film thickness is observed. In order to explore this issue further, in Fig. 11a), the logarithm of the transmitted light is plotted as a function of film thickness. If relation (1) was applicable in our experiment, the measured data should lay on a straight line, which is clearly not the case. We therefore conclude that in our experiments the absorption length κ is not constant, but varies with time: $\kappa = \kappa(t)$. Since the film thickness $d(t)$, the

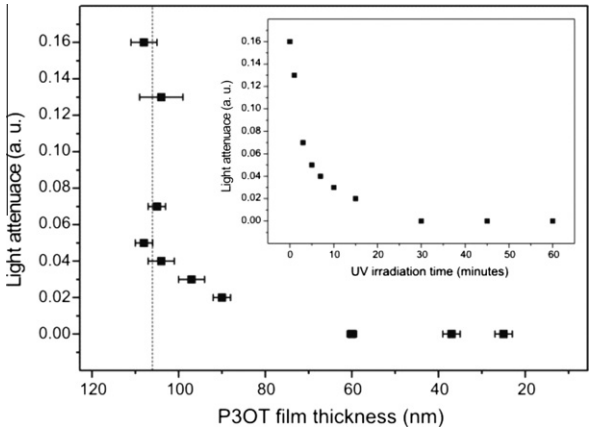

Fig. 10. Light attenuation of the polymer film as function of film thickness obtained from Fig. 5. Inset: light attenuation of the polymer film as function of UV/ozone irradiation time.

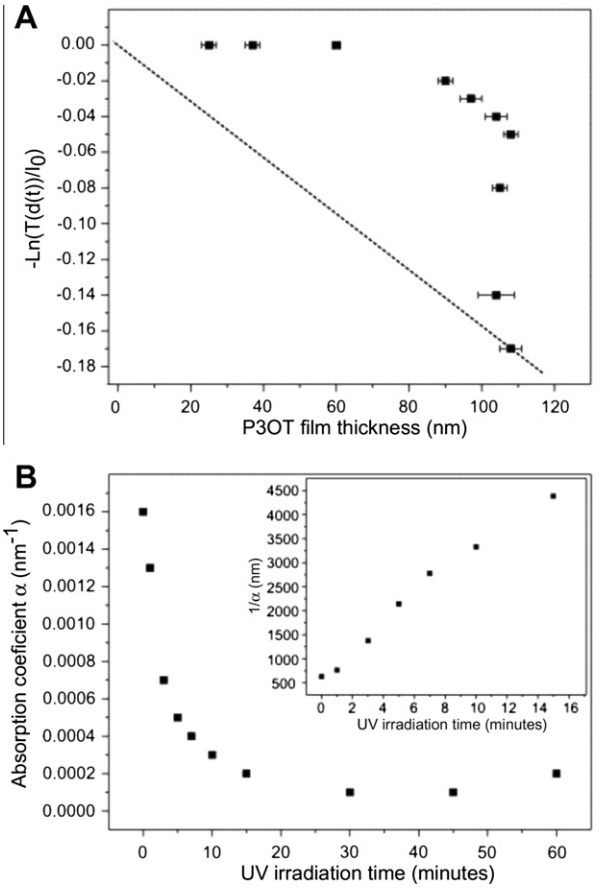

Fig. 11. (a) $-\mathrm{Ln}[T(d(t))/I_0]$ as function of film thickness. (b) Evolution of the absorption coefficient (α) as function of the UV/ozone irradiation time. Inset: evolution of the absorption length $\lambda = 1/\alpha$ as a function of the UV irradiation time.

transmission $I(d(t))$ as well as the transmission without film are known, the absorption coefficient αt and absorption length the can be computed for each time. The corresponding data is shown in Fig. 11b). Interestingly the absorption length increases approximately linearly during the first 15 min. During this period, the absorption length increases by almost an order of magnitude; from about 600 nm to 4500 nm. After the first 15 min, the errors in the measurement of the absorption coefficient increase drastically, since the film has become almost transparent. In addition, for long irradiation time the surface roughness becomes comparable to the film thickness, therefore light transmission may not only be affected only by absorption, but also by light scattering of the rough surface and the simple assumption $A(d) + T(d) = I_0$ may not be applicable because it does not take into account scattering effects.

In order to determine the main degradation mechanism (UV or ozone) an additional experiment has been carried out. Three equivalent samples were prepared as described in detail in the experimental section by deposition of polymer films onto a glass substrate. The three samples were put inside our UV/ozone cleaning system at the same time, the first one without protection (that is, as exposed in the experiments described above), the second one shaded from the UV radiation but exposed to the ozone produced by the UV lamp and the third one protected from the ozone but exposed to the UV radiation from the lamp. This experiment is summarized in Fig. 12, where the light attenuation coefficient is shown as a function of UV/ozone exposure time for the three samples. In addition, an exponential fit is plotted for the two data sets that show a clear non-linear behavior (unprotected and UV-protected sample) and a linear fit is plotted for the ozone-protected sample. Clearly, the unprotected and UV-protected samples degrade very similarly with a typical time scale of a few minutes, as observed in the experiments discussed above, while the sample that is exposed only to UV irradiation is degraded (at least) an order of magnitude slower. Therefore, for our experiments, the bleaching of the samples is clearly attributed to the degradation by ozone exposure.

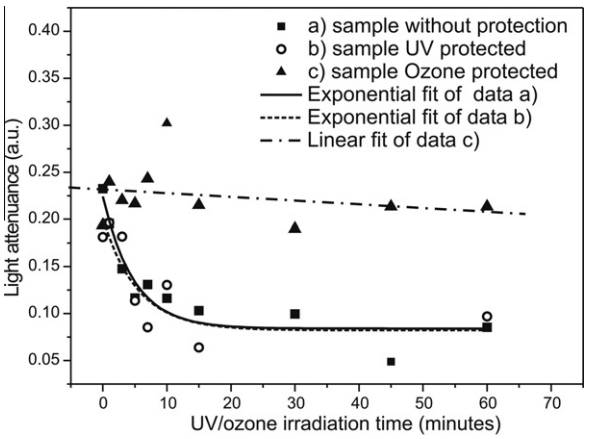

Fig. 12. Light attenuation coefficient as function of UV/ozone exposure time for the samples: (a) sample without any protection (squares), (b) sample protected against UV radiation (circles) and (c) sample protected against ozone exposure (triangles). In addition to the experimental data a linear fit is shown for the data corresponding to the ozone protected sample, and exponential fits are shown for the two other samples (unprotected and UV-protected).

4. Conclusions

The UV/ozone degradation on P3OT thin films was investigated by means of SFM and classical optical microscopy. Our experimental set-up allows to perform a nanoscale study of the same area of the sample, therefore we can attribute individual changes of the film morphology to the effect of UV irradiation. We find that during the first 10 min of exposure neither the overall film morphology nor its thickness change. The nanoscale electrical properties, however, do change significantly in this initial stage of irradiation: on the one hand the overall contact potential varies by about 0.4 V, and on the other hand the conductivity becomes inhomogeneous and decreases locally on a nanometer scale. The variation of contact potential is in good agreement with results reported in the literature [18] where a shift of the Fermi level of 0.4 V of P3HT is observed. During the initial stage of UV irradiation also the macroscopic optical properties change. In fact, already a simple visual inspection of the samples shows that the color of the sample is lost, that is, the light attenuation significantly decreases and after 10–15 min the film is essentially colorless.

We clearly find that electro-optical and morphological processes are decoupled, indicating that the degradation process occurs in two distinct stages: during the first stage (first 5–10 min) a degradation occurs which varies the electro-optical properties (light absorption, contact potential and local conductivity) of the material and only after this process the film morphology varies and its thickness decreases. Based on the results of the literature, in particular in reference [18], and taking into account the results of Fig. 12, we propose that both effects, the electro-optical, as well as the morphological degradation are due to the reaction of P3OT with ozone generated by the UV-radiation. In Ref. [18] the degradation of P3HT is studied using UV/VIS and photoelectron spectroscopy. There it is shown that in a typical laboratory environment at AM 1.5 the degradation of P3OT films by chemical reaction with ozone is two orders of magnitude lower than the rate of direct photo oxidation. In addition, it was shown that the two mechanisms of degradation have different paths: while ozone reacts with the double bonds in the thiophene ring, photo-oxidation is initiated at the ends of the polymer chain and at the alkyl chain of the corresponding monomer [19] leading to reactive peroxides which subsequently cause the oxidation of sulfur and the destruction of the thiophene ring [18].

In our case, even though (direct) photochemical degradation as well as ozone generation (see Fig. 2 in [18]) should increase linearly with UV irradiation, we propose that chemical reaction with ozone is the predominant degradation mechanism (note that our UV irradiation system is closed, and ozone generated is thus accumulated in the system, which does not happen with the photons). This is confirmed by the reaction kinetics observed in the corresponding experiments: the decay of absorption occurs

exponentially in our case (inset of Figs. 11 and 12) as well as in the experiments reported in [18] for ozonisation, while direct photo-oxidation leads to a linear decay of absorption (Fig. 1 in [18]).

A similar degradation behavior as that discussed here for P3OT thin films has been reported in the literature for the UV/ozone degradation of polypropylene films [29,30]. These works show that after 1 min of UV/ozone treatment the chemistry of the surface is modified, while the morphology remains unchanged. However, after 4 min of UV/ozone treatment the morphology changes completely, as the result of the polymer surface oxidation, resulting in the formation of low molecular weight oxidized material.

In conclusion, from the experiments reported in this work as well as from previous experiments reported in the literature, we conclude that degradation of P3OT thin films when irradiated by UV light occurs in two steps: in a first initial process a chemical reaction with ozone generated by the UV irradiation varies the optical absorption and the contact potential (Fermi level) of the films. We attribute these changes to the breaking of the conjugated bonds of the polymer chain. In addition, the local conductivity is reduced. In a second step, the films are etched away by further chemical reaction with ozone. With respect to the implications for the operation of Organic Solar Cells, already the first process will degrade device performance, since it will on the one hand reduce optical absorption, and on the other – probably even more important – change the band structure within the cell, in particular change the open circuit voltage, which is a fundamental parameter for device operation.

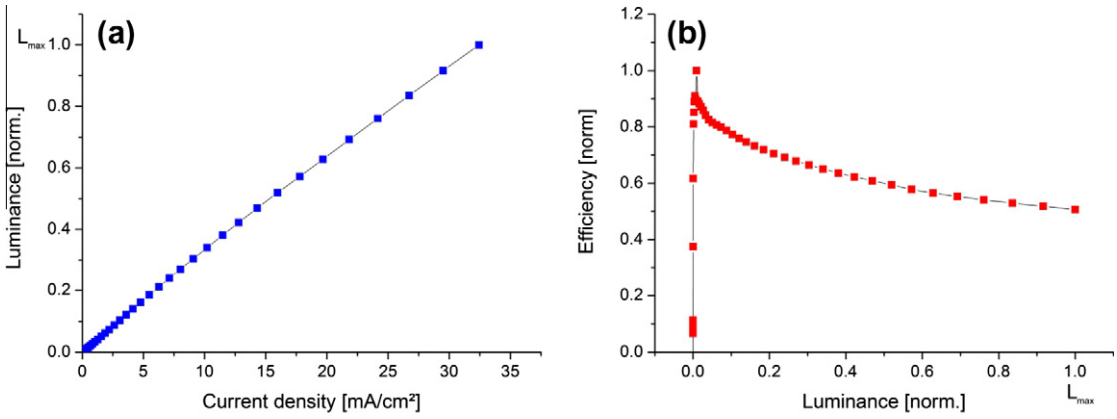

Fig. 1. Current density–luminance plot (a) and device efficiency (b).

2. Explanation of the coupled electrothermal model

2.1. Electrical model

The electrical model considers an OLED as a system of three conducting thin layers (anode, stack of organic films and cathode) (Fig. 2). The thickness of these conducting layers is much smaller (100–250 nm) than the lateral dimensions (>1 cm), which leads to high aspects ratios. Anode and cathode are connected at the edges. As a consequence, the following approximations are acceptable:

(1) Lateral (x- and y-direction) current densities are much higher than vertical (z-direction) currents along anode and cathode layers.
(2) Current flow through organic films between anode and cathode has only a vertical component (negative z-direction).

Combining these approximations with Ohm's law [12], the potential distribution along anode and cathode can be described by continuity equations [7]

$$\frac{1}{R_{sh,A}} div(grad\ \Phi_A) = -J_Z \tag{1}$$

for the anode potential and

$$\frac{1}{R_{sh,K}} div(grad\ \Phi_C) = J_Z \tag{2}$$

for the cathode potential, with R_{sh} as sheet resistance of the contact, Φ_A and Φ_C as contact potentials and J_Z as vertical current density through the organic stack.

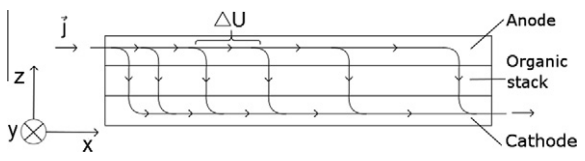

Fig. 2. Schematic delineation of current flow in an OLED. The organic films are summarized to one conducting layer in the model. ΔU is the horizontal voltage drop.

The charge transport through the organic layers is described by a lumped-element model (Fig. 3a). $G(V,T)$ describes the conductivity of the organic layers, C the geometric OLED capacitance. The conductivity is a voltage (V)- and temperature (T)-dependent element. Under the assumption of a homogenous current distribution, which is approximately correct for devices smaller than 1 cm^2, the current density J_Z can be described by

$$J_Z = \frac{V \cdot G(V,T) + C\frac{dV}{dt}}{A} \tag{3}$$

with A as device area. The voltage is defined by the potential difference between anode and cathode ($V = \Phi_A - \Phi_C$). The term $C\frac{dV}{dt}$ describes currents caused by time dependent change of voltage and allows transient simulation.

The model calculates the potential distribution as a result of current density in the organic layers. Current density itself is a function of voltage resulting from the potential distribution in the anode and cathode layer. Consequentially, the electrical model is an iterative one.

We use a small 5×5 mm^2 device to extract $G(V,T)$ from I–V–T measurements and assuming a homogeneous current distribution for such a small geometry. From the I–V–T curve, the G–V–T behavior can be derived with

$$G(V,T) = \frac{I(V,T)}{V} \tag{4}$$

Fig. 3b shows the measured G–V curves at different temperatures. A strong increase of conductivity with temperature, which is typical for organic semiconductors [13], can be recognized. During the measurement the OLED was immersed into a temperature controlled oil bath.

The sheet resistance of anode and cathode contacts was determined by four-point-probe measurements [14]. Voltage dependency for OLED capacitance has been investigated by impedance spectroscopy [15]. There is only a negligible voltage dependency of this capacitance, which allows a simple calculation of C. The geometric capacitance is described by

$$C = \varepsilon_r \varepsilon_0 \frac{A}{d} \tag{5}$$

with ε_r as dielectric function, ε_0 electrical permeability, A as electrode area and d as electrode distance. We

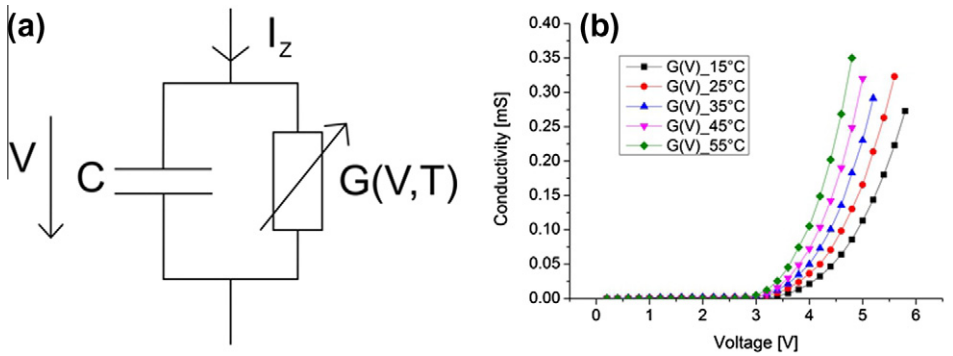

Fig. 3. Lumped-element model for current density J_Z [$I_Z = J_Z \cdot A$] (a) and G–V–T measurement results for characterizing thermal behavior of OLED (b).

calculated values for C with given geometric properties of our devices and assume a temperature- and voltage-independent dielectric function ($\varepsilon_r = 3$) [16].

The extracted parameters are summarized in Table 1.

2.2. Thermal model

The thermally modeled device is an encapsulated OLED processed on a glass substrate. The encapsulation is performed via a lid with a thin getter material layer which protects the device from residual air and humidity.

The device geometry was implemented into a CAD drawing, which provides as a basis for the thermal model. The single elements of this geometry are divided into different subdomains representing different materials.

Following assumptions for the thermal model are being made:

(1) Heat transport inside the device is carried by thermal conduction.
(2) Thermal exchange with the ambient is based on convection and thermal radiation.

The heat equation is described by [17]

$$\rho c_p \frac{dT}{dt} + div(-\lambda\, grad\, T) = Q \tag{6}$$

with ρ as material density, c_p as specific heat capacitance, λ as specific heat conductivity and Q as heat source. For the interfaces between the device and ambient, boundary conditions for exchange by convection and radiation are calculated with [16]

$$\vec{n}(-\lambda\, grad\, T) = h(T - T_{amb}) + \epsilon\sigma(T^4 - T_{amb}^4) \tag{7}$$

with $\vec{n}$ as normal vector to the boundary, h as heat transfer coefficient, ϵ as emissivity, σ as Stefan–Boltzmann constant [18] and T_{amb} as ambient temperature (we assume that the convective air flow has the same temperature as the ambient).

Table 1
Parameters used in the electrical OLED model.

C (nF) (5×5 mm^2)	$R_{sh,A}$ ($\Omega/\square$)	$R_{sh,C}$ ($\Omega/\square$)
5	20	0.3

We have solved this problem by the finite-element method using *Comsol 3.5* [19]. Material parameters (Table 2) have been taken from literature [20,21].

We consider an ambient temperature of 298 K with calm-air conditions (h = 5) [22].

The active OLED (anode, organics and cathode) is modeled as a thin layer with $Q \neq 0$. The connection of the thermal and electrical model by this layer is part of the following chapter. All the other subdomains of the model are solenoidal ($Q \neq 0$).

2.3. Coupling to the electrothermal model

Heat generation in an operating OLED is caused by joule-heating. The heating power density is equal to the scalar product of electric field and current density ($Q = p = \vec{E} \cdot \vec{J}$). We consider the total power density of the device as the sum of electrical losses in the three conducting layers

$$p = p_{Anode} + p_{Org} + p_{Cathode} \tag{8}$$

The power densities are calculated in the electrical model

$$p_{Anode,Cathode} = \frac{1}{d\,R_{sh\,A,C}} |\, grad\, \Phi_{A,C}|^2; \quad p_{Org} = \frac{|J_Z|^2}{\sigma_{Org}(V,T)} \tag{9}$$

with d as contact thickness and $\sigma_{Org}(V,T) = G(V,T) \cdot d_{Org}/A$ as organic specific conductivity.

The coupled electrothermal model is iterative, too. The values for p are calculated in the electrical model which contains the temperature dependence of the organic films. Fig. 4 demonstrates the complete iterative system.

The following chapters compare and analyze the thermoelectrical behavior of an OLED. All measurements and simulations were performed with an applied voltage of 5.4 V and a total current flow of 300 mA.

Table 2
Parameters used in the thermal OLED model.

	ρ (kg/m^3)	c_p (kJ/K kg)	λ (W/K m)	ϵ
Glass	2500	0.80	1.0	0.86
Air	1.24	0.712	0.024	–
Getter	2500	0.80	1.8	–
OLED	2000	0.90	100	–
Aluminum	2700	0.912	250	–

3. Validation

There are many ways to measure the surface temperature of an OLED [23]. We have used infrared spectroscopy results to compare measured with simulated stationary results. The measurements were taken from a free-standing (surrounded by calm air) $5 \times 5\,cm^2$ OLED. Fig. 5 shows both results for temperature distribution at the OLED bottom side (light emitting side). We recognize a qualitatively good agreement between measured and simulated temperature distribution. There is a U-shaped hot area in the devices center and decreasing temperatures at the edges.

The quantitative validation of the model is performed by a comparison along two defined lines which are marked in Fig. 5 (green lines). We denote the horizontal line as *x*- and the vertical line as y-axis. Fig. 6 presents the comparison.

The horizontal temperature profiles show two local maxima at about 55 °C. Simulation shows a symmetric profile while measured results weakly differ from symmetry. The measurement shows a stronger temperature decrease to the edges. These differences are probably affected by the measurement setup holders (dark areas in Fig. 5a). These work as additional heat drains, which are not accounted for the simulation.

There is a second decrease of temperature to the center of the device. In this case, the measured decrease is lower than the simulated one. Differences of sheet resistance or layer thickness between measured and simulated device are possible explanations for this deviation.

The vertical profiles show decreasing temperatures from top to bottom edge. A good agreement of measured and simulated result can be achieved. The measured decrease of temperature to the edges is stronger again.

Despite some differences, there is a good qualitative and quantitative agreement of the temperature distribution across the OLED. Deviations can be explained by experimental conditions not covered by the simulation.

4. Thermal OLED analysis

4.1. Stationary

As a first analysis, we discuss the development and consequences of temperature distribution for a $5 \times 5\,cm^2$ OLED. Fig. 7 shows the simulated distribution of power density *p*.

We have recognized a strong correlation between temperature und power distributions. The maximum values of power density are found at the edges while maximum temperature values are located more central to the device area. The simulation predicts higher heat currents at the device edges caused by a large temperature gradient between the actively heated OLED and its encapsulation (heat current $\vec{q} \sim -grad\,T$). As a result, there is a stronger cooling at the edges.

Most publications assume a direct correlation between potential distribution along the TCO, current distribution and distribution of power density. Fig. 8 shows the distribution of anode potential and the distribution of vertical current J_Z.

Obviously, the correlation between current distribution and power distribution is much stronger than the correlation between potential distribution and power distribution (Fig. 7). From Eqs. (8) and (9) we can also deduce that the power density is dominated by the contribution of the organic layer ($p_{Org}/p \geqslant 0.9$). It has a quadratic relation to J_Z. That causes the strong correlation between J_Z and *p*. In contrast to the potential distribution, the current density in the organic layers shows strong temperature dependence, which is neglected in published models [7,8]. This results in a significant difference between merely electrical and coupled electrothermal analysis of large-area OLED. An example profile of current density J_Z along the *x*-axis is shown in Fig. 9a.

Note the two local maxima anticipated by the electrothermal model simulation. They are based upon a rise of temperature overcompensating the drop of voltage along this axis.

As a second example, an investigation of the vertical temperature profile (across the air gap) will be presented. Fig. 9b demonstrates the simulated profile through the OLED center.

There is a strong decrease of temperature along the air gap between the glass lid and OLED, which corresponds to the low thermal conductivity of air. The temperature difference between OLED and substrate surface is very small (<1 K), caused by the low thermal resistance of the thin glass substrate. That is the reason why knowledge about substrate temperature seems to be a good indicator to estimate OLED temperature.

We demonstrate the benefits of our stationary electrothermal model for characterization of large-area OLED. Especially the results for current distribution give useful

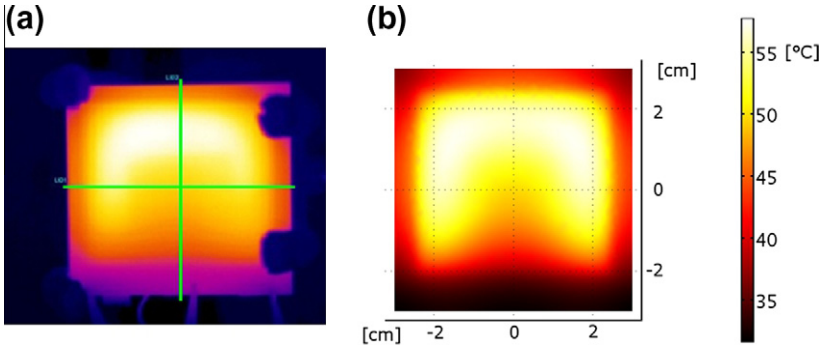

Fig. 5. Comparison of measured (a) and simulated (b) temperature distribution at the bottom side of an OLED. Hot areas are signed by brighter colors. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

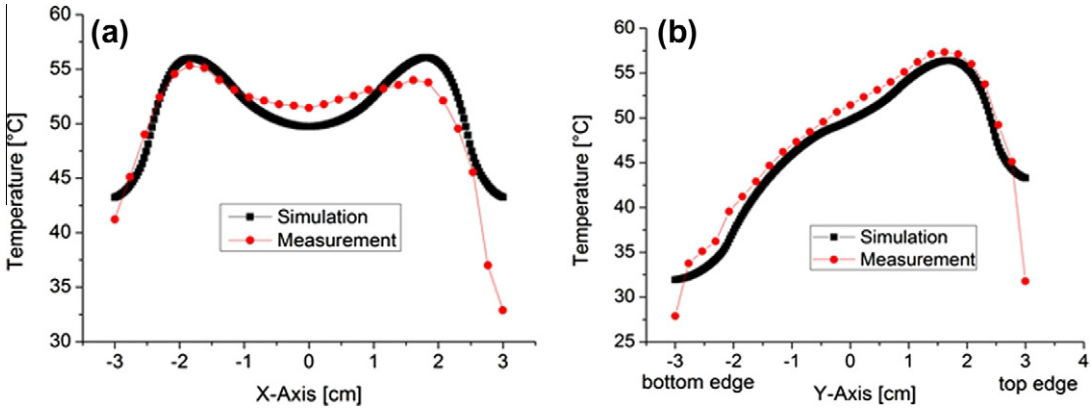

Fig. 6. Temperature profile along *x*- (a) and *y*-axis (b).

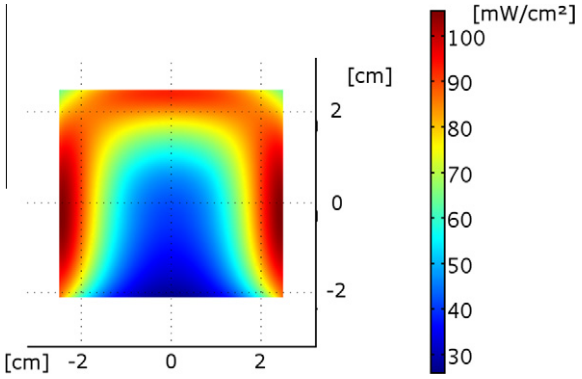

Fig. 7. Distribution of power density over the OLED area.

information for the development of large-area devices with homogeneous luminance distribution.

4.2. Transient

Beside stationary analysis to characterize the homogeneity of an OLED, transient characteristic have to be investigated to analyze switching behavior. Although the electrical relaxation time of an OLED is in the order of ms [24], stationary luminance characterization of a large-area OLED need some minutes under constant electrical operating conditions [19]. This is the result of the long thermal relaxation time and the temperature dependence of organic semiconductors. We simulate the transient behavior of T and J_Z in the center of the 5×5 cm^2 OLED (Fig. 10).

The OLED with an applied voltage of 5.4 V has been simulated (Fig. 10a). The transient behavior of temperature and current density is almost equal. It can be described by an exponential function, which corresponds to a time-dependent solution of the thermal equivalent circuit

$$y = y_0 + a\left(1 - e^{\frac{-t}{\tau}}\right) \tag{10}$$

Following values fit this function for the values of Fig. 10a:

$$y_{0_T} = 25.23; \quad y_{0_J} = 49.65; \quad a_T = 22.13; \quad ; a_J = 32.24; \quad \tau_T = \tau_J = 215.4$$

y_{0_T} and y_{0_J} are temperature and current values at room temperature (25 °C), respectively, α_T and α_J represent the temperature and current hub at steady-state conditions. τ_T and τ_T are the temperature and current relaxation times.

The simulation predicts the same relaxation time for current density and temperature of 215.4 s. It is possible to accelerate current relaxation by voltage regulation. An

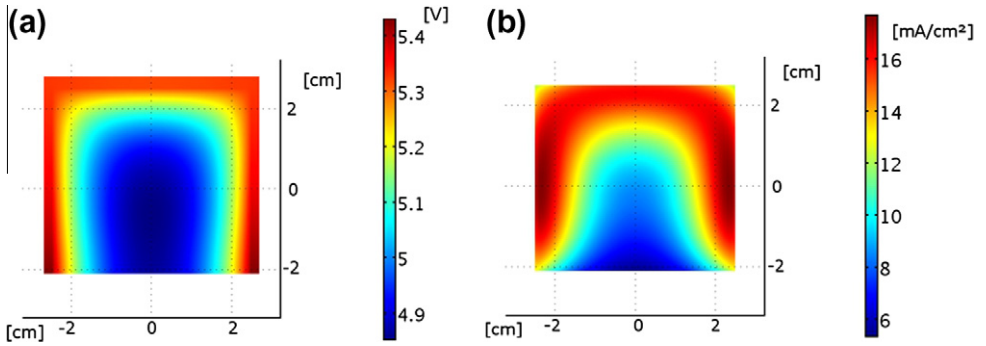

Fig. 8. Anode potential (a) and current distribution (b) of the 5×5 cm^2 OLED.

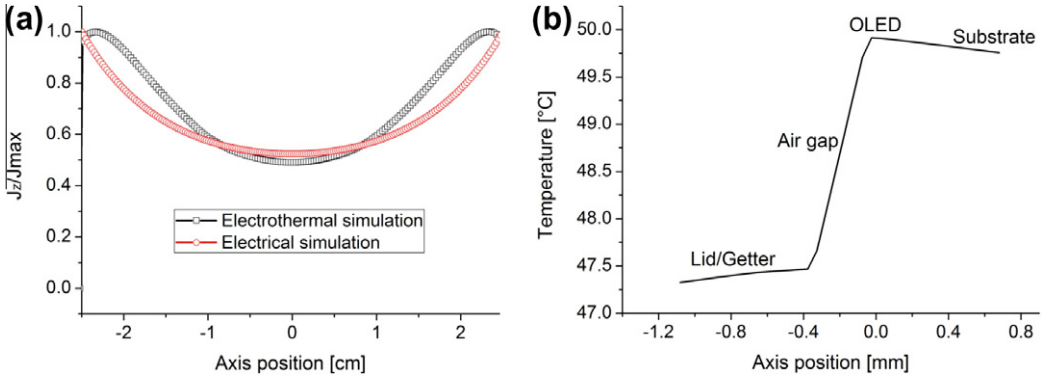

Fig. 9. Normalized current profile along the *x*-axis for the merely electrical and the coupled electrothermal model (a) and vertical temperature profile of the glass encapsulated 5×5 cm^2 OLED (b).

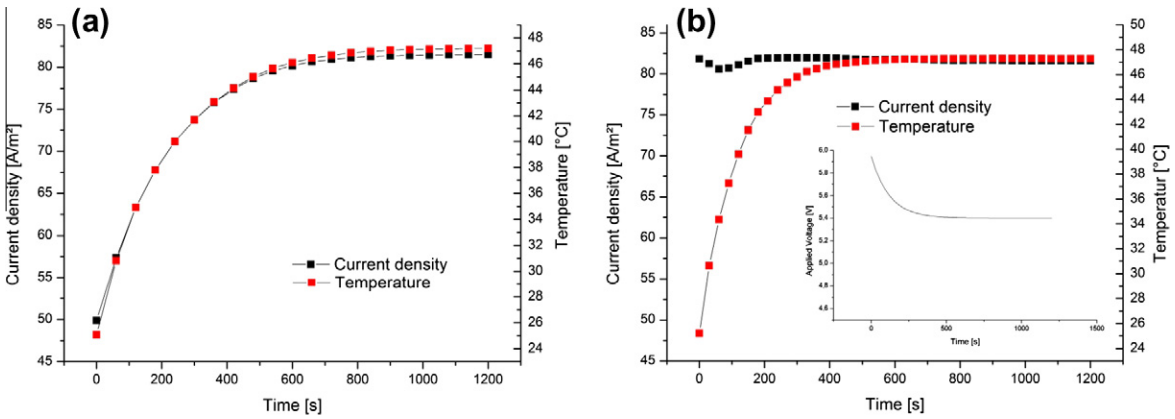

Fig. 10. Time-dependent simulation of temperature and current density in the center of the 5×5 cm^2 OLED at constant driving voltage (a) and with an exponentially decaying driving voltage (b).

exponentially decaying voltage as regulation has been simulated:

$$u_0 = 5.4V + 0.55Ve^{\frac{-t}{120}}$$

Fig. 10b demonstrates the reduction of current and temperature relaxation time for this case.

This result underlines the importance of transient electrothermal characterization for an optimized regulation of OLED switching. Our model serves as a helpful tool to analyze the reasons for the dynamic behavior of a large-area OLED.

5. Summary and outlook

We demonstrate the advantages of electrothermal OLED characterization for analysis and development of

large-area devices. The validation by comparison of simulated and measured temperature profiles was successful. Significant differences between the results of an electrical and a coupled electrothermal model were shown. Results for current distribution have been demonstrated caused by its strong correlation to luminance distribution [25]. Another result documented the informative value of substrate temperature for estimations of OLED (i.e. organic layer) temperature. The impact of the thermal relaxation process on current relaxation has been shown. A possible acceleration of current relaxation by voltage modulation has been demonstrated.

Further steps to increase the informative value of our simulation have to be performed. Temperature-dependent voltage–luminance measurements promise direct information about luminance distribution including the drop of OLED efficiency with rising temperatures [10]. Temperature-dependent lifetime measurement will allow simulation of local aging under continuous operation. The integration of metal grid or shunt lines into our model could clarify many questions and actively support device development.

have a greater effect on this transition, compared to the electron-deficient building units. In other words, the position of the high-energy absorption band will be strongly influenced by the number of electron-rich moieties in the polymer backbone [11]. For TQ1, having only one thiophene donor between the electron deficient units, the high-energy peak is almost completely pushed into the UV-region, giving the polymer an intense blue color in its reduced state. Having two absorption bands in the visible or close to the visible region makes it possible to obtain cathodically coloring electrochromic polymers with a variety of colors, even green where both the red and blue light have to be absorbed simultaneously [12].

Besides PEDOT [13–15], several blue cathodically coloring electrochromic polymers have been reported [3,16–22]. However, only a few are solution processable [3,20–22]. Herein, we report on the electrochemical and electrochromic properties of TQ1. To gain understanding about the structure–property relationships of cathodically coloring electrochromic polymers, two additional polymers were synthesized (Scheme 1). TQ2, having oligoethylene oxide side chains, was designed with the intention of improved counter ion transport and adhesion to the substrate. TQ3 was designed having ethylhexyloxy sidechains on the pendent phenyl rings of the acceptor moiety.

2. Experimental

2.1. Synthesis

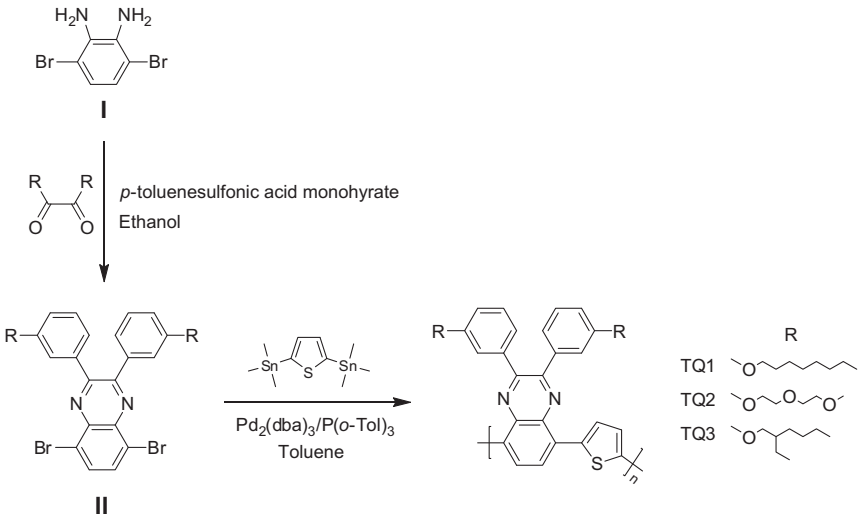
The synthetic routes to the polymers are presented in Scheme 1. The synthesis of TQ1 has previously been described [5]. Compound **I** was prepared following a previously published method [23]. All synthetic work was performed under nitrogen atmosphere. ^{1}HNMR spectra were recorded at ambient temperature on a Bruker Avance 500 MHz spectrometer, using chloroform-d as solvent. The peak values were calibrated relative to tetramethyl silane (δ_H = 0 ppm).

2.1.1. 5,8-Dibromo-2,3-bis(3-(2-(2-methoxyethoxy) ethoxy) phenyl)quinoxaline (*II*:*2*)

A solution of **I** (0.60 g, 2.26 mmol) in ethanol (40 mL) was stirred at 60 °C for 30 min. 1,2-Bis(3-(2-(2-methoxyethoxy)ethoxy)phenyl)ethane-1,2-dione (0.99 g, 2.26 mmol) was added and the reaction was continued for 24 h. After addition of *p*-toluenesulfonic acid monohydrate (50 mg, 0.27 mmol) the reaction was allowed to continue for an additional 24 h. The ethanol was evaporated and column chromatography on silica gel (dichloromethane/ethyl acetate, 7:1 as eluent) yielded **II:2** (0.99 g, 1.46 mmol, 65%) as a yellow oil. δ_H(500 MHz, $CDCl_3$, Me_4Si) 7.92 (2 H, d, ArH), 7.31 (2 H, s, ArH), 7.22 (2 H, t, ArH), 7.13 (2 H, d, ArH), 6.97 (2 H, d, ArH), 4.08 (4 H, t, OCH_2), 3.71 (4 H, t, OCH_2), 3.58 (4 H, t, OCH_2), 3.39 (6 H, s, OCH_3). δ_C(400 MHz, $CDCl_3$, Me_4Si) 158.8, 153.8, 139.3, 139.1, 133.1, 129.3, 123.7, 122.9, 116.5, 115.8, 71.9, 70.7, 69.6, 67.5, 59.1.

2.1.2. Poly(2,3-bis(3-(2-(2-methoxyethoxy)ethoxy)phenyl)-5-(thiophen-2-yl)quinoxaline)(TQ2) (general procedure for polymerization)

To a mixture of **II:2** (0.46 g, 0.69 mmol), 2,5-bis(trimethylstannyl)thiophene (0.28 g, 0.69 mmol), tris(dibenzylideneacetone)dipalladium(0) (25 mg, 0.027 mmol) and tri(*o*-tolyl)phosphine (67 mg, 0.22 mmol) was added degassed toluene (15 mL) and the reaction was stirred at 89 °C for 48 h. The reaction mixture was precipitated from methanol and filtered. The solid material was redissolved in chloroform (300 mL) and stirred with sodium diethyldithiocarbamate trihydrate solution (10 wt.% in water, 150 mL) at 60 °C for 1 h. The organic phase was concentrated and reprecipitated from methanol. Soxhlet extraction was performed using methanol, acetone, hexane, and chloroform. The chloroform solution was concentrated



Scheme 1. Synthetic route to TQ1, TQ2, and TQ3.

and precipitated from methanol yielding TQ2 (0.35 g, 84%) as a dark blue solid.

2.1.3. 5,8-Dibromo-2,3-bis(3-(2′-ethylhexyloxy) phenyl) quinoxaline (II:3)

To a mixture of **I** (0.18 g, 0.68 mmol), 1,2-bis(3-(2′-ethylhexyloxyphenyl)ethane-1,2-dione (350 mg, 0.75 mmol) and *p*-toluenesulfonic acid monohydrate (14 mg, 0.075 mmol) was added ethanol (20 mL) and the reaction continued at reflux overnight. The ethanol was evaporated and column chromatography on silica gel (dichloromethane/hexane, 1:1 as eluent) yielded **II:3** (0.44 mg, 0.57 mmol, 84%) as a yellow oil. δ_H(500 MHz, $CDCl_3$, Me_4Si) 7.93 (s, 2 H, ArH), 7.20–7.30 (m, 6 H, ArH), 6.97 (d, 2 H, ArH), 3.71 (d, 4 H, O–CH_2), 1.75–1.60 (m, 2 H), 1.55–1.2 (m, 16 H), 1.00–0.80 (t, 12 H). δ_C(500 MHz, $CDCl_3$, Me_4Si) 183.0, 161.9, 156.8, 142.0, 135.7, 132.0, 126.4, 125.1, 119.3, 114.7, 66.3, 41.8, 33.1, 31.7, 26.7, 26.4, 16.8, 13.7.

2.1.4. Poly(2,3-bis(3-((2-ethylhexyl)oxy)phenyl)-5-methyl-8-(5-methylthiophen-2-yl)quinoxaline) (TQ3)

Synthesized following the general procedure with **II:3** (0.47 g, 0.67 mmol) and 2,5-bis(trimethylstannyl)thiophene (0.28 g, 0.67 mmol) giving TQ3 (0.80 g, 90%) as a dark blue/purple material.

2.2. Size-exclusion chromatography

Size-exclusion chromatography on TQ1 and TQ3 was performed on a Waters Alliance 2000 with a refractive index detector. The working temperature was 135 °C and 1,2,4-trichlorobenzene was used as eluent with a flow rate of 1 mL min^{-1}. Size-exclusion chromatography on TQ2 was performed at ambient temperature on a Waters 486 with a UV detector. Tetrahydrofuran was used as eluent with a flow rate of 0.5 mL min^{-1}. Molecular weights and polydispersity indices were obtained by calibration relative to polystyrene standards.

2.3. Electrochemistry

All electrochemical measurements were performed on a CH Instruments 650D potentiostat with platinum wire or ITO-covered glass substrate as working electrode, platinum wire as counter electrode, and a Ag/Ag^+ reference electrode. The polymers were solution-casted onto Pt-wire or spray-coated onto ITO from chloroform solution. A solution of 0.1 M tetrabutyl ammonium hexafluorophosphate (Bu_4NPF_6) in anhydrous acetonitrile was used as supporting electrolyte. The electrochemical cell was purged with nitrogen gas prior to the measurements in order to remove electroactive impurities. During the scans the nitrogen inlet was moved above the electrolyte surface.

2.4. Spectroelectrochemistry

Polymers were dissolved in chloroform (5 mg/mL), filtered, and spray-coated onto cleaned ITO-covered glass slides. Spectroelectrochemical measurements were performed in a similar fashion to the above described electrochemical spectroscopy but in series with a Perkin Elmer Lambda 900 UV–vis–NIR spectrophotometer. Spectra were recorded, after obtaining a converging CV between 0 V and +1.0 V (vs. Ag/Ag^+) at 100 mV/s, by optical absorption measurements at 1500 nm/min under an external applied fixed potential.

3. Results and discussion

3.1. Polymer molecular weights

The molecular weight of polymers is an important property for non-emissive display applications. Besides guaranteeing an adequate conjugation length, a high molecular weight also improves the adhesion to the substrate. In non-emissive displays, the active material has to be resistant to not slowly dissolving in the supporting electrolyte. A high molecular weight will generally help maintaining a high optical contrast after repeatedly electrochromic switching.

Molecular weights of all polymers are presented in Table 1. Due to the easy synthetic procedure and the excellent photovoltaic properties, several batches of TQ1 have been prepared. The electrochromic properties presented herein are based on a batch of TQ1 with molecular weight averages according to Table 1. The octyloxy side chains in *meta*-position facilitate good solubility, yielding a satisfactory molecular weight by preventing precipitation of oligomer chains during the polymerization step. Furthermore, TQ2 and TQ3 also show satisfactory molecular weights. Molecular weight averages of TQ2 were analyzed using THF as eluent during the SEC-measurements as we experienced problems using 1,2,4-trichlorobenzene. To guarantee data reliability, we also analyzed molecular weight averages of TQ3 in THF, which showed similar values as the 1,2,4-trichlorobenzene measurements.

3.2. Electrochemistry

Electrochemical measurements are of great importance for evaluation of a conjugated polymer to work as electrochromic material. First, the distance between the potentials required to oxidize and reduce the polymer film can give an estimation of the electrochemical bandgap. Second, it can give information about the position of the individual energy levels, *i.e.* the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of the polymer. The oxidation potential is an important parameter for electrochromic polymers. There is a trade-off between a low oxidation potential, increasing the possibility of the conjugated polymer to switch reversibly without degradation from electrolyte-containing

Table 1
Molecular weights obtained by SEC using 1,2,4-trichlorobenzene at 135 °C (TQ1, TQ3) and THF at ambient temperature (TQ2).

Polymer	M_n	M_w	PDI
TQ1	56,000	170,000	3.0
TQ2	30,000	118,000	4.0
TQ3	15,000	26,000	2.2

species, *e.g.* oxygen and water [24], and a higher oxidation potential which will reduce the time-induced degradation processes. We employed square-wave voltammetry [25,26] to estimate the electrochemical bandgap and oxidation potential of the polymers. Results from square-wave voltammetry are presented in Fig. 1. The electrochemical bandgap of TQ1 was estimated to 2.4 eV from oxidation and reduction peak potentials. Although the oxidation potential of TQ1 is somewhat high, the sharpness of the oxidation peak allows high optical contrast changes within a small potential window for electrochromic switching. TQ2 and TQ3 both showed similar positions of oxidation and reduction peaks compared to TQ1, as is expected from the similarity in polymer structure.

The scan-rate dependence of spray-coated polymer films on ITO was investigated. The films were cycled between 0 and +1.0 V vs. Ag/Ag^+, varying the scan rate from 50 to 300 mV/s. The scan-rate dependence of TQ1 is depicted in Fig. 2. A linear relationship between the scan rate and the maximum current density was noticed for all three polymers, indicating that the polymer films are well adhered to the substrate and that the oxidation processes are non-diffusion limited [27].

3.3. Spectroelectrochemistry

To investigate the optical switching properties of the polymers, spectroelectrochemical measurements were performed (Fig. 3). All three polymers display similar absorption in the reduced state, with two distinct absorption bands. The high-energy peaks of TQ1–TQ3 are mainly absorbing in the UV-region, with minor tailing into the visible region, limiting the contribution of the high-energy peak to the color perceived by the human eye. On the other hand, the low-energy peaks, originating from the D–A interaction, have pronounced absorption in the red part of the visible region, making the polymers appear blue in the reduced state. The low-energy peak of TQ1 is sharp with a significant difference in absorption between the absorption maximum and the valley at 440 nm, yielding

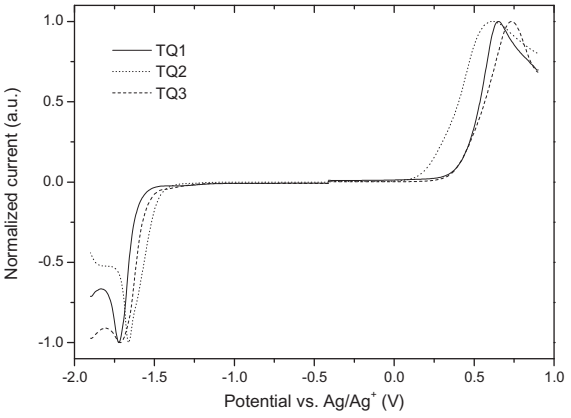


Fig. 1. Square-wave voltammetry of the polymers. 0.1 M Bu_4NPF_6/acetonitrile was used as supporting electrolyte. The plots were obtained by combining the oxidation and reduction scans.

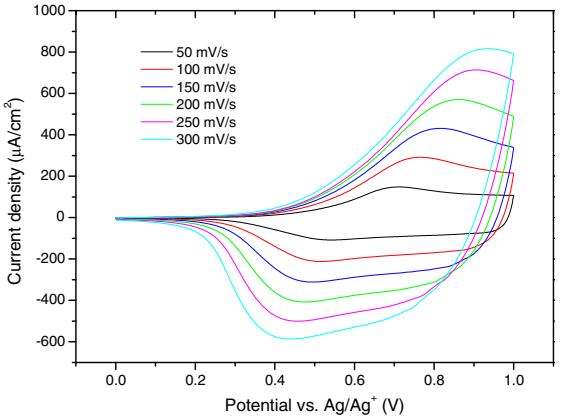

Fig. 2. Scan-rate dependence of TQ1 on ITO. 0.1 M Bu_4NPF_6/acetonitrile was used as supporting electrolyte.

an intense blue color as a result of good reflection of the shorter wavelength photons in the visible region. A broader peak, partly absorbing the blue light, will imply a blue-gray color.

The optical contrast ($\Delta T\%$), monitored at local low-energy absorption maxima, were 50%, 45%, and 37% for TQ1, TQ2, and TQ3, respectively. The excellent optical contrast of TQ1, switching from an intense blue color to a yellow-brown transmissive state, makes TQ1 an interesting polymer for electrochromic applications. The relatively low optical contrast of TQ3 has a couple of explanations. First, the ethylhexyloxy side chains to some extent induce more separated chains and a more ordered morphology of polymer films, giving vibronic features, as indicated by the broad absorption maximum of the low-energy absorption peak and the small absorption bump above 700 nm. The optical contrast of TQ3 is monitored at 645 nm, and because of the vibronic features, the optical contrast is increased to 41% at 600 nm (Fig. 4). Second, the charge-carrier peak at 800–900 nm is not as well depleted as for TQ1 and TQ2. Third, the discussed charge-carrier peak is somewhat blue shifted for TQ3, increasing the tailing into the visible region of the oxidized polymer, and hence a lower optical contrast.

3.4. Influence of film thickness on optical contrast

Evaluation of electrochromic polymers, based on their optical contrast, must be done with careful consideration of the film thickness. Obviously, the optical contrast, monitored at a fixed wavelength, will reach a maximum value at a certain film thickness. Using film thicknesses corresponding to maximum optical contrast will facilitate proper comparison of electrochromic polymers. The relationship between absorption in the reduced state and optical contrast was investigated for TQ1 (Fig. 5). The black and white squares represent experimental values from spectroelectrochemical measurements on spray-coated films with different thicknesses. The lines are based on calculations with the prerequisite that absorption values of the reduced state and the oxidized state can be normalized with

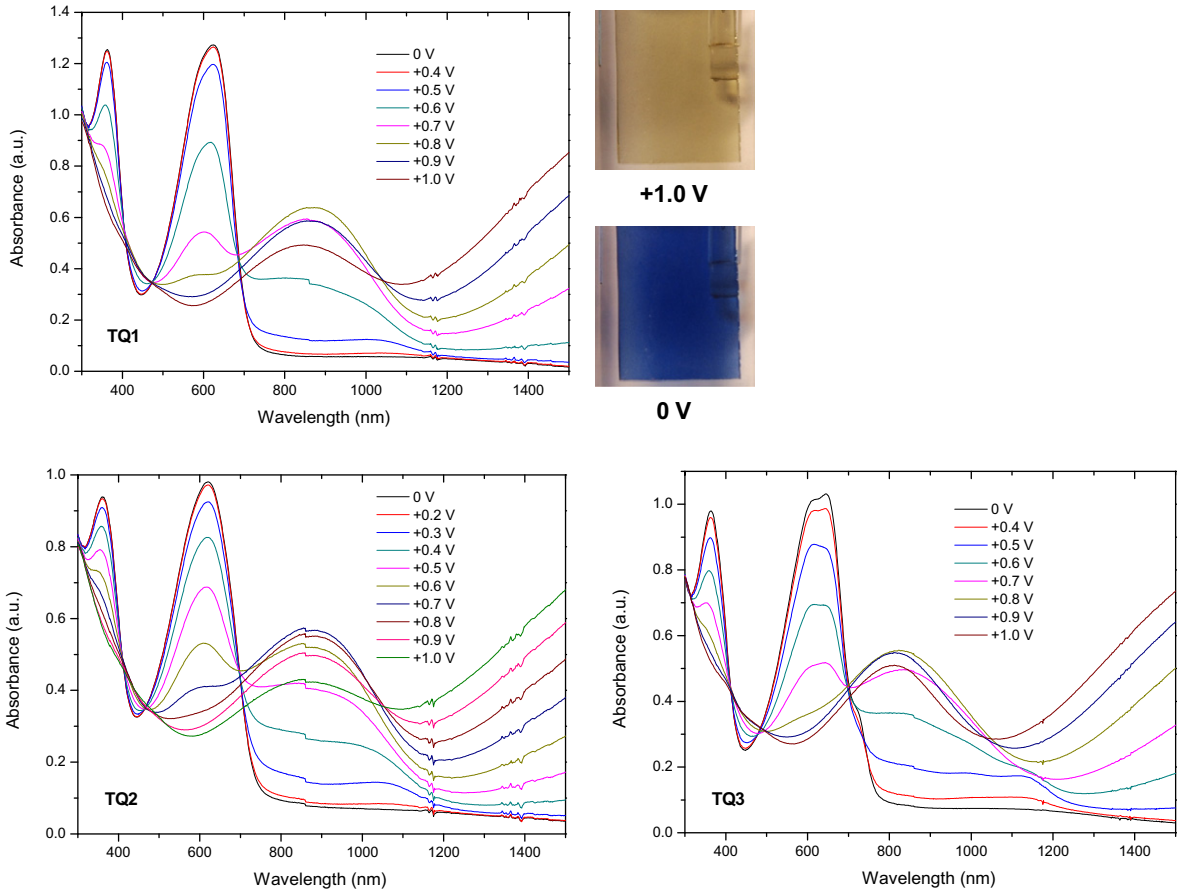

Fig. 3. Spectroelectrochemical measurements on TQ1–TQ3 films on ITO, using 0.1 M NBu_4PF_6 in anhydrous acetonitrile as supporting electrolyte. Potentials are vs. Ag/Ag^+. Photos show electrochromic switching of TQ1.

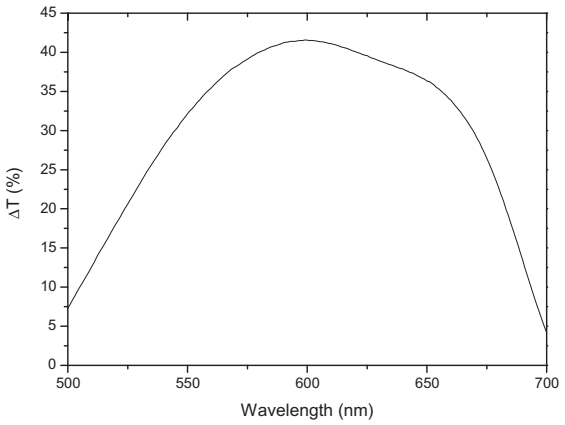

Fig. 4. Difference in optical contrast of TQ3 vs. wavelength.

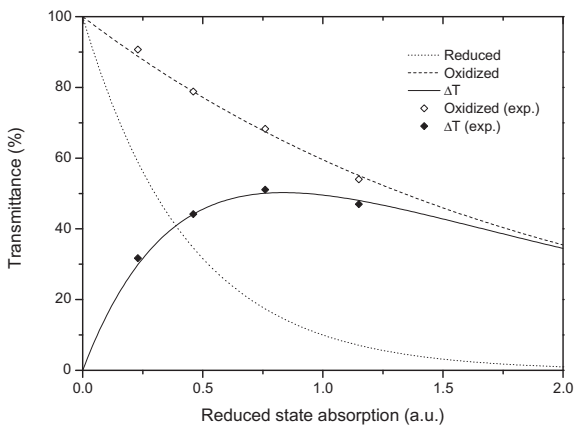

Fig. 5. Dependence of absorption in the reduced state on optical contrast for TQ1. Absorption/transmission data was monitored at the low-energy peak (623 nm).

respect to a single pair of data. The strong correlation between the experimental values and the calculated lines strengthens the hypothesis that the spectroelectrochemical data can be normalized. Looking at Fig. 5, it is clear that maximum optical contrast for TQ1 at 623 nm (50.2%) is reached at a film thickness giving an absorption of 0.84 a.u. for the reduced polymer. However, the shape of the curve allows for a small deviation from optimal film thickness, when comparing polymers, as it only will have a minor influence on the optical contrast. This is gratefully

acknowledged as spray-coating polymer films with a predetermined absorption of the reduced state is a challenging and patient task.

3.5. Kinetic studies

Switching properties and response times were analyzed monitoring the transmittance change at low-energy absorption maxima while applying a square-wave potential to spray-coated polymer films on ITO. The time of the applied potential pulse was successively decreased from 10 to 0.5 s. The results from the kinetic measurements are presented in Fig. 6. TQ3 shows the fastest response times where 92% of the transmittance modulation was maintained at switching times of 0.5 s. A reasonable explanation is that the branched side chains of TQ3 create an open morphology of the polymer film with less closely packed polymer chains, facilitating fast transport of charge balancing ions during the redox processes. TQ1 and TQ2 also display fast response times with 72% and 76% of the transmittance modulation maintained at switching times of 0.5 s. The polar oligoethylene oxide side chains of TQ2 to some extent improve the response times, compared to TQ1, *via* improved ion conductivity.

3.6. Stability measurements

As an initial test of the polymers resistance to electrochemical degradation, polymer films were repeatedly switched between the reduced and oxidized state. All three polymers show a decent stability after 200 full switches (Fig. 7). The observed loss in optical contrast is most probably due to the relatively high oxidation potential of the polymers. The oligoethylene oxide side chains did not result in improved stability for TQ2. A reasonable explanation for this is that the high molecular weight of the polymers already facilitates good film-forming properties and adhesion to the substrate.

4. Conclusions

Blue-to-transmissive electrochromic switching has been demonstrated for three donor–acceptor based polymers. The polymer TQ1 showed an impressive transmittance change of 50%, recorded at the low-energy absorption maximum (623 nm). The high optical contrast and fast response times makes the polymers interesting for non-emissive display applications. Moreover, the high correlation between experimental data and calculations

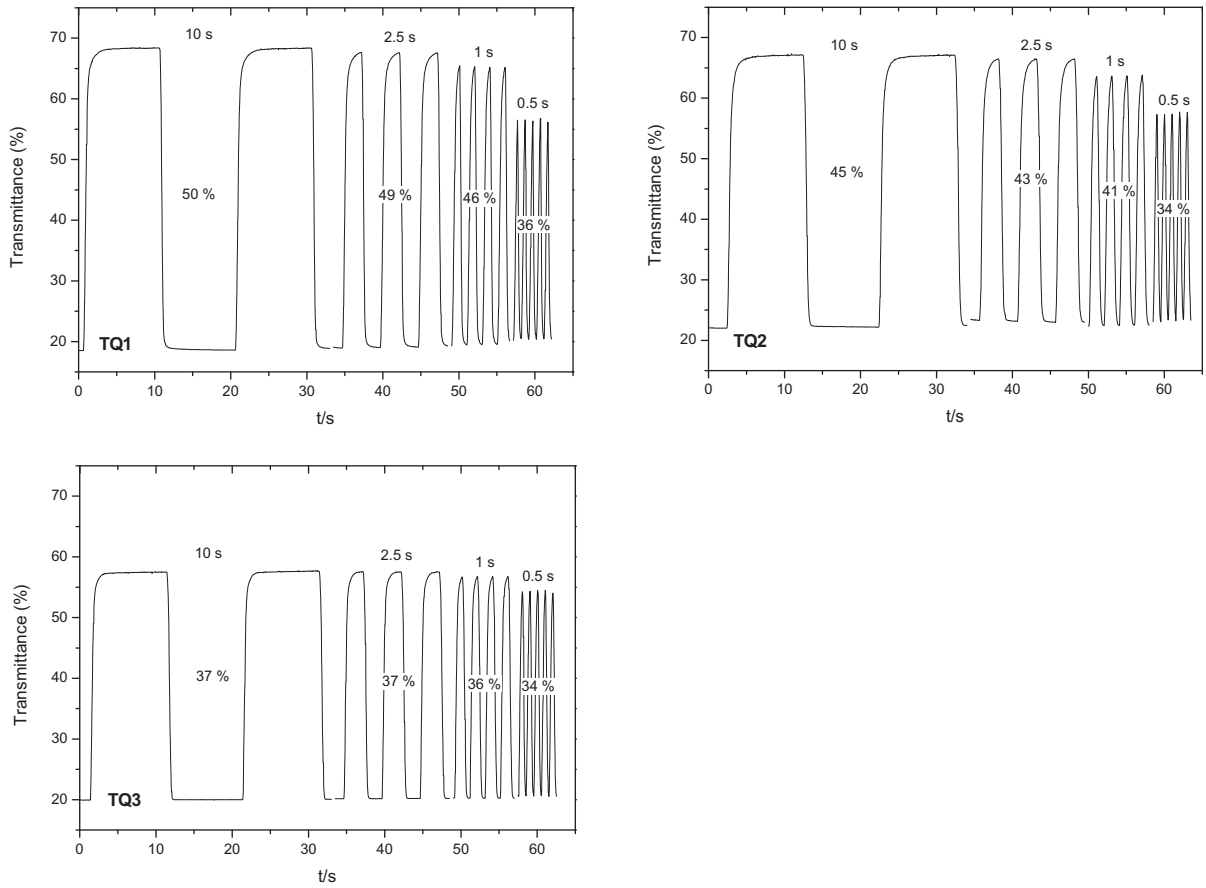

Fig. 6. Kinetic measurements on TQ1–TQ3 films on ITO, using 0.1 M NBu_4PF_6 in anhydrous acetonitrile as supporting electrolyte. Films were switched between 0 and +1.0 V.

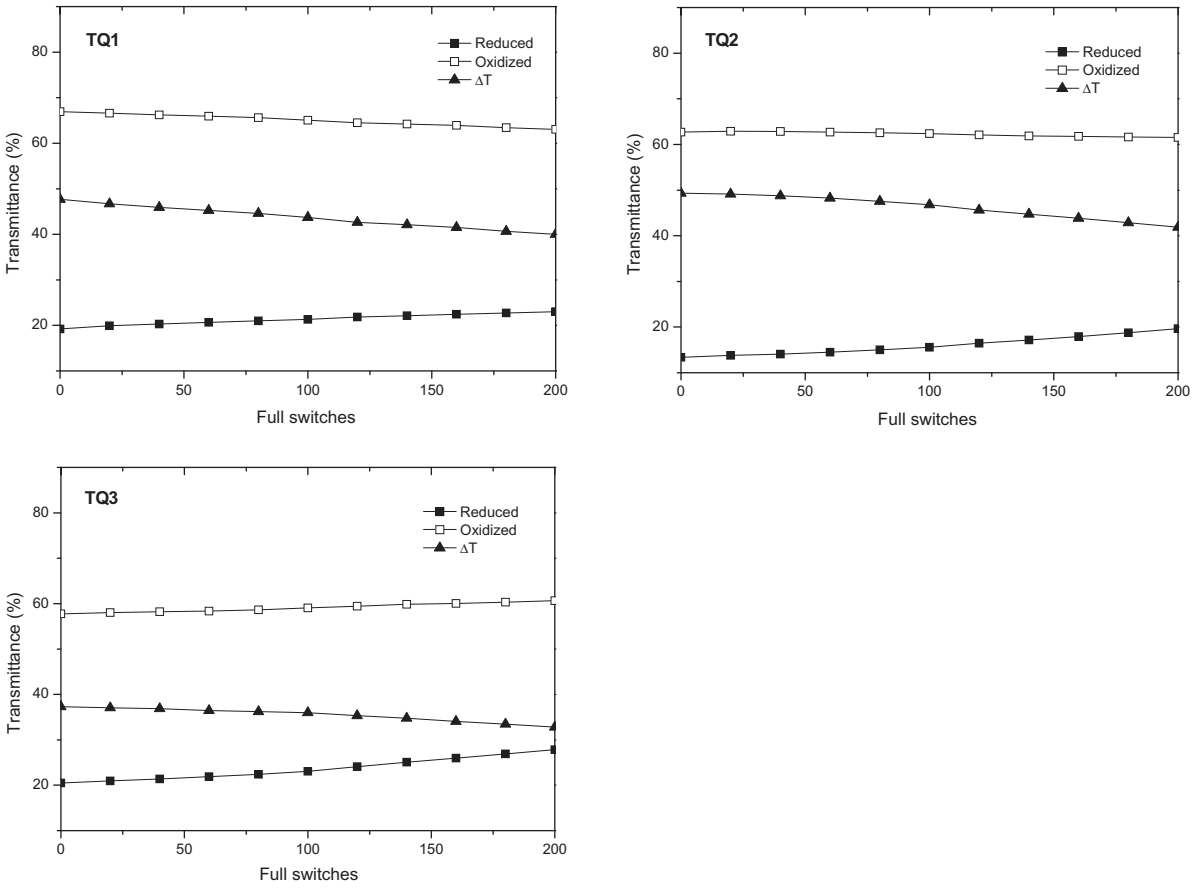

Fig. 7. Stability measurements of TQ1, TQ2, and TQ3. A square-wave potential, switching between 0 V and +1.0 V, was applied to polymer films on ITO in 0.1 M NBu_4PF_6/anhydrous acetonitrile. Switching times are 2 s. Total cycle is 4 s. Transmittance was recorded at low-energy absorption maxima.

strengthens the hypothesis that maximum optical contrast of electrochromic polymers, with respect to film thickness, can be estimated by normalizing absorption/transmission values of the reduced and oxidized state.

regioregular poly(3-hexylthiophene) (P3HT) has been extensively studied in organic field-effect transistors (OFETs) due to its comparatively high hole carrier mobility, simple solution processability, and commercial availability [4]. However, P3HT-based OFETs typically face the problem of relatively poor ambient stability and unfull flexibility, which has strongly limited its practical application for industry. The bending stability in relation to above device reliability is also one of the most challenging issues for choosing the suitable device structures towards fully flexible electronic device application.

In present study, we attempt to use the Si_3N_4 as passivation layer on the plasma treated HfO_2 film enable one to obtain reliable OTFT on a fully flexible PI substrate, as regards their mechanical flexibility and environmental stability. The device's electrical properties with respect to saturation mobility, on/off current ratio, and bending conditions (i.e., the numbers of bending times and the bending radii) are also carefully investigated.

2. Experimental section

2.1. Materials synthesis and device fabrication

Plastic 30 μm-thick DuPont Kapton® PI films were used as flexible substrates for device fabrication process. They were cleaned ultrasonically with ethanol (Fluka; water content <0.1%) for 30 min and deionized water for 10 min, and then high-pressure N_2 gas was used to remove the water and any remaining surface particles from the PI. PI films were annealed at 200 °C for 2 h in vacuum to achieve relatively thermal stable, and enhance the adhesion strength. Next, Cr (thickness: 50 nm; adhesion layer) and Au (thickness: 100 nm) films were sequentially deposited for the gate electrode over the PI substrate by using a thermal evaporation system under patterning with designed mask. To deposit the HfO_2 dielectric layer, a sol–gel solution was prepared by dissolving $HfCl_4$ (98%, Aldrich, USA) in ethanol (95%) at a suitable concentration. Ethanol (10 mL) as the solvent was prepared to yield a molar ratio of $HfCl_4$ to C_2H_5OH of 1:1000. Under a magnetic stirring condition, the solution was heated under reflux while stirring for 30 min. The dielectric film was grown by spin-coating the sol–gel solution over PI at 1000 rpm for 10 s and then 3000 rpm for 30 s at room temperature by using a spin coater. The as-prepared samples were treated with O_2 plasma for 2 min in an oxygen plasma reactor (Harrick Scientific Corp.), which supplied a plasma power of 30 W. The silicon–nitride (Si_3N_4) layer was deposited as a passivation layer onto the high-*k* film by plasma-enhanced chemical vapor deposition (Oxford-PECVD).

To deposit the channel layer, the commercially available poly-(3-hexylthiophene) i.e., P3HT (obtained from Merck) was used as an organic semiconductor layer. The desired solution was prepared when 1.2 mg P3HT were obtained and placed in a sealable clean glass container. Then, 10 mL of $CHCl_3$ was added to a flask containing the P3HT. The solution was then gently heated at 50 °C using a hot plate to further break down the polymer chains in solution. After stirring the solution with reflux for 1 h, and then placed in an oven to be cooled. The light intensity was shielded under a standard aluminum foil to minimize the oxidation. The organic semiconductor layer of mixed solution was fabricated by spin-coating a P3HT chloroform solution at 1000 rpm for 20 s. After the deposition, the film was dried at 80 °C for 2 min and then dried gel film was annealed in nitrogen atmosphere using different thermal treatment techniques for 1 h. Au electrodes (100 nm) for TFT devices on the PI sheet with a device structure as shown in Fig. 1(A) were formed through a shadow mask by using a thermal coater. The molecular structure of the P3HT was shown on right-side of Fig. 1(A). The channel width (W) and length (L) for our flexible device were 200 and 60 μm, respectively. Fig. 1(B) illustrated the semi-transparent images of 30 μm-thick DuPont Kapton PI film, demonstrating the text on the layer behind the PI substrate was clearly visible. Our P3HT-TFT device on plastic PI film under a large surface strain was displayed in Fig. 1(C), and the surface appeared no cracks.

2.2. Device characterization and measurements

The surface morphology of the flexible devices was evaluated by atomic force microscopy (AFM, Digital Instruments Nanoscope, D-5000). The surface morphology of the P3HT film as channel area on Si_3N_4–HfO_2/Au/Cr/PI substrate was obtained from AFM measurement under the tapping mode at 2 μm scan size and scan rate of 0.5 Hz. We used ellipsometry technique to measure the thickness of the HfO_2 and P3HT layers. The current density–electric field (*J*–*E*) measurements were performed by using an Agilent-4156 probe station. A customized bending machine (depicted and described elsewhere in this text) was used to perform the bending test in tension or compression modes where the bending radious ranged from 2 to 4 cm for both convex and concave types of bending.

3. Results and discussion

3.1. Effect of passivation layer on leakage-current density

Prior to achieve the flexible organic–inorganic hybrid TFT devices based on P3HT material, we firstly fabricated the metal–insulator–metal (MIM) device with 10 nm high-*k* HfO_2 as dielectric layer over fully flexible polyimide (PI) substrate. Under high electric field stress, the carriers of leakage current will impact the weak bonding and result in the high leakage current. We measured the quantitative leakage current to evaluate the electrical performance of the HfO_2 film which was fabricated by very simple and cost-effective sol–gel spin-coating technique in MIM configuration. Fig. 2(A) displayed the leakage current density and electric field (*J*–*E*) characteristics for the fully flexible MIM capacitors prepared by HfO_2 film with O_2 plasma treatment. The O_2 plasma treated sample did not have sufficiently high thermal budgets and many trap states still existed over film surface. Inset of Fig. 2(A) showed AFM image of HfO_2 film with existence of various trap states over film surface. The RMS roughness was about 1.52 nm.

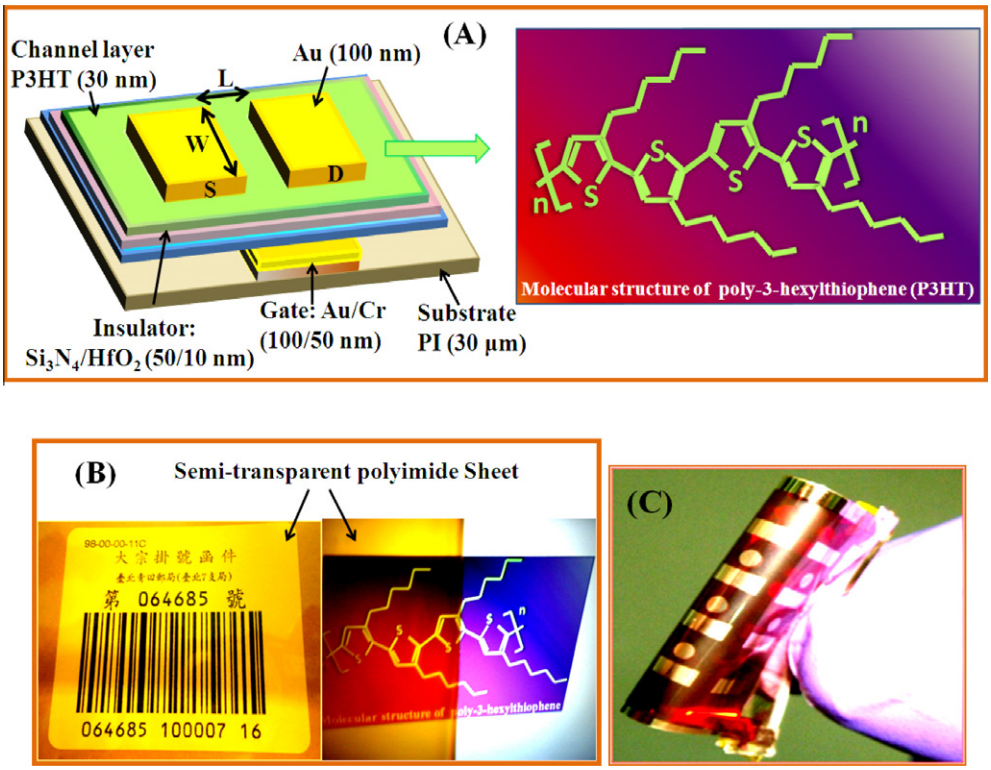

Fig. 1. (A) Schematic structure of P3HT-based OTFT with HfO_2–Si_3N_4 as a dielectric layer on PI substrate; (B) the photograph of semi-transparent polyimide sheet; (C) photograph of proposed TFT device on a 30 μm-thick flexible PI substrate and under a large surface strain.

Hence, their breakdown electric field was relatively low and their leakage current density was very high (i.e. 4.6×10^{-6} A cm^{-2}) at the applied voltage. This observation was attributed to the availability of the traps over film surface. In order to achieve the better device, the Si_3N_4 passivation layer was proposed to deposit onto the HfO_2 film in Fig. 2(B). Interestingly, the surface roughness was minimized by the passivation layer. AFM image in inset of Fig. 2(B) revealed that the surface of Si_3N_4 film was smooth, and rms roughness decreased almost 5 times from 1.52 to 0.34 nm. In addition, the superior low leakage current density for the corresponding films subjected to 50-nm Si_3N_4 as the efficient passivation layer on top of 10-nm HfO_2 film was found as low as 10^{-11} A cm^{-2} in Fig. 2(B) during voltage stressing. The proposed MIM device structure, including of Si_3N_4 layer on O_2 plasma-treated HfO_2 film, exhibited the superior low leakage current than that only O_2 plasma treated HfO_2 film. The high leakage current density from the sample adopted O_2 plasma treated HfO_2 film could be attributed to the existence of numerous traps over the film surface and hence poor dielectric characteristics. Similarly, the traps over the film surface could also affect the performance of the following TFT device. In a simple-minded classical approach, it might appear that electrons tunneled easily as moved through the trap states of HfO_2 surface. However, the trap induced breakdown effect was effectively suppressed by HfO_2–Si_3N_4 film structure.

In addition, the schematic energy band diagrams in Fig. 2(C) were proposed to explain the trap-dependent leakage and the passivation of traps over HfO_2 film surface. The traps in HfO_2 film had occurred and affected the energy band, indicating that the electrons can easily move through the HfO_2 film due to trap-assisted tunneling effect. This observation was responsible for high leakage current in the MIM device [9]. These trap centers created intermediate energy levels due to the presence of impurities in the material [10]. After surface Si_3N_4 film passivation, the reliability related current transport mechanism was improved from reduction of trap-assisted tunneling. Under passivation treatment with Si_3N_4 film, the potential barrier became thick enough not to allow electrons from gate to tunnel through the barrier. Thus, the leakage current densities apparently decreased as strong energy band-pass for electrons can shift toward a higher energy level. The O_2 plasma treated-HfO_2 film after Si_3N_4 passivation exhibited better reliability even under high electric field in Fig. 2(B). This observation suggested that HfO_2 film was extremely suitable as a gate dielectric in future flexible devices. From the formation of a passivated Si_3N_4 layer, the reduction of parasitic resistance could suppress the surface trap density effect and improve the performance of flexible devices.

3.2. Surface morphology of P3HT film

The surface morphology of the P3HT film by AFM measurement in tapping mode at 2 μm scan size was demonstrated in Fig. 3; the sample was deposited by sol–gel spin-coating process on Si_3N_4–HfO_2/Au/Cr-coated flexible PI film. It could be seen from the figure that the surface

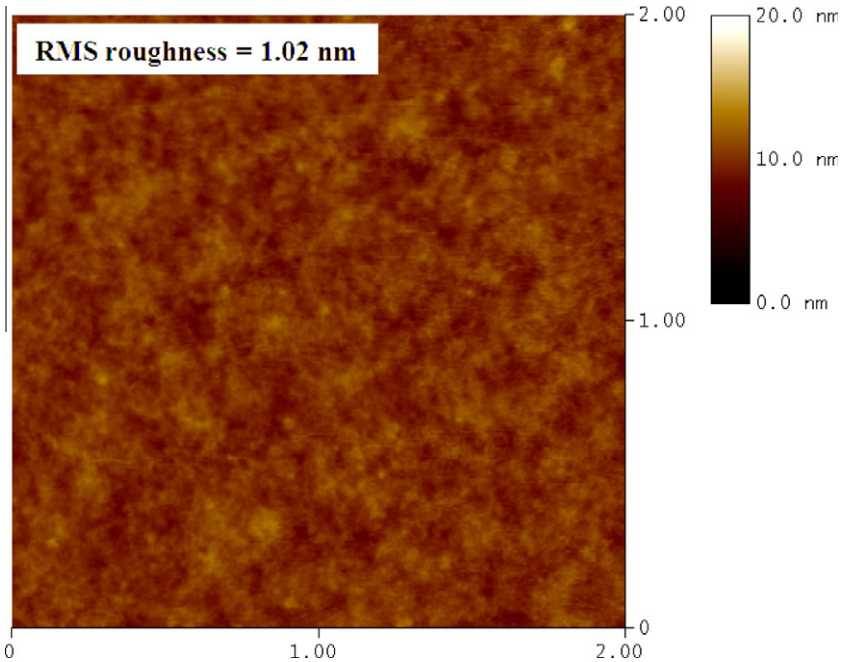

Fig. 3. AFM image from P3HT thin film as channel area on Si_3N_4–HfO_2/Au/Cr/PI substrate at a length scale of 2 μm (surface roughness: 1.02 nm).

morphology of the spin-coated P3HT film was dense and crack-free. Thin films of P3HT with regioregularity and order structure were obtained with the thermal treatment at 80 °C of curing, and the performance of the device would be enhanced. The average P3HT thickness was about to 30 nm measured by ellipsometery technique. The root-mean-square (RMS) surface roughness of the P3HT film grown on Si_3N_4–HfO_2/Au/Cr/PI surface was 1.02 nm. We observed that the fabrication process with chloroform solvent yields higher mobility over a wide variety of tested devices mentioned in the following. Goetz et al., revealed that P3HT films from chloroform solution behaved a higher tendency to form ordered fibrillar networks without sharp boundaries [11]. By the utilization of AFM for the analysis of the surface morphology of the P3HT film, we suggested that the sol–gel deposited P3HT film was crack-free, uniform, and well adhered on Si_3N_4–HfO_2/Au/Cr-coated PI for the fabrication of high performance flexible devices.

3.3. Transfer and output characteristics

The TFT devices were fabricated after the beneficial effect of HfO_2–Si_3N_4 film structure in MIM device was understood. To indicate the influence of the gate leakage current, we measured the transfer characteristic of P3HT-OTFT for HfO_2 as gate dielecric layer on flexible PI substrate where V_{DS} was set at −5 V. Fig. 4(A) and (B) showed the transfer and output characteristic curves of the P3HT-TFT on the flexible PI substrate with O_2 plasma treated HfO_2 film as dielectric layer. The output characteristics of the applied drain voltage (V_{DS}) ranged from 0 to −5 V with gate biases (V_{GS}) varying from 0 to −5 V in steps of 1 V. The trap state problem in the HfO_2 film of this TFT device might also contribute to leakage property. The transfer characteristic curve was abnormal and the output characteristics were only observed at a higher gate voltage. Even under −5 V of gate and drain voltage, reasonable device properties were not observed with an on/off current ratio of about 10^2, which would not afford to minimum requirement of TFT devices. Moreover, as Fig. 4(B) illustrated, the output characteristics were not stable and drain currents were not satisfactory.

The OTFT device achieved a much better performance while using Si_3N_4 as a passivation layer onto O_2 plasma treated HfO_2 film. As shown in Fig. 4(C), P3HT-OTFT exhibited typical p-type output characteristics [source-drain current (I_{DS}) versus drain voltage (V_{DS}) at different gate voltages (V_{GS})], when operated in the accumulation mode. The OTFTs operated in the accumulation mode when a negative gate voltage was applied, since positive carriers

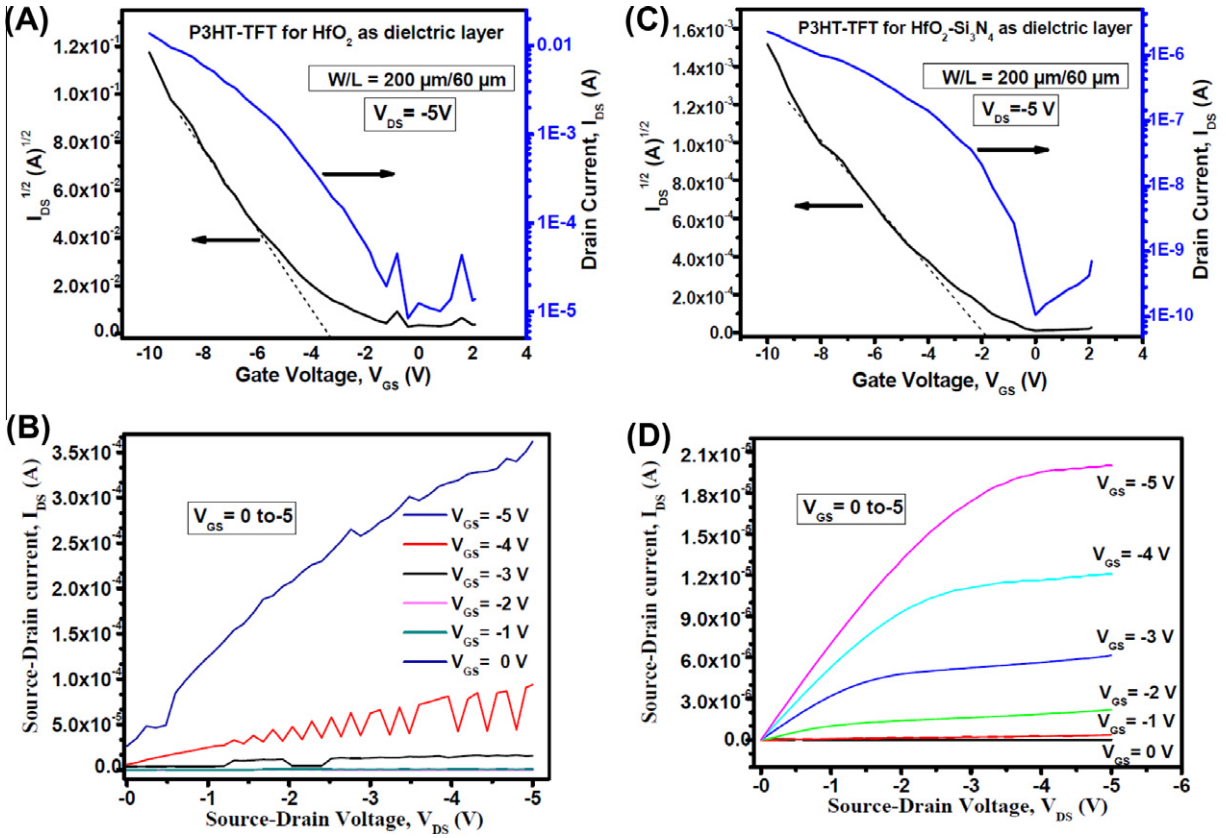

Fig. 4. (A) Plot of drain current and square root of drain current with respective to gate voltage (I_{DS}–V_{GS}) for P3HT-OTFT on flexible PI substrate by using HfO_2 as gate dielectric under V_{DS} = −5 V, and (B) output characteristic (I_{DS}–V_{DS}) as V_{GS} ranging from 0 to −5.0 V at 1 V step for above device. (C) Plot of drain current and square root of drain current with respective to gate voltage (I_{DS}–V_{GS}) for P3HT-OTFT on flexible PI substrate by using Si_3N_4–HfO_2 stacked film as gate dielectric under V_{DS} = −5 V, and (D) output characteristic (I_{DS}–V_{DS}) as V_{GS} ranging from 0 to −5.0 V at 1 V step for above device.

were generated in the P3HT organic semiconductor layer. In order to get a reasonable estimation for the possible dependence of the mobility along the TFT device channel, we have plotted the linear and saturated field-effect mobilities extracted from the transfer characteristics of the TFT according to Eq. (1) and (2). In the linear regime, the field-effect mobility (μ_{lin}) can be calculated from transconductance [12].

$$(g)m = \frac{\partial I_{DS}}{\partial V_{GS}}|V_{DS} = \text{const} = \frac{WC_i}{L}\mu_{lin}V_{DS} \quad (1)$$

where, C_i was the gate capacitance and W/L was the ratio of the channel width to channel length. In the saturation region ($V_{DS} > V_{GS}-V_{Th}$), I_{DS} can be described by following equation [12,13] and then the saturated field-effect mobility (μ_{sat}) can be calculated as

$$I_{DS} = W\mu_{sat}\frac{C_i}{2L}(V_{GS} - V_{TH}), \quad (2)$$

where, μ_{sat} was the field-effect mobility, C_i (=1.02 nF cm^{-2}) was the capacitance of the Si_3N_4–HfO_2 dielectric layer, W = 200 μm, L = 60 μm, and V_{Th} was the threshold voltage. As Eq. (2) implied, a plot of V_{GS} versus square root of I_{DS} gave a straight line, and V_{Th} was obtained. The threshold voltage and the field-effect mobility were to be −1.9 V and 0.041 cm^2 V^{-1}s^{-1}. The on/off current ratio was 2.0×10^4 when V_{GS} was scanned from +2 to −10 V. In addition, the output characteristic illustrated in Fig. 4(D) indicated that the device had good saturation behavior. The drain current increased linearly with an increase in drain voltage in the low drain–voltage regime, whereas it tent to saturate in the higher drain–voltage regime because of the pinch-off of the accumulation layer. Furthermore, a large increase of the electrical conductivity was expected due to an enhancement of the hole mobility in these crystalline P3HT domains. A thermal treatment had intense effects on the charge carrier for P3HT blending from chloroform. Annealing at 80 °C for this channel layer resulted in the formation of crystalline P3HT and thus enhanced the hole mobility in these regions by an order of magnitude. It was also likely to happen that the use of high-k materials as the gate insulator had reduced the device operating voltage for flexible devices. The field-effect mobility, on/off current ratio and threshold voltage of P3HT-based OTFTs on silicon/glass substrates were summarized in Table 1 for comparision with literatures [14–19]. The field-effect mobilities' obtained here were lower than previously reported values for other high performance TFTs but it was expected that higher field-effect mobility could be further improved through the optimization of the device fabrication process by choosing appropriate solvents as previously mentioned.

3.4. Bending treatment to three-point bending conditions

Mechanical stability was the most important factor for flexible devices when dealing with the long-term application. We estimated the electrical properties of our OTFT after different bending times, convex and concave type bending stages to make sure the possibility for use in advanced flexible electronic devices. Fig. 5(A) showed the transfer characteristics for plasma treated high-k HfO_2 film followed by Si_3N_4 layer subjected to number of bending times. Inset of Fig. 5(A) presented an image of the setup of the frontward and backward bending tests and the number of bending times. For the initial measurement, the on/off currents ratio was calculated about to 10^4 and remained almost unchanged even after bending the TFT up to 100,500 and 1000 times. Here in our case, the P3HT as channel material and HfO_2 film as gate dielectric followed by Si_3N_4 layer over flexible organic PI substrate revealed superior stability even after bending the TFT device up to 1000 times. After the bending test, the on/off current ratio and threshold voltage remained almost the same as it was prior to initial bending. This observation indicated that the sol–gel spin-coating method to form OTFT by using high-k film as gate dielectric passivation provided superior electrical performance and stability on PI substrate.

Furthermore, we tested two additional features of our OTFT on PI to explore its feasibility for use in practical applications. Namely, we estimated the transfer characteristics in both convex (Fig. 5B) and concave (Fig. 5C) settings, varying the radii of curvature (denoted by R_c) for 2 and 4 cm. Prior to manufacturing process, a hard plastic foil was used as a substrate support to provide these specific bending conditions. As Fig. 5(A) and (B) suggested, the P3HT retained its transfer characteristics after the both convex and concave types bending conditions. All of the curves demonstrated the on/off current ratio to be about 10^4 at applied V_{DS} = −5 V. This value of on/off current ratio was consistent with the ratio of pristine device. This observation implied that the plasma treated HfO_2 film followed by Si_3N_4 passivation as gate dielectric over flexible organic PI substrate revealed superior stability after bending the OTFT device. After the bending measurement, the threshold voltage (V_{Th}) was almost in the same with no bending condition (i.e. −1.9 V). Therefore, the dielectric Si_3N_4 passivation film was supposed to enhance the electrical

characteristics of the TFT devices at low temperature manufacturing. Our results demonstrated better performance when compared to the report for flexible OTFTs [14,16]. Zhang's group had fabricated the flexible pentacene-based TFT arrays, whose mechanical flexibility represented the best values till date [20]. From this concave and convex examinations, we concluded that the P3HT based TFT device fabricated on plastic substrate had an excellent stability even bending the device up to 2 cm in convex or concave status.

3.5. Improved device stability in ambient air

The ambient stability of the TFT device was monitored through the time-dependent performance for the device. To evaluate the reliability of the P3HT-transistor device, environment dependent transfer characteristic measurements were carried out under normal environment. Time-dependent transfer characteristic was measured in Fig. 5(D) for the period of 6, 24, and 48 h. The resultant mobilities were calculated between 0.04–0.05 $cm^2\ V^{-1}\ s^{-1}$, on/off currents ratio 10^4, and threshold voltage about −2.0 V for our flexible P3HT-TFT device. This observation was very close with the illustration in Fig. 4(C). By considering the performance, the data suggested that over a day period of time, our flexible P3HT-TFT did not degrade the mobility. Meanwhile, we had pointed out that the device stability actually reduced for a long period of time over 10 days or more although it was not illustrated here. However, this was not a challenge issue because the commercial flexible device required the package process to avoid contamination. But, less than 48 h, the air stability of our flexible OTFT device without package was observed in comparison with the P3HT-FET on bare SiO_2 substrate. This subtle difference in on/off currents ratio and mobility meant that our flexible TFT had an excellent reliability after placing the devices in normal environment for 48 h and was able to use for advanced microelectronic devices. Our flexible TFT device showed a relatively excellent bias stability with the use of Si_3N_4 layer passivation on the HfO_2 film. O_2 plasma treated high-k film and following Si_3N_4 layer seemed to improve the P3HT-OTFT stability and reduce the absorption effect of humidity, and thereby retarded the degradation of the OTFTs under ambient condition. These results suggested that the possibility of using highly reliable Si_3N_4–HfO_2 stacked heterostructure to fully flexible poly-(3-hexylthiophene) thin-film transistor for future commercial manufacturing.

4. Conclusions

We have fabricated a new and fully flexible organic poly-3-hexylthiophene (P3HT) p-type thin-film transistor (TFT) on a transparent flexible polyimide substrate using high-k

HfO_2 as dielectric layer and Si_3N_4 as passivation layer via very simple and cost-effective sol–gel spin-coating technique. Defects in the HfO_2 films are expected to be rarely induced, because of the low temperature deposition process and plasma treatment. Current–voltage characteristics of the device in metal–insulator–metal structural device imply the success of using Si_3N_4 over HfO_2 to achieve the satisfactory leakage current. The fabricated devices exhibit good electrical performance with saturation mobility of 0.041 $cm^2 V^{-1} s^{-1}$. Moreover, the device demonstrates stable performance over the course of bending up to 1000 times and radii of curvature minimum down to 2 cm in both convex and concave type structures. Our results suggest that the P3HT semiconductor material in together with HfO_2 film followed by Si_3N_4 as passivation layer are promising materials for the low-cost flexible electronic devices.

Recently, improved performance of OPV cells with higher external quantum efficiency in the spectral range of 500–700 nm has been demonstrated by replacing C_{60} with fullerene C_{70} of higher visible light absorption arising from a relaxation of symmetry-forbidden transitions in C_{70} [18–20]. The C_{70} derivative, $PC_{70}BM$, is also utilized in polymer-based OPV devices to provide photocurrent enhancement over devices with $PC_{60}BM$ due to the greater long-wavelength absorption of $PC_{70}BM$ [21].

Besides the selection of effective OPV materials, it is well recognized that the electronic structures of organic interfaces, especially the energy level offsets at DA heterojunctions, play a crucial role in determining charge generation and transport processes in OPVs [22–25]. For instance, the open-circuit voltage (V_{OC}) is proposed to be dependent on energy level offset (ΔE_{DA}) between the highest occupied molecular orbital (HOMO) of the donor and the lowest unoccupied molecular orbital (LUMO) of the acceptor at the DA interface [26–28]. According to previous reports, the electronic structures at a planar DA bilayer interface differ from that of a mixed DA BHJ [23,24]. However, the related works are still scarce, and it is of interest to clarify the electronic properties of C_{70}-involved DA heterojunctions for the understanding and optimization of OPV cells. In this work, we report the detailed electronic structures and energy level alignment at DA heterojunctions consisting of C_{70} and copper phthalocyanine (CuPc) in the form of a planar C_{70}/CuPc bilayer structure and a mixed C_{70}:CuPc BHJ. The influence of thermal annealing on the mixed C_{70}:CuPc BHJ is also addressed.

2. Experimental

Interface studies were carried out in a Kratos AXIS Ultra-DLD ultrahigh vacuum photoemission spectroscopy system, which is composed of a fast entry air lock, a multiport carousel chamber, an evaporation chamber, and an analysis chamber. The base pressures in the four chambers were better than 1×10^{-8} Torr, 5×10^{-10} Torr, 5×10^{-10} Torr, and 3×10^{-10} Torr, respectively. Indium tin oxide (ITO) coated glass substrates (30 Ω/sq.) were *ex-situ* solvent cleaned and treated by UV-ozone for 20 min. Prior to film deposition, all the materials were entirely outgassed. CuPc and C_{70} were *in situ* thermally deposited onto the room-temperature substrates with a growth rate of 1–2 Å/s in the evaporation chamber. The C_{70}:CuPc mixture was formed by co-evaporating C_{70} and CuPc sources from separately Ta boats. Film thickness and deposition rate were monitored by a quartz crystal microbalance. The annealing procedure with a temperature ramp rate of ~10 °C/min was also carried out in the evaporation chamber with a heating stage. After each deposition or annealing step, samples were transferred to the analysis chamber without breaking vacuum for ultraviolet and X-ray photoelectron spectroscopy (UPS and XPS) measurements. UPS analysis was performed to characterize the valence states and vacuum level (VL) by using the HeI excitation line (21.2 eV) from a Helium discharge lamp with a total instrumental energy resolution of 100 meV, and samples were negatively biased to enable the observation of secondary electron cutoff. XPS measurements using a monochromatic Al Kα source (1486.6 eV) were carried out to study chemical reactions and the development of energy level bending. All the spectra were obtained at room temperature. The binding energy scale was calibrated by determining the $Au4f_{7/2}$ peak position and Fermi level (E_F) edge of the Au film, which was cleaned by Ar^+ ion sputtering. Fermi level is referred as the zero binding energy (BE) in all the UPS and XPS spectra.

OPV cells were fabricated on patterned ITO glass with a sheet resistance of 30 Ω/sq. The UV-ozone treated ITO substrates were loaded into a high-vacuum chamber with a base pressure of 1×10^{-7} Torr. The organic layers and metal cathode were thermally evaporated from separately Ta-heated quartz or BN crucibles. The mixture ratio of C_{70} and CuPc based on the wt% measured using the thickness monitor was fixed at 1:1, unless otherwise noted. A shadow mask was used to define the cathode and to make four 0.1 cm^2 devices on each substrate. Current density–voltage (J–V) characteristics of the PV cells without any device encapsulation were measured with a programmable Keithley model 2612 power source in the dark and under AM 1.5 solar illumination from a Newport 150 W solar simulator. Illumination intensity was measured with a calibrated Oriel radiant power meter.

3. Results and discussion

3.1. Electronic structures of the planar C_{70}/CuPc bilayer structure

The electronic structure evolution at the planar C_{70}/CuPc interface on UV-ozone treated ITO substrate was measured by UPS. Fig. 1 shows the HeI UPS spectra of the C_{70}/CuPc interface with increasing C_{70} overlayer on a 100 Å-thick CuPc layer deposited on ITO substrate. The

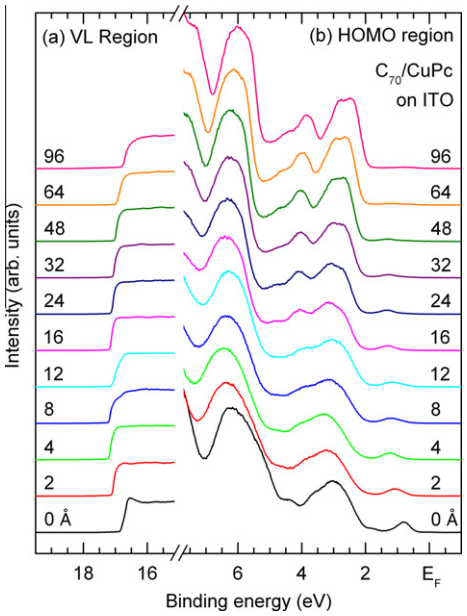

Fig. 1. Expanded UPS spectra of (a) the secondary electron cutoff and (b) the HOMO region for C_{70}/CuPc bilayer as a function of incremental C_{70} deposition on 100 Å-thick CuPc on ITO substrate.

top spectrum corresponds to the photoemission from a 96 Å-thick C_{70} layer. It is noted that upon deposition of C_{70}, the spectral features of CuPc are attenuated progressively, while those of C_{70} are concurrently increased and finally saturated. As shown in Fig. 1(a), the secondary electron cutoff at high BE region, from which the VL position can be inferred, exhibits a slight shift towards higher BE at the initial stage of C_{70} deposition, and then gradually shifts towards lower BE with increasing thickness of C_{70}. A similar shift is also observed for all the spectral features of both C_{70} and CuPc. Meanwhile, it is evident that there is no emergence of new features in the organic energy gap region with the deposition of C_{70} overlayer, implying a physical adsorption process at the C_{70}/CuPc interface. The slight BE shift of spectral features with respect to the increase of film thickness might be associated with electric dipoles produced in the film by a gradient change in the molecular orientation even if the molecule has no permanent electric dipole [29]. In addition, the collected UPS spectra were found not to be shifted or changed with irradiation time, which eliminate the influence of surface charging on the accuracy of the measurements for thick films. According to the Fig. 1(b), the HOMO onsets of CuPc and C_{70}, estimated by linear extrapolation at low binding energy side of the HOMO peak maximum, locate at 0.4 and 1.95 eV below E_F, respectively. The corresponding ionization potential (IP) values, which were determined by the energy difference between the VL position and HOMO onset, are 4.8 eV for CuPc and 6.35 eV for C_{70}, respectively.

XPS measurements were also taken after each deposition step. Fig. 2 displays the corresponding XPS C1s core level spectra at the C_{70}/CuPc interface, which are normalized to their peak maximum intensity. For CuPc, the C1s spectrum reveals three distinctive peaks as shown in the bottom spectrum of Fig. 2. As pointed out elsewhere, [25,30] these three peaks are associated with the aromatic carbon of the benzene rings, pyrrole carbon linked to nitrogen, and a π–π^* satellite feature from the pyrrole carbon, respectively. Correspondingly, the XPS spectrum of the C_{70} film is composed of the C1s main line and π–π^* shake-up structures caused by kinetic-energy losses of the photoelectrons due to simultaneously excited π–π^* transitions from the occupied to unoccupied molecular orbitals [31]. As shown in Fig. 2, there is neither additional component nor peak broadening except for the gradual changes of spectral intensity and positions. The results further confirm the absence of a chemical reaction at the C_{70}/CuPc interface, as demonstrated in the UPS measurements (see Fig. 1).

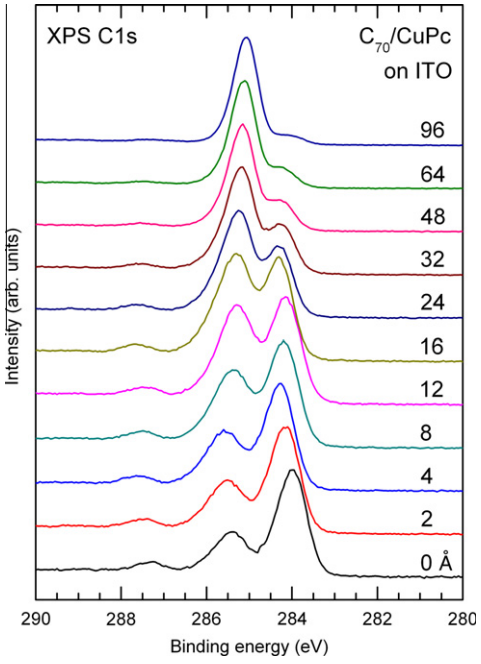

Fig. 2. XPS C1s core level spectra obtained upon formation of the C_{70}/CuPc bilayer on ITO substrate.

3.2. Electronic structures of the mixed C_{70}:CuPc BHJ

Fig. 3(a) and (b) shows the HeI UPS spectra of the incremental deposition of a mixed C_{70}:CuPc BHJ (1:1 by weight) on ITO substrate, where the C_{70}:CuPc thickness increases from submonolayer (~2 Å) to 100 Å. The bottom UPS spectrum in Fig. 3(a) and (b) was recorded from the UV-ozone treated ITO. It is noted that upon deposition of a 2 Å-thick C_{70}:CuPc mixed layer on ITO substrate, the VL cutoff exhibits a shift of ~0.3 eV towards higher BE, which is in good agreement with the formation of the CuPc/ITO interface [32]. With increasing mixed C_{70}:CuPc thickness, there is negligible shift for all the spectral features as well as VL cutoff, which is also observed in the XPS measurements (not shown here). More specifically, the UPS spectrum of 100 Å-thick C_{70}:CuPc layer is very similar to that of 16 Å-thick C_{70}/CuPc bilayer as shown in Fig. 1.

To accurately determine the HOMO onsets for C_{70} and CuPc in the mixed C_{70}:CuPc layer, the UPS spectrum of 100 Å-thick mixed C_{70}:CuPc layer is fitted with the spectral line shapes of pure CuPc and C_{70}, which are the same as those in Fig. 1. As evident in Fig. 3(c), the UPS spectrum of the deposited C_{70}:CuPc layer is deconvoluted into the superimposed spectra of CuPc (thin solid line) and C_{70} (thin dashed line). The HOMO onsets for C_{70} and CuPc in mixed C_{70}:CuPc layer are thus estimated to be at 1.7 and 0.4 eV below E_F, respectively.

3.3. Energy level alignment of C_{70}/CuPc and C_{70}:CuPc heterojunctions

According to the results from UPS and XPS measurements, the corresponding energy level alignments at the planar C_{70}/CuPc bilayer interface and the mixed C_{70}:CuPc BHJ are obtained and schematically illustrated in Fig. 4(a) and (b), respectively. Here, the charge transport gaps are taken to estimate the LUMO positions of C_{70} and CuPc, which were determined from UPS plus inverse photoemission spectroscopy (IPES) measurement (that is 2.1 eV for C_{70} and 1.9 eV for CuPc, respectively) [32,33]. The interface dipole (Δ) was determined from the VL cutoff shift. As shown in the energy level diagrams, the energy level lineup in the planar C_{70}/CuPc bilayer structure (Fig. 4(a)) is remarkably different from that in the mixed C_{70}:CuPc BHJ (Fig. 4(b)). In particular, the ΔE_{DA} between the donor-like

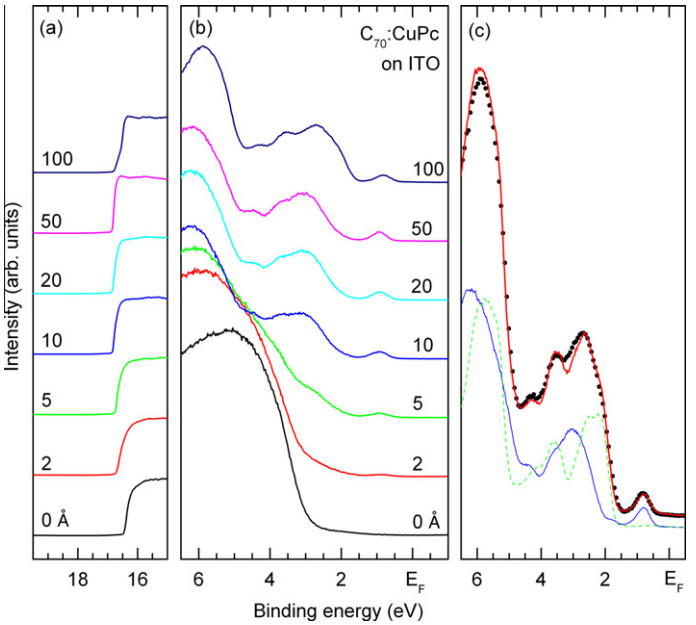

Fig. 3. Expanded UPS spectra of (a) VL region and (b) HOMO region for mixed C_{70}:CuPc BHJ for increasing thickness of C_{70}:CuPc on ITO substrate. (c) Decomposition of the UPS spectrum of C_{70}:CuPc BHJ with experimental data (open circles) and fitting curve (solid line).

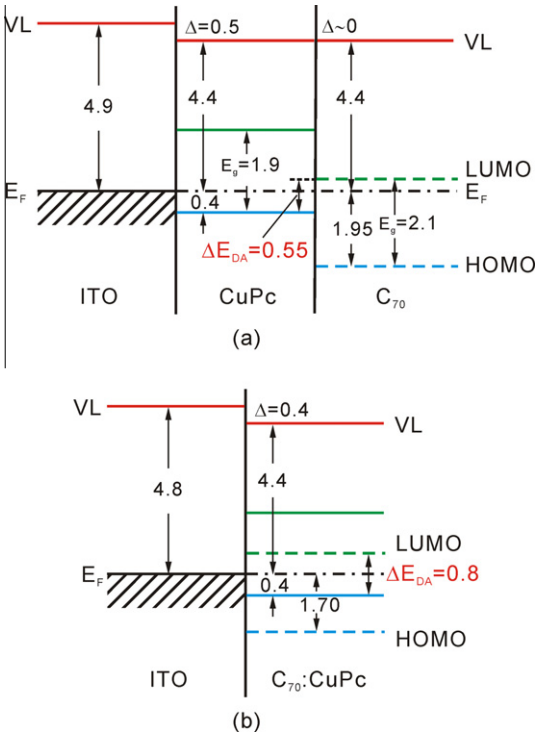

Fig. 4. Schematic energy level diagrams of (a) C_{70}/CuPc bilayer and (b) C_{70}:CuPc BHJ on ITO substrate, respectively. All the values shown are in unit of eV. The molecular levels of CuPc are presented in solid line, while that of C_{70} in dashed line. VL, E_F and HOMO energies are deduced from UPS measurements, and LUMO energies are derived from charge transport gaps plus HOMO.

CuPc and the acceptor-like C_{70} increases from 0.55 eV in the planar C_{70}/CuPc bilayer (Fig. 4(a)) to 0.8 eV (Fig. 4(b)) in mixed C_{70}:CuPc BHJ. Similar results have also been observed in other metal phthalocyanine–C_{60} systems, such as C_{60}–CuPc and C_{60}–ZnPc [23,24]. As ΔE_{DA} is related to the theoretical maximum of V_{OC} in OPV cells, it is expected that the mixed C_{70}:CuPc structure can induce a larger V_{OC} than the planar C_{70}/CuPc bilayer.

To validate the above analysis, the OPV devices using a planar C_{70}/CuPc bilayer and a mixed C_{70}:CuPc BHJ as the photoactive area were fabricated and compared. The OPV cells have a structure of ITO/CuPc (200 Å)/C_{70} (400 Å)/Bphen (100 Å)/LiF (5 Å)/Al (1000 Å) and ITO/CuPc (150 Å)/CuPc:C_{70} (150 Å)/C_{70} (300 Å)/Bphen (100 Å)/LiF (5 Å)/Al (1000 Å), respectively, where Bphen (4,7-diphenyl-1,10-phenanthroline) is used as exciton blocking layer, and LiF/Al as a bilayer cathode. Fig. 5 shows the *J*–*V* characteristics measured under simulated AM 1.5G solar illumination with an incident intensity of 100 mW/cm^2, and the parameters of the cells are summarized in Table 1. As evident in Fig. 5, the V_{OC} dramatically increased from 0.35 to 0.46 V with respect to the replacement of the C_{70}/CuPc bilayer with C_{70}:CuPc BHJ. In addition, J_{SC} of the cell with a C_{70}:CuPc BHJ is almost 2 times larger than that with a C_{70}/CuPc bilayer, resulting in a higher η_P of 1.51%. The results observed in Fig. 5 and Table 1 are consistent with the trend observed in Fig. 4, confirming the influence of the electronic structure at DA interface on the device performance.

It has been reported that the ΔE_{DA} increase in the C_{60}:CuPc BHJ was affected by the underlying substrate work function and charge transfer between two molecules [23], whereas the ΔE_{DA} increase for C_{60}:ZnPc system was attributed to the relatively small energy level bending

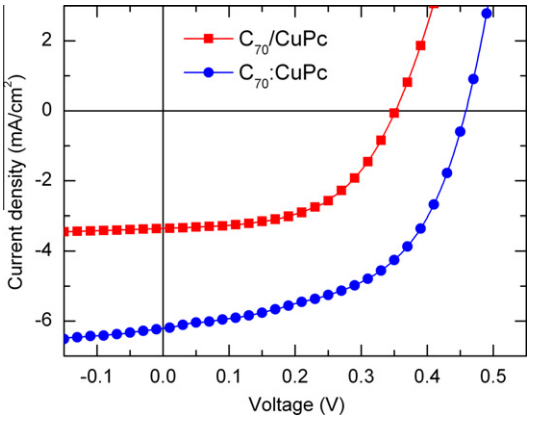

Fig. 5. Comparison of current density vs. voltage characteristics of the OPV cells with a C_{70}/CuPc bilayer (solid squares) and a C_{70}:CuPc BHJ (solid circles) under simulated AM1.5G solar illumination of 100 mW/cm^2.

Table 1
Structure and performance comparison of OPV cells incorporating a C_{70}/CuPc bilayer and a C_{70}:CuPc BHJ as the photoactive region, respectively, under AM1.5G simulated solar illumination with an intensity of 100 mW/cm^2.

Device configuration	V_{OC} (V)	J_{SC} (mA/cm^2)	FF	η_P (%)
ITO/CuPc (200 Å)/C_{70} (400 Å)/Bphen (100 Å)/LiF (5 Å)/Al (1000 Å)	0.35	3.35	0.55	0.64
ITO/CuPc (150 Å)/CuPc:C_{70} (150 Å) /C_{70} (300 Å)/Bphen (100 Å)/LiF (5 Å)/Al (1000 Å)	0.46	6.21	0.53	1.51

and doping effects (electron transfer from ZnPc to C_{60}) [24]. However, the observed difference in ΔE_{DA} between C_{70}/CuPc bilayer and C_{70}:CuPc mixture in Fig. 4(a) and (b) cannot be explained by the proposed mechanisms for C_{60}–CuPc or C_{60}–ZnPc systems. As shown in Fig. 4(b), the absence of a strong charge transfer in the C_{70}–CuPc couple suggests that the flat energy level lineup in the C_{70}:CuPc BHJ is different from the energy level bending occurring in C_{60}:CuPc and C_{60}:ZnPc. This can be understood in term of ΔE_{DA}. Since the CuPc HOMO level is 0.8 eV lower in energy than the C_{70} LUMO (see Fig. 4(b)), an energy barrier of 0.8 eV has to be overcome for charge transfer from CuPc to C_{70}. Moreover, the ΔE_{DA} increase in C_{70}:CuPc BHJ is because the energy level positions of C_{70} in the mixed layer differ from those in a bilayer structure, possibly due to the different polarizabilities of C_{70} and CuPc molecules in the mixed layer from that of pure films [34].

3.4. Thermal annealing effect on the electronic properties of mixed C_{70}: CuPc BHJ

To improve the performance of BHJ OPV cells, thermal annealing is extensively employed to modify the morphology and molecular arrangements of BHJs for governing the balance between exciton dissociation and charge transport property [2,10]. It has been revealed that annealing treatment at various temperatures results in lateral or vertical phase separation with different molecular arrangements in the BHJ [2,3,9,35]. Besides its influence on the morphology change, it is of importance to clarify the effect of thermal annealing on the electronic properties of mixed DA BHJ, e.g., C_{70}:CuPc.

Fig. 6 shows the HeI UPS spectra recorded from a 100 Å-thick C_{70}:CuPc BHJ after annealing treatment at different temperatures for 30 min. Fig. 6(a) and (b) display the zoom-in plots of the VL and HOMO regions. The bottom spectrum in Fig. 6 is the same as that of 100 Å-thick C_{70}:CuPc mixture in Fig. 3. To accurately distinguish the spectral contributions of C_{70} and CuPc to that of the C_{70}:CuPc mixture, the HOMO regions of UPS spectra (Fig. 6(c)) are fitted with the spectral line shapes of pure CuPc and C_{70} as used in Fig. 3. Relative to the spectral intensity of pure C_{70} and CuPc, the contribution ratio of C_{70} to CuPc is determined as shown in Fig. 3(c). It is evident that the spectral contribution of C_{70} to the C_{70}:CuPc mixture is gradually attenuated with increasing annealing temperature. However, increasing annealing temperature does not result in a shift of VL or HOMO, and thus the energy level offsets between C_{70} and CuPc remain almost constant during the thermal annealing process.

Fig. 7 displays the normalized XPS C1s core level spectra of the mixed C_{70}:CuPc layer annealed at different temperature, which are least-squares fitted with individual subspectra of CuPc (dashed area) and C_{70} (shadowed area) components to fit the C1s photoemission data. As depicted in Fig. 7, thermal annealing does not cause the appearance of additional component or the shift of spectral features in the C_{70}:CuPc mixture except for a continuous increase of CuPc peak intensity relative to that of C_{70} component, which is consistent with the UPS measurements (see Fig. 6). According to the decomposition of XPS C1s spectra, the C_{70} to CuPc molecular ratios at the C_{70}:CuPc surface upon different annealing temperatures can be obtained by comparing the integrated peak areas of C_{70} to CuPc as well as taking into account the number of carbon atoms per molecule. As summarized in the inset of Fig. 7, the C_{70}-to-CuPc molecular ratio is estimated to be ~1.2:1 for as-grown C_{70}:CuPc mixture, and decreases with increasing annealing temperature. As the XPS signals represent a weighted average collected from the sample surface, the lateral changes of the molecular ordering or morphology will not significantly influence the relative intensity change as observed in Fig. 7. The results in Figs. 6 and 7 are similar to the C_{60}:CuPc system [25], implying an annealing-induced vertical phase separation into a CuPc-rich region near the surface and a C_{70}-rich region adjacent to the substrate in the C_{70}:CuPc mixture. As previously proposed, the difference in the surface energy of CuPc and C_{70} might be the major factor contributing to the vertical segregation of components in the annealed mixture [25,36].

It has been reported that V_{OC} in C_{70}-involved BHJ OPV cells was increased after annealing [18]. As demonstrated in Figs. 6 and 7, thermal annealing has little effect on the electronic structures, especially ΔE_{DA}, of the C_{70}:CuPc BHJ, indicating that the theoretical maximum of V_{OC} remains unchangeable. Therefore, the increase in V_{OC} after annealing cannot be attributed to the change in ΔE_{DA}, rather it proba-

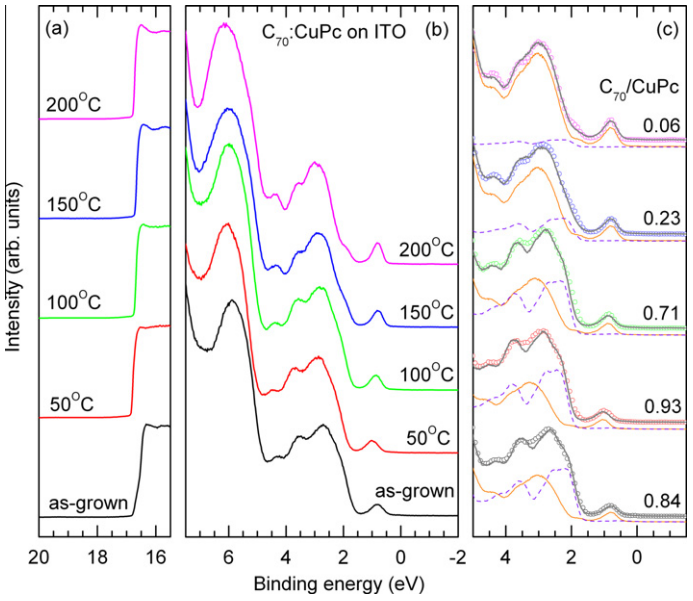

Fig. 6. UPS spectra of C_{70}:CuPc BHJ on ITO substrate upon thermal annealing with different temperatures. (a) VL region, (b) HOMO region, and (c) spectral decomposition.

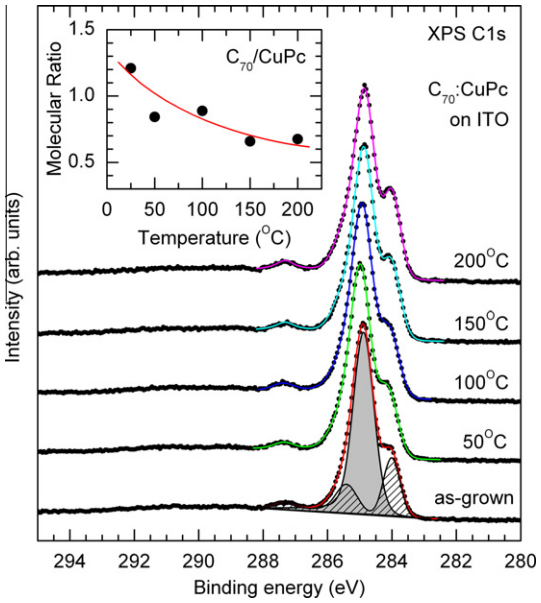

Fig. 7. XPS C1s core level spectra obtained upon thermal annealing of C_{70}:CuPc BHJ at various temperatures. Solid lines represent resultant fitting curves on the experimental date. bly arises from the decrease of cell series resistance. The major contributions to cell series resistance include the bulk resistances of organic materials and electrodes, and their contact resistance. An interpenetrating network of spatially distributed CuPc and C_{70} domains is formed during the annealing process, due to the spherical shape of the C_{70} molecules that allows close packing [35]. Consequently, the crystalline domains provides percolating pathways for the transport of dissociated holes and electrons to the respective electrodes, leading to the decrease of the cell series resistance. Still, more work is required to clarify the relation among ΔE_{DA}, V_{OC}, and cell series resistance.

4. Conclusions

The detailed electronic structures of planar C_{70}/CuPc bilayer and mixed C_{70}:CuPc BHJ have been studied by photoemission spectroscopy. The planar C_{70}/CuPc and mixed C_{70}:CuPc heterojunctions exhibit significantly different energy level alignments. The energy offset between donor-like CuPc HOMO and acceptor-like C_{70} LUMO is increased from 0.55 eV in the bilayer structure to 0.8 eV in the mixed BHJ. This increase is consistent with a V_{OC} enhancement in the OPV cells, and is possibly associated with the polarizability changes of C_{70} and CuPc molecules in the mixed materials. The influence of thermal annealing on the mixed C_{70}:CuPc heterojunction is also investigated, revealing annealing-induced vertical phase separation with compositional gradient along the cross-section. These results reported here are beneficial to the design of OPV cells with C_{70} as the acceptor.

The similar idea of stacked OLED/OPV devices has also been explored for possible application in optical sensor and energy-circle optoelectronic components using ambient illumination, though such integration still faces some challenges [12–15]. One of them is to achieve an optical matching between the spectral responsivity of the OPV cell and the EL emission spectrum of the OLED in the integrated device. In other applications, when the OPV cell in an OLED/OPV structure is operated based on the absorption of the light emitted from the OLED component for application in optical sensors, it is then desired that the spectral responsivity of the photovoltaic component matches with the EL emission spectrum of the OLED [13]. The sensor platform technology, based on an integration of organic light transmissible devices, such as an OPV cell and an OLED with polymer waveguides [14], provides significant cost benefit as well as the functional superiority for application in low cost bioassay device, sign monitoring, and compact information systems.

We report here our efforts to develop a high performance organic optoelectronic device through the integration of a front semitransparent OPV cell [6,16,17] with a bottom OLED. In the integrated functional OPV/OLED systems, the photoactive materials used in the OPV cell are chosen in such a way that the OPV component has a very low absorption in the wavelength region of the light emitted by the integrated OLED unit. The front OPV cell is transparent to the EL emission of the underneath OLED. In this work, an 8-tris-hydroxyquinoline (Alq_3):10-(2-benzothiazolyl)-1,1,7,7-tetramethyl-2,3,6,7-tetrahydro-1H,5H,11H(1)benzopyrano(6,7,8-ij)-quinolizin-11-one (C545)-based OLED and a zinc phthalocyanine (ZnPc): fullerene (C_{60})-based OPV cell were used for fabrication of the integrated OPV/OLED device. Alq_3:C545-based OLED has a peak EL emission at ~530 nm, while the spectral response of ZnPc:C_{60}-based OPV cell has a very low photoresponse at the same wavelength, but relatively high absorption over the visible light wavelength range. Hence, the combination of a ZnPc:C_{60}-based semitransparent OPV cell and an Alq_3:C545-based OLED in an integrated OPV/OLED structure allows the light emitted from the OLED unit to pass through the front OPV cell without significant loss.

The integrated device was fabricated on an indium tin oxide (ITO) glass substrate with a sheet resistance of 12 Ω/sq. The organic and electrode materials were thermally evaporated in a vacuum system having a base pressure $<10^{-6}$ mbar. The ITO substrates were subjected to an O_2 plasma treatment at 100 W for 10 min. The OPV cell consists of a co-evaporated ZnPc:C_{60} layer (35 nm), a C_{60} acceptor layer (25 nm), a BPhen exciton-blocking layer (7 nm) and a semitransparent Ag cathode layer (30 nm). The Ag cathode was then modified with CF_X plasma, forming a plasma-polymerized CF_X fluorocarbon layer (~1 nm). The surface of the CF_X-modified Ag serves as an anode contact for the OLED [18]. The OLEDs consist of a *N*,*N*′-bis(l-naphthyl)-*N*,*N*′-diphenyl-1,l′-biphentl-4,4′-diamine (NPB) layer (55 nm), an emitting layer of Alq_3 doped with C545 (0.8%), and an electron-transporting layer of undoped Alq_3. Finally, a 150 nm thick of Al electrode was deposited on the organic layers through a shadow mask that defines an active area of 3 mm × 3 mm. The *J*–*V* characteristics of the OPV cells were measured using an AM1.5G solar simulator, calibrated by a KG-5 filtered photodiode.

In order to achieve an efficient light output, a microcavity OLED (MOLED) was used in the integrated device in order to achieve a narrow emission spectrum [19,20] to maximize the light output through the front semitransparent OPV cell. An optimization of the structure of semitransparent-OPV/MOLED thin film system was investigated. From optical point view, an integrated OPV/MOLED device can be considered as a multi-layer thin film system composed of absorbing and non-absorbing materials. Optical admittance analysis was utilized to optimize various parameters for enhanced light absorption in the front semitransparent OPV cell and output of the emitted light by the underneath MOLED. For a multilayered thin film system with m layers, assuming normal incidence, the total transmittance, $T(\lambda)$, of these m layers can be expressed as [21,22]:

$$T(\lambda) = [1 - R(\lambda)] \prod_{j=1}^{m} \Psi_j, \tag{1}$$

where $R(\lambda)$ is the total reflectance, and Ψ_j is the ratio of the real parts of the effective optical admittance for $(j+1)$th and jth layers, the net absorptance of the jth layer, $A_j(\lambda)$, in an m layered structure can be determined by:

$$A_j(\lambda) = \left[1 - R(\lambda)\right]\left[1 - \Psi_j(\lambda)\right] \prod_{i=1}^{j} \Psi_i. \tag{2}$$

Therefore the optical properties and optimal structure of a semitransparent-OPV/MOLED device can be investigated by applying optical admittance analysis technique, using Eqs. (1) and (2). This method has been applied successfully for the design of semitransparent heterojunction OPV cells [6,17]. In this work, the wavelength dependent refractive indices of indium tin oxide (ITO) and organic semiconducting layers in the semitransparent-PV/MOLED system were measured using the variable angle spectroscopic ellipsometry. An optimal structure of ZnPc:C_{60} (35 nm)/C_{60} (25 nm)/4,7-diphenyl-1,10-phenanthroline (Bphen) (7 nm)/Ag (30 nm)/CF_X /NPB (55 nm)/Alq_3:C545(25 nm)/Alq_3 (25 nm)/LiF (0.7 nm)/Al (150 nm) was thus optimized to enhance the absorption in the front semitransparent OPV cell and high output of the emitted light by the MOLED unit at 530 nm.

In addition to the device design and the materials selection, an optical transparent and electrical conductive inter electrode that functions simultaneously as a cathode for the front semitransparent OPV cell and an anode for the MOLED unit plays a critical role in determining the device performance. An ultra-thin plasma-polymerized fluorocarbon film (CF_X)-modified silver interlayer (Ag/CF_X) was used to vertically connect the front OPV cell and the rear MOLED unit. An Ag/CF_X bi-layer has been applied for making high performance top-emission OLEDs [18] and can be made easily without causing damage to the underlying organic layers. An optical admittance analysis was used to study the optical properties and optimize the structure of the semitransparent-OPV/MOLED devices. The performance

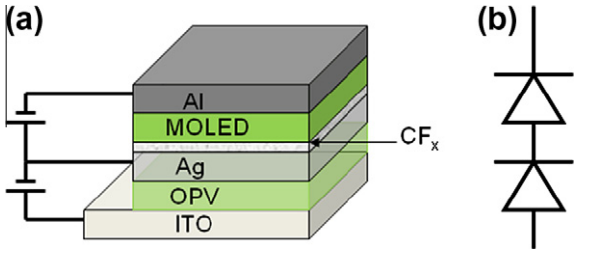

Fig. 1. Device structure and circuitry diagram of the device components. (a) Schematic diagram of an integrated OPV/MOLED device, with a layer configuration of glass/ITO/ZnPc:C_{60} (35 nm)/C_{60} (25 nm)/Bphen (7 nm)/Ag (30 nm)/CF_X/NPB (55 nm)/Alq_3:C545 (25 nm)/Alq_3 (25 nm)/LiF (0.7 nm)/Al (150 nm). (b) A schematic equivalent circuitry of the integrated device.

of the OLED and OPV components in the stacked devices was shown to have a luminous efficiency of 11.5 cd/A operated at 4.5 V and a PCE of 3.30%, achieving as high as 88% of the performance measured for the discrete control OPV cell. A cross sectional view of the structure of the integrated device is shown in Fig. 1(a). A schematic equivalent circuitry of the semitransparent-OPV/MOLED device is illustrated in Fig. 1(b).

The incident photon to current conversion efficiency (IPCE) measured for the semitransparent OPV cells and the EL spectra measured for the MOLEDs in the integrated device are plotted in Fig. 2(a). ZnPc:C_{60}-based semitransparent OPV cells thus fabricated have an optical transparency of >70% at 530 nm, allowing the emitted light from the bottom MOLED with a peak EL wavelength of 530 nm to pass through with a very low absorption lost. As shown in Fig. 2(a), the emission peak from the MOLED complementarily falls within the valley of the IPCE spectrum of the front semitransparent OPV cell. Such a result is achieved through an optical and optimal design of the device structure.

The results of the effect of the Ag interlayer thickness on the normalized absorbance of the front OPV cell and luminous efficiency of MOLED in the integrated device, with the normalization taken reference with the control OPV and MOLED devices, are presented in Fig. 2. The luminous efficiency of an OLED without microcavity structure is about 45%, as depicted by the dash line in Fig. 2(b). The calculation results indicate that the maximum luminous efficiency of the MOLED in the integrated devices can be achieved at an Ag interlayer thickness of 20 nm. On the other hand, the maximum light absorption by the front semitransparent OPV cell occurs when the thickness of the Ag layer is over 60 nm. A shaded region as depicted in Fig. 2(b) corresponds to the required Ag interlayer thickness to achieve high light absorption by the front semitransparent OPV cell and the high luminous efficiency of the rear MOLED in the integrated device. Based on the simulation results, an Ag interlayer thickness of 30 nm was selected as an optimal solution, corresponding to a light absorbance in the front OPV cell equivalent to 97% of a control OPV cell and, a luminous efficiency of a rear MOLED equivalent to 86% of a control MOLED, respectively.

The results of simulated and measured EL spectra obtained for a normal OLED, a discrete MOLED and an MOLED in the integrated devices are shown in Fig. 3(a) and (b). The wavelength of peak emission by the MOLED in the integrated device is located at 521 nm, which is hypsochromically shifted from 526 and 531 nm, the emission wavelengths for the single MOLED and the OLED, respectively. The full width at half maximum (FWHM) of the emission band is 33 nm, which is the same as that for the control MOLED and smaller than 58 nm for a conventional OLED.

The current density–voltage (J–V) characteristics of the OPV in the integrated device as well as that for a control cell, measured under air mass 1.5 global (AM1.5G) irradiation of 100 mW/cm^2, are shown in Fig. 4(a). The control cell, with a configuration of glass/ITO/ZnPc: C_{60}(35 nm)/C_{60}(25 nm)/Bphen(7 nm)/Ag(100 nm), was fabricated for comparison studies. The control device shows a PCE of 3.76%, a fill factor (FF) of 58.9% and a short-circuit current density (J_{SC}) of 11.4 mA/cm^2. The corresponding values for the upper OPV cell in the integrated semitransparent-OPV/MOLED device are 3.30%, 57.2% and 10.5 mA/cm^2. The open circuit voltages (V_{OC}) measured for the front OPV cell in the integrated device is the same as

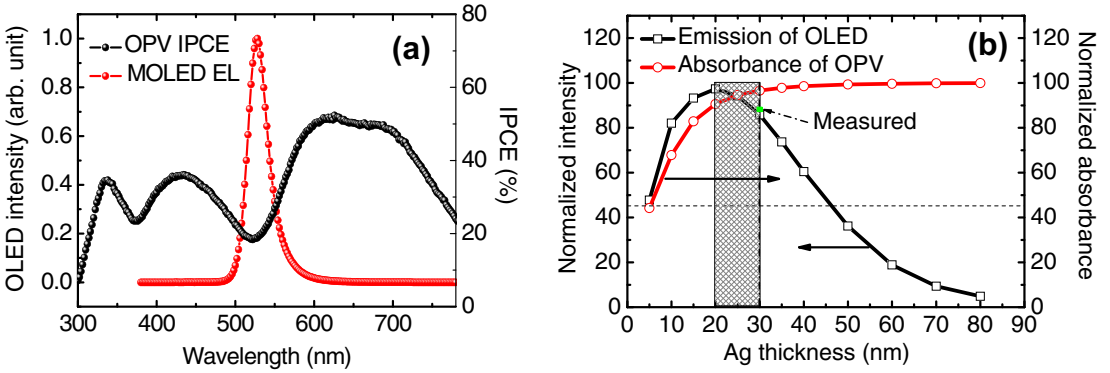

Fig. 2. Spectral response and electroluminescence characteristics of the device. (a) IPCE and EL emission spectra measured for the semitransparent OPV cell and the MOLED in the integrated device. (b) Calculated results showing the effect of Ag interlayer thickness on absorbance and emission of the integrated device (normalization is taken with reference to a discrete MOLED and a semitransparent OPV cell having identical structures used in the integrated device). The dash line refers to the normalized luminous efficiency measured for a normal OLED, which is equivalent to 45% of an MOLED.

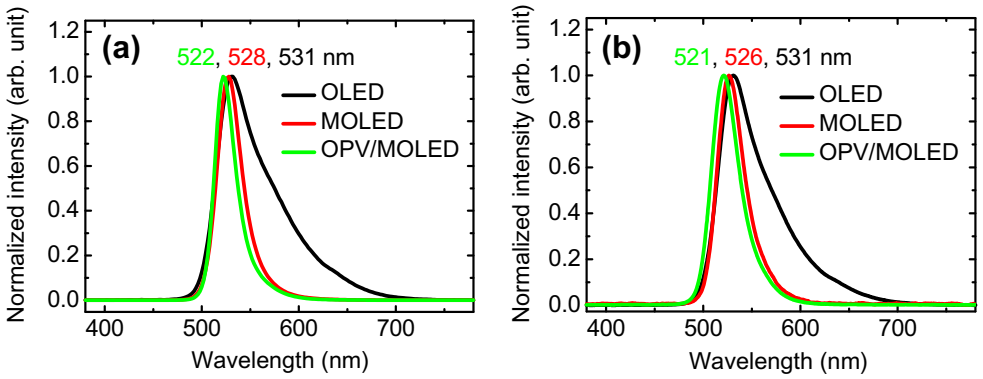

Fig. 3. Electroluminescence of OLEDs. (a) Simulated EL spectra obtained for a set of structurally identical light emitting diodes of a normal OLED, a discrete MOLED and an MOLED in an integrated device. (b) EL spectra measured for a normal OLED, a discrete MOLED and an MOLED in an integrated device.

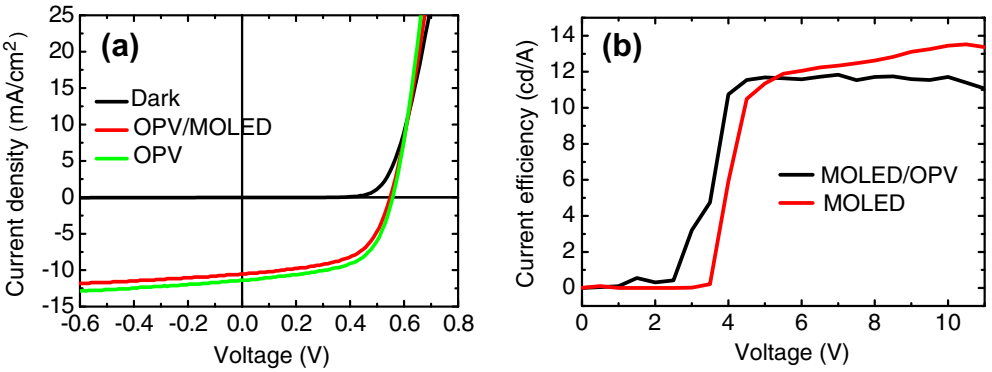

Fig. 4. Power conversion and luminous efficiency of the device, (a) *J–V* characteristics measured for a control OPV cell and a semitransparent OPV cell in the integrated device under AM1.5G. (b) Luminous efficiency measured for a control MOLED and an MOLED in the integrated MOLED/OPV device.

Table 1
A summary of luminous efficiency measured for a control MOLED and an MOLED in the integrated OPV/MOLED device at 4.5 V, and photovoltaic characteristics measured for a control OPV and a front semitransparent OPV in the integrated OPV/MOLED device under AM1.5G irradiation.

Device	EL peak position (nm)	FWHM (nm)	Luminous efficiency (cd/A)	
Control MOLED	526	32	10.5 (at 4.5 V)	
OPV/MOLED	521	33	11.5 (at 4.5 V)	
	V_{OC} (V)	FF (%)	J_{SC} (mA/cm^2)	PCE (%)
Control OPV	0.56	58.9	11.4	3.76
OPV/MOLED	0.55	57.2	10.5	3.30

the control device. It is interesting to note that the PCE obtained for the integrated device is as high as 88% of that for the reference OPV cell, labeled as "Measured" in Fig. 2(b). The results of the luminous efficiency measured for a discrete MOLED and an MOLED in the integrated device are given in Fig. 4(b). The luminous efficiency of the rear MOLED unit in the integrated device achieves 11.5 cd/A as compared to that of 10.5 cd/A for a control MOLED at 4.5 V, as shown in Fig. 4(b). Table 1 lists a summary of luminous efficiency measured for a control MOLED and an MOLED unit in the integrated OPV/MOLED device, as well as the photovoltaic characteristics measured for a control OPV and a front semitransparent OPV unit in the integrated OPV/MOLED device. The functional semitransparent-OPV/MOLED, based on an integration of organic light transmissible devices thus demonstrated, has the potential to create an organic optical sensor system capable of providing the power by absorption of the ambient illumination by the front semitransparent OPV cell. The accomplishment of this work would help to develop an organic sensor platform technology for application in organic electronics including organic optical switches and other organic photonic logic circuits.

In conclusion, a high performance integrated organic electronic device comprises of a ZnPc:C_{60}-based semitransparent OPV cell and an Alq_3:C545-based OLED was demonstrated. The front OPV cell is highly transparent to the emitted light from the underneath OLED unit. It serves as an ambient light absorbing coating to improve the optical signal/noise contrast of the OLED. The integrated functional semitransparent-OPV/OLED device possesses both a high power conversion efficiency of 3.30% measured under AM1.5G irradiation and a high luminous efficiency of 11.5 cd/A operated at 4.5 V.

as $CuInS_2$ and CdSe, the organic and inorganic phase are expected to contribute differently to charge carrier generation [9,14,15]. The resulting distribution of the carrier concentration and, consequently, the driving forces experienced by the charge carriers will be strongly dependent on the position within the device. In the organic phase, light absorption gives rise to the formation of excitons. As in all purely excitonic solar cells [1–3,16,17], these excitons need to diffuse to the heterojunction interface within their lifetime in order to dissociate into free charges. In the instant of dissociation, the hole remains in the organic phase, while the electron resides in the inorganic material. Then, a strong gradient in the chemical potential drives electrons and holes away from the exciton dissociation interface; in doing so, this gradient complements the action of the built-in voltage within the organic phase [18]. In the inorganic semiconductor, on the other hand, electron–hole pairs are photo-generated and separated directly in the bulk wherever a non-vanishing electric field is present. The such generated electrons and holes reside in the same material (i.e., chemical phase) and have a similar spatial distribution. Thus, the gradient of the chemical potential drives carriers in the same direction rather than selectively to the cathode or anode, respectively [18]. It is the interplay between this diffusional motion and the carrier drift due to the electric field that determines the output characteristic of the devices. Major processes determining the cell operation such as carrier separation, recombination, and transport, be that in the bulk or at the interface, have, at least in part, these driving forces in common. These forces depend, of course, on material-related transport parameters such as the carrier mobility μ and the static relative dielectric constant ϵ_r.

The values of these parameters that can be possibly achieved in inorganic materials are much larger than those associated to the organic materials. The values of ϵ_r for small band-gap inorganic materials exceed 8.0 in the crystal [12,13]; in some cases, such as PbS, also values beyond 100.0 can be reached. For typically employed organic materials, on the other hand, the values of ϵ_r range from 2.5 to ca. 4.0 [19,20].

In all hybrid inorganic–organic solar cells, the inorganic component nominally serves as electron transporting material due to low injection barriers towards common cathode materials and electron mobilities exceeding 250 $cm^2/V\,s$ in bulk samples [12]. When going to thin films, the electron mobility drops by at least an order of magnitude (e.g., $\mu_{Hall} = 30\ cm^2/V\,s$ at 300 K for CdS [21]) due to the presence of grain boundaries [21], local variations in stoichiometry, and impurities [22]. Nevertheless, such electron mobilities surpass the highest reported values for organic semiconductors, i.e., $\mu_{FET} = 3\ cm^2/V\,s$ for a perylene diimide single crystal [23]. The highest hole mobility value reported for organic semiconductors is $\mu_{FET} = 20\ cm^2/V\,s$ for a rubrene single crystal [24].

There has been considerable theoretical effort in elucidating the role of the carrier mobility in purely excitonic solar cells [25–31]. Macroscopic simulations based on a drift–diffusion model demonstrated the profound impact of the carrier mobility [27,28] and, more specifically, its field-dependence [25,26] on the *I–V* curve. As another quantity, that strongly depends on the carrier mobilities and ϵ_r, the bimolecular recombination rate was shown to be of significant importance for the understanding of the behavior of the devices [18,27]. The extent to which this rate influences the *I–V* characteristic was shown to depend on the heterojunction morphology, i.e., whether recombination occurs in a perfectly blended (i.e., effective medium) [28], in a partially blended [27], or an entirely phase-separated system [18,25]. Microscopic simulations have been employed to describe the interplay of carrier generation, recombination mechanisms, and transport processes in a given heterojunction geometry at a consistent level of theory [29–31]. Such studies point out that the device efficiency is predominantly determined by the *ratio* μ_p/μ_n of the majority carrier mobilities in their respective preferentially conducting material rather than being influenced by the absolute values of the mobilities [29–32]. Moreover, these works jointly state that any mismatch between the carrier mobilities, i.e., any ratio μ_p/μ_n differing from unity, detrimentally affects the PCE of the solar cell.

The scope of this work is to theoretically investigate the impact of the charge carrier mobilities μ and the dielectric constants ϵ_r on the operation of organic–small band gap inorganic hybrid devices. We particularly focus on comprehending the influence of the two distinct carrier generation mechanisms on the subsequent charge carrier transport and, hence, on relevant device output parameters, i.e., the open circuit voltage, V_{oc}, the short circuit current, j_{sc}, the shape of the *I–V* characteristic, and the power conversion efficiency (PCE). In addition to μ and ϵ_r, also the transport levels can be considered as material-related transport parameters. We demonstrated in a previous work, that the offset between hole transport levels (or the lack thereof) crucially influences the shape and V_{oc} of the *I–V* characteristic [15]. The inclusion of the transport level *offsets* into our study is, thus, pivotal to achieve a more detailed understanding of the relation between the material properties and the driving forces of the photocurrent. One major challenge in this context is to discriminate between the various effects that might be caused by changes in μ and ϵ_r; these two parameters were demonstrated to enter a subtle interplay of field-dependent mobilities, recombination rates, generation-, as well as morphology-determined processes in excitonic solar cells [25–32]. To conveniently monitor quantities and processes that depend on μ and ϵ_r, we utilize a two-dimensional drift–diffusion approach [15] rather than a microscopic description. In the framework of such a model, the generation of charges and its dependence on the heterojunction morphology can be controlled by introducing a spatially dependent generation rate. To further separate possible influences of the field-dependent mobilities and the recombination rates on the *I–V* curve from morphology-determined processes, we will concentrate on transport in a bilayer structure. The impact of the heterojunction geometry and the nature of the contacts, both representing two major efficiency-limiting factors, has already been studied in detail elsewhere [15].

Below, we will first introduce the details of the model. Then, a representative set of material parameters is presented that allows us to comprehensively study the extent to which changes in μ and ϵ_r (i) depend on the generation

mechanism and (ii) affect the I–V curves due to field-dependent mobilities and altered recombination rates. Based on the leading effects identified to that point, we will analyze different (fictitious) level alignment situations and, finally, heterojunctions formed by actual materials.

2. The device model

2.1. Model equations

To get a deeper understanding of the device behavior due to variations (i) of the transport level offsets between the donor and acceptor material and (ii) of the mobility and dielectric constants in the light of the interplay of bulk and interface carrier generation, a drift–diffusion model for the simulation of carrier transport in a two-dimensional device cross-section is proposed. Such a two-dimensional model offers, in principle, the possibility to regard the actual geometry of the heterojunction. The modeled cross-section, shown in Fig. 1(a), comprises a 100×100 nm active area containing the two semiconducting materials. Throughout this work, a flat heterojunction is placed at the center of the cell parallel to the electrodes (dotted line in Fig. 1(a)). In all devices considered in this work, ohmic contacts were assumed (cf. Appendix). Due to this choice of contacts, the carriers are instantaneously abstracted from the device when reaching the contact-semiconductor interface. The details of the system of model equations (comprising the continuity, current density, and Poisson equation) and the determination of the incoming photon flux $\Phi(\mathbf{r})$ are shown in Appendix.

For each position of the device, a generation $\mathbf{G}(\mathbf{r})$ rate needs to be specified to account for the appropriate generation mechanism. Upon photon absorption, charges are generated (i) indirectly via exciton formation in the organic phase and dissociation at the heterojunction and (ii) directly throughout the inorganic material. In order to get an overall understanding of the role of the two generation mechanisms, we explicitly introduce two scenarios that yield the boundaries of the possibly generated number of charge carriers, i.e., an upper limit and a lower limit. In both limits, incoming light is assumed to directly generate charge carriers. The upper limit can be expressed as

$$G_{(n,p)}(\mathbf{r}) = \Phi(\mathbf{r}) \tag{1}$$

with $\mathbf{r} = (x_i, y_j)$ being a discrete grid point anywhere within the device. Keeping in mind that our device is separated in two different parts (A: acceptor, D: donor) with different intrinsic parameters, a generation confined to the inorganic phase yields the following expression for the lower limit:

$$G_{(n,p)}(\mathbf{r}) = \begin{cases} 0 & \mathbf{r} = (x_i, y_j) \in D \\ \Phi(\mathbf{r}) & \mathbf{r} = (x_i, y_j) \in A. \end{cases} \tag{2}$$

Here, we assume that the charge carrier generation is driven thermodynamically in the inorganic phase due to low exciton binding energies [12]. Beyond these limiting cases, our model is capable to consider the actual carrier generation due to exciton formation in the bulk of the organic phase. The associated method aiming at modifying G due to exciton migration and dissociation at the *heterojunction* is shown in detail elsewhere [15]. Note that field-assisted exciton dissociation rates as introduced in [33,34] and used in [35,36], i.e., the possibility to generate carriers from excitons in the *bulk* of the organic phase, were not taken into account.

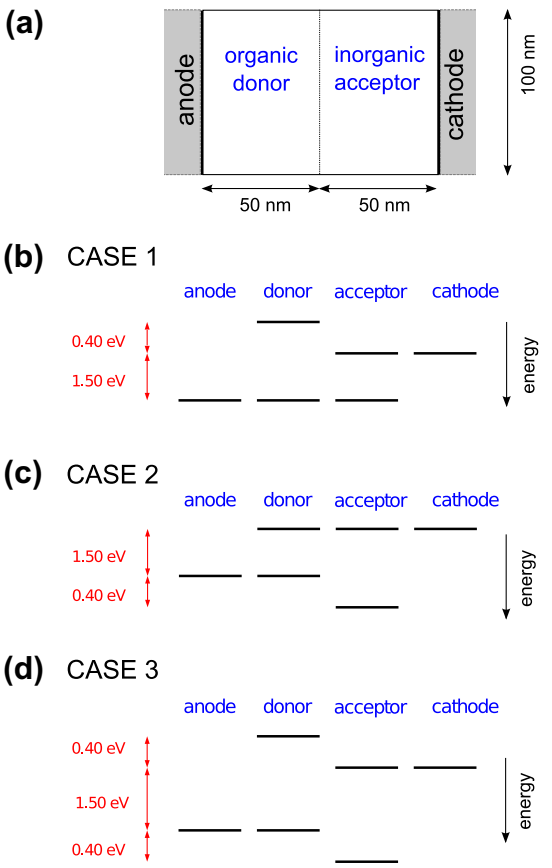

Fig. 1. (a) Schematic cross-section of the device containing the modeled area (solid rectangle), the location of the heterojunction (dotted line), and the location of the boundaries associated to Ohmic contacts (bold black lines). (b–d) Illustration of the energetic alignment of the transport levels for the model systems studied in this work. (b) Case 1, vanishing hole transport level offset ($\Delta E_p = 0$, $\Delta E_n = 0.4$ eV) (corresponds to P3EBT/$CuInS_2$). (c) Case 2, vanishing electron transport level offset ($\Delta E_p = 0.4$ eV, $\Delta E_n = 0$). (d) Case 3, equally set off transport levels $\Delta E_p = \Delta E_n = 0.4$ eV.

Also in the case of charge carrier recombination a distinction between the organic and the inorganic phase is necessary. The bimolecular charge carrier recombination in organic material is expressed by a Langevin-type rate

$$R_{(n,p)}(\mathbf{r}, \mathbf{E}, t) = k_r(\mathbf{r}, \mathbf{E}) n(\mathbf{r}, t) p(\mathbf{r}, t) \tag{3}$$

where the recombination rate constant k_r is given by [37]

$$k_r(\mathbf{r}, \mathbf{E}) = \frac{q}{\epsilon(\mathbf{r})} \left[\mu_n(\mathbf{r}, \mathbf{E}) + \mu_p(\mathbf{r}, \mathbf{E}) \right] \tag{4}$$

Recent investigations of the validity of this recombination rate quantitatively demonstrate how the relationship $k_r(\mu)$ depends on the structure of the material at the nanoscale [29]. Assuming a bimolecular recombination rate being proportional to $n(\mathbf{r}, t) p(\mathbf{r}, t)$, k_r according to Eq. (4)

represents the upper limit [29]. However, the overall deviation of k_r expressed by Eq. (4) from the actual value, that is known from microscopic simulations, becomes minimal for the ratio μ_e/μ_h of unity [29,38], i.e., the ratio that is used throughout this study (*vide infra*). Note that this ratio μ_e/μ_h must not be confused with the ratios $\mu_e^{\text{inorganic}}/\mu_e^{\text{organic}}$ and $\mu_h^{\text{inorganic}}/\mu_h^{\text{organic}}$, respectively. Reduced recombination rates as described by Deibel et al. [28,39] or Arkhipov and co-worker [40] were not taken into account.

Finding an appropriate description for the recombination in the inorganic phase is more involved, since the morphology of the inorganic layers can strongly vary depending on the processing conditions [4,5,7,9,42]. While there are studies with single- and polycrystalline layers available [5,9,42], also an agglomeration of nanoparticles served as inorganic layer [4,7]. One can readily expect that both cases have in common that recombination is strongly influenced by the probability of electron–hole encounter, since the motion of carriers is predominantly limited by hopping. The corresponding diffusion-limited recombination rate is, thus, proportional to $n(\mathbf{r},t)p(\mathbf{r},t)$. However, to the best of our knowledge, comprehensive theoretical models that supply an accurate expression for $k_r(\mu)$ in such disordered inorganic solids are not available. Yang et al. [14] suggested that Shockley–Read–Hall (SRH) recombination can become a dominating pathway for polycrystalline layers forming inorganic heterojunctions. Such SRH-type rates rely on cross-sections that describe the capture of mobile carriers by trap states. The concept of cross-sections is based on scattering theory [43] and is, thus, inherently inappropriate for disordered materials. Moreover, the parameters entering the cross-sections are largely undetermined due to the mostly unknown number and electronic nature of the traps involved. On the other hand, "classic" Langevin k_r (i.e., Eq. (4)) have been shown to profoundly overestimate the experimentally determined recombination rates [43]. Considering the arguments above, the most straight-forward and convenient way is, therefore, to consider (i) a Langevin rate according to Eqs. (3) and (4) and (ii) to consider this rate as an upper-limit for bimolecular recombination. Even with such significantly overestimated rates, the impact of recombination is far less pronounced than the influence of other parameters under study here (*vide infra*).

The field dependence of the charge carrier mobility is given in a Poole–Frenkel form ([44]) by

$$\mu_{(n,p)}(\mathbf{r},\mathbf{E}) = {}^0\mu_{(n,p)}(\mathbf{r})\exp(\gamma\mid\mathbf{E}\mid) \tag{5}$$

with ${}^0\mu_{(n,p)}(\mathbf{r})$ denoting the mobility at zero field and the constant $\gamma = 0.5\times10^{-4}\ \mathrm{m}^{-\frac{1}{2}}\mathrm{V}^{\frac{1}{2}}$ [36].

2.2. Material properties

The major material-intrinsic parameters relevant for the carrier transport are the electron and hole mobilities, the dielectric constants, and the relative position of the electron and hole transport levels. To capture the influence of the energetic alignment of the transport levels, we propose three representative model systems, whose specific level alignment is illustrated in Fig. 1. In the first model system, Case 1, depicted in Fig. 1(b), the hole transport levels lack an offset. This level alignment corresponds to an actual heterojunction consisting of P3EBT (poly[3-(ethyl-4-butanoat)tiophene-2,5-diyl] (Fig. 2) and $CuInS_2$ [15]. Moreover, fictitious systems with degenerate electron transport levels (Case 2) and transport levels with equivalent electron and hole barrier heights (Case 3) are proposed. The transport level offsets $\Delta E_n = |E_C - E_{LUMO}|$ and $\Delta E_p = |E_V - E_{HOMO}|$ are summarized in Table 1. In addition to these three model systems, two systems combining the polymer P3HT (poly(3-hexyltiophene-2,5-diyl)) or F8T2 (poly[(9,9-dioctylflourenyl-2,7-diyl)-co-(bitiophene)]), Fig. 2, with the inorganic acceptor $CuInS_2$ were studied. Their characteristic transport level alignment is given in Table 1 as well. All further default input-parameters for the simulations are given in Table 2. Note, that a default value of $\epsilon_r = 1$ in the organic layer yields the largest possible recombination rate (cf. Eq. (4)) with respect to the dielectric constant.

The mobilities ${}^0\mu(\mathbf{r})$ are varied such that both $\mu_e^{\text{inorganic}}$ and $\mu_h^{\text{inorganic}}$ remain larger or at least equal with respect to the values of μ_e^{organic} and μ_h^{organic}. By default, the inorganic mobilities are assumed to exceed the organic mobilities by two orders of magnitudes (cf. Table 2). However, we assume that μ_e equals μ_h within a phase.

3. Results and discussions

We study the three different energetic cases listed in Fig. 1 by varying the ratio of the mobilities and the dielectric constants between the organic and inorganic phase. The ohmic contacts ensure that the built-in voltage $V_{\text{built-in}}$, given by $E_C - E_{HOMO}$, is fixed at a value of 1.5 V. Further, we will have a look at (i) the two different charge carrier generation scenarios, Eqs. (1) and (2), and (ii) at the impact of field-dependent charge carrier mobilities and recombination rates on the device performance and the shape of the *I–V* characteristic. If not denoted differently, the default input parameters for all calculations can be found in Table 2. In the last section, we apply the model

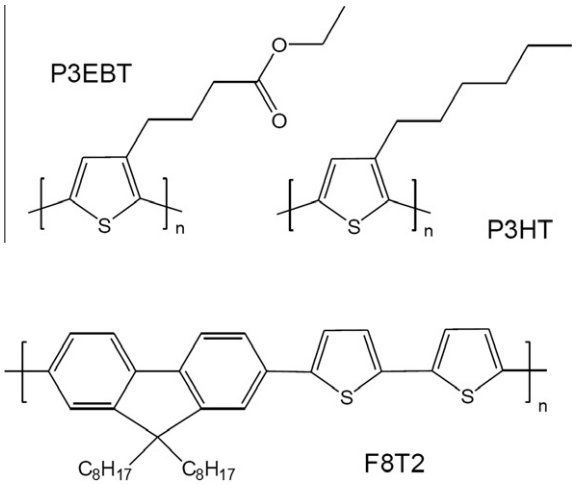

Fig. 2. Chemical structure of the polymers considered in this work.

Table 1
Energetic alignment of the transport levels for the actual and artificial materials considered in this work. The difference in the electron and hole transport levels are denoted by ΔE_n and ΔE_p, respectively.

	Case 1 (P3EBT/$CuInS_2$)	Case 2	Case 3	P3HT/$CuInS_2$	F8T2/$CuInS_2$
ΔE_n/eV	0.40	0.00	0.40	0.60	1.60
ΔE_p/eV	0.00	0.40	0.40	0.40	0.20

Table 2
Default input values of the temperature and the parameters zero-field mobility ${}^0\mu$, dielectric constant ϵ_r, and absorption coefficient α for the organic donor and the inorganic acceptor layer.

	Donor	Acceptor
${}^0\mu_n/\mathrm{cm}^2/\mathrm{V\,s}$	10^{-8}	10^{-6}
${}^0\mu_p/\mathrm{cm}^2/\mathrm{V\,s}$	10^{-8}	10^{-6}
ϵ_r	1	10
α/m^{-1}	2×10^7	2×10^7
T/K	298.15	298.15

to the three systems P3EBT/$CuInS_2$, P3HT/$CuInS_2$, and F8T2/$CuInS_2$.

3.1. Impact of generation profiles and recombination

To gain a better quantitative understanding of the interplay of charge carrier generation mechanisms that differ between the organic and inorganic materials, we discuss first two scenarios that limit the actual number of generated carriers from above and below: (i) in a best-case scenario, Eq. (1), all excitons formed in the polymer are assumed to dissociate instantaneously, i.e., all incident photons are directly converted to charge carriers. (ii) In the worst case scenario, the number of excitons that are formed and migrate towards the interface are assumed to give rise to negligible amount of mobile carriers. Thus, only carriers generated in the inorganic acceptor contribute to transport. This generation scenario is a valid lower limit due to an excitonic binding energy in inorganic materials being in the range of k_BT. Fig. 3 displays the I–V curves corresponding to the two generation scenarios in a Case 1-type device for varying mobilities μ and dielectric constants ϵ_r. During the variation of the ratio $\epsilon_r^{\mathrm{inorganic}}:\epsilon_r^{\mathrm{organic}}$, we keep the ratio $\mu_{p,n}^{\mathrm{inorganic}}:\mu_{p,n}^{\mathrm{organic}}$ at a default constant value of 10^2. Vice versa, the ratio $\epsilon_r^{\mathrm{inorganic}}:\epsilon_r^{\mathrm{organic}}$ is fixed at a value of 10 while changing $\mu_{p,n}^{\mathrm{inorganic}}:\mu_{p,n}^{\mathrm{organic}}$. In a first step (Fig. 3(a)–(d)), we omit (i) a possible field dependence of μ arising from local electric field changes and (ii) recombination effects the rate constant of which is indirectly proportional to the dielectric constant ϵ_r and directly proportional to the mobility.

A comparison of the set of curves displayed in Fig. 3(a), (b) and (c), (d) reveals that the photocurrent drops by at least a factor of ca. 4 when the carrier generation is confined to the inorganic material. The absolute value of the current density is, therefore, crucially determined by the efficiency of the charge generation in the organic material. The yield of charge carriers generated in the organic phase via exciton dissociation is limited by diffusion and therefore highly dependent on the interface structure of the solar cell [8,6,15,25]. Consequently, in the case of a flat interface as considered here, the second scenario according to Eq. (2) yields a more realistic number of photogenerated carriers than the first one, Eq. (1). When going to highly interpenetrated phases, such as observed, e.g., in polymer:PCBM blends [27,45] or nanoparticle:PCBM blends [7], carrier numbers approaching the first scenario need to be anticipated.

However, the qualitative trends in the *evolution* of the photocurrent–voltage dependence with varying transport parameters are independent from the actual generation scenario. The I–V curves change profoundly with increasing ϵ_r and μ in the inorganic phase (Fig. 3(a)–(d)). Inspecting the I–V curves in Fig. 3(b) and (d) corresponding to μ-ratios of 10^2 (squares) and 10^4 (diamonds) reveals an s-shaped section in the power quadrant. With increasing μ-ratio, this formation progresses, i.e., the slope of the curve at the inflection point becomes less steep. As can been seen further from the I–V curves in Fig. 3(c) (stars-circles), this s-shape appears to progress also with an increasing ratio of ϵ_r. Even though the I–V curves obtained for uniform generation (Fig. 3(a)) retain a diode-like shape, the maximum achievable slope in the power quadrant is reduced with increasing $\epsilon_r^{\mathrm{inorganic}}$. Such changes in the shape of the I–V curve result in photo-currents, in particular, short circuit currents j_{sc} that decrease with increasing ϵ_r- and μ-ratios. The open circuit voltage V_{oc}, on the other hand, remains (i) essentially unaffected by a change in the ϵ_r ratio and (ii) shifts only slightly towards lower values when increasing the μ-ratio (cf. curves stars-diamonds in Fig. 3(b) and (d)).

The trend in ϵ_r can be rationalized in terms of the electric field strength in the donor and acceptor phase that follows the condition $\epsilon_{\mathrm{D}}|\mathbf{E}|_{\mathrm{D}} = \epsilon_{\mathrm{A}}|\mathbf{E}|_{\mathrm{A}}$. When increasing the values of ϵ_r in the inorganic acceptor, the corresponding electric field $|\mathbf{E}|_{\mathrm{A}}$ is reduced with respect to its organic counterpart $|\mathbf{E}|_{\mathrm{D}}$. For $V_a < V_{\mathrm{oc}}$, the current density j, in particular the short circuit current density j_{sc}, decreases with increasing ϵ_r due to the smaller field in the inorganic phase (Fig. 3(a) and (c)). Values of ϵ_r as high as 10^2 limit the motion of the carriers almost to diffusion, since the drift force being proportional to $|\mathbf{E}|_{\mathrm{A}}$ becomes negligible. In the positive regime, i.e., $j > 0$, the current is determined by the amount of electrons that is able to pass the barrier of 0.4 eV into the organic phase (see Fig. 1(b)) at a given external voltage. This number is increased if the electric field $|\mathbf{E}|$ is higher in the organic than in the inorganic field phase, i.e., the ϵ_r-ratio exceeds 1:1. Beyond a certain ϵ_r-ratio, however, the electron current becomes insensitive to the actual field strength and saturates with $\epsilon_r^{\mathrm{inorganic}}$. Since this threshold is rather quickly reached, i.e., at an ϵ_r-ratio of ca. 5, j increases only slightly with increasing ϵ_r-ratio. The enhanced electric field $|\mathbf{E}|_{\mathrm{D}}$ is also responsible for the earlier onsets of the current increase and a slight increase of the open circuit voltage for higher dielectric constants.

Upon restricting generation to the acceptor, all I–V curves adopt an s-shape (Fig. 3(c) and (d)) apart from the one obtained for a μ-ratio of unity (stars). The appearance of the s-shape is due to the particular alignment of the

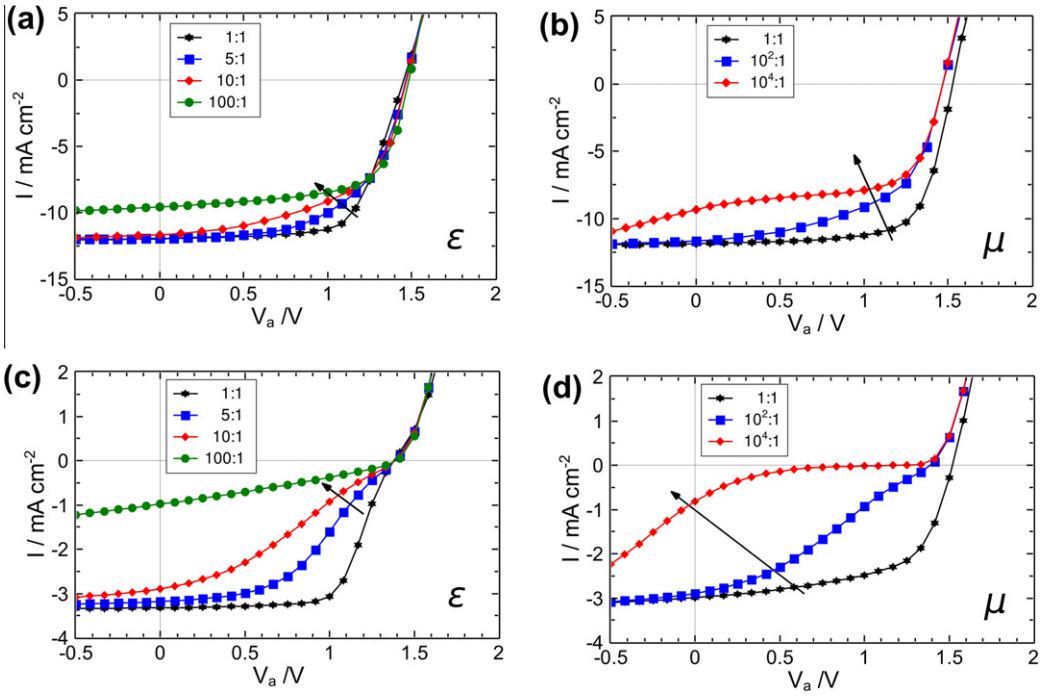

Fig. 3. *I–V* characteristics for a Case 1-type device (Fig. 1(b)) for different ratios of $\epsilon_r^{\text{inorganic}} : \epsilon_r^{\text{organic}}$ (left column) and $\mu_{(n,p)}^{\text{inorganic}} : \mu_{(n,p)}^{\text{organic}}$ (right column). Carrier generation is assumed to (i) occur homogeneously across the device (a), (b) and (ii) be confined to the inorganic phase (c), (d). The arrows indicate the evolution of the *I–V* curves with increasing ratios.

transport levels of the P3EBT/$CuInS_2$ system [15], as schematically indicated in Fig. 4(a). For biases approaching V_{oc} from below, the electric field can drive *holes* unhindered from anywhere in the device to the cathode due to the lack of an offset between the hole transport levels. This migration of holes is expected to occur even more pronounced in devices in which the energy E_V corresponding to the valence band edge of the inorganic component is less negative than the HOMO position E_{HOMO} of the organic material; such a situation is realized, e.g., in a ZnPc/n-Si hybrid solar cell [42]. However, electrons still cannot pass the energetic barrier (0.4 eV). Thus, their motion is determined by diffusion towards the cathode. As a result, electrons and holes move in the same direction and, therefore, lower the current density at voltages $V_a \approx V_{oc}$. This process is even supported by the fact, as we will discuss in detail below, that there is a higher charge carrier mobility in the acceptor phase which means that there is an *effective diffusional force* pointing from the anode to the cathode.

Increasing mobilities in the inorganic phase profoundly decreases the fill factor of the device Fig. 3(b) and (d). This is directly related to a mismatch in the hole mobilities $\mu_p^{\text{inorganic}}$ and μ_p^{organic}. Considering that diffusion is, according to the Einstein relation, determined by a diffusion constant being proportional to the mobility, holes diffuse faster through the inorganic layer than through the polymer. This spatial dependence of the diffusion constant is schematically indicated by arrows of differing lengths in Fig. 4(a). A hole located directly at the heterojunction experiences a diffusion constant being higher when facing the cathode than when facing the anode. Thus, there is an *effective diffusional force* drawing charge carriers into the inorganic phase [46]. It is important to note that this diffusion direction is not necessarily linked to the steepest gradient in carrier concentration. If the mobilities are assumed to be the same in both layers, there is no primarily preferred diffusion direction and, therefore, the motion is solely dominated by the drift term. It has to be emphasized that then also V_{oc} slightly increases (cf. Fig. 3(b) and (d)). For biases exceeding V_{oc}, the current increases due to higher mobilities in the inorganic phase.

When confining the carrier generation to the inorganic layer, any mobility ratio differing from 1:1 (i.e., $\mu_{(n,p)}^{\text{inorganic}} > \mu_{(n,p)}^{\text{organic}}$) yields an s-shape in the *I–V* characteristic (cf. Fig. 3(d)). We emphasize at this point that this particular shape arises solely due to the abovementioned diffusional advantage in the inorganic phase; neither recombination nor field-dependent mobilities were taken into account at this point.

Finally, we want to investigate to which extent the picture gained above is altered when field-dependent mobilities $\mu(\mathbf{E})$ and recombination effects R are taken into account. The situation is now more involved, since $\mu(\mathbf{E})$ (Eq. (5)) combines the influence of ${}^0\mu = \mu(\mathbf{E} = 0)$ and the ϵ_r-ratio due to the impact of the latter on the electric field distribution. Likewise, the recombination rate R, cf. Eqs. (3) and (4), is indirectly proportional to ϵ_r and directly proportional to the mobility $\mu(\mathbf{E})$. The corresponding *I–V* curves obtained for carrier generation confined to the inorganic phase are shown in Fig. 5(a) and (b). These *I–V* characteristics are clearly reminiscent to the curves obtained in Fig. 3(b) and (d); their qualitative evolution can be

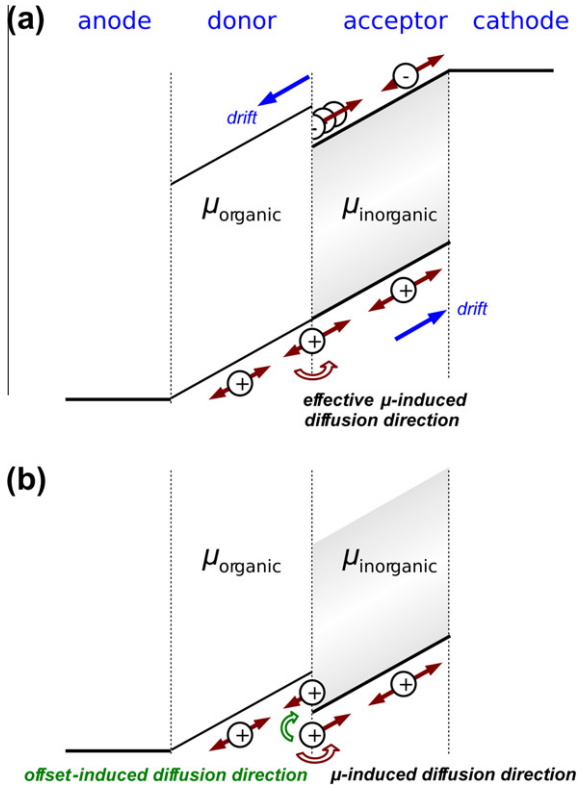

Fig. 4. Schematic illustration of the effective hole diffusion induced by (a) a difference in $\mu_p^{inorganic}$ and $\mu_p^{organic}$ and (b) by an offset in hole transport levels. Solid arrows at the charge carriers symbolize the diffusion current contribution for an acceptor-generated charge carrier at a given spot in the device for $V_a \lesssim V_{oc}$. Furthermore, the direction of motion dictated by the electric field is indicated by the "drift" arrows.

understood in terms of what has been discussed in Fig. 3(a), (c) and (b), (d). To better illustrate this behavior, the curves obtained in Fig. 3(c) and (d) are also indicated in Fig. 5(a) and (b) with open symbols and are connected to their respective counterparts (filled symbols) by an arrow.

When increasing the μ- or the ϵ_r-ratio, the values of the photocurrent do not follow the trend in the μ- and ϵ_r-ratio. This absence of an overall trend can be readily observed among the values of the short circuit current $j_{sc}(\mu, \epsilon_r)$ that are summarized in Table 5 in Appendix. Rather, two cases need to be distinguished due to the field-dependence of μ. (i) For a mobility ratio of 1:1 (Fig. 5(b), circles), the short circuit current (filled circles) becomes less negative compared to the ${}^0\mu$ case (open circles). Then, the *actual* mobilities associated to the two phases differ due to an electric field-strength $|\mathbf{E}|_D$ being larger than $|\mathbf{E}|_A$, i.e., an ϵ_r-ratio being larger than unity. (ii) For mobility ratios exceeding unity (squares and diamonds), the difference in electric field strengths gives rise to a *decrease* in the actual mobility ratio. As result, the short-circuit current becomes more negative. Moreover, this shift becomes more pronounced with increasing μ-ratio. The latter relationship has been already reported by Deibel et al. for effective media taken as a model for perfect donor–acceptor blends [28]. Along the same lines, the trend in the ϵ_r-ratios (Fig. 5(a)) can be rationalized: (i) an ϵ_r-ratio exceeding unity (squares and diamonds) enhances the difference in the electric field strength and, thus, decreases the actual $\mu(\mathbf{E})$ ratio. Then, more negative photo-currents are obtained (compare open and filled symbols). Increasing the ϵ_r-ratio (squares and diamonds) beyond unity increasingly enhanced this shift. (ii) Solely for the ϵ_r-ratio of 1:1 (circles) the behavior is reversed: due to a spatially constant field, the mobility-*ratio* becomes field-independent. The reduction of the photocurrent (closed circles) with respect to the ${}^0\mu$-case (open circles) is, thus, related to an enhanced recombination rate arising from the $\mu^{inorganic}(\mathbf{E})$ contribution.

3.2. Impact of the transport level alignment

Since, as discussed above, a vanishing hole transport level offset gives rise to a disadvantageous s-shaped *I–V* curve (Fig. 3(c) and (d)), it is interesting to compare these *I–V* curves to two other representative situations: (i) in Case 2 of Fig. 1, the electron transport levels are degenerate rather the hole ones. Based on previous experience in organic solar cells, material combinations with such a vanishing offset were avoided due to a small anticipated carrier generation efficiency. Until recently, it was considered an established fact that efficient exciton dissociation

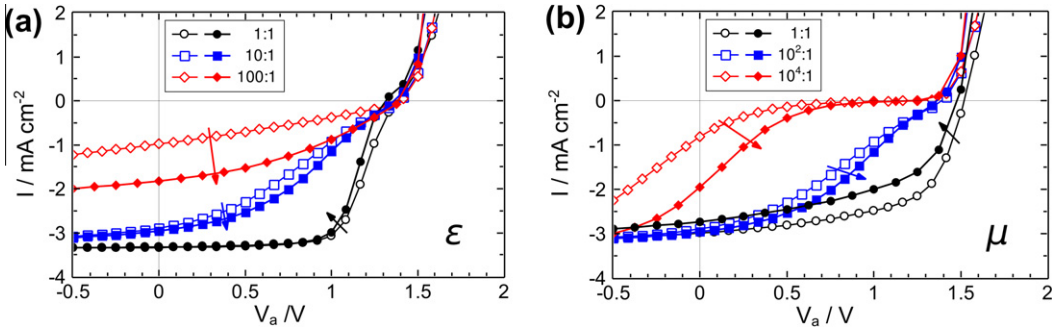

Fig. 5. *I–V* characteristics for a Case 1-type device (Fig. 1(b)) for different ratios of $\epsilon_r^{inorganic} : \epsilon_r^{organic}$ (left panel) and ${}^0\mu_{(n,p)}^{inorganic} : {}^0\mu_{(n,p)}^{organic}$ (right panel) with consideration of recombination and field-dependent mobilities. Carrier generation is assumed to be confined to the inorganic phase. For comparison, the *I–V* curves corresponding to field-independent mobilities and omitted recombination (Fig. 3(c) and (d)) are indicated with open symbols; arrows link the associated curves.

would require a minimum offset $\Delta E_n^{\min}$ [45,47,48]. However, efficient carrier generation was recently demonstrated in bulk heterojunction despite a very small offset in the electron transport levels [49]. It is, thus, worthwhile to investigate the impact of degenerate electron transport levels on carrier transport. (ii) Case 3 of Fig. 1 refers to non-vanishing offsets between the electron and the hole transport levels; this situation is realized for most combinations of materials. To be able to directly compare the values of the short circuit currents and open circuit voltages corresponding to these two level alignments with the P3EBT/$CuInS_2$ system (Case 1 of Fig. 1), we set non-vanishing level offsets to 0.4 eV.

In the following, we will restrict our discussion to the charge carrier generation in the inorganic acceptor according to Eq. (2). As shown in the previous section, this generation scenario reliably yields the major trends in the *I–V* curves upon parameter variation and, moreover, quantitative insights for flat heterojunctions. Also field-dependent mobilities and charge carrier recombination effects will not be considered, because they only have a minor influence on the dependence of the device performance when varying the dielectric constant and mobility ratio between the two different layers (cf. Fig. 5(a) and (b)). Thus, it needs to be stressed that *all* effects observed in the following are transport effects solely caused by the material specific parameters, i.e., the transport levels, the dielectric constants, and the mobilities.

In Fig. 6, one can see the *I–V* characteristics resulting from the variation of the material parameters μ and ϵ_r in the case of degenerate electron transport levels (Fig. 6(a) and (b)) and equidistantly set off transport levels (Fig. 6(c) and (d)). In comparison to the case of vanishing hole transport levels (Fig. 3(c) and (d), the variation of the *I–V* curves with μ and ϵ_r are considerably less marked. In strong contrast to Case 1, where the vanishing offset ΔE_p in the *hole* transport level leads to an s-shape in the *I–V* characteristic, the vanishing *electron* transport level offset ΔE_n preserves a diode-shaped *I–V* curve. The reason for this effect is twofold. (i) In order to contribute to the photo-current, electrons are required to diffuse to the cathode (cf. Fig. 4(a)). As the electrons are already generated next to the cathode, a level offset at the interface is not limiting the diffusion current. On the contrary, *electrons* are subject to a mobility-induced effective diffusion as observed before for holes; electrons that are trying to diffuse away from the cathode into the polymer are drawn back to the inorganic material and are, thus, enhancing the overall diffusion current. (ii) Holes contribute to the photo-current if they diffuse to the anode. As shown schematically in Fig. 4(b), holes located at the heterojunction consider migration into the polymer energetically favorably if a positive energetic offset is present. This effective diffusion of holes into the *donor* is enhancing the photocurrent.

Taking further the argument from above, we would immediately expect that the situation encountered in Case 1 is only recovered if the mobility is higher in the organic phase than in the inorganic phase, i.e., the μ-ratio becomes smaller than unity. Then, an effective μ-induced diffusion should decrease the photo-current, since it drives electrons away from the cathode. Indeed, the simulated *I–V* curve for a μ-ratio < 1 (not shown) exactly coincides with the

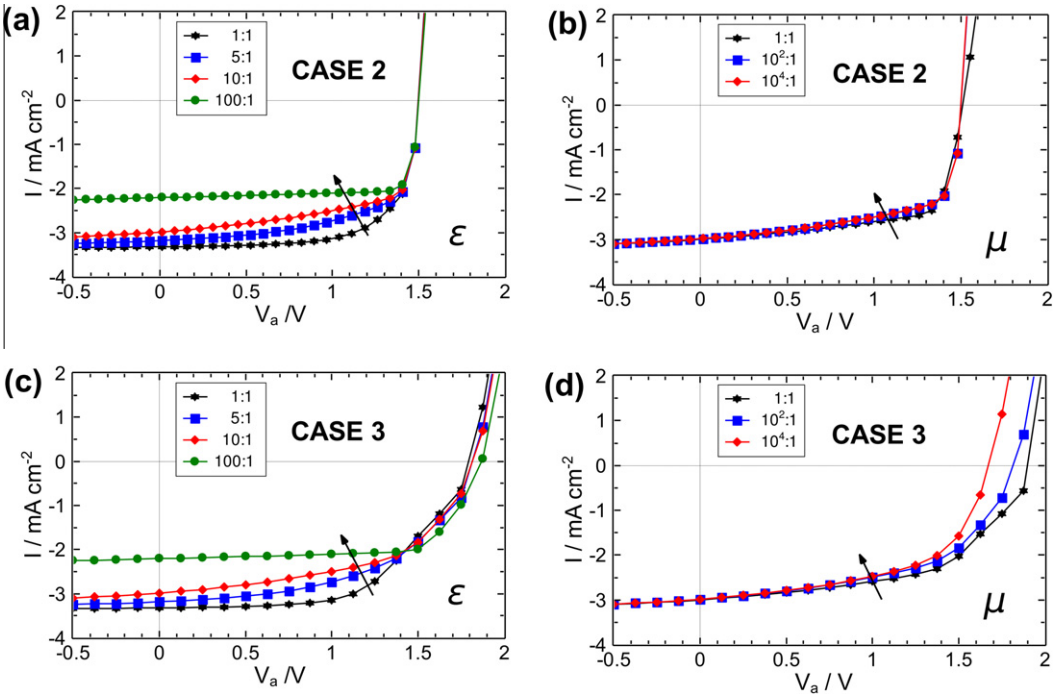

Fig. 6. *I–V* characteristics for generation of charge carriers only in the inorganic phase according to Lambert–Beer's law for different ratios of $\epsilon_r^{\text{inorganic}} : \epsilon_r^{\text{organic}}$ and $\mu_{(n,p)}^{\text{inorganic}} : \mu_{(n,p)}^{\text{organic}}$ corresponding to the energetic alignments Case 2 (upper panels) and Case 3 (lower panels) as illustrated in Fig. 1. The arrows indicate the evolution of the *I–V* curves with increasing ratios.

s-shaped *I–V* curve obtained for Case 1 with the inverse μ-ratio.

Thus, provided that the carriers are more mobile in the inorganic than in the organic material, the absence of an offset in the electron transport levels precludes a disadvantageous effect of μ or ϵ_r on the efficiency of the device. As in Case 1, the short-circuit current becomes less negative with increasing dielectric constant ratio, however, the device efficiency is almost not influenced by this fact (cf. Table 3). Increasing the mobility in the acceptor phase has even no influence on the device performance at all: electrons are not affected by a difference between $\mu^{\text{inorganic}}$ and μ^{organic} as they are already generated next to the cathode (cf. Fig. 4(a)). The migration of holes from the donor into the acceptor (cf. Fig. 4(b)) is aided by the level offset. This means that one is able to produce a very stable system with respect to the ratios of the dielectric constant and the mobilities between two different materials if (i) the inorganic material is situated at the cathode and (ii) the electron transport level offset vanishes.

The *I–V* characteristics resulting from the consideration of the third alignment configuration corresponding to Fig. 1(d) are shown in the Fig. 6(b) and (c). In this case we have the same non-zero energetic barrier for electrons and holes. As seen in the previous cases, an increase of the ϵ_r-ratio (Fig. 6(c), (stars-circles)) leads to decreasing short-circuit currents and increasing V_{oc}. However, the efficiency of the solar cell is almost unaffected by the change of the dielectric constant (cf. Table 3). A change in the mobility ratio, as shown in Fig. 6(d), has a marked impact on the V_{oc} value. The higher the ratio, the smaller V_{oc} becomes (Fig. 6(d), stars-diamonds). This sensitivity of V_{oc} to the μ-ratio relates to a μ-induced diffusion of *holes* into the acceptor (cf. Fig. 4). Moreover, Fig. 6(d) represents the first instant at which we encounter a V_{oc} profoundly exceeding the built-in voltage of 1.5 V. A qualitative and quantitative discussion and interpretation of this effect will follow in the next section.

Table 3
Evolution of the short circuit current (j_{sc}), open circuit voltage (V_{oc}), fill factor (FF), and power conversion efficiency (PCE) as a function of selected parameter ratios for carrier generation confined to the inorganic phase for the transport level alignments shown in Fig. 1. The default parameter ratios according to Table 2 are highlighted in bold numbers.

3.3. Comparison of donor materials

Now we will make use of the knowledge gained by analyzing the previous characteristics and apply it to the case of three different polymers, i.e., P3EBT, P3HT, and F8T2. Throughout the calculations, these polymers are assumed to differ in their particular HOMO/LUMO levels (see Table 2), while all other transport parameters were set to the default values given in Table 2. The resulting *I–V* curves are depicted in Fig. 7. The P3EBT/$CuInS_2$ curve (squares) possesses a saddle point at $V_a = V_{\text{oc}}$. The occurrence of such a saddle point relates in this case, as discussed above, to the vanishing offset between the hole transport levels. Uhrich et al. found such a behavior also for combinations of (purely organic) hole transporting materials [50].

Remarkably, all three donor materials yield approximately the same value of 1.4 V for V_{oc} (cf. Fig. 7), even though $V_{\text{built-in}}$ is not the same (cf. Table 4). This coincidence relates to a combination of individual, material-dependent contributions to the open circuit voltage: the value of V_{oc} in organic solar cells can be approximated by the sum of (i) the built-in voltage, (ii) the lowest band offset (which is in these three cases the hole transport level offset), and (iii) an additional term arising from diffusion [18]. In our particular case, the diffusion term should be sensitive towards the mobility ratio between the two different materials, i.e.,

$$qV_{\text{oc}}^{D/A} = V_{\text{built-in}}^{D/A} + \min_{D/A}(\Delta E_n, \Delta E_p) + \Delta E(\mu^{\text{inorganic}} : \mu^{\text{organic}}). \quad (6)$$

In the case of the three different polymers, the mobility ratio is always set to $\mu^{\text{inorganic}} : \mu^{\text{organic}} = 10^2 : 1$. Hence, the correction to V_{oc} due to diffusion should always be the same. Indeed, the inspection of the values of $V_{\text{built-in}}$ and $\min(\Delta E_n, \Delta E_p)$ entering V_{oc}, which are listed in Table 4, reveals that these two quantities sum up to

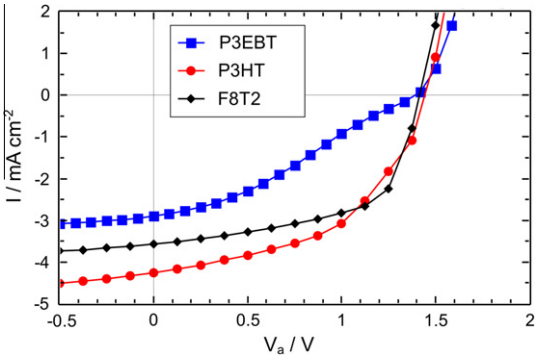

Fig. 7. Simulated *I–V* curves for the polymers P3EBT, P3HT, and F8T2 (Table 2) for a charge carrier generation confined to the inorganic $CuInS_2$ phase.

Table 4
Contributions to the open circuit voltage of polymer/$CuInS_2$ devices.

Polymer	$V_{\text{built-in}}$/V	ΔE_n/eV	ΔE_p/eV	$\min(\Delta E_n, \Delta E_p)$/eV	$qV_{\text{built-in}} + \min(\Delta E_n, \Delta E_p)$/eV	V_{oc}/V
P3EBT	1.5	0.4	0.0	0.0	1.5	1.4
P3HT	1.1	0.6	0.4	0.4	1.5	1.4
F8T2	1.3	1.6	0.2	0.2	1.5	1.4

1.5 eV for all donor materials (2nd column from the right in Table 4). Thus, there is a polymer-independent contribution $\Delta E/q$ to V_{oc} of -0.1 V.

To further test, whether ΔE can be related to the mobility-*ratio*, we try to predict V_{oc} for a material combination complying with the level alignment Case 3 (Fig. 1(d)) by using Eq. (6) and our empirical μ-dependent correction $\Delta E(100:1)/q$ of -0.1 V:

$$qV_{oc}^{\text{Case 3}} = V_{\text{built-in}}^{\text{Case 3}} + \min_{\text{Case 3}}(\Delta E_n, \Delta E_p) + \Delta E$$
$$(\mu^{\text{inorganic}} : \mu^{\text{organic}} = 100:1) \approx (1.5 + 0.4 - 0.1)\text{eV} = 1.8\text{eV}.$$

This value is in excellent agreement with the open circuit voltage associated to the *I–V* curve obtained for a μ-ratio of 100:1 (Fig. 6(d), squares).

From the arguments above, it is clear that $\Delta E(\mu^{\text{inorganic}} : \mu^{\text{organic}})$ must not be present in all systems in which mobility ratios larger than unity cannot induce a preferential diffusion direction, i.e., in systems with degenerate electron transport levels (Case 2). Indeed, the V_{oc} values (cf. Table 5) for Case 2 are almost entirely insensitive to the mobility ratio. Thus, it is possible to conclude that the diffusion correction to the open circuit voltage is mainly determined by the *ratio* of mobilities rather than their absolute values.

4. Conclusion

The carrier transport in inorganic–organic hybrid cells has been studied in the light of the interplay between carrier generation occurring at the heterojunction (due to dissociation of the donor excitons) *and* in the bulk of the acceptor material (due to direct generation in the small band gap inorganic material). Particular attention has been paid to the influence of (i) the carrier mobilities, (ii) the dielectric constants, and (iii) transport level offsets on the efficiency of collecting photogenerated carriers at the terminal contacts. Each of the three factors influences the power conversion efficiency of hybrid organic–inorganic solar cells. They predominantly affect the open circuit voltage, V_{oc}, and the shape of the *I–V* curve. The short circuit current, j_{sc}, is hardly affected by the transport-related phenomena studied here; in this context, slight variations that were nevertheless observed relate directly to the occurrence of s-shaped *I–V* characteristics. The leading effect originates from offsets in the transport levels and is, as shown in [15], comparable to the influence of non-ohmic contacts or more complex heterojunction morphologies on the PCE. All μ- and ϵ_r-induced changes have a significantly less marked impact on the *I–V* curve.

Due to the strongly differing nature of the two generation mechanisms, it is possible to judge the individual impact of the factors on the carrier transport in a semi-quantitative fashion solely on the basis of the directly generated carriers in the acceptor. In case flat heterojunctions are considered, this treatment becomes quantitative. As another striking consequence of the differing generation mechanisms, there is a pronounced asymmetry between level offsets formed for electrons and holes. A lack of a hole transport level offset ($\Delta E_p = 0$) represents the most serious loss factor encountered in this study; large variations in the PCE can be observed solely due to a pronounced sensitivity of the shape of the *I–V* curve towards μ and ϵ_r. In strong contrast, a degenerate electron transport level ($\Delta E_n = 0$) gives rise to values of V_{oc}, j_{sc}, and PCE that are almost insensitive towards actual mobility and ϵ_r values. Consequently, the mobilities cannot be used as a tuning handle to influence V_{oc}. Vice versa, a non-vanishing electron transport level offset is necessary to achieve a V_{oc} beyond $V_{\text{built-in}}$ at all.

The smaller the *mismatch* in μ *and* ϵ_r between organic and inorganic phase, i.e., the less their ratios differ from unity, the larger the short circuit current and, provided that $\Delta E_n > 0$, V_{oc} becomes. The variations due to ϵ_r are, however, much smaller than those caused by μ. Additionally, the effective mobility-induced diffusion of *holes* from the organic to the inorganic layer gives rise to a s-shaped section in the *I–V* curve. The steepness of this section increases when the μ-ratio is decreased. Such a minimal μ-mismatch requirement coincides with the findings for purely excitonic bulk heterojunction solar cells [30–32]. This result is probably not surprising, when we keep in mind that carrier generation predominantly occurs non-locally throughout a bulk phase both in such bulk heterojunctions and in the devices considered in this work.

From the considerations above, it is possible to derive the following guidelines to select suitable material combinations, provided that ohmic contacts can be formed: (i) to suppress the formation of an s-shaped *I–V* curve, holes need to be driven from the acceptor into the donor by means of a level offset-induced diffusion at the heterojunction. This is achieved for values of E_V being more negative than the value of E_{HOMO}. (ii) A non-vanishing offset ΔE_n between the electron transport levels is favorable, as then the open circuit voltage can exceed the built-in voltage due to a non-zero minimal offset term lessened by a diffusion term. In order to minimize the detrimental contribution from the mobility-dependent diffusion term, the mobility ratio should be as close to unity as possible. It should be noted at this point, however, that the requirement of $\Delta E_n \neq 0$ must not be confused with a minimum value $\Delta E_n^{\min}$ that has been demanded to guarantee

efficient exciton dissociation in purely excitonic cells [45,47,48].

A.1. Model equations

The equations for the electron and hole drift–diffusion currents $\mathbf{J}_n(\mathbf{r},t)$ and $\mathbf{J}_p(\mathbf{r},t)$, respectively, at a particular position $\mathbf{r}=(x,y)$ and time $t \geqslant 0$ are given by ([51])

$$\mathbf{J}_n(\mathbf{r},t) = q\mu_n(\mathbf{r},\mathbf{E})n(\mathbf{r},t)\mathcal{E}_n(\mathbf{r}) + \mu_n(\mathbf{r},\mathbf{E})k_BT\nabla n(\mathbf{r},t), \quad (7)$$

$$\mathbf{J}_p(\mathbf{r},t) = q\mu_p(\mathbf{r},\mathbf{E})p(\mathbf{r},t)\mathcal{E}_p(\mathbf{r}) - \mu_p(\mathbf{r},\mathbf{E})k_BT\nabla p(\mathbf{r},t), \quad (8)$$

where $n(\mathbf{r},t)$ and $p(\mathbf{r},t)$ denote the electron and hole densities, and $\mu_{(n,p)}(\mathbf{r},\mathbf{E})$ the mobility of charge carriers as a function of the electric field $\mathbf{E}_{(n,p)}$. Further, k_B is Boltzmann's constant and T the temperature. The generalized electric field $\mathcal{E}_{n,p}(\mathbf{r})$ is related to the generalized potential $\Psi_{(n,p)}(\mathbf{r},t)$ that describes the motion of charge carriers under the influence of the material specific transport levels and the local charge carrier concentration [15,51]. It is given by the difference of the electrostatic potential $\psi(\mathbf{r},t)$ and the so-called band parameters $\Theta_{n(p)}$: $\Psi_{(n,p)}(\mathbf{r},t) = \psi(\mathbf{r},t) - \frac{\Theta_{(n,p)}(\mathbf{r})}{q}$. The electrostatic potential is gained by solving the Poisson equation

$$\nabla\cdot[\epsilon(\mathbf{r})\nabla\psi(\mathbf{r},t)] = -\rho(\mathbf{r},t), \quad (9)$$

where $\epsilon(\mathbf{r}) = \epsilon_0\epsilon_r(\mathbf{r})$ stands for the dielectric constant and $\rho(\mathbf{r})$ for the charge density given by $\rho(\mathbf{r},t) = q[p(\mathbf{r},t) - n(\mathbf{r},t)]$ with the elementary charge q. The additional terms $\Theta_{n(p)}(x,y)$ are associated to the spatial energetic alignment of the transport levels [51,52]. In disordered materials, $\Theta_{n(p)}(x,y)$ is directly given by the relative spatial alignment of the transport levels [52]. For convenience, we set the band parameters to zero in the organic donor, $\Theta_{n(p)} = 0$, and to the transport level offsets in the inorganic acceptor, i.e., $\Theta_n = E_C - E_{LUMO}$; $\Theta_p = E_V - E_{HOMO}$. Therein, $E_{C(/V)}$ refers to the conduction (/valence) band edge of the inorganic semiconductor and $E_{HOMO(/LUMO)}$ to the energy of the highest occupied (/lowest unoccupied) molecular orbital of the organic compound. The associated electric fields $\mathbf{E}_{(n,p)}$ and $\mathcal{E}_{n,p}(\mathbf{r})$ that were formally introduced in Eqs. (7) and (8), are given by

$$\mathbf{E}_{(n,p)} = -\nabla\psi(\mathbf{r},t) \quad \text{and} \quad \boldsymbol{\mathcal{E}}_{(n,p)} = -\nabla\Psi(\mathbf{r},t). \quad (10)$$

The continuity equations for electrons and holes are given by ([51])

$$\frac{\partial n(\mathbf{r},t)}{\partial t} = \frac{1}{q}\nabla\cdot\mathbf{J}_n(\mathbf{r},t) + \Gamma_n(\mathbf{r},t), \quad (11)$$

$$\frac{\partial p(\mathbf{r},t)}{\partial t} = -\frac{1}{q}\nabla\cdot\mathbf{J}_p(\mathbf{r},t) + \Gamma_p(\mathbf{r},t), \quad (12)$$

where $\Gamma_{(n,p)}(\mathbf{r},t)$ depict the corresponding generation and recombination terms, $\Gamma_{(n,p)}(\mathbf{r},t) = G_{(n,p)}(\mathbf{r},t) - R_{(n,p)}(\mathbf{r},t)$.

Assuming a Lambert–Beer type absorption profile across the device, the number of phonons absorbed per second and volume at position $\mathbf{r}$ in the device reads as

$$\Phi(\mathbf{r}) = \int_{\lambda_{min}}^{\lambda_{max}} d\lambda\,\Phi_0(\lambda)\,\alpha(\lambda)\exp[-\alpha(\lambda)d(\mathbf{r})], \quad (13)$$

where λ stands for the wavelength and is limited by λ_{min} and λ_{max} according to the band gap. Further, $\Phi_0(\lambda)$ is the incoming photon flux at a particular wavelength λ according to the reduced sun spectrum AM 1.5 with roughly 1000 W m^{-2} [53]. The absorption coefficient related to

the organic and inorganic species is denoted by α and $d(\mathbf{r})$ is the distance of a point within the device with position $\mathbf{r}$ to the surface in direction of the incident light.

In this formulation, Eq. (13) yields the photon number as a function of the material-dependent absorption and, in reasonable first approximation, the morphology of the device. As we intend to focus on solely investigating *carrier transport*-related phenomena, we will exclude additional effects that may originate from strongly spatially varying absorption profiles [54] by introducing the following simplifications: (i) α enters Eq. (13) as a wavelength- and material-independent parameter and (ii) the optical band gap $E_{gap} = 1.5$ eV is treated as material-independent. This means that both materials are considered to be capable of absorbing the same number of photons per volume and time. Then, the actual number of photons absorbed anywhere in the device is only determined by Lambert Beer's law, i.e., is solely dependent on the position of the considered volume element with respect to the transparent electrode. The coefficient α is set to the representative value of $2 \times 10^7\ m^{-1}$ according to [36]. With the help of the simplifications made above, we are able to quantitatively compare transport phenomena of materials, whose optical absorption profile is not identical.

The ohmic contacts are modeled by choosing appropriate boundary conditions [15]. The intrinsic charge carrier concentration at the contacts was set as $N_{cv} = 10^{22}\ \mathrm{m}^{-3}$. The resulting coupled system of equations given by the continuity equations, current density equations, and the Poisson equation is solved self-consistently on a two-dimensional mesh with variable grid spacing [15].

rapid thermal annealing technique. Although this approach offers an alternative way to fabricate rubrene TFT without SAM treatment, the produced rubrene active layers still contain a number of undesired structures including discontinuous grains that is leading a relatively low device performance.

Here we present a very simple but effective approach to produce rubrene OTFTs with characteristics better than a-Si:H TFTs. Only by an abrupt heating process, the crystalline rubrene thin films that consist of highly ordered, uniaxially oriented single-crystalline grains are created, and the grains are interconnected with one another to form

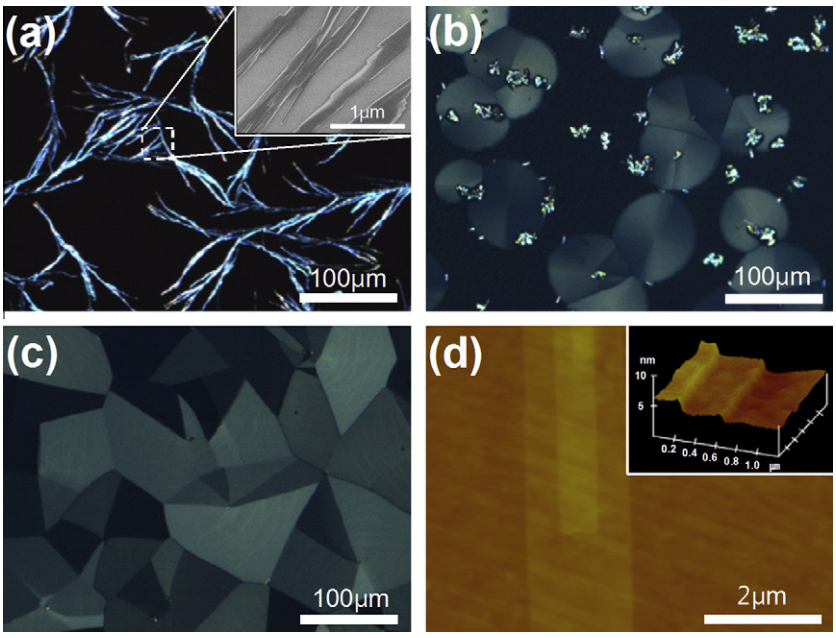

Fig. 2. POM images of the crystalline rubrene thin films fabricated by the abrupt heating process at various temperatures and time: (a) 125 °C for 5 min, (b) 150 °C for 5 min (c) 170 °C for 1 min. continuous films over the whole dielectric surfaces. Such high-quality crystalline rubrene thin films are remarkably rapidly produced in 1 min through this approach. Moreover, the approach does not require any surface modification of gate dielectrics of OTFTs, which is generally indispensable in the other methods developed to date for enhancing the performance of OTFTs.

2. Experimental

Rubrene powder (sublimed grade) was purchased from Sigma–Aldrich, Inc. Amorphous rubrene thin films were deposited on 100 nm thick SiO_2 dielectric surfaces underlying heavily doped *n*-type silicon substrates (2 cm × 2 cm) that were kept at room with a base pressure below 10^{-5}. The substrates were cleaned in isopropyl alcohol in an ultrasonic bath for 5 min, followed by drying under a nitrogen flow. The evaporation speed was ~5 nm/min. After the deposition, the as-deposited rubrene thin films were abruptly heated by placing the samples onto a pre-heated hot plate and taken out of the plates after the abrupt heating process. The abrupt heating process was carried out inside a nitrogen-filled glove box at various combinations of heating temperature (T_{ah}) and heating duration. In order to fabricate top-contact rubrene TFTs, gold was evaporated for source and drain electrodes through a shadow mask, and 16 TFTs were fabricated on a substrate.

Polarization images were captured using an Olympus BX51 microscope. The topographies and the thicknesses of the films were examined with an AFM (Veeco D3100) and a field-emission SEM (Hitachi S-4800). DSC of amorphous rubrene powder which was raked out from the as-deposited rubrene film was characterized on differential scanning calorimeter DSC-204 Phoenix (Netzsch). The TEM images and SAED patterns were taken with a Tecnai G2 Spirit BioTWIN (FEI Company) TEM operating at 120 kV. For TEM observation, rubrene films were prepared on SiO_2 coated TEM grids using the same abrupt heating method. GIXD measurements were performed using the 4C2 beam line at the Pohang Accelerator Laboratory (PAL), Pohang, Korea. The diffraction patterns were

recorded using a MarCCD detector. The grazing-incidence angle of the X-ray beam (λ = 1.3807 Å) was varied between 0.14° and 0.25°, and the sample-to-detector distance (143.5 mm) was calibrated using a silver behanate standard sample and the footprint of the X-ray beam on the specimen surface was 1 mm × 5 mm. The diffraction data were displayed as an intensity map in which q_{xy} is the in-plane momentum transfer and q_z is the out-of-plane momentum transfer. The TFT characteristics were evaluated under ambient air conditions with a Keithley 4200 semiconductor characterization system.

3. Results and discussion

The high-quality crystalline rubrene thin films were produced simply by abrupt heating of amorphous rubrene films that were thermally evaporated on 100 nm thick SiO_2 dielectric layers underlying heavily doped *n*-type silicon substrate (Fig. 1) The abrupt heating process was carried out by placing as-deposited rubrene films on a pre-heated hot plate in a nitrogen environment for a short time. Fig. 2a–c shows the polarized optical microscopy (POM) images of the rubrene thin films (thickness: 20 nm) that

were abruptly heated at different temperatures. The as-deposited rubrene film did not display a crystalline feature under polarized light (Supporting Information, Fig. S1a). However, the rubrene films that underwent the abrupt heating process exhibited strong birefringence in the POM images, indicating that crystalline structures were formed [22]. Upon abrupt heating at a relatively low temperature of 125 °C for 5 min, branch-like crystalline structures appeared (Fig. 2a). Scanning electron microscopy (SEM) images show that the branch-like crystallites with widths of a few 100 nm and lengths of several μm are embedded in an amorphous rubrene matrix (inset of Fig. 2a). Interestingly, when T_{ah} was increased to 150 °C, disk-shaped platelet crystallites with diameters of several tens μm were formed in addition to the branch-like crystallites (Fig. 2b). With a further increase of T_{ah} to 170 °C, novel crystalline rubrene films, that is, continuous crystalline films consisting of large-sized and well-faceted domains were created over the whole SiO_2 surfaces (Fig. 2c). No colour variation was observed within a single domain under POM investigation, suggesting that a domain is composed of a single crystalline grain. The average grain size was ca. 80 μm and the grains were interconnected with one another, as shown in the POM image of Fig. 2c [23]. These interconnected large grains are beneficial in OTFTs because large grains lead to a low density of grain boundaries that act as barriers on the carrier transport and because loosely connected grains prevent charge transport across grain boundaries [24]. Note that an OTFT can be prepared even on a single large grain in the film. Atomic force microscope (AFM) images show that the surfaces of the crystalline rubrene thin films are flat and smooth (the root mean square roughness was 0.36 nm for the flat area shown in Fig. 2d). Meanwhile, long platelets consisting of a few parallel layers were observed on the surface of the film, as shown in Fig. 2d. The layer spacing is ~1.3 nm, which corresponds to the half *c*-axis length of an orthorhombic rubrene unit cell [25].

For the systematic investigation of the evolution of crystalline structures during heat treatment, we examined thermal transition of the amorphous rubrene using POM and differential scanning calorimetry (DSC). Fig. 3a shows the POM images of abruptly heated rubrene film at various temperatures for 1 min. From this result, we found that branch-like crystalline structures begin to form in earnest at 110 °C and amount of the crystallites increase with the temperature elevation. Furthermore, the disk-shaped platelet crystallites were evoluted from T_{ah} of 150 °C. These

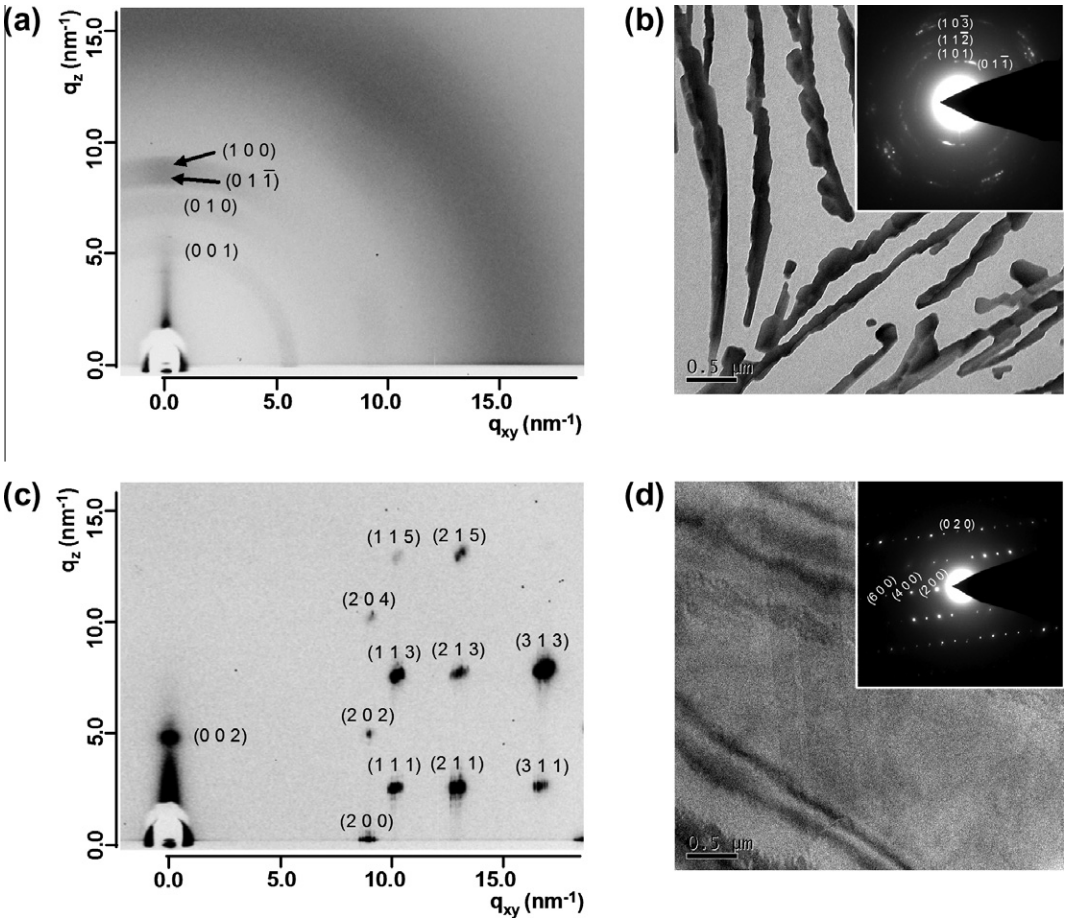

Fig. 6. Two dimensional GIXD patterns of the crystalline rubrene thin films produced at (a) 125 °C for 30 min, (c) 170 °C for 1 min. TEM images of the crystalline rubrene thin films prepared at (b) 125 °C for 30 min and (d) 170 °C for 1 min. The insets in (b and d) are the corresponding SAED patterns, respectively. The SAED pattern of the inset of (d) was recorded along the [0 0 1] zone axis of the orthorhombic rubrene.

temperature-dependent crystallization behaviours were consistent with the result of differential scanning calorimetry (DSC) analysis. As shown in the DSC heating thermogram (Fig. 3b), two distinct crystallization exotherms at 116–142 °C ($T_{cryst:1st}$) and 148–170 °C ($T_{cryst:2nd}$) were recorded. Combined with the results shown in Fig. 3a, the DCS analysis reveals that the branch-like crystallites and the disk-shaped platelet crystallites are formed at the temperature of the first and the second crystallization exotherms, respectively.

The high-quality crystalline rubrene thin films were incredibly rapidly produced in just 1 min by the abrupt heating process at 170 °C. We found that heating time, film thickness, and heating rate as well as T_{ah} were crucial parameters obtaining such high-quality crystalline rubrene films. The optimum T_{ah} was around 170 °C, and an insufficient heating time induced a partial coverage of the crystalline film over the SiO_2 surface, whereas an excessive heating time resulted in pores on the crystalline films (Fig. 4a). Furthermore, films thicker than the optimum value of 20 nm generated cracks on the crystalline films, while too thin films resulted in many discontinuities on the films (Fig. 4b and c). Particularly, we observed that when the amorphous rubrene film was heated at a low heating rate from room temperature to the optimum temperature of 170 °C, branch-like crystallites as well as platelet crystallites were always created (Fig. 4d). If the heating rate is low, the temperature of the film is slowly increased and thus the organic material can get enough time for the crystallization at the temperature zone of $T_{cryst:1st}$. Consequently, formation of the undesirable branch-like crystallites cannot be avoided. However, sufficiently high heating rate can prevent the formation of the branch-like crystallites because the organic material does not have enough time for the formation of the branch-like crystallites (Fig. 5). Therefore, high-quality rubrene crystalline films consisting of only platelet crystallites can be successfully fabricated by the abrupt heating process since it provides very high heating rate.

To identify the crystalline nature of the rubrene thin films produced by the abrupt heating process, transmission electron microscope (TEM) and two-dimensional grazing-incidence X-ray diffraction (2D GIXD) measurements were carried out. Selected area electron diffraction (SAED) patterns clearly confirm that as-deposited rubrene thin films are amorphous (Fig. S1b). However, a set of diffraction spots in the SAED pattern (Fig. 6b) and a highly scattered diffraction pattern along the Debye rings obtained from the 2D GIXD measurement (Fig. 6a) show that the branch-like structures prepared by the abrupt heating process at 125 °C, corresponding to the sample shown in Fig. 2a, are randomly oriented crystallites. The indexing of the 2D GIXD and the SAED patterns confirms that the branch-like crystallites have a triclinic (*P-1*) crystalline phase with lattice parameters of $a = 7.26$ Å, $b = 8.69$ Å, $c = 11.87$ Å, $\alpha = 97.5°$, $\beta = 104.7°$, and $\gamma = 98.8°$. In contrast, the GIXD pattern of the rubrene thin film prepared at 170 °C, corresponding to the sample shown in Fig. 2c, was indexed to an orthorhombic unit cell (*Cmca*) with the lattice parameters of $a = 14.14$ Å, $b = 6.86$ Å and $c = 25.91$ Å (Fig. 6c). Particularly, many strong and sharp reflection spots of the 2D GIXD pattern along the q_z at a given q_{xy} indicate that highly ordered crystals are formed in the film in both vertical and lateral directions.[26,27]. The 2D GIXD pattern further reveals that the *c*-axes of all the crystals in the film are uniaxially aligned perpendicular to the substrate surface, while *ab* planes of all the crystals in the film are perfectly oriented parallel to the substrate surface, which is desirable to obtain high charge carrier mobilities [28]. TEM images of the rubrene thin film clearly show that the film is composed of large grains well-connected with one another without discontinuity (Fig. S1c). The SAED patterns reveal that a single grain in the film has an orthorhombic rubrene single-crystalline phase (Fig. 6d). Therefore, from these analyses, combined with the POM and AFM results, we can conclude that continuous and highly-ordered crystalline rubrene thin films comprising large-sized grains with preferred molecular orientations can be rapidly and controllably fabricated by the abrupt heating approach.

To confirm the effectiveness of the abrupt heating method in actual devices, OTFTs were fabricated with the highly-quality crystalline rubrene thin films obtained by the illustrated method. The transfer and output characteristics of representative OTFT devices are presented in Fig. 7. The channel length and width were fixed at 50 and 1000 μm, respectively. The fabricated devices exhibited high performance with saturation mobilities as high as

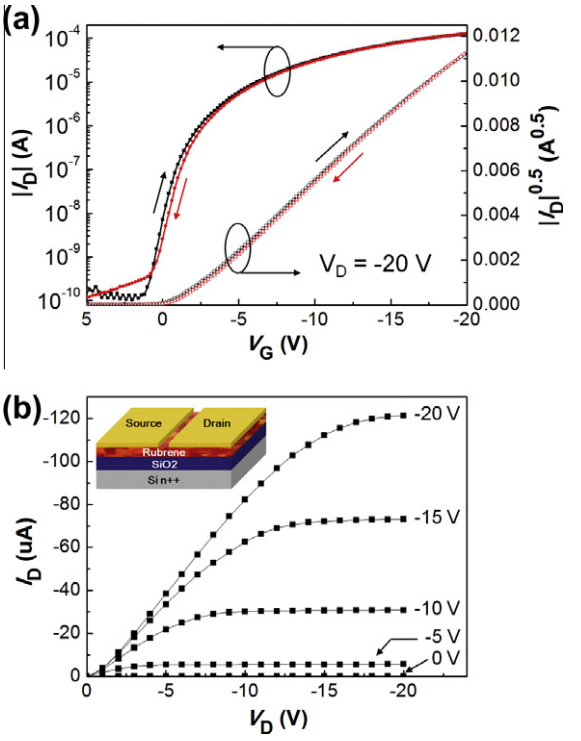

Fig. 7. (a) Drain current (I_D) and square root of the drain current versus gate voltage (V_G) curves scanned in the forward (black line) and reverse (red line) direction at a drain–source voltage of −20 V. (b) Drain current versus drain voltage characteristics for various gate voltages (V_D). The inset shows schematic transistor structure. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

1.21 $cm^2 V^{-1} s^{-1}$ and on/off current ratios higher than 10^6 under ambient conditions. Threshold voltages deduced by the linear extrapolation of the saturation region in the square root of the drain current versus gate voltage were as small as −1.0 V. In addition, as shown in Fig. 5a, the devices showed little hysteresis between forward and reverse scans, and their subthreshold swings were as low as 0.62 V/decade. Both low hysteresis and small subthreshold swing indicate that the prepared high-quality crystalline rubrene films have a low density of traps [29]. It is noteworthy that the overall characteristics of our TFT devices are quite comparable to those of the state-of-the-art OTFTs [30,31]. From the random testing of 10 devices, a good uniformity in device performance was also observed: the average motility was 1.03 $cm^2 V^{-1} s^{-1}$ with a standard deviation of 0.11 $cm^2 V^{-1} s^{-1}$, and the average threshold voltage was −0.65 V with a standard deviation of 0.18 V.

4. Conclusions

We have presented a straightforward approach to fabricate high-quality crystalline rubrene active layers for OTFTs. Simply by an abrupt heating process, crystalline rubrene semiconductor thin films comprising large, highly ordered, and interconnected single-crystalline grains with desirable molecular orientation can be controllably fabricated. High-performance OTFTs with characteristics better than a-Si:H TFT devices were reproducibly produced using the rubrene thin films. Such high-quality crystalline rubrene thin films are remarkably rapidly produced without any surface modification of gate dielectrics, thereby demonstrating that the approach is a very simple yet effective route to produce high-performance OTFTs. Moreover, the approach is also compatible with polymeric substrates due to the short processing time at a relatively low temperature of 170 °C, as shown in our preliminary results (Fig. S2). We believe that our approach is very promising for practical applications of rubrene semiconductors to organic electronics.

conductivities are still lacking [11–17]. Conductivity (σ) depends both on the carrier concentration (p) and the carrier mobility (μ), and these quantities are related by the simple relation $\sigma = pq\mu$, where q is the elementary charge [2]. Thus improvement in conductivities may arise from enhancements in both p and μ, or by p or μ alone. In this study, we present the effects of how TMOs dopants affect the conductivities of an archetype hole-transporting material N'-diphenyl-N,N'-bis(1-naphthyl)(1,1'-biphenyl)-4,4'diamine (NPB) [see Fig. 1, inset]. Three TMOs, namely, MoO_3, WO_3, and V_2O_5 were used in this study. Thin film transistor (TFT) configuration was employed to extract free both p or μ in one experiment. We show that after doping, there is a substantial increase in the hole concentration; in contrast, there is general reduction in the hole mobilities for all three TMOs. Thus the increase in conductivities of TMO-doped NPB can be solely attributed to the increase in the free carrier concentrations. Among the three TMOs, MoO_3 turns out to be the most effective dopant. At a doping concentration of 5% (by volume), conductivity of about 2.2×10^{-7} Scm^{-1} and a free carrier concentration of 1.4×10^{17} cm^{-3} was achieved.

2. Experimental

All TMOs, including molybdenum(VI) oxide (99.998%), tungsten(VI) oxide (99.9994%), and vanadium(V) oxide (99.995%), were purchased from Strem Chemical, Inc. NPB was purchased from E-Ray Optoelectronics Technology Co., Ltd. To evaluate the conductivities of pristine NPB and TMO-doped NPB, thin film transistors in top-contact configuration were fabricated. A p^+-Si wafer, with 300 nm of thermally grown SiO_2, was used as the substrate. Prior to TFT fabrication, the substrate was first cleaned by filtered acetone, followed by a UV–Ozone treatment. Doping was achieved by co-evaporating NPB and the TMO under high vacuum conditions. The doping concentration was 5 vol.% for all three oxides. The evaporation rates of the TMOs were between at 0.1–0.2 Å/s, and the total evaporation rate was kept at 2.0–4.0 Å/s depending on the kind of TMOs used. The active layer had a thickness of 100 nm. Subsequently, source (S) and drain (D) electrodes were coated on the active layer. Both the S and D electrodes are identical and consist of Au interposed by a thin layer (20 nm) of TMO between Au and the underlying organic layer [see Fig. 3(d)]. The channel width (W) and length (L) were 6 mm and 50 μm, respectively. After device fabrication, all TFTs were transferred immediately to a temperature-controlled cryostat for electrical measurements. The temperature of the sample can be regulated between 235 and 360 K. All measurements were performed in vacuum. In plane conductivities of the organic films were measured by holding $V_G = 0$ V while varying V_{DS}, and capturing I_{DS}. In addition to TFTs, UV–NIR absorption measurements (PerkinElmer Lambda Model 750 UV/NIR Spectrometer) were performed to analyze the interactions of the TMOs with NPB. Samples (100 nm) for absorption measurements were prepared on quartz substrates. Moreover, the structures of the organic films were checked by grazing incidence X-ray diffraction (Bruker AXS Model D8 Advance). All films remained amorphous before or after doping.

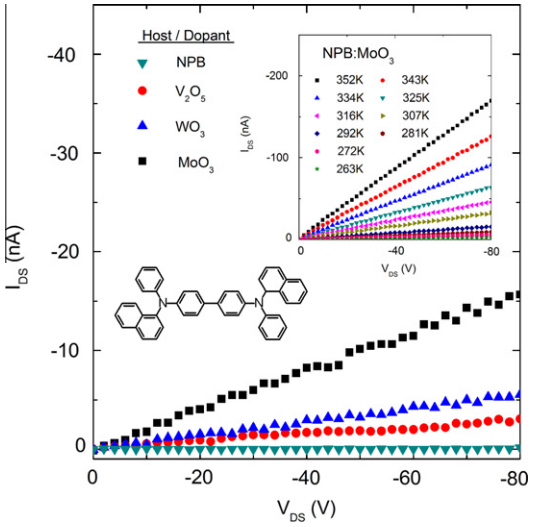

Fig. 1. Current–voltage characteristics of NPB and TMOs-doped NPB at $V_G = 0$ V. Inset: Temperature dependent I–V characteristics at $V_G = 0$ V for NPB:MoO_3 device; molecular structure of NPB is also shown.

3. Results and discussion

The room temperature current–voltage (I–V) characteristics of pristine and TMO-doped NPB samples were shown in Fig. 1. Only hole conduction is expected in all devices as there exists a large energy offset between the work functions of TMOs (>5 eV) and the LUMO of NPB (~2.4 eV). For pristine NPB, only background leakage currents of fractions of nA could be observed. After doping with TMOs, all samples exhibit clear and linear I–V characteristics, indicative of Ohmic conduction. The conductivity of each sample can be extracted from the slope of the I–V curve. Among the three TMOs, MoO_3 appears to be the most effective dopant as it results in a sample with the best conductivity. In contrast, V_2O_5 results in a sample with relative poor conductivity. For MoO_3-doped NPB, the conductivity at room temperature is 2.2×10^{-7} Scm^{-1}, followed by WO_3 (5.1×10^{-8} Scm^{-1}), and V_2O_5 (2.8×10^{-8} Scm^{-1}). The changes in conductivities after doping are comparable to recent reports of TMO-doped NPB [11–13]. The inset in Fig. 1 shows temperature dependent I–V characteristics of MoO_3-doped NPB between 263 and 352 K. A gradual increase in the conductivity with temperature is clearly observed. Similar observations were obtained for the other two TMO-doped samples. Fig. 2 shows a summary of temperature dependent conductivities. However, from the I–V curves alone, or from the conductivities data, one cannot determine if the improvement in conductivity is due to improvement in hole concentration or the hole mobility.

To differentiate the roles of the hole concentration and the mobility, we performed TFT measurements to extract the hole mobilities of the doped sample. Fig. 3 shows the results the TFT measurements at room temperature. For pristine NPB [Fig. 3(a)], well-defined p-channel field-effect

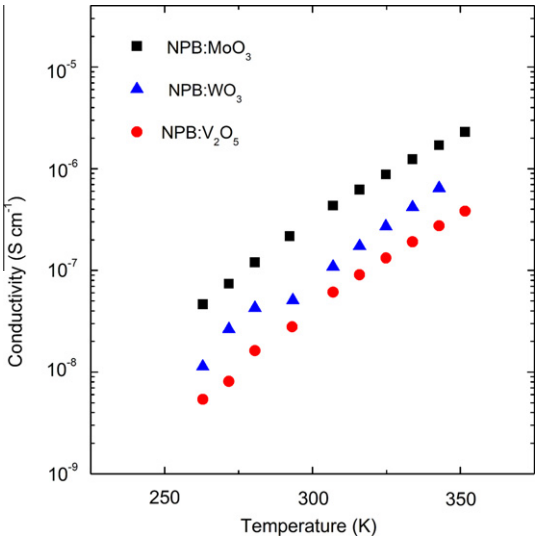

Fig. 2. Conductivity vs. temperature for NPB:MoO_3, NPB:WO_3, and NPB:V_2O_5.

behaviors with well-defined linear and saturation regions in the source-to-drain currents can be observed. The saturation (μ_{Sat}) and linear (μ_{Lin}) region mobilities can be evaluated by the standard equations: [3]

$$I_{DS} = \frac{W}{L}\mu_{Lin}C_i\left[V_{DS}(V_G - V_T) - \frac{V_{DS}^2}{2}\right] \quad (1)$$

$$I_{DS} = \frac{W}{2L}\mu_{Sat}C_i(V_G - V_T)^2 \quad (2)$$

where I_{DS} is the measured source to drain current, W is the channel width, L is the channel length, C_i is the capacitance of the gate dielectric per unit area; V_G, V_{DS} and V_T are the applied gate bias, the source to drain voltage, and the threshold voltage of the OTFT, respectively. For pristine NPB, the saturation and linear region mobilities are 1.1×10^{-5} cm^2/Vs and 7.8×10^{-6} cm^2/Vs, respectively. The results are essentially the same as our previous report [18]. After doping [Fig. 3(b)–(d)], field-effect behaviors can still be observed. However, the field-induced source-to-drain current, I_{DS}, is now on the top of a linear background current (the off-current). As a result, the resulting I_{DS} is now tilted upwards in the positive-x direction. The amount of tilt is clearly determined by the conductivities of the doped-sample in the "off-state" (with $V_G = 0$ V). A similar observation is also found in a previous report [14]. The TFT data can be modeled by a TFT in parallel with a leakage resistance R_{leak}. For the pristine case, R_{leak} is infinite as the amount of free carriers is negligible. For the doped-samples, R_{leak} depends only on the conductivity of the

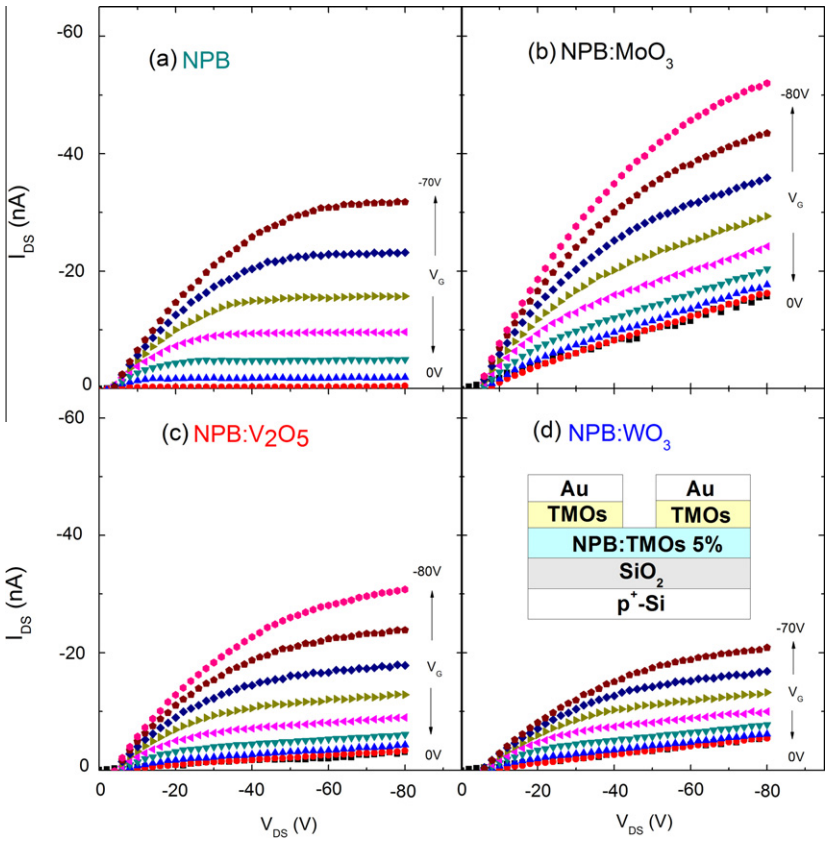

Fig. 3. Output characteristics of pristine NPB and TMOs-doped NPB OTFTs at room temperature. The gate voltage increased in steps of −10 V starting at $V_G = 0$ V. Inset: Bottom-gate top-contact OTFT device based on NPB:TMOs systems.

TMO-doped NPB. The field-effect mobility of a doped sample can, therefore, be extracted by removing the contribution of the background current (I_{DS} at $V_G = 0$ V) arising from a finite R_{leak}. Following this argument, we subtracted all I_{DS} from the background current. The resulting TFT characteristics can be fitted by Eqs. (1) and (2) again to extract both the linear and saturation mobilities. The results at room temperature are summarized in Table 1, columns 3 and 4. Generally, there is a slight reduction of the hole mobilities after doping. For MoO_3-doped NPB, the mobilities in the linear and saturation regions decrease to 9.4×10^{-6} cm^2/Vs and 7.5×10^{-6} cm^2/Vs, respectively. The reduction in the hole mobility is not surprising as ionized oxides (anions) are expected to be present in the doped-sample. The negatively charge oxides are fixed, but they have tendencies to trap holes temporarily, resulting in a reduction in hole mobilities. Trapping of holes was previously observed in the NPB:F4-TCNQ system [14].

As conductivity $\sigma = pq\mu$, we are now ready to extract free hole concentrations (p) in the doped samples using the conductivity data from Fig. 2 and the mobility data derived from Fig. 3. We use the FE mobilities extracted in the saturation regions as they are less susceptible to contact effects. For MoO_3-doped NPB, the free carrier concentration is 1.4×10^{17} cm^{-3} and is the highest among three TMOs. The free carrier concentrations for WO_3 (5.7×10^{16} cm^{-3}) and V_2O_5 (2.4×10^{16} cm^{-3}) doped samples are lower. To further explore the interactions of the three TMOs with NPB, we performed temperature dependent measurements. Fig. 4 shows the hole concentrations against the reciprocal of the absolute temperature T. It can be clearly seen that for each sample, all the temperature dependent data lie essentially on a straight line. The data can be fitted by the standard Arrehnius equation:

$$p = N_V \exp\left(-\frac{\Delta E}{k_B T}\right) \quad (3)$$

where p is the free hole concentration, k_B is the Boltzmann constant, N_V is the effective hole density of states, and ΔE is the activation energy. The solid lines in Fig. 4 are best fits to the data using Eq. (3). From the slope and the y-intercept, one can extract ΔE and N_V of each sample, respectively. These two parameters deserve additional comments. First, when TMO is doped into organic semiconductors, charge-transfer (CT) complexes can be formed [13,16]. In the case of TMO-doped NPB, due to the large electron affinities of the TMOs, NPB will partially donate some electron density to the oxide, resulting in a CT complex [19]. ΔE can be interpreted as the average energy required to ionize the CT complexes. The products are

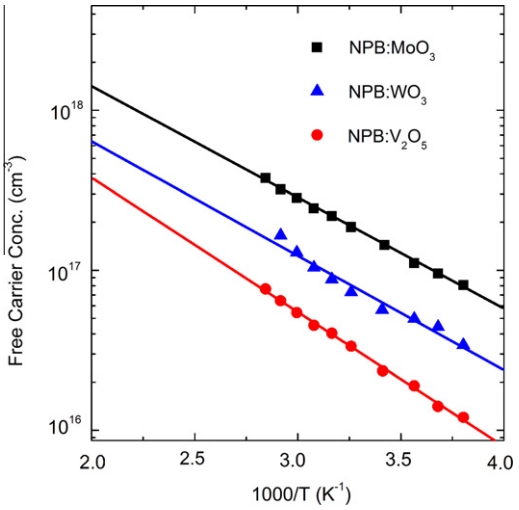

Fig. 4. Free hole concentrations vs. 1000/T plot for TMOs-doped NPB.

negatively charged TMO, and a free hole. Second, N_V, the prefactor in the exponential term in Eq. (3), can be interpreted as the number of states available for hole generation in the doped samples. For TMO-doped NPB, the oxide component tends to form nano-clusters [20]. Only those NPB molecules that are in the immediate neighborhood of the TMO nano-clusters are available for charge generation. As the three TMOs can conceivably have, on average, different sizes of nano-clusters in NPB, they may lead to different values of N_V. In our experiment, we found that both ΔE and N_V are the most favorable for the NPB:MoO_3 system in terms of carrier generation. The system has the lowest activation energy (138 meV) when compared to WO_3 (142 meV) and V_2O_5 (166 meV). Furthermore, N_V are between $\sim$2–3 $\times 10^{19}$ cm^{-3} for all doped samples, but is the largest for NPB:MoO_3. The results for ΔE and N_V are summarized in the last two columns in Table 1. Thus the temperature dependent data provide a thermo-dynamical explanation to the observation that MoO_3 is the best dopant among the TMOs.

To substantiate the temperature dependent data, we performed UV–NIR absorption spectra on pristine NPB and the three doping systems. Fig. 5 shows typical absorption spectra of 100 nm pristine and doped NPB on quartz substrates. Pristine NPB has a monotonically decreasing background from about 550–1300 nm. In contrast, after doping with TMOs, new absorption peaks can be found in the same spectral region. For the case of MoO_3-doped NPB, a well-defined peak occurs at about 500 nm.

Table 1
Conductivities (σ), field effect mobilities (μ_{Sat}, μ_{Lin}), free carrier concentrations (p), activation energies (ΔE) and the effective density of states (N_V) of NPB and TMOs-doped NPB.

	σ Conductivity (Scm^{-1})	μ_{Sat} (cm^2/Vs)	μ_{Lin} (cm^2/Vs)	p free carrier conc. (cm^{-3})	ΔE (meV)	N_V (cm^{-3})
NPB	–	1.1×10^{-5}	7.8×10^{-6}	–	–	–
NPB:V_2O_5 5%	2.8×10^{-8}	7.4×10^{-6}	6.6×10^{-6}	2.4×10^{16}	166	1.8×10^{19}
NPB:WO_3 5%	5.1×10^{-8}	5.6×10^{-6}	4.1×10^{-6}	5.7×10^{16}	142	1.8×10^{19}
NPB:MoO_3 5%	2.2×10^{-7}	9.4×10^{-6}	7.5×10^{-6}	1.4×10^{17}	138	3.5×10^{19}

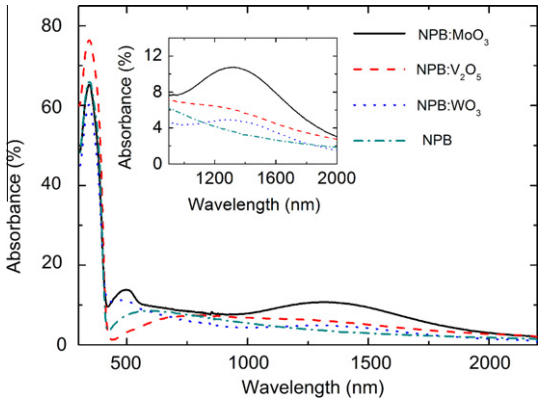

Fig. 5. Absorption spectra of NPB, NPB:MoO_3, NPB:V_2O_5, NPB:WO_3 films (100 nm) on quartz substrates. Inset shows the selected region from 900–2000 nm of the same spectra.

Furthermore, a broad peak, centered at about 1300 nm can be clearly observed (Fig. 5 inset). Similar broad peaks can be observed for the other two doped samples, but their intensities are significantly weaker. From the literatures, these peaks can be attributed to the charge transfer (CT) complex formed between the NPB and the TMOs molecules [13,16]. Their precise origins are still not known, but they may arise from resonant absorptions of the CT complexes. So their relationship with the activation energy ΔE is not clear. However, the absorption data do support again the observation that the reaction between MoO_3 with NPB is the strongest, resulting in the liberation of the largest amount of free carriers among the three TMOs.

4. Conclusions

The transport properties of NPB:TMOs systems were studied in details by field-effect transistors technique. After doping NPB with different TMOs, there is only a slight reduction in carrier mobilities in each case. Despite the reduction in carrier mobilities, the conductivities of all TMO doped systems were increased significantly. We concluded that this increase in conductivities is primarily due to an increase in the free carrier concentration when the oxide is doped into NPB. Among the three different oxides, MoO_3 is the most effective dopant as evidenced by its lowest activation energy of 138 meV and highest free carrier concentration of 1.4×10^{17} cm^{-3} in NPB. This is consistent with the independent UV–NIR absorption spectrum measurement, indicating that MoO_3 – NPB has the strongest interaction comparing with V_2O_5 and WO_3.

quantum efficiency over 20.0% was demonstrated in the two color and three color PHWOLEDs using the PPO27 as the host material in the red:blue emitting layer. In addition, the effect of the thickness of each emitting layer in the red:blue/green stack structure was investigated.

2. Experimental

The basic device structure of the two color PHOLEDs was indium tin oxide (ITO, 50 nm)/N,N′-diphenyl-N,N′-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4′-diamine (DNTPD, 60 nm)/N,N′-di(1-naphthyl)-N,N′-diphenylbenzidine (NPB, 5 nm)/N,N′-dicarbazolyl-3,5-benzene (mCP, 10 nm)/PPO27:iridium(III) bis(4,6-(di-fluorophenyl)-pyridinato-N,C′) picolinate (FIrpic):iridium(III) bis(2-phenylquinoline) acetylacetonate (Ir(pq)$_2$acac) (30 nm, 15%:*x*% doping)/diphenylphosphine oxide-4-(triphenylsilyl)phenyl (TSPO1, 20 nm)/LiF (1 nm)/Al (200 nm). The doping concentration of FIrpic was 15%, while the doping concentrations of the Ir(pq)$_2$acac were varied as 0.7%, 1.0% and 1.5%. Three color PHWOLEDs had the device structure of ITO (150 nm)/DNTPD (60 nm)/NPB (5 nm)/mCP (10 nm)/PPO27:FIrpic:Ir(pq)$_2$acac (*x* nm, 15%:0.7%)/bis-9,9′-spirobi[fluoren-2-yl]-methanone (BSFM): tris(2-phenylpyridine) iridium (Ir(ppy)$_3$)(30 − *x* nm, 3%)/TSPO1 (20 nm)/LiF (1 nm)/Al (200 nm). The thickness of the red:blue and green emitting layers was changed to study the effect of the emitting layer thickness on the device performances of PHWOLEDs. The thicknesses of the red:blue emitting layer were 3, 4, 5, 10 and 20 nm. Chemical structures of the PPO27 and BSFM are shown in Fig. 1 in addition to the device structure and energy level diagram of WOLEDs fabricated in this work. The PPO27 host material was synthesized according to the method reported in other work [17]. BSFM was reported in other work showed high triplet energy of 2.6 eV for energy transfer to green phosphorescent dopant [18]. Energy levels of the BSFM are shown in the energy level diagram of Fig. 1. All devices were fabricated by thermal evaporation at a vacuum pressure of 7×10^{-7} torr. The evaporation rate of the charge transport layers and host materials was 0.1 nm/s and the doping concentration was controlled by managing the deposition rate of the dopant. All devices were encapsulated with a glass lid and a CaO getter after device fabrication. Electroluminescence (EL) characteristics and EL spectra of PHWOLEDs were measured with Keithley 2400 source measurement unit and CS 1000 spectroradiometer.

3. Results and discussion

The PPO27 was reported as the high triplet energy host material for blue PHOLEDs and was effective to improve the quantum efficiency and driving voltage of blue PHOLEDs [17]. A high quantum efficiency of 23.9% and a high power efficiency of 37.5 lm/W were reported in the blue PHOLEDs. Therefore, the PPO27 can be effectively used as the host material for the two color and three color PHWOLEDs.

Two color PHWOLEDs with a single emitting layer doped with red and blue triplet emitters were fabricated and the doping concentration of the red dopant was optimized. Fig. 2 shows the current density–voltage-luminance curves of the PHWOLEDs according to the doping concentration of the red dopant. The current density of the PHWOLEDs was similar irrespective of the doping concentration of the red dopant and the luminance showed the same tendency as the current density. As the doping concentration of the red dopant was low compared to that of the blue dopant, the doping concentration of the red dopant did not greatly affect the current density of the PHWOLEDs. The turn-on voltage of the device was 3.0 V and the driving voltage at 1000 cd/m^2 was 5.6 V.

Quantum efficiency–luminance curves of the PHWOLEDs are shown in Fig. 3. The quantum efficiency of the three PHWOLEDs was similar over all luminance range irrespective of the doping concentration. The maximum quantum efficiency of the PHWOLEDs was over 20.0% and the quantum efficiency at 1000 cd/m^2 was over 16.0% in all PHWOLEDs. The PHWOLEDs showed high quantum efficiency because of charge balance and efficient light emission of Ir(pq)$_2$acac in the emitting layer. It was reported that the PPO27 based blue PHOLEDs exhibited good charge balance due to bipolar charge transport properties of the PPO27 host, which also balances holes and electrons in the emitting layer of PHWOLEDs[17]. The efficient light emission of the Ir(pq)$_2$acac also contributes to the high quantum efficiency of the PHWOLEDs. The main light emission mechanism of the PHWOLEDs is the cascade energy transfer from PPO27 to FIrpic followed by energy transfer to Ir(pq)$_2$acac and charge trapping by the dopant. In particular, the charge trapping is important for the light emission of the red dopant material. Therefore, the Ir(pq)$_2$acac should have high quantum efficiency to obtain high quantum efficiency in the emitting layer. As reported earlier, the Ir(pq)$_2$acac based devices showed high quantum efficiency over 20%, which improved the quantum efficiency of the PHWOLEDs [19].

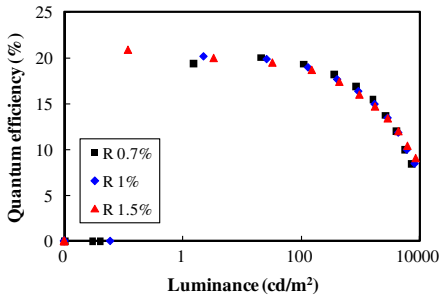

Fig. 3. Quantum efficiency–luminance curves of two color PHWOLEDs according to red doping concentration. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

EL spectra of the PHWOLEDs are presented in Fig. 4 according to the doping concentration of the Ir(pq)$_2$acac. The red intensity was gradually increased according to the increase of the red doping concentration. As the energy transfer from FIrpic to Ir(pq)$_2$acac is the main light emission process for the single emitting layer PHWOLEDs, the increase of the Ir(pq)$_2$acac doping concentration intensified the red emission because of the blue absorption by the red dopant followed by red emission. The relative light intensity of the red and blue emission was balanced at a doping concentration of 0.7% and the color coordinate of the 0.7% Ir(pq)$_2$acac doped PHWOLEDs was (0.38, 0.37). Detailed device data are summarized in Table 1.

As high quantum efficiency could be obtained from the two color PHWOLEDs, three color PHWOLEDs were developed using the PPO27 based emitting layer. Red and blue co-doped PPO27 emitting layer was combined with phosphorescent green emitting layer to fabricate PHWOLEDs. Electron transport type host, BSFM, was adopted as the triplet host for the green emitting layer. As the optimum doping concentration of the BSFM based green PHOLED was 3%, the 3% Ir(ppy)$_3$ doped BSFM layer was used as the green emitting layer. The green emitting layer was

stacked on the red:blue emitting layer and the thickness of each emitting layer was changed to control the emission spectra and device performances of PHWOLEDs.

The thickness of the whole emitting layer was fixed at 30 nm and the thickness of the red:blue and green emitting layers was changed. Fig. 5 shows the current density–voltage-luminance curves of the three color PHWOLEDs according to the thickness of red:blue emitting layer. The current density was high in the device with 5 nm thick red:blue emitting layer and was reduced in the devices with less than 5 nm thick red:blue emitting layer. The reduced current density of the PHWOLED with thin red:blue emitting layer is caused by the poor hole injection properties originated from the incomplete film formation. It is difficult to form continuous film using the 3 nm and 4 nm thick red:blue emitting layer and the hole transport layer is partially covered by BSFM green emitting layer, leading to partially direct hole injection from the hole transport layer to the BSFM green emitting layer. As the BSFM is an electron transport type host, the hole injection from the hole transport layer to the BSFM is worse than that from the hole transport layer to the PPO27 layer. As the coverage of the red:blue emitting layer on the hole transport layer was increased, the current density was also increased. However, the current density was reduced again in the device with thick red:blue emitting layer (10 and 20 nm) due to rather poor charge transport properties of the red:blue emitting layer compared with those of green emitting layer. The poor charge transport properties of the red:blue emitting layer is mostly due to charge trapping by the red dopant [20]. The difference of the luminance data is caused by the different recombination efficiency of the PHWOLEDs depending on the thickness of each emitting layer.

The quantum efficiency–luminance data of the PHWOLEDs are presented in Fig. 6. The maximum quantum efficiency of the PHWOLED was in the range from 18.4% to 20.8%, while the range of quantum efficiency at 1000 cd/m^2 was from 14.9% to 18.2%. The quantum efficiency was minimized in the device with 5 nm thick red:blue emitting layer and was maximized in the device with 20 nm thick red:blue emitting layer. At high red:blue emitting layer thickness, the BSFM green emitting layer played a role of electron transport layer as shown in the EL spectra of the three color PHWOLEDs, resulting in quantum efficiency similar to that of the two color PHWOLEDs. As the BSFM has good electron transport properties and electrons are little trapped by the $Ir(ppy)_3$ in the BSFM emitting layer, the recombination zone was close to the hole transport side, leading to weak green emission in the three color PHWOLEDs. The quantum efficiency was reduced as the thickness of the red:blue emitting layer decreased up to 5 nm because of less electron injection into the red:blue emitting layer. The increase of the quantum efficiency below 5 nm can be explained by the high quantum efficiency of the green emitting layer. As the red:blue emitting layer cannot form continuous film on the hole transport layer, some part of the device has the device structure with only green emitting layer and the other part of the device has the device structure of red:blue and green emitting layers. Although the quantum efficiency of the red:blue and green stacked part is reduced at a thickness below 5 nm, the quantum efficiency of the green emitting part is as high as 25.1% (this was not shown here). Therefore, the quantum efficiency of the PHWOLEDs is increased again at a low red:blue emitting layer thickness. The efficiency value of the PHWOLEDs fabricated in this work is one of the best efficiency values reported in PHWOLEDs.

Power efficiency of the three color PHWOLEDs was plotted against luminance in Fig. 7. The power efficiency was maximized at the red:blue emitting layer thickness of 3 nm because of strong green emission. The green intensity was reduced at high red:blue emitting layer thickness, resulting in the decrease of the power efficiency. The maximum power efficiency value of the PHWOLEDs was 42.2 lm/W and the power efficiency at 1000 cd/m^2 was 25.1 lm/W.

EL spectra of the three color PHWOLEDs are shown in Fig. 8 according to the thickness of the red:blue emitting layer. All EL spectra were normalized to monitor the change of the relative emitting intensity of red, green and blue emissions. The green intensity was very weak in the PHWOLED with 20 nm thick red:blue emitting layer and it was not intensified although the thickness of the red:blue emitting layer was reduced up to 10 nm. The green intensity was a little increased at the red:blue emitting layer thickness of 5 nm and was sharply increased at the red:blue emitting layer thickness of 4 nm. It was even more intensified at the red:blue emitting layer thickness of 3 nm. As explained in the device data, the direct hole injection from the hole transport layer to the green emitting layer at low red:blue emitting layer thickness intensified the green emission. This indirectly proves the incomplete film formation of the red:blue emitting layer below 5 nm. The color coordinate of the three color PHWOLEDs was changed from (0.45,0.39) to (0.38,0.48) according to the decrease of the red:blue emitting layer thickness from 20 nm to 3 nm. Color coordinate of the PHWOLEDs is summarized in Table 2 in addition to other device data. The color rendering index (CRI) was high in the PHWOLED with 5 nm thick red:blue emitting layer and it was 74. CRI of all devices are summarized in Table 2.

4. Conclusions

In conclusion, high efficiency two color and three color PHWOLEDs with a emitting layer stack structure of red:blue/green could be effectively developed using PPO27 as the host material for the red:blue emitting layer. High quantum efficiency over 20.0% was achieved in both two color and three color PHWOLEDs using the PPO27 host material and the device performances could be effectively managed by changing the thickness of the emitting layer. It was found that the red:blue/green stacked PHWOLEDs with the PPO27 host is promising as the high efficiency PHWOLEDs in display and lighting applications.

addition of non-volatile additives to DCB can significantly improve the performance of P3HT:PCBM devices [7]. Thus, controlling the interactions between P3HT, PCBM, and solvent during the drying process appears to be an effective route to modulating device performance and could potentially enable fabrication of high performance devices without the use of halogenated solvents. The use of solvent mixtures of differing compositions provides one facile route to modulate the solvent quality.

In an attempt to rationally select candidate solvent mixtures, we have utilized Hansen solubility parameters (HSP), which describe the total cohesion energy, E by three contributions: the dispersion interactions, E_d, permanent dipole-permanent dipole molecular interactions, E_p, and the hydrogen bonding molecular interactions, E_h. This energy is directly related to the solubility parameters (δ), which are the square root of the cohesion energy density (E/V) [12]

$$\delta^2 = \delta_d^2 + \delta_p^2 + \delta_h^2 \quad (1)$$

The application of solubility parameters have been utilized in understanding the solubility of polymers [13] and pharmaceuticals [14] in solvent mixtures. Fig. 1 illustrates the HSP for a number of different solvents. The solvents that can dissolve the P3HT and PCBM mixture (chloroform [$CHCl_3$], ortho-dichlorobenzene [o-DCB], chlorobenzene [CB], biphenyl, mesitylene [MS], carbon tetrachloride [CCl_4], diethylbenzene, ethylbenzene, toluene and xylene) are grouped together in HSP space that define the interaction radius (R_0) wherein solvents dissolve the polymer and solvents outside of the volume defined by R_0 will not dissolve the polymer. As DCB tends to yield devices with better performance, a mixture that matches its solubility parameters (δ_d = 19.2, δ_p = 6.3, δ_h = 3.3 $MPa^{1/2}$) would be desired based upon these solubility arguments. As illustrated by the line in Fig. 1, a mixture of MS and AP can closely mimic DCB. In this work, we describe the use of MS/AP mixtures to fabricate BHJ solar cells based upon P3HT and PCBM blends. With proper choice of relative MS/AP composition, device efficiencies approaching that obtained from those cast from DCB can be obtained.

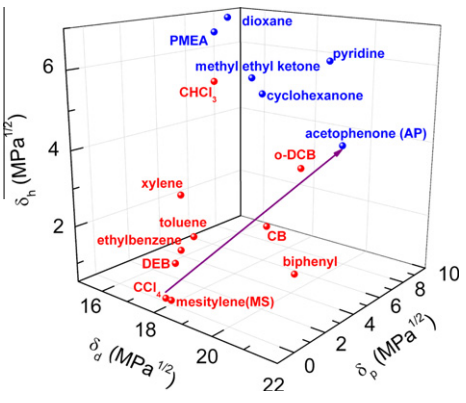

Fig. 1. Hansen solubility parameters (HSP) for selected solvents and solvent mixtures. Solvents in red are considered as good solvents for P3HT/PCBM blend and in blue are non-solvents. (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.)

2. Experimental details

2.1. Materials and device fabrication

Bulk-heterojunction solar cells based on P3HT/PCBM blend were fabricated in the following simple device stack structure: Indium tin oxide(ITO)/poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate)(PEDOT:PSS)/P3HT:PCBM/bathocuproine(BCP)/Al. Regioregular P3HT (Rieke Metals, 4002E) and PCBM (99.5%, Solenne) were dissolved in a 1:1 ratio to 1.0 wt.% in mixtures of MS (99.0%, Sigma–Aldrich) and AP (99%, Sigma–Aldrich) by heating and stirring for 2 h at 75 °C in a nitrogen atmosphere. These solutions were then cooled slowly to ambient temperature. For comparison devices, the P3HT:PCBM blend (1.5 wt.%, 1:1 weight ratio) was dissolved in DCB (99%, Sigma–Aldrich) and stirred for 24 h at 40 °C. Before the fabrication of the devices, the substrates were cleaned by scrubbing with detergent and ultrasonic treatment in deionized water, acetone and isopropyl alcohol sequentially and UV-ozone (Jelight model 42) treatment for 40 min. The cleaned ITO-coated glass substrates were modified by spin-coating a thin layer (~40 nm) of PEDOT:PSS (Clevios, 4083) and cured at 200 °C for 30 min. The polymer blended films were spin-coated in a nitrogen-filled glove box onto the PEDOT:PSS modified substrate. The as-cast films were dried overnight in nitrogen atmosphere at ambient temperature. After drying, the samples were thermally annealed at 140 °C for 30 min. Finally, BCP (~14 nm) and Al cathode (~100 nm) layers were thermally deposited on top of the active layer and each device had an active area of 0.04 cm^2.

2.2. Device characterization

The current density–voltage characteristics were measured using a solar simulator (Newport, 150 W) with an AM 1.5G filter in a nitrogen filled glovebox at room temperature. The intensity of illumination was set for 100 mW/cm^2 using a Si reference Hamamatsu cell (Model C24 S1787-04) calibrated by the National Renewable Energy Laboratory (NREL), USA. The spectral mismatch of the solar simulator was estimated to be less than 10%. External quantum efficiency data were measured with monochromatic light by varying the excitation wavelength from 300 to 850 nm at intervals of 10 nm, under a white bias light of 100 mW cm^{-2} (Optronics Laboratories, Inc.). The surface morphology of the thin films was measured using atomic force microscopy (Park Systems XE-150) operating in non-contact mode with 2 μm × 2 μm scan size. The film thickness was measured using a Variable Angle Spectroscopic Ellipsometer (VASE M-2000, J.A. Woollam Co.).

3. Results and discussion

Fig. 2 shows the device performance with the use of pure MS and various MS/AP solvent mixtures. The J–V curves show a significant increase in the magnitude of short circuit current (J_{sc}) with the addition of AP to the MS solution. However, further increase of the AP concen-

tration from 20 vol.% to 30 vol.% lead to a negligible increase in J_{sc} and a small decrease in open-circuit voltage (V_{oc}). These changes in performance can be quantified by comparing the power conversion efficiency (PCE) of the devices as illustrated in Fig. 2b. The device fabricated from the 80–20 vol.% MS–AP mixture has a larger PCE than both 90–10 and 70–30 vol.% MS–AP mixtures. This result suggests that there is an optimal concentration for device performance. However, it may be noted that the composition of the solvent mixture (80–20 vol.% MS–AP) is far removed from the ideal composition (27–73 vol.% MS–AP with $\delta_d = 19.2$, $\delta_p = 6.3$, $\delta_h = 2.9$ MPa$^{1/2}$) that matches DCB based on the HSP selection rules. One explanation could be solvent electron density, which has been shown to be critical for surfactant solubility [15], is not explicitly addressed using HSP selection rules. Moreover, HSP does not account for any electrostatic interactions that will be important in this system. However, the normal boiling point difference between MS (165 °C) and AP (202 °C) results in significant concentrating of the AP during solvent evaporation in the film formation process. Thus during film formation, the solvent quality (from HSP arguments) would be evolving due to differential evaporation of the components in the solvent mixture. Thus, it would be expected that as the film forms the solvent quality will trend towards, and hopefully

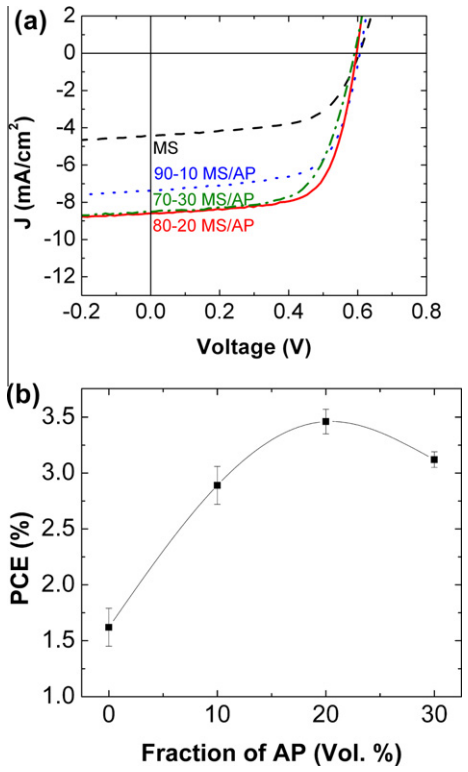

Fig. 2. (a) The *J–V* characteristics under illumination of 100 mW cm^{-2} (AM 1.5G) for devices fabricated from pure mesitylene and various MS/AP mixtures and (b) PCE values of devices fabricated from pure mesitylene and various MS/AP mixtures as a function of the amount of acetophenone (vol.%) in the solvent mixtures.

approach, that of DCB, due to comparably low boiling temperature of MS.

Nonetheless, this mixed solvent system of MS–AP does offer a route to improved device performance. Similarly, Bouman et al. [16] illustrated the potential of mixed solvent systems using chloroform–methanol mixtures and these mixtures have been shown to be effective in P3HT/PCBM system [8], but the origins of the improvement are not clear and halogenated solvent was still utilized. In this case, the HSP for methanol ($\delta_d = 15.1$, $\delta_p = 12.3$, $\delta_h = 22.3$ MPa$^{1/2}$) would not suggest an improvement in the match of the solvent quality to a system with well-known good performance such as DCB. Thus, the solubility parameters of the solvent are not be the only factors impacting performance; the wettability, solvent partitioning, solution aggregation and other factors will also be important. However, simply adding a poor solvent will not necessarily improve the performance. We have examined a mixture of MS with cyclohexanone; from the HSP arguments, it should be possible to form a mixture that is between chloroform and DCB (see Fig. 1). For all of these mixtures, the performance of the device was degraded in comparison to the pure MS. The overall solubility of the P3HT and PCBM decreased with the added cyclohexanone, but the cyclohexanone is also more volatile than MS. These two factors likely explain the degraded performance of this mixture as the solvent quality during film formation will evolve towards pure MS. Despite these differences, the performance of the device fabricated with 80–20 vol.% MS/AP mixture appears to be tremendously improved over typical devices fabricated from solely non-halogenated solvents. As this mixture provides the best performance with this solvent pair, it would be meaningful to compare its performances to analogous devices fabricated from the standard DCB.

Fig. 3 illustrates the difference in device performance obtained for the P3HT:PCBM blend depending upon the casting solvent used. First, the *J–V* curve illustrates the significant difference in the short circuit current for the device fabricated from MS in comparison to DCB as would be expected [9]. The performance of the device fabricated from DCB can be approached by addition of 20 vol.% AP to the MS with J_{SC} increased from 4.7 mA cm^{-2} to 8.9 mA cm^{-2}, R_{SA} decreased from 3.4 Ω cm^2 to 2.8 Ω cm^2, and the fill factor is increased from 59% to 66%. These changes in *J–V* characteristics results in a significant increase in PCE from 1.6% to 3.4% for MS and MS–AP mixture. Additionally, the external quantum efficiency (EQE) increases from a maximum of 35% at 500 nm for the device from MS by a factor of two up to 69% for the mixed solvent as shown in Fig. 3b. These are significant improvements in the device performance, although the performance for the pure MS is known to be poor. Thus, we have also compared the performance of the device formed from the mixed solvent system to those cast from DCB. From Fig. 3a, the short circuit current and open circuit voltage are both slightly larger for the 85 nm thick device from DCB, but at similar thickness (65 nm) the device performance is nearly indistinguishable between the device from DCB and from the MS–AP mixture. Similarly, the EQE for the thicker DCB sample is slightly larger at wavelengths exceeding 500 nm.

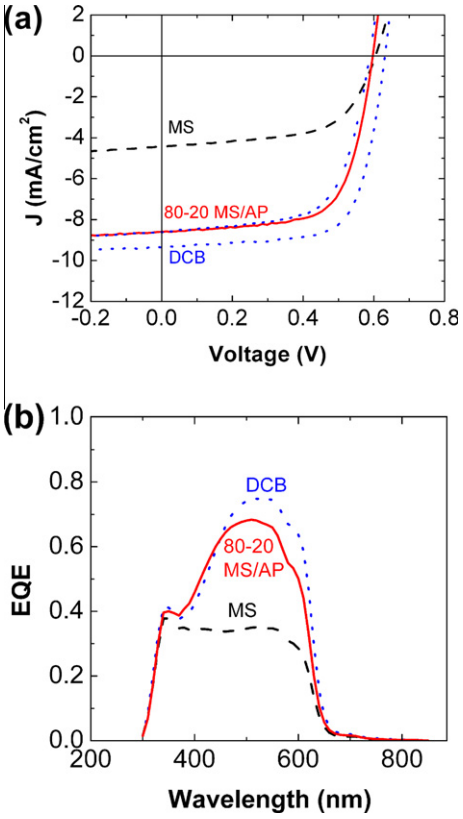

Fig. 3. (a) The *J–V* characteristics under illumination of 100 mW cm^{-2} (AM 1.5G) and (b) external quantum efficiency (EQE) measurements data for devices fabricated from DCB, MS, and 80 vol.% MS-20 vol.% AP mixture.

Table 1 summarizes the performance characteristics for devices from the three different solvents: pure MS, 80–20 MS–AP and pure DCB. One important point to note is that the performance is highly reproducible with at least 6 devices tested for each to calculate the standard deviations in performance characteristics. For the mixed solvent system, the PCE varies between 3.2% and 3.8%; for comparison, the performance for the 85 nm thick devices from DCB varies between 3.6% and 4.3%. However, it is well known that the efficiency for P3HT:PCBM solar cells is thickness sensitive for thin film less than 150 nm thick [17], which is consistent with the decrease in performance for the 65 nm thick devices from DCB. Difficulties in obtaining similar drying and spin coating conditions limited the ability to fully match the film thickness for the different solvent systems. However for thin films, the performance from the mixture closely mimics that obtained for DCB at similar active layer thickness. In addition to HSP arguments, one could also imagine that the relative solubility of P3HT and PCBM in each component of the solvent mixture would provide a route to control the structure. Recently, a mixture of pyridine and chlorobenzene, which good solvents for carboxylated polythiophenes and PCBM, respectively, has been utilized to fabricate OPV devices as the polymer is only marginally soluble in chlorobenzene [19]. For the MS–AP mixture, MS readily dissolves both P3HT and PCBM; the solubility of the components in AP is significantly less with PCBM soluble to >10 mg/mL and P3HT nearly insoluble in AP (<0.05 mg/mL).

We hypothesize that the improved device performance of the MS–AP mixed solvent system originates predominately from two contributions: a decrease in the series resistance (refer to Table 1) and the change in morphology of the active layer caused by the solvent quality upon phase separation of the PCBM and P3HT. The slower evaporation rate of the high boiling point component (AP) during spin coating and drying process may also facilitate reorganization in the blend to a more appropriate morphology for charge transport and exciton dissociation. However, the changes in device performance can generally be attributed to the morphology of the P3HT:PCBM that is dependent on the processing conditions [8,18]. To begin to understand the morphology of the blends processed with different solvents, the surface after annealing is interrogated using AFM. Fig. 4 illustrates the topography and phase images of the P3HT:PCBM films spun from the different solvents. It is clear from these micrographs that the morphology of the blend formed from the MS–AP mixed solvent closely resembles that of the film cast from DCB. For the film cast from MS, the surface is rough with large domains clearly visible in the micrograph. Conversely, no large domains are observed for the film formed from the solvent mixture or from DCB. We attribute this morphological change in the mixed solvent system to the solvent quality evolution during drying due to the lower vapor pressure of the AP that changes the thermodynamic interactions in the solution. Both the intramolecular interactions and interactions between P3HT and PCBM are

Table 1
Summary of device performance for various BHJ solar cell devices in the work.

	MS	80–20 vol.% MS/AP mix.	DCB (thin)	DCB (thicker)
Thickness (nm)	60	60	65	85
J_{sc}^{*} (mA cm^{-2})	4.68 ± 0.76	8.88 ± 0.67	8.34 ± 0.26	9.15 ± 0.15
V_{oc} (V)	0.56 ± 0.04	0.58 ± 0.02	0.59 ± 0.01	0.63 ± 0.01

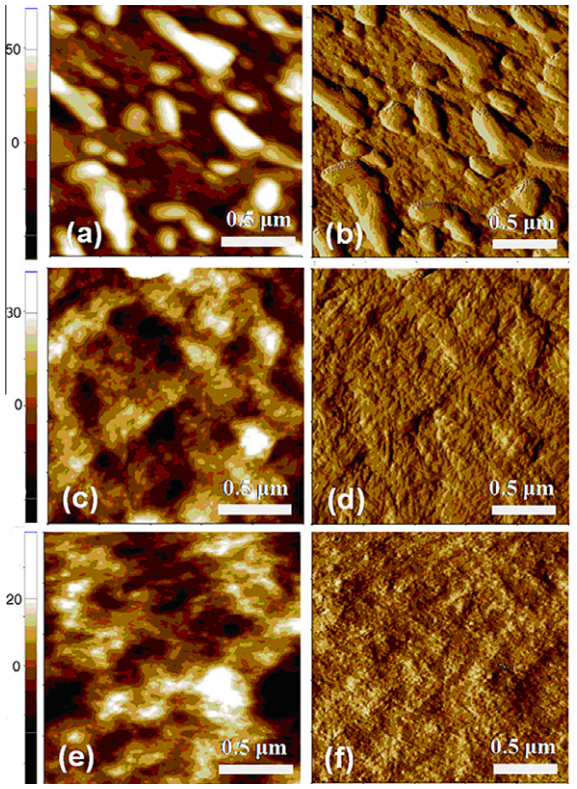

Fig. 4. AFM topography and phase images of P3HT/PCBM blend films cast from (a,b) MS, (c,d) 80 vol.% MS-20 vol.% AP mixture, and (e,f) DCB (scale bar for topology in nm).

mitigated by the solvent initially and the solvent quality upon crystallization of one phase or phase separation will dictate how the morphology evolves. The film cast from DCB exhibits the smallest domain size of the three films, but the surface morphology for the solvent mixture is very similar to that for the DCB. This similarity in morphology is in good agreement with the *J–V* characteristics of the analogous devices. These results suggest that high performance organic BHJ solar cells can be fabricated with proper choice of halogen-free solvent pairs. The elimination of the use of halogenated solvents without compromising the fabrication condition could prove to be important for the potential commercialization of polymer based BHJ solar cells. Future work will focus on extending these concepts to other donor–acceptor pairs that have higher theoretical efficiencies, especially when one component is not soluble in typical solvents (i.e. DCB).

4. Conclusion

In conclusion, we demonstrate the use of the non-halogenated solvent mixtures for the fabrication of BHJ organic solar cells. In comparison to a pure aromatic solvent, i.e. mesitylene, the use of a mixture containing 20 vol.% AP in MS results in more homogeneous morphology of the P3HT:PCBM film with a corresponding improvement in PCE from 1.6% to 3.4% and EQE from 35% to 69%. We find an optimal composition in this solvent mixture; either increasing to 30 vol.% AP or decreasing to 10 vol.% AP results in a decrease in PCE. The overall device performance of the device fabricated from the non-halogenated MS–AP mixed solvent system can be comparable to that of a standard device from DCB. Further optimization of this work could enable the use of fully, non-halogenated solvent mixture systems for scale-up manufacturing of high performance BHJ organic solar cells.

density; when there are enough carbon nanotubes mixed into the organic semiconductor film to drastically enhance mobility, the density of the CNTs appears to approach the percolation threshold, thus limiting the maximum mobility achievable before the percolation of CNT reduces the on/off ratio of such a hybrid organic/CNT transistor. Graphene, a two-dimensional lattice of carbon with single atom thickness, has generated significant attention due to its outstanding electronic, mechanical and physical properties [13]. As with the addition of CNTs, it is expected that few-layer and single-layer graphene flakes can provide good connection between the crystalline regions of the semiconductor film. Compare to CNTs, increased area in the conduction channel of an organic semiconductor transistor can be covered by graphene flakes before they start to percolate and reduce the on/off ratio. As a result, the mobility of organic transistors with graphene flakes would be expected to show higher values than what can be accomplished using CNTs before device on/off ratio drops.

Recent progress with liquid exfoliation of graphene provides cost efficient methods to prepare graphene dispersions [20–22]. Coleman et al. first reported the exfoliation of graphene in *N*-methyl-2-pyrrolidone (NMP) [20], and then the Tour and Barron groups reported exfoliation of graphene in ortho dichlorobenzene (ODCB) with higher graphene concentration [21]. In our method, graphite was exfoliated in ODCB. Not only is ODCB a good solvent for organic semiconductors, but also graphene flakes can be dispersed in ODCB without the aid of surfactants. Therefore ODCB appears to be a good solvent for hybrid organic semiconductor/graphene films. In this paper, we present a general approach for the preparation of solution processable organic semiconductor/graphene hybrid thin film transistors. Compared to FETs with pure organic semiconductors, hybrid FETs exhibit much higher effective mobility while keeping the on/off ratio of devices sufficiently high.

2. Materials and methods

In this work, poly(3,3-didodecylquaterthiophene) (PQT-12) was chosen as the organic semiconductor material because of its good air stability. Additionally, poly-(3-hexylthiophene) (P3HT), an organic semiconductor widely used for both organic transistor and organic photovoltaic device studies, was also studied to prove that our method is a general route to enhance the performance of polymer transistors.

We synthesized PQT-12 according to $FeCl_3$-mediated oxidative coupling polymerization [25]. Our PQT-12 showed almost the same thermal behavior in the differential scanning calorimetry (DSC) thermogram with Xerox's PQT-12 [26,27]. Regioregular P3HT (94.5%, M_n = 13,000 and M_w = 26,200 g/mol) was purchased from Merck and used without further purification. Graphene dispersions were prepared by an adaptation of the solution sonication method reported previously by the Tour and Barron groups [21]. Briefly, graphite (Asbury Graphite Mills Inc.) was added into ODCB at a concentration of 5 mg/ml. The mixture was then sonicated for 45 min with an ultrasonicator (Heilscher 400) at 50% power. After ultrasonication, graphene dispersions were left to settle for about 1 h to allow thick graphite flakes to sediment out of solution. The top portion of the solution was then centrifuged at 1500 rpm for 1 h. The supernatant from the top half of the solution yielded a graphene dispersion which contained single-layered and multi-layered graphene flakes. Three milligrams of PQT-12 or P3HT was then added to 1 ml of this graphene dispersion. The mixture was heated to allow the polymer to dissolve completely. The hot solution was then subjected to ultrasonic agitation and cooled to room temperature [24]. This yielded a dark-purple solution with polymer nanoparticles and graphene flakes suspended in ODCB. A heavily doped silicon wafer with 300 nm thermally grown SiO_2 was used as a substrate material. Wafers were cleaned by sonication in acetone, isopropanol and DI water, respectively, followed by N_2 drying. Some of the substrates were used as cleaned, while others were treated with an octyltrichlorosilane (OTS-8) self-assembled monolayer (SAM). OTS-8 self-assembled monolayer was deposited on a wafer surface by immersion into a 10 mM solution of OTS-8 in toluene at 60 °C for 15 min, subsequent rinsing with toluene and ethanol, and then blow-drying with nitrogen before use [24]. Hybrid field-effect transistors were fabricated by spin coating the PQT-12/graphene (or P3HT/graphene) composite solution onto a substrate at 1200 rpm for 60 s followed by vacuum drying to give 20–50-nm thick semiconductor layer. Control devices were fabricated with pure PQT-12 (or P3HT) films using the same procedures but without the addition of graphene flakes to the ODCB solution. Following deposition of the organic semiconductor films, gold source-drain electrodes were deposited by thermal evaporation through a shadow mask with channel length L = 130 μm and channel width W = 2 mm. As indicated in the text, some of the resulting devices were annealed in a vacuum oven at 140 °C for 20 min, followed by slow cooling.

All the current–voltage (I–V) curves were measured at room temperature under ambient conditions using a Cascade probe station connected to two Keithley 2400 source/measure units. The effective field-effect mobility of each transistor was extracted from the transfer characteristics using a linear fit to the plot of the square root of saturation source-drain current as a function of the gate voltage V_g.

3. Results and discussion

The concentration of graphene in the hybrid films was measured by two methods. First, graphene dispersion with known volume was slowly dropped onto a heated glass slide. After complete solvent evaporation, the mass change of the glass slide was carefully measured. With this method, the concentration of graphene in the dispersion was calculated to be about 0.055 mg/ml. In another method, the graphene concentration was determined by UV–vis–IR absorption spectroscopy (see Supplementary data). The spectra are featureless in the visible–IR region as expected [23]. An average absorption coefficient for graphene of 2460 L/g m at a wavelength of 660 nm was

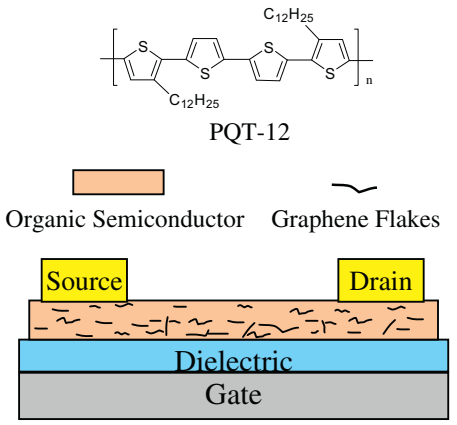

Fig. 1. Structure of organic semiconductor/graphene hybrid FET.

used for the calculation [20]. Therefore, optical methods can be employed to measure the concentration of graphene which was calculated to be about 0.045 mg/ml in the deposition dispersion. The first method gives a slightly higher concentration, which is believed to be due to the residual decomposed ODCB solvent on the heated glass slide.

As shown in Fig. 1, graphene flakes incorporated into an organic semiconductor film is expected to provide "fast lanes" for charge carriers within the conduction channel, enhancing the effective mobility of the entire transistor device. That is, the addition of graphene flakes might effectively reduces the conduction channel length, which acts to enhance the output source-drain current of the field-effect transistor. This activity is realized in the ambient laboratory atmosphere.

Transistors with and without substrate surface treatment or post-fabrication annealing process were all studied. For transistors fabricated without any substrate surface treatment or post annealing process, PQT-12/graphene hybrid FETs exhibited source-drain current about 10 times higher than that of a control device (containing only PQT-12 with no added graphene). Fig. 2 compares *I–V* characteristics of a control device and a PQT-12/graphene hybrid transistor both on a cleaned SiO_2 surface without any customized surface treatment. The mobility of the control device is 0.012 $cm^2 V^{-1} s^{-1}$, while the mobility of the PQT-12/graphene hybrid FET is 0.17 $cm^2 V^{-1} s^{-1}$. The on/off ratios of both devices are on the order of 10^3 but better on/off ratios could be achieved by post-fabrication annealing the devices as described below.

When substrate surface treatment and post-fabrication annealing process are performed, both PQT-12/graphene hybrid FETs and control devices exhibit better performance, but PQT-12/graphene hybrid FETs show significantly greater enhancement. Fig. 3 shows source-drain *I–V* curves and transfer curves for both control devices and hybrid FETs fabricated on substrate surfaces that were treated with octyltrichorosilane (OTS-8) and were vacuum annealed after fabrication. The effective mobility of the control device is 0.15 $cm^2 V^{-1} s^{-1}$, which is comparable to previously reported values [24]. In contrast, the effective mobility of the PQT-12/graphene hybrid FET is 0.55 $cm^2 V^{-1} s^{-1}$, which is remarkably high for a PQT-12 FET. In comparison, the highest prior report mobility for pure PQT-12 is 0.2 $cm^2 V^{-1} s^{-1}$ [24]. The on/off ratio of both devices are as high as 10^5 with the off current on the order 10^{-9} A when measured in air after vacuum annealing. The low off current obtained suggests that densities of graphene flakes in these PQT-12/graphene hybrid films are still lower than the percolation threshold of graphene.

To study the dependence of device performance on graphene dispersion concentration, hybrid PQT-12/graphene films containing higher densities of graphene flakes were also studied. Graphene dispersions at higher concentration can be prepared by first preparing graphene dispersion according to procedures described in Section 2, followed by removing some of the ODCB solvent either by rotary evaporation or by rapid heating in a shallow poly(tetrafluroethylene) (PTFE) dish. These high-concentration graphene dispersions are then mixed with PQT-12 semiconductor and deposited on substrates. It should be noted that if the graphene dispersion is heated in air for a long time (more than 10 min), graphene flakes will start to aggregate and precipitate, probably due to the adsorption of water into solution. This can be avoided by using a shallow dish with large surface area to reduce the time needed for the graphene dispersion to be exposed to air, or using a rotary evaporator to exclude water during the process. Sometimes during concentration, a small

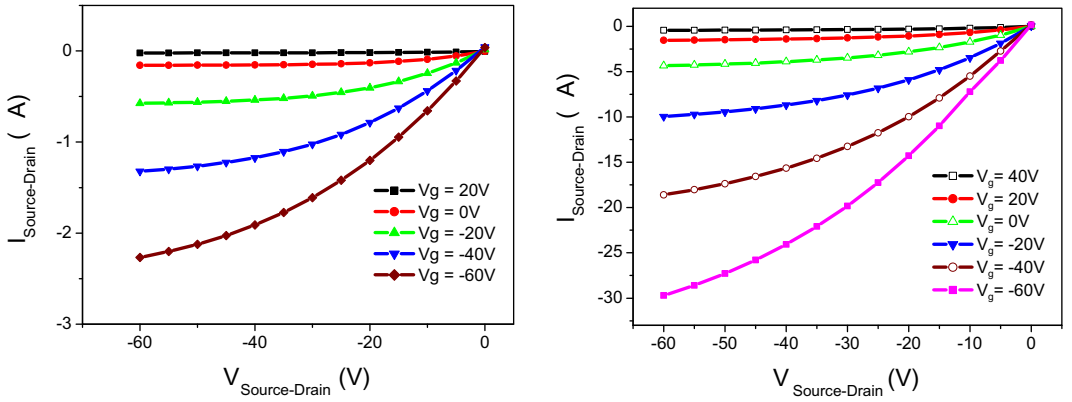

Fig. 2. Source-drain *I–V* curves of a pure PQT-12 FET (left) and a PQT-12/graphene hybrid FET (right).

amount of graphene precipitates out, but can be re-dispersed into suspension by ultrasonication for 5 min. The resulting ink-like graphene dispersions at higher concentrations are only stable for a short time, and hence should be used right after preparation. For this study, graphene dispersions concentrated by 4 times and 10 times were prepared and mixed with PQT-12 semiconductor immediately after graphene dispersion preparation, followed by 5 min sonication. Hybrid transistors were then fabricated using these organic semiconductor/graphene composite solutions according to the same procedures as described above and are referred to below as PQT-12/4× graphene FETs and PQT-12/10× graphene FETs, respectively.

Fig. 4 summarizes the maximum mobilities, average mobilities and on/off ratios of all transistors measured. Error bars in the figure show the highest mobilities measured for each type of device, while the columns show averaged values. Field-effect transistors fabricated from 4× concentrated graphene dispersions exhibited average mobility of 0.32 $cm^2 V^{-1} s^{-1}$, which is lower than that of devices made from graphene dispersion at normal concentration. This is probably due to the fact that, when too many graphene flakes are present in PQT-12 film, the structural order in the PQT-12 is decreased. This is supported by X-ray diffraction results showing a loss of crystallinity with increasing graphene concentration, as

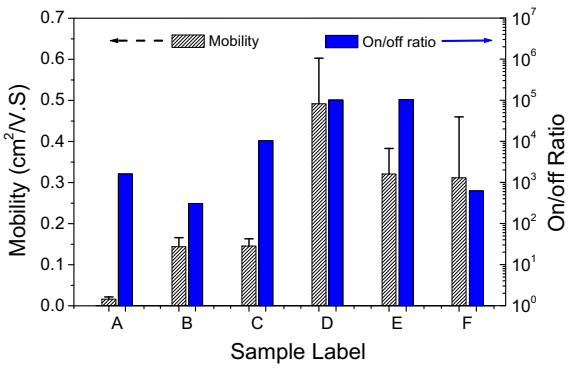

Fig. 4. Summary of mobilities and on/off ratio of all PQT-12 transistors with/without graphene: (A) PQT-12 FET no OTS8 and no annealing. (B) PQT-12/graphene FET no OTS-8 and no annealing. (C) PQT-12 FET with OTS-8 and annealing. (D) PQT-12/graphene FET with OTS-8 and annealing. (E) PQT-12/4×-graphene FET with OTS and annealing. (F) PQT-12/10×-graphene FET with OTS and annealing.

shown in the Supplementary data. Although more graphene flakes can provide more "fast lanes" for charge carriers in conduction channels, more disordered PQT-12 semiconductor layers ultimately reduce the effective mobility of devices. At this concentration, the density of graphene flakes in polymer is believed to be still lower than the percolation threshold, so that the on/off ratios of

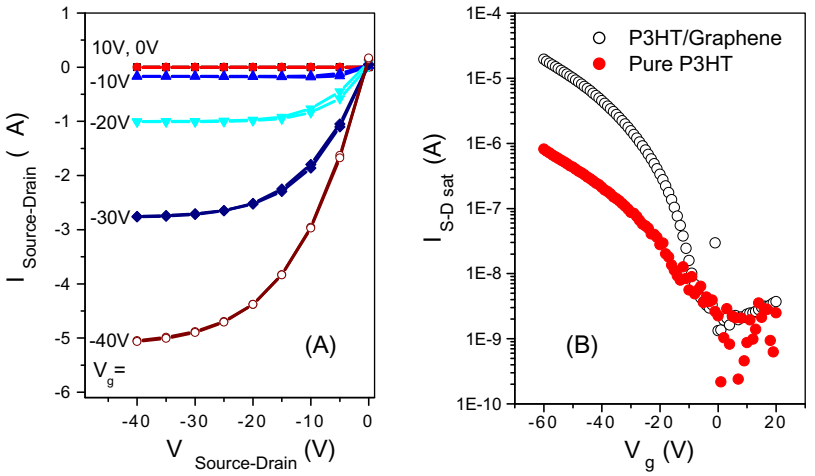

Fig. 5. (A) Source-drain *I–V* curve of a P3HT/graphene hybrid FET. (B) Transfer characteristics of pure P3HT and P3HT/graphene hybrid FET.

PQT-12/4× graphene FETs remain in the same order of magnitude as transistors with regular graphene concentration. However, when 10 times concentrated graphene dispersion was added into PQT-12 semiconductor, the on/off ratio of transistors was decreased significantly, suggesting that the density of graphene flakes in the polymer exceeds the percolation threshold. Off currents of these PQT-12/10× graphene FETs are on the order of 10^{-7} A, hundreds of times higher than that of PQT-12/graphene FETs with graphene dispersion at normal concentration.

Additionally, P3HT was also studied to demonstrate that our approach is a general route to enhance the performance of transistors made from polymer semiconductors. P3HT/graphene hybrid FETs were fabricated using the same methods on OTS-8 treated substrates, and again, all devices were fabricated and measured under ambient conditions. The measured current–voltage characteristics for P3HT/graphene FETs show well-defined gate modulation. As an example, Fig. 5A depicts the current–voltage characteristics of a P3HT/graphene FET, and Fig. 5B compares the transfer characteristics of a P3HT/graphene hybrid transistor to that of a pure P3HT FET. As can be seen, much higher current was obtained from the device with graphene. The P3HT/graphene FET exhibits mobility as high as 0.17 $cm^2\,V^{-1}\,s^{-1}$, which is more than 20 times higher than that from the pure P3HT FET (0.007 $cm^2\,V^{-1}\,s^{-1}$). The on/off ratio of the P3HT/graphene FET is on the order of 10^4, which is surprisingly an order of magnitude *higher* than that of the pure P3HT FET in contrast to what is observed in P3HT/carbon-nanotube composites. [14] This is because both devices exhibit similar off currents, while the P3HT/graphene FET shows much higher on current. These results suggest that our method is a general route to enhance the performance of polymer electronics.

4. Conclusions

In conclusion, we have developed composite field-effect transistors containing both polymer semiconductor materials and graphene flakes, and we have shown that effective mobilities of polymer/graphene hybrid FETs can be significantly higher than that of a pure polymer FET. When graphene dispersions with concentrations at about 0.05 mg/ml are mixed with PQT-12 semiconductor, effective mobilities as high as $0.5 \pm 0.1\ cm^2\,V^{-1}\,s^{-1}$ can be obtained in ambient conditions, while the on/off ratio of these devices can be on the order of 10^5 and was not reduced due to the addition of graphene flakes. This is attributed to the high percolation threshold of graphene. When the concentration of graphene flakes in the semiconductor film was increased by 4 times, the effective mobility was decreased to $0.32 \pm 0.06\ cm^2\,V^{-1}\,s^{-1}$ because the high density graphene flakes in the organic semiconductor layer probably resulted in a more disordered film. The on/off ratio of hybrid FETs significantly decreased when the concentration of graphene flakes in semiconductor film was increased by 10 times, which is believed to exceed the percolation threshold of graphene flakes. We also found that effective mobilities of P3HT/graphene hybrid FETs can be more than 20 times higher than that of pure P3HT FETs we fabricated. We expect that adding graphene flakes to organic semiconductors is a general route to enhance the performance of organic electronics, providing a low-cost avenue for enhancing OFET performance.

inserting alkali-metallic materials, such as Cs_2CO_3, as an interfacial layer, and even by doping [9–11]. In our previous study, a self-assembled monolayer (SAM) was employed to modify a TiO_2 surface to tune the energy level of the conduction band [12]. Unfortunately, the inferior electron mobility of TiO_2 inhibited electron injection, reducing eletroluminescence (EL) efficiency. ZnO is an excellent alternative to TiO_2 because it has a similar bandgap but higher electron mobility. The resistivity of ZnO can be adjusted from $10^{-4}\,\Omega$ cm to $10^{12}\,\Omega$ cm by controlling the annealing conditions and doping[13]. Moreover, ZnO is widely utilized in organic optoelectronic devices such as O/PLEDs [6,10,14], and polymer photovoltaic cells [15].

In the present investigation, ZnO thin film was prepared using the sol–gel process and its energy level was modified by grafting thereon N-[3-(trimethoxysily)propyl]ethylenediamine (PEDA-TMS), which acted as an electron injection layer. The sol–gel-derived ZnO thin film was used to investigate the effect of heat treatment on the PLED performance. Following annealing at 300 °C, an inverted PLED exhibited a performance close to that of a conventional PLED. Furthermore, the effect of annealing on ZnO characteristics is determined in terms of the degree of grafting of PEDA-TMS and its relation to the amount of active –OH groups, the electron mobility owing to crystallinity of ZnO, and hole blocking effect, which enhances effective recombination.

2. Experimental

ZnO thin films were prepared using sol–gel technology [16]. Zinc acetate dehydrate (99.999%, J.T. Baker) as a precursor was dissolved in a mixture of 2-methoxyethanol and 0.1 M acetic acid aqueous solution at a 1:1 volume ratio. The concentration of zinc acetate was 0.1 g/ml. Before the zinc acetate solution was spin-coated, an ITO substrate (RITEK Corp., 15 Ω/square) was ultrasonically cleaned with detergent, deionized water, acetone, and isopropyl alcohol, sequentially. Contaminants on the ITO surface were removed using UV-ozone treatment. The mixing solution was spin-coated on ITO (approximately 100 nm) and the layers were subsequently annealed with different temperatures for 30 min. The modified ITO was immediately immersed in 1 wt.% PEDA-TMS (Aldrich, 97%) from a toluene solution for 2 min in an ultrasonic bath and cleaned. SAMs were bonded onto the ZnO surface using a hydrolyzed process described in a previous study [12]. Then, PLED devices with ITO/ZnO/SAMs/emissive layer/MoO_3/Au/Ag architecture were fabricated. Polyfluorene Green B (G-PF) (Dow Chemical Corp.) as an emissive layer (thickness of ca. 50 nm) was spin-coated on ZnO modification layer from a toluene solution, which was then baked at 65 °C for 30 min. The device was placed in a high vacuum chamber with a pressure of 10^{-6} Torr for the thermal evaporation of MoO_3 (6 nm), Au (20 nm), and Ag (80 nm). A conventional PLED was fabricated for comparison. ITO/PEDOT:PSS (Baytron P AI 4083) and Ca/Al were utilized as a anode and an cathode, respectively. Ca (60 nm)/Al (100 nm) was utilized as an anode in the electron-only device to characterize the electron injection ability.

The current density–voltage–luminescence (J–V–L) characteristics of the devices were measured with a Keithley 2400 source measure units and Keithley 2000 digital multimerter along with a silicon photodiode, calibrated using a Minolta LS-100 luminance meter. The capacitance–voltage (C–V) measurements were conducted with an Agilent 4284A precision LCR meter. C–V measurements were carried out under applied voltage of 0–3.8 V and a modulated voltage of 10 mV at 10 k Hz. The overall measurement was in an inert nitrogen atmosphere. Here, the threshold voltage (V_{th}) and turn-on voltage ($V_{turn\text{-}on}$) indicated the majority carrier injection point and luminescence point in J–V–L diagram.

Atomic force microscopy (AFM) was performed with a NanoScope IIIa (Digital Instruments Inc.) run in the tapping mode to observe the morphology of the ZnO surface. The vacuum level shifts of ZnO under various conditions were studied using ultraviolet photoelectron spectroscopy (UPS) with a VG CLAM4 surface analysis system equipped with a non-monochromatic He(I) UV source (21.2 eV) at the National Synchrotron Radiation Research Center. The UPS measurements were conducted at a base pressure of operated below 8×10^{-10} Torr.

3. Results and discussion

Annealing temperature affects the orientation and crystallinity of ZnO. Fig. S1 shows the X-ray diffraction patterns of ZnO thin film that has been annealed at various annealing temperatures. The extent of growth of the (0 0 2) orientation was directly proportional to the annealing temperature, indicating the presence of a Wurtzite structure with charge mobility [17,18]. AFM was used to investigate the surface morphologies. As shown in Fig. 1a–c, ZnO exhibits nano-ridge structures at various annealing temperatures. The root mean square (rms) roughness values following annealing at 150 °C, 300 °C, and 450 °C are 8.639 nm, 7.984 nm, and 25.422 nm, respectively. The roughest surface was obtained at an annealing temperature of 450 °C, indicating that the crystalline grains were largest at that temperature. When PEDA-TMS was grafted onto the ZnO electrode, the rms roughness did not change significantly (not shown), which finding is attributable to the coverage of only a monolayer on the ZnO surface.

Fig. 2a plots the current density–voltage–luminescence (J–V–L) curves of a conventional device and inverted devices with and without PEDA-TMS following annealing at 150 °C. From the J–V curves, the threshold voltage for the inverted devices without PEDA-TMS is unclear. The threshold voltage is a function of $\Delta\varphi + \phi$, where$\Delta\varphi$ is the build-in potential that results from the difference between the work function of the cathode and that of the anode and ϕ is the barrier height of majority carriers injection. In the device with an electron injection/buffer layer of ZnO, hole is regarded as the majority carrier owing to the inferior electron mobility of G-PF. The threshold voltage (V_{th}) for this device is indeterminable, attributing to the low build-in potential and high leakage current. However, the devices with the PEDA-TMS had a clear threshold voltage at 1.5 V. Since no substantial change occurred in the anode,

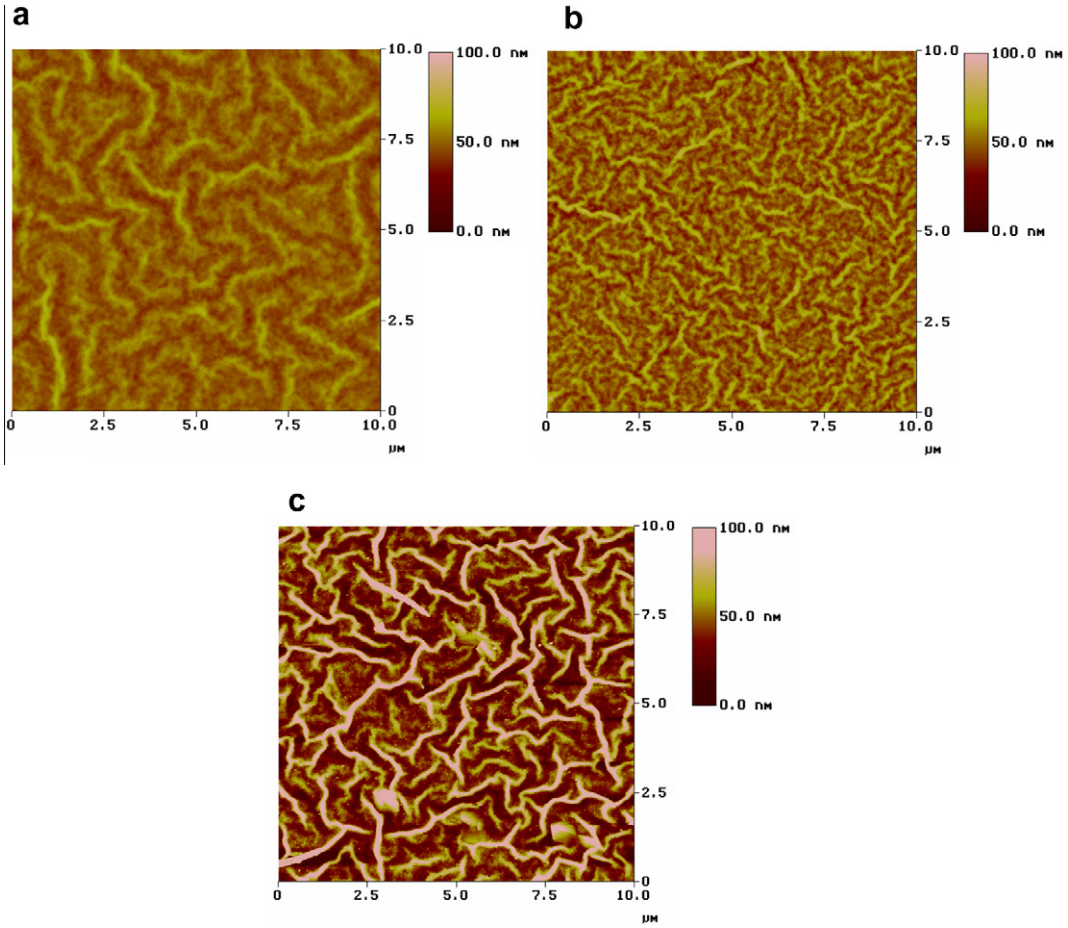

Fig. 1. AFM images of ZnO thin films annealed at various temperatures: (a) 150 °C, (b) 300 °C, and (c) 450 °C.

this result reflects the facts that the PEDA-TMS layer can effectively reduce the work function of ZnO, which increased the build-in potential of the device and modify its surface ZnO, which lowered the leakage current of the device. The luminescence is greatly increased by the presence of PEDA-TMS. The performance of a modified inverted device is close to that of a conventional device. Notably, the turn-on voltage ($V_{\text{turn-on}}$) is 0.5 V highly (conventional device: 2.3 V; inverted device: 2.8 V) because the formation of a space-charge field induces electron injection, indicating the build-up of hole accumulation near the G-PF/ZnO interface [5]. Fig. 2b presents the effect of ZnO annealing temperature on device performance. The current density increased with annealing temperature. Following annealing at 450 °C, the coarse surface of ZnO caused excess leakage current. A higher luminance value was observed following annealing at 300 °C. Fig. 3 plots the EL efficiencies of the devices. The EL efficiency gradually increased with voltage to a maximum of 7 cd A^{-1} for an inverted device that was annealed at 300 °C. This value is close to that of a conventional device. However, the EL efficiency of ZnO that was annealed at 450 °C was very low. The effects on device performance are related to the barrier height between ZnO and G-PF as well as the intrinsic electron mobility of the modified ZnO. The formation of dipole moments results in the decrease of barrier height by grafting self-assembled monolayer on the surface of ZnO. Consequently, X-ray photoelectron spectroscopic (XPS) and UPS measurements were made to analyze the interfacial characteristics of modified ZnO electrodes.

PEDA-TMS was bonded onto the surface of ZnO using a hydrolysis reaction [12]. The extent of conversion in the reaction depends on the number of —OH groups. The surface characteristics of ZnO were analyzed using XPS spectroscopy to investigate the oxidation states of both Zn and O. Fig. S2 presents the energy of the O 1s peak from as-modified ZnO that was annealed at various temperatures. The ratio of —OH to O (−2) were 1.14, 0.91, and 0.78 with increasing annealing temperatures of 150 °C, 300 °C, and 450 °C, respectively. The drop of the number of —OH groups reduced the amount of grafted PEDA-TMS. Fig. 4 shows the secondary cutoff edge regions of UPS spectra of ZnO with and without PEDA-TMS following annealing at various temperatures, to determine the shifts in the vacuum energy level. Herein, the HOMO edge region is not shown but the work function of the modified ZnO is carefully determined using the formula $\Phi = h\upsilon - \Delta E$, where $h\upsilon$ represents the photon energy (21.2 eV) and ΔE

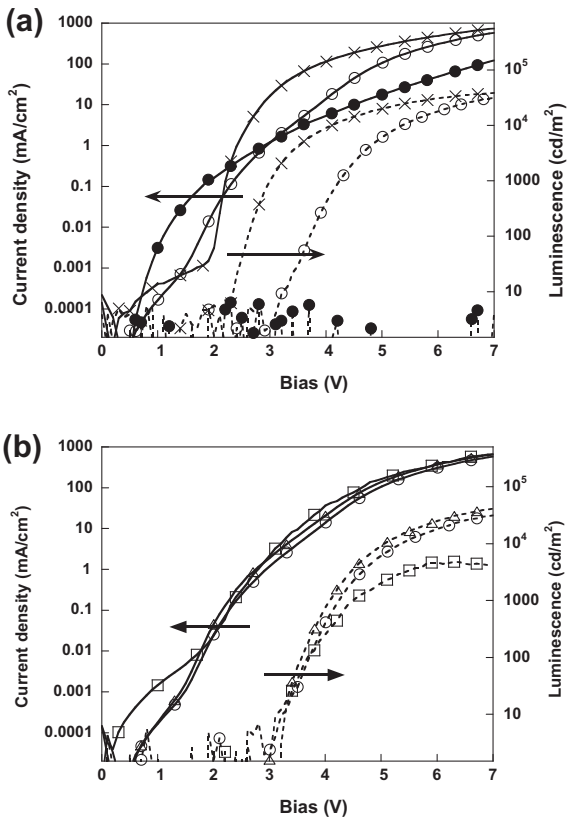

Fig. 2. *J–V–L* characteristics of PLED devices: (a) conventional device (X), inverted device without PEDA-TMS (●), and inverted device with PEDA-TMS (○); (b) inverted device with PEDA-TMS for various annealing temperatures: 150 °C (○), 300 °C (△), and 450 °C (□).

is determined from the distance between the binding energy at the secondary electron emission cutoff edge and that at the HOMO edge [19]. The values of l were 3.58, 3.52, and 3.77 eV following annealing at 150 °C, 300 °C, and 450 °C, respectively. When bare ZnO substrates were annealed at high temperatures, the cutoff edge slightly shifted toward higher binding energies, indicating that the conduction band of ZnO shifted toward a more positive energy owing to the increase of the direct band gap [20]. After PEDA-TMS was modified onto the ZnO surface, the vacuum energy level was shifted to a substantially lower binding energy, indicating that the barrier between ZnO and G-PF was lowered. The overall shifts of vacuum energy levels were 0.83 eV, 0.84 eV, and 0.58 eV following annealing at 150 °C, 300 °C, and 450 °C, respectively. Despite the fact that the number of —OH groups following annealing at 300 °C was slightly lower than that following annealing at 150 °C case, the work function of ZnO was changed by PEDA-TMS modification. The inferior shift associated with annealing at 450 °C case is attributable to the inadequacy of the number of —OH groups and the disordered dipole moment of PEDA-TMS that was grafted onto the coarse surface. The (ZnO/PEDA-TMS electrode that was annealed at 300 °C had an energy level that facilitated electron injection.

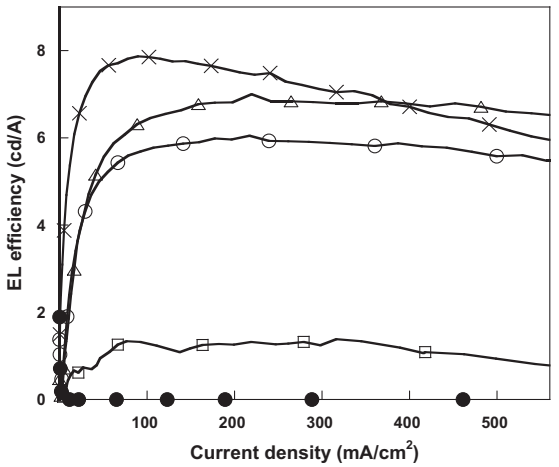

Fig. 3. EL efficiency as a function of current density: conventional device (X), inverted device without PEDA-TMS for 150 °C annealing temperature (●), inverted device with PEDA-TMS for various annealing temperatures: 150 °C (○), 300 °C (△), and 450 °C (□).

The electron mobility of intrinsic ZnO can influence device performance because electrons are regarded as the minor charges in an inverted device. Fig. 5 plots the *J–V* curves of an electron-only device following annealing at various temperatures. A comparison with a previous investigation [10] reveals that the inverted devices based on ZnO had a higher electron injection current than did those based on TiO_2, resulting in a significant improvement in device performance. Additionally, modified ZnO electrodes that are annealed at higher temperatures exhibit a higher electron injection ability because they have a greater crystallinity. However, poor device performance was observed following annealing at 450 °C, even though this temperature led to the greatest injection of electrons into the EL layer. This finding is inconsistent with the EL mechanism of a conventional device, indicating that the enhancement of minority charge injection increases EL efficiency.

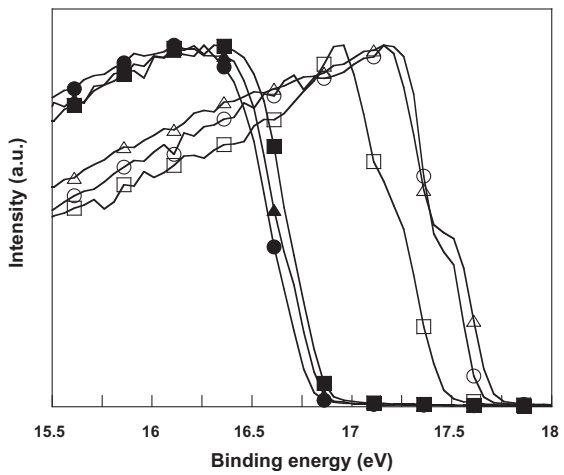

Fig. 4. Secondary cutoff edge regions of UPS spectra of ZnO with and without PEDA-TMS for various annealing temperatures: without PEDA-TMS at 150 °C (●), 300 °C (▲), and 450 °C (■); with PEDA-TMS at 150 °C (○), 300 °C (△), and 450 °C (□).

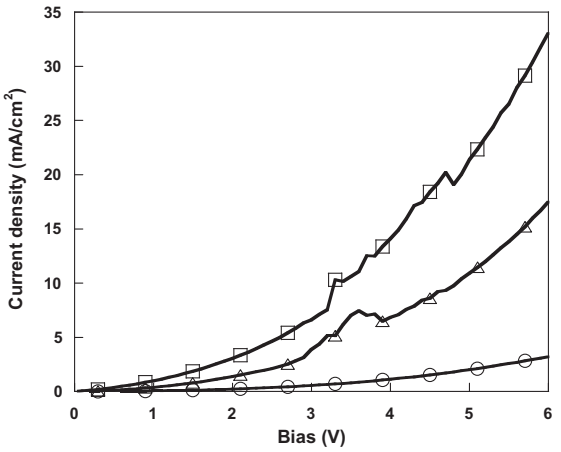

Fig. 5. *J–V* characteristics of electron-only devices for various annealing temperatures: 150 °C (○), 300 °C (△), and 450 °C (□).

The EL mechanism of inverted devices is considered to be based on metal oxide as an electron injection/buffer layer. A space-charge field is formed upon the accumulation of holes and then electrons are thus induced to enter the EL layer. To clarify the recombination condition of dual-carriers, Fig. 6 plots the capacitance–voltage (*C–V*) characteristics of the conventional device and inverted devices that were annealed at various temperatures. The *C–V* behaviors are correlated with the threshold voltage (majority charge injection) and turn-on voltage (minority charge injection). In the conventional device, the capacitance initially increased until the turn-on voltage was reduced due to the dark current and the injection of majority carriers (holes) and their accumulation in the G-PF layer. Then, the minority charge (electron) injection occurred, inducing the recombination of electrons and holes. The amount of charges in the G-PF layer was significantly diminished, and hence the capacitance sharply declined after the turn-on voltage was reached [21,22]. In contrast, the capacitance of the inverted device substantially increased after the threshold voltage was passed because the ZnO/G-PF interface blocked the majority charges (holes), so most charges accumulated in the polymer. Notably, the capacitance declined just before the turn-on voltage was reached about 2.4 V [21]. A few electrons are assumed to have been charge-induced to inject into the ZnO/G-PF interface. However, insufficient driving voltage led to electron and hole recombination in the ZnO region, which quenched exitons for radiative emission. Further increasing the bias caused the recombination region to shift into the G-PF layer. When the turn-on voltage was exceeded, the capacitance was substantially decreased by energetic charge recombination and effective photon emission. Following annealing at 300 °C, capacitance fluctuated significantly, presumably because of the increase in the intrinsic mobility of ZnO. However, the increase in capacitance associated with annealing at 450 °C is unobvious, indicating that ZnO does not mainly block holes or induce the injection of electrons into the G-PF layer for effective recombination because of its coarse morphology. The performance of ZnO annealed at 450 °C is inferior to that of ZnO annealed at 300 °C. The latter has high electron mobility and effectively blocks holes, supporting the favorable performance of the inverted device.

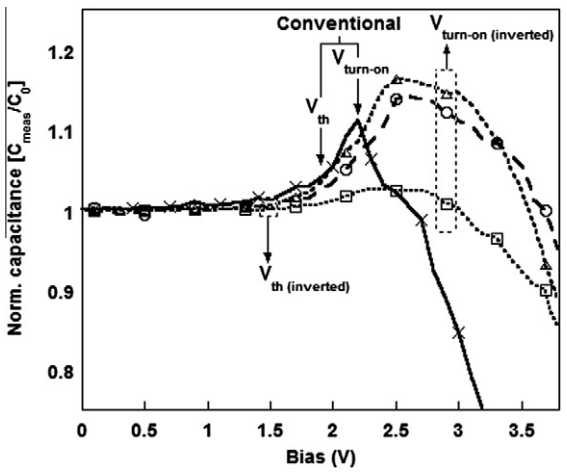

Fig. 6. Normalized *C–V* characteristics of conventional device (*X*) and inverted devices for various annealing temperatures: 150 °C (○), 300 °C (△), and 450 °C (□). Here, C_0 is the capacitance of the device at 0 V.

4. Conclusion

Inverted devices with high EL efficiencies were fabricated using stable ZnO/PEDA-TMS as electron injection/hole blocking layers. The effect of ZnO annealing temperature on device performance was analyzed in terms of charge injection barrier, electron injection ability of the modified electrode, and the recombination region of electrons and holes. The optimal annealing temperature of ZnO is about 300 °C. The adequate number of —OH groups on the surface of ZnO easily hydrolyze to form PEDA-TMS monolayer, reducing the barrier height between ZnO and the G-PF layer. The high crystallinity of ZnO associated with annealing temperature enhances the injection of minority carriers (electrons), helping to balance the ratio of electrons and holes in the active layer. The hole blocking effect dominates the region of recombination of electrons and holes in the G-PF polymer.

[25]. Therefore, the general belief is that interaction between C_{60} and noble metal surfaces has an ionic character. However, Wang and Cheng reported that this interaction is covalent with some ionic features [28]. By comparison, there are far less studies for C_{60} evaporated onto HOPG [29–32]. Only one of them investigates the nature of the C_{60}-substrate interaction, and finds that C_{60} adsorbs on HOPG by van der Waals interactions [30].

Scanning tunneling spectroscopy (STS) is a unique technique that allows a direct measure of the local density of states (DOS) near the Fermi energy. In order to study the electronic structure, STS has been performed on thin films of C_{60} deposited by sublimation onto different substrates and changes in HOMO, LUMO and HOMO–LUMO gaps are studied. These values have been reported for single C_{60} molecules and ultrathin C_{60} films (thickness < 1 ML) on Si [25,33–35], Au [17,36–40] and HOPG [41], for different adsorption sites and surface conformations. The overall tendency is that the gap values for C_{60} on Si are smaller (*ca.* 1.7 eV) than those obtained on Au surfaces (*ca.* 2.55 ± 0.25 eV), due to charge transfer from Au to the C_{60} molecules.

In contrast to the large amount of literature concerning the C_{60} electronic properties at submonolayer or monolayer coverages, less attention has been paid to these properties for C_{60} films on Si, Au and HOPG at coverages above 4 ML. There is even less information on the electronic properties of thin C_{60} films exposed to ambient conditions, despite the fact that in many cases manipulation and applications of these films are performed under light and atmospheric oxygen levels. It is known that under these conditions, changes in macroscopic physical and chemical properties of C_{60} films take place [17,42–45]. For example, exposure to light and oxygen induces changes in the C_{60} films from diamagnetic to ferromagnetic [45]. Light and oxygen exposure of these films can also affect the electronic properties of these films [46–49]. Therefore, further knowledge on their electronic properties under these conditions is a key point for predicting their performance under normal ambient conditions, and could affect many technological developments.

In this paper, we present a study on the magnetic and electronic properties of C_{60} thin films (film thickness $\geqslant$ 4 ML) sublimated onto naturally oxidized Si(1 0 0), Au films, glass, and HOPG surfaces exposed to ambient conditions. The films are characterized by atomic force microscopy (AFM) and X-ray photoelectron spectroscopy (XPS) while magnetic and electronic properties are studied by magnetic force microscopy (MFM) and scanning tunneling spectroscopy (STS), respectively. In particular we estimate for the first time the gap energies for the above mentioned thin films allowing a direct comparison with the values reported at lower coverages and under vacuum conditions. We have also determined the influence of the substrate and thickness of the films on their morphology, electronic structure and adhesion strength/wear resistance. This article is organized as follows: first we explore the structure of the films by AFM, then, we characterize the systems by XPS and MFM, and finally we explore their electronic structure by STS.

2. Experimental

Fullerene films were grown by sublimation of C_{60} (Sigma–Aldrich Company, USA, 99.5%) on clean Au films deposited onto glass (250 nm gold thickness, Arrandees™), freshly cleaved highly oriented pyrolytic graphite (HOPG), naturally oxidized Si(1 0 0) surfaces and glass. An Edwards 360 metal coater operating at 10^{-6} Torr was used for the deposition. Films were simultaneously prepared on all four kinds of substrates mounted at the same distance and geometry from the C_{60} source, in single evaporation experiments, to assure similar preparation conditions at each given film thickness. The films were then stored in ambient conditions for several days and finally cleaned under nitrogen flux immediately before characterization.

Film morphology was characterized by imaging the samples with an atomic force microscope (Nanoscope IIIa, Digital Instrument/Veeco) operating in the contact mode, with silicon nitride tips. The chemical composition of the films and the nature of the chemical bonds of the species present were corroborated by X-ray photoelectron spectroscopy (XPS). Photoelectrons were excited with a Mg Kα source (XR50, Specs GmbH) and detected with a hemispherical electron energy analyzer (PHOIBOS 100, Specs GmbH). A two-point calibration of the energy scale was performed using sputter-cleaned gold (Au $4f_{7/2}$, binding energy BE = 84.00 eV) and copper (Cu $2p_{3/2}$, BE = 933.67 eV) foils.

Electronic properties of the films were determined by STS measurements using a scanning tunneling microscope (Nanoscope IIIa, Digital Instruments/Veeco) operating in air at room temperature. Pt–Ir tips were used for these measurements. The tunneling current vs bias voltage (I vs V) curves were averaged over at least three different regions of the samples. The dI/dV plots shown in this paper are the average of ten measurements. These measurements were taken under the same experimental conditions, but performed on different regions of each sample. Smoothening of the dI/dV plots was performed by using the Savitzky–Golay differentiation [50].

Film thickness was determined by AFM measurements of films grown by stencil lithography patterning through a hexagonal mask, in parallel with the other C_{60} films. The height difference between the masked and the exposed regions has been taken as a measure of the film thickness of the set of samples grown under the same experimental conditions, taking into account that once the film has nucleated, film thickness growth, on average, proceeds independent of the substrate employed [51].

Magnetic force gradient (MFM) and topographic sample images were obtained simultaneously with a NanoScope IIIa scanning probe microscope (Digital Instruments/Veeco) at room temperature in air. The microscope was operated in the tapping/lift™ scanning mode, i.e., the AFM tip was made to scan the sample at different heights above the topographic height of the sample at each point in order to separate short range topographic effects from long range magnetic signals. Lift-heights ranging from 25 to 100 nm were selected. Images were taken at a scanning rate of 1 Hz using a MESP (60–100 kHz, 1–5 N/m) scanning probe

coated with a magnetic CoCr alloy thin film. In addition, silicon FESP tips with the same range of frequency, force constant and dimensions, but uncovered (non magnetic) were used to compare the contrast phase signal obtained with both tips at different heights of the sample. This procedure was also applied with the bare substrates. Prior to acquiring images, the tips were exposed to a 0.3 T magnetic field.

3. Results and discussion

3.1. AFM characterization

Fig. 1 shows AFM images of C_{60} films of different thickness (h); that were grown by sublimation on the native SiO_x substrates. AFM images show that the films are formed by nanometric aggregates that entirely cover the SiO_x surface.

The average size (d) of the aggregates increases from ≈20 to ≈70 nm as h is increased from 3 nm (≈4 monolayers) to 70 nm (≈100 monolayers) and remains constant for thicker films, as determined by power spectral density analyses (right panel in Fig. 1). The mean square roughness (Rq) corresponding to the films with h of 3, 40, 70 and 100 nm are 1.06, 1.13, 2.75 and 3.46 nm, respectively.

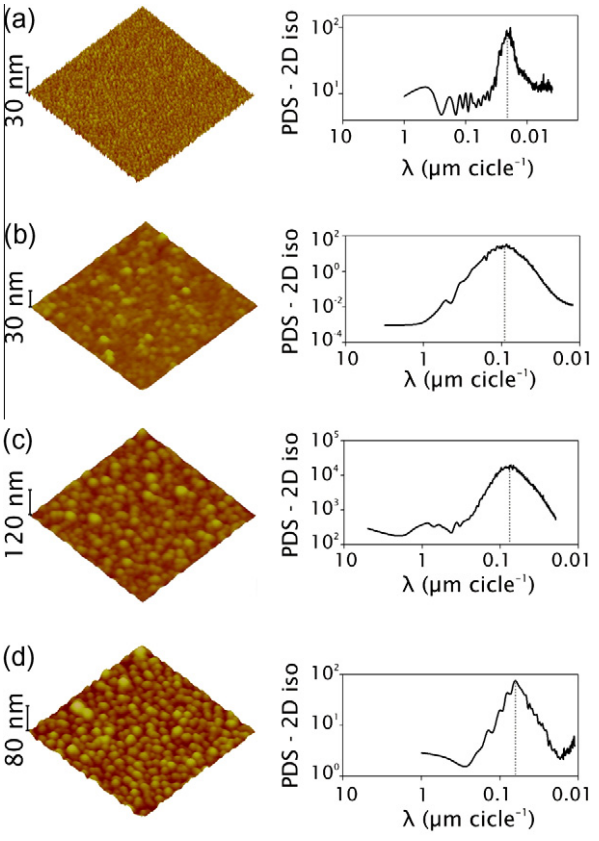

Fig. 1. Left: three-dimensional AFM images (1×1 μm^2, contact mode) of C_{60} films with different thickness (h) on silicon oxide substrates. Right: power spectral density (PSD) data corresponding to the AFM images on the left, after high-pass filtering. The grey lines indicate the average grain size (d). (a) h = 3 nm and d = 19 nm. (b) h = 40 nm and d = 55 nm. (c) h = 70 nm and d = 74 nm. (d) h = 100 nm and d = 60 nm.

Comparing h and Rq for each film, we note that for thin films (h = 3 nm) the roughness is 35.3% of the total film thickness, that is, the film topographical morphology is very irregular. On the other hand, the roughness parameter for the films with h of 40, 70 and 100 nm is 2.8%, 3.9% and 3.5% of the film thickness, respectively, which suggests a high degree of smoothness.

We observe that the films with h > 70 nm exhibit good adherence to the substrates, remaining stable under repetitive scanning with the AFM tip in the contact mode. In contrast, the adherence and wear resistance are poor for films with h = 3 nm, where repetitive scans with the tip finally open a window. In the irregular morphology present in the 3 nm thick films we expect that the outer C_{60} molecules exhibit weak van der Waals interactions so that the outer layer can be easily removed by the AFM tip. On the contrary, thicker films consist of large clusters where one expects stronger molecular interactions, and accordingly, the C_{60} molecules remain stable under tip scanning. We also note that the variations in the film thickness is accompanied by a change in the sample color from a pale brown (h = 3 nm) to green–blue (h > 40 nm). As we will see later, this color change is not related to the gap value and is mainly due to a light interference phenomenon.

Each film thickness was estimated by stencil lithography of a sample prepared in parallel with the continuous films (Fig. 2a). The height difference between the masked and exposed regions (Fig. 2b) has been taken as a measure of the film thickness for the set of samples grown during the same C_{60} sublimation experiment.

Fig. 3 shows high-pass filtered images for films of similar thicknesses grown in different sublimations on oxidized Si, HOPG, Au and glass. The images reveal a similar aggregate morphology irrespective of the substrate, but in the films grown on Au, the size of aggregates and the channels separating them are larger than on other substrates. While the high-pass filtered images allow a direct and easy comparison of the aggregate size, it loses the z-component of the image. The conventional top-view images in Fig. 4 illustrate the difference in film structure providing also information in the z-direction. Here we show C_{60} films prepared simultaneously in the same evaporation chamber on oxidized Si (Fig. 4a) and Au (Fig. 4b), both with a thickness of $h \approx 30$ nm. The images not only reveal larger aggregates for the C_{60} film grown on Au, but

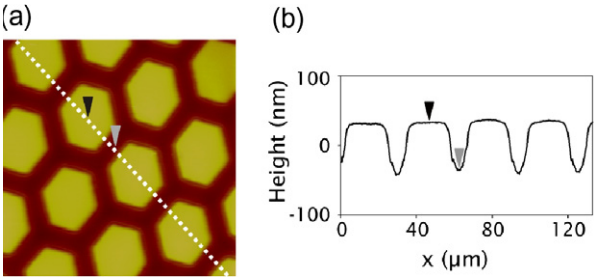

Fig. 2. (a) AFM image (2D view, 1×1 μm^2) of a patterned C_{60} film on SiO_x/Si. (b) Cross section profile across the dashed line in (a); the height difference between the black and grey arrows is h = 70 nm.

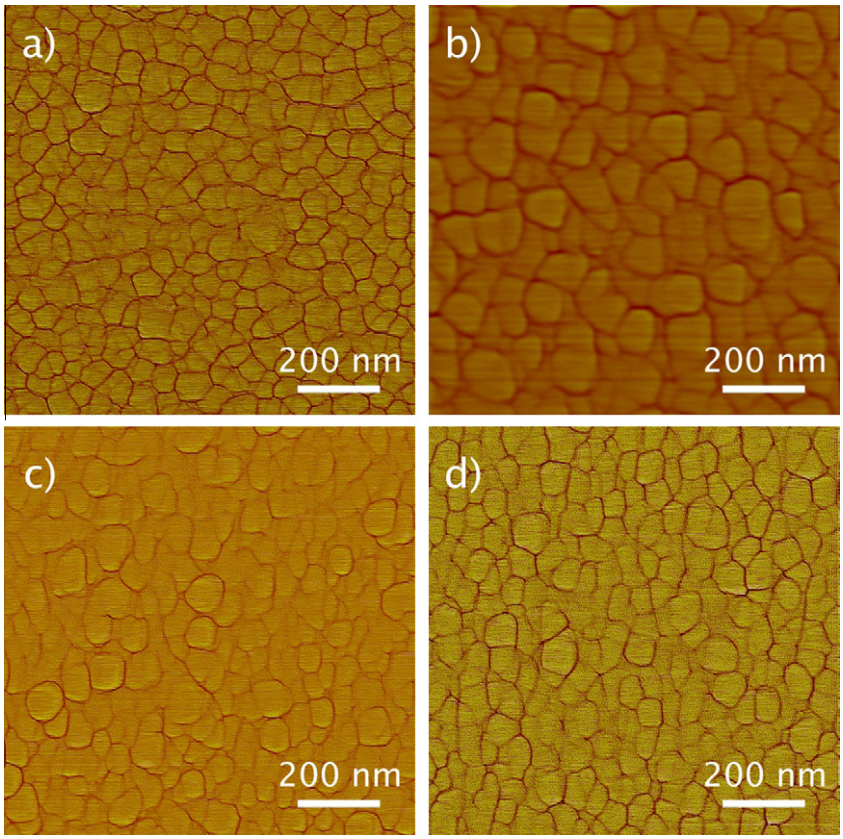

Fig. 3. AFM images (2D view, high pass filtered, $1 \times 1\ \mu m^2$) of C_{60} films grown in different sublimations on different substrates. (a) Si, $h = 100$ nm, (b) Au, $h = 140$ nm, (c) HOPG $h = 80$ nm, (d) glass, $h = 100$ nm.

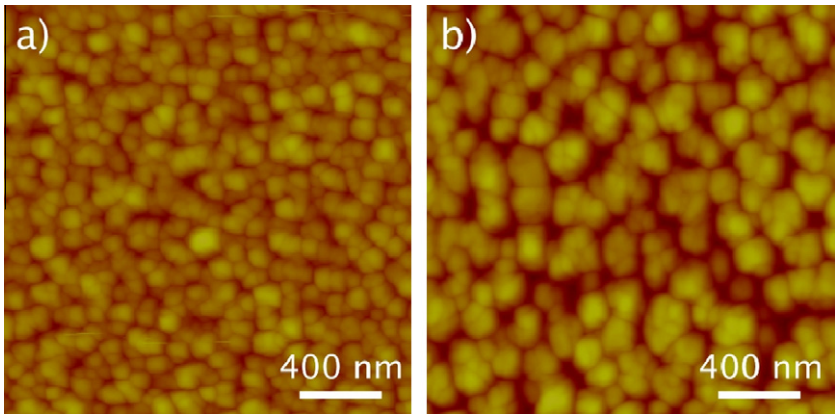

Fig. 4. AFM images (2D view, $2 \times 2\ \mu m^2$) of C_{60} films ($h = 30$ nm) prepared simultaneously on (a) oxidized Si(1 0 0) and (b) Au.

also a smaller connectivity between them, since they are separated by wider and deeper channels. The difference between aggregate size in Fig. 4, can be explained if we consider that, for submonolayer coverages, the C_{60} molecules have higher mobility on Au, facilitating the formation of large islands [21] and trenches, in contrast to what happens to the films grown on SiO_x, HOPG or glass where the first C_{60} molecules are isolated and dispersed on the surfaces, forming many more cluster seeds [15,52]. As a result, at higher coverages, the films grown on Au show larger clusters than those obtained on the others substrates (SiO_x, HOPG and glass).

3.2. XPS data

The XPS data for C_{60} films deposited onto SiO_x ($h = 70$ nm) are presented in Fig. 5. The survey spectrum (Fig. 5a) exhibits a strong C signal. Some O and only small

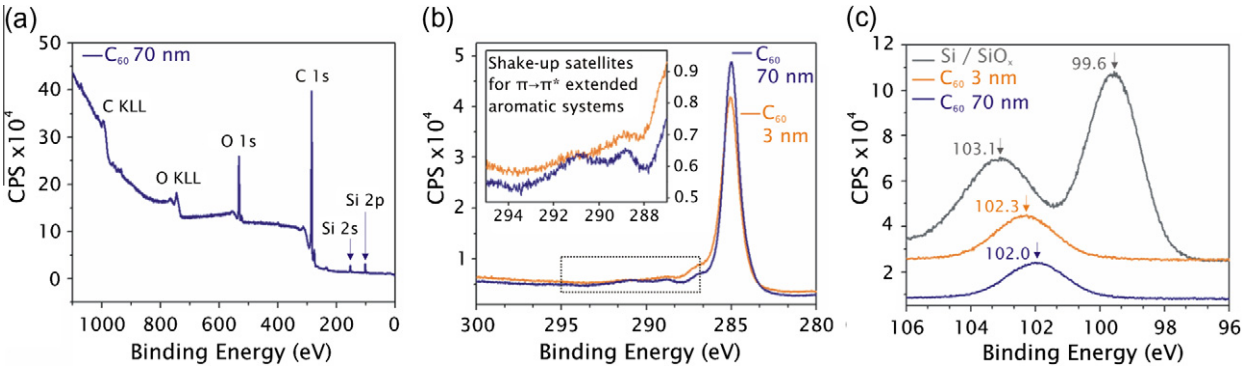

Fig. 5. XPS data for C_{60} films on oxidized silicon support: (a) survey spectrum (70-nm film), (b) C 1s spectra for 3 nm (orange) and 70 nm (blue) thick C_{60} films. Inset shows shake-up satellites attributable to C_{60} presence (c). Comparison Si 2p region between the same two C_{60} films and a SiO_x/Si reference (grey curve). C_{60} films interact with silicon substrate and show a kind of SiO_xC_y species (102.2 ± 0.1 eV) [56]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

amounts of Si are detected, in agreement with the film thickness and morphology (almost complete coverage of SiO_x by C_{60}) as determined by AFM. The atomic ratio between O and Si is roughly 4:1. The excess O can be associated with the extreme reactivity of C_{60} crystals to (atmospheric) oxygen [53], which quickly penetrates into the bulk fullerene. No traces of metallic contaminants can be observed in the spectra.

Fig. 5b shows XPS spectra of C 1s core level and shake-up satellites (inset in Fig. 5b) for C_{60} with film thicknesses of 3 nm (orange)[1] and 70 nm (blue),[1] and a large peak at 285 eV, typical for C_{60} films. The absence of components at energies below 283 eV is indicative of the lack of Si–C bonding in the films [17,25,54]. The inset in Fig. 5b illustrates the expanded region covering the C1s shake-up satellites. We resolved by high-resolution photoelectron spectroscopy two peaks for the deposited C_{60} film at 3.7 and 6 eV relative to the C1*s* binding energy; these results are consistent with two of the four peaks obtained in the report by Enkvist [55]. This result indicates that no significant degradation of the C_{60} films takes places under our experimental conditions.

Fig. 5c shows XPS spectra of the Si 2p core level region for a SiO_x/Si reference surface and C_{60} films of 3 and 70 nm thickness on SiO_x/Si(1 0 0). For the reference surface, two peaks are seen at 99.6 and 103.1 eV corresponding to Si^0 (Si–Si) and Si^{+4} (SiO), respectively. For the fullerene films, only one peak is found at 102.3 eV (3 nm film) or 102.0 eV (70 nm film) corresponding to Si^{+3}. By analogy with reports on oxidation of SiC [56], we can conclude that the SiO_x–C_{60} interface is mainly composed by SiO_xC_y.

3.3. MFM characterization

MFM was used to characterize magnetic properties of the C_{60} films. In order to enhance the magnetic contrast we used hexagonally patterned C_{60} films prepared by stencil lithography, as shown in Fig. 2. In Fig. 6 we show the topographic image (a) and magnetic phase contrast (b) of these films on glass. Magnetic contrast concentrated on the hexagons is evident in the C_{60} film as shown in Fig. 6b. On the other hand, the same experiments (Fig. 6c–d) under identical imaging conditions but using a non-magnetic tip give no evidence of the hexagons in the phase contrast magnetic image (Fig. 6d). Similar results are obtained for the C_{60} films deposited on the different substrates used in this work. Therefore, the MFM characterization indicates that our films are magnetic. While pristine van der Waals C_{60} crystals are diamagnetic, this behavior changes when the sample is exposed to oxygen under the action of the visible light [17]. These conditions apply to our films exposed to light under atmospheric conditions, since they contain excess amounts of oxygen as shown in the XPS data (Fig. 5a). It is known that light exposure during 2.5 h brings noticeable features of ferromagnetism: non-linear magnetization process at low fields and magnetization increases related to an increase in the exposure time [42,53].

The MFM images at high resolution (insets in Fig. 6a–b) show that the magnetic field corresponds closely to the C_{60} aggregates present on the glass substrate. However, a detailed analysis of these images indicates that the magnetic contrast does not directly map onto the aggregates, consistent with locally induced polymerization of C_{60} films [45]. After having verified that our films exhibit the ferromagnetic behavior expected for C_{60} exposed to oxygen and light we will characterize their electronic properties and discuss them in relation to previous work obtained under UHV conditions.

3.4. STS: electronic properties

Typical curves of tunneling current vs. bias voltage for C_{60} films prepared on three different substrates are shown in Fig. 7. We used metallic (Au), semi-metallic (HOPG) and semiconductor (oxidized Si) substrates in order to gain insight on the influence of the substrate on the electronic structure of C_{60} films on materials with different bulk electronic properties. As a way to calibrate our STS measurements, we first measured the averaged *I/V* curves for the bare substrates (Fig. 7, left panels). The *I/V* curve for Au shows an almost linear behavior,

[1] For interpretation of the references to colour in this figure, the reader is referred to the web version of this article.

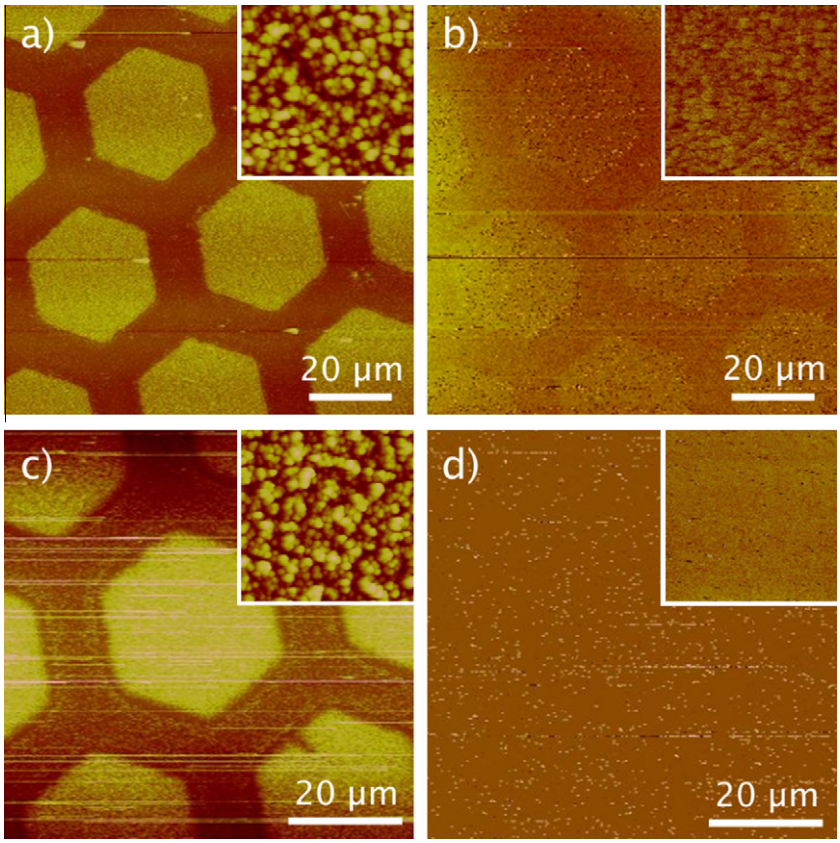

Fig. 6. (a and b) MFM images of patterned C_{60} films on glass. (a) Topographic image, 100 × 100 μm^2; inset: detail of the hexagon (3 × 3 μm^2) (b) magnetic phase contrast, 25 nm lift scan height, 100 × 100 μm^2; inset: detail of the hexagon (3 × 3 μm^2). (c and d) AFM images of patterned C_{60} films on glass. (c) Topographic image, tapping mode, 72.7 × 72.7 μm^2; inset: detail of the hexagon (3 × 3 μm^2). as expected for metallic conductors [57]. In contrast, those recorded for SiO_x/Si(1 0 0) show zero current near the Fermi level, typical of semiconductors [58]. Meanwhile, the observed behavior for HOPG is intermediate between Au and SiO_x/Si(1 0 0). On the other hand, all *I/V* curves for the C_{60} films (Fig. 7, right panels) exhibit a response characteristic of semiconductor materials. Comparing the curves on the left of Fig. 7 with the curves on the right, it is clear that C_{60} masks the electronic properties of the pristine sample surfaces. For Au and HOPG, the change is very dramatic, while for SiO_x/Si(1 0 0) the only difference is that the width in the zero current response is greater for C_{60}/SiO_x/Si(1 0 0) than for SiO_x/Si(1 0 0), thus suggesting that the gap for the C_{60} film is larger than the corresponding for pristine support. The main difference observed between the three curves on the right is that the width of the linear response current region is greater for C_{60}/Au than for either C_{60}/HOPG or C_{60}/SiO_x/Si, which suggests that the gap width for the C_{60} film evaporated onto Au is higher than on either SiO_x or HOPG. While this same trend is observed for ultrathin C_{60} films (thickness < 1 ML) in UHV, where the gap is larger on Au [17,36–40] than on either Si [25,33–35], or HOPG [41]), it is very unlikely that STS can detect charge transfer from the substrate to films several layers high.

A better indication of the electronic state of a sample-surface and charge transfer processes involved can be obtained from the derivative tunneling spectra, *dI/dV*, (Fig. 8) which is a measure of the local density of states (LDOS) of a surface [59]. Our main objective was to quantify and compare the gap for all the fullerene films. The averaged derivative STS spectra for Au, HOPG and SiO_x/Si(1 0 0) were obtained at constant sample-tip separation conditions given by sample biases of 1.0, 0.5 and 2.0 V, respectively and a current of 1.0 nA.

The spectrum for Au (Fig. 8a) shows the expected metallic behavior, with a little curvature close to the Fermi level. On the other hand, the spectrum for HOGP (Fig. 8b) shows a slightly asymmetric parabolic shape of LDOS around the Fermi level as already reported for HOPG conductance data in ambient conditions [60,61].

Moreover, the spectrum for SiO_x/Si(1 0 0) exhibits a semiconductor behavior with a gap of 1.0 ± 0.1 eV. It shows good agreement with the values obtained in Refs. [62,63] and indicates that the average SiO_x thickness is at least 0.2 nm [62]. Our results are consistent with those reported in the literature, thus indicating that the ambient experimental conditions employed (open air and room temperature) are not responsible for the variations measured between bare and C_{60}-covered surfaces.

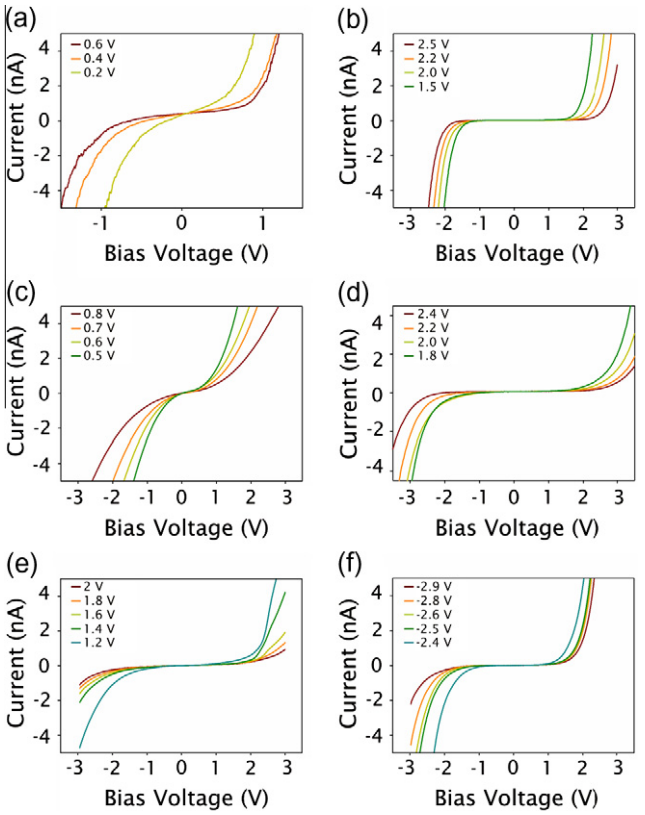

Fig. 7. *I*/*V* curves for bare substrates (left side) and C_{60} films (right side). All curves were taken at sample bias range from −3 V to +3 V and I = 1.0 nA. (a) Au, (b) C_{60}/Au, (c) HOPG, (d) C_{60}/HOPG, (e) SiO_x and (f) C_{60}/SiO_x.

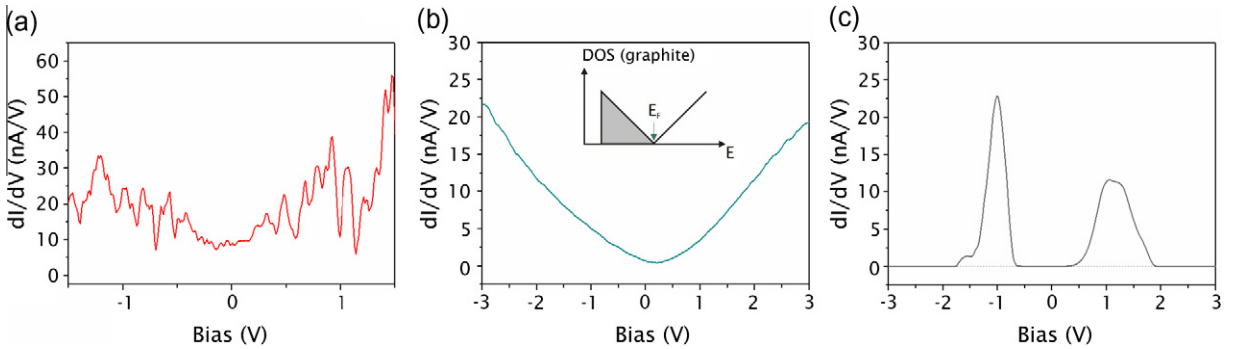

Fig. 8. The dI/dV curves measured for (a) Au (sample bias: 1 V), (b) HOPG (sample bias: 0.5 V) and (c) $Si0_x$/Si(1 0 0) (sample bias: 2 V) respectively. The current used in all spectra was 1.0 nA.

Fig. 9 shows *dI*/*dV* spectra for C_{60} films of different thicknesses prepared on SiO_x/Si(1 0 0). Our purpose was to address the electronic behavior of C_{60}/SiO_x/Si(1 0 0) system as the film thickness increases. Fig. 9(a) shows the STS spectrum for the 3 nm thick film (4 ML). The band gap obtained was 1.4 ± 0.1 eV with HOMO and LUMO at −1.0 and +0.4 eV, respectively. The Fermi level is shifted toward the LUMO band, which implies that there is a charge transfer from the SiO_x/Si(1 0 0) substrate to C_{60} consistent with the XPS data shown in Fig. 5c for the Si 2p signal, and in agreement with the results reported by Wang et al. for this system [17].

Fig. 9(b–d) summarizes STS data recorded for films thicker than 57 ML (40 nm). The gap values obtained are 1.6 ± 0.1, 1.6 ± 0.1 and 1.7 ± 0.1 eV, with HOMO energies of −0.7, −0.8 and −0.8 eV, and LUMO energies of 0.9, 0.8 and 0.9 eV for 40, 70 and 100 nm film-thicknesses, respectively. These results show that the gap is independent of thickness for smooth and thicker films and that their value correlates well with the gap for free C_{60} molecules [35], thus discarding the possibility that the film color could be caused by changes in the HOMO–LUMO position. In addition, we did not observe a LUMO shift towards the Fermi level (the spectra are symmetrical), suggesting that

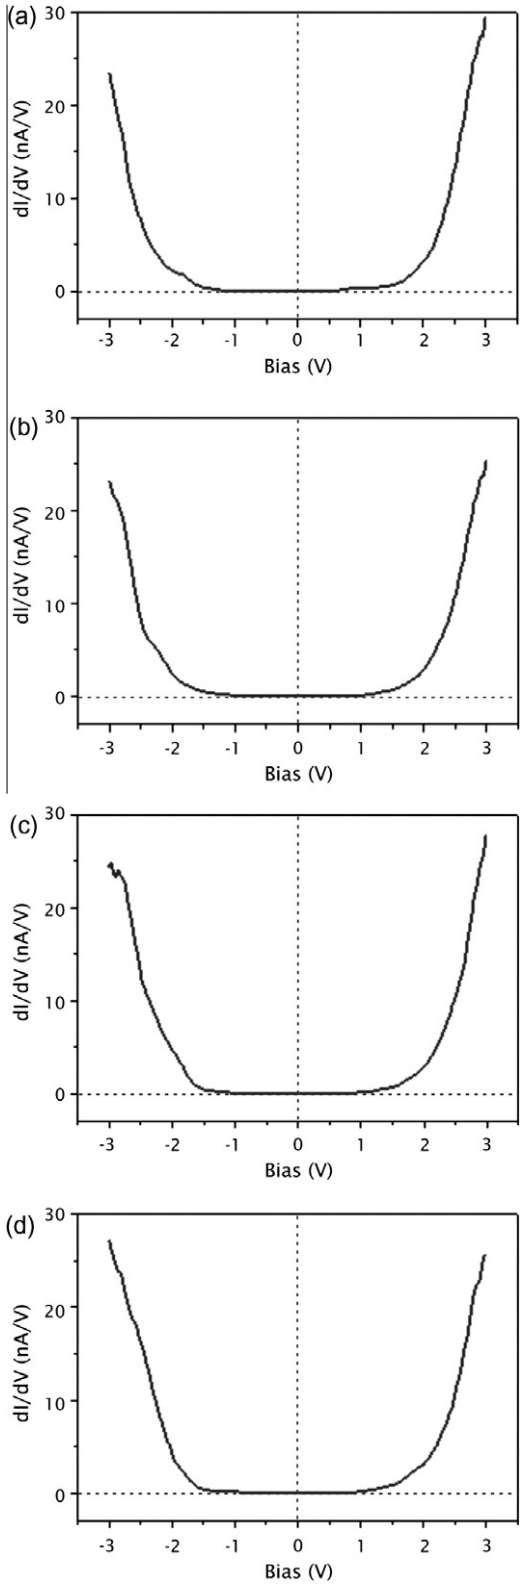

Fig. 9. STS spectra of $C_{60}/SiO_x/Si(1\,0\,0)$ for different film thicknesses: (a) 3 nm, (b) 40 nm, (c) 70 nm and (d) 100 nm. All curves were taken at sample bias of −3 V and current of 1.0 nA. The dashed line is shown to aid the gap visualization, and shows the symmetry with respect to the Fermi level.

there is no detectable charge transfer between Si and the outer C_{60} molecules, as expected for films with these thicknesses. In conclusion, we found that at high coverages (>57 ML) of C_{60} molecules deposited on $SiO_x/Si(1\,0\,0)$, the electronic characteristics of C_{60} films are very similar to those for C_{60}.

We have also tested the electronic properties of C_{60} films grown on Au and HOPG (Fig. 10). The clean Au and HOPG substrates exhibit ambient *dI/dV* curves typical of conducting materials (Fig. 8). However, after C_{60} deposition, the *dI/dV* plots show a semiconductor behavior with a gap of 1.6 ± 0.1 eV (HOMO = −0.8 eV and LUMO = +0.8 eV) and 2.5 ± 0.1 eV (HOMO = −1.3 eV and LUMO = +1.2 eV) for C_{60}/HOPG and C_{60}/Au, respectively. Both films have a thickness of 70 nm (100 ML of C_{60}) and show symmetrical behavior with respect to the Fermi level. The gap for C_{60}/HOPG is close to that obtained both for bulk C_{60}, and for the $C_{60}/SiO_x/Si$ film at the same coverage as above. In contrast, the gap of 2.5 ± 0.1 eV obtained for C_{60}/Au is higher than that for C_{60}/HOPG and Si substrate-surfaces, and comparable to those reported for single molecules and 1 ML of C_{60} deposited onto Au (gap values of 2.3–2.8 eV) [36–40]. The difference in the gap values measured for C_{60}/Au with respect to the C_{60} films

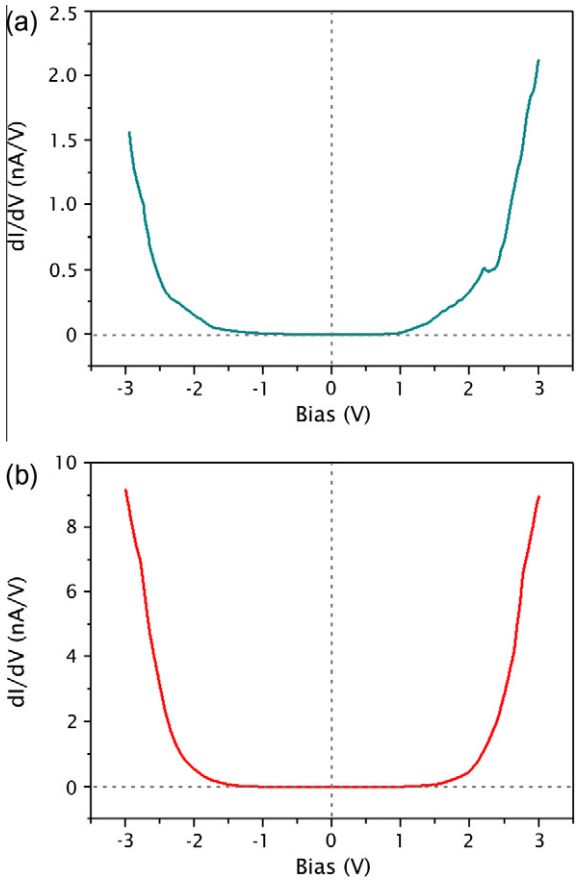

Fig. 10. STS spectra of (a) C_{60}/HOPG and (b) C_{60}/Au taken at sample bias of −3 V and current of 1.0 nA. The dashed line aids to visualize the gap of the film and shows the symmetry with respect to the Fermi level. The film thickness in both cases is 70 nm.

on the other substrates can, in principle, have multiple origins. While at first it is tempting to assign this value to charge transfer from Au to C_{60}, as for ultrathin C_{60} films, dI/dV curves are symmetric, essentially ruling out this possibility.

We next consider the structural differences in these films. Fernández-Torrente et al. [36] have shown that, for C_{60} films on Au(1 1 1), the gap obtained by STS changes in relation to the molecular environment. The differences in gap values measured for C_{60}/Au(1 1 1), with respect to the other substrates, seems to imply that the molecular environment for C_{60} on Au is different from the one in C_{60}/SiO_x/Si(1 0 0) and C_{60}/HOPG. If we take into account that the fullerene films were prepared simultaneously, in single evaporation experiments and with the same experimental setup, on all substrates, such preparation conditions imply that the mass of deposited fullerenes per unit surface area is the same for each sample, except perhaps during the very early stages of nucleation. However, once the steady growth state [51] is assumed to set in, (Fig. 4, $h \approx 30$ nm) the C_{60} films on Au (Fig. 4b) portray larger fullerene aggregates, and wider and deeper channels between them, than for example, on oxidized silicon (Fig. 4a). Bearing in mind that the mass of deposited fullerenes per unit surface area must be the same for each sample, under the same preparation conditions, the different morphologies could imply a local lowering of C_{60} density in the more extended grain-boundaries, resulting in a smaller number of C_{60} neighbors within the grain-boundaries. While this factor locally produces an increase in gap values, it is little likely that this change is detected by STS on an individual grain. Given that the initial thicknesses are comparable for all four kinds of substrates, these differences in gap values on Au could be a post-preparation effect, as we discuss below.

The fact that the electronic properties of the C_{60} films are not strongly modified by ambient conditions is at first surprising, particularly considering that their magnetic properties are modified. It has been reported that oxygen physisorbs (with a very small charge transfer) onto fullerene films, decreasing dramatically their conductivity [48]. Two distinct types of adsorbed oxygen were proposed [46]: oxygen incorporated at intergrain boundaries that rapidly quenches electronic transport, decreasing the intrinsic conductivity of C_{60} by one or two orders of magnitude, and oxygen at interstitial spaces of the C_{60} crystallites, resulting from slow diffusion, that lowers the conductivity of the material by about another two orders of magnitude. It has been shown, as well, that water diffusion is also important in C_{60} film degradation [49]. In principle, our results can be explained considering the kind of oxygen present in our C_{60} films and the different types of electronic measurements made by us and by other researchers. We propose that in our thicker film (where $d \approx h$) on Si, Au and HOPG, with nanometer sized grains, the dominant kind of physisorbed oxygen is at domain boundaries, so that it does not affect the molecular conductance measured by STS. Here we must recall that STS measures local properties resulting from electron transfer inside each nanometer-sized aggregate, and not the average properties of the films measured in other work, with non-local probes, where the contribution of domain boundaries is larger. In the case of C_{60}/Au, the larger grain boundary regions possibly enable a faster incorporation of oxygen at grain boundaries, that in turn could then interdiffuse into the grains, producing both swelling [45] and lowering of the conductivity, thus contributing to the increased gap of 2.5 eV observed for C_{60}/Au. In this case, the oxygen, initially incorporated into the more extended and deeper grain boundary regions of the film, can diffuse to interstitial C_{60} sites, thus effectively decreasing the local conductivity in the STS measurements. In summary, of the possible effects that could concurrently be responsible for the larger local band gap of C_{60} films on Au: charge transfer from the substrate to C_{60} molecules, as in ultra thin films; a local lowering of the grain-boundary packing density; and diffusion of oxygen to interstitial C_{60} sites; the latter is most probably the cause of the increase in the measured band gap on Au.

4. Conclusions

We have investigated the structure, chemical composition, magnetic and local electronic properties of thin C_{60} films (film thickness $\geqslant$ 4 ML) grown by sublimation on native silicon oxide, Au films, highly oriented pyrolytic graphite and glass, and subsequently exposed to ambient conditions. The films exhibit a structure consisting of nanometric aggregates, whose size increases with film thickness, irrespective of the substrate. Larger aggregates are systematically found on Au. The XPS data indicate no significant degradation of the C_{60} film although important amounts of oxygen are present in the films. The MFM data confirm that oxygen and light impact on the magnetic properties of C_{60}. In contrast, the STS measurements show little influence of ambient conditions on the local electronic properties. In fact, they are similar to those reported for ultrathin films grown and studied on the same substrates in UHV, i.e., in the absence of oxygen. For 4 ML of C_{60} on SiO_x, XPS data indicate the formation of a SiO_xC_y interface, in agreement with STS data showing charge transfer from SiO_x to C_{60}. The gap values for this film are close to those obtained in previous reports at lower coverages. On the other hand, thicker C_{60} films on SiO_x/Si and HOPG have gap values similar to those found for bulk C_{60}. In contrast, the electronic properties for C_{60} films on Au films show a larger gap value than those obtained on either HOPG or oxidized Si surfaces that, in our case, could be attributed to changes in the thin film structure, as a result of deep and extended domain boundaries. These extended boundaries on Au could facilitate the diffusion of oxygen to interstitial C_{60} sites, thereby increasing the band gap. The good adhesion and wear resistance of the thicker C_{60} films (40 nm < h < 100 nm), as well as the nearly constant local HOMO–LUMO gap on each substrate could become relevant for applications requiring manipulation, storage and operation under ambient conditions.

been reported, including the mixing of polymers with different emission colors in single or multilayer devices, or the blending of small molecules in a appropriate ratio of red, green and blue (RGB), host–guest systems, in single or multiple layers [3,5–10]. The doping with phosphorescent complexes or fluorescent dyes in a polymer matrix or small molecule host exciplexes in bilayer devices or still a single polymer with different chromophores have also been reported [5,11–13].

The main issue for achieving white light through the blending of two or more chromophoric materials is the energy transfer among the various components. This energy transfer has to be incomplete, since all the colors should appear in the electroluminescence spectrum, requiring a judicious control in the concentration balance and miscibility of the mixture materials [14,15]. The basic operating mechanism involves the charge carriers injection, a partial energy transfer in order to avoid cascade non-radiative decays that will lead only to the lower-laying emission from the excited state [16,17]. The selected color in the donor–acceptor system is obtained by setting the appropriate dopant concentration. The range of dopant variation is limited, usually less than 1% and 10% for fluorescent and phosphorescent materials, respectively [10]. The upper limit is dictated by aggregate formation; since higher amounts lead to non-radiative self-quenching or intermolecular energy transfer processes [3,17]. Electroluminescent polymer blends are systems containing at least one active material which generally presents a better performance as compared to the material itself [18]. This effect can be explained by the synergic contribution of several factors, including the de-aggregation of associated species in the active medium (as ground state dimmers or excimers), the presence of heterojunctions between polymeric phases, improvement of the interfacial adhesion and of the optical properties, etc. These factors contribute to higher efficient exciton formation, charge transport and charge recombination [18–21]. When two or more active materials are blended, color tunability can also be obtained [19,20].

In this work a single layer device was explored, in which the blue emitter [poly(9,9-dihexyl-2,7-fluorene)] (LaPPS10) is the matrix host, and the green and red emitters poly[(9,9-dihexyl-9H-fluorene-2,7-diyl)-1,2-ethenediyl-1,4-phenylene-1,2-ethenediyl] (LaPPS16) and poly [2-methoxy-5-(2-ethylhexoxy)-1,4-phenylene vinylene] (MEH-PPV), respectively, were the guest components. The performance of this blend was compared with another using a second blue component, a copolymer of poly (methyl methacrylate-*co*-methyl antracenyl methacrylate), P(MMA-*co*-MMAnt) that was responsible by the improvement of the optical quality of the material [22]. The chemical structures are depicted in Fig. 1.

The choice of a polyfluorene for the main component was based on the fact that this class of polymer has emerged as an important class of blue emitter, with intense photoluminescence, good charge transport and thermal stability properties [23–26]. The other components, all of them also electroluminescent in a different spectral range, were chosen as an attempt to achieve white light emission. White light electroluminescent devices with organic materials can be built in multi-layer configuration composed by several different materials where each layer emits in a different region of the visible spectrum, generating white light output [27]. Here, single-layer devices were built, using blends with emitting materials of different band gap energies, exploring partial energy transfer [28]. Single layer devices are more attractive due to its ease of fabrication, large scale production and cost effective features, and according to published data they are more stable than those built with emitters in separated layers [20,29–31]. Therefore, for a system where the emission of one material spectrally overlaps with the absorption of another, a separating material had to be incorporated into the blend so as to prevent complete energy transfer and to give white emission with a wide spectral range [32]. To achieve this goal, morphology control of the polymer film is a crucial step and plays a main role on the device performance.

2. Experimental

2.1. Materials

The light emitting polymers poly(9,9-dihexyl-2,7-fluorene) (LaPPS10) poly[(9,9-dihexyl-9H-fluorene-2,7-diyl)-1,2-ethenediyl-1,4-phenylene-1,2-ethenediyl] (LaPPS16), poly(methylmethacrylate-*co*-methyl-antracenyl methacrylate P(MMA-*co*-MMAnt) (molar composition of 35:1 of MMA:MMAnt) were synthesized in our laboratory (LaPPS) as described in previous papers [20,22,33]. MEH-PPV was used as purchased from Sigma–Aldrich. Structures are in Fig. 1. The solvent chloroform (Vetec) was used without further purification. The solutions were mixed in different ratios, according to the blend's composition desired. LaPPS10:LaPPS16:MEH-PPV = 100:0.01:0.20 (w/w) (JF14) and LaPPS10:P(MMA-*co*-MMAnt):LaPPS16:MEH-PPV = 100:40:0.01:0.20 (w/w) (JF17). Blends were formed by casting from chloroform solutions and dried at room temperature for several days.

2.2. Samples for photophysical measurements

LaPPS10, LaPPS16, P(MMA-*co*-MMAnt) and MEH-PPV were dissolved in chloroform separately, in 10^{-5} mol L^{-1} concentration. Films were obtained from the solutions filtered through 0.2 μm Millex-FGS Filters (Millipore Co.), deposited by casting on quartz plates and allowed to dry slowly in a controlled solvent ambient. The film's thickness was adjusted in order to assure optical behavior according to Beer's Law.

2.3. Device preparation

The EL device fabrication with the configuration ITO/PEDOT-PSS/emissive layer/Al followed the procedure: the substrates were cleaned with detergent, acetone and isopropyl alcohol and subsequently underwent a process of hydrophylization with plasma ozone. Next a layer of PEDOT-PSS (Bayer) was deposited by spin coating at a speed of 4000 rpm, resulting in a 60 nm thick layer. The

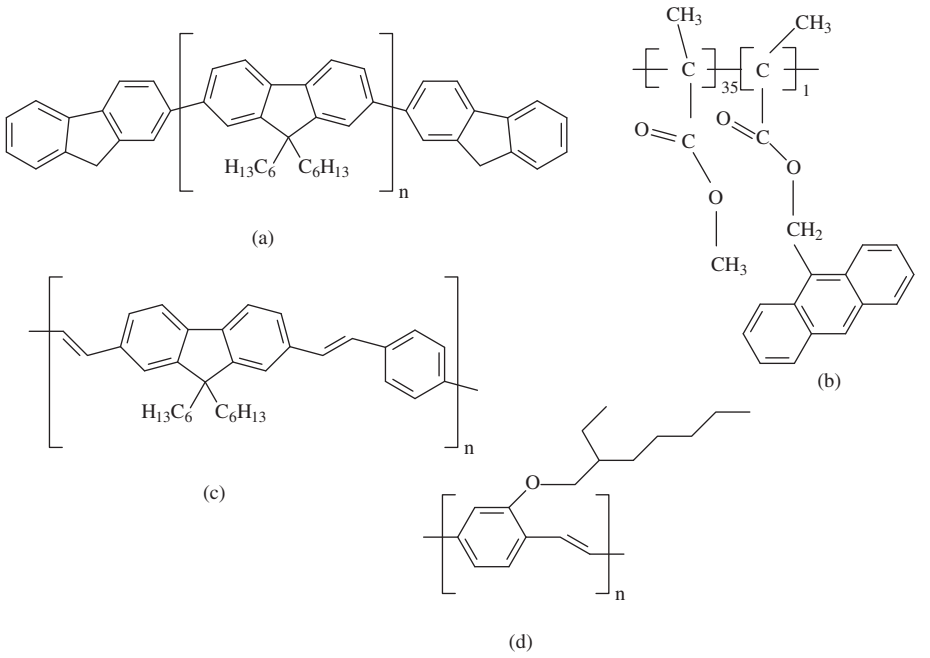

Fig. 1. Chemical structures of the emitting polymers: (a) LaPPS10 (blue), (b) P(MMA-*co*-MMAnt) (blue), (c) LaPPS16 (green) and (d) MEH-PPV (red). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

components of each material (polymer blend, JF14 and JF17) were dissolved in chloroform, with 25 mg/mL concentration. Films were obtained from the solutions filtered through 0.2 μm Millex-FGS Filters (Millipore Co.), deposited by spin coating using a rotation of 3000 rpm, forming films of 70 nm. The aluminum cathode was vacuum-deposited onto the blend layer under a pressure of about 10^{-6} mbar resulting in a layer 100 nm thick, completing the device preparation. The two devices are also named JF14 and JF17, according to their blends.

2.4. Optical analyses

UV–vis spectra were recorded on a Shimadzu model UV 2401 PC spectrophotometer, single beam, in the range of 250–750 nm. Steady-state emission spectra were acquired in a Shimadzu 5301 PC spectrofluorimeter, in the visible range of 390–780 nm. A 1.0 cm quartz square cuvette was used for solutions and a home-made optical support for film samples.

Fluorescence decays were recorded using time correlated single photon counting in an Edinburg Analytical Instruments FL 900 spectrofluorimeter using a pulsed hydrogen lamp, in a frequency rate of 40 kHz. Measurements were performed with wavelength excitation of λ_{exc} = 320 nm and the emission signals were collected in λ_{em} = 440 nm, respectively for solutions and for films. The sample cuvette was evacuated for 15 min and sealed under vacuum. The sample decay signal was deconvoluted from the lamp signal using the scattering from a Ludox® sample. The experimental curves were fitted using the software F900 provided by Edinburg. The analysis was performed by fitting the decays with multiple exponential functions using non-linear least-squares routines minimizing the χ^2. Good fits were obtained when χ^2 is close to 1.

$$I(t) = B_1 \exp\left(\frac{-t}{\tau_1}\right) + B_2 \exp\left(\frac{-t}{\tau_2}\right) + B_3 \exp\left(\frac{-t}{\tau_3}\right) + \ldots \quad (1)$$

τ_i is the fluorescence lifetime, B_i is the corresponding pre-exponential term and represents the contribution of each decay time to the total curve.

Epifluorescence optical images were recorded in a Leica DM IRB inverted microscope operating with a mercury lamp for UV–vis excitation in the transmission configuration. Pairs of optical filters for excitation and emission (dichroic mirrors) were selected in the range of λ_{exc} = 330–380 nm and λ_{em} > 440 nm, respectively. Photomicrographs were recorded using two microscope configurations: epifluorescence using UV-excitation and epifluorescence combined with lamp transmission to improve the image contrast. In this last configuration small bright domains could be visualized.

The CIE coordinates were calculated from data taken from the EL or PL emission, using the software CIE 31 xyz.xls.

2.5. Electroluminescence spectra, JxV and LxV measurements

The current–voltage measurements were performed using a 2400 Keithley Source. The EL spectra were acquired using a Labsphere Diode Array Spectrometer 2100 connected with Labsphere System Control 5500. The luminance–voltage was measured by 238 Keithley connected with a sensible photodiode. The samples were kept in a sealed Janis chamber with high vacuum.

3. Results and discussion

3.1. Photoluminescence properties

3.1.1. Solution properties

Fig. 2 presents the absorption and emission spectra of each polymer separately, recorded from the respective chloroform solutions (10^{-5} mol L^{-1}). Absorption of the P(MMA-*co*-MMAnt) is composed by a well defined vibronic structure in the range from 300 to 398 nm, characteristic of the anthracenyl moieties with the 0–0 band centered at $\lambda_{abs(0-0)}$ = 387.8 nm, and emission with the 0–0 band centered at $\lambda_{em(0-0)}$ = 393 nm [22,34,35]. Considering the 0–0 band for both absorption and emission, the Stokes shift is 341 cm^{-1}.

The LaPPS10 absorption band is broad and centered at $\lambda_{abs(0-0)}$ = 378.2 nm, strongly overlapped with that of P(MMA-*co*-MMAnt). Differently of the absorption, the LaPPS10 emission has a well resolved vibronic structure, with the 0–0 band at $\lambda_{em(0-0)}$ = 415.8 nm. The Stokes-shift taken as the difference between the absorption maximum and the 0–0 band of the emission is 2391 cm^{-1}. Absorption and emission spectra were not mirror images, indicating that the emission arises from a relaxed Franck–Condon state and are provided by energy transfer or by energy migration processes [37]. The LaPPS16 absorption band is also broader, two maxima were observed in the vibronic structure, at 430 nm and $\lambda_{abs(0-0)}$ = 454 nm. Its fluorescence emission has a partially resolved vibronic structure with the 0–0 band at $\lambda_{em(0-0)}$ = 472 nm. The Stokes-shift considering the 0–0 band in the absorption and emission spectra is 840 cm^{-1}. This smaller Stokes-shift suggests that Franck–Condon states with similar geometry are involved in the ground and electronic excited states due to the more rigid structure composed by a sequence of fluorene–vinylene alternated groups.

The MEH-PPV absorption band is also broader and centered at λ_{abs} = 491.5 nm. Emission is centered at $\lambda_{em(0-0)}$ = 554 nm, with a Stokes-shift of 2295 cm^{-1}. Therefore, taking this set of individual polymers, the absorption bands range from 325 to 550 nm, and the photoluminescence bands in solution that appears in the 400–600 nm range, cover almost the entire visible region.

3.1.2. Film properties

Fig. 3 presents the absorption and emission spectra of each component in the solid state. The P(MMA-*co*-MMAnt) absorption is composed by a well resolved vibronic

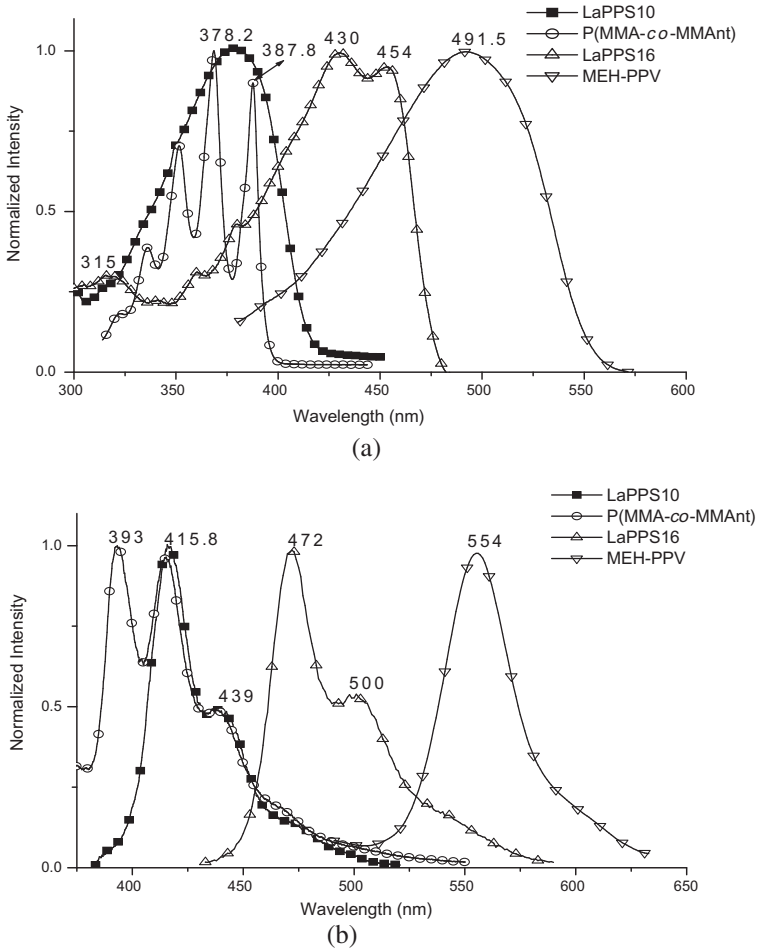

Fig. 2. Electronic absorption (a) and fluorescence (b) spectra of the polymers in 10^{-5} mol L^{-1} chloroform solutions. All samples were excited at λ_{exc} = 380 nm.

structure in the range of 300–420 nm, characteristic of the anthracenyl moieties, with the 0–0 band centered at $\lambda_{abs(0-0)}$ = 390.2 nm [22,34,35]. This spectrum is broader and red-shifted by 2.5 nm compared to the dilute solution. The lower energy peak at $\lambda_{abs(0-0)}$ = 410.4 nm can be attributed to ground state aggregates. Its emission is also broader with the 0–0 band centered at $\lambda_{em(0-0)}$ = 421.8 nm with a maximum located around 442.8 nm and

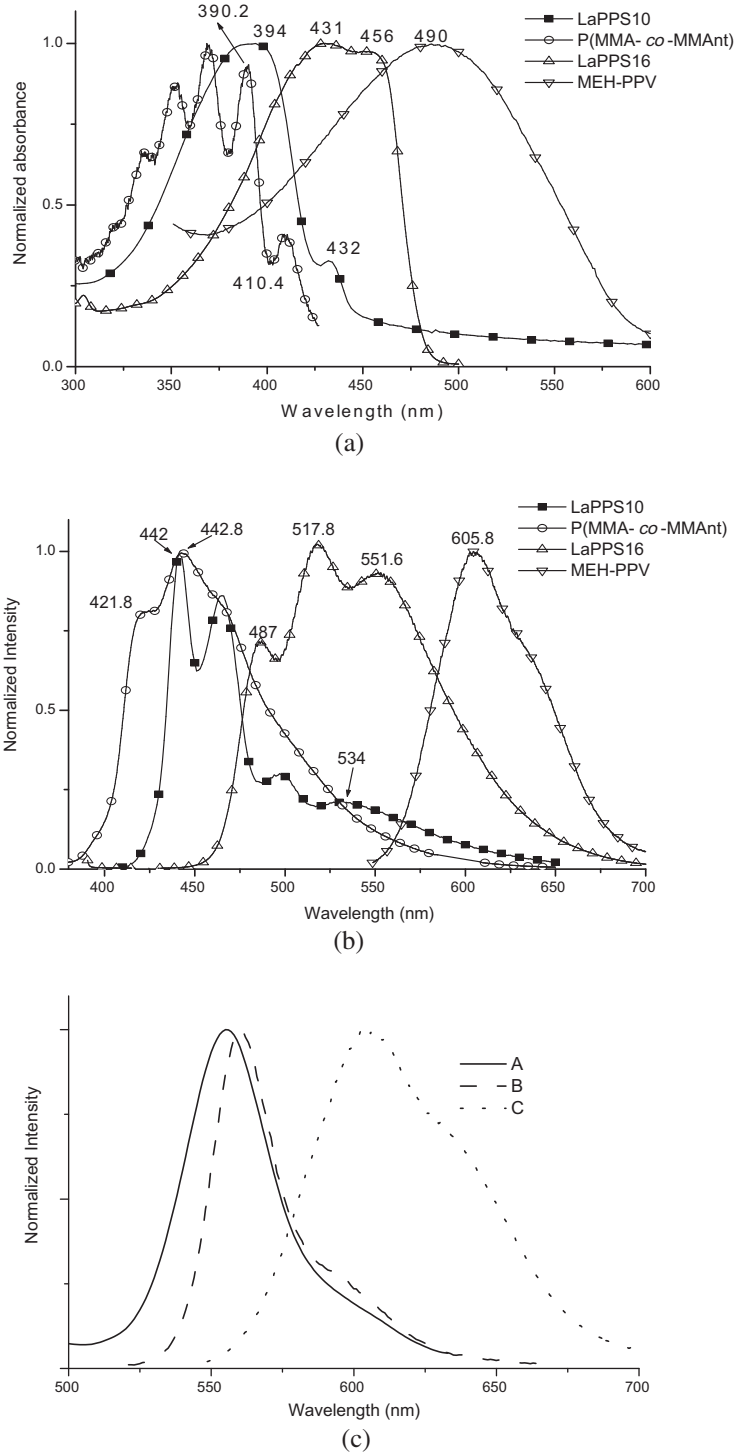

Fig. 3. Electronic absorption (a) and fluorescence (b) spectra of the polymers in film form. LaPPS10, LaPPS16 and P(MMA-*co*-MMAnt) were excited with λ_{exc} = 380 nm and MEH-PPV was excited with λ_{exc} = 490 nm. (c) Progresses red shift MEH-PPV emission with concentration, chloroform solutions (A) 10^{-7} mol L^{-1}, (B) 10^{-5} mol L^{-1} and (C) film.

with a Stokes-shift of 1920.0 cm^{-1}. The emission band has a red-edge tail, due to the presence of anthracenyl aggregates [22]. Generally, the presence of broad emission bands can be attributed to conformational disorders of the polymer chains where differences of microenvironment around every lumophore modifies their state densities [34]. Due to the large distance between two anthracenyl groups bonded to the main chain (35 MMA units) no excimer or aggregate emissions were observed in diluted solutions, and thus we ascribed the red-edge emission tail to aggregation of the lumophores in the solid state [34]. Emission of anthracenyl aggregates has been described and their formation requires very specific orientation of the polymer chains [37].

The LaPPS10 absorption band is broad and centered at λ_{abs} = 394 nm, red-shifted by 16 nm compared to the dilute solution. The presence of the low intensity band at λ_{abs} = 432 nm is a strong evidence that during the film formation some chains or chains segments are arranged in the β-conformation, a more planar orientation of the backbone [36,38–41]. The differences in the emission spectra of the blue emitter LaPPS10 in solution and in film form give further support for the presence of the β phase. The emission has a well resolved vibronic structure, with the 0–0 band at $\lambda_{em(0-0)}$ = 442 nm, with a Stokes-shift of 2756 cm^{-1}, red-shifted compared with the spectrum in solution by 27 nm. The emission in films of polyfluorenes in the 440 nm region has been assigned to the β-phase, and since its band gap is smaller than that of amorphous polymer, it may act as acceptors of resonance energy transfer [42]. That could be in part responsible for the absence of the higher energy bands seen in dilute conditions. The additional red-edge emission band at λ_{em} = 534 nm is characteristic of the LaPPS10 aggregates [41].

The LaPPS16 absorption band is also broader, with a poor resolved vibronic structure with two maxima at λ_{abs} = 431 nm and $\lambda_{abs(0-0)}$ = 456 nm. Its fluorescence emission is much broader than that in solution with the 0–0 band at $\lambda_{em(0-0)}$ = 487 nm, red-shifted by 15 nm compared to the dilute solution. In addition, two other strong bands at 517.8 and 551.6 nm are observed, possibly originated from aggregates [41]. Further, the LaPPS16 aggregate emission has a greater contribution to its total emission than that observed for LaPPS10.

The MEH-PPV absorption band is also broader compared to the solution and centered at $\lambda_{abs(0-0)}$ = 490 nm. Again, this spectral broadening can be ascribed to the inhomogeneous broadening in solid state produced by a larger distribution of states of individual chains in addition to the chain aggregation in more ordered regions. Its photoluminescence spectrum is not as broader as the absorption and centered at λ_{em} = 605.8 nm in the solid state, red-shifted by 52 nm compared to the solution spectra, with a larger Stokes-shift of 3985 cm^{-1}. Because of the relatively sharper and strongly red-shifted photoluminescence we suggest that its emission is occurring in more aggregated domains [43].

Putting all the individual absorption profiles together, we can see that they cover practically the entire visible spectral range (including part of the UV) whereas the photoluminescence ones also cover the entire visible spectrum, from the violet to the red (400–700 nm). Additionally, it can be seen from Fig. 3 that there is a strong overlap between the absorption from LaPPS16 and the photoluminescence from both LaPPS10 and P(MMA-*co*-MMAnt), as well as the absorption from MEH-PPV and the photoluminescence from LaPPS16. These spectral overlaps among the absorption and emission of the blend components play an important role on the photophysical properties of their polymer blends, since this is an important requirement for the resonant energy transfer process [44].

Fig. 4 shows the absorption and emission spectra of the blends: LaPPS10:LaPPS16:MEH-PPV = 100:0.01:0.20 (w/w) (JF14) and LaPPS10:P(MMA-*co*-MMAnt):LaPPS16:MEH-PPV = 100:40:0.01:0.20 (w/w) (JF17). The difference between the blends JF14 and JF17 is the presence of the methacrylic copolymer in JF17 as the second major component. The addition of this copolymer brings about at least three important consequences: it greatly enhances the optical quality of the films; there is an improvement of the film adhesion on the substrate leading to more flat surfaces; and there is a relative decrease of the contribution of the β-phase still present from the blue emitter LaPPS10 (absorption and emission bands at 432 and 442 nm, respectively). Dilution effect in polymer blends has been observed in several systems leading to a separation of the polymer chains and to the decrease of interchain interactions [33,45–47]. Moreover, the contribution of the β-phase in the JF17 blend seems to be less important than in the JF14, indicating that the improved optical quality produced by the inclusion of the acrylic copolymer is associated to the film morphology.

Fig. 4 also depicts the photoluminescence spectra of the blends. Emission in the higher energy edge is characteristic of the LaPPS10, where the 0–0 band occurs at 442 nm and a second vibronic peak appears at 465 nm, the same observed for this individual polymer in Fig. 3. However, the vibronic ratio is not constant for the three systems in solid state: LaPPS10, JF14 and JF17 blends. The lower vibronic ratio I_{465}/I_{442} observed for blend JF14 can be explained by a dilution effect which reduces the homopolymer interchain resonant energy transfer, whereas the higher vibronic ratio I_{465}/I_{442} and the spectral broadening observed for the JF17 can be explained by the contribution to the emission of the P(MMA-*co*-MMAnt) acrylic copolymer. Finally, the broad band at 540 nm present in both blends can be assigned to a contribution of the emission of LaPPS10 and LaPPS16 aggregates, along with that of MEHPPV. It is worthwhile to note that the emission of this polymer is very sensitive to concentration. In diluted solution (Fig. 2(b)) it peaks at 554 nm, whereas in the film the emission redshifts to 605.8 nm (Fig. 3(b)). Literature data reports r redshiftings of 100 nm for blends of MEHPPV with PMMA from concentrations of 12.5% in relation to the pure polymer film [48]. When diluted in polyfluorene, the emission around 600 nm which appears as a shoulder in the blends containing 3% to 1%, is no longer detected when MEHPPV is present in the concentration of 0.4% [20]. This progressive MEH PPV redshifting with concentration is illustrated in Fig. 3(c). Therefore, the broad band of the PL emission extending from 520 to 600 nm (see inset in

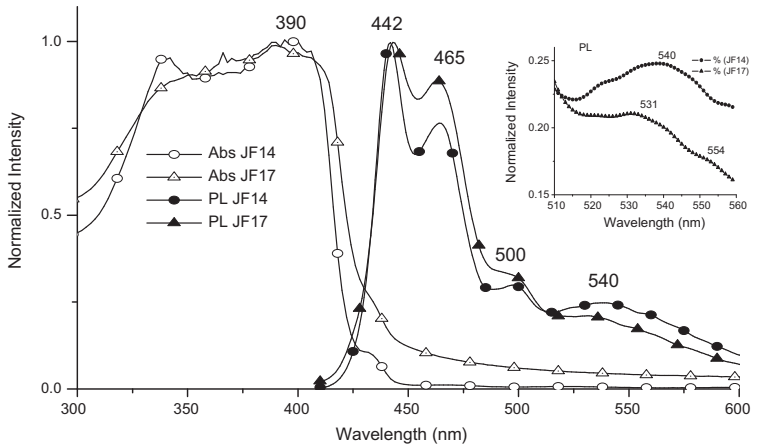

Fig. 4. Electronic absorption and emission spectra of blends JF14 and JF17 (λ_{exc} = 380 nm) in film form.

Fig. 4) can be attributed to the dopants LaPPS16 and MEH PPV, which do not appear separately due to their low concentration. It should be noted that the intensity in the region of 540 nm is higher for the JF14 than for JF17, characterizing a more efficient energy transfer in the former.

The spectral overlap among the absorption and emission of the blended components is a necessary condition for the resonant energy transfer from a donor polymer to an acceptor, which, in addition, also requires a close proximity between the components (distance within the Förster radium). Nevertheless, this condition must be avoided to some extent if a white emission is desired in a photoluminescent system. In other words, in a white emitting device, the resonant energy transfer process should not be completely efficient since the entire emission spectral range of white color must have contributions of the several chromatic components. Thus, from the photophysical point of view, to achieve white emission, only partial energy transfer processes and inner filter effects must be allowed in a photoluminescent system. Polymer blended systems with phase separation may undergo white emission because the domains are independent emissive sites, and the inner filter effect may be controlled by the thicknesses. Fig. 4 shows that the photoemission has a strong blue component, indicating that the energy transfer processes from the higher energy donors (LaPPS10 and P(MMA-*co*-MMAnt)) to the lower energy acceptors (LaPPS16 and MEH-PPV), are not complete suggesting that both blends underwent phase separation processes and the emission from the lower energy components are prevented by the inner filter, inhibiting their excitation.

In an attempt to explain the photoluminescence spectra observed for the two blends, we analyzed the morphology by epifluorescence optical microscopy. In Fig. 5a the morphology of the JF14 film under UV excitation (λ_{exc} = 330–380 nm, λ_{em} > 440 nm) is shown. A uniform blue emission over the entire samples is observed which is characteristic of LaPPS10, the major component, based on the emission spectra in Fig. 4. Nevertheless, more detailed images by combining the UV excitation with white lamp revealed also some blue spots of the LaPPS16 component (sizes smaller than 1 μm) (Fig. 5b) and under excitation with visible light (λ_{exc} = 480–500 nm, λ_{em} > 550 nm) red spots from the MEH-PPV component are the only one observed (Fig. 5c). Thus, the morphology of the JF14 blend can be described as a dispersion of the LaPPS16 and MEH-PPV domains in a blue matrix of LaPPS10. A phase separation is clearly seen. The morphology of the JF17 blend is completely different and since the only change is the addition of P(MMA-*co*-MMAnt), this is the responsible by the change. In Fig. 5d using UV excitation (λ_{exc} = 330–380 nm, λ_{em} > 440 nm), two types of blue domains can be seen: dispersed interconnected blue darker domains in a light blue matrix of LaPPS10. The dispersed domains are better visualized when with the combination of UV and white illumination (Fig. 5 – right side) and now, in addition to the interconnected domains we also identity dispersed spherical blue domains whose diameters are around 20 μm, which were ascribed to the P(MMA-*co*-MMAnt) (Fig. 5e). This combination also showed the presence of some interconnection of blue domains through a interphase, probably due to the LaPPS16 or some non-segregated P(MMA-*co*-MMAnt) components. Again the MEH-PPV red domains can be seen using visible light (λ_{exc} = 480–500 nm, λ_{em} > 550 nm) (Fig. 5f).

Therefore, from the morphological point of view, the components of these blends have a very low (if some) miscibility, forming a matrix of LaPPS10 and segregated domains of LaPPS16 and MEH-PPV in the case of JF14, and of LaPPS16, P(MMA-*co*-MMAnt) and MEH-PPV in the case of JF17. Even with phase separation, the acrylic copolymer played an important role on the film morphology, creating the possibility of interconnected domains formation in the JF17 blend. Nevertheless the changes of the photoluminescence spectra are not substantial. Because of this apparent poor miscibility in both JF14 and JF17 blends, we would not expect a complete energy transfer processes from the donors to the acceptors even though their absorption and emission are strongly overlapped. This result is an interesting example of the interplay between photophysical behavior and morphology. However, steady-state

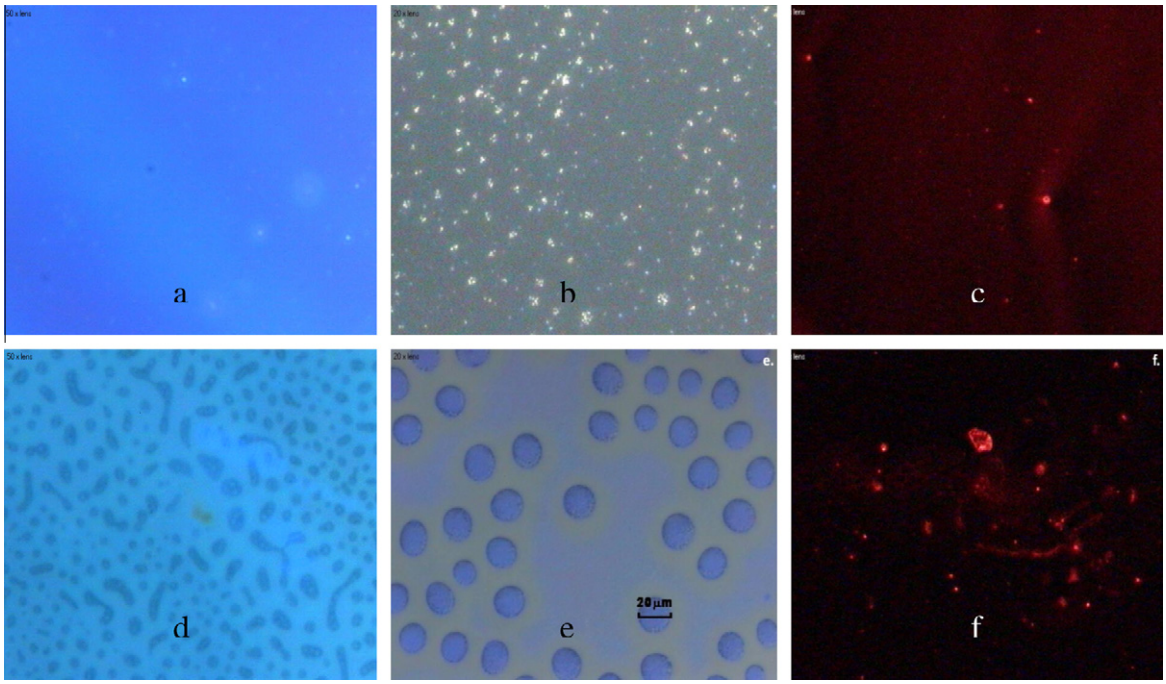

Fig. 5. Epifluorescence images of (a–c) JF14 and (d–f) JF17 and (d) UV excitation (λ_{exc} = 330–380 nm, λ_{em} > 440 nm); b and e (combining UV and white light to improve the contrast); c and f (λ_{exc} > 490 nm, λ_{em} > 550 nm). Amplification 22×.

fluorescence spectroscopy is not the most useful tool to evaluate the energy transfer processes when samples depict complex or overlapped emission spectra.

In order to get additional insight about the possibility of energy transfer processes from LaPPS10 and P(MMA-*co*-MMAnt) to LaPPS16 and MEH-PPV, fluorescence decays of the donors were measured in blends (in the presence of the acceptors), and compared these values with those of each isolated polymer in both solution and in film form. The LaPPS10 photoluminescence decays in degassed chloroform solution (10^{-5} mol L^{-1}) (λ_{exc} = 320 nm, λ_{em} = 440 nm) is bi-exponential with τ_1 = 0.48 ns (54%) and 0.79 ns (46%) (Table 1) and becomes mono-exponential in films with a lifetime of 0.31 ± 0.07 ns. This lifetime range is in accordance with those reported for polyfluorenes in diluted solution (from 0.08 to 5.0 ns) [36,49–52]. The decrease in lifetime in the solid state can be attributed to the formation of aggregates as well as to several possibilities of quenching processes in the solid state, apart from resonant energy transfer from disordered to β phases.

For the JF14 polymer blend in solution (λ_{exc} = 320 nm, λ_{em} = 440 nm), the decay is practically the same as the LaPPS10 in solution (bi-exponential with τ_1 = 0.48 ns (54%) and 0.76 ns (45%) (Table 1)), indicating that the presence of other components is not interfering with the LaPPS10 photophysics, and that no resonant energy transfer processes are occurring. Nevertheless, JF14 film exhibits a bi-exponential decay with the faster component of 0.41 ± 0.07 ns (86%), practically the same of the isolated LaPPS10 films and a longer component with τ_2 = 2.98 ± 0.01 ns with a smaller contribution (13%), that is absent in solution. Apart from a possible assignment of this longer decay to molecular aggregation in the ground state, as shown by the absorption and emission spectra, the complexity of the morphology makes the assignment of this transition very difficult.

Decays in JF17 blend-films, on the other hand, are mono-exponential, as also observed for solutions. Nevertheless, there is a pronounced decrease of the fluorescence lifetime in solid state (not observed in JF14) compared with the solution, which suggests that some non-radiative resonant energy transfer processes from LaPPS10 to the other components are occurring. It is very well documented in the literature that chain interpenetration favors the resonant energy transfer processes because the

Table 1
Fluorescence decays of the pure blend components in several conditions, using λ_{exc} = 320 nm, λ_{em} = 440 nm; *B* is the contribution of every lifetime to the entire decay, χ^2 measures the quality of the exponential fitting.

Materials	τ_1 (ns)	B_1 (%)	τ_2 (ns)	B_2 (%)	χ^2
LaPPS10 (solution)	0.48 ± 0.08	54	0.79 ± 0.06	46	1.041
LaPPS10 (film)	0.31 ± 0.07	100			1.089
P(MMA-*co*-MMAnt) (film) [22][c]	2.5	72	7.4	28	
JF14 (solution)	0.48 ± 0.07	55	0.76 ± 0.08	45	1.135
JF14 (film)[a]	0.41 ± 0,08	86	2.98 ± 0.01	13	1.161
JF17 (solution)[b]	0.62 ± 0.03	97			1.097
JF17 (film)	0.28 ± 0.08	97			1.080

[a] λ_{em} = 465 nm.
[b] λ_{em} = 410 nm.
[c] λ_{exc} = 370 nm, λ_{em} = 415 nm.

donor–acceptor distances approaches of that equivalent to the Förster radius [44]. This result can be correlated with the epifluorescence micrographs which showed the presence of interconnected domains that would lead to chain interpenetration. Based on this analysis we can conclude that the presence of the P(MMA-*co*-MMAnt) induces a better dispersion of the components, interferes with the interface energy, improves the optical quality of the films and facilitates the energy transfer from the donor to the acceptors.

3.2. Electroluminescence

Fig. 6 shows the electroluminescence spectra of LaPPS10 and of the JF14 and JF17 blends. The EL spectrum of LaPPS10 shows a band emission with vibronic structure, where the most intense band (0–0 band) is at 453.5 nm, 11 nm red-shifted as compared to the PL (Fig. 4). The vibronic progression occurred at 478.7 and 515.3 nm with a broad and less intense shoulder at 558 nm. It is particularly interesting that the relative intensities of the vibronic bands in the EL spectrum decrease at about half intensity on going the 0–0 to 0–1, from 0–1 to 0–2 and from the 0–2 to 0–3 vibronic bands which is completely different of the PL spectrum (Fig. 3), where systematic decrease of the emission was not observed. The EL spectrum is also sharper, showing, therefore, a better spectral resolution. These differences indicates that the EL is originated from other exciton species than those responsible for the PL. PL is originated from a very broad distribution of different species either by direct excitation or by several types of possible energy transfer processes. Moreover, considering the presence of the β-phase in the solid state identified by the sharper absorption band at 432 nm, red-shifted compared to the absorption of the amorphous disordered chains, and the emission band at 442 nm, we suggest that the EL is probably produced in the ordered β-phase of the LaPPS10.

Significant differences between EL and PL spectra were also observed for the JF14 and JF17 blends. The EL spectrum of the JF14 blend is similar to that of LaPPS10 in terms of spectral range, but significant differences were noted in the relative intensities of the red-edge peaks. The blue peak at 453 nm is present in all EL spectra (0–0 band of LaPPS10), but those at 514 nm (green) and 550–560 nm (yellow) were more intense, providing additional contribution to the visual color of the entire emission. The relative contributions of these red-edge peaks are greater in the EL compared with the PL spectra (Fig. 4). There are two possible explanations for the relatively more intense red-edge emission in EL. First, is that the excitation efficiency by photons in the PL is proportional to the amount of each component in the blend, in the absence of efficient energy transfer processes. Since we are using excitation in the blue region, the efficiency of the photoexcitation of the LaPPS16 and of the MEH-PPV are lower and thus their emissions are also relatively lower. This is not relevant for the EL spectrum. The second explanation is that the EL emission is proportional to the efficiency of the charge transport across each phase, to the charge recombination and to the efficiency of the exciton recombination. The first two processes are intrinsically associated with properties of each material and cannot be correlated with the PL. If they are more efficient for the LaPPS16 and for the MEH-PPV, it will be expected that the relative EL from these two components will be greater, as we effectively observed. Moreover, the band around 550–560 nm was attributed to the emission from the LaPPS16 aggregates, and again the EL seems to be more efficient at the more ordered crystalline phase of this polymer, as it does for LaPPS10. The EL is redshifted as compared to the PL, and that can be accounted for the charge trapping in the dopants domains, apart from energy transfer. The dopants emission in both JF14 and JF17 are enveloped the 500–700 nm region. In the EL spectrum of the JF14 blend a shoulder is seen at 590 nm which was attributed to the MEH-PPV domains, according to epifluorescence images. (See inset of Fig. 6). According to published data, the work function of the β phase regions is ca. 5.3 eV, i. e. 0.3 eV lower than that (5.65 eV) of the polyfluorene matrix [40], suggesting that hole carriers tend to be injected into the β phase rather than into the polyfluorene disordered matrix. It has been demonstrated that the β phase in poly(9,9-dioctylfluorene) is an energetically

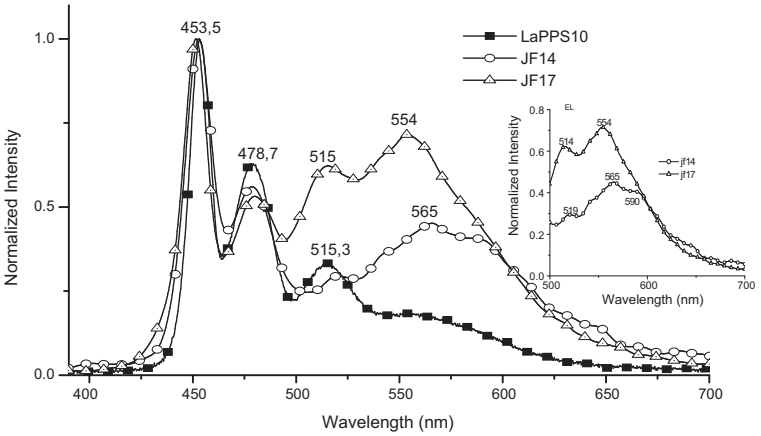

Fig. 6. EL spectra of the LaPPS10 film and JF14 and JF17 blends.

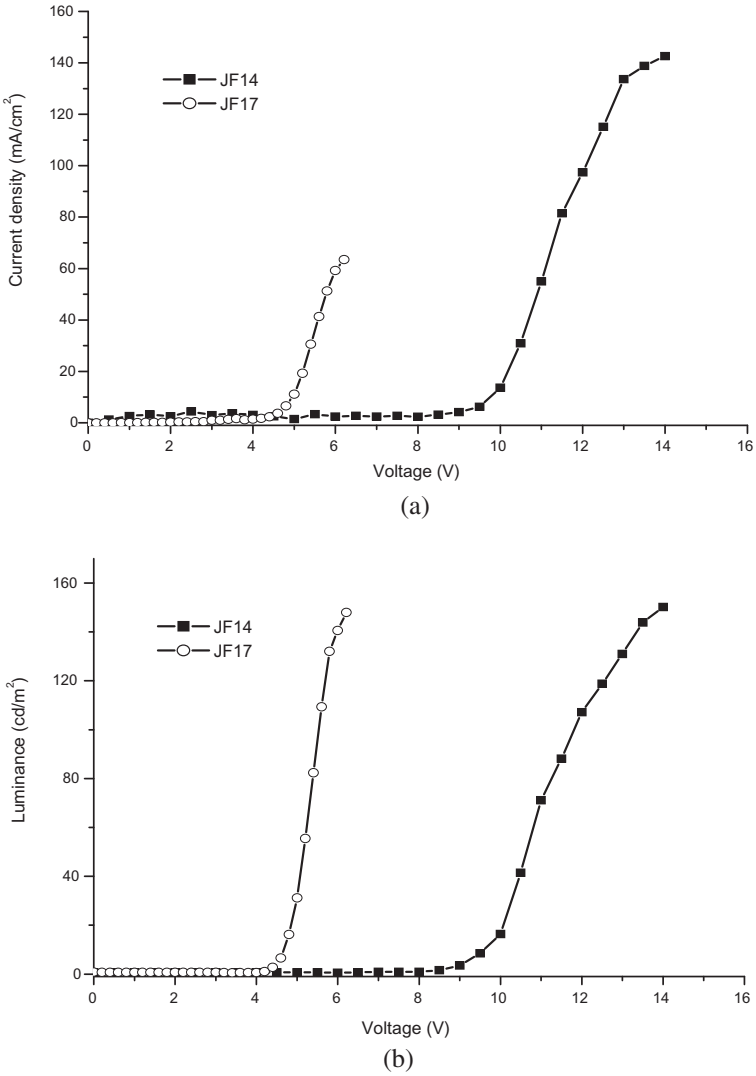

Fig. 7. (a) Current density × voltage and (b) luminance × voltage graphs of devices built with blends JF14 and JF17.

favorable environment for charge carriers, with an enhanced charge carrier mobility [53]. Due to its smaller band gap it can act also as traps for carriers, competing with other species in excitonic energy transfer processes, and more importantly, as carrier trapping/recombination sites.

The addition of P(MMA-*co*-MMAnt) in JF17 resulted in considerable differences in the EL profile as compared to LaPPS10 and JF14. There is a pronounced relative increase of the red-edge emission compared with the LaPPS10 and compared with the JF14. As previously mentioned, the EL emission is strongly correlated to the charge transport and charge recombination that seems to be enhanced by the addition of the acrylic copolymer. Taking into account the morphological and the photophysical properties, we can conclude that the formation of interconnected phases in JF17 are favoring not only the energy transfer processes (lifetime decreased) and the optical quality of the film but also the charge transport as already indicated for systems forming bulk heterojunctions [42]. Bulk heterojunctions are in JF17 enhancing the emission of LaPPS16, as indicated by the increase of the relative intensity of the bands at 515 and 554 nm. If the hypothesis of the heterojunction favoring the charge transport is correct, we should also expect changes on the electrical performance of these devices.

In the operation of an organic light-emitting diode (OLED) either the operating voltage or the luminance efficiency, depends firstly on the effective injection of carriers from both electrodes. It also strongly depends on the charge transport, the exciton generation and the recombination process. To achieve the lowest possible threshold voltage, the contact (cathode or anode) with the organic layer should approximate to ohmic condition. In general, this condition is easily reached with the anode, the transparent contact, in which the work function is close to the HOMO of the organic conjugated molecule. The injection of electrons, on the other hand, requires a more sophisticated technology to avoid the unbalance between electrons and holes.

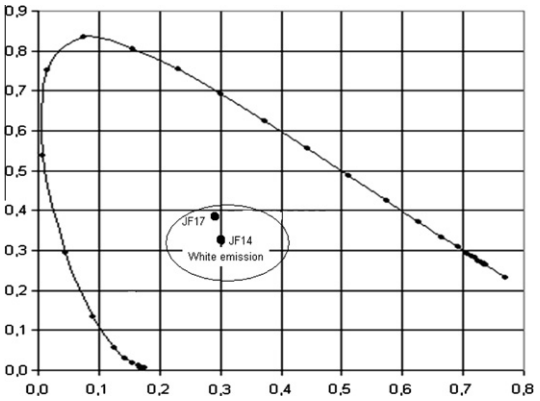

Fig. 8. CIE diagram relative to the electroluminescence of blends JF14 (0.30 and 0.32), JF17 (0.29 and 0.38).

In the present devices we used a simple structure, with a hole transport layer (PEDOT:PSS), and only one aluminum layer in the cathode (without an electron transport layer). Even so, both JF14 and JF17 devices showed a good performance as white OLED, as shown in Fig. 7. Fig. 7a shows the current–voltage curves for JF14 and JF17 devices, both exhibiting a diode characteristic. JF17 operates with lower voltage, having a threshold voltage below than 5 V and with a luminance, while the threshold voltage for JF14 was at about 10 V. Similar response was observed in the luminance vs. voltage curves. JF17 device reached 150 cd/m^2 at 6 V (60 mA/cm^2), while the JF14 presented the same luminance at 14 V (140 mA/cm^2). Therefore, the performance of JF17 was superior, since it achieved a luminance efficiency (cd/A) 2.5 higher, i.e. the same luminance at lower voltage and electric current. Fig. 8 exhibits the CIE coordinates of both devices (JF14 and JF17), and, as it can be seen in the CIE diagram, they emits in white region.

The HOMO and LUMO levels of the components used in the blends of JF14 and JF17 are shown in Table 2. The work functions of ITO and aluminum are about 4.8 and 4.1 eV, respectively. The values corresponding to LaPPS16 and MEHPPV were taken from Refs. [54,20], and those of poly(methyl methacrylate-*co*-methyl antracenyl methacrylate) were determined by cyclic voltammetry and UV–vis spectroscopy. The latter is in the same range of published data for poly(methyl methacrylate) copolymers with pendant chromophores: the reported HOMO and LUMO for the polymer with pendant azodyes are −6.08 and −3.21 eV, respectively [55].

Since the active layer of each luminescent diode is a blend composed by several components, it is not possible to sketch a sequence of energy barriers faced by the charge carriers, either for injection or transport mechanisms. The basic difference between JF17 and JF14 is that the blend of the former includes P(MMA- *co*-MMAnt), whose HOMO value is higher than the others. However, JF17 exhibited a better electrical and optical performance, as can be seen by the threshold voltage in the current and luminance curves (Fig. 7). Most probably this improvement brought about by P(MMA- *co*-MMAnt) to the blend is related to morphological modifications bringing the molecules in closer interactions one to another.

Table 2
HOMO and LUMO values in eV.

	PEDOT:PSS	P(MMA- *co*-MMAnt)	LaPPS10	LaPPS16	MEH-PPV
LUMO	3.50	3.90	2.60	3.04	2.80
HOMO	5.20	6.80	5.97	5.60	4.90

4. Conclusions

This study with the blends JF14 and JF17 showed that due to several mechanisms of energy transfer processes, an emission profile proportional the composition of every component is not the outcome of the device. The performance of the blends were compared, the segregated domains of the green and red emitters in the blue matrix brought about different behaviors. In the JF17 blend, the methacrylic non-conjugated copolymer was the predominant component in the dispersed phase, whereas for JF14 the MEH-PPV (red emitter polymer) was the main component of the domains. The differences in the EL and PL indicated that the mechanisms involved in the dynamics of excited states and/or in quenching processes are different in both cases. The EL emissions suggested that the cascade mechanism for the charge migration, charge recombination or energy transfer processes are incomplete, which opens possibility for more than one type of mechanism, resulting in emissions at different wavelengths. Spectroscopic data brought evidence of the formation of the β phase in the polyfluorene matrix, and due to differences in band gap, it was concluded that hole carriers tend to be injected into that phase rather than into the disordered one. The device with blend JF17 presented a better performance when compared with device JF14. Its turn on voltage was 4 V whereas that of JF14 was 9 V. The maximum luminance attained was 148 cd/m^2 at 6 V with current density maximum of 63 mA/cm^2 for JF17, compared to 142 cd/m^2 at 14 V for JF14.The behavior of the blue LED built with the pure matrix is inferior to those of the blends: turn on 13 V, maximum luminance 3.4 cd/m^2 at 20 V at 7.6 mA/cm^2. The CIE coordinates for EL emission of JF14 blend the coordinates are (0.30, 0.32) and for JF17 blend are (0.29, 0.38) corresponding to white light emission. It is worthwhile to note that these EL devices were not optimized; they were built in a standard configuration for comparison purposes, and focused in white light emission.

as multifunctionality and miniaturization [39]. In contrast to these numerous applications of pyrene derivatives, regioregular polymeric systems with pyrene scaffold in the main chain are uncommon [40], albeit a few random copolymers of pyrene with pyrrole [41], 3,4-ethylenedioxythiophene [42] and bithiophene [43] have been reported.

In this paper, we wish to report the synthesis and properties of a novel processable regioregular PEC which is based on pyrene (**Py**) and didecylpropylenedioxythiophene (**P**). In this unique combination, **P** units provide solubility and low oxidation potential as well as electrochromic features whereas **Py** scaffold contributes with its fluorescence to this dual electrochromic and luminescent system. It is noteworthy that this novel processable PEC has a specific optical band gap (2.2 eV) to reflect or transmit the yellow color in the neutral state, which can be switched to a navy state upon doping. Furthermore, the optical and electrochemical features of this PEC were investigated.

2. Experimental details

All chemicals were purchased from Aldrich Chemical and used as received unless otherwise noted. 0.1 M tetrabutylammonium hexafluorophosphate (TBAH) dissolved in dichloromethane (DCM) and acetonitrile (ACN) was used as electrolyte solution. A platinum disk (0.02 cm^2) and a platinum wire were used as working and counter electrodes, respectively, as well as a Ag/ AgCl reference electrode (calibrated externally using 10 mM solution of ferrocene/ferrocenium couple which is an internal standard calibrated to be 0.44 V in ACN solution vs. Ag/AgCl). Repetitive cycling or constant potential electrolysis was used to obtain the polymer films. Electro-optical properties were investigated by using an indium tin oxide (ITO, Delta Tech. 8–12 Ω, 0.7 × 5 cm) electrode as well as a platinum wire as counter electrode and an Ag wire as a pseudo-reference electrode. For the spectroelectrochemical measurements, **P5** polymer film was coated on ITO electrode via cyclic voltammetry (between 0 and 1.15 V, 10 cycles) from a solution of **5** (5×10^{-3} M) in 0.1 M TBAH/ACN. In order to break in the polymer film, it was switched between 0.0 and 1.25 V in a monomer-free electrolytic solution during five cycles. Electroanalytical measurements were performed using a Gamry PCI4/300 potentiostat–galvanostat. The electro-optical spectra were monitored on a Hewlett–Packard8453A diode array spectrometer. FTIR spectra were recorded on Nicolet 510 FTIR with an attenuated total reflectance (ATR). High resolution mass spectrometry analysis of **5** was done via Water, Synapt HRMS instrument. GPC analysis of polymer was carried out with Polymer Laboratories PL-GPC 220 instrument. TGA analysis was done via Perkin Elmer Pyris 1 TGA under nitrogen atmosphere with 10 °C/minute heating rate. Bromination of pyrene (**1**) [44] and the synthesis of **4** [20] were carried out according to previously reported procedures.

2.1. Synthesis of 5

To an argon-degassed solution of **2** (150 mg, 0.417 mmol) and **4** (635 mg, 0.875 mmol) in dry toluene (30 mL) was added $Pd(PPh_3)_2Cl_2$ (62 mg, 0.0875 mmol) and the mixture was heated under reflux during 5 days. After being cooled to room temperature, the solvent was removed under reduced pressure. The crude mixture was chromatographed on silica gel by eluting with hexane: methylene chloride (10:1, v/v) to give **5**. 56% yield, yellow viscous liquid.

^{1}H NMR (400 MHz, $CDCl_3$, δ, ppm): 8.18–7.93 (m, 8H, Ar H), 6.55 (s, 2H, Ar H), 3.92 (s, 4H), 3.80 (s, 4H), 1.46–1.09 (m, 72H), 0.88–0.76 (m, 12H).

^{13}C NMR (100 MHz, $CDCl_3$, δ, ppm): 149.64, 146.35, 131.00, 129.89, 129.14, 129.11, 127.20, 126.26, 124.89, 124.56, 120.36, 103.98, 77.02, 49.56, 38.08, 31.92, 30.50, 29.65, 29.63, 29.56, 29.34, 22.96, 22.69, 14.11.

FTIR (ATR, cm^{-1}): 2926, 2950, 1609, 1509, 1487, 1467, 1405, 1375, 1270, 1176, 1042, 942, 849, 808, 732, 683.

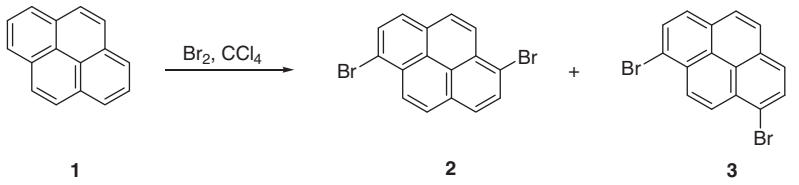
2.2. Chemical polymerization of 5

Compound **5** (145 mg, 0.135 mmol) was dissolved in chloroform (50 mL). A solution of anhydrous $FeCl_3$ (110 mg, 0.675 mmol, 5 equiv) in nitromethane was added dropwise over a period of 45 min to the stirred monomer at room temperature (the bright yellow monomer solution turned progressively dark blue with addition of oxidizing agent). The mixture was stirred 48 h at room temperature. It was then precipitated into methanol (300 mL). The precipitate was filtered, redissolved in chloroform (300 mL), and stirred for 6 h with hydrazine monohydrate (6 mL) (the color of the solution was turned from dark blue to yellow after addition of the hydrazine monohydrate). After evaporation, the concentrate (dark blue) was precipitated into methanol (300 mL), the precipitate was filtered through a Soxhlet thimble and purified via Soxhlet extraction for 48 h with methanol. The polymer was extracted with chloroform and concentrated by evaporation. Then, the polymer was precipitated in methanol (300 mL) and collected as a black solid (52% yield).

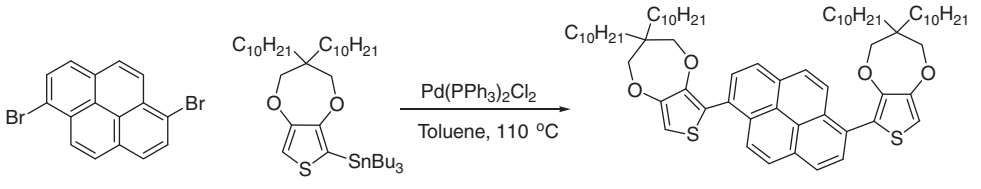
3. Results and discussion

The synthesis of the target compound **5** (**PPyP**) started with the bromination of pyrene (**1**), as outlined in Scheme 1. This reaction yielded a mixture of 1,6- (**2**) and 1,4-dibromopyrene (**3**), from which 1,6-regioisomer (**2**) was isolated by repeated recrystallization from toluene [44,45]. Stille coupling reaction of 2 with tributyl(3,3-didecyl-3,4-dihydro-2H-thieno[3,4-b][1,4]dioxepin-8-yl)stannane (**4**) [20] in the next step provided **5** in a yield of 56% (Scheme 2). Compound **5** was initially characterized by spectral (^{1}H, ^{13}C NMR, FTIR, see supporting information Fig. S1–S3) data, which was in well aggreement with the structure.

UV–vis absorption and emission spectra of **5** were depicted in Fig. 1. It was found that **5** emits blue light (431 nm) in THF solution as it is the case for many pyrene derivatives. It should be noted that organic compounds with emissions in the solid state are quite rare, since even bright organic fluorophores pack very tightly in the crystalline state or amorphous solid phase (as thin films), leading to very significant quenching [46–48]. As π–π stacking is



Scheme 1.



Scheme 2.

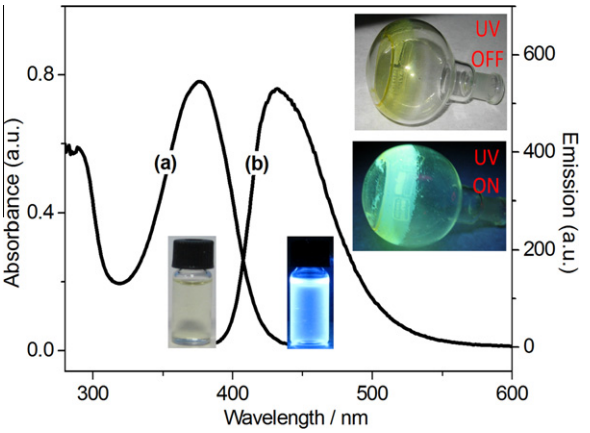


Fig. 1. (a) UV–vis absorption and (b) emission spectra (λ_{exc} = 377 nm) of **5** in THF. Inset: photographs of **5** under day (up) and UV (down) light.

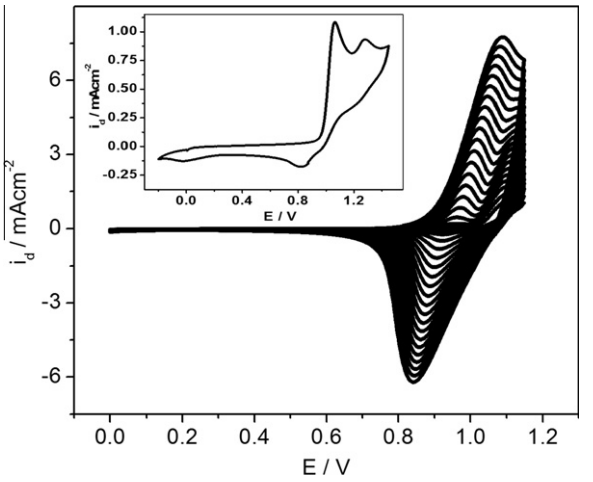

Fig. 2. Repetitive cyclic voltammogram of **5** (5×10^{-3} M) in order to obtain **P5** in 0.1 M TBAH/ 1:1 (v/v) DCM-ACN with a scan rate of 100 mV/s vs. Ag/AgCl. Inset: First anodic scan of **5** (5×10^{-3} M) under the same conditions.

mainly responsible for the quenching of the emission in the solid state for most of the aromatic fluorophores, it is assumed that **P** units on the core structure of **5** are effective in keeping the π-systems apart, where π–π stacking is hindered.

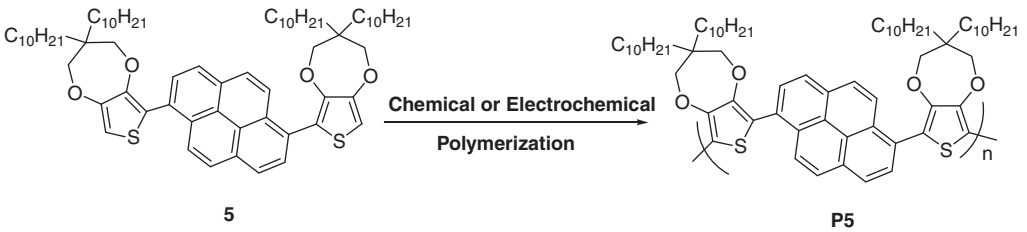
The electrochemical behavior of **5** was investigated by cyclic voltammetry in an electrolyte solution consisting of 0.1 M TBAH dissolved in DCM and ACN by 1:1 volume ratio. Upon anodic scan, two oxidation peaks were observed at 1.06 and 1.28 V, which were attributed to **P** and **Py** units, respectively (Fig. 2, inset). The second oxidation peak looks quite irreversible during the polymerization process (taking place at 1.06 V), which probably precludes the reversibility of the redox behavior of the pyrene units.

In order to get an electroactive polymer film, repetitive anodic scans were performed between 0.0 and 1.15 V. During this process, a new reversible redox couple was observed at 0.95 V. The increase in the current intensities of this redox couple clearly indicated the formation of the polymer film **P5** on the electrode surface (Fig. 2, Scheme 3).

When the as-prepared **P5** film (Scheme 3) was anodically scanned in a monomer free electrolyte solution of 0.1 M TBAH/ACN (Fig. 3), two reversible redox couples were observed at 1.02 and 1.28 V, which were ascribed to the **P** and **Py** units, respectively. Unlike monomer behavior, pyrene units have reversible redox couple since the polymerization was completed and the charges formed on polymer backbone do not prevent the reversibility. The onset potentials of this novel system, 0.91 and 1.07 V, were lower when compared to dodecylthiophene or fluorene based systems [40].

As shown in Fig. 3, inset, a linear increase in the peak currents as a function of the scan rates confirmed that the polymer film was tightly bounded to the electrode surface and the redox process is non-diffusional.

The oxidative polymerization of **5** was also carried out with $FeCl_3$ in order to get **P5** by chemical methods



Scheme 3.

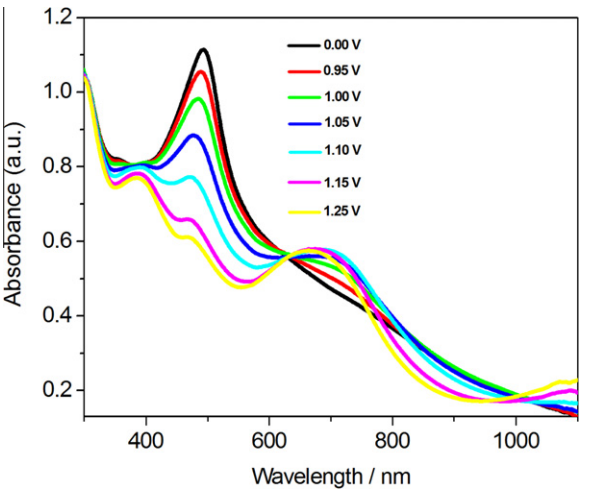

Fig. 5. Spectroelectrochemistry of **P5** film on an ITO coated glass slide in 0.1 M TBAH/CAN between 0.0 and +1.25 V vs. Ag wire.

(Scheme 3). It was found that both electrochemically and chemically obtained polymer, **P5**, was quite soluble in THF and partially soluble in common organic solvents: dichloromethane (DCM), $CHCl_3$, DMF (*N*,*N*-dimethylformamide). More importantly, **P5** reflects or transmits the yellow color in the neutral state. Note that soluble neutral state yellow PECs, which require a specific optical band gap (*vide infra*), are not enough. Additionally, the polymer has a maximum wavelength of emission resulting in yellowish green (524 nm) and yellow (545 nm) emission in the solution and in the solid phases, respectively (Fig. 4).

The molecular weight determination of the polymer was carried out by gel permeation chromatography (GPC) by using polystyrene as the standard and THF as the eluent.

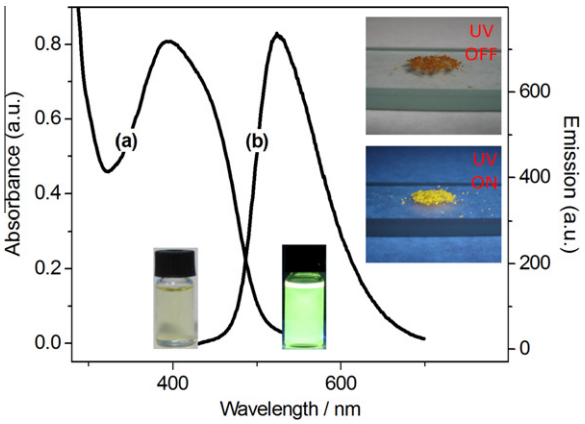

Fig. 4. (a) UV–vis absorption and (b) emission spectra (λ_{exc} = 391 nm) of **P5** in THF. Inset: photographs of **P5** under day (up) and UV (down) light.

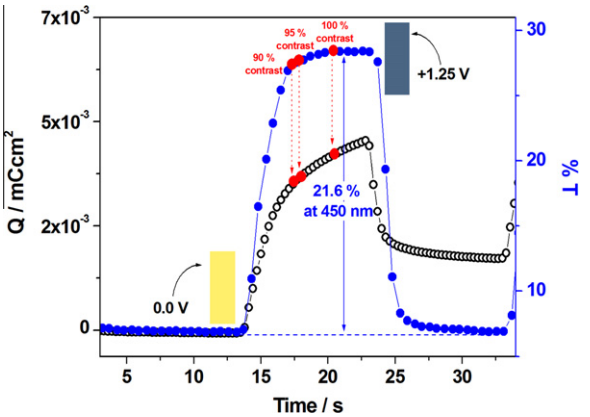

Fig. 6. Chronoabsroptometry and chronocoluolmetry tandem experiment of **P5** between 0.0 and +1.25 V at 495 nm.

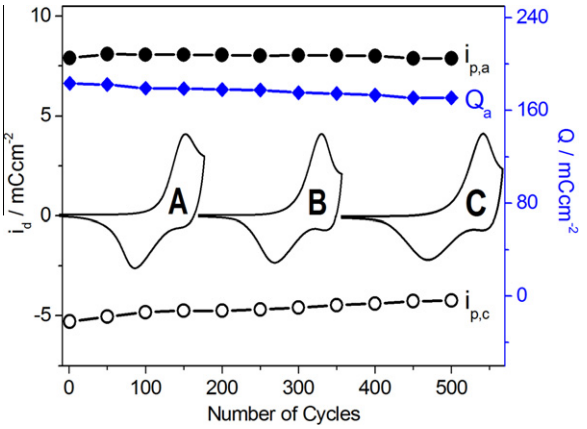

Fig. 7. Stability test for **P5** (5 mC/cm^2) film in 0.1 M TBAH/ACN via square wave potential switching between 0.0 and 1.3 V and cyclic voltammetry at 75 mVs^{-1}as a function of number of at: A: 1st; B: 100th, C: 500th. Q_a: Anodic charge stored; $i_{p,a:}$ Anodic peak current; $i_{p,c}$: Cathodic peak current.

The measurements indicated that **P5** had a weight-averaged molecular weight (Mw) of 9052 (*Mn* = 4316), with a polydispersity index (PDI) of 2.09, respectively. Although the Mw of **P5** was moderately low when compared to precedent analogs [40], it was evident that the polymer chain of **P5** consisted of approximately 25 repeating units.

In order to elucidate the electrochromic features of **P5**, a simple electrochromic device was constructed and the spectroelectrochemical behavior of the polymer film coated on ITO electrode was examined under a variety of voltage pulses between 0.95 and 1.25 V (p-doping). During p-doping, the higher energy absorbances at wavelengths shorter than 500 nm (π–$\pi*$ transition) started to decrease with an apparent new absorption band at around 680 nm, which was attributed to the formation of polaron charge (Fig. 5). Upon further oxidation, the polaron charge carriers turned into the bipolaron charge carriers above 1000 nm. In this process, it was assumed that charge carriers (polarons and bipolarons) were delocalized as the conformation of the polymer was planarized to an extent. As a result of these variations in the conformation and the absorption spectrum of **P5**, the color of the polymer changes from yellow in the neutral state to a navy state upon doping.

On that basis, the band gap (E_g) of polymer **P5** was calculated from the onset of π–$\pi*$ transition at 450 nm, and it was found to be 2.2 eV. The percentage transmittance change (Δ%T) and coloration efficiency (CE at 95% of the full optical switch, after which point the naked eyes couldn't sense the changes in the color) of the polymer film were also calculated to be 21.6% and 287 cm^2/C at 450 nm during p-doping, respectively. Also, the CE values were found as 252 and 298 cm^2/C for 100% and 90% of full optical switch (Fig. 6). The response time of the polymer film was found to be 3.4 s for 95% of full optical switch.

Stability of the material is a key parameter for any potential application of the polymers. For that reason, the electrochemical and thermal stability of the polymer were examined. First of all, the electrochemical stability of **P5** was tested by switching between neutral (0.0 V) and oxidized (1.25 V) states. It was found that **P5** retained 93% of its electroactivity even after 500 of cycles (Fig. 7).

Finally, the thermal stability of **P5** was determined by thermogravimetric analysis (TGA) as depicted in Fig. 8. Though light weight losses were observed during the analysis, the polymer shows the onset temperature of weight loss at 350 °C under nitrogen atmosphere. Note that polypyrene shows the onset temperature of weight loss at around 290 °C [42]. The data for **P5** suggested that the polymer would be thermally robust during metal deposition for optical device applications such as LED and solar cells, where thermal stability is very important. On the

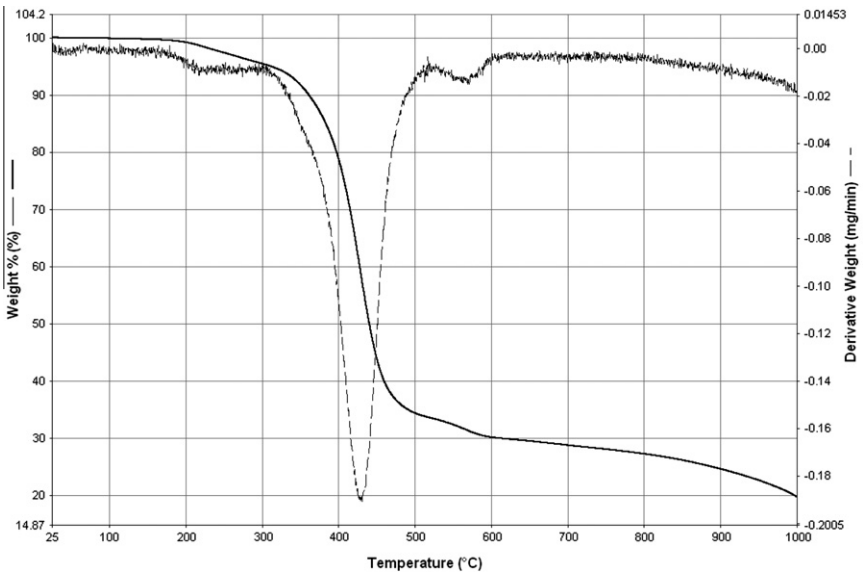

Fig. 8. Thermogravimetry curve of chemically prepared **P5**.

other hand, when the temperature was rised above 350 °C, the total weight loss was increased due to the decomposition of the material.

4. Conclusion

In conclusion, the design and synthesis of novel materials (**5** and **P5**) with pyrene scaffold were described. Interestingly, both of these systems were emissive in both solution and the solid states. It is assumed that **P** units on the core structure hinder π–π stacking thus rendering the emission in the solid state. Furthermore, a novel soluble PEC, **P5**, which has a specific optical band gap (2.2 eV) to reflect (or transmit) the yellow color in the neutral state was introduced herein to extend the repertoire of available colors of processable PECs (blue, green and black etc.), which are essential for full color displays [49]. The electrochemical and thermal stability of the polymer indicated that **P5** is a promising candidate for electrochromic applications. Work in this line is currently underway in our laboratories.
